Abstract:
Water electrolysis performed by renewables allows to produce green Hydrogen: this process can boost the penetration of clean energy sources into electric grids. This work presents a model developed in Aspen HYSYS® aiming at evaluating the performance of a low-temperature alkaline (ALK) electrolyzer while varying the main operating conditions (e.g., power supply, temperature, and pressure). A Semi-empirical model published in the scientific literature, which describes the physic-chemical processes at the system level, has been implemented in Aspen HYSYS® and used for resembling the operational behaviour of an ALK electrolyzer. The model consists of common system-level blocks with a customized spreadsheet: semi-empirical correlations, which have been calibrated via multiple non-linear regression fittings of experimental data from the scientific literature, allowed to implement the main electro- and thermochemical-equations of the electrolysis process. Simulated results showed a good agreement with respect to the experimental ones for all the studied operating conditions in terms of Normal Root Mean Square Error (NRMSE). Regarding the Hydrogen flow rate, the comparison between the model and the experimental results showed NRMSE values ranging between $4.208e^{-05}$ and $6.415e^{-05}$, where the former is the lowest threshold value obtained in this analysis. On the other hand, as far as the Hydrogen-to-Oxygen (HTO) is concerned, NRSME values vary between $2.486e^{-04}$ and $5.519e^{-04}$, where the latter is the highest threshold value obtained in this analysis. Finally, this model can be considered a good starting point for creating a Hydrogen-integrated system through the connection of the electrolyzer with a Hydrogen storage system and a fuel cell.

Keywords:
Alkaline electrolyzer, Aspen HYSYS®, Green Hydrogen, Water Electrolysis.

1. Introduction

Nowadays, the need to reduce greenhouse gas emissions, which are the main cause of climate change, is urgently needed as well as having energy systems capable of responding fastly to the increasing energy demands [1]. Current research on the energy sector is focused on the development of technologies capable of exploiting renewable sources in different ways (e.g., direct and indirect) to drastically reduce polluting emissions in the upcoming years.

In such a scenario, Hydrogen seems to be a valid option for easing the ecologic transition; in particular, Water electrolysis through the electricity produced by renewables (green Hydrogen) can provide flexibility to the electric grid, thus increasing the penetration of renewables [2]. Water electrolysis was performed for the first time in 1789 [3] and it consists of three components: the anode, the electrolyte, and the cathode. During the oxidation phase of Hydrogen at the anode, cations reach the cathode via the electrolyte and free electrons flow to the external circuit. Cations and electrons reduce Oxygen to Water at the cathode [4]. Hydrogen produced by Water electrolysis has been thought to be the best energy carrier to counteract the variable nature

of renewables and operate as a middle/long-term energy storage solution in different energy applications [5]. Furthermore, Hydrogen is a non-pollutant molecule since it produces only Water when it undergoes a combustion reaction, thus being considered the cleanest, most efficient, and sustainable fossil fuel alternative [6].

The most known and well-established electrolyzers are alkaline (ALK) and Polymer Exchange Membrane (PEM) ones [7], although the ALK electrolysis is the most reliable in terms of cost and ease of use [8]. The modeling of these electrolyzers is fundamental for simulating and properly resembling the behaviour of Hydrogen-generating systems. Realistic modeling of the overall electrolyzer is important when it is coupled to renewables since it has to correctly face the variable power source; furthermore, it also allows to properly analyse, control, size, manage, and optimize this kind of technology. Besides the technologies previously mentioned regarding the ALK and PEM electrolyzers, this technology is also differentiated by low- and high-temperature operating conditions. Typically, ALK electrolyzers operate at a current density of about 400 mA/cm^2, at moderate temperatures of 70-90 °C, with a cell voltage in the range of 1.85-2.2 V, and conversion efficiencies in the range of 50-70%. ALK electrolyzers do not depend upon a noble metal catalyst for Hydrogen production, and they are easily handled due to the low-temperature operation. The PEM electrolyzer can operate at a current density of 2000 mA/cm^2 at 90 °C and with 2.1 V. The kinetics of Hydrogen and Oxygen production reaction is faster than in ALK electrolyzers due to the acidic nature of the electrolyte and the metal surface of the electrodes. PEM electrolyzers do not use caustic electrolytes as in ALK ones, which might be highly toxic for human beings if a failure occurs. In addition, PEM electrolyzers offer the possibility to use high pressure on the cathode side, while the anode can be operated at atmospheric pressure. When dealing with high-temperature electrolysis, it means that the operating temperature range is above 100°C and Water is in vapor form. This operating condition increases considerably the electrolysis efficiency, but it leads to more complex management of the electrolyzer as well as higher costs due to the use of specific materials. However, technologies like Solid Oxide (SO) electrolyzers are still in development and not yet ready for being commercialized [9]. As for the high-temperature electrolysis, Motazedi et al. [10] examined Hydrogen production from both environmental and economic points of view using Aspen HYSYS® models. Along the same line, JaeHwa et al. [11] developed a SO electrolyzer model in Aspen HYSYS® to perform a sensitivity analysis by varying different operating conditions (e.g., current density, temperature, and pressure).

Moving to ALK electrolyzers, Sánchez et al. [12] have developed a model in Aspen Plus® to resemble the behaviour of the ALK electrolyzer. Nevertheless, to the authors' knowledge, in the scientific literature there are no user-friendly models developed in Aspen HYSYS® related to the ALK Water electrolyzers. The novelty of the present work consists of the development of a user-friendly model related to a low-temperature Water ALK electrolysis stack in the Aspen HYSYS® environment, which is capable of providing the main performance parameters (e.g., electric potential and Hydrogen-to-Oxygen (HTO)) according to different input conditions (e.g., pressure, temperature, current density). As previously said, besides being easily used by end-users, this model can be tailored according to the main specific characteristics of the ALK electrolyzer to be resembled.

The model has been calibrated through regression fitting of semi-empirical process relations and validation with respect to experimental data obtained by [12, 13]. In order to model the stack of the ALK electrolyzer and to carry out the regression of experimental data, the authors based the model development on the analysis carried out by Sánchez et al [13] where a semi-empirical model of the electrochemical behavior of a 15 kW ALK electrolyzer has been proposed. In addition, the work performed by Amores et al. [14] has been used as well because they provided a paradigm for modeling the behaviour of an ALK electrolyzer, modifying the Ulleberg equation [15] with the aim of considering the influence of both temperature and pressure, the electrode/diaphragm distance, and the electrolyte concentration.

The paper is structured as follows: Section 2 presents the methodology used to model the ALK electrolyzer analytically, as well as providing an overview of the Aspen HYSYS® model. Section 3 is devoted to the results obtained by the simulations at different operating conditions in terms of both pressure and temperature, which have been then compared to the experimental results available in the scientific literature by making Normal Root Mean Square Error (NRMSE) comparison. Finally, Section 4 reports the conclusions of the work.

2. Methodology

The models that describe the behaviour of a low-temperature ALK electrolyzer stack with different operating conditions (e.g., current density, temperature, and pressure) typically include the simulation of the following

quantities: i) electric potential, ii) Faraday efficiency, iii) HTO, iv) flow rate of produced Hydrogen, v) electric power absorbed by the stack, vi) thermal power generated by the stack, vii) stack efficiency, and viii) specific consumption. The trend of the last five items is obtained by the first two. In the scientific literature, there are multiple mathematical correlations that describe the same physical phenomenon occurring within the stack. Based on the experimental data obtained by [13], a semi-empirical modeling approach has been chosen and used in this work. The mathematical model used for the stack electric potential is the one proposed by Sánchez et al. [12, 13], which is an improvement of the equation proposed by Ulleberg [15] as reported by Eq. (1).

$$U = U(T,P,i) = U_{rev} + [(r_1 + q_1) + r_2 T + q_2 P] \cdot i + s \cdot \log_{10}\left[\left(t_1 + \frac{t_2}{T} + \frac{t_3}{T^2}\right) \cdot i + 1\right] \quad (1)$$

where U is the cell electric potential, T is the temperature in [°C], P is the pressure in [bar], i is the current density [A/cm^2], and r_i, q_i, and t_i are experimental constants. The total potential U is the sum of the reversible potential U_{rev}, which is given by thermodynamics, the activation, and the ohmic overpotentials related to the kinetic losses of the electrolysis process. It is worth noting that the polarization curve is not investigated in the field of concentration overpotential since it would require a more complex model and experimental data at higher current densities.
The cell reversible potential U_{rev} is a purely thermodynamic quantity and depends on the Gibbs free energy variation ΔG between products and reactants as a function of the operating temperature and pressure as reported by Eq. (2).

$$U_{rev}(T,P) = \frac{\Delta G}{zF} = \frac{\Delta G_{H_2}(T,P) + \frac{1}{2}\Delta G_{O_2}(T,P) - \Delta G_{H_2O}(T,P)}{zF} \quad (2)$$

Regarding Water electrolysis, the reversible cell potential U_{rev}^0 under standard conditions (P^0=1bar, T^0=25°C) is equal to 1.229 V. The value of the reversible voltage is a function of temperature and pressure, thus assuming different values from the standard one as expressed by Eq. (3) that is the Nernst's equation [16]:

$$U_{rev} = U_{rev}^0 + \frac{R \cdot T_K}{z \cdot F} \cdot \ln\left(\frac{p_{H2} \cdot \sqrt{p_{O_2}}}{a_{H_2O}}\right) \quad (3)$$

where T_K is the temperature in [K], R is the universal constant of gases (8.314 J/K mol), z is the number of electrons transferred in the electrolysis reaction (2 mol$_{e^-}$/mol$_{H2}$), F is the Faraday constant (96,485 C/mol), a_{H2O} is the coefficient of activity of Water, p_{O2} and p_{H2} are the partial pressure expressed in [bar] of Oxygen and produced Hydrogen, respectively. Assuming that the membrane is subjected to the mechanical equilibrium, the partial pressures of Hydrogen are the same as the Oxygen ones (p_{O2}=p_{H2}=p_{tot}) and, assuming that the coefficient of activity of the Water is approximately equal to 1 [17], Eq. (3) can be written as follows:

$$U_{rev} = U_{rev}^0 + \frac{R \cdot T}{z \cdot F} \cdot \ln\left(P_{tot}^{\frac{3}{2}}\right) \quad (4)$$

The reversible cell potential U_{rev}^0 can be also calculated considering isobaric conditions (at standard pressure P^0 equal to 1 bar) and thus reducing its dependency only on the temperature [17]. In the scientific literature, there are different empirical relationships such as the one proposed by Hammoudi et al. [18] as reported by Eq. (5).

$$U_{rev}^0(T,P^0) = 1.50342 - 9.956 \cdot 10^{-4} T_K + 2.5 \cdot 10^{-7} {T_K}^2 \quad (5)$$

Finally, the reversible potential is calculated by the set of Eq.s (4) and (5). The electrolyzer under investigation consists of 12 cells installed in series; thus, the stack voltage is obtained by multiplying the cell voltage by the number of cells.

$$U_{stack} = N_{cell} \cdot U \tag{6}$$

where N_{cell} is the number of cells installed in series.

The Hydrogen production rate $\dot{n}_{H2}$ [mol/s] is strictly related by the stoichiometry of the reaction and to the applied current *I* [A], which is the same for all the cells connected in series. The Hydrogen production rate is equal to the current density *i* times cell area A_{cell} as reported in Eq. (7) that is the Faraday's equation. As far as the Faraday efficiency η_{Far} is concerned, Sánchez et al. [12, 13] introduced a modification to the η_{Far} Ulleberg's relation [15] with the use of experimental parameters f_{ij} to include also the effect of the temperature as reported by Eq. (8).

$$\dot{n}_{H2} = \eta_{Far} \frac{I}{zF} \tag{7}$$

$$\eta_{Far} = \frac{i^2 \cdot (f_{21} + f_{22} T)}{(f_{11} + f_{12} T) + i^2} \tag{8}$$

As for the HTO, the equation proposed by Hug et al. [19], which describes the HTO dependence on both current density and temperature, has been used by Sánchez et al. [12, 13] and modified by introducing the dependence of pressure as reported by Eq. (9).

$$HTO = C_1 + C_2 T + C_3 T^2 + (C_4 + C_5 T + C_6 T^2) \cdot \exp\left(\frac{C_7 + C_8 T + C_9 T^2}{i}\right) + E_1 + E_2 P + E_3 P^2 + (E_4 + E_5 P + E_6 P^2) \cdot \exp\left(\frac{E_7 + E_8 P + E_9 P^2}{i}\right) \tag{9}$$

where C_1 to C_9 are constants that represent the influence of the temperature in the HTO, and from E_1 to E_9 there are constants that represent the relations between the gas purity and the pressure.

The electrical power absorbed by the stack $\dot{W}_{el}$ allows to evaluate the specific electrical consumption and the stack efficiency as well, as described by Eq. (10).

$$\dot{W}_{el} = U \cdot N_{cell} \cdot i \cdot A_{cell} \tag{10}$$

Regarding the specific consumption c_{sp}, it can be expressed as the ratio between electric power $\dot{W}_{el}$, which is expressed in [kW], and the mass flow rate of the produced Hydrogen $\dot{m}_{H2}$ expressed in [kg/h].

$$c_{sp} = \frac{\dot{W}_{el}}{\dot{m}_{H2}} = \frac{U(i,T,P) \cdot 2F}{10^3 \cdot \eta_F(i,T) \cdot 7.257168} \tag{11}$$

where 7.257168 is a conversion factor in [s•kg/h•mol] that allows to express the molar flow rate of Hydrogen in [kg/h] knowing its value in [mol/s].

Stack electrical efficiency, η_{stack} , is defined as the ratio between the chemical energy contained in the produced hydrogen and the electrical power needed for its production, as shown by Eq. (12).

$$\eta_{stack} = \frac{\dot{n}_{H2} \cdot LHV}{\dot{W}_{el}} \tag{12}$$

where LHV stands for the Lower Heating Value of hydrogen that is equal to 241.82 kJ/mol.

The thermal power $\dot{Q}_{th}$ involved in the electrolysis process, which must be removed to maintain the isothermal condition, is calculated as:

$$\dot{Q}_{th} = i \cdot A_{cell} \cdot (U(i,T,P) - U_{tn}(T,P)) \quad (13)$$

where U_{tn} is the thermoneutral potential of the stack, which is a function of both temperature and pressure.

As previously described, the electrochemical process model is integrated into the Aspen HYSYS® environment using a spreadsheet since the software does not present pre-build blocks for modeling electrochemical components. The rest of the electrolyzer stack (e.g., inlet and outlet fluid management, temperature and pressure settings, etc.) is represented by the common tools made available by the software. Steady-state operations have been considered and the fluid thermodynamic conditions (e.g., pressure and temperature) are set (e.g., isothermal and isobaric conditions are considered for the whole process). The selected *Fluid Package* is the "*Peng-Robinson*". The Water dissociation reaction is defined as a conversion reaction occurring in the "*Electrolysis reactor*", which represents the set of electrodes. Based on the thermodynamic operating conditions (e.g., temperature, pressure) and load current, the reactor sources the main electro- and thermo-chemical equations from the spreadsheet defining the reaction products and the electric power required. U_{rev} is calculated from the thermodynamic fluid property databases, which are embedded in the software, using Eq. (2). The reactor has two material flows at the output: "*Reaction Gas*" and "*Liquid Product*", where the latter is always null since the molar flow rate of the Water entering the model is equal to the molar flow rate of the Hydrogen that is calculated in the spreadsheet using the Faraday equation. The mixture of Hydrogen and Oxygen "*Reaction gas"* is sent to the second component that is the "*Component splitter*" called "*Electrode separator*": through this component it is possible to separate the oxidation and the reduction semi-reactions in the anode and in the cathodic chambers of each cell, respectively. The separator is set up so that the flows are chemically pure at the outputs (no crossover phenomena). The current output flows are corrected with the HTO that is calculated in the spreadsheet: indeed, the amount of Hydrogen separated from the anode flow by the "*Flow splitter",* here called "*Crossover_Tee*", is subsequently mixed to the Oxygen in the anode.

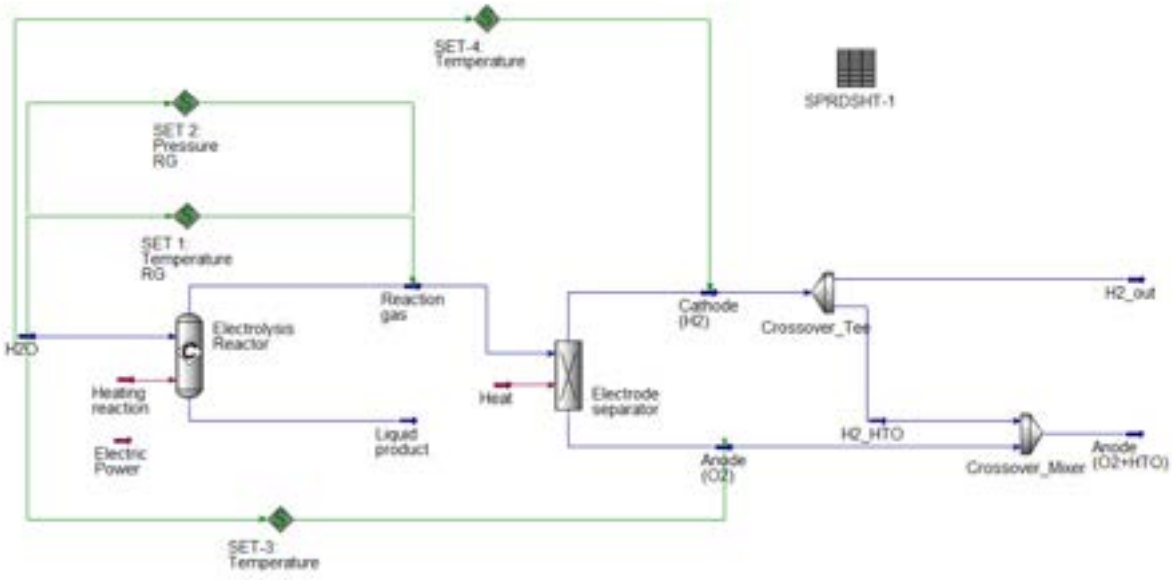

Figure. 1. Model of the low-temperature alkaline electrolyzer developed in Aspen HYSYS®.

In order to obtain comparable simulation results, the electrolyzer that has been modeled is the same one that has been characterized experimentally by Sánchez et al. [12, 13]. It is a small-sized, laboratory scale electrolyzer and its main characteristics are listed in Table 1. To obtain the experimental parameters previously described, the available experimental data have been fitted by using the Matlab® "*Curve Fitting Tool"*. The

regressions are non-linear and multiple, namely two in the case of the Faraday efficiency and three in the case of electric voltage and HTO.

Table 1. Characteristics of the alkaline electrolyzer analysed by Sánchez et al. [12, 13].

Main characteristics	Numerical value	Units of measurement
Hydrogen production flow rate	2.5	m^3/h
Maximum operating pressure	30	bar
Electric potential range	0-120	V
Electric current range	0-500	A
Maximum power	15	kW
The active area of the electrodes	1,000	cm^2
Number of cells	12	-
Electrolyte concentration	30-40	wt% KOH

3. Results and comments

The simulations results, in terms of electrolyzer performance, are evaluated as a function of the current density (between 0-0.5 A/cm^2 with steps of 0.005 A/cm^2) and the parametrization of both pressure and temperature (between 55-85°C with steps of 5°C, and between 1-29 bar with steps of 4 bar). Aspen HYSYS® allows to perform parametric "case studies" and investigate how each variable affects the results while keeping the remained parameters fixed. Figure 2 shows the results related to the stack potential at different values of temperature and pressure. It is worth noting that the trends of the other quantities such as Hydrogen flow rate, etc. have not been here reported.

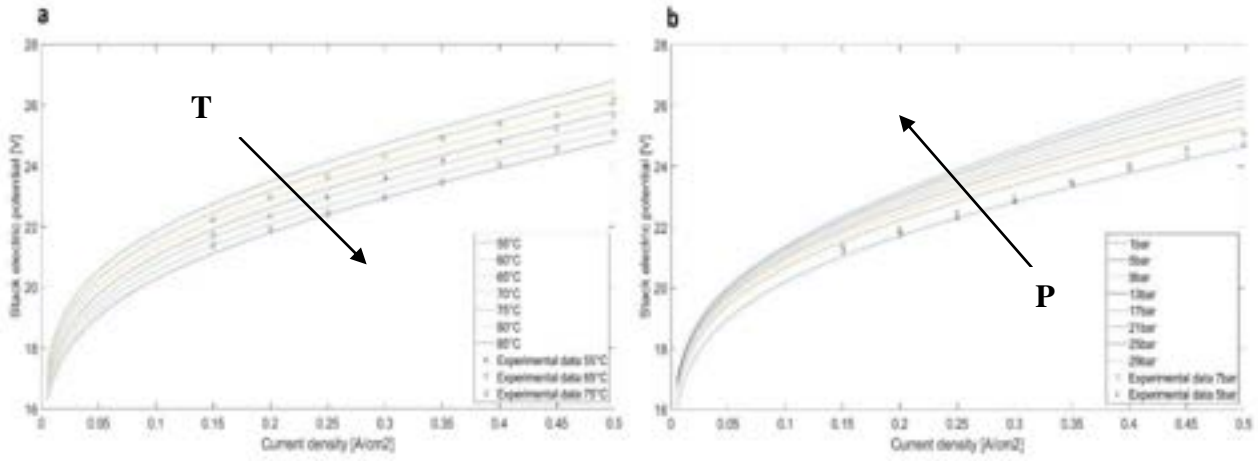

Figure. 2. (a) Stack voltage trend as a function of current density and temperature (pressure equal to 7 bar), and (b) of current density and pressure (temperature equal to 75°C).

In particular, the voltage decreases while the system temperature increases because part of the electric energy required for the electrolysis process is replaced by the associated thermal energy developed during the reaction (see Figure 2). The increase in temperature also improves the reaction kinetics by reducing the activation overpotentials as well as impacting the U_{rev} through the Nernst potential. Furthermore, the electric potential rises when the pressure increases due to the Nernst potential and the one related to the ohmic overpotential.

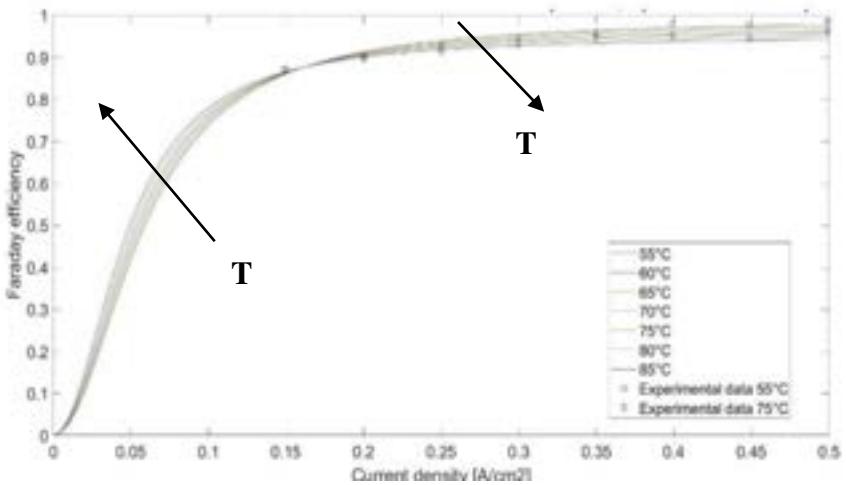

Figure. 3. Faraday efficiency trend as a function of current density and temperature (pressure equal to 7 bar).

Figure 3 shows the trend of the Faraday efficiency as a function of current density and temperature according to Eq. (8). The Faraday efficiency quickly reaches values close to 1 when current density values higher than 0.4 A/cm^2 are used. Conversely, Faraday efficiency decreases when current density values lower than 0.17 A/cm^2 and the increase of temperature leads to lower Faraday efficiency values.

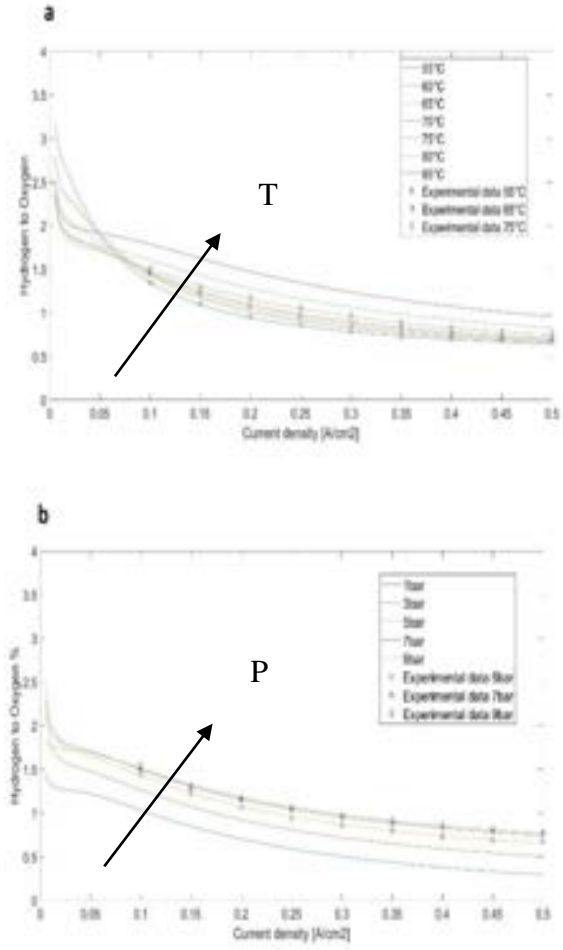

Figure. 4. (a) HTO trend as a function of current density and temperature (pressure equal to 7 bar), and (b) of current density and pressure (temperature equal to 75°C).

Figure 4a shows that the HTO increases when the current density decreases and tends to increase with the increasing temperatures. For this reason, operations with very low values of current density are undesirable because it would be preferable to avoid a HTO beyond the flammability limit of a H_2/O_2 mixture that could lead to combustion or explosion [20]. The higher amount of Hydrogen in the Oxygen stream at higher temperatures is caused by the higher diffusion velocity at elevated temperatures [17]. Figure 4b still shows an increase of the HTO as the current density decreases and as the operating pressure increases. For increasingly small current density values, the HTO model shows an asymptotic behaviour with anomalous variations due to lack of experimental data for very low currents: this means that the model is only valid for the range of density current values for which HTO measurements are available.

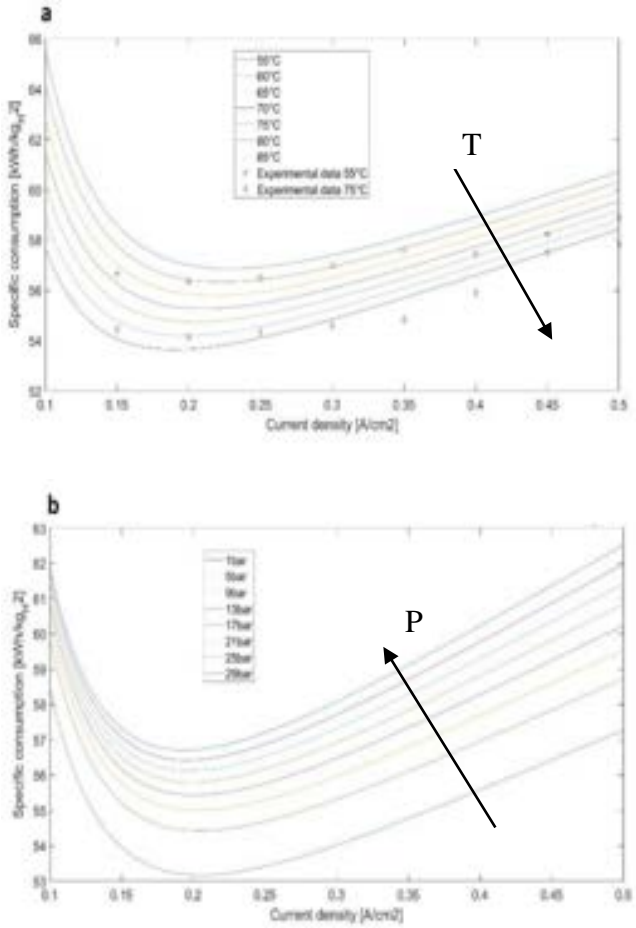

Figure. 5. (a) Specific consumption trend as a function of current density and temperature (pressure equal to 7 bar), and (b) of current density and pressure (temperature equal to 75°C).

Figure 5 shows a non-linear dependence of the specific consumption on the current density. In [13], no experimental data are available for the specific consumption, but these were obtained with data on Faraday efficiency and stack electric potential through Eq. (11). The specific consumption function reaches its minimum value at 0.2 A/cm^2, and it decreases with increasing temperature (see Figure 5a) due to the decrease of the electric potential and increases with the increasing pressure (see Figure 5b) due to the increase of the electric potential. The increase of the specific consumption, when the current density decreases below the threshold of 0.2 A/cm^2, is due to a decrease of the Faraday efficiency that is faster than the electric potential as expressed by Eq. (11). The Faraday efficiency and the electric potential increase with the current density, resulting in an increasing curve for current densities greater than 0.2 A/cm^2. The specific consumption is always between 53 and 63 kWh/kg$_{H2}$.

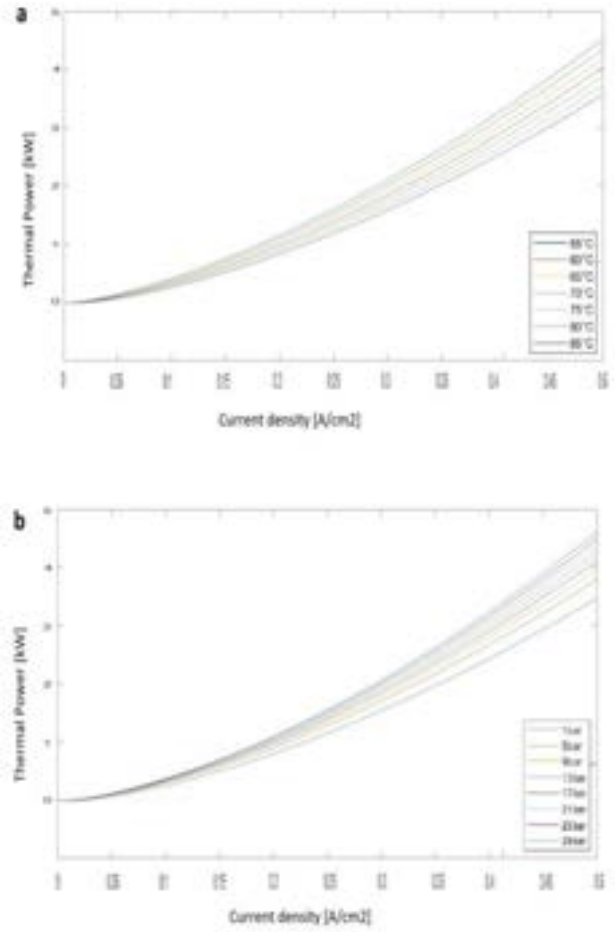

Figure. 6. (a) Thermal power trend as a function of current density and temperature (pressure equal to 7bar), and (b) of current density and pressure (temperature equal to 75°C).

As for the thermal power, Figure 6 shows how it increases with increasing current density and how this trend tends to decrease as the operating temperature increases and to increase as the operating pressure increases. This behaviour can be explained by the influence of both temperature and pressure exert on the stack potential: as the temperature increases the stack potential decreases, while as the pressure increases the potential increases. However, the thermoneutral potential can be considered approximately constant in every case. There are not experimental data for the thermal power. To evaluate the results from the developed model, the *Normal Root Mean Square Error* (NRMSE) has been calculated with respect to the literature experimental values in the same operating conditions reported in [13] (see Table 2).

Table 2. NRMSE values: comparison between model and experimental results.

	7 bar, 55°C	**7 bar, 65°C**	**7 bar, 75°C**	**5 bar, 75°C**	**9 bar, 75°C**
Electric potential	$4.066e^{-04}$	$3.990e^{-04}$	$4.095e^{-04}$	$4.317e^{-04}$	-
Faraday Efficiency	$8.253e^{-05}$	-	$4.871e^{-05}$	-	-
HTO	$5.519e^{-04}$	$2.486e^{-04}$	$3.932e^{-04}$	$4.115e^{-04}$	$3.213e^{-04}$
Specific consumption	$4.859e^{-04}$	-	$4.155e^{-04}$	-	-
Stack efficiency	$4.452e^{-04}$	-	$3.903e^{-04}$	-	-
Electric power	$4.153e^{-04}$	$3.295e^{-04}$	$3.865e^{-04}$	$2.078e^{-05}$	-
Hydrogen flow rate	$6.415e^{-05}$	-	$4.208e^{-05}$	-	-

The regression in Matlab of the cell potential from experimental data was conducted by using the set of Eq.s (4) and (5) where the reversible cell potential U_{rev}^{0} is only a function of the temperature (considering isobaric conditions (at standard pressure P^0 equal to 1 bar) according to [18], while In Aspen HYSYS the reversible cell potential is calculated automatically by implementing Eq. (2). The result is that the numerical value of the reversible cell potential calculated in Aspen HYSYS® is on average greater than the one calculated with the combination of Eq.s. (4) and (5) by 0.0395 V: this is mainly due to the fluid package selected that evaluates the trend of the state function of the components in the system. As a result, an average overestimation of 0.474 V of the electric stack potential of the model developed in Aspen HYSYS® is obtained compared to the experimental data; therefore, also other results are overestimated (e.g., specific consumption and electric power consumed). Conversely, the stack efficiency is underestimated compared to the experimental data. A possible way to increase the accuracy of the model is to perform regressions of the experimental data by firstly calculating the reversible potential according to Eq. (2), and then determining the experimental coefficients from the equation given by the combination of Eq.s. (1) and (2).

4. Conclusions

This work presents and discusses the development of a semi-empirical simulation model developed with Aspen HYSYS® related to a low-temperature Water alkaline electrolysis stack. The main performance parameters (e.g., electric power required and stack efficiency) are evaluated according to different input conditions (e.g., current density, pressure, temperature, etc.).

The trend of the electric potential has been obtained as the sum of the reversible potential and the overpotentials obtained through non-linear multiple regressions performed in Matlab® with the "*Curve Fitting Tool"* of several empirical parameters.

Results show a good agreement with the data made available by the scientific literature (experimental data) for all the analysed quantities within the selected range of operation parameters. Slight differences have been found due to the overestimation of the cell/stack potential related to the electrochemical model: indeed, the comparison between the model and experimental results showed NMRSE values ranging between $3.990e^{-04}$ and $4.317e^{-04}$. Moving to the Faraday efficiency, values ranging between $4.871e^{-05}$ and $8.253e^{-05}$ have been obtained. Then, the specific consumption values varied between $4.155e^{-04}$ and $4.859e^{-04}$, the electric power variation goes from $2.078e^{-05}$ to $4.145e^{-04}$, and the Hydrogen flow rate from $4.208e^{-05}$ to $6.415e^{-05}$ where the former is the lowest threshold value obtained in this analysis. On the other hand, as far as the HTO is concerned, NRSME values vary between $2.486e^{-04}$ and $5.519e^{-04}$, where the latter is the highest threshold value obtained in this analysis. It is worth noting that these results denote that a simple thermodynamic model with the addition of few semi-empirical corrections can represent quite well the operation of the electrolyzer stack without requiring excessive simulation efforts in terms of both kinetic and dynamic behaviours.

The present model will be subsequently implemented in a wider system resembling the behaviour of an integrated Hydrogen system composed by, besides the electrolyzer, a metal hydrides Hydrogen storage and a fuel cell. Furthermore, the future complete model will also take into account both Water recirculation and gas purification processes, which are fundamental in the electrolysis process.

Abstract:
Water electrolysis performed by renewables allows to produce green Hydrogen: this process can boost the penetration of clean energy sources into electric grids. This work presents a model developed in Aspen HYSYS® aiming at evaluating the performance of a low-temperature alkaline (ALK) electrolyzer while varying the main operating conditions (e.g., power supply, temperature, and pressure). A Semi-empirical model published in the scientific literature, which describes the physic-chemical processes at the system level, has been implemented in Aspen HYSYS® and used for resembling the operational behaviour of an ALK electrolyzer. The model consists of common system-level blocks with a customized spreadsheet: semi-empirical correlations, which have been calibrated via multiple non-linear regression fittings of experimental data from the scientific literature, allowed to implement the main electro- and thermochemical-equations of the electrolysis process. Simulated results showed a good agreement with respect to the experimental ones for all the studied operating conditions in terms of Normal Root Mean Square Error (NRMSE). Regarding the Hydrogen flow rate, the comparison between the model and the experimental results showed NRMSE values ranging between $4.208e^{-05}$ and $6.415e^{-05}$, where the former is the lowest threshold value obtained in this analysis. On the other hand, as far as the Hydrogen-to-Oxygen (HTO) is concerned, NRSME values vary between $2.486e^{-04}$ and $5.519e^{-04}$, where the latter is the highest threshold value obtained in this analysis. Finally, this model can be considered a good starting point for creating a Hydrogen-integrated system through the connection of the electrolyzer with a Hydrogen storage system and a fuel cell.

Keywords:
Alkaline electrolyzer, Aspen HYSYS®, Green Hydrogen, Water Electrolysis.

1. Introduction

Nowadays, the need to reduce greenhouse gas emissions, which are the main cause of climate change, is urgently needed as well as having energy systems capable of responding fastly to the increasing energy demands [1]. Current research on the energy sector is focused on the development of technologies capable of exploiting renewable sources in different ways (e.g., direct and indirect) to drastically reduce polluting emissions in the upcoming years.

In such a scenario, Hydrogen seems to be a valid option for easing the ecologic transition; in particular, Water electrolysis through the electricity produced by renewables (green Hydrogen) can provide flexibility to the electric grid, thus increasing the penetration of renewables [2]. Water electrolysis was performed for the first time in 1789 [3] and it consists of three components: the anode, the electrolyte, and the cathode. During the oxidation phase of Hydrogen at the anode, cations reach the cathode via the electrolyte and free electrons flow to the external circuit. Cations and electrons reduce Oxygen to Water at the cathode [4]. Hydrogen produced by Water electrolysis has been thought to be the best energy carrier to counteract the variable nature

of renewables and operate as a middle/long-term energy storage solution in different energy applications [5]. Furthermore, Hydrogen is a non-pollutant molecule since it produces only Water when it undergoes a combustion reaction, thus being considered the cleanest, most efficient, and sustainable fossil fuel alternative [6].

The most known and well-established electrolyzers are alkaline (ALK) and Polymer Exchange Membrane (PEM) ones [7], although the ALK electrolysis is the most reliable in terms of cost and ease of use [8]. The modeling of these electrolyzers is fundamental for simulating and properly resembling the behaviour of Hydrogen-generating systems. Realistic modeling of the overall electrolyzer is important when it is coupled to renewables since it has to correctly face the variable power source; furthermore, it also allows to properly analyse, control, size, manage, and optimize this kind of technology. Besides the technologies previously mentioned regarding the ALK and PEM electrolyzers, this technology is also differentiated by low- and high-temperature operating conditions. Typically, ALK electrolyzers operate at a current density of about 400 mA/cm^2, at moderate temperatures of 70-90 °C, with a cell voltage in the range of 1.85-2.2 V, and conversion efficiencies in the range of 50-70%. ALK electrolyzers do not depend upon a noble metal catalyst for Hydrogen production, and they are easily handled due to the low-temperature operation. The PEM electrolyzer can operate at a current density of 2000 mA/cm^2 at 90 °C and with 2.1 V. The kinetics of Hydrogen and Oxygen production reaction is faster than in ALK electrolyzers due to the acidic nature of the electrolyte and the metal surface of the electrodes. PEM electrolyzers do not use caustic electrolytes as in ALK ones, which might be highly toxic for human beings if a failure occurs. In addition, PEM electrolyzers offer the possibility to use high pressure on the cathode side, while the anode can be operated at atmospheric pressure. When dealing with high-temperature electrolysis, it means that the operating temperature range is above 100°C and Water is in vapor form. This operating condition increases considerably the electrolysis efficiency, but it leads to more complex management of the electrolyzer as well as higher costs due to the use of specific materials. However, technologies like Solid Oxide (SO) electrolyzers are still in development and not yet ready for being commercialized [9]. As for the high-temperature electrolysis, Motazedi et al. [10] examined Hydrogen production from both environmental and economic points of view using Aspen HYSYS® models. Along the same line, JaeHwa et al. [11] developed a SO electrolyzer model in Aspen HYSYS® to perform a sensitivity analysis by varying different operating conditions (e.g., current density, temperature, and pressure).

Moving to ALK electrolyzers, Sánchez et al. [12] have developed a model in Aspen Plus® to resemble the behaviour of the ALK electrolyzer. Nevertheless, to the authors' knowledge, in the scientific literature there are no user-friendly models developed in Aspen HYSYS® related to the ALK Water electrolyzers. The novelty of the present work consists of the development of a user-friendly model related to a low-temperature Water ALK electrolysis stack in the Aspen HYSYS® environment, which is capable of providing the main performance parameters (e.g., electric potential and Hydrogen-to-Oxygen (HTO)) according to different input conditions (e.g., pressure, temperature, current density). As previously said, besides being easily used by end-users, this model can be tailored according to the main specific characteristics of the ALK electrolyzer to be resembled.

The model has been calibrated through regression fitting of semi-empirical process relations and validation with respect to experimental data obtained by [12, 13]. In order to model the stack of the ALK electrolyzer and to carry out the regression of experimental data, the authors based the model development on the analysis carried out by Sánchez et al [13] where a semi-empirical model of the electrochemical behavior of a 15 kW ALK electrolyzer has been proposed. In addition, the work performed by Amores et al. [14] has been used as well because they provided a paradigm for modeling the behaviour of an ALK electrolyzer, modifying the Ulleberg equation [15] with the aim of considering the influence of both temperature and pressure, the electrode/diaphragm distance, and the electrolyte concentration.

The paper is structured as follows: Section 2 presents the methodology used to model the ALK electrolyzer analytically, as well as providing an overview of the Aspen HYSYS® model. Section 3 is devoted to the results obtained by the simulations at different operating conditions in terms of both pressure and temperature, which have been then compared to the experimental results available in the scientific literature by making Normal Root Mean Square Error (NRMSE) comparison. Finally, Section 4 reports the conclusions of the work.

2. Methodology

The models that describe the behaviour of a low-temperature ALK electrolyzer stack with different operating conditions (e.g., current density, temperature, and pressure) typically include the simulation of the following

quantities: i) electric potential, ii) Faraday efficiency, iii) HTO, iv) flow rate of produced Hydrogen, v) electric power absorbed by the stack, vi) thermal power generated by the stack, vii) stack efficiency, and viii) specific consumption. The trend of the last five items is obtained by the first two. In the scientific literature, there are multiple mathematical correlations that describe the same physical phenomenon occurring within the stack. Based on the experimental data obtained by [13], a semi-empirical modeling approach has been chosen and used in this work. The mathematical model used for the stack electric potential is the one proposed by Sánchez et al. [12, 13], which is an improvement of the equation proposed by Ulleberg [15] as reported by Eq. (1).

$$U = U(T,P,i) = U_{rev} + [(r_1 + q_1) + r_2 T + q_2 P] \cdot i + s \cdot \log_{10}\left[\left(t_1 + \frac{t_2}{T} + \frac{t_3}{T^2}\right) \cdot i + 1\right] \quad (1)$$

where U is the cell electric potential, T is the temperature in [°C], P is the pressure in [bar], i is the current density [A/cm^2], and r_i, q_i, and t_i are experimental constants. The total potential U is the sum of the reversible potential U_{rev}, which is given by thermodynamics, the activation, and the ohmic overpotentials related to the kinetic losses of the electrolysis process. It is worth noting that the polarization curve is not investigated in the field of concentration overpotential since it would require a more complex model and experimental data at higher current densities.
The cell reversible potential U_{rev} is a purely thermodynamic quantity and depends on the Gibbs free energy variation ΔG between products and reactants as a function of the operating temperature and pressure as reported by Eq. (2).

$$U_{rev}(T,P) = \frac{\Delta G}{zF} = \frac{\Delta G_{H_2}(T,P) + \frac{1}{2}\Delta G_{O_2}(T,P) - \Delta G_{H_2O}(T,P)}{zF} \quad (2)$$

Regarding Water electrolysis, the reversible cell potential U_{rev}^0 under standard conditions (P^0=1bar, T^0=25°C) is equal to 1.229 V. The value of the reversible voltage is a function of temperature and pressure, thus assuming different values from the standard one as expressed by Eq. (3) that is the Nernst's equation [16]:

$$U_{rev} = U_{rev}^0 + \frac{R \cdot T_K}{z \cdot F} \cdot \ln\left(\frac{p_{H2} \cdot \sqrt{p_{O_2}}}{a_{H_2O}}\right) \quad (3)$$

where T_K is the temperature in [K], R is the universal constant of gases (8.314 J/K mol), z is the number of electrons transferred in the electrolysis reaction (2 mol$_{e^-}$/mol$_{H2}$), F is the Faraday constant (96,485 C/mol), a_{H2O} is the coefficient of activity of Water, p_{O2} and p_{H2} are the partial pressure expressed in [bar] of Oxygen and produced Hydrogen, respectively. Assuming that the membrane is subjected to the mechanical equilibrium, the partial pressures of Hydrogen are the same as the Oxygen ones (p_{O2}=p_{H2}=p_{tot}) and, assuming that the coefficient of activity of the Water is approximately equal to 1 [17], Eq. (3) can be written as follows:

$$U_{rev} = U_{rev}^0 + \frac{R \cdot T}{z \cdot F} \cdot \ln\left(P_{tot}^{\frac{3}{2}}\right) \quad (4)$$

The reversible cell potential U_{rev}^0 can be also calculated considering isobaric conditions (at standard pressure P^0 equal to 1 bar) and thus reducing its dependency only on the temperature [17]. In the scientific literature, there are different empirical relationships such as the one proposed by Hammoudi et al. [18] as reported by Eq. (5).

$$U_{rev}^0(T,P^0) = 1.50342 - 9.956 \cdot 10^{-4} T_K + 2.5 \cdot 10^{-7} {T_K}^2 \quad (5)$$

Finally, the reversible potential is calculated by the set of Eq.s (4) and (5). The electrolyzer under investigation consists of 12 cells installed in series; thus, the stack voltage is obtained by multiplying the cell voltage by the number of cells.

$$U_{stack} = N_{cell} \cdot U \tag{6}$$

where N_{cell} is the number of cells installed in series.

The Hydrogen production rate $\dot{n}_{H2}$ [mol/s] is strictly related by the stoichiometry of the reaction and to the applied current *I* [A], which is the same for all the cells connected in series. The Hydrogen production rate is equal to the current density *i* times cell area A_{cell} as reported in Eq. (7) that is the Faraday's equation. As far as the Faraday efficiency η_{Far} is concerned, Sánchez et al. [12, 13] introduced a modification to the η_{Far} Ulleberg's relation [15] with the use of experimental parameters f_{ij} to include also the effect of the temperature as reported by Eq. (8).

$$\dot{n}_{H2} = \eta_{Far} \frac{I}{zF} \tag{7}$$

$$\eta_{Far} = \frac{i^2 \cdot (f_{21} + f_{22} T)}{(f_{11} + f_{12} T) + i^2} \tag{8}$$

As for the HTO, the equation proposed by Hug et al. [19], which describes the HTO dependence on both current density and temperature, has been used by Sánchez et al. [12, 13] and modified by introducing the dependence of pressure as reported by Eq. (9).

$$HTO = C_1 + C_2 T + C_3 T^2 + (C_4 + C_5 T + C_6 T^2) \cdot \exp\left(\frac{C_7 + C_8 T + C_9 T^2}{i}\right) + E_1 + E_2 P + E_3 P^2 + (E_4 + E_5 P + E_6 P^2) \cdot \exp\left(\frac{E_7 + E_8 P + E_9 P^2}{i}\right) \tag{9}$$

where C_1 to C_9 are constants that represent the influence of the temperature in the HTO, and from E_1 to E_9 there are constants that represent the relations between the gas purity and the pressure.

The electrical power absorbed by the stack $\dot{W}_{el}$ allows to evaluate the specific electrical consumption and the stack efficiency as well, as described by Eq. (10).

$$\dot{W}_{el} = U \cdot N_{cell} \cdot i \cdot A_{cell} \tag{10}$$

Regarding the specific consumption c_{sp}, it can be expressed as the ratio between electric power $\dot{W}_{el}$, which is expressed in [kW], and the mass flow rate of the produced Hydrogen $\dot{m}_{H2}$ expressed in [kg/h].

$$c_{sp} = \frac{\dot{W}_{el}}{\dot{m}_{H2}} = \frac{U(i,T,P) \cdot 2F}{10^3 \cdot \eta_F(i,T) \cdot 7.257168} \tag{11}$$

where 7.257168 is a conversion factor in [s•kg/h•mol] that allows to express the molar flow rate of Hydrogen in [kg/h] knowing its value in [mol/s].

Stack electrical efficiency, η_{stack} , is defined as the ratio between the chemical energy contained in the produced hydrogen and the electrical power needed for its production, as shown by Eq. (12).

$$\eta_{stack} = \frac{\dot{n}_{H2} \cdot LHV}{\dot{W}_{el}} \tag{12}$$

where LHV stands for the Lower Heating Value of hydrogen that is equal to 241.82 kJ/mol.

The thermal power $\dot{Q}_{th}$ involved in the electrolysis process, which must be removed to maintain the isothermal condition, is calculated as:

$$\dot{Q}_{th} = i \cdot A_{cell} \cdot (U(i,T,P) - U_{tn}(T,P)) \quad (13)$$

where U_{tn} is the thermoneutral potential of the stack, which is a function of both temperature and pressure.

As previously described, the electrochemical process model is integrated into the Aspen HYSYS® environment using a spreadsheet since the software does not present pre-build blocks for modeling electrochemical components. The rest of the electrolyzer stack (e.g., inlet and outlet fluid management, temperature and pressure settings, etc.) is represented by the common tools made available by the software. Steady-state operations have been considered and the fluid thermodynamic conditions (e.g., pressure and temperature) are set (e.g., isothermal and isobaric conditions are considered for the whole process). The selected *Fluid Package* is the "*Peng-Robinson*". The Water dissociation reaction is defined as a conversion reaction occurring in the "*Electrolysis reactor*", which represents the set of electrodes. Based on the thermodynamic operating conditions (e.g., temperature, pressure) and load current, the reactor sources the main electro- and thermo-chemical equations from the spreadsheet defining the reaction products and the electric power required. U_{rev} is calculated from the thermodynamic fluid property databases, which are embedded in the software, using Eq. (2). The reactor has two material flows at the output: "*Reaction Gas*" and "*Liquid Product*", where the latter is always null since the molar flow rate of the Water entering the model is equal to the molar flow rate of the Hydrogen that is calculated in the spreadsheet using the Faraday equation. The mixture of Hydrogen and Oxygen "*Reaction gas"* is sent to the second component that is the "*Component splitter*" called "*Electrode separator*": through this component it is possible to separate the oxidation and the reduction semi-reactions in the anode and in the cathodic chambers of each cell, respectively. The separator is set up so that the flows are chemically pure at the outputs (no crossover phenomena). The current output flows are corrected with the HTO that is calculated in the spreadsheet: indeed, the amount of Hydrogen separated from the anode flow by the "*Flow splitter",* here called "*Crossover_Tee*", is subsequently mixed to the Oxygen in the anode.

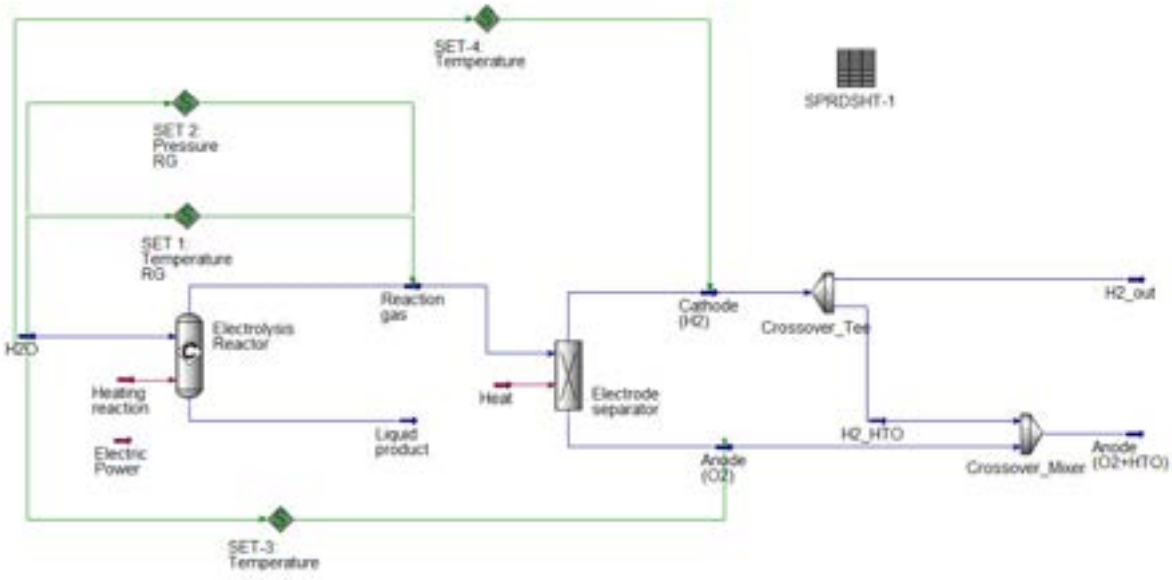

Figure. 1. Model of the low-temperature alkaline electrolyzer developed in Aspen HYSYS®.

In order to obtain comparable simulation results, the electrolyzer that has been modeled is the same one that has been characterized experimentally by Sánchez et al. [12, 13]. It is a small-sized, laboratory scale electrolyzer and its main characteristics are listed in Table 1. To obtain the experimental parameters previously described, the available experimental data have been fitted by using the Matlab® "*Curve Fitting Tool"*. The

regressions are non-linear and multiple, namely two in the case of the Faraday efficiency and three in the case of electric voltage and HTO.

Table 1. Characteristics of the alkaline electrolyzer analysed by Sánchez et al. [12, 13].

Main characteristics	Numerical value	Units of measurement
Hydrogen production flow rate	2.5	m^3/h
Maximum operating pressure	30	bar
Electric potential range	0-120	V
Electric current range	0-500	A
Maximum power	15	kW
The active area of the electrodes	1,000	cm^2
Number of cells	12	-
Electrolyte concentration	30-40	wt% KOH

3. Results and comments

The simulations results, in terms of electrolyzer performance, are evaluated as a function of the current density (between 0-0.5 A/cm^2 with steps of 0.005 A/cm^2) and the parametrization of both pressure and temperature (between 55-85°C with steps of 5°C, and between 1-29 bar with steps of 4 bar). Aspen HYSYS® allows to perform parametric "case studies" and investigate how each variable affects the results while keeping the remained parameters fixed. Figure 2 shows the results related to the stack potential at different values of temperature and pressure. It is worth noting that the trends of the other quantities such as Hydrogen flow rate, etc. have not been here reported.

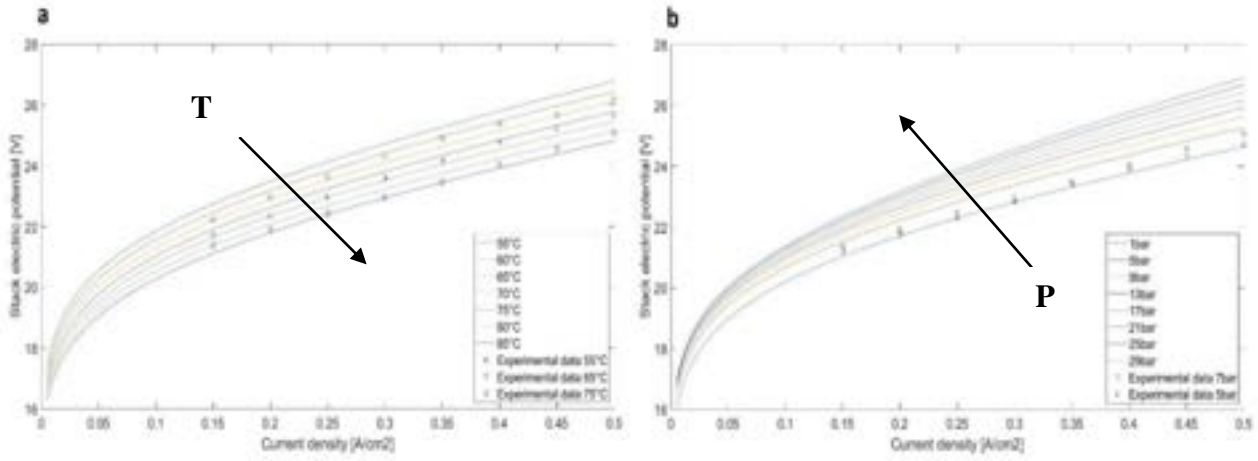

Figure. 2. (a) Stack voltage trend as a function of current density and temperature (pressure equal to 7 bar), and (b) of current density and pressure (temperature equal to 75°C).

In particular, the voltage decreases while the system temperature increases because part of the electric energy required for the electrolysis process is replaced by the associated thermal energy developed during the reaction (see Figure 2). The increase in temperature also improves the reaction kinetics by reducing the activation overpotentials as well as impacting the U_{rev} through the Nernst potential. Furthermore, the electric potential rises when the pressure increases due to the Nernst potential and the one related to the ohmic overpotential.

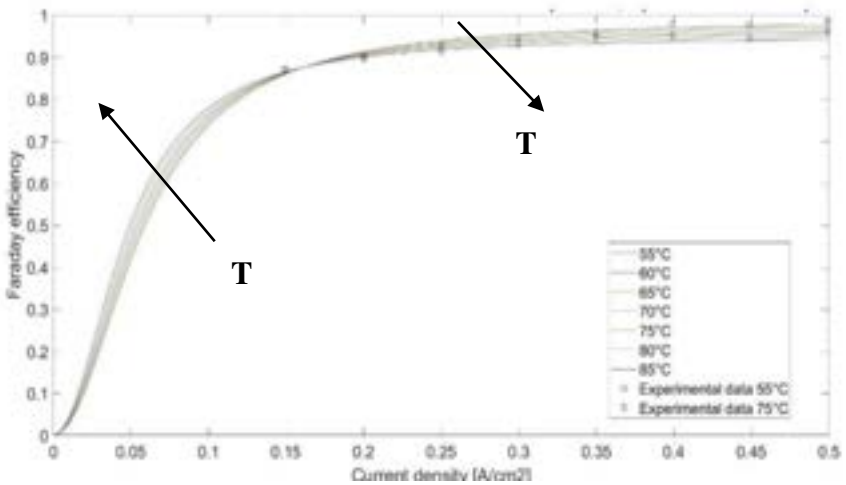

Figure. 3. Faraday efficiency trend as a function of current density and temperature (pressure equal to 7 bar).

Figure 3 shows the trend of the Faraday efficiency as a function of current density and temperature according to Eq. (8). The Faraday efficiency quickly reaches values close to 1 when current density values higher than 0.4 A/cm^2 are used. Conversely, Faraday efficiency decreases when current density values lower than 0.17 A/cm^2 and the increase of temperature leads to lower Faraday efficiency values.

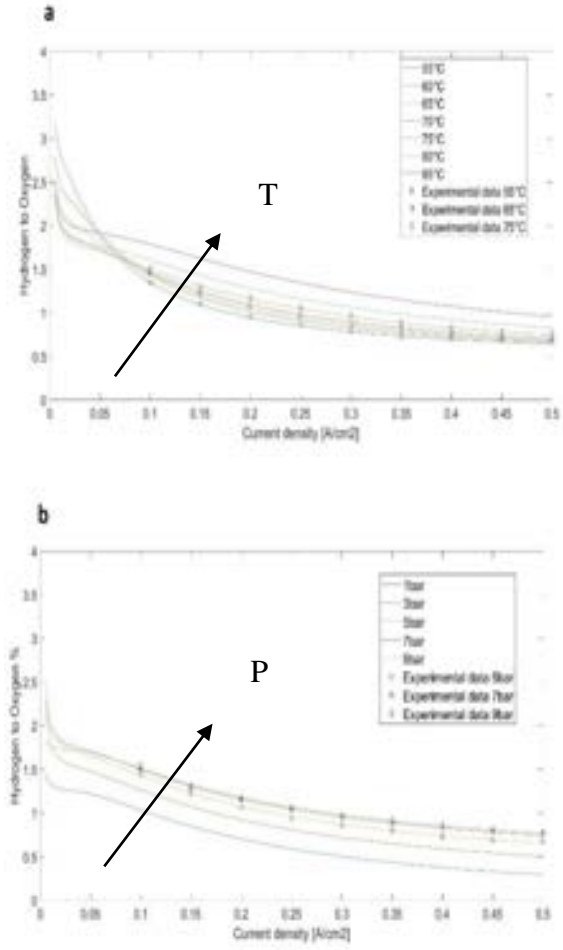

Figure. 4. (a) HTO trend as a function of current density and temperature (pressure equal to 7 bar), and (b) of current density and pressure (temperature equal to 75°C).

Figure 4a shows that the HTO increases when the current density decreases and tends to increase with the increasing temperatures. For this reason, operations with very low values of current density are undesirable because it would be preferable to avoid a HTO beyond the flammability limit of a H_2/O_2 mixture that could lead to combustion or explosion [20]. The higher amount of Hydrogen in the Oxygen stream at higher temperatures is caused by the higher diffusion velocity at elevated temperatures [17]. Figure 4b still shows an increase of the HTO as the current density decreases and as the operating pressure increases. For increasingly small current density values, the HTO model shows an asymptotic behaviour with anomalous variations due to lack of experimental data for very low currents: this means that the model is only valid for the range of density current values for which HTO measurements are available.

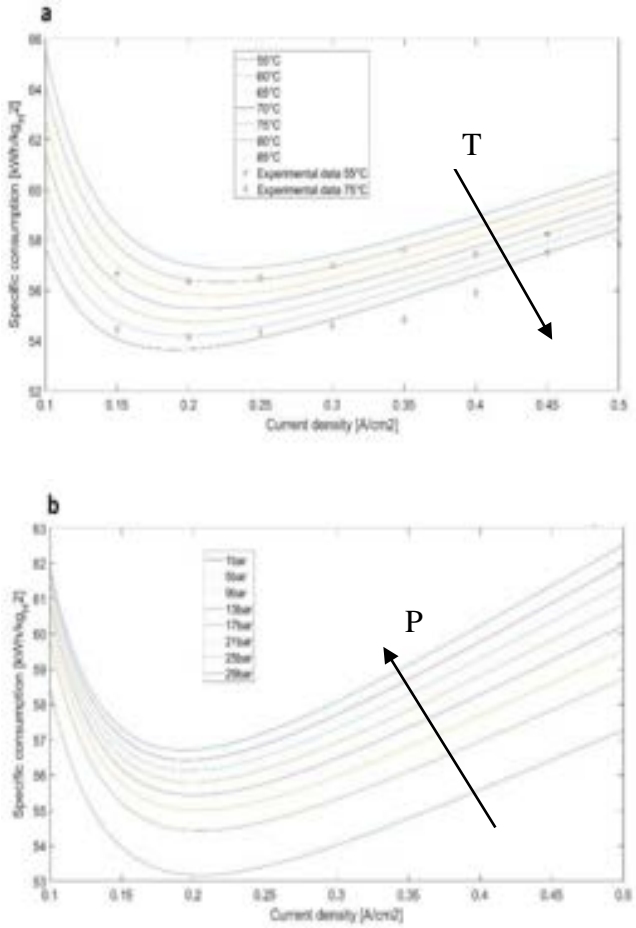

Figure. 5. (a) Specific consumption trend as a function of current density and temperature (pressure equal to 7 bar), and (b) of current density and pressure (temperature equal to 75°C).

Figure 5 shows a non-linear dependence of the specific consumption on the current density. In [13], no experimental data are available for the specific consumption, but these were obtained with data on Faraday efficiency and stack electric potential through Eq. (11). The specific consumption function reaches its minimum value at 0.2 A/cm^2, and it decreases with increasing temperature (see Figure 5a) due to the decrease of the electric potential and increases with the increasing pressure (see Figure 5b) due to the increase of the electric potential. The increase of the specific consumption, when the current density decreases below the threshold of 0.2 A/cm^2, is due to a decrease of the Faraday efficiency that is faster than the electric potential as expressed by Eq. (11). The Faraday efficiency and the electric potential increase with the current density, resulting in an increasing curve for current densities greater than 0.2 A/cm^2. The specific consumption is always between 53 and 63 kWh/kg$_{H2}$.

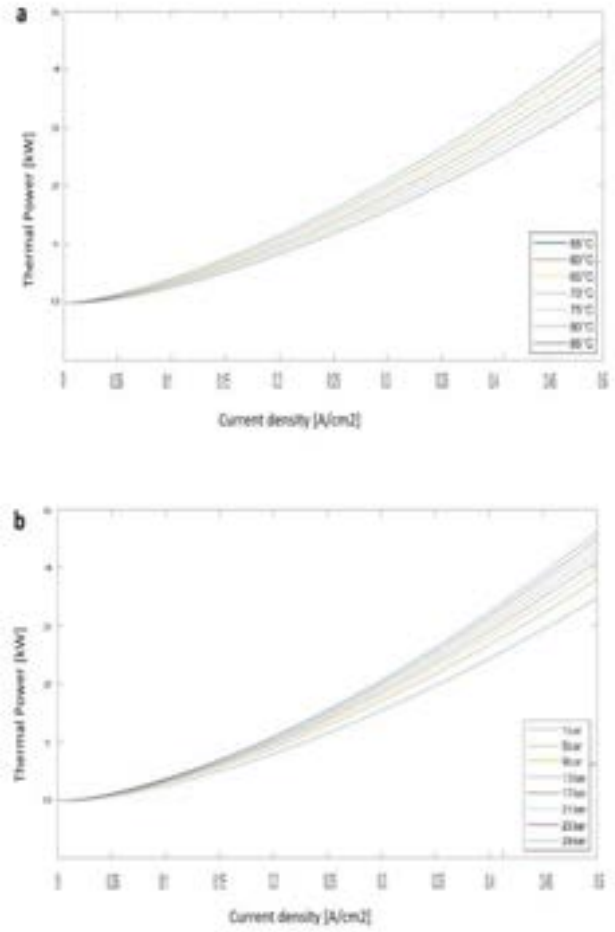

Figure. 6. (a) Thermal power trend as a function of current density and temperature (pressure equal to 7bar), and (b) of current density and pressure (temperature equal to 75°C).

As for the thermal power, Figure 6 shows how it increases with increasing current density and how this trend tends to decrease as the operating temperature increases and to increase as the operating pressure increases. This behaviour can be explained by the influence of both temperature and pressure exert on the stack potential: as the temperature increases the stack potential decreases, while as the pressure increases the potential increases. However, the thermoneutral potential can be considered approximately constant in every case. There are not experimental data for the thermal power. To evaluate the results from the developed model, the *Normal Root Mean Square Error* (NRMSE) has been calculated with respect to the literature experimental values in the same operating conditions reported in [13] (see Table 2).

Table 2. NRMSE values: comparison between model and experimental results.

	7 bar, 55°C	**7 bar, 65°C**	**7 bar, 75°C**	**5 bar, 75°C**	**9 bar, 75°C**
Electric potential	$4.066e^{-04}$	$3.990e^{-04}$	$4.095e^{-04}$	$4.317e^{-04}$	-
Faraday Efficiency	$8.253e^{-05}$	-	$4.871e^{-05}$	-	-
HTO	$5.519e^{-04}$	$2.486e^{-04}$	$3.932e^{-04}$	$4.115e^{-04}$	$3.213e^{-04}$
Specific consumption	$4.859e^{-04}$	-	$4.155e^{-04}$	-	-
Stack efficiency	$4.452e^{-04}$	-	$3.903e^{-04}$	-	-
Electric power	$4.153e^{-04}$	$3.295e^{-04}$	$3.865e^{-04}$	$2.078e^{-05}$	-
Hydrogen flow rate	$6.415e^{-05}$	-	$4.208e^{-05}$	-	-

The regression in Matlab of the cell potential from experimental data was conducted by using the set of Eq.s (4) and (5) where the reversible cell potential U_{rev}^{0} is only a function of the temperature (considering isobaric conditions (at standard pressure P^0 equal to 1 bar) according to [18], while In Aspen HYSYS the reversible cell potential is calculated automatically by implementing Eq. (2). The result is that the numerical value of the reversible cell potential calculated in Aspen HYSYS® is on average greater than the one calculated with the combination of Eq.s. (4) and (5) by 0.0395 V: this is mainly due to the fluid package selected that evaluates the trend of the state function of the components in the system. As a result, an average overestimation of 0.474 V of the electric stack potential of the model developed in Aspen HYSYS® is obtained compared to the experimental data; therefore, also other results are overestimated (e.g., specific consumption and electric power consumed). Conversely, the stack efficiency is underestimated compared to the experimental data. A possible way to increase the accuracy of the model is to perform regressions of the experimental data by firstly calculating the reversible potential according to Eq. (2), and then determining the experimental coefficients from the equation given by the combination of Eq.s. (1) and (2).

4. Conclusions

This work presents and discusses the development of a semi-empirical simulation model developed with Aspen HYSYS® related to a low-temperature Water alkaline electrolysis stack. The main performance parameters (e.g., electric power required and stack efficiency) are evaluated according to different input conditions (e.g., current density, pressure, temperature, etc.).

The trend of the electric potential has been obtained as the sum of the reversible potential and the overpotentials obtained through non-linear multiple regressions performed in Matlab® with the "*Curve Fitting Tool"* of several empirical parameters.

Results show a good agreement with the data made available by the scientific literature (experimental data) for all the analysed quantities within the selected range of operation parameters. Slight differences have been found due to the overestimation of the cell/stack potential related to the electrochemical model: indeed, the comparison between the model and experimental results showed NMRSE values ranging between $3.990e^{-04}$ and $4.317e^{-04}$. Moving to the Faraday efficiency, values ranging between $4.871e^{-05}$ and $8.253e^{-05}$ have been obtained. Then, the specific consumption values varied between $4.155e^{-04}$ and $4.859e^{-04}$, the electric power variation goes from $2.078e^{-05}$ to $4.145e^{-04}$, and the Hydrogen flow rate from $4.208e^{-05}$ to $6.415e^{-05}$ where the former is the lowest threshold value obtained in this analysis. On the other hand, as far as the HTO is concerned, NRSME values vary between $2.486e^{-04}$ and $5.519e^{-04}$, where the latter is the highest threshold value obtained in this analysis. It is worth noting that these results denote that a simple thermodynamic model with the addition of few semi-empirical corrections can represent quite well the operation of the electrolyzer stack without requiring excessive simulation efforts in terms of both kinetic and dynamic behaviours.

The present model will be subsequently implemented in a wider system resembling the behaviour of an integrated Hydrogen system composed by, besides the electrolyzer, a metal hydrides Hydrogen storage and a fuel cell. Furthermore, the future complete model will also take into account both Water recirculation and gas purification processes, which are fundamental in the electrolysis process.

Abstract:

In current times, climate change due to greenhouse gas (GHG) emissions and rising fossil fuel prices create the need to focus more on renewable energy to become energy independent. The combustion of solid fuels such as biomass is a reliable option for thermal energy production and for combined heat and power production. This work focuses on the quality analysis of carbon-rich solid fuel produced by Hydrothermal Carbonization (HTC) of green waste (such as leaves, small branches, and grass). The combustion and emission performances of the HTC pellets are compared to those of conventional softwood pellets. Thermogravimetric analysis, kinetics assessment, and final use tests on a fixed bed boiler were carried out for both fuels. Combustion efficiency, boiler efficiency, and emissions factors were experimentally determined, computed and compared. Thermogravimetric analyses of the fuels show some qualitative and quantitative differences, in particular a third peak of burning rate corresponding to the oxidation of solid carbon, with a high activation energy. For similar parameters of boiler operation with HTC pellets, a 7% increase in combustion efficiency and a 7% increase in boiler efficiency were observed. However, higher particulate matter and CO emissions were observed. Results suggest that the air/fuel ratio can be further optimized for the use of HTC pellets for this type of boiler. This makes HTC pellets a promising fuel to help tackle climate change.

Keywords:

HTC pellets; softwood pellets; thermogravimetric analysis; boiler efficiency; PM; gaseous emissions.

1. Introduction

In the last few decades, biomass as an energy resource has been considered an attractive alternative to fossil fuels in reaching the European target to reduce carbon dioxide emissions [1]. Nevertheless, others transformation routes of biomass into more valorized goods can be considered, such as biochemical products and raw materials for other industries. This could transform the perspective of biomass as an energy resource, especially woody biomass [2]. Biomass resources from agriculture wastes, grass, leaves, sludge from anaerobic digestion, and urban green wastes have great potential as energy resources. However, such resources with low energy density, high moisture, and high alkali content are still challenging to direct combustion in conventional boilers, especially in issues related to ash formation [3]. Therefore, biomass resource pre-treatments and raw biomasses upgrade into better-quality biofuels have a substantial potential to increase the feasibility of their use for heat and power generation [4, 5].

Hydrothermal carbonization (HTC) has been considered an efficient alternative for upgrading raw combustible material [6], especially for organic feedstock with high moisture contents [7]. Nevertheless, the final use of

such solid fuel, as well as biomass fuels, brings some attention to the emissions issues, especially particulate matter emissions [8, 9]. Therefore, the present study aims to carry out a thermal and emission characterization of HTC pellets through a kinetics description of the fuel, as well as a final use combustion experiment in a 40 kW pellets boiler for efficiency and emission assessment.

2. Material and methods

HTC pellets produced via HTC treatment of green waste were tested and compared to softwood pellets as a reference. The kinetics description was developed by employing Thermogravimetric Analysis (TGA) in a Mettler Toledo TGA/DSC 3+ STARe System. The TGA experiments were conducted under an air atmosphere of 60.0 mL/min, for both softwood pellets and HTC pellets.

The thermal and environmental efficiency of HTC pellets combustion was assessed at the Vrije Universiteit Brussel biomass laboratory on a 40 kW laboratory boiler manufactured by HS TARM (USA). It has a gas-in-tube heat exchanger with helical rods. The boiler is designed for fuels in the form of pellets and chips. It is connected to the thermal network equipped with a PLC control system from Siemens (Desigo CC Compact). It is equipped with various sensors to control and measure the flow rate and temperatures along the network and on the exhaust gas. Two combustion tests were carried out, the first using a high-quality fuel as wood pellets, which was taken as a reference for the second test using HTC pellets. In both tests, the exhaust gas composition was measured with a portable emission analyzer HORIBA PG-250. The particulate matter was measured using an ELPI+ (Electrostatic Low-Pressure Impactor). Additionally, the flue gas temperature and circulation water temperatures were measured. Also, the fuel hopper was continuously weighted to account for the fuel consumption rate.

2.1. Experimental setup for emissions assessment

Figure 1 shows a scheme of the measurement equipment used for conducting the softwood pellets and HTC pellets tests.

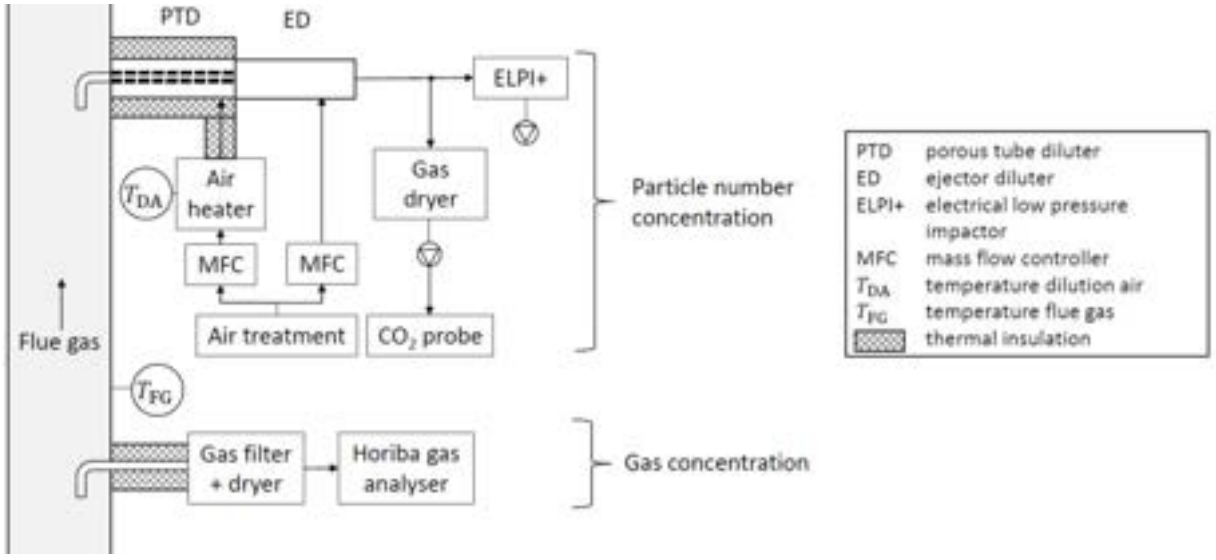

Figure. 1. Scheme of equipment for measuring particulate and gaseous emissions. Source: taken from [10] and modified by the authors.

While performing the particulate matter (PM) measurement with the ELPI+, the flue gases were first diluted in a dilution system to control parameters like temperature, humidity, and particulate concentration according to the specifications of the measuring device. This configuration increases the instrument's life and minimizes the probability of modifications in the PM distribution due to aerosol chemistry during the measurement process. In this particular setup, a two-stage dilution system manufactured by Venacontra has been used, as shown in [11].

2.2. Indexes for combustion characterization and kinetics

The ignition and burnout characteristics of a fuel are commonly related to the ignition temperature (T_{i}) and the burnout temperatures (T_b). Ignition temperatures are estimated graphically (Tangent Method), and the first peak point of the TG first-derivate (DTA) is used as an intersection point with the TG curve, as it is described in [12, 13].

The fuel thermal degradation is expressed as Eq. (1) shows, with W_i being the initial mass fraction of the sample, W the remaining mass fraction of the sample, and W_{f} the final mass fraction of the sample

$$\alpha = \frac{W_i - W}{W_i - W_f}. \quad (1)$$

The burnout temperature can be estimated via the "Conversion Method", suggested by [14]. The method uses a simple criterion for selecting the burnout temperature, which considers T_b at the point where the fuel reaches 99% of thermal degradation $(\alpha = 0.99)$. Also, the tangent method can be used. Nevertheless, authors such as Liu et al. suggest that in cases where the air is used as a carrier gas during TGA two distinct peaks appeared; then the tangent method should be used for the estimation of burnout temperature by using the second DTG peak as intersection point instead of the first DTG peak [12].

Combustion characteristics of biomass fuels can be assessed by the index *S* [15], Eq. (2) shows the formula to compute a comprehensive combustion index

$$S = \frac{(\mathrm{d}X/\mathrm{d}t)_{\max} \cdot (\mathrm{d}X/\mathrm{d}t)_{\mathrm{mean}}}{T_{\mathrm{i}}^2 \cdot T_{\mathrm{b}}}. \quad (2)$$

The index considers the maximum fuel conversion rate $[(\mathrm{d}X/\mathrm{d}t)_{\max}]$ and the average value $[(dX/dt)_{\mathrm{mean}}]$. According to [16], a higher comprehensive combustion index represents a higher fuel reactivity and thus a better combustion performance of the fuel. In a biomass combustion process, pyrolysis is one of the most difficult stages to accurately account for. Nevertheless, some general conversion routes can be assumed, of the form: biomass → char + volatiles + gases. Depending on the pyrolysis regime, the amount of products can vary [17, 18]. In this work, the combustion reaction kinetics of softwood pellets and HTC pellets are studied by using data obtained from TGA experiments. There are several methods available in the literature for modelling the combustion reaction kinetics, such as the Kissinger-Akahira-Sunose (KAS) method [19, 20], Ozawa-Flynn-Wall method (OSF) [21, 22] or Coats – Redfern method [23]. The present study selected the Coats – Redfern method, considering the simplicity of the method and the possibility to estimate the activation energy as well as the pre-exponential factor.

2.3. Efficiency and emission factor calculation

Besides the theoretical study of the combustion reaction kinetics of the HTC pellets, the final use application of this HTC fuel was also assessed experimentally. In the present study, the boiler and combustion efficiencies are calculated from the parameters measured during the experiments, in this case using a more practical approach. Equation (3) shows the efficiency calculation of a boiler using the direct method

$$\eta_B = \frac{\dot{Q}_L}{\dot{Q}_{\mathrm{F}}}. \quad (3)$$

$\dot{Q}_L$ represents the thermal power transferred from the fuel to the feeding water of the boiler. As the water vapour in the exhaust gases is not condensed, the LHV is used to compute the thermal power from the fuel $\dot{Q}_F$. The indirect method for computing the efficiency in the boiler is a more interesting option, considering the possibility to identify the critical point related to all the effects that cause a reduction in boiler efficiency. However, a boiler and combustion efficiency calculation by the indirect method require a representative sampling of bottom and fly ashes in the boiler. In a small fixed-bed boiler, at least 24 hours of operation will be necessary to get an expected amount of bottom ash, completing one cycle of ash out of bed. Nevertheless, Good and Nussbaumer have proposed and simplified method for computing the combustion efficiency of biomass boilers [24, 25]. The method has been successfully applied if CO ≤ 0.5 vol%, CO_2 ≥ 5 vol% and for exhaust gas temperatures below 400°C [26].

$$\eta_C = 100 - L_{\mathrm{Th}} - L_{\mathrm{Ch}}, \quad (4)$$

Equation (4) relates the combustion efficiency to two parameters: the thermal (L_{Th}) and chemical losses (L_{Ch}).

$$L_{\mathrm{Th}} = \frac{(T_{\mathrm{fg}} - T_{\mathrm{A}})\left\{1.39 + \frac{122}{\mathrm{CO_2 + CO}} + 0.02 \cdot u\right\}}{\frac{\mathrm{LHV}}{100} - 0.2442 \cdot \mathrm{u}}, \quad (5)$$

$$L_{\mathrm{Ch}} = \frac{\mathrm{CO}}{\mathrm{CO_2 + CO}} \frac{11800}{\frac{\mathrm{LHV}}{100} - 0.2442 \cdot u}. \quad (6)$$

T_{fg} and T_{A} stand for the temperature of the exhaust gases and atmosphere. CO and $\mathrm{CO_2}$ are the carbon monoxide and carbon dioxide volume fractions of the dry flue gases. *u* represents the fuel moisture expressed in percentage.

Additionally, expressing the energy balance on the boiler, some approximation of the losses regarding unburned carbon on bottom and fly ash can be made. Equation (7) represents the energy balance for a steady-state operation of the boiler

$$\dot{E}_{\mathrm{in}} = \dot{E}_{\mathrm{out}}. \quad (7)$$

Then, identifying all energy flows involved in the process, as Eq. (8) shows, an estimation of energy losses regarding unburned fuel $(\dot{Q}_{\mathrm{UBF}})$ can be computed as

$$\dot{Q}_{\mathrm{F}} = \dot{Q}_{\mathrm{L}} + \dot{Q}_{\mathrm{FG}} + \dot{Q}_{\mathrm{UBF}} + \dot{Q}_{\mathrm{RC}}. \quad (8)$$

The values of the thermal load and thermal power from the fuel are known values from the direct method mentioned earlier. The losses by radiation and convection $(\dot{Q}_{\mathrm{RC}})$ of the boiler can be neglected. However, Lyubov et al. found that for industrial hot-water boilers, the losses by convection and radiation to the environment are less than 0.5% of the thermal power supplied by the fuel to the boiler furnace [27]. Then, with the value of losses by unburned fuel, Eq. 9 can be used to compute the combustion efficiency, which is based on the total power from the fuel and the power not used by unburned fuel.

$$\eta_{\mathrm{C}} = \left(1 - \frac{\dot{Q}_{\mathrm{UBF}}}{\dot{Q}_{\mathrm{F}}}\right), \quad (9)$$

The emission factors (*EF*) are computed on an energy density basis, allowing to compare emissions factors from different combustion tests without considering differences in oxygen concentrations.

$$EF_{\mathrm{e}} = \frac{\dot{m}_{\mathrm{i}}/\Delta t}{(\dot{m}_{\mathrm{f}}/\Delta t)\cdot \mathrm{LHV}}. \quad (10)$$

In Eq. (10), m_{i} represent the mass of each pollutant emitted during the considered time window (Δt). The emissions factors for particle number of $\mathrm{PM}_{2.5}$ and PM_{10} are computed according to Eq. 9-10.

$$n_{\mathrm{PM}} = \mathrm{y_n} \cdot \mathrm{DR}_2 \cdot \dot{V}_{\mathrm{fg,dil,dry}}, \quad (11)$$

$$\mathrm{EF}_{\mathrm{PMx}} = \frac{\mathrm{n}_{\mathrm{PM}}/\Delta t}{(\dot{\mathrm{m}}_{\mathrm{f}}/\Delta t)\cdot \mathrm{LHV}}. \quad (12)$$

In Eq. (11), y_{n} represents the particle number, DR_2 stands for dilution ratio at dilution stage two and $\dot{V}_{\mathrm{fg,dil,dry}}$ represent the volumetric flow of diluted exhaust gases at dry conditions.

3. Results and discussions

3.1. Characterization of fuel combustion

Table 1 summarizes the significant properties of physicochemical characterization of the fuels burned during the TGA experiments and the combustion tests. It can be noticed that HTC pellets have a higher Lower Heating Value (LHV) than softwood pellets, about 18% higher. The higher LHV of the HTC pellet is reflected in the higher fixed carbon content, which is expected in a highly carbonized product obtained from the HTC process. From elemental composition, chlorine compound is present in the tested HTC pellets, in low amounts but still the potential source of corrosion issues.

Table 1. Physicochemical characterization of the analyzed fuels. Source: data adapted from [10, 28, 29].

Property	Units	Softwood pellets	HTC pellets
Bulk density	kg/m^3	≥630	696
Lower Heating Value	MJ/kg_db	≥18.8[a]	23.12
Higher Heating Value	MJ/kg_db	≥20.2[a]	24.36
Moisture content	wt%, ar	<8	5.8
Volatile matter	wt%, ar	(77.7)	69.1
Fixed carbon	wt%, ar	(22.3	30.9
Ash content	wt%, ar	(0.3)	11.0
Carbon (C)	wt%, db	(52.2)	57.9
Hydrogen (H)	wt%, db	(5.9)	5.7
Nitrogen (N)	wt%, db	≤0.3	1.26
Oxygen (O)	wt%, db	(39.1)	23.3
Sulfur (S)	wt%, db	≤0.04	0.137

wt%: percentage on weight basis; ar: as received; db: dry basis; daf: dry basis and ash free. The values in brackets are the median of similar softwood pellets taken for the original author [10] from the public Phyllis2 database. [a]The heating values were computed by the original author [10] using the Boie model [30].

In general, during TGA experiments of lignocellulose-biomass under oxidative conditions, an initial drying step can be observed (of free water, crystal water and absorbed water) which extends from room temperature up to about 170°C (A). The second step is when volatilization and combustion of volatiles start, which could extend from about 120°C up to about 420°C (B). Then, a third step of char oxidation starts from a range temperature

of about 310°C up to about 520°C (C). Finally, the burnout step appears, when all remaining char is depleted, starting at about 480°C (D) [31, 32]. The temperature range of each step of biomass combustion shown by the TGA experiments varies with the type of biomass and is also affected by the heating rate. However, the values showed could be taken as reference values for other biomass samples, considering that the mentioned author analysed 12 different biomass resources with heating rates of $10\,℃/\mathrm{min}$ and $20\,℃/\mathrm{min}$.

Figure 2(b) shows the TGA of softwood pellets and Fig. 2(a) shows the derivative thermogravimetric curve (DTG) of softwood pellets. The drying step extends from 25°C up to 95°C. It is followed by an almost flat zone, where a nearly constant weight loss rate (of about 0.42%) is observed, over a temperature range of about 100°C. The more active drying range and the almost constant weight loss rate were grouped into step A. Step B corresponds to the release and combustion of volatiles, coming from the hemicellulose at the beginning of the step and cellulose at the end of the step. It is where the highest weight loss is observed, between 197°C and 357°C. Step C is in a range of about 357°C to 500°C, where the char coming from the lignin is oxidized, however, some authors point out that some char could appear at the end of step B as well [17, 33, 34]. The burnout step starts from 500°C, where char is completely oxidised. For the purpose of the present analysis, two zones were further studied, zone I (197°C - 357°C) and zone II (357°C - 500°C).

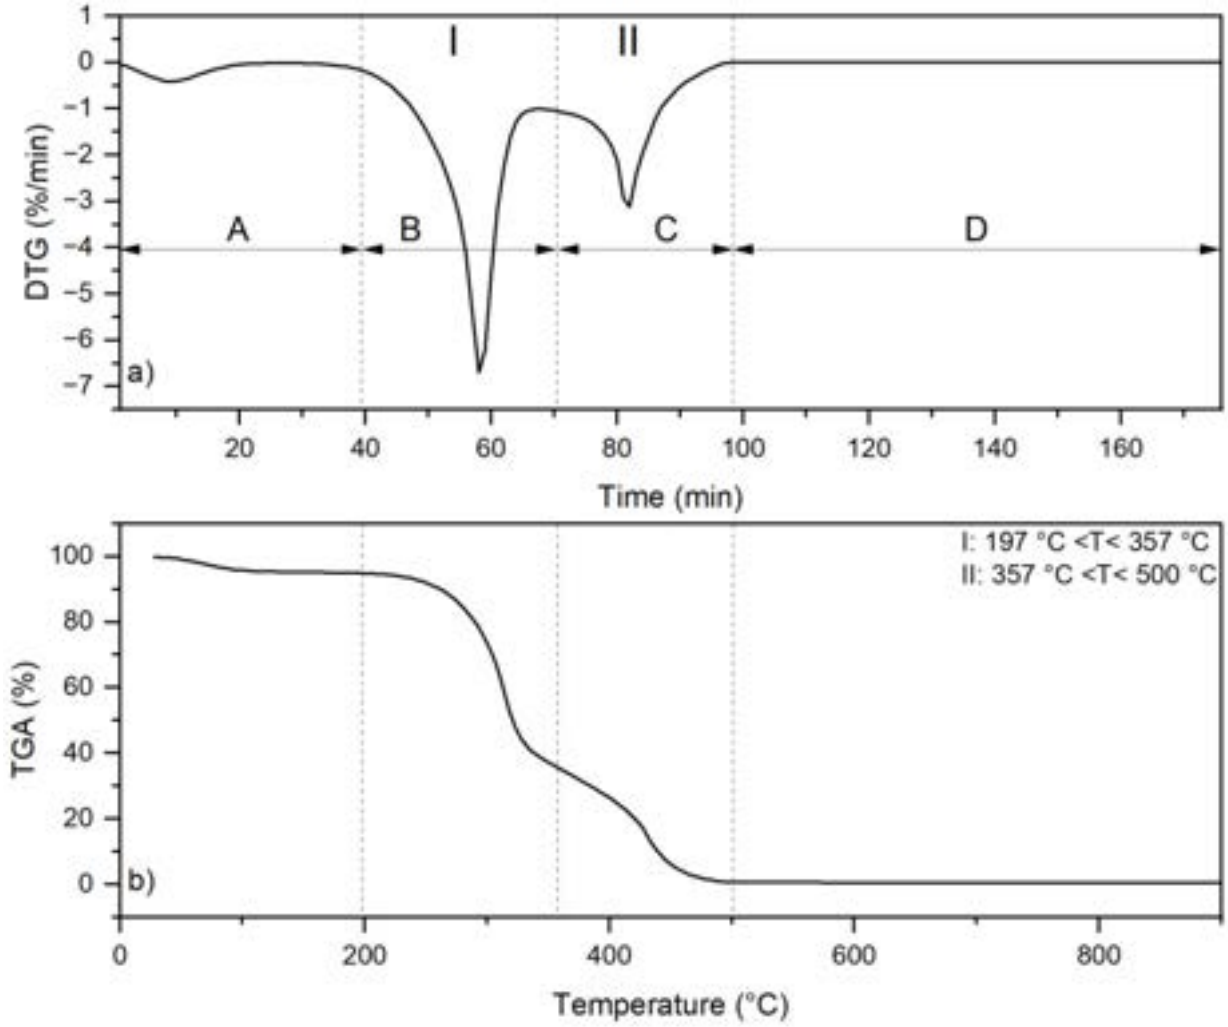

Figure. 2. Thermal degradation of softwood pellets, a) the derivative of thermogravimetry (DTG) analysis and b) thermogravimetry analysis (TGA).

Figure 3(b) shows the TGA of HTC pellets and Figure. 3(a) shows the derivative thermogravimetric curve (DTG) of HTC pellets. As for the softwood pellets, four steps can be identified (A to D), but there are some important differences in these combustion steps. Step A extends in the temperature range of about 15°C more for HTC pellets than for softwood pellets. Additionally, two distinct peaks can be appreciated. The first one is from 25°C to 117°C, which is assumed to correspond to the evaporation of free water in the fuel and the second from 117°C to 212°C, corresponding to the evaporation of the crystal water and absorbed water, contained in the ashes which in this case is about 36 times higher than for softwood pellets. Step B extends from 212°C to 322°C. The temperature span for this step is 50°C less for HTC pellets than for softwood pellets, which suggests a smaller quantity of volatiles released for the HTC pellets case, as confirmed by the volatile contents given in Table 1.

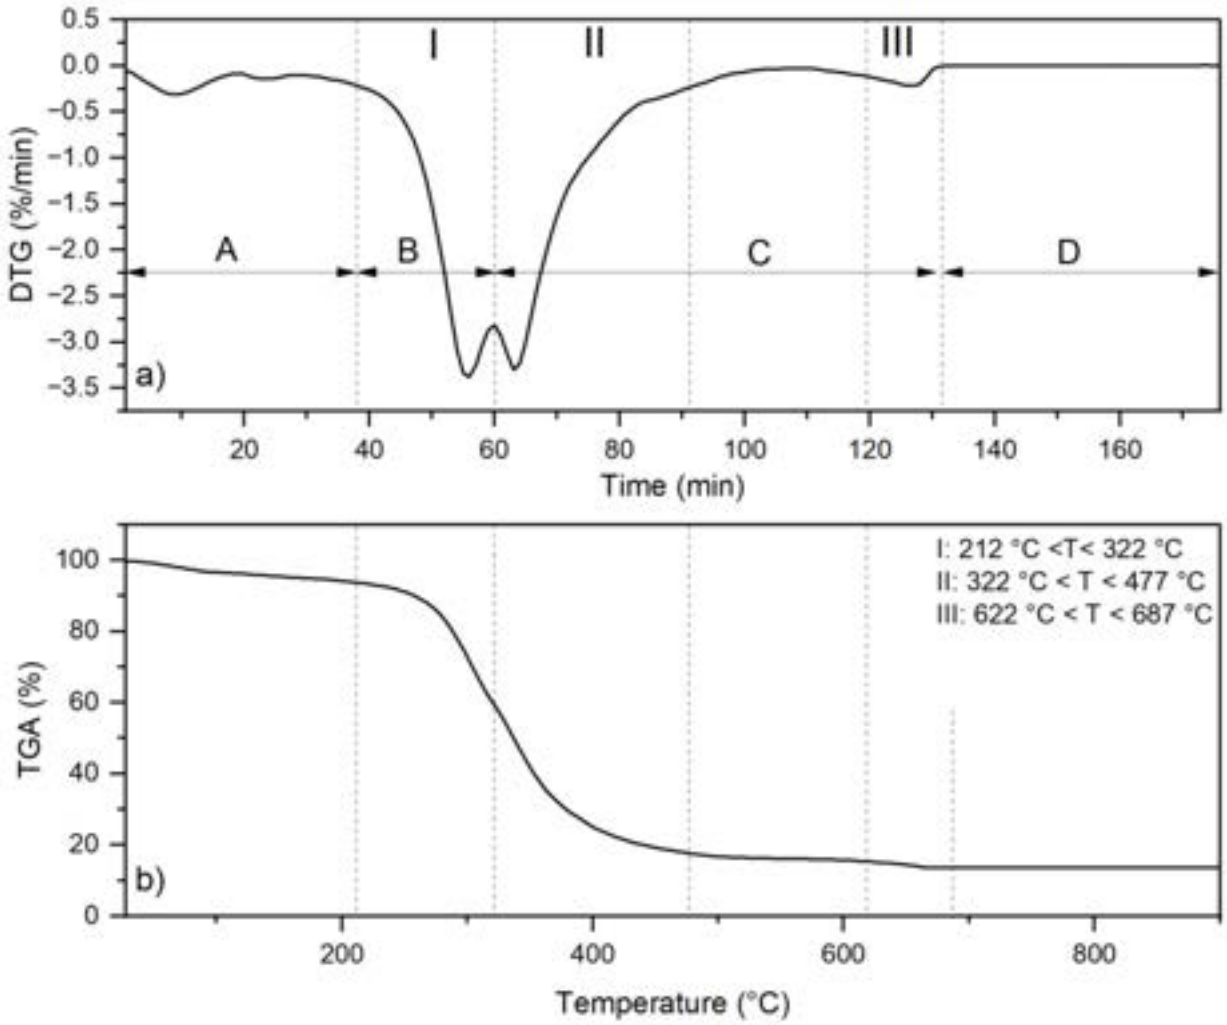

Figure. 3. Thermal degradation of HTC pellets, a) the derivative of thermogravimetry (DTG) analysis and b) thermogravimetry analysis (TGA).

Step C, from Figure 3a, shows a quite different shape for HTC pellets than for softwood pellets. The peak corresponding to the zone of maximum burning rate for step C is similar to the peak observed in step B. Also, the burning rate is quantitatively similar, however, step C starts at 322°C and ends at about 477°C. For the softwood pellets the higher part of the fuel mass is released in step B: 59.3% versus 34.9% during step C. The opposite trend is observed for HTC pellets, 34.5% of the mass is released in step B, versus 45.4% in step C. Another peculiarity of step C is that there is a second peak, after a big peak there is a trend in the TGA (Figure 3b) where the mass burned remains almost constant from 477°C to 622°C, with a weight loss of only 1.8%. But after 622 °C, the weight loss starts to increase making a second peak in step C. It can be noticed in a clearer way from DTG curve (Figure 3a) from 622°C up to 687°C The peaks shown in the DTG curve of HTC pellets were defined as three zones of kinetics interest for further analysis, as pointed out in Figure 3a. In general, the smaller difference in the burning rate of the two peaks showed by the HTC pellets, compared to the bigger difference between the two peaks of step B and C of softwood pellets, strongly suggest a less chaotic burning rate and better combustion stability for the HTC pellet.

Table 2. Characteristic combustion parameters for softwood pellets and HTC pellets.

Biomass sample	Ignition Temperature (°C)	Burnout Temperature (°C)	Temperature at maximum burning rate $(\%/\mathrm{min})$	Index S $(\mathrm{min}^{-2}\cdot\mathrm{K}^{-3})$
Softwood pellets	257	474 (500)[a]	293	$1.45\cdot10^{-10}$ $(1.23\cdot10^{-10})$[b]
HTC pellets	259	392 (687)[a]	301	$1.450\cdot10^{-9}$ $(2.57\cdot10^{-10})$[b]

[a] The value in brackets represents the estimated burnout temperature using conversion methods. [b] The value in brackets corresponds to the recomputed comprehensive combustion index, based on the new burnout temperature.

Table 2 shows the comprehensive combustion index *S*, where it clearly can be seen that the index is bigger by about one order of magnitude for HTC pellets than for softwood pellets. Some authors claim that a higher

S index indicates a higher fuel reactivity and a better fuel combustion performance. The ignition temperature of both fuels is quite similar, which means that HTC pellets are as easy to ignite as softwood pellets.

Nevertheless, the burnout temperature obtained from the tangent method is smaller for HTC than for softwood pellets but considering Figures 2 to 3, it can be noticed that the tangent method showed a poor physical meaning regarding burnout temperature. Then, using the conversion method, as it is suggested by Lu and Chen [14], HTC pellets and softwood pellets burnout temperature can be estimated again, which leads to 500°C and 687°C for softwood pellets and HTC pellets, respectively. The new burnout temperature allows recomputing a comprehensive combustion index, which in this case is for both cases in the same order but slightly better for HTC pellets.

Char oxidation is a multi-phase phenomenon and between 477°C and 722°C the inorganic compounds from the ashes form the bigger part of the remaining fuel mass. It can be that some small amount of char is trapped in the ashes, and as a consequence, a higher temperature and longer time could be required for the diffusion of oxygen to reach the char and be completely depleted. This can be the reason for higher burnout temperatures; in some way, a higher temperature will enhance the porosity of the remaining particles and as result, oxygen diffusion to the char can be enhanced.

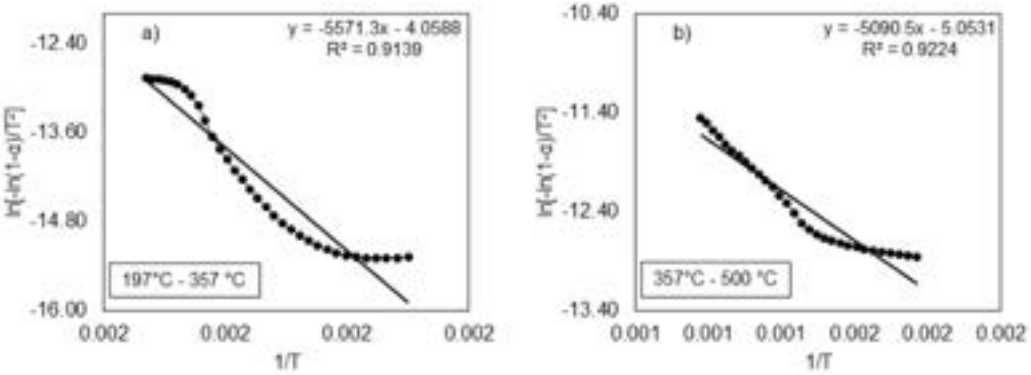

Figure. 4. Fitting curve for thermal reaction stages of softwood pellets.

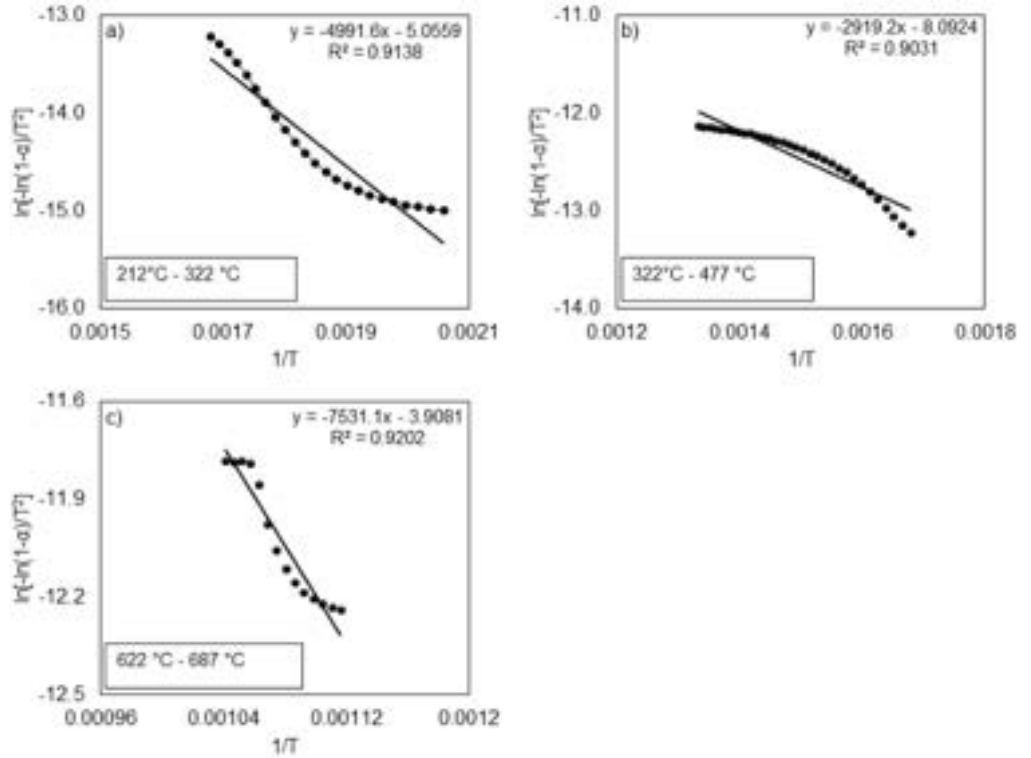

Figure. 5. Fitting curve for reaction stages of HTC pellets.

Figure 4 to 5 show the fitting curves of softwood pellets and HTC pellets for different combustion reaction stages, by means of multiple first-order reactions. The TGA DTG curves for softwood pellets were divided into two main reaction stages or reaction zones, in the temperature range of 197°C to 357°C (zone I in Figure (2a)) and from 357°C to 500°C (zone II in Figure (2a)). In both reaction zones, the correlation coefficients are higher than 0.91, which suggests that the assumption of a first-order reaction might be sufficient for first-order

modelling of the pyrolysis and char oxidation processes. The first reaction zone considers the volatilization and combustion of volatiles and the second is the volatilization and combustion of char. The time of both reaction zones is quite the same, but zone II occurs at a lower burning rate than zone I, about 2.2 times lower than zone I. Table 3 shows the kinetic parameters for tall reaction zones, outlined in Figure 4 to 5. The required activation energy is bigger for zone I than for zone II, suggesting a slower reaction rate for such zones.

Table 3. Kinetic parameters in different temperature ranges.

Biomass sample	Temperature range (°C)	Activation energy $(\mathrm{kJ/mol})$	Pre-exponential factor $(\mathrm{min^{-1}})$
Softwood pellets	197-357	46.32	$1.61 \cdot 10^6$
	357-500	42.32	$3.98 \cdot 10^6$
HTC pellets	212-322	41.50	$3.92 \cdot 10^6$
	322-477	24.27	$4.77 \cdot 10^7$
	622-687	62.61	$1.88 \cdot 10^6$

The TGA DTG curves for HTC pellets were divided into three main reaction zones, showing correlation coefficients above 0.90. The first reaction zone represents the volatilization and combustion of volatile and the second is the volatilization and combustion of the major part of char. In this case, as a highly carbonized fuel obtained by means of the HTC process, the fixed carbon is in a higher quantity than conventional lignocellulosic biomass and therefore burning rate peaks are quite similar. However, the activation energy of the reaction in zone II is 1.7 times smaller than the activation energy in reaction zone I. The combustion zone III can be assumed as an extension of the char volatilization of zone II, which requires the highest activation energy of all zones considered in HTC pellets. The analysis of zone II and III together or even the analysis of zone III alone, suggests that there is a small amount of char that is the reaction rate limiting, which kinetically speaking is the critical route of HTC pellets combustion.

3.2. Characterization of the final use of HTC pellets

Figure 6 shows the difference in boiler efficiencies between the tests performed with softwood pellets and HTC pellets, which is around 6% higher for HTC pellets.

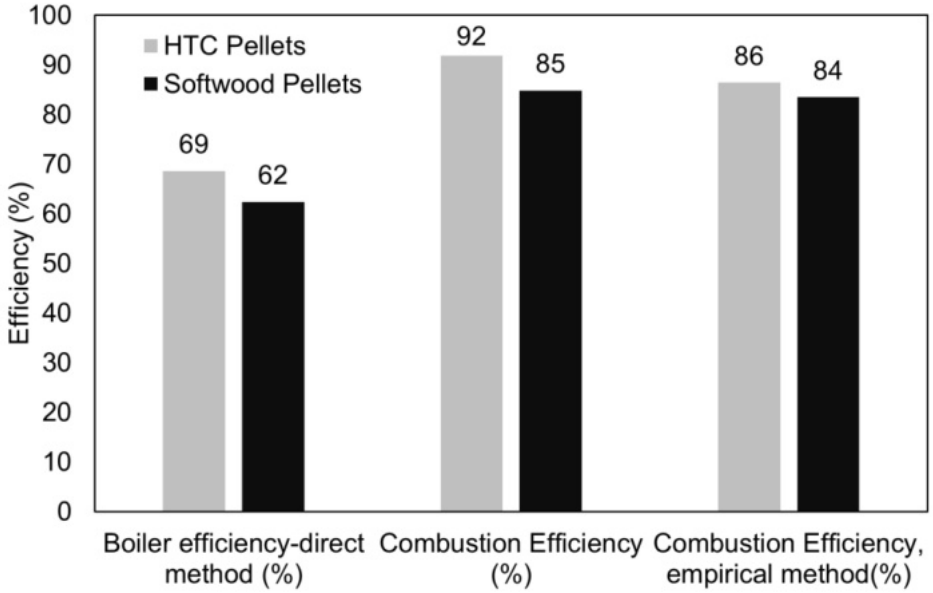

Figure. 6. Boiler efficiency (direct method) and combustion efficiency calculated from indirect method and using the empirical method.

The indirect method for the calculation of the boiler efficiency showed that flue gas losses accounted for about 18% for HTC pellets and 22% for softwood pellets. The losses regarding the unburnt fuel ($\dot{Q}_{\mathrm{UBF}}$ term in Eq. (8)) of HTC pellets and softwood pellets were about 8% and 15%, respectively. Visual observation at the end of the tests confirmed the values obtained for losses by unburned fuel. Figure 7 shows the bottom ash collected at the end of each test. The highly unburnt charcoal in the bottom ash of softwood pellets could suggest the need for more extended boiler operation (more than 3 hours) in steady-state operation for bottom ash sampling. A complete cycle of ash out boiler bed could be necessary. Nevertheless, for the HTC pellets test without complete bottom ash out of the boiler bed, the picture of Figure 7a shows a higher charcoal burnout.

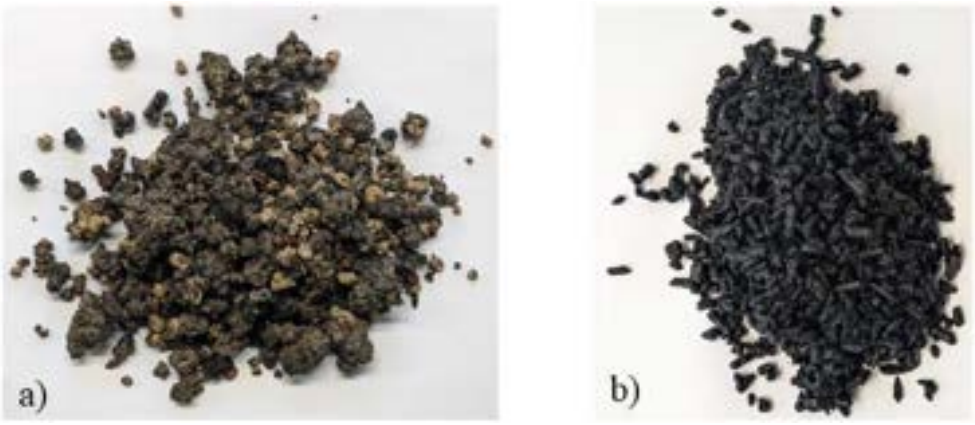

Figure. 7. State of bottom ash at the end of the tests, a): HTC pellets and b): softwood pellets.

The temperature difference between exhaust gases and the environment for both fuel tests is nearly the same, with only two degrees Celsius difference between each test. Still, the difference in a loss regarding hot gases is mostly by the mass flow rate. Both fuels are burned with similar air-fuel ratios (AFR): $29.3\ \mathrm{kg_{air}/kg_{fuel}}$ for softwood pellets and $29.5\ \mathrm{kg_{air}/kg_{fuel}}$ for HTC pellets. Despite AFR for HTC pellets being slightly higher than for softwood pellets, the low energy density of softwood pellets makes it necessary to supply more fuel mass into the combustion chamber than for the other fuel. As a result, more air is needed, and more exhaust gases are obtained, leading to more heat losses to the atmosphere. Figure 3 shows that the combustion efficiency of HTC pellets is higher than the combustion efficiency of softwood pellets. Despite the quantitative differences shown by the methods, consistent results are obtained, as both methods tend to show that HTC pellets are more efficiently burned.

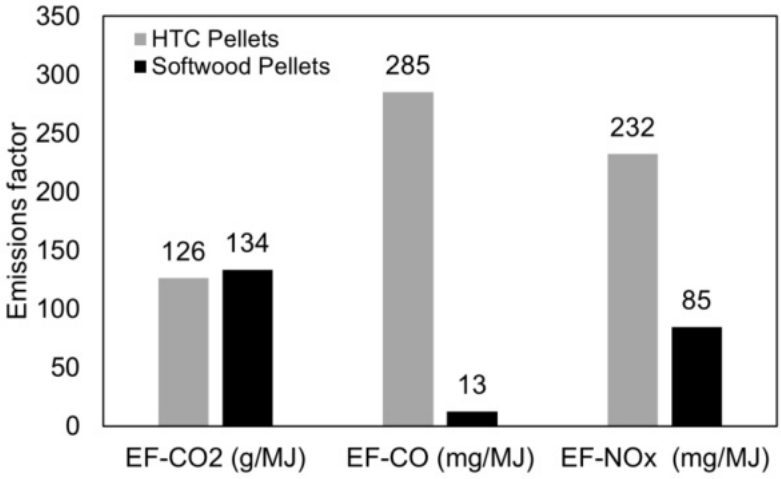

Figure. 8. Emission factor for softwood and HTC pellets.

Figure 8 shows the emission factor (EF) for the measured gaseous emissions, where it can be seen that the softwood pellets emit more carbon dioxide per unit of fuel energy (7 g/MJ). This slightly higher EF for carbon dioxide could mean that softwood pellets tend to convert more carbon during the pyrolysis and gasification phases, see zone II as illustrated in Figure 4a. Indeed, the peak of the char gasification for softwood pellets occurs at a higher temperature than for HTC pellets (416°C for Softwood pellets and 336°C for HTC pellets). The volatiles released during this stage therefore find better kinetics conditions for the complete oxidation of gaseous combustible material. As expected, carbon monoxide EF is bigger for HTC pellets than for softwood pellets, which is related to the slow reaction rate of the kinetics in reaction zone III, shown in Figure 3a. On the other hand, the HTC pellets have a higher fixed-carbon content with 8.6% more fixed carbon than the softwood pellets. In general, the lower combustion efficiency showed by the softwood pellets is related to the amount of unburned char found in the bottom ash. The lower density and lower LHV of softwood pellets than HTC pellets lead to a higher mass flow rate of pellets in the fixed bed of the boiler, making it more difficult for the conditions, in terms of combustion aerodynamics and heat transfer, to reach complete char gasification and consequently oxidation.

The NO_x emissions in the boiler come from two main sources, i.e., thermal NO_x and fuel NO_x. The thermal NO_x formation route is the NO_x source attributed to the high temperature in the furnaces. The second one is associated with nitrogen content in the fuel. The first sources could be minimaxed by managing the boiler's air

supply and reducing the furnace's average temperature. However, regardless of how the fuel is burned, about a third of the nitrogen in solid biofuel is converted to nitrogen monoxide [35]. EF-NO_x of HTC pellets shows a considerably higher value than softwood pellets, which was expected considering that elemental analysis (see Table 1), nitrogen in the fuel is more than four times higher for HTC pellets than softwood pellets. But, considering the higher energy density of HTC pellets, thermal NO_x formation could play an essential role in the NOx emission behaviour shown during the test.

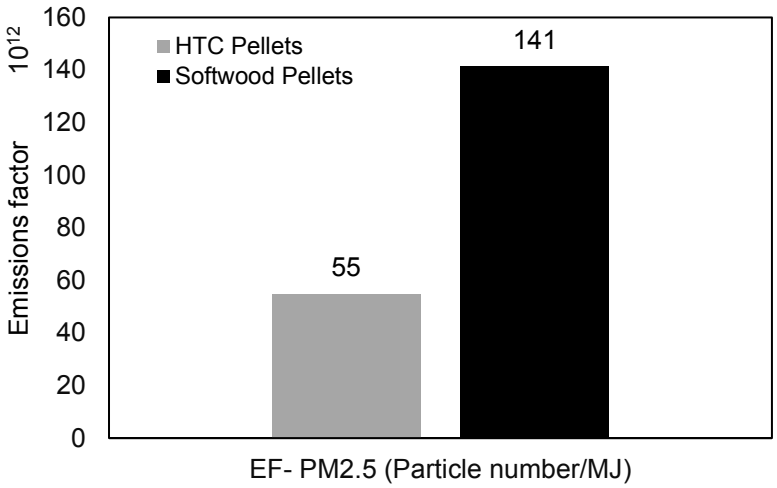

Figure. 9. Emissions factor of softwood and HTC pellets for PM2.5.

The particulate matter measurements show that more than 99% of the particle's emissions were concentrated up to 2 μm. Then, the emission factor for particulate emission was computed only for PM2.5 (see Figure 9). The EF-PM2.5 for HTC pellets was more than two times higher than for softwood pellets. Figure 9 shows that for particles diameter between 0.0091 to 0.0248 μm, PM emission for softwood pellets was higher than for HTC pellets. Still, for particle diameter from 0.0406 to 3.0169 μm HTC pellets, PM2.5 emission was far higher than for softwood pellets. It can be realized that more than 99% of particles' emissions up to 2 μm are concentrated between particle diameters from 0.0091 μm to 0.43 μm.

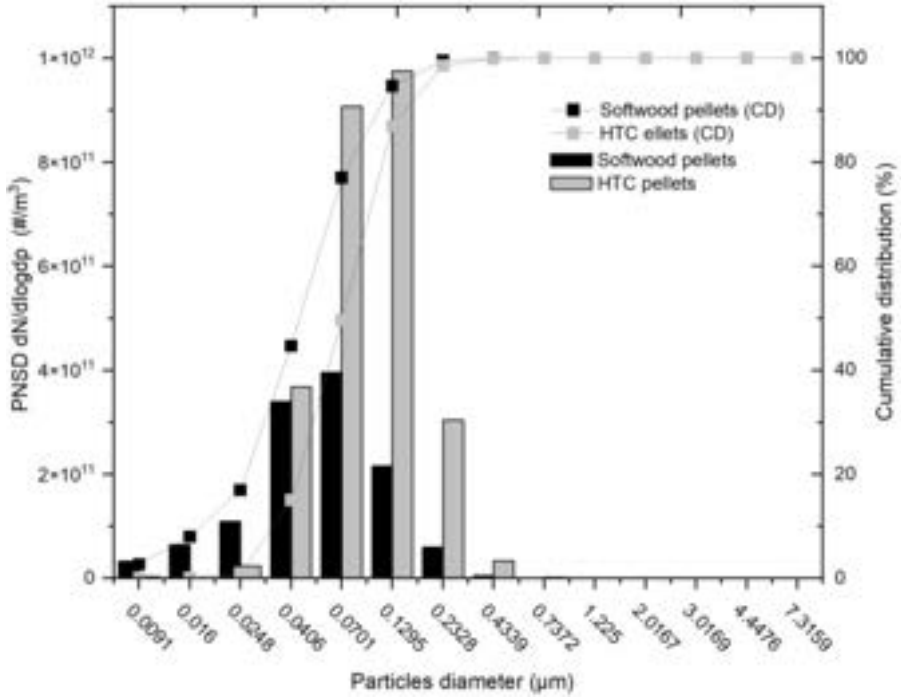

Figure. 10. Particle number distribution and distribution of cumulative particle diameter.

Figure 11 clearly shows how the PM emission of softwood pellets is higher in the zone of smaller particle diameter and higher particle diameter than HTC pellets particles emission. Nevertheless, the total particle number emission was higher for HTC pellets than for softwood pellets.

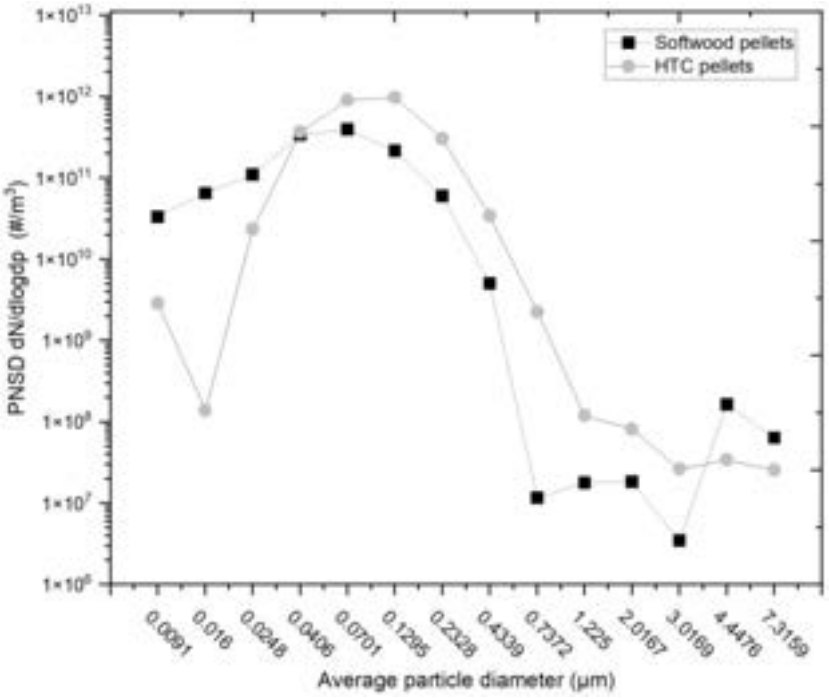

Figure. 11. Particle-number size distribution (PNSD) versus average particle's diameter in logarithm coordinate.

4. Conclusions

In this paper, a comparative study has been carried out on the combustion kinetics, efficiencies and emissions of HTC pellets and softwood pellets.

The kinetics study of softwood pellets showed two characteristic peaks in combustion zone I and II, as expected and the activation energies were found to be quite similar in both reaction zones. However, HTC pellets showed a presumed small amount of char to be gasified in reaction zone III, which takes quite a higher activation energy to start its conversion and therefore gives rise to a very slow reaction rate.

The combustion tests of softwood pellets and HTC pellets have shown that HTC pellets outperform softwood pellets in terms of boiler efficiency and combustion efficiency. However, HTC pellets showed a higher emission factor for carbon monoxide and NOx compared to softwood pellets. For both emission factors, it seems that some optimization in terms of the air-fuel ratio can be performed to reduce the average temperature in the combustion chamber and to increase the mixing of the air and the fuel. Both effects are highly desired to minimize thermal NOx and CO emissions, respectively. Nevertheless, the particulate emission showed a high number of particles in the combustion of HTC pellets. Therefore, special attention is required for the correct setting of the air-fuel ratio during the combustion of HTC pellet fuel.

Improving the carbon efficiency of two-stage DME synthesis based on wheat-straw gasification

René Kofler [a] *, Lasse Røngaard Clausen [a]

*[a] Section of Thermal Energy, DTU Construct, Technical University of Denmark, Kgs. Lyngby, 2800, Denmark. * renekof@dtu.dk*

Abstract:

For a future fossil-free energy system, solutions for hard-to-abate sectors like maritime transport need to be found. Dimethyl ether (DME) produced from sustainable biomass, like wheat straw, is a promising fuel for substituting fossil Diesel fuels in marine engines. In this work, biorefineries based on wheat straw gasification were designed and analysed. The biorefineries produced DME via two-stage synthesis, where syngas was first synthesized to methanol, before methanol was dehydrated to DME in a second step. In addition, bio-ash was produced, which acts as a soil amendment and carbon sink, when returned to the fields. The biorefineries included alkaline electrolysers for producing hydrogen to increase the carbon and energy efficiency of the plants. In this work, the addition of hydrogen at different process locations was investigated: 1) at high temperatures, enabling the conversion of CO_2 to CO via the reverse water gas shift reaction or 2) at low temperatures. In addition, the amount of hydrogen added through the electrolysers and the amount of gas (containing mainly H_2, CO and CO_2) purged after the methanol reactor were varied. By increasing the amount of hydrogen in the system, carbon efficiencies >98 % were achieved, independent of the location of the hydrogen addition and purge ratios used. Reducing the purge ratio enabled to produce more DME at the same amount of hydrogen added, leading to higher energy efficiencies. Hydrogen addition at low temperature achieved higher energy efficiencies compared to hydrogen addition at high temperatures, because it enabled the operation of the electrolysers at high pressures of 30 bar and reducing the electricity consumption in the compressors. In general, any measures of increasing the energy and carbon efficiency led to an increase in the size of the methanol reactor, leading to a trade-off between investment and operational costs.

1. Introduction

A transition from the fossil fuel based energy system we live in today to an energy system based on renewable energy sources is necessary for reducing climate change. In many sectors this can be achieved by implementing electricity production from renewables, like wind and solar, and electrifying processes. However, there are hard-to-abate sectors like the maritime transport and the aviation sector, where electrification is not possible. Lund et al. [1] show that sustainable use of biomass for producing fuels for these sectors is important for achieving the decarbonization goals. For Denmark, wheat straw has been identified as an important feedstock for a sustainable production of fuels for the maritime transport sector via gasification and similar processes [1], [2].

The use of wheat straw in gasification is challenging due to a high ash content and its low melting temperature. The low-temperature circulating fluidized bed (LT-CFB) gasifier is designed for enabling the efficient conversion of difficult residual biomasses, like straw and manure [3]. In addition to the efficient conversion, the LT-CFB gasifier enables also the production of bio-ash or bio-char, which acts as a carbon sink and improves soil properties, when returned to the fields [4]. The produced gas from the LT-CFB gasifier contains a high tar content, making it unsuitable for downstream fuel synthesis without further treatment.

In our previous works, fuel production plants based on the LT-CFB gasifier were designed and analysed based on their carbon efficiency [5] and exergy efficiency [6]. The carbon efficiency describes, how much of the carbon in the feedstock (i.e. wheat straw) is ending up in the produced fuels and bio-ash. This value is an important measure, because plants with a high carbon efficiency enable to replace a larger part of the fossil-based fuels with the same amount of limited biomass resources. In the studies, the tars are catalytically deoxygenated and then condensed, yielding a high-quality bio-oil. The remaining tar-free gas is used to produce electricity, synthetic natural gas (SNG) or dimethyl ether (DME). In the SNG and the DME production

plant, electrolytic hydrogen is produced and used for increasing the amount of produced fuel. The results show that the SNG production plant reaches the highest carbon and exergy efficiencies, followed by the DME and the electricity production plant. The results show that the DME production plant suffers from an inefficient conversion of tar-free gas to DME, due to the hydrocarbons remaining in the gas after the bio-oil condensation.

The DME production plant was further investigated, because of the promising properties of DME as a substitute for fossil fuels in marine diesel engines [7]. In [8], we showed that the carbon efficiency of a DME production plant based on the LT-CFB gasifier can be increased significantly by changing the plant layout. The carbon efficiency can be improved by using a partial oxidation step after or instead of the tar deoxygenation and condensation. This enables the reforming and cracking of the hydrocarbons (and tars, in the cases without bio-oil condensation) and making the carbon available for DME synthesis. The use of two-stage DME synthesis instead of one-stage synthesis further increases the carbon efficiency. In the two-stage synthesis, methanol is first synthesized from the tar-free gas. The methanol is then dehydrated to DME and water in a second reactor. In the one-stage synthesis, both reactions are taking place in the same reactor, leading to the production of CO_2 as a by-product, reducing the carbon efficiency of the plants. Lastly, a hydrogen quench, where hydrogen is added at high temperatures directly after the partial oxidation step, can further increase the carbon efficiency. The analysis of 14 different plants showed that in most of the cases, an increase of the carbon efficiency also leads to an increase in energy efficiency. Higher efficiencies also mean that more hydrogen and hence more electricity is needed in the plants. While the study showed how the carbon efficiency can be increased by changing the plant layout, the influence of different design parameters was not investigated, due to the complexity of the study, caused by the number of plants included.

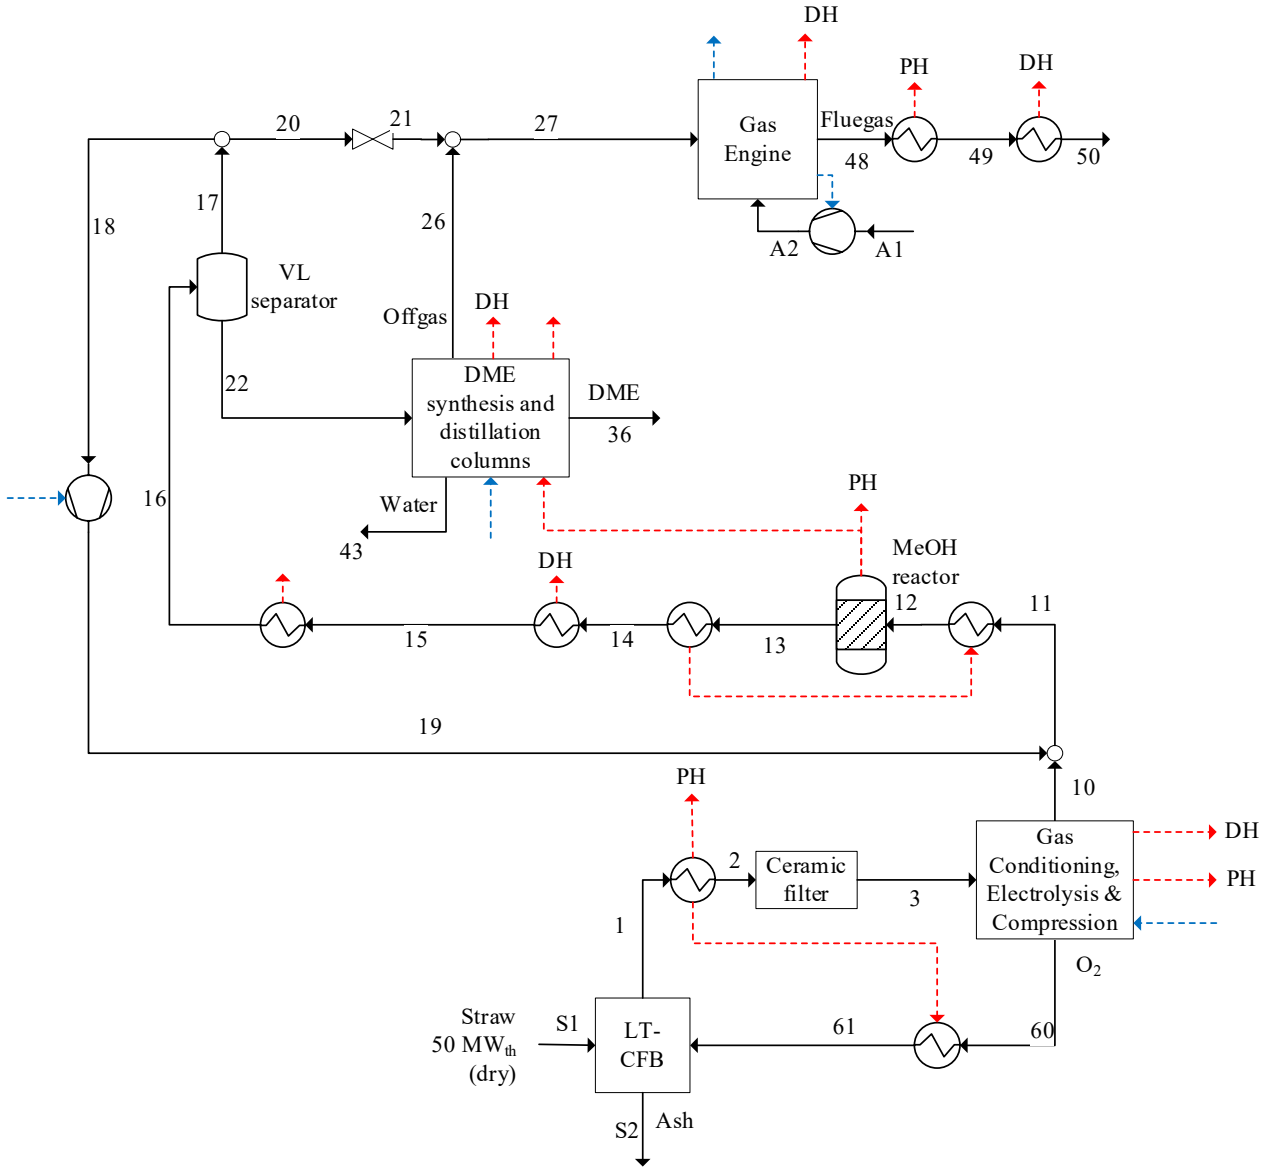

Figure 1. General flowsheet of the investigated plants. Note: The difference between the investigated plants lays in the block "Gas Conditioning, Electrolysis & Compression" as shown in Figure 3

In this work, two of the most promising plants were used for investigating the influence of two important design parameters, the amount of hydrogen addition and the purge ratio in the methanol synthesis loop, on the carbon efficiency and the energy efficiency. In addition, the influence of these parameters on the size of the methanol reactor, a key component in the synthesis part, was evaluated by analysing the change in mole flow rate to the reactor. The two investigated plants as well as the design parameter variation are explained in detail in the following section.

2. Methods

2.1. System layout

In this work, two different plant layouts for the production of DME and bio-ashes from wheat straw were investigated. Figure 1 shows the general plant design of the two different plant layouts. Wheat straw (stream S1) was gasified in the LT-CFB gasifier, using oxygen (61) from an alkaline electrolyser, producing a tar-laden gas (1) and bio-ash (S2). The tar-laden gas was then cooled from 660 °C to 500 °C before any remaining particles were removed in a ceramic filter. After that, the gas (3) entered a block, where the tars and hydrocarbons in the gas were cracked and reformed, before adding electrolytic hydrogen and compressing the gas to the required synthesis pressure. The pressurized gas (10) was then mixed with the recycling stream (19) and preheated before entering the methanol reactor (12).

The mixture of methanol, water and other light fractions out of the methanol reactor was then cooled down (streams 13-16) before entering a vapor-liquid (VL) separator. The vapor exiting the top (17) was split, with the major part (18) being recycled to the methanol reactor and a smaller purge stream (20) being sent to a gas engine in order to avoid the accumulation of inerts in the system. Liquid at the bottom (22) was sent to the block for DME synthesis and distillation columns. The detailed layout of the block is shown in Figure 2. The DME synthesis block yielded a DME stream (36) with a purity of 99.99 %, an offgas from the topping column (26), which is sent to the gas engine and a water stream (43) from the methanol column. The purge gas (21) and the offgas (26) were burned in a turbo charged gas engine, producing electricity and district heating, using air (A1) as oxidant. The exhaust gas (48) from the gas engine was cooled, providing district heating and process heat.

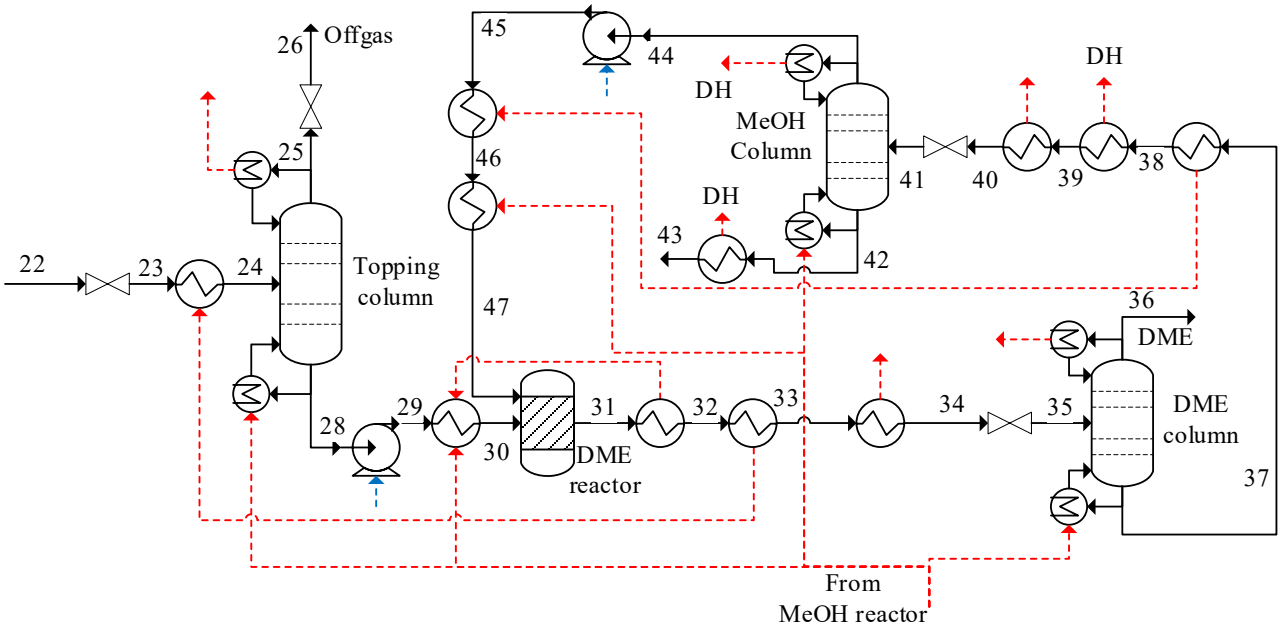

Figure 2. Detailed flowsheet of the DME synthesis and distillation columns section.

Figure 3 depicts the two different layouts for the gas conditioning block. In both cases, the tar-laden gas (stream 3) was first preheated to $T_{\mathrm{POX,preheat}} = 600\ °C$ before entering the partial oxidation (POX) reactor. Pure oxygen (52-57) from the electrolyser was used for the POX. The oxygen was also preheated to $T_{\mathrm{POX,preheat}} = 600\ °C$ and mass flow rate was controlled to reach an outlet temperature of $T_{\mathrm{POX}} = 1200\ °C$.

The differences between the two investigated layouts lay in the location of hydrogen addition. In the first layout (without hydrogen quench), hydrogen was produced in an alkaline electrolyser and added at low temperatures (51). This enabled to operate the electrolyser at a pressure of 30 bar and mixing the hydrogen with the tar-free gas after cooling and compressing the gas in a 4-stage compression with intercooling. The gas and hydrogen mixture (9) was then compressed to a pressure of 85.1 bar in the final compression stage. The high-pressure electrolysis also enabled the expansion of preheated oxygen (53) using turbines, recovering some electricity.

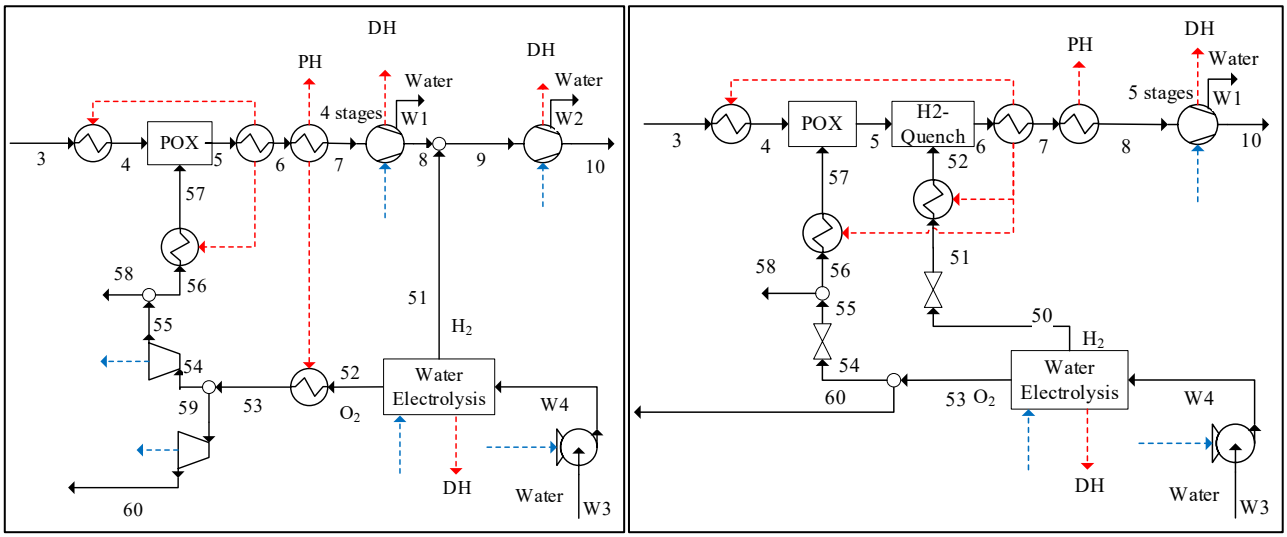

Figure 3. Flowsheet of the gas conditioning block of the two different plant layouts. Left: Plant without hydrogen quench (hydrogen addition at low temperature). Right: Plant with hydrogen quench (hydrogen addition at high temperature directly after POX).

In the second layout (with hydrogen quench), hydrogen was preheated to 600 °C and injected directly after the POX in a hydrogen quench reactor (stream 52). At temperatures above 900 °C, the reverse water gas shift (rWGS) reaction is promoted [9], leading to the conversion of CO_2 to CO, as shown in eq. (1). This process is referred to as hydrogen quench. Due to the addition of hydrogen after the POX at low pressures, the alkaline electrolysis was operated at low pressures as well.

$$CO_2 + H_2 \leftrightarrow \mathrm{CO} + \mathrm{H_2O} \qquad 41\ \mathrm{kJ/mol} \qquad (1)$$

2.2. Modelling and assumptions

The plants were modelled and simulated using the software Aspen Plus V11 [10]. The components were modelled in a zero-dimensional approach [11]. The property method RK-SOAVE (Redlich-Kwong-Soave) [12] was used for the LT-CFB gasifier, gas conditioning and gas engine, including the heat exchangers used before and after these components. SR-POLAR (Schwartzentruber and Renon) [13] was used for the remaining components. Vapor-liquid equilibrium (VLE) was assumed for all streams, except of those, where DME, methanol and water were present. In those streams vapor-liquid-liquid equilibrium (VLLE) was calculated. The solid streams and more complex liquids, namely straw, char, bio-ash, and tars were handled as so-called non-conventional streams. Non-conventional streams are only characterized by a constant heat capacity and a higher heating value (HHV) and are not considered in the chemical equilibrium. The HHV for the non-conventional compounds was estimated using eq. (2) [14], as implemented in Aspen Plus.

$$\mathrm{HHV} = [146.58\ \mathrm{C} + 568.78\ \mathrm{H} + 29.4\ \mathrm{S} - 6.58\ \mathrm{A} - 51.53(\mathrm{O} + \mathrm{N})] \cdot 10^2\ \left[\frac{\mathrm{Btu}}{lb} = 2.326\frac{\mathrm{kJ}}{\mathrm{kg}}\right] \qquad (2)$$

In eq. (2), C, H, S, O, N and A denote the carbon, hydrogen, sulphur, oxygen, nitrogen and ash content in wt.-%, respectively.

For the plants, a wheat straw input of 50 MW_{th} based on the lower heating value (LHV) was used. That corresponded to a mass flow rate of $\dot{m}_{Straw} = 3.41\ kg/s$ with the composition shown in Table 1. The LT-CFB gasifier was modelled for operating temperature of 660 °C and 700 °C in the pyrolysis and char reactor, respectively. The pyrolysis model was based on experimental data [15], while chemical equilibrium was assumed for the char reactor. The resulting gas composition was validated against the experimental results. A detailed description of modelling of the pyrolysis reactor can be found in the supplementary material of our previous work [5].

Table 1. Proximate and ultimate analysis of wheat straw pellets used as feedstock for experiments which the model was calibrated to [15].

Proximate Analysis (wt.%, as received)		**Ultimate analysis (wt.%, dry and ash free)**	
Moisture	8.5 %	N	0.8 %
Volatiles	46.2 %	C	46.2 %
Ash	6.6%	H	6.6 %
Fixed carbon	17.9 %	O	46.4 %

Oxygen for the LT-CFB gasifier, coming from the electrolyser was preheated to 560 °C. For heat exchangers used for preheating and cooling streams, as well as provision of process heat and district heating, $\Delta T_{Gas/Water} = 10\,K$ and $\Delta T_{Gas/Gas} = 30\,K$ were used if no other information are given. Process heat was defined as provision of saturated steam at 200 °C. For district heating, water was heated from 40 °C to 75 °C.

The electrolysers were operated at 30 bar and 1.63 bar, for the system with hydrogen addition at low and high temperatures, respectively. The pressure was set by pumping water to the respective pressure. For pumps, compressors and turbines, isentropic efficiencies of $\eta_{is} = 0.8$ and mechanical efficiencies of $\eta_{mech} = 0.94$ were used. For the electrolysers, an LHV-efficiency of 70 % was used. The electrolysers were operated at 90 °C, enabling the provision of district heating, by cooling the electrolysis stacks.

For the POX, all streams entering the POX were preheated to 600 °C. The outlet temperature was set to 1200 °C by varying the oxygen supply to the POX. The hydrogen for the hydrogen quench was preheated to $T_{\mathrm{H_2,preheat}} = 600\,°\mathrm{C}$. The outlet temperature from the hydrogen quench depended on the amount of hydrogen added. However, in all investigated cases the outlet temperature was higher than 880 °C, and hence high enough for achieving the spontaneous, non-catalytic rWGS reaction [9]. The resulting tar-free gas was then cooled and compressed to 85.1 bar in a 5-stage compression with intercooling.

A boiling-water reactor was used for the methanol synthesis. The outlet temperature was set to $T_{\mathrm{MeOH\ reactor}} = 240\,°C$. Chemical equilibrium with temperature approach was assumed for the occurring reactions shown in eq. (3) and (4).

$$4\,\mathrm{H_2} + 2\,CO \leftrightarrow 2\,CH_3OH \qquad \text{-182 kJ/mol} \qquad \Delta T_{approach} = 15\,K \tag{3}$$

$$\mathrm{CO} + \mathrm{H_2}O \leftrightarrow CO_2 + H_2 \qquad \text{-41 kJ/mol} \qquad \Delta T_{approach} = 15\,K \tag{4}$$

The gas stream flowing to the methanol reactor was preheated to $T_{\mathrm{preheat}} = 210\,°\mathrm{C}$. After the reactor, the stream was cooled in several heat exchangers to 25 °C before entering the vapor-liquid separator. The vapor part was then split. The biggest part was recycled to the methanol reactor, while a smaller purge stream was sent to the gas engine to avoid the accumulation of inerts in the synthesis loop. The remaining CO_2 in the liquid stream from the VL-separator was removed in a topping column after throttling, before the methanol/water mixture was pumped to a pressure of 46.1 bar and preheated to 210 °C for the DME reactor. An adiabatic reactor was used for the DME synthesis. For the methanol dehydration (eq. (5)), chemical equilibrium with temperature approach was assumed. The produced DME was purified in the DME column after cooling and throttling the stream. The bottom stream was sent to the methanol column, where methanol was separated and returned to the DME reactor while the water was disposed.

$$2\,CH_3OH \leftrightarrow CH_3OCH_3 + H_2O \qquad \text{-23 kJ/mol} \qquad \Delta T_{approach} = 100\,K \tag{5}$$

The gas engine was turbo charged to 2 bar. The air mass flow rate to the engine was set to achieve an excess air ratio of $\lambda = 2$, assuming complete combustion. The gas engine was cooled using district heating water. The exhaust gas at 400 °C was cooled to 80 °C providing both process heat and district heating.

A more detailed description of the modelling approach for the different components and the assumptions used can be found in our previous work [8]. The plant layouts investigated in this work correspond to the plants LP_POX-2st and LP_POX-H2_QNCH-2st from [8] for the system with hydrogen addition at low and high temperatures, respectively.

2.3. Parameter variations

In this work, the influence of two key parameters in the plants were investigated: a) the amount of hydrogen added to the system; b) the amount of gas being purged from the methanol synthesis loop.

The amount of hydrogen in the system was varied by increasing the water mass flow rate of stream W3 going to the electrolyser (see Figure 3). The water mass flow rate was gradually increased from the values used in [8] (1.68 kg/s for hydrogen addition at low temperatures and 2.08 kg/s for hydrogen addition at high temperatures) to 5 kg/s. This corresponds to a variation of the hydrogen flow rate of 0.19 – 0.56 kg/s and 0.23 – 0.56 kg/s for the plant with hydrogen addition at low and high temperatures, respectively. The amount of water added to the electrolysers in [8] was determined in order to achieve an H2/CO ratio of two at the inlet of the methanol reactor (stream 12 in Figure 1).

The amount of purged gas after the vapour-liquid separator in the methanol synthesis loop was varied by varying the purge ratio between 5 %, as used in [8], and 1 %, in steps of 1 %. The purge ratio PR is defined according to eq. (6), where the stream numbers in the subscripts reference to the stream numbers shown in Figure 1.

$$\mathrm{PR} = \frac{\dot{m}_{20}}{\dot{m}_{17}} \tag{6}$$

Both variations were conducted simultaneously, meaning that for each value of purge ratio, the amount of hydrogen in the system was varied. The performance of the two plants at different hydrogen mass flows and purge ratios was evaluated by using the energy efficiency η_{main} and the carbon efficiency γ_{tot}, as defined in eq. (7) and eq. (8), respectively.

$$\eta_{\mathrm{main}} = \frac{\dot{m}_{DME} \cdot LHV_{DME}}{\dot{m}_{Straw} \cdot LHV_{Straw} + |\dot{W}_{net}|} \tag{7}$$

$$\gamma_{\mathrm{tot}} = \frac{\dot{m}_{C,DME} + \dot{m}_{C,Bio-ash}}{\dot{m}_{C,Straw}} \tag{8}$$

In addition to the efficiencies, the influence of the variations on the investment cost and the operational cost was estimated. For the investment cost, the biggest variation within each plant was expected to be experienced in a change in methanol reactor size. The size of the reactor was assumed to be proportional to the inlet volume flow rate of the reactor. Since the inlet temperature and pressure were equal for all investigated plants, the volume flow rate was proportional to the inlet mole flow rate to the reactor. In order to estimate the change in reactor size for the different simulations, the relative increase $\varepsilon_{\mathrm{Reactor}}$ was calculated according to eq. (9), where $\dot{n}_{12}$ denotes the inlet mole flow rate to the methanol reactor for the investigated plant and $\dot{n}_{12,\mathrm{ref}}$ denotes the inlet mole flow rate to the methanol reactor for the reference plant. The plant with hydrogen addition at high temperatures (with quench) from [8], corresponding to the plant with hydrogen quench and a purge ratio of 5 % was used as reference case.

$$\varepsilon_{\mathrm{Reactor}} = \frac{\dot{n}_{12} - \dot{n}_{12,\mathrm{ref}}}{\dot{n}_{12,\mathrm{ref}}} \tag{9}$$

For the operational cost, the variation in the net electricity consumption was used as a measure, because the biomass used was kept constant for the investigated plants. The variation was estimated by looking at the increase in net electricity consumption $\varepsilon_{\mathrm{EL}}$, as calculated in eq. (10). $\dot{W}_{\mathrm{net}}$ denotes the net electricity consumption of the investigated plant and $\dot{W}_{\mathrm{net,ref}}$ denotes the net electricity consumption of the reference plant.

$$\varepsilon_{EL} = \frac{\dot{W}_{\mathrm{net}} - \dot{W}_{\mathrm{net,ref}}}{\dot{W}_{\mathrm{net,ref}}} \tag{10}$$

3. Results

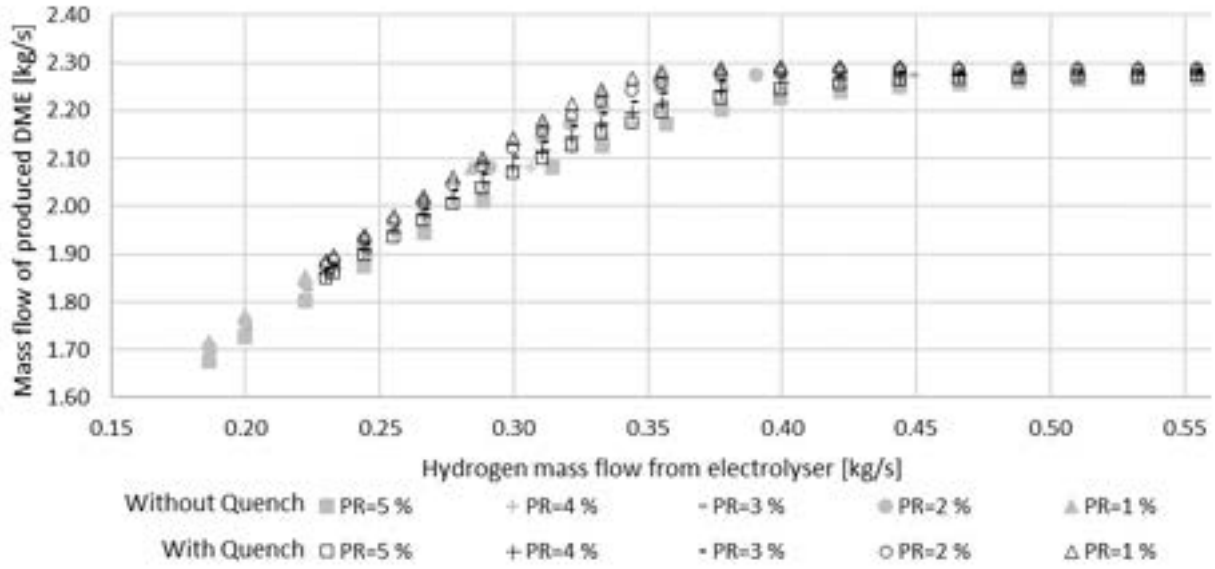

Figure 4. Mass flow rate for produced DME over hydrogen mass flow rate added by the electrolyser for the two different plants at different purge ratios (PR). Note: the grey, filled symbols denote the plant with hydrogen addition at low temperature (without quench), while the black, empty symbols denote the addition at high temperature (with quench).

In this section, the results of the conducted parameter variations are shown. Figure 4 shows the mass flow rate of produced DME for different hydrogen mass flows from the electrolyser. The grey, filled symbols show the results for the plant with hydrogen addition at low temperatures (without quench) and the black, empty symbols show the results for hydrogen addition at high temperatures (with quench). The different symbols denote the different purge rates (PR) used in the methanol synthesis loop.

The amount of produced DME increased with increasing hydrogen addition. The trend of the increase was similar for all the investigated plants and purge ratios with a strong increase in DME production up to a hydrogen addition of around 0.35 kg/s to 0.4 kg/s before flattening towards a maximum achievable DME flow rate. The results show that a decrease in the purge ratio increases the amount of DME produced at constant hydrogen flow rate added as well as the maximum achievable DME mass flow. It can also be seen that in the plants with hydrogen addition at high temperatures (with quench), more DME was produced when adding the same amount of hydrogen, compared to the plants without quench. The difference was more distinct with higher purge ratios, while the difference was almost negligible for a purge ratio of 1 %.

As it can be seen in eq. (8), an increase in DME production led to an increase in carbon efficiency, since the other two carbon flows in the system were kept constant for all plants, i.e. the carbon flows in wheat straw and bio-ash. Hence, an increase in hydrogen addition through the electrolyser led to an increase in carbon efficiency, and a reduction in purge rate led to a higher carbon efficiency at constant hydrogen addition.

Figure 5 shows the energy efficiency of the plants over the carbon efficiency. Based on the results from Figure 4, we know that moving from left to right, i.e. from lower to higher carbon efficiencies, was equivalent to adding more hydrogen to the system. In Figure 5, it can be seen that by reducing the purge rate, higher energy efficiencies were reached for achieving the same carbon efficiency. This was connected to requiring less hydrogen in the system for yielding the same DME production, leading to a reduction in electricity used for the electrolysers and hence a lower net electricity consumption (see also Figure 6). Additionally, the diagonal lines visible in Figure 5 show that reducing PR at constant hydrogen addition led to an increase in both energy and carbon efficiency. That shows that using low purge ratios is very beneficial for improving the performance of the plants.

With increasing carbon efficiencies, the energy efficiency slowly increased until reaching a maximum at different locations for different plants and purge ratios and started decreasing slowly until it reaches a rapid fall at high carbon efficiencies. For a purge ratio of 1 %, the energy efficiency was almost constant for both plants up to a carbon efficiency close to 98 % before rapidly falling at higher carbon efficiencies. This introduced the possibility to yield almost all of the carbon in the straw to end up in DME and bio-ash. For higher purge ratios, the decrease in energy efficiency started earlier. The strongest decrease was seen for a purge ratio of 5 %, where a significant reduction was already seen around a carbon efficiency of 90 %.

At very high carbon efficiencies, a rapid decrease in energy efficiency with little to no increase in carbon efficiency can be observed. This area corresponded to the part of Figure 4, where no additional DME was produced by adding more hydrogen to the system. With purge ratios of 4 % and 5 %, the rapid decrease in energy efficiency occurred earlier, and it was not possible to achieve carbon efficiency of 99 %, no matter how much hydrogen was added to the system.

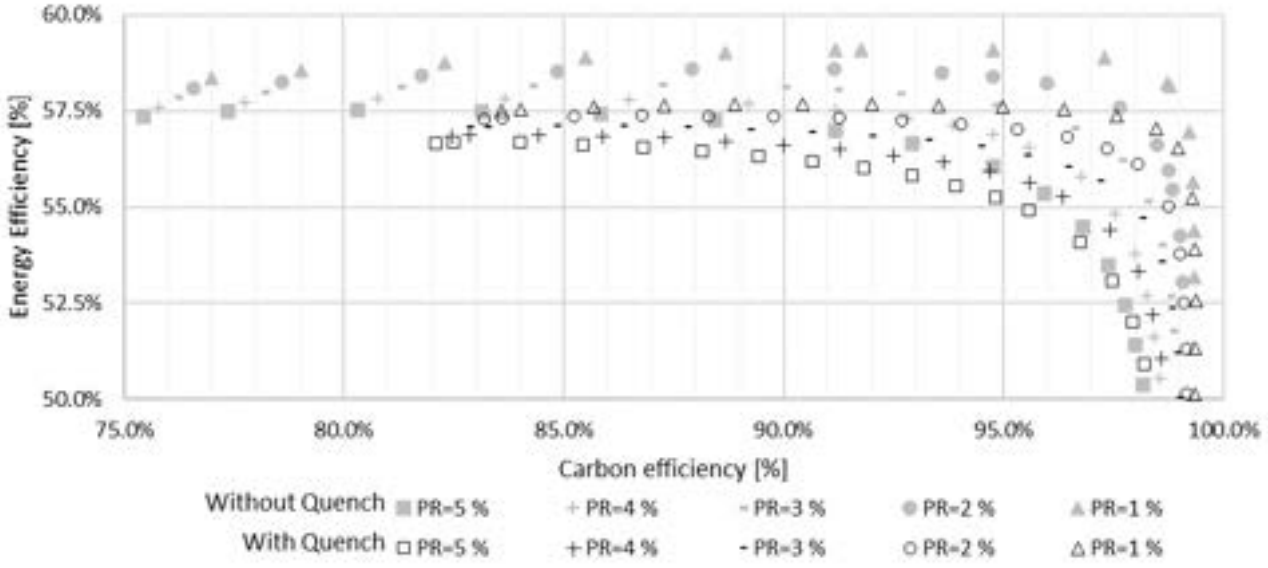

Figure 5. Energy efficiency over carbon efficiency the two different plants at different purge ratios (PR). Note: the grey, filled symbols denote the plant with hydrogen addition at low temperature

(without quench), while the black, empty symbols denote the addition at high temperature (with quench).

Figure 6 shows the electricity consumption in the two different plant layouts for purge ratios of 5 % and 1 %, respectively, for achieving a carbon efficiency of 95 %. It can first be seen that at higher purge ratios (Figure 6, left), more hydrogen was needed for producing the same amount of DME than for lower purge ratios (Figure 6,right), shown by the higher electricity consumption of the electrolyser. The higher amount of hydrogen in the system led also to a higher electricity consumption of the turbomachinery for the plant with hydrogen quench (6.1 vs. 5.7 MW), because more hydrogen needed to be compressed from ambient pressure to the high pressure of 85 bar for methanol synthesis.

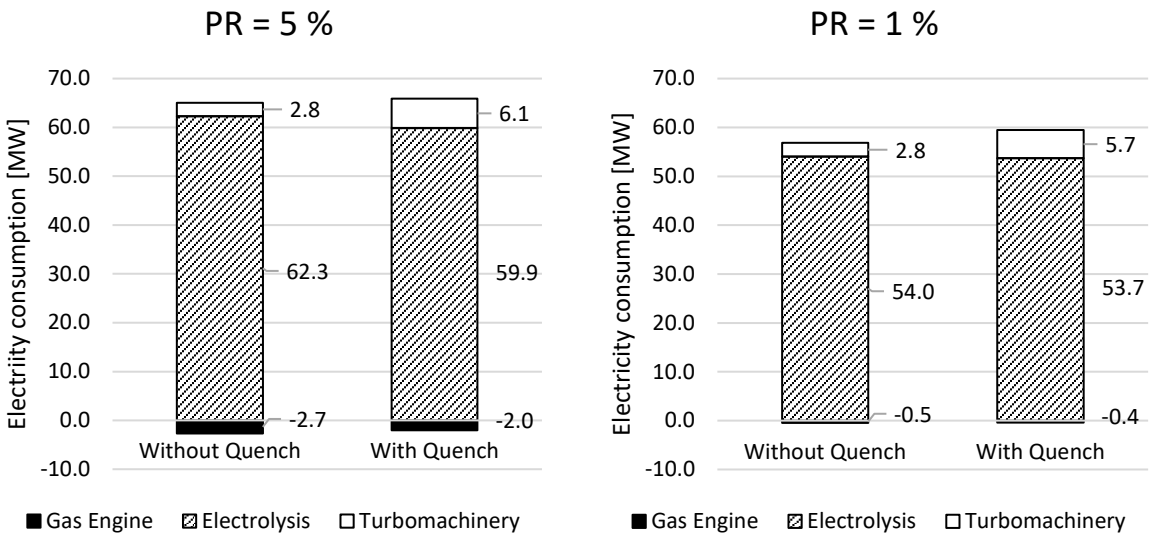

Figure 6. Electricity consumption and production of the different components in plants with a carbon efficiency of $\gamma_{tot} = 95$ %.

This effect was not seen for the plant without hydrogen quench, where the electricity consumption of the turbomachinery remained constant, due to two factors. Firstly, the electrolyser was operated at 30 bar, reducing the influence of the hydrogen on the overall electricity consumption in the turbomachinery. Secondly, the operation at 30 bar introduced the use of turbines for expanding the oxygen produced in the electrolyser, which reduced the electricity consumption with increasing hydrogen production. Additionally, for a purge rate of 5 % the electricity production in the gas engine was higher than at lower purge rate. The higher production derived from significantly more hydrogen and unconverted CO being purged and combusted in the gas engine, leading to both lower energy efficiency and carbon efficiency.

In general, higher energy efficiencies were achieved in the plants with hydrogen addition at low temperatures (without quench), as seen in Figure 5. At first, this may seem surprising, since there was more or equal as much hydrogen required to yield the same amount of DME, as seen in Figure 4. However, in Figure 6 it can be seen that for all purge rates, the higher electricity consumption for electrolysis in the plants without hydrogen quench was compensated by a lower electricity consumption in the turbomachinery, leading to a lower net electricity consumption for the same DME production. The increased electricity consumption for the plants with hydrogen quench derived from the necessity of operating the electrolysers at ambient pressure, leading to compression of hydrogen from ambient pressure to 85.1 bar (instead of 30 bar to 85.1 bar for the plants without hydrogen quench) and not having any electricity generation from expanding the produced oxygen in turbines. The electricity consumption in the 5-stage compression train was increased from 3.81 MW for the plant without hydrogen quench to 6.03 MW for the plant with hydrogen quench at $PR = 5$ % and from 3.70 MW to 5.71 MW for $PR = 1$%. The electricity production in the oxygen turbines for the plant without hydrogen quench was 1.09 MW for $PR = 5$ % and 0.94 MW for $PR = 1$ % . The electricity consumption of the remaining turbomachinery, i.e. pumps and recycling compressor, was significantly smaller than the aforementioned consumption and production and their influence on the variation of the net electricity was negligible.

Lastly, we looked at the influence on the mole flow rate into the methanol reactor for three different carbon efficiencies, i.e. 82 %, 90 % and 95 % (Figure 7). The increases are shown as relative increases compared to a reference case as defined in eqs.(9) and (10). The reference case was the plant with hydrogen addition at high temperatures (with quench) from [8]. It had a purge ratio of 5 % and a carbon efficiency of 82 %.

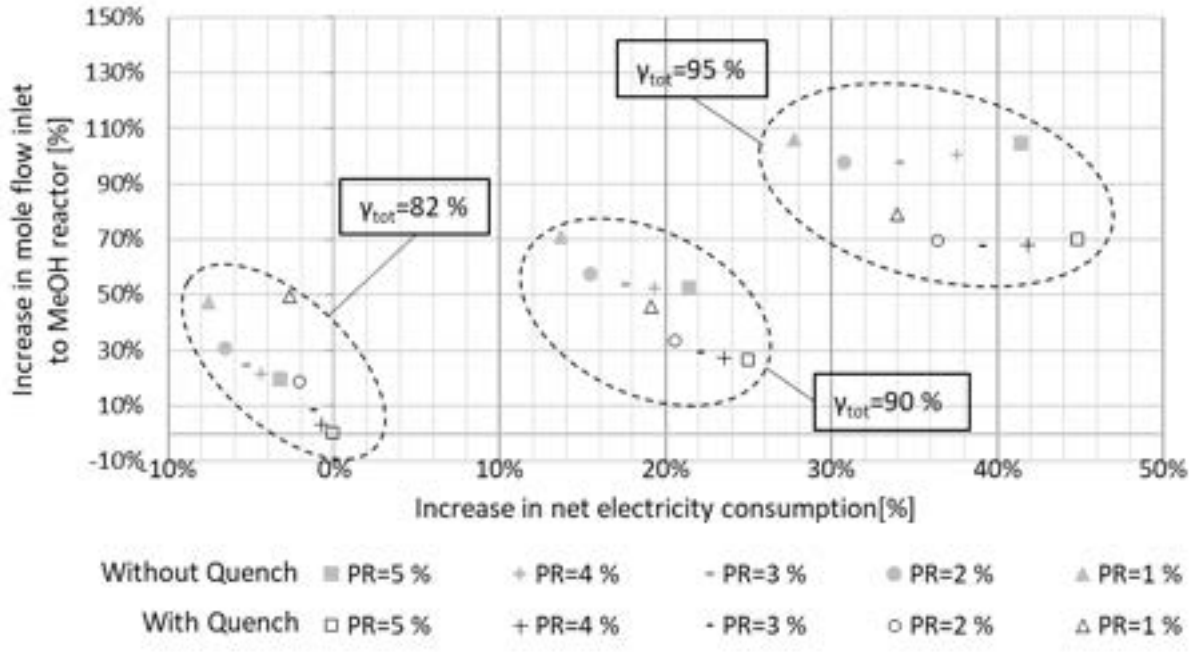

Figure 7. Increase in mole flow rate into the methanol reactor as an indicator for the reactor size over increase in net electricity consumption as an indicator for the operational cost for the different plants at varied purge ratios (PR) for three different carbon efficiencies γ_{tot}. Note: the grey, filled symbols denote the plant with hydrogen addition at low temperature (without quench), while the black, empty symbols denote the addition at high temperature (with quench).

In general, it can be seen that a reduction in purge ratio led to a lower electricity consumption, while the inlet mole flow rate to the methanol reactor increased. The reduction in electricity consumption was already explained above. The increase in mole flow rate to the reactor at lower purge ratios derived mainly from increased recycling the inert nitrogen, but also from a higher CO and CO_2 mole flow rate through the higher recycling. For a carbon efficiency of 95 % a change in the general trend for the mole flow into the reactor was observed, where the inlet mole flow rate initially decreases when reducing the purge ratio from 5 % before starting to increase again for lower purge ratios. The behaviour derived from requiring significantly more hydrogen to achieve a carbon efficiency of 95 % at higher purge ratios, leading to higher mole flow rates into the methanol reactor, despite recycling less nitrogen, CO and CO2.

Looking at the results for the plants with a carbon efficiency of 82 %, for the plant with hydrogen quench, the mole flow rate into the methanol reactor was increased by 50 % by reducing the purge ratio from 5 % to 1 %, while the electricity consumption was reduced by 2.6 %. When not including a hydrogen quench, the electricity consumption was reduced by 3.2 % and the reactor inlet mole flow rate was increased by 20 % for $PR = 5\ \%$, while for $PR = 1\ \%$, a reduction in 7.6 % at a mole flow rate increase of 47 % was achieved. It was observed that all plants without hydrogen quench consumed less electricity than any of the plants with hydrogen quench, while the reactor size was larger at purge ratios between 2 % and 5 %.

For the plants with a carbon efficiency of 90 %, the electricity consumption was higher than for the reference case, as expected, due to the higher hydrogen demand for achieving higher carbon efficiencies. The trends for the two plants looked similar to those for the lower carbon efficiency, but the differences in reactor size were smaller, as seen by the flatter curves. For the plant with hydrogen quench, the electricity consumption was increased by 25 % and 19 % for the plants with $PR = 5\ \%$ and $PR = 1\ \%$, respectively, while the molar flow rate into the methanol reactor was increased by 27 % and 46 % compared to the reference case, respectively. For the plant without hydrogen quench, the increases in electricity consumption were 21 % and 14 % and for the mole flow rate 52 % and 71 %, respectively.

The highest electricity consumption and reactor size were found for the plants with a carbon efficiency of 95 %, due to the amount of hydrogen needed. The increase in electricity consumption was 45 % and 34 % for the plant with hydrogen quench at $PR = 5\ \%$ and $PR = 1\ \%$, respectively, and 41 % and 25 % for the plant without hydrogen quench. The mole flow rate to the methanol reactor was increased by 70 % and 79 % for the plants with hydrogen quench and by 105 % and 106 % without hydrogen quench.

4. Discussion

The results showed that higher energy efficiencies were achieved for plants without hydrogen quench compared to the plants with hydrogen quench (see Figure 5). This derived from avoiding the compression of hydrogen from ambient pressures up to a methanol synthesis pressure of 85 bar. Instead, the hydrogen could be added at 30 bar, enabling pressurized operation of the alkaline electrolyser, reducing the electricity consumption by pumping water to 30 bar instead. Reducing the purge ratio from 5 % increased the energy efficiency of the plants, by better utilizing the hydrogen in the system, leading to a lower hydrogen demand and hence lower electricity consumption. The highest energy efficiency of the investigated plants with $\eta_{\mathrm{main}} = 59.1\ \%$ was achieved with the plant without hydrogen quench and purge ratio of 1 %. This energy efficiency was reached when adding between 0.28 kg/s and 0.32 kg/s of hydrogen to the system, yielding carbon efficiencies of around $\gamma_{tot} = 90 \ldots 95\ \%$. The energy efficiency was almost constant and always larger than $\eta_{\mathrm{main}} \geq 58.3\ \%$ in the range of carbon efficiencies of $\gamma_{tot} = 77 \ldots 98\ \%$. For carbon efficiencies higher than 98 %, the energy efficiency dropped rapidly.

For the plant with hydrogen quench and a purge ratio of 1 %, the energy efficiency was as high as $\eta_{\mathrm{main}} = 57.7\ \%$ in the range of carbon efficiencies $\gamma_{tot} = 88 \ldots 94\ \%$. The energy efficiency was always higher than $\eta_{\mathrm{main}} \geq 57\ \%$ in the range of $\gamma_{tot} = 82 \ldots 98\ \%$. Pressurized operation of the LT-CFB gasifier and the downstream POX would reduce the difference in energy efficiency between the plants with and without hydrogen quench, because this would enable to use pressurized electrolysis also for the plant with hydrogen quench. If the gasifier is pressurised to 30 bar, it is expected that the plants with quench would achieve higher energy efficiency than the plants without quench. Pressurization of the LT-CFB gasifier could be economically feasible for large-scale plants, because it would reduce the size of the component. However, challenges with the biomass feeding may arise. Additionally, it could perhaps impact the tar formation mechanisms in the pyrolysis reactor and increase the risk of tar condensation and subsequent damage of components.

The evaluation of the size of the methanol reactor, described by the mole flow rate into the reactor, showed that for carbon efficiencies of 90 % and lower, a higher energy efficiency (i.e. lower electricity consumption) required a larger methanol reactor. This denotes that there is a trade-off between the investment cost (reactor size) and the operational cost (electricity consumption) of the plants. An economic analysis of the plans would be necessary in order to quantify, which of the factors has a larger influence on the overall plant economics. At higher carbon efficiencies (e.g. 95 %) a different trend was observed, where higher purge ratios led to both higher electricity consumption and larger methanol reactor. There it was clearly beneficial to choose a small purge ratio.

The same trade-off was observed in the comparison between plants with and without hydrogen quench. In order to achieve the same carbon efficiency, the plants with hydrogen quench required more electricity, while the methanol reactor was smaller. It should however be considered, that for the plants with hydrogen quench additional investment would be required for the hydrogen quench. This would consist of either increasing the size of the POX reactor and adding a hydrogen injection or adding an additional reactor for the hydrogen quench after the POX. An economic comparison between the system is necessary for making a clear conclusion.

Lastly, it should be noted that using the mole flow rate into the methanol reactor as a measure for the size of the reactor gives a first estimate of the required investment of the methanol reactor. However, comparing inlet mole flows to the reactor enables only to compare the cross-sectional area of the reactor, i.e. the diameter of or the number of tubes in the reactor, since it is proportional to the volume flow rate into the reactor. The shown results could not be used for making any suggestions on required changes in the length of the reactor, because the length depends strongly on the kinetics of the methanol synthesis reactions. Since the inlet composition to the reactor varied strongly between the different plants, due to the variations in purge ratio, amount of hydrogen addition and the use of hydrogen quench, the use of a kinetic model for estimating the length of the reactor could give further insides into the influence of these parameters on the economic performance of the different plants.

5. Conclusion

In this work we investigated the influence of the amount of electrolytic hydrogen and the purge ratio of the gas after the vapour-liquid separator in the methanol system in two different DME production plants. Both plants produced DME from wheat straw gasification using two-stage DME synthesis, where methanol was synthesized in a first step, and then dehydrated to DME and water in a second step. The plants used a partial oxidation (POX) step after the gasifier for reforming and cracking the tar and hydrocarbons in the produced gas. The difference between the plants was the location of hydrogen addition. In the plants without hydrogen quench, the hydrogen was added after the gas from the POX was cooled and compressed to 30 bar. The gas hydrogen mixture was then compressed to 85 bar. In the plant with hydrogen quench, the hydrogen was added at high temperatures directly after the POX, leading to a spontaneous reverse water gas shift reaction, converting CO_2 and H_2 to CO and H_2O.

The analysis showed that increasing the amount of hydrogen in the system led to a higher DME production and hence a higher carbon efficiency. Carbon efficiencies higher than 98 % were achieved for all plants and

purge ratios. By reducing the purge ratio, the carbon efficiency was increased at constant hydrogen addition, Because the hydrogen in the system was used more efficiently. At the same time, it also increased the energy efficiency of the plants. The plants with hydrogen quench produced more DME then the plants without hydrogen quench, when using the same amount of hydrogen and purge ratio. Despite the lower hydrogen demand, the electricity consumption was higher for the plants with hydrogen quench, due to increased compression work. The compression work was lower for the plants without hydrogen quench, due to adding the hydrogen at 30 bar, enabling to pump water to the electrolyser instead of compressing the hydrogen.

Additionally, the changes in the required size of the methanol synthesis reactor were estimated by comparing the mole flow rate at the inlet of the methanol reactor. The analysis showed that for most of the cases, measures leading to an increase in energy and/or carbon efficiency led also to an increase in reactor size, highlighting a trade-off between investment cost (larger reactor) and operational cost (lower electricity consumption/higher DME production). A detailed economic analysis is proposed to be conducted for further insights into the economic performance of the plants.

Abstract:
A research community to encompass efforts towards the development of the whole value chain of hydrogen and fuel cells related technologies has been set up at UPM. Such community has as main goal to unite the multidisciplinary expertise of the different engineering schools and faculties of UPM (more than 17 in several technological disciplines) to provide research and innovation services to face the challenge of developing medium and high scale hydrogen-related technologies deployment. Such critical mass of knowledge will be needed to highlight the contribution of high education institutions to the technological development for the energy transition. In this communication, we will show a portfolio of research infrastructures at UPM covering the whole value chain of the hydrogen economy: from production to utilization. The knowledge of available infrastructures is a first step to boost collaboration with other institutions.

Keywords:

Hydrogen; Infrastructures; fuel cells; hydrogen storage; hydrogen transport; hydrogen production.

1. Introduction

The climate crisis, that the anthropogenic activity catalyses, is boosting a systemic transformation towards a more sustainable energy system. The main challenge for such transformation is the deep reduction of greenhouse gases emissions, as to avoid expected catastrophic consequences by limiting global warming of the atmosphere below 2 ºC. In such decarbonization process, that should reach every sector, hydrogen is being considered [1] as one of the relevant technologies contributing in the future to comply with emission reduction targets. The deployment of the hydrogen economy needs the development at high scale of its whole value chain, from high capacity production facilities to their consumption at every sector of the society (industry, services, transport, mobility, residential, ...)., Such value chain includes transport/storage infrastructures, market regulation, and sector coupling. To achieve such targets, a paramount funding support has been activated at the highest level [2] as a clear bet for hydrogen to comply with United Nation Sustainable Development Goals [3,4].

The billion-size funding, that will be allocated at national and international level to develop as fast as possible the hydrogen economy, demands a huge coordination effort between different stakeholders to address efficiently such task. A dialogue between several public research funding agencies (including the EU Research & Innovation Framework Programs), industry, research, academic, professional association, technological platforms and social institutions is required. An example of such dialogue is the Clean Hydrogen Partnership [5], that support the European Commission to organise many of the hydrogen related activities in the framework of the EU Green Deal [2].

A significant contribution of a high education institution, as UPM, implies the adaptation to a research and innovation scheme that goes far beyond the classical submission and execution of low Technological Readiness Projects (TRL) for basic research, demanding a modest amount of economic and material resources. The hydrogen economy needs to successfully implement large projects to produce a high impact into the socio-economic structure of the society. In many projections, hydrogen is expected to manage a very significant amount of the worldwide energy demand. For instance, according to some serious prospections, hydrogen is predicted to manage 5% of the energy demand in 2050 in the order of 240 Mton H_2 [6].

At UPM we have created a research community financed by own resources to tackle the challenge to transfer to our socio-economic environment the added value to contribute to the development of the hydrogen related technologies. One of our commitments is to build the human expertise, that is one of the bottlenecks [7] of the fast development of the hydrogen economy. For such purpose, we have designed a master program as one of our activities. We plan to increase our expertise by a close collaboration with the private sector to support their developments with our contribution to project consortia at national and international level, offering the

access and utilization of the experimental infrastructures that are available at UPM. Another relevant action to keep our education standards to comply the needs of the productive sector is to be able to contribute to high scale projects.

The first task in relation within UPM was to create an inventory of our current capacities, that has been created by different groups and institutes, to provide a map of infrastructures. Infrastructures has been classified versus the different stages of the hydrogen value chain. Such classification provides a picture of our capabilities at first sight, and allows to identify weaknesses and strengths in our organization at that respect. The classification of our infrastructure has been done attending to the following position into the hydrogen value chain:

- Hydrogen production
- Storage
- Transport
- End uses
- Skills

The current infrastructures for hydrogen research at UPM are the result of our previous research activity in cooperation with industry and research funding agencies. Our commitment is to upgrade such infrastructures to face the challenges of the new projects to come in the field, in which TRL is expected to be much higher. That means that this portfolio of facilities that will be introduced is being updated depending on the requirements of the current and future projects, and the available funding, mostly in the framework of large-scale projects to develop.

2. Hydrogen production

We are working on several methods for production to extract hydrogen from water or hydrocarbons. Regarding the development of electrolysis, we are working at experimental size to test the sensitivity of electrodes with different water composition, not only to test electrodes, but some biological waste treatment. Such activities are in the first stages of development. Additionally, at UPM we are working testing electrodes and membrane configuration to electrolyse seawater (Figure 1) as well as testing of direct methanol fuel cells and electrolysers (Figure 2) at School of Naval Arquitecture and Marine Engineering (ETSIN).

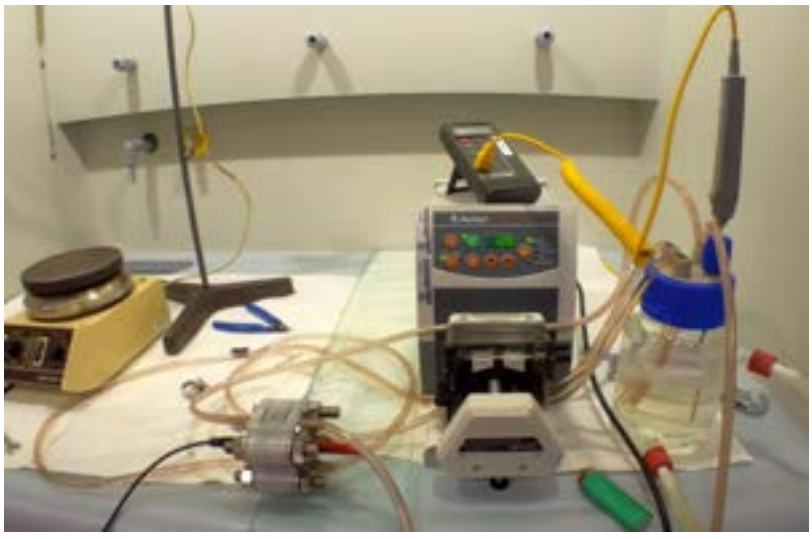

Figure 1: Thermostatic 3d printed alkaline electrolysis cell. Temperature up to 70 °C. Cell used for tests with desalinated seawater as feed

Figure 2: Test bench for direct methanol fuel cell and methanol electrolyser

Regarding Hydrogen integration, it has been installed a demonstration installation in the roof of the School of Engineering and Industrial Design (ETSIDI) consisting of a 260 W PEM electrolyser to produce hydrogen from FV panels located in the roof. In addition, a hydrogen storage system based on metallic hydrides with a capacity of 3 Nm^3 at 6-12 bar is used to manage energy production in combination with a Li-ion battery with a capacity of 2 kWh.

Other capabilities are under development at the School of Industrial Engineering (ETSII), as laboratories for instrumentation testing, or for surface coating that may be applied to the development of materials and temperature or pressure sensors to be integrated in hydrogen production facilities. As an example, we have available sputtering equipment for manufacturing nano-structures for the surface coating of material layers to be used for new electrodes or membranes. A high temperature reactor for methane pyrolysis based on liquid metal technology is also under development, that will constitute a facility for hydrogen production from thermal processes in the future with a capacity of some kW.

Figure 3: Nano-coating sputtering equipment.

3. Hydrogen storage

Hydrogen storage is one of the critical technologies for the development of the hydrogen economy. In particular the availability of high capacity hydrogen tanks and reservoirs is of paramount importance for the viability of hydrogen as energy vector. Hydrogen as reserve storage, even for seasonal storage, depends on the possibility to accumulate large volumes and quantities of hydrogen, for instance, into caverns, what is one of the most recognised expertise at the School of Mines and Energy Engineering (ETSIME). For such purpose, we have specific equipment for rock physical analysis to measure rock density (Accupyc II 1340), porous material envelope (Geopyc 1360), gas permeability (Gasperm), currently used in the UNDERGY project. An example of other equipment for measurement of physical rock properties are presented in Figure 4.

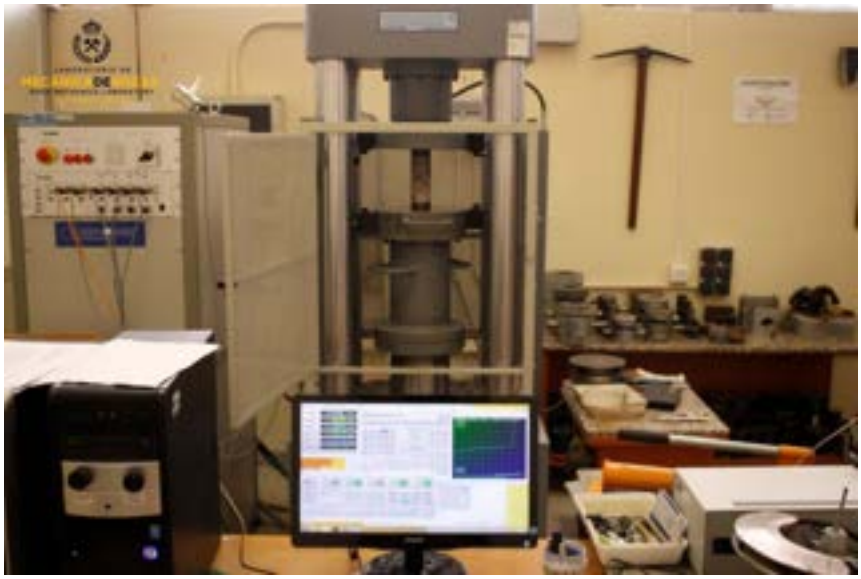

Figure 4: Simple Compressive Strength Measuring Equipment

4. Hydrogen transport

The transport of huge amounts of hydrogen trough dedicated networks, as the existing for oil and natural gas, is on the agenda of many stakeholders related to the hydrogen development and energy supply chain in the European Union and beyond. Research and development in the field of materials, and the effect of high pressure hydrogen in transport ducts are of paramount importance for the technical viability of many projects that are ongoing, The hydrogen corridor proposed [8] by Spain, Portugal and France are the clear example of infrastructure that will need some support in terms of technological development to be safely implemented. At UPM, at the CIME (Centro de de Investigación en Materiales Estructurales/Center for Structural Materials Research) of the School of Civil Engineering (ETSICCP) is available a chamber for high pressure test (up to 100 bar) of structural materials in hydrogen atmospheres, what will be a key information for the choice of structural materials for ducts.

Figure 5: High pressure hydrogen chamber for material testing.

5. Hydrogen end uses

The end use of hydrogen is one of the final steps on its value chain. There are many challenges in this area. One of those challenges is the implementation of hydrogen as energy sources in mobility. That includes, for instance, a test bench for fuel cells operating in hybrid mode for terrestrial vehicle power trains, including Heavy Duty ones. The Test Bench installed at the University Institute of Automobile Research of the UPM (INSIA) can prove Powertrains up to 200 kW and 9600 N.m on each wheel (Figure 6).

Figure 6: Test bench for hybrid power trains.

One of our most important groups, with decades of activity in relation with the development of fuel cells, is PiCOHIMA, of that is currently working in the development of a fuel cell test bench up to a few hundreds of kW (Figure 7), that is expected to be operative at the end of the GreenH2-CM project supported by the Madrid regional government and the Spanish Government trough the “Plan de Recuperación, Transformación y Resiliencia” (PRTR). We have some equipment for evaluating the combustion of gas mixtures, including fraction of H_2, CO_2 and CH_4, that are useful for the characterization of biomass to hydrogen [9,10] conversion and the heating value of the products (Figure 8). Such facility is available at TECMINERGY, a centre depending of the School of Mines and Energy Engineering.

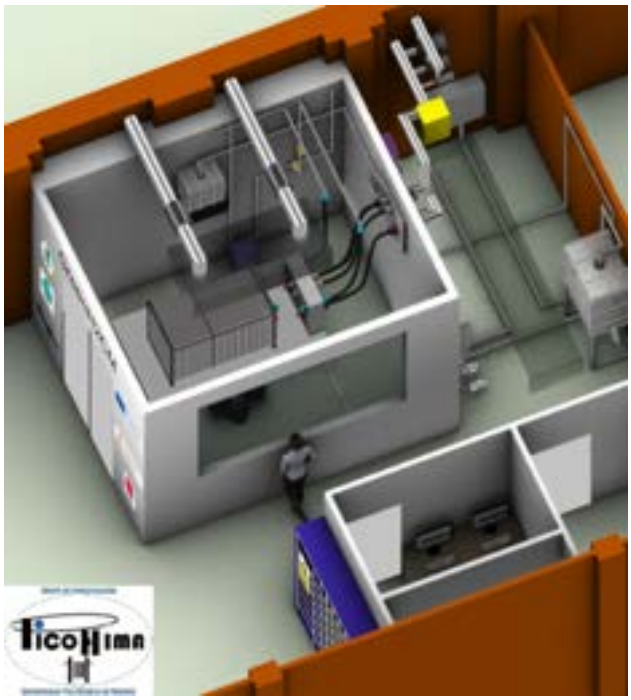

Figure 7: Sketch of the fuel cell test bench under design.

Figure 8: Combustion chamber CO_2 lung (combustion tests of the ternary mixture $CH_4/CO_2/H_2$).

6. Skills

Technology is implemented by people, and the impressive challenge of put into practice the huge projects that are planned to transform the expectations of the hydrogen economy into a reality, demands thousands of skilled people. So many hands will come from fresh young graduates as well as by reskilling of many workers already in related industries. For such purpose, our role as university is to provide tools to allow the access of the Society to the knowledge in order to feed such demand. We have designed a master program [11] of 60 ECTS for the specialization of post-graduated individuals in the whole value chain of the hydrogen economy, from generation to utilization, including regulation and normative as a basic stone for the hydrogen sector.

Conclusion

The hydrogen research and development ecosystem have the societal need to transfer, as fast as possible, knowledge that has been produced for decades into one of the pillars of the energy and productive system.

High education institutions must contribute to the development of high TRL projects in cooperation with industry to transfer such knowledge, as well as for the training of skilled manpower that is needed for such purpose. At UPM we have initiated a process to respond to the needs of a fast implementation of the hydrogen economy in the Society. One of those needs is to gain critical mass and capacity to support large size projects. We have elaborated a first inventory of the existing laboratory infrastructures at UPM to evaluate our own capacity to face such projects. The variety of engineering disciplines at UPM is a strength of the institution to participate in multidisciplinary projects, as required for large scale hydrogen implementation. The expertise at UPM covers the whole value chain of the hydrogen economy. From this first infrastructure inventory, we are trying to upgrade and improve our facilities to face the enormous challenge and contribute to the implementation of a more sustainable society.

Acknowledgments

Abstract:

Nowadays, Hydrogen is considered an important energy vector through which the decarbonization process can be carried out if it is produced by Water electrolysis using renewables. Then, Hydrogen is stored for performing medium- and long-term storage, which is suggested for those sources that face considerable electricity production variability throughout the days/months like renewables, and sent to Fuel Cells (FCs) for producing again electricity. The coupling of the electrolyzer, storage, and FC constitutes an integrated Hydrogen system. This work presents a model of a 5 kW-Proton Exchange Membrane Fuel Cell (PEMFC), which has been developed in Aspen HYSYS®, to evaluate its performance by varying its operating conditions (e.g., current density, temperature, and pressure). The simulation is based on the determination of a semi-empirical mathematical model of the electric potential related to a single 25 cm^2 cell through the regression of experimental data taken from the scientific literature. Normal Root Mean Square Errors (NRMSEs) were obtained by the comparison between the results of the electric potential model of the single cell and the experimental ones, showing a good agreement. The model developed in Aspen HYSYS® allows to predict the behaviour of the PEMFC by identifying the optimal conditions in terms of temperature and pressure. Results showed that the PEMFC performance improves by increasing the temperature up to 80°C, while it is not suggested to operate at pressure values higher than 3 atm due to a lower net electric power and overall system electric efficiency.

Aspen HYSYS®, Fuel cell modeling, Green Hydrogen, Proton Exchange Membrane Fuel Cell.

1. Introduction

In recent years, the issue of environmental sustainability has become increasingly important. Problems related to both pollution and global warming led the international community to pay more attention to the research of new technologies for energy production through the exploitation of renewable sources. In the context of the ecological transition, Hydrogen can play a fundamental role; indeed, governments and companies have focused on this type of chemical element to further contribute to the decarbonization process. Hydrogen is an energy carrier, and it has a higher energy density than fossil fuels. Because of its properties, it represents a valid solution for energy storage and production; in the latter case, Fuel Cells (FCs) use Hydrogen to produce electricity without pollutant emissions.

Nowadays, FCs have considerable attention as they constitute the key technology for further deploying this type of energy carrier [1]. Among the different types, Proton Exchange Membrane Fuel Cells (PEMFCs) are

mostly applied in automotive and small stationary applications due to their high electric efficiency, power density, and reliability. In a PEMFC, the fuel is Hydrogen that reacts with the Oxygen contained in the air to generate electricity, Water, and heat. Electrochemical reactions as well as the transport of ions, electrons, energy, and species in gas and liquid phases across a heterogeneous media are involved. However, this technology is currently developing to further increase its efficiency and applicability ranges, especially when dealing with cogeneration purposes in both residential and industrial sectors [2-4].

To better understand the phenomena behind the operation of FCs, several experiments have been carried out so far and interesting results have been already reported in the scientific literature; however, numerical models aiming to resemble the behaviour of FCs, according to their typology, would fasten and further contribute to the development of this technology, being less time consuming and less economically demanding as well. Among the most known simulation environments, Aspen Technology® is one of the most used since it allows to easily design, manage, and integrate several parts of a system in one macro-system as well as provide preliminary data of how it would run. In this regard, Beheshti et al. [5] developed an Aspen Plus® model to simulate the behavior of an integrated gasification system with a PEMFC stack by coupling the Aspen Plus® software with dedicated FORTRAN subroutines. Effects of critical parameters (e.g., current density, feed gas humidity, equivalence ratio, steam/biomass ratio, and biomass moisture content) on the cell potential and gasification efficiency have been discussed. Results showed that a higher feed humidity at the cathode side is more favorable for the improvement of the voltage output, while the biomass moisture content has a negative impact on the cell potential. Barelli et al. [6] studied a micro-cogeneration Combined Heat and Power (μCHP) energy system based on a PEMFC to evaluate both the performance and energy/economic feasibility of the system to fulfil the thermal and electrical demands of apartments. A zero-dimensional model of the PEMFC has been developed in Aspen Plus® and simulations at different operating conditions have been carried out. Subsequently, optimal operating conditions of the PEMFC have been identified; in particular, these operating conditions have been obtained by fixing constraints to the electricity production/supply as well as to the return temperature and pressure of hot Water at 105 °C and 2 atm, respectively. Zuliani et al. [7] carried out a performance analysis of a 1 kW-High Temperature PEM Fuel Cell (HT-PEMFC). The performance of this FC has been predicted through a zero-dimensional, semi-empirical model implemented in FORTRAN and subsequently integrated into Aspen Plus®. The aim of the work was to perform an energy analysis to investigate how the system operates at partial load operating conditions and assess the difference with Low-Temperature PEM Fuel Cell-based (LT-PEMFC) systems. Results showed that a more reliable balance of plant is obtained with HT-PEMFCs than LT-PEMFCs, while the system efficiency is unchanged.

To the authors' knowledge, as also previously discussed, there are several models of FCs in Aspen Plus® available in the scientific literature, but no references have been found on PEMFCs modeling with Aspen HYSYS®. Aspen Plus® is mostly used with fine chemistry, general chemistry, electrolytes, and polymer modeling, while Aspen HYSYS® is devoted to resemble petrochemical refining, oil assays, and all related industries, thus having wider use in chemical applications. Thus, the modeling of a PEMFC block in this kind of environment can be of interest to those researchers/scientists that would like to use this specific model in a more complex chemical system since it would be easier to be embedded.

This work consists of the development of a numerical model in Aspen HYSYS® related to a stack of a 5 kW-Proton Exchange Membrane Fuel Cell (PEMFC), whose experimental data are available in [8], to study its behaviour by changing its operating conditions (e.g., current density, temperature, and pressure). In particular, the model could be considered as a starting point for then applying an optimization procedure to optimally manage the electricity production of PEMFCs according to a specific load trend. The paper is structured as follows: Section 2 presents the used methodology to analytically model the FC stack, as well as provides an overview of the Aspen HYSYS® model [9]. Section 3 is devoted to the results obtained from the simulations at different operating conditions (e.g., current density, temperature, and pressure). Finally, Section 4 reports the conclusions of the work.

2. Methodology

The models that describe the behaviour of a FC by varying the operating conditions (e.g., current density, temperature, and pressure) typically include the analysis of the following quantities: i) electric potential, ii) net electrical power generation, iii) electrical efficiency, and iv) heat power production. The present analysis has been carried out by considering the experimental data of [8]. The regression of the experimental data allowed to develop a model to predict the performance of the analysed PEMFC. After the validation of the numerical results with the experimental ones, the characteristics of the PEMFC (e.g., dimensions and the number of cells) have been scaled up to analyse the performance of the same PEMFC having a power output of 5 kW. This FC has a stack consisting of 72 cells in series, each of them having an area of 196 cm^2. The modelling of

the PEMFC involves mathematical relationships, thus resulting from empirical or semi-empirical analyses. Figure 1 shows the block diagram that sums up the eight steps used in the present methodology to carry out this study. It is worth noting that some of these steps have been performed in parallel and, for this reason, they have been placed in the same row.

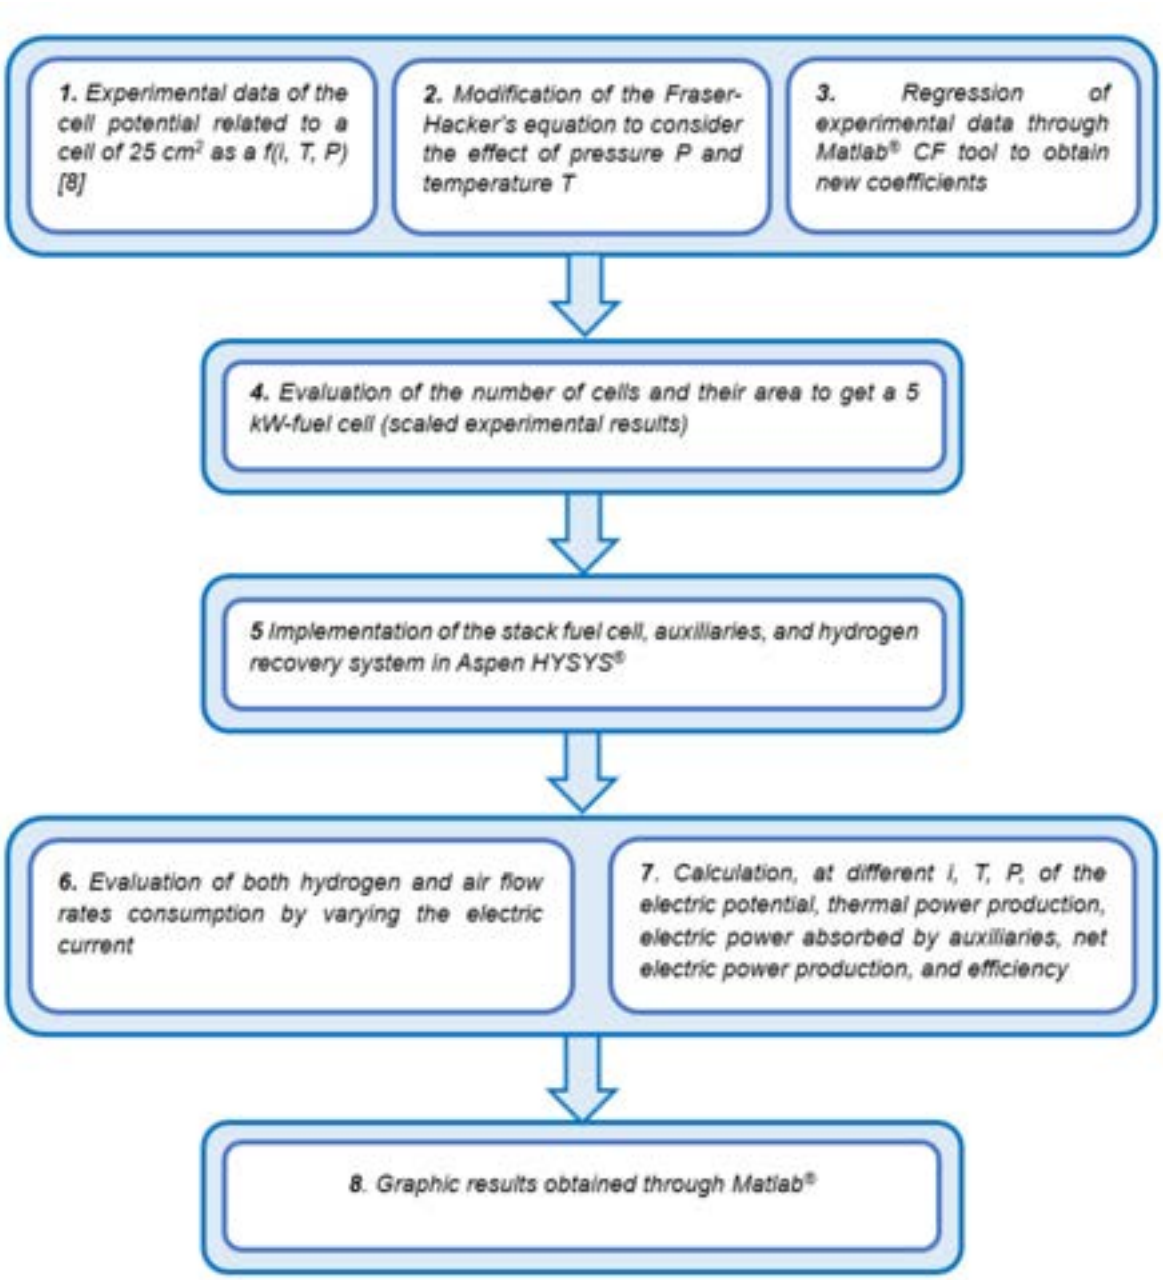

Figure 1. Block diagram with the eight steps used in the present methodology.

The polarization curve that describes the relationship between the output voltage and the current density is a good indicator of the FC performance. The most known semi-empirical fuel cell model to draw up the trend of the electric potential as a function of the current density is Fraser-Hacker's one [10], which is reported in Eq. 1:

$$E_{cell} = E_{rev} - b \cdot log\left(\frac{i+i_{int}}{i_0}\right) - R \cdot i - m \cdot e^{(n \cdot i)} \quad (1)$$

where E_{rev} [V] is the reversible cell voltage and it is computed as a function of the cell temperature and the partial pressures of the active species according to the Nernst's equation, b [V] is the charge transfer overvoltage fitting parameter (V), i_{int} and i_0 [A·cm^{-2}] are charge transfer overvoltage fitting parameters, R [Ω·cm^2] represents the Ohmic overvoltage fitting parameter, m and n are mass transport overvoltage fitting parameter [10] that represent the mass transport limitations and the rapid decrease of E while increasing i, respectively. The reversible thermodynamic voltage E_{rev} is calculated from the modified Nernst's equation that considers both temperature and pressure dependence [11]:

$$E_{rev} = E^0 \cdot \frac{\Delta\hat{s}}{n_e \cdot R}(T - T_0) - \frac{R_g \cdot T}{n \cdot F} \cdot ln\left(\frac{a_{H_2O}}{a_{H_2} \cdot a_{02}^{1/2}}\right) \quad (2)$$

where E^0 is equal to 1.229 V and it is the standard-state reversible cell voltage, Δŝ is the reaction entropy (assuming that it is independent of the temperature and it is equal to -163.28 J·mol^{-1}·K^{-1}), R_g is the universal constant of the gases (8.314 J·mol^{-1}·K^{-1}), n is the number of electrons transferred in the chemical reaction (2 mol$_{e^-}$/mol$_{H2}$), F is the Faraday's constant (96,485 C/mol), a_x is the activity of x that for an ideal gas becomes $a_x = p_x/p_O$ (where p_x is the partial pressure of x, p_o is the standard pressure of 1 atm [11].

It is possible to substitute the constants in Eq. 2 so that the reversible voltage can be also described as a function of both temperature and pressure:

$$E_{rev} = 1.229 - 8.46 \cdot 10^{-4}(T - 298.15) - 4.31 \cdot 10^{-5} \cdot T \cdot ln\left(\frac{1}{p_{H2} \cdot p_{O2}^{1/2}}\right) \quad (3)$$

Fraser-Hacker's equation (Eq. 1) considers only the dependence of the electric potential on the current density [7]. An important step of the present work was the modification of Fraser-Hacker's equation to consider the dependence of the electric potential, as well as the current density, temperature, and pressure. The modified equation is the following:

$$V = E_{rev} - \left(b_t + b_p\right) \cdot log\,10\frac{(i + i_l + i_{lp})}{(i_{0t} + i_{0p})} - \left(r_t + r_p\right) \cdot i - \left(m_t + m_p\right) \cdot e^{[(n_t + n_p) * i]} \quad (4)$$

where the parameters with the subscript t indicate that they are temperature dependent, while those with the subscript p indicate that they are pressure dependent. The dependence of each parameter on both temperature and pressure was derived through the regression of the experimental data of [8], and it has been carried out with the Matlab® Curve Fitting Tool.

The process simulation of the entire system has been developed using Aspen HYSYS® [9]. Regarding the implementation of the model, it is required to identify both involved elements and chemical compounds, the components of the PEMFC, and the methodology to calculate the thermophysical properties of the streams. The selected fluid package is the "*Peng-Robinson*" one [9]. The oxidation-reduction reaction is defined as a *"Conversion reaction"* that takes place in the conversion reactor (CRV-100, see Figure 2), which constitutes the electrode. The mixture of Hydrogen and Oxygen, called reaction gas, is sent to the second component that acts as a membrane (X-100, see Figure 2) and it is capable of perfectly separating the excess of Hydrogen that has not reacted and then recirculating towards the *Mixer*. Based on the thermodynamic operating conditions in terms of both temperature and pressure, the spreadsheet evaluates the value of the main electrochemical and thermochemical equations that define the reaction products and the electrical power produced. Through the spreadsheet, the equations that allow to calculate the fundamental outputs of the model have been implemented such as the stack electric potential, the electrical power produced, the electrical efficiency, and the thermal power to be disposed of. Other relationships have also been implemented such as Faraday's equation (5) for calculating the flow rate of Hydrogen consumed $\dot{n}_{H_2}$ as a function of electric current I.

$$\dot{n}_{H_2} = \frac{I \cdot N_{cell}}{2 \cdot F} \quad (5)$$

where N_{cell} is the number of cells that constitute the stack and F is Faraday's constant, equal to 96,485 C/mol.

The stack electric potential V_{stack} is implemented in the spreadsheet starting from Eq. 4. Eq. 3 is preferred to calculate the reversible potential for ease of implementation. Eq.s 3 and 4 refer to the cell potential, thus to obtain the stack potential the number of cells in series is multiplied by the cell potential. The calculation of the electric potential allows the calculation of the other variables of interest. The net electric power of the PEMFC, $\dot{W}_{el}$, is calculated as the product of its electrical voltage and the electric current minus the electric power required by the air compressor, $\dot{W}_{ac}$. It is worth noting that the electric power of the air compressor is calculated by Aspen HYSYS® and depends on both the pressure ratio and the Hydrogen flow rate. The air compressor allows to maintain the air pressure in the stack equal to that of the Hydrogen, as well as to maintain a stoichiometric ratio between the anode and the cathode.

$$\dot{W}_{el} = \dot{V_{stack}} \cdot I - \dot{W}_{ac} \tag{6}$$

The electric efficiency η_{el} is expressed as the ratio of the net electric power generated by the FC, $\dot{W}_{el}$, and the product between the Lower Heating Value (LHV) of Hydrogen and its molar flow $\dot{n}_{H_2}$ as described in Eq. 5:

$$\eta_{el} = \frac{\dot{W_{el}}}{LHV_{H_2} \cdot \dot{n}_{H_2}} = \frac{V_{stack}}{V_{LHV}} \tag{7}$$

The generated heat power that has to be disposed of $\dot{Q}$ depends on the difference between the thermoneutral potential of the reaction V_{LHV} and the electric stack potential. The thermoneutral potential is related to the Hydrogen Lower Heating Value (LHV) and it is equal to 1.25 V.

$$\dot{Q} = (V_{LHV} - V_{stack}) \cdot N_{cell} \cdot I \tag{8}$$

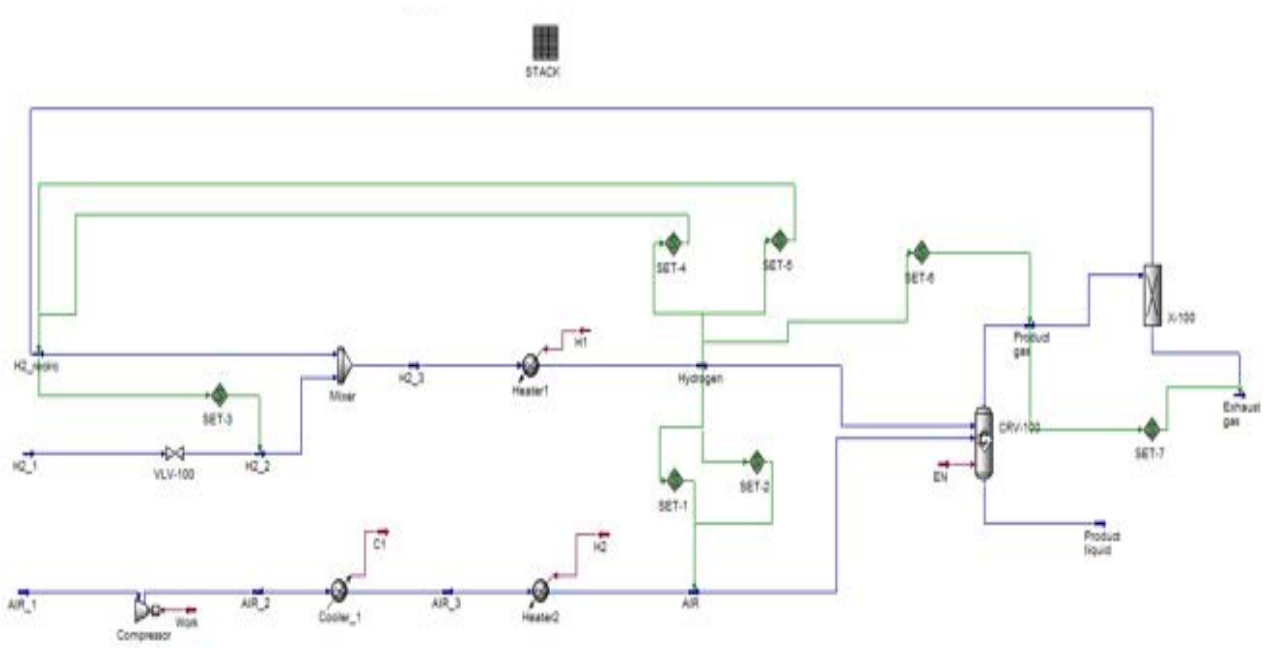

Figure 2. Model of a PEMFC developed in Aspen HYSYS®.

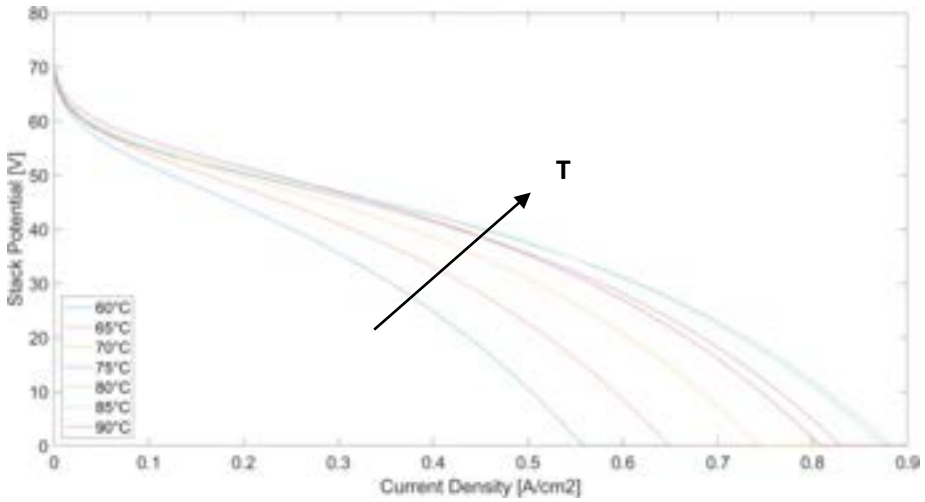
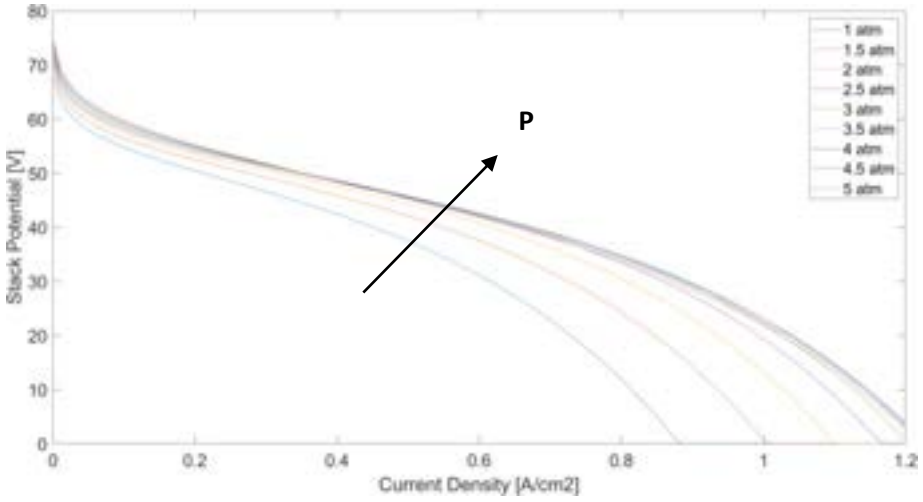
The trends of the performance variables such as temperature, pressure, and current density variation have been obtained by setting up “for cycles” in Aspen HYSYS® called “nested case studies”, which allow to study the trend of multiple dependent variables as a function of multiple independent variables. The numerical results of the analysis were processed in Matlab® to obtain the graphs shown in the next section.

3. Results and comments

The results of the PEMFC performance are evaluated as a function of the current density (range of 0-0.9 A/cm^2), and they depend either on the temperature (range of 60-90°C with steps of 5°C) or the pressure (range of 1-5 atm with steps of 0.5 atm). Precisely, Figure 3, Figure 4, Figure 5, and Figure 6 show the stack electric potential curve, the electric power curve, the electric efficiency curve, and the produced heat trend, respectively.



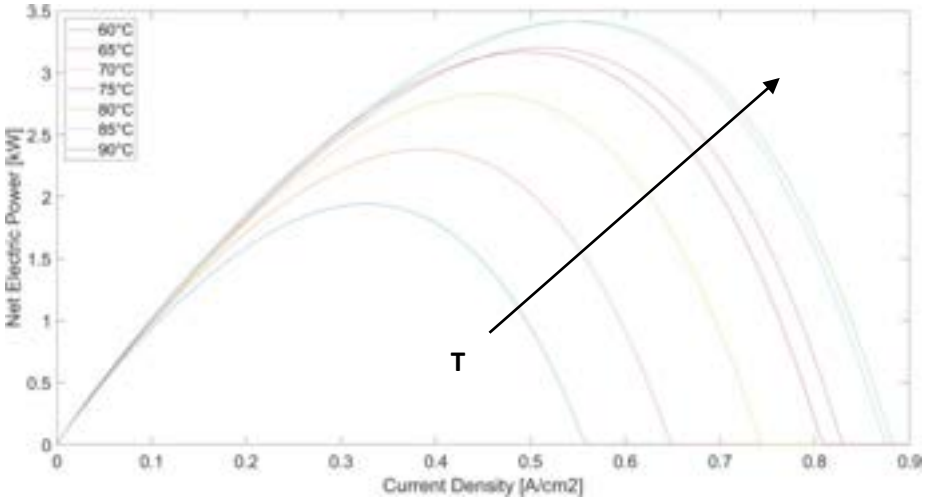
a)



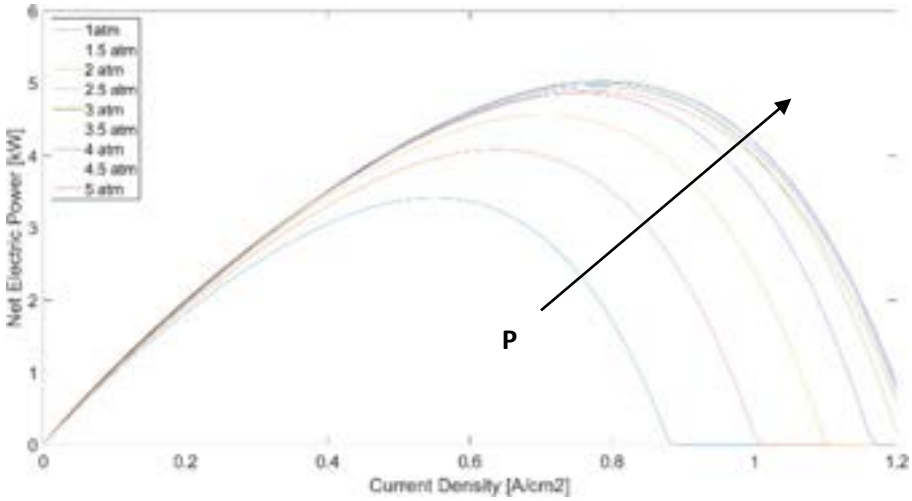
b)

Figure 3. (a) The electric stack potential as a function of both the current density and the temperature (pressure equal to 1 atm), and of (b) both the current density and the pressure (temperature equal to 80°C).

The results confirm the positive effect on the stack performance of increasing both the temperature and the pressure. Figure 3a highlights that the performance of the FC improves while increasing the temperature up to 80°C; beyond this value, it starts to lower due to membrane hydration issues linked to a decrease of the relative humidity in the reaction environment. Polarization curves at different operating pressures show that the performance improves while increasing the pressure (see Figure 3b). The polarization curves undergo a positive increase while increasing the pressure as it produces high partial pressures of the reactants near the electrodes, thus improving the transport phenomena and the solubility of gases in the electrolyte as well.



a)

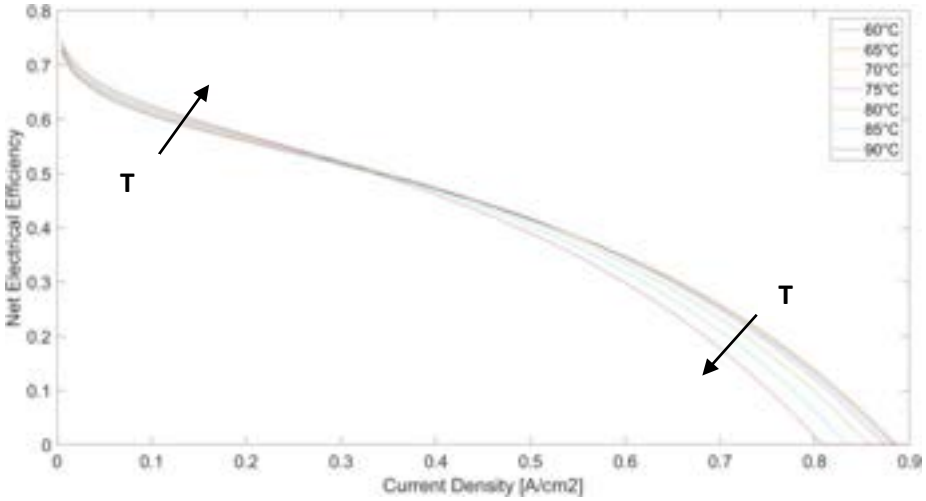


b)

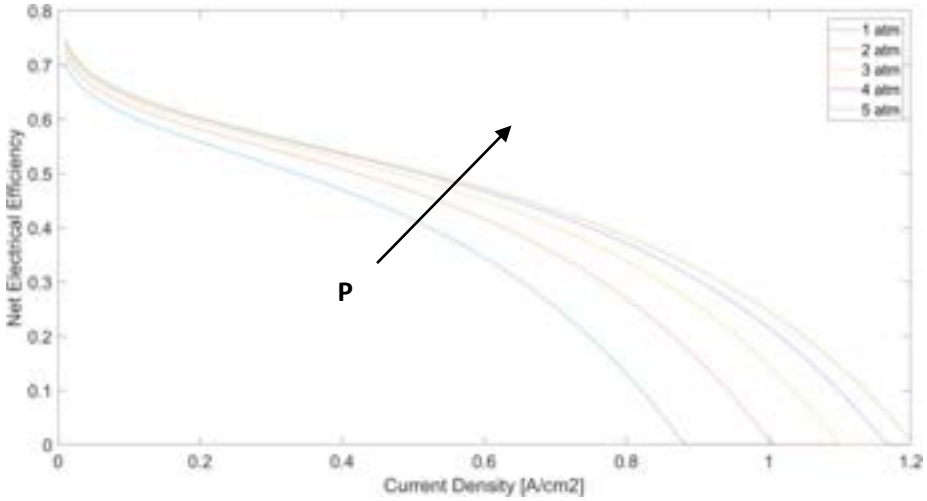
Figure 4. (a) The net electric power as a function of both the current density and the temperature (pressure 1 atm) and of (b) both the current density and the pressure (temperature 80°C).

As it can be noticed in Figure 4a, the net electrical power of the stack improves while increasing the temperature up to 80°C, and then decreases due to the lower electrical potential caused by hydration problems. The net electric power also shows an initial increase with the current density (range 0-0.3 A/cm^2), while it starts to decrease afterward due to the prevalence of the effects due to overvoltage losses.

Figure 4b shows the same trend while changing the operating pressure of the fuel cell, being almost unchanged with pressure values equal to or greater than 3 atm; indeed, higher pressures make the energy power of the compressor increase, thus balancing the electrical production and keeping fixed the net electric power at a constant value.



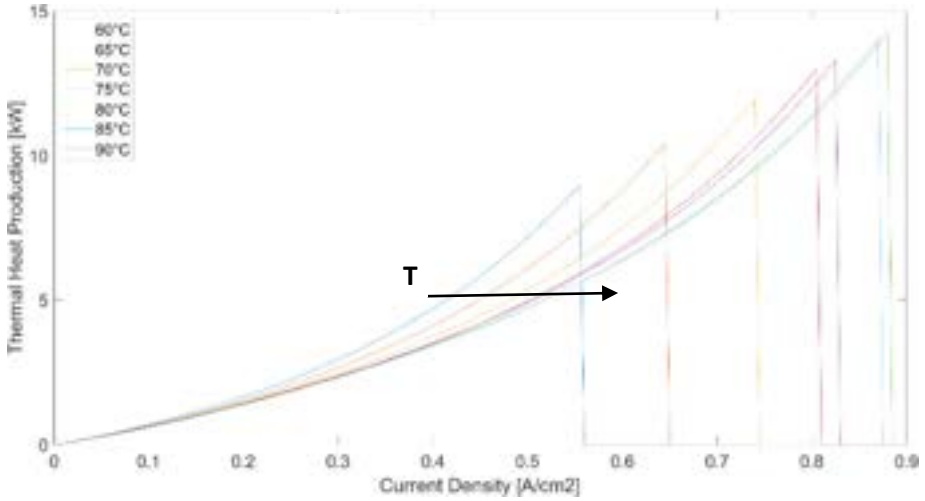
a)



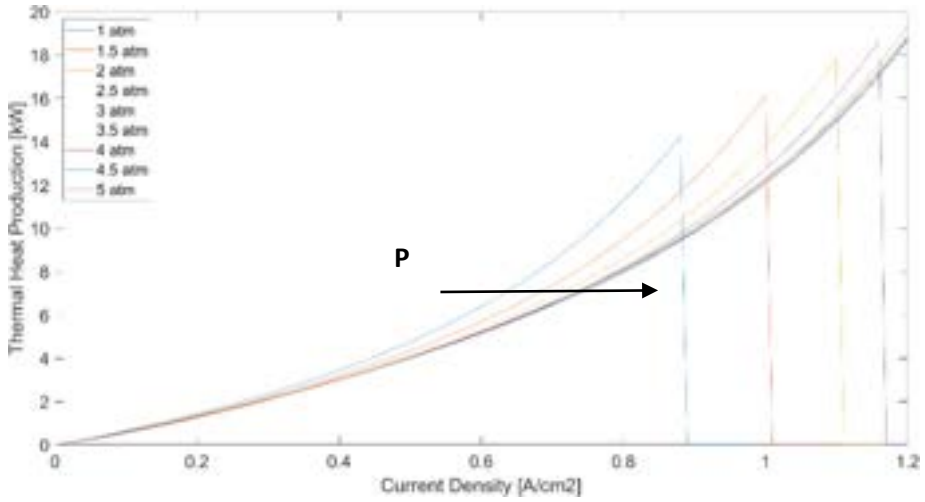
b)

Figure 5. The net electric efficiency as a function of both the current density and the temperature (pressure of 1 atm), and (b) both the current density and the pressure (temperature of 80°C).

Figure 5 shows that the trend of the net electric efficiency depends on the electric potential as it is the result of the ratio between the latter and the thermoneutral potential referred to the LHV, which it can be considered constant in the analysed temperature and pressure ranges.



a)



b)

Figure 6. (a) The thermal heat production as a function of both the current density and the temperature (pressure of 1 atm), and (b) both the current density and the pressure (temperature of 80°C).

Figure 6 shows an increase in the thermal power while increasing the current density. As it can be noticed, although the curves seem to drop down sharply toward zero beyond certain current density values, the jump in thermal power production depends on the lack of data available from [8]. The thermal power production decreases while increasing the temperature due to the higher electric potential; however, it increases with temperatures higher than 80°C. The thermal power production, considering the same current density values, decreases as the pressure increases due to the increase of the electric potential.

4. Conclusions

The present work shows the development of a PEMFC model with Aspen HYSYS® to evaluate its performance in terms of electrical potential, net electric power, electric efficiency, and thermal power production by changing its operating conditions in terms of current density, temperature, and pressure. The semi-empirical model developed by modifying Fraser-Hacker's equation showed a good agreement with experimental data taken from [5]. Aspen HYSYS® has proved to be a valid tool to simulate FCs, thus allowing to evaluate the performance of a 5 kW-PEMFC under different operating conditions, starting from the mathematical model developed for the single cell.

Results confirmed the positive effect on the FC stack performance by increasing both temperature and pressure. Indeed, the performance of the FC improves with increasing temperatures up to 80°C; beyond this value, it lowers mainly due to membrane hydration issues. Furthermore, the performance improves with increasing pressure as it enhances the transport phenomena and the solubility of gases in the electrolyte. Consequently, the net electrical power of the stack improves with increasing temperatures up to 80°C, while it decreases due to hydration problems. Regarding the influence of pressure, a pressure equal to or greater than 3 atm leads to higher energy consumption of the air compressor and thus to a lower net electric power and overall system electric efficiency. Regarding thermal power production, the increase of both temperature and pressure leads to its decrease due to a higher electric potential.

The simulation of the PEMFC performed with Aspen HYSYS® allowed to make other evaluations that have not been reported here. A further step of the work could be the coupling of this system with the models of both the electrolyzer and the storage system to form an integrated Hydrogen system, which can provide flexibility to the current electric network increasingly fed by renewables.

Abstract:

Storage systems are necessary in microgrids based on renewable energy sources to maintain the balance between production and demand. Currently, hydrogen is being promoted by the European Union to be used as new renewable energy vector (green hydrogen) in order to use it for the generation of electrical power, consequently reducing greenhouse gas emissions. Renewable energy sources used to produce hydrogen, such as photovoltaic and wind, are intermittent, therefore an optimal sizing of the hydrogen storage system is required. Another advantage of using hydrogen as an energy vector is the flexibility obtained in the electrical system. This article proposes a technical and optimal solution to create an electric microgrid for a residential area with 100 dwellings using a green hydrogen storage system powered with renewable energy. Results show that a self-sufficient hybrid photovoltaic and wind turbine microgrid with hydrogen storage system can be economically more attractive than a regular photovoltaic collective self-consumption installation. In addition, the self-sufficient gained with hydrogen as energy vector, means a total decarbonisation of the energy sector.

Keywords:

Green hydrogen, microgrid, decarbonisation, renewable energy, resilience.

1. Introduction

Since the Industrial Revolution, the greenhouse gas emissions have been steadily increasing up to the present day. The rising population, linked to the consumerist society in which we live, has led to an increase of the average temperature in the planet. The European Union has set ambitious targets for renewable energies (REs), energy efficiency and greenhouse gas reduction in order to brake climate change. Today, one of those main objectives pursued by the European Union is to decarbonize the energy sector [1] and become the first climate-neutral continent by 2050. In the particular case of the Canary Islands, it is even more ambitious and aims to bring decarbonisation forward by 10 years [2], so that total decarbonisation in the Canary Islands is set for the year 2040.

To achieve those goals, the European Union and their member states are creating and adapting regulations [3,4] to promote RE generation power plants (GPP), so that clean energy can be attractive to the consumers and be competitive in the market. The most common and available energy resources are solar energy and wind energy. Thus, photovoltaic (PV) and wind turbine (WT) technologies are two of the most widespread technologies used worldwide in renewable energy generation power plants (RE GPP). Nevertheless, the implementation of RE GPP have many challenges and limitations [5] due to the integration into the existing grid infrastructure and the need of huge energy storage systems (ESSs). Because of the excellent solar energy resources available in Spain and the relatively low cost of the PV technology, for the last years, the Spanish government [6] has been working on different policies to facilitate the access to the PV self-consumption to the Spaniards.

This paper intends to provide a solution for the decarbonisation of the Canary Islands. The solution studied consists on a self-sufficient microgrid using PV and WT technologies to generate electricity to feed one hundred dwellings. The self-sufficiency of the microgrid is ensured by a green hydrogen-based energy storage system combined with a battery, to improve the resilience [7] of the microgrid. Whereas an isolated microgrid could be a valid solution, a grid connected GPP could give worth to the excess of electricity generated, reducing the levelized cost of energy (COE) of the consumers. In this sense, a discussion of the Spanish PV collective self-consumption regulation is opened, by comparing the benefits of the legislation if it could be applied to hybrid generation power plants.

To achieve an accurate vision, the rest of the paper is structured in the following way. In section 2, *Background*, the Spanish regulation is exposed identifying weaknesses of PV self-consumption and hydrogen systems legislation. Section 3, *Study area*, identifies a valid location for the microgrid according to the RE resources, the proximity to possible consumptions and the feasible locations according to the current legislation. After this, the section 4, *Methods and modelling of study cases*, shows the methodology followed to build the different study cases using HOMER Energy software [8] and the alternative scenarios proposed. The results from the different scenarios considered are exposed in section 5, *Results*, with a discussion of the findings and its limitations. Finally, section 6, *Conclusion,* summarizes the main ideas concluded from this paper.

2. Background

2.1. Current Spanish self-consumption regulations

In 2019, the Spanish government published the Royal Decree 244/2019 [7], which regulates the administrative, technical and economic conditions for the self-consumption of electrical energy. One of the biggest steps of this regulation is the recognition of different self-consumption modalities [9], distinguishing:

- Self-consumption without surplus
- Self-consumption with surplus
  - Net billing: limited to a maximum GPP of 100 kW, this modality allows to inject the surplus to the general electricity grid (GEG) receiving the prosumer a fixed economic compensation per kWh. The electricity bill cannot have a negative value, this means, the retailer will never pay you for the surplus, but make a discount on your bill. This modality has practically no administrative formalities neither taxes applied to the surplus.
  - Direct Sell (DS): the surplus are sold at market prices, with no constrain. Taxes regarding to the generation and the incomes must be paid. The GPP needs to register as an electricity generator.
- Individual self-consumption
- Collective self-consumption: group of several consumers who are supplied, on an agreed basis, with electrical energy from production facilities close to and associated with those of consumption.

Also, the Royal Decree 244/2019 enables the self-consumption not only to installations connected to the consumers internal grid, but also through the general electricity grid. More in depth, collective self-consumption is allowed in the modality of self-consumption with surplus through the general electricity grid when the generation and the consumers are connected to the low voltage GEG within 500 meters distance of each other.

After the Royal Decree 244/2019, the Spanish government has approved new constraints regarding the self-consumption in the Royal Decree-Law 18/2022 [10] and the Royal Decree-Law 20/2022 [11]. On the one hand, the Royal Decree-Law 18/2022 claims that generation linked to self-consumption is mainly photovoltaic and therefore generated at low voltage, it is the reason why the maximum distance cannot be larger, in order to transport the energy without causing high voltage drops and high losses. At the same time, the regulation promotes self-consumption through the GEG by increasing the distance to the consumption up to 1000 meters in the case of power plants located on the rooftop. On the other hand, the Royal Decree-Law 20/2022 encourages self-consumption through the GEG by increasing the distance of self-consumption up to 2000 meters in the case of photovoltaic power plants located on rooftops, industrial land and artificial structures for other purposes, such as those used to cover parking spaces or other uses.

In a nutshell, the actual Spanish law allows self-consumption with surplus through the general electricity grid when distances between the distance between generation and consumption are under 2000 meters radio and they use PV GPP.

2.2. Current Spanish hydrogen regulations

Although the "Report on current regulations and legislative development needs, November 2019" [12] highlights the need for a new regulation on hydrogen production by hydrolysis, hydrogen production in Spain is currently classified as a chemical industry and is therefore considered an industrial activity, regardless of the production method, storage capacity or purpose of the same. For this reason, until updated regulations are approved, hydrogen production facilities must be located in industrial areas [13].

3. Study area

Self-consumption using RE generation power plants requires critical characteristics of the location, which are:

- High renewable energy resources
- Proximity to residential areas

In addition, the solution proposed in the paper pretends not only to implement self-consumption, but also to ensure the self-sufficiency of the microgrid using a hydrogen-based energy storage system. Therefore, according to the current legislation an extra condition is required:

- Compliance with regulatory requirements, particularly for the hydrogen storage system

Considering those key aspects, the placement chosen for the project is the Arinaga Industrial Estate (Polígono Industrial de Arinaga).

3.1. Location

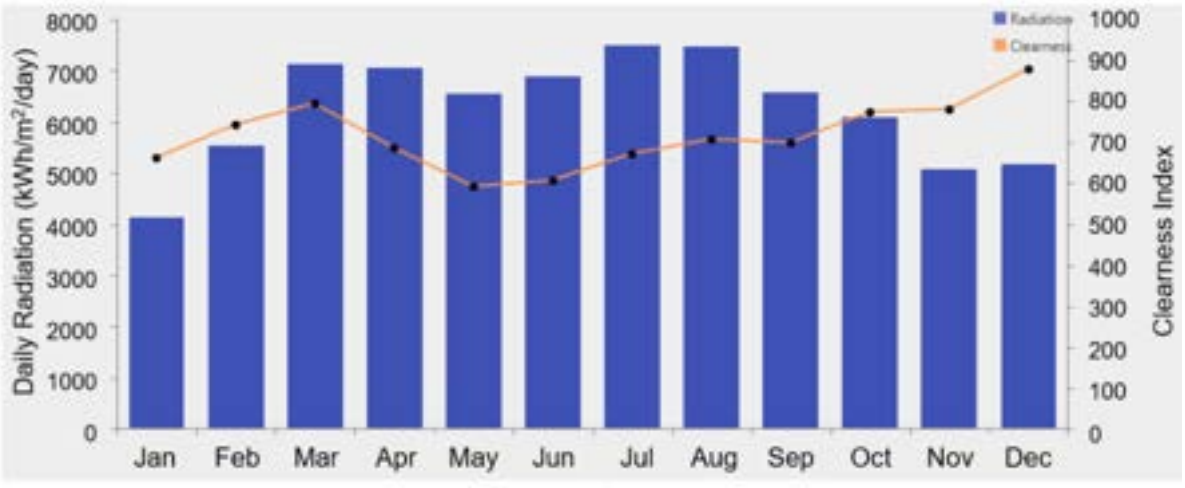
Arinaga Industrial Estate has good renewable energy resources and different neighbourhoods within 2000 meters radio, as shown in Figure. 1. It is an industrial area which allows chemical industries [14, 15] and energy infrastructure use.

Figure. 1. Location for the proposed microgrid [16]

3.2. Energetic resources

3.2.1. Solar energy

The solar radiation and temperature data were taken from the "PVGIS-SARAH2" database [17] published by the European Commission and correspond to the hourly data for 2006. Figure. 2 shows a monthly average of hourly data on solar radiation and temperature in the location of Arinaga Industrial Park.



(a)

Figure. 2. Solar radiation and temperature in the Industrial area of Arinaga, year 2006. (a) Average daily solar radiation (kWh/m^2/day). (b) Average daily temperature (ºC)

3.2.2. Wind energy

The wind data taken as a reference correspond to hourly measurements at 10 meters height on the Arinaga dock in 2006. The wind speed data have been corrected due to the variation in height from the anemometer height (10 m) to the wind turbine hub height (65 m) applying the logarithmic variation of the wind speed profile with a roughness factor of 0.1. Figure. 3 shows a monthly average of hourly data on wind speed.

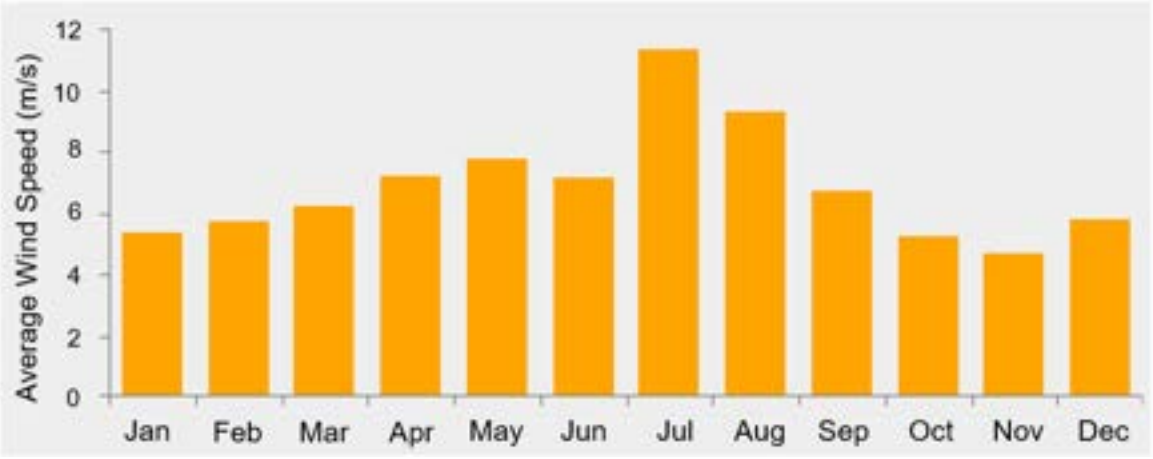


Figure. 3. Wind speed in the Industrial area of Arinaga at 65 m height, year 2006 (m/s)

The chosen year, 2006, had in Gran Canaria an average speed wind under the mean speed during the period 2001-2014, according to Ref. [18]. Taking as reference a year with unfavourable wind resources, the reliability and the resilience of self-sufficiency of the system is increasing.

3.3. Electric demand

To elaborate a base demand power curve profile, real hourly data over the year 2021 for a set of 40 residential meters in the municipality of Alojeró, on the island of La Gomera, were taken as reference. After this, the power curve profile was scaled for a group of 100 dwellings by knowing the minimum power prevision according to the Spanish regulation [19], 5750 W per residence with a simultaneity coefficient of 54.8 %, which results in a total peak power prevision of 315.1 kW. Figure. 4 shows the power curve profile obtained from the reference data. The main electric demand characteristics for 100 dwellings, after scaling the base data according to the minimum installed peak power required, are shown in Table. 1.

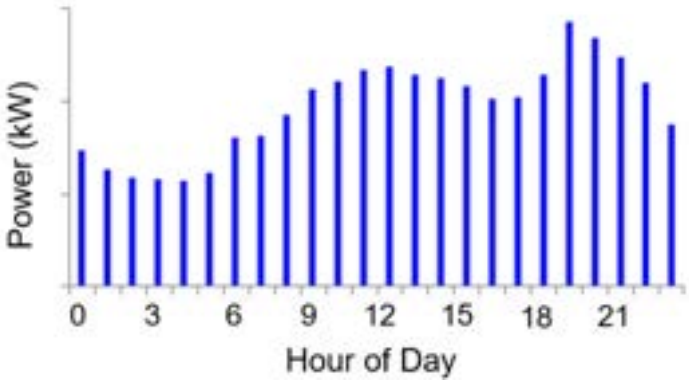

Figure. 4. Daily base demand power curve profile

Table. 1. Electric demand

	Average Energy (kWh/day)	Average Power (kW)	Peak Power (kW)
Base data 40 dwellings	226.5	9.4	21.5
100 dwellings (study case)	3321.1	138.4	315.1

The data presented in Table. 1 show that the base data taken as reference had a very poor electric consumption, the reason behind this fact, is that Alojeró is a municipality where most of the dwellings are second residences and therefore, the mean electrical consumption is very low. Nevertheless, the power curve profile obtained from the data is correct for residential use. The study case has been obtained by scaling the base data until reach the minimum installed power (or Peak Power) for new residences according to the Spanish current regulations, therefore, the scale factor between the real base data and the theoretical study case is nonlinear. Regardless, the study case for 100 dwellings is coherent, with an average power of 1.38 kW per dwelling. This possible oversizing of the demand, just results in a higher resilience of the system and can be justified by the possibility of increasing the number of dwellings attached to the collective self-consumption microgrid in a real case application.

4. Methods and modelling of study cases

The paper's goal is to evaluate the feasibility of a renewable energy self-sufficient green hydrogen microgrid in Gran Canaria to achieve the decarbonisation, attending to the actual legislation, in particular the collective self-consumption and also attending to the actual cost of RE GPP and ESSs technologies.

In order to guarantee the self-sufficiency of the system, an energy storage system is needed to meet the energy demand in the most unfavourable energy resource situations. The solution adopted for this problem is to use green hydrogen as an energy vector. Green hydrogen's greatest virtue is its 100% renewable origin and its small carbon footprint, compared to other storage systems such as conventional batteries. On the other hand, the lack of development of hydrogen technology makes its installation more expensive. At the same time, hydrogen has a great energy density (Wh/kg) but a relatively low power density (W/kg). Whereas a higher energy density indicates a longer autonomy, a low power density means a slower transient response [20]. To solve this problem, another ESS is implemented, a Li-ion battery, which has a lower energy density but a higher power density compared to hydrogen. With the combination of those two ESS, the resilience of the microgrid increases. Furthermore, the minimum power output of proton exchange membrane fuel cells is around 20-30% of its nominal power, for this reason, the use of two ESS is not only justified but also indispensable.

HOMER ENERGY [9] is the software used to design and model different scenarios to determine the best technical solution optimizing the cost of the proposed scenarios. All scenarios are located in the same area, so that all cases have the same RE resources. At the same time, the same electric demand (3.3 Electric demand) is considered for the different scenarios. Same costs of equipment and same lifetime have been considered, which are shown in Table. 2. Equipment costs are set according to the reference bibliography [21,22,23,24,25,26] taken into account.

Table. 2. Equipment, economics and characteristics

Equipment	Symbol	Capital cost	Replacement cost	Lifetime	O&M cost	Other characteristics
Photovoltaic (PV) GPP		1100 €/kW	760 €/kW	25 years	0.1 €/kW year	STC efficiency: 20.9%
Wind turbine (WT)		1180 €/kW	1000 €/kW	25 years	5 €/kW year	Hub height: 65 m
Converter		100 €/kW	100 €/kW	15 years	-	Efficiency: 95%
Electrolyzer		1400 €/kW	1400 €/kW	15 years	28 €/kW year	Efficiency: 75%
Hydrogen tank		669 €/kg	669 €/kg	30 years	6.69 €/kg year	Tank type: IV Pressure: 380 bar
Fuel cell		1800 €/kW	1800 €/kW	25000 hours	0.01 €/op. hr	Slope: 65 g H_2/h/kW Minimum load: 20%
Li-ion battery		650 €/kWh	650 €/kWh	15 years	10 €/kWh year	Minimum SoC: 20%

According to section 2.1 Current Spanish self-consumption regulations & [10], the self-consumption regulation allows the direct sell of the surpluses. Regarding to this, the grid was modelled introducing two different prices of energy:

- Power price: is the price of the energy purchased from the grid (€/kWh). Those data correspond to the monthly mean prices of the voluntary pricing for small consumers tariff 2.0 (PVPC 2.0 TD) [27] during the year 2022. The data used in the study is available on Spanish Consumers and Users Organisation website [28].
- Sellback rate: is the price of the energy dumped on the GEG. Those data correspond to the hourly prices of the day ahead market during 2022. These prices are set by the Spanish market operator (OMIE) [29].

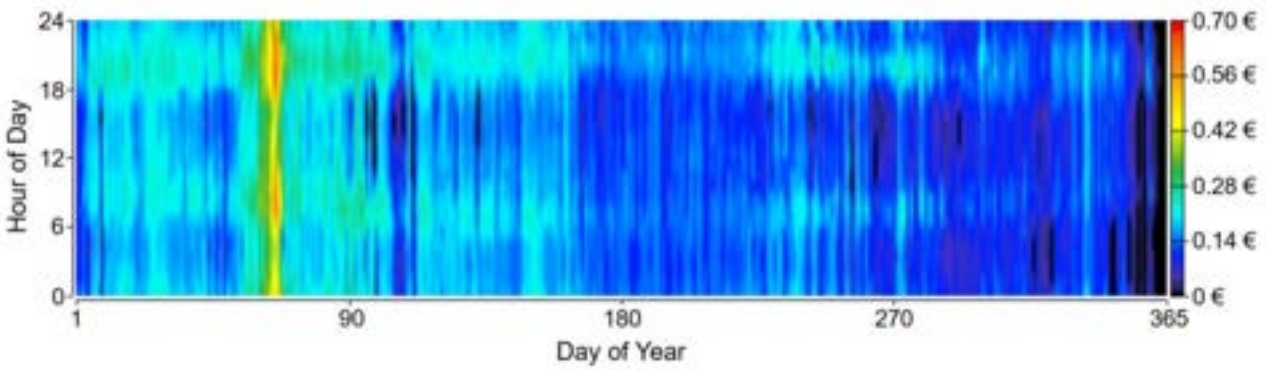

Figure. 5. 2022 Day ahead market prices (OMIE)

The different scenarios Figure. 6, where modelled according to the methodology set out as follows. The first scenario considered, *4.1 Grid connected PV generation plant. Scenario (*A), corresponds to a usual collective self-consumption modality, according to the regulation, which will be the starting point to compare the cost of energy from different alternatives. After this, *Isolated PV self-sufficient microgrid. Scenario (*B), and an *Isolated PV + WT self-sufficient microgrid. Scenario (*C), are modelled to estimate the capacity of the RE GPP and the hydrogen storage capacity in order to satisfy the electrical demand in an isolated self-sufficient microgrid. Whereas scenario (B) makes use of PV technology, scenario (C) utilize a hybrid PV and WT GPP. Lastly, scenario (D) and scenario (E) sections *4.4* and *4.5* respectively, maintain the same self-sufficiency restriction (same ESS capacity and same RE GPP capacity compared to scenarios (B) and (C) respectively)

but are connected to the GEG, with the aim of reducing the cost of energy using the collective self-consumption with surplus through GEG and direct sell modality.

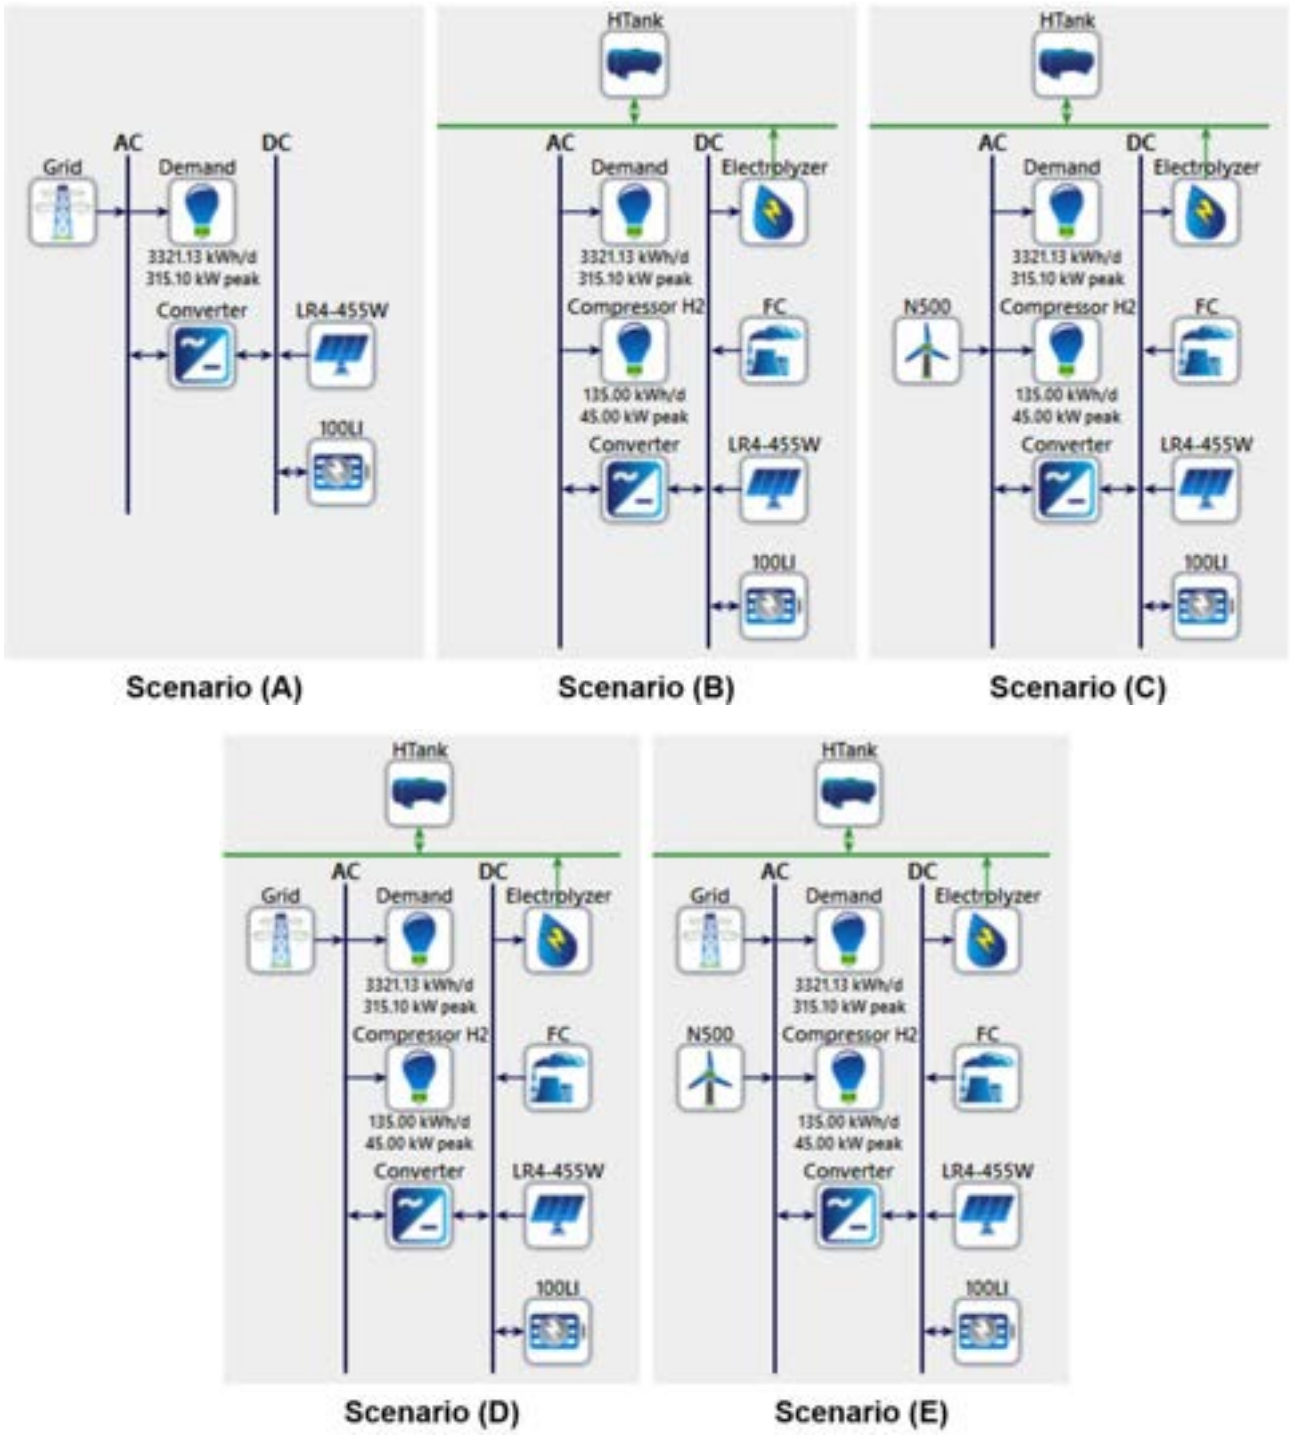

Figure. 6. Study cases scenarios

Table. 3. Study cases scenarios characteristics and equipment capacities

	SS	GEG DS 350 kW	PV (kW)	WT (kW)	Converter (kW)	Li-ion battery (kWh)	Electrolyzer (kW)	H_2 Tank (kg)	FC (kW)
Scenario A	-	✓	1098	-	700	100	-	-	-
Scenario B	✓	-	1665	-	700*	100	1000	1000	250
Scenario C	✓	-	450	500	700*	100	300	1000	250
Scenario D	✓	✓	1665	-	700*	100	1000	1000	250
Scenario E	✓	✓	450	500	700*	100	300	1000	250

*: 700 kW converters are used in every scenario to match the same costs of the equipment required in the most critical scenario.

The GEG is modelled limiting the maximum power output to the grid to 350 kW, so that all systems are equivalent in relation to the access power required and therefore all scenarios can sell the same maximum amount of power. One of the limitations of this methodology is the differentiation made by HOMER between the GEG and the loads, not considering the loads through the GEG, but in a direct line to the consumers. For this reason, a 700 kW converter is chosen in Scenario A, so that the system is able to supply the peak power of the electrical demand considered, and dump up to 350 kW to the GEG at the same time.

All scenarios are compared attending to the levelized cost of energy, which is the average cost per kWh of useful electrical energy produced by the system [9]. With units in €/kWh, HOMER calculates the COE dividing the annualized cost of producing energy by the total electric load served as given in Eq. (1).

$$COE = \frac{C_{ann,tot} - c_{boiler} H_{served}}{E_{served}} \quad (1)$$

Where:

- $C_{ann,tot}$ is the total annualized cost of the system (€/year), which is the annualized value of the total net present cost.
- c_{boiler} is the boiler marginal cost (€/kWh) of thermal energy from the boiler.
- H_{served} is the total thermal load served (kWh/year), which is the total amount of energy that served the thermal load during the year.
- E_{served} is the total electrical load served (kWh/year), which is the total amount of energy that went towards serving the primary and deferrable loads during the year, plus the amount of energy sold to the grid.

As the second term in the numerator results from the thermal load served, this term is zero for RE technologies, as for example PV or WT.

4.1. Grid connected PV generation plant. Scenario (A)

Scenario A is the reference study case. It is an ordinary PV GPP in the modality of collective self-consumption through the general electricity grid with direct sell of the surplus, not being self-sufficient. Scenario A is modelled using HOMER optimiser to size the PV capacity to reach the lowest COE. The sizing of the system is presented in Table. 3.

4.2. Isolated PV self-sufficient microgrid. Scenario (B)

Scenario B intends to model an isolated self-sufficient microgrid by using PV as GPP. The aim of this scenario is to size the PV capacity and ESS needed in order to achieve self-sufficiency, only using PV technology. Two ESS are implemented, hydrogen and Li-ion battery, combined to improve the dynamic response of the system. As shown in Table. 2, the hydrogen tank works at 380 bar pressure, therefore two electrical loads are considered, one hundred dwellings electrical demand and a hydrogen compressor. Hydrogen compressor load refers to the electrical consumption of a 45 kW compressor. This load has been scheduled to work only 3 hours a day. Those 3 hours are the ones with the highest RE penetration.

4.3. Isolated PV + WT self-sufficient microgrid. Scenario (C)

After modelling scenario B, scenario C pretends to size the RE GPP capacity and ESS needed in order to achieve self-sufficiency when two technologies are combined, PV and WT. So, Scenario C, an isolated hybrid microgrid (PV + WT), is dimensioned by HOMER optimizer maintaining the same constrains as scenario B, which are self-sufficiency, combination of green hydrogen and Li-ion battery as ESSs and two electrical loads (100 dwellings electrical demand and hydrogen compressor).

4.4. Grid connected PV self-sufficient microgrid. Scenario (D)

Scenario D matches the same equipment capacities as scenario B differentiating each other in the connection to the GEG. By matching the same generation an ESSs capacities, scenario D ensures self-sufficiency, only using PV technology. In addition, scenario D is in line with the constraints of the regulations, which only allows self-consumption through the general electricity grid when distances between the distance between generation and consumptions are under 2000 meters radio and they use PV GPP. In this scenario, by connecting to the GEG, there is no need to build a private distribution line to the consumers and, at the same time, there is the possibility to sell the surplus.

4.5. Grid connected PV + WT self-sufficient microgrid. Scenario (E)

Scenario E is a hybrid PV and WT microgrid connected to the GEG. With same sizing of the RE GPP and ESSs as Scenario C, this new scenario E, is self-sufficient and at the same time is capable of dumping and selling the surplus to the GEG.

5. Results

A summary of the different scenarios is presented on Table. 4, where the generation of the different technologies are shown not only in MWh/year, but also its percentage out of the total energy production (GEG purchased energy is also considered production). In addition, Table. 4 exhibit two economic parameters, which are the COE and the initial capital cost. These economic parameters are closely related to the total amount of energy discharged to the GEG (GEG sales) of each scenario. All scenarios cover the energy demand of 1261.5 MWh/year required by the 100 dwellings as a whole.

Table. 4. Scenarios analysis: generation, GEG exchange and economics

	SS	PV (MWh/year)	WT (MWh/year)	H_2 FC (MWh/year)	GEG Purchases (MWh/year)	GEG Sales (MWh/year)	Initial capital (€)	COE (€/kWh)
Scenario A	-	2238.2 (78.9 %)	-	-	598.1 (21.1%)	1095.4	1.37 M	0.0503
Scenario B	✓	3393.9 (83.4%)	-	674.3 (16.6%)	-	-	4.50 M	0.409
Scenario C	✓	917.1 (22.9%)	2903.6 (72.4%)	190.8 (4.76%)	-	-	2.76 M	0.217
Scenario D	✓	3392.9 (76.5%)	-	873.4 (19.7%)	171.3 (3.8%)	131.3	4.52 M	0.363
Scenario E	✓	917.1 (20.3%)	2903.6 (64.4%)	570.9 (12.7%)	115.5 (2.6%)	1253.6	2.78 M	0.0450

Scenario A is the only non-self-sufficient study case. As a result, scenario A purchase a total of 598.1 MWh/year energy to cover the total electrical demand. This GEG purchased energy is a 21.1% over the total energy production (as GEG purchased energy is also considered production to the microgrid), but a 47.41 % out of the total load of 1261.5 MWh/year required by the 100 dwellings. Canary Islands power system generates electricity mainly out of diesel groups and combined cycle groups, therefore the GEG purchased energy has an associated CO2 emissions factor of 0.776 kg CO_2/kWh, as [30] states. At the end of the year, scenario A adds to the atmosphere 464062 kg carbon dioxide per year. Although scenario A has the second lower COE because of the difference between the energy sold and the energy purchased, this scenario does not contribute to the target of total decarbonisation set in the Canary Islands for the year 2040.

Scenarios B and C are isolated self-sufficient microgrids. The fact of not being connected to the GEG and being a self-sufficient system out of RE implies that it has no associated emissions from energy purchased from the GEG. Otherwise, compared to scenario A, the initial capital costs of scenarios B and C are higher because of the need for a higher GPP capacity and because of the ESSs implemented to ensure the self-sufficiency of the system. Thus, and because of not having the possibility to sale the surplus to the GEG, the COE are higher for both scenarios, in the particular case of scenario B, it has the highest COE from all cases considered.

Scenarios D and E, pretend to reduce the COE of the systems B and C maintaining the condition of self-sufficiency. Both scenarios, D and E are connected to the GEG, so that the surplus can be sold and therefore, the COE decreases. Scenarios D and E could not have any carbon dioxide emission associated as they are dimensioned with the same generation capacities as both isolated systems, B and C respectively.

When a location matches a good mixture of solar and wind renewable energy sources, a hybrid WT and PV generation power plant is the optimal system [31] increasing the average production among the year. Therefore, a hybrid generation system has the advantage of being able to generate enough electricity those days when one of the energy sources is not available, increasing the reliability and the self-sufficiency of the microgrid. As a result, hybrid GPP in scenarios C and E, generate more energy at the end of the year with a lower power capacity compared to scenarios B and D, which only use PV technology.

When focusing on the economics, there is also a clear tendence in the costs reduction of a self-sufficient system if two generation power plants are used, PV and WT. As a PV and WT hybrid system require a lower generation capacity and less energy storage capacity compared to PV microgrid, the initial capital cost is reduced comparing scenario C and B and comparing scenario E and D. On the other hand, the COE is reduced dramatically when the system is connected to the GEG and can sell the surplus. This can be clearly identified by comparing scenarios D and B and comparing scenarios E and C respectively.

Additionally, a GEG connected microgrid (scenarios D and E) improve the resilience of the power system, so that the electrical demand can be covered at every single moment even the years with lower RE penetration. A grid connected system, also allows the microgrid to stop working for programmed maintenance. The resilience of scenarios B, C, D and E is also increased by the use of two ESS, a Li-ion battery and a green hydrogen based ESSs [32]. The combination of both energy storage system improves the energy storage

capacity and the dynamic response of the microgrid when the hydrogen fuel cell starts up [33], and when the minimal load of the FC is not covered.

5.1. Discussions

The results presented show that a hybrid PV and WT GPP self-sufficient microgrid (scenario E) is a cleaner solution compared to scenario A and it can also can be an economically better solution in comparison with a regular PV self-consumption GPP (scenario A). Because more energy is generated with a lower power capacity in the proposed hybrids microgrids, when the microgrid works in the modality of self-consumption with surplus through the general electricity grid and direct sell, the hybrid microgrid results in a lower COE. Nevertheless, the present Spanish laws Royal Decree 244/2019, Royal Decree-Law 18/2022 and 20/2022 only allow collective self-consumption with surplus through the general electricity grid for PV GPP because it is the most extended technology used in self-consumption. The restriction of a maximum distance of 2000 meters pretends to avoid high voltage drops and high losses. This condition does not make any sense as there is not a restriction on the maximum power of the GPP in the self-consumption DS modality, as the voltage drops depends not only on the distance but also depends on the power. According to the current regulation, only scenarios A and D could work in the modality of self-consumption with surplus through the GEG and DS.

A key aspect of the collective self-consumption consumption with surplus through the general electricity grid and direct sell is the possibility of using the GEG in a radio of 2000 m. This allow a GPP to provide electricity to different locations within an area, which makes the collective self-consumption more accessible to the consumers and at the same time, more attractive to the companies, reducing the costs from building a new distribution line. The current regulation does not provide this opportunity to generation technologies other than photovoltaics, as for example mini wind turbine, biomass or other RE technologies.

If decarbonation is a real objective for the Spanish government, as part of the European Union, it is opened the discussion, whether the collective self-consumption regulation could be applied also for hybrid PV generation power plants. As shown on the results, hybrid microgrids can be economically competitive and with an appropriate energy storage system they can provide 100 % green energy to the society.

5.2. Limitations

The methodology followed to develop this work have some important limitations which conditionate the results presented. The limitations are detailed below:

- No generation taxes are considered: Spanish legislation provides for a tax on generated electricity supplied to GEG of 7 % and a grid access fee of 0.5 €/MWh. HOMER optimizations were not executed considering these generation taxes.
- No construction costs and no land acquisition costs have been considered.
- Simulations have only been carried out over one year. HOMER does not run multi-year simulations with hydrogen systems. Therefore, the COE showed on the results have only been calculated considering direct sales of surpluses over one year and not over the 25-year life of the project.
- Simulations were executed under 2022 electricity prices. 2022 has been the year with the highest energy prices in Europe history, so the direct sell of the surplus turns out in the highest incomes compared to other years. On contrary, the purchased energy in 2022 was the most expensive too.

Although these important limitations denote that the COE obtained is not accurate, they apply equally to all scenarios. Consequently, the simulations are valid to identify which system is the most economically profitable.

6. Conclusion

This work studies different microgrids scenarios to reach the decarbonisation of the energy sector in the Canary Islands attending to the current self-consumption regulations in Spain. To reach the decarbonisation, self-sufficient renewable energy generation power plants microgrids with green hydrogen energy storage systems are proposed. Different combinations of photovoltaic and wind turbines generation technologies are proposed in search of an economic competitive system.

After studying the current Spanish self-consumption and hydrogen regulation, a study area and a location in proposed. The location chosen in the industrial area of Arinaga is in compliance with the regulation and counts with suitable renewable energy resources, which are presented in detail. All microgrids proposed are dimensioned with an electrical demand modelled for 100 dwellings.

The methodology and different scenarios are presented. For the self-sufficient scenarios, two energy storage systems are considered, hydrogen due to the its energetic density and Li-ion battery to improve the dynamic response of the system. The results show that hybrid photovoltaic and wind turbine microgrids are more economic for the particular study case compared to a photovoltaic microgrid. In addition, a self-sufficient hybrid microgrid can be economically more attractive than a self-consumption non-self-sufficient regular photovoltaic power plant. Consequently, a discussion is opened whether the collective self-consumption regulation could be applied also for hybrid photovoltaic generation power plants.

Abstract:

The growing demand for renewable energy sources, sometimes far from the place of consumption, has led to consider the conversion of these energies into fuels, allowing its transport and storage. This is the case of hydrogen, which can be transported in form of methanol, more suitable for transport and storage, obtained by the synthesis process of CO_2 and hydrogen. In this way, the application of methanol as an energy vector arises. Once methanol reaches its place of use, it can be used as a fuel in Direct Methanol Fuel Cells (DMFC) or transformed back into hydrogen using methanol electrolysis. However, there are at present several challenges to be forced. While DMFC present several still unsolved issues such as poor methanol oxidation reaction, fuel crossover or high demand of noble metal, methanol electrolysers have operational limits produced by problems related to active site blockage by the formation of adsorbed carbonaceous species, sluggish kinetics, or methanol crossover.

For the study of DMFC and methanol electrolysers and implement improvements in their design, a test bench that allows testing both devices independently has been designed and built. It allows plotting polarization curves, analysing crossover and developing electrochemical impedance spectroscopy studies, as well as the control of operating temperature of the devices, the mass flow, pressure and temperature of the oxygen or nitrogen introduced in the DMFC and methanol flow rate. These features will become key factors for the development of technologies for improving the use of methanol as an energy vector.

1. Introduction

Renewable energy sources are those obtained from inexhaustible natural resources, such as the sun or wind. These energy sources have the advantage of being cleaner and more sustainable than fossil fuels. However, renewable energies also present some challenges, such as their intermittency. Energy that is not consumed during peak energy production from renewable sources can be stored in chemical form and used when needed. One of the fuels that can be generated using electricity is hydrogen [1]. This is the most abundant element in the universe and can be used to generate electricity or power vehicles [2]. Hydrogen has a high specific energy and its consumption in fuel cells produces only water, making it a very attractive option for reducing greenhouse gas emissions [3]. Green hydrogen, which is produced from renewable energies sources, is environmentally friendly, but also expensive and not easy to store and transport [4].

Methanol is an alcohol that can be used as an alternative fuel for internal combustion engines or fuel cells [5]. This fuel can be produced from a variety of sources, such as hydrogen and carbon dioxide [6]. Methanol has the advantage that it takes up less volume than hydrogen and can be more easily transported and stored because methanol is a liquid chemical compound at ambient temperature and pressure. In addition, methanol can be produced using electricity from wind or solar power to generate hydrogen and then combining it with carbon dioxide captured from the atmosphere or industrial sources [7]. This fuel is known as e-methanol and produces a carbon-neutral fuel that contributes to the decarbonisation of the economy [6].

Methanol can be used to generate electricity or hydrogen. Direct methanol fuel cells (DMFC) are devices that use methanol as fuel and produce electricity, water and carbon dioxide [8]. However, they also present some challenges, such as low efficiency, high methanol permeation loss through the membrane, low CO tolerance and degradation of components [8-9]. DMFC fuel cells are fed with methanol and oxygen to produce direct current electricity. Methanol in aqueous solution is fed to the anode and oxygen is fed to the cathode. The reactions that occur during the operation of a DMFC single cell are shown in Eqs. (R1-R2). Equation (R1)

represents the half-reaction at the anode, Eq. (R2) represents the half-reaction at the cathode and Eq. (R3) represents the overall reaction [10].

Anode: $CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^-$ (R1)

Cathode: $\frac{3}{2}O_2 + 6H^+ + 6e^- \rightarrow 3H_2O$ (R2)

Overall: $CH_3OH + \frac{3}{2}O_2 \rightarrow 2H_2O + CO_2$ (R3)

Methanol electrolysers are devices that use electricity to produce hydrogen from aqueous methanol. They have the advantage that the hydrogen produced is of high purity. However, they also present some challenges, such as low efficiency [11-12]. Methanol is introduced at the anode, while no reactant is introduced at the cathode. In Eqs. (R4-R6) are presented the half-reactions taking place at the anode, cathode and the overall reaction, respectively [11-12].

Anode: $CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^-$ (R4)

Cathode: $6H^+ + 6e^- \rightarrow 3H_2$ (R5)

Overall: $CH_3OH + H_2O \rightarrow CO_2 + 3H_2$ (R6)

Several lines of research are underway to improve the performance of DMFC and methanol electrolysers. For example, the development of new membranes with lower permeability to methanol, higher ionic conductivity and higher chemical and mechanical stability [13]. Also, the development of new catalysts with higher activity and selectivity for methanol oxidation and oxygen reduction is undertaken [14]. In addition, the channel configuration of the bipolar plates can be studied to increase the power density of DMFC or to decrease the voltage required for a methanol electrolyser [9,15]. In order to study how these modifications affect the performance of both devices, a test bench is needed.

This work presents the design and operation of a test bench for a DMFC and methanol electrolyser. In the first section, the configuration of the test bench is presented. The second section presents the results obtained for DMFC and methanol electrolyser. Finally, the conclusions are exposed.

2. Configuration of the DMFC and methanol electrolyser test bench

There are several tests that can be conducted to study the performance of DMFC and methanol electrolysers, and the configuration of the test bench depends on these tests. This section presents some of the tests that can be performed and the characteristics of the test bench designed in this work.

2.1. Tests to be performed with the test bench

The aim of this work is to design and build a test bench to investigate the performance of a DMFC and a methanol electrolyser under different operating conditions. To determine this performance, various tests can be carried out for both devices, including polarization curve tracing, crossover tests and electrochemical impedance measurements [16].

A polarization curve test is used to determine the operation and performance of a fuel cell or an electrolyser. With this measurement, the relationship between the voltage and current generated or applied to the cell can be obtained, as well as the voltage losses due to different types of factors. To do this test a DMFC single cell in this work the evolution of the current density generated by the cell is measured as the voltage decreases. To test a methanol electrolyser single cell with this bench the voltage is measured as the current density increases.

A crossover test is used to measure the amount of fuel diffusing through the membrane from the anode to the cathode without being oxidised at the anode. This measurement can provide information on the efficiency and durability of the cell. The test performed consists of feeding the anode with the fuel and the cathode with an inert gas (e.g., nitrogen) and measure the current generated by the reaction of the fuel present in the cathode.

An electrochemical impedance spectroscopy (EIS) test is used to characterise the electrochemical behaviour of a fuel cell. This measurement can provide information on the internal resistance, reaction kinetics and mass transport processes occurring in the fuel cell. The test consists of applying a small sinusoidal current to the cell and measure the frequency response of the system.

All these tests are performed by setting the values of oxygen or nitrogen mass flow rate and pressure, methanol mass flow rate and the temperature at which the device is operating.

2.2. Experimental test bench

Depending on the type of test to be performed and the device under study, the test bench has different configurations. Figure 1 shows the diagram of the test bench for the DMFC study. In this diagram, a dashed line for the supply and treatment of oxygen or nitrogen can be seen. There is a cylinder for each gas used (1) to which a pressure regulator (2) is connected to control the pressure of the gas to be introduced into the system. A flow controller (3) is located downstream of this valve, which allows the flow rate of the gas introduced during the tests to be set. Before being introduced into the DMFC, the oxygen or nitrogen passes through a humidification system (4) so that the DMFC membrane is always wet during the tests (13). This system consists of two scrubber flasks arranged inside a thermostatic bath. After leaving the DMFC, the gas passes through a water trap (5) to prevent liquid water produced during the reaction from reaching the pressure controller (6), which controls the operating pressure of the DMFC. Fuel is supplied to the DMFC from an aqueous methanol tank (7) using a pump (8).

To control the temperature at which the tests are carried out, there are two chambers (9). The device to be tested is placed in the inner chamber and kept at the desired temperature. To achieve this effect, there is a refrigerated and heating circulator (10) which circulates distilled water to a heat exchanger (11) at the temperature required to increase or decrease the temperature inside the chamber. To force the recirculation of air between the two chambers, a fan is connected to the heat exchanger and powered by a power source (12).

Finally, a potentiostat-galvanostat (14) connected to a computer (15) is used to control the voltage values at which the DMFC operates, while the current and impedance parameters are recorded during the tests for subsequent analysis.

Diagram of the test bench when it is used to test Direct Methanol Fuel Cells. 1 - Compressed O_2/N_2 cylinder. 2 - Pressure reduction valve. 3 - Gas flow controller. 4 - Gas humidification system. 5 - Water trap. 6 - Gas pressure controller. 7 - Aqueous methanol tank. 8 - Methanol pump. 9 - Chamber. 10 - Refrigerated and heating circulator. 11 - Heat exchanger. 12 - Power source. 13 - DMFC. 14 - Potentiostat-galvanostat. 15 - Computer.

3. Results and Discussion

After the assembly and set-up of the test bench presented in Fig. 2, it has been possible to obtain polarization curves of a DMFC single cell and for a methanol electrolyser single cell. The single cells of both devices consist of 316L steel plates with serpentine channels, with an active area of 16 cm^2. The MEA used for each device consists of a Nafion® 117 membrane and commercial electrodes corresponding to the cathode and anode. The cathode uses Freudenberg carbon paper as support with a Pt 1mg/cm^2 catalyst load. For the anode, the same support is used, but with a Pt-Ru charge of 3 mg/cm^2.

Figure 2. The test bench designed and built to study DMFC and methanol electrolysers.

3.1. DMFC polarization curves

Figure 3 shows the polarization and power density curves obtained for the DMFC with the test bench at different oxygen mass flow rates to study the effect of this parameter on the DMFC performance. All curves have been obtained at a temperature of 60 °C, 1 bar pressure and a methanol concentration of 1 M and flow rate of 3 ml/min.

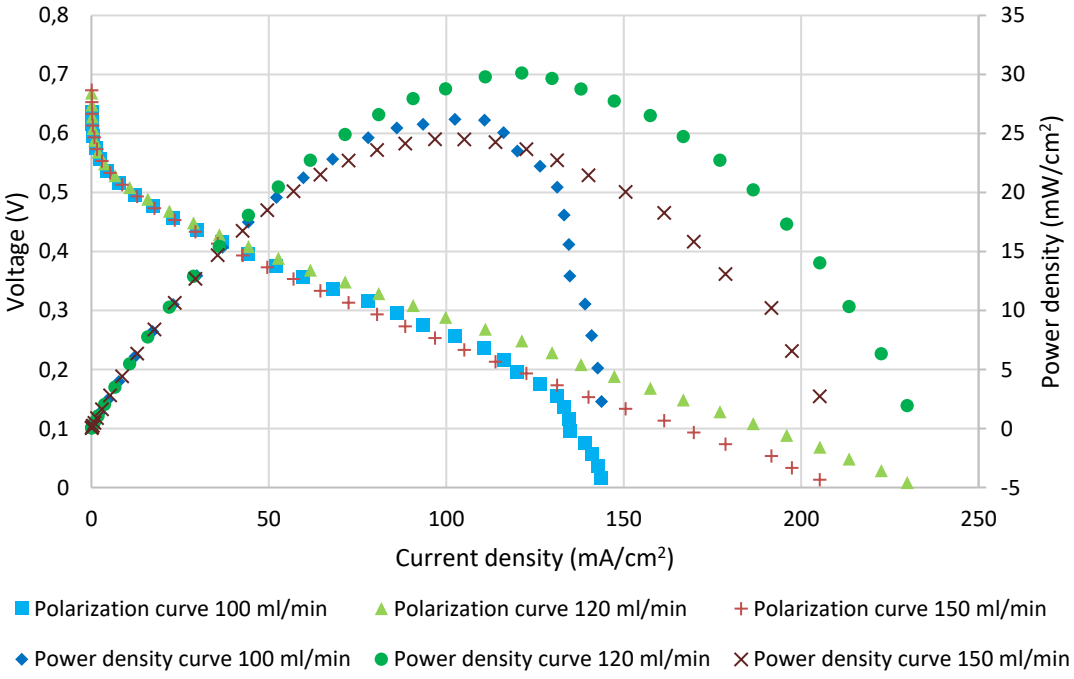

Figure 3. Polarization and power density curves of the DMFC single cell for different oxygen flow rates obtained at a temperature of 60 °C, pressure of 1 bar and a methanol concentration of 1 M and flow rate of 3 ml/min.

It can be seen from Fig. 3 that for a volumetric oxygen flow rate of 110 ml/min the current density increases slightly as the voltage values decrease below 0.23 V, with the current density not following the trend shown up to this voltage value. This results in a large decrease of the power density after having reached the maximum value. This behaviour of the single cell for this volumetric flow of oxygen can be attributed to that this flow is not able to extract from the cathode channels the water that has been generated during the polarization curve, thus blocking the reaction at the last points of the curve. To avoid this, the oxygen flow rate is increased, with best results at 120 ml/min. However, when increasing the flow rate to 150 ml/min, the Nafion® membrane probably starts to dry out during the polarization curve and for this reason the peak power density value is lower.

3.2. Methanol electrolyser polarization curves

Figure 4 shows the polarization curves of the methanol electrolyser obtained with the test bench at different temperatures to evaluate the effect of this parameter in the performance of the electrolyser. The concentration of methanol used to feed the electrolyser is 1 M and the aqueous methanol flow rate is 6 ml/min.

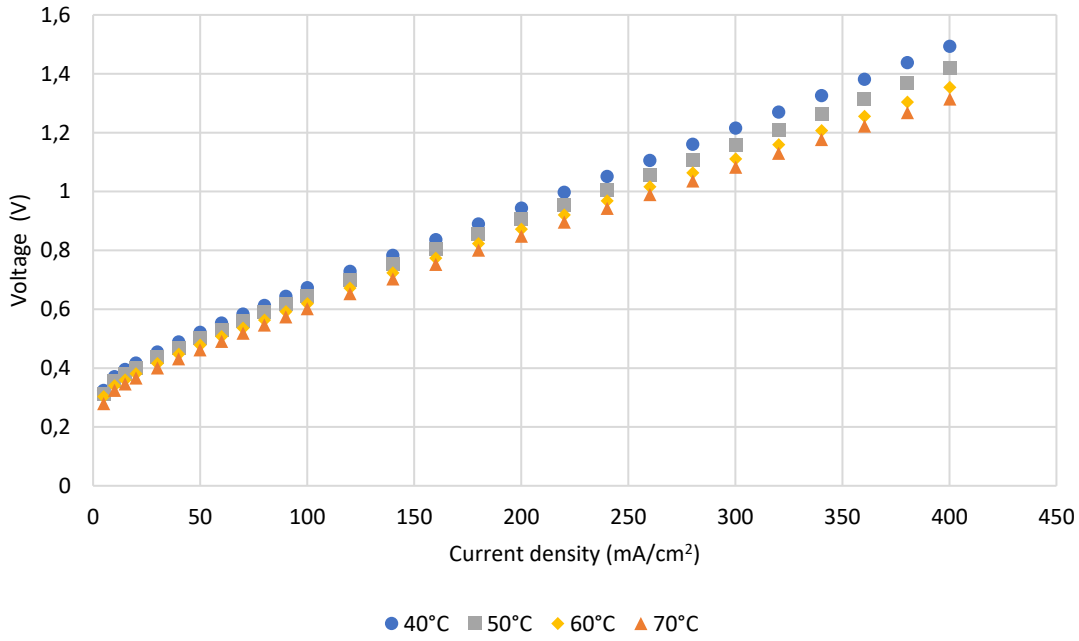

Figure 4. Polarization curves of the methanol electrolyser single cell for temperatures of 40 °C, 50 °C, 60 °C and 70 °C obtained with aqueous methanol of concentration 1 M and methanol flow rate of 6 ml/min.

In Fig. 4 can be observed that while increasing temperature, the voltage decreases for the same current density. This results in a lower electrical energy consumption to produce the same mass of hydrogen with the methanol electrolyser when increasing temperature.

4. Conclusions

This article describes the design and assembly of a test bench to analyse the behaviour of DMFC and methanol electrolysers. The bench makes it possible to control the pressure and flow of oxygen or nitrogen, the flow of methanol in aqueous solution and the temperature at which the tests are carried out.

By performing polarization curves, crossover and EIS measurements with this test bench, the effects of each of the DMFC and electrolyser components, such as membranes, catalysts, electrodes or the flow path of the bipolar plates, on these devices can be evaluated.

From the results obtained so far it can be seen that the choice of the oxygen flow rate is an important parameter for a DMFC, as too little flow rate may indicate that the cathode channels become waterlogged and too much flow rate may indicate that the membrane dries out and blocks the reactions from taking place. It has also been shown that an increase in temperature in the case of the methanol electrolyser implies a decrease in energy consumption to continue producing the same amount of hydrogen with this device.

The test bench presented in this work allows to obtain very useful experimental results to study the influence of different parameters and components, both at experimental and commercial level, on the performance of a DMFC and a methanol electrolyser, allowing to further improve the technology of these devices.

Abstract:
Optimization methods are essential to improve the operation of energy conversion systems including energy storage equipment and fluctuating renewable energy. Modern systems consist of many components, operating in a wide range of conditions and governed by nonlinear balance equations. Consequently, identifying their optimal operation (e.g. minimizing operational costs) requires solving challenging optimization problems, with the global optimum often hidden behind many local ones. In this work, we propose a hybrid method that advantageously combines Bayesian optimization (BO) and Interior Point OPTimizer (IPOPT). The BO is a global approach which exploits Gaussian process regression to build a surrogate model of the cost function to be optimized, while IPOPT is a local approach which uses quasi-Newton updates. The proposed BO-IPOPT combination allows leveraging the parameter space exploration of the BO with the quasi-Newton convergence of IPOPT once solution candidates are in the neighbourhood of an optimum. Using a challenging constrained test function, we test BO-IPOPT in accuracy, robustness and computational efficiency. Finally, we showcase the proposed hybrid method in the optimal operation of an industrial energy conversion system for renewable steam generation.

Nonlinear global optimization, Bayesian optimization, IPOPT, Hybrid method, Renewable steam generation.

1. Introduction

Numerical optimization is widely used to define the optimal operation [1–4] of energy conversion systems with many component combinations. A large number of system components, their interactions and included control parameters such as temperatures, mass flows or bypasses, combined with their nonlinear response, renders the optimization of these systems that are usually high dimensional and nonconvex. Yet, global optimization is required for model predictive control framework [5–7], where optimization methods with high accuracy and low computational cost are necessary.

Optimization methods can be classified into local and global, see e.g. [8,9]. Local methods use the information in the neighbourhood of a candidate solution to propose an update (improvement). Depending on whether the update relies on the cost function's gradient computation, these can be further classified as gradient-free (e.g. Nelder–Mead) and gradient-based (e.g. quasi-Newton methods). Local methods converge faster (i.e. with fewer cost function evaluations) than global ones if the starting point is sufficiently close to the optimum or if the cost function is (at least locally) convex. However, these methods are more prone to get stuck into local minima. A simple approach to mitigate this risk is to use multi-start (MS) algorithms [10], consisting in repeating the local optimization from multiple starting points. Leveraging the fast convergence of local methods, this approach can capture a large distribution of local optima, from which the one with the best objective function value can be taken as the best guess for the global optimum.

Global methods can be classified into deterministic and stochastic. Deterministic global optimization is mainly based on concepts of enumeration, generating cuts, and bounding to feasible regions that do not contain any optimal solution [9]. Nevertheless, commercial deterministic global solvers, like BARON [11], are extremely computational expensive especially in nonlinear nonconvex problems, where the CPU time increases exponentially with the number of variables and constraints. Common simplifications, which aim to reduce the complexity of the problem so that a global method like BARON can provide the global solution in reasonable time, are the linear modeling of system components [12] and the linearization of nonlinear component equations [13]. However, the former does not always guarantee a realistic system behaviour, whereas the latter requires an appropriate linearization technique depending on the model complexity, where a balance between accuracy and time efficiency must be found for the definition of the grid fineness.

An alternative to the deterministic global search is the random search of stochastic global optimization. These can be further classified into single candidate (e.g. simulated annealing) or population-based (e.g. genetic algorithms or particle swarms) [14] depending on the number of solutions that are iterated upon, or into metaheuristics or surrogate-based depending on the criteria used for the update. Metaheuristic methods (such as genetic algorithms or particle swarms) use a bio-inspired heuristic strategy to advance candidate solutions, while surrogate-based approaches (such as Bayesian optimization [15–18]) build a surrogate model of the function to optimize and use the model to drive the new evaluations. Global stochastic methods can avoid local minima, but tend to require a much larger number of cost-function evaluations than local ones.

The complementary advantages of these methods have motivated various hybrid approaches combining global and local methods [14, 19, 20]; the reader is referred to [21] for an overview of hybridization strategies. While most hybrid methods have combined metaheuristics with local methods, the recent focus seeks to combine surrogate-based methods and gradient-based optimization [22–24] to maximize the sample efficiency of the hybrid formulation.

This work explores the combination of Bayesian optimization and a quasi-Newton local approach to determine the optimal operation of energy conversion systems. In particular, we use the classic BO with Gaussian process regression (GPR) and expected improvement [15] together with the Interior Point OPTimizer (IPOPT) [25, 26]. Our combination is similar to the one proposed in [24], but differs in how the local method is integrated with the GPR, as further detailed in Section 2.3..

This paper is organized as follows: Section 2. gives an overview of the background of the proposed method BO-IPOPT. Section 3. presents the test cases analyzed in this work, namely a constrained test function with known global solution and the constrained optimization problem arising from the operational management of a renewable steam generation system to test the performance of our proposed method. Finally, Section 4. summarizes the main conclusions and provides perspective for future works.

2. Optimization Methods

In this work, we consider the general constrained optimization problem, defined as:

$$\min_{\boldsymbol{x}\in\Omega} \left\{ f(\boldsymbol{x}) \;\text{ s. t. }\; \boldsymbol{h}(\boldsymbol{x}) = \boldsymbol{0}, \boldsymbol{g}(\boldsymbol{x}) \leq \boldsymbol{0} \right\} \tag{1}$$

with $\boldsymbol{x} \in \Omega \subseteq \mathbb{R}^n$ the n-dimensional decision variable contained in set Ω, $f : \mathbb{R}^n \to \mathbb{R}$ the objective function, $\boldsymbol{h} : \mathbb{R}^n \to \mathbb{R}^p$ the set of equality constraints, and $\boldsymbol{g} : \mathbb{R}^n \to \mathbb{R}^q$ the set of inequality constraints. The functions $f, \boldsymbol{h}, \boldsymbol{g}$ can be nonlinear and nonconvex, but are assumed to be sufficiently smooth.

We aim to develop an optimization method that provides a sequence of candidate solutions $\{\boldsymbol{x}_K\}$ converging towards the global minimum $\boldsymbol{x}_K \to \boldsymbol{x}^\star$ with the highest probability and the fewer iterations K. In what follows, we briefly introduce the BO and IPOPT methods and motivate our interest in their combination.

2.1. Bayesian Optimization (BO)

BO is a global black-box optimization approach, i.e. requiring no mathematical definition of the objective function. The main idea is to use the sampling at the candidate solutions $\{\boldsymbol{x}_K\}$ to build a surrogate model of the cost function. Following [15], the surrogate model is usually built with GPR, which is a kernel regression method [27] allowing the analytical computation of both the regression and its uncertainties. The uncertainties of the model can be used to balance exploitation, i.e. the tendency to sample where the surrogate predicts best objective values, with exploration, i.e. the tendency to sample where the surrogate has the highest uncertainty.

An approach to deal with optimization constraints is to augment the objective function as follows according to [14]:

$$u(\boldsymbol{x}) = f(\boldsymbol{x}) + \boldsymbol{\rho}\boldsymbol{h}(\boldsymbol{x})^2 + \boldsymbol{\lambda}\max(\boldsymbol{0}, \boldsymbol{g}(\boldsymbol{x}))^2 \tag{2}$$

where $\boldsymbol{\rho}, \boldsymbol{\lambda} \geq \boldsymbol{0}$ are penalty weight vectors associated with the magnitude of constraint violation. The two ingredients in the BO are described as follows:

1. *GPR*: The GPR builds the surrogate model considering it as a Gaussian process (GP), i.e. a multivariate Gaussian distribution in the domain Ω. This distribution is initialized with a *prior* mean $m(\boldsymbol{x})$ and covariance defined by a kernel function, usually taken as a Gaussian $k(\boldsymbol{x}, \boldsymbol{x}') = \exp(-d(\boldsymbol{x}, \boldsymbol{x}')^2/2l^2)$, with l the length scale of the kernel and $d(\cdot,\cdot)$ the Euclidean distance between points in Ω. As sample points $\{\bar{\boldsymbol{x}}_1, \ldots, \bar{\boldsymbol{x}}_{N_c}\}$ and associated objective values $\bar{u}_n = u(\bar{\boldsymbol{x}}_n)$ are collected, the GPR updates the underlying GP using standard conditioning rules [27] such that the (surrogate) predictions in $\boldsymbol{x} \in \Omega$ become $\hat{u}(\boldsymbol{x}) \sim \text{GP}(\mu(\boldsymbol{x}), \boldsymbol{\Sigma}(\boldsymbol{x}))$ with mean $\mu(\boldsymbol{x})$ and covariance $\boldsymbol{\Sigma}(\boldsymbol{x})$ functions defined as:

$$\mu(\boldsymbol{x}) = \boldsymbol{K}_*^T \left(\boldsymbol{K}_{**} + \alpha \boldsymbol{I}\right)^{-1} u(\bar{\boldsymbol{x}}) \quad \text{and} \quad \boldsymbol{\Sigma}(\boldsymbol{x}) = \boldsymbol{K} - \boldsymbol{K}_*^T \left(\boldsymbol{K}_{**} + \alpha \boldsymbol{I}\right)^{-1} \boldsymbol{K}_* \tag{3}$$

where $\boldsymbol{K} = k(\boldsymbol{x}, \boldsymbol{x})$, $\boldsymbol{K}_* = k(\boldsymbol{x}, \bar{\boldsymbol{x}})$, $\boldsymbol{K}_{**} = k(\bar{\boldsymbol{x}}, \bar{\boldsymbol{x}})$, $\boldsymbol{I}$ is the identity matrix of appropriate size and α is a regularization parameter that avoids the fully interpolative behaviour of the GPR. The main hyperparameters of the regression are the kernel's length scale l and the regularization α; the first determines the smoothness of the function, while the second regularizes the sensitivity of the regression towards noise in the case of stochastic objective functions.

2. *Acquisition function*: This function controls the location of the new candidate solutions. The common approach, also used in this work, is to use the expected improvement (EI) function. This is defined as:

$$\mathrm{EI}(\boldsymbol{x}) = \begin{cases} (\hat{u}(\boldsymbol{x}^+) - \mu(\boldsymbol{x}) - \xi)\Phi(Z) + \sigma(\boldsymbol{x})\phi(Z) & \text{if } \sigma(\boldsymbol{x}) > 0 \\ 0 & \text{if } \sigma(\boldsymbol{x}) = 0 \end{cases} \quad \text{with} \quad Z = \begin{cases} \frac{\hat{u}(\boldsymbol{x}^+) - \mu(\boldsymbol{x}) - \xi}{\sigma(\boldsymbol{x})} & \text{if } \sigma(\boldsymbol{x}) > 0 \\ 0 & \text{if } \sigma(\boldsymbol{x}) = 0 \end{cases} \tag{4}$$

where Φ and ϕ denote the cumulative distribution function and the probability distribution function, respectively. The first term controls the exploitation: this term is large if the new samples are close to the expected optima according to the surrogate model. The second term controls exploration: this term is large if the new samples are in the area of large $\sigma(\boldsymbol{x}) = \mathrm{diag}(\boldsymbol{\Sigma})$. The parameter ξ sets a threshold over the minimal expected improvement that justifies the exploration and is a hyperparameter of the BO; hence the larger this value, the more exploration is produced.

In the classic BO, the algorithm begins with a set of randomly chosen candidate solutions and iterates alternating one update of the GPR and the maximization of EI to define new candidates.

2.2. Interior Point OPTimizer (IPOPT)

The open-source software package IPOPT [25] is a popular tool for solving large-scale nonlinear optimization problems. The solver is mainly based on a primal-dual interior-point method combined with a filter line-search method [26]. IPOPT can also be applied to nonconvex problems, but should be at least once, ideally twice, continuously differentiable.

Algorithmically, IPOPT transforms any inequality constraints of the original problem (1) into natural logarithmic barrier terms in the objective function, including a barrier parameter, thus considering a parametric problem. Based on this, a sequence of equality-constrained problems (barrier problems) is solved for decreasing values of the mentioned barrier parameter. This approach is repeated until a point satisfies the first-order Karush-Kuhn-Tucker optimality conditions. Note that also maximizers and saddle points satisfy the latter optimality conditions, but IPOPT internally uses a Hessian regularization that avoids obtaining maximizers and saddle points. For each barrier sub-problem, a Newton-type algorithm with line search is applied, including the solution of indefinite sparse symmetric linear systems. In particular, the overall performance (runtime, accuracy and robustness) strongly depends on the properties of the chosen sparse linear solver.

Overall, IPOPT is a highly efficient solver to find a local solution of a large-scale nonlinear nonconvex constrained optimization problem. However, the computed local optimum depends strongly on the selected starting point. Consequently, the initialization determines the rate of convergence to a solution and to which optimum the algorithm converges. It should be noted that the local optimization method can also perform poorly and even fail if the initial guess is unfavorable.

2.3. Hybrid Method BO-IPOPT

The proposed BO-IPOPT combination is illustrated in Algorithm 1. The algorithm starts with a set of initialization points to generate a first surrogate model via GPR (cf. lines 1-4). In doing so, the evaluation of the initialization points is possible, since the objective function is assumed to be known. The main part of the algorithm consists of alternating steps of BO and IPOPT until the total number of outer iterations K is satisfied (cf. lines 6-13). More specifically, new candidates for the GPR are first selected by evaluating the acquisition function EI. However, instead of updating the surrogate model directly with the newly selected candidates (as in classical BO), IPOPT is applied to the best candidates, so the surrogate model is then updated based on these local optima. It should be noted that the proposed approach uses only feasible solutions (in line 9): if the solution of IPOPT is not feasible, the algorithm selects the next best candidate.

The advantage of the proposed BO-IPOPT method is that IPOPT increases the convergence of the BO by moving some of the candidate solutions towards optimal locations. When these are local optima, the EI evaluation allows for maintaining global exploration and improving the regression where needed. If any of these is a global optimum, the EI keeps favouring its sampling in the following iterations. Overall, this method is not only efficient for BO to speed up its convergence but also for IPOPT to effectively determine good initial points. It is worth noticing that any local solver could replace IPOPT, which was chosen here because of its efficient, robust, open-source implementation.

As mentioned in Section 1., the recently proposed approach BOwLS [24] (cf. corresponding Algorithm 3 in the mentioned article) is similar to ours. In [24], the BO framework is also used to determine the local solver's

Algorithm 1 Hybrid Method BO-IPOPT

Input: length scale l; regularization term α of GPR; amount of exploration ξ; number of initialization points N_0; number of candidates N_c considering in EI; number of best candidates N_{bc} selected at each iteration; penalty weight vectors $\boldsymbol{\rho}, \boldsymbol{\lambda}$; number of outer iterations K;

1: generate a number of points $\{\boldsymbol{x}_1, \dots, \boldsymbol{x}_{N_0}\}$ in Ω;
2: evaluate $y_n = u(\boldsymbol{x}_n)$ for $n = 1 : N_0$;
3: let $D_0 = \{(\boldsymbol{x}_n, y_n)\}_{n=1}^{N_0}$;
4: construct a GPR model $\hat{u}_0$ from D_0;
5: $n = N_0, j = 0$;
6: **while** $j < K$ **do**
7: generate a new group of points $\{\bar{\boldsymbol{x}}_1, \dots, \bar{\boldsymbol{x}}_{N_c}\}$ in Ω;
8: $\{\boldsymbol{x}_{n+1}, \dots, \boldsymbol{x}_{n+N_{bc}}\} = \arg\max \mathrm{EI}(\bar{\boldsymbol{x}}_i; \hat{u}_n)$ for $i = 1 : N_c$;
9: solve $[y_k^\star, \boldsymbol{x}_k^\star] = \mathrm{IPOPT}(\boldsymbol{x}_k)$ for $k = n+1 : n+N_{bc}$;
10: $D_{j+1} = D_j \cup \{(\boldsymbol{x}_{n+1}^\star, y_{n+1}^\star), \dots, (\boldsymbol{x}_{n+N_{bc}}^\star, y_{n+N_{bc}}^\star)\}$;
11: update GPR model $\hat{u}_{j+1}$ from D_{j+1};
12: $n = n + N_{bc}, j = j + 1$;
13: **end while**
14: **return** $y_{\min} = \min\{y_i\}_{i=1}^n$;

Algorithm 2 MS-IPOPT

Input: Number of outer iterations K;

1: **for** $i = 1 : K$ **do**
2: generate a random point $\boldsymbol{x}_i$ in Ω;
3: solve $[y_i^\star, \boldsymbol{x}_i^\star] = \mathrm{IPOPT}(\boldsymbol{x}_i)$;
4: **end for**
5: **return** $y_{\min} = \min\{y_i^\star\}_{i=1}^K$;

starting points and thus create a suitable MS formulation. However, it should be noted that there are some technical differences to our version. First, the initial GPR model is built from the results of the local searches (not random ones); this brings the risk of restricting the sampling region of the GPR. Second, the initial and updated GPR models are based on the value of the objective function from the local optima but on the inputs of the initial points *before* using the local solver ($\boldsymbol{x}$ instead of $\boldsymbol{x}^\star$). Consequently, the GPR at each iteration does not approximate the underlying function but another one that shares the same local minima identified thus far. Finally, BOwLS uses the conjugate gradient method from the SciPy package as a local search, thus not accounting for constraints and the feasibility set of the problem.

3. Numerical Examples

In this section, we showcase the proposed BO-IPOPT approach on (i) a test function and (ii) the optimization of a renewable steam generation system. In both test cases, the performance of BO-IPOPT is compared with the classical random-based MS-IPOPT (cf. Algorithm 2) and the BOwLS [24] in terms of accuracy, CPU time and robustness. All algorithms were implemented in Python 3.8. More specifically, BO was implemented using the sklearn library [28] for the GPR, while IPOPT is used via the Python Optimization Modeling Objects (Pyomo) software package [29]. To provide the first and second derivative, Pyomo uses the automatic differentiation features in the Ampl Solver Library.

All computations were carried out on a machine with Intel(R) Core(TM) i7-8665U CPU. To allow for a fair comparison between hybrid approaches, we implement IPOPT as the local solver for the BOwLS since the conjugate gradient method from the SciPy package used in [24] is not designed to handle constrained problems. Additionally, for consistency, we consider the same parameters for both hybrid methods, i.e. $N_0 = 10$, $N_c = 1,000$, $N_{bc} = 2$, $\xi = 0.01$, $\alpha = 0.1$, $l = \rho = \lambda = 100$, and the same acquisition function EI. Concerning the random-based MS-IPOPT, we implement it with $N_{bc} = 2$ (cf. line 2 in Algorithm 2), meaning that two random points are generated for each outer iteration K and used as starting points for the IPOPT solver.

3.1. Constrained Ackley Function

The first test case is the well-known Ackley function, often used to test optimization algorithms [30]. This function is nonconvex and highly multi-modal with multiple local minima and one global minimum. Since the Ackley function was originally designed as an unconstrained optimization test case, we add two inequality

constraints as in [30]. The resulting constrained optimization problem is defined as follows:

$$\min \quad -20\exp\left(-0.2\sqrt{\frac{1}{n}\sum_{i=1}^{n}x_i^2}\right)-\exp\left(\frac{1}{n}\sum_{i=1}^{n}\cos(2\pi x_i)\right)+20+e \tag{5}$$

$$\text{s. t.} \sum_{i=1}^{n} x_i \leq 0, \quad \|\boldsymbol{x}\|_2 - 5 \leq 0, \quad \boldsymbol{x} \in [-5,10]^n \tag{6}$$

where n denotes the problem's dimension, set to $n = 100$ for this experimental study. The optimization problem (5)-(6) has a global minimum at $\boldsymbol{x} = \boldsymbol{0}$ with objective function value 0, i.e. $f(\boldsymbol{x}) = 0$. Since all implemented algorithms are based on a certain randomness, our numerical experiments were repeated 100 times with a number of outer iterations $K = 300$.

The optimization results of all three methods are shown in Fig. 1. The figure on the left compares the averaged minimum objective function value, while the figure on the right compares the averaged CPU time versus the number of outer iterations. It can be seen that the proposed BO-IPOPT outperforms the others in convergence and robustness. As expected, MS-IPOPT and BO-IPOPT start with a higher minimum objective function value than BOwLS because both methods use a random initialization, while BOwLS considers local optima as initialization for the initial GPR model. Obviously, BO-IPOPT converges faster towards the global minimum, which can be explained as follows: on the one hand, MS-IPOPT naturally converges more slowly to the global optimum because it strongly depends on its randomly chosen starting points. On the other hand, the GPR in BO-IPOPT has better performance in providing a better surrogate model since the sampling is more spread than in BOwLS, which narrows the sampling near the local optima. Regarding CPU time, the simplest MS-IPOPT outperforms both hybrid methods, as shown on the right side of Fig. 1; this gives an order of magnitude of the costs for training the GPR surrogate model in the two hybrid methods.

It should be underlined that an exhaustive comparison of the two hybrid methods should also include a broader range of hyperparameters; this will be carried out in the extended version of this work. For the investigated test case, the performance gap appears to depend on the outer iterations K: as shown in Fig.1, at $K = 100$, BO-IPOPT is well ahead in the averaged minimum objective function value, but BOwLS reaches similar objectives at $K \approx 170$. The number of initialization points N_0 is a second crucial parameter. It is expected that larger values will favour BO-IPOPT, since they enable better exploration of the solution space, while the local optimization in BOwLS restricts the exploration of the BO. Moreover, increasing N_0 increases the number of (initial) local searches in the BOwLS and thus directly leads to higher computational costs, in contrast to BO-IPOPT. Finally, the number of local searches before the updating of the GPR model is expected to have a significant impact on the balance between accuracy and computational cost and will also be investigated in future work.

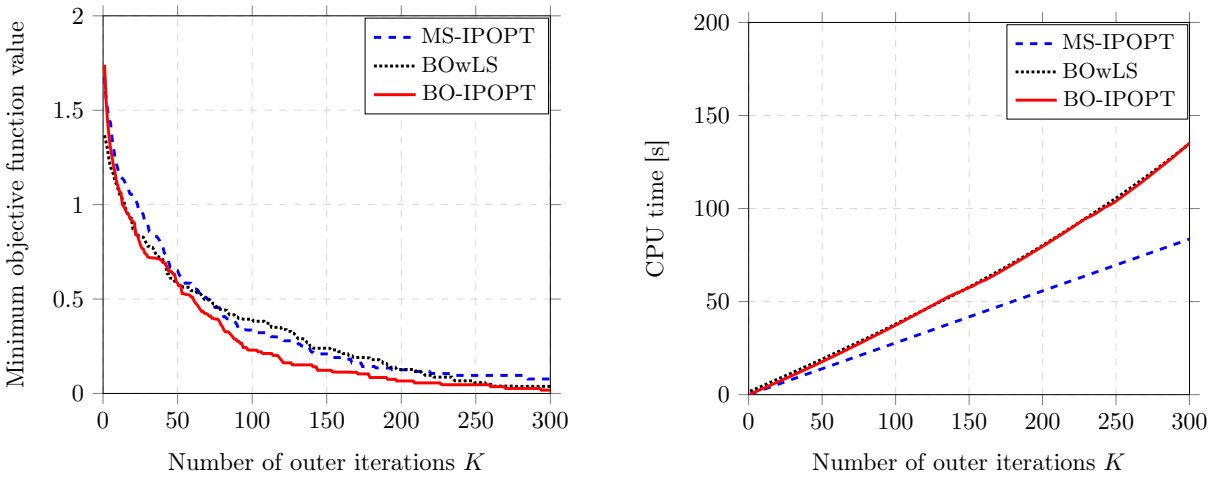

Figure 1: Optimization results for the constrained Ackley function (5)-(6): comparison of the averaged minimum objective function value (**left**) and averaged CPU time (**right**) over 100 trials using MS-IPOPT, BOwLS and BO-IPOPT in relation to the number of outer iterations K.

3.2. Renewable Steam Generation

The second test case is the operation optimization problem of an industrial energy conversion system for renewable steam generation. This power-to-heat system (cf. Fig. 2) was recently proposed in [31] and is currently used as a practical benchmark to evaluate the algorithms. In the following, we first briefly describe the test case and the resulting optimization problem (Section 3.2.1.) and then present and discuss the results of the optimization (Section 3.2.2.).

3.2.1. Problem Description

The considered electrified system shown in Fig. 2 aims to provide constant process heat in the form of superheated steam for an industrial process. The multi-component system mainly consists of 4 units: (i) a wind turbine (WT) to produce renewable electricity driving the system; (ii) a closed reverse Brayton cycle high-temperature heat pump (HTHP), powered by electricity from the WT or the power grid, to generate process heat; (iii) a sensible thermal energy storage (TES) to store excess thermal energy generated during periods of high wind power or low electricity prices; (iv) the steam generator (SG) for providing process steam via an intermediate thermal oil stream and controllable fluid bypasses.

The HTHP and SG models were created with a process simulation software, with the former being able to simulate part load behaviour. The TES model is developed using a lumped capacitance approach, while the WT power output is modeled from the specific power curve at hub height, i.e. the power curve determines the wind power generated as a function of the wind speed extrapolated to the corresponding height.

In the system configuration (cf. Fig. 3), the HTHP provides high-temperature process heat to an intermediate circuit routed through the TES or directly to the SG via a controllable fluid bypass. Thermal oil is chosen as heat transfer fluid (HTF) in the intermediate loop due to its compactness and fluid phase within the temperature range. During the charging process, the temperature in the TES is heated up by the HTF before it enters the SG; discharging operation is vice versa. In discharge mode, the HTHP's power consumption can be significantly reduced since less heat has to be supplied to the intermediate loop to ensure constant steam generation. In idle operation, the TES is completely bypassed by the HTF. The cold outlet stream is not used for cooling applications in the current setup. For more details, we refer the reader to [31].

Optimization aims to determine the cost-optimal operation, i.e. minimizing operational costs considering the fluctuating wind energy and electricity prices. To build an algebraic model problem, the underlying HTHP and SG models are converted into an algebraic form using polynomial surrogate models, as described in [31]. This results in an algebraic nonlinear nonconvex constrained optimization problem that can be formulated in a discrete setting as:

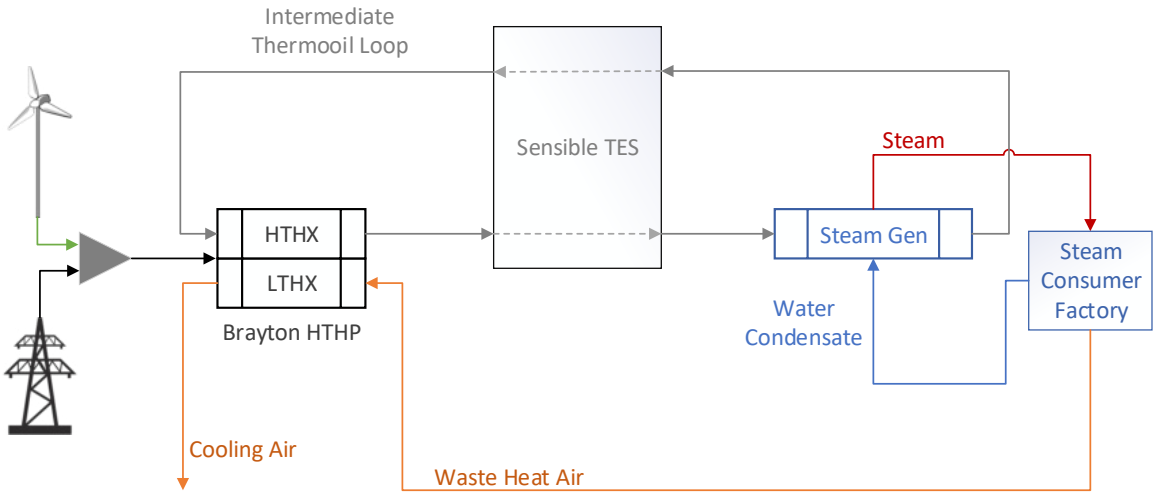

Figure 2: Illustration of the investigated industrial energy conversion system for electrified steam generation recently proposed in [31]. The system consists of a HTHP, a TES and a SG, where the HTHP is powered by electricity from a wind turbine or the power grid. The HTHP uses waste heat air stream as a heat source and enables charging and discharging of the TES via an intermediate thermal oil stream. Furthermore, constant heat demand for the steam consumer factory must be satisfied.

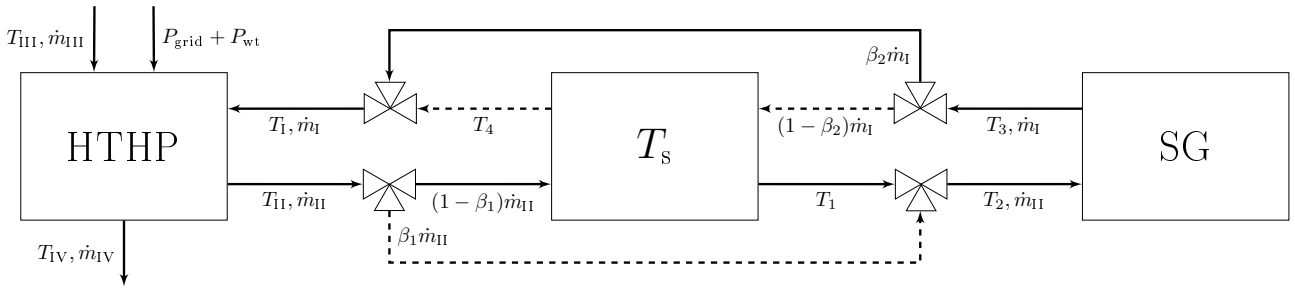

Figure 3: Detailed flow chart [31] of studied system (cf. Fig. 2) including HTHP, TES and SG. HTHP and SG are represented by polynomial surrogate models, while TES is modeled by an effectiveness model. An adjustable fluid bypass $\beta_1 \in [0,1]$ is used to control the heat input to the TES and SG, conversely the bypass $\beta_2 \in [0,1]$ regulates the heat input to the HTHP depending on the thermal state T_{s} of the TES and SG outlet stream. The *solid* and *dashed* lines indicate the charging and discharging mode in a simplified way. In addition, simultaneous charging and discharging is not allowed. For example, *charge* mode is $\beta_1 \in [0,1), \beta_2 = 1$, *discharge* mode implies $\beta_2 \in [0,1), \beta_1 = 1$, and *idle* mode represents $\beta_1 = \beta_2 = 1$.

s. t.

$$P_{\mathrm{grid}}^k + P_{\mathrm{wt}}^k = 3F_{\mathrm{HTHP}}\big(T_{\mathrm{I}}^k, \dot{m}_{\mathrm{I}}^k, T_{\mathrm{III}}^k, R^k\big), \quad T_{\mathrm{II}}^k = F_{\mathrm{HTHX}}\big(T_{\mathrm{I}}^k, \dot{m}_{\mathrm{I}}^k, T_{\mathrm{III}}^k, R^k\big), \quad T_{\mathrm{IV}}^k = F_{\mathrm{LTHX}}\big(T_{\mathrm{I}}^k, \dot{m}_{\mathrm{I}}^k, T_{\mathrm{III}}^k, R^k\big) \tag{8}$$

$$T_2^k = T_{\mathrm{II}}^k \beta_1^k + T_1^k\big(1-\beta_1^k\big), \quad T_{\mathrm{I}}^k = T_3^k \beta_2^k + T_4^k\big(1-\beta_2^k\big) \tag{9}$$

$$T_2^k = 201.92 + \tfrac{1819.32}{3\dot{m}_{\mathrm{II}}^k}, \quad T_3^k = 196.3 - \tfrac{188.4}{3\dot{m}_{\mathrm{I}}^k} \tag{10}$$

$$\dot{Q}_{\mathrm{s,ch}}^k = 3\dot{m}_{\mathrm{II}}^k c_{p,\mathrm{f}}\big(T_{\mathrm{II}}^k - T_1^k\big)\big(1-\beta_1^k\big), \quad \dot{Q}_{\mathrm{s,dch}}^k = 3\dot{m}_{\mathrm{I}}^k c_{p,\mathrm{f}}\big(T_4^k - T_3^k\big)\big(1-\beta_2^k\big), \quad \dot{Q}_{\mathrm{s,ch}}^k \dot{Q}_{\mathrm{s,dch}}^k \le \gamma \tag{11}$$

$$T_1^k = T_{\mathrm{II}}^k - \epsilon_{\mathrm{ch}}\big(T_{\mathrm{II}}^k - T_{\mathrm{s}}^{k-1}\big), \quad T_4^k = T_3^k - \epsilon_{\mathrm{dch}}\big(T_3^k - T_{\mathrm{s}}^{k-1}\big), \quad T_{\mathrm{s}}^k = T_{\mathrm{s}}^{k-1} + \tfrac{\dot{Q}_{\mathrm{s,ch}}^k - \dot{Q}_{\mathrm{s,dch}}^k}{m_{\mathrm{s}} c_{p,\mathrm{s}}} \Delta t \tag{12}$$

$$T_{\mathrm{s}}^0 = \widetilde{T}_0, \quad T_{\mathrm{s}}^n = T_{\mathrm{s}}^0 \tag{13}$$

$$T_{\mathrm{I}}^k \in [177, 250],\ \dot{m}_{\mathrm{I}}^k \in [5, 16],\ T_{\mathrm{III}}^k \in [60, 100],\ R^k \in [0.8, 1.53] \tag{14}$$

with a uniformly spaced time grid $t_k = \Delta t_k$ for $k = 1, \ldots, n$, so that the functions are considered only at the discrete time points, i.e. $T_l^k := T_l(t_k)$. The linear objective function (7) relies on the system's operating cost that is directly related to the consumed grid power of the HTHP. The power balance and outlet temperatures of the HTHP are described by (8), where F_{HTHP}, F_{HTHX}, and F_{LTHX} represent the corresponding surrogate models as a function of inlet temperatures, mass flow and rotational shaft speed. The bypass modeling is represented by (9), while (10) reflects the SG surrogate models. The charging and discharging heat flows (11) depend on the HTF mass flow, the temperature level and the fluid flow bypasses. Moreover, charging and discharging at the same time is not allowed. The constraints (12) relate to the TES effectiveness model and the storage temperature change. For a complete set-up, an initial storage temperature $\widetilde{T}_0$ is required, which is assumed to be the same at the end of the operating period (13). The simplified models in (8) are valid within the box constraints in (14), while other variables are naturally limited by the system itself. The factor 3 in (8), (10) and (11) arises because the surrogate models were derived for a single HTHP, but three HTHPs are operated in parallel to keep the component dimensions within a moderate scale.

3.2.2. Optimization Results

This section presents the optimization results of the proposed system for renewable steam generation. We consider a one-day system operation and set the time step to $\Delta t = 1\,\mathrm{h}$, giving the total number of discrete steps $n = 24$. The scenario for the WT power production and the grid electricity price are displayed in Fig. 4

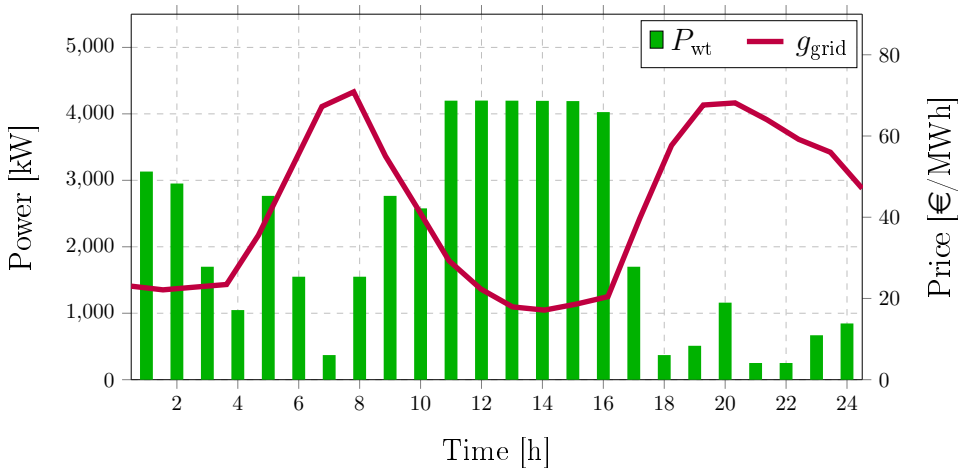

Figure 4: Visualization of 24h reference data P_{wt} (WT power output) and $g_{\text{pr,grid}}$ (electricity price) to minimize operating cost in (7)-(14).

as a function of time during 24h. The time horizon considered, resulting in 408 decision variables controlling the system, makes this test case unfeasible for a commercial global optimization solver like BARON.

The optimization results are presented in Fig. 5. As in Section 3.1., we compare the performance of the proposed BO-IPOPT to MS-IPOPT and BOwLS. The same hyperparameters as in the previous test case are considered. Our numerical experiments are repeated 20 times for averaging out the stochastic nature of the optimizers. We reduce this number with respect to the previous test case because this optimization problem requires larger computational time due to the larger dimension and the large set of equality constraints. Since the global minimum of this optimization problem is unknown, we use MS-IPOPT with 10,000 different initialization points to explore the parameter space. The best result, herein considered as an estimate of the global optimum, lies at 1,046.53€. This optimum is shown in Fig. 5 on the left.

As in the previous test case, BO-IPOPT outperforms the other approaches in convergence and robustness, while both hybrid methods converge faster towards the best reference solution than the MS-IPOPT. The same observations made from the previous test case on the role of the initial point for BO-IPOPT and BOwLS apply to this case. However, it is worth noticing that none of the optimizers approach the best known solution (estimated by the 10,000 IPOPT iterations) within the $K = 300$ outer iterations on average. This, together with the minor improvements achieved by all optimizers, highlights the complexity of the optimization problem at hand. In terms of computational cost, Fig. 5 on the right shows a nearly linear trend for both the hybrid methods and the MS-IPOPT, with the slope being much larger than in the previous test case because of the larger dimensionality of the problem. Nevertheless, this shows that the increased computational cost of the GPR, produced as more samples are available, weighs much less than the objective function evaluation itself for the number of initialization points ($N_0 = 10$) considered in this test case.

The choice of hyperparameters clearly influences the performance of both hybrid methods. Among these, the number of candidates N_{bc} updated via the local solver appears a critical parameter governing the optimization convergence as well as the computational effort. Fig. 6 shows the impact of this hyperparameter in the optimization convergence, both in terms of average convergence and CPU time. A significant increase in the computational cost results in a minor improvement in the convergence. This highlights that much of the cost in the hybrid formulation is due to the local solver and not the GPR updating. Future work will analyze the impact of various hyperparameters in optimization performance with the proposed hybrid method in more depth.

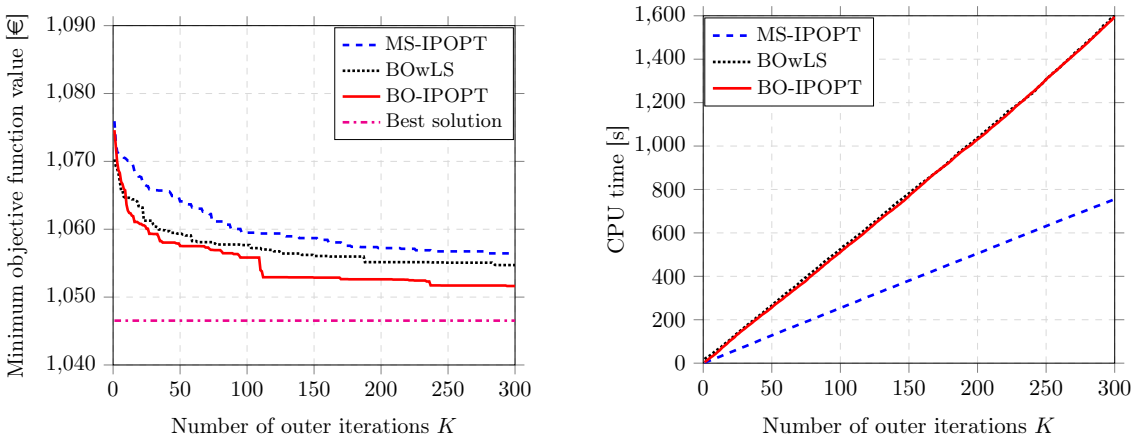

Figure 5: Optimization results for the use case renewable steam generation (7)-(14): comparison of the averaged minimum objective function value (**left**) and averaged CPU time (**right**) over 20 trials using MS-IPOPT, BOwLS and BO-IPOPT in relation to the number of outer iterations K. The best known solution (computed by 10,000 IPOPT iterations) is also visualized as an estimate of the global optimum on the left in the figure.

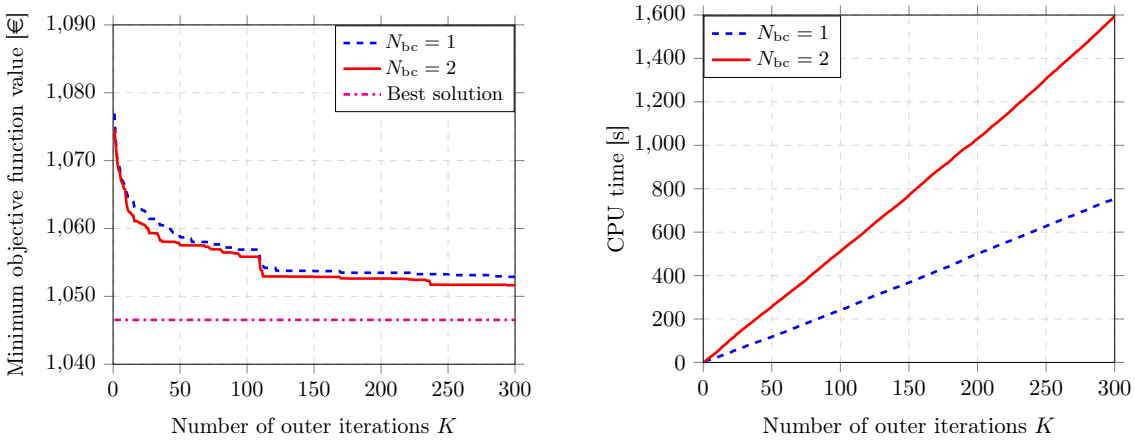

Figure 6: Optimization results for the use case renewable steam generation (7)-(14): comparison of the averaged minimum objective function value (**left**) and averaged CPU time (**right**) over 20 trials using BO-IPOPT with $N_{\mathrm{bc}} = 1$ and $N_{\mathrm{bc}} = 2$ in relation to the number of outer iterations K. The best known solution (computed by 10,000 IPOPT iterations) is also visualized as an estimate of the global optimum on the left in the figure.

4. Conclusion

This work presents a novel method called BO-IPOPT to determine the optimal operation of energy conversion systems. BO-IPOPT beneficially combines Bayesian optimization and Interior Point OPTimizer, allowing profit from the global exploration of the surrogate modelling in the BO with the quasi-Newton local convergence. In BO-IPOPT, BO is made aware of the constraints via penalty terms in the objective function, while IPOPT is naturally aware of the constraints during its updates.

We demonstrate the proposed method in a challenging constrained test case and the optimization of a complex industrial energy conversion system for renewable steam generation. The optimization performance is compared to the classical MS-IPOPT with random initialization and the recently introduced hybrid BOwLS. In both cases, the proposed hybrid method outperforms BOwLS and MS-IPOPT in convergence rate and robustness. The performance gain with respect to BOwLS appears to be linked to the different initialization criteria and the use of surrogate models that approximate the original function. Regarding the computational cost, the overhead of the hybrid methods is mostly linked to the construction of the GPR at each iteration. Nevertheless, this is found to be negligible in both cases. On the other hand, the major increase in the CPU time for both hybrid methods is primarily due to the additional number of best candidates leading directly to more IPOPT evaluations. However, these can be carried out independently and could be easily parallelized. This will be the subject of future work. Finally, future work will address the problem of hyperparameter optimization for BO-IPOPT and consider the sensitivity of its performance to identify the optimal balance between accuracy and computational cost.

Nomenclature

Letter symbols

c	specific heat capacity, J/(kgK)
D	set of points
$d(\cdot,\cdot)$	Euclidean distance
EI	expected improvement
F	surrogate model
f	objective function
$\boldsymbol{g}$	set of inequality constraints
g	electricity price, €/(MWh)
$\boldsymbol{h}$	set of equality constraints
$\boldsymbol{I}$	identity matrix
J	operating costs, €
$\boldsymbol{K}$	kernel matrix
K	number of outer iterations
k	kernel function
l	length scale
$\dot{m}$	mass flow, kg/s
m	mass, kg
N	number of points
n	number of dimensions
P	electric power, kW
$\dot{Q}$	heat flow rate, kW
R	rotational shaft speed
T	temperature, °C
$\bar{u}$	objective value of u at $\bar{\boldsymbol{x}}$
$\hat{u}$	GPR model of u
u	objective function with penalty terms
$\bar{\boldsymbol{x}}$	$\boldsymbol{x}$-value of sample points
$\boldsymbol{x}$	n-dimensional decision variable
y	objective value of f at $\boldsymbol{x}$

Greek symbols

α	regularization term of GPR
β	fluid bypass
γ	relaxation parameter
Δt	discrete time step, s
ϵ	effectiveness
$\boldsymbol{\lambda}, \boldsymbol{\rho}$	penalty weight vectors
μ	mean value
ξ	amount of exploration
$\boldsymbol{\Sigma}$	covariance function
σ	standard deviation
Φ	cumulative distribution function
ϕ	probability distribution function
Ω	set of $\mathbb{R}^n$

Subscripts and superscripts

0	starting condition
bc	best candidates
c	candidates
ch	charge mode
dch	discharge mode
f	thermal oil
grid	electricity grid
HTHP	high temperature heat pump
HTHX	high temperature heat exchanger
k	discrete time point
LTHX	low temperature heat exchanger
min	minimum value
p	pressure, N/m^2
s	storage
wt	wind turbine

Abstract:
The industrial sector accounts for a huge amount of energy- and process-related CO_2 emissions. One decarbonization strategy is to build an energy concept which provides electricity and heat for industrial processes using combination of different renewable energy sources such as photovoltaic, wind turbine, and solar thermal collector system combined with energy conversion power-to-heat components such as heat pump, electric boiler etc. The challenge for the industries is the economic aspect of the decarbonization, as industries require a cost-efficient solution. The total cost for an industrial energy concept includes investment and operating costs. This complex problem of minimizing cost and emission requires two major tasks: (I) modeling of components and (II) multi-objective coupled design and operation optimization of the energy concept. The optimal design and capacity of the components and optimal system operation depend majorly on the modeling of the components. The modeling of the components is either physics-driven or data-driven. The corresponding multi-objective coupled optimization is a complex problem with a large number of variables and constrains involved. This paper shows different types of physics- and data-driven modeling of energy components for the multi-objective coupled optimization for minimizing cost and emission of an industrial process as a case study. The optimization problem is solved as single-level problem and bi-level problem with different combinations of physics- and data-driven models. Different modeling techniques and their influence on the optimization are compared in terms of computational effort, solution accuracy and optimal capacity of components. The results show that the combination of physics and data-driven models have computational time reduction up to 37% with high accuracy compared to complete physics-driven models for the considered case study. Specific combination of physics-driven and polynomial regression models show the best trade-off between computational speed and accuracy.

energy concept, renewable energy sources, coupled optimization, data-driven modeling

1. Introduction

Sustainable development is one of the most pressing challenges for the industrial sector today. Industrial sector accounts for 34% of the end-energy-related CO_2 emissions in Europe [1]. A very crucial hurdle that needs to be overcome for sustainable future is the immense use of fossil fuels. The associated greenhouse gas emissions require urgent solutions to mitigate their effects on climate. Renewable energy sources (RES) such as wind and solar can be promising alternatives to fossil fuels as they are abundantly available and provide cleaner means of energy [2]. Energy transition concepts such as integrated energy systems (IES) combining RES, conversion components and fuel-based energy generation components could effectively improve the utilization of RES as well as promote the mitigation of CO_2 emissions. Energy-efficiency of such concepts plays a vital role in reducing CO_2 emissions. Efficient design and operation decisions of IES combine ecological and economic aspects; i.e., it does not only have potential for reducing CO_2 emissions, but it also supports significant cost savings as shown in various literature for industrial energy systems [3–5], district and urban energy systems [6–8] and building energy systems [9,10]. The design decisions are determined before and implemented during the development of the energy concept, such as the capacity of the energy components involved. The operation decisions are implemented after development of the energy concept, such as the physical conditions under which the system is operated [11]. However, complex energy component capacity configuration and various operation strategies make further development of such energy concepts for minimizing cost and emission difficult [12].

Multi-objective design and operation optimization is one of the most effective methods for solving such problems [13]. This optimization problem falls under coupled optimization category, where design and operation of the IES have to be optimized together to achieve the multi-objectives such as minimum CO_2 emissions and

minimum costs. Different literature have shown coupled optimization solved with different methods, such as bi-level and single-level optimization. Bi-level solution strategy is where an upper level problem decides the capacity of the components and a lower level decides the operation strategy based on the design decisions from upper level. Single-level solution strategy integrates design and operation optimization in a single mathematical problem. The authors in [7] showed a mixed integer linear program (MILP) of bi-level coupled optimization of district energy systems (DES) for minimizing overall cost as a single objective. In [14] a multi-objective, non-linear coupled optimization with bi-level problem formulation is presented. In [15] single-level MILP multi-objective coupled optimization for buildings is discussed. In [16] topology optimization of DES as MILP single-level formulation with scenario based operating conditions is presented. Above discussed researches have not majorly focused on industrial processes with multi-objective single-level coupled optimization. In this paper the multi-objective coupled design and operation optimization problem of an energy concept is solved using single-level as well as bi-level methods.

Modeling is an important aspect of energy system's design and operation optimization. Physics-driven modeling of energy components are majorly non-linear involving large number of variables and constraints, which makes the coupled optimization computationally expensive [16]. Data-driven models have opened new possibilities for energy system modeling [17]. Data-driven models could imitate the same physical relations hidden in the data sets without focusing on physical description of the process, which makes them quite flexible to use in an optimization problem [18]. The recent advancement in machine learning (ML) has a capability to handle high complexity of such energy system modeling arising from non-linearity of the physics [17]. In this paper data-driven models for solar thermal (ST) collector system and heat pump (HP) are used to formulate reduced order optimization problem and are compared with the physics-driven counterparts in terms of accuracy, computational efforts and optimal capacity of components. Comparison is carried out for both single-level and bi-level multi-objective optimization problem to show the optimization results' consistency.

2. Methods

The coupled design and operation optimization problem in this paper is formulated for a case study energy concept of a small- to medium-sized food and cosmetic company in Germany. Fig. 1 shows the proposed initial energy concept for the case study. It includes RES such as photovoltaic (PV), wind turbine (WT), ST; energy conversion components such as HP, gas boiler (GB), electric boiler (EB); electric grid (EG) and gas grid (GG) to suffice the consumption demand of the production. The heat is required for the steam generation, which is further used for heating and pasteurizing the products in batches. Electricity producing components and electricity consuming components are connected to an electricity hub (EH). In the same manner heat producing and consuming components are connected to a heat hub (HH). Energy storage components such as battery-storage (BAT) and thermal energy storage (TES) are not considered in this paper for the optimization, but can be integrated in future energy concepts for higher flexibility of operation. The coupled optimization

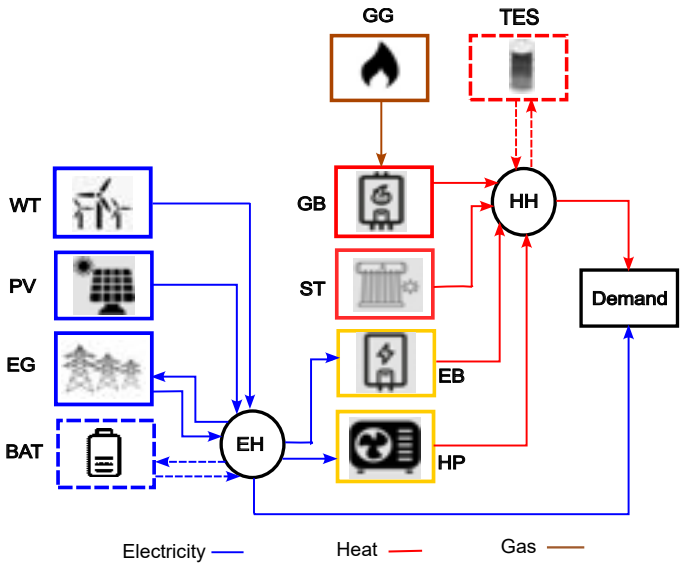

Figure 1: Concept of IES

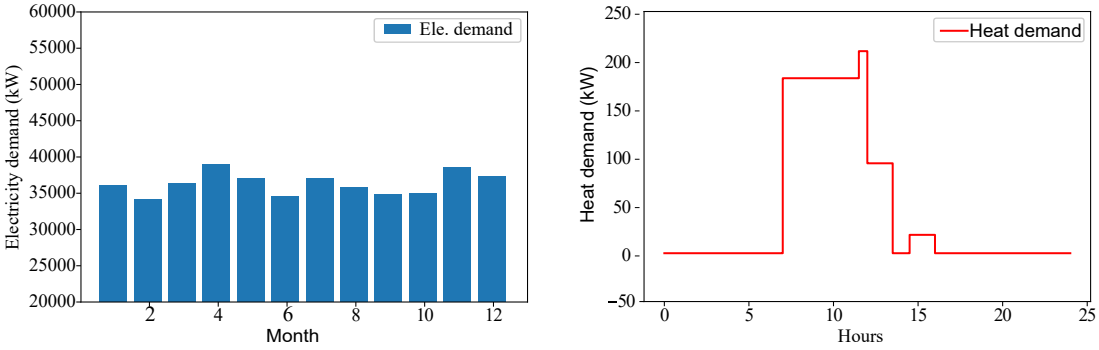
problem of the energy concept shown in Fig. 1 is complex due to large number of continuous variables such as capacity of the components, power consumption of the components etc., and binary variables such as existence of component in the energy concept are involved with non-linear modeling of the energy components consisting large number of constraints. The total number of variables and constraints involved in this

optimization problem are 1741 and 2748, respectively. It falls under the general category of mixed-integer non-linear programming (MINLP) non-convex problems, which is computationally very expensive to solve [19]. Different types of physics- and data-driven models are integrated into multi-objective coupled optimization. Physics-driven modeling of the components is majorly followed as described in [20]. Solution accuracy and computational efforts of different models in optimization are compared later in section 3. The time horizon for



(a) Electricity demand

(b) Heat demand

Figure 2: Monthly electricity and daily heat demand of the case study considered

the operation optimization is 1 year with an hourly time-step. The operation of the plant takes place for 5 days in a week daily for 8 hours. 21 days in a month are working days and 9 days are assumed to be off-days. The operation of the plant is assumed to be scenario-based for the optimization, where 1 working day and 1 off-day in each month are taken as the representative days. The heat demand for working day is shown in Fig. 2 (b). It can be seen that heat demand is divided into 4 operating scenarios for different operating hours on a working day for different batch processes. Off-days have base load requirement of 200 kWh of electricity. Monthly electricity demands are shown in Fig. 2 (a).

2.1. Problem formulation

This case study problem has two objectives to minimize: Total annualized cost (TAC) and global warming impact (GWI). TAC includes investment cost C and operational cost OC. The production facility of the case study is already built. The investment cost for building the facility is excluded. GWI is the measurement of the CO_2 emission. The minimization problem is formulated as

$$\min_{\mathbf{x},\mathbf{y}}[TAC(\mathbf{x},\mathbf{y}), GWI(\mathbf{x},\mathbf{y})], \tag{1}$$

with TAC and GWI as the minimization objectives. The first minimization objective TAC includes operational cost of the energy concept and investment cost of each component, which is defined as

$$TAC(\mathbf{x},\mathbf{y}) = OC(\mathbf{x},\mathbf{y}) + \sum_{i\in S} C^i(x^i), \tag{2}$$

where, the operational costs depends on the net electricity and gas bought from the grids. Which is shown as

$$OC(\mathbf{x},\mathbf{y}) = \sum_{m\in M}(p^{el}_{buy}\cdot E^{el}_{in,m} - p^{el}_{sell}\cdot E^{el}_{out,m}) + p^{gas}_{buy}\cdot E^{gas}_{in,m}), \tag{3}$$

and the investment cost C^i of each component is represented as

$$C^i = \left(\frac{(\beta+1)^\tau\cdot\beta}{(\beta+1)^\tau - 1} + \alpha\right)\cdot CAPEX, \tag{4}$$

which includes capital expenditure $CAPEX$, maintenance cost factor α, interest rate β and time horizon τ for financing cost [20]. $CAPEX$ is calculated based on reference capacity x^i of each component as

$$CAPEX = CAPEX^0\cdot\left(\frac{x^i}{x^0}\right)^\gamma, \tag{5}$$

where, γ represents the scaling exponent for the nominal capacity [20]. The second minimization objective GWI is presented as

$$GWI(\mathbf{x},\mathbf{y}) = \sum_{m\in M}(g^{el}\cdot(E^{el}_{in,m} - E^{el}_{out,m}) + g^{gas}\cdot E^{gas}_{in,m}), \tag{6}$$

where, $M = \{Jan, Feb...., Dec\}$ and $S = \{PV, WT, SH, GB, EB, HP\}$. $\mathbf{x} = [A^{PV}, P^{WT}_{nom}, Q^{GB}_{nom}, Q^{EB}_{nom}, Q^{HP}_{nom}]$ are the design variables and $\mathbf{y} = [E^{el}_{in,m}, E^{el}_{out,m}, E^{gas}_{in,m}]$ are the operational variables for the objective function. GWI is calculated based on the net buying of electricity and gas from the grid. Each net consumed unit of electricity $E^{el}_{in,m} - E^{el}_{out,m}$ and gas $E^{gas}_{in,m}$ has been given corresponding CO_2 factors g^{el} and g^{gas}, respectively, for the calculation of GWI. Parameters for the OC and GWI are shown in Table 1. Table 2 shows the parameters for calculating investment cost of each component and it also shows the minimum part load requirement λ_{min} for the components.

Table 1: Cost and emission parameters for grids taken from [20, 21]

Name	Parameter	Value
electricity buying price	p^{el}_{buy}	0.31 [€]
electricity selling price	p^{el}_{sell}	0.06 [€]
gas buying price	p^{gas}_{buy}	0.15 [€]
CO_2 factor for net consumed electricity	g^{el}	0.349 $[kg - CO_2eq/kWh]$
CO_2 factor for consumed gas	g^{gas}	0.244 $[kg - CO_2eq/kWh]$

The heat demand constraint is shown as

$$Q^{dem} - (Q^{ST} + Q^{GB} + Q^{EB} + Q^{HP}) \leq 0, \tag{7}$$

which indicates that the heat generated from ST, GB, EB and HP should fulfill the heat demand of the production in each time step. Constraint on the capacity of the components is shown as

$$x^i_{min} \cdot z^i \leq x^i \leq x^i_{max} \cdot z^i \qquad \forall i \in \mathbf{x} \quad and \quad z^i \in \{0, 1\}, \tag{8}$$

where, x^i_{min} and x^i_{max} are the lower and upper bounds of the capacity of each components. z is the binary variable, which is linked to the existence of the component in the concept. Equations (1)-(8) represent single-level multi-objective coupled design and operation optimization problem.

Table 2: Component parameters for investment costs and part-load constraints [20]

Components	reference capacity x^0	$CAPEX^0$[€]	γ	α	β	τ[a]	λ_{min}
PV	A^0 $[m^2]$	1400	0.95	0.01	0.03	10	0
WT	P^0_{nom} $[kW]$	5000	0.95	0.03	0.03	10	0.33
ST	A^0 $[m^2]$	400	0.95	0.02	0.03	10	0
GB	Q^0_{nom} $[kWh]$	2700	0.45	0.02	0.03	10	0.2
EB	Q^0_{nom} $[kWh]$	70	0.95	0.01	0.03	10	0
HP	Q^0_{nom} $[kWh]$	1655	0.66	0.02	0.03	10	0

2.2. Modeling of components

Modeling of the components is a crucial part of the optimization problem. In this subsection, for each component integrated in the energy concept either a physics-driven and/or data-driven models are explained. List of all variables, constant parameters and input parameters for physics-driven component modeling is presented in Table 3.

2.2.1. Photovoltaic

The electrical power P^{PV}_{out} generated by the PV unit is constrained by the solar irradiance I, the efficiency of PV unit η^{PV} and total area A^{PV}_{nom} of the PV system. It is represented by

$$P^{PV}_{out} \leq A^{PV}_{nom} \cdot \eta^{PV} \cdot I. \tag{9}$$

The case study facility already has some PV panels built on the terrace, with a tilt angle 5° for the PV model. Moreover, PV unit has the maximum output power limited to its nominal capacity, which is presented as

$$P^{PV}_{out} \leq A^{PV}_{nom} \cdot P^{PV}_{nom}, \tag{10}$$

Table 3: Component variables including binary variables, parameters and inputs for single-level problem

Components	Design variables **x**	Operational variables **y**	Constant parameters **c**	Input paramters in each timestep	Total number of variables
PV	A_{nom}^{PV}	P_{out}^{PV}	η^{PV},P_{nom}^{PV}	I	3
WT	P_{nom}^{WT}	λ^{WT},P_{out}^{WT}	-	v	4
GB	Q_{nom}^{GB}	λ^{GB}, E_{in}^{gas}	η^0	-	4
EB	P_{nom}^{EB}	λ^{EB}, P_{in}^{EB}	η^{EB}	-	4
ST	A_{nom}^{ST}	T_{out}^{w}, T_{out}, T_{in}	I_{AM}, η_0, $\dot{m}^{ST}$	I, T_{amb}, $\dot{m}^{w}$	5
HP	Q_{nom}^{HP}	λ^{HP}, h_{out}^{w}, T_{out}^{w}, P_{in}^{HP}	a, b, c, d, T_{in}^{c}, T_{in}^{w}	$\dot{m}^{w}$	6
Electric grid	-	E_{in}^{el}, E_{out}^{el}	-	-	2
Gas grid	-	E_{in}^{gas}	-	-	1

where, P_{nom}^{PV} is chosen as 0.171 kWm^{-2} [20] and efficiency η^{PV} is chosen to be 0.09 in order to meet the actual output data of PV panels built on the case study facility. P_{out}^{PV} is an operational variable and A_{nom}^{PV} of the unit is a design variable. Total number of variables in Table 3 shows number of design, operational and binary variables to be computed in each time step in optimization problem.

2.2.2. Wind turbine

The power output P_{out}^{WT} of WT is limited by the wind velocity, which in turn determines the part-load behavior of WT and its nominal power [22]. The output power of WT is given by

$$P_{out}^{WT} \leq \eta^{WT}(\lambda^{WT}) \cdot P_{nom}^{WT}, \tag{11}$$

where, P_{out}^{WT} is an operational variable and P_{nom}^{WT} of the wind turbine is a design variable. Operational variable λ^{WT} depends on the wind velocity ($\lambda^{WT} = v/v_{ref}$, where $v_{ref} = 12m/s$ [20]). The efficiency of wind turbine $\eta^{WT}(\lambda^{WT})$ is given by

$$\eta^{WT}(\lambda^{WT}) = \begin{cases} 0 & \text{if } \lambda^{WT} \leq 0.33 \\ 1.5393 \cdot \lambda^{WT} - 0.5091 & 0.33 \leq \lambda^{WT} \leq 1 \\ 1 & \lambda^{WT} \geq 1. \end{cases} \tag{12}$$

2.2.3. Gas boiler

Heat output of the GB is determined by the part-load efficiency, which is given as

$$\eta^{GB}(\lambda^{GB}) = \frac{21.75378 \cdot \lambda^3 - 7.00130 \cdot \lambda^2 + 1.39731 \cdot \lambda - 0.07557}{20.66646 \cdot \lambda^3 - 5.34196 \cdot \lambda^2 + 0.67774 \cdot \lambda + 0.03487} \cdot \eta^0, \tag{13}$$

where η^0 is chosen to be 0.8 [1], which is called nominal efficiency. The heat output depends on the efficiency shown in (13), consumed gas power to heat up the incoming fluid P_{in}^{gas} and nominal capacity Q_{nom}^{GB}, which is presented as

$$Q_{out}^{GB} = \eta^{GB}(\lambda^{GB}) \cdot P_{in}^{gas}, \qquad Q_{out}^{GB} = \lambda^{GB} \cdot Q_{nom}^{GB}. \tag{14}$$

Here, heat output Q_{out}^{GB}, consumed power P_{in}^{gas} and the part-load λ^{GB} are operational variables and nominal capacity Q_{nom}^{GB} is the design variable. The integration of consumed power P_{in}^{gas} over the operation horizon delivers the total energy E_{in}^{gas} consumed from gas grid.

2.2.4. Electric boiler

EB is modeled in the same manner as GB. Efficiency η^{EB} for EB is assumed to be constant at 0.95. The operational variable heat output of the EB depends on operational variables such as consumed electric power P_{in}^{EB}, part-load λ^{EB} and design variable nominal capacity Q_{nom}^{EB}. It is shown as

$$Q_{out}^{EB} = \eta^{EB} \cdot P_{in}^{EB}, \qquad Q_{out}^{EB} = \lambda^{EB} \cdot Q_{nom}^{EB}. \tag{15}$$

2.2.5. Solar thermal collector

There are two kinds of ST collectors generally used in the market, flat plate and evacuated tube. For this case study, flat plate collectors with tilt angle of 40° are chosen to be integrated in the energy concept [23]. ST model is based on the quadratic efficiency model developed by [24], which is shown as

$$\eta^{ST} = \eta_0 - \frac{a_1 \cdot \Delta T}{I} - \frac{a_2 \cdot \Delta T^2}{I}, \tag{16}$$

where η_0 represents optical collector efficiency, a_1 and a_2 are loss coefficients related to linear and quadratic terms, ΔT represents temperature difference between collector fluid temperature and ambient temperature, and I as mentioned before is global solar irradiance on the collector surface. European EN 19275 standards prescribe the collector fluid temperature as average collector temperature of its inlet and outlet temperature [25].

Complete hourly weather data for the location of the case study plant has been gathered from European commission photovoltaic geographical information system [26]. The global solar irradiance and ambient temperatures are the important data for the ST collector model. Complete physical ST collector model is shown in (17) - (20). The ST collector efficiency is shown as

$$\eta^{ST} = \eta_0 \cdot I_{AM} - \frac{a_1 \cdot (T_m - T_{amb})}{I} - \frac{a_2 \cdot (T_m - T_{amb})^2}{I}, \tag{17}$$

where, I_{AM} represents incidence angle modifier, which corrects the optical efficiency for the irradiation not perpendicular to the surfaces [23]. T_m is the average collector fluid temperature, which depends on inlet and outlet temperature T_{in}^{ST} and T_{out}^{ST}, respectively. The optical collector gain is represented by

$$Q_0 = \eta_0 \cdot I_{AM} \cdot I \cdot A_{nom}^{ST}, \tag{18}$$

and thermal losses due to temperature difference between average fluid temperature and ambient temperature is modeled as

$$Q_L = \left(a_1 \cdot (T_m - T_{amb}) - a_2 \cdot (T_m - T_{amb})^2\right) \cdot A_{nom}^{ST}, \tag{19}$$

where, collector surface area is A_{nom}^{ST} of the collector surface is the design variable.

$$Q_u = \begin{cases} Q_0 - Q_L, & \text{if } Q_0 > Q_L \\ 0 & \text{if } Q_0 \leq Q_L \end{cases} \tag{20}$$

Equation (20) shows the useful solar gains with the condition of positive net solar gains. The authors in [23] compared this simplified physical model with detailed simulation model in TRNSYS. The parameters for the physical models are collected in [27], in which extensive research has been carried out for different ST flat collector manufacturers data in Germany and related parameters. Parameters chosen for the case study are shown in Table 4. Fig. 3(a) shows the ST collector with the heat-exchanger (HEX) used in the energy concept. The heat transfer over HEX is given by

$$Q^{ST} = \dot{m}^w \cdot c_p^w \cdot (T_{out}^w - T_{in}^w). \tag{21}$$

For calculating the operational variable heat transfer Q^{ST} over HEX in each time step, 5 different equations (17)-(21) must be solved in the physical model, which consist 3 additional operational variables such as collector inlet temperature T_{in}^{ST}, collector outlet temperature T_{out}^{ST}, water/steam outlet temperature T_{out}^w and one design variable, area A_{nom}^{ST} of the collector surface. Large number of variables and constraints make the optimization expensive. In order to reduce the number of variables and constraints, data-models are trained and used in the optimization.

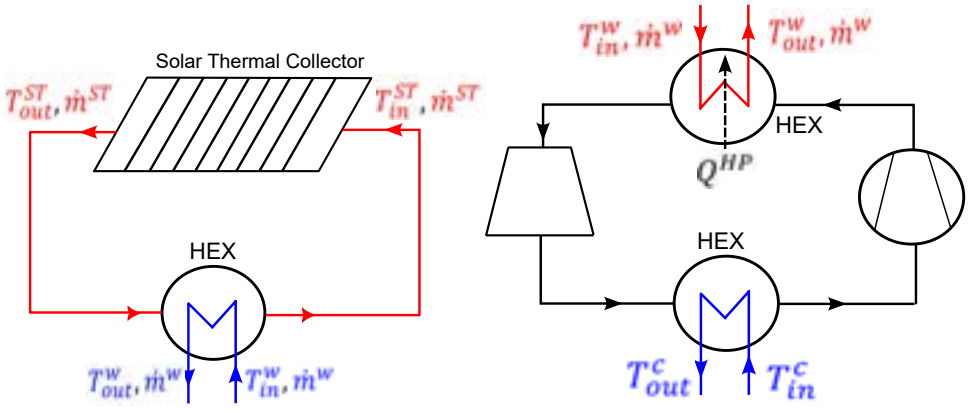
Data-driven approach to model ST collector could have some advantages over physical model. Proposed data-driven approach is presented as

$$Q^{ST} = f(T_{in}^w, \dot{m}^w, I, A_{nom}^{ST}), \tag{22}$$

where, operational variable heat output of the whole ST collector system depends on 4 inputs. These inputs include only one design variable A_{nom}^{ST}, 3 input parameters T_{in}^w, $\dot{m}^w$, I and none of the operational variables shown before. f in (22) represents a generic data-driven model. This data-driven model represents the relationship between the given input parameters including the design variable area A_{nom}^{ST} with the output variable heat output Q^{ST}. In this paper data-driven models such as linear regression (LR), polynomial regression (PR) and artificial neural network (ANN) are considered. These data-driven models are trained with the input and output data generated from the physical model. In this manner, operational variables to be optimized are reduced to 1 in each time step and all other constraints are eliminated.

Table 4: Parameters for ST flat collector

Collector	η_0	a_1 $[W/(m^2K)]$	a_2 $[W/(m^2K)]$	IAM
Flat plate	0.79	4.03	0.0078	0.86



(a) Solar flat plate collector with HEX

(b) HP consisting a compressor, 2 HEX and a turbine

Figure 3: ST collector and HP schematic diagram

2.2.6. Heat pump

HP can use the industrial waste heat as a thermal energy source as well as renewable electricity as the power input to decarbonize industrial thermal processes, which makes it an essential technology [28]. In this case study, waste heat is considered as constant. Renewable electricity is generated from PV and WT. There are many different physical models to describe the performance of the HP. The authors in [28] have investigated different case studies of different types of HPs and came up with different coefficient of performance (COP) regression models. Fig. 3(b) shows a heat pump consisting of two HEXs (condenser and evaporator), a compressor and a turbine. T^c_{in} and T^c_{out} represent input and output temperatures on cold side, whereas T^w_{in} and T^w_{out} are the input and output temperatures on the hot side, respectively. The heat output of the HP depends on its nominal capacity Q^{HP}_{nom} and part-load λ^{HP}, which is shown as

$$Q^{HP}_{out} = \lambda^{HP} \cdot Q^{HP}_{nom}. \tag{23}$$

The output temperature T^w_{out} on the hot side depends on the outlet pressure of water/steam p^w_{out} on hot side and enthalpy h^w_{out} of water/steam, which is a function of heat output Q^{HP}_{out} and inlet temperature T^w_{in} of water on the hot side, shown as

$$T^w_{out} = f(h^w_{out}(Q^{HP}_{out}, T^w_{in}), p^w_{out}). \tag{24}$$

The COP is calculated based on the model

$$COP = a \cdot (\Delta T_{lift} + 2b)^c \cdot (T^w_{out} + b)^d, \tag{25}$$

suggested by [28]. The coefficients a,b,c and d of this model are chosen according to the suitable temperature ranges of the case study ($80°C < T^w_{out} < 160°C$). The heat output is a function of COP and the consumed electrical power P^{HP}_{in}, as well as the input and output enthalpy h^w_{in} and h^w_{out} of water/steam on hot side, which is shown as,

$$Q^{HP}_{out} = COP \cdot P^{HP}_{in}, \qquad Q^{HP}_{out} = \dot{m}^w \cdot (h^w_{out} - h^w_{in}). \tag{26}$$

Equation (23)-(26) represent the physics-driven model of HP. The detailed list of design and operational variables of HP are shown in Table 3. As seen from the physical model, 5 different equations need to be solved in each time step, which include 5 operational variables Q^{HP}_{out}, COP, P^{HP}_{in}, λ^{HP}, T^w_{out} and one design variable Q^{HP}_{nom}. Data-driven approach for HP is shown as

$$COP = f(\dot{m}^w, T^c_{in}, \lambda^{HP}, Q^{HP}_{nom}), \tag{27}$$

which includes 1 design variable Q^{HP}_{nom}, 1 operational variable λ^{HP} and 2 input parameters $\dot{m}^w$ and T^c_{in} as inputs to compute the output variable COP without any constraints. Table 5 shows the total number of variables and

constraints over the whole time-horizon for the single-level multi-objective coupled optimization. It is evident from Table 5 that the total number of variables and constraints involved in coupled optimization problem decreases with the use of data-driven models compared to the complete physics-driven models of ST and HP. Data-driven models for ST and HP reduce the number of variables by 388 and constraints by 504, which is 22% and 18% less than the complete physics-driven models.

Table 5: Total number of variables and constraints in single-level multi-objective coupled optimization problem for different combinations of physics-driven and data-driven models of HP and ST

ST	HP	Total number of variables	Total number of constraints
Physics-driven	Physics-driven	1741	2748
Data-driven	Data-driven	1353	2244
Data-driven	Physics-driven	1525	2316
Physics-driven	Data-driven	1669	2676

3. Results

3.1. Comparison of data-driven models

As shown in Table 5, the data-driven models have fewer variables and constraints to compute in coupled optimization. Table 6 shows the inputs, outputs, number of parameters and amount of data samples. This data samples are divided into training and validation data. 75% of the data samples is used for training the models and 25% of the data samples is used for validating the trained models. Table 7 shows the training time and comparison of accuracy between physical models (actual values) and different data-driven models (predicted values) based on coefficient of determination R^2 method [29]. Three types of data-driven models: LR, PR

Table 6: Data-driven models' input, output and number of samples

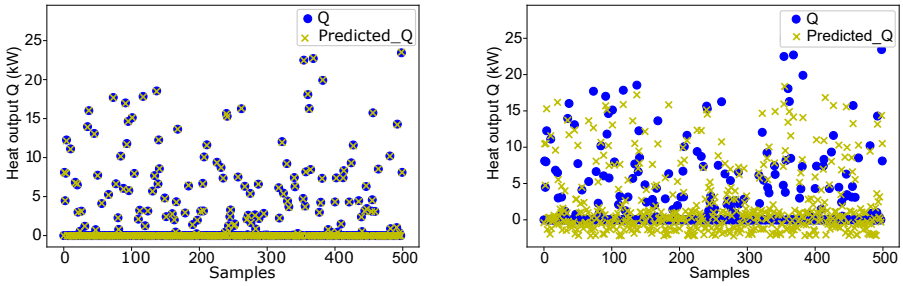
Component	Inputs	Output	Number of data samples
ST	T_{in}^{w}, $\dot{m}^{w}$, I, A	Q^{ST}	439199
HP	$\dot{m}^{w}$, T_{in}^{c}, λ^{HP}, Q_{nom}^{HP}	COP	206054

and ANN are trained for ST and HP. In particular, PR models have two variant such as 2^{nd} degree PR (PR-1) and 3^{rd} degree PR (PR-2) models. Furthermore, ANNs are feed forward neural networks with two different specifications: (I) 2 hidden layers, 5 neurons in each hidden layer (ANN-1) (II) 3 hidden layers, 7 neurons in each hidden layer (ANN-2). The number of hidden layers and number of neurons in each hidden layer are optimized using hyper-parameter tuning technique. ANNs are trained with k-fold cross validation method with k=4 [30].

It can be seen from Table 7 that the R^2 score of ST is less for ANN-2 compared to ANN-1. See also Fig. 4 (b), where for ANN-2 the predicted output data does not match properly with actual output data. In contrast, Fig. 5 shows results for the two different ANN models of HP, where ANN-2 showing better fitting performance

Table 7: Data-driven models' training time and accuracy

Model	Specification	Training time for ST [s]	Training time for HP [s]	R^2 for ST	R^2 for HP
LR	degree 1	2.12	1.82	0.96	0.45
PR-1	degree 2	5.33	4.31	0.972	0.68
PR-2	degree 3	11.26	9.25	0.986	0.825
ANN-1	2 hidden layers 5 neurons each	1254	1008	0.999	0.862
ANN-2	3 hidden layers 7 neurons each	1852	1369	0.845	0.982

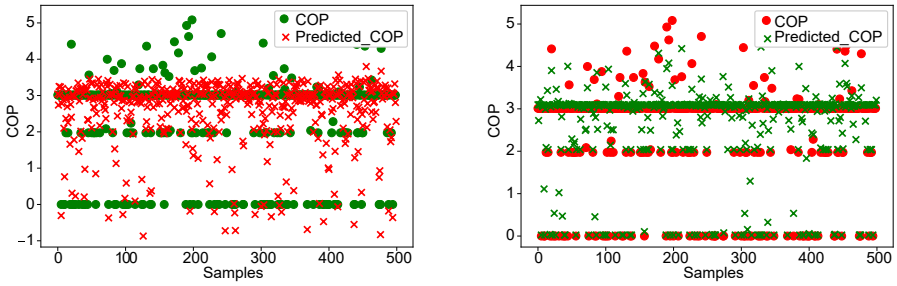


(a) ANN-1 (2 layers, 5 neurons each)

(b) ANN-2 (3 layers, 7 neurons each)

Figure 4: Comparison of ANN models output prediction to actual output of ST

compared to ANN-1. Therefore, the optimized ANN for ST is ANN-1 and for HP is ANN-2. As expected, LR and PR models for HP have lower values of R^2 score compared to ANN models. On the other hand ST has quite higher R^2 score for LR and PR models. Training time for LR and PR models are lesser than their respective ANN models. Training time for ANN is higher due to large number of weights and biases involved in the ANN model. ANN-1 model and ANN-2 model have 35 and 112 such coefficients (and constants), respectively, which makes them time-expensive to compute when these ANN models are integrated into the coupled optimization.



(a) ANN-1 (2 layers, 5 neurons each)

(b) ANN-2 (3 layers, 7 neurons each)

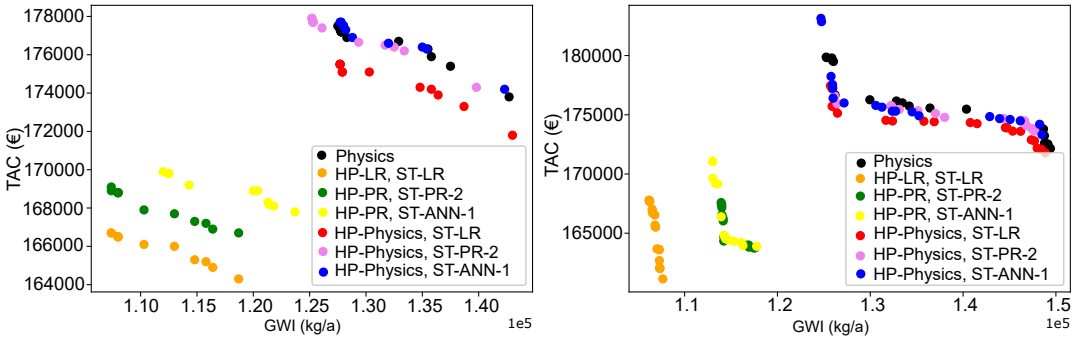
Figure 5: Comparison of ANN models output prediction to actual output of HP

3.2. Comparison of optimization results

Fig. 6 shows several Pareto-fronts of TAC and GWI as results of multi-objective coupled design and operation optimization of the case study energy concept. These pareto-fronts are formed by various combinations of physics- and data-driven models. In particular, Fig. 6 (a) shows the single-level optimization results and (b) shows bi-level optimization results for different combinations of ST and HP models. The optimal Pareto-front of complete physics-driven model (black dots) of the IES is used as the reference solution to evaluate the accuracy and computational effort of the different model combinations.

The original multi-objective MINLP optimization problem is linearized and converted into a MILP optimization problem. The MILP problem is solved with GUROBI solver [31] on PYOMO platform included in COMANDO [22]. More specifically, the single level multi-objective pareto-front is generated by the augmented ϵ-constraint method [32]. Bi-level problem is not linearized and solved on PYMOO platform with non-sorting genetic algorithm (NSGA-II) on the design level and differential evolution on the operation level [33]. Both optimization problems, single-level and bi-level problem, are solved on 11th Gen Intel(R) Core(TM) i7-1185G7 with 16 GB RAM. It can be seen from Fig. 6 (a) and Fig. 6 (b) that the physics-driven model of HP with ANN-1 data-driven model of ST (blue dots) gives the most accurate results, which is close to the complete physics-driven model. The second most accurate result is provided by physics-driven model of HP and PR-2 data-driven model of ST (violet dots). This trend applies to both, single-level and bi-level optimization.

Fig. 7 shows the comparison of computational time and solution accuracy of the coupled optimization results for combination of different models. Accuracy is calculated based on R^2 method, where complete physics-driven model is reference. It can be seen that the best trade-off between computational time and accuracy is found for HP physics-driven model and ST PR-2 model (violet dots). This combination of models reduces the coupled optimization computation time up to 37% with optimization results being approximately 90% accurate



(a) Single-level coupled optimization

(b) Bi-level coupled optimization

Figure 6: Comparison of the optimization results for different model combinations of ST and HP

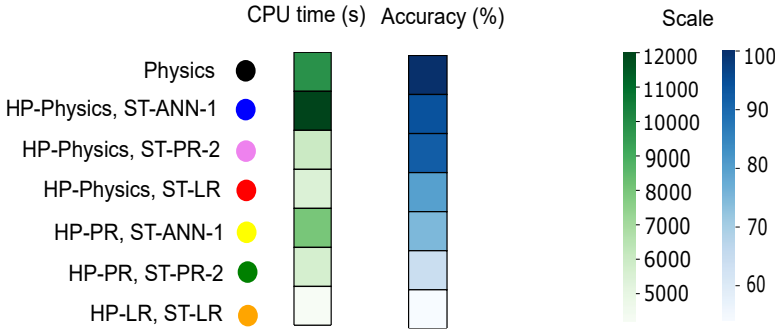


Figure 7: Time and accuracy comparison for different combination of models in single-level multi-objective optimization

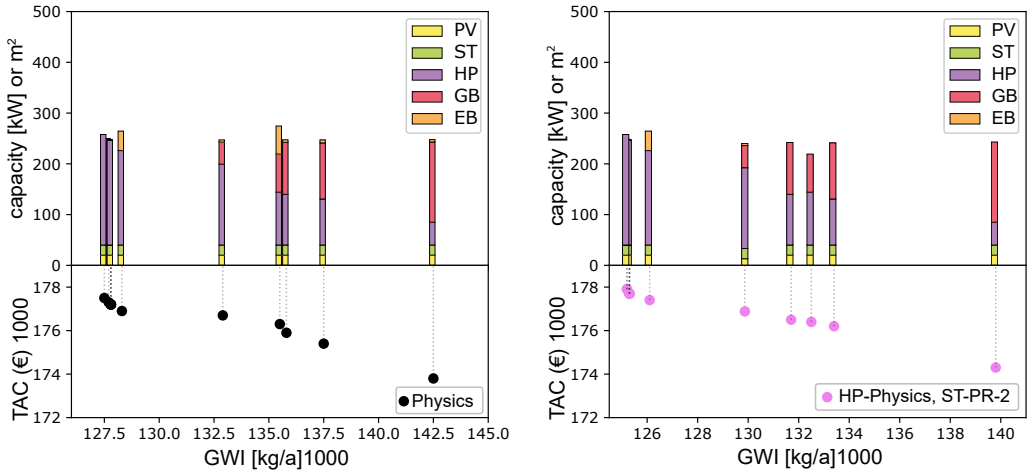
compared to complete physics-driven models. In contrast, ST ANN-1 model with HP physics-driven (blue dots) model in coupled optimization is also very accurate, but the computational time for solving the coupled optimization problems with ANN-models are very high due to large number of weights and biases.



(a) Complete physics-driven model

(b) HP-Physics, ST-PR-2 model

Figure 8: Capacity of components for reference solution and best trade-off solution for single-level coupled optimization

Fig. 8 shows the optimal capacity of the components for the total physics-driven models and the best trade-off combination of physics- and data-driven models, which is chosen based on best trade-off between computational time and solution accuracy according to Fig. 7. Both Fig. 8 (a) and 8 (b) show that for minimum TAC small HP and large GB is required to meet the heating demand, while for minimum GWI large HP is required. The size of ST and PV remains almost constant in all of the Pareto-results. In some solutions, EB is needed

when HP and GB are not sufficient to provide the required heat. The optimal capacity of the components follow a similar trend for complete physics-driven and combined physics-data-driven models, demonstrating the credibility of the combined models.

4. Conclusion and outlook

This paper showed a multi-objective coupled design and operation optimization of an energy concept of a food and cosmetic industry as a case study. Single-level optimization for minimizing TAC and GWI as well as design and operation variables for each component involved is described. The aim of this paper is to compare different types of physics- and data-driven models and to integrate them into a coupled optimization problem to reduce the computational time while maintaining the accuracy of the optimization results. The results showed that the combination of data-driven PR model of ST and physics-driven HP model better than all other combinations in terms of computational time and solution accuracy. The accuracy of the optimization result is up to 90% compared to complete physics-driven model and the computational time is reduced by 37%.

Future work for this case study is to include energy storage models into the energy concept. Integration of thermal and electrical storage can increase the flexibility. Different scenarios such as retrofit designs, greenfield designs, cost neutral solutions and emission free solutions can be optimized for the given case-study and different design-operation solutions can be provided. Combination of physics-data models can be very useful in optimizing these scenarios at less computational efforts and high accuracy.

Abstract:

For operation planning in industrial energy systems mixed integer linear programming (MILP) is the go-to method because of its reliability and the huge advances in MILP algorithms in recent years. MILP is especially well suited for planning the use of storage units, even if including the non-linear operating behavior of thermal storages is still a big challenge – especially if partial load cycles are considered. To model the storage behavior, a multi-variate non-linear function has to be linearized and incorporated into the MILP model. The key for good performance in MILP is using as few linear pieces as possible to achieve the required accuracy. We consider two types of piecewise-linear models: triangulation on a grid and general triangulation.

In this paper, we present different heuristics for computing efficient piecewise-linear approximations of non-linear functions. As a use case we consider the behavior of a thermal storage unit. We apply the heuristics to compute piecewise-linear approximation of the non-linear operating behavior and discuss the results. We then compare the performance of the models in a MILP model for the operation planning of an energy system. For translating the piecewise-linear function to MILP we consider state-of-the-art approaches with a logarithmic number of binary variables.

Our results show that gridded triangulation models in combination with logarithmic MILP formulations can be used for data-driven modeling of non-linear operating behavior of devices. We highlight the potential of this approach for realizing adaptable operation optimization of energy systems.

Keywords:

Thermal energy storage, Packed bed reactor, Unit commitment, MILP, Data-driven modeling.

1. Introduction

In an effort to curb climate change governments are imposing increasingly strict emission targets on industry. The recent increase in energy prices puts additional pressure on companies. Companies, especially in the energy-intensive industries, are forced to reduce primary energy consumption and increase energy efficiency. To do this, companies will have to employ a wide range of different solutions. Re-using excess heat on site, i.e. reducing waste heat, is getting more and more important.

The total global waste heat potential in 2016 was estimated to be more than 68 TW h [1]. Large parts of it can be attributed to the industrial and power generation sectors. In many cases, excess heat remains unused because heat demand occurs at another time than waste heat is available. Thermal energy storage (TES) systems can store a considerable share of the available waste heat and make it available. In this way, TES not only increase the flexibility of energy-intensive industrial processes [2, 3] but they also help increasing the overall energy efficiency and reducing green house gas emissions.

To operate the storage efficiently a lot of planning is required, especially for non-periodic processes. For operation planning in industrial energy systems unit commitment (UC) methods based on mixed integer linear programming (MILP) are the go-to methods because of their reliability [4]. The huge advances in MILP algorithms in recent years allows it to solve UC problems very quickly [5]. MILP has the advantage (compared to genetic algorithms and heuristic storage management techniques) that it reliably finds the optimal storage trajectory because, as a deterministic optimization method, it always converges to the global optimum. UC can be used to organize energy supply in a cost-optimal manner and to ensure that energy demand is always met.

For the present study, we consider a packed bed regenerator (PBR) that is to be used for waste heat recovery from the off-gas in a steel production process [6]. Because of the harsh operating conditions, slag dust is

expected to accumulate inside the storage over time, which will change the operating behavior. In an ongoing research project a digital twin platform is being developed to monitor the PBR and to operate the storage efficiently and reliably during its whole lifetime [7]. The digital twin platform features a thermal model of the PBR that is adapted regularly to model the operating behavior of the storage accurately at all times. This thermal model can be used to predict the behavior of the storage, but it cannot be integrated into the UC model.

To model the behavior of the PBR in the UC model accurately, the dependence of the maximum charging and discharging power on the state of charge has to be considered. The maximum power diminishes, when the storage is almost fully charged or discharged, because the power depends on the position of the thermocline inside the packed bed [4]. When the storage operates in partial charging and discharging cycles (which will usually be the case), the state of charge at the time of switching also has to be considered [4].

A big challenge with modeling the PBR for the UC is automatically deriving an accurate model for its non-linear operating behavior. The model, which was proposed in [4], was set up by hand. For this reason, it cannot be used for the automated model adaption which we intend to realize on our digital twin platform.

In this paper, we discuss different methods for modeling the storage behavior in the UC model and evaluate their performance both in terms of how well they approximate the operating behavior and how they affect the solving time of the UC problem. We show that gridded models are viable for incorporating data driven models in MILP. With this approach, we can adapt the UC model to the changing operating behavior of the PBR and thus realize reliable and accurate operation planning for an energy system with a TES over its whole lifetime.

2. Methods

2.1. Modeling non-linear operation characteristics in MILP

As the name suggests, mixed integer linear programming (MILP) is limited to linear relations between continuous and integer variables. To include non-linear characteristics, they have to be approximated by piecewise-linear functions. These piecewise linear functions are then incorporated into the MILP model by using auxiliary binary variables to distinguish between the individual pieces of the piecewise-linear function.

The ability to (approximately) include non-linear behavior in MILP comes at a price: Since the complexity of MILP problems increases exponentially with the number of binary variables, detailed piecewise-linear functions can severely affect the performance.

Piecewise linear-functions can be incorporated into a MILP problem with different formulations. For functions with one independent variable, the formulation is known as Special Ordered Set of type 2 (SOS2). For functions with more than one independent variable (as in our use case), different formulations were suggested [8,9] which differ in the number of auxiliary binary variables that are required to distinguish the simplices (pieces).

The direct extension of the concepts of SOS2 formulations to higher dimensional functions is known as Convex Combination (CC) [8]. This formulation can be used for any piecewise-linear function that uses simplices and the required number of auxilary binary variables increases linearly with the number of simplices. When the simplices are arranged in a rectangular grid, a more efficient formulation (log CC) can be used, where the number of auxilary binary variables increases only logarithmically with the number of simplices [9]. For piecewise-linear functions with many simplices, this can result in considerable savings.

2.2. Approximating storage behavior for MILP

In a packed bed regenerator, the maximum charging and discharging power depends on the state of charge and and on the initial state of charge of the charging/discharging cycle [4]. This behavior can be described by a non-linear function with two independent variables (state of charge and initial state of charge). To model the storage behavior in a UC problem in MILP, this non-linear function has to be approximated by a piecewise-linear function.

We assume that the non-linear function is given by a data-set (e.g. simulation data from a thermal finite volume model). A general piecewise-linear model with two independent variables is a triangulation of the domain with function values at each vertex. The goal of the approximation is, thus, to determine the optimal triangulation and to estimate the values at the vertices. For this problem, hardly any solutions have been proposed in literature.

From a MILP perspective gridded models have the advantage of more efficient MILP formulations, but with free triangulations (i.e. triangulations that are not confined to a grid) the target accuracy could potentially be achieved with much less simplices. Which modeling approach is more viable thus boils down to how many simplices are needed to achieve the target accuracy and by how much the solving time of the UC problem can be accelerated by using a logarithmic formulation.

For approximating a two dimensional function with a (non-gridded) triangulation, a heuristic was proposed [10]. Starting from an initial triangulation of the domain, the simplices are split according to a specific strategy, until

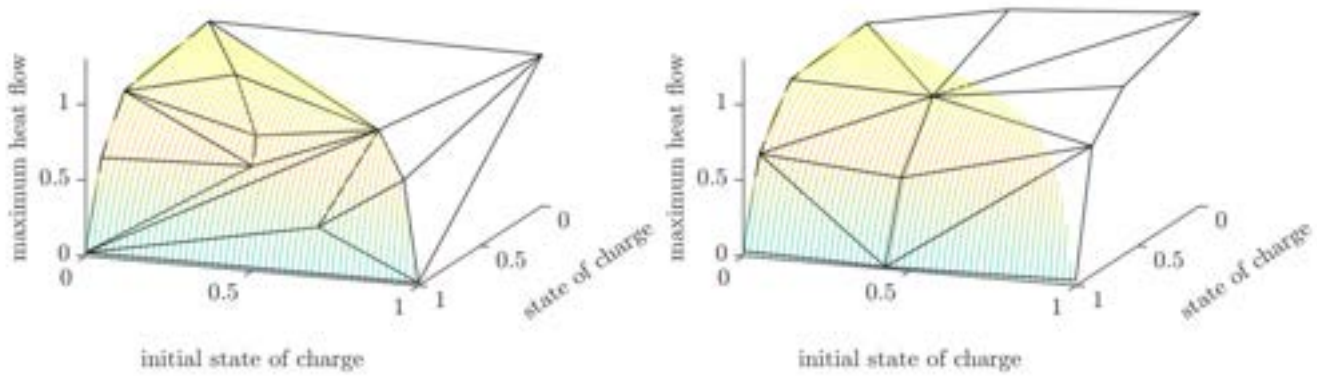

Figure 1: Illustration of the linearization of the maximum charging power with normalized axes. Free triangulation (left) and gridded triangulation (right), both with a root mean square error of $2 \cdot 10^{-2}$.

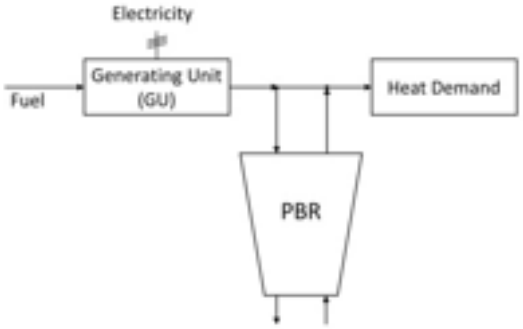

Figure 2: Illustration of the energy system for the unit commitment. Adapted from [4]

the required accuracy is achieved. We found that results with this method were barely satisfactory. Also, this kind of triangulation does not allow for the most efficient logarithmic formulation.

For this reason, we developed our own approximation algorithm for models that use a gridded triangulation. Determining the optimal grid positions and function values at the vertices is posed as a non-linear least-squares problem. As long as the target accuracy is not reached, additional grid lines are added with a heuristic and the optimization is repeated. To improve the convergence, gradients of the non-linear optimization problem are computed analytically. Gradient and grid position regularization is used to improve the quality of the model. A detailed description of the algorithm is beyond the scope of this paper but may be the content of a future publication.

Figure 1 shows an illustration of the piecewise-linear approximation of the maximum charging power of the PBR with each heuristic. In both cases, the target accuracy in terms of the root mean square error (RMSE) was $2 \cdot 10^{-2}$. The model using a free triangulation needed 16 simplices while the one with the gridded triangulation needed only 12. Unfortunately, the heuristic for fitting non-gridded triangulations cannot consistently exploit the additional degrees of freedom and compute better approximations with fewer simplices.

2.3. Unit commitment model

For evaluating the performance of each modeling approach and the effect of the logarithmic formulation, we used the same UC model as Koller et al. [4]. In this UC model, a very simple energy system (see Figure 2) consisting of a generating unit (GU), the PBR as a heat storage and a heat demand is considered. The heat demand of the process has to be covered at all times. The GU produces both heat and electricity. Electricity is sold at the electricity market at a fluctuating but known price. To allow the GU to shut down during times of low electricity prices, the PBR is used to store heat and supply the demand.

The UC model has a prediction horizon of 8 days with time steps of 1 hour. This results in 192 time steps. A detailed documentation of the model and its parameters can be found in [4].

The output of the UC problem is illustrated in Figure 3. The diagram on the top shows how the heat demand is covered by either a heat flow from the GU or from the PBR. The fluctuating electricity price that affects the optimal operation of the GU is also shown. In the bottom diagram, the operating trajectory of the PBR is shown.

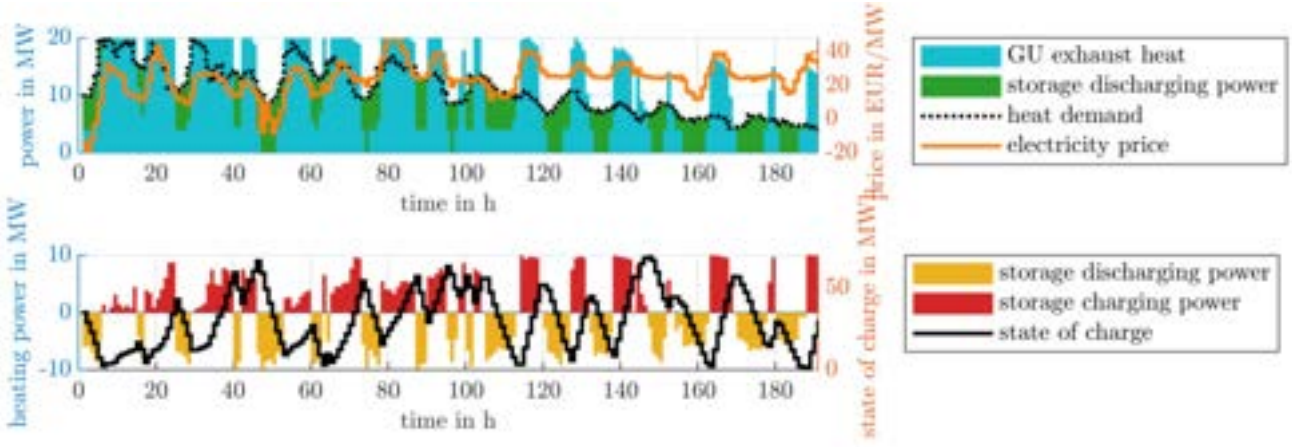

Figure 3: Illustration of the output of the unit commitment problem.

Table 1: Number of simplices, number of auxilary binary variables and resulting solving time in MILP for each model type and MILP formulation.

	RMSE	simplices	auxilary binary variables	solving time in s
free, CC	$1 \cdot 10^{-1}$	10	10	17
	$5 \cdot 10^{-2}$	10	10	18
	$2 \cdot 10^{-2}$	32	32	160
	$1 \cdot 10^{-2}$	64	64	7423
grid, CC	$1 \cdot 10^{-1}$	16	16	49
	$5 \cdot 10^{-2}$	16	16	49
	$2 \cdot 10^{-2}$	24	24	72
	$1 \cdot 10^{-2}$	60	60	1651
grid, log CC	$1 \cdot 10^{-1}$	16	6	5
	$5 \cdot 10^{-2}$	16	6	5
	$2 \cdot 10^{-2}$	24	8	28
	$1 \cdot 10^{-2}$	60	12	54

The bars illustrate heat flow to and from the storage. The line shows the state of charge.

3. Results and discussion

The aim of this study is to determine the most efficient way to derive data-driven models for the operating behavior of a PBR for use in a UC problem.

We consider two types of piecewise-linear models: free triangulation and gridded triangulation. Both types of models can be included with the MILP formulation known as Convex Combination (CC). The gridded model also allows for a logarithmic formulation (log CC). Which approach is more efficient depends 1) on the number of simplices that each modeling heuristic requires to reach the target accuracy and 2) on the speed-up due to the reduced number of auxiliary variables with the log CC formulation.

We used each fitting heuristic with the target accuracies, in terms of the root mean squared error (RMSE), of $1 \cdot 10^{-1}, 5 \cdot 10^{-2}, 1 \cdot 10^{-2}$. The results are aggregated in Table 1. To approximate both the maximum charging and discharging power at an accuracy of $1 \cdot 10^{-1}$ and $5 \cdot 10^{-2}$, 10 simplices were required with the heuristic using a free triangulation, while the heuristic using a gridded triangulation needed 16 simplices. At higher accuracies, the heuristic with free triangulation needed a few more simplices than its gridded couterpart. It could not leverage the additional degrees of freedom to achieve the target accuracy with fewer simplices.

The fourth column in Table 1 shows the number of auxiliary binary variables that is required to include the piecewise-linear function in the UC problem. The number of binary variables can be expected to have a huge impact on the solving time since 1) the complexity of MILP problems increases exponentially with the number of binary variables and 2) the models describing the operating behavior of a device in UC have to be replicated at every timestep. Since our UC problem has 192 timesteps, a model that requires 10 auxiliary binary variables introduces 1920 additional binary variables into the MILP problem.

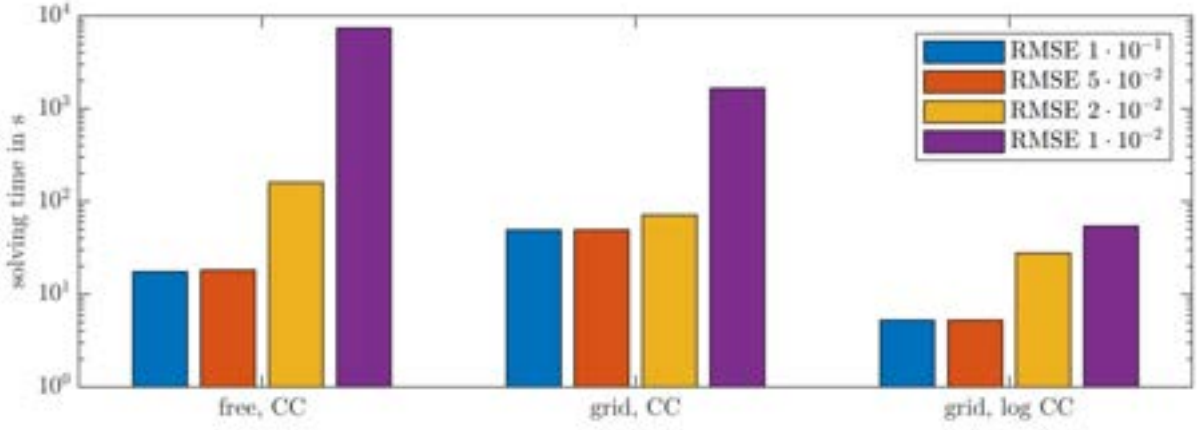

Figure 4: MILP solving time with different models for the operating behavior of the thermal energy storage.

The UC problem was formulated using YALMIP R20210331 [11] in Matlab R2022a. The problems were solved using Gurobi 10.0.0 on a 128-core system (AMD EPYC 7702P) with 256 GB RAM. The results are shown in the last column in Table 1 and are illustrated in Figure 4.

The exponential increase of solving time with the increasing number of simplices and consequently auxiliary binary variables is clearly visible (note the logarithmic scaling of the y-axis). The heuristic using a free triangulation performs slightly better than its gridded counterpart at low accuracies where it managed to make due with fewer simplices. Nevertheless even there it is outperformed by the gridded model using the logarithmic formulation.

4. Conclusion

In this paper we compared two heuristics for deriving data-driven models of the operating behavior of a thermal storage unit in a unit commitment problem. This data-driven modeling approach will be applied in a model adaption service of a digital twin that provides operation planning functionality. The goal is to manage the storage optimally taking into account the degradation of the charging/discharging performance due to harsh operating conditions.

The first heuristic used a free (i.e. non-gridded) triangulation to approximate the non-linear storage behavior, while the other used a grided triangulation. Even if — in theory — the free heuristic should be capable of achieving the target accuracy with fewer simplices than its gridded counterpart, it only did so at low accuracies. Since much more efficient MILP formulations can be used to incorporate gridded models into the unit commitment problem, this model type showed the best performance across the board.

Our results demonstrate that gridded models in combination with the logarithmic MILP formulation are well suited for deriving data-driven models of non-linear functions with multiple independent variables for MILP problems. This allows us to realize adaptable operation optimization on a digital twin platform. Research is already underway to test our approach in a lab test environment and evaluate its potential in a steel mill.

Another interesting direction for future research would be to improve the heuristics for deriving models with a free triangulation. If the additional degrees of freedom can be exploited, this would lead to very efficient models especially if no high accuracy is required or if the function has features that are incompatible with the main grid directions.

Abstract:
The operation of building energy systems contributes significantly to thermal comfort and energy efficiency. In turn, the operation is influenced by the control quality of local closed-loop controllers. However, in practice controllers are often commissioned without sufficient testing, due to the lack of time and budget, leading to reduced performance and energy efficiency. To facilitate controller testing and assessment, this work presents a three-step simulation-based testing method using little user input to provide an automated evaluation of the controller performance. For the assessment, a model of the controlled system is used to enable the evaluation of controller behavior for different scenarios. The controller performance is assessed in each scenario utilizing different Key Performance Indicators (KPIs). The model of the controlled system also allows the estimation of the optimal control behavior, which is used as reference control to provide further feedback for possible improvements to the user. All three steps are implemented and deployed as a cloud service allowing the controller under test to communicate with the controlled system model via an HTTP API. The testing method is applied to two different control loops of an air handling unit. The tested controllers show poor control quality when assessed with different KPIs. The results of the testing method provide direct improvements for both controllers. By applying these improvements to the two controllers, the control quality, assessed with the Integral Time-weighted Absolute Error (ITAE), was improved by 85 % and 63 % respectively.

1. Introduction

In 2020, buildings accounted for 36 % of global energy consumption, emphasizing the need for energy-efficient building operations to mitigate climate change [1]. Advanced control strategies like model predictive control (MPC) promise energy savings from 15 % to 50 % [2]. Furthermore, advanced control strategies often rely on local feedback controllers [3]. Additionally, even without advanced control strategies, poor-performing local controllers lead to inefficient operation. Therefore, local controllers highly influence the overall efficiency of buildings. However, in practice, controllers are often not tested sufficiently. One reason is that controller tuning is not done at all or performed manually based on expert knowledge during installation [4]. This can lead to poor performance, especially in operating points not present during the installation period. One promising approach for controller performance assessment is to use models to decrease the required time and cost [5]. In addition, the manual effort can be reduced by clearly defining and automating the testing process.
Jelali identifies a five-step process for controller performance assessment [6]. First, the current control is assessed by performance figures. Second, a benchmark for performance is selected. Afterward, deviations from the benchmark are detected for every control loop inside the system. Fourth, the reason for the deviation is detected. Finally, options for improvement are suggested. The author points out that especially the last two steps are the most challenging and are usually done manually. Matinnejad et. al. present a search-based testing method, which investigates the controller in different scenarios using models [7]. Scenarios are benchmarked against each other based on Key Performance Indicators (KPIs) assessing the controller performance. The aim is to detect worst-case scenarios, which can then be used for further manual testing and improvement of the controller. The BOPTEST framework enables benchmarking different control strategies by providing standardized models as use cases [8]. This allows testing different control strategies on the same system with the same environmental conditions, creating a reference for these use cases. However, the focus

is on advanced control strategies in a building energy management system and not on local controllers like PID. In [9] a framework is presented, which investigates controller performance by step response. The step signals are applied directly to the actual system and are investigated based on monitoring data. This requires an already existing building management system and technical requirements as well as the time to write directly to the system.

In the current literature, a lot of frameworks are developed to assess the performance of modern control and energy management systems. However, these systems often rely on local control loops, which are often not tested sufficiently. Furthermore, the testing process for these local controllers, if conducted, is often costly and time-consuming. Therefore, in this work, we present a three-step simulation-based testing method utilizing minimal user input to assess and, if needed, improve closed-loop controller performance in various scenarios. To benchmark the controller performance, a model of the controlled system is used to calculate a reference controller behavior. As a result of the method, direct suggestions for improvement are given. The testing method is implemented as a cloud service and can be used for the installation of new controllers or during operation since it does not interfere with the actual building. We demonstrate the method by applying it to two local control loops of a reheater of an air handling unit (AHU).

In the following, we explain the testing method and all its processes. Subsequently, the use case and the results of the application are presented and discussed.

2. Methodology

In this section, we first present the nomenclature for this paper and afterward the three steps of the simulation-based testing method for assessing closed-loop controller performance.

The most used controller in building energy systems is still the PID controller [4]. The control behavior of a PID controller is defined by the following equation, with K_p, T_i and T_d being the parameters for the proportional, integral and derivative terms:

$$u(t) = K_p \left[e(t) + \frac{1}{T_i} \int_0^t e(\tau)\mathrm{d}\tau + T_d \frac{\mathrm{d}}{\mathrm{dt}} e(t) \right] \tag{1}$$

In a closed loop, the controller interacts with the controlled system as shown in Fig. 1. The controller output u influences the process variable y, which, together with the setpoint r, is used as feedback for the controller. The controller is therefore directly influenced by the controlled system and the corresponding disturbances z. To fully assess the controller performance, the proposed testing method investigates both, the controller and the system, in various scenarios.

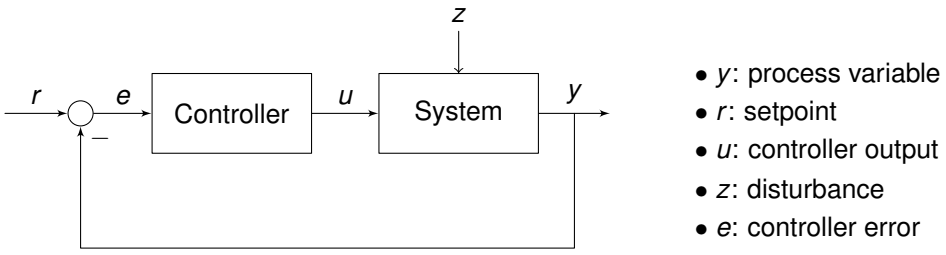

Figure 1: Closed loop control with used nomenclature

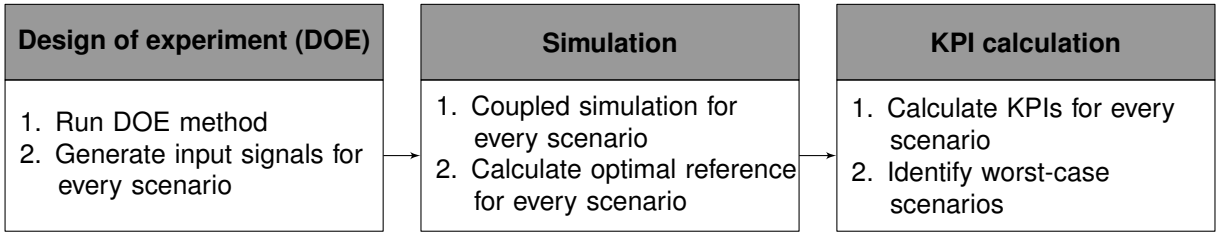

Figure 2: Process of the simulation-based testing method

Figure 2 shows the three different steps of the simulation-based testing method. Each step requires minimal user input and therefore enables an automatic calculation process. As a first step, a Design of Experiment (DOE) method is run, to parametrize the different scenarios in which the controller is assessed. In the second step, the closed loop system is simulated with these scenarios, and for each scenario, an optimal reference

controller is calculated. In the last step, KPIs for each scenario are calculated. This allows the user to identify those scenarios, which performed worst.
In the following, a more detailed description of the three steps of the simulation-based testing method is given.

2.1. Design of experiment

Since a controller's behavior strongly depends on the current operation of the system, a systematic performance assessment needs to investigate controller performance at different operational points. One of the main benefits of using models for controller performance assessment, in comparison to real-world systems, is the ability to easily investigate controller behavior under different environmental conditions. For a control loop, these environmental conditions are specified by the disturbances and the setpoint. Both act as external signals, which can not be influenced by the controller or the system. Therefore, for an assessment of the controller performance, these external signals need to be varied inside the operational boundaries.
Applying constant values for disturbance and setpoint would lead to a static operation, which does not represent the actual operation of a real system. Thus, to keep dynamic operation, a function is parametrized for each external signal resulting in a time series as input for the simulations. We call the combination of an input function for the disturbance and the setpoint a *scenario*. A scenario is defined by the parameter set for the input functions and the type of function.
The parameter sets are chosen from a parameter space, which is limited by the operational boundaries of the corresponding system, by **running a DOE method**. For every parameter set, a scenario is generated. By selecting numerous different parameters for the input functions, long calculation times due to a high number of simulations are needed. Therefore, the combinations of parameters need to be chosen systematically and under consideration of the total amount of combinations. Latin Hypercube Sampling (LHS) is a DOE method that randomly chooses different operational conditions by considering the input dimensions and trying to cover most of the input space [10]. The number of combinations of parameters is defined by an input to the LHS. With this, it is possible to simulate a defined number of parameter combinations while still covering most of the scenario parameter space.
As a result of the DOE method, different sets of parameters are chosen, which are then used **generate input signals for every scenario** by parametrizing functions. Within the methodology, multiple different types of functions can be used for the setpoint and the disturbance. However, in this paper, we focus on two different types of functions: a constant function for the disturbance and a step function for the setpoint. The constant function keeps one value for the whole time period, while the step function changes its value instantly from a start to an end value at a defined time. The combination of these functions allows an isolated assessment of the step response of the controller for different disturbances.
For the DOE, these two functions result in a three-dimensional parameter space: the constant value for the disturbance as well as the start value and end value of the step. The limits of this space, i.e. the operational boundaries, and the time period of the signal are given by the user and depend on the controlled system.
With the created input time series for both the disturbance and the setpoint, the controller and the system model can be simulated.

2.2. Simulation

During the simulation process, the controlled system is simulated separately from the controller. The **coupled simulation for every scenario** is achieved by periodically communicating all necessary variables between the controller and the controlled systems within a specified time step over a defined interface. This interface includes all needed variables for a closed-loop controller: process variable y, setpoint r, disturbance z and controller output u. This allows providing the testing method as a cloud service, by implementing the communication interface as an application programming interface (API). With this, the controller can either be a simulation model or a hardware controller, as long as it is able to send and receive the variables defined by the interface through the API.
In this work, we assess controllers using models that are implemented in the modeling language Modelica [11]. The models are exported as Functional Mock-up Units (FMUs) using the Functional Mock-up Interface (FMI) standard [12]. Within Modelica, the communication interface is realized using the *bus* model, which is based on the expandable connector concept [13]. A *bus* allows the grouping of variables under a specified naming scheme. This naming scheme can then be utilized for communication with external tools like Python. Therefore, a *bus* model is created, which defines the above-mentioned necessary variables for the closed-loop controller. The *bus* model is used to adapt existing models from the Modelica library AixLib, which includes various building energy system models like air handling units and thermal zones and is developed at the Institute for Energy Efficient Buildings and Indoor Climate [14].

Depending on the type of function used to create the input signal for the coupled simulation of the controller and controlled system, different conditions apply to the simulation. For the step function, it is necessary that the system is in a quasi-steady state before the step can occur. Furthermore, it is important to run the simulation long enough to see the effects of the step signal after the step occurs. Therefore, two important parameters for

each simulation are the initialization time and the total simulation time. The initialization time defines the time until the step occurs and the starting time for the assessment. The total simulation time describes the length of the full simulation. Both time values heavily depend on the time constant of the controlled system. For this reason, these values are provided by the user. Additionally, the communication step size for the communication interval between the controller and the system has to be provided by the user.

As a basis for the performance assessment of the controller, the model of the controlled system is also used for the **calculation of an optimal reference**. The calculation is performed for each scenario and in parallel with the coupled simulation. Section 2.3. provides a more detailed description of this process.

2.3. KPI calculation

The KPI calculation is based on the simulation results and evaluates the controller performance by **calculating KPIs for every scenario**. Numerous KPIs for the assessment of controller performance based on different approaches are defined in the literature. Table 1 shows a selection of a few KPIs, which are based on an integral term of the control error $e(t)$. For a more detailed description of these KPIs, the reader is referred to the literature [15].

Table 1: Selection of integral-based KPIs [15]

KPI	Description	Equation
IAE	Integral Absolute Error	$\int \lvert e(t) \rvert \, \mathrm{d}t$
ITAE	Integral Time-weighted Absolute Error	$\int t \cdot \lvert e(t) \rvert \, \mathrm{d}t$
ISE	Integral Squared Error	$\int e(t)^2 \, \mathrm{d}t$

The goal of assessing the controller is to identify the scenarios where the controller performs worst. Since most KPIs represent a single value, it is not possible to directly assess the potential of the tested controller. For example, a controller of a boiler might produce bad KPI values for a downward setpoint step signal, which are not caused by the controller, but by the inability to actively cool. Therefore, to identify these worst-case scenarios, a reference controller is needed. Reference [15] introduces the Harris index, which allows rating the controller performance against minimum variance control (MVC). The index η_{MVC} is defined as:

$$\eta_{MVC} = \frac{\sigma^2_{MVC}}{\sigma^2_y} \tag{2}$$

The variable σ^2_{MVC} describes the variance for the minimum variance control, whereas σ^2_y refers to the variance of the tested controller. MVC describes the best possible controller behavior for achieving the smallest output variance. In analogy to the Harris index, an index can be determined for each KPI, which relates the optimal value to the value of the tested controller. For the ITAE, this leads to the ITAE-Index η_{ITAE}:

$$\eta_{\mathrm{ITAE}} = \frac{\mathrm{ITAE}_{opt}}{\mathrm{ITAE}_y} \tag{3}$$

To estimate the KPI of the optimal reference, an optimization problem is solved by minimizing the corresponding KPI for a coupled simulation of the controlled system and a PID controller. The PID controller is chosen as a reference since it is one of the most used controller types in building energy systems [4]. The optimization problem is shown in (4).

$$\min_{K_p, T_i, T_d} \quad \mathrm{ITAE} \tag{4a}$$

$$\text{subject to} \quad lb \leq K_p, T_i, T_d \leq ub, \tag{4b}$$

The upper boundary (ub) and the lower boundary (lb) for each of the three PID parameters influence the runtime of the optimization. For different systems, default values based on experience are provided, but the user can provide individual values if needed. The ITAE is calculated as a result of the simulation. For every scenario, the optimization leads to optimal PID parameters and the optimal ITAE_{opt}.

The resulting control behavior of the optimal PID heavily depends on the type of KPI that is used for the minimization. Here, the ITAE is used, since [4] shows that the ITAE leads to a low overshoot and a short rise time for heating, ventilation and air conditioning systems.

Based on the ITAE-Index η_{ITAE}, the **worst-case scenarios are identified**. For these scenarios, the behavior of the optimal controller and the tested controller is used as the basis for improving the tested controller. If the tested controller is a PID, the optimal PID parameters can be directly applied.

2.4. User input

The whole three-step process is implemented in a Python framework, which utilizes minimal user input to run an automated performance assessment. The necessary input provided by the user is shown in Table 2. Since this framework aims at testing specific control loops, a lot of the input is also specific for each use case. Nevertheless, some recurring components of building energy systems are modeled and provided with default values for the user input. This enables testing similar systems with low effort.
The user input itself is provided by a config file based on the *JSON Schema*. This setup provides a simple interface, which can be used on a local machine as well as over an HTTP API.

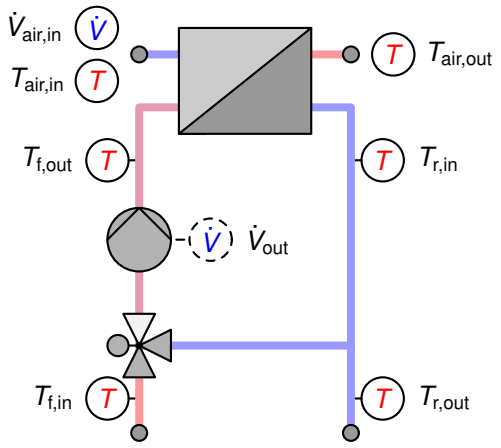
Table 2: Necessary input for the simulation-based testing method provided by the user

Configuration File		
DOE	**Simulation**	**KPI**
• Number of scenarios • operational boundaries • DOE method	• simulation and initialization time • communication step size • system/controller model • optimal PID parameter boundaries	• KPI for index calculation

3. Application to an air handling unit

3.1. Use case description

The simulation-based testing method is tested with a reheater of an air handling unit. The schemata of the reheater as well as the measured variables of the real system are shown in Fig. 3.



- $T_{f,in}$: primary circuit supply water temperature
- $T_{f,out}$: secondary circuit supply water temperature
- $T_{r,in}$: primary circuit return water temperature
- $T_{r,out}$: secondary circuit return water temperature
- $\dot{V}_{out}$: secondary circuit water volume flow
- $T_{air,in}$: inlet air temperature
- $T_{air,out}$: outlet air temperature
- $\dot{V}_{air,in}$: air volume flow

Figure 3: Reheater structure and measured values

The reheater consists of a heat exchanger and a hydraulic circuit, including two actuators, a three-way valve and a pump. The hydraulic circuit is split into a primary circuit containing the heat exchanger and a secondary circuit, from which the reheater is provided with hot water. The dashed volume flow sensor indicates that this value is not measured directly, but calculated and provided through an interface by the vendor.
The investigated control consists of two different control loops with PID controllers. One control loop controls the outflowing air temperature $T_{air,out}$ with the pump speed, from now on referred to as *pump control loop*. The other controls the inflowing water temperature into the heat exchanger $T_{f,out}$ with the valve position, referred to as *valve control loop*. These two control loops interact with each other resulting in one controller being a disturbance to the other one. A more detailed description of the control can be found in [16].

To analyze the control behavior of the implemented control of the reheater, the step responses for both control loops are investigated. The step responses of the pump and valve control loop are shown in Fig. 4 and Fig. 5. The step occurs at 0 min and both signals are recorded for 30 min. In each, the upper figure shows the step response of the process variable and the corresponding setpoint. The lower figure shows the relative control output between 0 % and 100 %. The installed pump allows relative speeds from 10 % to 100 % and runs on a minimum speed of 500 rpm for values below 10 %.

For the pump control loop, a setpoint step from 292.15 K to 297.55 K leads to an ITAE of 358.66. The control output is not at its maximum value of 100 % even though the process variable does not reach its final value after 30 min. Considering an advanced control strategy, which might send new setpoints every 10 to 15 min, this could lead to high discomfort or energy losses. The valve control loop also doesn't reach the final setpoint value for a step from 295.5 K to 300.5 K with the control output also not utilizing its full range, leading to an ITAE of 333.05.
The step responses indicate that both control loops show significant rise times and need to be adjusted to reach the setpoint within a reasonable amount of time. Therefore, the simulation-based testing method is applied to both control loops. For this, the model used is described in the next section.

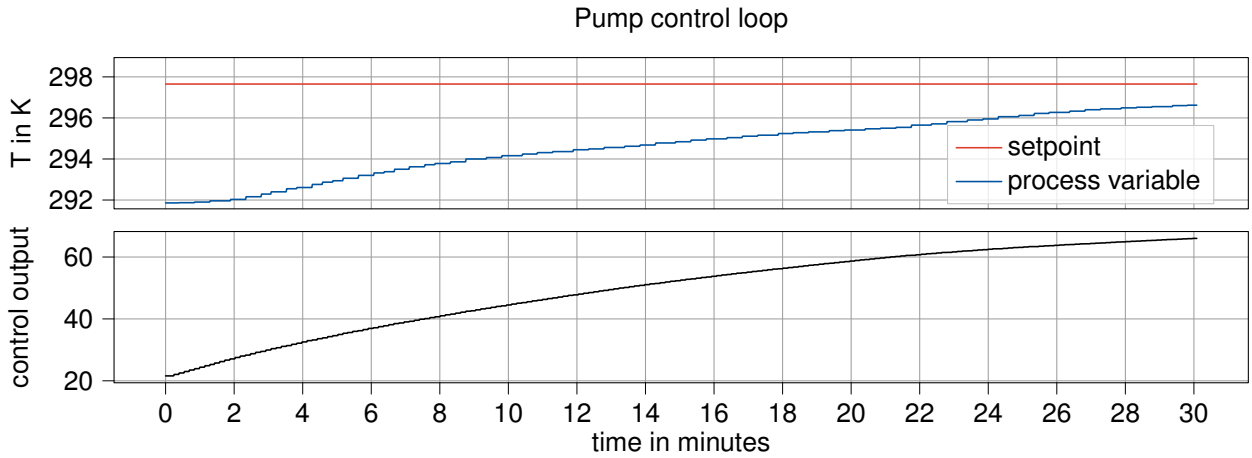


Figure 4: Measured response of the tested pump control loop

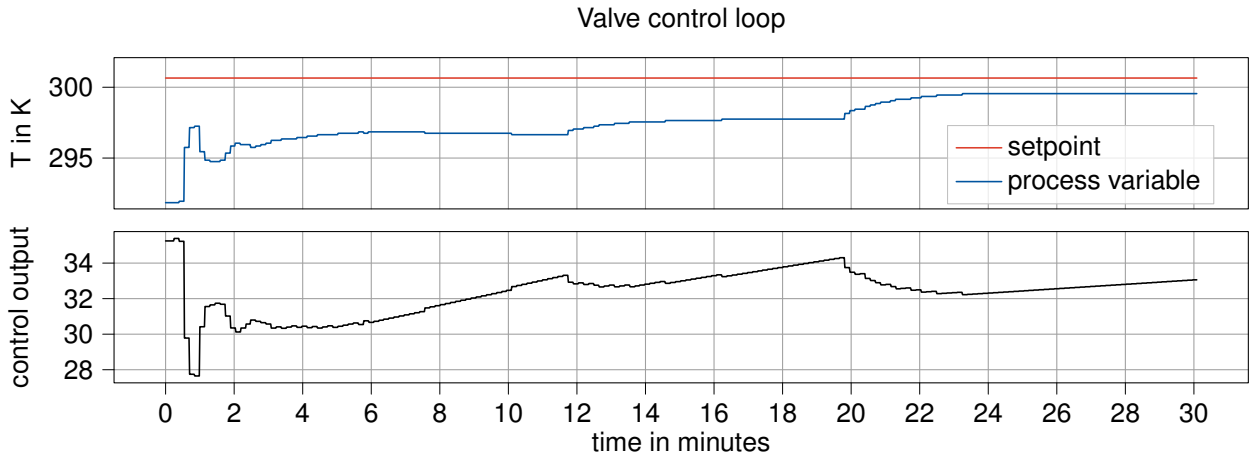

Figure 5: Measured step response of the tested valve control loop

3.2. Models for the reheater

The model for the reheater is created with Modelica using the library AixLib. To reduce the modeling effort, the model is designed so that the user only has to provide parameters that can be found in datasheets. Thus, even a non-professional can use the models. A more detailed description of the model, its assumptions and its application in a use case are given in [13].
The model is calibrated to represent the behavior of the real system. This is done using the AixCaliBuHa framework, which allows the automatic calibration of Modelica models [17]. As input for the calibration, 58 h of measurements of the variables displayed in Fig. 3 are taken. The calibration process is done in two separate steps. First, the volume flow in the secondary circuit is calibrated by varying the pump characteristics and pressure losses of the circuit. In the second step, the outlet air temperature is calibrated by adjusting the parameters of the heat exchanger and temperature losses in the circuit. For both steps, the measured values of the valve position, pump speed and inlet temperatures for the secondary circuit and air are taken as inputs to the model. As the objective for the calibration, the normalized root mean squared error (NRMSE) is used.

With n being the amount of measured data points, y being the measured value and $\hat{y}$ the simulated value, the NRMSE is defined as:

$$\text{NRMSE} = \frac{\sqrt{\frac{1}{n}\Sigma(y_i - \hat{y}_i)^2}}{y_{max} - y_{min}} \tag{5}$$

The results of the calibration for the volume flow and the air temperature are shown in Fig. 6 and Fig. 7 respectively. The calibration resulted in an NRMSE of 0.025 for the volume flow and 0.113 for the air temperature. The bigger NRMSE of the air temperature compared to the volume flow is caused by two major aspects. One

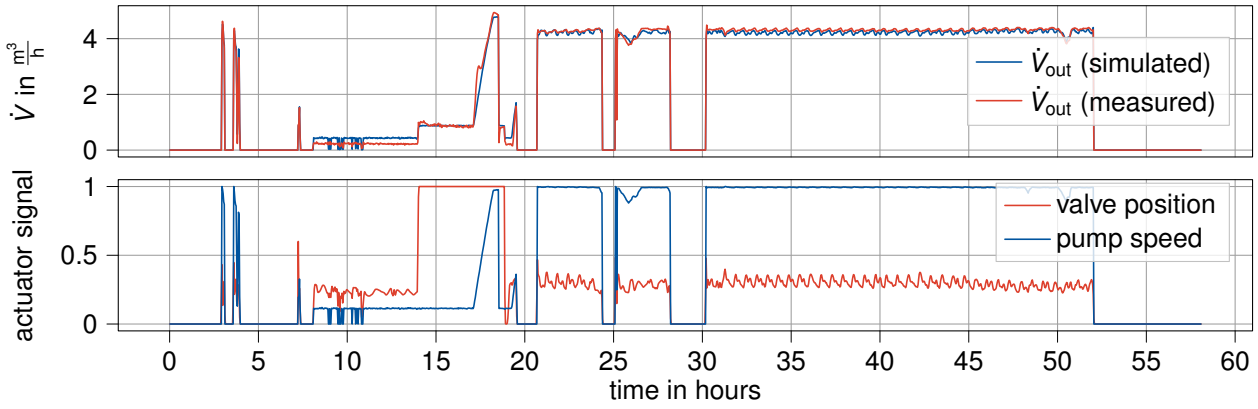

Figure 6: Measured and simulated volume flow in the primary circuit (top) and actuator inputs (bottom) for the calibrated model

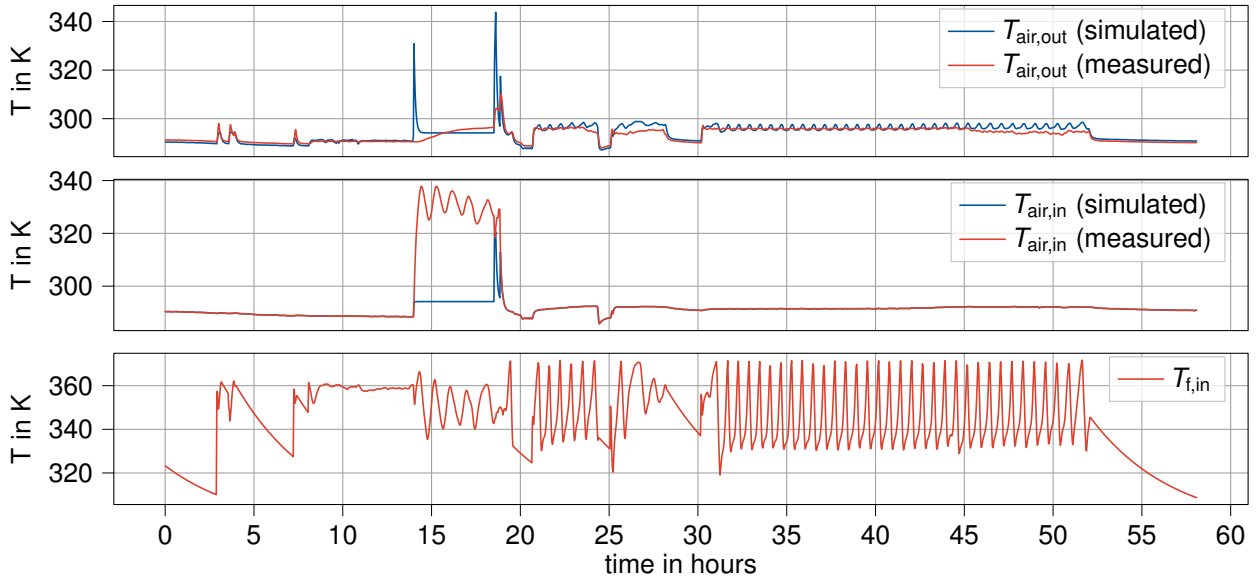

Figure 7: Measured and simulated outlet air temperature (top), measured and simulated inlet air temperature (middle) and water supply temperature as input (bottom) for the calibrated model

aspect is that the temperature sensors of the real system are not calibrated. This leads to high uncertainty of the measurements and fluctuating temperature values over time under otherwise unchanged conditions. The other aspect is the selected time frame for the validation of the calibration. After 14 h, the simulated outlet air temperature rapidly rises, while the measured value only increases slightly over time. A similar behavior occurs after 18 h. Here, two peaks are occurring right after one another. This leads to high deviations and negatively impacts the NRMSE. The deviations are caused by the air volume flow $\dot{V}_{air,in}$ dropping to 0 m^3/h at 14 h and staying at this value until jumping back to 7500 m^3/h at 18 h. Both processes take roughly 300 s. Therefore, during these times, the volume flow reaches values near zero, leading to the first and third peaks in the outlet air temperature due to the unchanged supply water temperature. This behavior is not seen in the measured value. But since this effect only applies to small volume flows, this is only relevant in situations where the AHU is turned on or off. Therefore, this does not influence the model quality for the controller tests.

During the first and third peaks, after the volume flow hits 0 m^3/h, the outlet air temperatures of the simulation and the measurement tend towards the environment temperature of 295.15 K. For the second peak, a rise in the measurement is also seen. This is because the air inside the heat exchanger heats up when the air volume flow is 0 m^3/h and is measured as soon as the air flows again. The measurement shows a similar peak.
The inlet air temperature also shows a deviation from the measurement during the period of 14 h to 18 h. The simulated value tends towards the environment temperature, while the measured value tends towards the supply temperature $T_{f,in}$. This is due to the real temperature sensor being placed near the heat exchanger. Therefore, the air around the heat exchanger heats up according to the supply temperature. In the simulation model, the temperature sensor is only affected by heat losses to the environment.

The NRMSEs for both variables show that the calibrated model sufficiently describes the reheater for the relevant operating points. Therefore, the model is used as input for the testing method.

3.3. Applying the simulation-based testing method

With the calibrated model, the two control loops are investigated using the simulation-based testing method. The method is applied once for each control loop with the tested controller parametrization, which led to the deviations displayed in Fig. 4 and Fig. 5. In the following, the results are presented and discussed using the pump control loop as an example.
As disturbance for the pump control loop, three different variables are possible: the supply temperature at the inlet of the hydraulic module $T_{f,in}$, the volume flow in the air canal $\dot{V}_{air,in}$ and the inlet air temperature $T_{air,in}$. Since monitoring data showed a more or less constant value for the air volume flow over the operation of one year and the supply temperature influences the mixing temperature, controlled by the valve control loop, the inlet air temperature is chosen as the disturbance. For each test run, the other two disturbances are not investigated further and are kept at their average operation values.
The two control loops and the respective actuators influence each other as well. Therefore, the setpoint of one controller is set to a constant value within the operation area, if the other controller is tested. This allows the isolated assessment of each controller.

The value ranges for the different input variables with which the scenarios are generated are given in Table 3. The setpoint represents the setpoint for the outlet air temperature and the disturbance stands for the inlet air temperature. The ranges are based on monitoring data. The control output, here the pump speed, can take values between 0 % and 100 %.

Table 3: Value ranges for the simulation-based testing method

Variable	Value range
setpoint	290 K - 298 K
disturbance	285 K - 295 K

Figure 8 shows the resulting step responses for one exemplary scenario. Each scenario was simulated for 3600 s with an initialization time of 1800 s at which the step occurs. Here, the step function is parametrized with a start value of approximately 291.5 K and an end value of roughly 297 K. The constant function for the disturbance has a value of about 291.55 K. The process variable of the tested controller shows similar behavior to the one displayed in Fig. 4. The outlet air temperature also does not reach its setpoint within the simulation time. Conversely, the optimized controller does reach the setpoint 500 s after the step. The optimal controller reacts more actively to the step by immediately generating a control output of over 60 %, whereas the tested controller never reaches the same output as the optimal controller. This leads to an ITAE for the tested controller of 869 501 K s^2 and for the optimal controller of 9064 K s^2. Thus, the ITAE-index results in 0.01, implying that the tested controller only reaches 1 % of its maximum potential.

Figure 9 highlights the ITAE for every scenario in dependence of the optimal PID parameters (Fig. 9a) and the input function parameters (Fig. 9b). The parameters of the scenarios are given as P_1, the start value of the step signal for the setpoint, P_2, the end value of that signal and P_3, the constant value for the disturbance.
A cluster of low ITAE-indexes η_{ITAE} and therefore worst-case scenarios is located around big values for K_p and small values for T_i and T_d (Fig. 9a). Compared to a PID controller with these values, the tested controller performs worse. Also, the derivative parameter T_d does not seem to have a high impact, since every optimal PID chooses small values for the parameter.
Figure 9b implies that the tested controller performs well for scenarios in which the start value of the step is close to the end value of the step. However, especially for bigger step sizes, the controller performs worse, indicating a passive behavior as seen in Fig. 8.

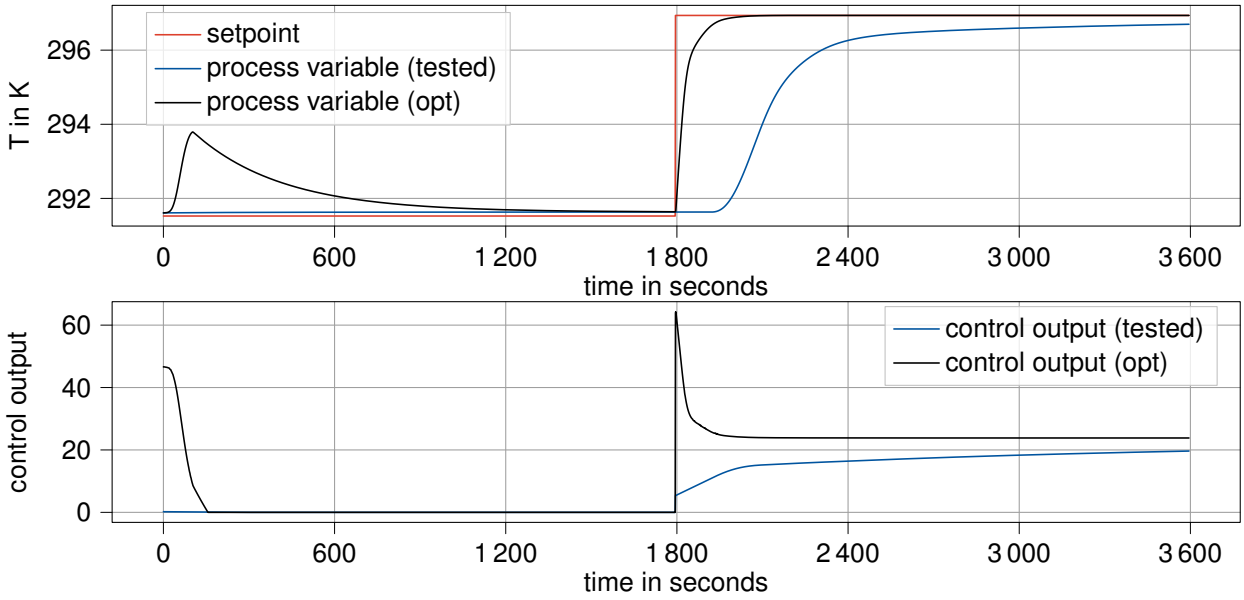

Figure 8: Simulated step response for the tested controller and the optimal reference control

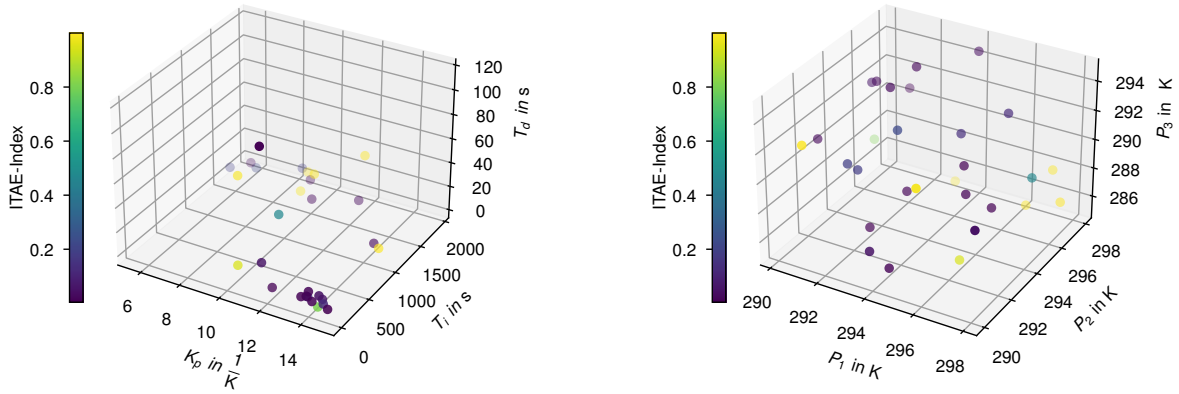

(a) ITAE-Index over optimal PID parameters

(b) ITAE-Index over input function parameters

Figure 9: ITAE-Index for every simulated scenario

Using the graphical representation of the controller performance given in Fig. 9, the tested controller is improved. Since the tested controllers are PIDs, the parameters given by the cluster described in Fig. 9a are applied to improve the controller. The derivative parameter T_d is set to zero since its impact seems to be low. Analog to the pump control loop, the valve parameters are improved. The adapted PID parameters for both control loops are given in Table 4.

Table 4: Different PID Parameters before and after applying the simulation-based testing method

(a) Tested controller

Controller	K_p in $\frac{1}{\mathrm{K}}$	T_i in s	T_d in s
Valve	1.5	850	0
Pump	1.2	130	0

(b) Improved controller

Controller	K_p in $\frac{1}{\mathrm{K}}$	T_i in s	T_d in s
Valve	1	180	0
Pump	11.25	300	0

The initial experiment for the reheater is repeated. The results are shown in Fig. 10 and Fig. 11. With the improved PID parameters, both the outlet air temperature and the primary supply temperature reach their setpoint within a reasonable time. The pump controller shows a small overshoot. The valve control is disturbed by two sudden temperature changes in the secondary supply temperature $T_{f,out}$, leading to two small deviations from the setpoint. Nevertheless, the ITAE of the pump control was reduced to 54.01 K s^2, while the ITAE of the valve has a value of 122.541 K s^2. This results in a relative improvement of approx. 85 % for the pump and approx. 63 % for the valve.

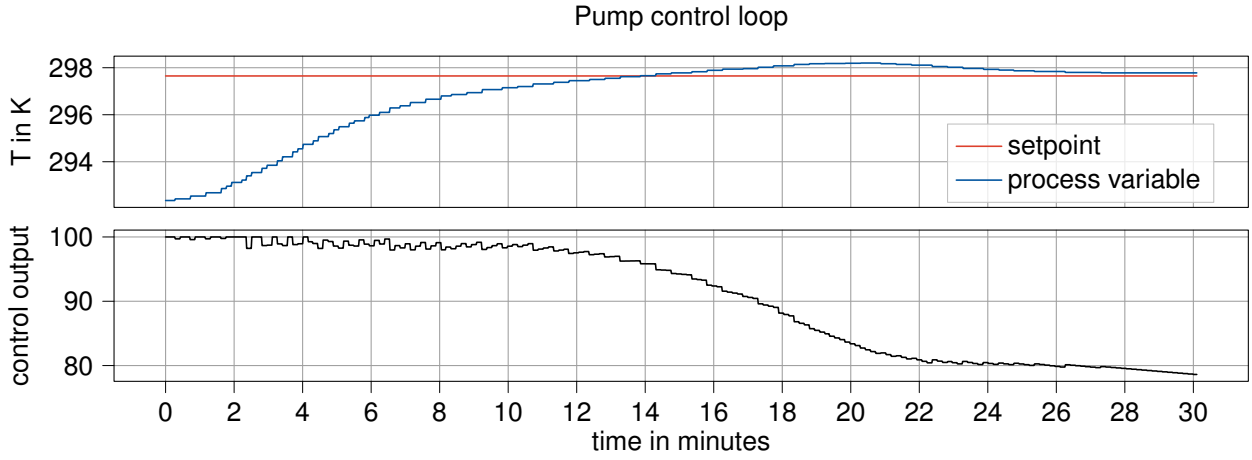

Figure 10: Measured step response of pump control loop with improved PID parameters

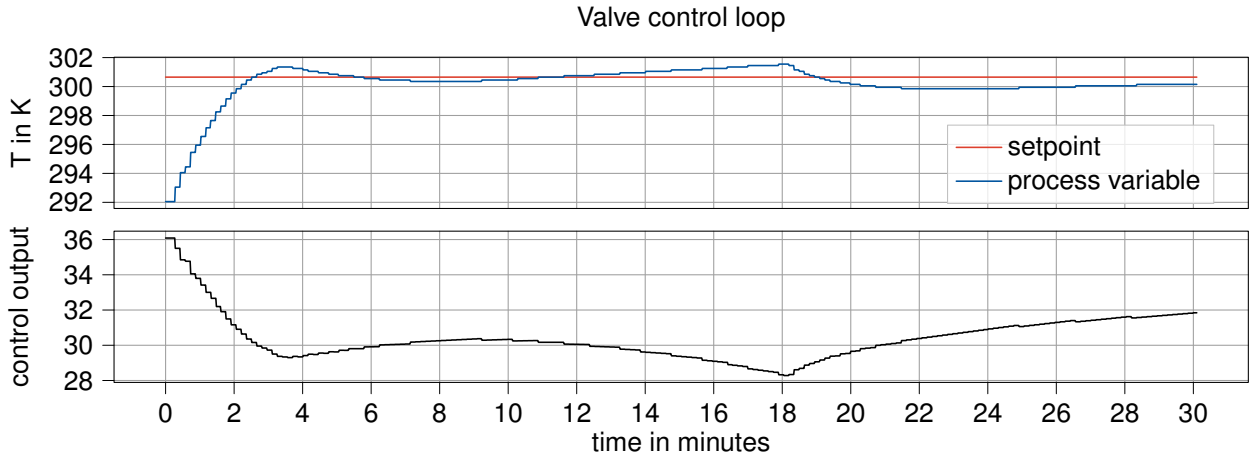

Figure 11: Measured step response of valve control loop with improved PID parameters

4. Conclusion

In this work, we presented a three-step testing method, which utilizes a model of the controlled system to investigate controller performance in various scenarios. The system model is also used to calculate an optimal reference for each scenario to benchmark the tested controller. To receive the optimal control, an optimization problem is solved by varying the parameters of a reference PID controller to minimize the ITAE. With this, the controller performance is assessed in every scenario and worst-case scenarios are identified. These scenarios are then improved utilizing the optimal control.

By applying the method with calibrated models to two different control loops of a reheater of an air handling unit, we have shown that the method can improve the controller behavior. Even when multiple control loops interact with each other, the different scenarios created by the method allowed for isolating and therefore assessing each controller's performance separately. The improved controllers showed enhanced control behavior for two different scenarios, leading to an improvement of the ITAE by 85 % and 63 % respectively.

The presented simulation-based testing method is a promising approach to avoid time-consuming tests on a real system. Even when the used models are not fully calibrated to the real behavior of the controlled system, the derived adjustments improve control behavior. This allows the time-consuming modeling process to be

done once for each type of controlled system and to only invest minimal effort for each specific system the method is applied to. Due to minimal user input, the method can be automated, reducing effort further.
Future work should investigate the automated improvement of controllers or the concrete suggestion of improvement measures based on the optimal reference. In addition, research is needed to assess the disturbance rejection of controllers.

Abstract:

Metal fuels such as iron represent potential energy carriers for large-scale storage and transport of renewable energy. In a circular process renewable energies can be stored in form of iron by thermochemical reduction of iron oxide and the required energy can be released via thermochemical oxidation, time and location independent from the storage process. While existing infrastructure such as coal-fired power plants could be retrofitted to meet the needs for the oxidation process, the conceptualization and construction of new infrastructure for the storage process by reduction is required. This opens up the possibility for a thorough techno-economic assessment of potential processes in order to ensure the optimal process design. Therefore, a techno-economic model of an innovative reduction plant utilizing the flash ironmaking technology for the reduction reactor is developed. The resulting mathematical model describes the operation of the reduction plant in dependence of design variables defining the plant components' dimensions. These design variables together with further process variables are optimized using mathematical optimization with respect to an economic objective function, i.e. the levelized cost of iron, in order to obtain the economically optimal process design. Thorough analyses are performed to assess the impact of changing economic boundary conditions on the optimal process design. Numerical results demonstrate a strong dependence of the cost optimal design on the available renewable energy prices and the obtained levelized cost of iron varies between 0.05 $/kg iron and 0.68 $/kg iron. Thus, choosing appropriate reduction locations with access to low renewable energy prices is crucial for the economic competitiveness of the considered process. The results further confirm an expected trade-off between total investment costs and yearly energy consumption of the plant components. With increasing cost for renewable energy, energetically more efficient system designs also become economically advantageous, i.e. an increase in the energetic efficiency from η_{sys} = 55.6% to η_{sys} = 69.3% is observable. The electrolyzer turns out to be the dominant plant component both, economically and energetically. Future work will take uncertainties into account to ensure a robust process design and couple the reduction plant to location specific renewable energy systems.

1. Introduction

While the ongoing energy crisis sets various challenges, it also acts as an accelerator for the global renewable capacity expansion [1]. Thus, the role of renewable energies (REs) becomes even more important in the endeavor to tackle climate change. However, the potential for RE is not equally distributed around the globe and their availability is subject to fluctuations over time. This turns the efficient global use of REs into a challenge especially for countries with low RE potential.

Suitable carbon-neutral energy carriers could remedy the situation by allowing long-term storage and secure transport of energy from RE sources. This way the energy carrier could be charged with energy from RE sources in locations with high RE potential, transported to locations with low RE potential, but high demand and the energy could be further stored on-site or released according to current demands.

Metal fuels are currently under investigation [2–4] as candidates for such energy carriers due to their high volumetric energy density [3] and their advantageous storage and transport properties. Especially iron seems to be a promising alternative to hydrogen as RE energy carrier [2, 5].

Using iron as an energy carrier, RE can be stored at sites with high RE potential via the thermochemical reduction of iron oxide with green hydrogen to produce iron. The resulting iron can then be transported to regions where energy is required and released via an oxidation reaction through combustion with air. The produced iron oxide is recycled and can again be charged from RE sources (cf. Fig. 1) leading to a circular

energy economy.
While the retrofit of coal-fired power plants for the iron combustion proves to be a promising way for making use of already existing infrastructure and assets [4, 6], the need for developing cost and energy efficient infrastructure at the reduction sites persists. Therefore, this work focuses on an optimal process design for an innovative plant reducing iron oxide to iron using green hydrogen obtained from RE sources.
The considered reduction plant uses a flash ironmaking reactor, which is described in [7] and found to be advantageous with respect to the size and energy requirements compared to common shaft furnace reduction plants. Figure 2 depicts the considered plant with all associated components including the water electrolysis for the production of green hydrogen. The goal of this work is to find an optimal process design for the assessed plant with respect to techno-economic objectives.

Figure 1: The iron energy cycle

Table 1: Design variables of the process components

Component	Design variable	Unit
Flash Reactor	Volume V	m^3
Air Heater Iron Oxide Preheater Hydrogen Preheater Condenser	Area A	m^2
Air Fan Recycle Compressor Electrolyzer	Electric power P_{el}	MW

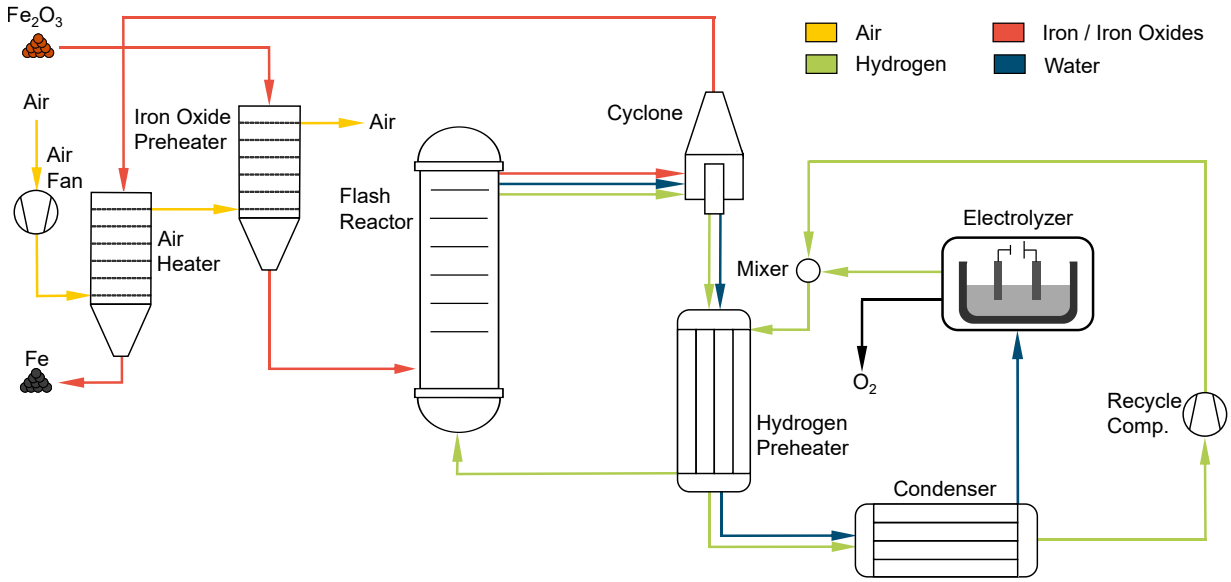

Figure 2: Components of an innovative plant for thermochemical reduction of iron oxides to iron

2. Process description

Blast furnace-based ironmaking remains dominant for steel production, but a more sustainable approach is emerging with the shaft furnace reduction method. Unlike blast furnaces that use coal as a reduction agent, shaft furnaces can reduce CO_2 emissions by utilizing natural gas or green hydrogen. While pure hydrogen-based shaft furnace direct reduction on a large scale has not yet been achieved, it has been technically proven feasible. However, iron oxide pellets are required as feedstock, and must be processed further into iron powder for the oxidation. An alternative technology is the flash ironmaking process [8, 9], which directly utilizes fine iron ore particles without additional pre-treatment, eliminating the need for pelletization and powder production. The flash reactor reduction technology is a high-intensity process that operates at high temperatures, unlike other gas-based ironmaking processes (shaft furnaces or fluidized-bed reactors). To attain these temperatures, the hydrogen reduction of iron oxide requires an external heat source. This heat can be generated internally by burning a portion of the reducing agent.
The reduction process depicted in Fig. 2 starts with fine iron oxide powder, the product of the previous oxidation, which is preheated in a bulk solid heat exchanger (iron oxide preheater). Subsequently, it is fed into the flash reactor where it reacts with a preheated hydrogen stream, yielding iron and water (R1). Heat is supplied

to the reactor, to sustain this endothermic reaction. The reactor effluent is then separated through a cyclone, with the hot iron being cooled down by a bulk solid heat exchanger (air heater) that uses the available heat to preheat the iron oxide feed via heat transfer to a secondary fluid (air). The hot gaseous reaction products (water and unreacted hydrogen) leaving the cyclone are used in a regenerative heat exchanger (hydrogen preheater) to preheat the gaseous reactants and the majority of the water is condensed out in the condenser. The remaining hydrogen is then recycled and merged with hydrogen produced by the electrolyzer, before being fed to the hydrogen preheater and finally entering the flash reactor.

The conversion of iron oxides (Fe_2O_3) to iron (Fe) and water (H_2O) through reduction with hydrogen (H_2) is described by the global reaction (R1). However, it is actually a step wise reaction sequence that involves intermediate iron oxides other than hematite (Fe_2O_3) [10]. These intermediate steps are not taken into account in accordance with the later-used kinetic model [8]. Furthermore, excess hydrogen, which is quantified with a hydrogen equivalence ratio λ_{H_2}, is required due to thermodynamic equilibrium limitations [8, 10] that may inhibit the full conversion.

$$Fe_2O_3 + 3\,\lambda_{H_2} H_2 \longrightarrow 2\,Fe + 3\,\lambda_{H_2} H_2O + 3\,(\lambda_{H_2}\text{-}1)\,H_2 \qquad \Delta H_r(\lambda_{H_2} = 1) = 98.77\,\mathrm{J\,mol^{-1}} \tag{R1}$$

The reaction is modelled on the basis of a global nucleation and growth rate equation for the overall reduction processes derived by Chen et al. [8]:

$$\frac{dX}{dt} = 4.41 \cdot 10^7 e^{\frac{-E_A}{R \cdot T}} \cdot \left(p_{H_2} - \frac{p_{H_2O}}{K_{eq}}\right) \cdot (1 - X), \tag{1}$$

where X is the fractional reduction degree, R is the universal gas constant, T the reaction temperature in K, $E_A = 214\,000\,\mathrm{J/mol}$ the activation energy of the reaction, p_s corresponds to the partial pressures in atm and K_{eq} to the equilibrium constant. From the rate law it becomes clear that the presence of water negatively affects the reduction by lowering the partial pressure of hydrogen but also decreases the thermodynamic reducing power of the gas due to the equilibrium limitations. This can have further implications on the whole process, since the gaseous effluent should be recycled and in ideal case purified into pure hydrogen to inhibit the negative impact. The kinetic law was derived based on hematite particles with an average size of 20 µm and a temperature range between 1423 K-1623 K [8]. This temperature range is used as variable bound for the reactor temperature during the optimization process to assure its correct operation.

3. Mathematical model

Detailed process analyses are crucial in the development of new technologies. Thermodynamic feasibility studies and energetic assessments offer valuable insights into the energetic efficiency of new processes. However, to evaluate the potential profitability and competitiveness of new processes, techno-economic considerations must also be taken into account. Therefore, a techno-economic assessment of the previously described reduction process is performed by directly applying mathematical optimization. This requires an explicit mathematical process description which is then used to obtain the cost optimal design of the system components for varying conditions (i.e. price for RE) by applying mathematical optimization algorithms to an economic objective function. Thus, a cost optimal design refers to a process design minimizing the economic objective, in this case the levelized cost of iron.

Every module in the reduction plant is modelled via incoming and outgoing mass flow rates $\dot{m}_{in,s}$ and $\dot{m}_{out,s}$ associated with species s, temperatures T_{in} and T_{out}, system pressures p_{in} and p_{out} as well as further component specific variables. Appropriate variable bounds on these process variables (e.g. reactor temperature) assure the correct operation of the modules. The underlying processes of each module are then described in terms of (in)equality constraints, including mass, species, and energy balances, as well as pressure changes and equations specific to individual components. The formulation of these technological constraints is closely linked to the cost functions of the equipment, which results in a complex nonlinear interplay between the employed thermodynamic and economic models.

3.1. Design variables

Since the optimization objective aims at finding the cost optimal process design, the functionalities of the modules are described in dependence on design variables, which are summarized in Table 1, responsible for the dimensioning of the modules.

In the case of the heat exchangers and the condenser, their respective area A together with the heat transfer coefficient U, the maximum temperature difference ΔT_{max} and the minimum temperature difference ΔT_{min} determines the heat flow $\dot{Q}_{therm}$ transferred from the hot flow to the cold flow [11]:

$$\dot{Q}_{therm} = \frac{\Delta T_{max} - \Delta T_{min}}{\ln\left(\frac{\Delta T_{max}}{\Delta T_{min}}\right)} \cdot U \cdot A. \tag{2}$$

For compressors, the necessary electric power P_{el} for obtaining an output pressure of p_{out} is determined in dependence of the inlet pressure p_{in}, temperature T_{in}, mass flow rate $\dot{m}_{in}$, specific heat capacity $c_{p,in}$ as well as the electric drive efficiency η_{mot} and the isentropic efficiency η_{is}:

$$P_{el} = \frac{1}{\eta_{mot} \cdot \eta_{is}} \cdot \dot{m}_{in} c_{p,in} T_{in} \cdot \left(\left(\frac{p_{out}}{p_{in}} \right)^{\frac{\kappa-1}{\kappa}} - 1 \right). \tag{3}$$

Lastly, the required electric power for the electrolyzer is determined via the produced mass flow of hydrogen $\dot{m}_{out,H_2}$, its lower heating value $LHV(H_2)$ and the electrolysis efficiency η:

$$P_{el} = \frac{1}{\eta} \cdot \dot{m}_{out,H_2} \cdot LHV(H_2). \tag{4}$$

The reactor modeling including the interplay of its volume V (i.e. residence time) and the time dependent reduction process is addressed in more detail, subsequently.

3.2. Reactor modeling

The flash reactor is at the heart of the reduction plant and its model is therefore crucial for the analysis of the entire process. While the other components do not require a temporal resolution of the residence time, this is crucial for the adequate description of the reduction reaction taking place in the reactor. Recall the global rate equation (1) modeling the time dependent fractional reduction degree X. The considered plug flow reactor model further assumes time dependent partial pressures p_{H_2}, p_{H_2O} within the reactor to account for the impact of the proceeding reaction (i.e. change in partial pressure lead to a change in reaction rate). In the real process the required external heat is provided by partial oxidation of some hydrogen. However, in the deployed reactor model isothermal conditions are assumed, which are achieved by external heat supply. As before, let $\dot{m}_{in,s}$ denote the mass flow rate of species s at the reactor inlet and in addition let $\dot{m}_{R,s}(t)$ denote the mass flow rate of species s throughout the residence time in the reactor R and $\overline{M}_s$ the molar mass of species s. Then, the mass balances of the components considering the global reaction (R1) are described by

$$\dot{m}_{R,Fe_2O_3}(t) = (1 - X(t)) \cdot \dot{m}_{in,Fe_2O_3}, \qquad \dot{m}_{R,Fe}(t) = 2X(t) \cdot \dot{m}_{in,Fe_2O_3} \frac{\overline{M}_{Fe}}{\overline{M}_{Fe_2O_3}}, \tag{5}$$

$$\dot{m}_{R,H_2O}(t) = \dot{m}_{in,H_2O} + 3X(t) \cdot \dot{m}_{in,Fe_2O_3} \frac{\overline{M}_{H_2O}}{\overline{M}_{Fe_2O_3}}, \qquad \dot{m}_{R,H_2}(t) = \dot{m}_{in,H_2} - 3X(t) \cdot \dot{m}_{in,Fe_2O_3} \frac{\overline{M}_{H_2}}{\overline{M}_{Fe_2O_3}}. \tag{6}$$

These representations can be used to define the time dependent partial pressures

$$p_s(X(t)) = p_{in} \frac{\frac{\dot{m}_{in} x_{R,k}(t)}{\overline{M}_k}}{\frac{\dot{m}_{in} x_{R,H_2}(t)}{\overline{M}_{H_2}} + \frac{\dot{m}_{in} x_{R,H_2O}(t)}{\overline{M}_{H_2O}}}, \quad s \in \{H_2, H_2O\}. \tag{7}$$

Using (1) and (5) to (7) the reactor is modelled as follows

$$\frac{dX}{dt} = 4.41 \cdot 10^7 \cdot e^{\frac{-E_A}{R \cdot T}} \cdot \left(p_{H_2}(X(t)) - \frac{p_{H_2O}(X(t))}{K_{eq}(T(t))} \right) \cdot (1 - X(t)), \qquad X(0) = 0. \tag{8}$$

To use the presented reactor model as optimization constraints, the differential equation (8) is discretized using an implicit Euler discretization scheme with a fixed number of discretization steps N and a variable discretization step length h to represent the solution X_ℓ at time steps $t_\ell, \ell = 0, \dots, N-1$. The residence time within the reactor is thus given by t_{N-1} and has to coincide with the ratio of the reactor volume V and the volumetric flow rate $\dot{V}$, i.e. $t_{N-1} = \frac{V}{\dot{V}}$, where $\dot{V}$ is defined by the general gas law.

3.3. Economic objective function

The overall goal of industrial production is to maximize profits, which can be accomplished by either raising the product's selling price or lowering production costs. The latter is typically achieved through the analysis of marginal production costs. To this end, the levelized cost of iron (*LCOI*) serves as the economic objective function, taking into account various costs such as capital expenditures (*CAPEX*), operational expenditures (*OPEX*), energy costs (C_{el}), and transport expenses (C_{trans}), all relative to the yearly production of iron ($m_{Fe,year}$):

$$LCOI = \frac{CAPEX + OPEX + C_{el} + C_{trans}}{m_{Fe,year}}. \qquad [\$/\text{kg iron}] \tag{9}$$

Within the framework of the previously outlined iron-energy cycle (cf. Section 1.), transport costs are linked to long-distance transport costs, while the expenses associated with the feedstock (Fe_2O_3) are not taken into

consideration, as it is continuously recycled. Similarly, costs pertaining to short-distance transport and related logistics are excluded from this investigation. Additionally, it is assumed that the reduction degree of the iron has little effect on its suitability for the generation of high-temperature heat or electricity. Nevertheless, it is important to note that reducing the degree of reduction leads to an increase in the amount of material transported, resulting in higher transportation costs that are taken into account in the objective function.

3.3.1. Capital expenditures

The annuity method is a widely recognized approach for assessing projects from an economic viewpoint because of its simplicity and transparency [12]. It involves computing uniform yearly capital expenditures *CAPEX* that correspond to the present value of the initial investment expenses (*CC*), which can be determined by applying a capital recovery factor (*CRF*), i.e. a constant discount rate i over the project's economic life span n:

$$CAPEX = CRF \cdot CC = \frac{i \cdot (1+i)^n}{(1+i)^n - 1} \cdot CC. \qquad [\$/\text{year}] \tag{10}$$

3.3.2. Operational expenditures

The *OPEX* contrasts the *CAPEX* and comprises maintenance and operating costs. It is commonly provided as a fraction γ of the capital costs: According to [13], the yearly maintenance cost can be estimated to be 6% of the fixed capital cost *CC*. This yields

$$OPEX = \gamma \cdot CC. \qquad [\$/\text{year}] \tag{11}$$

3.3.3. Energy cost

The energy cost for the presented reduction plant refers to the electricity cost c_{el} assumed to come from RE sources and used for the water electrolysis, the compressors, as well as for the heat requirements of the reactor:

$$C_{el} = (P_{el}^{electrolyzer} + P_{el}^{air\ fan} + P_{el}^{recycle\ compressor} + \dot{Q}_{therm}^{reactor}) \cdot c_{el} \cdot t_{year}, \qquad [\$/\text{year}] \tag{12}$$

where P_{el}^{i} denotes the electric power of component i, $\dot{Q}_{therm}^{reactor}$ accounts for the consumed power of the reactor's external heat supply and t_{year} denotes the operation hours within one year.

3.3.4. Transport cost

As previously explained, only long-distance transport costs will be considered. Therefore, it is assumed that the yearly produced iron $m_{Fe,year}$ and the yearly remaining iron oxide $m_{Fe_2O_3,year}$ have to be transported over a long-range distance $dist_{trans}$ at a daily transport cost of $c_{trans,day}$ using n_{ships} with vessel size m_v each travelling with velocity v_{trans}. In total, this yields the following yearly transport costs:

$$C_{trans} = \frac{dist_{trans}}{v_{trans}} \cdot n_{ships} \cdot c_{trans,day} = \frac{dist_{trans}}{v_{trans}} \cdot \frac{m_{Fe,year} + m_{Fe_2O_3,year}}{m_v} \cdot c_{trans,day}. \qquad [\$/\text{year}] \tag{13}$$

3.3.5. Fixed capital cost

The fixed investment costs are based on the cost for the major equipment used in the process (i.e. within the given flow diagram in Fig. 2), which is a common way to derive appropriate estimates in early stages of process synthesis [13, 14]. The cost of each module is determined in dependence of the module size, i.e. the design variables introduced in Section 3.1. The estimated capital cost then results in the sum over all estimated equipment costs. The different components of the capital cost are briefly summarized in the following, for further details please refer to [13].

Costs are commonly represented as power law of capacity, i.e. the equipment cost C_E with capacity Q_E is given by $C_E = C_B\left(\frac{Q_E}{Q_B}\right)^M$, with known base costs C_B of the equipment with base capacity Q_B and an equipment dependent constant M.

Furthermore, the validity of economic data is highly dependent on the publishing date and therefore requires normalization to a common basis which can be done by the means of cost indices (e.g. Chemical Engineering Plant Cost Index (CEPCI) [15]). To account for different materials, design pressures, and temperatures, additional correction factors are used to determine the purchase costs of equipment. These factors include f_M for materials, f_p for design pressure, and f_T for design temperature. In addition, piping costs are accounted for with the factor f_{PIP}, while other direct costs, such as equipment erection and instrumentation, and indirect costs, including engineering and construction, as well as working capital are considered in the total cost calculation with the factor f_{misc}. This leads to the following representation of the fixed capital costs:

$$CC = \sum_j \left(\left(f_M f_p f_T (1 + f_{PIP}) \right)_j + f_{misc} \right) \frac{CEPCI_{year}}{CEPCI_{reference\ year}} C_{B,j} \left(\frac{Q_{E,j}}{Q_{B,j}} \right)^M. \qquad [\$] \tag{14}$$

3.4. Properties and assumptions

Modern ironmaking plants produce between 0.3 Mio and 3 Mio tons of iron per year [7]. Therefore, it is assumed that the continuous Fe_2O_3 feed into the reduction plant amounts 50 kg s^{-1}, leading to 34.97 kg s^{-1} of produced iron when assuming a fractional reduction degree of $X = 1$ and thus to 0.99 Mio tons/year when assuming 328 continuous operating days of the reduction plant and to 1.06 Mio tons/year when assuming 350 continuous operating days.

In the following, several properties and assumptions used in the model definition are summarized. Note that in the computation of numerical results (cf. Section 4.) for properties characterized by feasible ranges, as long as not stated otherwise, the mean value of the range is considered.

Thermodynamic properties such as molar masses are taken from [16]. In order to avoid an increase in the model complexity by modelling discontinuous piecewise polynomial representations for the temperature dependent enthalpy using NASA Glenn coefficients [16], a linear approximation for the enthalpy is computed and used to determine temperature independent constant specific heat capacity values.

When analyzing the numerical results, besides the already presented metrics also the energetic efficiency of the considered system will be assessed. This metric is defined by

$$\eta_{sys} = \frac{HV(Fe) \cdot \dot{m}_{Fe}}{(P_{el}^{electrolyzer} + P_{el}^{air\ fan} + P_{el}^{recycle\ compressor} + \dot{Q}_{therm}^{reactor})}, \tag{15}$$

i.e. the ratio of the energy stored in iron (given by the product of the heating value $HV(Fe)$ of iron and the produced mass flow rate of iron $\dot{m}_{Fe}$) and the total energy supplied to the process as defined in (12).

Table 2: General economic and transport assumptions

Variable	Value/Range	Reference
OPEX fraction γ of *CC*	6%	[13]
Interest rate i	5–8 %	[17]
Economic life time n	20–25 years	[17]
Price for RE c_{el}	0.01–0.10 \$/kWh	[18]
Operational days	328–350 days	[17]
Transport distance	3000–20 000 km	Assumption
Vessel size	160 000 t	[5]
Daily transport costs	5000–50 000 \$/day	[19]
Transport speed	624 km/day	[5]

3.4.1. Technological assumptions

Heat Exchangers

It is assumed that any heat loss originating from other components than the reactor is associated to the heat exchangers, i.e. the air heater, the iron oxide preheater, the hydrogen preheater and the condenser. It is estimated that between 1–5 % of the transferred heat will be lost to the environment instead of being transferred to the cold medium. Further assumptions concerning the heat exchangers are summarized in Table 3.

Cyclone

By assumption, all of the hot reduced iron is separated from the gaseous residual stream within the cyclone. While the cyclone is not specifically designed and optimized for this process, values from a high loaded hot gas cyclone given in [11] are used. Based on this design, the pressure drop is expected to be within the range of $\Delta p = 0.1 - 0.2$ bar.

Electrolyzer

The system efficiency based on the lower heating value of the electrolysis is predicted to be in the range of 50-74 % according to IEA and IRENA [20, 21]. In this use case an efficiency of $\eta = 71\%$ is assumed.

Compressors

For the air fan and the recycle compressor an isentropic efficiency of $\eta_{is} = 85\%$ and an electrical drive efficiency of $\eta_{mot} = 95\%$ is assumed. The heat capacity ratio κ as in (3) is assumed to be $\kappa = 1.4$ for both, the air compressor and the hydrogen recycle compressor.

Table 3: Heat exchanger assumptions including type, pressure drop Δp and heat transfer coefficient U

Component	Type	Δp [bar]	U [W m^{-2} K^{-1}]	References
Iron Oxide Preheater Air Heater	Bulk solid heat exchanger	0.14	100-144	[22–25]
Hydrogen Preheater	Alternating regenerators	0.14	6	[11]
Condenser	Tube and shell	0.05	300-1200	Assumption / [11, 22]

3.4.2. Economic assumptions

As presented in Section 3.3.5. the fixed capital cost includes several correction factors and economic indices for cost normalization. The correction factors are chosen according to [13] and take the following values. For all components except for the electrolyzer the material correction factor f_M is assumed to be f_M = 3.4 (high grade stainless steel), the pressure correction f_p = 1.0, the piping correction factor f_{PIP} = 0.7 and the remaining factors are summarized in f_{misc} = 5.1. The electrolyzer and associated periphery costs are directly taken from the literature. Consequently, the correction factors are set to $f_M = f_p = f_{PIP}$ = 1.0 and f_{misc} = 0. In order to account for potential high process temperatures, a correction factor for temperature is extrapolated based on values given in [13]: $f_T = \max(1,\ 2.75\,^{\circ}\mathrm{C} \cdot 10^{-3} \cdot T_{max} + 0.742)$ with T_{max} denoting the maximum process temperature for each component. The costs are normalized to the year 2021 using the CEPCI of 708.0 [15]. All base costs, base capacities, reference years and indices can be found in Table 4. According to [20, 21] the electrolyzer capital cost can be estimated to be in the range of 450-1400$/kW multiplied by the electric power.

Table 4: Capital costs of equipment; the hydrogen preheater costs are based on [26], the cost of the electrolyzer is estimated based on [20, 21] and the cost functions of all other components are based on [13]

Component	Ref. year /CEPCI	$C_{B,j}$[$]	$Q_{B,j}$	M	$C_{E,j}$
Iron Oxide Preheater Air Heater Condenser	2000 / 391.1	$3.28 \cdot 10^4$	80 m^2	0.68	
Air compressor Recycle Compressor	2000 / 391.1	$9.84 \cdot 10^4$	0.25 MW	0.46	$\frac{CEPCI_{2021}}{CEPCI_{reference\ year}} C_{B,j} \left(\frac{Q_{E,j}}{Q_{B,j}}\right)^M$
Reactor	2000 / 391.1	$1.15 \cdot 10^4$	5 m^3	0.53	
Hydrogen Preheater	1981 / 297.0	$0.85 \cdot 10^6$	6555 m^2	0.6	
Electrolysis	–	–	–	–	925 \$/kW$_{el}$ $\cdot P_{el}$

4. Numerical results and discussion

The presented techno-economical model with the introduced *LCOI* (cf. (9)) as objective is optimized using mathematical optimization algorithms in order to obtain the optimal process design and operation of the reduction plant for varying economic assumptions (i.e. price for RE, *CRF*). Given the significant variation in RE prices depending on the location and type of renewable energy plant [18], and the sensitivity of annualized capital costs to the *CRF* - and consequently to the assumed interest rate and economic lifetime - the impact of these economic constraints on the *LCOI* and the resulting optimized plant designs is evaluated. It should be noted that the *LCOI* is primarily influenced by the total capital cost (*CC*) in terms of both capital expenditure (*CAPEX*) and operating expenditure (*OPEX*), as well as the yearly energy consumption in terms of C_{el}. Additionally, the transportation costs (C_{trans}) and annual iron production ($m_{Fe,year}$) are indirectly impacted by the yearly energy consumption, as the energy consumed during the electrolysis process determines the quantity of produced iron, which subsequently affects the mass fractions of unreduced iron oxide and produced iron, ultimately influencing the transportation costs. Therefore, it is expected that the solutions, obtained by minimizing the *LCOI*, represent trade-offs between the yearly energy consumption and the total capital cost. To investigate and quantify this trade-off, the optimization is performed multiple times with varying values for c_{el} and *CRF* weighting the yearly energy consumption and the total capital costs in the objective function.
The resulting optimization problem is implemented using PySCIPOpt [27], an interface to the mixed-integer nonlinear problem solver SCIP [28], relying on a spatial branch-and-bound algorithm.
Although SCIP is able to perform global optimization, the following results could not be certified to be global solutions within reasonable time due to the complexity of the model characterized by nonlinear model equations as well as the discretized ODE constraint presented in Section 3.2. The solutions are obtained by a local NLP solver used as heuristic in the SCIP framework and therefore constitute local optimal solutions.

4.1. Fixed CRF and varying energy costs

In a first step, the optimization problem is solved for varying energy costs $c_{el} \in \{0, 10, 55, 70, 100, 150, 200\}$ [$/MWh] with a fixed *CRF* $\approx$ 0.085, i.e. assuming an economic life time of n = 23 years and an interest rate of i = 6.5%. The obtained objective values and the corresponding shares of *CAPEX*, *OPEX*, energy and transport costs are depicted in Fig. 3. The resulting *LCOI* varies between 0.05 \$/kg iron and 0.68 \$/kg iron. As to be expected there is a close to linear relation between the energy price and the resulting *LCOI*. The variance in the *LCOI* showcases the high dependency of the competitiveness of the investigated process on suitable locations with low prices for RE. The figure also shows that the transportation costs play an insignificant role for the *LCOI*. This suggests, that it could be beneficial to choose reduction locations with rather high transport distances if in return RE is available at low prices. The results further show that at high prices for RE (e.g.

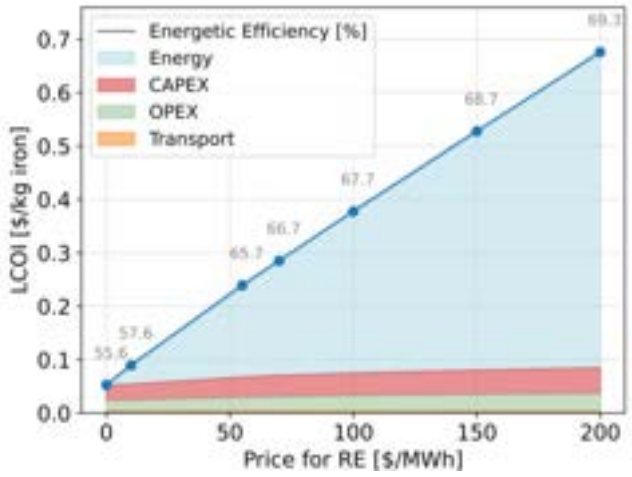

Figure 3: Objective values obtained by minimizing the *LCOI* with a fixed *CRF* ≈ 0.085 and varying values for the energy cost c_{el} of RE

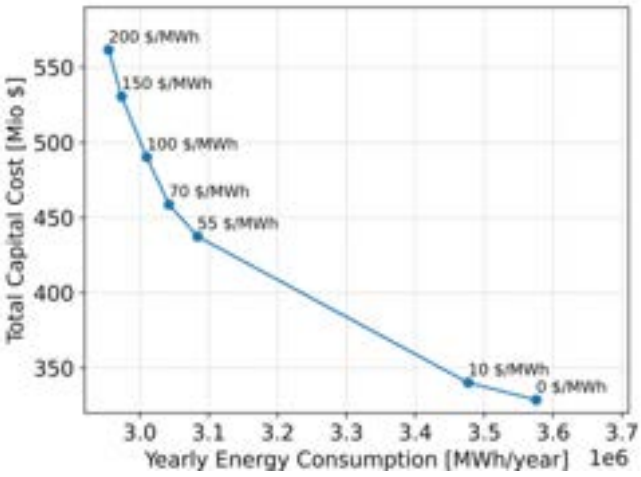

Figure 4: Yearly energy consumption versus total capital cost at the optimization solutions for fixed *CRF* and varying values for c_{el}

200 \$/MWh), energy costs are dominant, accounting for a significant percentage (87.5%) of the *LCOI*. In contrast, at low energy prices (e.g. 10 \$/MWh), a balance is observable between energy and equipment-related costs, with energy costs contributing 39.8% to the *LCOI*. Additionally, with increasing cost for RE, also the energetic efficiency of the system increases from η_{sys} = 55.6% to η_{sys} = 69.3%. For further analyses Fig. 4 shows the relationship between the yearly energy consumption and the total capital cost for the different values of c_{el}. The results indicate that as the price for RE increases, process designs with lower energy demands (and therefore higher energetic efficiencies), but higher total capital costs (due to larger component dimensions) are economically more advantageous. This suggests that an optimal design of the considered reduction plant represents a trade-off between the yearly energy consumption and the total investment costs and is highly dependent on the cost assumptions for RE.

The optimal design variables illustrate the described behaviour. With increasing c_{el} the reactor volume increases from 1574 to 5519 m^3 and the fractional reduction degree X increases from 94.6% to 97.6%, while the reactor temperature remains constant at 1423 K and the hydrogen equivalence ratio λ_{H_2} only varies slightly between 2.55 and 2.32. The increase in the reduction degree is directly related to an increase in the required electrical power $P_{el}^{electrolyzer}$ of the electrolyzer. The condenser area shows an increase from $0.73 \cdot 10^3$ to $1.53 \cdot 10^3$ m^2, the air preheater area an increase from $0.03 \cdot 10^3$ to $3.56 \cdot 10^3$ m^2 and especially the hydrogen preheater an increase from $1.53 \cdot 10^3$ to $55.4 \cdot 10^3$ m^2. The increasing dimensions of the design variables account for the higher total capital cost with increasing RE prices. Regarding the yearly energy consumption, the values for the recycle compressor and the air compressor only vary little, and the yearly energy consumption of the electrolyzer increases from 2.46 to 2.54 TWh due to the increasing reduction degree as explained before. However, the yearly energy consumption of the external heat supply for the reactor decreases from 1.1 to 0.4 TWh. This leads to the overall decreasing yearly energy consumption for increasing RE prices.

Upon examining the shares of the total capital cost of each component, as depicted in Fig. 5, it can be noted that in a scenario where RE is free of charge, the electrolyzer comprises over 80% of the investment cost. As the cost of RE increases, the proportion of investment cost attributed to the electrolyzer declines, yet it still constitutes over 50% of the investment cost at the highest considered cost for RE. Furthermore, the electrolyzer is responsible for nearly 70% of the yearly energy consumption with c_{el} = 0 \$/MWh and for more than 85% with c_{el} = 200 \$/MWh. Considering that the electrolyzer incurs substantial capital costs and energy demand, it has the highest potential for reducing energy demand, capital costs, and consequently the *LCOI* through technological improvements.

Although the costs for turbo-machinery are negligible, the cost shares of the heat recovery equipment, including the air heater, the iron oxide preheater, and the hydrogen preheater experience a significant increase with increasing costs of RE. As the sizes of the associated heat exchangers increase, along with their corresponding costs, a greater amount of the available sensible heat within the reactor effluents can be recovered, resulting in decreased energy dissipation in the condenser and lower residual energy within exiting streams. Ultimately this leads to a reduced energy demand of the reactor. Especially the regenerative hydrogen preheater plays a crucial role for the heat recovery and the reduced energy demand, which is reflected by its increasing share of the capital costs for higher energy costs.

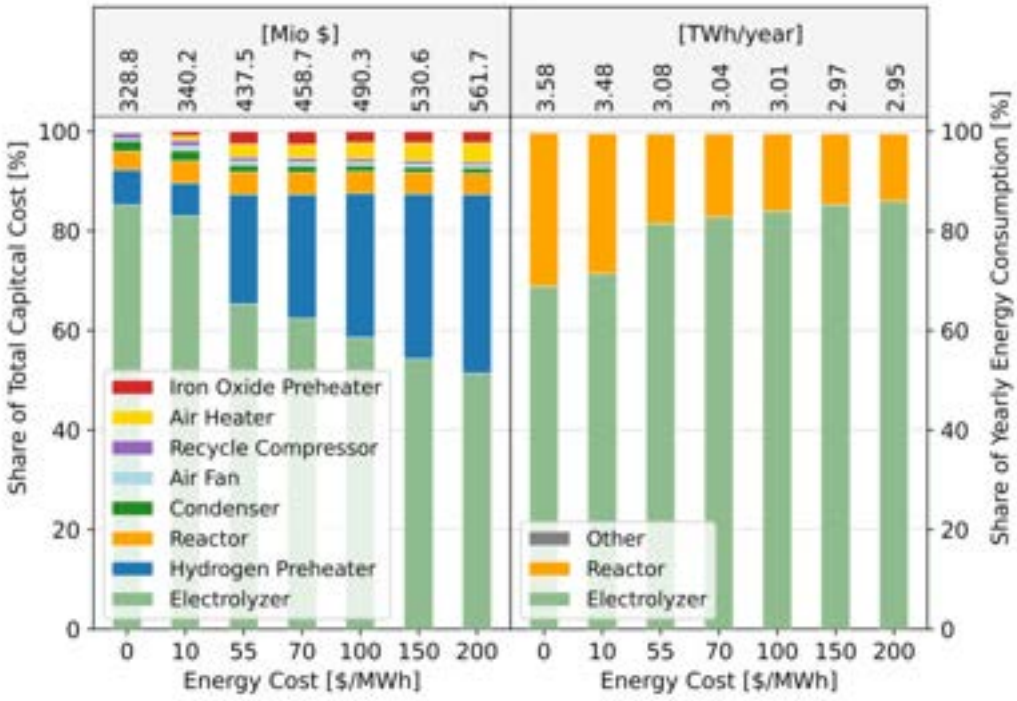

Figure 5: Components' shares of the total capital cost and the yearly energy consumption at the optimization solutions for fixed *CRF* and varying values for c_{el}.

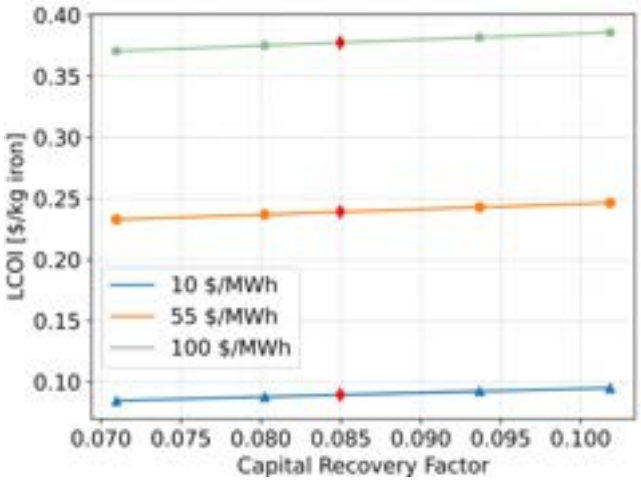

Figure 6: Objective values obtained by minimizing the *LCOI* with varying values for $CRF \in \{0.071, 0.080, 0.094, 0.102\}$ and $c_{el} \in \{10, 55, 100\}$ [$/MWh]; red diamonds represent base *CRF* (n = 23 years, i = 6.5%)

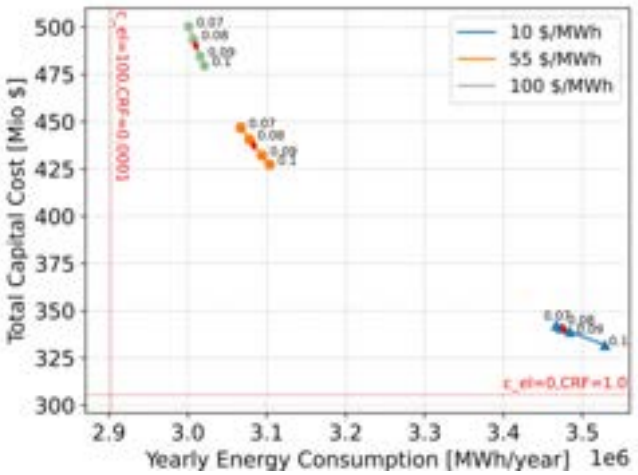

Figure 7: Yearly energy cost versus total capital cost at the optimal solutions for varying values of *CRF* and c_{el}; red diamonds represent base *CRF* (n = 23 years, i = 6.5%); lower bounds obtained by optimization with the specified parameters

4.2. Varying CRF and varying energy costs

As mentioned earlier, the impact of capital costs on the *LCOI* is significant at low to moderate prices for RE. However, the annualized capital costs demonstrate high sensitivity to the assumed *CRF*, and thus, to the assumed interest rate and economic lifetime. To address this uncertainty, the optimization problem was solved for varying energy costs $c_{el} \in \{10, 55, 100\}$ [$/MWh] and varying values for $CRF \in \{0.071, 0.080, 0.094, 0.102\}$ corresponding to economic life times of n = 20 and n = 25 years and interest rates of i = 5 and i = 8%. Figure 6 shows the obtained objective values for the different RE costs in dependence of the *CRF* values together with the *LCOI* for the base case (n = 23 years, i = 6.5%, red diamonds) considered in the previous section. Again

an expected nearly linear relation and a clear shift depending on the energy cost is observable. For c_{el} = 10 \$/MWh, the *LCOI* depending on the *CRF* varies between 0.085 \$/kg iron (-5.5% compared to base *CRF*) and 0.095 \$/kg iron (+6.1% compared to base *CRF*), for c_{el} = 55 \$/MWh between 0.233 \$/kg iron (-2.6%) and 0.246 \$/kg iron (+3.1%) and for c_{el} = 100 \$/MWh between 0.371 \$/kg iron (-1.8%) and 0.386 \$/kg iron (+2.2%) demonstrating the sensitivities of the *LCOI* depending on c_{el} and *CRF*. The results show that the relative impact of the *CRF* assumptions increases for low RE prices.
In addition, the total capital cost is plotted against the yearly energy consumption in Fig. 7 for the varying values of *CRF* and c_{el}. It can be seen, that the total capital cost decreases with increasing values of *CRF* and decreasing values of c_{el}, whereas the yearly energy consumption increases with increasing values of *CRF* and decreasing values of c_{el}. This again indicates the trade-off between the total investment costs and the yearly energy consumption mentioned before. The red lines show the lower bounds for the total capital cost and the yearly energy consumption. On the one hand, the lower bound for the capital cost is obtained by solving the optimization problem with c_{el} = 0 and *CRF* = 1.0, resulting in *CC* = 305.6 Mio \$/year. On the other hand, the lower bound for the yearly energy consumption is obtained by solving the optimization problem with c_{el} = 100, *CRF* = 0.0001 and γ = 0.0 (*OPEX* fraction of *CC*), resulting in a yearly energy consumption of 2.9 TWh/year. These extreme cases result in energetic efficiencies of η_{sys} = 71.6% for high c_{el} and low *CRF* and η_{sys} = 55.4% for low c_{el} and high *CRF* underlining the strong dependence of the optimal process design on the economic boundary conditions and showing the techno-economic limits (highest achievable efficiency vs. lowest achievable capital cost) for the investigated reduction plant.

5. Conclusion and outlook

This work has presented a techno-economic analysis of an innovative reduction plant, based on the flash ironmaking technology, that could be part of a circular energy economy allowing the large-scale storage and transport of RE using iron as energy carrier. The assessment was performed with the goal of investigating the influence of changing economic boundary conditions (price for RE, *CRF*) on the economically optimal process design.
Based on the performed analyses, it can be concluded that the price for RE has a significant impact on the *LCOI*. The resulting *LCOI* varies between 0.05 \$/kg iron and 0.68 \$/kg iron for energy costs between 0 \$/MWh and 200 \$/MWh, respectively. The investigation reveals that changing RE prices lead to noteworthy differences in design parameters such as component dimensions. As the cost of RE rises, effective heat recovery becomes increasingly important with respect to the *LCOI*, resulting in higher capital costs due to larger equipment, but lower energy demands and higher energetic efficiencies (η_{sys} = 55.6% to η_{sys} = 69.3%). In addition, the results emphasize that access to low-cost RE can offset the expenses linked with long-distance transportation. Since RE costs outweigh transport costs, it can be inferred that selecting appropriate reduction sites with access to affordable RE is crucial. Varying *CRF* values (i.e. economic lifetime and interest rate) further reinforce the trade-off between total capital costs and yearly energy consumption, even though the influence of the considered *CRF* values is less prominent than the change in RE prices. Yet, for lower RE prices, the relative effect of changing *CRF* assumptions increases.
Throughout the analysis, the reduction plant was assumed to operate continuously for a fixed number of operating days, assuming continuous availability of RE. However, due to the volatile nature of RE availability, intermediate storage options for green hydrogen and/or RE are necessary to ensure the continuous operation of the reduction plant. In future work, the model will be expanded to integrate such storage options and to couple the reduction plant model with models for RE systems, such as photovoltaic and wind power plants. This would enable the optimization of the entire storage process for the iron energy cycle and result in location specific optimal designs, based on different geographic locations and their RE potential. Additionally, considering uncertainties, e.g. fluctuations in the price or availability of RE, and applying robust optimization strategies to obtain robust process designs, would be a valuable direction for future research.

Abstract:

Using the exhaust gases from the steel mill generation to produce chemicals can be a promising carbon capture and utilization (CCU) concept. Applying the model-based mathematical approach with mixed-integer linear programming (MILP) makes it possible to determine the optimal production pathway. However, the MILP aims the uncertain future to evaluate the long-term feasibility. It requires a hypothetical construction to show possible future states. This study aims to develop scenarios as input data for MILP models, representing a comprehensible future description. The investigation domains are determined as the technical, economical, and ecological perspectives to fulfil the multi-criteria evaluation. The factors from domains are projected qualitatively and quantitatively through objective estimations. The mutual relationships between the factors from the different domains such as the electricity price, Carbon footprint, and technical efficiency are implemented properly. The result is represented as five different scenarios: (1) Business as usual (BAU), (2) CO_2 reduction & RE share target (RE-Boom), (3) Technical improvement & Market booming (Market-Boom), (4) Energy & Market crisis (Crisis) and (5) Hydrogen booming (H_2-Boom). The scenarios depict the meaningfully different condition of the CCU concept with the most consistent and plausible combination of the key factors. Additional remarkable results from this study are the rough estimations of the initial capital and operating expenditures through the independently developed method. Consequently, the generated scenarios can be used for MILP models to promote the transparency and traceability of the further decision-making process.

Keywords:

Carbon Capture and Utilization; Multi-criteria Evaluation; Renewable Energy; Scenario Development.

1. Introduction

This study investigates a CCU concept which couples the carbon-emitting steel industry with the chemical and energy industry [1]. Exhaust gases from the blast-furnace, coke oven and basic-oxygen furnace containing large amounts of carbon monoxide, carbon dioxide, methane, hydrogen, and nitrogen serve as raw materials to produce chemicals. Hydrogen is identified as the limiting reactant. Therefore, external supplements utilizing renewable energy (RE) are required to increase its quantity. The exhaust gas can be used to produce products for different markets like methanol (MeOH), acetic acid (AA), ammonia (NH_3) and urea.

The implication of this concept is in a less developed phase. It is still being determined the technical layout of the plant, profitability, and potential environmental impacts. For this reason, a model-based mathematical approach with MILP is suggested to evaluate the long-term feasibility of the system [2]. The target of the MILP model is to find the optimal producing pathway, which includes technologies, design, and time dependent operation conditions. However, the MILP aims for an uncertain future, so the results are depending on the given future situation. From this perspective, this study aims to develop reliably formulated scenarios as input data for MILP. The optimal pathway is represented differently depending on the scenarios. A scenario is presented as a specific part of the future by considering relevant key factors rather than a comprehensive picture. Combining individual factors forms the space of common development of all these aspects. The expanding slice of future developments is described with the scenario funnel in Figure 1.

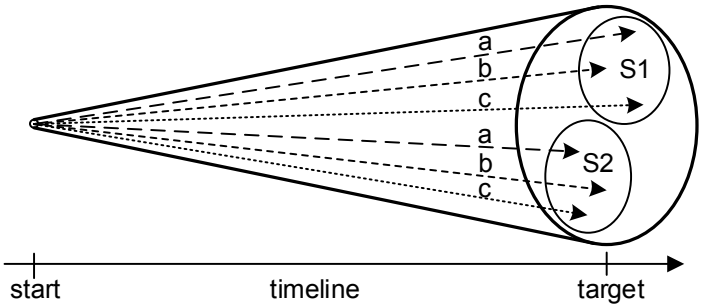

Figure. 1. Scenario funnel for representing the developments from a specific start time to a target time.

Different scenarios in Figure 1, here S1 and S2, now depict the different future possibilities in the target year from the start. For that, the possible projections of the different key factors (a, b, and c) are selected and condensed into scenarios. It should be noted that the meaning of the projection is not identical to the "forecast", which claims the actual probability of the occurrence, but the hypothetical construction to implicitly refer to the possibility of alternative futures [3].

There are some approaches to utilize the scenarios in this CCU context. Here, a short overview of recent contributions and preparatory work in the investigated field is given.

Stießel et al. [4] utilize a single scenario for the target year, 2030. The main target of the research is to identify cross-industrial process concepts of a CCU approach. The authors focus on external influences to formulate the scenarios. The process concept is evaluated in specific desired operating conditions by forcing the factors to be eco-friendly projected. Schlüter et al. [5] investigate a process concept of using steel mill exhaust gases for chemical production in three different operating conditions. The scenarios are developed focusing on the internal technical perspectives. The results are analyzed under time-dependent boundary conditions; thus, the limiting factors for the binding of carbon are identified. Sadlowski et al. [6] discuss the ecological potential of flexible methanol production from steel mill exhaust gases with a MILP model. The authors set up scenarios with three key factors which are external H_2 production, power supply sources and storage capacities. The outcomes are analyzed based on the carbon binding potential for this CCU concept.

In contrast to the concept of recent publications which focusing on a specific perspective to evaluate the CCU approach, the objective from the present work is extended to a multi-criteria evaluation with three different domains. It can be understood as a new and novel approach as the complicated relationships between the different domains are implemented. This approach of scenario development clearly shows the huge difference from the previous studies as it offers more comprehensive future descriptions. In other words, the generated scenarios can be utilized to evaluate the genuine feasibility of the CCU concept with a MILP model.

2. Properties of scenarios for a MILP model

All interconnections for the various technologies and exhaust gas conditions are implemented in the MILP model (e.g., reactors, storages, compressors, separators etc.). The options to be the final products are also set up in the decision point [2]. A detailed description of the model can be found in [6]. The outcome of the model is the optimal pathway, including the selection of technology, products, design and operation of the plants, and it depends on the given future states in form of scenarios.

The generated scenarios from this work can utilized as the input data in a linear optimization model. For that, they involve the special properties which are clearly different from the general scenario development.

First, the scenarios from this study are formulated based on the multi-criteria evaluation. Considering diverse internal and external influences brings reliable results about the technical plant's feasibility, investment decisions, or environmental effects. Secondly, projecting the selected factors from three domains involves the quantitative value in either numeric or linear dependencies to suit the feasibility. The quantitative values are assumed through the independently developed method or mathematically created functions. Finally, the individual relationship between the factors is examined through the software-based method. The cross-impact analysis (CIA) is conducted to find the most consistent and plausible combinations of factors.

3. Scenario development process

An existing method for scenario development is adapted to consider the functions of the scenarios. Based on the scenario technique from von Reibnitz [7]. A modified modelling concept involving the exploratory and quantitative approach is created for generating the five multi-criteria scenarios.

3.1 Premise

Scenario-specific assumptions for further considerations are defined within the premise. The definitions are supplemented by the boundary conditions to form a basis for the scenario development. Table 1 shows a short description of the determined premise.

Table 1. Short overview of the scenario-specific premises.

Parameters	Premise
Time Horizon	25 years (5 years construction + 20 years' operating life span)
Target year	2040 (middle of operating life span)
Maximum generation	40 % of the market volume [8, 9]
Market boundary	European market model
Discount rate	Constant as 2 % annually for life span
Technical parameters	Given from previous studies and project work

The time horizon of the CCU system is estimated as 25 years, with five years of construction and 20 years life span – operating from 2030 to 2050. The target year is 2040, the middle of life span. The maximum generation is restricted under German competition law prohibiting market dominance [9]. The market share-based presumption provides a first indication of dominance where a company's market share exceeds 40 percent [8]. Therefore, the maximum chemical product quantity is 40 percent of its market volume. The overall market assumption in scenario development is based on the system boundaries of and the cross-border trade with European neighbours. The profitability assessment requires the revision of the future cash flows to be compared with the current capital value. The discount rate is assumed to be constant at 2 % annually during the whole amortization period. The technical parameters like possible plant connections, efficiencies, reaction conditions, exhaust gas amounts etc. are given from previous studies, project work and own calculations.

3.2 Key factor selection

First, the domains of influence are determined. For such environmental and energy scenario development, economic, political, ecological, technical, and social influence domains are suggested in practice [10]. However, the social and political influences are excluded from our scenario boundary. The CCU concept can be sensitively affected by adverse social acceptance, which may give policymakers a false sense of security, leading to even a rebound effect [11]. Nevertheless, they are not suitable for our scenario's target. First, the factors from these aspects are often measured in a qualitative approach. For example, political inclination may function importantly in evaluating the feasibility but is formulated qualitative rather than exact values (e.g., left and right orientation). Secondly, the issues depend on subjective assessment. For example, the social acceptance and benefit of CCU concepts can be understood totally different. Based on these reasons, the technical, economic, and ecological domains are determined as the investigation fields' demarcation.

In a first step, 106 internal and external influencing factors from the domains are determined. The importance of the influencing factors is identified through influence analysis. A detailed explanation of the method can be found in [3]. The influence analysis examines the relationships between the factors. All possible pairs of factors are measured on a four-level scale from 0 (no effect) to 3 (strong effect) regarding their mutual impact [10]. As a result, each influencing factor is represented with its active and passive sum. The factors with a high active sum are selected as key factors out of the 106 influencing factors since they have the biggest influence of the overall system [7]. This procedure leads to the final 24 key factors to set up further scenario development.

3.3 Reference scenario

The reference scenario assumes that there will be no new measurements by the target year [10]. The logic is also called "Business as usual" (BAU). The current values are based on well-founded knowledge. Extrapolations in the target years (2040 for operating time and 2025 for investing time) are suggested by a meta-study of different reports about energy and chemical market development scenarios. If a reliable development is unavailable, the assumptions made through trend analysis. It is carried out by collecting historical data as long as possible, and past trends are extended to the future [3].

The time series of the electricity price in 2040 are derived from a forecasting model [12]. This model assumes an energy-only market and calculates the operating plans of the power generation systems. The projected time series of the carbon footprint CF_t for future energy production and RE_t share for 2040 is determined based on the CF_t in 2020 derived with historical data from AGORA [13]. The future CF_t is calculated based on the hourly based data from 2020 and the varied fraction of *RE* share in the German grid mix according to Eq. (1):

$$CF_{t,2040} = CF_{t,2020} \cdot \frac{(100 - RE_{t,2040})}{(100 - RE_{t,2020})} \quad (1)$$

The exemplary results of the projected time series of the CF_t are shown in Figure 2. Figure 2(a) shows the dimensionless sorted annual CF_t of the year 2020 (*RE* = 48 %) and the projection to reference scenario of 2040 (*RE* = 85 %). Figure 2(b) shows an example of a two-week period of the CF_t. The average value for the reference scenario is projected to ca. 110 g_{CO2}/kWh_{el}. Electricity prices are calculated in a similar way.

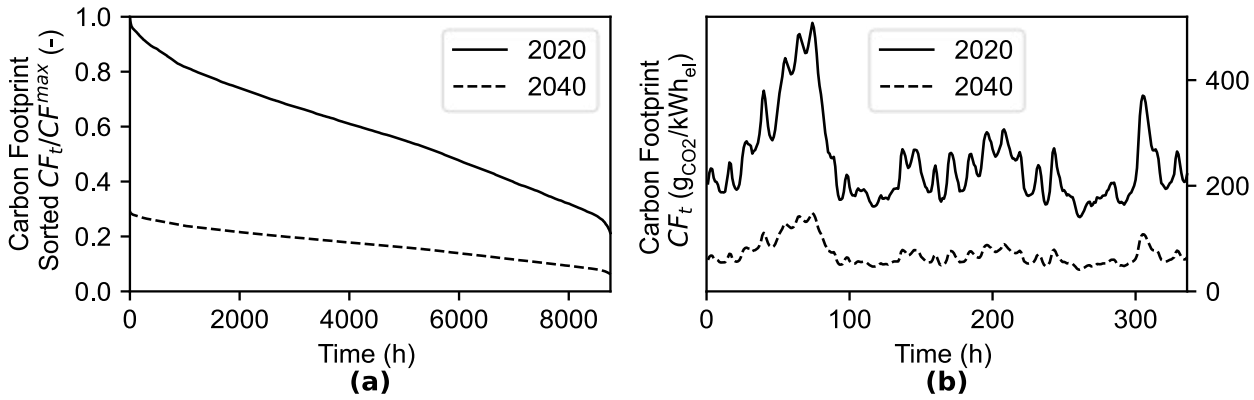

Figure. 2. Time series of carbon footprints (*CF*) for 2020 (48 % *RE*-Share) and BAU projection to 2040 (85 % *RE*-Share): a) Sorted annual dimensionless *CF*, b) exemplary two-week period of the *CF*.

It is necessary to specify fuel prices for natural gas and coal, as well as the CO_2 certificate prices to determine the marginal cost. The prices in the target year are taken from the EU [14] and Bloomberg [15]. H_2 price plays an important role in defining the potential of *RE* and green electricity. The price is derived from the IEA [16].

Market prices of the chemicals are the biggest part of the revenue. Oxygen as by-product from water electrolysis is also considered a part of revenue. The prices are assumed by the trend analysis based on the historical data from 2019 to 2021. Plus, the chemicals' market volumes dramatically affect the size of the plant and expenditure as the maximum generation is regulated by 40 % of the market share limit. They are taken from the IEA [17].

Table 2 shows the data of the most probable BAU scenario. Data from technology domain are shown as relative value (1 = no changes) and are derived from project internal communications and plant development reports. The H_2 generation is a crucial aspect of the system. Therefore, H_2 efficiency, the electricity required to generate the external carbon-free H_2, is considered as a separate factor from the overall energy requirement.

Table 2. Key factors and their values of the reference business-as-usual (BAU) scenario.

Class	Key factor	Current value	Source	BAU-value	Unit
Input	a. Electricity price	41.3	[18, 19]	47.4	€/MWh
	b. Natural gas price	31.4	[19]	46.7	€/MWh
	c. Coal price	7.5	[19]	11.8	€/MWh
	d. H2 price	3000	[16]	2400	€/t

	x. Operating cost	1.0	[27]	1.0	-

The target year of the capital expenditures (CAPEX) is set as 2025 following a five-year construction period. CAPEX is calculated for each plant, including the gas conditioning, external H_2 production and chemical synthesis plants. Calculation is based on the capacity method [27]. The CAPEX of a plant C_b and its capacity

S_b is estimated based on the reference CAPEX C_a and its capacity S_a [27]. The reference data is taken from various techno-economic analysis studies and the C_a is extrapolated to the target year of investing 2025. It is extrapolated to 2025 value by applying the chemical engineering plant cost index (CEPCI), as i, to account for inflation rate. The publication years of the studies are between 2006 to 2021. Original CAPEX C_0, capacity S_a and CEPCI i_0 for all technical plants and years are used or derived from these studies. The CEPCI value for the year 2025 i_a is determined through trend analysis from the last five years. Therefore, the reference CAPEX C_a is calculated with Eq. (2):

$$C_a = C_0 \cdot \frac{i_a}{i_0} \tag{2}$$

The CAPEX development of the hydrogen production plants is assumed to be lower in the future. According to [28], it is assumed that the CAPEX for alkaline (ALK) and proton-exchange membrane (PEM) electrolysis are reduced by 14 % and 22.5 % in next five years, caused by reduced manufacturing costs and assumed technological breakthroughs. Based on the updated C_a to 2025, the C_b is calculated via the capacity method in Eq. (3). Where f is the degression coefficient for the economy of scale for chemical plants with a value from 0.6 to 1.0.

$$C_b = C_a \cdot \left(\frac{S_b}{S_a}\right)^f \tag{3}$$

However, the final S_b of the plant is not determined in the scenario development process. Therefore, the C_b of the individual component is represented as the function within possible installed capacity range of S_b^{min} and S_b^{max}. The C_b^{max} of S_b^{max} is where the exhausted gas utilization is maximized based on the market restriction. It should be noted that the S_b^{max} of each plant is differently estimated depending on the final products due to the varied size of the market volume. C_b^{min} is assumed to be 10 % of C_b^{max}. Lower than 10 % of C_b^{max} it's not worth to install these plants because a significant emission reduction is required for the CCU concept. Table 3 shows the range of S_b and C_b of a water gas shift (WGS) plant for each chemical as an example.

Table 3. Range of S_b (capacity) and C_b (CAPEX) of possible water gas shift plants for each chemical.

Final product	S_b^{min}, kg/s	S_b^{max}, kg/s	C_b^{min}, M€	C_b^{max}, M€	Market volume, Mt/a
Acetic acid	2.33	39	0.88	8.8	2.1
Urea	5.2	86	1.7	17	3.9
Methanol	7.2	120	2.2	22	5.4
Ammonia	22.7	376	5.7	57	15.3

The C_b should be represented in a full range of the plants S_b regardless of the production route. In the case of WGS plant, then, the CAPEX is resulted in the function within the overall range of S_b from 2.33 to 376 kg/s.

If f of the component is less than 1 like WGS plant (0.82), the C_b is a root-function. The MILP model requires linearity of C_b and therefore should be revised as a linear approximated function $C_{b,lin}$. The linearized functions maximum relative error tolerance from the original C_b is set as 10 %. If this doesn't match, an additional sampling point for piecewise linear approximation is considered till it reach the <10 % criteria. In the case of the WGS plant, two linear functions are generated with one piecewise sampling point and a maximum relative error of 7.4 %. Figure 3 presents the original C_b function on the left side and the derived piecewise linear functions $C_{b,lin1}$ and $C_{b,lin2}$ on the right for the WGS plant.

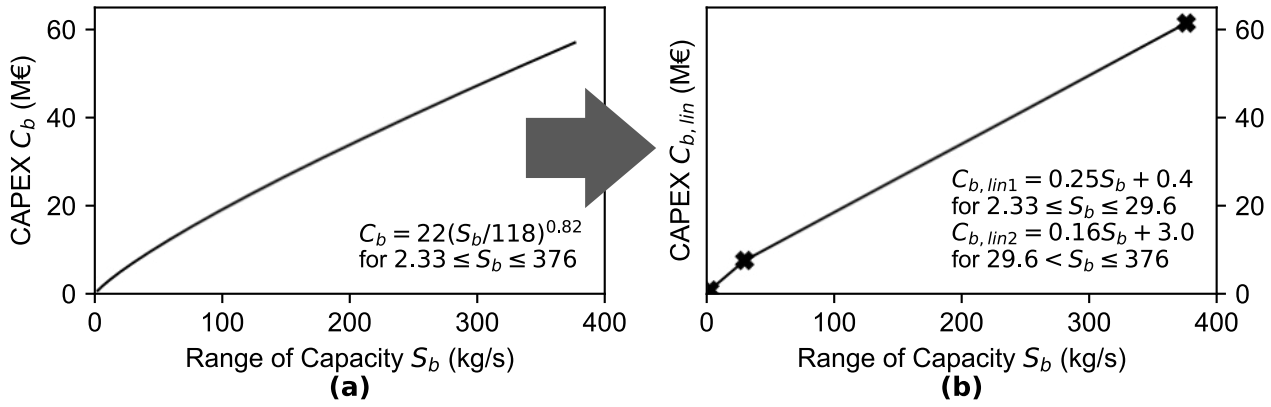

Figure. 3. CAPEX functions of WGS plant: a) Cost function through capacity method C_b, b) linearized cost functions $C_{b,lin}$.

Other plants CAPEX is calculated in a similar way. The maximum relative error is detected in NH_3 synthesis plant as 9.4 %. The range of CAPEX for each plant, regardless of the production pathway, is generated.

The operating cost (OPEX) is the expenditures incurred in the plant. It considers the variable, fixed, and other costs of the system. The variable costs, including the raw and auxiliary materials, are calculated differently depending on the operating time and final production pathway. The fixed and other costs are structured based on [29]. The projected OPEX in BAU scenario is estimated to be constant by the target year.

3.4 Future projection

Each key factor is projected into the future in alternative states. Qualitative projections are created at first. This includes the possible projections of highly decreasing (↓↓), moderately decreasing (↓), constant (-), moderately increasing (↑) and highly increasing (↑↑). Not all projections make sense (e.g., decreasing projection of CO_2 certificate price) so the number of varied projections differs between three or five depending on the key factor. As mentioned, each projection involves quantified numerical values. If the data from the BAU scenario is available, the projection is based on it. The variation rate from the current value to fixed projection of the BAU scenario is applied to other alternative projections identically.

It should be noted that some key factors involve deliberately exaggerated or passive quantification. The factors that contain exaggerated quantification is the “driving factor”. The extreme value of these driving factors brings a clear difference from other projections. On the other hand, the passive quantification is for the case that the value from the BAU scenario is over-predicted. The scenario which involves the projection may cause discord with other elements. Thus, they are quantified at a lower variation rate. Passive quantification makes the combination of the factors more consistent.

If the data from the reference scenario is unavailable, it is quantified based on the independently estimated assumption. For example, the H_2 efficiency has an improving rate of 5 % for projection (↑) and 10 % for (↑↑), according to [16]. The factors, conversion efficiency and energy efficiency, are assumed to be identical in improving rates of H_2 efficiency. It is not plausible to assume that they have greater improvement than external H_2 supplements because these plants are at a state-of-art level.

The investment cost is projected through the independently generated method. A scaling factor, “*s-factor*”, is applied to the generated $C_{b,lin}$ function of each plant to switch the range of CAPEX by multiplying itself. The *s-factor* is derived from the water electrolysis’ CAPEX as it is available to get reliable data on future development. Plus, it can be compared with the current CAPEX as the *f* is equal to 1 - It is not affected by the varied size of the capacity. Table 4 presents the assumed CAPEX of ALK and PEM in diverse future situations.

Table 4. Development of specific CAPEX of ALK and PEM water electrolysis in varied situations.

Unit	Current CAPEX	BAU CAPEX	Future situation	CAPEX in future	**Rate**	Unit	Current CAPEX	BAU CAPEX	Future situation	CAPEX in future	**Rate**
			Pessimistic	1.0	**1.16**				Pessimistic	1.0	**1.29**
ALK	1.0	0.86	Regular	0.79	**0.92**	PEM	1.0	0.775	Regular	0.66	**0.85**
			Optimistic	0.72	**0.84**				Optimistic	0.55	**0.71**

* Rate is the variation rate of future CAPEX from the BAU CAPEX, and it functions as the *s-factor*.
* The higher *s-factor* demonstrates the higher initial expenditures.

In the BAU scenario, the specific CAPEX for ALK and PEM is estimated to be decreased to 86 % or 77.5 % by the target year, respectively [28]. In a pessimistic future, the CAPEX is assumed to be constant as the current value. A regular projection assumes 50 % higher decreasing rate of the CAPEX than the BAU scenario. In the optimistic situation, the decreasing rate is doubled by the BAU scenario. The variation rates of future CAPEX from the BAU CAPEX are the *s-factor.* They are applied to all considered plants of the CCU concept depending on the scenario concept and the result of a cross-impact analysis. Through the process, the range of the component’s CAPEX is newly assigned for each scenario. Another external H_2 supplement option, methane pyrolysis (MP), is applied an identical *s-factor* with the ALK.

3.5 Scenario formation

Based on the projections of key factors, the actual formation of scenarios takes place. The scenario technique of cross-impact analysis (CIA) is applied to ensure consistent combinations [10]. The CIA analyses the relationships between the key factors and the probabilities of occurrence of future events by considering their direct and indirect mutual effects [30].

A cross-impact matrix is first created, which assesses the conditional probability of specific projections if another future event has occurred according to the seven-level scale from -3 (Strong inhibitory influence) to 3 (Strong promoting influence) [30]. After that, the concept of each scenario is developed. The scenario concepts focus on the state of the specific domain to be improved or regressed or the worst or the best operating situations. Based on the concept of the scenarios, the corresponding factors are fixed in a particular projection to fulfil the determined idea. Four different scenarios, excluding the reference scenario, are created. A brief explanation of the different scenario concept and targets is shown below.

3.5.1 CO_2 reduction & RE share target (*RE-Boom*)

The *RE-Boom* depicts the best condition from the ecological perspective. Table 5 presents seven key factors which are forced to demonstrate the scenario.

Table 5. Forced projections for the ecological optimistic scenario *RE-Boom.*

Fixed factor	Projection	Fixed factor	Projection
e. CO_2 price	Highly decreasing (↓↓)	n. Urea market vol.	Highly increasing (↑↑)
f. CO_2 certificate price	Highly increasing (↑↑)	o. Ammonia market vol.	Highly increasing (↑↑)
g. *CF* & *RE* share	Highly decreasing (↓↓)	p. Acetic acid market vol.	Highly increasing (↑↑)
m. Methanol market vol.	Highly increasing (↑↑)		

The key factors, CO_2 certificate price, and *CF* & *RE* share, are forced environment friendly. The chemicals market volume is fixed to be highly increased to remove the market restriction for more possible CCU production. The CO_2 price is defined to be decreased to reduce the availability of direct CO_2 sales options.

3.5.2 Technical improvement & Market Booming (*Market-Boom*)

Scenario *Market-Boom* set the perfect condition from the economic and technical perspectives. Table 6 shows the eleven fixed key factors to fulfil the scenario concept.

Table 6. Forced projections for the economic optimistic scenario *Market-Boom.*

Fixed factor	Projection	Fixed factor	Projection
h. O_2 price	Highly increasing (↑↑)	r. Energy efficiency	Highly increasing (↑↑)
i. Methanol price	Highly increasing (↑↑)	s. Hydrogen efficiency	Moderately increasing (↑)
j. Urea price	Highly increasing (↑↑)	t. Steel mill energy demand	Highly decreasing (↓↓)
k. Ammonia price	Highly increasing (↑↑)	u. Part load range	Highly increasing (↑↑)
l. Acetic acid price	Highly increasing (↑↑)	v. Dynamic operation	Highly increasing (↑↑)
q. Conversion eff.	Highly increasing (↑↑)		

The key factors related to the revenue are all fixed to be highly increased to maximize the profits. The factors in the technology class are defined to be highly advanced. However, the H_2 efficiency is estimated to be moderately increased to make a clear difference with the *H_2-boom* scenario in section 3.5.4.

3.5.3 Energy & Market crisis (*Crisis*)

Crisis scenario projects the worst situation from the economic perspective. The concept refers to the current Ukraine war and an economic crisis. Table 7 presents eight forced factors for the scenario concept.

Table 7. Forced projections for the negative extreme scenario *Crisis*.

Fixed factor	Projection	Fixed factor	Projection
a. Electricity Price	Highly increasing (↑↑)	i. Methanol price	Highly decreasing (↓↓)
b. Natural Gas price	Highly increasing (↑↑)	j. Urea price	Highly decreasing (↓↓)
c. Coal Price	Highly increasing (↑↑)	k. Ammonia price	Highly decreasing (↓↓)
h. O_2 price	Highly decreasing (↓↓)	l. Acetic acid price	Highly decreasing (↓↓)

The factors related to the profitability are all negatively assumed. Prices of raw materials goes up immensely, and revenue of the products is reduced substantially. Regarding the product's market condition, it is evaluated from the perspective of the supplier. In other words, it is assumed that the chemicals market is in depression, so the supplier must sell the product at a lower price.

3.5.4 Hydrogen booming (*H_2-Boom*)

The *H_2-Boom* focuses only on the best condition of H_2 generation from the technical aspects. Table 8 shows six essential key factors to satisfy the scenario concept.

Table 8. Forced projections for Hydrogen optimistic scenario *H2-Boom*.

Fixed factor	Projection	Fixed factor	Projection
d. H_2 Price	Highly decreasing (↓↓)	s. Hydrogen efficiency	Highly increasing (↑↑)
q. Conversion efficiency	Constant (-)	u. Part load range (only H_2)	Moderately increasing (↑)
r. Energy efficiency	Constant (-)	v. Dynamic operation (only H_2)	Moderately increasing (↑)

H_2 price is assumed to be reduced following a drop in generation cost due to highly increasing manufacturing cost and technology breakthroughs. It aims on the hydrogen subdomain from the overall technical domain.

3.6 Scenario generation and selection

Based on the formulated cross-impact matrix and the scenario concepts, the CIA is conducted to determine the most consistent combination. It tests all theoretically possible combinations to analyse their contradictions with the framework conditions. However, the generated matrix involves more than a billion possible combinations. The CIA, thus, can only be checked with algorithm-based software support. For this reason, the *ScenarioWizard*® software is used. Plus, the economic factors related to the chemicals (price and market volume) are combined into a single factor to manage the complexity. It is judged by the fact that the scenario concepts mostly do not involve the comparison of the superiority between the chemicals. A merge does not affect the quantitative values for each factor but merely has an identical qualitative projection. As a result, the bundle containing the possible candidates to be a final scenario is generated for each scenario. In our case, eight options for *RE-boom*, five for *Market-Boom*, two for *Crisis*, and fifteen for *H_2-Boom* are generated.

To select the final most consistent combination out of the candidate's pool, the Consistency Value (CV) and Total Impact Score (TIS) function as the evaluation criteria [30]. TIS means the sum of the impact scores of all selected scenario variants. The CV is the parameter to evaluate if the chosen combination of the factors is consistent. In the case of a positive or zero CV, the combination is accepted as consistent [30]. Based on the scenario selection criteria, the final scenarios are determined. All scenarios have the CV equal to 0 and the highest TIS out of the possible candidates, so they involve the most consistent combination.

4. Results

4.1 Final scenarios

Table 9. Final five scenarios with qualitative (QLT) and quantified values (QNT) for the 24 key factors (a - x).

Key factors with units	BAU		RE-Boom		Market-Boom		Crisis		H2-Boom	
	QLT	QTY	QLT	QTY	QLT	QTY	QLT	QTY	QLT	QTY
a. Electricity price (€/MWh)	(↑)	47.38	(↓↓)	20.66	(-)	41.32	(↑↑)*	72.31	(-)	41.32

[1] Scaling factors (s-factors) for investment cost calculations are plant-dependent and shown in Table 10.
* The factors with subscript * denote the predetermined fixed projection.

Additional to Table 9, with all numerical values, the scenarios additional includes the time series for electricity price and *CF* (Figure 2) plus all linearized and scaled CAPEX functions C_s. The explanation for CAPEX, which is determined after CIA, is given below. Table 10 shows different s-factors for all hydrogen production plants.

Table 10. Scaling factor *(s-factor)* to estimate future CAPEX of hydrogen production plants for the scenarios.

Scenario	ALK	PEM	MP	Other components
BAU	1.0	1.0	1.0	1.0
RE-Boom	0.92	0.85	0.92	0.92
Market-Boom	0.92	0.85	0.92	0.85
Crisis	1.16	1.29	1.16	1.23
H2-Boom	0.84	0.71	0.84	1.0

The qualitative projection of CAPEX for the *RE-boom* and *Market-boom* are calculated to be decreased ($s < 1$) through the CIA. The CAPEX of the H_2 supplement is determined to be regularly improved for both scenarios following the projection of H_2 efficiency, moderately increasing. Regarding other components, the *s-factor* is estimated to be identical to the ALK for *RE-boom* and the PEM for *Market-boom*. It is more plausible that *Market-Boom* has a bigger reduction rate than *RE-Boom* as the technical factors of other components is assumed to be improved at a higher rate in *Market-boom*.

Qualitative projection of CAPEX for the *Crisis* scenario is calculated to be increased through the CIA. The CAPEX of the H_2 supplement is decided to be the worst development ($s > 1$). The *s-factor* of other components is assumed as the average value of ALK and PEM.

The CAPEX of the H_2 supplement is determined to be the optimistic future under the projection of H_2 efficiency. The *s-factor* is not applied to other components as the concept of the *H_2-boom* focuses only on the H_2 improvement, so it clarifies the difference with the *RE-boom* and *Market-boom*. It may look illogical that the qualitative projection of CAPEX is calculated to be decreased through the CIA. However, the result of the CIA can be varied depending on the weight of the influence. It is plausible that the CAPEX reduction is mainly because of the H_2 efficiency factor, as it has a more significant impact on the CAPEX.

The s-*factor* is multiplied to $C_{b,lin}$ function for individual plants of each scenario to reach the final scaled CAPEX functions C_s. Figure 4 presents the derived C_s function of the WGS plant for each scenario as an example.

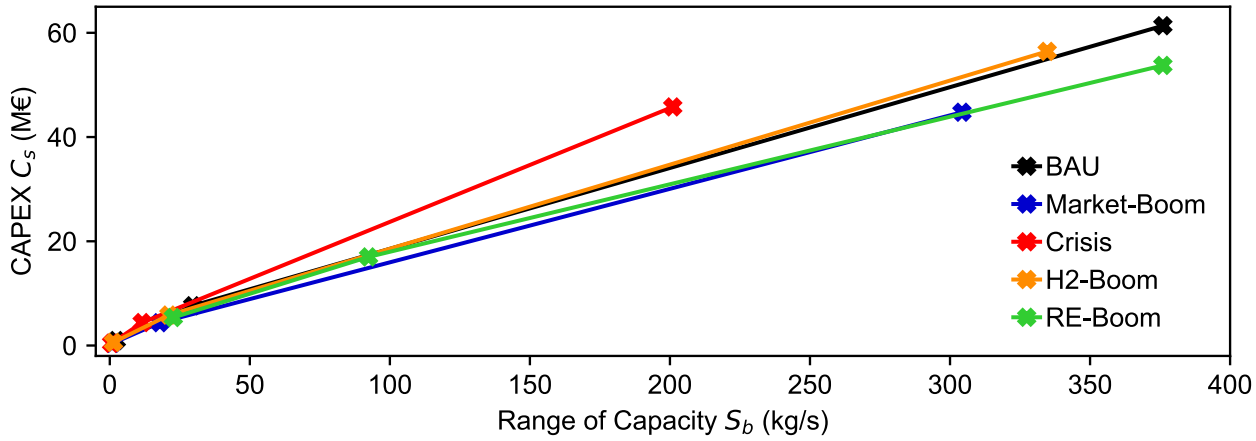

Figure. 4. The five developed linear CAPEX functions Cs of the water gas shift plant for each scenario.

4.2 Scenario evaluation

All combinations from CIA (Table 9) are evaluated based on the three criteria: plausibility, consistency, and differentiation. The BAU scenario is not part of the scenario evaluation due it is generated by the independent method (3.3 Reference scenario). Plus, consistency is already measured in the scenario selection process (3.6 Scenario generation and selection).

4.2.1 Plausibility

Plausibility check of the scenarios is assessed if the combination of the scenario is well matched with the aimed concept and the relationship between the fixed factors and the remaining factors are plausibly formulated.

Scenario *RE-boom* depicts the condition that minimizes the CO_2 emission and simultaneously maximizes the quantity of used exhausted gas. The concept is well satisfied with fixed factors from Table 5. The combination of remaining factors is also well structured. Significantly, the prices of energy raw materials (factors a. to c.) are decreased by the CIA. As the *CF* is assumed to be 0, it is plausible that the prices are decreased accordingly. However, the coal price is less affected as it relates more to steel production.

Main idea of *Market-boom* is the maximization of profitability and technical performance. The concept is well fulfilled by optimizing the product price and technical development in Table 6. Among the remaining factors, the chemicals market volume is resulted to be constant by the CIA even if the prices are incremented. It may

look illogical in general price and market relationship. However, the generated combination results from all factors' mutual interaction, not a pair of two factors. It is plausible to assume that the chemicals market volume is resulted to be constant because of other factors' indirect influences.

The *Crisis* represents the worst situation with the forced factors from Table 7. A discord between the combination of the key factors and the scenario concept is identified. The ecological factors (f. and g.) resulted in highly increased and decreased, respectively, through the CIA calculation as the prices of energy raw materials are forced to be highly increased. It is plausible from the perspective of three considered domains, like the case of *RE-Boom.* However, it does not align with the scenario concept, which refers to the ongoing Ukraine conflict. The current abnormal situation decouples the general relationship of the energy complex. According to the [31], the price of CO_2 permits reached a high of 97 €/kWh_{el} in 2020. After the start of the conflict in 2022, the price dropped to almost 60 €/kWh_{el}. It is reported as the biggest crash since 2014. To elaborate this unique situation, social or political aspects (e.g., acceptance or political trends) should be included. It may function as a "joker", making the retrogress trend plausible.

H_2-boom scenario focuses on the improvement of the overall H_2 generation, a subdomain in the technical and economic field. The concept is fulfilled with the fixed factors from Table 8. Regarding the energy raw materials from the remaining factors may look more plausible to be reduced rather than constant. Assuming that the H_2 price is reduced and the H_2 efficiency is notably advanced, a significant price drop is expected. It is particularly true if a high proportion of green electricity is used, leading to low market prices and *CF*. However, the scenario from this study assumes that the perfect transition to an emission-free system is impossible by the target year. According to the [32], the existing infrastructure has limited application regarding H_2 as an energy source. Germany's current gas supply network can tolerate only 10 % of H_2 by volume in total [32]. However, it is also evident that H_2 gradually contributes to the energy system, simultaneously. It becomes obvious by comparing it with the BAU scenario. As the H_2 price in the BAU scenario decreases at a lower rate than *H_2-boom*, the energy raw materials prices are assumed to be moderately increased. So, even if H_2 as the energy source cannot change the energy system in a flash, it positively influences the gradual transition. Consequently, it is more plausible that the prices of energy raw materials will be constant for *H_2-Boom*.

4.2.2 Differentiation

The differentiation between the scenarios is assessed if the generated scenarios depict the meaningfully varied condition to prevent further calculation results in an identical outcome. *Market-Boom* and *Crisis* scenarios can be understood as the antipodes in the scenario funnel from the economic point of view. The combinations of all the factors in both scenarios are formulated oppositely. They offer different situations in terms of economic conditions. Both, *Market-Boom* and *H_2-Boom,* involve technical improvement by the target year. Because of the similar relationship between the factors, most other elements from the different domains resulted in similar projections. It may be considered a false combination because both slices depict a similar situation. However, the technical concept of these scenarios is distanced - *Market-Boom* for overall improvement, but *H_2-Boom* for mainly H_2 subdomain. Thus, comparing the results from the scenarios bring clearly different results to evaluate the CCU concept. Finally, the *RE-Boom* concentrates on the sole independent domain, the ecological criteria. The combination of *RE-Boom* is conspicuously different. In other words, the generated slice is sketched at a totally distanced area from other scenarios, so it can offer new criteria to evaluate the feasibility of the CCU concept. Figure 5 presents the simplified development process and a qualitative classification to elaborate the differentiation of the scenarios.

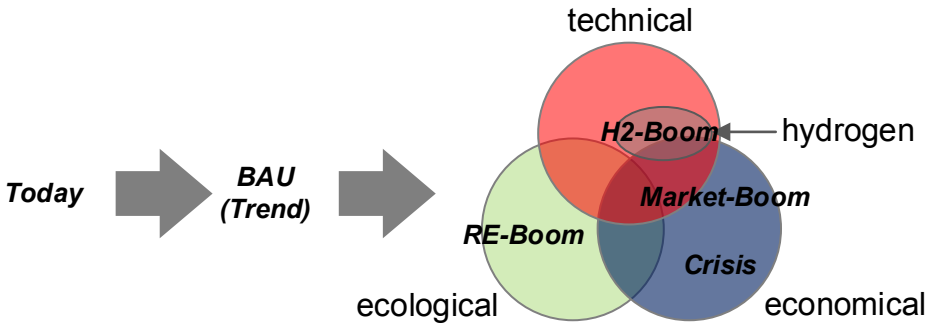

Figure. 5. Simplified development and differentiation of the scenario concepts as a Venn diagram.

5. Conclusion and Outlook

This research aimed to build up consistent, plausible, and meaningfully different scenarios as input data for MILP models to evaluate the long-term feasibility of the desired exhausted gas utilization concept. The generated five scenarios involve internal and external key factors from three main criteria. To build up the BAU scenario, they are extrapolated to the target years for investing (2025) and operating (2040). Especially, the

formulation of the investment cost offers a rough sketch of the initial expenditures. A linear approximation method for CAPEX functions is applied to be suited for the later use in MILP models. It fulfils the criteria for a maximum error tolerance of 10 % from the original nonlinear function.

All 24 key factors are qualitatively and quantitatively projected into the target years to construct the hypothetical future development. The process is carried out in an objective methodology, utilizing the BAU scenario data rather than forecasting the random value. It also involves exaggerated or passive projection so that further evaluation of the CCU approach becomes more evident. If the data from the BAU scenario is unavailable, then the quantification is determined based on independently estimated assumptions. The investment costs are quantitatively projected by applying a scaling factor (*s-factor*). The *s-factor* is derived from the water electrolysis CAPEX and ranges from 0.71 to 1.29. It is applied to other plants to switch the amplitude of CAPEX functions and offering varied economic situations. An s-*factor* greater 1 is represents economically unfavourable scenarios due to higher initial expenditures. This compositional work provides new insight into the probable future development of the "Hot-potato" factors - such as the electricity price, RE share, or the chemicals market.

The concept of each scenario is determined in advance of the scenario formulation. In other words, the scenarios are developed based on the deliberately specified condition. Four scenario concepts are generated: 1. CO_2 reduction & RE share target (*RE-Boom*), 2. Technical improvement & Market booming (*Market-Boom*), 3. Energy & Market crisis (*Crisis*), and 4. Hydrogen booming (*H_2-Boom*). The *RE-Boom* depicts the best condition from the ecological perspective. The *Market-Boom* set the perfect condition from the economic and technical perspective. The *Crisis* projects the worst situation from the economic domain. Finally, the *H_2-Boom* focuses only on the best condition of H_2 generation from the technical and economic aspects.

Based on the predetermined concept, the CIA is carried out to find the most consistent combination of the key factors within the fixed condition. The calculated combinations are considered highly reliable consequences. First, regarding consistency, all scenarios have the desired CV and the highest TIS out of the possible candidates. Secondly, the determinations of the remaining factors' projections through the CIA calculation are also plausible to describe the scenario concept within the investigation domains. Finally, the results also offer meaningfully different operating conditions. These results build on existing evidence of the reliably structured scenarios. The generated scenarios can now be directly utilized in a MILP model for the CCU approach.

In conclusion, the generated five scenarios represent a comprehensible description of the possible situation of the CCU concept in the target years based on a complex network of factors from different impact parameters. All scenarios have consistent, plausible, and meaningfully different combinations of the key factors. Consequently, the optimal solutions for utilizing the exhausted gas are calculated by the MILP optimization model in varied ways depending on the scenarios. It promotes the transparency and traceability of the further decision-making process of the CCU concept.

Abstract:

Currently, there is a set of variables that directly and indirectly influence the level and quality of life of human beings. Climate change, pandemic situations and wars raise questions about their survival. Thus, the development of systems allowing efficient monitoring of the surrounding environment seems appropriate. In this sense, since the agricultural sector is a pillar of modern societies, the application of technologies such as IoT (Internet of Things), for its sustainable development is the motivation for this multidisciplinary work. The work carried out uses emerging technologies, wireless communication networks, alternative energy sources, control systems and friendly human-machine interfaces. Communication between the devices uses LoRa (Long Range) technology due to its low consumption. Depending on the location to be monitored, alternative sources of energy, solar and hydropower, are selected individually, using an algorithm that monitors the power available at each instant. Data acquired such as temperature and humidity by several network nodes (peripheral towers), communicate to a gateway (main tower). These data are stored, treated statistically, and presented in a user-friendly application for different users. The system was installed in an urban vegetable garden in the Vila Nova de Famalicão municipality. After its operational validation, the temperatures and humidity values were registered. In conclusion, the developed system is low cost, autonomous, modular, flexible, has a low energy consumption and uses alternative energies, allowing the optimization of techniques and types of cultivation.

Keywords:

IoT systems; LoRa technology; Renewable energy; Agricultural sector; Sustainability.

1. Introduction

The internet of things, also known as IoT, is a current concept that continues to demonstrate great relevance, mostly because it allows autonomous interaction between different entities of a system endowed with technology. In practice, the IoT consists of a system of devices that are related to each other, which can represent equipment with a mechanical or digital operation, intelligent objects and people or animals monitored by sensors. Each entity in the system must have a unique identifier in order to enable communication/data transfer over a network without the need for human interaction. According to Fortino et al.[1], the IoT represents a seamless interaction between dynamic communities of users, smart objects and traditional computer systems that have the possibility to interact with each other and with the surrounding environment. When building an IoT system from smart objects, another important aspect is being able to differentiate several types of smart objects.

In [2], Kortuem and his co-authors present a classification of these types of objects where they highlight their most relevant differences. The authors refer to three fundamental aspects of intelligent objects, such as "Awareness", "Representation" and "Interaction". The first represents the ability of an object to interpret and react to events and activities that occur in a real physical context. The second denotes the digital representation of the object obtained through an applied programming model. The latter represents the ability of the object to interact with the user concerning the input, output and data visualization. The authors also mention that IoT systems based on smart objects raise research questions such as *"What is the right balance for the distribution of functionality between smart objects and the supporting infrastructure? How do we model and represent smart objects' intelligence? What are appropriate programming models? And how can people make sense of and interact with smart physical objects?".* These questions may have different answers according to the context of the problem. However, they must be considered when defining the project objectives.

Over time, different architectures for IoT systems have been defined, some more detailed than others (number of layers in the model) that are being adapted to emerging technologies. An exhaustive literature review of the IoT architecture evolution and main concerns was provided by [3]. The review considered architectures from 2008 to 2018 and the IoT challenges, for example, security and privacy issues. More attention to data security is being paid over the last years due to the massive data gathering and analysis. IoT can be applied to different areas of activity, however, all systems provide an architecture where data collection and transport, data storage, processing and data availability are required [4]. In general, the most comprehensive system must incorporate the requirements identified in Table 1 that are associated with an inherent technological process.

Table 1. Summary of IoT system requirements and respective process description

IoT system requirements	Process description and inherent methods or technology
Transport and collect data	The system in real physical context contains objects connected to local data collection points that can establish communication through wired technology such as fibre optics or ethernet or through wireless networks such as Wi-Fi or LoRaWAN.
Storage data	The transmitted information is stored in databases appropriate to the context of the problem, using database management systems as MongoDB or SQLServer.
Processing data	Data processing occurs through data analysis techniques, based on statistical procedures, data mining, programming models and artificial intelligence techniques. Several methods can be used, such as exploratory data analysis, exact methods, heuristics, among others.
Make data available	The data must be made available to the user in a summarized form, providing only the information necessary for the process under analysis. This can be available through APIs or GUIs, such as a web application or a dashboard.

In the agriculture sector, IoT systems are increasingly used to allow better monitoring, support decision-making and, consequently, an increase of the business value. IoT can be applied in different ways in agriculture, from telemetry systems, computational software, data collection and efficient automation control. IoT enables data generation, which can be analysed to improve how agricultural activities are carried out [5]. The applications in irrigation are emerging in the literature [6–8]. Syrmos et al [5] presented an intelligent modular water monitoring IoT system for real-time data collection to sustain operational reliability. The authors discuss the relevance of IoT communications and infrastructure maturity, which are the foundation for a robust smart water metering solution. The proposed system uses LoRaWAN as the communication protocol and the flowmeter is equipped with a gyroscope for detecting movements. The limitation of the system is the cost since the proposed system cannot be adopted for domestic use due to frequent sensor replacement costs and an increased energy consumption. LoRaWAN defines the communication protocol and system architecture for the network, while the LoRa physical layer enables the long-range communication link. LoRaWAN is also responsible for managing the communication frequencies, data rate, and power for all devices [9]. Cheema et al. [10] proposed an IoT applied in a farm, based smart system equipped with accessible and economical devices and sensors to capture real-time parameters, such as temperature, soil moisture and pH level or humidity at frequent intervals of time. The IoT system evaluates these environmental factors, facilitating the decision-making.

Ragnoli et al. [11] proved that implementing low power wide area network technologies in IoT-oriented wireless sensor grids because it can help to good energetic performances, which are essential for energy harvesting in powered devices.

Thus, there is a need for emerging technologies to reduce energy consumption and cost-effectiveness in control and monitoring systems [12,13]. It has been predicted that the global energy consumption of IoT edge devices will reach of about 46TWh by 2025 [14]. Thus, it is of utmost importance to use renewable energy sources to power IoT devices, in line with the ambitioned sustainable development of modern society. Outdoor IoT devices can use photovoltaic panels to power themselves. Liu and Ansari [14] presented an example of a green energy solution to power IoT devices.

This study proposes the development and implementation of a monitoring system based on open IoT hardware and software platforms. Also, a LoRa supporting low-power long-distance network is applied through a low-cost solution. The IoT system can be powered by alternative energy sources, solar panels and a μhydroelectric plant. An algorithm was developed to monitor and collect several parameters, such as temperature and humidity by the different network towers, which communicate with the main gateway. These data are stored, statistically treated and presented in a user-friendly application.

This system's novelty is related to the possibility of using different renewable energy sources since the microcontroller can switch from solar to hydroelectric, which ensures constant battery power. Also, to increase their efficiency, the peripheral towers were programmed to remain in active mode only during the data sending and receiving. Otherwise, the microcontroller of the peripheral tower remains on standby. This aspect also enhances the batteries' useful life span.

2. System design and architecture

The IoT monitoring system consists of three main parts: the First is an energy IoT node that collects data, a second is IoT gateway that receives and stores data from nodes at remote locations, and the last is the low-cost LoRa network which is support wide area networking and low costed wireless solution. In this research work, when referring to IoT systems, one should keep in mind their properties and limitations. In this sense, an IoT system should be, when possible, battery-powered, have a small size, low cost and perform simple tasks. The assigned restrictions imply a study of consumption, autonomy, computational power, and specific tasks.

2.1. Schematics of the system design

The methodology used in this work for monitoring air and soil quality in an agricultural environment is based on the principles of IoT systems in which it seeks to find adequate solutions for its limitations. Figure 1 presents a general design of the developed system. The system is composed by peripheral towers for acquisition of soil-related variables; a main tower for monitoring variables related to air quality and to serve as a gateway of all information; a server to store and analyse data and an informatic application to query and monitor it.

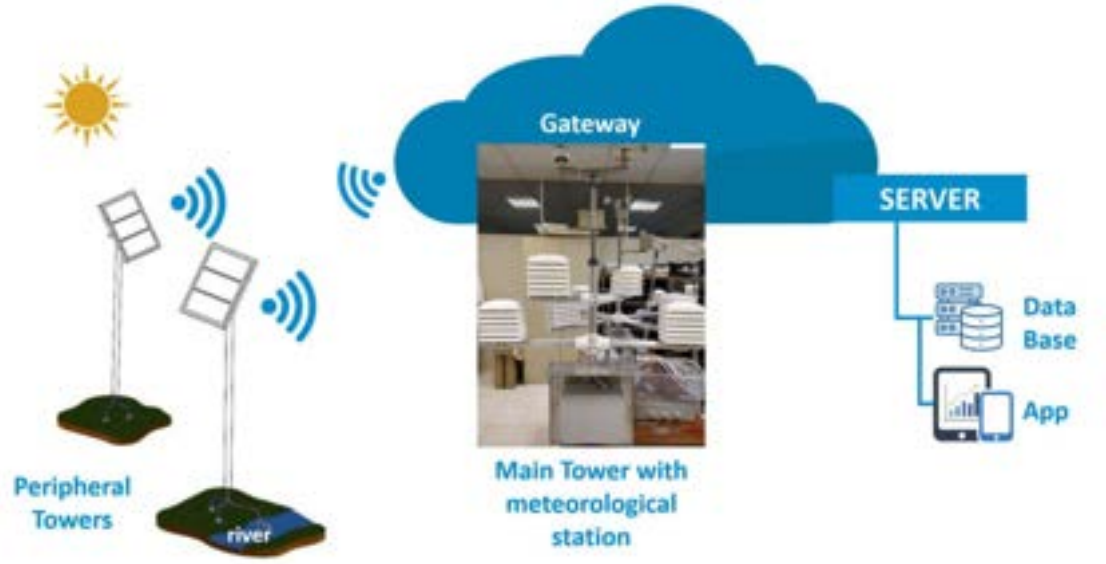

Figure. 1. Schematics of the system design.

2.2. Characterization of data acquisition towers

The data acquisition subsystem includes the main tower and the peripheral towers, both equipped with sensors and communication systems. Each peripheral tower, Figure 2 (a), is composed of temperature and soil humidity sensors. These sensors are connected to a data acquisition developed board capable of communicating with the main tower through a wireless network (LoRA at 868 MHz).

Regarding the power supply of each tower (battery), this is charged by using renewable energy that comes from the solar panel installed. Figure 2(b) depicts a peripheral tower installed to collect soil parameters.

The main tower, Figure 2(c), serves as a gateway to the data acquisition system. In this tower, there is also a meteorological station that provides information on atmospheric pressure, air temperature and humidity, wind direction and speed and precipitation rate, as well as, CO_2, O_3 or particles (e.g., PM2.5, PM10). The air quality information is provided through sensors installed. Data is sent over the internet to a remote server.

(a) (b) (c)

Figure. 2. Data acquisition subsystem: (a) detail of peripheral tower with the solar panel to feed the battery and the antenna; (b) peripheral tower installed in the urban garden near the river flow; (c) main tower with the meteorological station.

2.3. Architecture of the energy feeding system

One of the requirements of this project is that the peripheral towers are powered by using renewable energy. Renewable energy sources cause some disturbances in electrical power grids. In this sense, designing a system that monitors the available power in real time is required, whereas the energy is provided from solar panels or hydroelectric plants, with the use of small generators.

The monitoring system comprises two components: hardware and software. Regarding the hardware, it is necessary the physical interfaces connected to the current and voltage intensity sensors, necessary for the calculation of the available power. Power drives were also developed to charge the battery responsible for powering the electronic system (microcontrollers, relays, development board and others) implemented in each peripheral tower. In addition to the software that controls the hardware, an algorithm was also developed to articulate historical or via satellite information regarding the seasonality and predictability of the variables to be monitored, for a specific location (agricultural zone) with the data coming from physically implemented sensors. Figure 3 shows the flowchart of the developed algorithm.

The algorithm developed is based on the history of available information and it was created to consider two types of energy input, i.e., solar energy and/or hydroelectricity. For instance, on a summer day, the hours from sunrise to sunset and the hours of highest solar irradiance are both known. So, if the power available from the solar panel is below the nominal power to charge the battery, then, the algorithm commutes to the alternative energy source. In case there is only solar energy available, its current intensity is calculated to power the system during the night.

Figure 4 shows the flow of information between the different components. The available power from each of the alternative energy sources are measured (product of the current intensity by the voltage) and compared to determine the highest one. Afterwards, the microcontroller (development board) activates an output for the relay drive. Through a relay contact, the current intensity is physically routed to the circuit that charges the battery. Once the alternative energy source has been chosen, the others are blocked by the auxiliary contacts of the relay associated with that source. A hysteresis cycle was also implemented in the algorithm, which prevents the switch whenever the instantaneous power available is of a higher energy than the current one that is charging the battery.

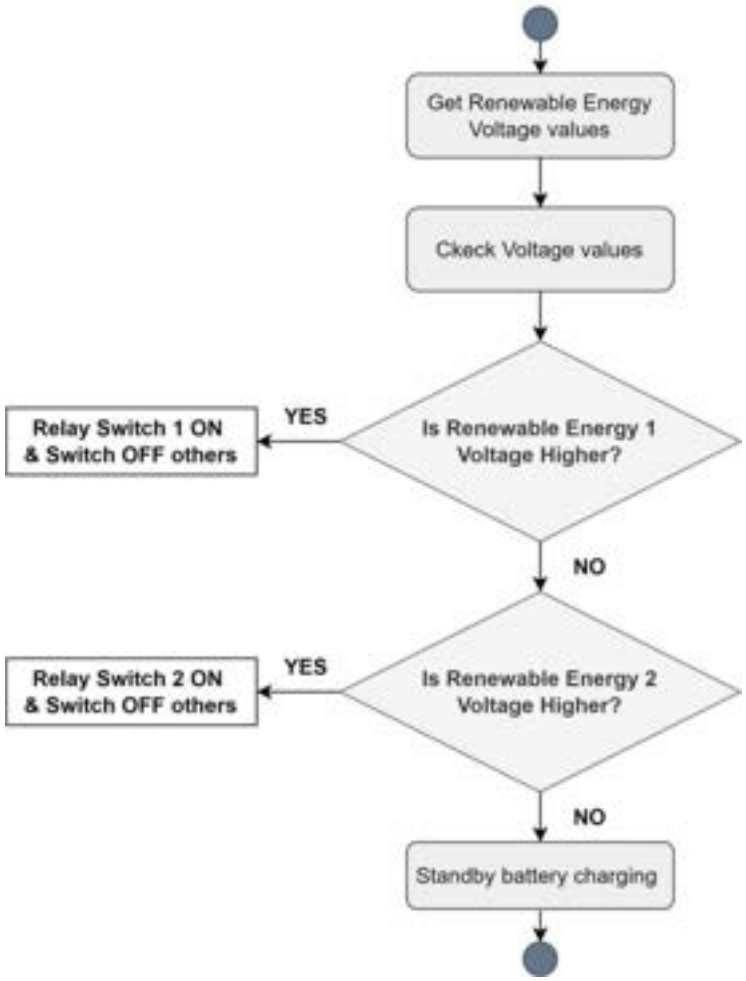

Figure. 3. Flowchart of the developed algorithm to manage the architecture of the energy feeding system.

The implementation of renewable energies in the project facilitates the acquisition of data in remote locations, mostly where there are no conventional energy sources. The supplying companies offer a set of equipment solutions with several sizes and available capacities. However, regarding the hydroelectric production, it is difficult to obtain components with potentials available for IoT applications. In this sense, this project includes the design of an innovative μhydroelectric plant.

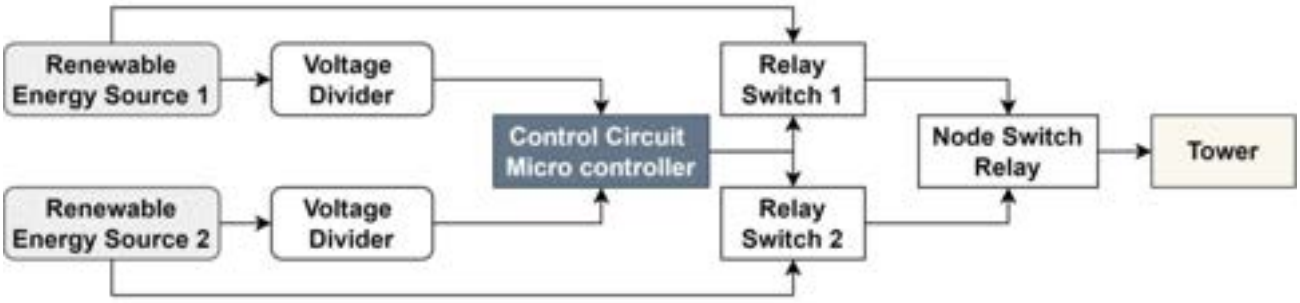

Figure. 4. Information flowchart between the system components.

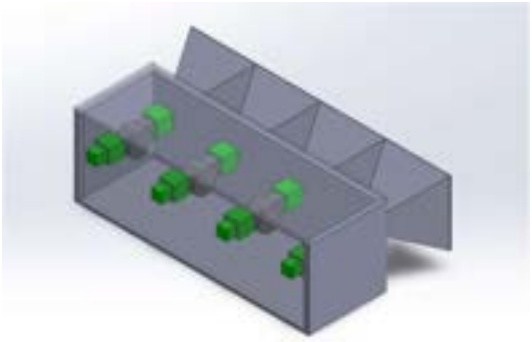
An optimized printed circuit board was developed with hardware improvements, allowing a better efficiency of the switch system between alternative energy sources. Despite to the fact that, in this study, only solar and hydroelectric energy sources are assessed, the developed printed circuit board allows the switch between 3 different types of alternative energies. The optimized printed circuit board layout is presented in Figure 5.

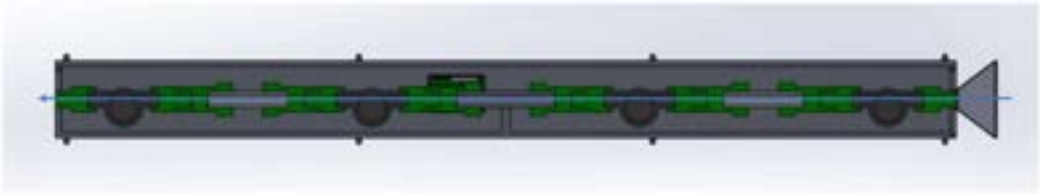
Figure. 5. Optimized printed circuit board layout.

The μhydroelectric plant was designed based on a modular architecture, capable of adapting to the most diverse scenarios related to its installation. Different configurations were studied, according to the environmental conditions related to natural water courses. The two basic configurations, turbines arranged in series (Figure 6(a)) or in parallel (Figure 6(b)), can be adapted to different natural river bed scenarios. The number of turbines can also change according to the intensity of electrical current required to power IoT devices.

As technical specifications, the turbines used in this work have the output Voltage of 5V DC and a maximum intensity of electrical current output of 150 mA for a constant water flow rate (4L/min). Solidworks® software was used for the development and testing of components. Depending on where the water is collected, for example, in a small river, if the bed is flat, the best turbine configuration is in series. That is, a use of the kinetic energy caused by the natural current of the river. On the other hand, if the riverbed is uneven, the best configuration is parallel. That is, the use of potential energy at a height of about one meter of distance towards to the turbine position. Mixed configurations (series/parallel) of turbines are also possible.



(a)



(b)

Figure. 6. CAD files of turbines developed for the project: (a) turbines arranged with a parallel flow architecture; (b) turbines arranged with a series flow architecture.

2.4. Definition of the communication protocols

Recent studies show a wide variety of IoT applications using the LoRaWAN Protocol. This defines the system architecture as well as the communication parameters in relation to LoRa technology.

In this work, the technologies involved were considered, seeking to standardize the power supply voltages of the devices, powers involved and communication networks. In this sense, the WEMOS TTGO ESP32 SX1276 LoRa development board was chosen. As main features, this board is low cost, composed by the ESP32 microcontroller and a LoRa SX1276 radio communication module.

The ESP32 is a 32-bit microcontroller with integrated Wi-Fi and Bluetooth connectivity, which has several advantages, such as low power consumption associated with high processing performance. The SX1276 LoRa radio communication module allows you to communicate with other LoRa devices over long distances, usually in the range of a few kilometres (about 10 km with an unobstructed view), depending on the environment and device configuration. It is usually used in projects that require long-range wireless communication with low data transfer rate and low power consumption.

The TTGO development board allows the use of an external antenna, in order to provide a greater performance of the LoRa technology. When choosing an outdoor antenna, it is important to consider the type of antenna that will best meet the specific needs of each project. There are two main types of antennas: omnidirectional and directional. Omnidirectional antennas emit signals in all directions, while directional antennas emit signals in a specific direction. Omnidirectional antennas are ideal in situations that require signal coverage in all directions, such as in urban areas or places with many obstacles. On the other hand, directional antennas are best suited in situations that require a strong signal in a specific direction, such as in rural areas or places where there are few obstacles. As presented in Figure 7, an omnidirectional antenna was chosen. Omnidirectional antennas provide easier installation compared to directional antennas, which require prior positioning in relation to the other nodes in the network. It is possible to add new nodes (sensors) to the LoRa network, which is one of the objectives of future work. The solar panel as a nominal capacity of 20 W.

The use of the TTGO development board that integrates the ESP32 microcontroller has the advantage of allowing operation in different energy modes. There are five power modes available on the ESP32, ordered from highest to lowest consumption: active mode (pre-set mode by default), modem-sleep mode, light-sleep mode, deep-sleep mode, and hibernation mode.

Figure. 7. Omnidirectional antenna installed in the peripheral towers.

The monitoring of the environmental variables and their transmission by the peripheral towers are carried out every 10 minutes, which makes it unnecessary to keep the microcontroller constantly in active mode. In this work, the efficiency of the peripheral towers is a relevant aspect, since they are powered by batteries, and it is important to guarantee their efficiency. To increase their efficiency, the peripheral towers were programmed to remain in active mode while reading and sending environmental variables. After this process, the microcontroller of the peripheral tower goes into sleep mode, leaving only the sensors connected to the GPIO (programmable input and output ports) and an RTC timer responsible for waking it up after 10 minutes. With this procedure, it is possible to improve the efficiency of the microcontroller, reducing the current consumption from 50 mA to 10 mA during the respective period of 10 minutes.

2.5. Development of the application interface

On the server, data is stored in a non-relational database DB (Mongo DB) created for this purpose. Some of the attributes that contributed to its choice were: easy adaptation to new data, open source, and familiarization with this DB. Data is treated statistically and presented in the form of an application (App) for users. This application is a user-friendly application because it was thought and designed considering the different ages of users. The system architecture for data storage and visualization is divided into three main components: backend, frontend, and database. The backend is composed by a NodeJS application that provides two different API's considering the requests that are served. Indeed, there is a specific API to receive and store the data provided by the central control tower.

The second API have methods to provide the necessary data or validations for the frontend application. The communication is based on HTTP requests and considers the different GET, POST, DELETE and PUT methods. The information is stored in a non-relational database (MongoDB). Finally, the frontend provides, through several HTML, CSS and Javascript files, the information to the user. A dashboard is made available through a web application accessible with an Internet connection. Such information contains plots with, for example, temperature and humidity data and has methods that enables the user to change the visualized data by a temporal period (e.g., reset the zoom of an axis). By separating the backend from the frontend, the system may be more responsive since the backend has the only goal of providing the information, whereas the frontend is responsible for formatting and display such information. Indeed, the backend server is not overloaded with graphical requests.

3. Results and discussion

The results obtained with this work are presented taking into account the validation of each component of the IoT monitoring system architecture, considering the improvements of each subcomponent. In this section, the process for data acquisition and communication protocol validation is presented, as well as the assessment of the μhydroelectric plant operation and the variables measurement which can be accessed by the dashboard developed for the informatic application.

3.1. Data acquisition and communication protocol validation

Although the main tower is prepared to operate, in a remote location, with a current intensity of 600 mA, for technical reasons related to the compatibility of the developed system and the existing internet devices in the urban garden, the power supply to the tower was carried out using the mains. The data from the peripheral towers are sent together with the data acquired in the tower to a remote server located in the University Laboratories. The sending cadence corresponds to a 10 minutes interval period.

Regarding the battery charging, the initial calculations were carried out for a battery capable of supplying the designed circuits for each one of the peripheral towers. It was determined a current intensity value of 480 mA. This current intensity would be required for the constant and continuous system operation.

Nevertheless, during the project development, improvements were made at both hardware and software levels, which lowered the initially calculated value to around 250 mA. Taking into account the values initially calculated for the current intensity and the inclusion of more sensors in the near future, the average current intensity stipulated for the development of battery charging systems is 600 mA.

Regarding the sensors calibration, the system was also optimized for the application in study. The sensors that are part of the peripheral towers to measure soil temperature (SONOFF SENSOR-DS18B20) and moisture (SKU: SEN0193 Analog Capacitive Soil Moisture Sensor) were calibrated according to the manufacturer's specifications.

The temperature sensors were calibrated with ice (for a reference temperature of 0ºC) and with boiling water (for the reference temperature of 100ºC) in order to maintain their linearity in the measurements taken. The humidity sensors were calibrated according to the resolution of the analogue to digital converter (ADC) of the development board microcontroller. For a 12-bit ADC resolution, the value of 1490 corresponds to 100% humidity (immersed in water) and the value of 2980 corresponds to 0% (dry value). Figure 8 shows a cycle of reading and sending temperature and humidity values from the peripheral tower to the main tower. After the RTC timer wakes up the device, the program reads the humidity and temperature and sends the information through LoRa. Afterwards, the system enters in deep-sleep again.

Figure. 8. Cycle of reading and sending temperature and humidity values.

3.2. Assessment of μhydroelectric plant operation

As previously stated, a μhydroelectric plant was developed as the second renewable energy source of the IoT monitoring system. Prior to the tests to monitor the turbines behaviour, they were calibrated individually, according to the manufacturer's specifications, using information from a flow sensor and an ammeter. This process ensured an output current intensity of 150 mA. The water supply pipe diameter of was also sized to guarantee a constant flow rate of 4 L/min.

Regarding the series configuration of the 4 turbines (Table 2), it was verified that the first turbine was producing 150.0 mA, the second turbine 147.9 mA, the third 145.8 mA and the fourth turbine 142.6 mA. The fact that all the turbines were not producing all 150 mA was caused by mechanical losses and junction losses. One of the solutions to solve the problem may be to increase the flow rate. Yet, the flow rate increase results in higher wear rates of the first and second turbines since, by increasing the flow rate, the maximum intensity of the current does not increase as they are already in saturation.

Regarding the parallel configuration of the 4 turbines, the performance improves, as it was possible to obtain a maximum current intensity of 600 mA through a summation circuit. The problem lies in the need for a gap of about one meter in the riverbed.

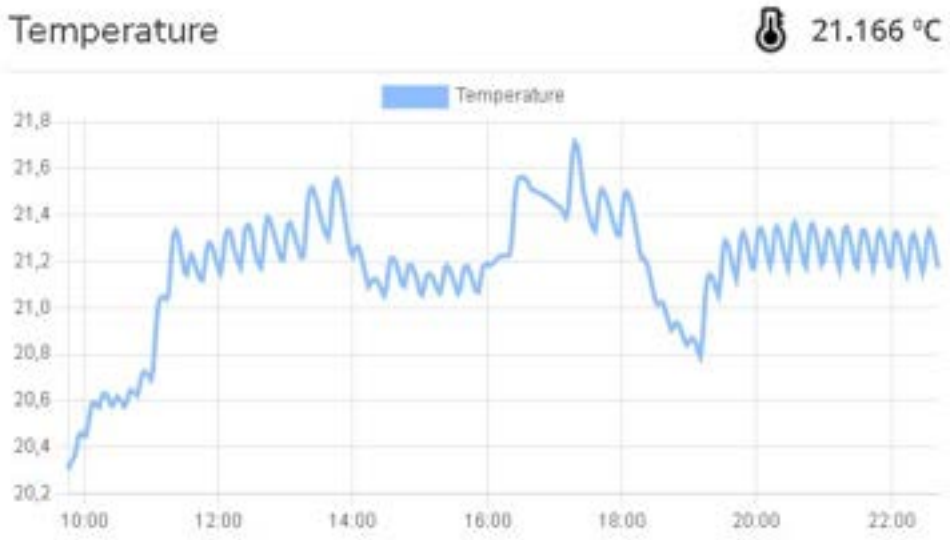
Table 2. Intensity of current produced by the turbines considering the series configuration

Generator equipment ID	Current intensity (mA)
Turbine 1	150.0
Turbine 2	147.9
Turbine 3	145.8
Turbine 4	142.6

At the moment, a hybrid system is being developed with the architecture of a parallel system of two turbines in series, capable of producing 600 mA. With this architecture it is possible to solve the problems described above. This configuration is being tested, so the data will be subject to future analysis.

3.3. Temperature and humidity measurements

The IoT system developed in this study aims to monitor environmental parameters registered at an urban vegetable garden located in the vicinity of a river stream in the Vila Nova de Famalicão municipality. Figure 9 shows the visualization dashboard obtained from the data of temperature and humidity registered in March 16th of 2023, between 10 a.m. and 11 p.m. The developed interface is able to estimate the mean obtained values.



(a)

(b)

Figure. 8. Temperature (a) and humidity (b) registered by the IoT monitoring system in March 16th of 2023, between 10 a.m. and 11 p.m.

Like the Portuguese national meteorological service (Portuguese Institute of the Sea and Atmosphere -IPMA) the interface is very user-friendly, since it uses a coloured code for variables range classification: light green (very good), green (Good), yellow (medium), orange (weak) and red (bad). In addition, the interface was programmed to disclose the collected data with statistically treated. The dashboard detailed by Figure 9 shows the average, maximum and minimum values for both temperature and humidity during the time of data acquisition. For instance, regarding the temperature data from March 16th, the application reported an average value of 21.18 ºC, with an amplitude ranging from 20.30 ºC to 21.72 ºC. The temperature standard deviation corresponds to ±0.25.

Statistic

Variable	Average	Standard Deviation	Max	Min
Temperature (°C)	21.18	0.25	21.72	20.30
Humidity (%)	54.37	2.03	58.37	50.48

Figure. 9. Print of the statistic information provided by the interface application dashboard, regarding the registered temperature and humidity values.

Thus, with this IoT monitoring system it is possible to define the best techniques and types of agricultural crops for a certain environmental pattern. Soil humidity sensors are used in detecting the changes which are required and to adjust the irrigation practices. Minor changes in irrigation practices increases the cultures growth and saves water.

For instance, a proper irrigation management using soil humidity level variation depends on the specific soil type. The modularity of the developed system also allows to design and size an economical, appropriate and a low maintenance solution for agricultural small-scale applications, mainly in rural areas.

4. Conclusions and final remarks

This paper presented the architecture and development of an IoT monitoring system to effectively collect environmental data such as temperature and soil humidity to facilitate agriculture activities. A LoRa supporting low power long distance network was applied through a low-cost solution, the WEMOS TTGO ESP32 SX1276 LoRa. The system can be powered by alternative energy sources, solar energy and hydroelectric and it uses an algorithm that monitors and collects several parameters by the different network towers, which communicate with the main gateway tower, which is equipped with an atmospheric station to collect air quality data.

All the stored data are statistically treated and presented in a user-friendly application that can be used by different users. The system was installed in an urban vegetable garden in the Vila Nova de Famalicão municipality.

The monitoring of the environmental variables and their transmission by the peripheral towers are carried out every 10 minutes. Since these towers are battery powered, the control circuit was optimized to reduce the current consumption, from 50 mA in activated mode to 10 mA in sleeping mode. The peripheral towers can also be feed by hydroelectricity, since an optimized printed circuit board was conceived allowing a better efficiency of the switch system between alternative energy sources. Due to the irregularities of the river bed, two configurations for the turbine connexion were studied – in series and in parallel. In series configuration, due to mechanical and junction losses, it is not possible to guarantee the intensity of 150 mA from all turbines. Hybrid configurations need to be implemented. Through the dashboard developed as the informatic application interface, it was possible to validate the IoT system by monitoring the temperature and humidity.

The use of different renewable energies makes this project thrive in all weather conditions and seasons, with wind and hydro energy for nights and winters and solar energy during the day and especially in summer. The implementation of renewable energies in the project facilitates the collection of data from remote places where there are no conventional energy sources. As future work, the IoT monitoring system will be able to select the most appropriate source from wind, water or solar, since the defined architecture allows to adapt the system to operate with three renewable energy inputs.

Abstract:

Sustainable energy solutions are highly dependent on the availability and costs of resources during their operation. For instance, power output of solar cells and wind turbines vary over time which impacts the technical, economic, and environmental feasibility of Power-to-X (P2X) systems. In addition, efficient system solutions for energy conversion will require an optimal heat integration between several technologies and conversion routes. Thus, several methods have been proposed to conceptualize and optimize the design and operation of process plants. However, the possibilities of heat integration and storage during dynamic operation of different P2X-processes have been rarely evaluated by existing methods in literature. In this context, this research aims to provide an optimization framework, based on linear optimization and pinch analysis, to fill this knowledge gap, crucial to the development of dynamic renewable systems. The novel method is exemplified in the optimization of a Power-to-Methanol plant using solid oxide cells (SOCs) subjected to varying electricity production of wind turbines. The optimization estimates a minimal methanol production cost of 1772-1793 USD/ton for integrated scenarios and 1820-1807 USD/ton for non-integrated cases. Thus, heat integration plays a crucial role in cutting up to 2% of fuel production cost, while storage and optimal operation reduces further 3.3 % of the electrolysis size compared with reference scenarios.

Keywords:

energy integration; energy storage; optimization; pinch analysis; power-to-methanol.

1. Introduction

The increasing capacity of renewable electricity generation, combined with goals to reduce the dependency on fossil fuels in the global economy, has driven interest in the electrification of the industry. For instance, by replacing natural gas with wind or solar power as the main source of energy in hydrogen production, several chemical products (such as ammonia, methanol, natural gas, etc.) could be produced sustainably, with regional security and possibly at a lower cost. Processes plants that focus on using electricity to produce chemical goods have been called Power-to-X plants in the literature. Recent studies indicate that Power-to-X systems will play a major role in energy storage and industry decarbonization, and several large-scale projects are currently under development [1].

In this context, research has been focusing on different challenges associated with the design and optimization of Power-to-X plants. Most of these studies rely on thermodynamic models and mixed integer linear optimization problems (MILP) to estimate and optimize key performance indicators of novel system solutions. With regards to the optimization framework, these works can be categorized by their methods into two major types: energy integration and multi-period optimization studies. The first aims to assess the best technology types and sizes that can be integrated using a heat exchanger network [2,3]. On the other hand, the second type focus on optimizing equipment sizes under variable production profiles and market prices [4,5].

However, energy integration studies usually disregard the effects of intermittent resources, partial load efficiencies and storage solutions. In addition, multi-period optimization usually oversimplifies the heat integration problem (i.e., reduced number of temperature levels) or assume lumped models with fixed heat connections. Thus, each optimization approach has gaps that could be fulfilled by combining the two approaches. For instance, recently Li et. al [6] has proposed a complex optimization that merges both approaches to optimize distributed energy systems. Nonetheless, the optimization of Power-to-X systems including the variability of resources, storage and detailed heat integration opportunities have seldom been studied in literature. For example, a Power-to-X operating solely with wind power may benefit from power

and heat storage to stabilize energy supply. However, the optimal size of storage and utility systems is interconnected with operation and therefore both aspects should be considered to minimize production costs.

Thus, this research aims to address this research gap by proposing a simple and generalized optimization framework merging pinch analysis and multi-period optimization for energy systems like Power-to-X plants. The method allows to select and size technologies while ensuring an optimal heat integration at each time step. To exemplify the method and assess its possible gains, the design and optimization of a Power-to-Methanol system is evaluated using the optimization framework and the results are compared with non-integrated solutions.

2. Case study: Power-to-methanol

The optimization framework proposed in this section is applied to design an off-grid Power-to-Methanol plant comprised of wind turbines, solid oxide electrolysis system, methanol synthesis and distillation, as illustrated in Fig. 1. Each technology is represented by a linear model based on previous investigations using different modelling environments (e.g., Julia, Aspen Plus, etc.) [7]. The lists of every technology input, output, heat transfer and costs considered in this analysis are provided in Appendix A. In addition, a brief description of the main technologies employed in this case study is given in this subsection.

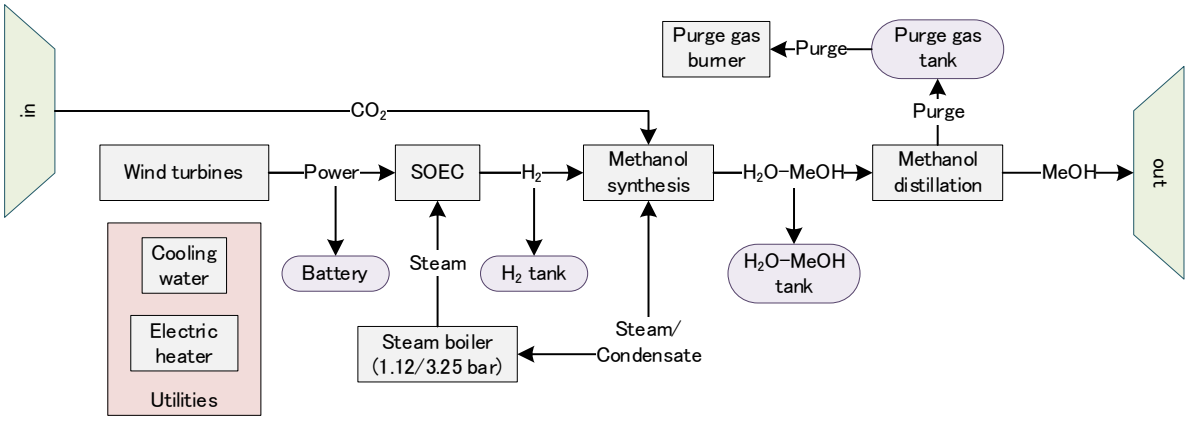

Figure. 1. Flowchart of the study case for a Power-to-Methanol plant (some resources and heat transfer were omitted for clarity)

The data of wind power generation reported by Champion, et al. [4] for an onshore wind turbine located in Esbjerg, Denmark was used to simulate the hourly power generation of a wind turbine. The main information about the wind turbine is reproduced in Table 1 from the source reference [4].

Table 1. Reference wind turbine parameters

Parameter	Value
Nominal power generation	3.15 MW
Rotor diameter (D)	142 m
Hub height	100 m
CAPEX	1.76 M€$_{2019}$/MW
Fixed OPEX	14.4 €$_{2019}$/kW/y
Variable OPEX	1.56 €$_{2019}$/MWh

The electrolysis system, Fig. 2, uses solid oxide cells to efficiently convert steam at high temperature (750 °C) and close to atmospheric pressure (1.12 bar) into hydrogen, which is compressed for storage and methanol production. A small portion of the products from the cathode of each cell are recirculated to maintain a minimal hydrogen concentration of 10% vol. in the reactants, which helps to control the electrochemical reaction, degradation, and thermal management. A detailed description of the process and modelling assumptions can be referenced in our previous works [7–9].

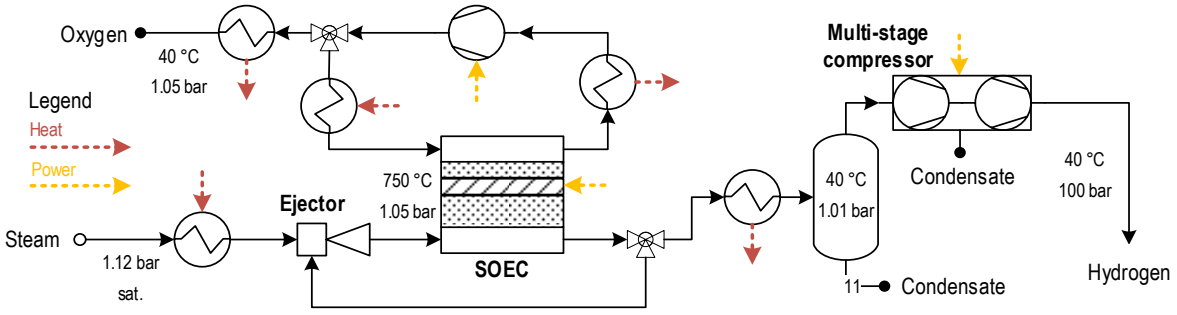

Figure. 2. Flowchart of the electrolysis system based on solid oxide cells (SOEC)

Methanol is produced in a quasi-isothermal reactor (265 °C, 90 bar) from the stoichiometric mixture of carbon dioxide and hydrogen ($CO_2+3H_2 \rightarrow CH_3OH+H_2O$). The chemical reactor is designed to achieve the same product's composition of 20 °C below the chemical equilibrium condition, as it is reported by previous works [10]. The reaction rate is estimated based on the model proposed by Bussche and Froment [11] for a copper/zinc oxide catalyst [12]. The methanol synthesis and distillation are divided as shown in Fig. 3 to include the possibility to store the water-methanol mixture (H_2O-MeOH) and operate the distillation on demand. Methanol distillation is an energy intensive process with little operational flexibility, therefore modelling it separately allows the optimization to reach more precise solutions. The detailed description of the process parameters and additional assumptions can be referenced in our previous work [7].

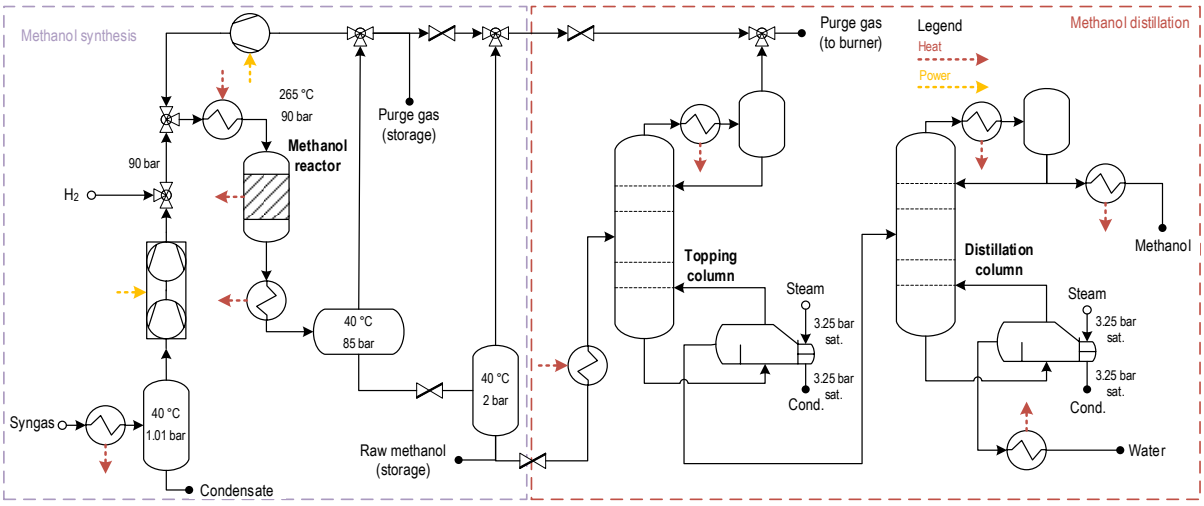

Figure. 3. Flowchart of the methanol synthesis and distillation units based on the isothermal reactor design.

The same technology and storage solutions shown in Fig. 1 and detailed in Appendix A are assumed to analyse optimal configurations under the same conditions, which are summarized in Table 2. In total, five scenarios are proposed to examinate how the wind power profile, heat integration and storage impact on the results. A summary of these scenarios is provided in Table 3.

Table 2. Summary of common parameters for optimization scenarios

Parameter	Value
Annual production of methanol (t/year)	54750
CO_2 cost (USD/ton)	30
Plant lifetime (years)	20
Interest rate of return (%/year)	8 %/year
Partial load limits (% nominal capacity)	0-100%
Installed capacity limits	≥ 0
Storage efficiency	100%
Ramping limits (% nominal capacity / h)	
Solid oxide electrolysis system	20 %/h
Methanol synthesis	20 %/h
Methanol distillation	20 %/h

Table 3. Summary of scenarios description

	Scenario acronym				
Characteristics	*AVG*	*NI-NS*	*NI-S*	*I-NS*	*I-S*
Wind power profile	No	Yes	Yes	Yes	Yes
SOEC/Methanol heat integration	Yes	No	No	Yes	Yes
Storage technologies	No	No	Yes	No	Yes

The base scenario, AVG, represents the usual energy integration optimization at steady-state conditions, where only an average of the power supply and costs is assumed. The other four scenarios include the possibility to heat integrate the electrolysis and fuel production (I – integrated; NI – non-integrated), as well as the use of storage to allow the processes to operate out of sync (S – storage; NS – no storage).

2. Methods

The objective function of the proposed optimization problem is the operating revenues of a process plant over a year discounting the amortized investment cost and fixed expenses, as expressed in Eq. (1). In this equation, $r_{i,t}^{in}$ and $r_{i,t}^{out}$ represent the rate of resources imported and exported by the process plant, respectively, while $c_{i,t}^{in}$ and $c_{i,t}^{out}$ denote their associated cost. In addition, the investment repayment and fixed expenses are estimated based on the grassroot cost for each technology (C_{GR}^{τ}) multiplied by the scale factor (f^{τ}) and capital recovery factor (β_{CRF}).

$$\max\left\{\sum_{t}^{T}\left[\sum_{i}^{I}\left(r_{i,t}^{out}c_{i,t}^{out}-r_{i,t}^{in}c_{i,t}^{in}\right)\right]-\sum_{\tau}^{\tau_n}f^{\tau}C_{GR}^{\tau}\beta_{CRF}\right\} \quad (1)$$

Technologies are divided into two categories, conversion and storage, which are denoted by the superscripts κ and σ, respectively. Each converting technology (κ) is represented by a black-box model consisted of a set of inlet resources ($r_i^{\kappa,in}$), outlet resources ($r_i^{\kappa,out}$) and heat transfers divided into temperature intervals (Q_k^{κ}), as exemplified in Figure 1. The main constraints of the optimization problem, Eq. (2) and (3), represent the balance of resources and heat between the boundary conditions of the process plant and its components (i.e., technologies). Moreover, resources and heat balances are influenced by transfers between technologies, which are affected by a temporal size factor (f_t^{κ}). This reflects the partial-load conditions of a technology in a particular timeframe (t).

$$r_{i,t}^{in}+\sum_{\sigma}^{\sigma_n}s_{i,t-1}^{\sigma}\eta_i^{\sigma}+\sum_{\kappa}^{\kappa_n}f_t^{\kappa}(r_i^{\kappa,in}-r_i^{\kappa,out})=r_{i,t}^{out}+\sum_{\sigma}^{\sigma_n}s_{i,t}^{\sigma}\quad\forall i,t \quad (2)$$

$$R_{k-1,t}+\sum_{\omega}^{\Omega}f_t^{\omega}\left(\sum_{n}^{N}Q_k^{\omega}\right)=R_{k,t}\quad\forall k,t \quad (3)$$

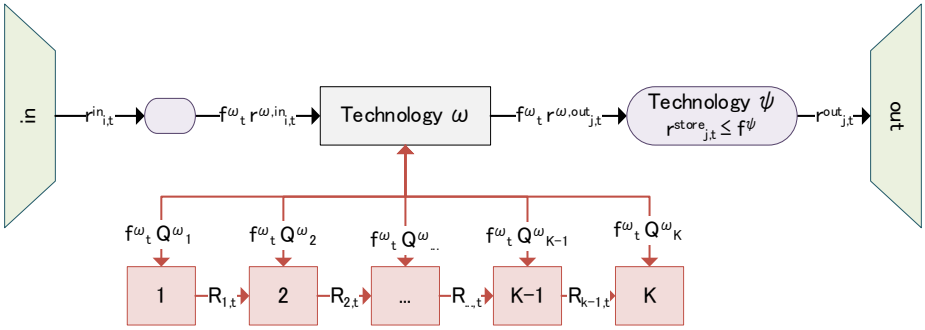

Figure. 2. Generalized sketch of a technology model in the optimization framework (where multiple technologies are coupled).

The heat cascade constraint, Eq. (3), is based on the work of Marechal and Kalitventzeff [13] and recently adapted by Li, et al. [6]. The heat transferred in a temperature interval, *k*, in a specific timestep ($R_{k,t}$) is positive to indicate a possible exchange from higher to a lower temperature level, and null in the extremes of the heat cascade (0 and K) [14]. These variable limits are represented in Eq. (4).

$$\begin{aligned} R_{k,t} &= 0, \quad k = 0, K \\ R_{k,t} &\geq 0, \quad otherwise \end{aligned} \tag{4}$$

On the other hand, storage technologies relate to accumulation variables ($s_{i,t}$) in Eq. (2) by limiting their maximum value to a size factor (f^{σ}), as written in Eq. (5). It's important to notice that storage losses can be modelled throughout an efficiency factor (η_i^{σ}) in Eq. (2), while inefficiencies in charging and discharging processes can be described by conversion technologies with an unequal balance of resources ($r_i^{\kappa,in} \geq r_i^{\kappa,out}$).

$$s_{i,t}^{\sigma} \leq f^{\sigma} \tag{5}$$

Resources can be imported or exported by the process plant under limited conditions that may vary depending on the problem analysed. For instance, a certain amount of product "*i*" may be delivered after a finite number of time steps (e.g., yearly demand of fuel), which can be represented by a constraint like Eq. (6). Another common scenario is that the supply and/or demand for each timestep is defined (e.g., hourly power generation or heat demand), as exemplified in Eq. (7).

$$\sum_t r_{i,t} = cte \tag{6}$$

$$r_{i,t} = cte \tag{7}$$

The technology size factors (f) are limited by upper and lower bounds, Eq. (8), while the temporal size factors for converting technologies (f_t) are restricted by maximum and minimal loads relative to their size (l_{min} and l_{max}, respectively), Eq. (9). In addition, some converting technologies may have ramping limits proportional to their size (r_{down} and r_{up}), which can be represented by Eq. (10).

$$f_{min} \leq f \leq f_{max} \tag{8}$$

$$l_{min} f \leq f_t \leq l_{max} f \tag{9}$$

$$r_{down} f \leq f_t - f_{t-1} \leq r_{up} f \tag{10}$$

The constraints described in Eq. (8) and (9) have been proposed by different authors [4,15] and they allow to optimize the technology sizes and operation loads simultaneously. However, these constraints don't allow to model operational discontinuities such as shutdown and standby periods without fixing the technology size. A possible alternative is to use a reformulation strategy as proposed by Voll et. al. [16] and recently employed by Li et al. [6].

3. Results

The main results for the optimization of each scenario are presented in Table 4. The cost estimates for methanol production and CAPEX excluding wind turbines vary between 1290-1820 USD/ton and 5123-8918 USD/t/y, respectively. Due to the current high investment of SOECs ($/kg$_{H2}$), these numbers are in the upper end range of those reported by IRENA and Methanol Institute [17] for e-methanol production through CO_2 from renewable sources (820-1620 USD/ton and 2000-9720 USD/t/y). The optimization results also exemplify how the variability of wind, heat integration and storage solutions can lead to different designs and costs.

For instance, the estimated costs for fuel production in the base scenario (AVG) are 27-29 % lower than other cases in which the influence of the wind power variability is considered. This difference can be explained by the need to oversize wind turbines, to compensate curtailment losses, and the Power-to-MeOH system, to match the varying rating of power generation, as it can be observed in Table 4. Figure 5 illustrates the distribution of CAPEX investments among all the technologies in each scenario. It is noticeable that the increase of SOEC size, due to the variability of wind power, represents the lion share (56-59%, 2766-2981 USD/t/y) of the CAPEX increase relative to the AVG scenario.

The optimization results also indicate the possibility to reduce 1-2% of methanol costs by integrating high temperature electrolysis with a methanol plant. This cost reduction can be attributed to the lower power consumption in the electric heaters for the integrated cases, as depicted in the Figure 6, which lowers the wind turbine sizes and, consequently, the total CAPEX investment. As can be observed by the integrated composite curves, heat provided by the condensation of the methanol reactor's products could be used to generate steam for the electrolysis system, reducing approximately 22% of electric heaters rating at steady state conditions (~1.5 MW).

Table 4. Main optimization results for each scenario proposed

	Scenarios				
Result	*AVG*	*NI-NS*	*NI-S*	*I-NS*	*I-S*
Size factors					
Wind turbine	1.00	1.25	1.24	1.22	1.21
SOEC	1.00	1.74	1.71	1.73	1.67

Methanol cost (USD/t)	1290	1820	1807	1793	1772

*The year base for economic values presented in this research is 2022

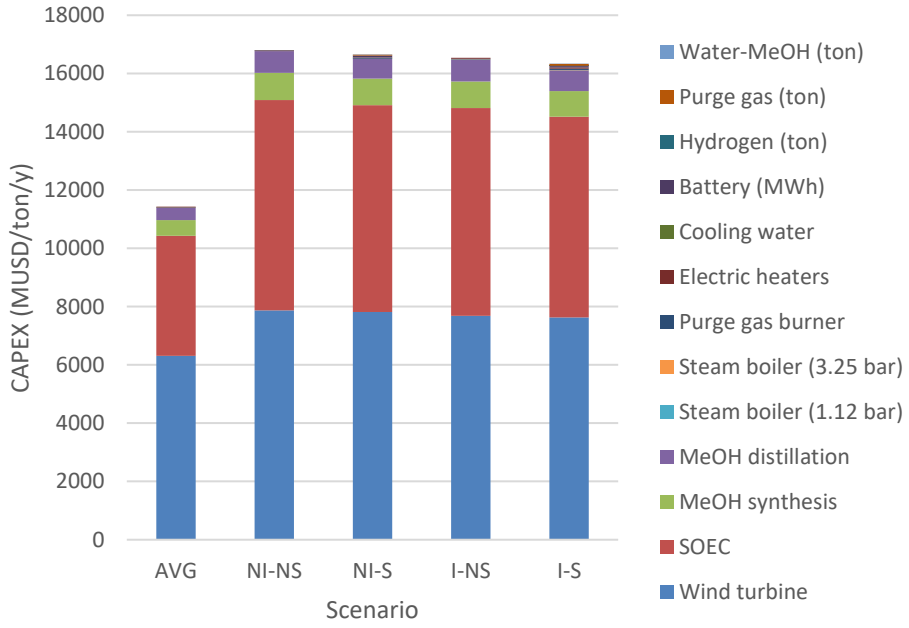

Figure. 5. Distribution of CAPEX investment for each scenario

The inclusion of storage solutions in scenarios NI-S and I-S allows an additional reduction in size of the wind turbines and electrolysis system and, consequently, lower the fuel costs in 0.7-1.2% compared with NI-NS and I-NS scenarios. It is important to highlight that a larger reduction in the electrolysis size is observed for the integrated scenario (3.3% against 1,6% for the non-integrated), which indicates that excluding heat integration during operating optimization could hide significant improvement opportunities. In particular, the I-S scenario operates differently depending on the wind power availability, as can be observed in Figure 7. For

instance, the system stores purge gas when wind power is close to maximum to be used when electricity availability is diminished. In addition, the optimal configuration also shuts-down the distillation process to reduce power consumption in electric heaters. This effect on the utility's consumption can be more clearly examined from the integrated composite curves depicted in Figure 8

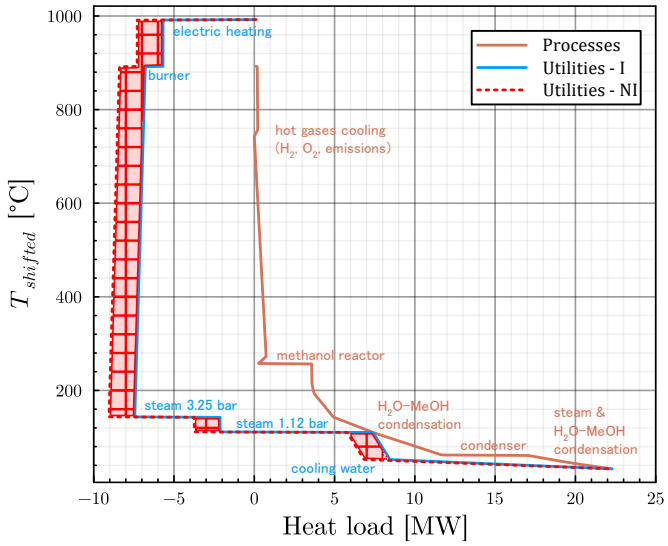

Figure. 6. Heat integration between utilities and processes for scenarios I and NI

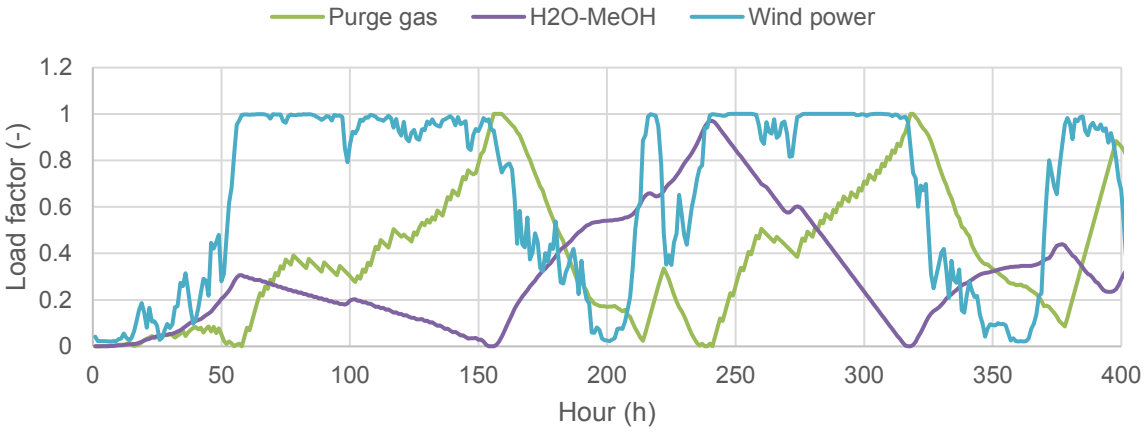

Figure. 7. Wind power and storage load variation of purge gas and H_2O-MeOH for the I-S scenario

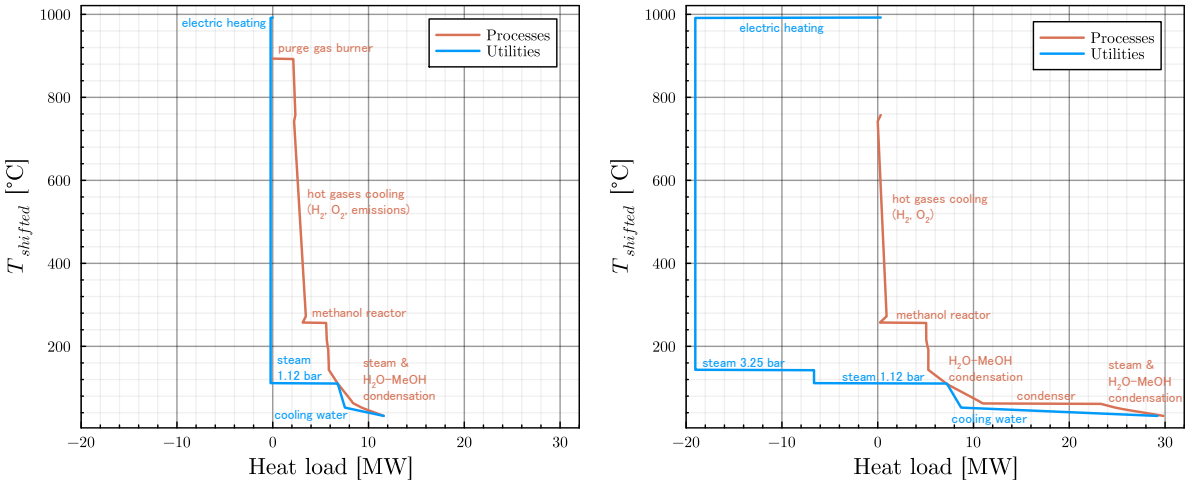

(a) Low wind power (t = 170 h) (b) High wind power (t = 277 h)

Figure. 8. Integrated composite curves for I-S scenario at different hours

3.1. Discussions

The results of the optimization study presented in the previous subsection exemplify how the steady-state assumption may hide costs and inefficiencies linked with the variability of renewable energies such as wind and solar power. This underestimation may also diminish the possible benefits of using biomass energy, which is usually less efficient than wind/solar power, but it can supply a stable source of energy. For instance, a possible alternative to further reduce the SOECs and wind turbine sizes is to complement wind power with biomass energy. The impact of this hybridization in the product costs, which could be assessed by the optimization framework proposed here, can't be fully evaluated from traditional steady-state integration studies.

In addition, the Power-to-Methanol example also demonstrates how heat integration is a crucial part of high temperature electrolysis systems such as SOECs. On the other hand, this may not be an important factor for traditional technologies, such as alkaline electrolysis, which may lead to unfavourable designs of Power-to-X plants for the future. For example, choosing to produce hydrogen separated from its use may not impact on product's cost today, but it may hinder the possibly benefits of switching from alkaline/PEM electrolysis to SOEC technology in the future. A similar observation can be drawn from the storage optimization scenarios, which may require oversized process parts (e.g., distillation and burners) from conception to reduce operating costs.

Previous studies have also pointed to possible improvements by generating steam from heat integration and proposed to reduce steam consumption by using co-electrolysis [2]. Other suggested modification indicated by Zhang et al. [3] is to operate at strongly exothermal conditions (0.9-1.1 A/cm^2, 1.42 V, 750-870 °C) to provide enough heat for steam generation and reduce cells size. However, the operation under exothermal conditions may severely increase cells degradation, which mostly likely will limit this optimization solution. On the other hand, the impacts of wind power variability and storage in the optimization of plant design and operation, as demonstrated in this study, have seldom been evaluated.

The optimization framework proposed in this study has several limitations, which can be overcome by including additional modelling strategies. For instance, the nonlinear properties of certain systems (e.g., efficiency and costs) can be approximated by a series of lines for specific intervals [16]. Another example is the details of the heat exchanger network, which can be designed to minimize the number of units to indirectly reduce the cost of the energy integration [8,14]. An extended version of this research work will focus on including these improvements and extending the Power-to-Methanol analysis.

4. Conclusions

An optimization framework is proposed to evaluate opportunities for heat integration on energy conversion and storage systems operating at dynamic conditions (e.g., fluctuating power loads, seasonal resources, etc.). The method aims to merge techniques from multi-period optimization with energy integration methods derived from pinch analysis to assist in the optimization of size and operation of future energy systems such as Power-to-X. The optimization of a Power-to-Methanol plant operating off-grid using wind power is used to exemplify the different insights provided by the optimization framework. For instance, the results indicate that conventional heat integration studies assuming constant power supply and costs may significantly underestimate technology sizes and costs (27-29 %). In addition, heat integration between high temperature electrolysis and methanol production may reduce up to 2% of fuel costs by reducing the required electric heating for steam generation. Moreover, a reduction of up to 4% in the electrolysis systems can be achieved by optimizing storage and operation including heat integration. This is possible by storing purge gas during high wind power periods and shutting down methanol distillation during low wind power generation. It is important to highlight that this size reduction is reduced by half in the case without including the possibility of heat integration, exemplifying the hidden opportunities for design in Power-to-X compared with previous studies of multi-period optimization.

Appendix A – Technologies details

The main details of each technology and storage options assumed in the optimization study are presented in Tables 5-8. The balance of resources and heat transfer, Tables A.1 and A.2, are based on thermodynamic models described in a previous study. The cost of investment, maintenance, and operation (Tables A.3 and A.4) were estimated following the equations proposed by Turton, et. al. [18] and Seader et. al. [19], except for the SOEC system and storage, which was determined based on values proposed by Refs. [4,20].

Table A.1. Balance of resources for each technology at reference size

	Inputs			**Outputs**		
Technology	*Type*	*Qnt.*	*Unit*	*Type*	*Qnt.*	*Unit*
Wind turbines				Electricity	0-130.5	MW
SOEC thermoneutral	Steam 1.12 bar	365.37	ton/d	Hydrogen	29.84	ton/d

Abstract:
This work presents a novel concept of reactor design in CLC technology. This is the second concept in a series of patents on the construction of air and fuel reactors. The first patent ”The combustion chamber design of a duo-fluidized bed reactor with circulating solid oxygen carriers of the CLOU type” was presented at the 6th International Conference on Chemical Looping in Zaragoza, Spain in September 2022.
The purpose of the presented solution according to the invention was to develop a simple reactor structure for the optimization of the chemical looping combustion process. According to the invention, the presented reactor dedicated to solid fuels combustion in the CLC system has two chambers of identical conical-cylindrical shapes, which are symmetrically and permanently attached with their upper conical parts to rotatably fixed transport pipes located on a common axis.
The simple and compact design of the reactor makes it economic & easy to manufacture and takes up significantly less space than a classical unit designed for the chemical looping combustion process. The proposed design enables uncomplicated process control due to fewer auxiliary devices as compared to the previous designs used for process control. Moreover, the reactor according to the invention has a lower energy expenditure because it uses lower gas velocities for effective operation than in a traditional CLC unit.

Keywords:
Chemical looping combustion, fuel reactor, oxygen carrier, moving bed.

1. Introduction

The currently visible climate changes encourage the reduction of pollutant emissions and the search for low-emission combustion technologies. There are many ways to mitigate climate change, but two are the most common. The first method includes all means that reduce CO_2 emissions into the atmosphere while increasing energy efficiency or using zero or low-carbon fuel sources. Another, also effective method is the use of negative emissions (NET) to reduce carbon dioxide from the atmosphere using sequestration techniques [1]. Commonly known and used CO_2 capture methods are: pre-combustion, oxy-fuel combustion, and post-combustion separation [2]. Another method of reducing carbon dioxide emissions into the atmosphere is oxy-fuel combustion. In this method, the combustion process takes place in a mixture of oxygen and CO_2 [3].

All of the above methods are effective, but at the same time energy-intensive, resulting in a significant decrease in overall combustion efficiency and consequently leading to higher energy prices [4].

1.1. CLC technology a brief characteristics

The Chemical Looping Combustion (CLC) technology is one of the methods of reducing CO_2 emissions. In the combustion process, fossil fuels release pollutants responsible for the greenhouse effect into the

atmosphere. Fossil fuels are estimated to be responsible for as much as one-third of global CO_2 emissions [5–7]. This undoubtedly has a significant impact on climate change. CLC allows to obtain a high concentration of CO_2 in flue gases, therefore it eliminates the need to use Carbon Capture and Storage (CCS) methods. This type of combustion can be classified under the category of oxy-combustion techniques, it has the advantage of producing nitrogen-free flue gases from the combustion air. It is an environmentally friendly method that reduces costs and time while reducing CO_2 emissions into the atmosphere [8–10].

A typical CLC unit consists of two separate reactors: an air reactor and a fuel reactor, which form two separate circulation contours (Figure. 1). In the literature, a system for chemical looping combustion of fuels is known, which was designed by Chalmers University of Technology (Sweden). A conventional unit consists of fuel and air reactors, a cyclone and two loop seals connecting the reactors. Each of the reactors has a different structure and dynamics of the fluidized bed, characteristic for a given chamber: a circulating fluidized bed in an air reactor and a bubble fluidized bed in a fuel reactor. The reactors are located parallel to each other, and the entire unit has a stationary structure [9,11].

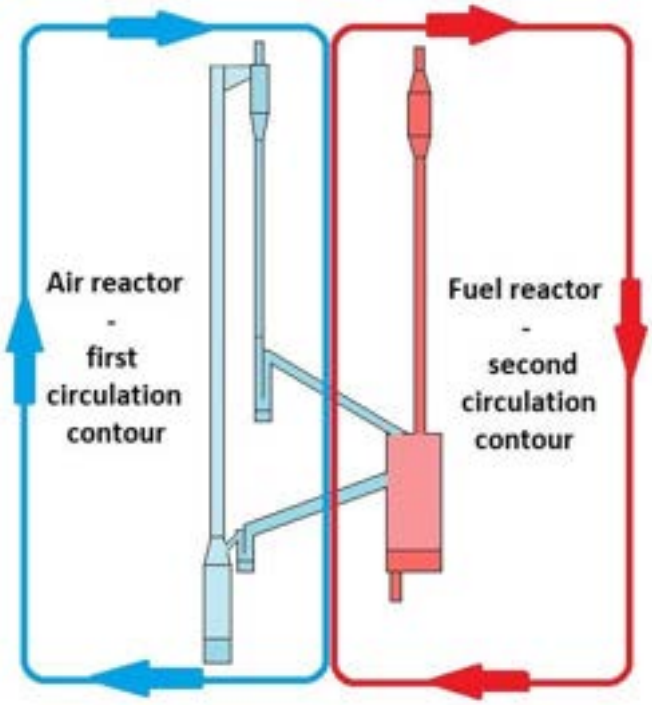

Figure. 1. Typical scheme of a CLC unit divided into circulation contours.

CLC technology applies solid oxygen carriers in the fuel combustion process, which are metals or metal oxides that carry oxygen between the air reactor and fuel reactor. Oxygen carriers play a vital role in the overall process because their oxygen-carrying capacity eliminates direct contact between air and fuel [12].

The selection of the appropriate oxygen carrier is a very important issue in the design of CLC combustion, as its properties affect the entire process. Therefore, the oxygen carrier should be: environmentally friendly, economically viable, resistant to abrasion and agglomeration. Additionally, the oxygen carrier should be characterized by the following features: high oxygen carrying capacity, reactivity, both during the oxidation and reduction stages, high melting point, ease of fluidization and mechanical resistance [13–16].

1.2. CLC pilot facilities

One of the largest pilot CLC installations with a capacity of 1MW is located at Darmstadt University of Technology. The air reactor and fuel reactor are designed as two separate circulating fluidized bed reactors. The inner diameter of the fuel reactor is 0.40 m, while the air reactor is 0.59 m. The height of the fuel reactor structure is 11.35 m, while that of the air reactor is 8.66 m. In addition, the entire system has been covered with insulating material to minimize heat losses. The use of insulation of the entire system is crucial because the reactors are not additionally heated with electric heaters. Tests studies were carried out on the pilot plant in Darmstadt using coal as fuel and Fe, Cu, Mn and ilmenite as oxygen carriers [17–19].

Another example is CLC pilot plant which is located at the Vienna University of Technology. The 120 kW test stand is dedicated to burn gaseous fuels [20]. The structure of the fuel reactor is designed to operate in a turbulent fluidization regime. This ensures better mixing of the gaseous fuel with the oxygen carriers in the

fluidized bed. In studies conducted on this pilot unit used nickel and ilmenite as oxygen carriers, while the fuel was natural gas and a gas mixture of CH_4, CO, H_2 and C_3H_8 [8,20,21].

Another well-known CLC pilot unit is located at Chalmers University in Sweden. The designed 100 kW system is dedicated to burn solid fuels. The pilot plant was developed as part of the European ÉCLAIR project coordinated by the ALSTOM concern. Tests were conducted using hard coal and ilmenite as oxygen carriers. During the test studies, a temperature of 1000°C was maintained in the fuel reactor and 970°C in the air reactor. A good CO_2 capture rate of 98 – 99% was achieved [17].

There are two CLC units in Poland. The first one is located at the Institute for Chemical Processing of Coal in Zabrze (IChPW). The second one is located at the Czestochowa University of Technology. The CLC unit located in the IChPW is dedicated for the combustion of gaseous fuels. The following gases are supplied to the installation: nitrogen, methane and process gases. The CLC plant operates at atmospheric pressure, at temperatures 800°C - 1000°C. The maximum feed rates for fuel, air and oxygen carrier are 1 m^3/h, 15 m^3/h and 40 kg/h, respectively. The height of fluidized bed reactors are 1 m high and 0.133 m in diameter [16].

The second unit for Chemical looping combustion of solid fuels is located at the Institute of Advanced Energy Technologies, Czestochowa University of Technology [5].

The CLC system for solid fuels consists of two main circulating contours [11]:

(1) an air reactor with a circulating fluidized bed, an ascending section and a return system comprising a cyclone and a precipitation section,

(2) a bubbling fluidized bed fuel reactor and a particulate collector.

The air reactor is constructed as a cylinder, which transitions into a cone at the top. In contrast, building a fuel reactor is more complex (Figure 2), as the structure is a cuboid with incomplete internal baffles. These baffles are designed to improve mixing processes and increase the residence time of the gas and material grains. The CLC stand is equipped with electric heaters with a total output of 72 kW. The heating system is located at full height on both sides of the stand [5,11,22,23].

a) b)

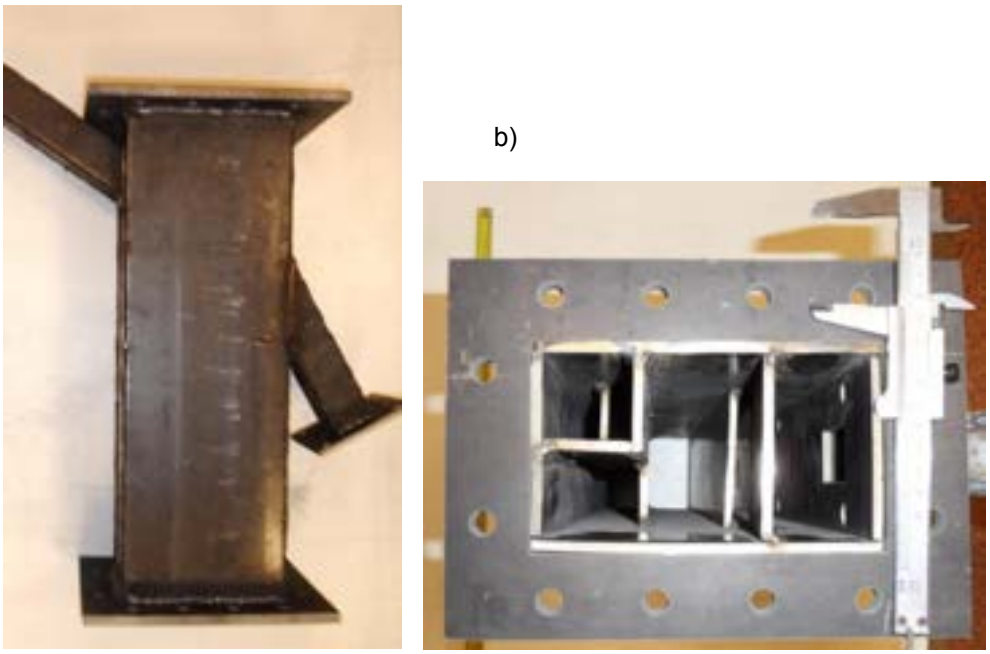

Figure. 2. Photo of the fuel reactor: a) side view; b) cross-section of the fuel reactor.

1.3. Motivation and scope of research

The proposed idea concerns the new design of the fuel reactor with a moving bed and is dedicated to solid fuels. It can be used in power plants and research laboratories. This reactor design allows for the implementation of subsequent processes of solid fuel combustion and regeneration of the oxygen carrier. In addition, this reactor design increases the efficiency of the system.

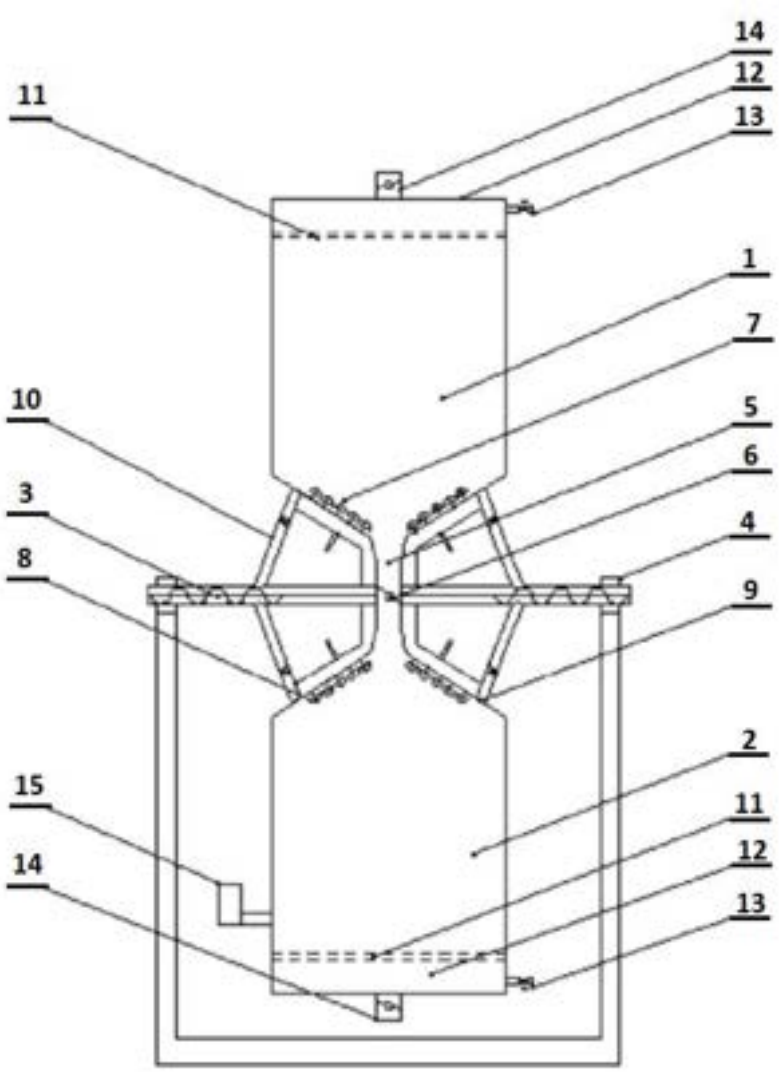
The reactor for solid fuels in a chemical looping combustion system, according to the invention has chambers of identical conical-cylindrical shapes, which are symmetrically and permanently fixed with their upper, conical parts to rotatably fixed transport pipes located on a common axis. In the channel narrowing between the conical parts of the chambers there is a material flow control valve, and in the conical part of the air chamber there are air supply nozzles. In the conical part of the combustion chamber there are gas

nozzles, while the outlets of the chute channels are located in both chambers in their conical parts from the side of the cylindrical parts.

2. Results and discussion

2.1. Two-bed reactor design

A novel two-bed reactor for a chemical looping combustion system with a moving bed is presented in this paper. The invention is the subject of patent No. PL 234783 (Czakiert et al., 2017). The novel fuel reactor is designed to ensure the more efficient performance of the CLC process in general. The idea of the construction is shown in Figure 3, and the details are provided below [24].



1 – air chamber
2 – combustion chamber
3 – transport pipes
4 – the supports of the frame structure
5 – channelled constriction
6 – control valve
7 – air nozzles
8 – gas nozzles
9 – outlets
10 – ash chute channels
11 – grate
12 – air box
13 – gas inlet port
14 – gas outlet stack
15 – fuel feeder

Figure. 3. Schematic of two-bed reactor for a chemical looping combustion system with a moving bed.

The chemical looping combustion reactor for solid fuels has two chambers (1) and (2) of identical conical-cylindrical shapes, with one chamber being air chamber (1) and the other combustion chamber (2).

Chambers (1) and (2) are symmetrically and permanently fixed with their upper conical parts to pivotally fixed transport tubes 3, for removing ash from the reactor, situated on a common axis. The transport tubes (3) are connected by bearings to the supports of the frame structure (4). The mobile connection of transport pipes (3) ensures that the entire reactor can rotate around the horizontal axis. Between the conical parts of chambers (1) and (2), which are connected to each other, there is a channelled constriction (5) in which a control valve (6) for the flow of material during the combustion process is fitted. In the conical part of the air chamber (1), nozzles (7) are fixed to supply air to the inside of the air chamber (1) and in the conical part of the combustion chamber (2) there are gas nozzles (8). Gas nozzles (8) in the combustion chamber allow air to be supplied when combustion chamber (2) is above air chamber (1), while, after the rotation of chambers (1) and (2), when combustion chamber (2) is below air chamber (1), gas nozzles (8) allow exhaust gases to exit combustion chamber (2). Both chambers (1) and (2) are equipped with outlets (9) of chute channels of ash (10) connected to transport pipes (3). The outlets (9) of chute channels (10) in chambers (1) and (2) are located in their conical parts on the side of the cylindrical parts. The positioning of the outlets (9) of the ash chute channels (10) close to the vertical walls of the cylindrical section allows efficient ash removal during reactor operation.

In the lower cylindrical part in each chamber (1) and (2), above the bottom, there is a grate (11) with an air box (12) equipped with a gas inlet port (13) and a gas outlet stack (14). Above the grate (11) in combustion chamber (2) there is a fuel feeder (15).

The reactor according to the invention, shown in Figure 3, allows pendulum movements during which, in an alternating cycle, once the air chamber (1) and once the combustion chamber (2) are in the upper position, while the other chamber is in its lower position. Depending on the position of chambers (1) and (2) in relation to each other, their functions change. The chamber in the lower position becomes combustion chamber (2), while the chamber at the top of the reactor becomes air chamber (1).

When the upper air chamber (1) of the reactor is emptied, chambers (1) and (2) rotate 180 degrees around the horizontal axis - the transport pipe (3). The lower chamber (2), which acted as the combustion chamber (2) and was fluidized with an inert gas in the form of carbon dioxide, henceforth becomes air chamber (1) and is fluidized with air. A channelled constriction (5) connecting chambers (1) and (2) equipped with a control valve (6) allows the flow of material between chambers (1) and (2). The gas in the lower chamber of the reactor constituting combustion chamber (2) is fed through a gas inlet port (13) via an air box (12) and grate (11), while in the upper chamber of the reactor constituting air chamber (2) it is fed through nozzles (7). Gas is discharged from air chamber (1) through a gas outlet stack (14) and from combustion chamber (2) through gas nozzles (8).

The solution according to the invention allows for the implementation of subsequent processes of solid fuel combustion and regeneration of the oxygen carrier.

To summarise the novel design concept of the CLC unit, the innovative reactor is characterised by:

1. The fuel and air reactors are made in the form of identical cylindrical-conical chambers connected by a flow channel.
2. The flow channel connecting the tops of the reactors is equipped with a valve to regulate the flow of material between the reactors.
3. The rigidly connected reactors, after emptying the upper chamber, perform a pendulum motion - a rotation of 180 degrees around the horizontal axis.
4. Nozzles are used in the reactors, which in the air reactor supply air to the chamber, while in the fuel reactor they are used to exhaust the flue gases.

The fuel combustion reactor design is simple and compact, so it is cheap to produce and takes up much less space than a classical unit designed for a chemical looping combustion process. The developed design allows for easier process control due to the smaller number of auxiliary devices previously used to control the process. In addition, the reactor according to the invention is characterised by lower energy expenditure because lower gas velocities are used in the reactor than in a traditional CLC unit to lift the fluidised layer. In addition, the reactor during operation is characterised by a lower consumption of the media and gases necessary for the fluidisation process needed for the chemical looping combustion process. The advantages mentioned above will affect the faster dissemination of ecological CLC technology in various industrial applications.

3. Conclusions

The CLC concept generally offers a highly concentrated CO_2 stream at the outlet of the power unit without any additional energy-consuming systems for gas separation (oxygen fractionations from atmospheric air or carbon dioxide capture from conventional flue gases), which makes this technology competitive with other

pro-CCSU (Carbon Capture, Storage and Utilization) technologies. However, the presented novel fluidized-bed fuel reactor, which is tailored to the use of solid oxygen carriers and the utilization of solid fuels, provides further reduction of operating costs with even higher inherent CO_2 capture efficiency.
The new fuel reactor concept was designed for solid oxygen carriers. Solid fuels, such as coal, and biomass, can be used as fuel. The proposed idea is characterised by an innovative reactor design that makes it economic and easy to manufacture. In addition, such a design takes up significantly less space than a classical unit designed for the chemical looping combustion process. These are undoubtedly the most significant advantages of the presented idea. As a result, the new fuel reactor concept ensures more efficient operation of the CLC processes.

Acknowledgments

This study was funded from Norway Grants in the Polish-Norwegian Research Programme operated by the National Centre for Research and Development, project: Innovative Idea for Combustion of Solid Fuels via Chemical Looping Technology, agreement number POL-NOR/235083/104/2014. The support is gratefully acknowledged.

The work was also funded by the statute subvention of the Czestochowa University of Technology, Faculty of Infrastructure and Environment.

Abstract:

Wastewater treatment (WWTP) is one of the major challenges due to the growing global population. Despite the complexity of the non-linearity and dynamic of environmental data, deep learning technologies should be created for WWTP. In this study, deep learning of long short-term memory (LSTM) is adopted to forecast permeate flux in membrane bioreactor of WWTP with five parameters involved such as permeate flux, transmembrane pressure (TMP), air flow, pump (voltage) and backwash. Three deep learning models derived from LSTM namely vanilla LSTM, bidirectional LSTM, and stacked LSTM including recurrent neural network (RNN) were constructed. The proposed LSTM's models provide promising results with 90 % accuracy of the predicted permeate flux model and can aid in establishing fouling backwashing process strategies, leading to reduced capital, energy consumption, and operational cost. Therefore, the proposed LSTM model is an adequate interpolation tool to predict the permeate flux of membrane bioreactor process in WWTP systems.

Keywords:

LSTM; Deep Learning; Neural Network; WWTP.

1. Introduction

One of the promising 21st-century technologies is the membrane bioreactor, which combines a biological process with permeable membranes. Since then, this technology has experienced constant advancement, and its uses have covered a wide range of industries, including water treatment, wastewater reclamation, juice concentration, dairy production, medical use, and cell harvesting [1-5]. But a serious issue that continues to restrict this technique's potential is membrane fouling. Fouling lead to an increase in operational costs due to more labour expenses for maintenance, increase energy demand, increase cleaning chemical expenses that will lead to shorter membrane life [6, 7]. It needs to be controlled and minimized through effective and efficient approaches.

The formation of fouling includes several mechanisms including adsorption, pore blockage and the formation of cake on the membrane [6]. Adsorption takes place when there is certain interaction between solutes/particles with the membrane. It results from the surface energy process and thermodynamic equilibrium process. Internal fouling caused by in-pore adsorption can contribute to overall flux drop as well as rise in transmembrane pressure (TMP) since the pore of membrane are equivalent to those of many macromolecules [8] [9]. Meanwhile the pore blockage is caused by entire or partial blockage by colloids and particles that cause pore obstruction [10]. Cake formation is the process by which particles accumulate on a membrane outside surface layer by layer, increasing the flow of permeates resistance. The additional resistance is known as a cake resistance, and the process is frequently referred to as the development of a fouling cake.

In order to maintain the membranes' ability to function sustainably, routine operations must include cleaning the membranes—both physically and chemically. Chemical cleaning is recommended to be avoided or limited in frequency in the full-scale application of submerged membranes due to the detrimental effects it has on the membrane [11]. However, by using efficient physical cleaning techniques, which would lengthen the membrane lifetime, the use of cleaning agents can be decreased. Procedures for backwashing are essential to the longevity and effective operation of low-pressure membranes. As a result, this operating technique has become essential to ensuring reliable, consistent, and high-quality water [12]. Backwashing is a vital

component of physical cleaning and is done by pushing a reversed flow through a membrane from the permeate side to the feed side while utilizing a specific kind of medium. Backwashing causes foulants that were deposited or adsorbed on the membrane surface or pores to become loosened or detached.

The widespread application of artificial intelligence (AI) in areas including healthcare, smart cities, intelligent search, big data, and pattern recognition, as well as its rapid development, present a huge chance to accomplish this goal. One of the most popular AI method used for water quality prediction is artificial neural network (ANN) [13]. ANNs are feedforward neural networks consisting of multiple layers of interconnected nodes, or neurons. They are primarily used for supervised learning tasks, such as image classification and regression, and are not well-suited for handling sequential data. As a typical representative of ANN, the conventional feed-forward neural network (FFNN) and its upgraded algorithm are a classic example of neural networks and have been successfully used to predict water quality [14-16]. Another neural network that has been extensively used in model prediction in various water environment is radial basis function (RBF), as it has a straightforward structure, quick training time and capacity to estimate any functions globally with arbitrary precision [17-19]. However, the above ANN's model are not designed to consider the sequential nature of data, and thus are not well-suited for tasks such as time-series prediction problems. Hence, the so-called time series is a collection of observations that have been made in a time. Compared to automatic water quality monitoring plant, automatically collects the quality water parameters at a defined time interval such as once per day and uploads it into a server to reflect the variations of water quality. As a result, time series data is presented for water quality metrics.

On the other hand, one of deep learning neural networks that are designed to handle sequential data, such as time series-data is known as long short-term memory (LSTM) is highly recommended for time-series prediction [20-22]. LSTMs are specifically designed to address the problem of vanishing gradients in recurrent neural networks (RNN), which can make it difficult to train models that rely on long-term dependencies in the input data. LSTMs use a gating mechanism to selectively remember or forget information over time, which makes them particularly useful for tasks such as speech recognition, machine translation, and sentiment analysis. In summary, while ANNs are used for a wide range of tasks and have a general-purpose architecture, LSTMs are specifically designed to handle sequential data and have a unique architecture that enables them to model long-term dependencies in the input data. Due to those characteristics of LSTM, the research has grown significantly as a result of their successful time-series prediction ability [23]. In our knowing, just a few research have used LSTM models to predict permeate flux in membrane for drinking water quality process [20, 24].

The main objective of the current study is to develop and validate the capabilities of deep learning neural network models based on LSTMs, including vanilla-LSTM, bi-directional LSTM, and stacked LSTM, in predicting the permeate flux in a submerged membrane bioreactor. In addition to LSTM models, a comparison will be made with another neural network model called RNN. The study utilizes a dataset consisting of approximately 4021 samples, encompassing five key parameters: permeate flux, transmembrane pressure (TMP), air flow, pump voltage, and backwash. These parameters are utilized to construct the predictive models. The results of the study demonstrate the potential of deep learning LSTM models in accurately predicting time series data, particularly within the context of a submerged membrane filtration system. The ability of LSTMs to capture long-term dependencies and model complex dynamics makes them suitable for accurately forecasting the permeate flux over time in this specific application.

2. Modeling methodology

2.1. Long short-term memory (LSTM)

Long short-term memory (LSTM) is a type of recurrent neural network (RNN) that specifically designed for time-series problem and their long-range dependencies more accurately than conventional RNNs [25]. Figure 1(a) shows the architecture of RNN network. An RNN can be viewed as the design of a normal feedforward MLP network with loops added. Recurrent neural networks have cycles that feed previous time step activations into the network as inputs to influence predictions at the current time step. The network's internal states, which are theoretically capable of storing long-term temporal contextual information, store these activations. As a result of this process, RNNs can take use of a contextual window that changes dynamically over the course of the input sequence history [25].

A LSTM memory cell contains one tanh layer in addition to three sigmoid layers. The input, forget, and output gates of the LSTM are used to maintain and refresh the memory cells while filtering out extraneous data. The forget gate first chooses whether data should be kept or removed from the model. The input gate also manages the reserve of data on the current cycle input. The input gate has two responsibilities. Finding the state of the cell that needs to be updated is the first task; the sigmoid function chooses the value that needs to be updated. The second duty is updating the data to reflect the current condition of the cell. The output gate is the final gate. The following hidden state is determined by the output gate.

2.2. Vanilla LSTM

A vanilla LSTM is a most basic LSTM model as it has a straightforward LSTM configuration as shown in Figure 1(b). LSTM have a input layer and output layer that directly connected to single hidden layer of LSTM memory cells to create predictions [26]. The LSTM architecture described in the original LSTM study from 1997 is the one that will perform well on the majority of minor sequence prediction challenges. Contrary to its extensions, vanilla LSTM still performs brilliantly on a range of datasets more than 20 years after its launch, according to Greff and K. et al. [27]. Nelson et al. [28] used Vanilla LSTM to predict stock prices for the first time, and they were encouraged by the findings.

2.3 Stacked LSTM

Stacked LSTM were introduced by Graves et al. [29], in their application of LSTMs to speech recognition, beating a benchmark on a challenging standard problem. In the same work, it was found that the depth of the network was more crucial to accurately modelling rather than the number of memory cell. A stacked LSTM architecture is made up from multiple LSTM layers. Instead of sending a single value to the LSTM layer below, an LSTM layer above sends a sequence of values. Instead of having one output time step for all input time steps, specifically, one output per input time step [30]. Figure 1© shows the architecture of stacked LSTM.

2.4 Bidirectional LSTM

In order to maximise the use of the input sequence, bidirectional LSTMs walk through input time steps in both the forward and backward directions [31]. In order to implement this design, the first recurrent layer of the network is duplicated so that there are now two layers side by side. The input sequence is then provided as-is to the first layer as input, and a reversed copy is provided to the second layer. This method was created in the past as a broad method for improving the effectiveness of recurrent neural networks (RNNs). Figure 1(d) shows the architecture of bidirectional of LSTM network.

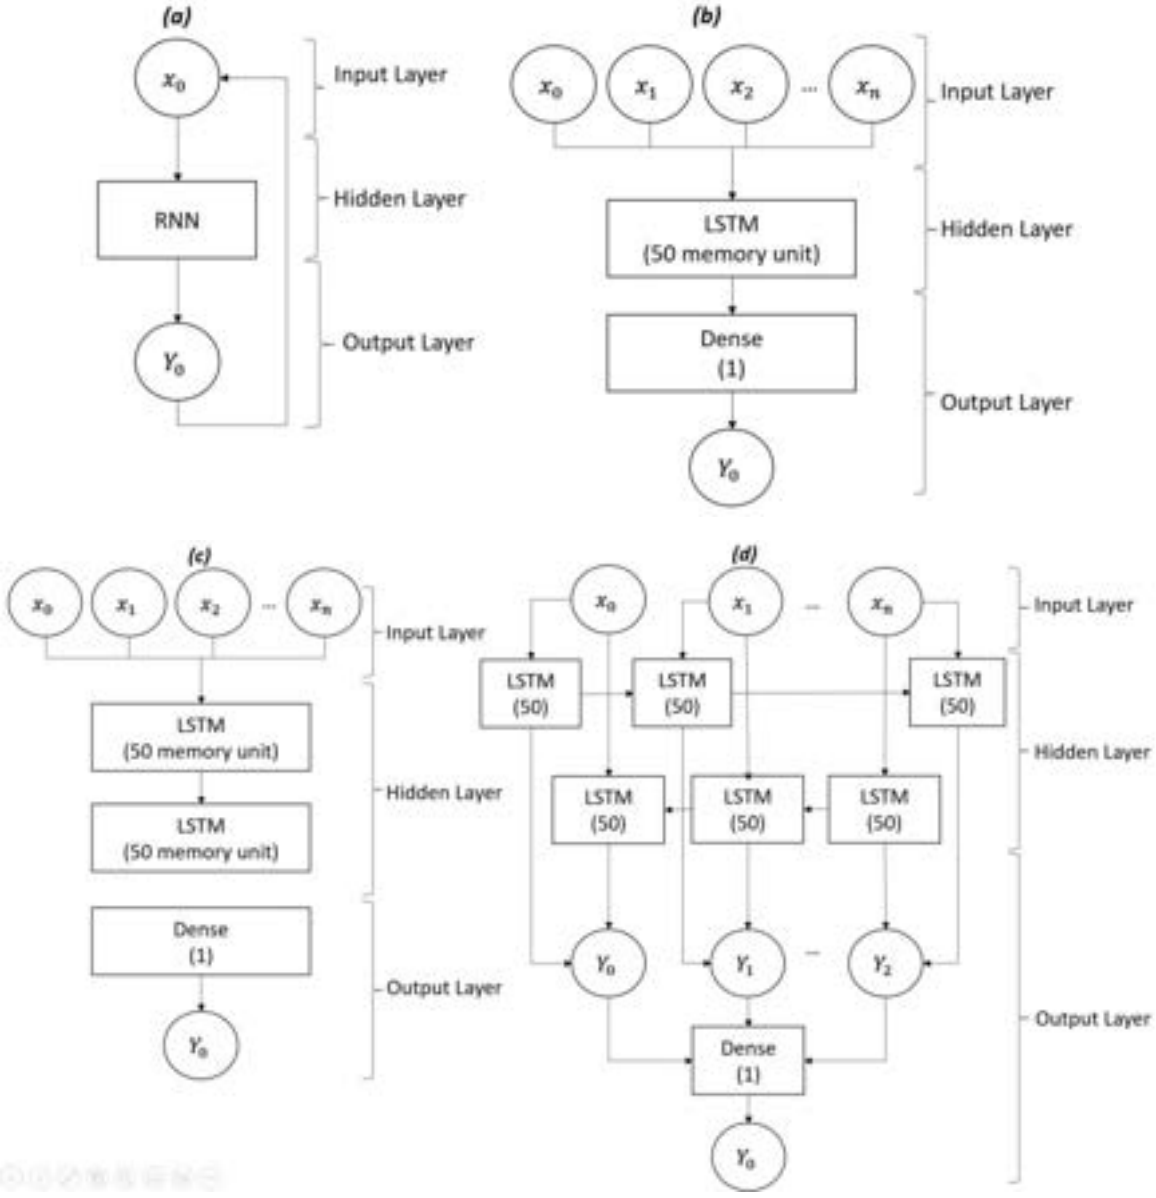

Figure. 1. Architecture of: (a) RNN (b) Vanilla LSTM (c) Stacked LSTM (d) Bidirectional LSTM.

3. Organization of paper

3.1. Pilot source water

A schematic diagram of submerged membrane bioreactor (SMBR) with four configurations of inlet stream, permeate stream, aeration and backwashing stream is illustrated in Figure 2. The permeate stream used diluted palm oil mill effluent (POME) collected from Mahamurni Plantation palm oil Sdn. Bhd., Wastewater treatment plant, located in Sedenak Johor Bahru as its source. The plant comprises of a single bioreactor tank that has been fitted inside with submerged hollow fibre and Polyethersulfone (PES) material is used to construct the hollow fibre membrane.

The POME was supplied into the 20 L bioreactor tank through the inlet stream. When the level reaches the specified level, the influent supply to the bioreactor will be stopped off by a mechanical level controller. The filtered influent is then pumped to the effluent tank down the pipe using a peristaltic pump (P-101). During permeate stream, the P-101 is activated to open the valve (SV-101). Electronic flow sensors are used to detect the permeate flux flow rate (FM-101). This part employs an electronic pressure sensor to monitor the transmembrane pressure (TMP) (P-101).

In order to study the long-term effects on transmembrane pressure (TMP) and membrane flux, the membranes were cleaned using just physical cleaning which are backwashing and aeration stream. The membrane was cleansed from the inside out in the backwash stream. When pump (P-102) is activated and valve (SV-102) is opened, the backwash procedure is complete. The membrane was cleaned by the backwash using filtered tap water that was kept in the backwash tank. The air that was pumped into the bioreactor using an air compressor (C-101). Electronic flow sensors are used to measure the air velocity under proportional valve (PV-101) control (FA-101). To produce bubbles, the air from the compressor is sent through the air diffuser.

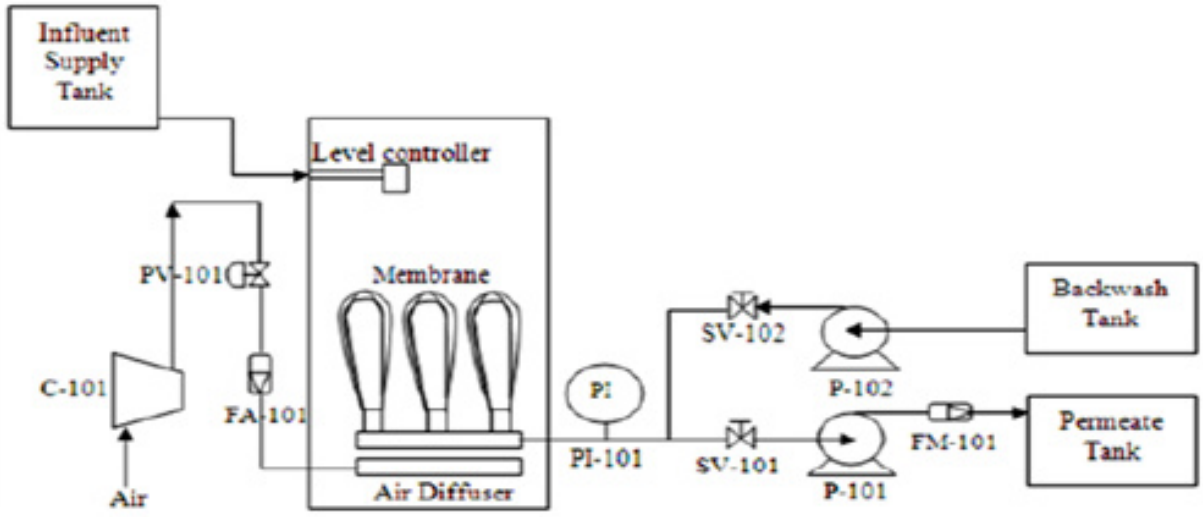

Figure. 2. Schematic diagram of submerged membrane pilot plant.

The pilot plant system was equipped with full monitoring and control using a data acquisition of National Instrument. Supervisory Control and Data Acquisition (SCADA) software is a type of graphical language-based programme that can be used with LabVIEW. For the aim of modelling, the software was created to record the collected data in the pilot plant. In this research, POME is used to generate fouling in the MBR filtration process. Figure 3 shows the actual sample used in the filtration process.

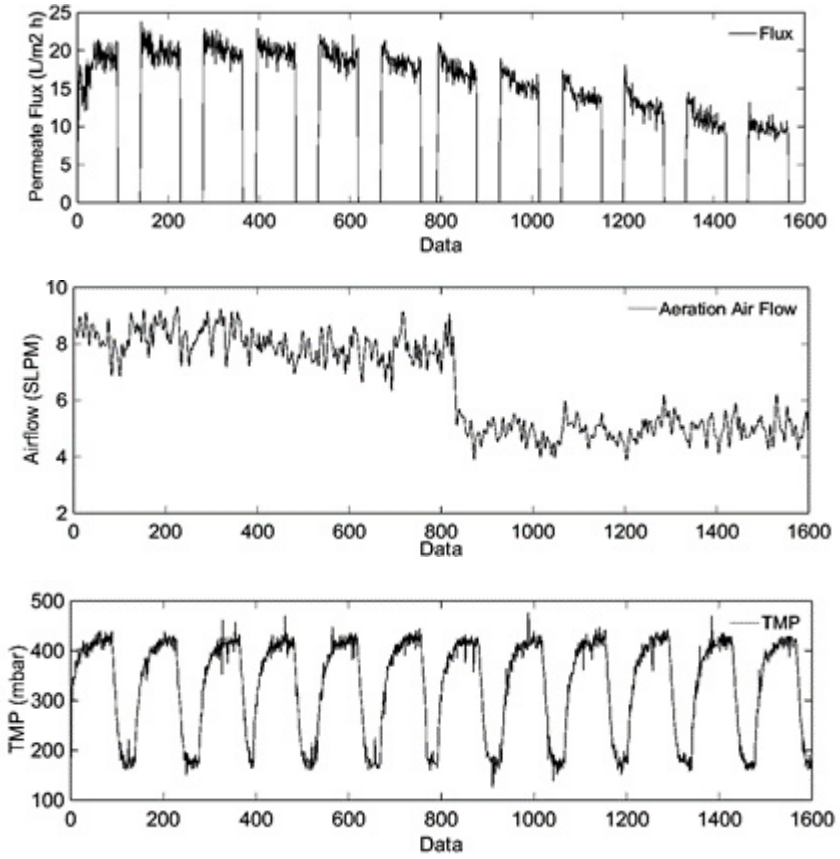

Figure. 3. Samples of the collected data using submerged membrane bioreactor plant.

3.2. Data pre-processing

Data pre-processing involved normalization or standardization of the data before they were used to train models. The normalization data is a method of scaled down the collected data that in the original range, so all values fall between 0 and 1. Meanwhile, standardize means rescaling the distribution values to have a mean of 0 and a standard deviation of 1. This can be thought of as subtracting the mean value or centering the data. Like normalization, standardization can be useful and required in machine learning algorithm when the data contains input values with different scale. Standardization makes the underlying assumption that your data has a Gaussian distribution (bell curve) with a well-behaved mean and standard deviation. If this assumption is not satisfied, an accurate result might not be able to achieve. The collected data was normalise using scikit-learn object MinMaxScaler and standardization can both be achieved using scikit-learn machine learning library in Python programming [32].

3.3. Transform time series data

A key function in Pandas library that is crucial tool for converting time series data into a supervised problems is Pandas shift () function. The shift() function can be used to make copies of columns that are pushed forward (rows of NaN values are added to the front) or pulled back (rows of NaN values added to the end). This is to generate columns of lag observations as well as columns of prediction observations. In terms of time series forecasting, forecasts are made using prior observations (t-1, t-n) and the current time (t), as well as future times (t+1, t+n). We can see how a time series containing sequences of input and output patterns can be utilised to generate a new DataFrame for a supervised learning task [32].

4. Result and discussion

4.1 Model performance

In this study, three different architecture of LSTM models such as Vanilla LSTM, Stacked LSTM and Bidirectional LSTM including RNN were developed to predict the permeate flux in submerged membrane bioreactor. During training these models, two loss function was used which are mean absolute error (MAE) and mean square error (MSE) to evaluate the performance of the models as it is suitable and recommended for time series problems. In this work, 100 epoch and 50 batch size were used. An epoch is an iteration over the entire training dataset. The model was iterating over the training data, multiple times until it achieves 100 epochs and updating the model's parameters at each time. The accuracy metric will be reported at each training epoch to reflect the performance of the model in addition to the loss function. The dataset consists of 4021 samples, and it were divided into 60/40 for each training and testing dataset. Figure 4 shows the loss

function graph of RNN, Vanilla LSTM, Stacked LSTM and Bidirectional LSTM models that were iterates for 100 epochs. From the graph, we can clearly seen that the model learned the problem by achieving towards zero error. A train (blue) and test (orange) line is created showing the MSE over the training epochs converged up to three decimal places which is a good sign for training models. The performance of the model suggests that the MAE and MSE error is a good match for a deep learning neural network LSTM's model as compared to RNN model which achieved MAE slightly lower than the others LSTM's model.

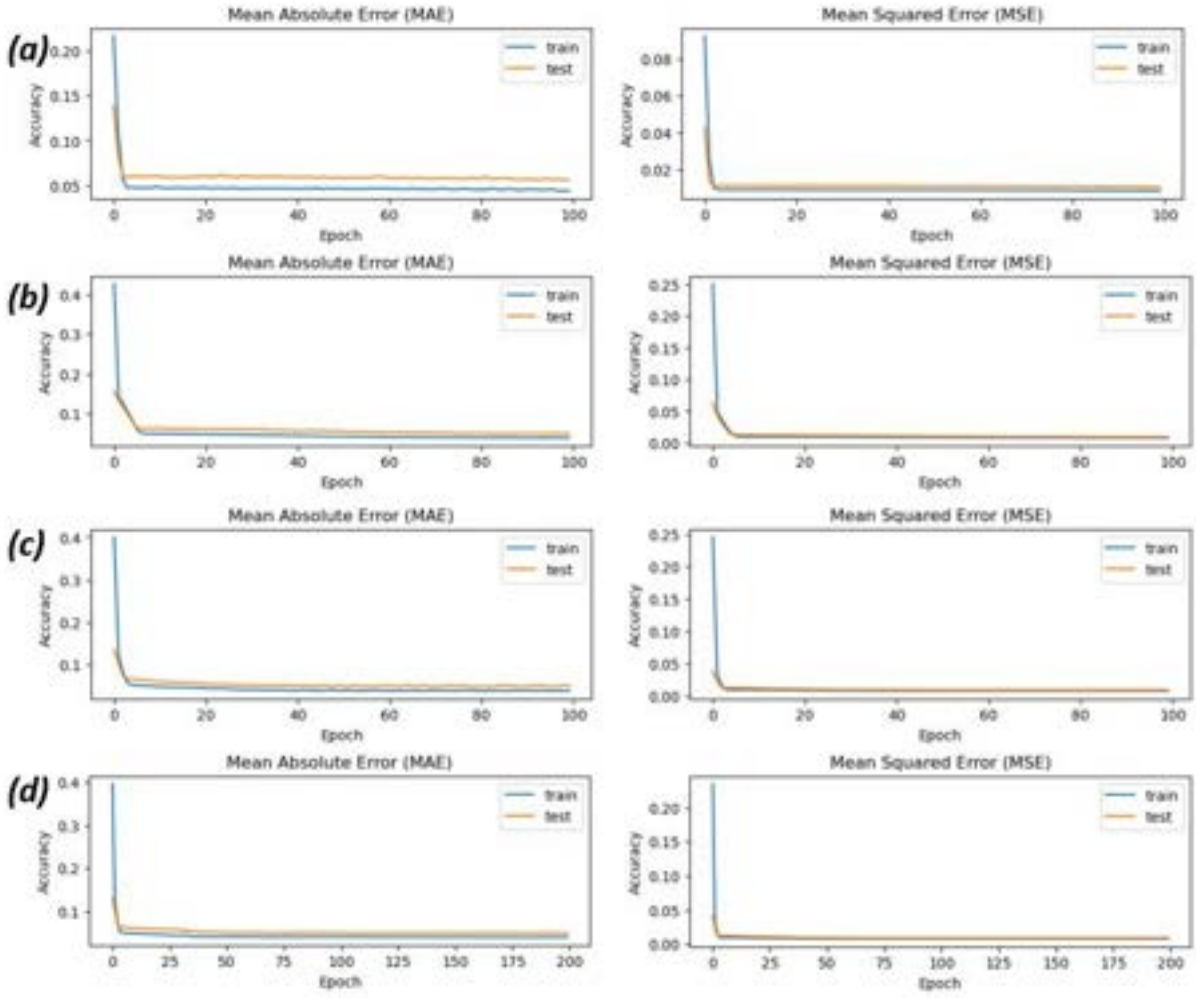

Figure. 4. (a) RNN, (b) Vanilla LSTM (c) Stacked LSTM (d) Bidirectional LSTM

After training using 60 % of dataset, the rest 40 % of the samples were used to predict the models. Figure 5 shows the plotted graph of training and testing dataset for RNN model. RNN model has the simplest architecture with 50 memory units, and it takes inputs from previous time steps direct to the output. From the training graph, RNN are able to forecast the training data set with 92.4 %. Meanwhile, the testing dataset only able to forecast the testing dataset with 89.0 %. Figure 6 shows the graph of vanilla LSTM. The architecture of Vanilla LSTM used 50 memory unit with 1 dense and batch size of 32. For training and testing dataset, it achieves 93.2% and 90.6 % respectively. As compared to RNN, Vanilla LSTM are able to improve the accuracy performance better when predicting the unknown model. Figure 7 shows the training and testing graph of stacked LSTM. For stacked LSTM, 50 memory unit were stacked with another 100 memory unit and 1 dense for its architecture. The results shows that 93.2% were achieve during training plot while 90.7% during the testing plot. The same result was obtained for bidirectional LSTM for both training and testing graph as shown in Figure 8. The overall accuracy performance results were also evaluated using root mean square error (RMSE) and it was tabulated in Table 1.

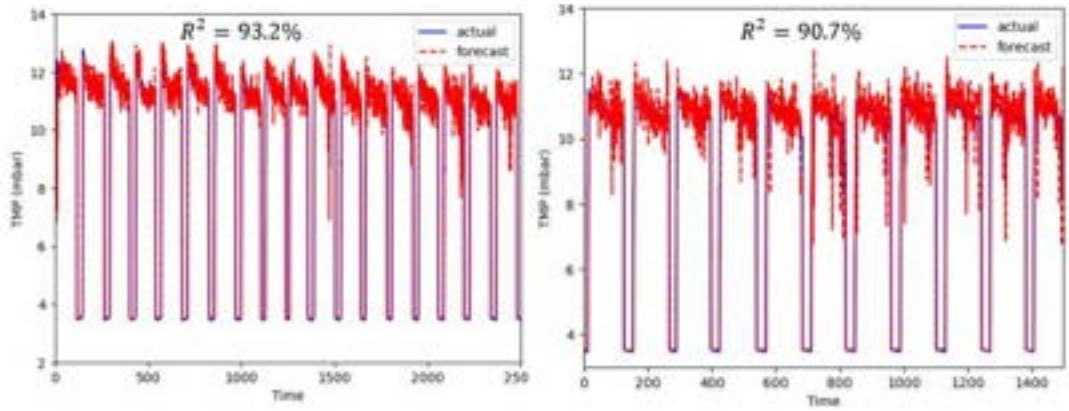

Figure. 7. The graph of training and testing dataset for Stacked LSTM model.

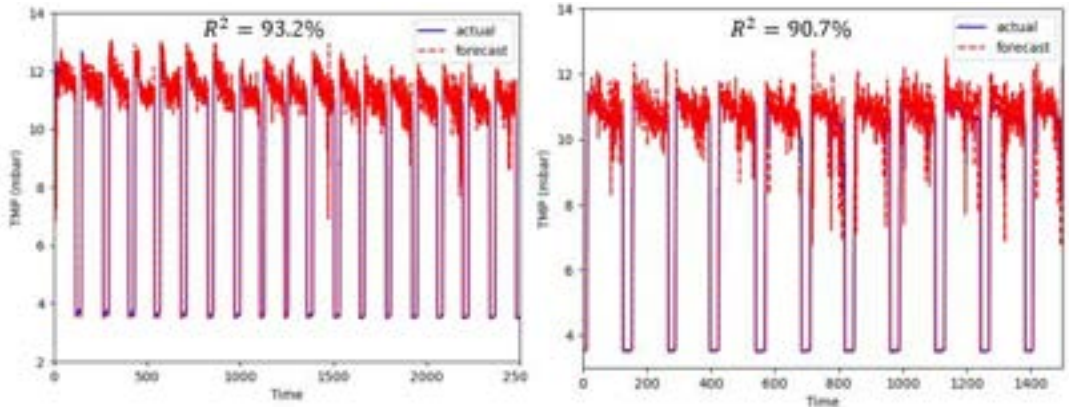

Figure. 8. The graph of training and testing dataset for Bidirectional LSTM model.

Table 1. Overall performance results of the models.

Model	Accuracy	Training	Testing
Vanilla LSTM	MSE	0.679	0.818
Epoch: 100	$RMSE$	0.824	0.905
Batch Size: 32	MAE	0.360	0.465
	R^2	0.932	0.906
Stacked LSTM	MSE	0.683	0.808
Epoch: 100	$RMSE$	0.826	0.899
Batch Size:32	MAE	0.363	0.466
	R^2	0.932	0.907
Bi-Directional LSTM	MSE	0.676	0.806
Epoch: 200	$RMSE$	0.822	0.898
Batch Size: 64	MAE	0.367	0.467
	R^2	0.932	0.907
RNN	MSE	0.762	0.955
Epoch: 100	$RMSE$	0.873	0.977
Batch Size: 32	MAE	0.414	0.534
	R^2	0.924	0.890

4.2 Conclusion

The good prediction model of submerged membrane filtration process can be a good useful in order to analysing backwashing strategies and helps to gaining some understanding on the fouling phenomena.

The main objective of the study is to compare the performance of two popular neural network architectures: RNN (Recurrent Neural Network) and LSTM (Long Short-Term Memory). Specifically, the researchers explored different types of LSTM models, including Vanilla LSTM, Stacked LSTM, and Bidirectional LSTM, to assess their effectiveness in comparison to RNN. Upon conducting the experiments, the researchers found that all three types of LSTM models Vanilla LSTM, Stacked LSTM, and Bidirectional LSTM yielded similar results. Despite their architectural differences, these variations of LSTM exhibited comparable performance, indicating that the core LSTM mechanisms were effective in capturing the underlying patterns in the data. However, when comparing these LSTM models with the RNN architecture, it was evident that the different types of LSTM consistently outperformed RNN. This suggests that LSTM's specialized design, which incorporates memory cells and gates to selectively retain and forget information, offers distinct advantages over the basic RNN architecture.

The improved performance of LSTM models can be attributed to their ability to capture and remember long-term dependencies in sequential data, thereby mitigating the vanishing gradient problem that hampers RNN performance. Vanilla LSTM, Stacked LSTM (which includes multiple LSTM layers), and Bidirectional LSTM (which processes input sequences in both forward and backward directions) all leverage these capabilities to achieve better results compared to RNN. These findings underscore the significance of employing LSTM architectures, in their various forms, for tasks involving sequential data or temporal dependencies. By utilizing the memory cells and gating mechanisms, LSTM models are better equipped to handle complex patterns and long-range dependencies in the data, leading to improved performance and more accurate predictions.

The performance of LSTM models can be further enhanced through various optimization strategies, including tuning the number of epochs, batch size, memory units, and dense architecture network. These adjustments aim to improve the accuracy and reliability of predictions. Additionally, the effectiveness of LSTM can be further amplified by integrating optimization techniques such as particle swarm optimization (PSO) or genetic algorithms (GA). These optimization methods assist in identifying the optimal architecture for the LSTM network, ensuring its efficiency and effectiveness in capturing complex patterns and delivering robust predictions. By leveraging these optimization approaches, LSTM models can be fine-tuned to achieve superior performance and more accurate results.

Abstract:

In this paper, an optimization algorithm based on a Mixed-Integer Linear Programming (MILP) solver is developed to determine the best energy generation solutions for marine applications. Environmentally sustainable systems (e.g., fuel cells and batteries), heat recovery devices (e.g., HRSG and Organic Rankine Cycles) and traditional power technologies (e.g., diesel generators and fired boilers) are modelled as linear systems to simulate their off-design performance. The tool considers thermal, electrical and propulsion power demands, space constraints, fuel type and availability for up to three main-vertical zones of the ship. From this information, the optimizer identifies the energy system configuration which minimizes a cost optimization function. The objective function considers the actualized capital costs of each technology (based on real market data and updated literature review), fuel costs and CO_2 emissions taxes.

In this article, the case study of a cruise ship is considered. The optimization is performed referring to real historical load demands of the cruise ship and several typical mission profiles are considered to simulate a whole operational year.

Then, the same optimization is performed after a reduction of the price of H2, which is expected in the near future according to the latest market forecasts. Thanks to this analysis, it is possible to determine the influence of this economic parameter on the optimal on-board power generation configuration.

It is worth noting that the approach presented here has a general validity and can be applied for the optimization of various typologies of maritime vessels. Moreover, the MILP algorithm could be easily expanded to consider additional demands (e.g. cooling power), constraints (e.g., weight), and power systems.

Keywords:

MILP; Energy systems; optimization model; sustainability; alternative fuels.

1. Introduction

It is a matter of fact that, as total final energy consumption is increasing more and more at global level (298 EJ in 2000, 365 EJ in 2010 and 418 EJ in 2019), CO_2 emissions are growing as well (22.3 Gtons in 2000, 30.6 Gtons in 2010, 33.6 Gtons in 2019) [1]. Despite recent international energy policies that are trying to limit the increase, it is evident that further efforts must be done to comply with the 2015 Paris agreement (COP21). According to IEA data, electricity and heat production is the most impactful sector (14.0 Gtons), followed by transports (8.2 Gtons). The maritime sector represents an important contributor, responsible for the emissions of nearly 3% in terms of CO_2 (1 Gton/year). In order to decrease the impact of this sector, the International Maritime Organization (IMO) set a long-term strategy in 2018, with the ambitious goal of reducing transport-related CO_2 emissions of 40% by 2030, with the final target cut of 70% by 2050, compared to 2008 levels [2]. In 2023 the strategy is going to be revised, with the possibility of introducing further reduction targets. Furthermore, the European Commission has recently proposed adding maritime transport to the EU Emissions Trading System (EU-ETS) [3]. More in detail, The Commission is proposing to extend the scope of the EU-ETS to cover CO_2 emissions from all cargo vessels and passenger ships above 5000 gross tons, regardless of the flag they fly. The extension will include, starting from 2024: (i) all emissions from ships calling at an EU port for voyages within the EU; (ii) 50% of the emissions from voyages starting or ending outside of the EU; (iii) emissions that occur when ships are at berth in EU ports [3]. To reach the ambitious targets of emissions reduction, many parallel strategies can be adopted [4][5], including optimization in vessel design, speed reduction in navigation, use of alternative systems for power propulsion (i.e. fuel cells) and alternative fuels (i.e. biofuels, e-fuels) [6][7]. As far as power systems are concerned, the use of different kinds of fuel cells has been investigated in recent literature [8][9][10], focusing on: (i) high temperature Solid Oxide Fuel Cells

(SOFC), usually in hybrid systems configuration to increase efficiency [11] (up to 60%); (ii) low temperature Proton Exchange Membrane Fuel Cells (PEMFC), directly fuelled by hydrogen, which represent a zero emissions solution. The latter solution is the most employed today, in particular in research vessels as reported in recent literature. Regarding fuels, many alternatives are possible to replace Heavy Fuel Oil (HFO) and Marine Diesel Oil (MDO), which are the most employed today and have high CO_2 emissions (about 3.1 $kgCO_2$/kg fuel). Natural gas is an alternative [12], however larger volumes are required for storage on-board and it only allows for a limited reduction (specific emission 2.75 $kgCO_2$/kg fuel). The use of hydrogen [13], ammonia [14], or other low carbon fuels is under investigation for several types of vessel [15].

To compare the different possible solutions in terms of power propulsion and storage technologies, it is important to develop reliable tools and models able to identify the best alternatives [16][17][18], taking into proper account the constraints of the problem, such as the volume and weight constraints of the vessel, the navigation route and the required performance in terms of autonomy and maximum power. The use of Mixed-Integer Linear Programming (MILP) models is largely recognized to optimize the distributed energy systems [19], also in presence of energy storage systems and not programmable renewable energy sources [20]. However, only a few applications of MILP models for power propulsion and fuel storage on-board maritime vessels are available in literature [21]. MILP models have never been developed before to investigate a wide spectrum of innovative technologies for a maritime application considering a time-dependent simulation on one year. In this paper, the tool developed by the Authors aims at: (i) choosing the optimal installation mix to meet the energy demands of the ship (electrical and thermal), while considering the most relevant constraints; (ii) minimizing an objective function which represents the annual costs.

2. Model Description

This section describes the optimization model developed for this study. It was designed as a tool capable of supporting the preliminary design phase of the energy systems installed on a ship. The optimization is performed by comparing different technologies for the generation of onboard electric and thermal power. The ship layout is split into three Main-Vertical-Zones (MVZ): each main-vertical-zone respects the tool constrains in order to identify the optimum location for each technology. The optimization model was tested considering a cost-based optimization function, which includes taxes on CO_2 emissions.

2.1. Library and user-interface

The optimization model was developed in MATLAB, while the optimization procedure relies on the BNB built-in solver of the Yalmip toolbox [19]. Within Yalmip, the GUROBI optimizer was adopted. This optimizer implements a standard branch & bound algorithm [20] to solve different kinds of mixed-integer problems [20][21]. The following technologies have been considered for electrical and thermal energy production:

- Internal Combustion Engines: Diesel Generators (DG).
- Heat Recovery System Generators (HRSG).
- Organic Rankine Cycles (ORC).
- Fire Boilers (FB).
- Heat Pump (HP)
- Battery Electrical Storage (BES).
- Proton-Exchange Membrane Fuel Cells (PEMFC).

Each technology requires a certain amount of primary energy source. Heat recovery systems (HRSG, ORC) or storages (BES) interact with the ship balance depending on their efficiency and usage. Then, Diesel Generators, Fired Boilers and PEMFCs require a primary energy source. The fuel of these technologies is considered by the tool as a limited energy source: if the fuel tank is empty, the associated technology is shut down. The type of fuel and storage systems implemented are:

- Tank for liquid storage: HFO, MDO, LNG, liquid hydrogen.
- Tank for gas storage: compressed hydrogen.
- Metal Hydrides (MH) for solid hydrogen storage.

Some system contributes to the production of both thermal and electrical power, which are requested to satisfy the demands of the ship. Assuming that a propulsion unit driven by an electric generator is installed on the ship, the propulsive power is included in the electricity balance. The propulsive demand is increased to consider an overall efficiency for energy transformation of 95%.

The user interfaces with an Excel worksheet (Figure 1) to specify which technologies will be considered in the simulation, the volumes allocated to each technology and their distribution in each main vertical zone.

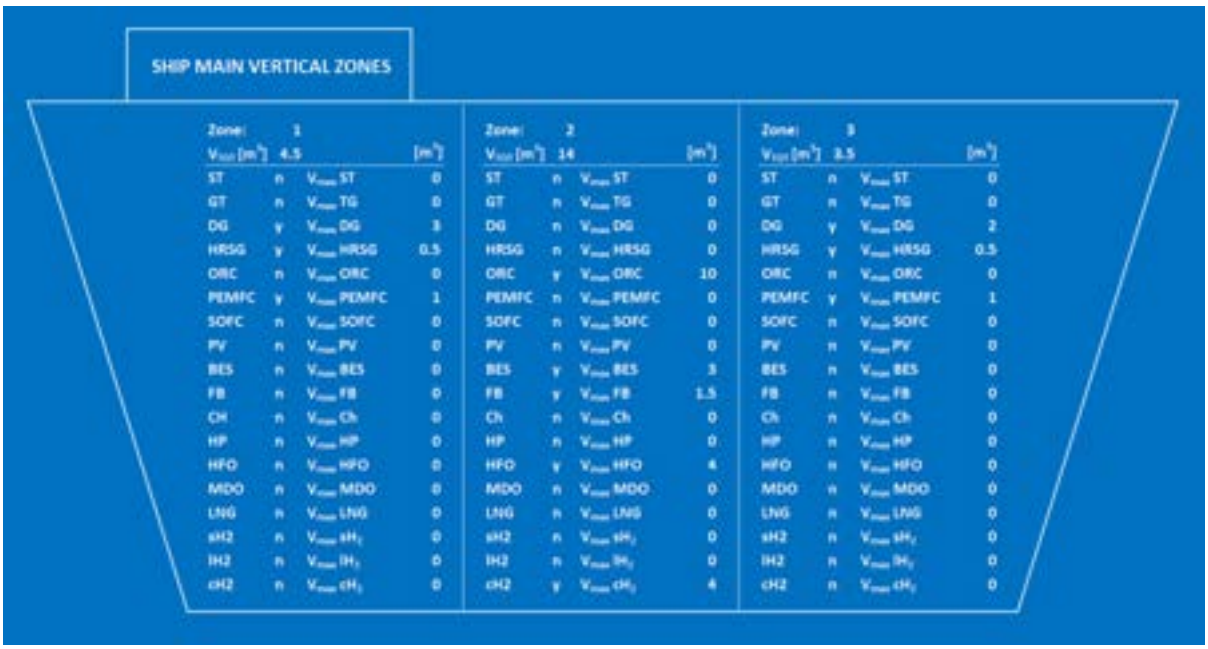

Figure 1 – The Excel user interface where the inputs of the MILP model can be defined.

Then, the user selects from a database the models to be compared during the simulation for each technology. The database contains the information required for optimisation computation and performance estimation of energy systems. **Appendix A** lists the data stored in the database. The model determines certain technical working characteristics of the systems under investigation based on their performance and thermal/electricity demands.

2.2. Constraints

The solution found by the MILP model is limited by four different types of constraints that are implemented on the algorithm:

- Operative constraints.
- Size constraints.
- Specific constraints of each energy system.
- Balance constraints: they allow the balance constraints of electrical and thermal demand and ensure continuity in the energy flow where energy systems interact (i.e. DG, HRSG ORC). They also verify the overall plant volume against the available space.

Operative constrains are necessary to guarantee that every variable under consideration have physical limits. Usually, all the technology considered in this tool have a minimum power output and a maximum power output. Size constraints ensure that each energy system respects an overall volume constraint. For each main vertical zone, the user defines both the volume dedicated to each specific technology and the total volume available in that main-vertical-zone. So, over imposing a total main-vertical-zone constraint is possible to guarantee that all the technologies installed don't exceed the volume available.
Every energy system must respect the constraints characteristic of the physics representing it, which correlate power (thermal and electrical), efficiency, current, consumption, etc (Table 1). In order to maintain the problem linear, the tool considers a linear correlation to evaluate the technologies off-design, as presented in the following table. Also, binary variables are limited to guarantee that a technology installed can be set on or off by the tool just in case it is installed.

Table 1 – System constrains description.

System constraints	
DG $\nabla d = 1 \dots N_{model}^{DG}$; $\nabla \mathrm{g} = 1 \dots N_{max}^{DG}$	$x^{DG} \leq y^{DG}$ $\eta^{DG} = \alpha\, P_{el}^{DG} + \beta\, x^{DG}$; $P_{th,diss}^{DG} = P_{el}^{DG}(1-\eta^{DG})$; $\dot{m}_{fuel}^{DG} = \frac{P_{el}^{DG}}{\eta^{DG} LHV_{fuel}}$
HRSG $\nabla \mathrm{h} = 1 \dots N_{model}^{HRSG}$; $\nabla \mathrm{r} = 1 \dots N_{max}^{HRSG}$	$x^{HRSG} \leq y^{HRSG}$ $\eta^{HRSG} = \alpha\, P_{th,out}^{HRSG} + \beta\, x^{HRSG}$; $P_{th,in}^{HRSG} = \frac{P_{th,out}^{HRSG}}{\eta^{HRSG}}$

ORC $\nabla o = 1 \dots N_{model}^{ORC}$; $\nabla c = 1 \dots N_{max}^{ORC}$	$x^{ORC} \leq y^{ORC}$ $\eta^{ORC} = \alpha\, P_{el}^{ORC} + \beta\, x^{ORC}$; $P_{th,in}^{ORC} = \frac{P_{el}^{ORC}}{\eta^{ORC}}$
FB $\nabla f = 1 \dots N_{model}^{FB}$; $\nabla b = 1 \dots N_{max}^{FB}$	$x^{FB} \leq y^{FB}$ $\eta^{FB} = \alpha\, P_{th}^{FB} + \beta\, x^{FB}$; $\dot{m}_{fuel}^{FB} = \frac{P_{th}^{FB}}{\eta^{FB} LHV_{fuel}}$
HP $\nabla h = 1 \dots N_{model}^{HP}$; $\nabla p = 1 \dots N_{max}^{HP}$	$x_{cool}^{HP} + x_{heat}^{HP} \leq y^{FB}$ $COP^{HP} = \alpha\, P_{heat}^{HP} + \beta\, x_{heat}^{HP}$; $EER^{HP} = \alpha\, P_{cool}^{HP} + \beta\, x_{cool}^{HP}$ $P_{el,in}^{HP} = (\alpha\, P_{heat}^{HP} + \beta\, x_{heat}^{HP}) + (\alpha\, P_{cool}^{HP} + \beta\, x_{cool}^{HP})$
PEMFC $\nabla p = 1 \dots N_{model}^{PEMFC}$ $\nabla e = 1 \dots N_{max}^{PEMFC}$	$x^{PEMFC} \leq y^{PEMFC}$ $\eta^{PEMFC} = \alpha\, P_{el}^{PEMFC} + \beta\, x^{PEMFC}$; $\dot{m}_{H_2}^{PEMFC} = \frac{P_{el}^{PEMFC}}{\eta^{PEMFC} LHV_{H_2}}$
BES $\nabla b = 1 \dots N_{model}^{BES}$ $\nabla s = 1 \dots N_{max}^{BES}$	$x_{ch}^{BES} + x_{disch}^{BES} \leq y^{BES}$ $C_{(t,w+1)}^{BES} = C_{(t,w)}^{BES} + \Delta t \left(P_{ch,(t,w)}^{BES} \eta_{ch}^{BES} - \frac{P_{disch,(t,w)}^{BES}}{\eta_{disch}^{BES}} \right)$; $C_{(t,1)}^{BES} = C_{max}^{BES}$ $\sum_w \left(P_{ch}^{BES} \eta_{ch}^{BES} - \frac{P_{disch}^{BES}}{\eta_{disch}^{BES}} \right) \geq 0$
FUELS	$SoC_{(t,w+1)} = SoC_{(t,w)} - \sum_{i=1}^{Numb.Techn.} \dot{m}_{fuel}^{i}$; $SoC_{(t,1)} = SoC_{max}$

2.2.1. Balance constraints

Balance constraints are presented in Table 2. These constraints have been introduced in order to guarantee the overall thermal and electrical energy balances of the ship. Also cooling demand has been introduced but it's not considered by the model at this stage.

Table 2 – Balance constraints description.

Balance Constraints
Electrical Balance
$\sum_d \sum_g P_{el}^{DG} + \sum_o \sum_r P_{el}^{ORC} + \sum_f \sum_c P_{el}^{PEMFC} + \sum_b \sum_s P_{disch}^{BES} - D_{el} - \sum_h \sum_p P_{el,in}^{HP} - \sum_b \sum_s P_{ch}^{BES} = 0$
Thermal Balance
$\sum_h \sum_r P_{th,out}^{HRSG} + \sum_f \sum_b P_{th}^{FB} + \sum_h \sum_p P_{heat}^{HP} - D_{th} = 0$ $\sum_d \sum_g P_{th}^{DG} - \sum_o \sum_r P_{th,in}^{ORC} = 0$

2.3. Optimization Function

The objective function adopted aims to minimise the costs of the ship considered. Furthermore, the tool includes fuel costs and CO_2 taxes. The main technologies costs considered by the objective function are:

- The total Installation Cost (1) obtained by the Capital Cost (CC) of each technology considered (s) and installed (i) adjusted by the Capital Recovery Factor (CRF).
- The total cost of the fuel consumed (2) during navigation into the time-lap considered (t) and every cruise profile (w). This equation takes into account the different costs for each fuel considered (f).
- Taxes due to CO_2 emissions (3).

$$Tot.Inst.Cost = \sum_s \sum_i CC_i\, CRF_i \qquad (1)$$
$$where, \quad CRF = \frac{(1-r)^{UL}}{(1+r)^{UL} - 1}$$

$$Tot.FuelCost. = \sum_w \sum_t \sum_f \dot{m}_f\, \Delta t\, c_{fuel} \qquad (2)$$

$$EmissionCost. = \sum_w \sum_t \dot{m}_{CO_2} \Delta t \; c_{tax} \quad (3)$$

The time lap adopted for simulation considers a whole cruise from port to port for one year. Costs are influenced by the number of cruise that the ship schedule during the year

3. Analysis and Results

3.1. Case study

To verify the correct operation of the MILP optimizer presented in Section 2, the case study of a passenger ferry boat was considered. The specifications of the boat, as well as its daily path and load profile were derived from the study by Rafiei et al. [22][5]. The ferry boat has an overall length of 47 m and in this specific scenario it sails with an average speed of 11 knots and a maximum speed of 13 knots. To guarantee the correct operation of the ferry boat, a propulsion system with at least 600 kW nominal power must be installed onboard. Moreover, the electrical power required by the auxiliary systems must be taken into account, both during navigation and while docked in port.

The ferry boat is used to carry passengers across a bay, following the same navigation plan every day:

- 06.00: departure from the port A
- 10.00: arrival at port B
- 13.00: departure from the port B
- 18.00: arrival at port C
- 20.00: departure from the port C
- 01.00: arrival at port A

Figure 2 shows the propulsion and auxiliary power demands for each hour of the navigation plan, specifying if the ferry boat is sailing or is docked in that moment.

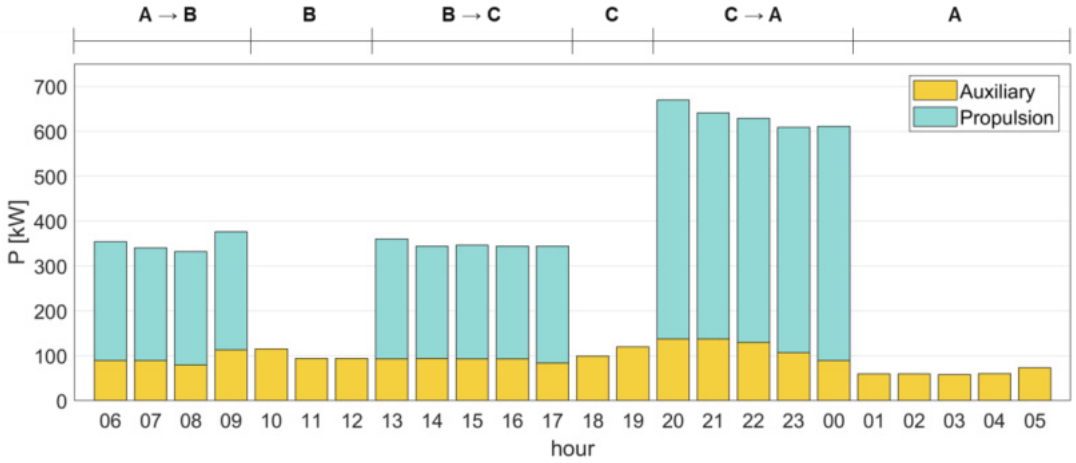

Figure 2 – Load profile of propulsive power and electrical power of the auxiliary systems; on the top it is specified if the ferry boat is sailing between ports or if it is docked.

For this analysis, only the port A is supposed to be equipped for cold ironing, and the BES are always completely charged at the beginning of each daily path (6.00).

The data used in [22] include only information of propulsive and auxiliary electrical loads. However, the MILP algorithm was designed to optimize the generation onboard of both electric and thermal power. Therefore, three possible daily weather conditions (i.e., hot, mild, cold) were defined, associating a different thermal load profile to each one of them:

- Hot weather: no thermal load – 92 days a year
- Mild weather: low thermal load – 151 days a year
- Cold weather: high thermal load – 122 days a year

Similarly to the electrical load of the auxiliary systems, the thermal load is present also when the ferry boat is docked. Figure 3 show the thermal load profiles for mild and cold weather, respectively.

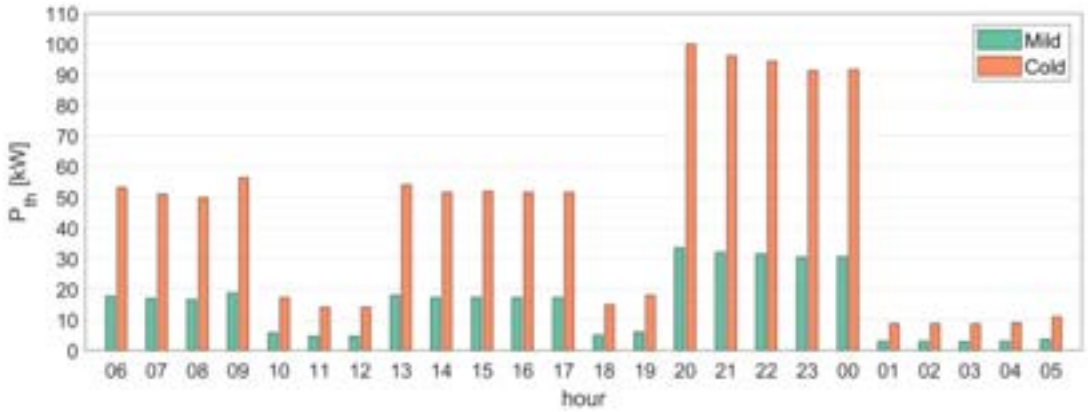

Figure 3 – Load profiles of thermal power for days with mild and cold weather.

3.2. Current scenario optimal solution

This section presents the results of a simulation using the current scenario: CO_2 tax 100€/ton, according to recent ETS [23] and hydrogen cost 6€/kg [24]. The technologies considered by the tool to minimise the objective function are listed in the Table 3, together with the best resulting configuration.

Table 3 – Optimization results, considering the actual scenario.

Supplier	Model	N° of elements installed	CAPEX / FuelCost [€/unit] / [€/y]
	Diesel Generator		
Solè Diesel	SDZ-205	1	35750
Solè Diesel	L1306C2 MSD	1	147500
Isotta Fraschini	SDZ-280	0	-

Nuvera	E-45-HD	0	-
Nuvera	E-60-HD	0	-
	Battery Electrical Storage		
Corvus Energy	Orca Pack249	0	-
Nidec	Marine battery pack	3	48000
	Heat Recovery System Generators		
Siemens Energy	100	2	9900
Siemens Energy	10	1	990
	Fired Boiler		
AlphaLaval	Aalbotg CHB	0	-
AlphaLaval	Aalbotg CHB	1	4000
	Fuel Considered		
DG:	Heavy Fuel Oil		249150
FB:	Heavy Fuel Oil		
PEMFC:	Compressed green hydrogen		-
	Emissions		
CO_2			177190

The selection of these items is the outcome of some preliminary tests necessary to roughly identify the size of the systems which may potentially be installed. Therefore, some technologies have been excluded as too small or too large for this case study.

The results (Figure 4 and Figure 5) led to a configuration where the PEMFC technology is not present due to the high fuel cost. However, three battery modules were installed to manage the electrical load in combination with a smart modulation of the diesel engines. The capital cost of this technology is offset by the lower fuel consumption of the engines and the reduction in annual CO_2 emissions. The configuration also includes the installation of 3 HRSGs and 1 FB. It is clear that in the current scenario the most competitive technology is still the Diesel Generator due to its compactness, low cost per unit of power and low fuel cost.

The tool also determines the best strategy for using these technologies to cover the electricity and heat demands. It is important to observe that the electrical load distribution in the first two mission profiles (hot and

mild weather) is similar, so it is presented only once in this article. On the other hand, in the third mission profile (cold weather), the electrical power generation strategy is notably influenced by the high thermal demand of the ferry boat.

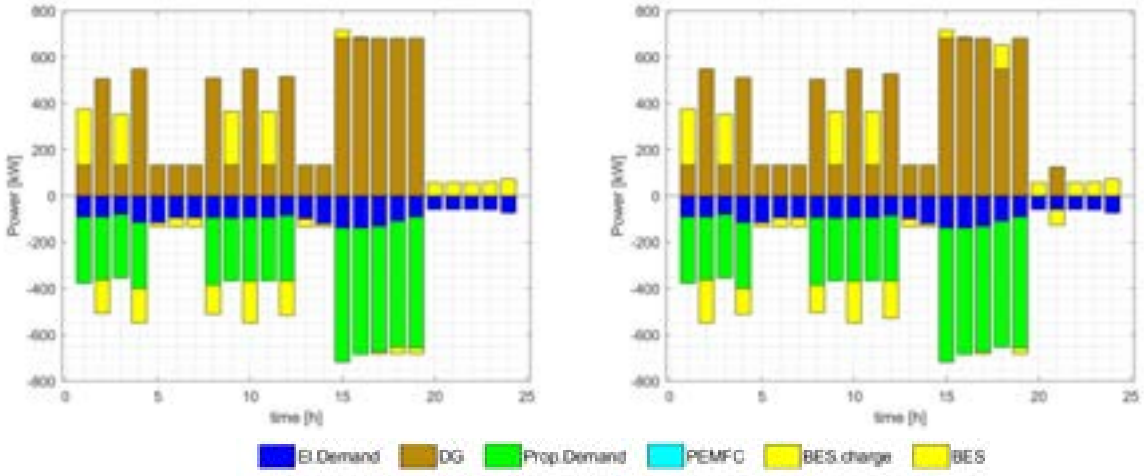

Figure 4 – Electrical load profile solutions for current scenario for mild (left) and cold weather (right).

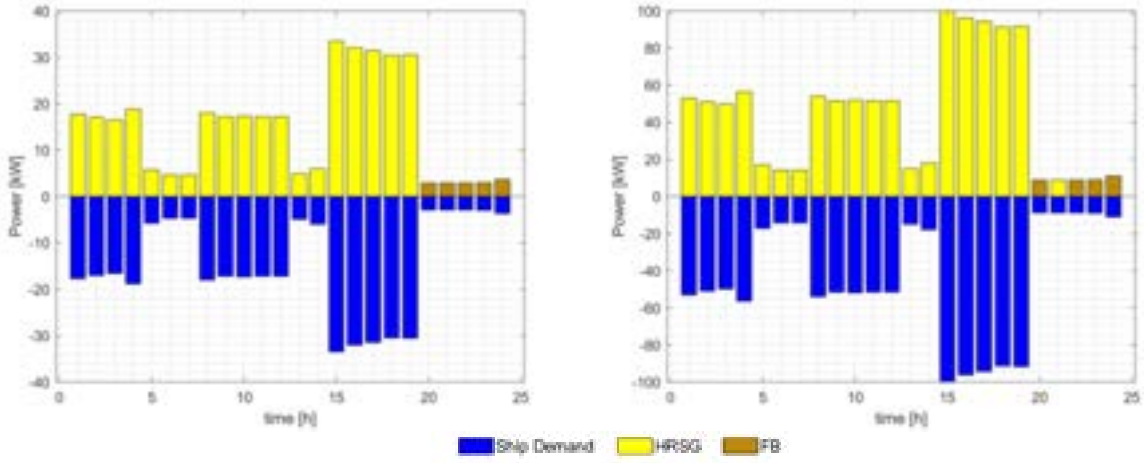

Figure 5 – Thermal load profile solutions for current scenario for mild (left) and cold weather (right).

Analysing the results, it can be observed that the batteries are used to operate DG technology as close as possible to the optimum point, in order to maximise the efficiency of the system by decreasing both consumptions and emissions. Regarding the thermal demand, HRSG units from DGs heat waste are used whenever possible. This technology requires a considerably higher investment compared to the fired boiler solution; however, it is justified by the fact that it saves fuel and reduces emission taxes. Turning on a fired boiler is necessary when demand is below the technical minimum.

3.3. Near future scenario optimal solution

This section presents the results of a simulation using a near future scenario, characterized by CO_2 tax [23] 100€/tons and hydrogen cost 1.5 €/kg, according to recent forecasts [25].
The technologies considered by the tool to minimise the objective function are listed in the Table 4 together with the best resulting configuration.

Table 4 - Optimization results, considering the actual scenario.

Supplier	Model	N° of elements installed	CAPEX / FuelCost [€/unit] / [€/y]
	Diesel Generator		
Solè Diesel	SDZ-205	1	35750
Solè Diesel	L1306C2 MSD	1	147500
Isotta Fraschini	SDZ-280	0	-
	Organic Rankine Cycle		

Orcan Energy	eP M 050.100 HP	0	-
Zuccato Energia	ZE-30-ULH	0	-
	Proton Exchange membrane Fuel Cell		
Genevos	HPM-15	0	-
Nuvera	E-45-HD	0	-
Nuvera	E-60-HD	1	88500
	Battery Electrical Storage		
Corvus Energy	Orca Pack249	0	-
Nidec	Marine battery pack	3	48000
	Heat Recovery System Generators		
Siemens Energy	100	2	9900
Siemens Energy	10	1	990
	Fired Boiler		
AlphaLaval	Aalbotg CHB	0	-
AlphaLaval	Aalbotg CHB	1	4000
	Fuel Considered		
DG:	Heavy Fuel Oil		213810
FB:	Heavy Fuel Oil		
PEMFC:	Compressed green hydrogen		40089
	Emissions		
CO_2			152230

According to the results of the tool, it appears that the price drop of hydrogen had a significant influence on the optimal energy mix. In this configuration, a PEMFC of 60 kWe is installed. Therefore, this technology currently has a major weakness: the price of fuel. However, the expected reduction of H2 price in the near future will make it a competitive solution, not only for their zero-emissions, but also from an economical point of view.

As shown by the load profile solution (Figure 6), the tool highlights that PEMFCs cannot be operated at maximum load all the time. This result is due to the SoC of the hydrogen stored in the ship: its energy density is fairly low, so the volume dedicated to hydrogen storage does not allow for a more intensive use of the fuel cells. However, it can be observed in Figure 6 how the fuel cells replace the batteries during the port stays.

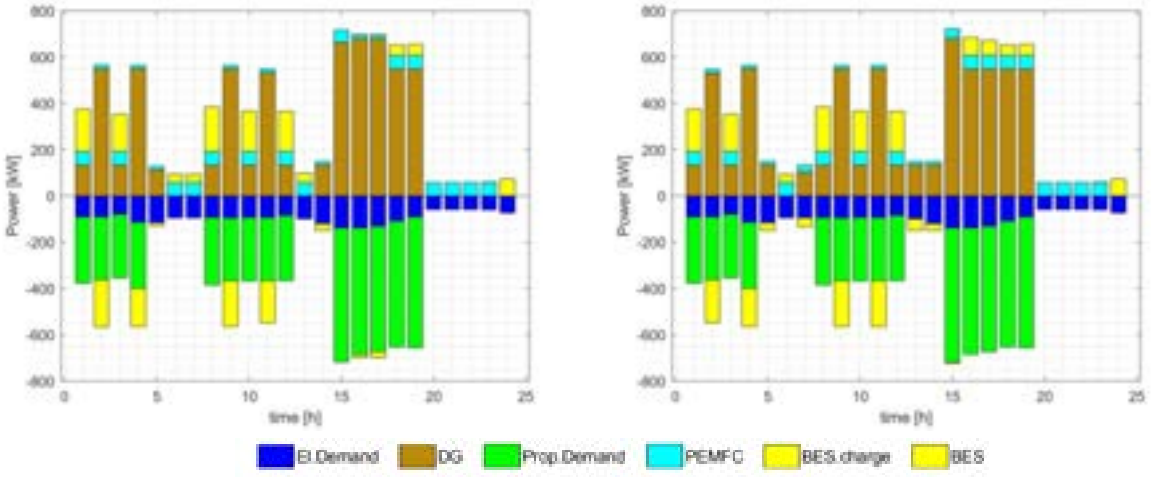

Figure 6 – Electrical load profile solution for the near future scenario for mild (left) and cold weather (right).

Figure 7 shows that the installation of the PEMFCs did not affect significantly the thermal power generation, compared to the results shown in Figure 5 for the current scenario. In fact, the thermal power is mostly supplied by the HRSG, with the FB that is turned on only when necessary.

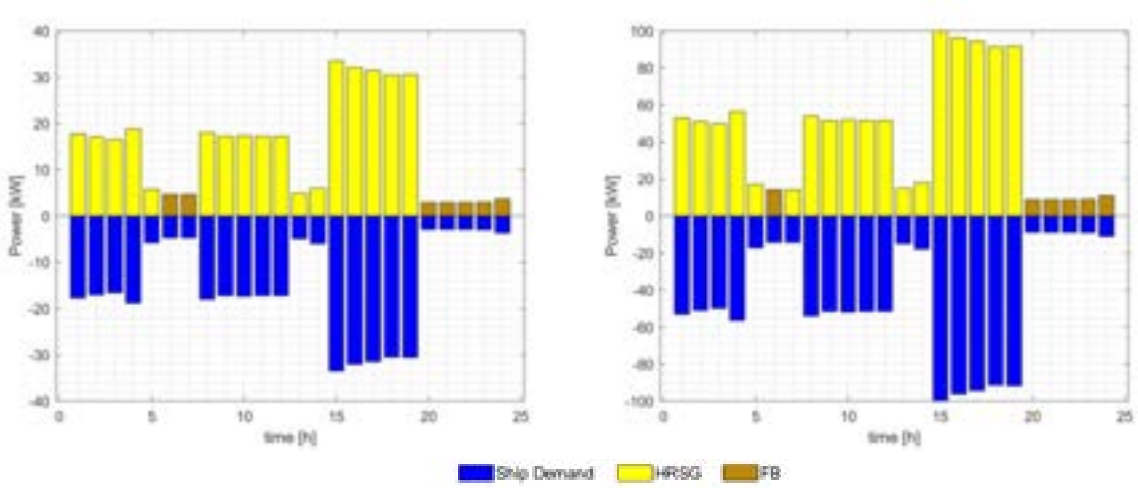

Figure 7 – Thermal load profile solutions for the near future scenario for mild (left) and cold weather (right).

4. Conclusions

This paper presented a MILP model designed to determine the best power generation mix to be installed on a ship and, at the same time, to optimize the operation of each energy system. The MILP model was developed in MATLAB environment relying on the Yalmip optimization toolbox. The model compares different technologies to find the layout that minimizes an objective function, representing the annual costs necessary to cover the electrical and thermal energy demands of the vessel. The analysis is performed considering the specific constraints of the problem, related to the available volume on-board, technical limitations for each technology and overall energy balances (electrical and thermal) to satisfy the demand in each period (hour) of the navigation year. Fixed costs, fuel costs and CO_2 taxation are included in the objective function. The case study of a small passenger ferry boat is considered, taking into account three different representative energy demand profiles, for hot, mild and cold season respectively. Different possible market technologies are considered for on-board installation and electrical (diesel generators, PEMFC, batteries, ORC) and thermal (HRSG, fire boilers) energy production. The following conclusions can be drawn from the results:

- In the current scenario, the optimal configuration mostly relies on traditional and consolidated technologies, i.e. DG and HRSG. These systems are installed and employed to satisfy the largest part of the demand, with a small contribute by electrical batteries.
- In the near future scenario, characterized by lower hydrogen price, PEMFC are installed as well on-board to generate a part of electrical energy. This fact leads to CAPEX increase, but also allows for a reduction in terms of CO_2 emissions and related fees.
- In all the scenarios, the largest costs are due to fuel and CO_2 taxes, which are both strongly dependent on international markets and environmental/energy policies: an increase in CO_2 fees or in fossil fuel prices, or a decrease in hydrogen production cost, can represent one of the key points for economic feasibility of more sustainable solutions.

In the future, the MILP model will be used to assess more precisely the impact of CO_2 taxation on the optimal energy solution. The library of components considered by the tool will be expanded, introducing electric boiler technology as an alternative to HFO-fuelled boilers. This solution expected to further reduce CO_2 emissions.

Moreover, the MILP tool will be tested on different types of vessels, to understand how different sizes and navigation plans change the best power generation strategy.

Abstract:
The operation of wastewater treatment plants (WWTP) faces numerous challenges. These facilities must guarantee effluent quality requirements addressing also economic and environmental issues in the presence of variable influent conditions. This work presents a comprehensive analysis of the influence of climate and meteorological conditions into the eco-efficiency aspects of control/operational strategies applied in WWTPs. The main novelty of this work is the consideration of dynamic environmental performance in the assessment method, which allows to identify the impact on eco-efficiency of the eventual and seasonal variations of temperature and precipitations. Different operation scenarios, with different wastewater temperature profiles and precipitation levels are defined, and eco-efficiency is evaluated in terms of emissions to water and energy consumption. Annual and monthly performance indicators are computed to provide a general view of plant behaviour in the different conditions. The Benchmark Simulation Model (BSM2) has been selected as a reference WWTP model. The analysis is performed from a plant-wide perspective, since the effects on different units of the plant are considered. The analysis makes possible to identify the operational issues and control problems that should be tackled to address environmental impacts as eutrophication and global warming potential, resulting in an improvement of WWTP eco-efficiency.

Keywords:
Wastewater treatment plants, eco-efficiency, sustainability, process control.

1. Introduction

The operation of wastewater treatment plants (WWTP) faces numerous challenges. These facilities must guarantee the imposed effluent quality standards, while attempting to address economic issues and environmental impact of the operation. These three aspects: emissions to water, environmental impact and economics have to be considered in a sustainability framework. In this study a comprehensive analysis of the influence of climate and meteorological conditions into the eco-efficiency aspects of control/operational strategies is performed.

The attainment of eco-efficiency targets when running WWTPs is a complex task because it includes the evaluation of environmental and economic performance indicators which are usually in conflict [1-3]. Then, a holistic viewpoint is necessary [4, 5] in the search for sustainable solutions for WWTP operation. Several performance indicators and assessment criteria for the evaluation of the eco-efficiency of WWTPs are available in the literature [1-5]. Among the different environmental performance indicators, measurements and criteria of a standardized procedure as the Life Cycle Assessment (LCA) are particularly interesting [1].

The variability of the characteristics of the incoming wastewater is one of the main issues that affect the operation of WWTPs. The influent flowrate and pollutants load are affected by different factors such as population activities, precipitations, sewer management, and industrial discharges [6]. Furthermore, wastewater temperature, that depends on ambient temperature and hot water discharges, is a relevant parameter [7-9] with a significant influence on biological processes kinetics, oxygen transfer processes and heating requirements of some WWTP processes. Therefore, WWTP operation should be accommodated to deal with the eco-efficiency, depending on the influent characteristics, while maintaining quality/cost aspects.

This study aims to determine the influence of climatological and meteorological conditions on treatment effectiveness and energy consumption in a conventional WWTP. The analysis is performed from a plant-wide perspective, since the effects on different units of the plant are considered. Some typical performance indicators [5, 10-12] and complementary efficiency indexes are selected to evaluate the effect of precipitations and temperature variations on the throughput of the WWTP. Dynamic evaluation of WWTP of performance [13] considering monthly operational windows for different weather scenarios is proposed to observe the influence of different operating conditions (and therefore costs) on the eco-efficiency of the operation. The Benchmark Simulation Model (BSM2) [10-12] has been selected as a reference WWTP model to drive the

study. The main idea is to provide an assessment tool that facilitates the integration of meteorological insights in the formulation of the WWTP operation strategy.

The remainder of this paper is organized as follows. The BSM2 simulation platform, its control system and the eco-efficiency indicators are described in section 2. Section 3 introduces the methodology for the eco-efficiency assessment under different meteorological conditions. The results of the simulations of BSM2 plant under different meteorological conditions and the analysis of performance are presented in section 4. Conclusions are presented in section 4.

2. Process and control system

The BSM2 simulation platform is selected to describe the behaviour of a conventional WWTP with activated sludge biological treatment and anaerobic digestion. This is a widely recognized simulation platform designed as a benchmark to test control strategies applied to wastewater treatment facilities from a plantwide perspective [10-12]. The BSM2 version used in this work [12] represents only nitrogen removal processes. The phosphorous removal processes are not considered.

The influent data available in the BSM2 platform is obtained from influent generation models [6] that contemplates temperature, influent flow and pollutants concentration variations characteristic of a WWTP in the Northern Europe region. The analysis presented in this paper concentrates on the effect generated by temperature variations and precipitations.

2.1. Process description

The BSM2 plant model, the simulation platform and the evaluation protocol are described in [10-12]. BSM2 layout includes primary clarification and activated sludge process units in the water line, and anaerobic digestion, thickening, dewatering units and a storage tank in the sludge line (Fig.1). The influent model is described in [6], temperature variation is represented using a combination of sine functions that represents daily and seasonal variations, and load data represents influent flow and pollutants concentration variations associated with population activities, industrial activities, sewer effects and rain effects. Table 1 summarizes characteristic influent parameters.

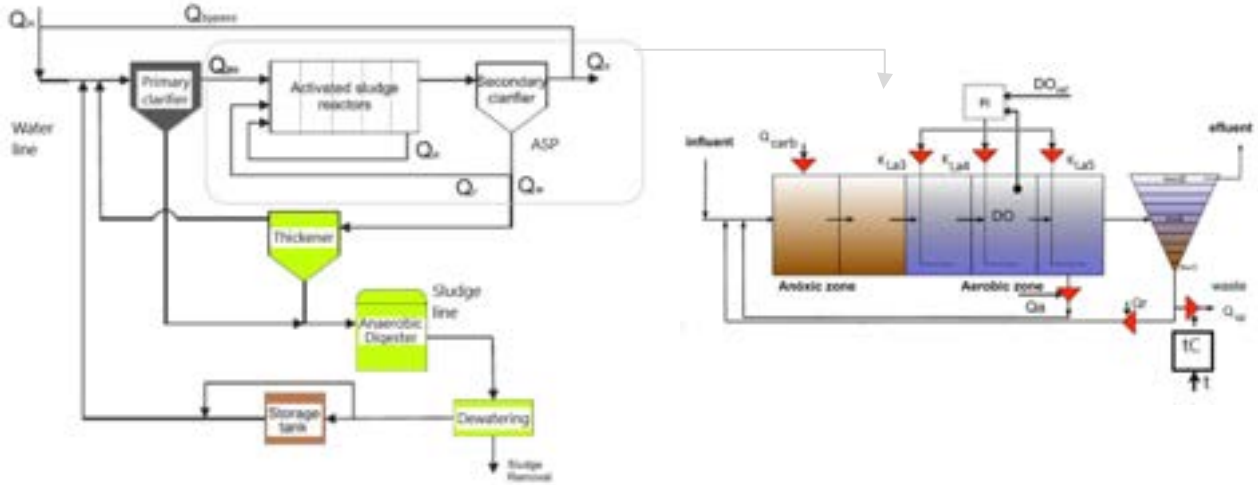

Figure. 1. BSM2 simulation platform layout and default control strategy

Table 1. Characteristic values of the significant variables of the influent profile

Variable	Average	Maximum	Minimum
T (ºC)	15	20.5	9.5
Q_{in} (m^3/d)	20648	85841	5146
N_{tot} influent (gN/m^3)	55.2	114.2	7.7
COD influent ($gCOD/m^3$)	592.2	1213.0	36.5

BSM2 activated sludge process (ASP) [10-12] is described here to facilitate comprehension of the paper. There are five bioreactors, denitrification process occurs first in two anoxic and perfectly mixed reactors. External carbon dosage (Q_{carb}) is required to keep denitrification, and internal recirculation (Q_a) is used to transfer nitrates from aerobic reactors. The 3rd to 5th reactors are aerobic to promote nitrification process. Oxygen is provided by an aeration system and the oxygen transfer is represented by oxygen transfer coefficients: KLa3, KLa4, Kla5 of each aerobic reactor. A settler separates the clean water (Q_e) that is discharged, and the sludge,

that is divided: wastage flow (Q_w) is fed to the sludge line thickener, and external recycle flow Q_r returns to the head of ASP.

The anaerobic digester produces biogas and stabilizes the sludge. An operation temperature of 35ºC is necessary, then BSM2 considers a micro gas turbine to produce the heat required by the digester [12] and immediate electricity. The energy content of biogas is estimated as 13.89kWh/kgCH_4, a biogas to electricity efficiency of 43% and a biogas to heat efficiency of 50% is considered in BSM2 performance evaluation.

2.2. Control strategy

The predetermined control strategy provided with the BSM2 platform [10-12] is employed for all the case studies presented in this paper. It consists on DO control in the 4th reactor and timer-based control of Q_w. In the aerobic reactors, the levels of dissolved oxygen (DO) should be between 1 to 2 gCOD/m^3 to promote nitrification. Then, BSM2 applies a control system for the regulation of DO in the 4th reactor manipulating the oxygen transfer coefficient of the fourth reactor (KLa4). A PID controller is implemented in the proposed control loop, the tuning parameters can be found in [13]. The coefficients KLa3 and KLa5 depends on KLa4, with proportional gains of 1 and 0.5, respectively. The DO concentration in the 3rd and 5th reactor is affected by control actions applied in the fourth reactor.

Sludge purge flow (Q_w) affects the sludge age or solids retention time (SRT). In the BSM2 platform a timer-based control of Q_w is applied. If the wastewater temperature is below 15ºC (colder season) wastage flow (Q_w) is set to 300 m^3/d, else Q_w is set to 450 m^3/d.

2.3. Eco-efficiency indicators

The eco-efficiency assessment of WWTPs includes the evaluation of environmental and economic performance indicators which are usually in conflict [1-3], then, the search for sustainable solutions for the operation of these facilities results in an interesting multi-objective problem. Several performance indicators and assessment criteria for the evaluation of the eco-efficiency of WWTPs are available in the literature [1-3]. The consideration of measurements and criteria of a standardized procedure as the Life Cycle Assessment (LCA) is recommended, especially, the metrics in the impact categories of Eutrophication Potential and Global Warming Potential [1] which are important issues for these facilities. The Eutrophication Potential is associated with the emissions to water, and Global Warming Potential is associated with the energy consumption and the corresponding indirect emissions to air in the energy sources.

BSM2 platform provides a systematic evaluation protocol of plant performance under the different control strategies tested in the plant. Relevant variables such as the load and concentration of pollutants in the influent and the effluent, production of biogas and sludge are computed for a given evaluation period, as well as indicators of the suitability of the WWTP operation, as influent and effluent quality, violations of the effluent requirements, energy consumption and operation costs.

In this work, some of the performance indicators proposed in BSM2 platform are used to evaluate the environmental performance of the WWTP. The selected indicators are focused on the level of pollutants in the influent and the effluent, the use of energy and production of biogas in the plant, and in the operation costs. A general description of the indicators is presented below, a detailed description including equations can be found in [5,12].

2.3.1. Environmental indicators associated with emissions to water

- Effluent Quality Index, EQI (kg/d): it is a measure of the total pollution load of the plant discharge for a given operation period (i.e.one year). It includes the following measurements of pollutants in the effluent: total Nitrogen (N_{tot}), ammonium (S_{NH}), nitrates (S_{NO}), total Chemical Oxygen Demand (COD), total Suspended Solids (TSS) and Biological Oxygen Demand (BOD5) [5, 12].
- Influent Quality Index, IQI (kg/d): it is a measure of the total pollution load of the influent for a given operation period (i.e.one year). It includes N_{tot}, S_{NH}, S_{NO}, COD, TSS and BOD5 load in the influent [5, 12].
- Violations of effluent requirements. Desirable limits of pollutants in the effluent (Total nitrogen, ammonium concentration, total Chemical Oxygen Demand (COD) and total suspended solids (TSS)) are given in BSM2 platform [1-3]: N_{tot} < 18 gN/m^3, S_{NH} < 4 gN/m^3, COD <100 gCOD/m^3, TSS<30 g/m^3.These values are in concordance with current effluent requirements in European countries. Deviation of the levels of pollutants in the effluent from desired limits are quantified in terms of number of events, extension of time of the infringements (absolute and relative), and magnitude of the violation [5, 12].

2.3.2. Environmental indicators associated with energy consumption

- Pumping energy, PE (kWh/d): it is computed considering the pumps available on each unit: the internal recycle flow Q_a, the external recirculation flow Q_r, the wastage flow Q_w, the primary clarifier bottom flow, the thickener feed flow and the dewatering unit bottom flow [5, 12].

- Aeration energy, AE (kWh/d): it depends on aeration system characteristics: type of diffuser, bubble size, depth of submersion. It is computed from oxygen transfer coefficient on each reactor and the volume of each reactor for Degrémont DP230 porous disks at an immersion depth of 4 m [5, 12].
- Mixing energy, ME (kWh/d): it is computed for activated sludge reactors if KLa<20 d^{-1} (ME_{AS}) and anaerobic digester (ME_{AD}), considering the volume of each reactor and digester volume, respectively [5, 12].
- Heating energy, HE (kWh/d) and heating energy net (HE_{net}): HE is the energy necessary to heat the sludge to the operation temperature required in the anaerobic digester, and HE_{net} is zero if methane produced in anaerobic digester (AD) covers its heating requirements, otherwise, HE_{net}=HE-7MET_{prod} [5, 12], it is computed considering that energy content of biogas is 13.89 kWh/kgCH_4 and biogas to heat efficiency is 50% [10]. MET_{prod} (kg/d) is the amount of biogas produced in AD.
- Electricity from biogas (EB, kWh/d): biogas is used in BSM2 to heat AD and to produce electricity simultaneously with an efficiency of 43%, then electricity from biogas is computed as 6MET_{prod} [10].

2.3.3. Economic indicators

- Operational Cost Index (OCI): it is defined in BSM2 as the net energy costs, the sludge production for disposal (SP) costs and external carbon addition (EC) costs [5, 12].

$$OCI=AE+PE+3SP+3EC-6MET_{prod}+HE_{net} \quad (1)$$

2.3.4. Efficiency indicators

Efficiency indices formulated as the ratio between interesting indicators are considered [10, 11].

The energy efficiency (EE), defined here as the ratio between pollution removed by BSM2 plant in kg and the energy consumed to achieve such objective (kWh):

$$EE=\frac{IQI-EQI}{Electricity}\ (kg/kWh) \quad (2)$$

This performance indicator has been used in previous works [4-5] however, interpretation of the evolution of the index should be cautious. Increments of the index are supposed to indicate efficiency improvement, but in some cases the index increases due to limitations of the control system that affect the energy use, then the index increases, but elimination of pollution is incomplete.

The treatment efficiency (TE) that is the ratio between the load of pollutants removed and the load of pollutants in the influent:

$$TE=\frac{IQI-EQI}{IQI} \quad (3)$$

The heating methane harnessing (HMH) that is the ratio between available heating energy from methane 7MET_{prod} and anaerobic digester heating requirements:

$$HMH=\frac{7MET_{prod}}{HE} \quad (4)$$

The electrical methane harnessing that is the ratio between the electrical energy obtained from methane and the electricity requirements of ASP (E_{ASP}):

$$E_{ASP}=PE+AE+ME_{AS}\ (kW) \quad (5)$$

$$EMH=\frac{6MET_{prod}}{E_{ASP}} \quad (6)$$

3. Description of eco-efficiency assessment procedure under different meteorological conditions

Four scenarios characterised by different influent conditions have been defined to evaluate the influence of climate and meteorological conditions on treatment effectiveness and energy consumption in BSM2 plant. Then, fifth case studies are considered including the default BSM2 scenario. The predeterminate BSM2 control strategy described in section 2.2 is applied in all cases.

- Scenario 1. Default. The BSM2 influent characteristics as described in table 1.
- Scenario 2. Wider temperature profile variation (W. T.). Mean temperature: 15ºC, minimum temperature: 5ºC and maximum temperature: 25ºC.
- Scenario 3. Higher temperature profile (H.T.). Mean temperature: 19ºC, minimum temperature: 10ºC and maximum temperature: 27ºC.

- Scenario 4. Rainy year (R.Y.). The BSM2 influent data is modified copying and inserting data corresponding to rain events in the dry periods of the default influent profile.
- Scenario 5. Dry year (D.Y.). The BSM2 influent data is modified copying and inserting data corresponding to dry periods events in the rainy periods of the default influent profile.

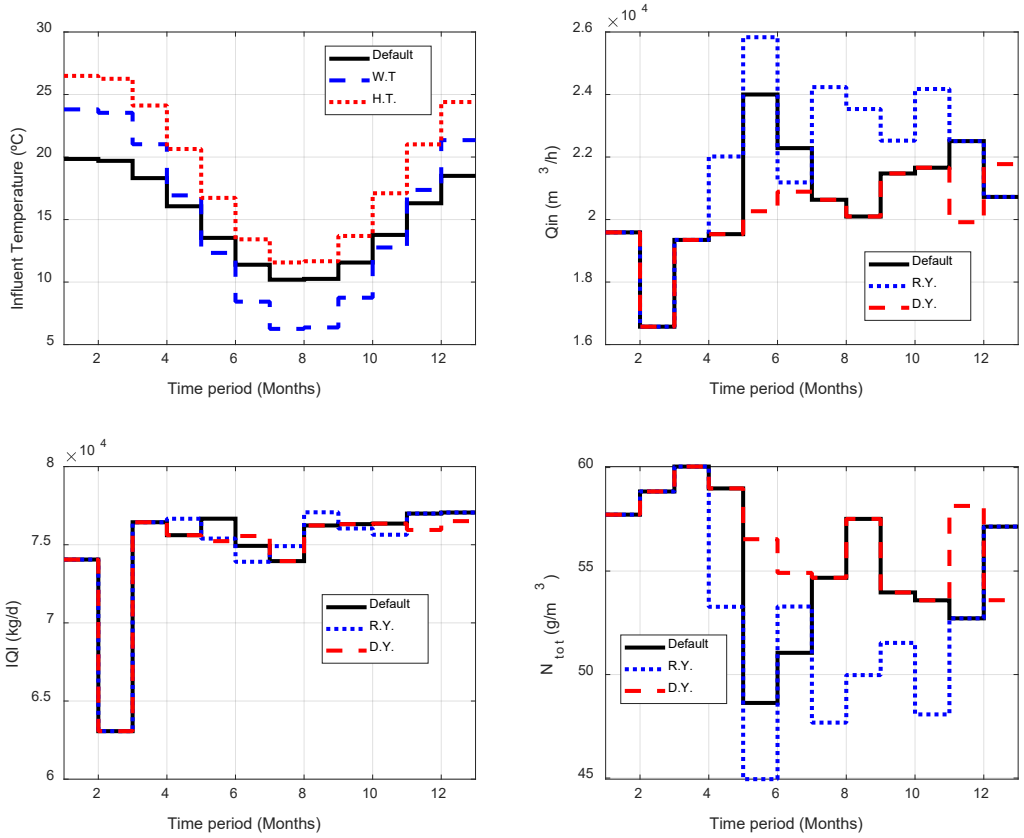

Figure. 2. Temperature and influent flow influent profiles for the different scenarios proposed to study the impact of meteorological conditions on WWTP performance.

An evaluation period of one year is recommended in the BSM2 protocol, the evaluation period starts the 1rst of July. A sample time of 15min is set in BSM2 platform, however monthly temporal windows are used here, to show the evolution of relevant variables. The monthly average profile of influent temperature and flowrate, Influent Quality (IQI) and total Nitrogen (N_{tot}) for the different scenarios is presented in Fig. 2.

The use of monthly windows facilitates the observation of seasonal changes of climate and meteorological conditions. In figure 2, in the representation of influent temperature, it is observed a step descend of temperature from summer season (1rst of July in the northern hemisphere) to winter (months 6 to 9) and the return to warmer periods at the end of the year. This trend is maintained in W.T. and H.T. scenarios within their corresponding range of variation. Regarding the influent flow, the first two months (July and August) are equal in all scenarios (dry weather and reduced influent flow due to holiday period), but average influent flow increases for precipitations, almost in all months in the R.Y. scenario, and decreases in winter and the beginning of summer in the D.Y. scenario. Precipitations affect the load of pollutants in the effluent as observed in IQI and N_{tot} profiles, N_{tot} concentration diminish in the rainy periods. Temperature variations do not affect influent pollutants concentration in BSM2 model.

4. Results

Simulations of plant behaviour, using the default BSM2 influent profile and the data adjusted according to the four scenarios describing temperature and precipitation changes, have been executed. Annual average performance and dynamic performance is evaluated and compared for the different scenarios. Control system performance is examined in the case that exhibits the worst behaviour associated with temperature and precipitations changes, to determine the possible drawbacks of the control system in these situations and to contemplate possible solutions.

4.1. Performance analysis in the different climate and meteorological scenarios

The annual average values of some performance indicators were computed to evaluate the overall performance in one year of operation. On the other hand, the dynamic evolution of relevant variables along

the year is represented using monthly average values. Dynamic analysis makes possible to observe the seasonal effects of the influent variations in the operation period.

4.1.1. Comparison of the annual average performance

The annual average values of selected indicators of performance are presented in table 2. IQI is used as indicator of the load of pollutants in the influent to be removed. Environmental indicators associated with emissions to water are EQI, N_{tot} and S_{NH} violations and TE. S_{NH} violations are measured as the period of time out the desired limits. Energy consumption is measured with indicators of electricity use in ASP (E_{ASP}) and heating energy of AD (HE), and the ratios: EE, HMH and EMH, that measure of the amount of electricity used for removing pollution, and the usefulness of biogas to produce the heat and electricity required for the plant operation. Evaluation of emissions to water and energy consumption are associated with the eutrophication potential and global warming potential, that are environmental impacts in the recognized Life Cycle Assessment. OCI indicates the overall operation costs.

According to annual average values presented in Table 1, in H.T. scenario the operation at higher temperatures is favourable for environmental performance. Heating efficiency (HMH, HE) improves because the difference between the operation temperature of AD (35ºC) and the temperature of the sludge decreases. Electrical efficiency increases (EE), but consumption of electricity in ASP (E_{ASP}) is the highest compared with the other evaluated scenarios. Then, the EE index increases due to the improvement of pollutants removal.

On the other hand, W.T scenario exhibits the minimum consumption of electricity (E_{ASP}) but the worst electrical efficiency (EE), which indicates a lower removal of pollutants. This is corroborated by environmental indicators with extremely long violation periods of S_{NH} and N_{tot} limits. This W.T. scenario exhibits the minimum OCI among the different cases studies, probably because it presents the minimum consumption of electricity (E_{ASP}). Then, the conditions that provoke the minimum operations costs, produce the poorer environmental performance.

In the case of the Rainy Year scenario (R.Y.), the indicators of violations of the S_{NH} and N_{tot} requirements in the effluent are acceptable, but it exhibits the worst EQI values, with an increment of 7.3% with respect to the Default scenario. The temperature profile is equal for the Rainy and the Default scenarios, but a lower heating efficiency (HE) is observed in the former, indicating that the Rainy influent profile produces changes in the load of the anaerobic digester that increases the energy demand.

Table 2. Annual average values of selected performance indicators

	Default	W.T	H.T.	R.Y	D.Y.
IQI (kg/d)	74783	74783	74783	74747	74584
EQI (kg/d)	5576.7	5809.1	5218.2	5984.0	5375.0
OCI (EUR/d)	9450.0	9368.4	9650.3	9462.7	9437.2
Electricity ($E_{ASP,}$ kWh/d)	5017.1	4941.0	5126.3	5012.3	5009.2
Heating energy (HE, kWh/d)	4225.3	4260.7	3357.2	4437.4	4130.6
N_{tot} violation (time d)	4.28	7.48	1.19	5.56	4.23
S_{NH} violation (time d)	1.49	19.20	0.51	4.17	0.98
Treatment Efficiency (TE)	0.93	0.92	0.93	0.92	0.93
Electrical Efficiency (EE)	12.72	12.86	12.54	12.65	12.74
Heat from methane/HE (HMH)	1.80	1.79	2.17	1.69	1.84
Electricity from methane/ E_{ASP} (EMH)	0.24	0.24	0.28	0.22	0.25

4.1.2. Comparison of the dynamic performance of BSM2 in the proposed scenarios

The evolution of environmental indicators: Effluent Quality, N_{tot} concentration, S_{NH} concentration and Treatment Efficiency (TE) is presented in Fig. 3. In the figure, it is noticed a superior performance of the WWTP in the W.T. scenario compared with Default scenario in the warmer months (months: 1-4, 10-12). In the colder months (5-9), temperature of W.T scenario ranges between 13-6ºC (Fig. 2), while the minimum temperature of Default and H.T scenarios is 10ºC. In this colder period of operation, EQI, N_{tot} and S_{NH} for the W.T scenario experiment a significant increase with respect to H.T and Default conditions. Moreover, the treatment efficiency (TE) representation shows how pollutants removal efficacy decreases in the colder period in all the cases studied, but the reduction in the W.T. scenario is significant due to the lower temperatures. This behaviour cannot be appreciated in an analysis based on annual average indicators.

Regarding energy consumption and methane exploitation, Fig. 4 shows the dynamic evolution of the corresponding indicators. Electricity consumption in the ASP presents an important reduction in the colder month for the W.T. scenario, that is reflected as an increment of the EE and EMH ratios. In this case, larger values of these indicators could be interpreted as an improvement in the electrical efficiency of the plant, however, the observation of the environmental metrics leads to detect an operation problem in the colder period of W.T scenario. The HMH ratio, in the fourth subplot, is related with the use of methane to cover heating

requirements of digester; it varies between scenarios in the periods of higher temperature, but attain similar values in the colder periods.

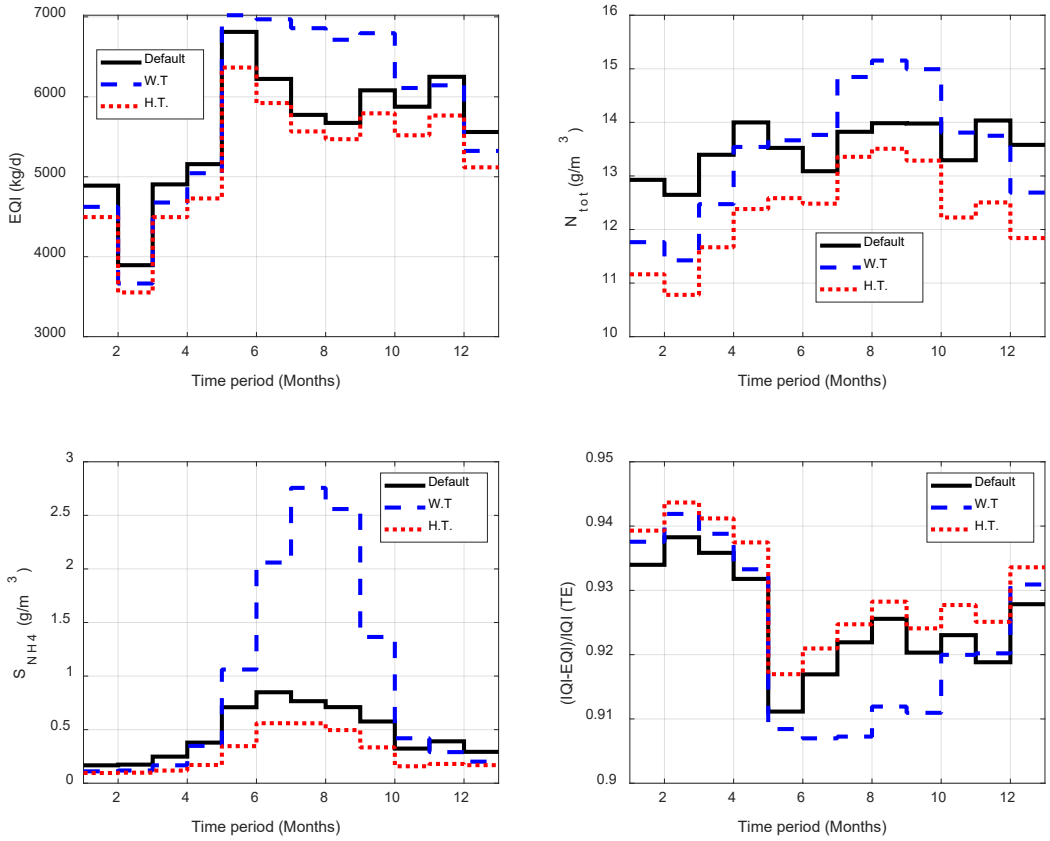

Figure. 3. Comparison of the effluent quality indicators for the operation scenarios focused on temperature variation (W.T., H.T.).

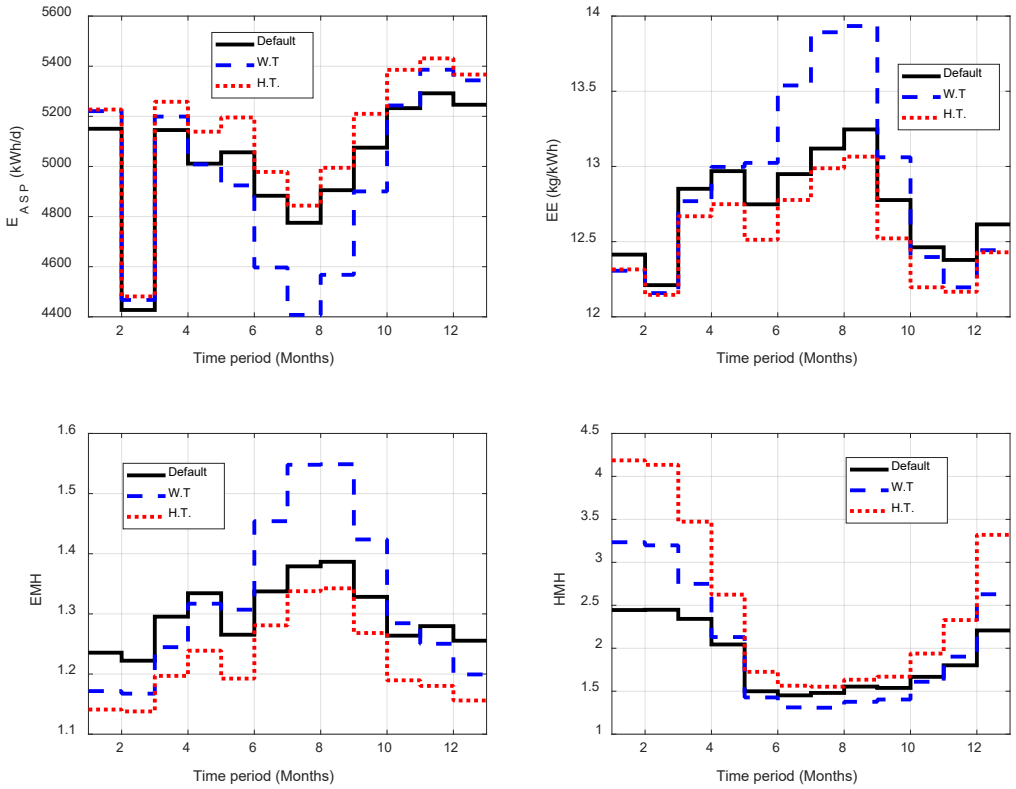

Figure. 4. Comparison of the energy efficiency indicators for the operation scenarios focused on temperature variation (W.T., H.T).

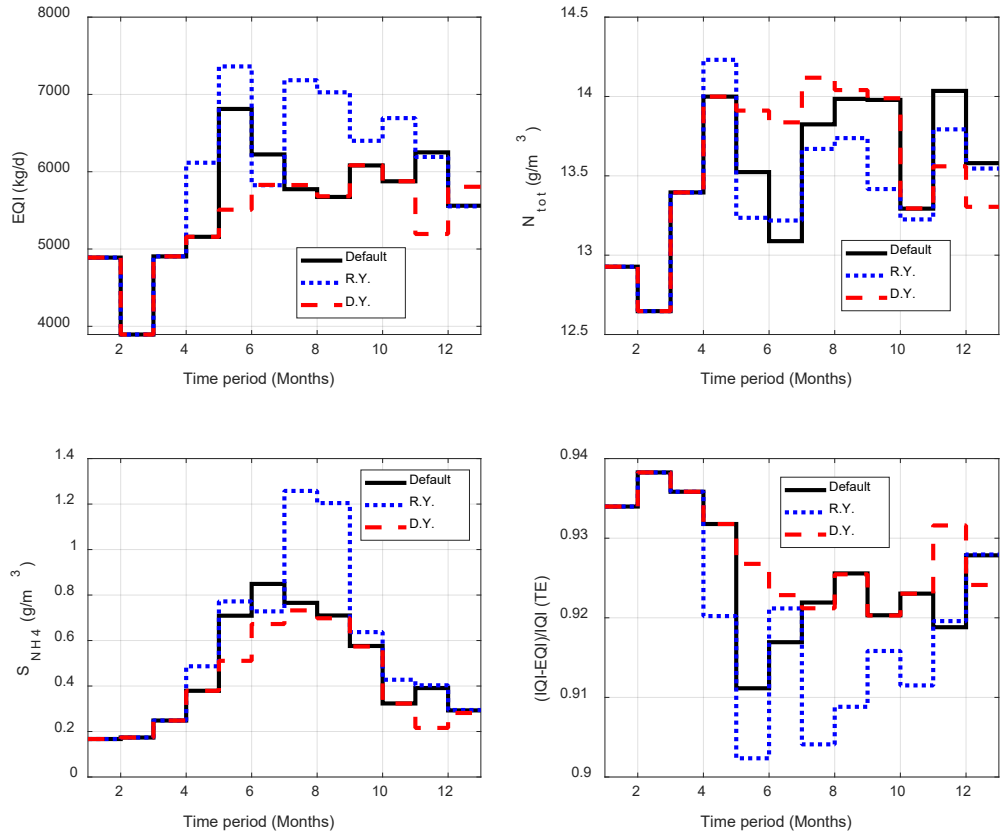

Figure. 5. Comparison of the effluent quality indicators for the operation scenarios focused on variation of precipitations (R.Y., D.Y.)

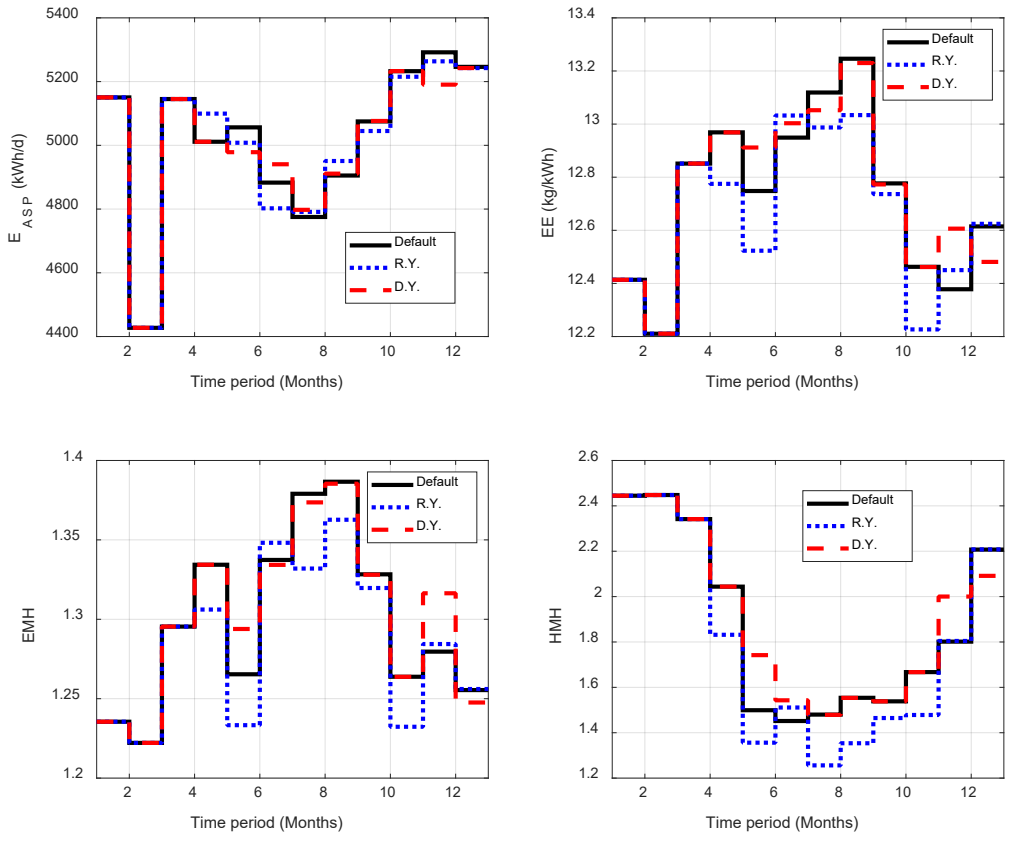

Figure. 6. Comparison of the energy efficiency indicators for the operation scenarios focused on variation of precipitations (R.Y., D.Y.).

Figure 5 shows the comparison of the environmental performance indicators for the Default, Rainy Year (R.Y) and Dry Year (D.Y.) scenarios. It is observed that continuous precipitations affect negatively the indicators of effluent quality, specially S_{NH} concentration and the Treatment Efficiency (TE), although total nitrogen (N_{tot}) is slightly improved. The dynamic evolution of the energy consumption indicators is presented in Fig. 6. Electricity consumption is similar for the three scenarios and the effect of precipitations on the efficiency indicators is not clear. The effect of precipitations requires a detailed analysis considering separately the effect of precipitations and the effect of human activities. In this study both effects are combined in the R.Y. and D.Y. scenarios.

4.2. Comparison of control system performance in the W.T. and Default scenario.

Dynamic control system performance is studied to find the issues behind the atypical behaviour observed for the operation in the W.T. scenario in the colder periods. Figure 5 and Fig.6 shows the control variables: KLa4, SO_4, SO_3 and SO_5 in the Default and W.T. scenarios, respectively.

In both scenarios, good tracking of SO_4 reference is achieved with reasonable movements of the manipulated variable Kla4, there are no saturations nor instabilities. It is noticed that average KLa4 decreases between the days 275-300, that correspond with the second month (August), that is the period with the lower load (see Fig.2). In the colder months (days: 400-500d, months 6-9), a slight reduction of KLa4 is observed in the Default scenario, that is significant in the W. T. scenario (blue lines). This behavior explain the reduction of the energy consumption in the W.T. scenario. Furthermore, controlled SO_4 is not affected by KLa4 reduction in the colder days, and good reference tracking is maintained, but SO_3 and SO_5 concentrations are affected.SO_3 increases and SO_5 decreases in the colder period. This effect is amplified in the W.T: scenario, with SO_5 concentration approaching to the minimum allowed DO levels (see Fig. 6) This situation possibly produces the poor environmental performance in the W.T. scenario that reaches the lower temperatures.

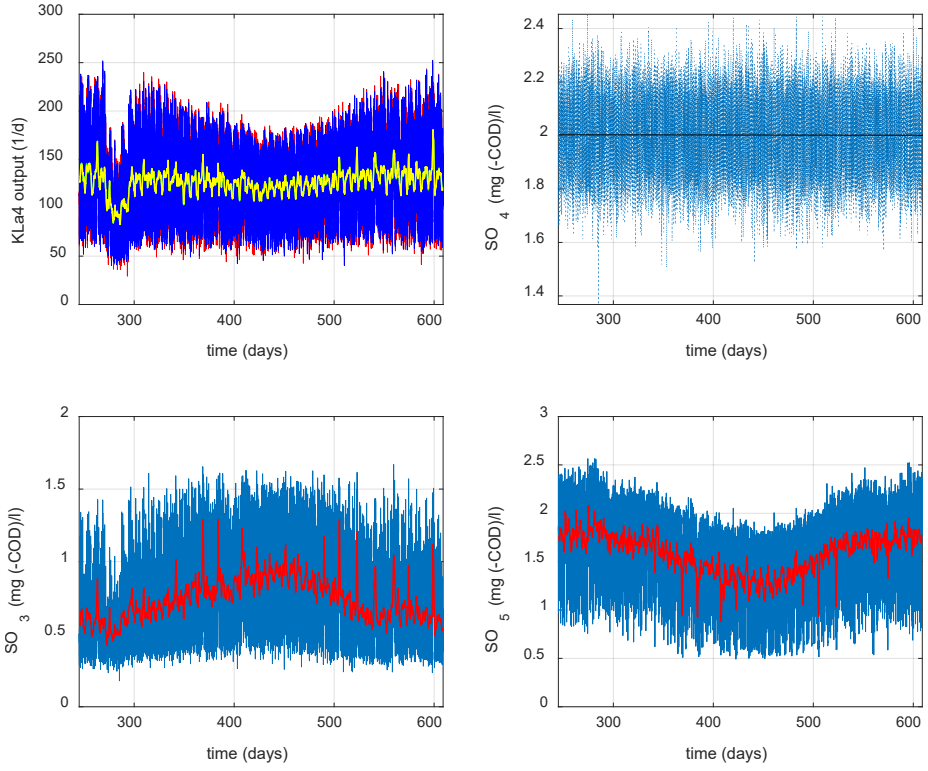

Figure. 5. Dynamic response of the plant in the default operation scenario. (SO_4 set-point: 2mgCOD/l. Yellow and red lines: filtered signals. Blue lines: samples obtained each 15min)

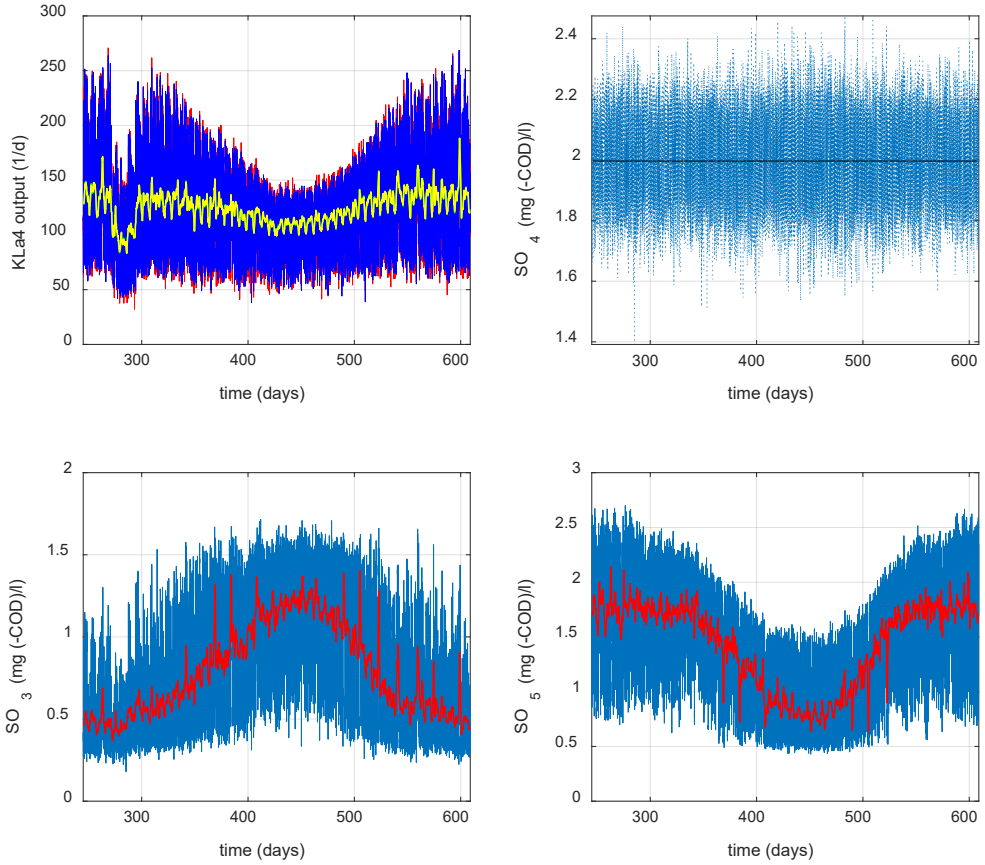

Figure. 6. Dynamic response of the plant in the W.T scenario (Wider temperature variation with respect to default scenario). (SO4 set-point: 2mgCOD/l. Yellow and red lines: filtered signals. Blue lines: samples obtained each 15min)

5. Conclusions

The evaluation of plant behaviour under different climate and meteorological scenarios has been carried out portraying annual performance, computing annual average eco-efficiency indicators, and dynamic performance, considering monthly operation windows. The analysis was performed from a plant-wide perspective, since the effects on different units of the plant were considered. The effect of weather conditions on environmental performance, in terms of emissions to water and energy consumption, an energy consumption was evaluated with appropriated indicators. The analysis showed that temperature variations affect significantly the environmental performance of the plant. Operational issues and control problems were detected in the periods of lower temperatures, that affect energy consumption. On the other hand, an influence of precipitations on indicators of emissions to water and energy consumption is observed, but deeper study of influent variations of concentration and influent flowrate is necessary. These problems should be tackled to address environmental impacts as eutrophication and global warming potential, save energy and reduce operation costs to make WWTP operation more eco-efficiency.

Acknowledgments

The authors wish to thank the support of the Spanish Government through the coordinate MICINN projects PID2019-105434RB-C31 and PID2019-105434RB-C33, project TED2021-129201B-I00, the Samuel Solórzano Foundation through project FS/11-2021 and the support from the Catalan Government under Project 2021 SGR 00197. The authors acknowledge the WWTP of Salamanca (Aqualia) for allowing our research group visiting the plant and the IWA Task Group from the Department of Industrial Electrical Engineering and Automation (IEA), Lund University, Sweden (Ulf Jeppsson, Christian Rosen) for the BSM2 models.

Abstract:

An accurate ship fuel consumption prediction model is the basis for ship energy analysis. Based on an established ship fuel consumption prediction model with input navigational features. We use the Gurobi solver to optimize the ship's speed to minimize fuel consumption on a given route. In addition, We compare the changes in the fuel-saving rate before and after applying the smoothing method and discuss the pros and cons. Compared with the historical average speed, the speed optimization can save 7.9% and 3.2% of fuel consumption before and after smoothing, respectively. Proved by experiments that ship speed optimization considering the influence of weather conditions can significantly reduce ship fuel consumption and provide decision support for shipping companies' operations.

Keywords:

Machine learning; Grey-box model; Ship fuel consumption prediction; Ship speed optimization; Data smoothing.

1. Introduction

In recent years, with the gradual warming of the global climate, the international community has paid more attention to the issue of greenhouse gas emissions. According to the Fourth International Maritime Organization (IMO) Greenhouse Gas (GHG) Study, the carbon intensity (i.e., CO_2 emissions per unit of Gross Domestic Product(GDP)) of international shipping decreased by about 11% between 2012 and 2018. Still, annual greenhouse gas emissions increased from 977 million tons to 1,076 million tons ([1], [2]). The emission of GHG is closely related to the fuel consumption of ships. As the carrier of waterway transportation, ships consume massive amounts of energy every year, producing a large amount of GHG. The IMO has already set strict limits on air pollutants to reduce GHG emissions from the shipping industry. At the same time, shipping companies are paying more attention than ever to the energy efficiency of their ships as fuel costs become an increasing proportion of their operating costs. Improving ship energy efficiency and reducing fuel consumption and GHG emissions through various energy efficiency optimization measures are essential for shipping companies to reduce ship operating costs and improve their competitiveness. Therefore, these resources need to be managed and utilized more effectively.

With the continuous development of ship intelligence and digitization, as well as the continuous improvement of machine learning, data mining, and other methods, through the intelligent and diversified monitoring of various parameters and indicators generated during the ship's navigation, as well as the weather, sea conditions and other information encountered and analysis, the decision support system can make more realistic suggestions for different situations in the course of the ship's navigation. Using data analysis to study ship fuel consumption has become a research hotspot. It is applied to analyze the massive data generated during ship navigation as a fuel consumption optimization analysis and decision support system [3].

The rest of the paper is organized as follows. Section 2 is an introduction to published articles in related fields. Section 3 is the data pre-processing and a short introduction to the proposed model, which we have covered in detail in another paper. Section 4 developed the function model of speed optimization and the introduction of Gurobi. Section 5 introduces the solution results of Gurobi before and after data smoothing using the EWMA. Finally, conclusions are drawn in Section 6.

2. Related work

Many researchers have devoted themselves to optimizing the navigation process of ships through mathematical formulas and calculation methods of ship energy consumption terms of ship energy consumption. Zaccone [4] proposed a three-dimensional dynamic planning-based ship navigation optimization method, which takes the minimum fuel consumption as the goal and selects the best route and speed for the ship's navigation according to the weather forecast map. The results show that the fuel-saving effect is very significant. Still, the percentage of fuel-saving and the influence of related parameters (trim, draft, etc.) on fuel consumption have yet to be reported. The mathematical model, the white-box model, derives the fuel consumption by calculating the resistance in different wind and wave conditions. Because of the derivation and superposition of the formula, the error will be magnified, and detailed hull parameters are required, which requires high accuracy.

Statistical data analysis is a prevalent and widely accepted method in optimizing ship energy consumption. It is necessary to study the data generated by ships in different states during operation through additional classification and clustering methods. Perera [5] analyzed different trim values of engine fuel consumption rates based on statistical data analysis and achieved optimal sailing conditions by identifying different draft values. In addition, he proposed a data processing framework, including data pre-processing with the data-driven model, sensor, and fault identification and post-processing. This data processing framework laid a foundation for the ship's data analysis platform [6].

Data analysis methods extract hidden information and knowledge by analysing various datasets to help explain information and make decisions [7]. Lu [8] discussed voyage optimization, which involved selecting the best route for a ship's voyage to increase energy efficiency and reduce greenhouse gas emissions, and proposes a semi-empirical ship operational performance prediction model that can accurately predict a ship's performance under different conditions. Venturini [9] proposed a mathematical model to solve the Berth Allocation Problem (BAP) in the container shipping industry, which extends to cover multiple ports in a shipping network, optimizes speed on all sailing legs, and reduces the total time of operation and fuel consumption, and emissions. Compared with the ship fuel consumption prediction model based on ship propulsion principles and mathematical formulas (white-box model) ([10]), the model based on the machine learning method (black-box model) ([11]) usually has higher prediction accuracy and can relatively accurately capture the impact of various weather/sea conditions and other external factors on the ship fuel consumption. Jeon [12] proposed a big data analysis approach for smart ships, using artificial neural network (ANN) to accurately predict the fuel consumption of main engines, after testing various hidden layers, neurons, and activation functions, which outperforms polynomial regression and support vector machine methods. Kee [13] proposes the multiple linear regression (MLR) methods to construct fuel efficiency profiles for working tugboats and the development of a Fuel Consumption Analysis System for real-time fuel consumption monitoring and operation at optimal fuel efficiency, demonstrating up to 37.1% fuel savings in real operational data. Omer [14] proposed a tree-based modeling approach using high-dimensional data to monitor ship performance under operational conditions. This model uses publicly accessible data, and the results show that the proposed model outperforms other methods, such as ANN and GP, in ship performance monitoring. The findings contribute to ship management companies in monitoring ship operational performance. The high accuracy of the black-box model has laid a solid foundation for multiple measures of ship energy efficiency optimization.

The inexplicability inside the black box model has caused many researchers to have concerns. However, its high accuracy and simple method for ship fuel consumption prediction provide a good example and research prospect for ship energy consumption analysis. Bialystocki and Konovessis [15] calibrated ship fuel consumption-speed curves by polynomial regression method based on 418-noon report data of transport ships, thus obtaining a set of ship fuel consumption-speed curves that can be used under most weather conditions and loading conditions. Yan [16]used the Hadoop framework and the MapReduce method based on the ship sensor data and realized the fine segmentation of the ship route. They optimized the engine speed of inland ships by obtaining the optimal segment set by the particle swarm optimization algorithm. Du [17] built an Artificial Neural Network (ANN) model to predict the ship fuel consumption by using the noon report data of ships and then optimized the speed and trim of ships during navigation by two-stage optimization method of shore-based and offshore. Because of the high nonlinearity of the ANN model, they proposed a dynamic programming algorithm to solve the objective function of the optimization problem. Their results show that optimizing speed and trim can reduce ships' fuel consumption by 2% - 7% in actual navigation. Yan [18] proposed a Random Forest model for fuel consumption prediction of dry bulk carriers based on 242 noon-report data. The Mean Absolute Percentage Error (MAPE) reached 7.91% in the model evaluation results. They used a linear programming solver to solve the speed optimization problem and the Savitzky Golay filtering method (SG) [19] to smooth the predicted fuel consumption and make the optimization result more reliable. Their results show that fuel consumption can be saved by 6.53% after speed optimization.

Through the above literature analysis, most researchers use the noon report data as the modeling dataset for the fuel consumption prediction model. In contrast, the sensor data is collected within a few seconds or minutes and can reflect the changes in fuel consumption during the ship's voyage than the noon report data collected by days and have a better modeling effect. Although there are studies using sensor data to build ship fuel consumption prediction models in speed optimization, their research objects are inland ships. Compared with inland ships, ocean-going ships have numbers and substantial power, and they have significant potential for energy conservation and emission reduction. Given the above reasons, We have established a gray-box model with meteorological conditions as input, combining the black-box model (XGBoost) with the Kwon formula in the white-box model. On this basis, we simulated the actual meteorological conditions (wind and waves) and the external parameters of the ship (trim, bow, stern draft, etc.). We applied the Gurobi solver to optimize the speed of a voyage with an ocean-going carrier as the research target. The Exponential Weighted Moving Average (EWMA) method is proposed for the prediction model to smooth the prediction results.

3 Data pre-processing and proposed model

Data pre-processing has a crucial impact on the establishment of models. This section briefly introduces a data pre-processing method and machine learning model proposed in previous work [27].

3.1 Data description and pre-processing

In this study, we analyzed a sailing test case from an oil tanker consisting of 496 data features, but due to sensor failure, some of the collected data had fault signals. We kept the remaining 378,468 (4.38 days) data records collected at one-second intervals. Raw data often contain noise that can negatively impact the model's generalization ability by causing over-fitting or leading to misleading decisions [20]. Hence, data pre-processing plays a vital role in improving the generalization performance of a supervised machine-learning algorithm [21].

This dataset includes alarm signal detection points, temperature, pressure, flow, and other signals, collected during a sailing test case from an oil tanker. Fuel consumption optimization is of utmost importance to shipping companies since it directly impacts the navigation economy, surpassing rpm and power. Therefore, the study aims to filter the data and select relevant features for modelings, such as speed, engine power, trim, and draft. The chosen parameters' influence on fuel consumption must be considered. The correlation between engine power and fuel consumption already thinks the impact of ship speed and other features. The modeling features include speed, fuel consumption rate (FCR), trim, fore and aft draft, and external features such as wind and waves. As the sensor dataset lacks wave and current features, wave data (wave high and wave direction) was obtained from ECMWF and matched into the sensor data using geographical location (latitude and longitude) and collection time. To consider the relative relationship between absolute wind direction and ship heading, the angle between the absolute-wind direction and heading was calculated as the relative wind direction. The wind from the port side and starboard side has an identical impact, so the relative wind direction was converted from 0° ~ 360° to 0° ~ 180°, with 0° meaning the wind is from the bow and 180° from the stern.

After extracting the above data features from the sensor dataset, the following data pre-processing is carried out: the data of FCR, wind speed, and wind direction less than 0 are removed; the data of speed beyond the range of 10~16.8 knots are removed. The dataset includes nine features: ship speed (V), fore draft (D_f), aft draft (D_a), trim (T), wave high ($Wave_h$), wave direction ($Wave_d$), absolute wind speed ($Wind_s$), wind direction ($Wind_d$) and FCR, 147845 rows after these steps. The data distribution of ship speed and fuel consumption is shown in Figure. 1. The data statistics are shown in Table 1.

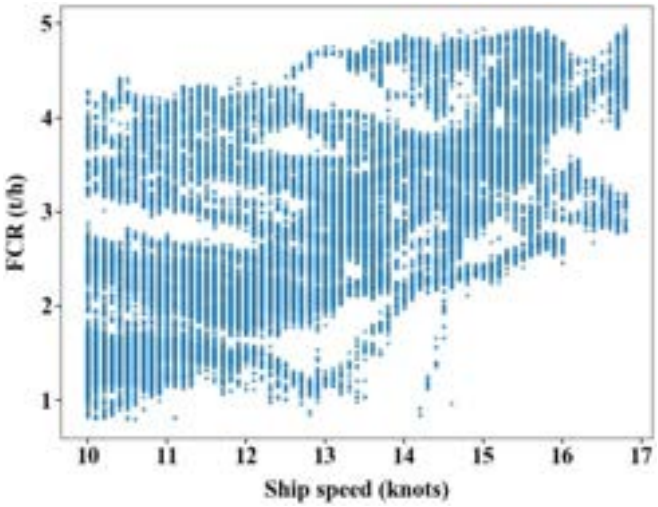

Figure. 1. Speed - fuel consumption data distribution after preliminary data pre-processing.

3.2. Proposed model

In this part, we use a grey-box model that have been proposed before [27], which is combined with the black box model (XGBoost) and the Kwon formula of the white box model. The white-box model is based on this ship's structural and main-engine parameters [10]. Kwon proposed corresponding formulas for calculating ship speed loss and additional effective power ([22], [23]):

$$\frac{\Delta P_E}{P_E} = (n{+}1)\frac{\Delta v}{v_1} \quad (1)$$

$$\frac{\Delta v}{v_1} \times 100\% = C_\beta C_U C_F \quad (2)$$

$$\Delta v = v_1 - v_2 \quad (3)$$

$$v_1 = F_r \cdot \sqrt{L_{PP} \cdot g} \quad (4)$$

where n is an empirical constant, related to ship type and loading status; P_E is the effective power of the ship in calm water; Δv is the speed loss caused by wind and waves, m/s; v_1 is the speed in calm water, m/s; v_2 is ship speed in selected weather (wind and irregular waves), m/s; C_β is direction reduction coefficient, related to weather direction angle (concerning the ship's bow) and Beaufort number (BN); C_U is the speed reduction coefficient, which is related to the ship's block coefficient (C_B), Froude number (F_r), and loading conditions; C_F is the ship form factor related to ship type, ship displacement (∇), and BN; L_{PP} is the ship length between perpendiculars, m; g is the local acceleration of gravity, m/s^2.

Black box model Based on the scale of sensor data, we select the XGBoost model based on decision trees. Xgboost is a distributed gradient boosting algorithm based on the gradient boosting framework, which aims to build boosting trees in order, efficiently, flexibly, and conveniently to solve the regression problem. We integrate the Kwon formula into the black box model's pre-processing process, calculate the ship's additional fuel consumption under the maximum wind value (Beaufort number (Bn) = 6) in the data, and remove it accordingly. Since we only consider the steady-state navigation process of the ship in the speed optimization process, the speed change process does not need to take into account (for ocean-going ships, the duration of this process is concise and can be ignored).

In the hyperparameter optimization (HPO), we used the grid search method to perform 5-fold cross-validation, and optimized the hyperparameters, 'n_estimators' and 'max_depth' together. The optimization range of the two parameters we specified is as follows: 'n_estimators' ranges from 100 to 3000, and every 200 is one step-size, resulting in a total of 15 parameter values; 'max_depth' ranges from 3 to 15, and each value is one step-size, resulting in a total of 12 parameter values. From this, HPO requires fitting five folds for each of the 180 candidates, totaling 900 fits. Regarding accuracy, we use R^2 to validate the model. Figure 2 shows the result of the optimization. And after the HPO, 'max_depth' is 9, and 'n_estimators' is 100."

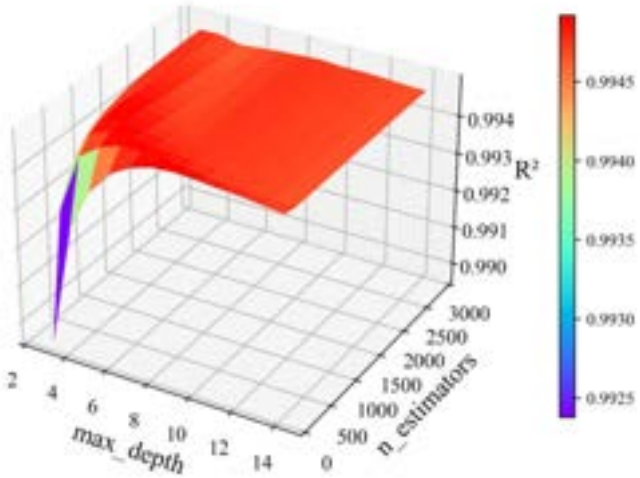

Figure 2. HPO result of the grey-box model

In order to comprehensively compare the prediction performance of the model, Mean Square Error (MSE), Root Mean Square Error (RMSE), Mean Absolute Error (MAE), MAPE, and R-Square (R^2) are used to evaluate the accuracy of the models, the evaluation index formulas are as follows:

$$MSE=\frac{1}{n}\sum_{i=1}^{n}(y_i'-y_i)^2 \tag{5}$$

$$RMSE=\sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i'-y_i)^2} \tag{6}$$

$$MAE=\frac{1}{n}\sum_{i=1}^{n}\left|y_i'-y_i\right| \tag{7}$$

$$MAPE=100\%\cdot\frac{1}{n}\sum_{i=1}^{n}\left|\frac{y_i'-y_i}{y_i}\right| \tag{8}$$

$$R^2=1-\frac{\sum_{i=1}^{n}(y_i'-y_i)^2}{\sum_{i=1}^{n}(\overline{y_i}-y_i)^2} \tag{9}$$

where n is the number of samples; y_i is the true value; y_i' is the predicted output value of the model; $\overline{y_i}$ is the average value of the samples."

The model results were evaluated ten times by randomly splitting the training–test dataset (training–test split) and calculating the result each time [27]. **Table 2** shows the model evaluation results that the model can achieve acceptable accuracy for predicting ship fuel consumption rate.

Table 2. Grey-box model evaluation results.

	Grey-box model

4. Ship speed optimization model

We study the ship speed optimization problem on a given route between two ports under a given time window constraint and speed constraints. And then, the ship's minimum fuel consumption is used as the objective function for speed optimization. The weather data (wind speed and wind direction) used in the research are all collected in real-time by sensors during the actual navigation of the ship. Usually, the route is divided into several segments according to the estimated sailing time or weather conditions. Therefore, divided according to the principle that the ship sails for about one day on each segment, and it is assumed that a segment has the same weather conditions (more segments can also be divided).

4.1. Objective function and constraints

The case route of speed optimization is the ocean route from Ceuta port in Spain to Miami port in the United States. The estimated sailing time on the route is 237 hours, excluding entering and leaving the port and only the sailing time between anchorages. The route is shown in Figure. 3, divided into ten segments according to the sailing days. The distance of each segment is calculated according to the longitude and latitude coordinates of the start and end of each segment by using the great circle route formula:

$$L_{Km} = 2R \cdot arcsin\left(\sqrt{sin^2\left(\frac{latA - latB}{2}\right) + cos(latA) \cdot cos(latB) \cdot sin^2\left(\frac{lonA - lonB}{2}\right)}\right) \quad (5)$$

$$L_{Nm} = 0.54 \cdot L_{Km} \quad (6)$$

where R=6378.14 km is the equatorial radius of the earth; $lonA$, $latA$, $lonB$, and $latB$ are respectively the longitude and latitude coordinates of point A and point B; $L_{Nm}$is the voyage of the great circle route between coordinates A and B, n mile. The distance and sailing time of each segment calculated by combining the average speed on the route and the above formula are shown in Table 3.

Figure. 3. Route map.

Table 3. Sailing segment distance and sailing time

Segment	Distance (n mile)	Time (h)
1	366	23.6
2	381	24.5
3	380	24.2
4	375	23.6
5	357	24.6
6	357	23.8
7	389	24.3
8	372	24.4
9	376	23.0
10	316	20.0

Under the dual pressure of economic interests and environmental protection, shipping companies are eager to reduce ships' fuel consumptions through various energy efficiency optimization measures. Ship speed optimization is such an energy efficiency optimization measure with fuel-saving potential. Currently, the objective functions of ship speed optimization mainly include the minimum ship fuel consumption, the minimum ship operating cost, the maximum ship revenue, and the minimum ship CO_2 emission. Considering that the fuel consumption of the main engine largely determines the fuel consumption, operating cost, and CO_2 emission of the ship, speed optimization is carried out to minimize the fuel consumption of the main engine. Therefore, the speed optimization objective function based on the grey-box fuel consumption prediction model is as follows:

$$M_{Gb} = f_i^{Grey-box}(v_i, t_i, wd_i, ws_i, fd_i, ad_i, wvd_i, wvh_i) \tag{10}$$

$$TotalFC = min\{\sum_{i=1}^{10} M_{Gb} \cdot (d_i/v_i)\} \tag{11}$$

where M_{Gb} is the grey-box model; $i = 1,\ 2,\ \ldots,\ 10$ represents the segment of the route; v_i is the ship speed on the segment i (knots); $t_i, wd_i, ws_i, fd_i, ad_i, wvd_i, wvh_i$ are the trim (m), wind direction (°), wind speed (knots), fore draft (m), aft draft (m), wave direction (°), and wave high (m) on the segment i, respectively; d_i is the distance of the segment i, calculated by latitude and longitude (n mile); $TotalFC$ is the total fuel consumption of the ship on the route (tons).

When ships sail on a given route, shipping companies usually provide a time for the latest arrival at the port of destination, so there is a time constraint in speed optimization. In addition, considering the operating performance of the main engine under low operating conditions and the main engine rated power limit, speed optimization usually has minimum and maximum speed constraints. The constraints of the latest arrival time and the minimum and maximum speed are as follows:

$$Speed_{lim}: \begin{cases} v_i \le v_{max} \\ v_i \ge v_{min} \end{cases} \tag{12}$$

$$Time_{lim}: \sum_{i=1}^{10} (d_i/v_i) \le T_{max} \tag{13}$$

Where, v_{max} and v_{min} are the maximum speed and minimum speed of the ship, which are determined by the ship test data. In this study,v_{max}=16.8 knots, v_{min} =10 knots; T_{max} is the latest arrival time, for this route set as T_{max}=237 h.

4.2. Transformation and solution of the speed optimization model

After obtaining the speed optimization objective function and constraints, the optimal speed of the ship can be obtained by applying appropriate optimization algorithms. For optimization problems involving machine learning models, conventional nonlinear numerical optimization algorithms (e.g., linear approximation method and interior point method) are difficult to solve effectively due to the highly nonlinear characteristics of machine learning models. Although emerging heuristic optimization algorithms (e.g., genetic algorithms [24] and differential evolution algorithms [25]) can obtain a well acceptable solution in a relatively short period, they cannot obtain the exact optimal solution of the optimization problem. Considering that the ship speed in actual navigation is usually accurate to 0.1 knots, the continuous optimization range of the ship speed [10, 16.8] is discretized according to 0.1 knots, and 0-1 variables are introduced at the same time to convert the nonlinear speed optimization problem to mixed-integer linear programming problem. Furthermore, this speed optimization problem can be solved by linear programming solvers such as Gurobi.

5. Results and discussion

We simulated the meteorological conditions of the ship's navigation process under actual conditions and used the model to predict the fuel consumption rate and optimize the speed.

5.1. Weather conditions and model prediction results

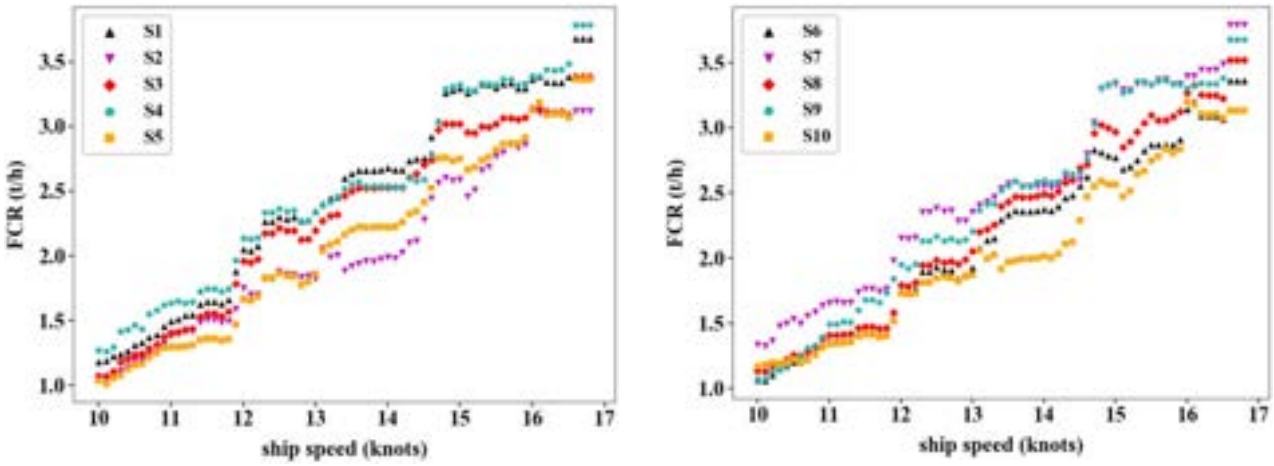
To evaluate the fuel-saving potential of speed optimization, the ship's historical voyage data on the research route are extracted from sensor data, as shown in **Table 4**. An established grey-box model is used to predict the ship fuel consumption rate at different speeds, and the results are shown in **Figure. 4**.

Table 4. The ship's historical voyage data on the route

Segment	Trim (m)	Draft aft (m)	Draft fore (m)	Wind direction (°)	Wind speed (knots)
1	4	22	18	56.3	5.8
2				128.5	13.6

3	48.9	12.1
4	162.3	14.6
5	146.3	18.3
6	65.4	21.3
7	175.3	22.9
8	170.3	16.3
9	140.3	15.2
10	100.6	10.6

Note: Segment is represented by S, for example, S1 represents segment 1.



(a) S1 ~ S5 **(b)** S6 ~ S10

Figure. 4. The predicted fuel consumption rate at different speeds in each segment.

The predicted results of the model conform to the cubic relationship between speed and fuel consumption. Due to different weather conditions, the results are different in different segments. At the speed of 14.5 and 16.5 knots, there is a step phenomenon in fuel consumption. This is because the data is not evenly distributed, there is missing data at this speed, which can also be seen in Figure. 1. The lack of speed data will lead to an abnormal step in the prediction result of the model to a certain extent.

5.2. Speed optimization results

To obtain the optimal speed of each segment and the minimum fuel consumption of the ship on the route, the corresponding optimization algorithm is developed using Python programming to call the Gurobi 9.0.2 solver to solve the speed optimization problem. Comparing the speed before and after optimization can reveal the reasons for the reduction of fuel consumption after optimization to a certain extent. Therefore, to evaluate the fuel-saving effect of speed optimization, the optimal speed is compared with the historical average speed in the segment. The speed on the segments before and after optimization and the fuel consumption (FC) predicted by the model are shown in Figure. 5 and Figure. 6, respectively.

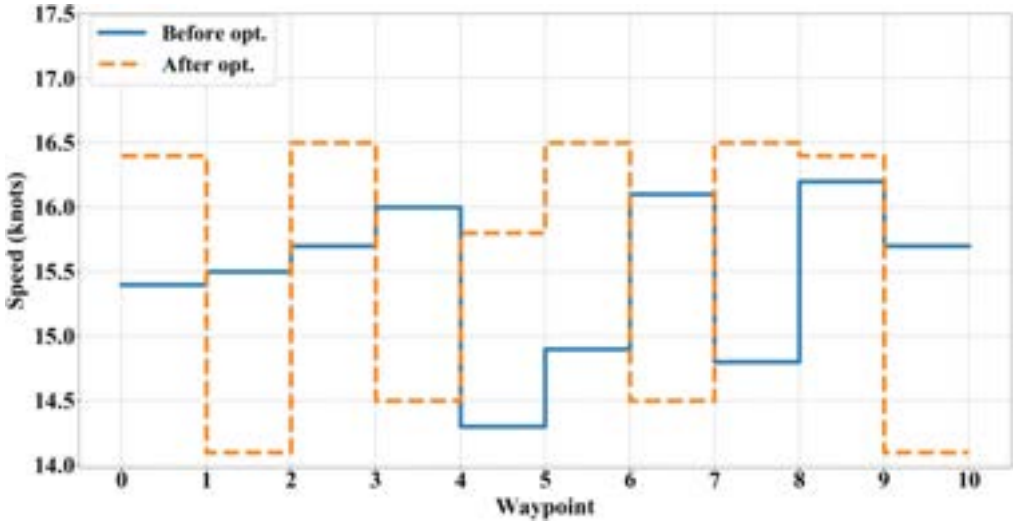


Figure. 5. Comparison of optimized speed results.

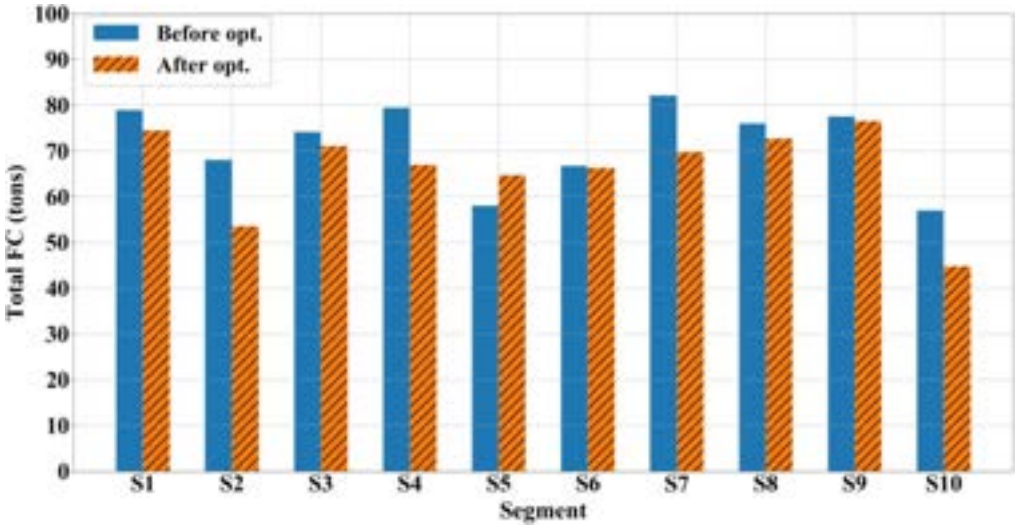

Figure. 6. Comparison of fuel consumption results.

The fluctuation of the optimized speed is mainly caused by the different weather conditions of each segment. Combined with Figure. 5 and Figure. 6, when the optimized speed is higher than the historical average speed, the fuel consumption after optimization is still saved than the historical average speed (segments 1, 3, 6, and 8). This is due to the small amount of data within the range of 16 ~ 16.5 knots speed, which leads to no significant upward trend of fuel consumption rate so the predicted fuel consumption rate is low at high speed. When the optimized speed is lower than the historical average speed, the fuel-saving effect is significant (segments 2, 4, 7, and 10), indicating that the model fully reflects the fuel-saving effect of the ship's slow-down sailing.

The ship speed, fuel consumption, and the fuel-saving rate on the route before and after optimization are shown in Table 5. Among them, the fuel consumption of the ship before and after speed optimization is FC1 and FC2, respectively. During the entire voyage, the total fuel consumption is reduced from 717.9 tons to 661.0 tons after optimization, the overall fuel saving is 56.9 tons, and the fuel-saving rate reached 7.9%. With the current price of marine fuel oil at US$500 per ton, the fuel-saving rate of 7.9% can save US$28,450 in fuel expenses during a single voyage. That's substantial for a single voyage.

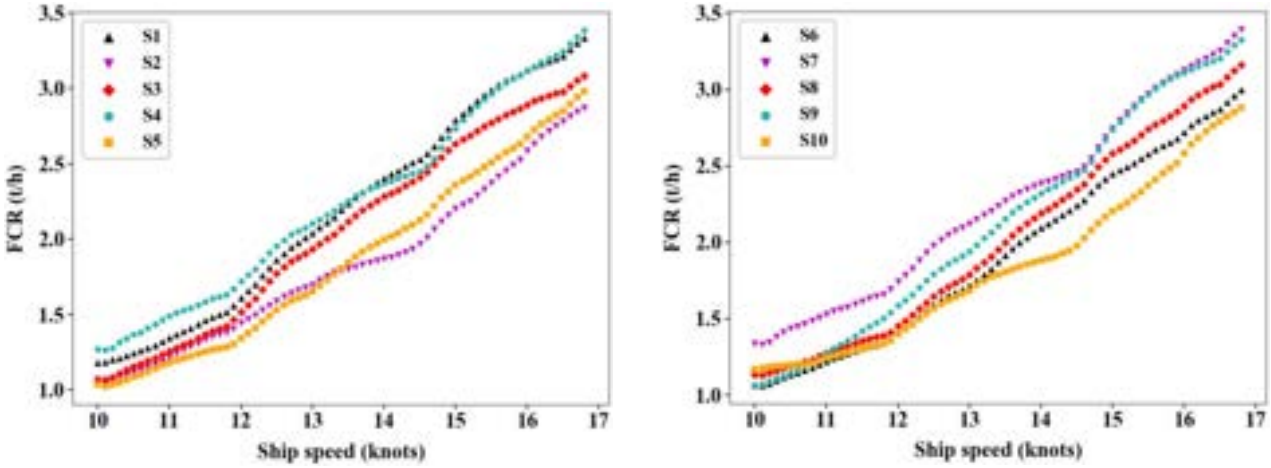
Table 5. Fuel consumption before and after optimization

	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	Total
FC1 (t)	78.9	68.1	74.1	79.5	58.0	66.7	82.1	76.0	77.5	57.0	717.9
FC2 (t)	74.5	53.6	71.0	67.0	64.8	66.3	69.8	72.7	76.5	44.8	661.0
Fuel-saving (tons)											56.9
Fuel-saving rate (%)											7.9

5.3. Optimization results after data smoothing

As shown in the prediction results in Figure. 4, ship fuel consumption rate has a certain degree of step in the speed range of 12~13 knots and 14~15 knots, which is due to the uneven distribution of the speed data used in the modeling. The step phenomenon of fuel consumption affects the reliability of the optimization results. For example, when the speed changes from 11.9 knots to 12 knots, there is a step in the fuel consumption rate. The fuel consumption savings brought by the 0.1 knots reduction in speed are considerable, which is not in line with the actual situation. To make the speed optimization results reasonable and reliable, it is necessary to smooth the fuel consumption results predicted by the model. The Exponential Weighted Moving Average (EWMA) [26] is used to process the predicted fuel consumption. EWMA gives different weights to the observed values, obtains the moving average according to different weights, and determines the predicted value based on the final moving average.

The data in a range under the same sailing speed and weather conditions are regarded as a window capacity, and certain weights are given. Different weights are used to determine that the current prediction result is close to the true value, which can make the prediction result more accurate. As shown in Figure. 7, After using the EWMA to smooth the prediction results of fuel consumption rate, the step phenomenon of fuel consumption rate is significantly alleviated. The optimization results are shown in Figure. 8 and Figure. 9 after smoothing the data.



(a) S1 ~ S5 **(b)** S6 ~ S10

Figure. 7. Fuel consumption prediction results after smoothing.

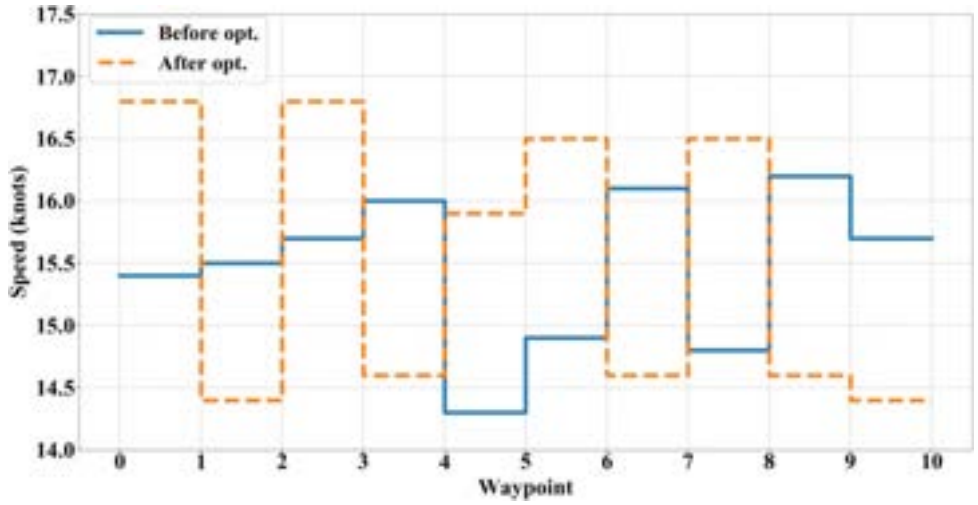


Figure. 8. Comparison of speed optimization results after smoothing.

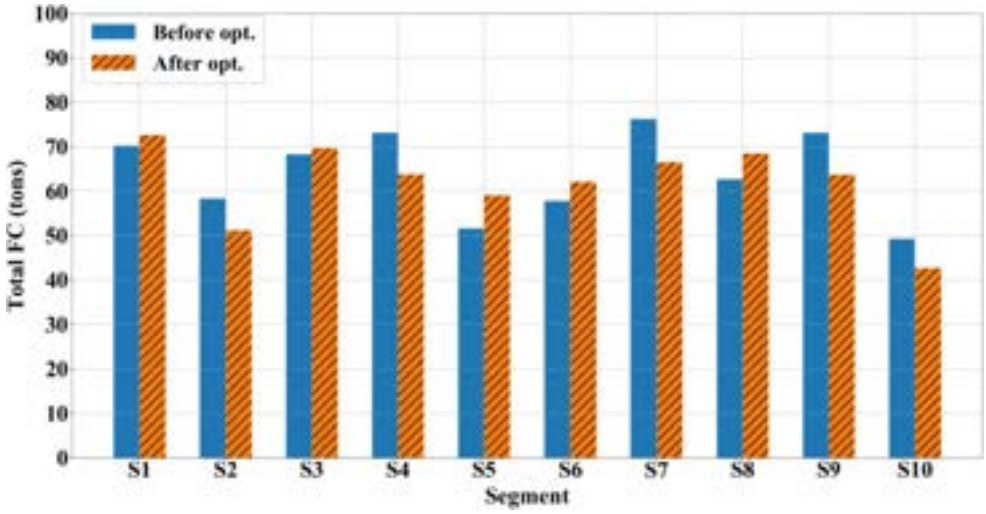

Figure. 9. Comparison of fuel consumption results after smoothing.

After smoothing, the fuel consumption of each segment rises smoothly with the increase of ship speed, the step phenomenon of fuel consumption at certain speeds has been significantly alleviated. At the same time, it also alleviates the insignificant upward trend of fuel consumption rate due to a lack of data under high-speed conditions (16~16.5 knots).

Table 6. Fuel consumption before and after optimization after smoothing

	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	Total
FC3 (t)	70.2	58.4	68.3	73.1	51.6	57.9	76.2	62.7	73.2	49.3	640.9
FC4 (t)	72.6	51.2	69.7	63.8	64.0	59.1	62.1	66.5	68.5	42.7	620.2
Fuel-saving (tons)											20.7
Fuel-saving rate (%)											3.2

The fuel consumption results before and after optimization are compared and shown in Table 6. The actual fuel consumption and optimized fuel consumption after data smoothing are FC3 and FC4, respectively. The fuel-saving rate for speed optimization after data smoothing is 4.7% lower than that before, but even so, it still reaches 3.2%. In the case of a 3.2% fuel-saving effect, speed optimization can still save $10,350 in fuel expenses. Speed optimization experiments confirm that ship speed optimization can significantly reduce ship fuel consumption, which can provide reliable decision support for shipping companies' ship operations.

6. Conclusion

Ship speed optimization is a crucial aspect of the shipping industry, directly affecting navigation economics. The cost of fuel consumption constitutes a significant portion of a shipping company's expenses, and reducing it by even a small percentage can result in substantial cost savings. In this paper, we based on the sensor data and ship parameters of an oil tanker, using the proposed grey-box ship fuel consumption model, consider the speed of the oil tanker is optimized in consideration of the influence of weather conditions to reduce the fuel consumption of the ship's navigation. Moreover, the data smoothing process is carried out for the model prediction step problem. The main conclusions obtained are as follows:

EWMA method is used to smooth the model prediction result, which can effectively solve the problem of fuel consumption rate step with the increase of ship speed. The relationship between fuel consumption rate and sailing speed is more continuous after smoothing, and the reliability of speed optimization results is improved.

The speed optimization results show that speed optimization considering the influence of weather conditions can save 3.2% and 7.9% of fuel for a single voyage, also $10,350 and $28,450, respectively. Although this study is only aimed at optimizing the speed of a tanker, the modeling and optimization methods used can also be extended to other ship types, which is foreseeable. Ship speed optimization based on actual ship operation data can provide strong support for ship energy saving and emission reduction decision-making.

Abstract:

Ice energy storage systems (ICES) in non-residential buildings are a promising technology for utilizing waste heat arising inside the building to efficiently provide heating and cooling without solar assistance. However, there are currently no recommendations for the dimensioning and operation of ICES in interconnected systems with a high level of supply security. Therefore, a detailed numerical investigation of a 500 m³ ICES in a research building is performed and compared with measurement data over one year within this work. Besides, an economic and ecological analysis, a multi-objective evaluation including direct and social costs caused by climate change damages is conducted. An optimization of different operation approaches is examined, ranging from a simple constant operating strategy over a year or representative week, to seasonal control, to an elaborate weekly varying strategy. Moreover, to determine an optimal storage sizing different system combinations are investigated, using a downhill simplex algorithm for each given configuration. Frameworks for Germany, France and EU27 average are used, whereby their influence is investigated by means of a sensitivity analysis. Through an optimized operation, the CO_2 emissions can be reduced by 37 % compared to a conventional system. The adaptation of the plant concept and the determination of an optimal storage dimensioning can also significantly increase the economic feasibility of the realization, whereby a high dependence on the prevailing boundary conditions is evident. The use of ICES leads to an ecological improvement in all regions considered, whereas the methodology can be applied to further building types in the future.

1. Introduction

The progressive climate change and its negative consequences represent an increasingly important challenge for society, which is why a more sustainable energy supply is unavoidable in all areas. The building sector is currently responsible for 15 % of direct CO_2 emissions from the end-use sector, and in fact, its share of emissions increases to about 30 % if indirect emissions from building electricity and heat consumption are considered [1]. According to the International Energy Agency (IEA), global emissions from space heating are steadily declining while cooling is becoming increasingly important. Thus, appliances and cooling are the fastest-growing uses of energy in buildings, and their growth is expected to continue. In 2019, only 15 % of the energy used for heating was required to meet space cooling demand in the building sector, with about 1 $GtCO_2$ generated through the use of electricity. Nevertheless, based on stated policy intentions, cooling demand is assumed to grow by more than 3 % per year over the next several decades. [2] Beside the higher requirements for air conditioning, especially in non-residential buildings (NRB), there are more and more technical devices like servers that require cooling. Rather than releasing this waste heat unused into the environment and operating refrigeration machines, its utilization represents an auspicious alternative. However, the main challenge is the mostly low-temperature level, complicating the search for technical solutions. [3]

A promising concept is the combined supply of heating and cooling, in which waste heat generated in the building is used directly. Especially NRBs can be suitable for this task, since unlike residential buildings, the demand for cooling does not only occur in the warmer half of the year and often there is even a simultaneous demand for heating and cooling. Nevertheless, Ghoubali et al. [4] show that the important ratio of simultaneous

heating and cooling demand is often insufficient even in these buildings due to temporal mismatch. In order to minimize the effects of this time offset, storage systems come into focus.

In this context, especially in recent years, there has been an increase in the amount of research. At this point, borehole systems, which are coupled with a heat pump, are often considered in order to achieve the required high storage capacity. Applications can range from industrial low-temperature waste heat [5] to ice rink and waste incineration [6] to data centers [7]. In the cases mentioned, both ecological and economic improvements can be achieved. However, the common feature of having borehole installations can be a constraint as well. Beside the high investment costs, more and more countries have stricter regulations for drilling, whereby these types of systems could not be deployed at all locations.

A promising extension or even alternative is provided by ice energy storage systems (ICES), which are not affected by any regulations. Contrary to numerous other phase change materials (PCM), water is an affordable alternative that is neither toxic nor flammable, has long-term stability, and offers a high storage density. The first attempts of applying an ice storage for waste heat utilization and simultaneous heat and cold supply already dates back to the year 1980 by Shipper [8]. Recently, for example, Philippen et al. [9] have investigated the use of waste heat from an air ventilation system in a multi-family house. In a previous paper, the use of an ICES entirely without solar support was considered in detail for the first time by Griesbach et al. [10]. In this paper, an ICES with a volume of 500 m³ in a research building and a corresponding numerical model are examined in detail. Over an evaluation period of 13 months, the ICES can provide therein a considerable share of 34 % of the cooling and 31 % of the heating demand. [10]

In an NRB requiring high security of supply, components such as the ice storage and the associated HP are generally integrated in conjunction with other heating and cooling equipment. However, complex mutual reciprocal interactions of the interconnected system complicate the identification of an optimal operating strategy. In addition, there are no recommendations in the literature so far for the dimensioning of the ICES and a prediction on the components which it should be combined with.

At that point this work sets in, whereby this gap should be filled. For this purpose, the existing model of the previous work [10] is supplemented by all generation plants of the compound system and in this context, for the first time, it is investigated as a case study. Over a period of one year (1st October 2020 to 30th September 2021), real plant and consumption data are monitored and compared with numerical results. For this purpose, a numerical model is introduced in MATLAB Simulink [11] with the help of the Carnot component library [12]. In a first step, the detailed numerical model, which considers the complex mutual interactions, is used to investigate the effects of different operating strategies and approaches for optimizing the operation. In addition, various plant configurations are investigated for which an optimal storage system is identified with the application of a downhill simplex algorithm [13]. To evaluate the operation as well as the dimensioning, an economic, an ecological as well as a combined consideration by social costs takes place. The boundary conditions of economic and ecological parameters from different locations on the optimization process are examined and concluded by a sensitivity analysis.

2. Description of the system

Within the framework of this work, a case study is presented, which is located at the Center of Energy Technology (ZET) at the University of Bayreuth in the Technology Alliance of Upper Franconia (TAO) building. From the 5,600 m² of the research building, about 4,000 m² can be attributed to laboratories and workshops. In addition to the heat demand for space heating, the non-residential building has a particularly high cooling demand, which occurs during the whole year. In addition to air conditioning, a high proportion is attributable to laboratory cooling water for machine cooling. Since the building is not connected to any district heating or cooling pipelines, all the required energy is supplied within the building itself. The nominal capacities of all loads and producers are provided in a previous publication [10]. This paper focused on the ice energy storage system and the development of a numerical model, including analytical validation and comparison with long-term measurement data. In the present work, on the other hand, the entire system is considered for the first time, whereby all plants are considered in a combined model.

An overview of the whole system is shown schematically in Figure 1. All heat consumers are supplied by a common heat distribution network, which is supplied by a conventional gas boiler (GB) and gas-fired combined heat and power plant (CHP). The cooling supply of the laboratory cooling water is carried out together with the air conditioning via a common network. As conventional generators, a compression chiller (CC) and the possibility of free cooling (FC) via dry coolers (DC) at low ambient temperatures are installed.

The ICES is located as an innovative interface between these two networks. The heat pump (HP) is able to act as the main heat generator, if its capacity is sufficient to cover the entire demand. In this case, the required flow temperature on the hot water side is set by a mixing valve. If the capacity is not enough, the HP is operated in combination with the GB and/or CHP. Then the HP is used to preheat the return flow of heating water, which reduces the load on the subsequent producers. The source of the HP is the ice storage or the chilled water network directly, the latter assuming that the appropriate heating and cooling demand prevails simultaneously. The ice storage is regenerated via the cold water network, which enables it to provide cooling in a time-shifted

manner. Since all components interact with each other in a complex way, the entire system is considered in a common interconnected system.

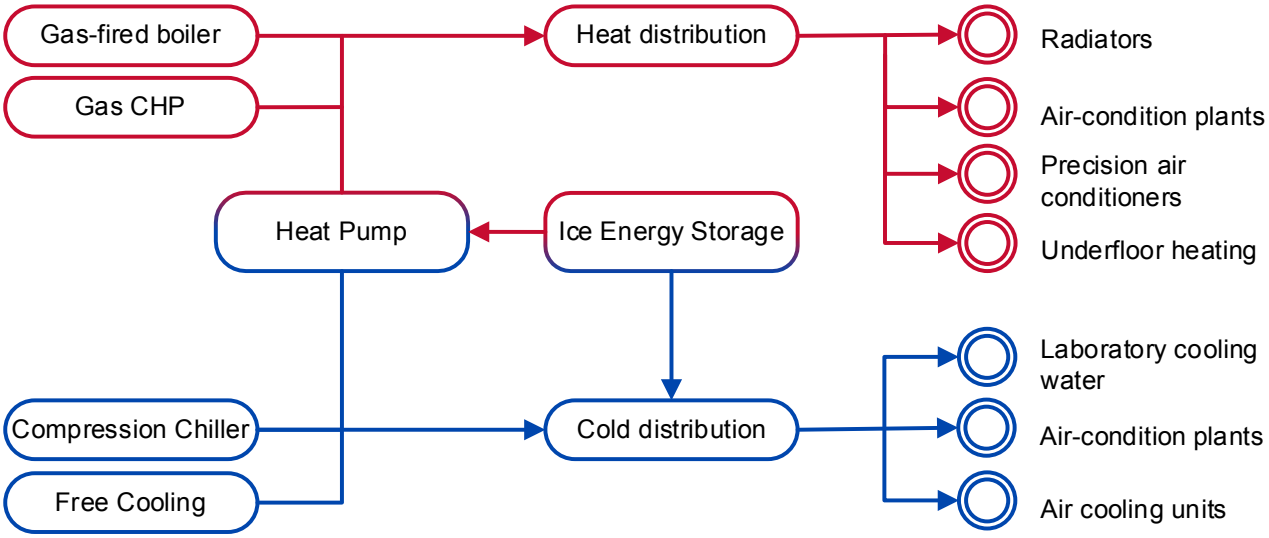

Figure. 1. Simplified scheme of the heat and cold supply system at the University of Bayreuth

A detailed data recording of the entire interconnected system up to the distribution takes place. For this purpose, over 150 data points are continuously logged with a resolution of 1 minute. These comprise all relevant temperatures and flow rates of the respective feed and return lines. The heat meters used are PolluWatt Duo II with an uncertainty of ±0.3 %; PolluStat E with an uncertainty ≤±1.5 % at all producers. At the sub-distribution, 22 PolluStat E are also installed to record in detail the demand of the different consumers. In addition to the provision of load profiles and the analysis of the realized system, the data can be used to validate the numerical models.

3. Methodology

3.1. Formulation of the numerical model

The heating and cooling supply system is entirely implemented in a numerical model in terms of the producers. The simulation environment applied is MATLAB Simulink [11] including the Carnot Toolbox [12]. The components contained therein are mostly adopted unchanged, for instance, the GB, buffer tank according to Patankar [14] and hydraulic components. The models of the HP as well as the CHP are extended by lookup tables, which are parameterized according to the manufacturer's specifications. To determine the electrical power consumption of the DC, the fan characteristic is calculated as a function of the airflow rate. The model of Griesbach et al. [10] is used for the ICES, which has been validated analytically in detail and compared with real long-term measurement data of over one year. Since it is adaptable in terms of dimension, it can also be used in the context of this work to analyse the effects of the dimensioning of the storage.

3.2. Evaluation of the numerical results

The evaluation of the plant operation and dimensioning is performed with regard to economic and ecological criteria as well as a combined evaluation including social costs. The economic consideration is carried out according to the guideline VDI 2067 [15], which combines single as well as recurring payments in a consideration period in a so-called annuity. The recommendation of 20 years is used as the period under consideration. The interest factor q is set at 3 %, the general price increase rate r at 3.1 % and the rate for electric power at 2 %. In addition, the energy tax refund for the CHP and the EEG surcharge of 40 % for self-consumed electricity are applied in the case of Germany. Using the methodology from [15], capital-related costs A_K are calculated including the initial investment and possible residual value as well as replacements. Demand-related costs are determined by the purchase of natural gas $A_{V,gas}$ and electricity $A_{V,el}$ from the power grid. Operating costs A_B include maintenance, inspection and operation of the plants. In addition, other costs A_S such as insurance or taxes can be considered. Proceeds A_E from self-production of electricity are subtracted from the costs. The Chemical Engineering Plant Cost Index (CEPCI) is used to relate the investment costs of the plants to the same reference year [16]. A summary of the costs and parameters used is shown in Table 1.

Table 1. Economic parameters of the heat and cold generators and the ice energy storage [15,17,18].

Component	A_0, €	T_N, yr	n	f_{Inst}, %	f_{W+Insp}, %	f_{Op}, h/a	$CEPCI$
GB	39,598	20	0	1	2	20	2012-2020
CHP	224,298	15	1	6	2	100	2012-2020
CHP (117 kW)	111,913	15	1	6	2	100	2012-2020
HP	60,180	20	0	1	1.5	5	2012-2020
CC	316,428	15	1	2	1.5	1	2012-2020
FC	13,387	20	1	2	1.5	0	2002-2020
ICES	498,031	50	0	1	1	0	2018-2020

In contrast to the established plants, there is no general cost function available for the relatively new technology of ice energy storages. The publication of Allan et al. [19] in which a function for a storage volume of 10 to 270 m³ is contained constitutes an exception. Since within the framework of this work also larger storage systems up to 750 m³ will be considered, an own function based on real costs from the system of the University of Bayreuth will be presented. In order to derive from the realized configuration to others, the so-called six tenth rule [20] with the default value of 0.6 is used. In addition to the storage volume V_{st}, the sum of the pipe length of the charging and discharging circuit l_{CH+DC} can be varied:

$$A_{0,ICES} = 44151 + 134769 \left(\frac{V_{st}}{443\ \mathrm{m}^3}\right)^{0.6} + 152862 \left(\frac{l_{CH+DC}}{6000\ \mathrm{m}}\right)^{0.6} \quad (1)$$

The ecological assessment considers CO_2 emissions from gas $\dot{Q}_{gas}$ and electricity consumption $\dot{Q}_{el,con}$ and power generation by the CHP $\dot{Q}_{el,gen}$. The total emission A_{CO_2} is calculated by means of CO_2 factors for gas $a_{CO_2,gas}$ and electricity $a_{CO_2,el}$ for the respective electricity mix of the grid. Since the entire electricity is self-consumed, a subtraction with the grid factor is performed:

$$A_{CO_2,i} = a_{CO_2,gas,i} \int \left(\dot{Q}_{gas,i}\right) \mathrm{d}t + a_{CO_2,el,i} \int \left(\dot{Q}_{el,con,i} - \dot{Q}_{el,gen,i}\right) \mathrm{d}t \quad (2)$$

The reference cases Germany (DEU), European average (EU27) and France (FRA) are utilized to identify the influence of the boundary conditions on the evaluation and optimization. A summary overview of the parameters applied is given in Table 2.

Table 2. Economic and ecological parameters [21–25].

Location	$A_{V,gas}$, €/kWh	$A_{V,el}$, €/kWh	$a_{CO2,gas}$, g_{CO_2}/kWh_{gas}	$a_{CO2,el}$, g_{CO_2}/kWh_{el}	hr, €/h
DEU	0.0564	0.2016		366	
EU27	0.0613	0.1584	194.3	226	73
FRA	0.0660	0.1099		57	

Frequently, an economic and ecological evaluation might not move in the same direction and may even be contrary to each other. In order to perform a combined evaluation, there is the challenge of applying a non-arbitrary weighting. Therefore, in this work, CO_2 emissions are attributed a price as a consequence of social costs in the form of climate consequential damages a_{clim,CO_2} in accordance with the German federal environmental agency [26]. These can be added to the direct costs of the plant operator, allowing a multi-criteria evaluation to be carried out. Two different values are given for the costs incurred to society by CO_2 emissions in Waldhoff et al. [27]. These differ in terms of the pure time preference rate (PTPR) and thus a weighting between the welfare of current and future generations. With a rate of PTPR of 1 %, only 74 % of the damage for the next generation (30 years) and 55 % of the damage for the generation after that (60 years) is considered. At a rate of 0%, on the other hand, the costs are weighted equally for all generations, resulting in higher values for a_{clim,CO_2}. The recommended values depending on the year under consideration are summarized in Table 3.

Table 3. German federal environmental agency recommendation on climate costs [26].

Year of consideration	a_{clim,CO_2} at PTPR=1 %, €/t CO_2	a_{clim,CO_2} at PTPR=0 %, €/t CO_2
2020	195	680
2030	215	700
2050	250	765

In order to obtain a combined evaluation parameter, the annuity of the overall system is added to the total CO_2 emissions, which are multiplied by a_{clim,CO_2}.

3.3. Plant operation optimization

Through the number of the different plants there are 24 possible rank orders of the possible plant operation on the cooling side (CCC) and 6 on the heating side (HCC), illustrated in Figure 2. Since these can be combined together in any desired way, there is a total of 144 possibilities for operating the compound system. The respective aggregate with the highest priority of the rank order under consideration is used first. Should its capacity not be sufficient, or if it is not available, the plant with the next higher priority is activated and further on. Generally, FC can only be enabled at ambient temperatures below 6.6 °C and the CHP at a heat demand of at least 70 % of its nominal capacity. HE CH can only operate at an average storage temperature below 5 °C in order to achieve a sufficient temperature difference to the cold-water network. HE HP is only applicable up to a maximum icing degree of 10 %. The HP can operate up to a degree of icing of 80 % or a minimum inlet temperature on the brine side of -9 °C. No separate restrictions exist for the GB and CC.

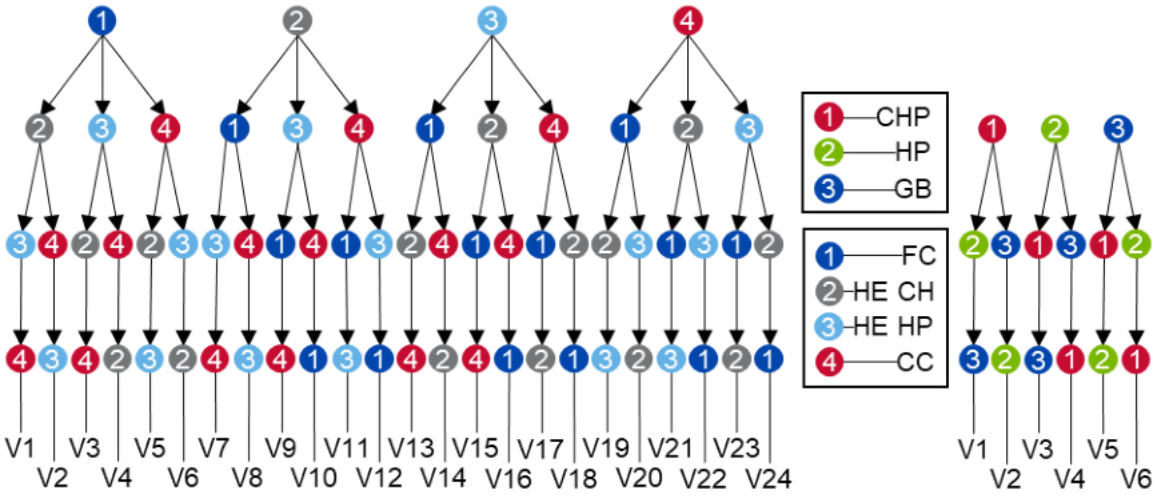

Figure. 2. Possible rank orders of the CCC (left) and HCC (right)

Since mutual interactions exist between the plants and the plant efficiency depends on the state of charge of the storage tank, no simple analytical solution can be formulated for identifying the optimal operation strategy considering all mentioned aspects. Therefore, different numerical optimization approaches to determine an optimal mode of operation are presented and investigated. In Figure 3 these approaches are summarized schematically.

The first and simplest variant is the constant control over the whole year (CCY). For each of the 144 possible combinations, an annual simulation is performed and the best one is selected. Henceforth, this will be enabled constantly over the entire year. In the second variant, on the other hand, only a simulation period of one week is used, i.e. summer (CCS), winter (CCW) and transition (CCT). In order to account for different states of charge of the storage, the model of the storage is initialized with four different degrees of icing. In each case, one week is simulated and the best variant is chosen in the process. Only with the best one a yearly simulation is carried out, which significantly reduces the simulation effort. In the third variant of the seasonal control (SC), an ice-building period $P_{i,b}$ is first defined. During this period, the priority of HE CH is reduced so that the storage is only charged if otherwise the CC has to be activated. The remaining time of the simulation period of one year, the respective strategy is used constantly, resulting in the same effort as for CCY. The best variant is then selected, which needs to be adjusted by the plant operator at the beginning and end of $P_{i,b}$. The fourth variant is the weekly adjusted control (WAC), which is also the most complex one. This is basically equivalent to a model predictive control with a perfect predictive model. Initially, the first week is simulated with all modes of operation and an optimum is selected. The next week is initialized with the final conditions of the previous week and an optimum is identified again. The procedure is repeated until a full year has been examined. For all strategies, both an economical and an ecological objective function can be defined.

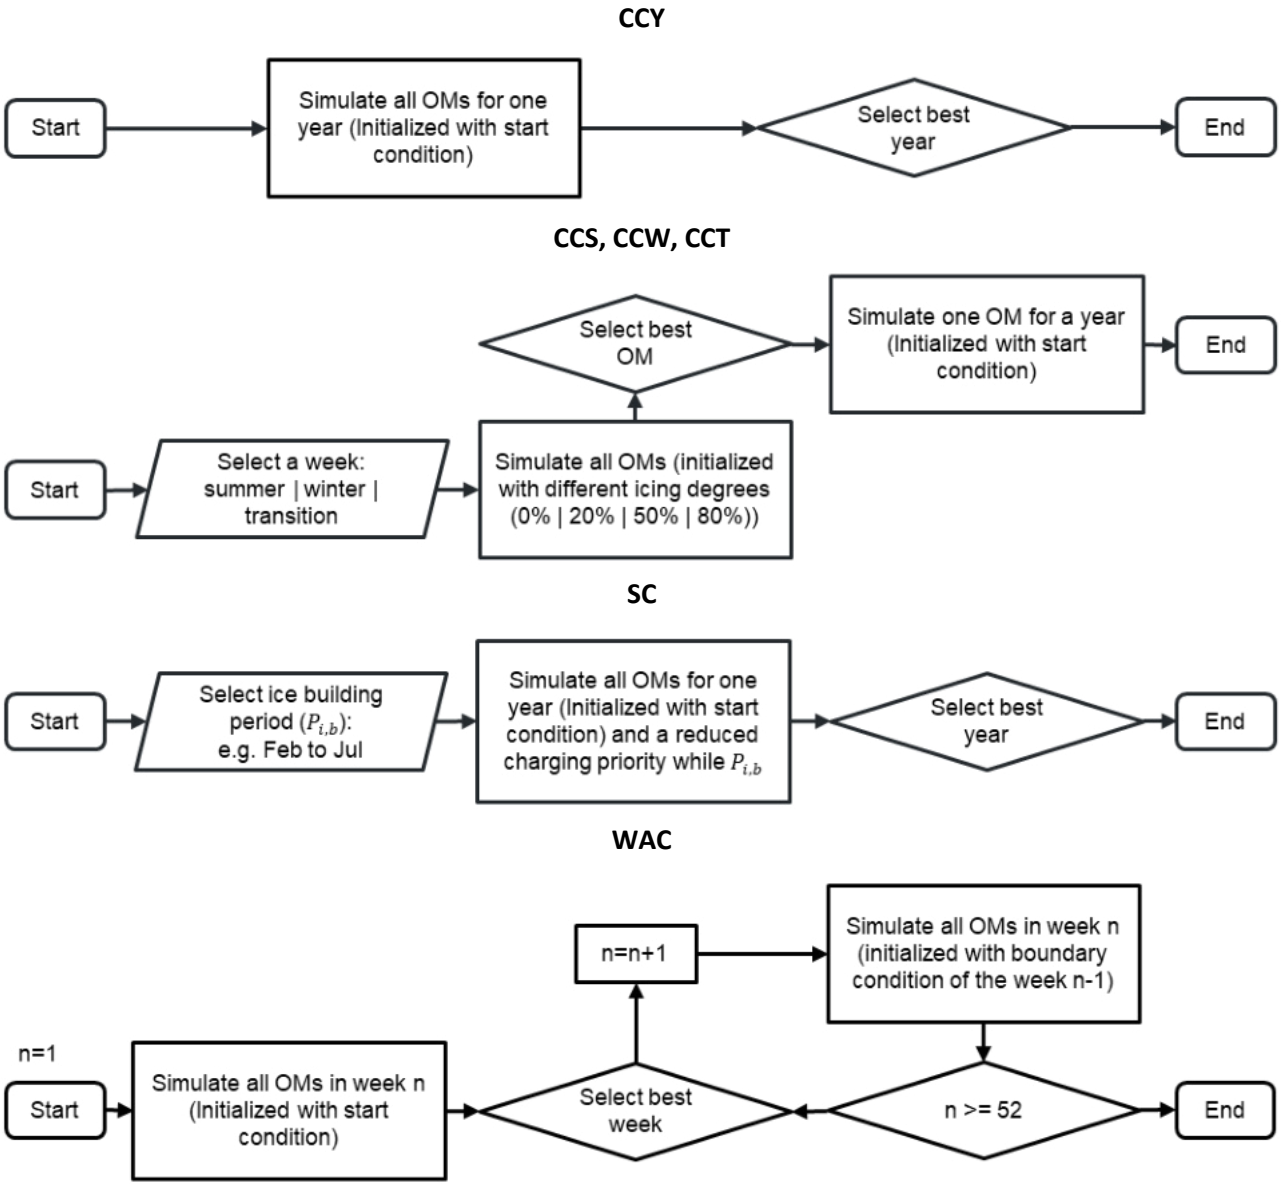

Figure. 3. Flowchart of the CCY (first), CCS, CCW, CCT (second), SC (third) and the WAC (last)

3.4. Plant dimensioning optimization

In addition to the analysis and optimization of the operation of the realized configuration, the influence of different plant dimensioning and configuration is investigated. The focus lies on the ICES here, so the remaining components are dimensioned according to established standard procedures. As the security of supply must be guaranteed, these must be able to cover the complete demand even if the storage tank is completely charged or discharged. Two reference variants (r) are defined and two variants with ICES (I) are considered, which are schematically illustrated in Figure 4. In each variant, the case without (S) and with CHP (C) is considered. FC is used in the S(r) and C(r) cases, whereas it is not applied in S(I) and C(I) in order to utilize as much of the waste heat as possible through the ICES. In the C cases, a CHP with a nominal power of 117 kW is utilized, allowing approximately 4500 full load hours to be obtained. The remaining components correspond to the realization, with the exception of the storage.

With the selected plant concept the dimensioning of the ice storage itself is carried out by a downhill simplex method [13], illustrated in Figure 5. Annual simulations with CCY (HCC: 1 & CCC: 15) are carried out during the optimization. The storage volume as well as the pipe lengths of both hydraulic circuits are continuously varied. The volume is mainly decisive for the storage capacity, which is especially relevant for seasonal considerations. The length of CH essentially influences the achievable regeneration power. The pipe length of DC determines not only the extraction capacity but also the ice layer thickness that forms around the pipes.

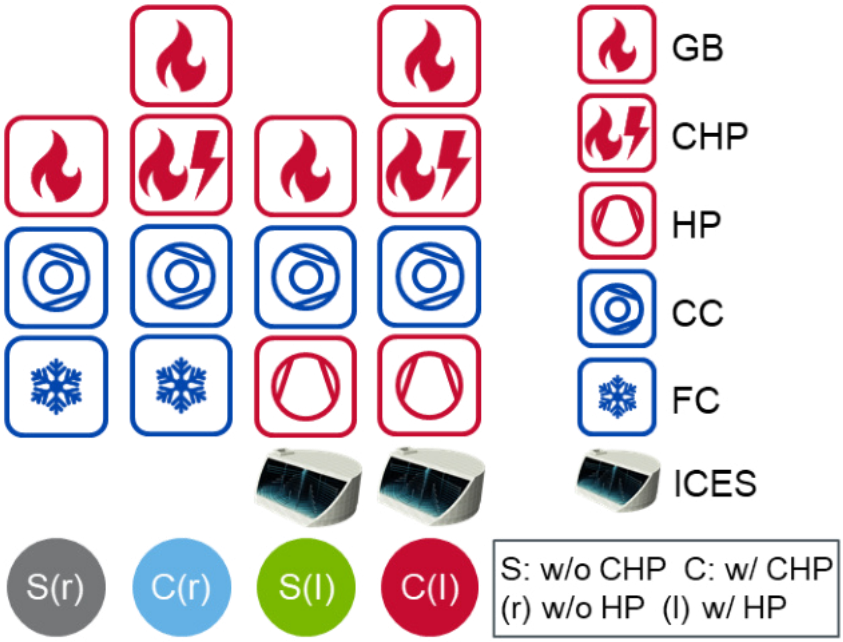

Figure. 4. Schematic overview of the examined combinations

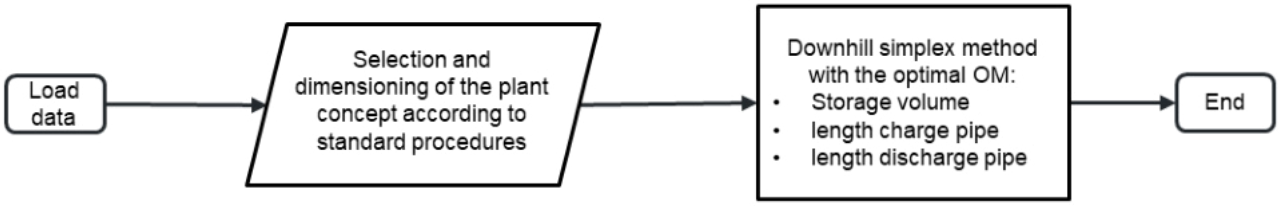

Figure. 5. Flowchart of the dimensioning optimization strategy

4. Results

In this chapter, the results of the plant operation and optimization of the realization concerning the real case study are presented first. Subsequently, different plant dimensions and configurations are investigated, identifying an optimal storage system for each of it. Finally, the chapter concludes with a sensitivity analysis to consider future developments of energy prices and CO_2 emissions of the electricity mix.

4.1. Plant operation

The results of the numerical optimization of the plant operation of the installed system at the TAO building of the University of Bayreuth are presented first. For this purpose, different optimization approaches are presented here instead of all prioritization variants, since especially weekly simulations result in too many variants to present them explicitly at this point. For this purpose, the resulting CO_2 emissions and the annuity for all strategies from chapter 3.3. for an economic (econ.) and an ecological (ecol.) optimization are indicated in Figure 6. The annuity ranges from 212 to 255 k€ and the CO_2 emissions from 148 to 195 metric tons per year.

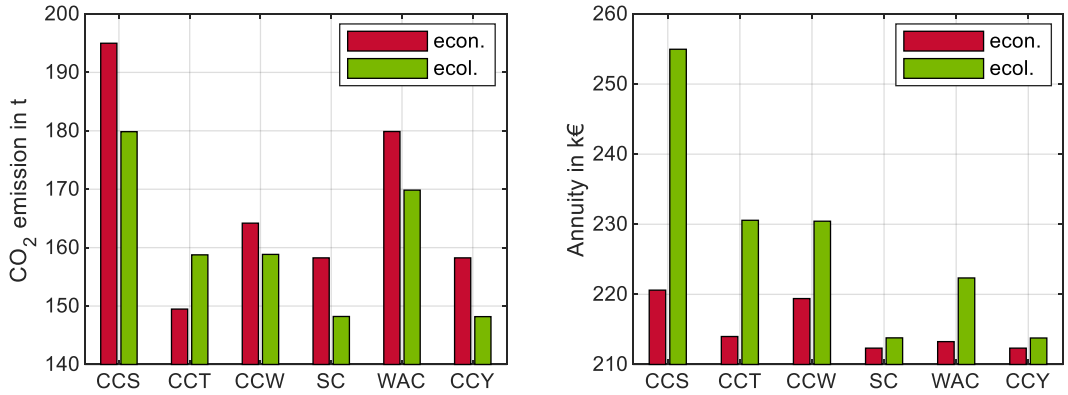

Figure. 6. CO_2 emissions (left) and the annuity (right) of all control strategies considered.

In general, using CCY yields the best results, however, an annual simulation must be conducted for each strategy to obtain these values. For the CCS, CCT and CCW variants, one week each is simulated with 4 different boundary conditions, resulting in the shortest computation time. Using the summer week in CCS performs worst for both optimization objectives from an economic as well as an ecological point of view. This can be explained by the fact that the full potential of the plant diversity cannot be exploited during this period. The heat demand is not sufficient for the use of the CHP and FC cannot be operated due to too high ambient temperatures. These limitations are not present in CCT, which provides a significantly better representation of potential annual plant usage. With an economic objective function, the ecological and economic optimum from CCY can be met with a distance of less than 1 %. From an environmental point of view, CCW can compete with CCT, while from an economic perspective it is noticeably less competitive. In SC, one annual simulation is also performed in each case, whereby the storage is charged with low priority during the ice build-up period. However, no improvement compared to CCY can be achieved, since in each case a variant is selected in which the ice build-up plays a subordinate role. The main reason stated for this is the complex mutual interactions of the system and the fact that the demand for cooling is relatively constant during the whole year. The last examined variant is the WAC, which is also the most complex one. This corresponds to a model predictive control with perfect prediction with a time horizon of one week. The economic objective function comes close to the optimum of the CCY, but from an ecological point of view it performs considerably worse. An ecological target function is not competitive regarding both evaluation parameters. This can be explained by the fact that for a time horizon of one week, the capacity of the long-term storage is not fully utilized. Due to the fact that the storage tank is not sufficiently cooled during economic optimization, it can hardly provide cold. However, the competitive ability of the system only increases with the combined provision of heating and cooling. In the case of ecological optimization, on the other hand, the CHP is increasingly displaced by the HP as the base load generator, thus noticeably limiting its operating time.

4.2. Plant dimensioning

In the second section of the results, the findings on plant dimensioning according to chapter 3.4. are presented. First, two reference simulations with and without CHP are performed, each with three different boundary conditions. As operating strategies, CCC 15 and HCC 1, which represent the optimum from chapter 4.1, are selected as fixed and non-existing components are omitted. A downhill simplex algorithm is utilized to optimize the storage configuration. The sum of annuity and climate impact costs with PTPR = 0 % is adopted as the objective function of this computationally intensive procedure. Similar to the reference simulations, the boundary conditions for DEU, FRA and EU27 are applied.

The identified optimal storage configuration in dependence of the location, the respective storage volume as well as the determined pipe lengths are listed in Table 1. In the S(I) scenario, the compound system consists of a GB and a CC in addition to the ICES. Using the DEU and EU27 boundary conditions, highly similar storage configurations are determined. In both cases, a significantly longer pipe length is also determined for DC compared to CH. Contrary to the FRA case, an ~5 times larger storage volume is adopted. However, also in this instance, a significantly increased pipe length is identified for CH compared to CH. In conclusion, relatively similar ratios between pipe length and storage volume are selected in all three situations.

In addition to the components from S(I), a CHP is applied in C(I). By means of DEU boundary conditions, a storage volume of 20 m³ is identified, which represents the lowest constraint of the optimization algorithm. Furthermore, a minimum pipe length is chosen, which makes the ICES contribution to the energy supply almost negligible. With the EU27 conditions, a larger storage is chosen than in S(I), whereby the length of CH is hardly shorter than that of DC. The subsequent FRA case identifies a smaller volume that is relatively comparable in scale to the S(I) cases of DEU and EU27.

In conclusion, the prevailing boundary conditions have a considerable influence on the resulting storage. While for S(I) the findings for DEU and EU27 are relatively similar, a significantly larger system is preferred for FRA. The higher investment costs are more rapidly compensated for by savings on the high $A_{V,gas}$ for GB, while the consumption of electricity by HP with low $A_{V,el}$ and $a_{CO2,el}$ is significantly less relevant. In combination with CHP, which represents an additional investment, a smaller ICES is generally identified. In the case of DEU, where CHP electricity generation is highly attractive due to high $A_{V,el}$ and $a_{CO2,el}$ and relatively low $A_{V,gas}$, the contribution by HP is minimized as it displaces the CHP and the additional investment is not viable. In FRA, the ICES advantage may not be as significant due to the CHP as the base load generator, so a significantly small system is identified.

Table 1. Pipe length and storage volume of all configurations for optimization with the boundary condition DEU, EU27 and FRA

Variant	Location	Storage volume, m³	Pipe length charge, m	Pipe length discharge, m
	DEU	142	562	1047
S(I)	EU27	149	589	1099
	FRA	732	2897	6126
	DEU	20	79	56
C(I)	EU27	213	843	974
	FRA	141	558	1060

A comparison of the annuity and the climate impact costs is presented in Figure 7 for all combinations. The reference case S(r) appears in all regions quite similar, as basically higher $A_{V,gas}$ are compensated by lower $A_{V,el}$ and the investment is equal. In addition, CO_2 emissions and thus the climate impact costs are primarily determined by $a_{CO2,gas}$, a factor that is independent of the location. In C(r), descending competitiveness from DEU over EU27 to FRA is clearly visible. For the annuity, this is largely determined by increasing $A_{V,gas}$ and simultaneously decreasing $A_{V,el}$, making the CHP less profitable. Parallel to this, the climate impact costs also increase due to lower $a_{CO2,el}$, making grid-related electricity savings less attractive. For S(I), the annuity is higher than for S(r), essentially determined by the additional investment of the ICES, which is not compensated by savings in demand-related costs. On the other hand, the CO_2 emissions and thus also the climate impact costs are significantly lower, resulting in benefits in a combined assessment. The most obvious outcome is for FRA, where the investment for the large storage increases the annuity, but minimal climate impact costs prevail at the same time. In C(I), the progression tends to be analogous to C(r) with the same reasons as in this case. For DEU, the annuity turns worse with no decrease in climate impact costs, as the additional investment hardly achieves any changes due to its low contribution. For EU27, the annuity increases while the climate impact costs decrease, yielding in sum similar results as in C(r). Finally, while with FRA constraints an altogether improvement of C(I) over C(r) can be considered, it is not preferable to the S cases, especially due to the highest annuity.

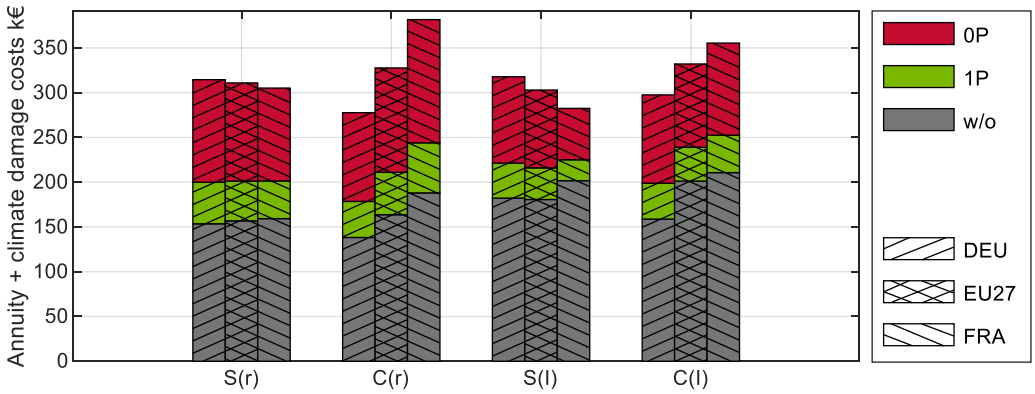

Figure. 7. Annuity plus climate damage costs for all considered regions and configurations.

4.4. Sensitivity analysis

In this last part of the results section, a sensitivity analysis is performed in order to consider the effects of varying boundary conditions. For this purpose, the gas and electricity prices as well as the CO_2 emissions of the electricity mix are varied by ±10 %. The parameter impact on costs or CO_2 emissions is determined according to Saltelli et al. [28] and illustrated in Figure 8. Negative values, as in the C cases, signify that an increase in the input parameter leads to a decrease in the output value.

For S(r), all regions are characterized by a similarly strong dependence on the gas price $A_{V,gas}$. In contrast, the influence of $A_{V,el}$ plays a subordinate role, which decreases slightly with the prevailing value. The influence of $a_{CO2,el}$ is similar, whereas it is almost negligible at FRA due to the low values of the CO_2 emissions of the electricity mix. In C(r), the dependence on $A_{V,gas}$ is reduced compared to S(r), whereas the dependence on the regional price is stronger. On the other hand, due to the self-production of electricity by the CHP, it is possible to benefit from rising electricity prices. As with $a_{CO2,el}$, there is a dependence on the location, which is determined by the respective absolute values. The negative values will increase the CO_2 emissions of the system when $a_{CO2,el}$ decreases due to the expansion of renewable energies in the electricity mix. For S(I), the ICES application results in a decrease in dependence on $A_{V,gas}$ compared to S(r), with an increase in dependence on $A_{V,el}$. However, at the same time, from an environmental point of view, it is also possible to

benefit from falling $a_{CO2,el}$, which are expected in the future. Finally, the distribution of the impact in C(I) looks similar to C(r). The reduced generation of electricity by the CHP and the increased consumption of electricity by the HP can reduce the impact of $A_{V,el}$ and $a_{CO2,el}$.

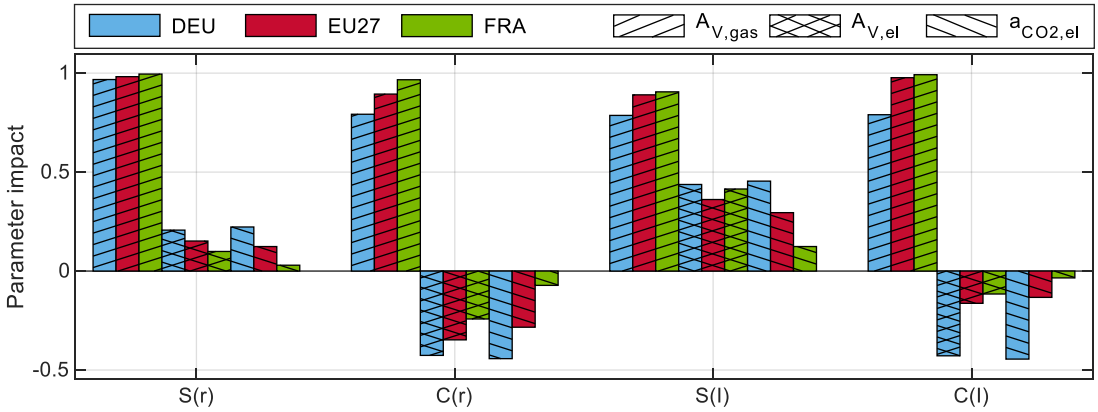

Figure. 8. Parameter impact of the gas and electricity price on the cost and CO_2 emission factor of the electricity mix on the CO_2 emission for all configurations and boundary conditions

5. Conclusion

A detailed numerical investigation of an ICES for the combined supply of heating and cooling energy to a research building is carried out. Therefore, the entire supply system including ice energy storage is implemented in MATLAB Simulink and validated with real long-term measurement data. By means of this, both approaches for the optimization of plant operation and dimensioning can be investigated. To evaluate them, an economic, an ecological as well as a combined analysis with the help of social costs is performed. The optimization of the operation, ranges from a simple constant operating strategy over a year or typical week, to seasonal control, to a sophisticated weekly varying strategy. Moreover, for the boundary conditions of DEU, EU27 and FRA, an optimal storage dimensioning with and without additional CHP is identified using a downhill simplex algorithm. This work is concluded by a sensitivity analysis of the constraints.

Depending on the approach, optimization results for plant operation range from 212 to 255 k€ for the annuity and from 148 to 195 t for CO_2 emissions. The best results can be achieved with a constant operating strategy over the whole year. Whereas computationally efficient weekly simulations are well suited for pre-estimation, neither a seasonal control nor a weekly adjusted strategy with perfect forecasting, both of which are complex to implement, can improve the performance. An ICES can reduce CO_2 emissions noticeably, wherefore an optimal storage is identified within the context of this work, depending on the plant location. Nevertheless, from an economic point of view, a higher annuity must be accepted for systems with ICES due to the additional investment. Combining these with social costs in the form of climate impact damages, an improvement compared to conventional systems can be achieved. Furthermore, the ICES can reduce dependence on natural gas and benefit from the future expansion of renewable energies in the electricity mix.
The approach can be applied in the future to other building types, such as hospitals or office buildings, which are characterized by high heating and cooling requirements. The determining parameters such as the absolute heating and cooling demand as well as the time shift between them should be identified.

Abstract:
Closed Brayton Cycles (CBC) can be integrated with many different energy sources, such as heliothermic, biomass, geothermal, etc. However, simplified models for the cycle components are required to optimize the system in its entirety due to all possible cycle configurations like the use of recuperation, intercooling, reheating, etc, together with operating variables such as rate of heat input and its temperature. This work discusses, therefore, the development of a surrogate model for a supercritical CO_2 CBC with recuperation, intercooling and reheating. It can indicate the optimal CBC from an economic point of view under varying boundary conditions. The cycle is first optimized for different heat inputs through its operational parameters (mass flow, minimum cycle pressure and cycle pressure ratios) and heat exchangers area. Compressor and expanders costs are obtained as a function of power while heat exchangers cost is obtained as a function of their area and pressure. Each solution is used to train a surrogate model that will act as an approximator for the optimized CBC and predict cost based on heat input.

Keywords:
CBC; Economic analysis; Machine learning; Surrogate; Thermodynamic analysis.

1. Introduction

Population growth, technological and industrial development are linked to increasing demand for energy, especially in recent years. The continuous reliance on fossil fuels to meet this demand on a global scale is causing negative impacts on the environment, meaning a more robust and sustainable energy matrix is necessary. Because of this, many renewable energy sources are being searched and some of them have become economically feasible such as wind and photovoltaic thanks to continuous investment in recent years. The heliothermic energy, or Concentrating Solar Power (CSP), is one of the first solar technologies to demonstrate grid potential and that could effectively reduce carbon dioxide emissions [1, 2]. That being said, the Closed Brayton Cycle (CBC) has been gaining much attention for its efficiency and possible application as a CSP Power block [3–5].

A CBC is typically more efficient and has a lower cost per power than more conventional cycles such as Rankine and Organic Rankine for heat sources in a temperature range of 600 to 1000°C [6–8]. The CBC also favours the construction of plants in arid locations with higher levels of insolation, i.e., no water is needed, thus being ideal for power generation with CSP.

Variations of the closed Brayton cycle using CO_2 as working fluid at supercritical condition (S-CO_2) are usually studied for heliothermic sources. They are dominant in the few works available in the literature on the use of CBCs to harness solar thermal energy below 600C [8–12]. This is because the closed Brayton cycle with minimum temperature and pressure values near the critical point of the working fluid experience a large reduction in compression work, increasing the thermal efficiency of the cycle [13]. The use of CO_2 as a working fluid stems from the proximity of its critical temperature ($T_c = 31.1$°C) to the ambient temperature [9–11].

The compatibility of CBC with heat sources below 600°C is uncertain. Garg et al [14] investigate a supercritical Brayton cycle using CO_2 with an efficiency potentially greater than 30% even for 820 K (~547°C)

sources. Milani et al. [11] evaluated several configurations of a Brayton Cycle using supercritical CO_2 as the working fluid for a hybridized CSP power source. The optimal configuration has a turbine inlet temperature (TIT) of 600°C and can reach a thermal efficiency of 52.7%. Utamura and Tamaura [9] studied the application of a CBC with S-CO_2, recuperation and pre-and inter-cooling in solar thermal sources with a TIT of up to 577°C. The authors found that the cycle can reach thermal efficiencies of up to 47%.

A widely explored option to optimize the performance of the closed Brayton cycle is the use of multistage (intercooling and/or reheating) compression and expansion plus recuperation. This is a common way to increase efficiency and reduce irreversibilities, which can improve the applicability of the cycle at heat source temperatures below 600C [15, 16]. In this case, a small pressure ratio enables high thermal efficiency and increases the recuperation potential, decreasing the size of the recuperator that would be required for a single-stage cycle.

The use of multistage compression and expansion will require the evaluation of multiple configurations of the cycle to determine the optimal or most economically feasible one. The optimization uses input data from the available heat source, i.e., inlet temperature and mass flow rate of the heat source fluid, as well as the rate in which heat is supplied. However, evaluating all possible configurations for each instance of the decision variables, like heat exchanger area, turbine inlet temperature, pressure ratio, etc., in the optimization process is computationally expensive. Thus, this work proposes an alternate method of optimization using Surrogates to reduce the processing time of the optimal CBC configuration while maintaining convergence to a global minimum specific cost value. Surrogate models, also known as metamodels, response surfaces, approximation models, etc., map an input-output relationship from data associated with some phenomenon to reproduce it in an approximate and often faster way [17, 18].

Using metamodels for complex process optimization is common for several engineering disciplines. Urquhart et al. [19] investigate the performance of two methods based on the construction of response surfaces for the optimization of aerodynamic shapes. Huang et al. [20] propose and study the use of Kriging models to perform global optimizations of stochastic systems. Carranza-Abaid et al. [21] created thermodynamically consistent Machine Learning-based Surrogate models to represent phase equilibria with multiple components.

In this work, a surrogate is created to replace the overall CBC model, reducing computational time, and allowing its use in broader optimization codes.

2. System Description

2.1. CBC Layout

Figure 1 displays a schematic of the proposed S-CO_2 CBC, while Fig. 2. shows its T-s diagram. The thermal and working fluids used are DOWTHERM A (in red) and CO_2 (in black), respectively. The optimal configuration and operating condition of the CBC varies depending on: (i) thermal fluid inlet temperature (T_Q^{in}); (ii) thermal fluid mass flow rate ($\dot{m}_Q$); and (iii) total heat transfer rate ($\dot{Q}_H = \dot{Q}_{H,0} + \dot{Q}_{H,1}$).

The working fluid at supercritical pressures goes through the compression process with intercooling (1-4) and then to the recuperator (4-5) as a cold stream. In the recuperator its temperature is increased by residual heat from the working fluid after expansion process. The CO_2 is heated up to turbine inlet temperature - TIT (5-6) before entering the re-heated expansion system (6-9) and the recuperator as hot stream (9-10). The working fluid is then cooled in (10-1) and returns to the cycle starting point (1).

The thermal fluid enters the reheaters and the main heat exchanger with the same temperature (T_Q^{in}). Different mass flow rates and output temperatures are allowed, which serve as decision variables chosen during optimization. The lower and upper boundaries of each global input are shown on Table 1.

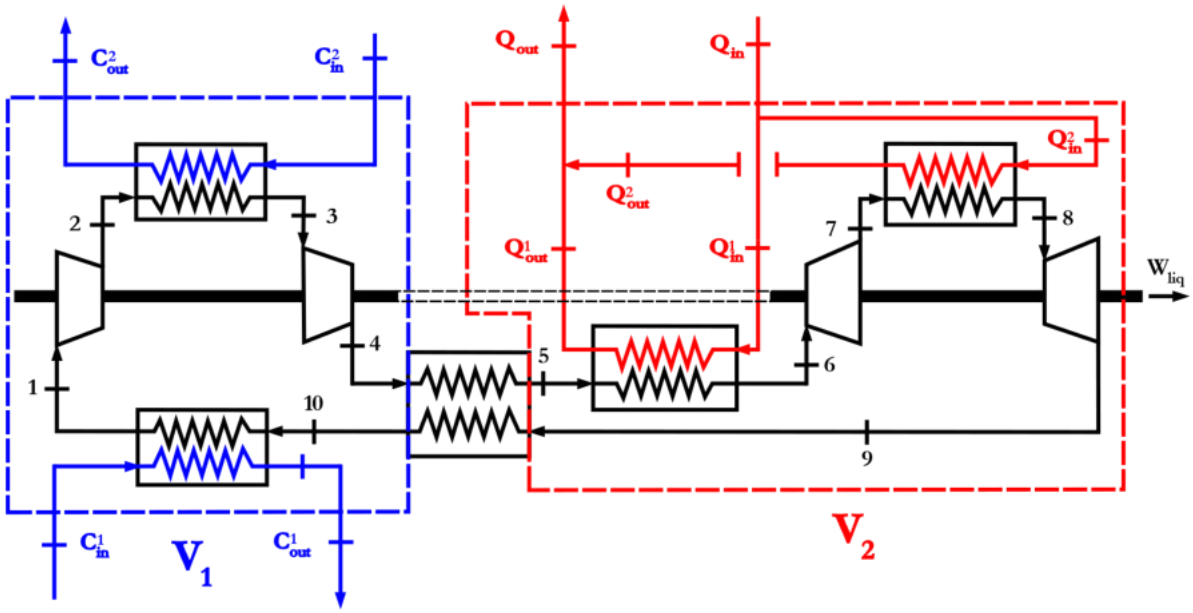

Figure 1. CBC diagram with supercritical CO_2.

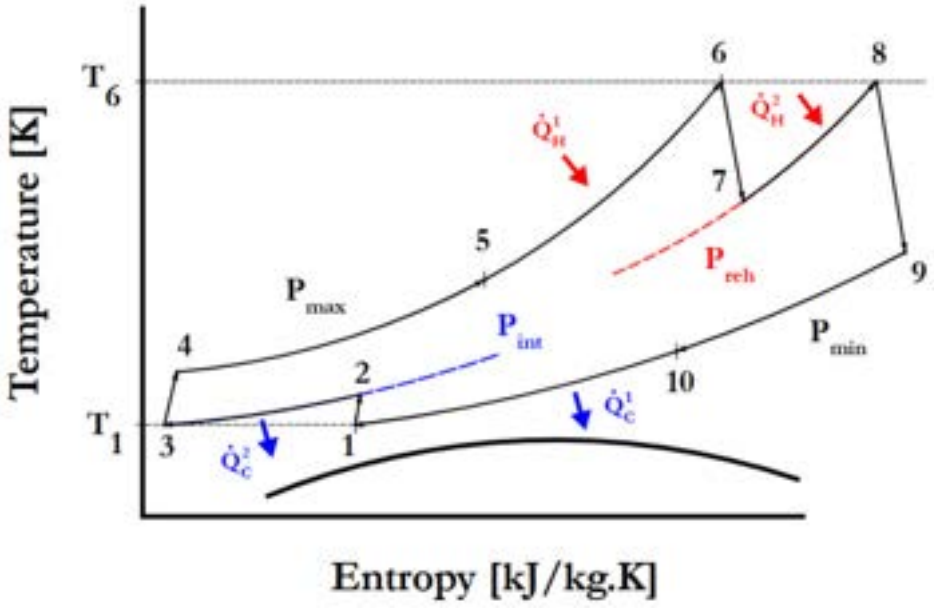

Figure 2. T-s diagram of CBC with supercritical CO_2.

Table 1. Operating range of the CBC input parameters.

	Lower boundary	Upper boundary
T_Q^{in}	200°C	390°C
$\dot{m}_Q$	100 kg/s	200 kg/s
$\dot{Q}_H$	100 kW	50000 kW

3. Thermodynamic Modelling

All components were modelled in a permanent regime, disregarding kinetic and potential energy effects and pressure drop in heat exchangers and piping. Table 2 presents the fixed parameters considered in the calculation of the thermodynamic states for CBC [22–24].

Table 2. Fixed parameters used to model CBC.

	Description	Value
$\eta_{ise,comp}$	Isentropic Compressor Efficiency	85%
$\eta_{ise,turb}$	Isentropic Turbine Efficiency	85%
η_e	Generator Efficiency	95%
T_C^{in}	Cooling Water inlet temperature	35°C
T_C^{out}	Cooling Water outlet temperature	42.55°C
$\overline{U}_{g/g}$	Overall heat transfer coefficient (gas/gas)	47.5 $W/(m^2 \cdot K)$
$\overline{U}_{g/w}$	Overall heat transfer coefficient (gas/water)	177.5 $W/(m^2 \cdot K)$
$\overline{U}_{g/o}$	Overall heat transfer coefficient (gas/oil)	274.5 $W/(m^2 \cdot K)$

The isentropic efficiencies of the compressor ($\eta_{ise,comp}$) and turbine ($\eta_{ise,turb}$) are calculated according to Eqs. (1) - (2), respectively. Their energy balances are represented by Eqs. (3) - (4). The energy balance of the recuperator is presented by Eq. (5) and assumes no heat losses to the environment.

$$\eta_{ise,comp} = \frac{h_{2s} - h_1}{h_2 - h_1} = \frac{h_{4s} - h_3}{h_4 - h_3} \quad (1)$$

$$\eta_{ise,turb} = \frac{h_6 - h_7}{h_6 - h_{7s}} = \frac{h_8 - h_9}{h_8 - h_{9s}} \quad (2)$$

$$\dot{W}_{turb,n} = \dot{m}_{CO2}(h_{in} - h_{out}) \quad (3)$$

$$\dot{W}_{comp,n} = \dot{m}_{CO2}(h_{out} - h_{in}) \quad (4)$$

$$\dot{m}_{CO2}(h_5 - h_4) = \dot{m}_{CO2}(h_9 - h_{10}) \quad (5)$$

Equations (6) - (7) show the energy balances of the cycle remaining heat exchangers.

$$\dot{m}_{CO2}(h_{out} - h_{in}) = \dot{m}_Q\left(h_{in}^Q - h_{out}^Q\right) \quad (6)$$

$$\dot{m}_{CO2}(h_{in} - h_{out}) = \dot{m}_{water}(h_{water}^{out} - h_{water}^{in}) \quad (7)$$

Liquid electric power ($\dot{W}_{liq}$) and cycle total efficiency (η_t) are given by Eqs. (8) – (10).

$$\dot{W}_{liq} = \sum_{i=1}^{n} \dot{W}_{turb,i} - \sum_{i=1}^{n} \dot{W}_{comp,i} \quad (8)$$

$$\dot{W}_{liq,e} = \eta_e \dot{W}_{liq} \quad (9)$$

$$\eta_e = \frac{\dot{W}_{liq,e}}{\dot{Q}_H} \quad (10)$$

Equations (11) – (13) are used to calculate the area for each heat exchanger present in the cycle.

$$\begin{cases} \Delta T_{in} = T_h^{in} - T_c^{out} \\ \Delta T_{out} = T_h^{out} - T_c^{in} \end{cases} \quad (11)$$

$$\Delta T_{ml} = (\Delta T_{out} - \Delta T_{in})/ln(\Delta T_{out}/\Delta T_{in}) \quad (12)$$

$$A_{hx} = \frac{\dot{Q}_H}{\overline{U} \cdot \Delta T_{ml}} \quad (13)$$

Most of the working fluid's thermodynamic properties were calculated through the use of CoolProp, a module dedicated to the calculation of thermodynamic states, and TesPy, a thermodynamic cycle simulation toolkit that was used to model the different components of the proposed CBC configuration [25, 26].

4. Economic Models

According to the literature, there are many different methods to estimate the acquisition cost of industrial equipment [27, 28]. The cost estimates in this work came from Eq. (14) of exponential cost of Bejan et al. [27]. Cost data from Peters et al. [28] for a centrifugal compressor, axial turbine and double-pipe and U-tube heat exchangers was used to adjust the equation.

$$C = C_{ref}\left(\frac{X}{X_{ref}}\right)^{\alpha}\left(\frac{CEPCI}{CEPCI_{ref}}\right) \quad (14)$$

Equation (14) indicates the equipment acquisition cost (C) using reference values for equipment size (X_{ref}) and cost (C_{ref}), the current size parameter (X) and an adjustable exponent (α). The ratio between $CEPCI$ (Chemical Engineering Plant Cost Index) and $CEPCI_{ref}$ serves as a correction factor for the cost of equipment in years other than the base year, which in this case is the year 2021 with $CEPCI_{ref} = 607.5$.
The total acquisition cost of CBC encompassing compression and expansion systems, is obtained by summing their respective individual equipment costs.
Table 3 displays the cost parameters of compressors and turbines used in the CBC. The heat exchangers acquisition cost varies according to the thermal load, operating pressure, and area. Tables 4 - 5 present the operational ranges in which each heat exchanger type has the lowest cost per area [27, 28].

Table 3. Cost estimation parameters for compression and expansion equipment.

Equipment	Size Parameter	Reference Size	Reference Cost [$]	α
Axial Turbine	Electric Power	10 kWe	16955.23	0.611
Centrifugue Compressor	Electric Power	100 kWe	105240.35	0.943

Table 4. General cost estimation parameters for heat exchangers.

Type	Exchanger Area [m²]	Size Parameter	Reference Size [m²]	α
Double-Pipe	0.25 – 20	Exchanger Area [m²]	0.25	0.063
U-Tube	20 – 1000	Exchanger Area [m²]	20	0.479

Table 5. Operating conditions and reference cost for heat exchangers.

Type	Pressure Range [MPa]	Reference Cost [$]
Double-Pipe	10 – 20	2321.89
	20 – 30	3605.73
	30 – 40	5494.36
U-Tube	10 - 20	9831.35
	20 – 30	10591.46
	30 - 40	11015.60

The cheapest heat exchangers were investigated and selected based on cost data from Peters et al. [28]. Figure 3 compares the specific cost curves of the cheapest exchangers with an operational pressure from 0.1 to 5 MPa. The plate exchangers (Welded and Gasketed Plate) have the lowest specific cost. However, their operating pressure limit goes up to 2.5 MPa, thus, in operating pressures above this value, Double-Pipe and U-Tube exchangers may be required.

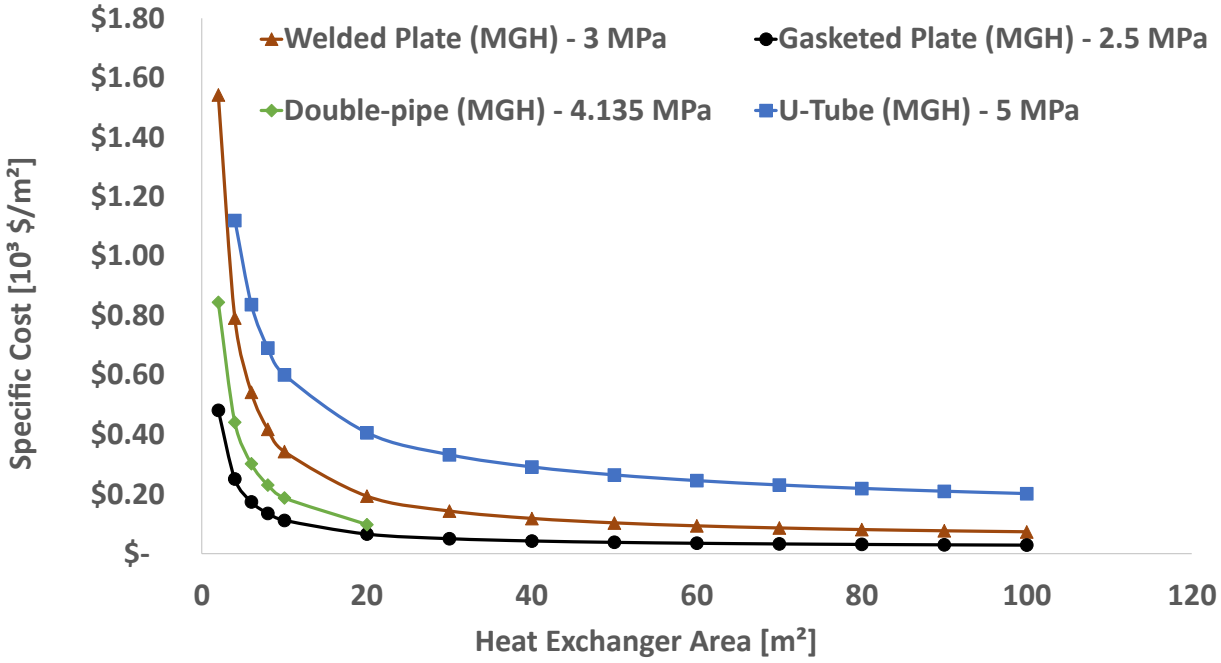

Figure 3. Specific cost curves comparison of different types of heat exchangers with operating pressure between 0.1 – 5 MPa.

5. CBC Optimization

The optimal cycle considered in this work is the one that has the greatest energy output for the lowest acquisition cost for its given heat input. Therefore, the CBCs objective function to be minimized is its specific cost, as per Eq. (15).

$$\min C_{e,CBC} = \frac{C_{total}}{\dot{W}_{liq,e}} \tag{15}$$

The optimizations were performed using Particle Swarm Optimization, implemented through the Pygmo library in Python, developing 50 individuals over a course of 30 generations [29, 30]. To facilitate data transfer between the power plant simulation in TESPy and the optimization a dedicated API was developed based on the work of Chen et al. [31] and made available in the most recent version of the software [32].

Many decision variables with general boundaries have been initially considered in the optimization process, such as working fluid mass flow rate, minimum cycle pressure, compression and expansion pressure ratios, thermal fluid split value between the heater and reheater, minimum temperature difference in the recuperator, main heater, and cooler, etc. To restrict their boundaries, 25 runs resulting in 25 champions have been performed and each of the decision variables was plotted against the obtained objective function values. The variables whose variation was of no consequence to the final result were set to a specific value. The final set of decision variables can be found in Table 6.

Table 6. Decision variables considered.

Decision Variable	Description	Value Interval
P_{min}	Minimum cycle pressure	10.1 – 13.0 MPa
ΔP	Total cycle pressure variation	2.0 – 8.0 MPa
$\dot{m}_{CO2}$	CO_2 mass flow rate	100.0 – 350.0 kg/s
ΔT_{min}^{reh}	Minimum Reheater temperature difference	3.0-20.0 ºC
f_q	Thermal fluid mass flow rate fractions	0 - 1
P_{int}^{comp}	Compression system intermediate pressures	P_{min} - P_{max} MPa
P_{int}^{exp}	Expansion system intermediate pressures	P_{min} - P_{max} MPa

6. Surrogate Model Development

This work used Scikit-Learn, one of the most used Machine Learning (ML) libraries in Python [33], to build the CBCs response surface. This approach used a supervised learning model with offline training. Unsupervised learning was implemented for dimensionality reduction of each model training set [34–36]. A regression model was trained on the champion population obtained as a result of the optimization process to predict the value of optimum specific cost for a given set of input variables.

Dimensionality reduction was performed using a Stratified Latin Hypercube (LHS) with *CenterMaximin* from the PyDOE2 library in Python which is a widely used technique in surrogate modelling [17, 37–39]. LHS is, by itself, used to generate smaller data sets with more information. *CenterMaximin* is a stratification criterion that allows LHS to further spread out those samples within their data regions [18, 37].

The surrogate was built using linear regression with a polynomial and a normalizing pre-processing step. These steps highlights trends and relationships in the data previously unknown to the ML model, augmenting their capacity [36, 40, 41]. The model was validated using *Cross-Validation* [17, 18, 36] which allows the exploration of the entire data set for both training and validation, through the use of an R^2 score.

7. Results and Discussion

7.1. Optimization Results

A total of 832 champions were obtained through the optimization process with an average of 8 champions/hour while using an Intel Core i7 processor computer with 16 GB of RAM memory and 8 logic cores. Although the champions are not always guaranteed to be global optima, they can still be used to verify the thermodynamic consistency of the developed objective function. As shown in Figure 4, the obtained values of specific cost tend to decrease with greater values of thermal input to the cycle, when considering a constant average heat source temperature of $200°C$. Figure 5 highlights that the optimum cycle efficiency tends to increase with a higher average heat source temperature, considering a constant Heat input of $20000\ kW$, as was to be expected.

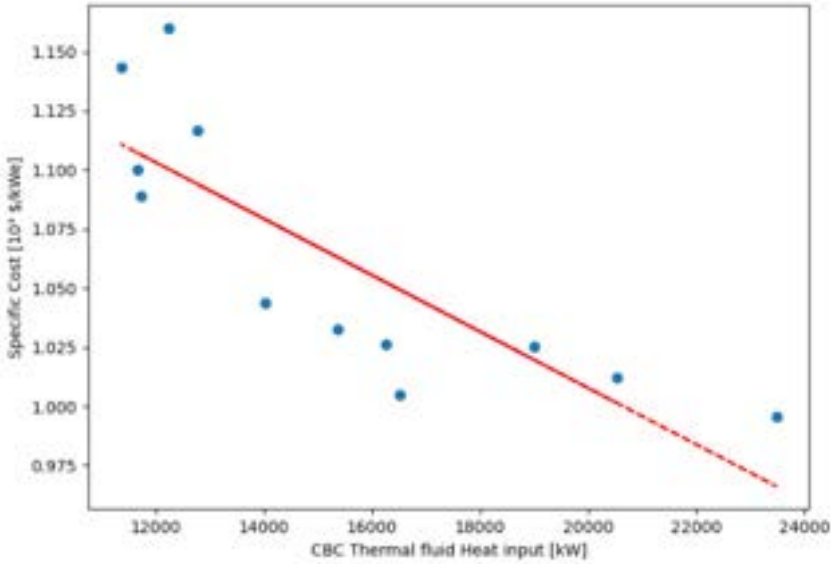

Figure 4. Specific cost versus CBC heat input, considering an average heat source temperature at 200°C.

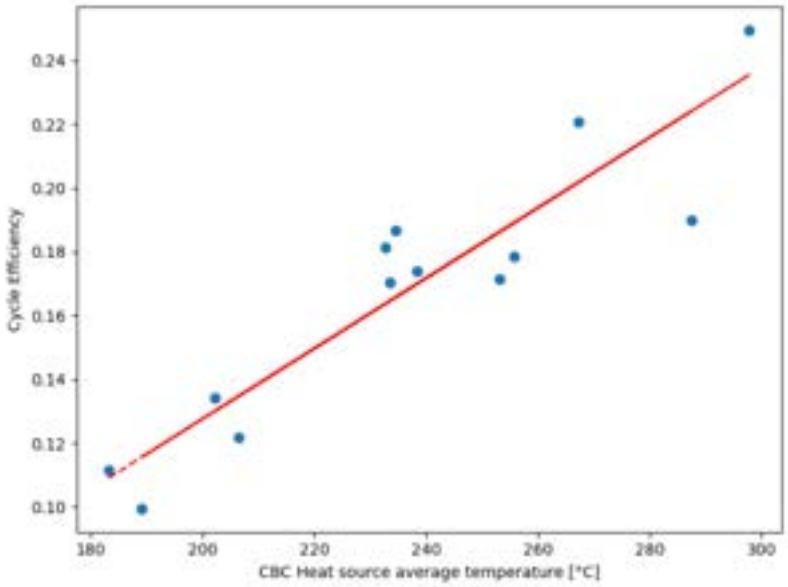

Figure 5. Optimum cycle efficiency versus heat source average temperature, considering a heat input of 20000 kW.

7.2. Surrogate Results

The most informative input format for training the Surrogate model was shown to be a combination of the original input variables (T_Q^{in}, $\dot{m}_Q$ and $\dot{Q}_H$) and implicit variables, calculated considering that the heat fluid possesses a constant pressure of $P_Q = 10.49\ MPa$, such as outlet thermal fluid temperature (T_Q^{out}) and the arithmetic average of the heat source temperature ($\overline{T}_Q$). Figure 6 is a correlation plot of each set of values for the mentioned variables and their respective optimal specific cost.

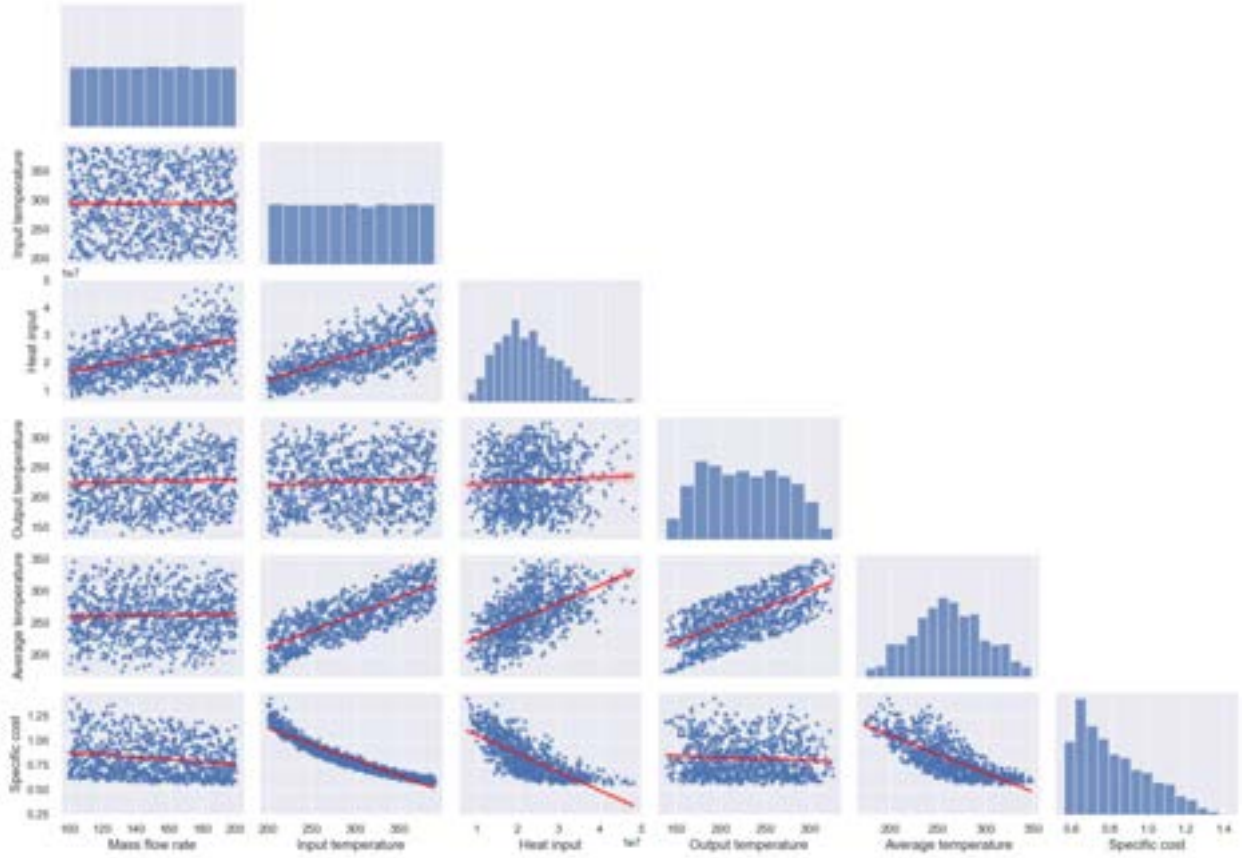

Figure 6. Correlation and distribution plot between Thermal fluid input variables (mass flow rate, input temperature, heat input, output temperature and average temperature) and optimum CBC specific cost.

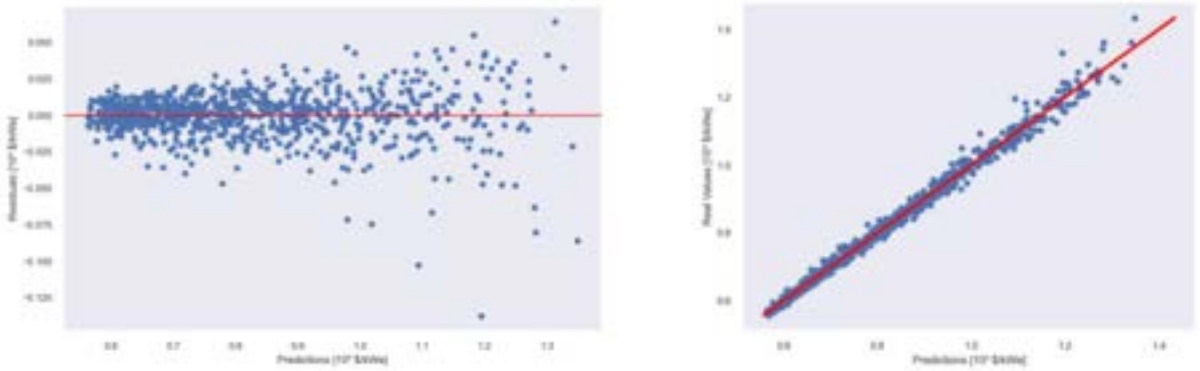
Using variables with a clear relationship to the objective tend to improve the final cross-validation score of the model [34, 36].

The regression Model in question is of the second degree and utilizes a normalizing pre-processing feature from Scikit-Learn to allow for a model with a higher R^2. All champions have been used to train the model, with its final cross-validation score being $R^2 = 0.9911 \pm 0.0022$. Figures 7(a) and (b) display the residuals and prediction versus real value plots for the trained model when predicting its training set, respectively. While the model has a precision score of 99.11%, there is still an amount of residual error that varies in its majority between $(-150, 50)\ \$/kW_e$. The model took approximately $0.004\ s$ to predict the specific cost of 832 different sets of input variables.



(a) *(b)*

Figure 7. Surrogate model (a) specific cost prediction residual plot, (b) specific cost prediction versus real values plot.

The created surrogate model is shown to be much faster to determine the optimum minimal specific cost of the CBC than the optimization method, at a very low precision cost, even though it only utilized 832 Champions to be created. The method presented in this work allowed for the creation of a deployable representation of the proposed Thermodynamic cycle that, while in this case was used to investigate the minimal specific cost, could also be used to evaluate other parameters of interest, such as number of intercoolers/reheaters, maximum cycle pressure, etc. as a function of a set of input variables.
It should be noted that an interesting application would be to use the model to perform a preliminary evaluation of the solution space for optimum CBC configuration and then perform a single optimization on the region most inclined to contain the minimum. This way the global solution space can be more thoroughly investigated at a very low computational burden. It should also be brought to attention that optimum CBC configurations can have a typical specific cost ranging from 600 to $1400\ \$/kW_e$ under the proposed ranges of input variables. Therefore, the closed Brayton cycle with Heat input from a low temperature source might be economically feasible given the right conditions.

8. Conclusion

The present work has shown that it is possible to create estimators that can allow for precise evaluations of a supercritical CBC using intercooling, reheating and a recuperator. First, the proposed cycle was optimized for multiple combinations of input variables, i.e. thermal fluid input temperature, mass flow rate and exchanged heat, so as to minimize the cycle's specific cost. After 832 champions were acquired, they were used to train a surrogate model that predicts optimum specific cost for the CBC based on a set of input variables. The difference in time between the optimization and the evaluation through the surrogate model on the specified machine is in the order of $10^8 s$. With a 99.11% cross-validation score, it can be considered as a viable estimator for the supercritical CBC.

Abstract:

Bolivia, despite being a relatively small country, has several small cities far away for the National Interconnected System. For this reason, these cities have Isolated Systems and almost 70% of their installed power are generated through thermoelectric plants, which ended up being a problem because of the high diesel fuel consumption. The diesel fuel supply in Bolivia is not guaranteed because the country depends on importation at very high prices. In this sense, this study intends to reduce the diesel consumption of the isolated power generation systems in Bolivia using an operational dispatch optimization model. First, there were chosen 3 Isolated systems in Bolivia, the Cobija Hybrid System, the Sena Hybrid System and the Gonzalo Moreno System. The latter is a purely thermal system, while the other two are hybrid systems (thermal and photovoltaic plants). Then, a comprehensive analysis of the power demand and supply has been completed for the three cases. Subsequently, an optimization model has been developed using the software Matlab and its complementary package knows as the Optimization Tool Box. Using this model, a comparison has been made between the operational dispatch of the energy system with and without optimization. The results indicate that it would be possible to save 2211 L/day, 182 L/day and 73 L/day of diesel consumption with an optimization process for the Cobija Hybrid System, the Sena Hybrid System and the Gonzalo Moreno Systems, respectively. These diesel fuel savings would represent more than 1.31 MM$ in money savings for the Bolivian Government.

Keywords: Optimization, hybrid energy system, diesel fuel consumption.

1. Introduction

In Bolivia, a country in South America, the largest population is concentrated in its main cities. The energy supply in the main cities is guaranteed because these cities are part of the National Interconnected System (NIS). The NIS connects 8 out of 9 departments in Bolivia, the only department that is not part of the NIS is Pando, which is located in the northern part of Bolivia in the middle of the Amazon forest.

Considering that there is a Department of Bolivia that is not connected to the NIS, the cities of this department have Isolated Systems (IS). Most of the isolated systems are thermoelectric plants that work with diesel fuel due to the difficulty of the natural gas transportation to these cities since most of them are in the middle of the Amazon Forest. The Isolated Systems in Bolivia are Cobija, El Sena, Gonzalo Moreno, Baures and Guayaramerin. Some of them are hybrid energy systems, which combines two or more types of energy generation.

According to [1], hybrid generation systems are a viable solution for electricity supplying especially when there are access difficulties to the location or when the city is too far away of the National Interconnected System. In the region, there are some examples of hybrid generation systems. For example, there is a photovoltaic-diesel hybrid system in Campinas, Amazonas – Brazil with a power capacity of 99.2 kW. In Rondonia - Brazil, the hybrid system of Araras presents an installed diesel power of 162 kW and 20.48 kW of power in the photovoltaic plant. On the other hand, there is also examples of hybrid generation system between wind generation and diesel thermoelectric generation like the energy system in Vila de Praia Grande, Brazil. In Bolivia, the hybrid systems are Cobija and El Sena, which are photovoltaic-diesel hybrid systems. Cobija has an installed capacity of 24.16 MW in diesel and 5.10 MW in photovoltaic, and El Sena has a total installed capacity of 4.62 MW [2].

As mentioned before, the hybrid systems in Bolivia use diesel as the source of energy. For this reason, the consumption of diesel in Bolivia in general has increased a lot the last decades. Figure 1 shows that the diesel consumption in the isolated systems System has been increasing rapidly the last ten years. In 2021, the isolated systems have expended approximately 57,800 m3 of diesel fuel.

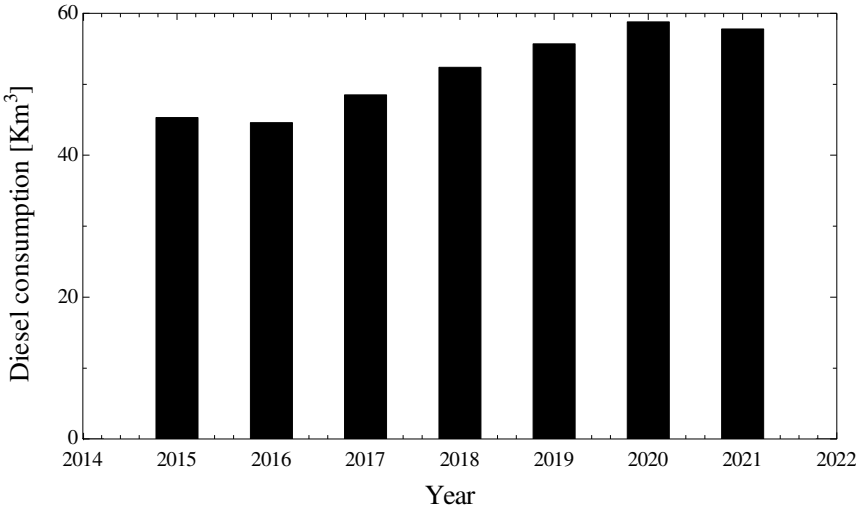

Figure. 1. Isolated systems diesel consumption in Bolivia per year.

Unfortunately, Bolivia does not produce diesel fuel. Hence, the country depends on the importation of this fuel and, therefore, on the international prices of the diesel. Figure 2 shows that the diesel in 2022 was approximately 10.1 Bs per liter (1.45 $ per liter). It's also worth to mention that the price of diesel is increasing since 2020 (8.6 Bs/liter), so it´s possible that the next years the price of the diesel is going to be even more than 10.1 Bs per liter.

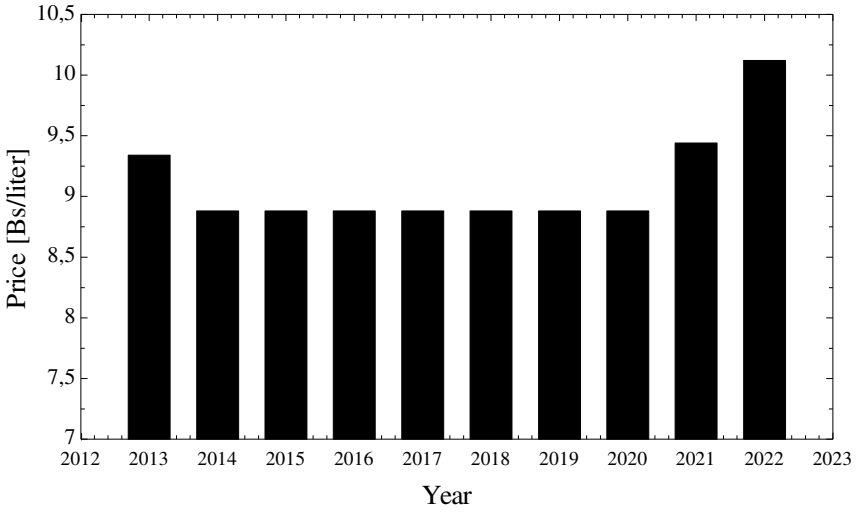

Figure. 2. Diesel price evolution [2], [3], [4].

On the other hand, the installed power of the Isolated Systems reached a value of 216.71 MW, of which 67.54% was thermally generated. So, Bolivia needs approximately 57800 m3/year of diesel fuel, which represents 84.5 MM$/year in order to keep the isolated systems working, and consequently, providing electric energy to a lot of small cities in the country.

Sempértegui-Tapia et al. [5] presented a case of study for the optimization of the Cobija Hybrid System. The authors recommended some changes in the operational dispatch of the energy system which allowed them to save 2622 L/day of diesel consumption. In this paper, we intend to further the mentioned study by including the analysis of 3 out of 5 isolated systems in the country. The Cobija Hybrid System will be analysed again, with updated data. Also, El Sena Hybrid System and the purely thermal Gonzalo Moreno System are going to be optimized. This way, the proposed optimization tool proposed by [5] is going to be validated and assessed using it for three different energy systems, which have very unique characteristics like number of generating units, installed power, load and demand factors, etc.

2. Mathematical model of the operational dispatch optimization

The mathematical model of the optimal operational dispatch consists on an objective function (OF), equality constraints (EC) and inequality constraints (IC), as shown in Eq. (1).

$$\text{Minimize} \rightarrow \mathbf{OF} \text{ subject to} \begin{cases} EC \\ IC \end{cases} \tag{1}$$

The modelling requires the objective function, which is formed by the energy consumption equations of the generating units; the equality constraints of the energy balance between demand and supply of the generating units and the inequality constraints that limit the power delivery of the generating units. Thus, taking into account that the energy consumption equations are second degree polynomial, the problem results in a non-linear program. Considering the characteristics of the "n" generating units in the IS (energy consumption equation and on-site effective power) and the isolated system type (hybrid or purely thermal), the mathematical model of the optimal operational dispatch is shown in Eq. (2).

$$\text{minf}(\mathrm{P}) = \sum_{\mathrm{i}=1}^{n} \mathrm{C_i} \text{ subject to} \begin{cases} \mathrm{d} - \sum_{\mathrm{i}=1}^{n} \mathrm{p_i} - \mathrm{p_s} = 0 \\ 0 \leq \mathrm{p_1} \leq \mathrm{p_{e1}} \\ \vdots \\ 0 \leq \mathrm{p}_n \leq \mathrm{p_{en}} \end{cases} \tag{2}$$

Equation (2) defines the operational dispatch problem. In order to solve this problem, the objective function has to be defined first and then the interior point algorithm will be used.

2.1. Objective function

The behaviour of a generating unit is described by the overall ratio of the heat input to the thermal unit in Btu/h vs the power output in MW. These behaviour is mathematically modelled by a second degree polynomial equation:

$$\mathrm{C_i} = \mathrm{a_i P_i^2} + \mathrm{b_i P_i} + \mathrm{c_i} \tag{3}$$

Therefore, the objective function will be composed by the sum of "n" energy consumption equations, one for each generating unit present in the isolated system.

2.2. Interior point algorithm

The interior point algorithm is normally used in nonlinear programming due to the speed of convergence and the ease of handling the inequality constraints. Besides, this method has advantages with quadratic-type constraints.

In this method, the approximation process starts from an initial point inside the plausible zone, moving internally until the global optimum point is found. In the case of the operational dispatch in thermal generation systems, 2nd order polynomial equations are presented to form the objective function and to determine the constraints. In other words, this method works with the Lagrange function modified by the inequality constraints present, the Karush Kuhn Tucker conditions and finally uses Newton Raphson to approximate the problem to an optimal solution.

Matlab and the Optimization Toolbox add-on provide a number of algorithms for solving a wide range of optimization problems. The optimal operational dispatch problem converges using the *fmincon* routine, that operates the interior point algorithm.

2.3. Multidimensional matrix

As mentioned before, the interior point algorithm is an iterative tool that starts from an initial point and travels through the interior of the solution space considering the constraints of the problem. In this way, the interior point algorithm must solve the following multidimensional matrix:

$$\begin{bmatrix} \mathrm{W_K} & \nabla \mathrm{R(P)} & -\mathrm{I} \\ \nabla \mathrm{R(P)^T} & 0 & 0 \\ \mathrm{Z} & 0 & \mathrm{P} \end{bmatrix} \begin{bmatrix} \mathrm{d_P} \\ \mathrm{d_\lambda} \\ \mathrm{d_z} \end{bmatrix} = - \begin{bmatrix} (\nabla \mathrm{f(P)} - \lambda \nabla \mathrm{R(P)} - \mathrm{z}) \\ \mathrm{R(P)} \\ (\mathrm{zPe} - \mu \mathrm{e}) \end{bmatrix} \tag{5}$$

It should be noted that the system has the form Ax=b, with the difference that the components of the matrix A and b are also matrices that will change size according to the dimension of the problem and its restrictions. The iterations will stop when d_p^{n-1}-d_p^n approaches 0.

For more detailed information about the mathematical model for this optimization dispatch problem, Sempértegui-Tapia et al. [5] should be consulted.

3. Optimization dispatch solver

The operational dispatch solver (ODIS) has 11 graphic windows elaborated with the help of Guide Matlab. These windows also have programming code where all the instruction for the correct operation of the tool are written. This way, this operational dispatch solver is very friendly with the user even more considering the graphical interface.

One of the main features of the program are the ability to work with a hybrid system and also with a thermal system. Also, the program allows the user to stablish a maintenance plan for the generating units and also allows the user to modify the maximum power delivery for the process.

On the other hand, the program provides the user with a power table that describes the optimum economic dispatch profile. More importantly, the solution includes an hourly consumption graphic that could be displayed globally for the isolated system of more detailed, considering all the components of the system.

The input and output parameters for the optimization dispatch solver are discussed next.

3.1. Input parameters

The parameters needed in order to optimize an energy system are:

1. Energy consumption equation: The behavior of a generating unit is considered through the general ratio between the heat input and the power output.
2. Characteristic days of demand: the user can select the characteristic days of demand of the energy system.
3. Available solar power: It refers to the photovoltaic solar power installed, which interacts with the thermal power plant.
4. Maintenance program: This program provides the information about the periods of time where some generating units will not be available.
5. List of available units: Determines the list of available generating unit to be considered to perform the optimization.
6. Effective power: The status condition of each generating unit is determine don site.
7. Rotating reserve: Corresponds to the percentage of the demand that is predicted to absorb the variation of the distribution system. The user can select this value up to 15%.

3.2. Output parameters

The first output parameter is the optimized power of the generating units. The tool also calculates the diesel consumption in liters and the hourly operating cost of the thermoelectric plant. With these output parameters, the program presents different kinds of figures to the user in the graphical interface.

4. Optimization tools applied to real hybrid power generation systems

The optimization tools were applied to three different isolated systems in Bolivia. Two of them are hybrid system (thermal and solar) and one of them is purely thermal.

4.1. General description of the isolated systems

4.1.1. Cobija Hybrid System (CHS)

The CHS is located in the Northern part of Bolivia, more specifically in the department of Pando. Also, it is one of the oldest and largest isolated systems in the country. Furthermore, is under the management of the National Electricity Company (ENDE) since 1990. This company not only supplies electricity to the city of Cobija, but also, to the towns that are within its operational area. Currently the Cobija System is a Hybrid System; due to the combination of two generation technologies; a diesel thermoelectric plant and a photovoltaic solar plant. Figure 3 shows a complete scheme of the CHS illustrating both plants.

The thermoelectric plant has diesel generating units of the Caterpillar brand. Until 2018, this thermoelectric plant had a total of 14 diesel generating units, with an approximate growth in demand of one generating unit per year (approx. 1.4 MW). The electric company ENDE, in order to properly identify the generating units, labelled each generating unit beginning with the code of the pant “BAH” and a numerical value according to the order of commissioning. As observed in the figure, the thermoelectric plant has two voltage levels in generation: 6.6 kV and 0.315 kV. The units that generate in 0.315 kV require a transformer that raises the voltage to 6.6 kV, so that they can be coupled to the 6.6 KV rigid busbar in the electrical substation.

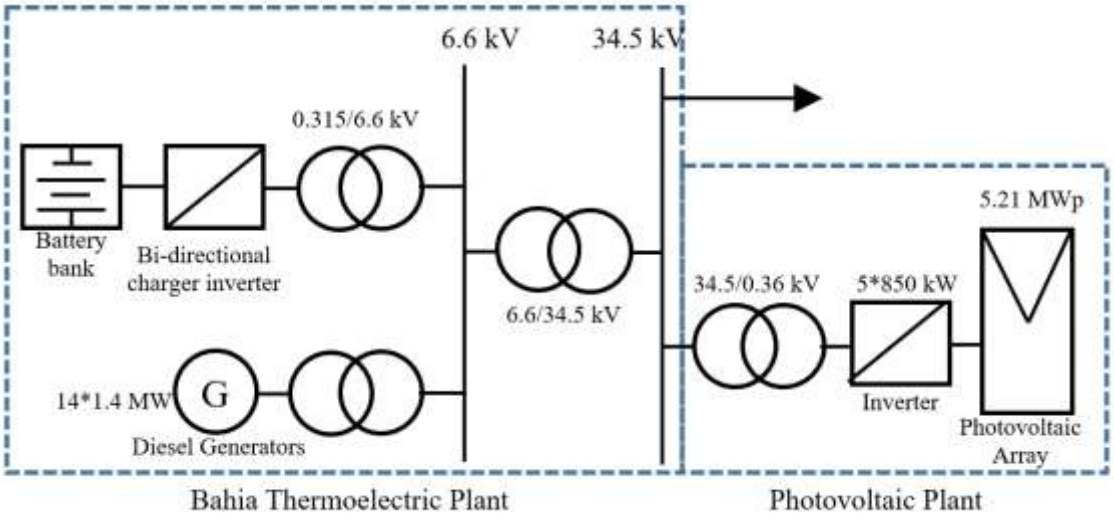

Figure. 3. Scheme of the Cobija Hybrid System.

The photovoltaic plant is comprised of 17,352 solar panels of 300 W. The total installed power is 5.21 MW. It is located about 7 km away from the city. Moreover, it is connected with the BAHÍA thermoelectric plant through a 34.5 KV sub-transmission line that reaches a 34.5 KV flexible bus from the substation (see Figure 3).

Also, a battery bank is located at the thermoelectric plant and uses energy generated by the CATERPILLAR generating units for its own consumption and also constantly supplies the grid. The SAFT brand battery bank is made up of 2 containers with Li-ion batteries.

Table 1 shows the operational limits and the 2nd degree equation of energy consumption for each generating unit of the CHS.

Table 1. Operational limits and 2nd degree equation of energy consumption for each generating unit, CHS.

Generating Unit	Operation limits	a	b	c
BAH01	P_{01}≤1400	-0.2528	10.05	-0.0092
BAH02	P_{02}≤1600	-0.1909	10.118	-0.0016

BAH16	P_{16}≤1600	-0.1022	9.9368	-0.0061

For more information on the Cobija Hybrid System see Sempértegui-Tapia et al. [5].

4.1.2. Sena Hybrid System (SHS)

The SHS is located in the Sena Municipality of the Madre de Dios Province in the Department of Pando, on the banks of the Manuripi River. This system has 9 generating units; two of them are Scania brand, 2 are CAT brand and 5 VOLVO brand. This system has also a photovoltaic plant of 436 kW of installed power. The configuration of this hybrid system can be observed in Figure 4.

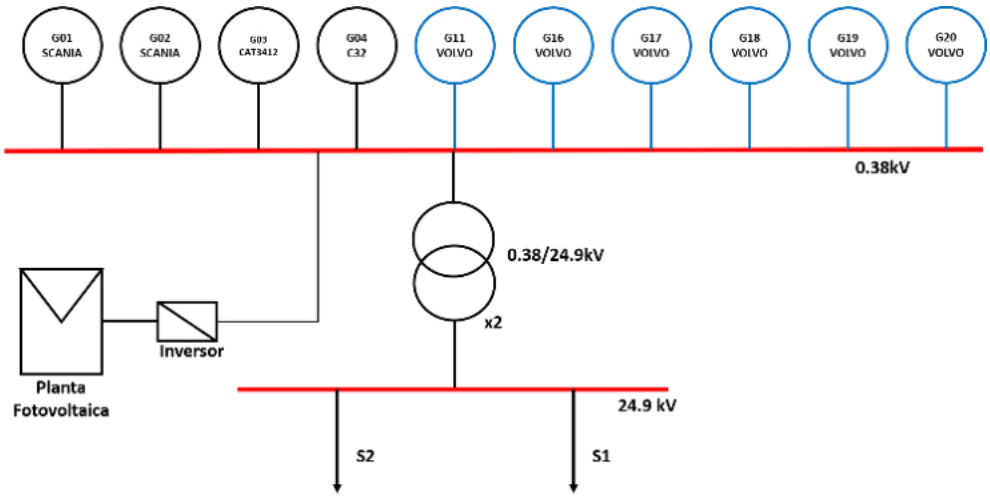

Figure. 4. Scheme of the Sena Hybrid System.

Table 2 shows the operational limits and the 2nd degree equation of energy consumption for each generating unit of the SHS.

Table 2. Operational limits and 2nd degree equation of energy consumption for each generating unit, SHS.

Generating Unit	Operation limits	a	b	c
G01(Scania)	$P_{G01} \leq 350$	-5.8857	11.934	-1.60E-03
G02(Scania)	$P_{G02} \leq 350$	-0.6945	11.577	0.0015

G20(VOLVO)	$P_{G20} \leq 200$	0.1113	11.623	-0.0015

4.1.3. Gonzalo Moreno System (GMS)

The GMS is located in the Municipality of Puerto Gonzalo Moreno in the province of Madre de Dios in the Department of Pando. It is responsible of three activities; generation, distribution and commercialization of electric energy. It has a powerhouse of 3 Volvo generating units (see Figure 4).

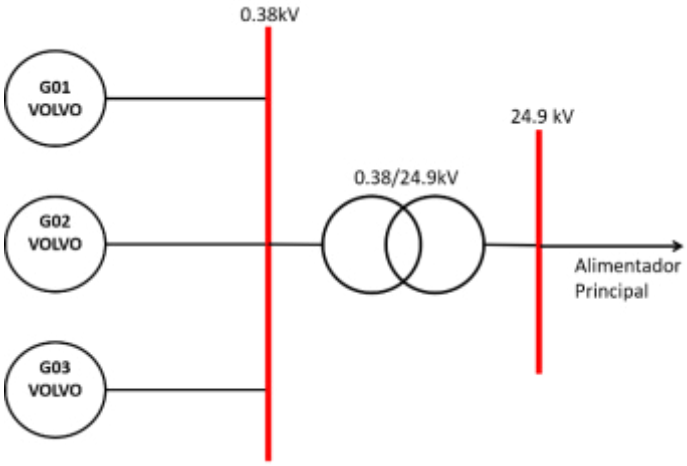

Figure. 5. Scheme of the GMS.

Table 3 shows the operational limits and the 2nd degree equation of energy consumption for each generating unit of the GMS.

Table 3. Operational limits and 2nd degree equation of energy consumption for each generating unit, GMS.

Generating Unit	Operation limits	a	b	c
G01(VOLVO)	$P_{G01} \leq 200$	-32.805	12.73	-4.00E-05
G02(VOLVO)	$P_{G02} \leq 200$	-0.357	10.722	0.0049
G03(VOLVO)	$P_{G03} \leq 200$	0	0	0
G04(VOLVO)	$P_{G04} \leq 200$	-1.8357	10.661	-4.00E-05
G09(VOLVO)	$P_{G05} \leq 200$	-3.5981	10.272	0.0002

4.2. Power demand analysis

Electricity demand is distributed by categories, the most important ones for their incidence are: industrial, commercial and residential. But also, there are other categories like public lighting, police, pumps, whose participation are not comparable to the aforementioned.

Typical demand curves have characteristics that differ from one another, a residential curve will rapidly increase its demand in the period from 18 to 21 hours; a commercial curve will slightly increase its demand in the same period; while an industrial curve will not have a noticeable demand between this period.

Figure 6 illustrates the demand of the three energy systems. Gonzalo Moreno is purely residential, Cobija has a demand associated with the commercial sector and Sena shows an intermediate behavior between residential with the commercial sector. Is worth to mention that neither of this cities show an industrial demand.

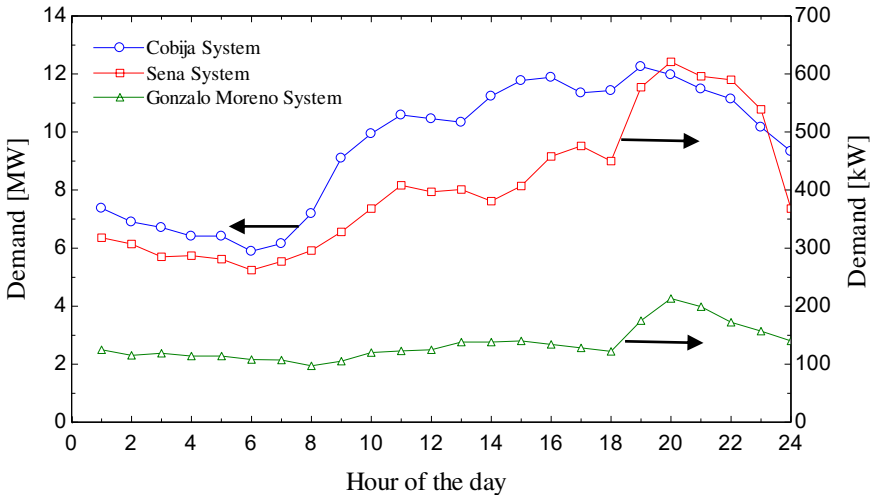

Figure. 6. One-day operational dispatch without optimizing.

To characterize the demand of the energy systems, representative curves were carefully calculated and plotted according to the procedure suggested by [6]. This analysis resulted in a total of 17 representative curves. Eight curves belong to business and non-business days, five curves related to the recorded temperature and four curves for operational events. All the generated curves are summarized in Figure 7 (see [5] for more detailed information).

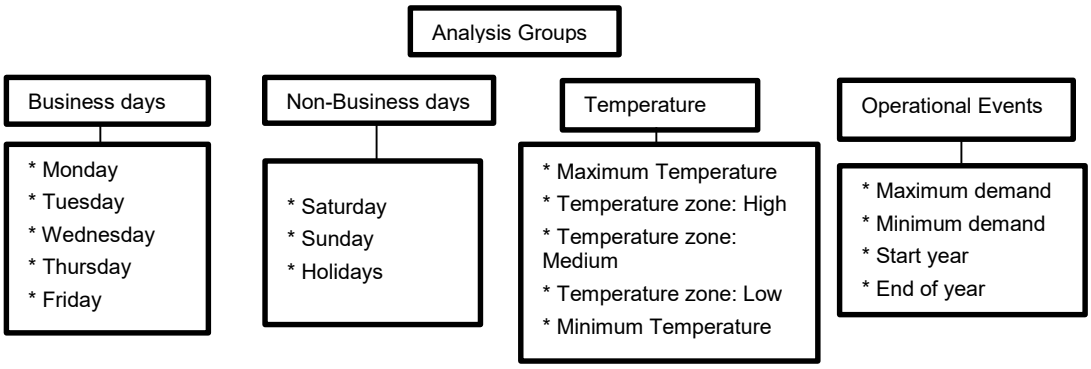

Figure. 7. One-day operational dispatch without optimizing.

4.3. Power supply analysis

Table 4 shows a summary of the important operating data for the three energy systems that are being analyzed.

Table 4. Operating data of the three energy systems.

Operating Data	CHS	SHS	GMS
Energy [MWh]	60160	2824	1019
Diesel consumption [m^3]	15981	878	287
Generating units	14	9	3
Installed thermal power [KW]	19800	2550	600
Photovoltaic panels	17352	1292	0
Installed solar power [KW]	5206	426	0
Maximum demand [KW]	12262	621	213

In order to analyze the power supply of the energy systems, three important variables were calculated for each of them. These performance indicators are the load factor, the demand factor and the specific consumption and can be observed in Figure 8.

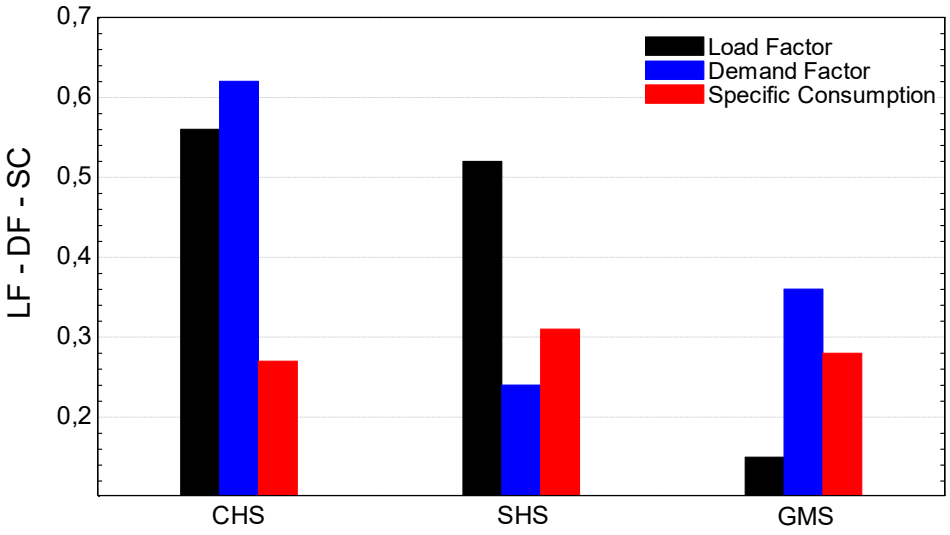

Figure. 8. Performance indicators for the three energy systems.

As it can be observed in the figure, the CHS has a very satisfactory relationship between demand and supply. On the other hand, the SHS has an installed power that exceeds the demand almost four times.

5. Results and discussions

To obtain the results, the three systems were run with the program. All the necessary data, including the demand analysis, operational availability, and others were the input parameters to obtain an optimized energy system. The rotating reserve used for the operation was 10%. Table 5 shows the general results of the optimization model for the three energy systems.

Table 5. Summary of the optimization results.

Indicators	CHS	SHS	GMS
S.C. (Actual) [L/KWh]	0.27	0.31	0.28
S.C. (Optimized) [L/KWh]	0.252	0.287	0.256
Savings [m^3/año]	807	66	27
Savings without subsidizing [KBs/year]	888	73	29
Savings with subsidizing [KBs/year]	8223	677	272

As observed in the table, the optimization results show savings in the fuel consumption for the 3 cases. It can be observed a reduction of the specific consumption for the optimized system compared to the real system. This indicates that the electricity demand could be meet by optimizing the energy resource. In economic terms,

it can be observed annual savings of 9172 KBs for the 3 energy systems. More detailed information about each one of the energy systems are discussed below.

5.1. Cobija Hybrid System (CHS)

Figure 9 shows an operational dispatch in a period of 24 hours for the CHS without the use of the optimization program. The shallow area represents the photovoltaic generation, and every other colour in the figure represent one generation unit added to the system. It can be noted that in order to meet the demand, eleven generating units must be working in addition to the photovoltaic plant. These 13 generating units consume 44260 liters of diesel fuel.

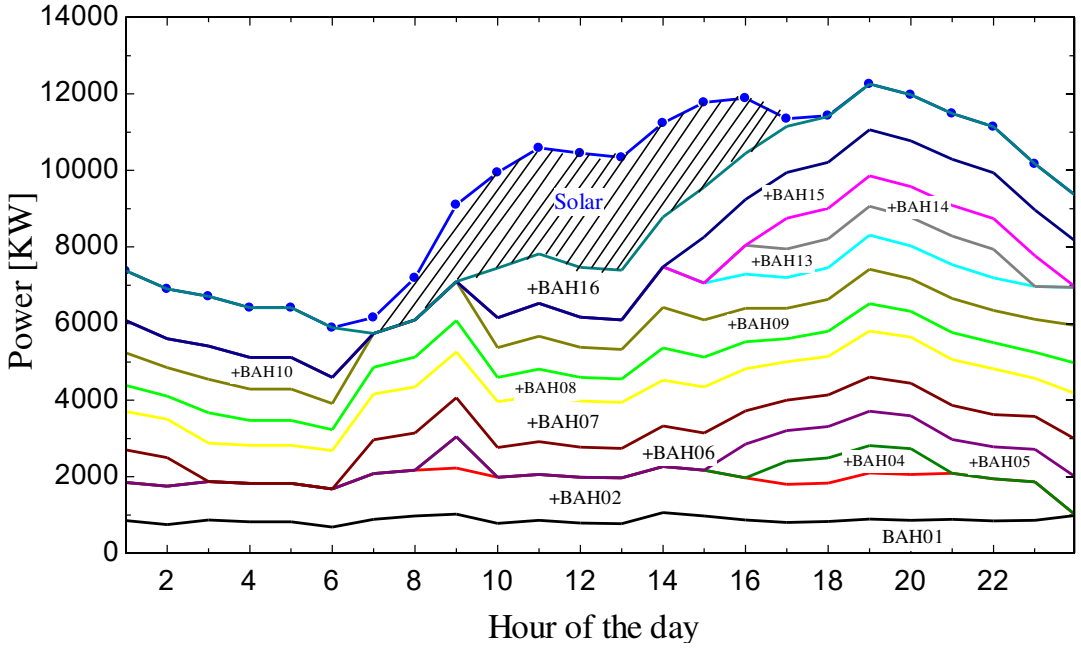

Figure. 9. One-day operational dispatch at the CHS without optimizing.

On the other hand, using the optimization algorithm, it´s possible to reduce the number of generating units dispatched on the same day to 10 (see Figure 10). Also, a better load factor of this equipment is achieved, which is demonstrated by the height of the areas shown by each generating unit. Furthermore, a better distribution of the service of generating units is achieved, minimizing the starts and taking full advantage of the contribution of the photovoltaic solar plant (shallow area). Finally, the CHS with the optimization model needs 42049 liter of diesel consumption, which means 2211 liters of diesel on savings.

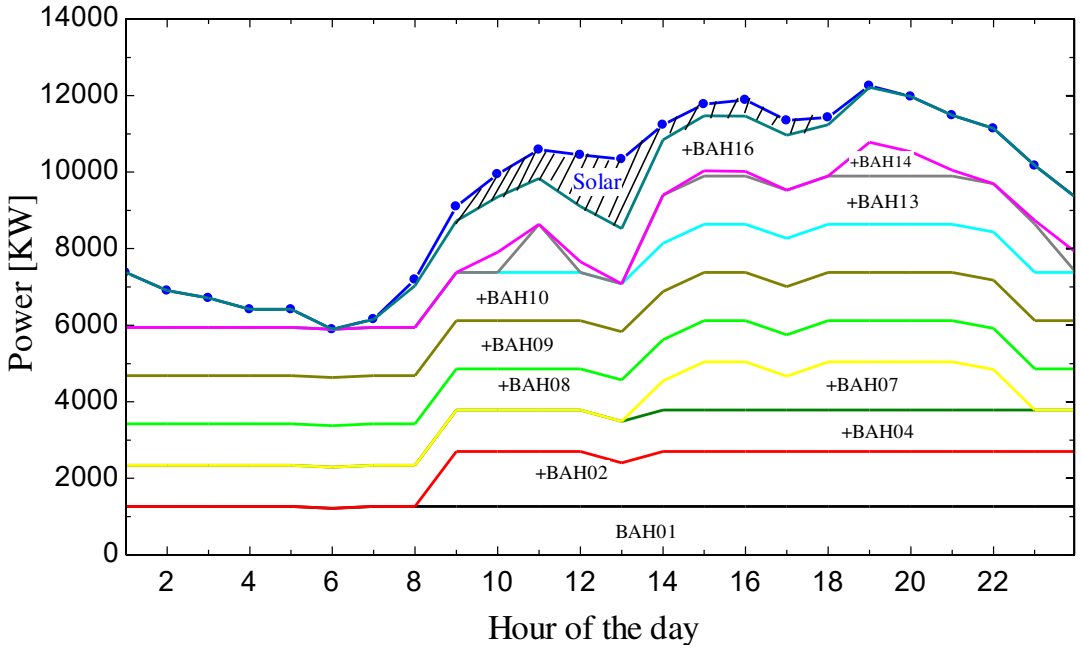

Figure. 10. One-day operational dispatch at the CHS with optimizing.

5.2. Sena Hybrid System

As observed in Figure 11, the Sena Hybrid System needed the operation of four generating units in addition to the solar energy contribution.

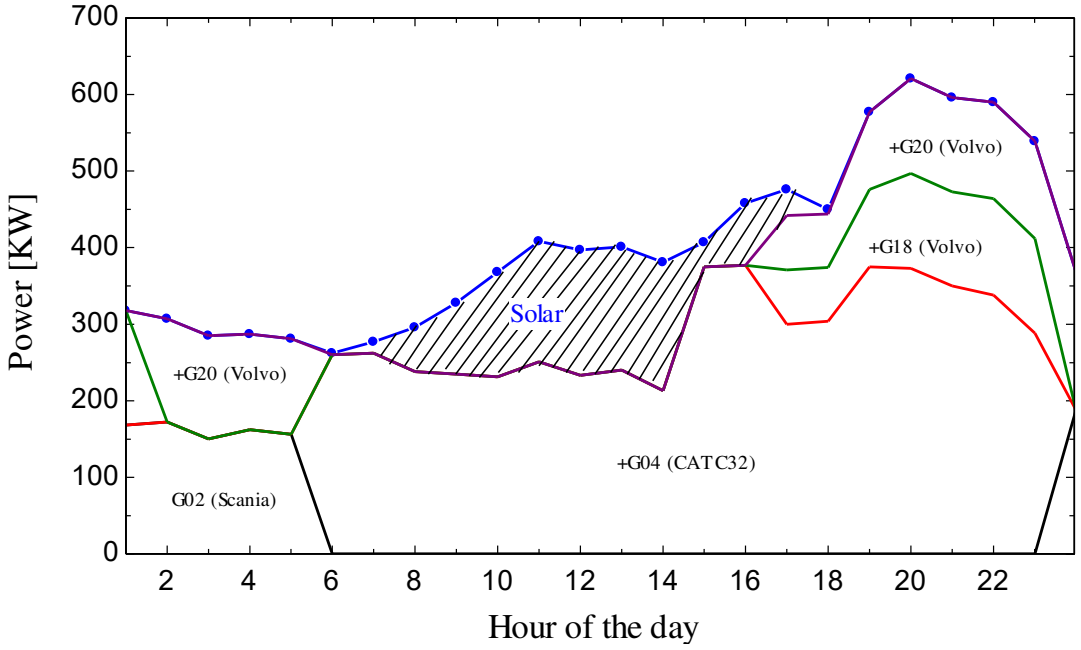

Figure. 11. One-day operational dispatch at the SHS without optimizing.

With the optimized model, the requirement reduces to 3 generating units, reducing at the same time the operative charge and use of personnel.

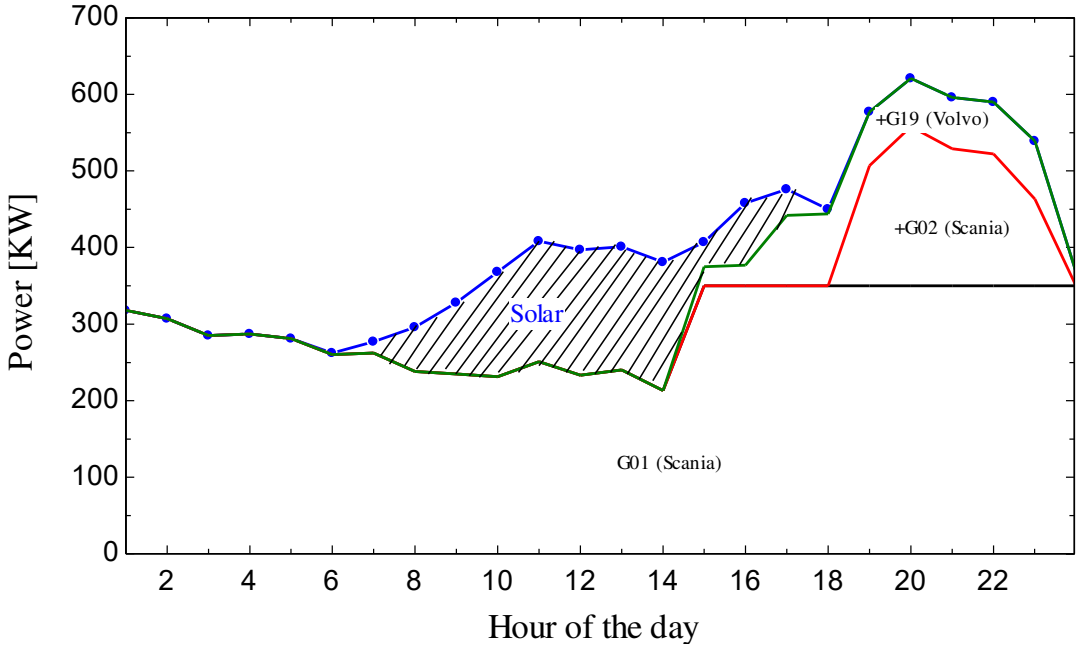

Figure. 12. One-day operational dispatch at the SHS with optimizing.

5.3. Gonzalo Moreno System

The Gonzalo Moreno System is a low-demand system, consequently, start-ups can create periods of time with no generation at all. As observed in Figure 13a, without the optimization the GMS required two units (G02 and G09) in one day, furthermore, the unit G02 was required on two occasions the same day. On the other hand, with the optimization model (see Figure 13b), the equipment should be connected 24 hours and produce a single start-up at least every three or four days, which is considered an appropriate period of time to make routine equipment inspections. Moreover, this slight change would allow us to save 73 L/day according to the optimization program.

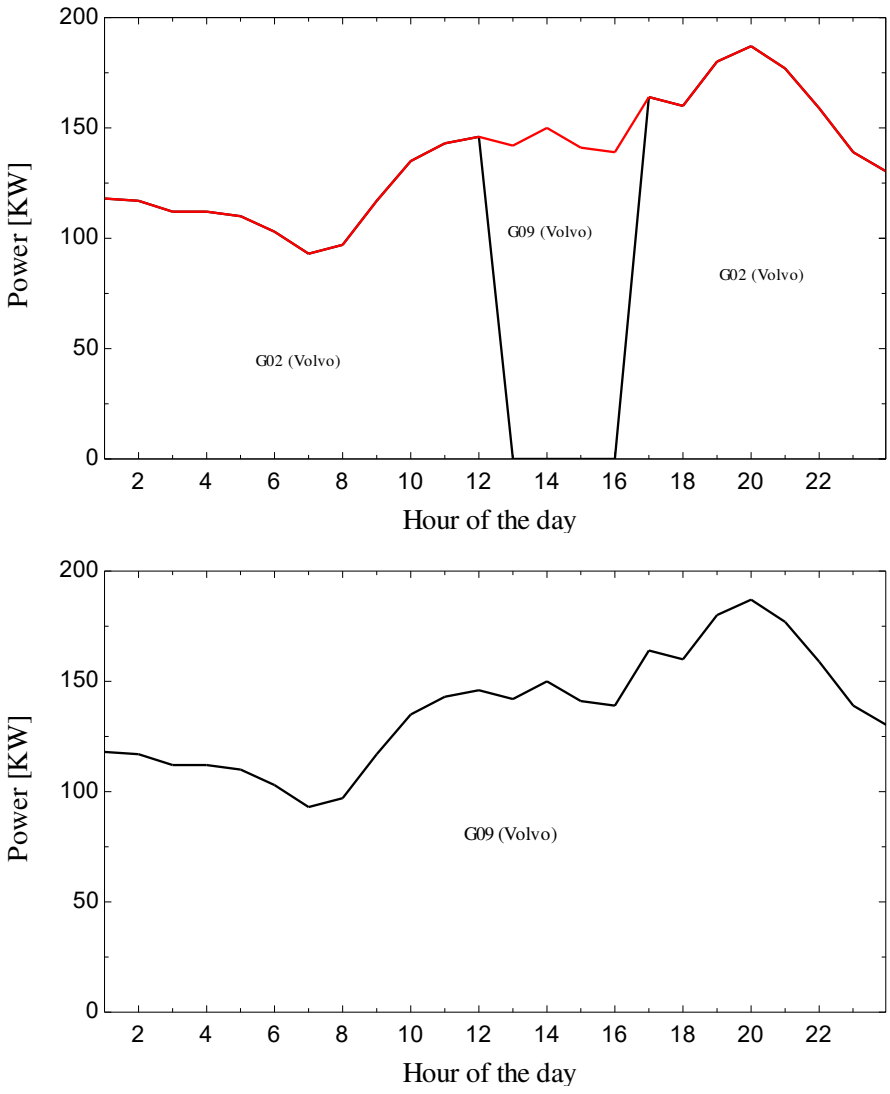

Figure. 13. *One-day operational dispatch at GMS, a) Without optimizing, b) With Optimizing*

7. Conclusions

The optimization tools for energy systems developed by Sempértegui-Tapia et al. [5] has been validated for three very different energy systems. The model works regarding the type (hybrid or purely thermal), the installed power (medium size cities or very small cities) or the demand characteristics (industrial, commercial or residential). The optimized energy systems provided an average daily savings in fuel consumption of 2211 L/day for the CHS, 182 L/day for the SHS and 73 L/day for the GMS. Which represent annual savings of 1.18 MM$ (CHS), 97 K$ (SHS) and 39 K$ (GMS). Thus, the savings obtained are between 5 and 9% of the annual cost of diesel fuel in Bolivia considering the international diesel fuel price (1.46 $/L).

Abstract:

Compared with hot air as drying medium, superheated steam has several advantages as drying agent, such as faster drying rates due to a higher overall heat transfer coefficient and lower viscosity allowing for better penetration of pores. It is already an established technology in drying processes in the food industry, as well as for biomass and pet food. In state-of-the-art paper production, the most energy intensive process step is drying with hot air. Using superheated steam for paper drying is an interesting alternative technology enabling more efficient heat recovery. This contribution presents different drying and heat recovery concepts, including air and steam drying as well as conventional energy supply by fossil fired boilers and heat pumps. It evaluates the potential reduction in final and primary energy consumption and CO_2 emissions based on process simulation in IPSEpro and compares the applicability of unused waste heat. Drying in steam atmosphere including steam compression for heat recovery was identified as the most beneficial concept. It allows for primary energy savings of 70% and CO_2 emission reductions of 88% compared to the benchmark concept with air drying.

Heat pumps; Heat recovery; Optimization; Paper drying; Process simulation.

1. Introduction

In the EU, the paper, pulp and printing industry consumed 1326 PJ or 13.7 % of the total final energy consumption in industry. Thus, it is the third largest final energy consumer after chemical and petrochemical industry (2121 PJ in 2020) and non-metallic minerals (1372 PJ). Most of the energy consumption is related to paper and paper products. To cover this demand, 30% of natural gas, 34% of renewables and biofuels and 21% of electricity are used. Minor shares are covered with other fossil fuels, such as oil or solid fuels. [1]

Typically, the type of produced goods in a paper mill has an impact on used energy carriers for energy supply. Factories producing both, pulp and paper, are often referred to as integrated factories. In comparison to factories producing only paper or board, in integrated factories a typical by-product is liquor from the chemical pulp production (cooking process) which is assessed as biogenous fuel. After pulp making, the used liquor is usually concentrated and burned afterwards in a liquor-boiler producing steam and in combination with a steam turbine also electricity. This leads to a high share of non-fossil energy supply for so called integrated factories.

However, other typical energy carriers for steam production in the pulp and paper sector, e.g., at sites using recycled fibres or (dry) pulp purchased from an external source, are natural gas, external waste streams, solid biomass, other biogenous residues or by-products from the production process such as internal waste streams, sludge or bark. Other possible, but less commonly used energy carriers are oil or coal. In order to provide energy in an efficient way, the following energy conversion technologies are often applied in those factories: steam turbines (often back pressure) in combination with gas turbines and / or different types of boilers, e.g. natural gas fired, but also using solids such as bark, sludge, coal or biomass as fuel. In general, the share of onsite electricity auto-production in the pulp and paper sector is rather high, usually realized with co-generation units. This is emphasized by an example from the Austrian pulp and paper sector. In 2021, 16000 GWh of energy were consumed, about 70% in the form of steam and 30% in the form of electricity. The on-site electricity production covered 65% of the electricity consumption. A total of 95% thereof was provided in co-generation units. [2]

The 2050 Roadmap of the Forest Fibre Industry [3], which covers pulp and paper as well as wood-based products in Europe, outlines how to reduce CO_2 emissions to reach an 80% reduction by 2050. A large impact is achieved by substituting fossil fuels, more electricity-based installations using renewable energy and efficiency increase due to the application of BAT – best available technologies. However, without breakthrough technologies only a reduction of 50-60% CO_2 emissions is achievable. The aim of the breakthrough technologies is to lower the heat demand in paper making, by reducing water use and improving drying processes. Paper drying accounts for 70% of fossil energy consumption and is therefore an important field of action.

In state-of-the-art paper mills, paper is first dewatered mechanically in the press section followed by the drying section. Most commonly, multicylinder dryers are used [4]. Cylinder dryers consist of a series of cylinders that are heated on the inside by condensation of steam. The paper is moved around the cylinders and water is evaporated. Thus, humid exhaust gas is formed that leaves the hood of the dryer. The principle is shown in Figure 1. A recent technology review of paper drying by Stenström [4] showed that the multicylinder design has not undergone significant changes in the last 20 years. The most important new developments are impingement dryers using hot air that is blown onto the paper and the development of new steel cylinders for through air drying (TAD), as shown in Figure 2. In the analysis of Stenström [4], energy use is considered as very important with special focus on the recovery of humid exhaust air from the hood. However, there was no progress on new drying technologies, such as the use of superheated steam that has been studied in the past by several researchers. There are no industrial units installed so far.

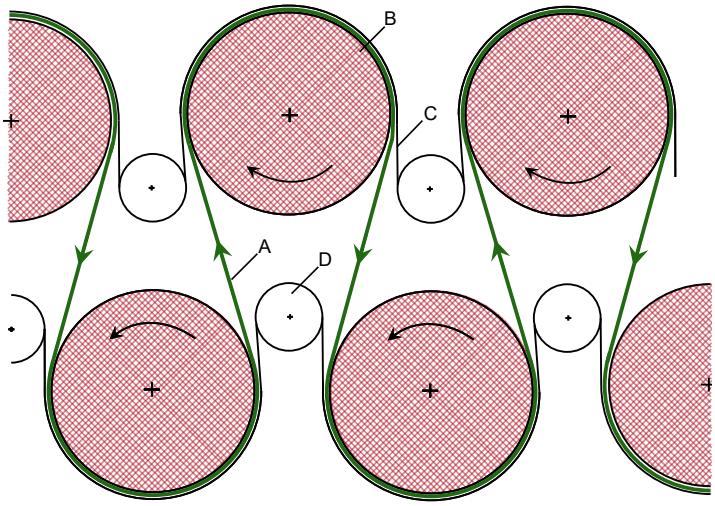

Figure 1. *Schematic visualization of steam heated cylinders in typical paper machines (A - paper, B - steam, C - felt, D - deflector roll)*

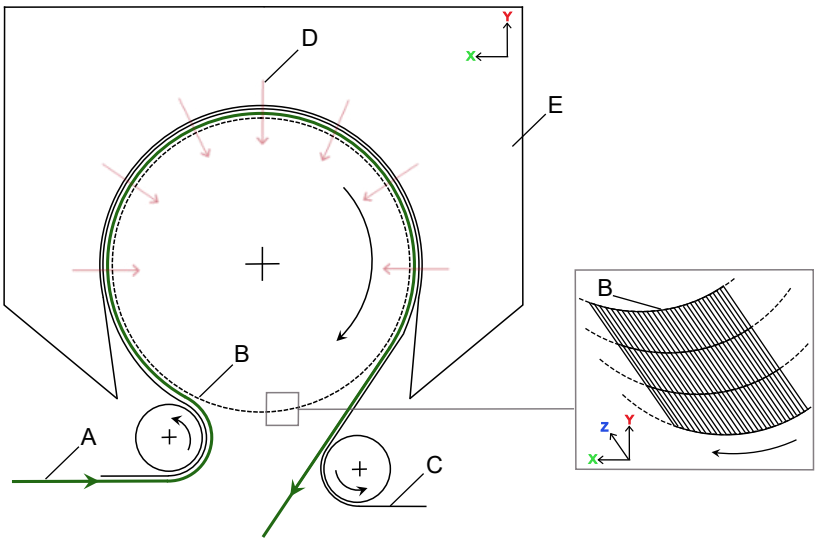

Figure 2. *Schematic visualization of Through-Air Drying (TAD) (A – TAD fabric, B – TAD cylinder, C – paper web, D – air flow, E – dryer hood)*

Superheated steam drying is already an established technology in the food industry, e.g. for distiller grains, beet pulp, rice, sea grass, dried fruit, potato products and tea, as well as for biomass and pet food. The main drivers to use superheated steam are an increase in product quality, less severe conditions for sensitive products and shorter duration of the drying process. [5-10] Recently an e-book [11] on superheated steam drying was published compiling the most important references in the field. The authors stated that activity was sporadic in the past, but it is now gaining momentum due to the potential energy savings.

In the field of paper production, superheated steam drying was studied experimentally by Kiiskinen et al. [12] in 2002 as steam drying offers many advantages, such as the potential to save energy and improve paper quality. It was a continuous steam dryer with a high velocity hood for steam impingement, that was operated with steam at 250°C. They studied paper quality, start up, the effect of non-condensable gases on heat transfer related to air intake and steam quality and impurities. It was found that steam drying offers advantages in terms of energy economy, if the exhaust steam can be used elsewhere in the process, e.g. in the drying cylinders, to heat the supply air in the dryer section, shower water, buildings, wire pits, paper web in the press section or in the calender, pulp, and to heat air or water in the power plant. The energy saving potential is 15-85% depending on the selected further use of the exhaust steam. Thus, heat recovery is based on cascaded use of steam provided in the conventional fossil fuel power plant.

This contribution presents different drying and heat recovery concepts, including air and steam drying as well as conventional energy supply by fossil fired boilers and heat pumps. It evaluates the potential reduction in energy consumption and CO_2 emissions based on process simulation in IPSEpro. The aim is identifying the most efficient process configuration as a contribution to the breakthrough technologies needed for efficient, decarbonized paper production.

2. Methodology

2.1. Process simulation in IPSEpro

The paper drying process, as well as the integration of heat recovery equipment, were investigated using the simulation software IPSEpro (Integrated Process Simulation Environment), which was developed for process simulations in the field of power plant and energy technology. It uses an equation-oriented solver for the calculation of mass and energy balances of steady state processes. [13]

The setup implemented as a flowsheet in IPSEpro corresponds to the actual process layout. The individual components of the process (unit operations such as the dryer, compressors, heat exchangers, etc.) are connected by streams that transfer mass and energy. The components are balanced according to conservation of mass and energy and the balances are strictly fulfilled for each component. The components can either be taken from the model library provided with the simulation software or they can be created by the user. Customized developed models for the dryer and the heat pump were used here.

Process data based on literature was used for the dryer model, which is explained in more detail in section 2.2. For the simulations, a simplified heat pump model was used. The model uses the temperature of the heat source and heat sink and the second law efficiency based on Carnot efficiency to calculate the power consumption, heat input and heat output of the heat pump. It is not necessary to specify the refrigerant or type of compressor in this model, so it can be used for potential assessment in a wide range of temperatures. The second law efficiency was chosen to be 0.45 based on the authors' experience.

2.2. Definition of benchmark process

A joint paper by the European Heat Pump Association (EHPA) and the Confederation of the European Paper Industries (Cepi) [14] published in 2023 is used to define the benchmark process of air drying for paper production as it summarizes the current status in the paper industry. According to [14], the dew point of the exhaust air is 60°C and typical steam pressures in the cylinders range from 1 to 9 bara. Typically, low pressures are used in the first cylinders and higher pressures in the last. Pressure levels are also influenced by paper grades and grammatures (max. 20%). It is found that 70% of steam use is below 6 bara and 50% below 5 bara in European paper mills, as it is illustrated in Figure 3.

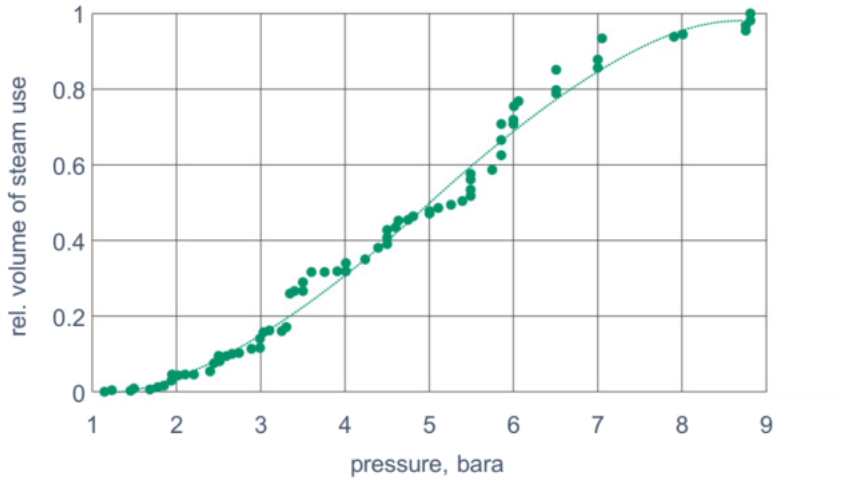

Figure 3. *Range of typical steam pressures in a paper machine, data from [14]*

In the benchmark process, 1 t/h of water is evaporated from the paper. When entering the drying section, the water in the paper has a temperature of 30°C. In the dryer, water is evaporated. For the sake of simplicity, only the enthalpy of evaporation for pure water is considered and enthalpy of sorption of water in the paper fibre structure is neglected. The enthalpy of evaporation amounts to 2257 kJ/kg for pure water at 1 bar. For example, enthalpy of sorption adds another 300 kJ/kg to reach 90% dry content and increases to 700 kJ/kg for 97-98% dry content [15]. In this evaluation, paper properties are kept constant for all concepts and are described by evaporation of 1 t/h. Thermal losses are neglected.

The steam cylinders in the dryer are supplied with saturated steam at 5 bara and 151.8°C. Steam is supplied from a combustion process operated with natural gas and a thermal efficiency of 90%.

Air is supplied from the production hall with a temperature of 30°C and is preheated with steam. The exhaust air from the dryer has a dew point of 60°C. It is assumed that it leaves the hood with 80°C followed by optional heat recovery using heat exchangers to preheat drying air. A total of 7454 kg/h of exhaust gas are formed when evaporating 1 t/h water from the paper. A pressure of 1 bar in the air system is assumed, pressure losses are neglected.

2.3. Environmental impact evaluation

Primary energy consumption:

Final energy is converted into primary energy using the primary energy factor f_{PE}. Primary energy also includes the production of the energy carrier itself, such as extraction, processing, storage, transport, conversion, transmission, and distribution to provide end energy. Primary energy consumption for electricity is predominantly influenced by the energy carriers and efficiencies used for electricity generation. For this comparison, factors based on current European averages are used. In 2019, the European Parliament defined the primary energy factor to be used for the calculation of the energy efficiency targets to 2.1 kWh/kWh for electricity [16], for natural gas, the factor amounts to 1.1 [17]

CO_2 emissions:

Like the primary energy consumption, CO_2 emissions are calculated based on the final energy demand and the emission factor f_{CO2} for CO_2-equivalent also considering other greenhouse gases such as methane or nitrous oxide. The emission factors f_{CO2} includes the production of the energy carrier itself, such as extraction, processing, storage, transport, conversion, transmission, and distribution to provide end energy. The CO_2 emissions from electricity are predominantly influenced by the energy carriers used for electricity generation. Currently, the use of electricity in the EU leads to 275 g_{CO2eq}/kWh [18], use of natural gas accounts for 268 g/kWh [19]. All factors are compiled in Table 1.

Table 1. Factors for the calculation of emissions, primary energy, and costs

	Unit	Electricity	Natural gas
CO_2 emissions factors (f_{co2})	g_{CO2eq}/kWh	275	268
Primary energy factors (f_{PE})	kWh/kWh	2.1	1.1

3. Results

3.1. Air drying

A1 is the benchmark process described above. Paper is dried in air atmosphere on drying cylinders that are supplied with steam at 5 bara (Figure 4). Steam is condensed in the cylinders at 151.8 and the condensate returns to the boiler in a closed cycle. The boiler is operated on natural gas and has a thermal efficiency of 90%. In this process, 876 kW of natural gas are required. Exhaust gas at 80°C leaves the hood of the dryer containing the latent energy of the water evaporated from the paper. A total of 754 kW can be recovered if the exhaust gas is cooled to 20°C ($\dot{Q}_{Rmax}$), thereof 47 kW above the dew point temperature of 60°C.

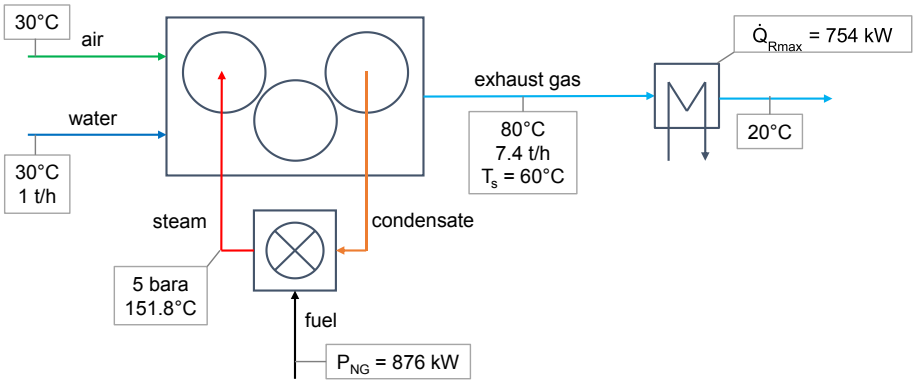

Figure 4. *Air drying with drying cylinders and steam from natural gas combustion (A1, benchmark)*

A2 accounts for heat recovery that is frequently implemented in paper mills (Figure 5). The exhaust gas is cooled to 55°C, a part of the heat is used to preheat the drying air to 65°C. Thereby, the natural gas demand is decreased to 805 kW. The remaining heat can be used for other sinks, such as preheating of water in other parts of the process.

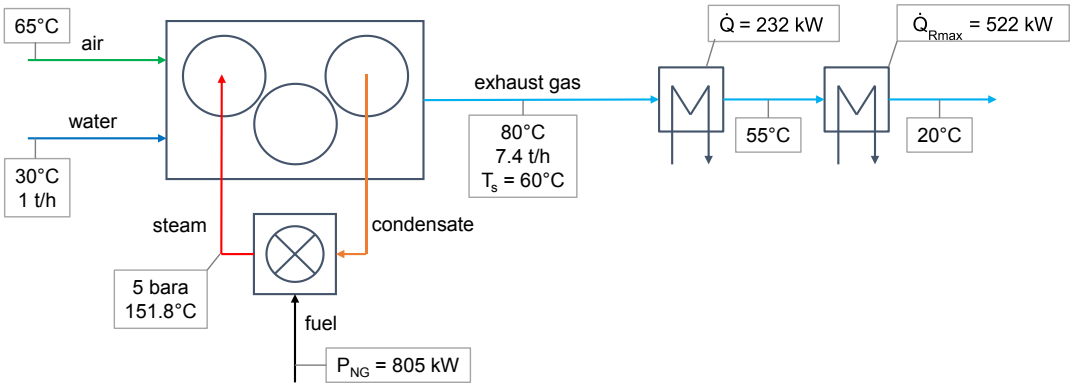

Figure 5. *Air drying with drying cylinders and steam from natural gas combustion and heat recovery (A2)*

In A3, heat from the exhaust gas is recovered with a heat pump (Figure 6). First, the exhaust gas is cooled to 38.7°C by an intermediate water cycle. The water cycle is the heat source of the heat pump, which is cooled by the evaporator of the heat pump. In the condenser, the heat pump produces saturated steam at a pressure of 1.05 bara (111°C) from the condensate of the cylinders. The steam is further compressed in steam compressors to 5 bara. In practise, a pressure difference of ca. 5 bar would require several compression stages with liquid injection to desuperheat the steam. About 5% of the steam are generated by injection for desuperheating. In the simulation, the setup is simplified to only one compressor with an isentropic efficiency of 70% without liquid injection.

In A3, the heat supply is fully electrified, the energy consumption amounts to 386 kW. The remaining heat recovery potential from the exhaust gas is 173 kW.

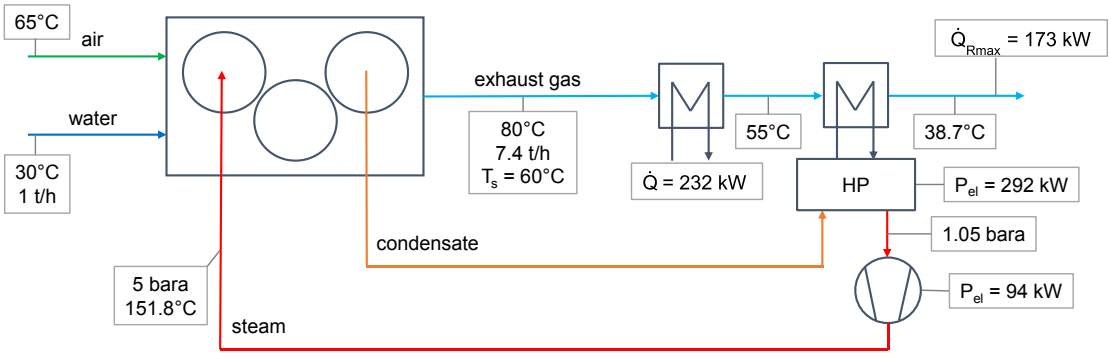

Figure 6. *Air drying with drying cylinders, heat recovery and heat pump (A3)*

In A4, there is no heat exchanger in the exhaust gas upstream of the heat pump (Figure 7). The exhaust gas is cooled by the intermediate water cycle that is the heat source of the heat pump. Thereby, the exhaust gas temperature after the heat pump is increased to 47.9°C. Due to the smaller temperature lift of the heat pump, it requires less energy. However, the drying air is preheated with steam in this concept, which increases the steam demand and the electricity consumption of the steam compressor. In total, 383 kW of electricity are needed. The remaining heat recovery potential from the exhaust gas is 333 kW.

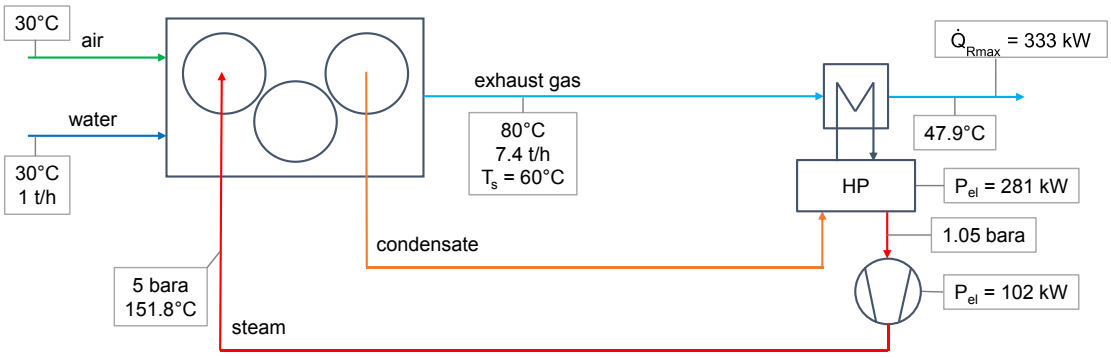

Figure 7. *Air drying with drying cylinders and heat pump (A4)*

3.2. Steam drying

In S1, the air atmosphere is changed to steam (Figure 8). Instead of drying air, superheated steam is supplied to the dryer with 151.8°C and a slight over-pressure of 1.05 bar to avoid air intake. To keep the inlet velocities constant, the drying steam volume flow is the same as the drying air flow in A1 (6261 m³/h). At the outlet of the dryer, the steam has a temperature of 111°C and has 10 K of superheat to avoid condensation on the paper. Water evaporated from the paper is present as excess steam which is discharged. The rest of the steam is reheated in the boiler and is recycled to the dryer.

Like A1, the cylinders are heated by another flow of saturated steam at 5 bara and 151.8°C. This stream is condensed in the cylinders and is reevaporated in the natural gas boiler. It is not in contact with the steam atmosphere.

In total, 794 kW of natural gas are needed. Heat recovery amounts to 726 kW if the excess steam is cooled to 20°C, whereas most of the heat occurs at the condensation temperature of 101°C.

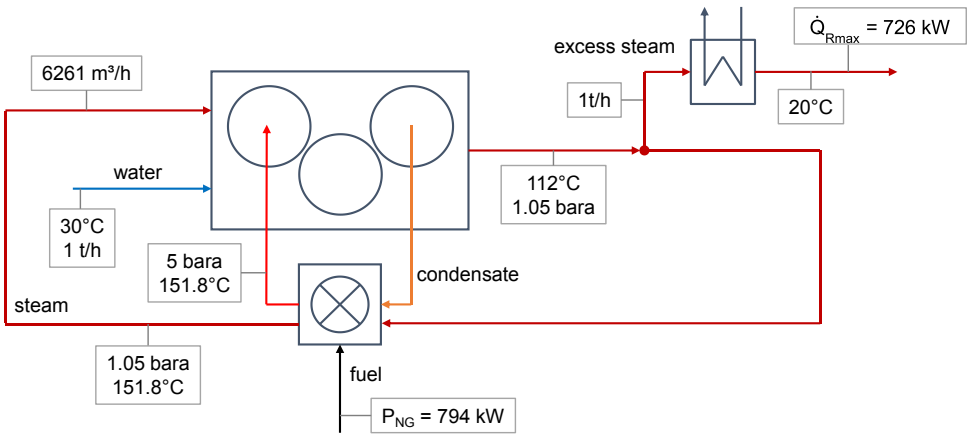

Figure 8. *Superheated steam drying with drying cylinders (S1)*

In S2, there are no cylinders, all energy for drying is supplied by steam like in impingement dryers or through-air-dryers (TAD). Thus, the heat distribution in the dryer is changed. However, there is no change in energy flows in this simple balance model (Figure 9). Natural gas demand amounts to 794 kW and the heat recovery potential to 726 kW as in S1.

The steam volume flow increases drastically by nine times to 59464 m³/h if steam is supplied at 151.8°C. If steam is supplied at 250°C, as it was in the lab test of Kiiskinen et al. [12], the volume flow is 21466 m³/h (3-fold increase compared to air drying). The increase in steam temperature lowers the volume flow of steam but has no relevant impact on the energy consumption of the natural gas boiler.

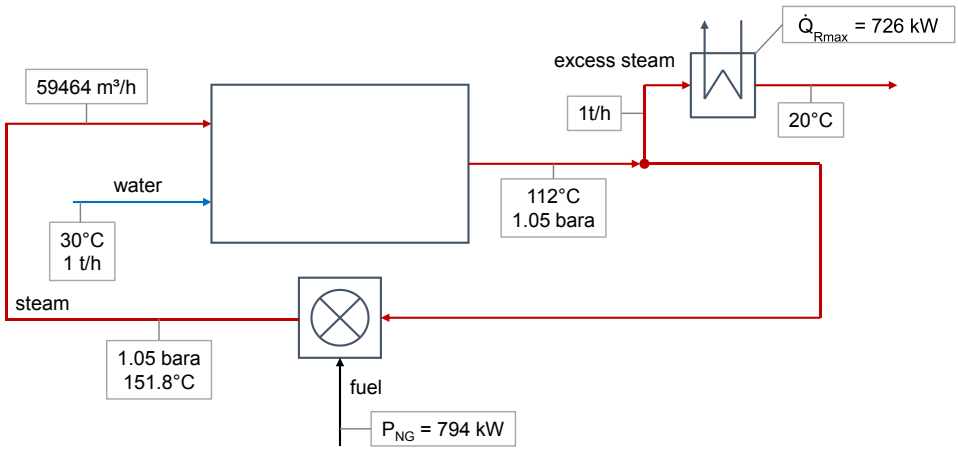

Figure 9. *Superheated steam drying without cylinders (S2)*

S3 is a full electric concept with superheated steam drying and cylinders (Figure 10). After the dryer, a slip stream of 1 t/h of steam is separated. It is the mass flow originating from the water in the paper. It is compressed in a steam compressor to 5.4 bar, thereby the condensation temperature of steam increases to 155°C. The slip stream is condensed and transfers the heat to the second steam cycle in the cylinders. Then, the slip stream condensate heats the steam for the steam atmosphere to 145°C. As in S1, the steam volume flow for the steam atmosphere amounts to 6261 m³/h. After heating the steam atmosphere, the slip stream condensate still has a temperature of 149°C.

The steam compressor requires 139 kW of electricity. The heat recovery potential from the slip stream condensate is 151 kW.

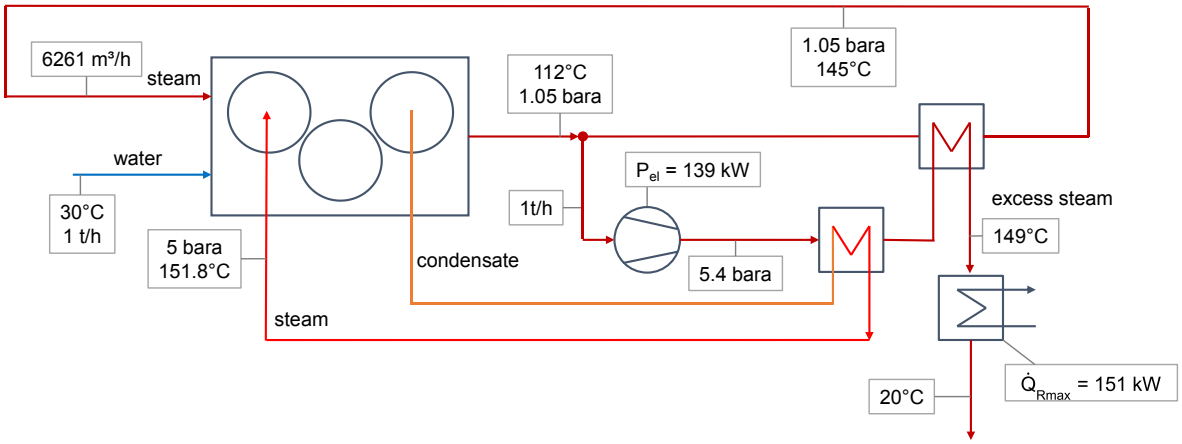

Figure 10. *Superheated steam drying with cylinders and steam compression (S3)*

S4 is another full electric concept based on a heat pump (Figure 11). The slip stream (1 t/h) is the heat source for the heat pump and it is partly condensed. The heat pump produces steam from the condensate returning from the cylinders at 1.5 bara. The outlet pressure on the sink side of the heat pump was set to 1.5 bara to have a small temperature lift over the heat pump. The steam compressor further increases the pressure to 5 bara. A part of the superheat is used to reheat the steam for the steam atmosphere, then the steam is sent to the cylinders, where it is condensed. Energy consumption amounts to 154 kW. From the slip stream, 166 kW can be recovered, if it is further cooled to 20°C.

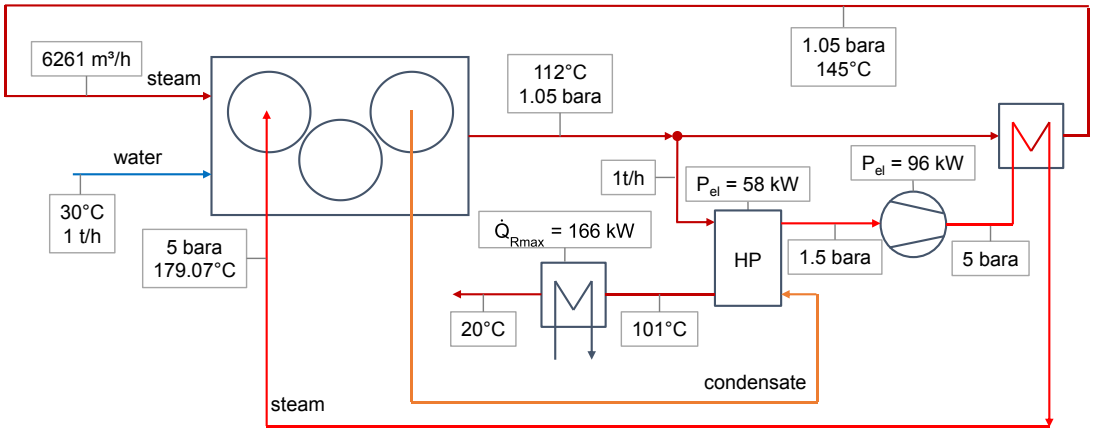

Figure 11. *Superheated steam drying with cylinders and a heat pump (S4)*

3.3. Discussion

Figure 12, Figure 13 and Figure 14 compare the concepts in terms of final energy consumption, CO_2 emissions and primary energy consumption. Final energy consumption decreases considerably for all concepts with heat pumps or steam compression (A3, A4, S3, S4), as they allow for recovery of the latent heat of the evaporated water from the paper. The same effect is found for CO_2 emissions. In terms of primary energy, the concepts A3, A4, S3 and S4 are still beneficial, but the difference to the concepts based on natural gas is smaller. The reason is the European primary energy factor, that is based on an electricity mix with less renewable energy than the one currently available in the EU.

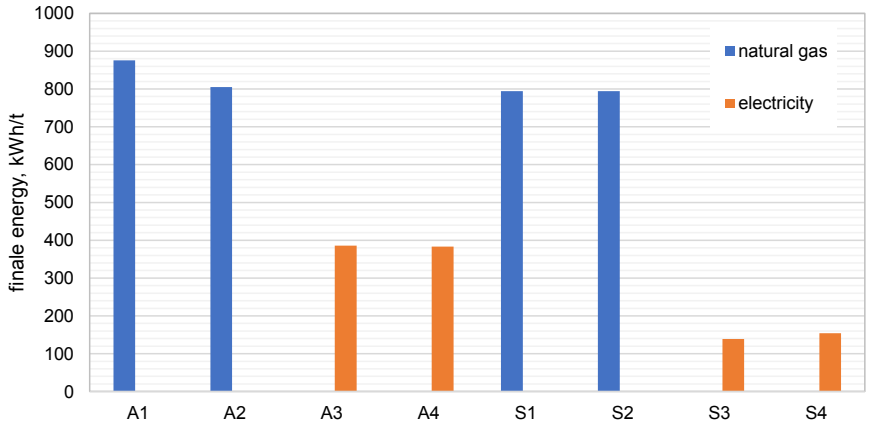

Figure 12. *Comparison of final energy consumption to evaporate 1 t/h water*

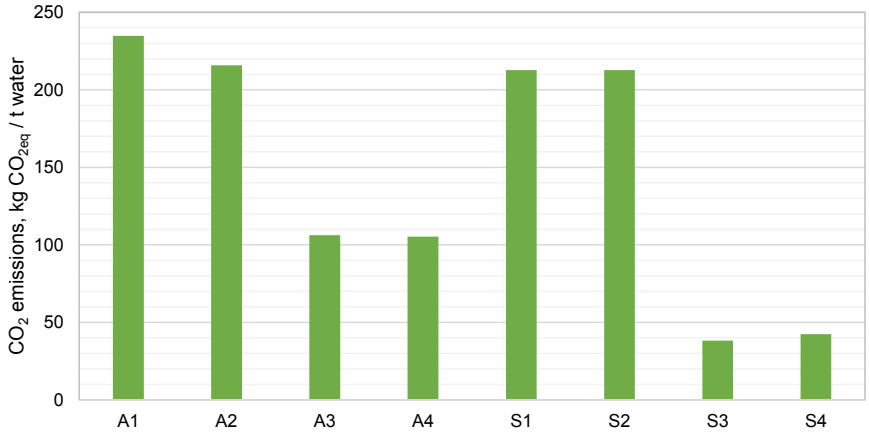

Figure 13*. Comparison of CO_2 emissions to evaporate 1 t/h water*

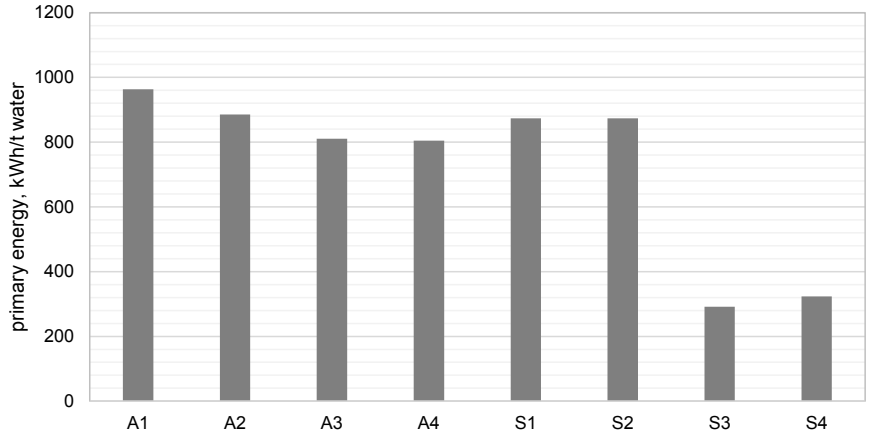

Figure 14. *Comparison of primary energy consumption to evaporate 1 t/h water*

The main difference between air and steam drying is that the dew point of the exhaust air is limiting heat recovery to low temperatures. A1 yields 754 kW, but mostly below 60°C. S1 and S2 yield 726 kW of excess steam that can be condensed at ca. 100°C. In the concept S3, the highest heat recovery temperature is available. Figure 15 visualises the heat recovery potential. The higher the temperature, the easier it is to find a suitable application. In A4, the heat pump is the only heat recovery measure. Compared to A3 (heat exchanger, then heat pump), more heat is available in A4 at a higher temperature. Energy consumption of A3 and A4 is in a comparable range. If there is no further heat demand at the paper mill, waste heat from steam drying can used for district heating, which is not possible for air drying.

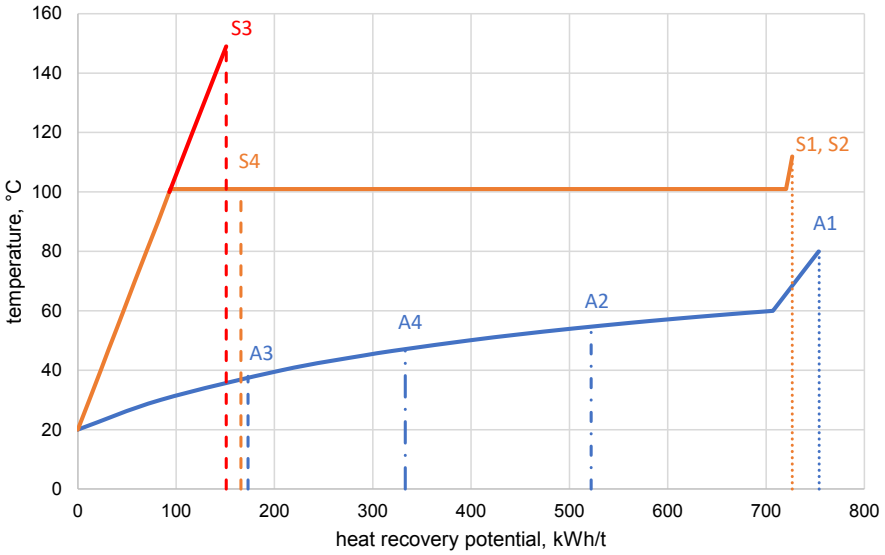

Figure 15. *Comparison of heat recovery potential for air and steam drying*

4. Conclusions and outlook

The most beneficial concept is S3 with steam atmosphere and steam compression for heat recovery. It reduces primary energy consumption by 70% and CO_2 emissions by 88% compared to A1, the benchmark concept with air drying. It also provides the highest excess steam temperature of 145°C that is well suited for further use.

The use of cylinders in the dryer is recommended to allow for low steam temperatures in the system. If the steam temperature is increased to 250°C, the volume flow is decreased. However, energy recovery with steam compression is more difficult, as the operation point moves closer to the boundaries of the operation envelope of steam compressors. The maximum allowable temperatures are typically at ca. 280°C, furthermore it must be considered that steam superheats strongly during compression.

To realize the concept S3, further research and demonstration is needed as an important part of the concept is that the steam for steam atmosphere is reheated and recycled. It has to be studied, what kind of impurities accumulate in the steam and how to remove them if necessary. Also, air intake should be avoided as it was already shown by Kiiskinen et al. [12]. In the simulation, a slight over-pressure of 1.05 bara was chosen for that reason. If the steam cannot be recycled, it can be condensed to evaporate clean steam. This would result in a more complex setup and in another temperature difference to overcome, which reduces the savings.

The simulation has shown that there is a huge potential in energy and emission savings if paper is dried in steam atmosphere using steam compression and condensation for heat recovery. Thereby drying is based on electricity only. The concept S3 is a suitable breakthrough technology to considerably improve paper drying.

Abstract:
Mathematical optimization is a widespread method in order to improve, for instance, the efficiency of energy systems. A simulation approach based on partial differential equations can typically not be formulated as an optimization problem, thus requiring interfacing to an external optimization environment. This is, amongst others, also true for the programming language Modelica. Because of high computation time, such coupled approaches are often limited to small scale optimization problems. Since simulation models tend to get more complex, simulation time and, in turn, associated optimization time rise significantly. To enable proper sampling of the search space, individual optimization runs need to be solved in acceptable times. This paper addresses the search for a proper optimization approach and tool to couple with Modelica/Dymola. The optimization is carried out on an exemplary power plant model from the ClaRa-Library using an evolutionary algorithm (SPEA2-based) with Ansys optiSlang. To verify and evaluate the results, a comparison with the standard Dymola optimization library is performed. Both parallelization and indirect optimization with surrogate models achieved a significant runtime reduction by a factor of up to 5.4. The use of meta models is particularly advantageous for repetitive optimization runs of the same optimization problem but may lead to deviations due to the calculated approximations.

1. Introduction

Process modeling and simulation is becoming increasingly important to achieve improvements in today´s complex energy systems and technologies [1]. The model formulation can be carried out via several programming languages. A frequently used language is the object- and equation-oriented programming language Modelica, which is particularly suitable for the representation of dynamic processes [2, 3]. To improve the handling of the modeling process, usually simulation environments such as Dymola are used [4]. Based on these models, extensive investigations such as design or control optimizations can be performed. A wide used method is the parameter variation, which is quite simple to perform, but becomes more time consuming as the complexity of the model increases. In these cases, mathematic optimization is used instead. Therefore, an optimization problem has to be defined and solved with the help of algorithms. The programming language Modelica, which is designed for simulation tasks, does not allow the formulation of such optimization problems. Thus, a coupling with external optimization languages or optimization environments is necessary [2]. In the field of energy systems, a wide variety of such environments have already been used for coupling with Dymola (see Section 3). This paper presents the first-time coupling of Dymola and Ansys optiSLang [5] in order to solve static optimization problems. For this purpose, the implemented workflow and its main features as well as the used algorithm are presented in Section 4 and 5. The verification of the results is finally done by a comparison with the standard Dymola optimization library (DLR Optimization Library [6]). This library offers a wide range of different optimization techniques that are easy to apply. However, a huge disadvantage is the

required runtime for optimization which will be further discussed in Section 6. For a better understanding of the results, relevant basics of mathematical optimization are presented first.

2. Mathematical optimization

The first step when dealing with optimization is the definition of the problem itself. Therefore, the objective function f(x), the optimization variable x and possible restrictions must be defined [7, 8]. For this study, we split optimization into the static and transient type, depending on the contents of the optimization variable. A typical application for static optimization is design optimization, where an optimal design of a component is determined disregarding transient features [9, 10]. Transient optimization is, for instance, used to calculate optimal process control strategies [11].

When choosing the appropriate algorithm, the specific properties of the algorithm as well as the specifications of the optimization problem must be considered [9, 12]. In application-related problems, multi-objective optimization tasks are the most common. In contrast to the single-objective optimization, several objective functions are optimized simultaneously. Usually, these functions are in conflict with each other. As a result, there is no solution where both objective functions reach their individual optimum [9, 13–15]. This context can be described by the so-called Pareto-Front (see Figure 1). Illustrated are the two fictitious objective functions $f_1(x)$ and $f_2(x)$, which are to be minimized by a variation of x. By using the single optima (x_1 and x_2), three characteristic ranges can be identified. While an increase of x in the range $x < x_1$ leads to an improvement of both functions, an increase for $x > x_2$ causes a deterioration of both functions. The relevant range is thus located between the two individual optima ($x_1 < x < x_2$). Within this range, an improvement of one objective function can only be realized by a deterioration of the other criterion. This means, that there is no longer a single optimum as in the case of the single-objective optimization. Instead, there is a set of different optima, also called the Pareto-Optimal set or Pareto-Solutions. By comparing the two objective functions, this set can be represented as a subset of the boundary curve (Pareto-Front on the right). By selecting a weighting factor, a problem-specific overall solution can then be determined. [9, 13–15]

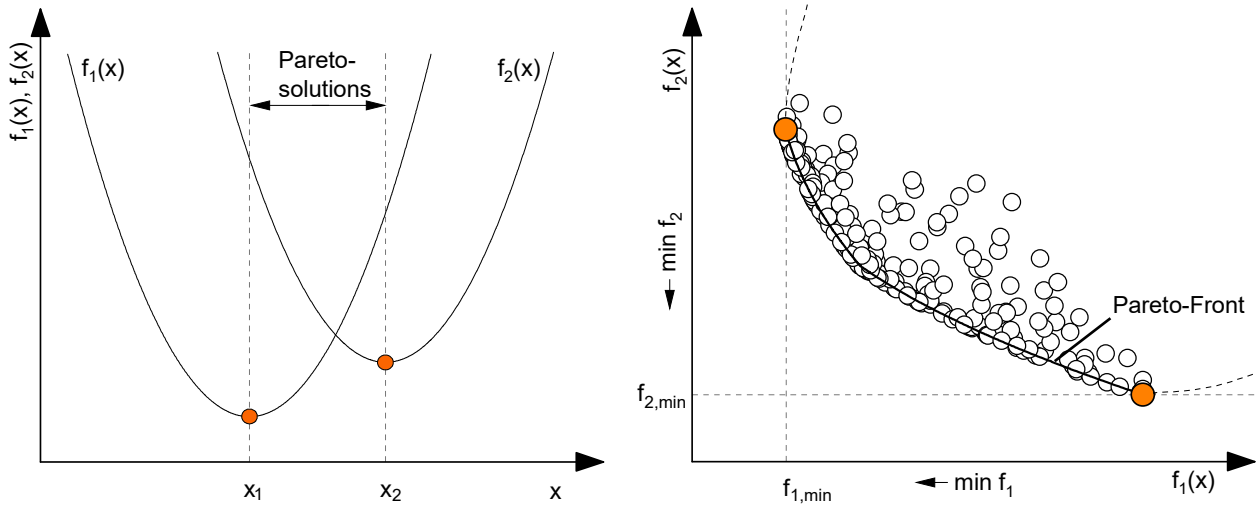

Figure. 1. Target function values of the fictitious functions $f_1(x)$ and $f_2(x)$ (left) and Pareto-Front of the fictitious functions (right) according to [9]

3. Optimization with Dymola

In the area of energy systems, various couplings between Dymola and different optimization environments have already been implemented. The choice of the appropriate environment is problem-specific and depends primarily on the type of optimization problem. Table 1 shows an overview of published investigations and lists the used optimization-tool. The DLR Optimization Library is fully integrated in Dymola and can be used to define multicriteria and trajectory optimization problems. In the three listed examples [16–18] different types of Models and optimization problems were investigated. Dymola is one of currently over 170 tools which support the FMI standard. It allows the export and exchange of simulation models into other simulation or optimization environments. The studies [19–21] are using this standard for an optimization in Matlab and Simulink with the focus on optimal control. In the study [22] Matlab is used as an optimization platform. Instead of FMI, an optimization workflow is presented. The workflow is using a Dymola script to run the simulation with different input parameters. The results are imported into Matlab from result files (dsres.mat) using pre-implemented functions. The study [23] is using the optimization environment OMOptim and Dymola as a simulation tool. To excess the model structure and adapt the input variables, OpenModelica is used. In the shown example, a

design optimization of a heat pump is presented. The optimization program GenOpt is a text-based system which uses the input and output files of a simulation software to perform the optimization. The studies [24–26] are presenting an optimal control problem and [27] are solving a design optimization with GenOpt. Pfeiffer [28] utilize the FISEMO environment to perform a numerical sensitivity analysis of Modelica models. Dymola is used for the modeling process and the export of the model into C-Code. The integration into the FISEMO environment is done by using the DASPK3.1 package.

Table 1. Couplings of Dymola and optimization environments in the field of energy systems.

Model	Method	Optimization-tool	Ref.
Chilled water plant	Real-Time Optimization	DLR Optimization Library	[16]
CO_2 heat pump and thermal storage	Optimal Control	DLR Optimization Library	[17]
Osmosis hybrid system	Design Optimization	DLR Optimization Library	[18]
Hybrid Energy systems (HES)	Optimal Control	Matlab	[19]
Decentralised energy supply	Optimal Control	Simulink	[20]
Thermal management system	Optimal Control	MUSCOD-II	[21]
Chiller plant	Optimal Control	Matlab	[22]
Heat pump	Design Optimization	OMOptim	[23]
Combined heat and power plant (CHP)	Optimal Control	GenOpt	[24]

Chiller plant	Optimal Control	GenOpt	[25]
Chilled water system	System configuration	GenOpt	[27]
Discontinuously Models	Sensitivity analysis	Fisemo	[28]

Most of the listed publications deal with transient optimization and focus on optimal control problems. The static optimization is less frequent and only addressed in two publications with small scale problems. In order to test the optimization framework optiSLang and contribute to the landscape of investigations of static optimization-simulation coupling, a proof of concept with a model of a coal-fired power plant is set up and carried out in this paper. One of the main advantages of optiSLang is the support of high-order parameter spaces, and thus, extensive sensitivity analysis as well as comparatively complex design optimization calculations. In the field of mechanical construction, for instance, optimization problems with up to 30,000 independent variables were solved [29]. Since there is currently no direct connection to Dymola, a workflow will be presented in the first step (Section 4). Solving dynamic optimization problems with optiSLang is possible as well but will not be further discussed within this paper.

4. Coupling of Dymola and Ansys optiSLang

Since there is no direct coupling option for Dymola and optiSLang yet, an appropriate workflow had to be developed. The implemented workflow presented in this paper enables an automatic data exchange between Dymola and optiSLang (see Figure 2). optiSLang works according to the principle of variance calculation, which is why several model simulations and modifications of the model have to be performed [5]. Therefore, a text-based solver chain is implemented within the optiSLang environment.

Dymola is used for the modeling process of the respective system in the programming language Modelica. The model can then be translated into C-Code and saved as an executable file with an associated input file. The input file contains essential initial values, model parameters and simulation settings which are needed for the simulation run of the model. After a successful simulation, the results are saved into output files. By modifying the input file, different model parametrizations and therefore results can be generated.

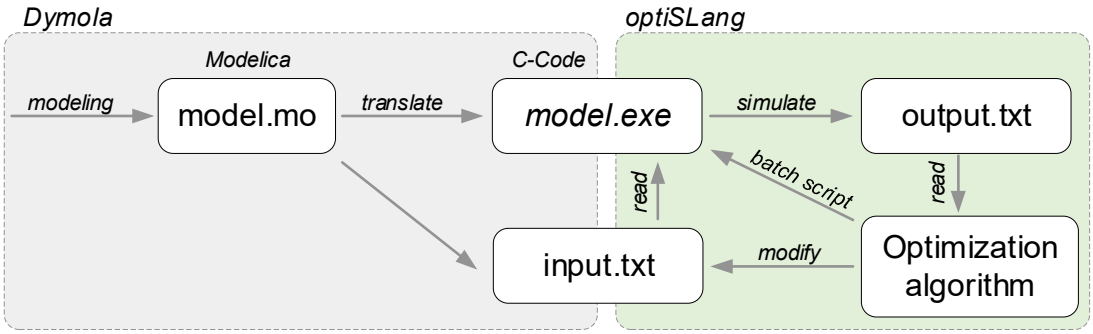

Figure. 2. Basic principle of the workflow for coupling Dymola and optiSLang

optiSlang is using these three files to perform the optimization. As a first step, the optimization problem must be defined in the optiSLang environment. In contrast to the original mathematical optimization, it is not necessary to develop a complex mathematical objective function. Instead, the optimization is performed using a black box model of the Dymola model (executable file). The input variables are set as optimization variables while the output variables are set as target criteria. The optimization variables (tuners) must be extracted from the input file. For each evaluation of the algorithm, one modified input file is created. Each of these files has different tuning values which are varied in a defined range in order to achieve the optimum. The validation of the optimum is done by using target criteria which are integrated in the model and calculated through a simulation (via batch-script). The results of each simulation are saved into individual output files. optiSLang extracts these values and evaluates them according to the chosen algorithm.

Although the black box model simplifies the definition of the optimization problem, it also means that there is no knowledge of the mathematical structure of the problem. However, this knowledge is usually necessary for the choice of a suitable algorithm. To counteract this problem, optiSLang offers the user a traffic light system which recommends an algorithm based on the determined internal optimization problem (number of inputs, single- or multi-objective problem etc.). It must be taken into account, that this recommendation depends on the mathematical solvability of the problem and does not guarantee the best possible result. Thus, it is still necessary to know about the functionality of the individual algorithms to select a suitable one for a given optimization problem.

5. Case study: coal-fired power plant

In order to validate the implemented workflow, an optimization run is performed using an example model of the open source library ClaRa [30]. The chosen model represents a coal-fired power plant with eight turbine stages including feedwater preheating. Fig. 3 shows a simplified schematic of the plant. After passing the boiler, the generated steam flows through the individual turbine stages until it is expanded to the condenser pressure. The collected condensate is then preheated by the four low-pressure preheaters (LP-PH) before it enters the steam-heated feedwatertank. The feedwater is preheated by the high-pressure preheater (HP-PH) before it enters the boiler. The power plant is designed to provide 580 MW_{el}. In the simulation scenario two load reductions to 70 percent load are performed. One simulation run of 10.000 seconds requires around 118 seconds simulation time.

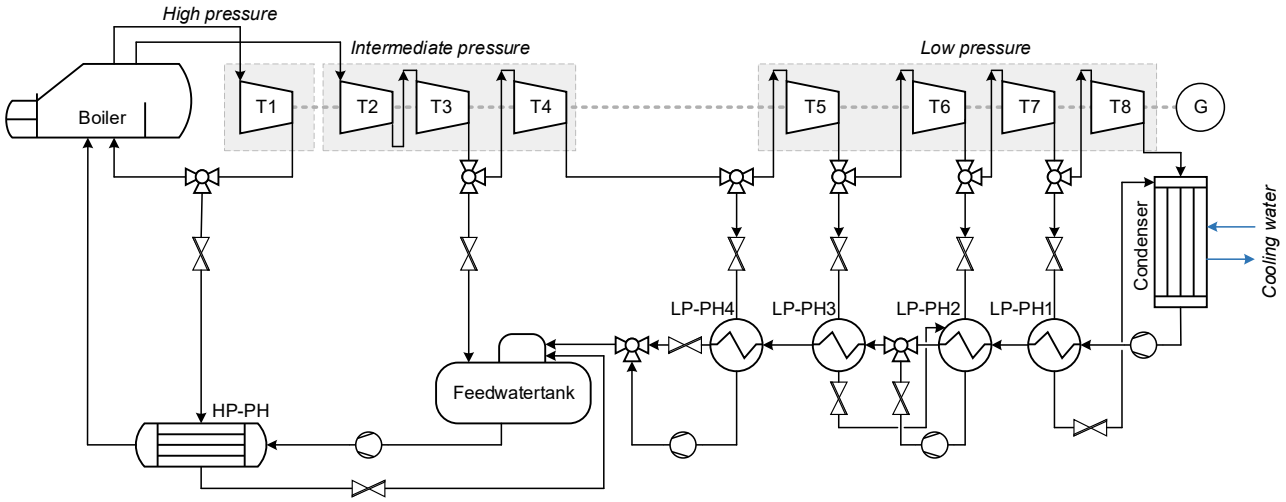

Figure. 3. *Simplified schematic of the coal fired power plant model SteamPowerPlant_01 from the open-source library ClaRa*

The optimization is carried out using the HP preheater as an example component due to its huge impact on the preheating section. The HP-PH model is a shell-and-tube heat exchanger for which selected tube parameters are to be optimized. Further information about the model can be obtained from the open source library ClaRa [30].

Table 2. Specifications of the optimization variables d_i, d_o and l.

Tuner	lower boundary [m]	initial value [m]	upper boundary [m]
d_i	0.015	0.020	0.024
d_o	0.025	0.028	0.031
l	9	10	11

The aim of the optimization is the improvement of the overall power plant efficiency with respect to the investment costs of the heat exchanger. Therefore, inner tube diameter d_i, outer tube diameter d_o and tube length l are to be optimized (Eq. (1)). The resulting multi-objective optimization problem is shown below. In many cases, optimization tools simplify a multi-objective problem to a single-objective problem by combining the multiple functions into a single sum-function with individual weights or by focusing on one function and introducing the remaining as constraints [31]. However, optiSLang is using an interactive method (see Section 2) instead, which allows to deal with several functions simultaneously. The resulting Pareto-Front can be used to identify the area of interest where focused optimization runs can be performed.

A simple degression function is implemented for estimating the investment costs (see Eq. (2)) [32, 33]. Therefore, the heat transfer surface is set in relation to a theoretical reference heat exchanger (A_{ref} = 1,500 m² and $K_{i,ref}$ = 800,000 €) and is simplified by Eq. (3) The degression exponent n was set to 0.6 [32, 33]. The price index effect from PI and PI_{ref} is neglected in this example. The efficiency is automatically calculated within in the model and is equal to the outlet-power and inlet-power ratio (see Eq. (4)). The negative equation sign is used to transform the maximization problem into a minimization problem. Table 2 shows the individual limits of the tuner variables. The initial values of the overall system efficiency η_{ref} and the investment costs $K_{i,ref}$ are 51,58 % and 802,545 €.

$$x = (d_o, d_i, l)^T \tag{1}$$

$$\min f_1(x) = K_{i,ref} \cdot \left(\frac{A(x)}{A_{ref}}\right)^n \cdot \left(\frac{PI}{PI_{ref}}\right) \tag{2}$$

$$A(x) = 2\pi \cdot \frac{d_o + d_i}{2} \cdot l \cdot n_T \tag{3}$$

$$\min f_2 = -P_{out}/P_{in} \tag{4}$$

5.1. Optimization algorithm

As solving algorithm a modified implementation of the Strength Pareto Evolutionary Algorithm 2 (SPEA2 [34]) is used. Figure 4 shows the general flowchart of the algorithm and indicates the interaction with the implemented workflow from Section 4.

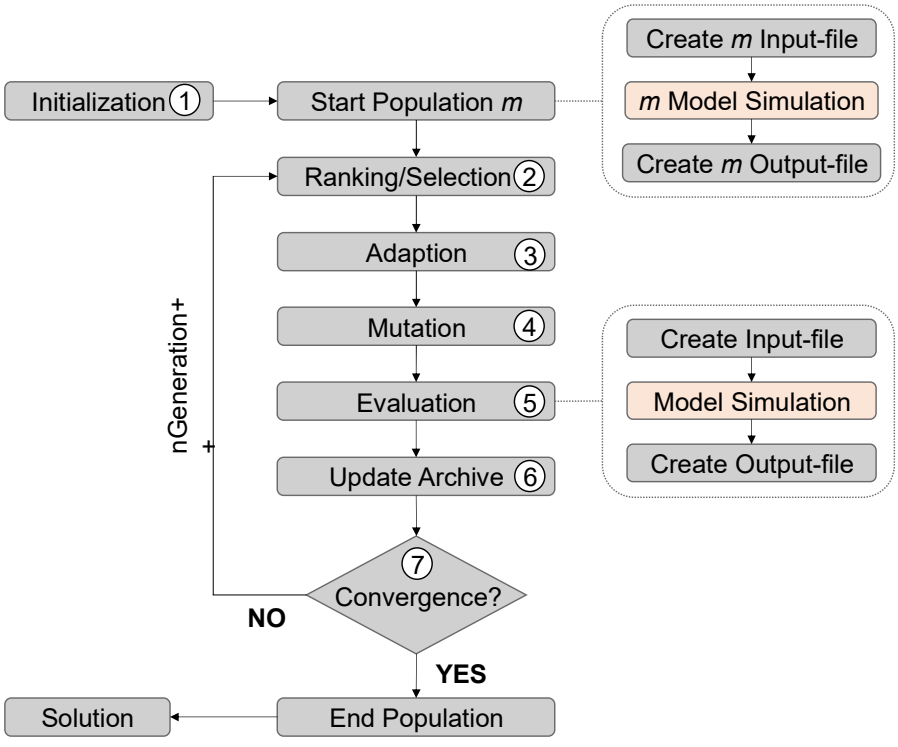

Figure. 4. General flowchart of the evolutionary algorithm (according to [14] and [35]) and the interaction with the implemented workflow

After initialization of the simulation model, a start population of the size *m* is generated (Step 1). Therefore, *m* modified input-files are created and *m* respective simulation runs are performed. A dominance-based ranking system is used to assign a corresponding fitness factor to each solution, which are extracted from the *m* output-files (Step 2). The iteration loop starts after the assignment process is done by using adaption (e.g. crossover or swarm movement) and mutation methods. The additional designs must be evaluated and ranked once more (Step 5). Therefore, new model simulations are required. Beneficial solutions are used to update the archive (containment for good solutions) and checked for convergence (Step 7). If the convergence criteria is reached, the optimization terminates and the end population is stated. In the negative case, step 2 to 7 are repeated until convergence or a termination criterion are reached. Since each evaluation requires one simulation of the model, optimization runtime is highly affected by simulation runtime and the number of total simulations. For a time-efficient optimization, both should be reduced as far as possible.

The described steps can be modified further by changing the algorithm parameter (e.g. mutation-rate or crossover method). This allows the user to adapt the algorithm to the specific problem. The optimization runs presented in this paper use the optiSLang standard settings. All calculations are carried out under Windows 10 on an Intel Core i5-6500 (3.2 GHz processor) with 8 GB RAM.

6. Results

6.1. Direct and indirect optimization

The optimization can be done as a direct or indirect optimization (Figure 5). In case of the direct optimization, an individual model simulation is carried out for each evaluation of the algorithm. The indirect optimization, on the other hand, uses a surrogate model (meta-model) of the simulation model. The meta-model is determined based on n model simulations (100 by default) via a sensitivity analysis (SA). The SA provides several response surfaces which mathematically describe the correlation between the target criteria and the chosen optimization variables. Both variants have individual advantages and disadvantages which are described in more detail below.

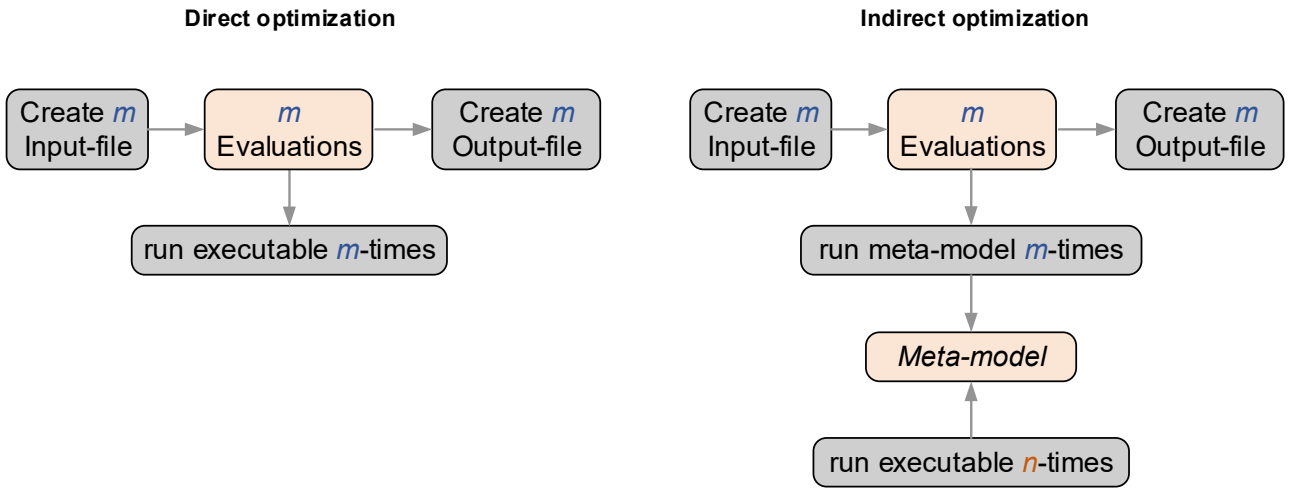

Figure. 5. Direct and indirect optimization using the executable file and surrogate models

Figure 6 shows an example response surface of the overall system efficiency and its correlation to the tube length and the inner tube diameter of the HP-PH. For the approximation a combination of several approximation techniques such as Kriging or neuronal networks are used. In this case the color scale indicates the local forecast quality of the approximation. Therefore, the so-called Coefficient of Prognosis (COP) is used. This value is a validation criterion developed by optiSLang to describe the quality of the approximation. It is calculated by using a cross-validation procedure [5]. In this case the COP is on a very high level across the entire surface. In systems with more complex and discontinuous process behavior generally lower COP values are reached. In such cases, it is possible to use other Design of Experiment (DoE) methods and/or to increase the number of samples (*n*). Another feature of the SA is the filtering of non-relevant parameters to simplify the optimization problem.

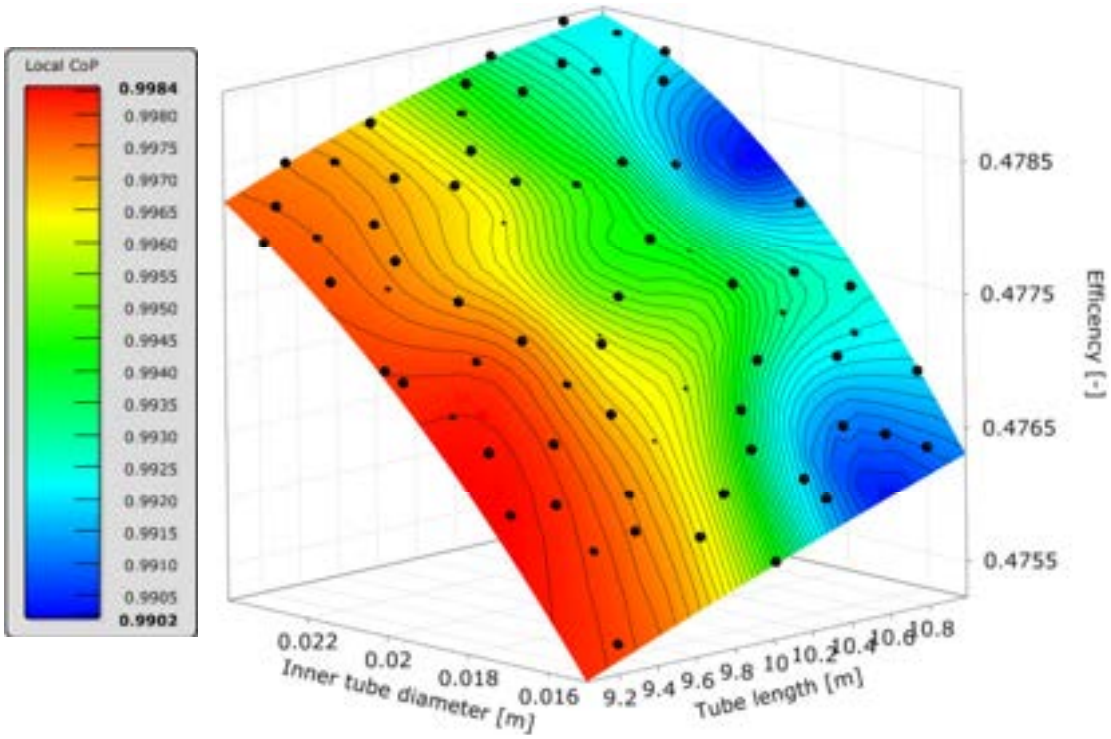

Figure. 6. Change of overall system efficiency depending on the tube length and the inner tube diameter of the HP preheater. Indication of the local COP by means of color scale

6.2. Runtime comparison of direct and indirect optimization

A comparison of the direct and indirect optimization method indicates a time advantage in favor of the indirect method. Both calculations are carried out with the same number of model simulations and algorithm evaluations. For the comparison, the overall runtime (t_{dir} and t_{indir}) is further separated into different categories (see Eq. (5) and Eq. (6)). Hereby a more detailed understanding of the optimization processes is achieved. The different categories are defined as the simulation time, the approximation time and the optimization time. The simulation time t_{sim} equals the total time for model simulation and can be calculated from the runtime for one simulation t_{model} and the total number of model simulations n_s (see Eq. (7)). The approximation time t_{approx} of the indirect variant corresponds to the time period for generating the surrogate model and is affected by the number of simulation and the complexity of the correlations. The remaining time is assigned to the optimization time. Both, the approximation time and the total runtime can be taken from the optiSLang log file.

$$t_{dir} = t_{sim} + t_{opt,dir} \tag{5}$$

$$t_{indir} = t_{sim} + t_{opt,indir} + t_{approx} \tag{6}$$

$$t_{sim} = t_{model} \cdot n_s \tag{7}$$

The resulting runtimes of the direct and indirect method are shown in Figure 7. The displayed percentage values describe the share of the respective category in the total runtime of the method. Due to the fixed number of model simulations, the direct and indirect optimization require the same simulation time. Although the indirect variant requires additional time due to the creation of the meta-model, the optimization can be done significantly faster because no further time-consuming simulation runs are needed. Compared to the direct method, the optimization time can be reduced by 97 % and the total runtime by 12 %. With increasing number of evaluations this time advantage increases even more. In addition, simulation and approximation are omitted in a new optimization run of the same problem since the determined approximation is reusable.

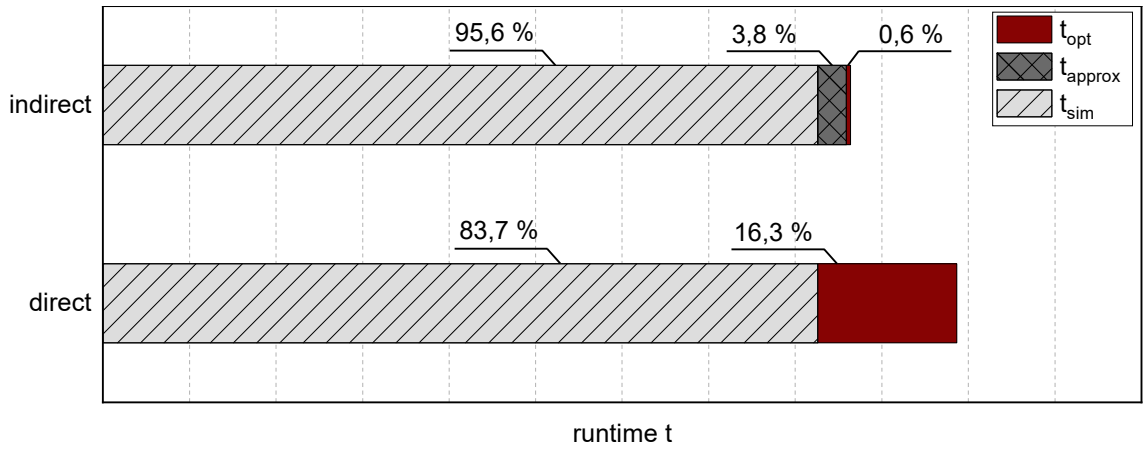

Figure. 7. Overall runtime of the direct and indirect optimization and the respective proportions of the simulation, approximation and optimization time

When using approximations, it must be taken into account that the results are affected by an error seen in Figure 8 which compares the Pareto-Front of the two methods. While the indirect Pareto-Front generates a very smooth graph, the direct method shows a much more complex behavior. The use of the approximation simplifies the system response, which in this example leads to areas where the investment costs are underestimated or overestimated. Because of these discrepancies, the indirect method should be used primarily as a first optimization step in order to reduce the overall computing time and to locate/constrain the relevant solution space [5].

With increasing model runtime, shortening methods are becoming more important. If no pre-optimization is desired, parallelization methods can be used alternatively. Since the simulations of each evaluation loop are executed parallel instead of sequentially, runtime reductions can be achieved without affecting the result. In the present work the runtime of the direct method could be reduced by up to 75 % using parallelization. A further reduction can be realized by using a computing cluster which grants access to more cores.

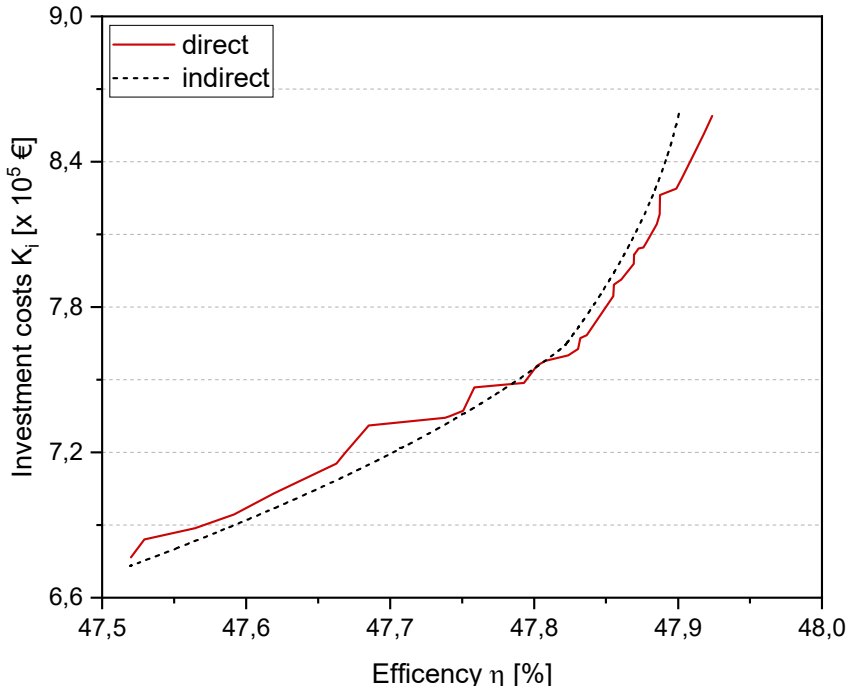

Figure. 8. Comparison of the direct and indirect Pareto-Front of the overall system efficiency and the investment costs of the HP preheater

6.3. Comparison of the DLR Optimization Library and optiSLang

In the following section, a comparison of the optiSLang workflow and the DLR Optimization Library is presented. Since the DLR Optimization Library uses weighting factors to transform multi-objective problems into single-objective problems, no comparison to the previous results could be made. Instead, a single-

objective optimization using the overall efficiency as the optimization goal is carried out. An evolutionary algorithm with standard specifications is used for the calculation and parallelization methods are considered.

All setups manage to improve the overall system efficiency (see Table 3). The optimized efficiency η_{opt} as well as the difference to the initial value $\Delta\eta$ are shown in the second column of the table and only differ slightly. For the further comparisons of the setups, the direct DLR setup is defined as reference. With regard to the optimized efficiency only minimal changes occur. On the other hand, large differences in the runtime were found. The direct optimization of the DLR Optimization Library is the most time-consuming setup. However, by using parallelization, the runtime can be more than halved. The direct optiSLang setup reduces the runtime by almost 40 %. By using additional parallelization, the runtime can be further reduced by a factor of four without influencing the results. The indirect optiSLang setup is faster than the direct DLR and direct optiSLang setup but slightly influences the optimized results negatively. A benefit of this setup is the generated surrogate model, which can be reused for further optimization runs.

Table 3. Overall runtime and maximum efficiency of the investigated setups for the single-objective optimization of the HP Preheater.

Method	$\boldsymbol{\eta_{opt}}$ $(\Delta\boldsymbol{\eta})$ [%]	$\boldsymbol{\eta_{DLR,direct} - \eta_{opt}}$ [%]	$\boldsymbol{t}$ [h]	$\frac{\boldsymbol{t}}{\boldsymbol{t_{DLR,direct}}}$ [-]
DLR Optimization Library direct	51.688 (+ 0.105)	0	11.4	1
DLR Optimization Library direct and parallel	51.688 (+ 0.105)	0	5.3	0.46
optiSLang direct	51.689 (+ 0.106)	0.001	8.2	0.72
optiSLang direct and parallel	51.689 (+ 0.106)	0.001	2.1	0.18
optiSLang indirect	51.686 (+ 0.103)	- 0.002	7.2	0.63

7. Conclusion

Since the programming language Modelica does not allow the definition of optimization problems, it is necessary to link up with external optimization environments or optimization languages. The simulation environment Dymola offers the integrated DLR Optimization Library which contains ready-made methods for static and transient optimization. These optimization methods are easy to use but only customizable to a limited extent. Therefore, it is barely possible to adapt the algorithm individually for different optimization tasks. Since the optimization is done directly, large simulation models cause long optimization times. For a runtime reduction parallelization can be used. To ensure a better optimization performance with higher flexibility, tools such as Ansys optiSLang can be used. An implementation of an appropriate workflow for coupling Modelica/Dymola and optiSLang is presented in this paper. It has been shown that the optimization via optiSLang can be more time efficient compared to the Dymola standard DLR Optimization Library. When using parallelization methods, the runtime of the examined test case has been reduced by the factor 4. This improvement is necessary to deal with large scale optimization problems in a suitable time. By using the sensitivity analysis, it is possible to obtain additional information about the system behavior. The determined surrogate model (meta-model) can also be used for an indirect optimization which is especially advantageous for a repeated optimization of the same model. Due to the deviations from the model behavior indirect methods should only be used for pre-optimizations.

The comparison with the DLR Optimization Library shows that the developed workflow makes it possible to solve static optimization problems very efficiently. Further investigations should focus on optimization problems with a higher complexity to identify the limits of the presented workflow. In addition, first investigations showed that dynamic optimization problems may be realized by adjusting the workflow. For this, the input signals/vectors need to be discretized into a finite number of static points, which can later be used like the tuners of the static optimization.

Nomenclature

f	Objective function	[-]
x	Optimization variable	[-]
d_i	Inner tube diameter	[m]
d_o	Outer tube diameter	[m]
l	Tube length	[m]

η	Overall system efficiency in nominal operation	[%]
η_{opt}	Optimized overall system efficiency in nominal operation	[%]
K_i	Investment costs	[€]
$K_{i,ref}$	Reference investment costs	[€]
A	Heat exchange surface	[m^2]
A_{ref}	Reference heat exchange surface	[m^2]
PI	Price index	[-]
PI_{ref}	Reference price index	[-]
P_{in}	Input Power	[MWh]
P_{out}	Output Power	[MWh]
n	Degression exponent	[-]
n_T	Number of tubes	[-]
n_s	Number of model simulations	[-]
t	Runtime	[h]
t_{model}	Model runtime	[h]
t_{sim}	Simulation time	[h]
t_{approx}	Approximation time	[h]
t_{opt}	Optimization time	[h]
t_{dir}	Runtime of the direct method	[h]
t_{indir}	Runtime of the indirect method	[h]
$t_{DLR,direct}$	Runtime of the direct DLR optimization Library method	[h]

Abstract:
Solar thermal plants operate in a highly variable environment, with variations in both the energy source and the heat demand. Moreover, weather and load forecasts contain uncertainty. Thermal energy storage helps to decouple the heat production from the heat supply and gives the solar thermal plant more flexibility while complexifying its operation. In this work, a Dynamic Real-Time Optimization (DRTO) methodology is presented. Firstly, a planning phase determines the best storage management policy, given the estimated weather and load forecasts. An economic DRTO algorithm is then used to update the optimal trajectories to minimize the operating costs of the plant while respecting the storage management policy determined at the planning level, despite disturbances in the weather conditions. This stage uses updated forecasts and real-time information to update the optimal trajectories. This methodology is tested on a "virtual solar plant" (a detailed dynamic model of an existing plant) in a case study, with real data for the weather forecasts and measurements and a variable heat demand. Results obtained without and with DRTO adjustment are compared. In the first case, the virtual plant is operated using trajectories computed with offline dynamic optimization (DO) at the planning phase and undergoing the real-time weather and load conditions, while in the second case, real-time modification of the operating trajectories is performed. We observe an improvement in the solar fraction used to satisfy the heat demand and a reduction in the operating costs with DRTO compared to DO, without degrading the storage management significantly. The results are promising for an application to an existing plant.

Dynamic Real-Time Optimization, Solar thermal energy, Simulation

1. Introduction

Greenhouse gases emissions need to be reduced to mitigate climate change. An efficient energy transition is crucial to achieve carbon neutrality. Heat represents a large part of the final energy consumption and mostly relies on fossil fuels for its production nowadays. Solar thermal plants are a good alternative to fossil fuels because they allow the production of heat from the solar irradiation, and thus without direct CO_2 emissions.

1.1. Solar thermal plants challenges and opportunities

In a solar thermal plant, the solar irradiance heats up a fluid flowing through solar collectors. High temperatures, suitable for steam and electricity generation can be achieved by concentrating the solar radiation with mirrors. In the present work, we consider a non-concentrating solar thermal plant for low temperature heat production suitable for space heating, domestic hot water and some industrial processes. Nevertheless, the methodology presented in the remaining parts of the paper could be applied to other solar thermal plants. Solar energy is intermittent, with daily and seasonal variations. On the other hand, the heat demand also varies, and generally its variations are not synchronized with the variations in solar heat production. To help to decouple solar heat production and supply, Thermal Energy Storage (TES) solutions are developed. Both daily and seasonal storage solutions exist, but only daily storage is considered in this work, in the form of a stratified water tank. The association of a variable energy source and a storage solution makes the solar thermal operation complex and with several operating modes possible: direct supply, storage discharge, storage charge, shut down. Optimization methodologies are particularly promising for a system with such degrees of freedom.

1.2. Solar thermal plants optimization

Mathematical optimization is a useful tool to make the most of a system. For example, it can reduce the investment and operation costs, or the environmental impact of a system. Given the large cost of a solar thermal plant, optimizing its design and operation can help to reduce its cost and thus can improve its competitiveness

against fossil fuels. The design of the system, such as solar panels area, storage tank volume, etc., can be optimized to minimize the investment cost while making sure that the heat demand can be met. Once the system is designed accordingly to the consumer needs, the operation of the solar thermal plant can also be optimized in order to help to meet the heat demand despite variable weather conditions, reduce the operating cost and cut down the fossil fuel consumption in heat production.

Nowadays, most solar thermal plants are operated with logic control rules, such as a constant temperature at the outlet of the solar field, the equality of calorific fluxes in heat exchangers or the discharge of the storage tank as soon as the heat demand is not met. To track the set points determined by these logic rules, basic controllers are mostly implemented [1]. However, a solar thermal plant is a highly non-linear system, with various dynamics and ever-changing environmental conditions. Hence, more advanced controllers are developed, with predictive features for example. In the recent years, an economic objective has been incorporated in complex controllers in order to optimize the operation of systems [2]. This has been tested for a solar thermal system with storage in [3], where the back-up fossil fuel consumption was minimized. A linear control oriented model was employed to reduce the computational time since the economic optimization has to be performed at each control time step. Moreover, the control time horizon is not long enough to plan a good storage management, since the storage tank has much slower dynamics than the rest of the plant. The economic optimization and the control of the system could be performed separately to avoid the over-simplification of the dynamic model of the system.

Dynamic optimization (DO) has been applied to solar thermal plants in order to determine optimal trajectories for the control variables over a given time horizon. This is also known as planning. For example, in [4], the flow rates in the different parts of the solar thermal plant were optimized over 36 hours using weather and heat demand forecasts. In particular, the use of storage was optimized. Dynamic optimization has been more commonly applied to concentrating solar thermal plants for electricity generation. For example in [5], the income from electricity selling is maximized, with a variable electricity price and TES to shift the electricity production. A hybrid system composed of a solar thermal plant and a back up fossil fuel burner has also been optimized, in [6] for example. These studies on dynamic optimizations allowed to improve the performances of the solar thermal plants by increasing the income and reducing the back-up fossil fuel consumption. However, they relied on weather and load forecasts which are uncertain. Dynamic optimization does not adapt the optimal strategy to the current disturbances. Thus, the trajectories determined might become sub-optimal or even impossible to track by the controllers.

An intermediate level between planning and control in the hierarchical operation of the plant is real-time optimization. For a solar thermal plant, Dynamic Real-Time Optimization (DRTO) could be applied to determine the optimal trajectories of the control variables, that will be tracked by controllers [7]. These trajectories are updated regularly with a new dynamic optimization run based on updated forecasts and current measurements of state variables and disturbances. This has been tested for a concentrating solar thermal field, without considering the storage tank, in [8]. Another work focused on the daily storage management of a solar district heating system [9], by optimizing the flow rate between a long term and a short term storage tanks. These two studies only optimized in real-time a single flow rate and not the complete solar thermal plant operation, although DRTO seems well-suited to optimize such a complex system operated in an ever-changing environment.

Storage management is a particularly challenging part of the operation of a solar thermal plant. Indeed, the optimal operation of the TES has to be determined over several days, since it has slow dynamics and its optimal operation requires a long term strategic vision. However, running a new accurate dynamic optimization regularly with a time horizon of several days might lead to prohibitive computational times. A hierarchical approach might improve storage management, as shown in [10] for an electric system with storage. In this paper, a top layer is in charge of planning the storage state over a longer time horizon and a bottom layer optimizes the operation of the electric system in real-time. A similar approach could be used for a solar thermal plant, as suggested in [11]. The association of a planning phase for storage management and DRTO for the operation of the plant was only tested in one paper [16] in a theoretical case study. Reduction in the operating cost compared to DO was achieved. These promising results need to be confirmed in a more realistic case study.

Based on this literature review, there is a lack of studies focusing on the DRTO of a solar thermal plant to optimize its performances despite varying environmental conditions and consumer needs and uncertain forecasts. Moreover, a methodology to ensure a good storage management, through hierarchical optimization layers should be developed and tested in realistic case studies.

1.3. Paper contents

In the present paper, a DRTO methodology in association with a planning phase for storage management is developed. The planned storage state is incorporated into the DRTO economic objective function. The methodology is tested in a realistic case study on a simulation model. Real data are used for the weather forecasts and measurements. The test is carried out over 96 hours, showing better performances than DO without real-time adaptation.

Section 2. presents the solar thermal plant layout and its modeling. Section 3. details the input information for the algorithm. Section 4. explains the methodology with the two-layer optimization algorithm. Section 5. presents the case study chosen to test the methodology and Section 6. shows the results obtained. Finally, Section 7. gives some conclusions and perspectives for this work.

2. System description and modeling

2.1. Presentation of the solar thermal plant considered

The solar thermal plant considered in this study is presented in Fig. 1 and corresponds to an initial design of a real system provided by our industrial partner NEWHEAT. It is composed of a solar circuit, with 12 loops of 15 flat plate collectors each, where the fluid is heated up by the solar irradiation. This represents an equivalent surface of 2873m^2 of solar collectors. The fluid inside the solar circuit is composed of 70% of water and 30% of glycol in volume. The fluid can by-pass the first heat exchanger by flowing through the recirculation loop. This allows a faster warm-up of the solar circuit. Once the temperature at the outlet of the solar field is high enough for the consumer needs, the fluid flows through the heat exchanger 1, to transfer the solar heat to the secondary circuit, filled with water. The main part of the secondary circuit is a short term thermal energy storage. The technology chosen is a stratified water tank with a volume of 500m^3 and a height of 12m. The storage tank can be charged, discharged and by-passed depending on the consumer need and weather conditions. For example, the storage tank can be charged when the solar heat produced exceeds the heat demand. It can be discharged when the storage tank contains valuable energy and not enough heat is produced in the solar field. Finally, it can be by-passed to deliver directly the solar heat produced to the consumer when the heat production and demand happen simultaneously. The temperature of the fluid flowing through the second heat exchanger can be adjusted by diluting the fluid from the solar field or the storage tank with fluid exiting the second heat exchanger after having transferred its heat to the consumer. This avoids exceeding the heat demand. Three variable speed pumps are used to move the fluid in the different parts of the system and three-way valves ensure the fluid distribution in the pipes. The different operational modes of the solar thermal plant make its operation flexible but also complex. In this context, optimizing the operation of the plant should be promising because of the large number of degrees of freedom in the system. In case the heat demand is not fully satisfied by solar energy, a gas burner will be used by the consumer to reach the target temperature. The gas burner is not represented in Fig. 1 and is not modeled in our work. However, the gas consumption will be computed in order to obtain the operational cost of the heat production.

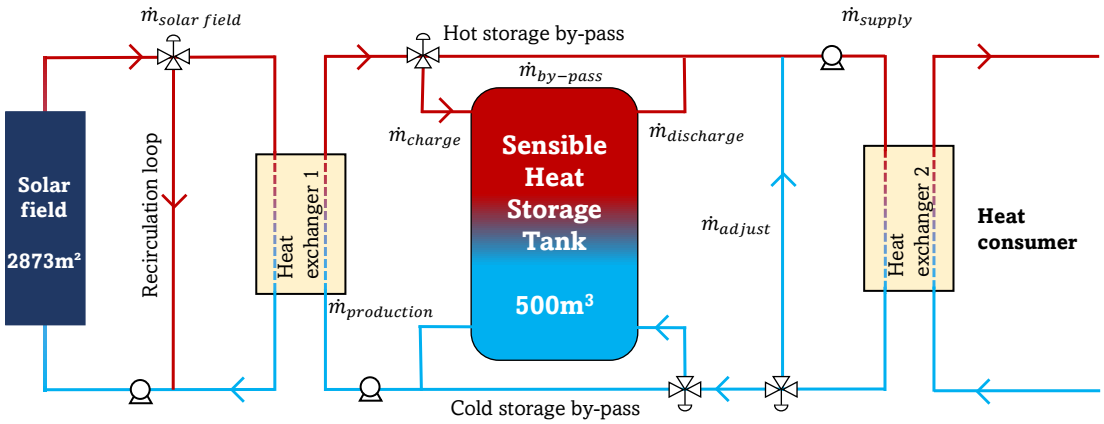

Figure 1: Solar thermal plant architecture

2.2. Modeling of the solar thermal plant

A solar thermal plant is intrinsically dynamic, with variations in the energy source and demand. The elements of the solar thermal plants have various dynamics. For instance, the solar field has fast variations while the storage tank state varies less rapidly. For these reasons, a dynamic model was chosen to represent the solar thermal plant. Moreover, nonlinear phenomena need to be represented. For example, power terms are written as the product of a flow rate and a temperature, which are both important to characterize the solar thermal plant operation. Hence, a nonlinear model was chosen. Since the optimization methodology will be tested on a simulation model, both an optimization and a simulation models are necessary. Both models are similar but some additional simplifying assumptions are made in the optimization model to keep the computational time low, as presented hereafter. The model for the solar thermal plant was developed in [4] and the main equations are detailed below, as well as some simplifying assumptions made to the original model.

2.2.1. Solar field

The solar field in this work is modeled as a single equivalent solar panel, with a total area A_{eq} equal to the sum of the areas of all the flat plate collectors in the solar field. The original model in [4] represented an equivalent loop of the solar field but considering a single equivalent solar panel speeds up the calculations without deteriorating the accuracy of the model significantly [12]. No spatial discretization of the collector and no heat losses between the collectors within a loop are considered. Moreover, the fluid distribution is assumed uniform between the loops. The equation modeling the solar field is the one node capacitance model written for the equivalent solar panel as follows:

$$\frac{\dot{Q}_{SF}}{A_{eq}} = \left(\eta_{0,b}(\eta_{sh}K_b(\theta)G_b + K_d G_d) - c_1(T_{mean} - T_{amb}) - c_2(T_{mean} - T_{amb})^2 - c_5\frac{dT_{mean}}{dt}\right) \quad (1)$$

This energy conservation equation allows us to calculate the mean temperature T_{mean} inside the solar field, taking into account the heat gain from the solar irradiance, using both the direct irradiation G_b and the diffuse irradiation G_d in the plane of the collectors, the heat losses to the ambient at the temperature T_{amb} and the equivalent inertia of the collectors. $\dot{Q}_{SF}$ is the power transmitted from the sun to the heating fluid in the solar field. $\eta_{0,b}$, c_1, c_2, c_5, $K_b(\theta)$ and K_d characterize the solar collectors and are provided by the manufacturer. $\eta_{0,b}$ is the optical efficiency of the collectors, c_1 is the heat loss coefficient in the collector at $T_{mean} = T_{amb}$, c_2 is the temperature dependence of the heat loss coefficient, c_5 is the effective thermal capacity, $K_b(\theta)$ is the incidence angle modifier for the direct irradiation and K_d is the incidence angle modifier for the diffuse irradiation. η_{sh} represents the reduction in efficiency due to the shading effect. The outlet temperature of the solar field is computed assuming a linear temperature distribution in the collectors. This simplified model can represent the transient behavior of the solar field in a short computational time.

2.2.2. Storage tank

The storage tank is modeled in 1D, only the variations of the temperature along the vertical axis are considered. The storage tank is divided into N layers of same height Δz. The temperature inside each layer is assumed uniform. The energy balance can be written for each layer i, numbered from 1 at the bottom of the tank to N at the top, composed of the stored fluid and the tank wall assumed in thermal equilibrium:

$$\rho C_p A \Delta z \frac{dT_i}{dt} = US_l * (T_{amb} - T_i) + \frac{k^* A}{\Delta z}(T_{i-1} - 2T_i + T_{i+1}) + \dot{m}_{charge}C_p(T_{i+1} - T_i) + \dot{m}_{discharge}C_p(T_{i-1} - T_i) \quad (2)$$

T_i is the temperature of the layer i. The charging flux enters the top of the tank at the temperature T_{charge} and flow rate $\dot{m}_{charge}$ while the return flow enters the bottom of the tank at the temperature T_{return} and flow rate $\dot{m}_{discharge}$. C_p is the specific heat capacity of the water only because the mass of water is larger than the mass of metallic wall and the heat capacity of the metal is smaller than the heat capacity of water. ρ is the fluid density. k^* is the effective conductivity of the fluid and the tank wall, because conduction through the wall participates in destratification of the tank fluid. Heat losses between each layer and the ambient air at T_{amb} are computed with an overall heat transfer coefficient U. The exchange surface is the lateral surface of a tank layer S_l. For the top and bottom layers, the exchange surfaces and heat transfer coefficients are different than for the interior layers.

The number of layers used in the model has a great impact on the accuracy of the vertical temperature profile computed, as shown in [13] for example. The effect of numerical diffusion tends to smooth the temperature profile when a small number of layers is chosen. However, a larger number of layers increases the computational time. For the accurate simulation model used in this work to test the methodology, 1000 layers are chosen. For the optimizations, a simplified model is required to ensure reasonable computational times. Hence, only 10 layers are used, similarly to [4].

One phenomenon not represented in Eq. 2 is the natural convection. When solar irradiation goes down, at the end of the day for example, it happens that the solar heat produced is at a temperature lower than the one achieved earlier in the day. Nevertheless, its temperature is still high enough for the consumer needs. Hence, this lower temperature heat can be charged and will arrive on top of warmer stored fluid. Due to buoyancy forces, the lower temperature fluid will sink inside the tank and exchange energy with the surrounding stored fluid. This phenomenon was neglected in the optimization model for simplicity and to reduce computational time [13]. For the simulation model, the temperatures inside the tank are regularly re-organized to ensure that the top of the tank is the warmest zone and the bottom of the tank is the coldest [14].

2.2.3. Heat exchangers

The two heat exchangers are the same, both plate heat exchangers with 97 plates of 1.5m^2 each. The model used for the heat exchangers is simple to keep the computational time low: no spatial discretization, no accumulation and no heat losses are considered. The ϵ-NUT model is used to compute the exchanged energy and the two outlet temperatures. A constant global heat transfer coefficient is chosen, $U = 4000 W.m^{-2}.K^{-1}$, to reduce the nonlinearities in the model.

2.2.4. Pipes

Each pipe in the system is modeled by developing the energy balance equation in 1D without spatial discretization but considering accumulation in the fluid. Heat losses are computed with either circulating fluid or static fluid. A thermal resistance is calculated to account for external convection and conduction through the insulation layer. The external convection coefficient is computed using Hilpert correlation. Internal convection and conduction through the wall are not modeled because we assume a very large heat transfer coefficient and thus a perfect heat transfer. For the mixing valves and the flow divisions, the mass and energy balances are developed neglecting the accumulation and heat losses.

2.2.5. Pumps

Part of the operational cost of the solar thermal plant is the electricity consumption of the variable speed pumps used to move the fluid in the different circuits of the plant. First, the maximum pumping power $\dot{P}_{hydrau}$ is computed with Eq. 3, when the pressure drop in the circuit is the highest ΔP_{max}, which corresponds to the maximum flow rate allowed in the pump $\dot{m}_{max}$. Then, the actual flow rate in the circuit $\dot{m}$ is used to compute the electric power $\dot{P}_{elec}$ with the overall efficiency η_{pump} of the pump in Eq. 4.

$$\dot{P}_{hydrau} = \frac{\dot{m}_{max}}{\rho} \Delta P_{max}(\dot{m}_{max}) \quad (3) \qquad \dot{P}_{elec} = \frac{\dot{P}_{hydrau}}{\eta_{pump}} \left(\frac{\dot{m}}{\dot{m}_{max}} \right)^3 \quad (4)$$

2.2.6. Representation of the various operating modes

The complete solar thermal plant model is built by connecting the models for the solar field, storage tank, heat exchangers, pipes and pumps. The difficulty of modeling a solar thermal plant operation is the existence of various operating modes depending on the heat demand, the state of the system and the environmental conditions. Sigmoid functions are used to represent the existence of a flow in an element with a continuous formulation, allowing to neglect very small flow rates that would not be implementable in the real plant (if the flow rate is near zero, the sigmoid function is 0, otherwise it is 1). A sigmoid function is expressed as follows, with β characterizing the steepness of the function and δ the threshold:

$$sig(x) = \frac{1}{1 + exp^{-\beta(x-\delta)}} \quad (5)$$

For example, this is necessary to represent the heat exchangers through which heat can be transferred. Big M formulations are used to represent the existence of an exchanged power $\dot{Q}_{hx}$ or not, in the optimization model. If the flow rate in the heat exchanger is negligible (for example lower than $\delta = 0.5 kg.s^{-1}$), then the exchanged power is zero, otherwise it is computed with the ϵ-NUT model, with ΔT_e the difference between the inlet temperatures on each side. This is expressed as follows, with M a scalar to adjust (10^8 here) :

$$-M\ sig \leq \dot{Q}_{hx} \leq M\ sig \quad (6)$$

$$-(1 - sig)M + \epsilon(\dot{m}C_p)_{min}\Delta T_e \leq \dot{Q}_{hx} \leq (1 - sig)M + \epsilon(\dot{m}C_p)_{min}\Delta T_e \quad (7)$$

If no energy is exchanged in the heat exchanger, the outlet temperature is equal to the inlet temperature on each side. These continuous formulations allow us to represent the different working modes of the solar thermal plant. In particular, the night mode when the solar circuit is shut down and no heat is transferred in heat exchanger 1, or a mode where no solar heat is supplied to the consumer through heat exchanger 2 because the storage tank is empty and the solar irradiation is too low.

3. Input data

The study is conducted for the city of Trappes (78), France (48° 46' 39.0000" N, 2° 0' 9.0000" E). In addition to the design parameters of the system, described in Section 2., the environmental conditions and the heat demand are the inputs of the model.

3.1. Weather data

Weather forecasts as well as meteorological measurements were provided by Météo-France for the whole year of 2021 at this location. The parameters of interest are the Global Horizontal Irradiance (GHI), the Direct Normal Irradiance (DNI), the ambient temperature and the wind speed (which impacts the convection coefficient used to compute the heat losses). The weather forecasts are computed with the ARPEGE model and updated every 6 hours. Their time horizon varies depending on the run: 103h for the run at 12am, 73h for the run at 6am, 103h for the run at 12pm and 61h for the run at 6pm. Hourly values are provided for each parameter. The forecasts will be used in the optimization algorithm, to determine the best operational strategy of the solar thermal plant for a given time horizon. The same 4 parameters are measured every hour with a meteorological station. The measurements differ from the forecasts and will impact the actual solar thermal plant operation.

3.2. Heat demand

The consumer considered in this work is a District Heating Network (DHN) supplying heat to a residential area. In a DHN, the heat demand varies throughout the day and throughout the year. It is not easy to find available public data on the heat consumption of a DHN. Moreover, the solar thermal plant considered should be sized accordingly for the specific DHN it supplies the heat to. To simplify this case study, the same daily heat demand profile is considered for every day of the year. The real heat demand would be greater in winter than in summer due to the space heating need. The daily profile has been created in order to be consistent with the specific solar thermal plant considered. The general shape of the daily profile was retrieved from [15]. We chose that the storage tank from the solar thermal plant can supply heat to the DHN for two days when it is full. The heat demand values were then adjusted accordingly. The daily heat demand profile created is presented in Fig. 2. We observe a peak in the heat demand around 8am, and the demand is the lowest around 4pm.

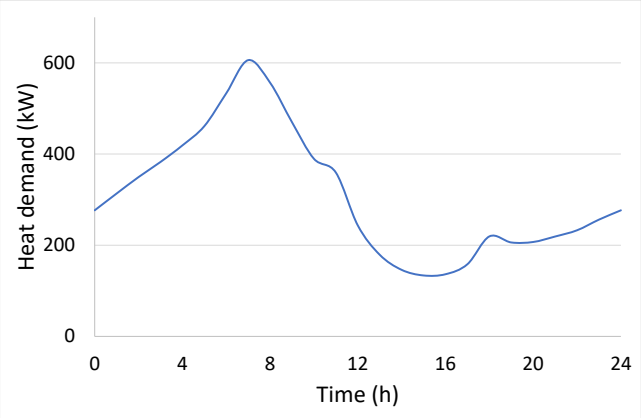

Figure 2: Daily heat demand

We consider that the DHN return temperature $T_{DHN\ return}$ is at 55°C, so the consumer inlet flow in Fig. 1 enters the heat exchanger 2 at 55°C. The target temperature T_{target} for the consumer flow after collecting the solar heat is 65°C. The flow rate of the consumer flow is variable depending on the heat demand, according to the following equation:

$$\dot{Q}_{demand} = \dot{m}_{consumer} * Cp * (T_{target} - T_{DHN\ return}) \quad (8)$$

$T_{DHN\ return}$ and $\dot{m}_{consumer}$ are both inputs of the system. The outlet temperature on the consumer side of heat exchanger 2 is calculated and should be as close as possible to T_{target} without ever exceeding it.

The variable heat demand is considered perfectly known in this work. No disturbance in the heat demand is introduced even though the methodology could be applied to an uncertain heat demand similarly to the uncertain weather conditions presented in subsection 3.1..

4. Optimization methodology

4.1. Two-level Algorithm

As explained in Section 1., the optimization methodology developed is composed of two hierarchical optimization layers to improve storage management. The methodology is tested in real-time on a simulation model, receiving the optimal trajectories and simulating the solar thermal plant actual behavior. The two-level optimization algorithm is presented in Fig. 3. The initial state of the system is that all temperatures are equal to the ambient temperature and the storage tank is half charged. The first step is the planning phase, which will be described in more details in Subsection 4.2.. It is an economic dynamic optimization that will optimize the operation of the solar thermal plant based on weather forecasts. As presented in Section 3., the longest time horizon for the weather forecasts obtained is 103 hours at 12am. Hence, the planning phase is implemented over 103 hours, starting at 0:00. The simulation model follows the optimal trajectories from the planning phase for the next 6 hours, since no weather forecast update is available. Then, the DRTO starts. Every 6 hours, a new weather forecast is available so a new DRTO is run to determine updated optimal trajectories for the next 12 hours. The DRTO economic objective function incorporates the planned storage state at the end of the DRTO time horizon. Planning is therefore used for storage management. Details on the DRTO will be provided in Subsection 4.3.. Between each DRTO run, the behavior of the system is simulated with the actual weather over the 6 hours before an update, and the simulation provides feedback to the DRTO algorithm. Details on the simulation are given in Subsection 4.4.. The complete simulation ends after 96 hours because no planned storage state is available for the next DRTO run. In a real implementation, this algorithm would be repeated continuously to optimize the operation of a solar thermal plant throughout the year, with a new planning computed regularly. In this work, the methodology was only tested for 96 hours.

4.2. Planning

The planning phase, which is an offline economic dynamic optimization follows the method developed in [4]. The degrees of freedom in the system are the 6 independent flow rates in the solar thermal plant at each time instant. The time discretization of the dynamic model for optimization is done with orthogonal collocation on

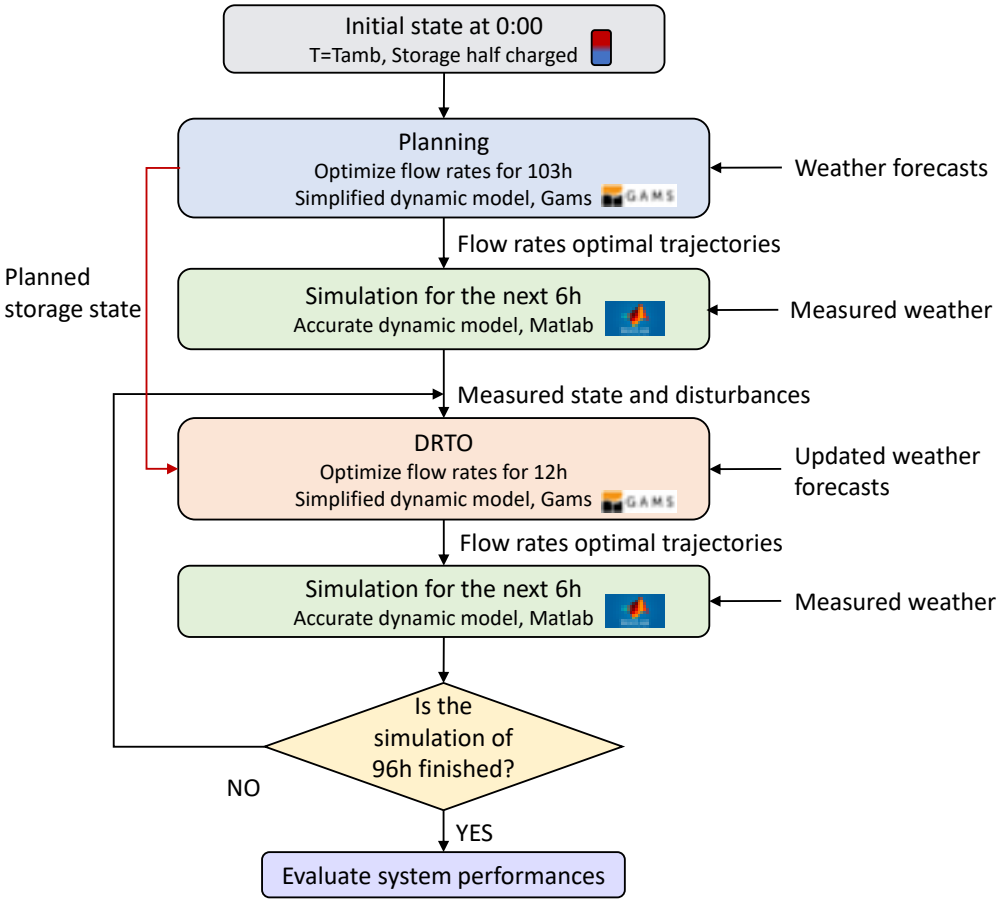

Figure 3: Two-level optimization algorithm

finite elements, with 1 hour long elements containing 9 collocation points each. The constraints in the dynamic optimization are the following:

- $T \leq 95°C$ for all temperatures T
- The flow rate in each pump is defined as follows:

$$\begin{cases} \dot{m} = 0 \text{ (corresponding to the pump turned off)} \\ \text{or} \\ 0.3\dot{m}_{max} \leq \dot{m} \leq \dot{m}_{max} \text{ (corresponding to the pump turned on, with } \dot{m}_{max} \text{ determined by the pump specifications)} \end{cases}$$

- $T_{consumer\ out} \leq T_{target}$ forbidding the heat supply to exceed the heat demand ($T_{consumer\ out}$ is the temperature of the consumer stream after collecting the solar heat)

The objective function to be minimized is the operating costs of the solar thermal plant, which are the electricity consumption of the pumps and the gas consumption of the back up burner. It includes the maximization of the stored energy at the end of the time horizon since it represents useful energy for the next hours and will allow to cut down the gas consumption. An additional term is added to smooth the trajectories obtained for the flow rates Φ_{var} and is affected by a weight γ_{var} that needs to be adjusted to achieve a good compromise between smooth flow rates trajectories and a good economic objective OF_{eco}. The formulation of the dynamic optimization problem is presented hereafter:

$$\min_{free\ \dot{m}} OF_{eco} - \gamma_{var}\Phi_{var}, \text{ with} \tag{9}$$

$$OF_{eco} = -GasPrice \int_0^{t_f} \dot{Q}_{gas}(t)\mathrm{d}t - ElecPrice \int_0^{t_f} \dot{P}_{elec}(t)\mathrm{d}t + 0.7 HeatPrice\ E_{stored}(t = t_f) \tag{10}$$

The prices used are the following: $GasPrice$ = 80€/MWh, $ElecPrice$ = 130€/MWh and $HeatPrice$ = 25€/MWh. The benefits associated to the stored energy are affected by a weight of 0.7 found appropriate in [4]. This

weight represents the decrease in energy quality between the moment it is stored and the moment it will be supplied. This dynamic optimization is solved with the NLP solver CONOPT in the software GAMS. The optimization is initialized with standard operating strategies ensuring that the local optimum found by CONOPT is implementable on the real plant. The planning phase takes around 2 hours to converge to an optimal solution on a laptop with the following characteristics: Intel Core i7-1065G7 1.3GHz. The stored energy throughout time determined during this planning phase will be passed to the next optimization level.

4.3. DRTO

The DRTO is also an economic dynamic optimization and is built similarly to the planning phase. Only the differences with the planning phase are presented hereafter. The time discretization is the same as planning but the time horizon is much shorter: 12 hours. With this time horizon, the methodology is applicable in real-time with a maximum computational time of 10 minutes for a DRTO on the same laptop. The economic objective function is also the same as the planning phase except for the term on the storage. In the planning phase, the stored energy at the end of the time horizon is maximized because it will be useful in the future. For the DRTO, the aim is to follow the plan established previously based on a long term strategic vision and weather forecasts. Hence, the difference between the planned stored energy and the actual storage state at the end of the DRTO time horizon is minimized. The difference is multiplied by the price of gas to obtain the order of magnitude of the cost of the non-respect of the plan, since the energy which should have been stored but was not will be replaced by gas. Finally, this term is affected by a weight ω which has been adjusted in [16] to obtain a good compromise between the following of the plan and the lowest operating costs. The value of 0.5 was chosen. This term is written as follows:

$$\omega.GasPrice.|E_{stored\ planning}(t = t_{f\ DRTO}) - E_{stored\ DRTO}(t = t_{f\ DRTO})| \tag{11}$$

Each DRTO run starts with an initial state retrieved from the simulation model, as explained in the next subsection.

4.4. Simulation

The online methodology needs to be tested on an actual plant. In this work, we replace the actual plant with a simulation performed with the solver ode15s in MATLAB. In the simulation model, perfect control is assumed so the controllers are not modeled and we assume that the optimal trajectories are perfectly tracked. The simulation model provides feedback to the DRTO algorithm. We assume that all states are measured and no state estimation step is included in the methodology. The simulation model undergoes the actual weather. It uses a more precise model for the storage tank, as explained in Subsection 2.2.2.. Since the DRTO algorithm regularly starts over with the actual system state, model error propagation due to the simplifying assumptions in the optimization model is mitigated.

5. Case study

The methodology was tested for one case study in Trappes in 2021, using the meteorological data from Météo-France. The period from the 12^{th} to the 15^{th} of May was chosen because the solar irradiance was not well predicted for this period, as shown in Fig. 4.

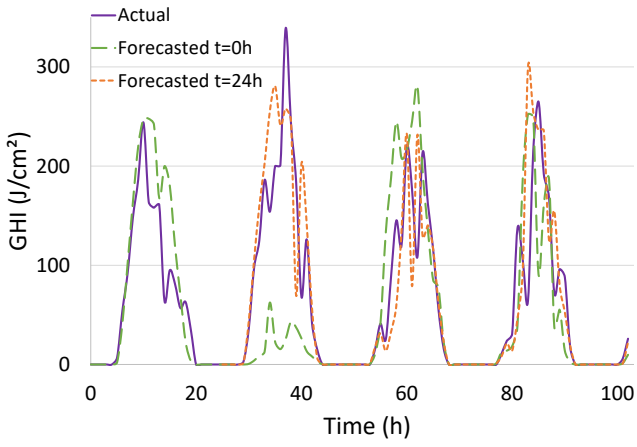

Figure 4: Predicted and actual solar irradiance for the test period in May

In this figure, the forecasted GHI plotted in dashed green line is the one used for the planning phase, at the beginning of the algorithm, while the solid purple line corresponds to the measured GHI. The solar irradiance was greatly underestimated for the second day. Forecasts are updated every 6 hours, and this underestimation is corrected in the next forecasts, which are used at the DRTO level. For example, the forecasted GHI at 24 hours is plotted in dotted orange line in Fig. 4. This forecasted GHI is closer to the measured GHI for the second day than the one predicted at 0 hours. The solar irradiation is quite variable during these four days, and the fast variations during the day are not perfectly estimated even a few hours in advance. Only the GHI was shown in Fig. 4 but a similar analysis can be conducted for the DNI.

The forecasts for the wind speed and ambient temperature are also uncertain but the differences between

forecasted values and measurements are not as large and these parameters do not impact the solar thermal plant operation as significantly as the GHI and DNI.

6. Results

6.1. Comparison between planning only and planning with DRTO

In order to assess the performances of the methodology developed, it will be compared with offline dynamic optimization (DO) without real-time adjustment, for the case study presented previously. Fig. 5 shows the comparison made.

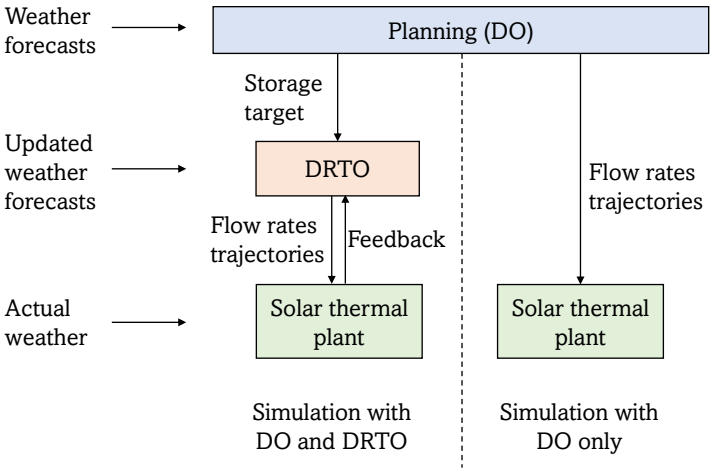

Figure 5: Comparison of simulations based on DO with DRTO and DO only

On one hand, our DRTO methodology is tested in a simulation undergoing the actual weather. The planning phase is used for storage management only, using weather forecasts. The simulation follows the optimal trajectories determined by the DRTO and regularly updated using updated forecasts. This is presented on the left side of Fig. 5. On the other hand, a simulation following the optimal trajectories determined during the planning phase (DO) is performed, with no update in the trajectories during the whole simulation undergoing the actual weather. This corresponds to the right side of Fig. 5. It was shown in the literature that offline dynamic optimization outperforms standard control strategies based on logic control rules [4]. In this section we show the interest of having real-time updates of the optimal trajectories.

6.2. Outputs

The results from the two simulations presented in the previous paragraph are compared. In Fig. 6, the flow rates in the solar field are plotted. The solid blue line corresponds to the flow rate determined during the planning phase (DO), without any update. The dash-dotted red line corresponds to the flow rate determined with our DRTO methodology. This curve is composed of sixteen portions, each six hours long, and determined by a new DRTO call. In Fig. 6, the flow rate determined by DO is zero for the second day. This is because a very low solar irradiation was predicted for that day, as shown in Fig. 4. When using our DRTO methodology, the flow rate determined during the second day is not zero because the updated weather forecasts used for the DRTO predicted a solar irradiation high enough for solar heat production. This shows that the DRTO allows the modification of the optimal trajectories when the weather forecasts are corrected.

Fig. 7 presents the temperature of the consumer stream after collecting the solar heat, $T_{consumer\ out}$, achieved for both simulations. It should be greater than the return temperature of the DHN of 55°C but lower than the target temperature of 65°C. We observe in Fig. 7 a few occurrences of a temperature lower than the DHN return temperature. This might be due to a sudden release of solar heat after a period with no supply from the source (either direct supply of from the storage). The pump is turned on but the temperature of the fluid inside the pipe has decreased due to heat losses. It takes a little time before the warm fluid reaches the second heat exchanger. There are also periods with a temperature exceeding the target temperature. For example, the temperature for DO on day 4 is much larger than 65°C. This is because the solar irradiation for this period was greatly underestimated, as shown in Fig. 4. The forecasted GHI presented a sudden decrease around hour 85 but the GHI measured actually presented a peak at that time. Hence, the operating strategy determined during planning led to exceeding the heat demand. On day 2, the solar irradiation was also greatly underestimated for the DO calculations. However, the heat demand was not exceeded on this day because the solar irradiation predicted was too low to start collecting solar heat and the storage tank was already empty at that time. Hence, the complete solar thermal plant was shut down, no solar heat was supplied and the

demand was thus not exceeded. However, for DRTO, the solar thermal plant was operated on day 2, delivering solar heat to the consumer. The heat demand was exceeded for part of the day because the updated forecast for the solar irradiation, although more accurate than the one used for planning and determined earlier, still underestimated the actual solar irradiation. In a real system, this behavior would be prevented thanks to local controllers forbidding to exceed the heat demand. Since our simulation model did not include controllers, nothing prevented the temperatures to go high. Adding the local controllers to our simulation model could improve the methodology before it can be tested on an actual plant. In order to avoid an optimal operating strategy that could lead to overheating, more frequent re-optimizations should be employed, based on more accurate forecasts. However, this requires access to updated forecasts very regularly. In this work, we were limited in the frequency of our DRTO runs because the weather forecasts were provided every six hours. Accurate forecasting of solar irradiation is an active area for research and new methods are developed. For example, sky imagers provide regular forecasts accounting for local clouds, or machine learning could help recomputing forecasts regularly. Figs. 6 and 7 showed that DRTO can adapt the optimal operating strategy to the actual conditions, thanks to regular re-optimizations using updated forecasts. In the next paragraph, the performances of the solar thermal plant in the two simulations are compared.

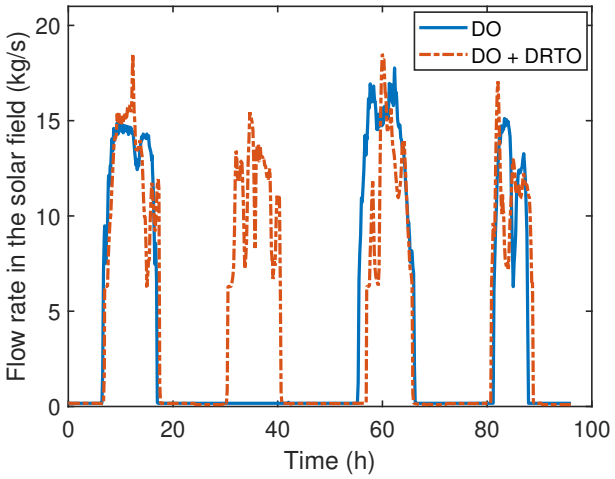

Figure 6: Comparison of the flow rates in the solar field

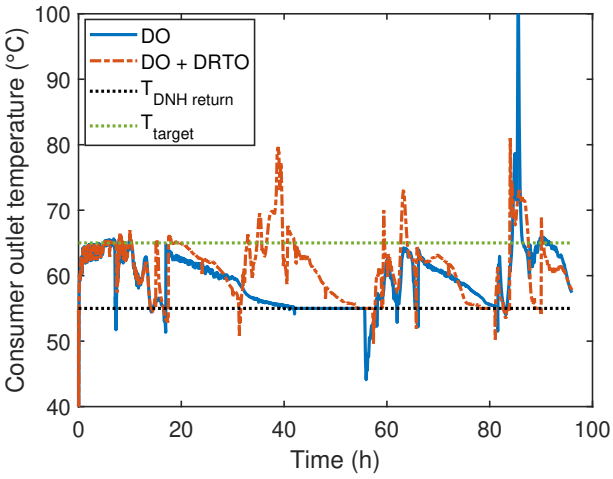

Figure 7: Comparison of the temperatures at the outlet of the consumer stream

6.3. Performances

The performances of the solar thermal plant are determined using several indicators:

- $E_{supplied}$ corresponds to the quantity of solar heat supplied at a temperature lower than the target temperature. This should be as high as possible to reduce gas consumption.
- E_{excess} corresponds to the quantity of solar heat delivered that exceeded the heat demand.
- E_{elec} corresponds to the electric consumption of the pumps.
- C_{tot} corresponds to the total operating costs of the plant (electricity and gas consumption)
- $E_{stock\ final}$ corresponds to the quantity of valuable energy inside the storage tank at the end of the simulation.

The value of each indicator for the two simulations are presented in Table 1. The total heat demand for the 96 hours of simulation is 29.8 MWh.

We observe an increase in the quantity of solar heat delivered to the consumer of about 31% with DRTO compared to DO only. This is mostly due to the solar heat supplied on the second day with DRTO, while no solar heat was produced for that day with DO. Our DRTO methodology led to more excess energy delivered in this case study, because the updated forecasts still contained inaccuracies. But this excess energy should not be delivered in a real system thanks to local controllers preventing this behavior. The electricity consumption is similar for both simulations. The total cost was reduced by 19% thanks to our DRTO methodology, because less gas was required to complete the heat demand. Finally, the quantity of energy inside the storage tank is only slightly decreased, by 1.4% of the storage capacity. However, in this case study, the storage tank is almost emptied at the end of both simulations because the solar irradiation is not very high. There is a need to study the best way to integrate storage management in the DRTO. There is probably no interest in following

Table 1: Comparison of the performances of the simulated solar thermal plant using DO only or DO+DRTO

Performance indicator	Simulation with DO only	Simulation with DO and DRTO
$E_{supplied}$ (MWh)	11.42	14.98
E_{excess} (MWh)	0.40	0.93
E_{elec} (MWh)	0.12	0.12
C_{tot} (€)	1487	1203
$E_{stock\ final}$ (MWh)	0.42	0.22

a plan determined with very inaccurate forecasts. The planning phase should be re-computed whenever the weather forecasts differ too much from the measured weather. This will be investigated in future work, with several case studies showing various levels of solar irradiation.

7. Conclusion and Perspectives

In this work, we presented a DRTO methodology using a planning phase for storage management to optimize the operation of a solar thermal plant providing heat to a DHN. The methodology was tested in a realistic case study, using real weather forecasts and measurements and a variable heat demand for four days in mid-season. The results obtained show the interest of having a real-time adaptation phase of the optimal trajectories to correct uncertainties in the weather forecasts. Thanks to DRTO, the quantity of solar heat supplied to the consumer increased, leading to a decrease in gas consumption and thus in the operating costs. The methodology developed includes the tracking of the storage state determined during the planning phase, which benefits from a better strategic vision. Thus, the DRTO is able to follow the plan while minimizing the operating costs. However, if the weather forecasts used during the planning phase are very inaccurate, following the plan is probably not optimal. A new plan should then be computed. In the mean time, a new storage management policy for the DRTO needs to be employed. Future investigations will focus on finding the best way to use the planning phase in order to improve storage management in the DRTO method. This will require testing of the methodology in various case studies.

Abstract:
The increasing energy and environmental crises require a shift in worldwide energy management, with the broader use of energy storage, and an increase in the share of renewable energy sources, in particular for electricity generation. Such a process is called energy transition. Thus, low-carbon (or green) hydrogen produced by water electrolysis from renewable electricity is one of the most promising options, since it can be used in fuel cells, with a high-efficiency operation, and without harmful emissions. Thus, this work investigates through a numerical simulation in Matlab, a cogeneration system used to supply electricity and heat demands for an on-grid residence in the city of Rio de Janeiro, Brazil. The original configuration for the hybrid combined heat and power (CHP) system is composed of photovoltaic (PV) panels, which exceeding energy feeds a proton exchange membrane electrolyzer cells (PEMEC) to produce hydrogen that is compressed and then stored. When the PV system is not able to supply the demand, the produced green hydrogen is then blended with natural gas to feed a solid oxide fuel cell (SOFC). Natural gas burner is used as an auxiliary source for heat generation when the SOFC is not operating. The energetic, exergetic, exergoeconomic, and environmental (4E) performances are assessed on a typical day of each season. Results indicate that the system can stably operate with moderate energy and exergy efficiencies for both the SOFC and PEMEC. Blending hydrogen with natural gas also allow a reduction of CHP specific emissions. The high availability of unused heat also strongly suggests the addition of an absorption chiller to increase the global system efficiency.

1. Introduction

The demand for low environmental impact and renewable power sources is steadily increasing. Thus, there is a growing installed capacity of power generation from renewable resources, particularly wind turbines (WT) and photovoltaic panels (PV), which are widely adopted. During the day, PV systems convert incident solar radiation into electricity, while WT systems harness the wind's favorable conditions to rotate the blades and produce electricity. Combining these two systems offers a viable solution for enhancing the reliability of power generation, even though they increased the complexity of the grid management. Since both PV and WT are intermittent energy sources, it is crucial to incorporate a storage system to enhance overall efficiency and provide the demand during the whole day. Hydrogen emerges as a promising alternative due to its high energy density in weight basis, minimal energy loss, well-established technology, on-site provision capability, and reliability comparable to conventional fuels such as coal, nuclear, and natural gas [1]. Among the most promising methods for hydrogen production is water electrolysis, while the current predominant approach involves fossil fuel conversion (mainly by steam reforming of natural gas). The resulting hydrogen, known as green hydrogen, has emerged as a potential solution for future decarbonization efforts [2].

Additionally, the interest in efficient technology that offers a wide range of useful energy products and services, such as polygeneration, is increasing significantly. Polygeneration system involves an integrated process that produces multiple energy outputs from a single energy source. Among the possible technology, the fuel cells are energy conversion devices that play a key role in generating electricity through an electrochemical reaction between a fuel (mainly hydrogen) and an oxidant. This direct conversion of chemical energy into electricity eliminates the need for a combustion process. Significant attention has been directed towards Solid Oxide Fuel Cells (SOFC) due to their superior efficiency, long-term stability, and low emissions during operation. Operating at high temperatures (ranging from 650 to 1000 °C), SOFCs enable the reforming process to occur within the cell itself. This allows the SOFCs to be fed with natural gas and remove the need to reduce the carbon monoxide content of the reformate, making them an excellent choice for cogeneration, trigeneration, and multigeneration applications [3]. Numerous studies have examined the feasibility and thermal performance of SOFCs within complex systems. In trigeneration systems, where electricity generation is the primary function of SOFCs, previous studies have observed the utilization of heat exchangers to recover exhaust gas heat, along with refrigeration systems (typically with absorption chillers) to provide cold demand [4–7]. Parameters such as current density [4,7–16] and SOFC operating temperature [4,8–10,14,17] have been extensively investigated in the literature. Furthermore, some studies have conducted exergoeconomic evaluations of the system [9–16,18], while a few have undertaken environmental analyses [10,12,14,18].

Many studies have focused on the utilization of electrolysis to produce hydrogen. Among the electrolyser technologies, the polymer electrolyte membrane electrolyser (PEMEC) is the most widely used in the recent projects and the literature showed that it is adaptable for integration with different systems. The advantage of PEMEC is its rapid response, making it suitable for transient conditions, while producing high-purity hydrogen at relatively low temperatures (around 50 to 90°C) [19]. Literature reviews have demonstrated the integration of PEMEC in systems that harness renewable resources [20–23]. Similarly to SOFCs, the process parameters investigated for the optimization of the PEMEC operation include current density [20,22,24] and operating temperature [21–23].

Even though the renewables reached 44.7% of the energy mix, with sugarcane biomass and hydroelectricity accounting for the largest shares at 16.4% and 11% respectively, a recent study examining the Brazilian energy matrix highlighted a decline in the contribution of renewable energy sources due to water scarcity and an increased reliance on thermoelectric plants. Despite solar and wind power having a smaller share at 2.5% and 10.6% respectively, they experienced significant year-on-year increases of 55.9% and 26.7%. In terms of energy consumption, the residential sector accounted for approximately 10.9% of Brazil's energy use, while the transport and industrial sectors combined represented a consumption of 64.5%. The installed capacity for energy generation demonstrated an overall increase of 3.9%, with solar and wind power leading the growth at 40.9% and 21.2% respectively. In the realm of micro/mini distributed generation, solar power witnessed a remarkable 88.3% increase compared to the previous year [25].

Regarding hydrogen in the country, the Energy National Plan 2050 (PNE 2050) recognizes hydrogen as a disruptive technology and a crucial element for the decarbonization of the energy matrix. The plan highlights the diverse uses and applications of hydrogen and provides recommendations for energy policies to promote the development of the chain values, including production, transport, storage, and consumption, in the country. Key guidelines include assessing opportunities for blue hydrogen production from natural gas and green hydrogen production using renewable energy sources, called “rainbow” approach. Additionally, the plan emphasizes exploring the production of hydrogen from biofuels (bioethanol, biomethane and glycerine) and using existing infrastructure for the transition, such as incorporating hydrogen into the natural gas pipeline network [26,27]. The integration of hydrogen into natural gas has the potential to enhance the role of natural gas, abundant in the Pre-salt fields, as a low-carbon transition fuel while simultaneously scaling up hydrogen production, particularly from renewable sources [2].

As demonstrated earlier, there are a limited number of studies in the literature that conduct a energetic, exergetic, economic, and environmental (4E) analysis of a cogeneration system. Furthermore, no research has been found that specifically examines the impact of seasonality on a hybrid system that integrates renewable power generation and consumption using both PEMEC and SOFC technologies. Although the share of solar power is not so expressive into the Brazilian energy matrix, its growth is noticeable, along with an increasing interest for hydrogen production. In light of these factors, this study aims to evaluate a hybrid combined heat and power (CHP) system with green hydrogen storage in Rio de Janeiro, Brazil. The evaluation focuses on a typical day from each season for a residential building. An hourly-based analysis is performed, considering the electricity and heat demand of a standard building. The study specifically assesses the energetic, exergetic, exergoeconomic, and environmental aspects of the system through a comprehensive 4E analysis. To achieve this, various parameters are examined, including system efficiencies, carbon dioxide emission rates, cost per unit of exergy, and the exergoeconomic factor. The aim is to provide a thorough understanding of the system's performance and quantify its impact in terms of energy, exergy, economics, and the environment.

2. System description

The representation of the hydrogen storage system is shown in Figure 1. A renewable module comprised of a set of photovoltaic panels in series and parallel is responsible for extracting energy from the sun and supplying an electric demand. If there is a surplus of power in this process, the system operates in what is called the generation mode, otherwise, if there is a shortage, it works in the consumption mode. In the first mode, the surplus energy from the renewable module is used to supply power for an electrolyzer which together with water, generates green hydrogen and oxygen. The hydrogen is compressed into a pressurized tank, to be later used in any case of need. To supply the heat demand, a natural gas burner is triggered. For the other mode of operation, hydrogen from the tank is withdrawn and goes through the expansion valve to be mixed with natural gas and then preheated in a heat exchange before entering the reformer. Water is also preheated before entering the reformer, and after the reforming process, the products and a preheated air feed the solid oxide fuel cell for the electrochemical process. The generated electricity passes through the inverter priorly to being supplied to the final user. The depleted fuel and air from the SOFC go into an afterburner for complete combustion of carbon monoxide, methane, and hydrogen, and the exhaust gases are used for preheating the mixture (hydrogen-natural gas), water, and air. Then, the exhaust gases pass by a heat exchanger to supply the user’s heat demand. This module consists of a hot tank, a pump, and a pair of heat exchangers (exhaust gas and hot water). The tank is assumed to be sufficiently large to be considered isothermal. Finally, the hot exhaust gases from the afterburner are cooled down to ambient temperature.

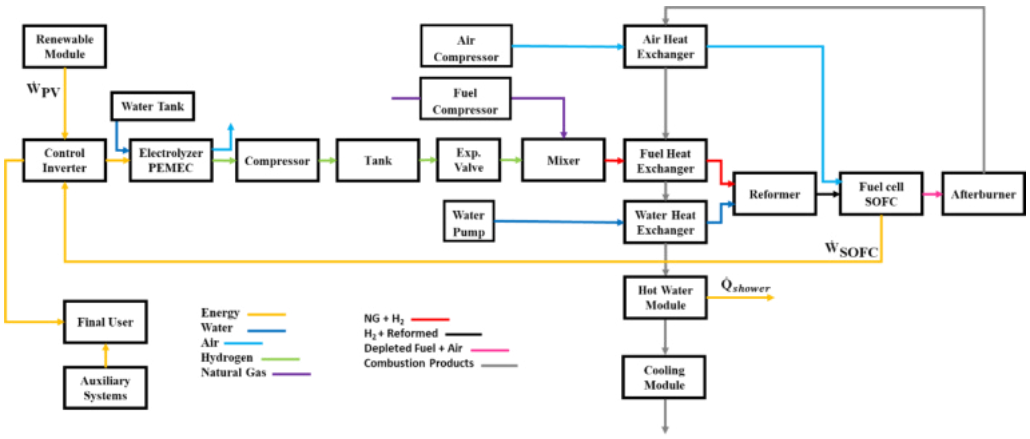

Figure 1. Schematic representation of the hydrogen storage system.

For this system's simulation, a steady-state condition under thermodynamic equilibrium is assumed for each investigated instant of time. All components are assumed to be well insulated, thus no heat loss from equipment to the environment is considered. Compressors and pumps operate with isentropic efficiency equal to 0.85, and the heat exchangers have a constant efficiency during operation of 0.9 with no pressure drop. The mixing chamber, reformer, natural gas burner, and afterburner operate at constant pressure, and their outlet species composition and temperature are calculated using energy and mass balance. The inverter has a constant efficiency of 0.95. All gases are treated as an ideal gas, dry air composition is considered 21% O_2 and 79% N_2, and natural gas is considered as pure methane. The compressed hydrogen is stored at 300 bar and ambient temperature. The properties of all fluids are based on the Peng-Robinson equation of state, having as reference state for gases temperature at 298.15 K and 0.101325 MPa.

3. Modeling

This section focuses on displaying the main equations for the system's components. The extensive equating can be found in Appendix A, and the parameters for the system in Appendix B [28].

3.1. Renewable module: photovoltaic panels (PV)

This module consists of a combination of photovoltaic panels producing electric power at an optimized current and voltage [29,30]. This system's performance presents a non-linear current-voltage curve, Eq. (1):

$$I=I_L-I_0\left(\exp\left(\frac{q(V+IR)}{\gamma k T_{cell}}\right)-1\right) \quad (1)$$

The panels are set to work at maximum power output adjusting both voltage and current to reach such conditions

3.2. Proton exchange membrane electrolyzer (PEMEC)

A proton exchange membrane electrolyzer is used to generate hydrogen using the surplus energy from the renewable module. The rate of the produced hydrogen is defined by a function of the current density and number of electrolyzers considered, Eq. (2) [5,31]:

$$\dot{n}_{H_2}=\eta_f\frac{NI}{2F} \quad (2)$$

The actual voltage of the electrolyzer is defined by a function of its reversible voltage and losses, Eq. (3) [11,32]:

$$V=V_0+V_{act}+V_{ohm} \quad (3)$$

3.3. Solid oxide fuel cell (SOFC)

The amount of hydrogen entering the anode in the electric reaction of the solid oxide fuel cell is also described by the current density operation, Eq. (4) [33]:

$$\dot{n}_{H_2}=\frac{JA\,(1-r+rU_f)n}{2\,F\,U_f} \quad (4)$$

The process for calculating the inlet on the cathode side and the outlet of both the anode and cathode are described in Colpan et al. [33].

The actual voltage of the solid oxide fuel cell is described in Eq. (5) [4,11,32]:

$$V=V_0-V_{act}-V_{ohm}-V_{conc} \quad (5)$$

3.4. Reformer

Fuel reforming reactions allow the conversion of fuel (natural gas blended with hydrogen into another one through a catalytic reaction, from a less active one into one more active. Thermodynamic equilibrium is assumed for the considered chemical reactions and described by the general equilibrium constant, Eq. (6):

$$K_{e,i} = \prod_i x_i^{v_i} \left(\frac{P}{P_0}\right)^{\sum_i v_i} \quad (6)$$

3.5. 4E analysis

Such analysis comprehends assessing the components, and the whole system, as control volumes through an energetic, exergetic, exergoeconomic, and environmental point of view. To do so, mass, energy exergy, and cost balances are considered, Eqs. (7-11) [34]:

$$\sum \dot{m}_o = \sum \dot{m}_i \quad (7)$$

$$\dot{Q} - \dot{W} = \sum_o \dot{m}_o h_o - \sum_i \dot{m}_i h_i \quad (8)$$

$$\dot{E}_D = \sum_j \left(1 - \frac{T_0}{T_j}\right) \dot{Q}_j - \dot{W} + \sum_i \dot{m}_i e_i - \sum_o \dot{m}_o e_o \quad (9)$$

$$\sum \dot{C}_i + \dot{C}_q + \dot{Z} = \sum \dot{C}_o + \dot{C}_w \quad (10)$$

$$\dot{C} = c\dot{E} \quad (11)$$

Table B.1 displays the capital equation of each component [28].

The environmental analysis considers the amount of carbon dioxide emitted during the system operation, through the combustion of natural gas and the depleted fuel of the solid oxide fuel cell, and its mitigation due to the addition of hydrogen in the blend with natural gas.

The electric and thermal efficiencies of the system are used to assess the system's performance. They are described as follows in Eqs. (12-15):

$$\eta_{ele,gen} = \frac{\dot{P}_{dem} + \dot{m}_{H_2} LHV_{H_2} + \dot{W}_{c,H_2}}{\dot{W}_{PV} + \dot{W}_{c,H_2}} \quad (12)$$

$$\eta_{ele.con} = \frac{\dot{P}_{dem} + \dot{W}_{c,all} + \dot{W}_{p,all}}{\dot{W}_{PV} + \dot{W}_{Grid} + \dot{m}_{H_2} LHV_{H_2} + \dot{W}_{c,all} + \dot{W}_{p,all}} \quad (13)$$

$$\eta_{ther,gen} = \frac{\dot{Q}_{dem}}{\dot{Q}_{bu}} \quad (14)$$

$$\eta_{ther,con} = \frac{\dot{Q}_{hxc,all} + \dot{Q}_{dem}}{\dot{Q}_{hxh,all} + \dot{Q}_{ts} + \dot{Q}_{rh} + \dot{Q}_{bu}} \quad (15)$$

For the exergoeconomic evaluation, the exergoeconomic factor, Eqs. (16-17), and unit cost of the SOFC and PEMEC are considered.

$$f_k = \frac{\dot{Z}}{\dot{Z} + \dot{C}_d} \quad (16)$$

$$\dot{C}_d = c_f \dot{E}_d \quad (17)$$

The unit cost expresses the average cost at which each unit of fuel is supplied to a component or the average cost at which exergy unit was supplied to a product. The exergoeconomy factor expresses the contribution of the capital cost to the sum of capital cost and exergy destruction, providing a measurement of the component cost-effectiveness.

4. Numerical solution

The solution of the system relies on the hourly interaction between the solar radiation and the electric demand of the building through one day for each season of the year. Figure 2 displays the flowchart of the steps taken for solving the system. The parameters considered in this work concerning the building, photovoltaic panels, SOFC, and PEMEC dimensioning are shown in Appendix B [28].

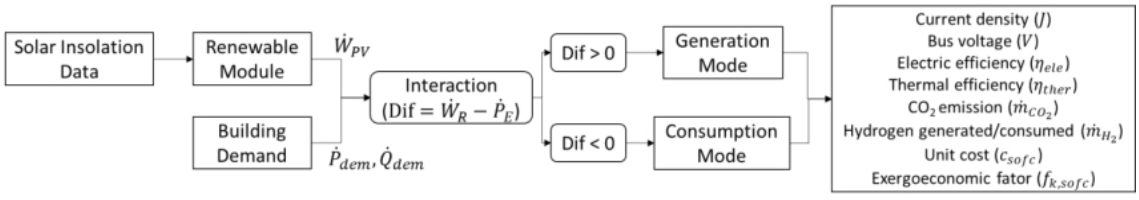

Figure 2: System's solution flowchart.

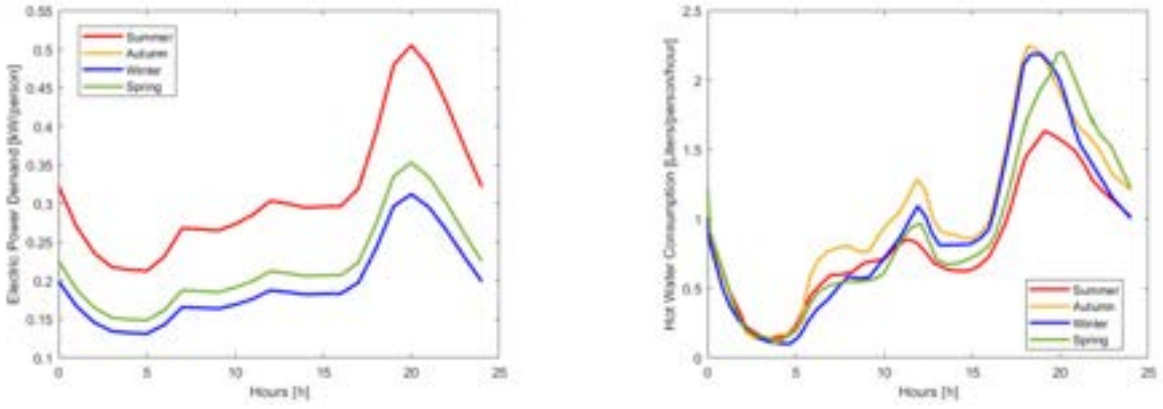
4.1. Electric power and heat demands

The electricity demand of a typical residential building from Rio de Janeiro is evaluated using the typical profile curve of residential consumption together with the historical average value for each month [35]. It is possible to observe a higher consumption in summer due to the hot temperatures in the country, as a higher amount of air conditioners are working. Spring and Autumn have similar electric demands. Water heating for showers is the only source of heat demand in the Rio de Janeiro context [36]. Both demands are displayed in Figure 3.

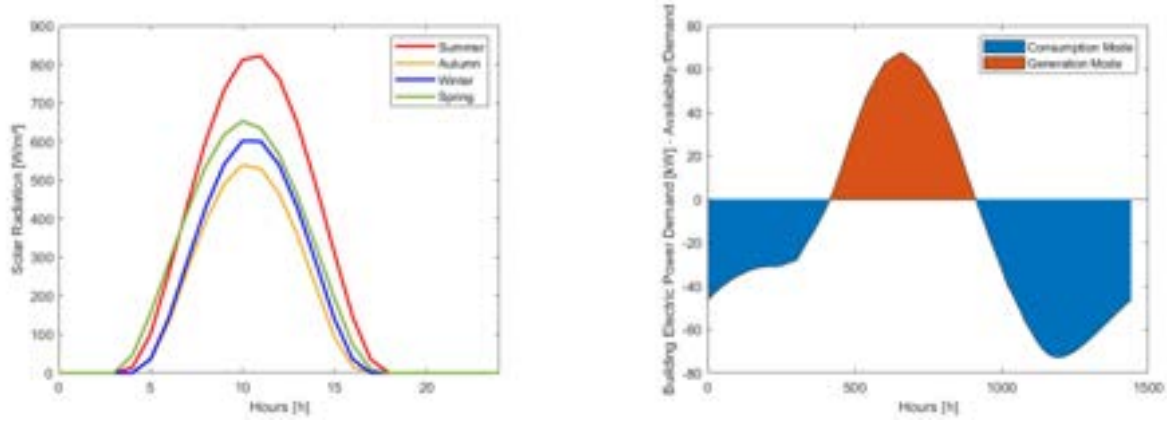


(a) (b)

Figure. 3. a) Electric power demand per person. b) Hot water profile of a typical Brazilian residential building.

4.2. Solar Radiation and interaction

As previously said, the difference between the electric power coming from the renewable module and the electricity demands dictates the functioning of the system. Figure 4 presents both the solar radiation for a characteristic day of each season in Rio de Janeiro and the aforementioned difference for the Summer. The area above the zero line (orange) corresponds to the generation mode, while the area under the line (blue) corresponds to the consumption mode.



(a) (b)

Figure. 4. a) Solar radiation in Rio de Janeiro for the characteristic day of each season. b) Data regarding availability and demand of electric power.

4.3. Generation path

The stacks of PEMEC work accordingly to the amount of available power, turning on and off to the necessary number of stacks for the operation. Both current density and the stack's bus voltage are adjusted in this process so the system can operate at the highest efficiency. Having the final condition set, the amount of green hydrogen produced and the electrolyzer's parameter can be calculated. The variables considered in this study for the PEMEC are displayed in Table B.4.

4.4. Consumption path

When the electric power from the renewable module is not enough to meet the user's demand, the stacks of solid oxide fuel cells are required to generate the missing power. Similarly to the generation path, the stacks can be turned on and off, as a function of the missing electric power, and the stack's current density and bus voltage are adjusted so the system can operate at the highest efficiency. The rate of hydrogen consumption is

calculated in function of the SOFC module's electric power output, and with that, it is possible to infer the amount of natural gas withdrawn from the grid, hydrogen from the tank, and steam necessary for the reforming process using a mass balance on the SOFC reformer. The parameters of the SOFC are shown in Table B.5. After the process in the SOFC, the depleted air and fuel passes through an afterburner for a complete combustion reaction. The hot combustion products are used to heat the hydrogen-natural gas blend and water entering the reformer, and the air entering the cell.

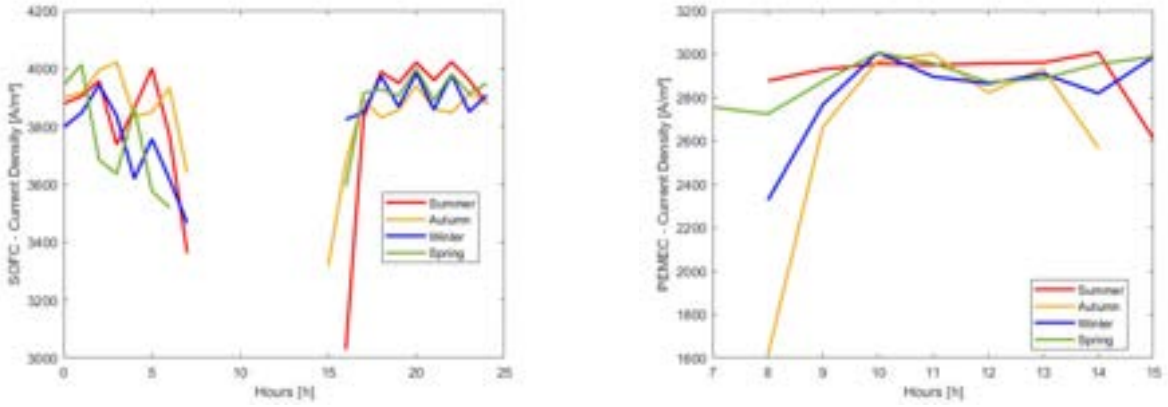
5. Results

5.1. Validation

Both PEMEC and SOFC were modeled according to data taken from the literature [37,38], and results are shown in Appendix B [28]. Tables B.6 and B.7 display a comparison with the values for voltages of each component, and it can be seen a good agreement between this study and the corresponding experimental data.

5.2. Season analysis

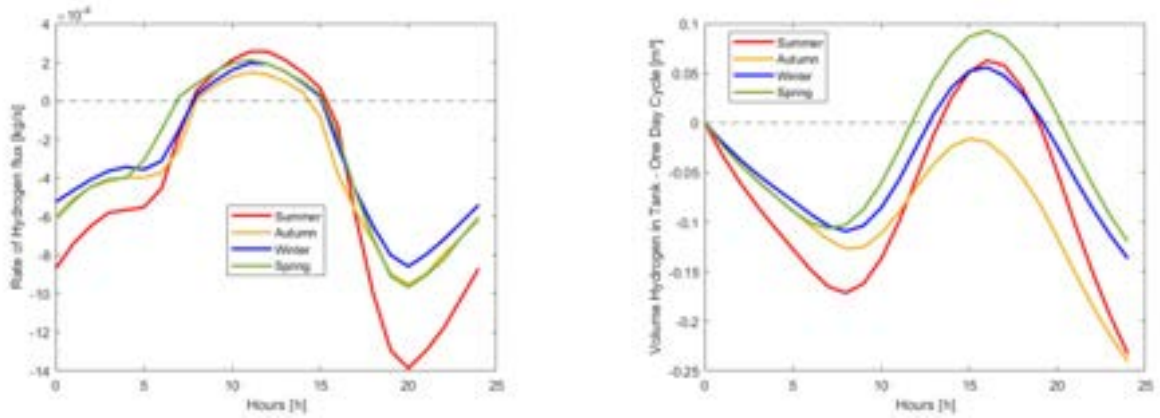
To assess the seasonality effect on the system, a characteristic day of each season was chosen, being in the middle of February, May, August, and November to represent Summer, Autumn, Winter, and Spring respectively. Thus, in each case, the current density and bus voltage of both SOFC and PEMEC are controlled and adjusted to supply and use the exact amount of electric power and operate at the highest efficiency. The adjustment for the current density is seen in Figure 5.



(a) (b)

Figure. 5. Current density. a) SOFC. b) PEMEC.

Figure 5 illustrates a distinct behavior in controlling the current density of both components. In the case of the SOFC, a decrease in current density corresponds to an expected increase in bus voltage, whereas for the PEMEC, the bus voltage decreases as the current density decreases. This phenomenon can be attributed to the nature of the actual voltage definitions for both components, as described in Sections 3.2 and 3.3. Specifically, a lower current density for the SOFC leads to higher voltages, while the opposite is observed for the PEMEC. The values of current density are determined by the electric power to be supplied or utilized by the components, where lower electric power results in lower current density.Hydrogen consumption and generation during operation are also a consequence of the electric power, as shown in Figure 6.

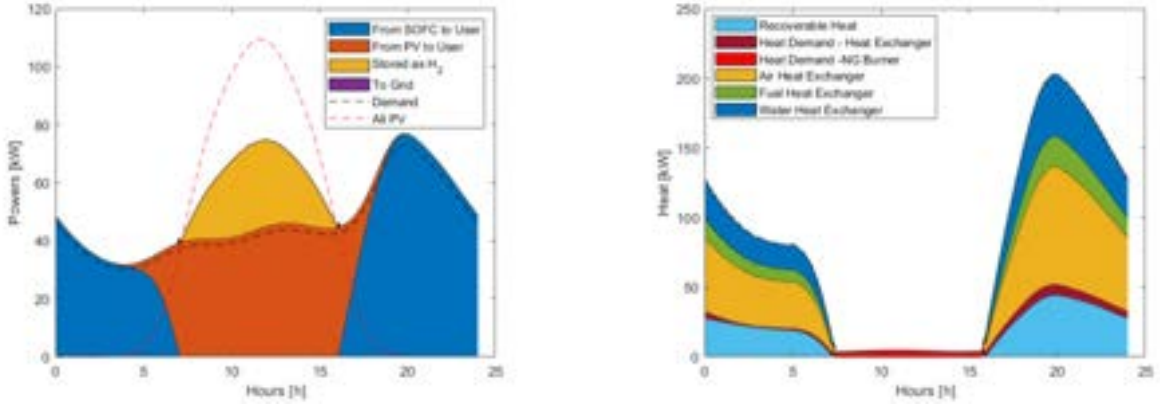


(a) (b)

Figure. 6. Rate of hydrogen generated and consumed. b) Hydrogen volume variation inside the tank.

In Figure 6a, when the curve has a negative or positive value, it corresponds to hydrogen consumption or generation, respectively. During the summer, higher generation and consumption are observed, as expected due to increased electric power demand and solar insolation, as shown in Figures 3a and 4a. Figure 6b illustrates the amount of hydrogen that entered or left the tank after a full day of operation. The greatest variations are observed in the summer, reflecting higher consumption and solar insolation. Consequently, there is a greater fluctuation in the hydrogen level within the tank. These results indicate that, under the given conditions, more hydrogen is consumed than generated each day during every season. By integrating the curve in Figure 6a, the total amount consumed can be calculated, confirming that summer has the highest consumption, followed by autumn, spring, and winter. These findings enable the design of storage tank autonomy and the development of a strategy to control hydrogen availability, such as limiting generation to specific times or blending hydrogen with natural gas in lower quantities.

Figure 7 helps to understand the behavior of the system to supply electricity, and consequently the heat demands.

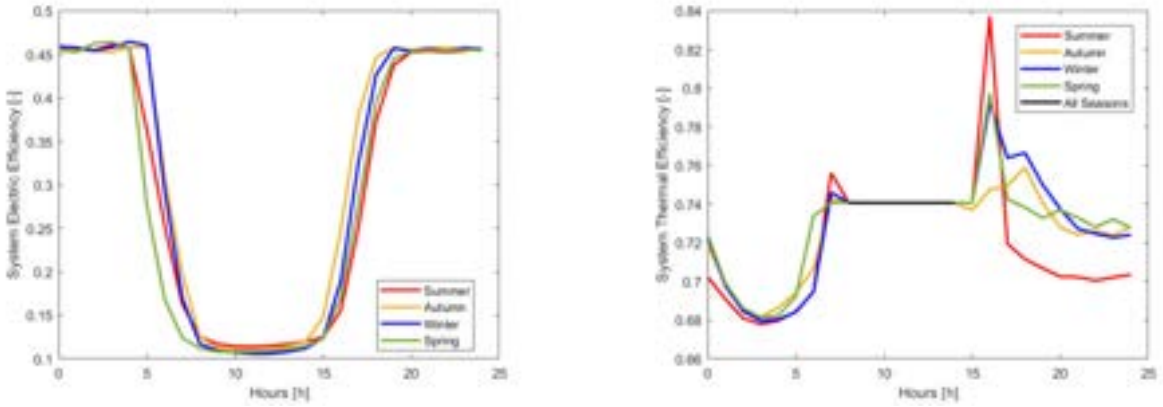


(a) (b)

Figure. 7. Month of February. a) Electric power supply. b) Heat supply.

When there is no energy being generated by the renewable module, the solid oxide fuel cell becomes responsible for supplying all the electric power (blue area). Its contribution gradually decreases as the photovoltaic system begins to supply a portion of the demand (orange area), until a point is reached where the photovoltaic system supplies all the energy, resulting in an excess. When there is an excess, the energy is converted into hydrogen (yellow area) and stored in a tank. Figure 7a shows the losses associated with hydrogen generation by comparing the total power supplied by the photovoltaic system (red dashed line) with the yellow area. It is important to note that both the solid oxide fuel cell and the photovoltaic system deliver more power than the electric demand to account for losses in the inverter. The heat response (Figure 7b) is directly proportional to the number of fuel cells in operation and exhibits a similar behavior to the electric power shown in Figure 7a. The exhaust gases from the afterburner can preheat the fuel, air, and water used in the process and fulfil the building's heat demand. The curve labelled "Recoverable Heat" represents the cooling of the exhaust gases to ambient conditions and could be utilized for a trigeneration process, such as powering an absorption chiller to meet the cooling demand.

The system's electric and thermal efficiencies are assessed in Figure 8.

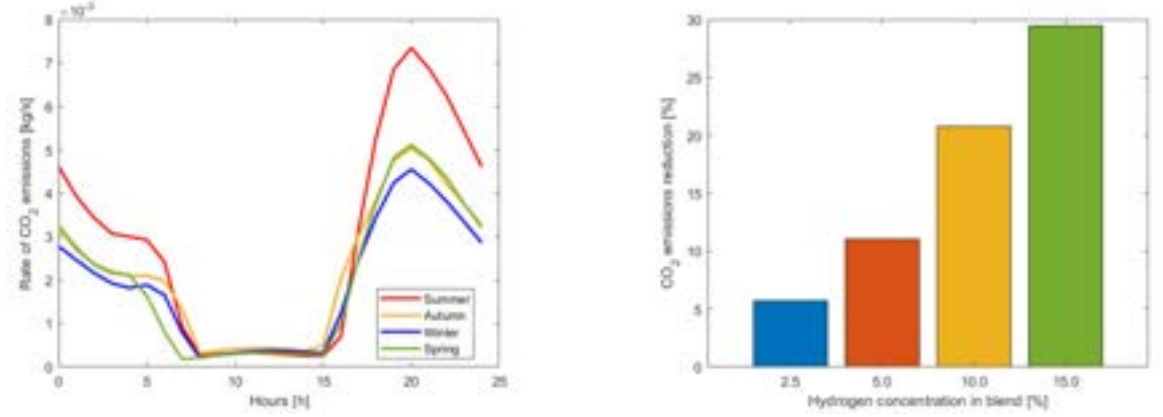


(a) (b)

Figure. 8. a) System's electric efficiency. b) System's thermal efficiency.

Figure 8a demonstrates that the system maintains a steady efficiency when only the SOFC operates to supply the electric power. This behavior is attributed to the control method, which adjusts both the current density and bus voltage to meet the electric power demand. As the photovoltaic panels begin to contribute to the electric power supply, the overall efficiency of the system starts to decrease due to the panels' lower efficiency. Additionally, in the energy surplus region, there is a further decrease in efficiency caused by losses in hydrogen generation through the PEMEC. By examining Figure 8b, it can be observed that the thermal efficiency of the system remains constant during the generation mode, with a natural gas burner efficiency of 0.74. However, during the consumption mode, the variations among seasons primarily stem from different hot water profiles and the number of operational cells.

Figure 9 displays the results for both the rate of CO_2 emitted and the influence of hydrogen in the blend during summer.

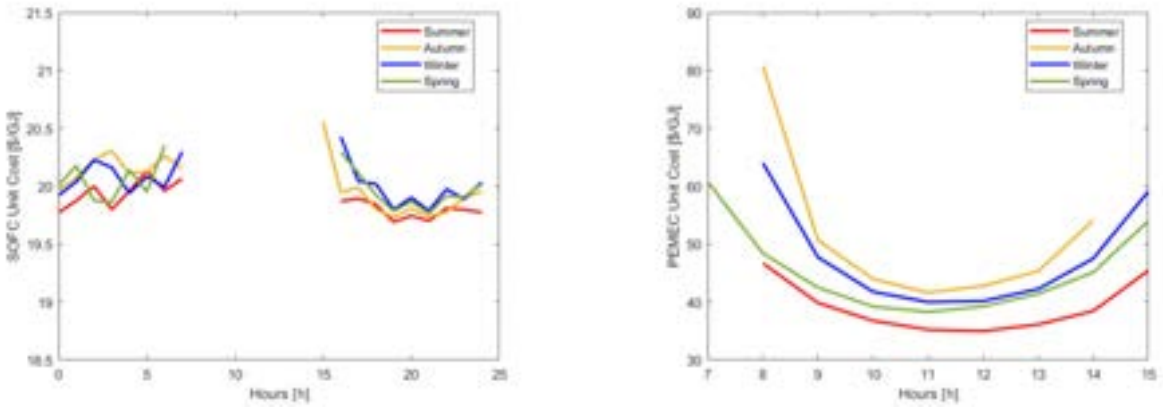


(a) (b)

Figure. 9. a) Rate of CO_2 emission. b) Carbon dioxide emission reduction due to hydrogen addition to the blend.

The carbon dioxide emission, Figure 9a, is described as a function of the electricity demand of the consumption mode, and as a function of heat demand of the generation mode. A higher amount of functioning fuel cells would imply a higher amount of hydrogen being withdrawn from the tank and natural gas from the grid. Consequently, after the whole process, higher emissions would be seen. It is expected to have a higher emission during the Summer, as the electric demand from the building is also higher. In the generation mode, the amount of emissions is dictated by the heat demand which is supplied by the natural gas burner. Figure 9b displays the influence of adding hydrogen to the blend with natural gas. A higher participation of hydrogen would reduce the emissions of carbon dioxide due to a lesser amount of CO_2 after the reforming process, and consequently after the electrochemical reaction in the SOFC. The addition of 15% of hydrogen, on a mass basis, to the blend would reduce up to 29% of these emissions.

Figure 10 shows the unit cost for both SOFC and PEMEC.

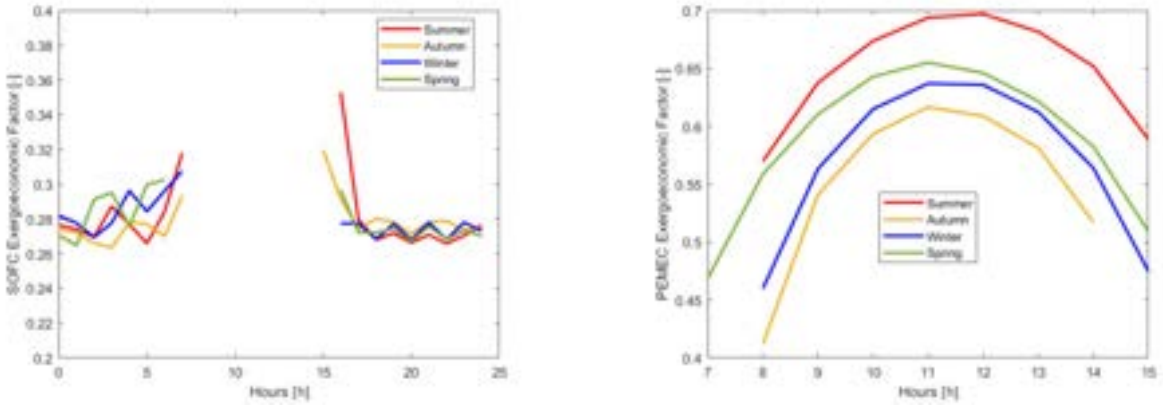


(a) (b)

Figure. 10. Unit cost. a) SOFC. b) PEMEC.

The unit cost of the SOFC shows only minor variations based on seasonality and the time of day. The capital cost of the SOFC is determined by the number of active cells, which is in turn influenced by the user's electric power requirements. Consequently, the relatively stable unit cost arises from the consistent operational efficiency of the system, where the current density is adjusted to meet the electric demand. On the other hand, the unit cost of operation for the PEMEC is greatly impacted by the excess electric power supplied by the PV system. During midday, when solar radiation reaches its peak, the unit cost of operation is lower due to increased hydrogen generation, despite the higher capital cost associated with the PEMECs.

Figure 11 displays the exergoeconomic factor for both components.



(a) (b)

Figure. 11. Exergoeconomic factor. (a) SOFC. (b) PEMEC.

The behavior of the exergoeconomic factor is similar to the unit cost. Regarding the SOFC, its value is constant for most of the operation, which fluctuations are a result of the current density adjustments. For the PEMEC, the exergoeconomic factor is highly influenced by the supplied electric power, due to the higher values at midday and due to the seasonality, where the summer has a higher radiation compared to the other seasons. A low value of the exergoeconomic factor indicates potential cost savings for the system by reducing exergy destruction, which can be achieved by improving component efficiency, even if it entails increased capital investment. Conversely, a high value of the factor suggests the possibility of reducing the investment cost of the component at the expense of its exergetic efficiency.

6. Conclusion

A hybrid combined CHP system using green hydrogen storage is evaluated in the city of Rio de Janeiro, Brazil. The system is assessed through a 4E standpoint while supplying both electric power and the heat demand of a typical building. The system is mainly composed of a photovoltaic system, a proton exchange membrane electrolyzer, and a solid oxide fuel cell. The system can perform at the rated electricity demand at maximum and stable efficiency while supplying all the heat necessary for its running and hot shower. The amount of hydrogen produced and consumed is estimated and it was seen that during summer, due to a higher solar insulation and electric demand, the variations inside the tank are higher when compared with any other season. Pollutant emissions are strictly related to the number of operating fuel cells, as they would require a higher

amount of fuel, and the addition of hydrogen would reduce the number of such emissions, as less natural gas would be burnt. Recalling the exergoeconomic, it has been shown that seasonality has little effect on the solid oxide fuel cell parameters, while the proton exchange membrane is highly affected by solar radiation. Finally, the system showed the possibility of introducing a cooling system utilizing the recoverable heat in an absorption chiller.

The system seems to be a good option to diversify the use of renewable resources in Brazil, which has hydropower as the main source. With the right design of the tank, the system would be able to sustain both the electricity and heat demand of a typical residential building. In the future, it is desired to analyze the system's functioning during a whole year, compare the results found with demands and weather conditions of other countries, and optimize the system to find the best functioning condition. Additionally, a comparison with other energy storage systems, such as compressed air (CAES), would allow a better understanding of the feasibility of these systems to substitute the ongoing ones.

Robust Optimization of the Energy Concept of an Industrial Process w.r.t. Uncertain Energy Costs and Environmental Conditions

Michael Lockan[a], Rushit Kansara[a]

Institute of Low-Carbon Industrial Processes, Cottbus, Germany,
michael.lockan@dlr.de

Abstract:

Due to the required CO_2 reduction to achieve global climate goals, the political, social, and economic pressure for decarbonizing industry increases rapidly. An essential step towards this goal is the replacement of fossil fuels by renewable energy sources making changes in technology for generating electricity, steam, and process heat an inevitable requirement. This raises the question about the combination of energy supply technologies (such as photovoltaic systems, wind turbines or solar thermal systems) with energy conversion units (such as heat pumps or electric boilers) to cover the demand of an industrial process at minimal cost. Optimization methods are increasingly used for the selection and dimensioning of such units. These methods can systematically and efficiently determine optimal energy concepts according to the multicriterial requirements of a specific industrial process.

The results of such deterministic optimizations depend heavily on assumptions of environmental conditions such as solar radiation and wind speed, the cost of purchasing and selling revenue of electric power, local infrastructure, and the demand of the industrial plant. Changes in these assumptions can result in significantly different costs or lead to an energy system, which is eventually incapable of covering the process demand. In this paper, the modelling of the required components is briefly described and a robust optimization approach is presented taking uncertainties of the assumptions into account during the optimization process. After a robust optimization for an industrial process is performed, the results are compared and discussed to those of a deterministic optimization. It can be shown, that the robust optimization allows to find energy concepts with less sensitivity and higher reliability when uncertainties are considered.

1. Introduction

For a successful decarbonization of industrial processes it is essential to integrate renewable energies in an appropriate way considering economic as well as environmental aspects. For this purpose, it is necessary to model the required units of the considered process and the energy concept sufficiently to gain an understanding of their interaction and characteristics. Due to the huge number of parameters involved describing an energy concept it is necessary and to use numerical optimization strategies in order to find optimal configurations.

1.1. Optimization of energy concepts

With the increasing complexity of the investigated systems and the associated number of parameters to be defined, as well as with increasing requirements, optimization processes are increasingly used. This includes almost all industrial areas in which designs and systems are consistently pushed to the limits of feasibility. Thus, the need for design and operational optimizations of energy concepts for industrial processes is also increasing due to the global economic competition and increasing political and social pressure to reduce CO_2 emissions. The design of an energy concept is typically formulated as mixed integer nonlinear problem, where the nominal capacity of the units is described by real number whereas with the integer variable the number of units used defined, [1]. In the context of this paper, the units used are specified, so that the complexity of the optimization problem can be reduced, while still using nonlinear modelling of the units, *Figure 1*. A more accurate unit modelling is usually used for operational optimizations involving e.g. non-linear model predictive control with real-time weather data or forecasts, [2]. Such a complex operational optimization is not carried out here, but a simplified operational optimization is need to determine the operating costs, which results in a two-level optimization problem. Thus, a stationary modelling of the components is sufficient for the design optimization of the energy concept.

1.2. Robust optimization strategies

Optimized systems often only behave ideally under the given boundary conditions, so that deviations can lead to undesired system behaviour or a loss of performance. The goal of a robust optimization is to consider uncertainties or possible deviations directly during design optimization process. There are many definitions regarding robustness, like a small scatter in the objectives or low failure probabilities, [3]. For each of the defined robust criteria there are sophisticated methods for their efficient estimation. In any case, the consideration of conditions away from the design point requires a number of function evaluations to determine the robust objectives. To avoid this, usually only selected scenarios are considered in current energy concept design processes [4]. However, response surface methods in connection with robust optimizations are often very suitable, which can be created on the basis of a few function evaluations and then used to carry out extensive statistical evaluations efficiently [5]. In this paper local response surfaces are used for the robust optimization of an energy concept, which are created around the design point in every design evaluation.

1.3. Structure of the paper

In the following section the mathematical modelling of the units under consideration is described and the corresponding analysis of the entire energy concept is explained*, Figure 1*. An electrical batterie is not directly considered in this paper, but since the energy balances are calculated on a daily basis, it is assumed that the corresponding amount of electricity can be stored for a short time. The unit modelling serves as the basis for the energy concept design process, in which the nominal capacities of the units are optimized. Finally, the robust optimization problem is presented and its solution is compared with a deterministic optimum.

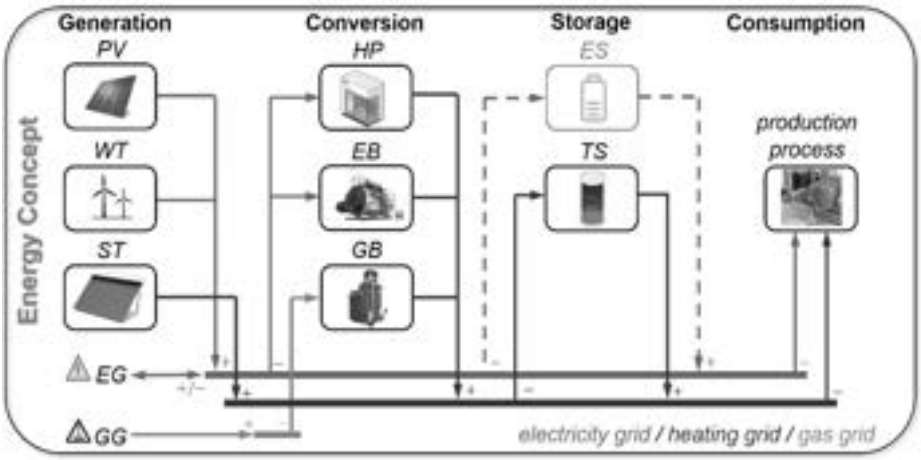

Figure 1 *overview of the energy concept to be optimized showing the electricity, gas and heating grid*

2. Modelling of the energy concept

In order to design and dimension the units shown in *Figure 1*, it is necessary to model them by an energetic point of view. The modelling then forms the basis for determining the electrical energy and heat produced in order to cover the production needs at all times. For this purpose, the formulations of the generation, conversion and storage units are first described in the following sections before the evaluation of the overall system is explained.

2.1. Generation units

The output of the generation units essentially depends on the installed capacity, solar radiations and wind speeds. The installed capacity is described by the area of the panels for the PV and ST units and by the nominal power for the wind turbine. The electrical power P^{PV} provided by the PV unit is thus calculated according to [2] by

$$P^{PV} = A^{PV}\eta^{PV}S^{pan} \tag{1}$$

with the unit area A^{PV}, penal efficiency η^{PV} and solar radiation S^{pan} which summarizes direct and diffuse radiations. The electrical power is limited by the nominal capacity P^{PV}_{nom}, such that

$$P^{PV} \leq P^{PV}_{nom} \qquad \text{with} \qquad P^{PV}_{nom} = A^{PV}P^{PV}_{nom,rel} = A^{PV}0.171. \tag{2}$$

Values for solar radiation are taken from monthly totals $S^{hor}_{\mathcal{M}}$ for a horizontal surface for the region of the industrial site from the DWD, [6]. Using the geometric relationships in *Figure 2a*, the corresponding solar radiation S^{inc} of the sun can be measured using its declination angle δ as well as the latitude φ of the industrial site:

$$S^{inc} = \frac{S^{hor}}{\sin\alpha} \qquad \text{with} \qquad \alpha = 90° - \varphi + \delta. \tag{3}$$

A tilt angle β of the PV module then corresponds to a decrease in latitude φ, so that the solar radiation on the module is calculated by

$$S^{pan} = S^{inc}\,sin(\alpha+\beta) = S^{hor}\frac{sin(\alpha+\beta)}{\sin\alpha}. \tag{4}$$

The efficiency of the PV unit was chosen with $\eta^{PV} = 0.09$ in such a way that calculated values correspond to the measurements of a PV unit already installed at the industrial site.

The electrical power provided by the wind turbine unit is determined by the nominal power P^{WT}_{nom} and a wind load fraction λ^{WT} dependent efficiency η^{WT}:

$$P^{WT} = \eta^{WT}(\lambda^{WT})P^{WT}_{nom} \qquad \text{with} \qquad \lambda^{WT} = \frac{v^{wind}}{v^{wind,0}} \tag{5}$$

where a reference wind speed of $v^{wind,0} = 12ms^{-1}$ is chosen for the present study. Due to the linear dependency in (5), only a single representative wind turbine unit is considered at this point, a separation into several wind turbines with different capacities does not take place here. The efficiency function is selected according to [2]

$$\eta^{WT}(\lambda^{WT}) = \begin{cases} 0 & if \quad \lambda^{WT} < 0.33 \\ 1.5393\lambda^{WT} - 0.5091 & if \quad 0.33 \leq \lambda^{WT} \leq 1.0 \\ 1 & if \quad \lambda^{WT} > 1.0 \end{cases} \tag{6}$$

and displayed *Figure 2b*. The wind speeds used here are taken from measurements at the industrial site. The same distributions of wind speeds and thus the same output of the wind turbine unit is assumed for each day in this paper. A distinction between days with a lot and little wind does not take place for the design of the wind turbine unit.

To determine the output of the solar thermal unit, a single equivalent solar panel is usually considered, for which the inlet and outlet temperatures w.r.t a given the mass flow are calculated, [7]. However, to find an appropriate design an optimization of the mass flow in the panels is required, which may necessary for an operational consideration, but not for the design. For the design, the calculation of the thermal performance

$$\dot{Q}^{ST} = A^{ST}\eta_0^{ST}S^{pan}f^{ST} \qquad \text{with} \qquad f^{ST} = 0.97 - 0.0367\left(\frac{a^*}{\eta_0^{ST}}\right) + 0.0006\left(\frac{a^*}{\eta_0^{ST}}\right)^2 \tag{7}$$

using the panel area A^{ST}, the zero-loss panel efficiency η_0^{ST}, the solar radiation on the penal S^{pan} as in (4) and a collector performance factor f^{ST}, [8]. Heat losses from the panel are considered using the performance

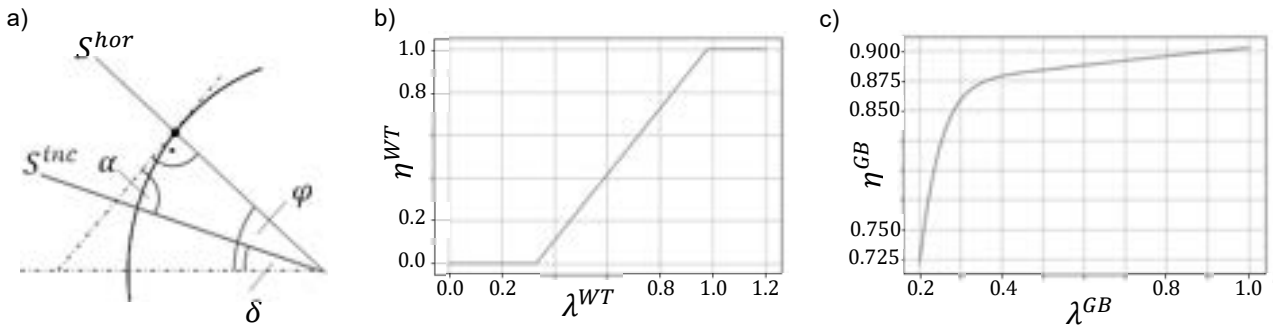

Figure 2 a) angles to calculate the solar radiation b) efficiency of wind turbines depending on the wind load and c) efficiency of the gas boiler depending on the load fraction

factor f^{ST}, which depends on the type of panel. For this paper, evacuated tubes with $\eta_0^{ST} = 0.6$ and $a^* = 3$ are used.

2.2. Conversion units

The task of the conversion units is to provide the heat required for the industrial process using electricity or gas. There are a lot of ways to generate heat, e.g. using combined heat and power units, but firstly only the components described below were considered in this work. The thermal output $\dot{Q}^{GB}$ of the gas boiler is calculated according to

$$\dot{Q}^{GB} = \dot{Q}_{nom}^{GB} \lambda^{GB} \tag{8}$$

with the nominal capacity $\dot{Q}_{nom}^{GB}$ and the load fraction λ^{GB} limited by lower and upper bounds $0.2 \leq \lambda^{GB} \leq 1.0$. The power P^{GB} required for generating $\dot{Q}^{GB}$ is calculated based on the efficiency η^{GB}, so that the behavior in part load can also be considered, [2]:

$$P^{GB} = \frac{\dot{Q}^{GB}}{\eta^{GB}} \quad \text{with} \quad \eta^{GB} = \frac{21.754\lambda^{GB^3} - 7.001\lambda^{GB^3} + 1.397\lambda^{GB} - 0.076}{20.666\lambda^{GB^3} - 5.342\lambda^{GB^3} + 0.678\lambda^{GB} + 0.035}\eta_{nom}^{GB} \tag{9}$$

and a nominal efficiency of $\eta_{nom}^{GB} = 0.8$, *Figure 2c.* In the calculation, λ^{GB} is set to $\lambda^{GB} = 0.2$ if $0.01 \leq \lambda^{GB} \leq 0.2$ and $\lambda^{GB} = 0.0$ if $\lambda^{GB} < 0.01$ to also consider the non-use of the gas boiler.

The electric boiler is calculated in the same way as the gas boiler. Thus, the thermal output $\dot{Q}^{EB}$ is determined according to

$$\dot{Q}^{EB} = \dot{Q}_{nom}^{EB} \lambda^{EB} \tag{10}$$

with the nominal capacity $\dot{Q}_{nom}^{EB}$ and the load fraction $0.0 \leq \lambda^{EB} \leq 1.0$. In contrast to the gas boiler, the entire range of the nominal capacity $\dot{Q}_{nom}^{EB}$ can be used. Furthermore, a constant efficiency $\eta^{EB} = 0.95$ is assumed, so that a required power is calculated by

$$P^{EB} = \frac{\dot{Q}^{EB}}{\eta^{EB}} = \frac{\dot{Q}^{EB}}{0.95}. \tag{11}$$

Finally, heat pumps are also considered for the heat supply, as these offer the possibility of providing heat very efficiently and on the basis of renewable energy sources, especially in connection with thermal energy storages and solar thermal systems. The thermal output $\dot{Q}^{HP}$ of the heat pump is also calculated by

$$\dot{Q}^{HP} = \dot{Q}_{nom}^{HP} \lambda^{HP} \tag{12}$$

with the nominal capacity $\dot{Q}_{nom}^{HP}$ and the load fraction λ^{HP}. As by the gas boilers, the load fraction is limited by an upper and lower bound, such that $0.2 \leq \lambda^{HP} \leq 1.0$. The efficiency of the heat pump is calculated according to [2] as the product of a constant 2nd law efficiency $\eta_{2nd}^{HP} = 0.36$ and the Carnot efficiency η^{carnot} that serves as theoretical maximum:

$$\eta^{HP} = \eta_{2nd}^{HP} \eta^{carnot} = \eta_{2nd}^{HP} \frac{T_{h,out}^{HP}}{T_{h,out}^{HP} - T_{c,in}^{HP}} \tag{13}$$

with the heat sink temperature $T_{h,out}^{HP}$ as output and the heat source temperature $T_{c,in}^{HP}$ as input of the heat pump. In (13) it becomes clear that a heat pump can work most effective when an appropriate high-quality

heat source is available and the difference between $T_{h,out}^{HP}$ and $T_{c,in}^{HP}$ is as small as possible. The required electrical power P^{HP} of the heat pump is then determined by

$$P^{HP} = \frac{\dot{Q}^{HP}}{\eta^{HP}}. \tag{14}$$

In addition to a minimum temperature difference of $T_{h,out}^{HP} - T_{c,in}^{HP} \geq 25K$ and a maximum output temperature $T_{h,out}^{HP} \leq 160°C$ are also taken into account, [9]. Using (13) and (14) the required thermal power $\dot{Q}_{TES}^{HP}$ taken from a connected thermal energy storage can be calculated for a given temperature difference:

$$\eta_{2nd}^{HP} \frac{T_{h,out}^{HP}}{T_{h,out}^{HP} - T_{c,in}^{HP}} = \frac{\dot{Q}^{HP}}{P^{HP}} = \frac{\dot{Q}^{HP}}{\dot{Q}^{HP} - \dot{Q}_{TES}^{HP}} \Longrightarrow \dot{Q}_{TES}^{HP} = \dot{Q}^{HP}\left(1 - \frac{T_{h,out}^{HP} - T_{c,in}^{HP}}{\eta_{2nd}^{HP} T_{h,out}^{HP}}\right). \tag{15}$$

Usually, only constant efficiencies of the heat pump are applied during the design process. However, this means that solar thermal unit, thermal energy storage and heat pump are considered separately, which can lead to an incorrect evaluation of the overall system.

2.3. Thermal energy storage

The thermal energy storage is used to store the thermal output generated by e.g. the solar thermal unit and to make it available for the generation of the required heat. It is used on the one hand for preheating but also as a source for the heat pump, *Figure 3a*. Starting from the currently stored thermal energy Q_0^{TES}, available thermal performance $\dot{Q}$ during the considered time frame Δt is used to charge the storage tank

$$Q^{TES} = Q_0^{TES} + \dot{Q}\Delta t. \qquad \text{with} \qquad Q^{TES} \leq Q_{nom}^{TES} \tag{16}$$

ensuring that the nominal capacity Q_{nom}^{TES} of storage is not exceeded. Due to the fact, only a hot water storage is used in this paper the temperature T^{TES} of the storage tank can be determined based on the stored thermal energy Q^{TES}, the storage mass m^{TES}, the specific heat capacity of the storage medium c_p^{TES} and initial temperature T_0^{TES}:

$$Q^{TES} = c_p^{TES} m^{TES}(T^{TES} - T_0^{TES}) \qquad \Longrightarrow \qquad T^{TES} = T_0^{TES} + \frac{Q^{TES}}{c_p^{TES} m^{TES}} \tag{17}$$

When discharging the storage, a simple calculation as in (16) is not suitable, because with the discharging of the storage, the storage temperature reduces and according to (15) also the thermal power taken from the storage by the heat pump. In order to be able to better describe the discharging, it is necessary to consider the power used for preheating $\dot{Q}_{TES}^{w}$ and for the heat pump $\dot{Q}_{TES}^{HP}$ within a single formulation

$$\dot{Q}^{TES} = -\dot{Q}_{TES}^{w} - \dot{Q}_{TES}^{HP} = -c_p^w \dot{m}^w (T^{TES} - \Delta T - T_{in}^w) + \dot{Q}^{HP}\left(\frac{T_{h,out}^{HP} - T^{TES}}{\eta_{2nd}^{HP} T_{h,out}^{HP}} - 1\right) \tag{18}$$

where the source temperature for the heat pump is set to the storage temperature $T_{c,in}^{HP} = T^{TES}$ and the output temperature for the preheating is chosen to be $T_{out}^{w} = T^{TES} - \Delta T$ in order to ensure a pinch in the heat exchangers of ΔT. By rearranging (18), formulation

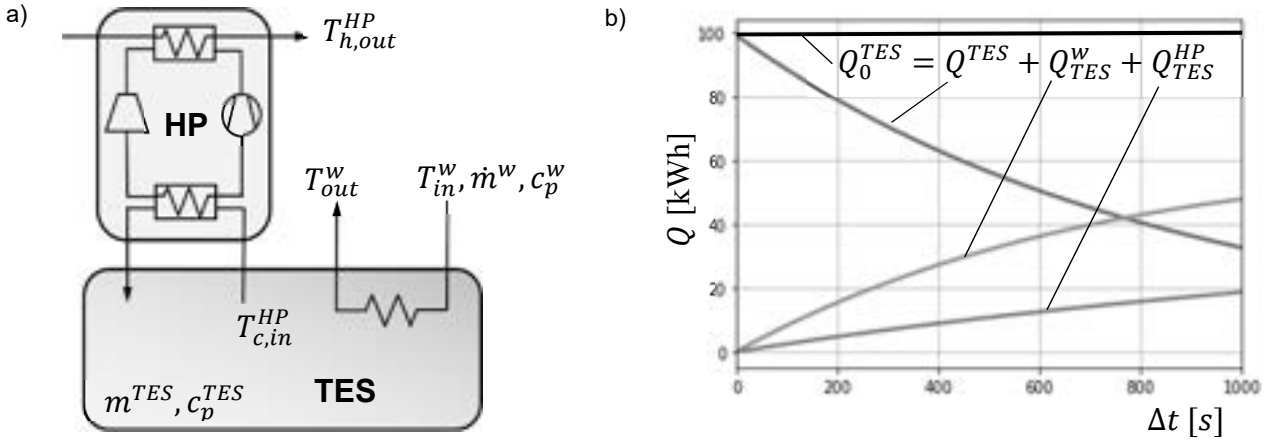

Figure 3 description of the two options for discharging the storage (a) and discharging of the storage according to (22) using $m^{TES} = 1000kg$, $c_p^{TES} = 4.19\,kJ/kgK$, $T_0^{TES} = 15°C$, $c_p^w = 4.19\,kJ/kgK$, $\dot{m}^w = 1.0\,kg/s$, $\dot{Q}^{HP} = 100kW$ and $T_{h,out}^{HP} = 100°C$ (b)

$$\dot{Q}^{TES} = \underbrace{\left[c_p^w \dot{m}^w (\Delta T + T_{in}^w) + \dot{Q}^{HP}\left(\frac{T_{h,out}^{HP}}{\eta_{2nd}^{HP} T_{h,out}^{HP}} - 1\right)\right]}_{c_1} - \underbrace{\left[c_p^w \dot{m}^w + \frac{\dot{Q}^{HP}}{\eta_{2nd}^{HP} T_{h,out}^{HP}}\right]}_{c_2} T^{TES} \tag{19}$$

is obtained, where the terms in the square brackets, that are assumed to be constant with time, are summarized by the constants c_1 and c_2. If the formulation of T^{TES} in (17) is used, equation (19) can be formulated such as

$$\dot{Q}^{TES} = c_1 - c_2 T^{TES} = c_1 - c_2\left(T_0^{TES} + \frac{Q^{TES}}{c_p^{TES} m^{TES}}\right) = \underbrace{c_1 - c_2 T_0^{TES}}_{c_3} - \underbrace{\frac{c_2}{c_p^{TES} m^{TES}}}_{c_4} Q^{TES} \tag{20}$$

with the constants c_3 and c_4, where (20) now depends on Q^{TES}. With this, the following problem can be formulated

$$\dot{Q}^{TES} = \frac{dQ^{TES}}{dt} = c_3 - c_4 Q^{TES} \qquad \Longrightarrow \qquad \frac{dQ^{TES}}{c_3 - c_4 Q^{TES}} = dt \tag{21}$$

which can be solved by integrating separately from Q_0^{TES} to Q^{TES} and t_1 to t_2, where $\Delta t = t_2 - t_1$:

$$Q^{TES} = \left(-\frac{c_3}{c_4} + Q_0^{TES}\right) e^{-c_4 \Delta t} + \frac{c_3}{c_4} \tag{22}$$

Using (22), the energy provided by the storage $Q^{TES} - Q_0^{TES}$ and $\dot{Q}_{TES}^{w}$ as well as $\dot{Q}_{TES}^{HP}$ can be calculated over different time ranges, taking into account the effect of (15) and the fact that also with decreasing storage temperature T^{TES} in the preheating less energy can be transferred, *Figure3b*. During the discharging of the thermal energy storage it is checked that $Q^{TES} \geq 0$.

2.4. Integration of the components

To model the entire energy concept of the industrial process, the components described in the previous chapter must be integrated to check whether the demand of the production process can be covered at any time. The heat requirement considered here corresponds to the batch process of an existing food processing process shown in *Figure 4*a, whereby this is only applicable on weekdays, due to the fact that there is no production at off days. Here the day is divided into 7 sections, with different time periods $\Delta t^{(i)}$ and heat requirements $\dot{Q}^{dem,(i)}$ with a peak load that is only required for a short period of time.

For the analysis of the system consisting of the described components with their nominal capacity, representative weeks are evaluated for each month of the year. This is necessary because the solar radiation and thus also the power of the PV and ST unit change greatly over the course of a year. To determine the daily solar radiation $S_{\mathcal{M},d}^{hor}$ for a specific month, the monthly values $S_{\mathcal{M}}^{hor}$ are divided by the corresponding number of days per month. The analysis of each week starts on Saturday with an empty thermal energy storage. This means that the storage can be charged over the weekend, since there is no heat demand for the production process here. In general, the charging level of the storage is calculated according to the sections in *Figure 4a* by

$$Q^{TES,(i+1)} = Q^{TES,(i)} - \left(\dot{Q}_{TES}^{w,(i)} + \dot{Q}_{TES}^{HP,(i)} - \dot{Q}^{ST,(i)}\right)\Delta t^{(i)} \quad \text{w.r.t.} \quad Q^{TES,(i+1)} \leq Q_{nom}^{TES} \tag{23}$$

where at weekends $\dot{Q}_{TES}^{w,(i)} = \dot{Q}_{TES}^{HP,(i)} = 0$. In order to determine $\dot{Q}_{TES}^{HP,(i)}$, according to (18) it is necessary to define the thermal output of the heat pump $\dot{Q}^{HP}$. Since the components in the batch process under consideration have to be operated at partial load, in sections with a lower heat demand $\dot{Q}^{dem,(i)}$ it is necessary to determine appropriate load fractions $\lambda^{GB}, \lambda^{EB}$ and $\lambda^{HP}$of the units. In this paper, this is realized by a load optimization with regard to minimal operating costs:

$$\min_{\boldsymbol{\lambda} \in L} f \qquad \text{s.t.} \qquad h = \dot{Q}^{dem,(i)} - \dot{Q}^{GB,(i)} - \dot{Q}^{EB,(i)} - \dot{Q}^{HP,(i)} - \dot{Q}_{TES}^{w,(i)} \leq 0 \tag{24}$$

with $f = p_{buy}^{el} E^{el,(i)} + p_{buy}^{gas} E^{gas,(i)}$, the price for electricity $p_{buy}^{el}$and for natural gas p_{buy}^{gas} as well as

$$E^{el,(i)} = \left(P^{HP,(i)} + P^{EB,(i)}\right)\Delta t^{(i)}, \qquad E^{gas,(i)} = P^{GB,(i)} \Delta t^{(i)}, \tag{25}$$

$$L = \{\boldsymbol{\lambda} = [\lambda^{GB}, \lambda^{EB}, \lambda^{HP}]^T \in \mathbb{R}^3 | h \leq 0, \boldsymbol{\lambda}^l \leq \boldsymbol{\lambda} \leq \boldsymbol{\lambda}^u\}. \tag{26}$$

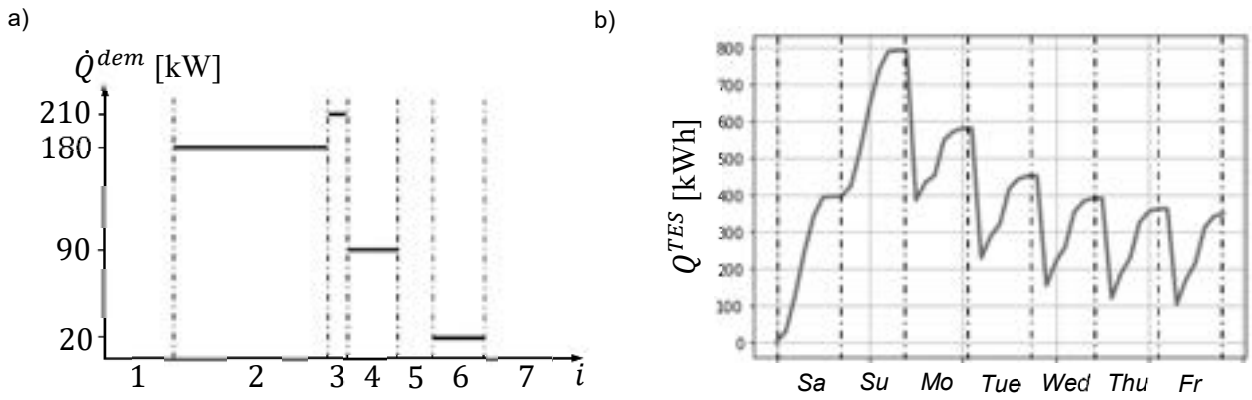

Figure 4 a) considered batch process with daily heat demand sections i and b) charging level of the thermal energy storage for one week in November and an exemplary energy concept

Due to $h \leq 0$ it can be ensured that the heat demand of the production process is covered with minimal operational cost. When calculating the required electrical energy $E^{el,(i)}$, the energy of the PV and WT unit is also taken into account, which is not required to cover the electricity demand of the production process. The total electricity demand of a day is then calculated according to

$$E_d^{el} = E_d^{BL} + E_d^{WL} - E_d^{PV} - E_d^{WT} + \sum_{j=1}^{7} \left(P^{HP,(j)} + P^{EB,(j)}\right) \Delta t^{(j)} \tag{27}$$

with daily energy generated by the PV unit E_d^{PV} and the WT unit E_d^{WT} as well as daily base load E_d^{BL} and load E_d^{WL} on the working days, which is needed e.g. to use the electrical machines. The daily gas demand is calculated according to

$$E_d^{gas} = \sum_{j=1}^{7} P^{GB,(j)} \Delta t^{(j)}. \tag{28}$$

The calculation of the daily demands is carried out consecutively for all days of the week. A negative energy demand means that more energy has been produced than is needed and this amount can be sold, a positive energy demand means that the corresponding amount has to be bought. The charging level of the storage is taken over from one day to the next, as shown exemplarily in *Figure 4b*. Since representative weeks with five working days are analysed for all months, a total of $4 \times 5 \times 12 = 240$ load optimizations (24) are required for an evaluation of the energy concept.

3. Deterministic optimization of the energy concept

The results of the analysis of the energy concept from section 2.4 essentially depend on the dimensioning or the nominal capacities of the units used. For example, larger PV or WT units lead to a larger amount of electrical energy being produced, which, according to (27), can reduce the energy demand. Furthermore, a larger ST unit with a corresponding thermal energy storage means that, according to (23), the heat pump also has a high-temperature source available or the energy in the storage can be used for preheating, so that less additional energy is needed. In addition, the CO_2 emissions can also be reduced by using renewable energy sources like PV, WT and ST units, although an increase in the normal capacities is also associated with increased investment costs. In order to find suitable trade-offs between economic criteria such as costs and ecological criteria such as CO_2 emissions, optimization processes are applied. Therefore, in the next section, the considered criteria will first be explained before the corresponding optimization problem is formulated and the optimization result is discussed.

3.1. Determination of the objectives

As already described, economic as well as ecological criteria are considered in the design process. The total annual costs TAC, which are calculated on the one hand from the required operating costs and on the other hand from the investment costs, are chosen as ecological criterion. The annual investment cost for each unit c^i , $i \in \{PV, WT, ST, GB, EB, HP, TES\}$ is determined according to

$$c^i = \left(\frac{(\beta+1)^\tau \beta}{(\beta+1)^\tau - 1} + \alpha^i\right) C^i \qquad \text{with} \qquad C^i = C^{i,0} \left(\frac{\dot{Q}_{nom}^i / Q_{nom}^i / P_{nom}^i / A^i}{\dot{Q}_{nom}^{i,0} / Q_{nom}^{i,0} / P_{nom}^{i,0} / A^{i,0}}\right)^\gamma \tag{29}$$

with total capital expenditure C^i for unit with nominal capacity $\dot{Q}^i_{nom}/Q^i_{nom}/P^i_{nom}/A^i$, cost $C^{i,0}$ and nominal capacity $\dot{Q}^{i,0}_{nom}/Q^{i,0}_{nom}/P^{i,0}_{nom}/A^{i,0}$ of a reference unit, scaling exponent γ, maintenance cost factor α^i and interest rate β as well as time horizon τ at financing, [10]. Thus, in c^i the annual rate for financing is combined with the maintenance costs. The values used here for the individual units are summarized in *Table 1*, [2], [11].

Table 1 values for calculating annual component costs c^i

	reference capacity	$CAPEX^0$[€]	γ [−]	α [−]	τ [−]	β [−]
PV unit	$P^{PV,0}_{nom} = 1$ kW	1400	0.95	0.01	10	0.03
WT unit	$P^{WT,0}_{nom} = 1$ kW	5000	0.95	0.03	10	0.03
ST unit	$A^{ST,0} = 1\ m^2$	240	0.95	0.5	10	0.03
GB unit	$\dot{Q}^{GB,0}_{nom} = 1$ kW	2700	0.45	0.015	10	0.03
EB system	$\dot{Q}^{EB,0}_{nom} = 1$ kW	70	0.66	0.02	10	0.03
HP system	$P^{HP,0}_{nom} = 1$ kW	2650	0.95	0.02	10	0.03
TES system	$Q^{TES,0}_{nom} = 1$ kWh	80	0.87	0.02	10	0.03

To calculate the operating costs, days with positive and negative energy demand E^{el}_d must be considered separately. Thus, in $E^{el}_{in,m}$, all positive energy demands of the considered representative week of each month m are summarized and in $E^{el}_{out,m}$ all negative ones. For the calculation of the weekly gas demand $E^{gas}_{in,m}$, however, the daily values E^{gas}_d are simply summed up. The total annual costs TAC can then be calculated:

$$TAC = \sum_{m\in\mathcal{M}} \left(p^{el}_{buy}E^{el}_{in,m} - p^{el}_{sell}E^{el}_{out,m} + p^{gas}_{buy}E^{gas}_{in,m}\right)4.3 + \sum_{i\in\mathfrak{I}} c^i \tag{30}$$

with $\mathcal{M} = \{Jan,\ Feb,\ \cdots,\ Dec\}$, $\mathfrak{I} = \{PV, WT, ST, GB, EB, HP, TES\}$, revenue for the sale $p^{el}_{sell} = 0.06\,€/\text{kW}$ and price for the purchase $p^{el}_{buy} = 0.35\,€/\text{kW}$ of electrical energy as well as price for natural gas $p^{gas}_{buy} = 0.13\,€/\text{kW}$. The weekly values are multiplied by 4.3 to get estimated monthly values.

The global warming impact GWI is considered as ecological criterion

$$GWI = \sum_{m\in\mathcal{M}} \left(g^{el}\left(E^{el}_{in,m} - E^{el}_{out,m}\right) + g^{gas}E^{gas}_{in,m}\right) \tag{31}$$

with the specific global warming impacts $g^{el} = 349\ \text{g}_{\text{CO2eq}}/\text{kWh}$ and $g^{gas} = 244\ \text{g}_{\text{CO2eq}}/\text{kWh}$ of electricity and natural gas, respectively [2]. It should be noted that the specific global warming impact from purchased energy is actually varying greatly over time, depending on the shares of e.g. renewable energies. Formulation (31) reduces the GWI through the purchase of energy to emphasize the positive contribution. It should be noted at this point that the manufacture of components or units also has an effect on the GWI, which, according to [12], is significantly lower than that caused by operation. However, the contribution of manufacturing to the GWI is not considered here.

3.2. Optimization problem formulation

The two optimization objectives (30) and (31) depend on the one hand on the investment costs of the installed units and on the other hand on the consumption of electrical energy and natural gas. Both criteria therefore depend on the nominal capacities of the installed units, which are to be determined as part of an optimal design. Thus, the design parameters $\mathbf{p}_{nom}$ of the energy concept are:

$$\mathbf{p}_{nom} = \left[A^{PV}, P^{WT}_{nom}, A^{ST}, \dot{Q}^{GB}_{nom}, \dot{Q}^{EB}_{nom}, \dot{Q}^{HP}_{nom}, Q^{TES}_{nom}\right]^T. \tag{32}$$

The multi-objective optimization problem for minimizing both objectives simultaneously is

$$\min_{\mathbf{p}_{nom}\in P} \begin{bmatrix} TAC \\ GWI \end{bmatrix} \qquad \text{with} \qquad P = \{\mathbf{p}_{nom} \in \mathbb{R}^7 | h_{max} \le 0, \mathbf{p}^l_{nom} \le \mathbf{p}_{nom} \le \mathbf{p}^u_{nom}\} \tag{33}$$

with the constraint $h_{max} = max\left(\dot{Q}^{dem,(i)} - \dot{Q}^{GB,(i)} - \dot{Q}^{EB,(i)} - \dot{Q}^{HP,(i)}\right)$, which is the maximum of all constraints h of the optimal solution of the problem (24). It can happen, that if the nominal capacities of the GB, EB and HP units are chosen too small, a valid solution of (24) is not possible, which result in $h > 0$. This constraint is essential, since the units are chosen to be as small as possible, particularly to reduce the investment costs. The lower limits for the design parameters are chosen to be $\mathbf{p}^l_{nom} = [0, 0, 0, 0, 0, 0, 0]^T$ and the upper limits to be $\mathbf{p}^u_{nom} = [4000, 24, 2000, 250, 250, 250,\ 5000]^T$. This means that individual units do

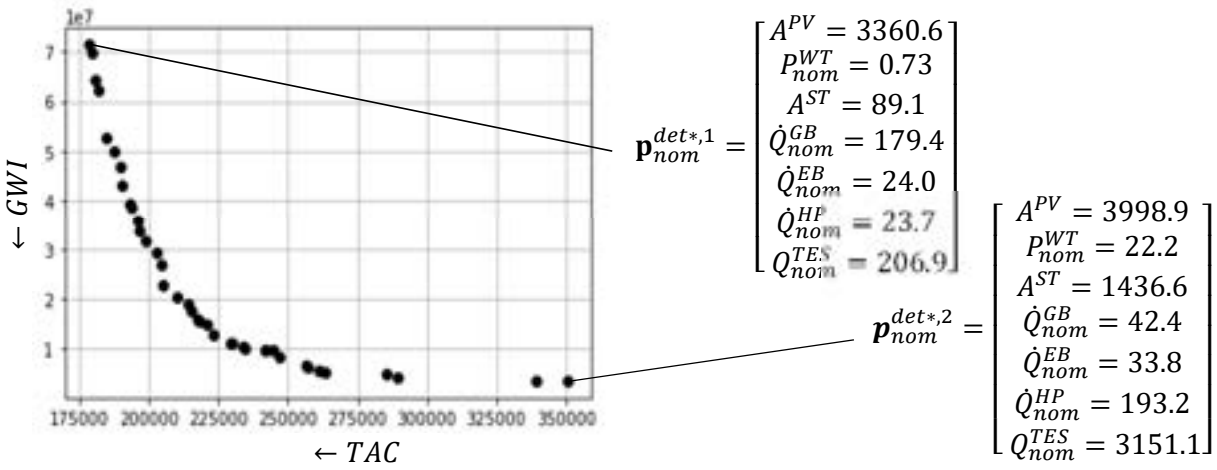

Figure 5 Pareto-front as solution of the multi-objective problem (33)

not have to be used and the entire heat requirement can be covered by GB, EB or HP. It should be noted here that the capacity of the units is modelled continuously, so that the results may not be directly implemented in practice, since e.g. PV units are only available in a certain size.

3.3. Discussion of the results

The optimization problem (33) is solved by the genetic algorithm NSGA2 which is implemented like the modelling of the units and the energy concept in Python, [13]. The result is a Pareto-front consisting of optimal compromises between the objectives, *Figure 5.* Here it can be clearly seen that the objectives TAC and GWI are contradictory and the design $\mathbf{p}_{nom}^{det*,1}$ for a minimum TAC causes only about half the annual costs as the design $\boldsymbol{p}_{nom}^{det*,2}$ for a minimum GWI. However, there are also compromises in between that can be chosen for implementation. The low TAC is realized mainly due to a low gas price p_{buy}^{gas} compared to the price of electricity p_{buy}^{el} and a high nominal capacity $\dot{Q}_{nom}^{GB}$ of the GB unit, while a low GWI is achieved through a high use of renewable energy sources, a large thermal energy storage and a high nominal capacity $\dot{Q}_{nom}^{HP}$ of the HP unit.

4. Robust optimization approach

The result of the optimization from chapter 3.3 depend decisively on the assumptions about e.g. prices for electricity and gas, unit performances, investment costs as well as assumptions about environmental influences such as wind speeds and solar radiation. Uncertainties in these assumptions can lead to deviating and undesirable system behaviour. It is the task of robust optimization to take this into account in the design process. In the following sections, the uncertainties assumed here are presented, the corresponding robust optimization concept is explained and finally the solution from deterministic and robust optimization is compared.

4.1. Description of uncertainties

In this paper uncertainties in the price of gas p_{buy}^{gas} and in the solar radiation S^{pan} on the panels are considered for a first investigation. This is realized in the form of two uncertainty factors f_1 and f_2 such that:

$$\tilde{S}^{pan} = S^{pan} f_1 \qquad \text{and} \qquad \tilde{p}_{buy}^{gas} = p_{buy}^{gas} f_2 \tag{34}$$

with $0.9 \leq f_1 \leq 1.0$ and $1.0 \leq f_2 \leq 2.0$. Thus, the gas price will change with an assumed increase of up to 100%. Solar radiation is assumed to be reduced by up to 10%, which corresponds to degraded panel performance, additional shading, or overestimation of solar radiation.

Local response surfaces are used to assess the influence of f_1 and f_2 on the optimization objectives (30) and (31), [14]. Response surfaces enable the relationship between input parameters and output of a function to be approximated on the basis of a few function evaluations in order to subsequently carrying out extensive statistical studies very efficiently. To set up the response surfaces, a random sample $\left[f_1^{(i)}, f_2^{(i)}\right], i = 1(1)4$ based on a Latin Hypercube Sampling is defined and analysed with $\mathbf{p}_{nom} = \mathbf{p}_{nom}^{det*,1} = const.$ Kriging models $\hat{y}_{TAC}$ and $\hat{y}_{GWI}$ are then created using the calculated values of $TAC^{(i)}$ and $GWI^{(i)}$, [15]. The response surface $\hat{y}_{TAC}$ is shown in *Figure 6a* as an example. A sample with $N = 1e3$ sampling points is then defined and

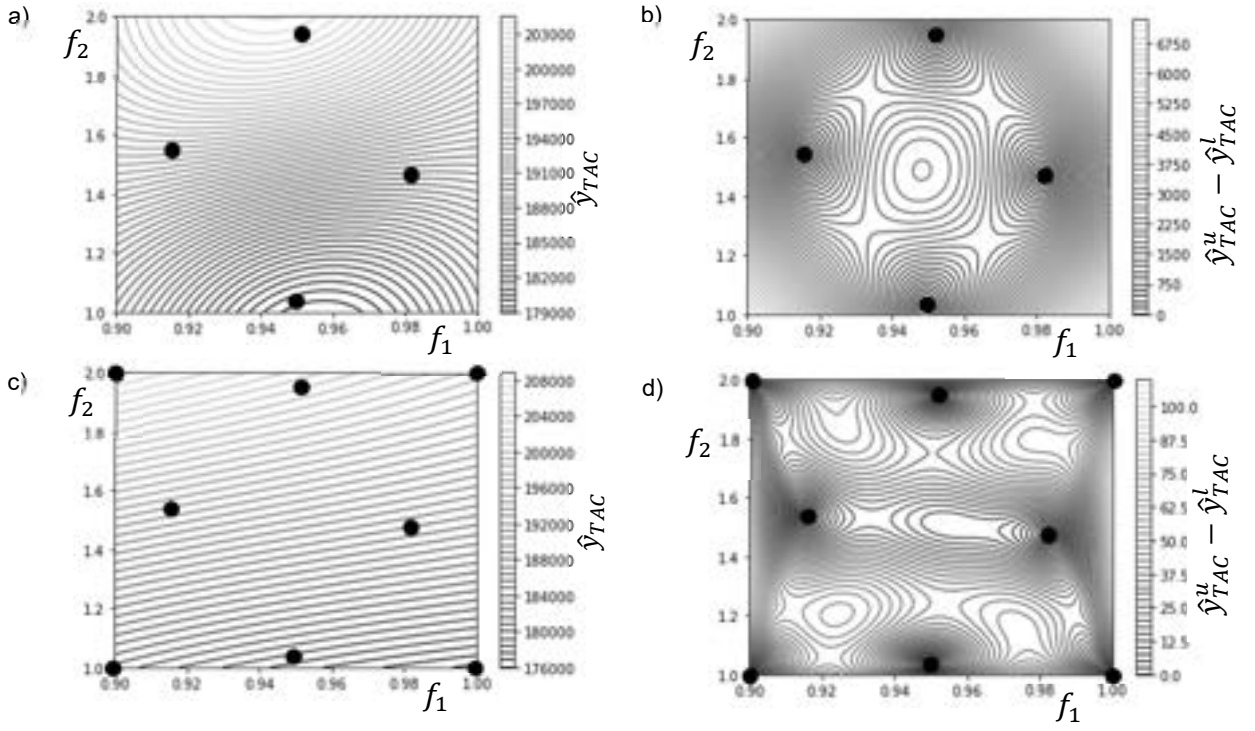

Figure 6 approximation of $\hat{y}_{TAC}$ using a) four and c) eight design evaluations (●) and the associated differences $\hat{y}^u_{TAC} - \hat{y}^l_{TAC}$ between upper and lower bound (b) and (d)

evaluated just using the response surfaces in order to determine the robust criteria. The 95% quantiles P_{95}^{TAC} and P_{95}^{GWI} of the objectives are chosen as criteria, which e.g. for TAC is defined as follows:

$$\frac{1}{N}\sum_{i=1}^{N} I(\hat{y}_{TAC}^{(i)}) = 0.95 \qquad \text{with} \qquad I(\hat{y}_{TAC}^{(i)}) = \begin{cases} 1 & \hat{y}_{TAC}^{(i)} \leq P_{95}^{TAC} \\ 0 & else \end{cases}, \tag{35}$$

and describes a value under which 95% of all elements of the sample are located. However, since the criteria were only determined on the basis of the response surfaces, the question arises as to how accurate these estimates were. For this purpose, the variances $\hat{s}_{TAC}$ and $\hat{s}_{GWI}$ of the Kriging estimates $\hat{y}_{TAC}$ and $\hat{y}_{GWI}$ can be used, [16]. This allows to define lower and upper limits, e.g.

$$\hat{y}_{TAC}^{l,(i)} = \hat{y}_{TAC}^{(i)} - 3\hat{s}_{TAC}^{(i)} \qquad \text{and} \qquad \hat{y}_{TAC}^{u,(i)} = \hat{y}_{TAC}^{(i)} + 3\hat{s}_{TAC}^{(i)}\,, \tag{36}$$

which define a range in which the actual value $TAC^{(i)}$ is within a probability of $\approx 99.99\%$, *Figure 6b*. With these lower and upper limits, the quantiles can then be determined according to (35) and thus a quantile range

$$R_{P,95}^{TAC} = P_{95}^{u,TAC} - P_{95}^{l,TAC} \tag{37}$$

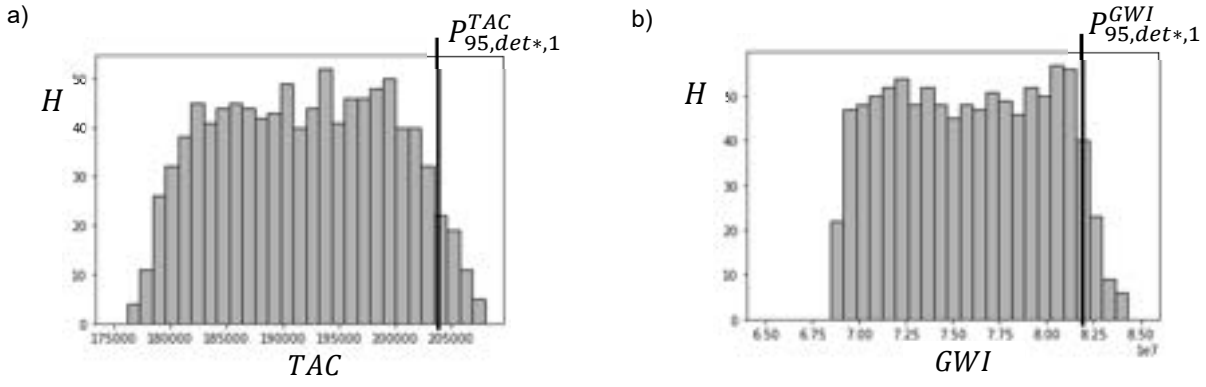

Figure 7 frequency distributions of the optimal solution $\boldsymbol{p}_{nom}^{det*,1}$ with respect to a) TAC and b) GWI

can be estimated. If this range is above a 1% limit of P_{95}^{TAC}, the response surface has to be refined. Appropriate update points are defined by solving the optimization problem

$$\max_{f_1,f_2} \hat{s}_{TAC} \qquad \text{with} \qquad 0.9 \leq f_1 \leq 1.0 \qquad \text{and} \quad 1.0 \leq f_2 \leq 2.0 \tag{38}$$

which finds the point where the estimation $\hat{y}_{TAC}$ has the greatest variance $\hat{s}_{TAC}$. This update process is carried out until the quantile range (37) is sufficiently small, *Figure 6c* and *d*. As can be seen, the response surface can thus be updated very efficiently using just a few iterations. The distributions and estimates for the quantiles $P_{95,det*,1}^{TAC}$ and $P_{95,det*,1}^{GWI}$ determined for the design $\mathbf{p}_{nom}^{det*,1}$ for minimal TAC using the updated response surfaces are shown exemplarily in *Figure 7,* where the spread in the TAC covers a range of $30\text{k}€$.

4.2. Robust optimization concept

As reference for the robust optimization the optimal design $\mathbf{p}_{nom}^{det*,1}$ of the deterministic optimization (33) is chosen, because it may be an appropriate choice from an economic perspective. Due to the fact, that the robust assessment is performed according to the adaptive local response surface procedure described in the previous section, where a number of energy concept evaluations are needed for a single design, just a single objective robust optimization approach is chosen in order to reduce the computational effort. This results in the optimization problem

$$\min_{\mathbf{p}_{nom} \in P} P_{95}^{TAC} \quad \text{with} \quad P = \left\{ \mathbf{p}_{nom} \in \mathbb{R}^7 \left| \begin{bmatrix} h_{max} \\ P_{95}^{GWI} - P_{95,det*,1}^{GWI} \end{bmatrix} \leq \mathbf{0}, \mathbf{p}_{nom}^{l} \leq \mathbf{p}_{nom} \leq \mathbf{p}_{nom}^{u} \right. \right\}, \tag{39}$$

where in addition to (33) a further constraint is added to ensure that an improvement of P_{95}^{TAC} is not be achieved by an increase of P_{95}^{GWI} and a comparability with the design $\mathbf{p}_{nom}^{det*,1}$ can be guaranteed.

4.3. Comparison of optimization results

The optimization problem (39) is solved using a differential evolution algorithm implemented in Python, whereby the computing time was approximately twice as high as with the deterministic multi-objective optimization (33). In contrast to multi-objective optimization, the result is not a set of optimal compromises but a single design

$$\begin{aligned} \boldsymbol{p}_{nom}^{rob*} &= \left[A^{PV}, P_{nom}^{WT}, A^{ST}, \dot{Q}_{nom}^{GB}, \dot{Q}_{nom}^{EB}, \dot{Q}_{nom}^{HP}, Q_{nom}^{TES}\right]^T \\ &= [3539.7,\ 0.3,\ 173.7,\ 3.5,\ 57.6,\ 161.9,\ 755.3]^T. \end{aligned} \tag{40}$$

Compared to the deterministic optimum $\mathbf{p}_{nom}^{det*,1}$, *Figure 5*, the TES and the ST unit were significantly increased and the nominal capacity of the GB unit was reduced to a small value. According to the selected robust criterion, the quantile value P_{95}^{TAC} and thus the high costs to be expected could be reduced, *Figure 8a*. However, over a wide range, the deterministic optimum $\mathbf{p}_{nom}^{det*,1}$ results in low TAC, whereas the robust optimum has a significantly smaller variance in the TAC. In any case, the robust optimum $\boldsymbol{p}_{nom}^{rob*}$ results in a significantly smaller GWI, *Figure 8b,* which was not a goal of the optimization but is an effect due to an increase in the share of renewable energies. The choice of a specific objective of the robust optimization or the desired properties of the energy concept depend heavily on individual factors and must be redetermined depending on the situation.

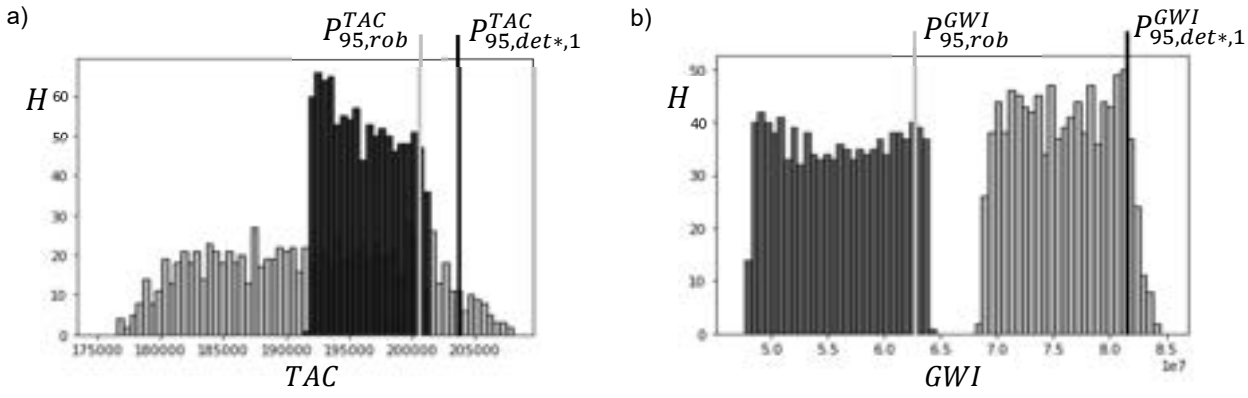

Figure 8 frequency distributions of the optimal solutions $\boldsymbol{p}_{nom}^{det*,1}$ (grey) and $\boldsymbol{p}_{nom}^{rob*}$ (dark grey) with respect to a) TAC and b) GWI

5. Conclusions

In this paper, the modelling of units of an energy concept was described and the procedure for the integrated analysis with regard to economic and environmental criteria was explained. Based on the analysis, a deterministic multi-objective and a robust single-objective optimization problem for the dimensioning of the units used were defined and corresponding optimizations were carried out.

It turns out that the results of the deterministic optimization depend strongly on the assumptions and boundary conditions used and deviations can lead to a large scatter in the objective functions. Furthermore, changes in the boundary conditions of the optimization can lead to different optimal configurations. As part of a robust optimization, assumptions about uncertainties in the price of natural gas and the solar radiation were considered and a design was found that has a lower scatter in the TAC and reduces the expected high costs compared to a selected reference design from the deterministic multi-objective optimization. This shows that the consideration of uncertainties is particularly necessary for long planning periods. In general, the result of a robust optimization strongly depends on the criteria and uncertainties considered, so that different criteria and more realistic assumptions of the uncertainties are investigated in further studies.

Integration of the Compression Units of the Processing Plant with an Organic Rankin Cycle for Power Generation and Cooling Process

Ali Allahyarzadeh Bidgoli[a], Jurandir Itizo Yanagihara[b]

[a] Department of Mechanical Engineering, Polytechnic School, University of São Paulo, São Paulo, Brazil, ali@usp.br

[b] Department of Mechanical Engineering, Polytechnic School, University of São Paulo, São Paulo, Brazil, jiy@usp.br,

Abstract:

The gas compression units in the processing plant are used for various purposes. Compression of the associated gas is designed to adjust for the different operating pressures. In addition, the injection of CO_2 into oil reservoirs is used for enhanced oil recovery (EOR) and/or reduction of environmental impact. These systems utilize dozens of megawatts of electrical energy and intercooling for each compression stage. Therefore, the equipment used is energy-intensive and not thermodynamically efficient. An Organic Rankine Cycle (ORC) technology produces electrical energy from heat sources with low to medium temperature levels (90°C - 150°C). In the present work, a model of an ORC integrated with the intercoolers of the compression units is used to simulate the energy conversion of the system. Next, various working fluids, such as R123, n-butane, n-pentane, hexane, and n-heptane, are considered. The results show a possibility of net power generation by R123 ORC of up to 40 MW. Furthermore, only an increase of 0.95% in the CO_2 molar fraction of the flue gas leads to an increase of 1.29E8 kJ/h in the cooling demands of the CO_2 removal and compression units. Moreover, the presented increase in cooling demands creates the possibility of net power generation of up to 41 MW by ORC. Furthermore, in terms of footprint, this integrated system can be implemented in onshore structures and with some modifications in the condenser in offshore plants. Finally, this integrated system reduces environmental impacts by generating power from waste heat sources.

Keywords:

Multi-stage compression, Intercooling, Organic Rankine Cycle, Power production, Thermodynamic efficiency.

1. Introduction

Based on the IPCC Climate Change 2022 report, it is estimated that there will be a decrease of one billion tonnes of carbon dioxide emissions by 2050 [1]. Accordingly, decarbonization is no longer a prestige option in industries but is also an obligation for several industries, especially oil and gas industries with massive GHG emissions. In addition to the CO_2 removal unit of the oil and gas industries, the proper processing plant needs high cooling demands for the different cooling steps in gas compression units [2]. Attending to these demands and considering the environmental impacts is a dual challenge for the future of processing plants.

Typical processing plants consist of more than five gas compression steps to prepare the desired condition for exportation or injection [3, 4]. These steps need precooling, intercooling, and cooling to meet the required operating temperature. Therefore, the required cooling demands reach 100 MW for a typical processing plant [5, 6]. Conversely, due to the high operating pressure and temperature of the gas compression unit, the equipment used is energy-intensive and is not thermodynamically efficient [7].

An Organic Rankine Cycle (ORC) system is a thermodynamic process utilized for small to medium-scale implementations in several operating temperature ranges and electricity productions using small to intermediate and high-temperature heat supplies varying from 80 to 400°C. With the help of a closed cycle, the limited heat that might otherwise be wasted can be used effectively [8, 9] for power generation. This technology can also mitigate environmental impacts by managing and using waste heating sources [10].

Vilarini et al. [8] and Morais et al. [11] show that the selection of an organic fluid for a system depends on the evaporation enthalpy, dry, isentropic (or wet) characterization, and the slope of the saturation vapor curve of the T-s diagram of the working fluid. In addition to traditional hydrocarbons as working fluids of ORC, such as

n-butane, heptane, propane, etc, the refrigerants of the R12XX family present outstanding performance [12, 13] for certain operating conditions. This positive effect on thermodynamic performance is more prominent when applying regenerative ORC [12].

To the author's knowledge, no other research group evaluated the performance of different working fluids for the cooling process of an ORC that uses the waste heat of compression units of a typical processing plant as the heating source. Moreover, the impact of the CO_2 molar fraction in the flue gas on the cooling demand of a processing plant and the analysis of using this waste heating for power production by ORC is not presented in the open literature.

Therefore, to fill the existing gaps and evaluate possible solutions, a model of an ORC integrated with the intercoolers of the compression units is used to simulate the energy conversion of the system. Next, various working fluids, such as R123, n-butane, n-pentane, hexane, and n-heptane, are considered. In addition, the impact of the variation of the CO_2 molar fraction in the process stream is investigated, and its effect on the cooling demands of the compression unit and the power generated for each working fluid is calculated. Finally, the dimensions of the installation for application in onshore and offshore structures and the environmental impacts of this integration are discussed.

2. Process Simulator and Problem Setup

2.1. System description

2.1.1 Compression units

As Figure 1 shows, the organic Rankin cycle uses the waste heating of the following unit to meet cooling and power generation demands:

1- **Main gas compression**
This unit is responsible for compressing the associated gas of the fluid reservoirs, including CO_2 and natural gas components, for the following processing units at operating pressures of up to 8500 kPa. The suction pressure of compression is 2000 kPa. This unit has precooling and cooling heat exchangers [3].

2- **Vapor recovery unit**
The vapor recovery unit increases and adjusts the operating pressure of the separated gas in different steps of the separation train and the suction temperature of the main gas compressor. This unit comprises two compressor stages with two operating conditions and cooling heat exchangers [14].

3- **Exportation Gas Compression**
The exportation gas system receives gas with the suction pressure of the compressors at 250 bar. Note that the cooling steps of the compression system provide heating sources for a Rankine cycle for power generation [15].

4- **CO_2 compression**
The gases separated in membrane CO_2 separators from the fluid reservoir and the CO_2 captured by the MEA solution-based mechanism from the combustion product are prepared in these systems. The discharge pressure of these units can reach up to 25 MPa. These units comprise four compression stages and the corresponding intercoolers [7].

5- **Carbon capture**
The carbon capture unit or the CO_2 removal unit presents a huge cooling demand for the condenser of the stripper tower, which is a significant source of waste heat for use in the organic Rankine cycle [5].

Table 1 shows the operating conditions of the compression unit of a typical processing plant (offshore and FPSO) that works with many gas and CO_2 in reservoir fluid.

Table 1. Specification of gas compression units [16].

Main unit	Description	Value
Gas treatment	Number of the main units	5
Vapor recovery	Operating pressure of suction-discharge (kPa)	770–2000
Main compression	Operating pressure of suction-discharge (kPa)	2000 –8500
	Compression capacity (Sm^3/d)	6,000,000
	Number of stages	2
Gas exportation	Operating pressure of suction-discharge (kPa)	4500–25,000
	Compression capacity (Sm^3/d)	3,000,000
CO_2 treatment	Number of main units	3
	Number of stages	4
CO_2 compression	Operating pressure of suction-discharge (kPa)	400–25,000

As shown in Figure 1, the heat transferred from three systems is the heat source for the organic Rankine cycle. In fact, in each unit, there are a number of heat exchangers (pre-coolers, intercoolers, and coolers) connected to the ORC system. From the point of view of the ORC system, the heating is absorbed in three stages: economizer, evaporator, and superheater. Furthermore, the ORC uses a regenerative heat exchanger to increase energy efficiency.

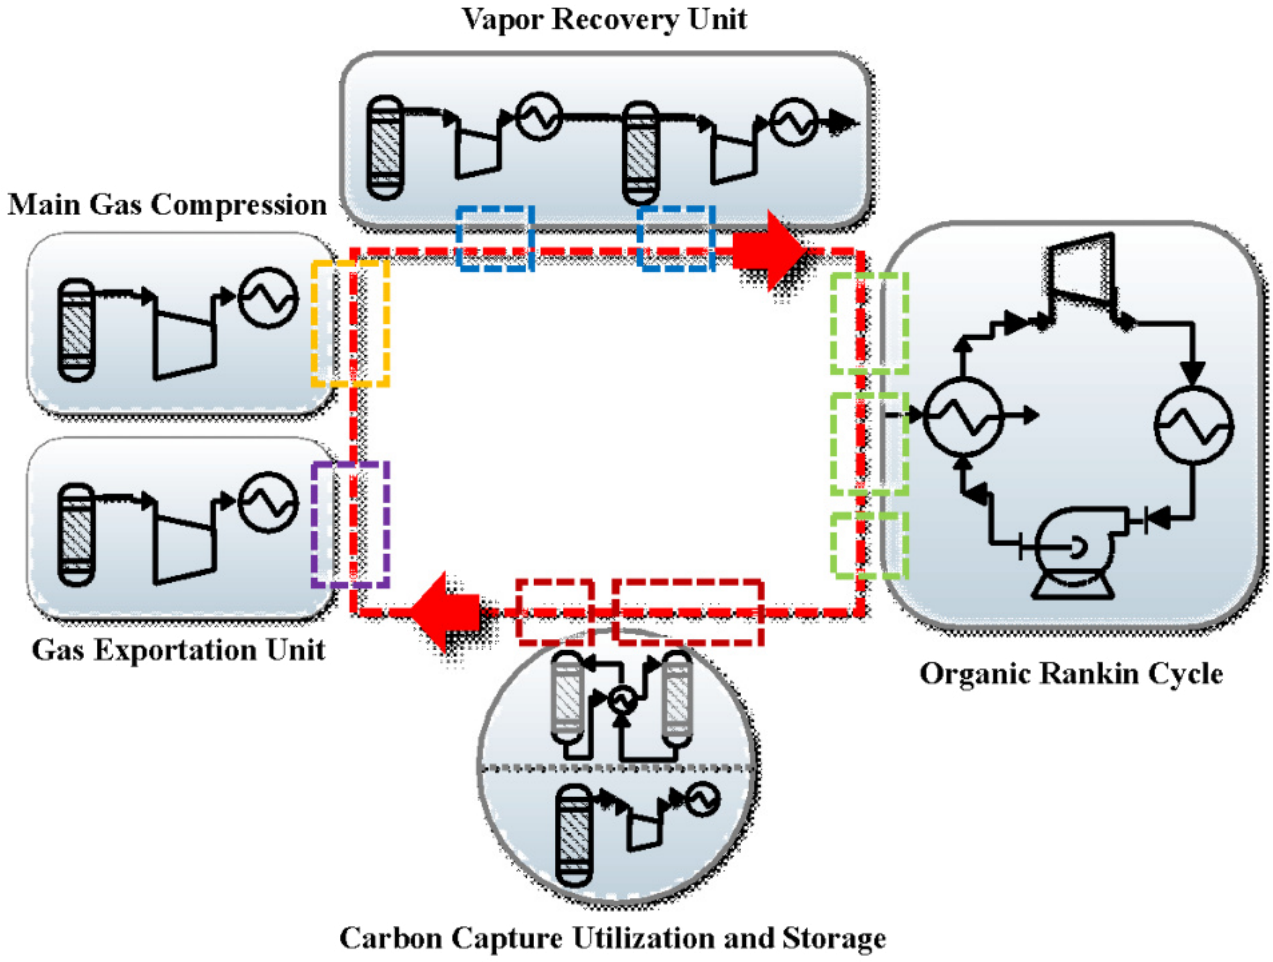

Figure 1. A Conceptual flow diagram of compression units and Organic Rankin Cycle

2.1.2 Organic Rankin Cycle

In this study, as previously mentioned, a regenerative ORC is simulated. To evaluate the performance of different working fluids with respect to the operating condition of the cooling heat exchangers, four distinct fluids with different thermodynamic properties are implemented, as seen in Table 2. In this case, n-butane presents the minimum boiling point and critical temperature, while the lowest critical pressure belongs to n-heptane. After R123, the next lowest critical temperature is for n-hexane. Figure 2 presents the temperature vs. entropy diagrams calculated for n-pentane in this study. Figure 2 also shows the quality lines, different pressure lines, and connected saturate states.

Table 2. Boiling point, critical temperature, and critical pressure of applied working fluids

Fluid	Boiling Point (°C)	Critical Temperature (°C)	Critical Pressure (kPa)
n-pentane	36.06	196	3367
n-butane	-0.50	152	3797
n-hexane	68.73	234.7	3032
n-heptane	98.4	267	2736
R123	27.8	183.6	3661

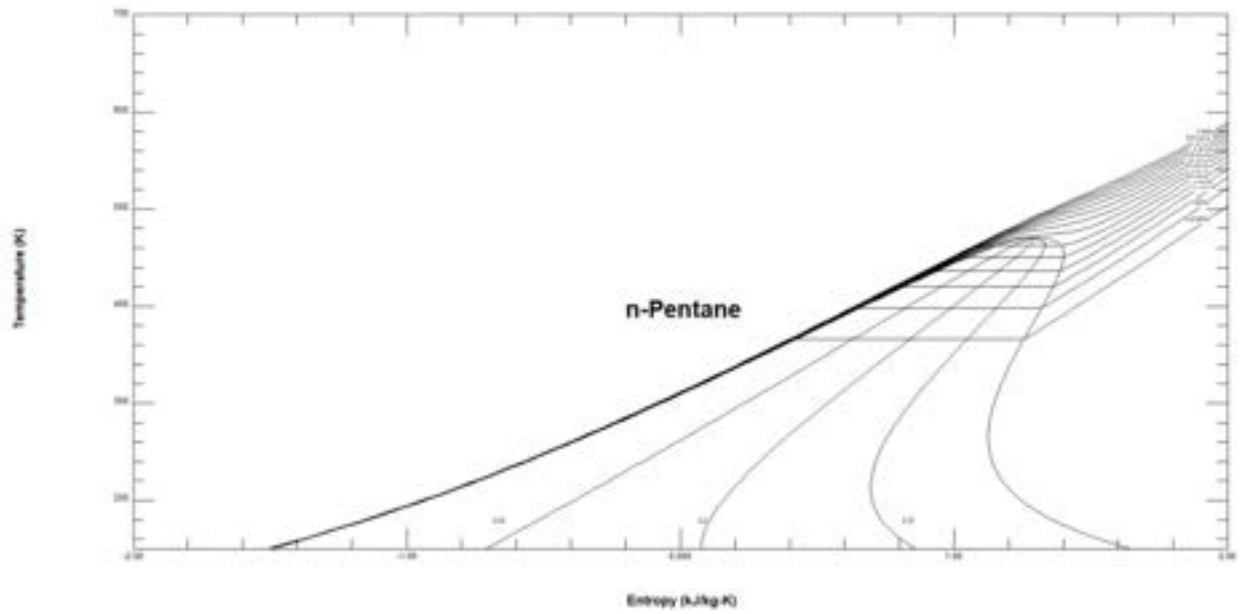

Figure 2. T-s diagram of the applied working fluid (n-pentane)

2.2 Assumptions and numerical modeling

The following assumptions are considered or adopted for numerical simulations:

- The environmental pressure is considered to be 101 kPa, and the ambient temperature is 25 ^{o}C [11].
- A polytropic efficiency of 85% is considered for all centrifugal compressors [7];
- The isentropic efficiency of the steam turbine is considered to be 90% [11];
- Aspen HYSYS [17] is used for model development. Due to the different operating pressures, temperatures, and compositions of each unit, a multi-EoS simulation (PR [18], Span-Wagner [19], and Acid Gas [20]) is considered for the calculation of thermodynamic properties;
- Heat loss and fluid leakage are considered negligible for the heat exchangers.
- The pressure drop of pre-coolers, intercoolers, and coolers is adjusted for 50 kPa based on technical documents, and the pressure drop in other heat exchangers is negligible [16];
- To avoid the temperature cross in the heat exchangers, the minimum temperature approach is set at 2 ^{o}C [3].

3. Methodologies

3.1. Thermodynamic analysis process

Equations 1 and 2 are the mass and energy balances for volume control in a steady state

$$\sum \dot{m}_{in} - \sum \dot{m}_{out} = 0 \tag{1}$$

$$\dot{Q} - \dot{W} + \sum \dot{m}_{in} h_{in} - \sum \dot{m}_{out} h_{out} = 0 \tag{2}$$

where $\dot{m}$ = mass flow rate

$\dot{Q}$ = heat generated or rejected

$\dot{W}$ = work consumed or produced

h = specific enthalpy

in and *out*= input and output.

The total heat transferred between the tube and shell sides (Heat Exchanger duty) can be defined in terms of the overall heat transfer coefficient, the area available for heat exchange, and the log mean temperature difference as Equation 3 presents

$$Q = UA\Delta T_{LM} F_t \tag{3}$$

where

U = overall heat transfer coefficient

A = surface area available for heat transfer

ΔT_{LM} = logarithmic mean temperature difference (LMTD)

F_t = LMTD correction factor

The following general relation applies to the shell side of the heat exchanger.

$$m_{shell}(h_{in} - h_{out})_{shell} - Q_{loss} + Q = \rho \frac{d(Vh_{out})_{shell}}{dt} \tag{4}$$

For the tube side

$$m_{tube}(h_{in} - h_{out})_{tube} + Q = \rho \frac{d(Vh_{out})_{tube}}{dt} \tag{5}$$

where:

m_{shell} = shell fluid flow rate

m_{tube} = tube fluid flow rate

ρ = specific mass

h = enthalpy

Q_{loss} = heat loss

Q = heat transfer from the tube side to the shell side

V = volume of shell or tube holdup

4. Results

This section presents and discusses the results of the integration of the compression unit with ORC. First, the calculated duty of each unit's heat exchangers that can be used as the heat source for the ORC is presented. Then, the power generated and applied operating conditions for the ORC are shown. In addition, the variation of the CO_2 molar faction in the process stream is discussed, and finally, a discussion regarding weight and footprint is presented.

4.1 Waste heat of compression units

Hydrocarbon fluid can be extracted directly from the processing plant for use as the working fluid in the ORC. As the operating conditions of precooling, intercooling, and condensers are different**,** it is essential to adjust the heat exchanger for feasible and acceptable heat transfer. For example, avoiding temperature cross is an important matter for using the waste heat of the compression unit in the ORC.

Figure 3 shows the waste heat available for recovery in the compression and CO_2 removal units. In that, a MEA-based solution to separate CO_2 presents a cooling demand of approximately 1.4 X 10^8 kJ/h that can be used for ORC. Figure 3 shows that this waste heat is more than 37% of the total heating source, being the highest. Next, the heat exchangers for precooling, intercooling, and cooling of the CO_2 compression unit, the exportation gas compression, the main gas compression, and the vapor recovery unit represent, respectively, 23.5%, 23.1%, 13.7 %, and 2.4% of waste heat recovery, as can be seen in Figure 3.

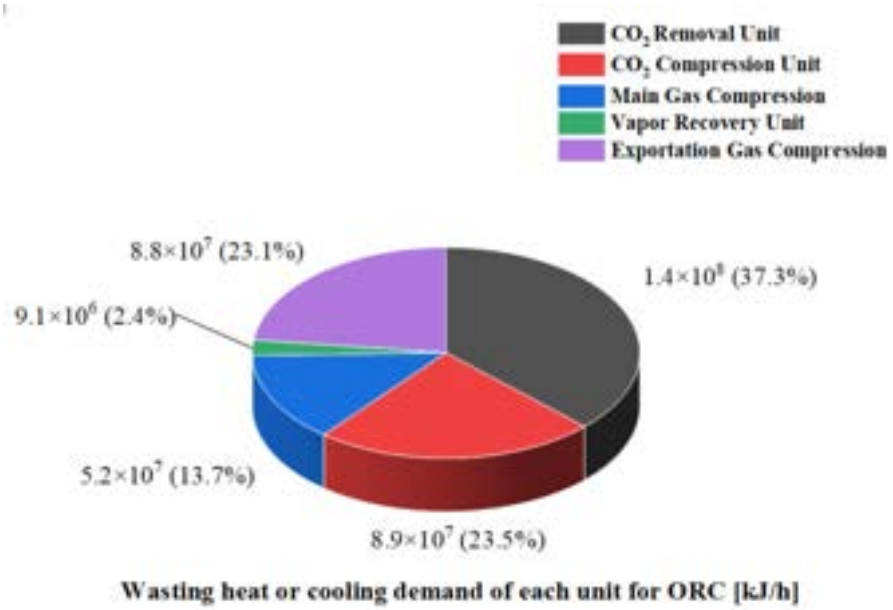

Figure 3. Existing duty of the applied heat exchanger for using the waste heat of coolers as the heat source of the ORC

Figure 4 shows the power generated by the different working fluids in Table 2. The performance of N-pentane, n-butane, hexane, n-heptane, and R123 is evaluated and presented in Figure 4. Figure 4 shows that R123 yields a power of 41 MW, and n-hexane achieves a power generation of 34.7 MW, which is more than 32% of the total power demand of a typical offshore structure [3, 15]. After n-hexane, n-pentane presents a power generation close to 32 MW and is in third place in terms of power generation. Furthermore, as shown in Figure 4, n-butane and n-heptane present a power generation of 18.6 and 27.8 MW, respectively. As can be seen here, R123 presents the highest power generated for the present operating conditions and the existing waste heat of a typical processing plant.

Figure 5 presents the work consumed by the pumps of ORCs. In that, an ORC with R123 as the working fluid needs a pump that consumes 973 kW of electrical energy. Next, the shaft work of pumps of the ORC working with n-pentane, n-butane, n-hexane, and n-heptane are 546, 375, 318, and 147 kW, respectively.

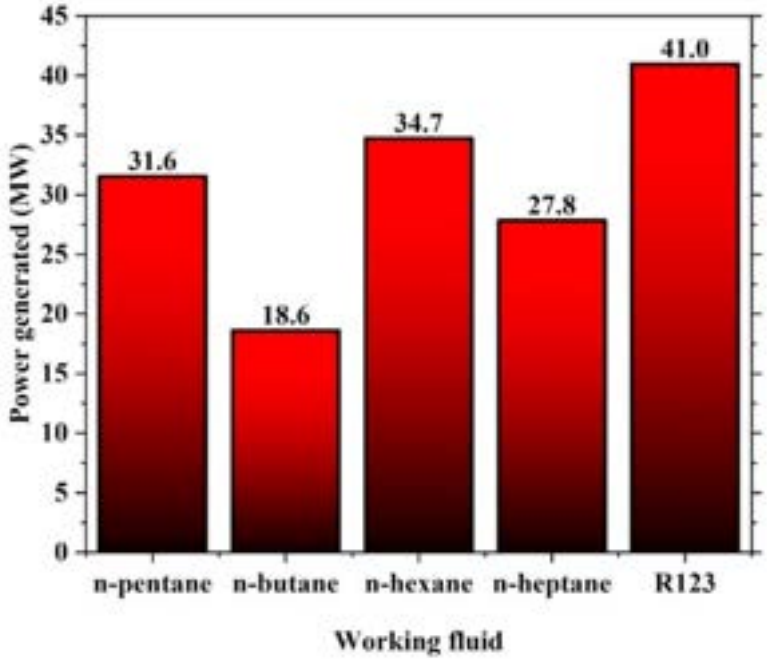

Figure 4. Power generated by working fluid applied in a typical processing plant of this study

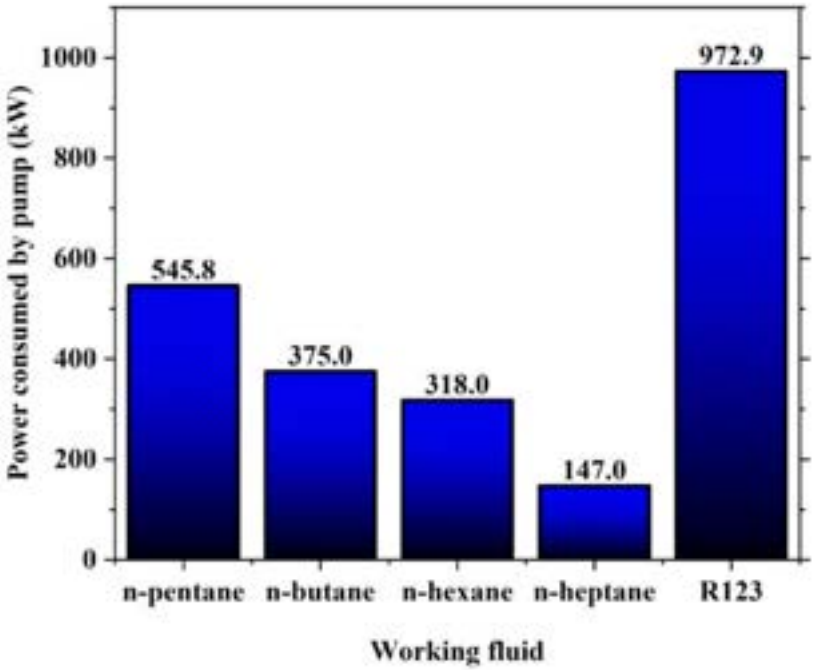

Figure 5. Power consumed by pumps of ORC working fluid applied in a typical processing plant of this study

Table 3 shows the operating condition of R123 ORC with the maximum power generated compared to other fluids. Based on that, the outlet temperature of the cold fluid from the regenerator is 36 °C, and the inlet temperature of the steam turbine is 123.3 °C, as can be observed in Table 3. The cooling demands of 10 heat exchangers from different units are used as the heat sources for the ORC. Table 3 shows that this arrangement generates 40 MW of power.

Table 3. Specification of R123 ORC

Section	Description	value
Organic Rankin Cycle	Operating fluid	R123
	Type of ORC	Regenerative
	Outlet temperature of cold fluid from the regenerator	36 °C
	Inlet temperature of steam turbine	123.3 °C
	Type of heating sources	Precooling, intercooling and cooling shell and tube HE
	Number of heating sources	10
	Net Power generation	40 MW
	Overall required power	973 kPa

4.2 Sensitivity analysis of CO_2 molar fraction on the power generation and heating sources of compression units

Figure 6 shows the effect of the CO_2 molar fraction of the flue gas on the power generation of the applied working fluids. In this case, CO_2 molar fractions of 2.65%, 3.1%, and 3.6% in the flue gas input mass flow rate are evaluated. This flue gas enters the CO_2 removal units, and then the separated CO_2 is sent to storage or utilization purposes. Note that as the mass flow rate increases, the required cooling demands increase for the condenser in the stripper tower of the CO_2 removal unit and the intercoolers of the CO_2 compression unit.

The increase in the heat provided to the ORC results in a higher temperature of the working fluid in the input of the steam turbine and ends with more power generated, as can be observed in Figure 6. In detail, with an

increase of 0.95% in the CO_2 molar fraction of flue gas, the power generated by R123 can increase to approximately 2% (41.81 MW), as can be seen in Figure 6. Moreover, Figure 6 presents the increase in CO_2 processing from the baseline of 2.63% to 3.6%, leading to an increase in the power generated by n-butane ORC of up to 20 MW (an increase of 1.45 MW).

Figure 7 introduces the effect of the CO_2 molar fraction of the flue gas on the waste heat of CO_2 processing plants, such as the CO_2 removal unit and the CO_2 compression unit. With a 0.02% increase in the CO_2 molar fraction of the flue gas, the cooling demand of the plants increases from 7.99E8 kJ/h to 8.28E8 kJ/h, as shown in Figure 7. Moreover, Figure 7 shows that an increase of 0.95% in the CO_2 molar fraction results in a waste heat of 9.19E9 kJ/h, which presents an increase of 15% (1.29E8 kJ/h).

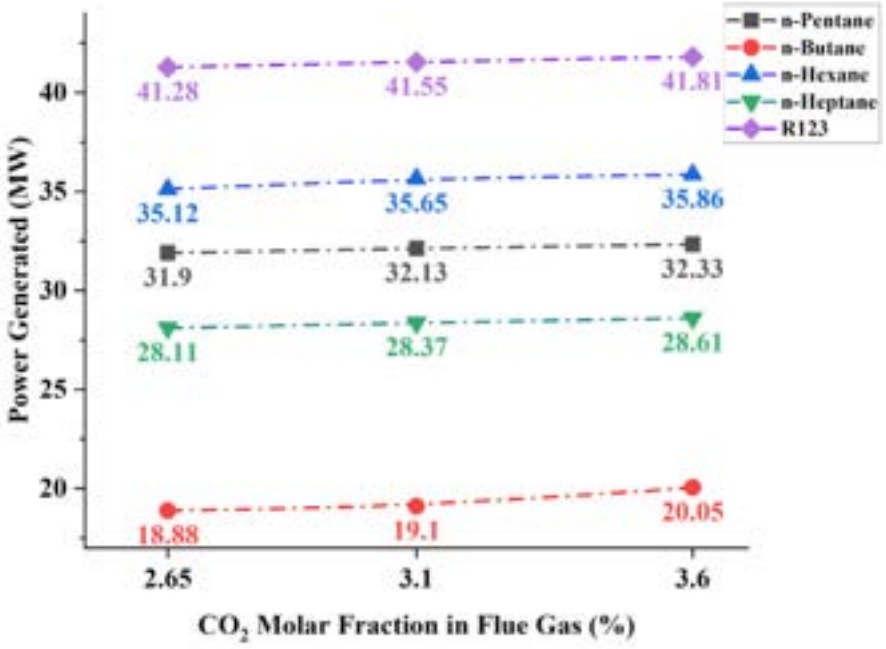

Figure 6. The effect of the CO_2 molar fraction of the flue gas on the power generation of working fluids.

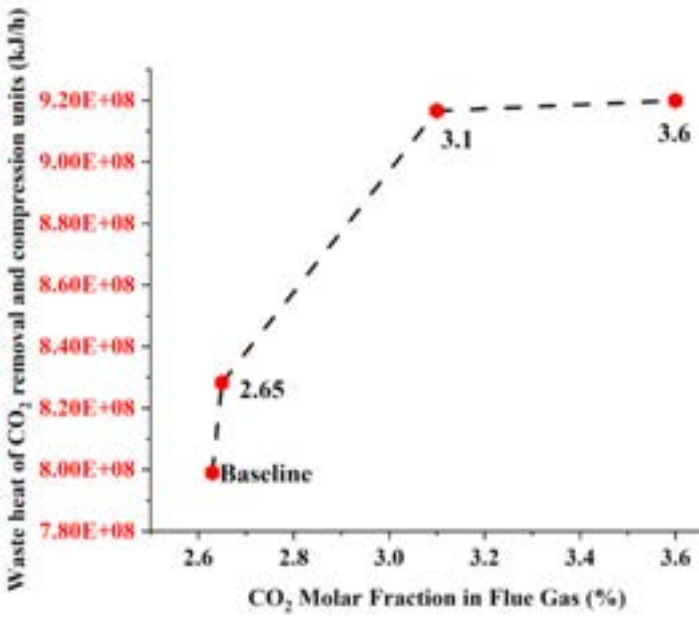

Figure 7. The effect of CO_2 molar fraction of flue gas on the waste heat of regarding processing plant to CO_2.

4.3 Footprint analysis of the proposed Organic Rankin Cycle

As a novelty of this work, there is no research in the open literature focused on the integration of compression units with an ORC for power generation and process cooling in an offshore processing plant. For such applications, the footprint and weight of any added system are crucial because they may imply a complete redesign of the whole haul [21].

For onshore applications, we present the following information. In terms of required footprint, based on the commercial data of an existing ORC system (without indicating the working fluid), for a geothermal heating source with an inlet steam temperature of 130 ^{o}C, a footprint for two 22.5 MW ORCs is approximately 30,000 m^2 [22]. These plants use radial outflow turbines that can work with two operating pressures.

As the satellite figures show (Figure 8, a and b), more than half the occupied footprint of these plants belongs to the air coolers of the condenser. In ORC integrated systems in processing plants, these air coolers can be replaced by shell and tube heat exchangers to meet the cooling demand, with a much smaller footprint. Although further studies focused on the topsides configuration are needed for offshore applications, the potential of this system for energy saving was clearly demonstrated.

Figure 8. ORC plants of up to 50 MW with geothermal heat sources: a) one of 22.5 MW, of two (Ken Kipaş), b) two of 24 MW (Kubilay I, II)

5. Conclusions

In this research, a model of an ORC integrated with the intercoolers of the compression units was used to simulate the energy conversion of the system. Next, various working fluids, such as R123, n-butane, n-pentane, hexane, and n-heptane, were applied for ORC to evaluate the most efficient with respect to power generation. Then, the variation of the CO_2 molar fraction in the flue gas was analyzed, and its effect on the cooling demands of the compression unit and the power generated for each working fluid was presented.

Integration was carried out successfully with ten heat exchangers, and R123 obtained up to 40 MW of net power generation. In addition, an increase of 0.95% in the CO_2 molar fraction of flue gas resulted in an increase of 15% in cooling demands of the units for CO_2 processing and the possibility of power generation of 41.81 MW by R123 ORC.

Regarding the required footprint for the presented ORC, it may be feasible to use it in onshore structures. Moreover, an offshore application can be made by redesigning the air cooler for the ORC condenser to use this heat source.

Furthermore, the presented system significantly decreases the environmental impact, namely the global warming effect of the compression units, because the cooling demands can be addressed by atmospheric air or seawater. On the other hand, any increase in the capacity of the CO_2 removal unit and its increase in cooling demands can be managed and converted to power generation. Finally, this system can be implemented for several industries with large gas compression units, and the recovered heat can be used to generate power.

Abstract:

The optimization of multi-energy systems (MESs) in which multiple energy carriers interact with each other is a complex problem. Their optimal operation and design can be determined through mathematical programming. A classical technology used in MESs is the combined heat and power units (CHP) whose efficiency is modeled through non-linear equations. These non-linear functions are approximated through piecewise linear ones by introducing binary decision variables, which generates a mixed-integer linear program (MILP). Consequently, optimizing such systems over a long time period with a high temporal resolution becomes infeasible in a reasonable amount of time. In this work, we propose a fast heuristic algorithm to optimize the design and operation of such an MES. Our case study is an MES at the scale of a district with five types of generation units, including a CHP, over a time period of one year with a temporal resolution of one hour. Comparison of the proposed heuristic and a state-of-the-art MILP solver over smaller time periods shows that the heuristic is up to 99.9 % faster, with a mean error of 2.3×10^{-4} % compared to the optimal solution. The heuristic can also solve the optimal design and operation problem over a year in about 10 minutes.

Keywords:

Combined Heat and Power, Part-Load Efficiency, Heuristic, Linearization, Multi-Objective Optimization.

1. Introduction

Energy systems may include several types of energy carriers, such as electricity or heat. However, these carriers are classically considered as separate systems. Combining them into a single multi-energy system (MES) can increase the energy efficiency of the system by taking advantage of the synergies and interactions between the energy carriers [1]. It helps to reduce costs or reduce environmental impact by integrating renewable energy sources (RES) more easily in the form of intermittent energy sources [2].

An MES can be optimized using techniques from Operational Research by modeling the system as a mathematical program. Optimization of an MES generally focuses on improving two main areas of the system: its *design*, and its *operation*. Optimizing the design aims to select which production technologies to use in the system, along with their installed capacity, configuration, etc. Optimizing the operation deals with planning the use of the technologies to meet the energy demands by choosing at each time step how much energy each technology produces [3].

Two important points to consider when optimizing an MES are the time horizon and the temporal resolution of the optimization problem [4]. A large time horizon is more accurate to optimize the design, but more complex to solve. Similarly, high temporal resolution impacts the accuracy, especially when intermittent RES are considered in the system [5].

Two main approaches are typically used to solve such optimization problems: *exact* or *approximate* methods. Exact methods (e.g., branch-and-bound) solve the problem to optimality; however, they are computationally expensive and may not be able to even solve medium and large instances of the problem due to the high complexity of MES models. [6] review different exact methods and their properties to solve an MES. On the other hand, approximate methods employ approximate algorithms (e.g., heuristics or metaheuristics) to solve the problem. As their name implies, the approximate algorithms do not guarantee optimality but are able to provide good solutions (i.e., close to optimal) in a reasonable computation time for complex MES models. As an example, [7] use Particle Swarm Optimization algorithm, as a metaheuristic algorithm, to minimize the cost of an MES with three energy carriers.

To deal with the high complexity of MES models, simplifications are sometimes necessary [8]. An example is the use of design days to make the model less complex. Instead of solving the model over a long time period (e.g. a full year), it is solved over smaller time periods of one or a few days that represent typical days (i.e.,

design days) of the year. [9] divide the year into 12 representative periods with a resolution of one hour, plus an extreme event, prior to the optimization. [10] represent the year using shiftable 24-hour periods.

There can also be simplifications in the mathematical model. Modeling an MES typically generates some non-linearities. Considering the difficulties in solving non-linear models, it can be more efficient to linearize the non-linear parts of a model to solve it using linear solvers. [11] linearizes the part-load efficiency of a combined heat and power unit (CHP) and optimizes the model over several typical 24-hour periods.

In this work, we aim to optimize a non-linear MES over a time period of one year with a temporal resolution of one hour. To do so, the system is first formulated as a non-linear mathematical programming model, which is then linearized using a set of auxiliary binary decision variables. Finally, the initial non-linear model is transformed into a mixed-integer linear programming (MILP) model. Solving the proposed MILP model for a period of one year with a temporal resolution of one hour is practically impossible using exact methods. Consequently, an innovative heuristic algorithm is proposed to solve the linearized model. Our proposed algorithm is significantly faster than commercial exact solvers (e.g., branch-and-bound) to solve the problem, while still obtaining good solutions very close to optimal ones.

The rest of this paper is organized as follows: Section 2. introduces the definition of the optimization problem and its mathematical formulation. Section 3. presents the proposed heuristic algorithm used to solve the problem. In Section 4. we employ the proposed algorithm to solve a real case study and compare the results of our algorithm with exact methods. Finally, Section 5. concludes the paper and provides further perspectives.

2. Problem definition

In this work, we study an MES with three energy carriers: electricity, heat, and gas, the latter being only used as fuel. The goal is to meet the energy demand of the system by optimizing the design and operation of the MES with a time resolution of one hour over a time horizon of one year.

The system is characterized by different generation technologies: a combined heat and power unit (CHP) to provide heat and electricity from gas using an internal combustion engine and a heat recovery system [12]; an electric boiler (EB) and a gas boiler (GB) to provide heat; two renewable energy sources (RES) that are photovoltaic (PV) panels to provide electricity and solar thermal (ST) panels to provide heat. The system can also interact with the grid to buy electricity or sell the surplus electricity produced by PV panels.

The system must provide energy to respond to the heat and electricity demands while optimizing two objectives: minimizing the cost of the system and maximizing the rate of RES. Therefore, the aim is to determine the design and operation of the MES while optimizing the two objectives and respecting the energy balance of the system.

2.1. Mathematical formulation

To perform the optimization, the MES is modeled as a mathematical program, shown in Equations (1a) to (1l). In this program and in the rest of this article, independent decision variables, which represent the optimal values to determine, are shown in bold (e.g. $\boldsymbol{P_{e,PV,t}}$). The other elements are parameters, i.e. fixed input data of the model.

$$\text{maximize} \quad ATCR = 100 * (1 - \frac{ATC_{MES}}{ATC_{ref}}) \tag{1a}$$

$$\tau_{RES} = 100 * \frac{\sum_{t\in\mathcal{T}}(\boldsymbol{P_{e,PV,t}} + \boldsymbol{P_{h,ST,t}})}{\sum_{t\in\mathcal{T}}(L_{e,t} + L_{h,t})} \tag{1b}$$

subject to

$$\boldsymbol{A_{PV}} + \boldsymbol{A_{ST}} \leq A_{total} \tag{1c}$$

$$\boldsymbol{P_{e,CHP,t}} \leq \boldsymbol{P_{CHP,nom}} \qquad \forall t \in \mathcal{T} \tag{1d}$$

$$\boldsymbol{P_{h,GB,t}} \leq \boldsymbol{P_{GB,nom}} \qquad \forall t \in \mathcal{T} \tag{1e}$$

$$\boldsymbol{P_{h,EB,t}} \leq \boldsymbol{P_{EB,nom}} \qquad \forall t \in \mathcal{T} \tag{1f}$$

$$\boldsymbol{P_{e,CHP,t}} = (a + b(\frac{\boldsymbol{P_{e,CHP,t}}}{\boldsymbol{P_{CHP,nom}}}) + c(\frac{\boldsymbol{P_{e,CHP,t}}}{\boldsymbol{P_{CHP,nom}}})^2)\boldsymbol{F_{g,CHP,t}} \qquad \forall t \in \mathcal{T} \tag{1g}$$

$$\boldsymbol{P_{h,CHP,t}} \leq \eta_{th,CHP}(\boldsymbol{F_{g,CHP,t}} - \boldsymbol{P_{e,CHP,t}}) \qquad \forall t \in \mathcal{T} \tag{1h}$$

$$\boldsymbol{V_{e,t}} + \boldsymbol{P_{e,PV,t}} = \boldsymbol{A_{PV}}\eta_{DC/AC}\eta_{ref}(1 - \alpha(30 + 0.0175(G_{\beta,t} - 300) + 1.14(T_{a,t} - 25) - T_{ref}))G_{\beta,t} \qquad \forall t \in \mathcal{T} \tag{1i}$$

$$\boldsymbol{P_{h,ST,t}} \leq \boldsymbol{A_{ST}}(G_{\beta,t}\eta_0 - U_{loss}(T_{w,m} - T_{a,t})) \qquad \forall t \in \mathcal{T} \tag{1j}$$

$$\boldsymbol{P_{e,CHP,t}} + \boldsymbol{P_{e,PV,t}} + \boldsymbol{U_{e,t}} - \frac{\boldsymbol{P_{h,EB,t}}}{\eta_{EB}} = L_{e,t} \qquad \forall t \in \mathcal{T} \tag{1k}$$

$$\boldsymbol{P_{h,CHP,t}} + \boldsymbol{P_{h,GB,t}} + \boldsymbol{P_{h,EB,t}} + \boldsymbol{P_{h,ST,t}} = L_{h,t} \qquad \forall t \in \mathcal{T} \tag{1l}$$

$$\boldsymbol{A_j} \in [A_j^{\min}, A_j^{\max}] \qquad \forall j \in \{PV, ST\} \tag{1m}$$

$$\boldsymbol{P_{j,nom}} \in [P^{\min}_{j,nom}, P^{\max}_{j,nom}] \qquad \forall j \in \{CHP, GB, EB\} \tag{1n}$$

$$\boldsymbol{P_{e,CHP,t}}, \boldsymbol{P_{h,CHP,t}}, \boldsymbol{F_{g,CHP,t}}, \boldsymbol{P_{h,GB,t}}, \boldsymbol{P_{e,PV,t}}, \boldsymbol{P_{h,ST,t}}, \boldsymbol{U_{e,t}}, \boldsymbol{V_{e,t}} \geq 0 \quad \forall t \in \mathcal{T} \tag{1o}$$

The first two formulas are the objective functions that are maximized: (1a) as the annual total cost reduction of the MES compared to a reference cost ATC_{ref}, and (1b) as the rate of RES used to respond to the energy demand. The annual total cost ATC_{MES} in (1a) is expressed as (2):

$$ATC_{MES} = \sum_{j \in \mathcal{M}} (C_{O\&M,j} + crf \cdot C_{inv,j}) - \sum_{t \in \mathcal{T}} I_{gr} \boldsymbol{V_{e,t}} + \sum_{t \in \mathcal{T}} (C_{gr,t} \boldsymbol{U_{e,t}} + C_g (\boldsymbol{F_{g,CHP,t}} + \frac{\boldsymbol{P_{h,GB,t}}}{\eta_{GB}})) \tag{2}$$

with $\mathcal{M} = \{CHP, GB, EB, PV, ST\}$ the set of technologies, $\mathcal{T} = (1, ..., 8760)$ the set of time steps of the year. I_g is the price of electricity sold, $\boldsymbol{V_{e,t}}$ the electricity sold at time t, $C_{gr,t}$ the cost of the electricity bought depending on the time of day t, $\boldsymbol{U_{e,t}}$ the electricity bought at time t, C_g the cost of gas bought, $\boldsymbol{F_{g,CHP,t}}$ the gas used by the CHP at time t, $\boldsymbol{P_{h,GB,t}}$ the heat of the GB at time t, and η_{GB} the efficiency of the GB.

The dependent variables $C_{O\&M,j}$ and $C_{inv,j}$ represent the operation and maintenance cost and the investment cost of each technology $j \in \mathcal{M}$, summarized in Table 1. *crf* is the capital recovery factor and represents the value of an annuity based on the number of annuities n and a discount factor i. It is expressed as $crf = i(1+i)^n/((1+i)^n - 1)$. Each technology j has an investment cost $\gamma_{inv,j}$, and an operation and maintenance cost with a fixed part $\gamma_{O\&M,j,f}$ and a variable part $\gamma_{O\&M,j,v}$. $P_{panel,nom}$ is the nominal power of a PV panel.

Table 1: Investment and operation costs of the technologies

Technology j	$C_{inv,j}$	$C_{O\&M,j}$
CHP	$\gamma_{inv,CHP} \boldsymbol{P_{CHP,nom}}$	$\gamma_{O\&M,CHP,v} \sum_{t \in \mathcal{T}} \boldsymbol{P_{e,CHP,t}}$
GB	$\gamma_{inv,GB} \boldsymbol{P_{GB,nom}}$	$\gamma_{O\&M,GB,f} \boldsymbol{P_{GB,nom}}$
EB	$\gamma_{inv,EB} \boldsymbol{P_{EB,nom}}$	$\gamma_{O\&M,EB,f} \boldsymbol{P_{EB,nom}} + \gamma_{O\&M,EB,v} \sum_{t \in \mathcal{T}} \boldsymbol{P_{h,EB,t}}$
PV	$\gamma_{inv,PV} P_{panel,nom} \boldsymbol{A_{PV}} / A_{panel}$	$\gamma_{O\&M,PV,f} P_{panel,nom} \boldsymbol{A_{PV}} / A_{panel}$
ST	$\gamma_{inv,ST} \boldsymbol{A_{ST}}$	$\gamma_{O\&M,ST,f} \boldsymbol{A_{ST}}$

The reference cost is calculated as the cost of responding to the demand using only the GB to generate heat and only buying electricity from the grid, calculated as (3):

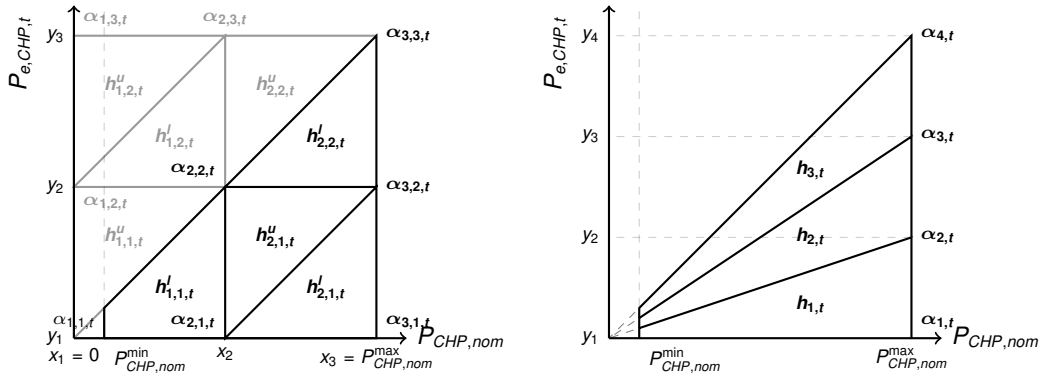
$$ATC_{ref} = \gamma_{O\&M,GB,f} \max(L_{h,t}) + crf \cdot \gamma_{inv,GB} \cdot \max(L_{h,t}) + \sum_{t \in \mathcal{T}} (C_{gr,t} L_{e,t} + C_g \frac{L_{h,t}}{\eta_{GB}}) \tag{3}$$

The other equations and inequations in the model represent physical constraints. Equation (1c) constrains the maximum area of solar panels, with $\boldsymbol{A_{PV}}$ and $\boldsymbol{A_{ST}}$ the area of PV and ST panels and A_{total} the total area available for solar panels. (1d) to (1f) represent the limitation of the production by the installed capacity of the technologies with $P_{e,j,t}$ the electricity generated by technology j at time t, $P_{h,j,t}$ the heat generated by technology j at time t, and $P_{j,nom}$ the installed capacity of technology j. Equations (1g) and (1h) represent the power and heat production of the CHP. $\boldsymbol{F_{g,CHP,t}}$ is the gas consumption of the CHP, a, b, and c are the coefficients of electrical efficiency of the CHP, used by the function $a + b(\boldsymbol{P_{e,CHP,t}}/\boldsymbol{P_{CHP,nom}}) + c(\boldsymbol{P_{e,CHP,t}}/\boldsymbol{P_{CHP,nom}})^2$ that represents the electrical efficiency, depending on the part-load ratio of the CHP [12]. $\eta_{th,CHP}$ is the thermal efficiency of the CHP. Equation (1i) represents the electricity production from the PV panels. PV panels can sell the surplus produced power to the grid, represented by the variable $\boldsymbol{V_{e,t}}$. $\eta_{DC/AC}$ is the efficiency of PV inverters, η_{ref} is a reference efficiency for PV, α the temperature coefficient of the PV, $G_{\beta,t}$ the global solar radiation at time t, $T_{a,t}$ the ambient temperature at time t, and T_{ref} a reference temperature. (1j) is the production of heat from ST panels. η_0 is the optical efficiency of ST, U_{loss} the thermal loss coefficient, $T_{w,m}$ the mean water temperature in the ST collector. Equations (1k) and (1l) force the power and heat balance of the MES, with η_{EB} the efficiency of the EB, $L_{e,t}$ the electricity demand at time t, and $L_{h,t}$ the heat demand at time t. Finally, (1m), (1n), and (1o) represent the domain of the design and operation variables, respectively.

However, as seen in (1g), the CHP is governed by a non-linear efficiency function representing the part-load efficiency of the power generation of the CHP. Using a non-linear solver to solve a non-linear problem does not guarantee the optimality of the solution. We, therefore, propose to approximate this non-linear function by a piece-wise linear function to be able to model the system as a MILP.

2.2. Linearization

The efficiency function of the CHP in (1g) is linearized through a piece-wise linearization with two decision variables, adapted to the shape of the function. The proposed method of this paper is inspired by the so-called "triangle method" proposed by [13], which we adapt to the problem at hand. This type of method works by



(a) "Triangle" method with $N = 3$ and $M = 3$ breakpoints (b) Adapted method with $N = 4$ breakpoints

Figure 1: Linearization methods examples

adding binary variables in the mathematical model to know which linear piece is selected. The mathematical program resulting from the addition of these binary variables is a MILP model, which can be solved by exact methods (e.g., branch-and-bound, branch-and-cut) [14], guaranteeing the optimality of the solution found.

The "triangle method" of [13] linearizes a function by introducing piece-wise linear parts in the form of triangles. However, in this work, half of those triangles are outside the feasible region of the problem. Figure 1a is an example of the application of the "triangle method". The x-axis is the variable $P_{CHP,nom}$, the y-axis the variable $P_{e,CHP,t}$, and the z-axis would be the function $F_{g,CHP,t}$ to linearize. $\alpha_{n,m,t}$ and $h_{n,m,t}$ represent the variables introduced in the model by this linearization method, N and M being the number of breakpoints on the x and y axes, respectively. As can be seen, half of the triangles are grayed out because they are outside the feasible region in our problem, enforced by Constraint (1d) of the model. This means that some variables and constraints would be added to the model without being useful in the present study. It also needs a large number of triangles to work with a small installed capacity of the CHP for this problem. Looking again at Fig 1a, for the linearization to be effective, the value of $\boldsymbol{P_{CHP,nom}}$ must be greater than x_2, otherwise it would be equivalent to a linearization with a single triangle. Furthermore, a MILP model, with binary or integer variables, while being able to be solved to optimality, is still harder to solve than a linear program (LP) with only continuous variables. Accordingly, reducing the number of binary variables can greatly reduce the complexity of the problem.

We therefore propose an "adapted" version of the triangle method to use fewer triangles and ignore the area outside the feasible region. The adapted method better follows the function we are looking to linearize and uses fewer binary variables, and it is not subject to the inaccurate linearization mentioned for the triangle method when there is a small installed capacity. It introduces continuous variables, noted $\boldsymbol{\alpha_{n,t}} \in [0,1],\ \forall n \in \{1,...,N\}, t \in \mathcal{T}$, and binary variables, noted $\boldsymbol{h_{n,t}} \in \{0,1\},\ \forall n \in \{1,...,N-1\}, t \in \mathcal{T}$, for each breakpoint $n \in \{1,...,N\}$ in the linearization and at each time step $t \in \mathcal{T}$. N is a parameter of the linearization and is the number of breakpoints introduced (and therefore $N-1$ is the number of triangles). We choose to linearize the function $F_{g,CHP,t}$ written as (4).

$$F_{g,CHP,t} = \frac{P_{e,CHP,t}}{a + b\frac{P_{e,CHP,t}}{P_{CHP,nom}} + c(\frac{P_{e,CHP,t}}{P_{CHP,nom}})^2} \tag{4}$$

We need the value of this function at different breakpoints over $P_{e,CHP,t}$, noted $y_n = P^{max}_{CHP,nom} \times (n-1)/(N-1)$:

$$f(y_n) = \frac{y_n}{a + b\frac{y_n}{P^{max}_{CHP,nom}} + c(\frac{y_n}{P^{max}_{CHP,nom}})^2} \tag{5}$$

Equations (6a) to (6f) represent the linearization constraints used to replace (1g). We consider N breakpoints, and a convex combination of the values $\boldsymbol{\alpha_{n,t}}$ can approximate the values of the linearized variables $\boldsymbol{P_{CHP,nom}}$, $\boldsymbol{P_{e,CHP,t}}$, and $\boldsymbol{F_{g,CHP,t}}$. Equation (6e) ensures that only one triangle h is selected at each time step, and (6f) ensures that only the coefficients α associated with the selected triangle have non-zero values, with dummy values $h_{0,t} = 0$ and $h_{N,t} = 0$. (6g) and (6h) constrain the domain of the linearization variables. An example with

N = 4 breakpoints is presented in Fig 1b.

$$\sum_{n=1}^{N} \boldsymbol{\alpha_{n,t}} \leq 1 \qquad \forall t \in \mathcal{T} \tag{6a}$$

$$\boldsymbol{P_{CHP,nom}} = \sum_{n=1}^{N} \boldsymbol{\alpha_{n,t}} P_{CHP,nom}^{\max} \qquad \forall t \in \mathcal{T} \tag{6b}$$

$$\boldsymbol{P_{e,CHP,t}} = \sum_{n=1}^{N} \boldsymbol{\alpha_{n,t}} y_n \qquad \forall t \in \mathcal{T} \tag{6c}$$

$$\boldsymbol{F_{g,CHP,t}} = \sum_{n=1}^{N} \boldsymbol{\alpha_{n,t}} f(y_n) \qquad \forall t \in \mathcal{T} \tag{6d}$$

$$\sum_{n=1}^{N-1} \boldsymbol{h_{n,t}} = 1 \qquad \forall t \in \mathcal{T} \tag{6e}$$

$$\boldsymbol{\alpha_{n,t}} \leq \boldsymbol{h_{n,t}} + \boldsymbol{h_{n-1,t}} \qquad \forall n \in \{1, ..., N\}, t \in \mathcal{T} \tag{6f}$$

$$\boldsymbol{\alpha_{n,t}} \in [0, 1] \qquad \forall n \in \{1, ..., N\}, t \in \mathcal{T} \tag{6g}$$

$$\boldsymbol{h_{n,t}} \in \{0, 1\} \qquad \forall n \in \{1, ..., N-1\}, t \in \mathcal{T} \tag{6h}$$

The problem is studied through a multi-objective perspective, optimizing both the cost of the MES and the rate of RES producing energy. It is not possible to improve both objectives at the same time, since the improvement of one objective implies a degradation of another one. Therefore, we calculate a set of non-dominated solutions on the so-called Pareto front. The ϵ-constraint method [15] is used to calculate a set of solutions on the Pareto front, from which the decision maker can choose the solution that best corresponds to his or her preferences, as a trade-off between the two objective functions. This method works by maximizing one objective function while setting a constraint on the other objective function. Modifying the value of this constraint allows us to obtain several optimal solutions.

Although linearizing the non-linear model makes it computationally easier to be solved, solving the proposed MILP model is still challenging. The binary variables introduced to the model make it combinatorial and NP-hard to solve. It is possible to obtain optimal solutions for shorter time horizons, up to a few weeks, but the resolution of the model over the time horizon of one year is intractable in a reasonable computation time.

In this work, our goal is therefore to improve the resolution time of this model while obtaining good quality solutions. To this end, we propose in the next section a heuristic to solve the problem over long time horizons while maintaining good-quality solutions.

3. Solution approach

We propose a heuristic algorithm to reduce the complexity of the model by letting the binary variables be continuous while guaranteeing the binary value of these variables. Heuristics are approximate algorithms that aim to provide good solutions to a specific problem in a limited computation time [16]. They do not guarantee the optimality of the solution, but are generally faster than exact methods.

The proposed heuristic is composed of two subsequent steps: 1) Initialization and 2) Iterative local search. The initialization generates an initial solution by relaxing the binary variables of the proposed MILP model, and the local search aims to iteratively improve the generated initial solution toward the optimal solution.

These two high-level steps are summarized in Algorithm 1. First, the MILP model is generated with the set of parameters $\mathcal{P}$ of the case study (line 2). A relaxed MILP model, detailed in Section 3.1., is then created from the MILP (line 3), and an initial solution is found after solving this model (line 4). Second, a local search, described in Section 3.2., is used iteratively on the initial solution until there is no improvement. The values of the objective functions are compared to their best values so far (line 5 of Algorithm 1), and if the new solution is better, the next iteration of the local search starts.

As there are two objective functions *ATCR* and τ_{RES} in the model, subscripts 1 and 2 indicate the first and second objective functions, respectively. In the proposed heuristic algorithm, the vector $(bestObj_1, bestObj_2)$ represents the best value of the objective functions found so far, and (obj_1, obj_2) is the vector of the objective functions of the current solution. We consider that the solution *a* is better than the solution *b* if the first objective function of *a* is better, or if the second objective function of *a* is better and the first objective function of *a* is at least as good. As an example, consider *ATCR* and τ_{RES} as the first and second objective functions, respectively. Solution *a* is better than *b* if $ATCR^a > ATCR^b$, or $\tau_{RES}^a > \tau_{RES}^b$ and $ATCR^a \geq ATCR^b$.

3.1. Initialization

As the first step of the heuristic algorithm, a relaxation method is used to generate an initial solution to the problem: the binary variables that allow knowing which triangle is selected at each time step are relaxed to be continuous (i.e., have a value between zero and one), transforming the MILP model into an LP model which is much easier to solve by using, for example, the Simplex class of algorithms. All other variables and constraints remain unchanged. The relaxed MILP model is solved as a linear model and, therefore, the continuous relaxed variables $\boldsymbol{h_{n,t}}$ have a value in $[0, 1]$.

This process is explained in Algorithm 2. The first relaxed MILP model is solved on line 2. Then, at each time

Algorithm 1 High-level algorithm

1: $(bestObj_1, bestObj_2) \leftarrow (-\infty, -\infty)$
2: $MILP \leftarrow$ GENERATEMILP($\mathcal{P}$)

6: $(bestObj_1, bestObj_2),\ bestSol \leftarrow (obj_1, obj_2),\ sol$
7: $(obj_1, obj_2),\ sol \leftarrow$ LOCALSEARCH($relaxedMILP$, $bestSol$) ▷ Improve the solution
8: **end while**
9: **return** *bestSol*

step $t \in \mathcal{T}$, the variable with the highest value among $\boldsymbol{h_{1,t}}, ..., \boldsymbol{h_{N-1,t}}$ is selected, and a constraint is added to the model to force this variable to be equal to 1, on line 3 of the algorithm. The relaxed MILP model is again solved with these additional constraints on line 4, obtaining this time a feasible solution with all the relaxed variables $\boldsymbol{h_{n,t}}$ having a value of 0 or 1, which gives us the initial solution for the heuristic.

In these algorithms, $\mathcal{N}$ is the ordered set of the triangle indices: $\mathcal{N} = (1, ..., N-1)$. H is the set of variables representing the triangles selected: $H = \{\boldsymbol{h_{n,t}},\ \forall n \in \mathcal{N}, t \in \mathcal{T}\}$. They have binary values in the MILP model or real values in the relaxed MILP model. *sol* is a vector of the index n of the triangle selected at each time step, i.e. $sol = (\{n : \boldsymbol{h_{n,t}} = 1, \forall n \in \mathcal{N}\},\ \forall t \in \mathcal{T})$ if the variables are binary.

Algorithm 2 Initial solution search algorithm

2: $(obj_1, obj_2),\ H \leftarrow$ SOLVE($relaxedMILP$) ▷ Solve relaxed MILP
3: $H_N^{\max} \leftarrow (\arg\max_n(\boldsymbol{h_{n,t}}),\ \forall t \in \mathcal{T})$ ▷ Get the max. argument n for each time step
4: $C \leftarrow \{\boldsymbol{h_{n,t}} = 1,\ \forall n \in H_N^{\max}, t \in \mathcal{T}\}$ ▷ Construct set of constraints to force a triangle to 1 at each time step
5: $(obj_1, obj_2),\ H \leftarrow$ SOLVE($relaxedMILP \cup C$) ▷ Solve relaxed MILP with additional constraints C
6: $sol \leftarrow (\{n : \boldsymbol{h_{n,t}} = 1, \forall n \in \mathcal{N}\},\ \forall t \in \mathcal{T})$ ▷ Get vector of arguments n where $\boldsymbol{h_{n,t}} = 1$ for each time step
7: **return** $(obj_1, obj_2),\ sol$
8: **end function**

3.2. Local search

The second step is to improve the initial solution found. For this aim, we developed a local search method to improve the initial solution by looking at its neighborhood. A local search method works by applying small local changes to a solution with the aim of improving the solution and is applied iteratively until a stopping criterion is reached, e.g. the solution does not improve further, or a time limit fixed in advance is exceeded.

In this work, the local search starts from the initial solution found previously using Algorithm 2. Adjacent linearization triangles of this initial solution are selected to obtain a better solution. For example, in Fig 1b, we can see that if $\boldsymbol{h_{1,t}} = 1$, the first triangle is selected, and if $\boldsymbol{\alpha_{2,t}} > 0$ and $\boldsymbol{\alpha_{1,t}} = 0$, that would mean that the point selected is on the edge between the first and second triangle, and we could choose to select the second triangle without degrading the solution.

Using this knowledge, our local search method selects the other triangle each time a value of the linearization is on the edge of a triangle, executed on lines 2 to 9 of Algorithm 3. For each time step $t \in \mathcal{T}$, for each triangle n selected, if the value of $\alpha_{n,t} = 0$ we select the next triangle, and otherwise if the value of $\alpha_{n+1,t} = 0$ we select the previous triangle. If no value $\alpha_{n,t}$ or $\alpha_{n+1,t}$ is null, we are not on the edge of the triangle and therefore keep the same triangle selected. The selected triangles become constraints in the linear program, i.e. a constraint $h_{n,t} = 1$ is added for the triangle n selected at time step t, $\forall t \in \mathcal{T}$. The linear model is again solved with the newly selected triangles. The new constraints to force the selected triangles are created on line 10, the relaxed MILP model is solved with these constraints on line 11, and the new solution is then constructed on line 12.

A new iteration of the local search is started if the new solution is better than the previous one. Otherwise, the algorithm stops and the best solution found is considered as the solution of the algorithm.

4. Case study

4.1. Description

An instance of the problem defined in Section 2. is used to compare the solutions of the heuristic algorithm and the MILP resolution with real-world data. The MES studied in the present case study covers an area of 33.5 hectares in the vicinity of Nantes, France. It includes the campus of IMT Atlantique, a French technological university, and 45 single-family houses. There are two objective functions to optimize: the maximization of the cost reduction of the MES (i.e. the minimization of the cost of the MES compared to a reference cost), and the maximization of the rate or RES used to respond to the energy demand. The values of the parameters of the

model for this case study are summarized in Tables 2 and 3. The energy demands, the temperature, and the global solar radiation over the year are time series parameters.

Table 2: Cost (investment and operation) parameters per technology

Technology j	$\gamma_{inv,j}$	$\gamma_{O\&M,j,f}$	$\gamma_{O\&M,j,v}$
CHP	1140 €/kW	-	21 €/MWh
GB	90 €/kW	3.15 €/(kW year)	-
EB	100 €/kW	1 €/(kW year)	0.8 €/MWh
PV	1000 €/kW	15 €/(kW year)	-
ST	615 €/m^2	10 €/(m^2 year)	-

4.2. Methodology

The model is solved using an MILP solver and the proposed heuristic algorithm to compare the two resolution methods. Three periods of the year of one week are studied: one week in winter when there is high demand variability and low RES generation, one week in summer when there are lower demands and high RES potential, and one week in mid-season when the demand is lower but there is still a high RES potential.

The time horizon of one week allows us to obtain the optimal solution for the MILP model, and therefore, by comparison, to evaluate the quality of the output of the proposed heuristic algorithm. For each of the three periods, 10 solutions are calculated on the Pareto front using the ϵ-constraint method explained in Section 2., with solution 1 being the solution with the most RES and solution 10 the solution with the highest cost reduction. The number of breakpoints for the linearization was set by trial and error at a value $N = 10$ (i.e. $N - 1 = 9$ triangles), giving a good trade-off between the precision of the linearization and the complexity of the model.

The two methods are compared in terms of the quality of the solution using a *Mean Ideal Distance* indicator to compare the Pareto fronts obtained. This indicator compares the solutions of the two Pareto fronts, as the mean difference of the distance of each solution to an ideal point at the origin, as detailed in (7), with $\mathcal{S} = \{1, ..., 10\}$ the 10 solutions calculated.

$$mean\ distance = \frac{1}{|\mathcal{S}|} \sum_{s \in \mathcal{S}} \left(\sqrt{ATCR_s^{optimal^2} + \tau_{RES}{}_s^{optimal^2}} - \sqrt{ATCR_s^{heuristic^2} + \tau_{RES}{}_s^{heuristic^2}} \right) \tag{7}$$

An error indicator also allows us to compare the result of the heuristic algorithm with the optimal solution, by calculating the error between the heuristic solution and the MILP solution for the two objective functions and the $|\mathcal{S}|$ solutions, as in (8).

$$error = \left\{ \left| \frac{f_s^{optimal} - f_s^{heuristic}}{f_s^{optimal}} \right|, \quad \forall f \in \{ATCR, \tau_{RES}\}, s \in \mathcal{S} \right\} \tag{8}$$

The maximum, mean, and standard deviation are calculated and shown in the table.

The solutions are also compared in terms of the total computation time for the $|\mathcal{S}|$ solutions.

An energy analysis is also performed to compare the two methods. The difference between the values of the operation variables for the two variables is presented at each time step, in the form of a boxplot. As an example, the set $v = \{P_{e,CHP,t}^{heuristic} - P_{e,CHP,t}^{optimal},\ \forall t \in \mathcal{T}\}$ would be presented as a boxplot for the electricity produced by the CHP. Whiskers are represented to show the 5th and 95th percentiles of each set. These figures are

Table 3: General parameters of the case study

$P^{min}_{CHP,nom}$ = 100 kW, $P^{max}_{CHP,nom}$ = 1000 kW	Minimum and maximum nominal power of the CHP
$P^{min}_{GB,nom}$ = 100 kW, $P^{max}_{GB,nom}$ = 3000 kW	Minimum and maximum nominal power of the GB
$P^{min}_{EB,nom}$ = 100 kW, $P^{max}_{EB,nom}$ = 3000 kW	Minimum and maximum nominal power of the EB
A^{min}_{PV} = 0 m^2, A^{max}_{PV} = 10 000 m^2	Minimum and maximum area of the PV panels
A^{min}_{ST} = 0 m^2, A^{max}_{ST} = 10 000 m^2	Minimum and maximum area of the ST panels
$L_{e,t}$ (kW)	Electricity demand of the system
$L_{h,t}$ (kW)	Heat demand of the system
a = 0.1, b = 0.4, c = -0.2	Electrical efficiency coefficients of the CHP
β = 0.3	Constant CHP electrical efficiency
$\eta_{th,CHP}$ = 0.8	Thermal efficiency of the heat recuperation system of the CHP
η_{GB} = 0.8	Efficiency of the GB
η_{EB} = 0.8	Efficiency of the EB
$\eta_{DC/AC}$ = 0.9	PV inverters' efficiency
η_{ref} = 0.155	Reference efficiency for PV
$G_{\beta,t}$ (W m^{-2})	Global solar radiation
α = 0.43 %/ ℃	Temperature coefficient of PV
T_{ref} = 25 ℃	Reference temperature
$T_{a,t}$ (℃)	Outdoor temperature
$P_{panel,nom}$ = 250 W	Nominal power of a PV panel
A_{panel} = 1.6 m^2	Area of a PV panel
η_0 = 0.8	Optical efficiency of ST
U_{loss} = 5 W m^{-2} ℃$^{-1}$	Thermal loss coefficient of ST
$T_{w,m}$ = 45 ℃	Mean water temperature in the ST collector
A_{total} = 10 000 m^2	Total area available for solar panels
$C_{gr,t}$ = 0.13 €/kWh	Cost of electricity bought from the grid (0h–7h)
$C_{gr,t}$ = 0.17 €/kWh	Cost of electricity bought from the grid (8h–23h)
C_g = 0.076 €/kWh	Cost of gas bought
I_{gr} = 0.1 €/kWh	Price of electricity sold to the grid

presented for each of the three one-week periods, each time for the $|\mathcal{S}| = 10$ solutions of the Pareto set. These figures will show the difference in the MILP and heuristic solutions from an operation standpoint by highlighting the difference in the power generated by the different technologies.

An energetic analysis will also be presented, with the energy balance of each technology being calculated for the worst solution of each season. Energy is calculated as the integral of the power generated by each technology over the time period, e.g. $E_{e,CHP} = \sum_{t\in\mathcal{T}} P_{e,CHP,t}$ for the electric energy balance of the CHP.

Capacity factors are also presented, showing the difference in the usage of each technology between the MILP and heuristic solutions. It is the ratio of the energy output of a technology over the maximum theoretical energy output based on the installed capacity. As an example for the GB, it is calculated as (9):

$$\mathrm{CF}_{GB} = 100 \times \frac{\sum_{t\in\mathcal{T}} \boldsymbol{P_{h,GB,t}}}{|\mathcal{T}|\boldsymbol{P_{GB,nom}}} \tag{9}$$

For the RES the maximum theoretical energy depends on the environmental conditions, as in 10 for the ST:

$$\mathrm{CF}_{ST} = 100 \times \frac{\sum_{t\in\mathcal{T}} \boldsymbol{P_{h,ST,t}}}{\sum_{t\in\mathcal{T}} \boldsymbol{A_{ST}}(G_{\beta,t}\eta_0 - U_{loss}(T_{w,m} - T_{a,t}))} \tag{10}$$

The installed capacity of the CHP is expressed in its electrical installed capacity, so the maximum theoretical heat energy is calculated using $\eta_{e,CHP} = 0.3$, which is the best theoretical electrical efficiency given the values of the parameters a, b, and c, which gives a capacity factor for the heat of the CHP calculated as (11):

$$\mathrm{CF}_{h,CHP} = 100 \times \frac{\sum_{t\in\mathcal{T}} \boldsymbol{P_{h,CHP,t}}}{|\mathcal{T}|\boldsymbol{P_{CHP,nom}}\eta_{th,CHP}(1-0.3)} \tag{11}$$

Finally, a resolution of the model is performed over the full year using the proposed heuristic algorithm. The computation time is compared with the resolution of the full year using a MILP solver with an optimality gap as a stop criterion, to have an idea of the time required to solve the full year to optimality.

4.3. Results

The optimal solutions are obtained using the Gurobi solver (version 9.5.2), and the heuristic was implemented in Python with the same version of Gurobi used to solve the relaxed MILP. All the solutions were computed

on a computation server with 400GB RAM and Intel Xeon Gold 6138 @ 2.00GHz CPUs, using 32 threads for Gurobi and one thread in Python.

Table 4 shows the computation times of the two methods for the three different periods (winter, summer, and mid-season). The optimal time and the heuristic time are the total time necessary to obtain the 10 solutions for each method and each period. The improvement is the relative difference between the two durations.

Table 4: Comparison of the total computation time over 3 one-week periods

Period	Optimal time	Heuristic time	Improvement
Winter	1182.4 s	4.1 s	99.7 %
Summer	42.3 s	1.1 s	97.4 %
Mid-season	1802.0 s	2.0 s	99.9 %

As can be seen for the mid-season period, the MILP solver can take a really long time to find the solution. This period is especially complex because it is the season where the energy demand varies the most from day to day, but there is still enough solar radiation to make the RES a good option to generate energy. On average, for the three periods computed here, the heuristic algorithm is 99.0 % faster than the MILP solver.

Table 5 shows the error of the heuristic method compared to the optimal solutions found when solving the MILP model, i.e. the maximum, mean, and standard deviation of the errors calculated from (8). It also shows how many times the heuristic algorithm found the optimal solution.

Table 5: Precision of the heuristic algorithm

Period	Error			Nbr. optimal solutions
	Max.	Mean	SD	(out of 10)
Winter	6.6×10^{-5}	6.8×10^{-6}	1.6×10^{-5}	4
Summer	2.5×10^{-15}	7.2×10^{-16}	6.9×10^{-16}	6
Mid-season	3.1×10^{-10}	1.6×10^{-11}	7.0×10^{-11}	4

We can see that the heuristic obtains good solutions, the maximum error being 6.6×10^{-5} and the average mean error 2.3×10^{-6}. Furthermore, the heuristic found the optimal solution 14 times out of the 30 solutions computed.

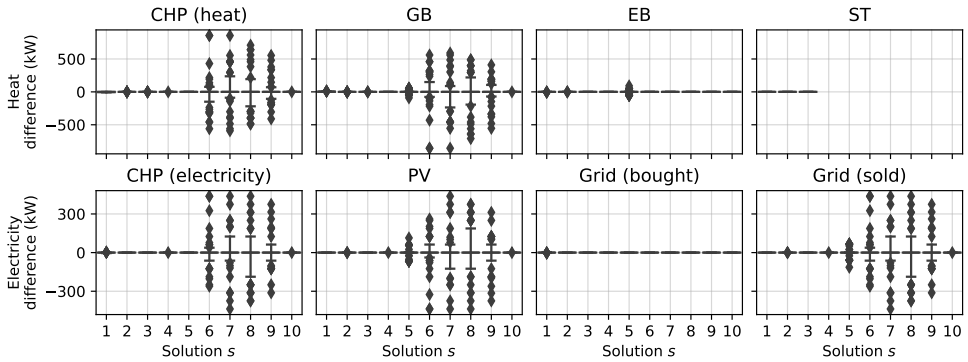
This shows that the heuristic method works well for small time periods, giving good-quality solutions with a much smaller computation time than the MILP.

Figure 2 presents boxplots of the difference between the values of the operation variables of the MILP and the heuristic resolutions. The x-axis of each subplot represents the 10 solutions of the Pareto front, and the y-axis is the difference in the operation's variables. When there is no symbol for ST, that means that no ST panels are installed for this solution. We can see that the ST panels are installed only in winter and on the first solutions, when we focus on maximizing the RES. In these boxplots, the whiskers represent the 5th and 95th percentiles, and the points are the outliers outside this range. As can be seen in the figure, the "box" is never visible, meaning that the first and third quartiles always coincide with the median; therefore, at least 50 % of the operation variables of each technology are identical between the solutions of the MILP and of the heuristic. Most of the time, the 5th and 95th percentile whiskers also coincide with the median, meaning that more than 90 % of the solutions are the same. The difference is larger in winter and smaller in summer. This can be explained because the energy demands have a larger variability with a greater maximum demand in winter.

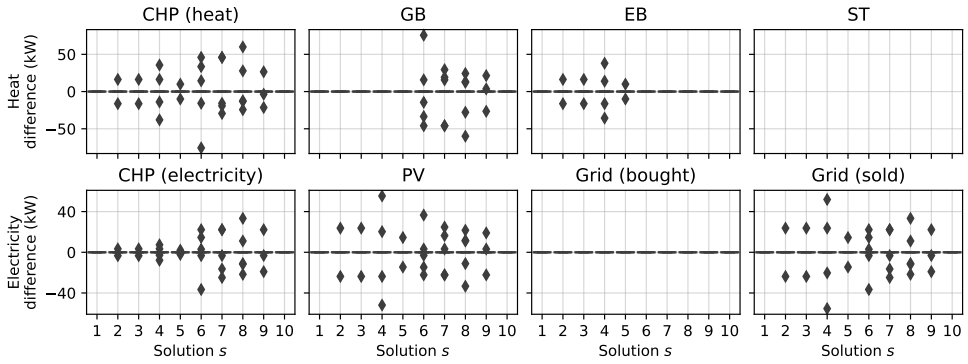
Another analysis that can be drawn from Fig 2 is that the two resolution methods can have different operation plans but still be optimal in terms of the mathematical program. During the winter week, for solutions 2, 3, 4, and 5 the MILP solver and the heuristic give the same values for the two objective functions, the same installed capacities, and the same triangles selected for the linearization. However, solutions 2, 3, and 4 on the boxplots 2a show that the operation variables are slightly different. The same is true for the summer week, with solutions 1, 2, 3, 4, 5, and 10 being optimal but having different values for the operation variables for solutions 2, 3, 4, and 5 on 2b, and for the mid-season week, with solutions 1, 2, 3, and 10 being optimal but solutions 2 and 3 having different operation values on 2c. This can happen because the energy balance is identical, but the energy might be used at different times of the week.

It can also be observed that ST panels are not installed during the summer and mid-season weeks, and ST panels appear in winter only when there is a high value for the objective function τ_{RES}.

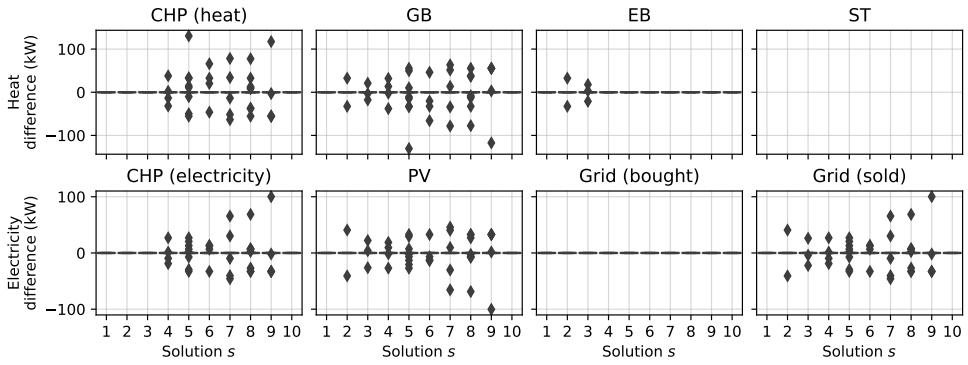
Table 6 presents the energy balance of the solution with the largest difference between the MILP and the heuristic solution for each time period. The underlined cells show the technologies with a difference between the two solutions. The relative differences in the values of the objectives functions for these solutions are



(a) 1 week in winter



(b) 1 week in summer



(c) 1 week in mid-season

Figure 2: Difference in the operation of the MILP and heuristic resolutions

6.6×10^{-3} %, 1.6×10^{-13} %, and 3.1×10^{-8} % for *ATCR*, and 0 %, 3.3×10^{-14} %, and 1.9×10^{-14} % for τ_{RES}, for the winter, summer, and mid-season week presented, respectively. As can be seen, the difference is small even in the worst cases. For the summer and mid-season solutions, only the heat produced by the CHP and the GB are different between the MILP and the heuristic solution, with the CHP heat energy being slightly higher for the heuristic and the GB energy slightly lower. For the winter week, the energy produced by the EB is also different, and there is also a difference in the electrical energy produced by the CHP and the electricity imported from the grid.

Table 7 presents the capacity factors, calculated using (9), (10), and (11), for the same selected solutions. For these solutions, the installed capacity is the same for the summer and mid-season solutions. The installed capacity is different for some of the technologies for the winter week, with the largest difference being only 11 kW for the GB or a relative difference of 0.8 %. The capacity factor is also very similar, the largest difference being 0.4 % for the electrical capacity factor of the CHP for the winter solution.

As an example, Fig 3 shows the operation of the 8th solution of the winter week for the MILP model and the heuristic algorithm. As can be seen in the figure, the operation can be different at certain time steps. However, the values of the objective functions are very similar, with a relative difference of 6.9×10^{-6} % for *ATCR* and 8.4×10^{-4} % for τ_{RES}. This can be explained by the fact that the operation variables intervene always as the sum of the variables over the time period considered, i.e. as the energy over the time period. Two solutions can be very similar in terms of energy but have different operation plans to reach the same energy. In other words,

Table 6: Energy balance of the most different solutions

Technology	Winter, solution 1 MILP	Winter, solution 1 Heuristic	Summer, solution 7 MILP	Summer, solution 7 Heuristic	Mid-season, solution 5 MILP	Mid-season, solution 5 Heuristic

the technologies produce almost the same energy at different time steps over the time period. However, the difference is acceptable in the objective of optimal design taking into account the operation (control aspects being out of the scope of this work).

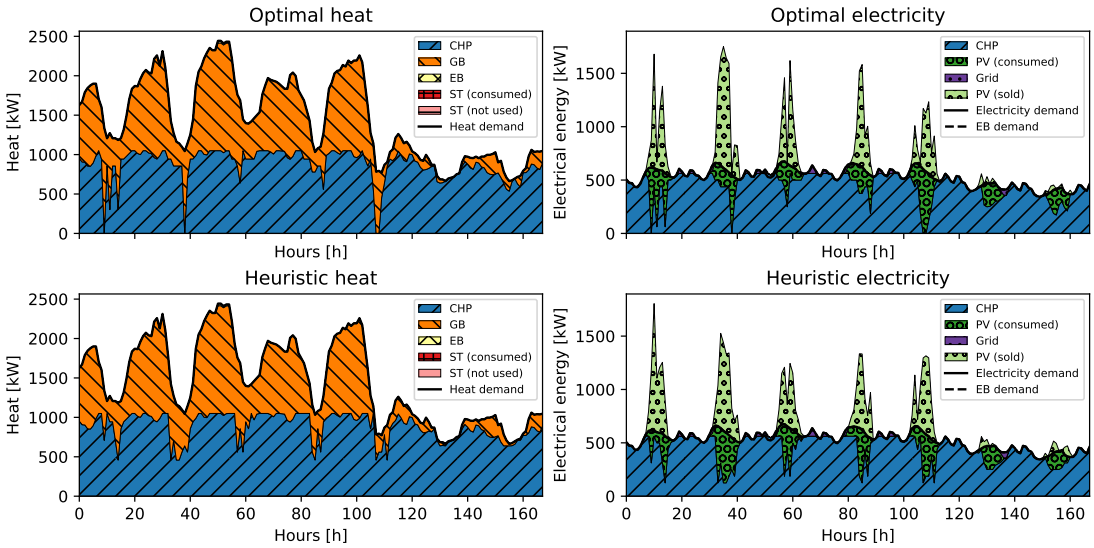

Figure 3: Operation for a MILP and heuristic solution (winter week, solution 8)

Finally, the model was solved with the heuristic algorithm for the full time period of one year, and a MILP solver was used to try to solve the same model for the entire year. The solver was stopped when its optimality gap reached 0.1 %, as it is not possible to obtain an optimal solution in a reasonable time.

The heuristic algorithm took 549.9 s to find results for the 10 solutions of the Pareto front. The MILP solver took 5.6×10^5 s, or 156.7 h to find the 10 solutions. That represents an improvement of 99.9 %. The average relative differences for the 10 solutions of the Pareto front are 1.1 % and -1.7 % for *ATCR* and τ_{RES}, respectively, with the heuristic giving better solutions than the MILP solver for *ATCR*. However the MILP solver was stopped before obtaining an optimal solution.

5. Conclusion and perspectives

This paper presented the modeling of an MES as a non-linear mathematical programming model. A piece-wise linearization method was used to linearize the model and obtain a MILP model. However, it has been shown that the computation time can be intractable for optimizing the MILP model over a long time period of one year. Consequently, a heuristic algorithm was proposed to solve the MILP model. The proposed algorithm finds an

initial solution through a relaxed MILP model, then uses a local search to iteratively improve the initial solution by finding which piece of the linearization to select.

A comparison of the resolution of small time periods of one week of the model through a MILP solver and through the heuristic algorithm showed that the heuristic is capable of finding solutions close to the optimum. It has also been shown that different operations of the MES can be optimal with regard to the mathematical program. Even when the solution found by the heuristic is not optimal, the capacity factors of the different technologies are close to the optimum values. The heuristic algorithm was shown to be faster than the resolution using a MILP solver, with an improvement of more than 99.9 % when solving a long time period of a year.

Although the proposed heuristic algorithm is very fast on the MES model presented in this article, further experimentation on other linearized models is still needed to determine if this method is generalizable for solving other problems. Additional work is also needed to evaluate the robustness of the initialization method and the local search, as relaxation of the MILP model could theoretically lead to infeasible solutions. Further experiments should also be conducted to compare the solutions of the heuristic algorithm and the MILP resolution over the full year, to assess whether the heuristic is still efficient when solving long time periods.

Abstract:
Synthetic fuels are needed to decarbonize the non-electrifiable parts of the transportation sector, such as shipping and aviation. The synthesis of fuels using power-to-liquid (PtL) processes has already been investigated and tested. However, economic implementation has failed to gain traction due to high plant and product costs and insufficient PtL-efficiencies. In this paper, we will use heat exchanger network synthesis (HENS) to optimize the heat integration of a novel 1 MW PtL-process. A unique feature of this case study is that the internal heat is supplied by oxidizing a Fischer-Tropsch tail gas within a combustion system (CS). The inlet and outlet temperatures of the exhaust gas flow of the three serially connected CS can be adjusted by the mass flow of excess air and the tail gas. Using HENS implies specifying inlet and outlet temperatures. We apply an adaptation of the HENS that allows for variable stream temperatures and flow capacities. This allows the CS, an internal hot utility, to be optimally tailored to the specific process. Linearization of the non-linear relations, such as stream- and stage-wise energy balance, is done with simplices. The linear approximation is transferred to MILP using highly efficient logarithmic coding. We show that implementing the CS in HENS significantly improves the total annual costs and PtL-efficiency. With the developed method, the design engineering of highly efficient PtL-processes can be successfully supported and the technology can be brought closer to an economically viable market maturity.

synthetic fuels, power-to-liquid, heat exchanger network synthesis, mixed-integer linear programming.

1. Introduction

In 2019, about 16.6 % of the global CO_2 emissions were caused by the transport sector. About three quarters of that are caused by road traffic [1]. The electrification of road traffic will lead to long-term emission reduction. However, replacing vehicles before they reach their lifetime will lead to higher emissions in the medium term. Climate-neutral transportation, using emission-free synthetic fuels (also known as eFuels), offers the possibility to continue using existing vehicles. Furthermore, due to the high energy density of liquid fuels, shipping and aviation will presumably continue to rely on them in the long term.

Despite a technology readiness level (TRL) greater than 7, large-scale industrial production of eFuels has yet not taken off [2]. The first commercial integrated PtL-plant Haru Oni was built by the lead developing company HIF and its partner network in Punta Arenas, Chile. In December 2022, the first tank was filled with eFuel, which was produced with one 3.4 MW wind turbine in the pilot phase. From March 2023, the goal is to produce 130 000 L liters of synthetic fuel per year.

A key inhibitor of this technology are the costs. A significant share of the costs arises from the energy required to heat and cool process streams. Efficient heat integration is a crucial element for cost-effectiveness. With heat exchanger network synthesis (HENS), cost-optimal heat integration can be realized using mathematical programming. Using the non-linear superstructure formulation from Yee & Grossmann [3], all stream and utility temperatures and flow capacities must be defined a priori. Furthermore, the utility heat transfer is only possible in one stage and without stream splits. Huber et al. [4] presented an extension of the superstructure formulation from Yee & Grossmann, which allows the implementation of utilities as streams with variable temperatures and flow capacities. It has been shown that significant cost savings result from variable temperatures and multi-stage heat exchanges with stream splits of utilities [4]. Utilizing only the sensible heat of a fluid such as thermal oil, water or flue gas, allow flexibility in selecting temperatures. As long as technical limitations are considered, both the outlet and inlet temperatures can be varied within a certain range. When designing new plants, integrating the design of the utilities into the HENS formulation offers significant advantages in terms of efficiency and total annual costs (TAC).

In this paper, we adapt the method presented by Huber et al. [4] to simultaneously optimize the internal heat supply and the heat exchanger network (HEN). As a use case, the design of a novel 1 MW PtL-plant is opti-

mized. The PtL-plant combines solid co-electrolysis (co-SOEC) with efficient CO_2 processing and a Fischer-Tropsch (FT) reactor. The internal heat supply is provided by three combustion systems (CS) where a process tail gas from the FT-reactor is oxidized. The hot exhaust gas streams from the CS are used as an internal hot utility. In this paper, we compare the design case with the results applying classical HENS. We additionally demonstrate that previously untapped potential for optimization can be activated by optimizing the CS stream temperatures and heat capacity flows. The results show that the TAC can be reduced, and the efficiency can be increased simultaneously. Thus, production costs of synthetic fuels can be lowered, and large-scale industrial deployment can be strengthened.

2. Methods

2.1. HENS superstructure formulation

The objective of the optimization is to minimize the total annual costs (TAC) of the heat exchanger network according to Equation (1).

$$\begin{aligned}\min TAC = {} & \underbrace{\sum_i c_{\mathrm{uc}}\, q_{\mathrm{uc},i}}_{\text{cold utility costs}} + \underbrace{\sum_j c_{\mathrm{uh}}\, q_{\mathrm{uh},j}}_{\text{hot utility costs}} \\ & + \underbrace{\sum_i \sum_j \sum_k c_{\mathrm{f}}\, z_{ijk} + \sum_i c_{\mathrm{f}}\, z_{\mathrm{uc},i} + \sum_j c_{\mathrm{f}}\, z_{\mathrm{uh},j}}_{\text{step-fixed investment costs}} \\ & + \underbrace{\sum_i \sum_j \sum_k c_{\mathrm{v}} \left(\frac{q_{ijk}}{U_{ij}\, LMTD_{ijk}} \right)^{\beta}}_{\text{variable HEX stream costs}} + \underbrace{\sum_i c_{\mathrm{v}} \left(\frac{q_{\mathrm{uc},i}}{U_{\mathrm{uc},i}\, LMTD_{\mathrm{uc},i}} \right)^{\beta}}_{\text{variable HEX cold utility costs}} + \underbrace{\sum_j c_{\mathrm{v}} \left(\frac{q_{\mathrm{uh},j}}{U_{\mathrm{uh},j}\, LMTD_{\mathrm{uh},j}} \right)^{\beta}}_{\text{variable HEX hot utility costs}}\end{aligned} \tag{1}$$

The mathematical formulation of the optimization problem is based on the superstructure formulation of Yee & Grossmann [3]. Huber et al. [4] extended this HENS formulation to implement utilities as streams with variable temperatures and flow capacities. Consequently, the utility heat exchange is possible in multiple stages with stream splits. In this context, utilities implemented as multi-stage streams are referred to as utility streams. Different sets of constraints were added to the Yee & Grossmann formulation, which are activated depending on the utility stream definition. This ensures that no utilities can be placed at the stream ends. Further constraints have been added to limit the heat capacity flows, inlet and outlet temperature to pre-defined ranges. The modifications to the superstructure formulation as well as all necessary constraints can be found in [4].

2.2. Piecewise-linear approximation

To apply fast MILP solvers and to prevent the solver from getting stuck in local optima, all non-linear terms such as reduced HEX areas for streams and utilities, LMTD and energy balances are piecewise-linear approximated and transferred to MILP. To increase the accuracy of the linearization and to decrease the number of binaries, the functions of the reduced HEX areas are trimmed to the feasible domain according to Beck et al. [5]. The three-dimensional function of the stream‘s reduced HEX area is piecewise-linear approximated with superpositioned planes, see Figure 3 (left) in Appendix A. The two-dimensional function of the reduced utility HEX area is approximated piecewise-linear with straight lines and transferred to MILP with an SOS2 approach, see Figure 3 (right) in Appendix A. The piecewise-linear approximation of the three-dimensional function for the LMTD, stage- and stream-wise energy balances is done with plane triangles, see Figure 4 in Appendix A. The plane equations are transferred to MILP with a highly efficient logarithmic coding according to Vielma & Nemhauser [6]. In all piecewise linear approximations, lines, planes, or triangles are added until a root-mean-square error (RMSE) of less than 1 % is reached.

2.3. PtL-efficiency

The performance of the PtL-process is evaluated from an economic point of view by TAC and from a technical point of view with the PTL-efficiency. The PtL-efficiency η_{PtL} is calculated with the ratio of the electrical energy input to the sum of the lower heating values, see Equation (2).

Since the output of synthetic fuels is independent of the heat integration, the PtL-efficiency is only affected by the additional required electrical energy. Depending on the heat integration, P_{base} is increased by the electrical energy demand for hot P_{uh} and cold utilities P_{uc}. For the cooling of hot streams, energy is dissipated to the environment, while the energy for hot utilities is provided by an electric steam generator. For both processes, it is assumed that an additional 5 % of electric energy must be supplied to operate the circulation pumps and

to cover losses. With these assumptions, the PtL-efficiency is calculated according to Equation (2).

$$\eta_{\mathrm{PtL}} = \frac{\sum LHV}{P_{\mathrm{base}} + P_{\mathrm{uh}} + P_{\mathrm{uc}}} = \frac{\sum LHV}{P_{\mathrm{base}} + 1.05 \cdot \sum q_{\mathrm{uh}} + 0.05 \cdot \sum q_{\mathrm{uc}}} \tag{2}$$

3. PtL-process

Within the research project *IFE* (Innovation Flüssige Energie, engl.: innovation liquid energy), a two-stage PtL-process with a H_2O + CO_2 high-temperature solid oxide co-electrolysis (co-SOEC) and Fischer-Tropsch (FT) synthesis is being fully conceptualized and basically engineered. The plant, powered by renewable electricity, has a total electric load of approximately 1 MW. A schematic diagram of the six major components is shown in Figure 1. In the stationary process, an industrial offgas from a cement production plant containing about 15 wt% CO_2 and N is conditioned and reformed together with steam in the co-SOEC to a gas of H_2 and CO. In the downstream FT-reactor, a syngas is reformed. The subsequent strippers separate the syngas into the components, naphtha, diesel and FT-wax. Annually, about 160 000 L of naphtha, 100 000 L of diesel and 360 000 L of Fischer-Tropsch wax are produced climate-neutrally. The sum of the lower heating values $\sum LHV$ is 650.31 kW. The electrical energy requirement of the system without utilities P_{base} is 1135.90 kW. A significant part of this, viz. 992.32 kW, is used by the co-SOEC. 143.59 kW are required for compressors, pumps and to cover losses.

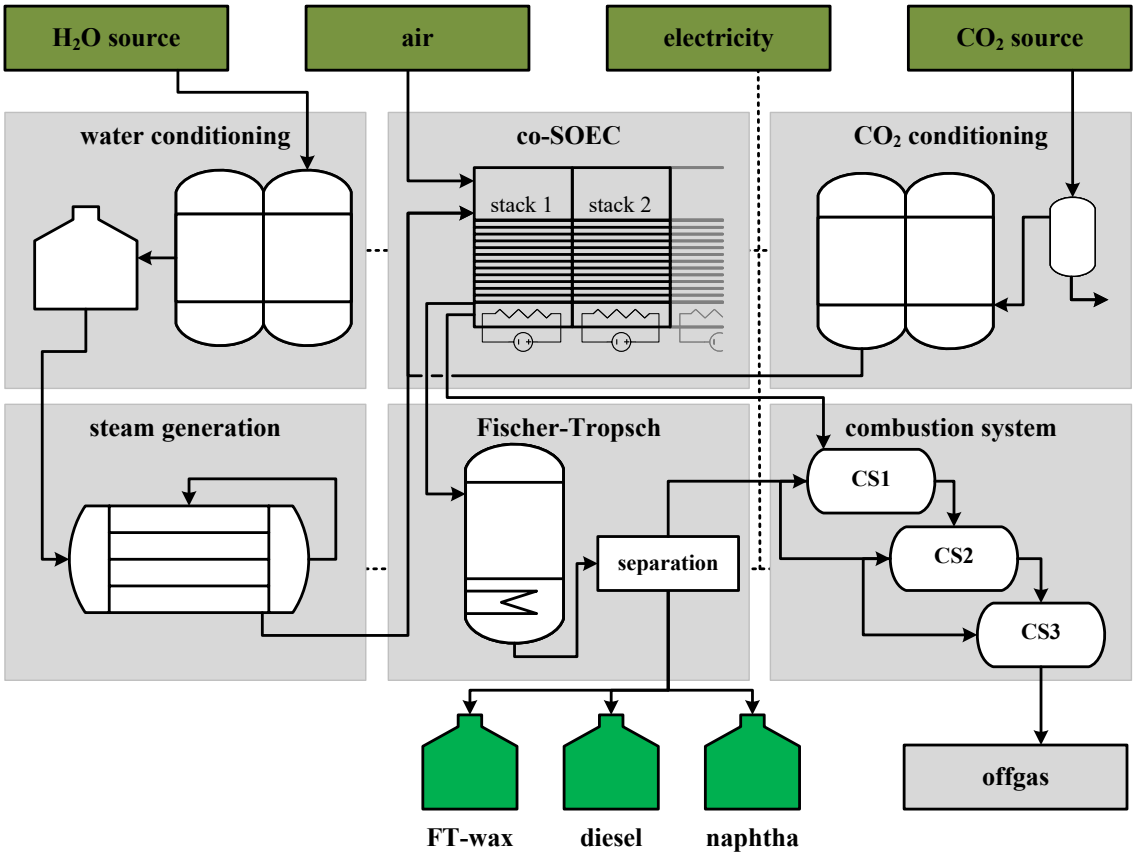

Figure 1: Schematic representation of the 1 MW PtL-process with the main components: water conditioning, CO_2 conditioning, steam generation, co-SOEC, Fischer-Tropsch reactor and combustion systems.

As a starting point for basic engineering, the entire PtL-process was modeled and simulated using Aspen HYSYS. The crucial process streams for heat integration can be reduced to 15 hot and 7 cold process streams. The stream data can be found in Table 1. The necessary energy for heating the cold process streams is provided by oxidizing a tail gas from the FT-reactor. The tail gas cannot be further circulated and must otherwise be flared. Together with the exhaust air from the co-SOEC, the tail gas is oxidized in three combustion systems (CS). The exhaust air of the co-SOEC has a temperature of almost 900 °C. Due to the high amount of sensible heat, the entire exhaust air is used for oxidation. The three CS are connected in series, with new tail gas being added at each stage. Regarding HENS, the CS's exhaust gas streams CS1 to CS3 are used as hot utilities to provide heating energy. The inlet temperatures of the CS streams of 848.90 °C, 893.16 °C and 492.60 °C result from the empirical definition of the fuel quantity at each stage. Additionally, a high-temperature electric steam generator serves as a hot utility. The energy needed to cool the hot process streams is provided by

cooling water. The cost parameters for utilities and HEX are shown at the bottom of Table 1. Parameterization of the degressive HEX cost function was performed using cost information from the DACE Price Booklet [7] and multiple feedback rounds with the project partners.

3.1. Case study

With this paper, we show that HENS is a highly efficient tool for determining cost-optimal heat integration. Applied to the actual design problem of a novel PtL-plant, basic engineering can be actively supported and the potential of HENS can be quantified. Implementing the CS's exhaust gas stream as utilities with variable outlet temperatures and heat capacity flows, the utility design problem can be optimized holistically using mathematical optimization. The following cases are investigated to quantify the method's potential in terms of cost reduction and efficiency increase.

base This case represents the plant design from basic engineering. The HEN and the temperatures of the CS streams were determined empirically. This case serves as a reference to evaluate the achievable improvements.

baseHENS Only the HEN configuration is optimized. The stream temperatures resulting from the process simulation remain unchanged. With these assumptions, we demonstrate the potential of classical HENS and provide a cost-optimal heat integration.

advancedHENS Both the HEN and the CS are optimized. The outlet temperatures and the flow capacities of the CS streams are included as variables in the optimization problem. In Table 1, the CS streams are shown with the allowed ranges for temperature and flow. The inlet temperatures of the streams CS1^v to CS3^v are set to the material-specific limit of 900 °C. The outlet temperature can range from 150 °C to 890 °C. The permissible range of the flow capacity F was determined to ensure that no energy balances were violated.

4. Results

The optimization problem in this paper was modeled in MATLAB R2022a [8] using Yalmip R20210331 [9]. Gurobi 9.5.2 [10] was used as the MILP solver on a 128-core system (AMD EPYC 7702P) with 256 GB RAM. As a termination criterion, a relative gap of less than 0.01 % was set. The relative gap is defined as the gap between the best feasible solution objective and the best bound.

4.1. Optimization

The results of the case study are summarized in Table 2. The corresponding stream plots are shown in Appendix B. Remarkably, no hot utility is needed in all three cases.

Table 2: Comparison of costs, PtL-efficiency, heat loads and HEX area.

case	TAC / €/y	η_{PtL} / %	q_{UC} / kW	q_{UH} / kW	A_{HEX} / m^2
base	29 394.70	56.04	244.60	0	60.15
baseHENS	27 213.00	56.04	244.30	0	55.68
advancedHENS	23 576.13	56.16	219.78	0	49.35

The base case with TAC of 29 394.70 €/y and a PtL-efficiency of 56.04 % is the most expensive case. With identical PtL-efficiency, the TAC for the baseHENS case are 27 213.00 €/y. Using HENS, a reduction of the TAC by 8.01 % can already be achieved. In both cases, the capacity of the cold utilities are almost identical at 244.60 kW and 244.30 kW, respectively. The base case requires 21 HEX and the baseHENS case requires 22 HEX. Despite the larger number of HEX in the baseHENS case, less HEX area is required, 60.15 m^2 compared to 55.68 m^2. It can be concluded that the savings from a smaller HEX area outweigh the increased fixed costs due to one additional stream match. Counter-intuitively, a HEN with more HEX can still lead to lower TAC.

The advancedHENS case is based on different stream data. As shown in Figure 7, the solution of the optimization problem results in outlet temperatures of 877.4 °C, 878.3 °C and 887.5 °C at the streams CS1^v to CS3^v, respectively. The high temperatures close to the inlet temperature of 900 °C ensure a large LMTD at the HEX. A large LMTD reduces the HEX area required for the same amount of heat to be transferred. Compared to the base case, the HEX area is reduced from 60.15 m^2 to 49.35 m^2. Also, instead of 21 or 22 HEX, only 19 HEX are required. The smaller HEX area and number of HEX are the main reasons for the significant cost savings. With TAC of 23 576.13 €/y, 24.68 % of the costs can be saved compared to the base case. Approx. 4.27 % of the cost savings, i.e. 248.20 €/y, result from the lower cold utility load. 95.73 % of the cost savings, i.e. 5570.37 €/y, results from the fewer HEX and the decreased HEX area.

4.2. Composite curves & PtL-efficiency

According to Equation (2), the highest possible PtL-efficiency would be 57.25 % if no utilities are required. Evaluation of the composite curves (CC) at different minimum temperature differences shows that the theoretically achievable PtL-efficiency can not be achieved and must be lowered. Figure 2 on the left shows the CC of the process for a fictive minimum temperature difference of 0 K. It should be noted that the cases base, respectively baseHENS (solid lines) and advancedHENS (dashed line), show different composite and PtL-efficiency curves due to the different stream data. The results show that in the advancedHENS case, considerably more heat is transferred in the upper-temperature range due to the higher temperatures of the CS streams. The higher temperature difference between the streams generally results in higher LMTD at the HEX. Therefore, less HEX area is needed and costs can be saved.

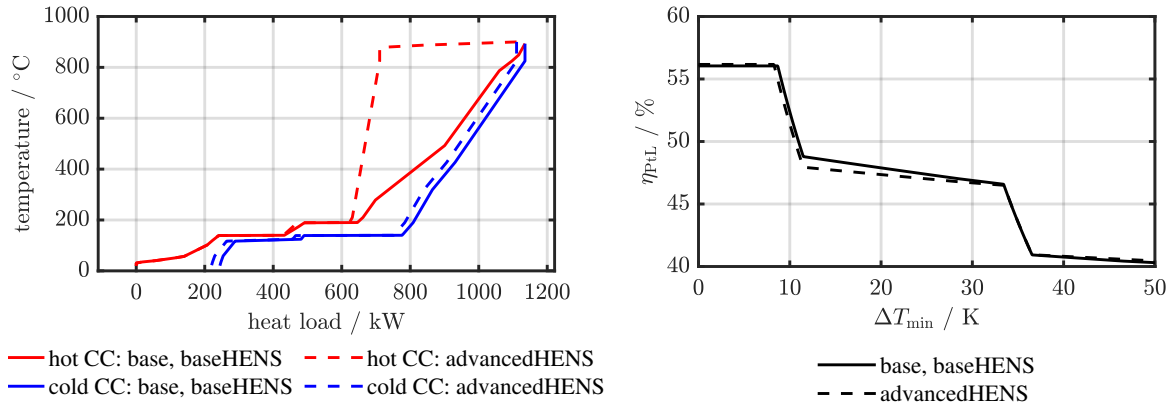

Figure 2: Left: Composite curve at a minimum temperature difference of ΔT_{min} = 0 K. Right: Maximum achievable efficiency as a function of the minimum temperature difference.

Figure 2 on the right shows the maximum achievable efficiency as a function of the minimum temperature difference. Up to a minimum temperature difference of 9 K, the pinch point is located at the upper right end of the CC. Consequently, no hot utilities are needed for the threshold problem. Up to ΔT_{min} of less than 9 K, a maximum efficiency of 56.04 % can be achieved for the base and baseHENS case. Due to optimized temperatures and flow capacities of the CS streams, the maximum achievable efficiency for the advancedHENS case can be increased to 56.16 %. Additional hot utilities are needed for ΔT_{min} higher than 9 K and the efficiency drops below 50.00 % for all cases. In all cases of the case study, the theoretical upper limit of the PtL-efficiency is reached.

5. Conclusion

Synthetic fuels are necessary to decarbonize the non-electrifiable transport sectors such as aviation and shipping. They also serve as a transitional solution for existing vehicles. High fuel production costs inhibit large-scale synthetic fuel production because of high total annual costs (TAC) and low PtL-efficiency. In this paper, we used an adapted HENS formulation and implemented the combustion systems (CS) of a novel 1 MW PtL-plant as internal hot utilities in the heat exchanger network design problem. The outlet temperatures and flow capacities of the internal hot utilities are implemented as optimization variables, unlike conventional HENS, and optimized simultaneously with the HEN. By coupling the optimization, a holistic examination is made possible, which opens up new potential for cost reduction and efficiency increase.

In the base case, the design case from the process simulation with Aspen HYSYS, as well as the baseHENS case, a PtL-efficiency of 56.04 % could be achieved. Using HENS in the baseHENS case, it was possible to find a HEN that is 8.01 % less expensive with TAC of 27 213.00 €/y. In the advancedHENS case, the inlet temperature of the CS streams has been set to the upper technical limit of 900 °C. The outlet temperatures resulting from the optimization problem are above 850 °C, compared to the base and baseHENS case. The high temperatures and the small temperature differences between the feed and return ensure a large LMTD at the heat exchangers. This allows smaller and also less expensive HEX to be used. TAC can be reduced by 24.68 % to 23 576.13 €/y. It can be concluded that the temperature of hot utilities should always be set as high as possible as long as the utility costs are not affected. Optimizing the temperature and flow capacity of the CS streams, allows the CS streams' heat flow to be reduced. The resulting shift in composite curves subsequently reduces the need for cold utilities. Therefore, the PtL-efficiency can be increased to 56.16 % and cold utility costs can be lowered.

In this paper, we showed that for given stream parameters, TAC can be significantly reduced using classical HENS. A key finding is that the coupled optimization of stream parameters and HEN lead to significant cost reductions and efficiency improvements simultaneously. From the results, it can be concluded that the main cost reduction stems from the higher temperatures of the hot utilities and the simultaneously optimized lower-cost HEN. With this paper, we show that the coupled optimization of utility parameters and HEN enables the activation of previously untapped potential for optimization. Applied to the use case of a PtL-plant, we can accelerate the economically viable production of synthetic fuels. Therefore, decarbonization of the transport sector can be achieved more quickly and emissions can be reduced in the long term.

Identifying the ideal process configuration for a green methanol production plant dependent on economic boundary conditions

Simon Maier[a], Yoga Pranata Rahmat[a], Ralph-Uwe Dietrich[a]

[a] German Aerospace Center (DLR), Institute of Engineering Thermodynamics, 70569 Stuttgart, Germany, simon.maier@dlr.de

Abstract:

The production of second-generation biofuels from agricultural waste products represent a sustainable option for future fuel and chemical industry. Yet, due to the local biomass availability, the identification of process designs dependent on the site-specific boundary conditions is mandatory to assess their potential contribution to a sustainable transition. While biomass-based routes have the advantage of mature technologies, the combination with renewably-generated hydrogen provides the opportunity to significantly increase the extent of carbon utilisation. Via dual fluidized bed gasification, gas cleaning, and a subsequent methanol synthesis and purification, grade AA methanol can be synthesised. With its ability of a direct CO_2-conversion at a high selectivity towards methanol, the methanol synthesis constitutes a promising option to chemically store fluctuating renewable energy. The potential of a biomass-to-liquid concept is analysed incorporating economic constraints into the process design to allow the identification of regionally adjusted process designs. The production costs of the concepts are estimated by setting up a detailed flowsheet simulation in AspenPlus®. A techno-economic evaluation methodology has been extended by an automated utility integration to identify European sweet spots. The conducted evaluation includes two different process configurations for two different biogenic feedstocks, including the integration of hydrogen produced through renewable sources. A correlation between economic boundary conditions such as the electricity and heat market, and the process design will be presented. Finally, the potential contribution of the investigated (power&)biomass-to-liquid process to a green methanol economy is discussed.

Keywords:

Techno-economic analysis, Green methanol, Second-generation biofuels, Process design

1. Introduction

The Intergovernmental Panel on Climate Change (IPCC) is once again urging the energy, transport, and agriculture sectors to take decisive action to achieve the Paris climate targets of reducing greenhouse gas emissions by 80 to 95 % by 2050 compared to 2010 [1]. To promote the use of renewable energy sources in the transport sector, the European Union has adopted the Renewable Energy Directive (RED) in 2009 [2], and its 2018 revision (RED II) [3], which require EU member states to achieve minimum shares of alternative and renewable energy sources in the transport sector (RED: 10 % by 2020, RED II: 14 % by 2030). The Fuel Quality Directive (FQD) [2] is another instrument used to monitor energy carriers in the transport sector, which aims to reduce the lifecycle greenhouse gases of fuels and defines greenhouse gas reduction targets for fuels placed on the market [2]. Fuel suppliers are obligated to report GHG emissions for the fuels they place on the market. As a result, there is an increased interest in renewable alternative fuels that can be produced from renewable power sources or waste materials derived from municipal, forestry, or agricultural wastes.

Methanol synthesis from biomass is a promising approach to meet the future demand for renewable fuels. Synthetic methanol can be produced through biomass-to-liquid (BtL) processes using a methanol synthesis and purification system, to achieve high methanol purity [4].

Renewable power-based methods are facing challenges in scaling up their technologies, particularly in water electrolysis and running a chemical production plant with varying feed sources [5, 6]. In contrast, biomass-based methods have a higher technology readiness level and require limited adaptations to use biomass as a feedstock, benefiting from the experience gained from coal gasification and large-scale fuel synthesis in coal-to-liquid plants like Sasol in South Africa [7-9]. However, there are also scalability concerns with biomass-to-liquid (BtL) processes due to the availability and transportation distance of biomass, which impacts overall greenhouse gas emissions and production costs. To overcome these challenges, BtL plant size can be kept small to medium or located near waste material sources. Alternatively, an efficient and ecologically friendly method to provide enough biomass is needed to benefit from economies of scale.

Based on the gasification and gas cleaning track described in [10] a decentralised process configuration for a biomass-to-methanol process is set up and extended by a proton exchange membrane electrolyser. For the methanol synthesis two different reactor concepts are investigated in order to analyse their performance for different boundary conditions.

In contrast to the work of Poluzzi et al. [11], two different feedstocks are investigated. Nevertheless, since the process setups are very similar to the ones modelled by Poluzzi et al. they are used as a benchmark for the conducted analyses.

Other studies looking into the biomass-to-liquid process often have Fischer-Tropsch syncrude as their product since it can easily integrated into the existing refinery structure [12, 13]. Another difference is the plant scale, since the biomass transport is a main driver for the feedstock's costs and its global warming potential, the investigated plant size is limited to 200 MW_{th} [14].

Simply evaluating pre-defined process configurations for multiple boundary conditions to find economically viable plant locations may not result in optimal designs, as there is no way to adjust the process itself. Therefore, this study aims to analyse the potential of multiple configurations under different economic boundary conditions while ensuring flexibility. This has been enabled by changed way of how TEPET accesses the AspenPlus® simulation files and to allow the modification of certain parameters through TEPET. To evaluate the process potential and its ideal configuration for achieving the lowest production costs, data was gathered on regional biomass potential, prices for straw and bark, other raw material prices, labour and transportation costs, and applicable revenues in the heat market.

2. Methodology

To evaluate the different process design a detailed flowsheet model [10] is utilized and adapted for the conducted investigation of methanol production. The process models are linked to the DLR inhouse tool TEPET [15] and its extension described in [10].

2.1. Flowsheet model

The basic flowsheet model is well described in the previous work of Maier et al. [10] which is based on the work within the EU-project COMSYN [16] and the experimental and simulative work of [17, 18]. The process schemes for the biomass-to-liquid and the power&biomass-to-liquid process can be seen in Figure 1.

The main difference is the introduction of an electrolyser into the model to provide some additional hydrogen for the methanol synthesis and to replace the air for the reformer by pure oxygen.

While the settings for the gasification and gas cleaning steps are well described by Maier et al. [10], the electrolyser, the methanol synthesis, and the purification units are described in the following chapters. The two investigated biomass types, bark and straw, differ the most in the assumed moisture content and a slight difference in the carbon, oxygen and ash contents. While bark is received with 50 wt.% moisture and its dry matter analysis results in 52.5 wt.% carbon, 38.5 wt.% oxygen and 2.6 wt.% of ash, straw is received with 10 wt.% moisture and 47.3 wt.% carbon, 41.4 wt.% oxygen and 4.7 wt.% ash. Hence, the bark is firstly led into a drying section to reduce its moisture content to 12 wt.% [10, 19]. In case of using straw as the feedstock, a certain amount of chlorine content is assumed which needs to be removed before the reformer by quenching the raw syngas before the filtration step from 730 °C to 550 °C.

Electrolyser

The PEM electrolytic cell was modelled through a black box approach with conversion factor 1 (with regard to water) and operating conditions of 40 bar and 80 °C. The electrical energy demand of 61.6 kWh per kg of H_2 was used for electrolysis corresponding to an electrical efficiency (power to HHV_{H2}) of approximately 64 % [20]. It was assumed that pure oxygen can be separated from the anode, which is utilized to operate the reformer with pure oxygen, significantly reducing the amount of inerts in the syngas. The amount of hydrogen is adjusted to achieve a H/C ratio of 3 at the entrance of the MeOH synthesis loop.

Methanol synthesis

The methanol section consists of a compression to the 90 bar operating pressure, a plug flow reactor model (RPlug) with an isothermal cooling liquid at 240 °C. The reactor model is representing a tube-and-shell reactor concept as it is commonly used for large methanol production plants. The entering temperature is set to 235 °C. The pressure drop is calculated using the Ergun equation [21]. A recycle with a purge rate of 5 % ensures that impurities such as nitrogen are not accumulating within the recycle loop. For the reaction modelling the simplified kinetic model from Van-Dal and Bouallou [22] of the in-depth model of Vanden Bussche and Froment [23] with the readjusted parameters from Mignard and Pritchard [24] is implemented. The whole section is modelled with the IDEAL property method as suggested by Graaf et al. [25].

Methanol purification

For the purification a two-column approach is applied. While the first column divides the gaseous side-products from the methanol, the second column separates the methanol from the water. The methanol is purified until

a purity of grade AA (99.85 wt.%) is achieved. The methanol purification section is modelled using ELECNRTL to achieve a better description of the azeotropic methanol-water separation.

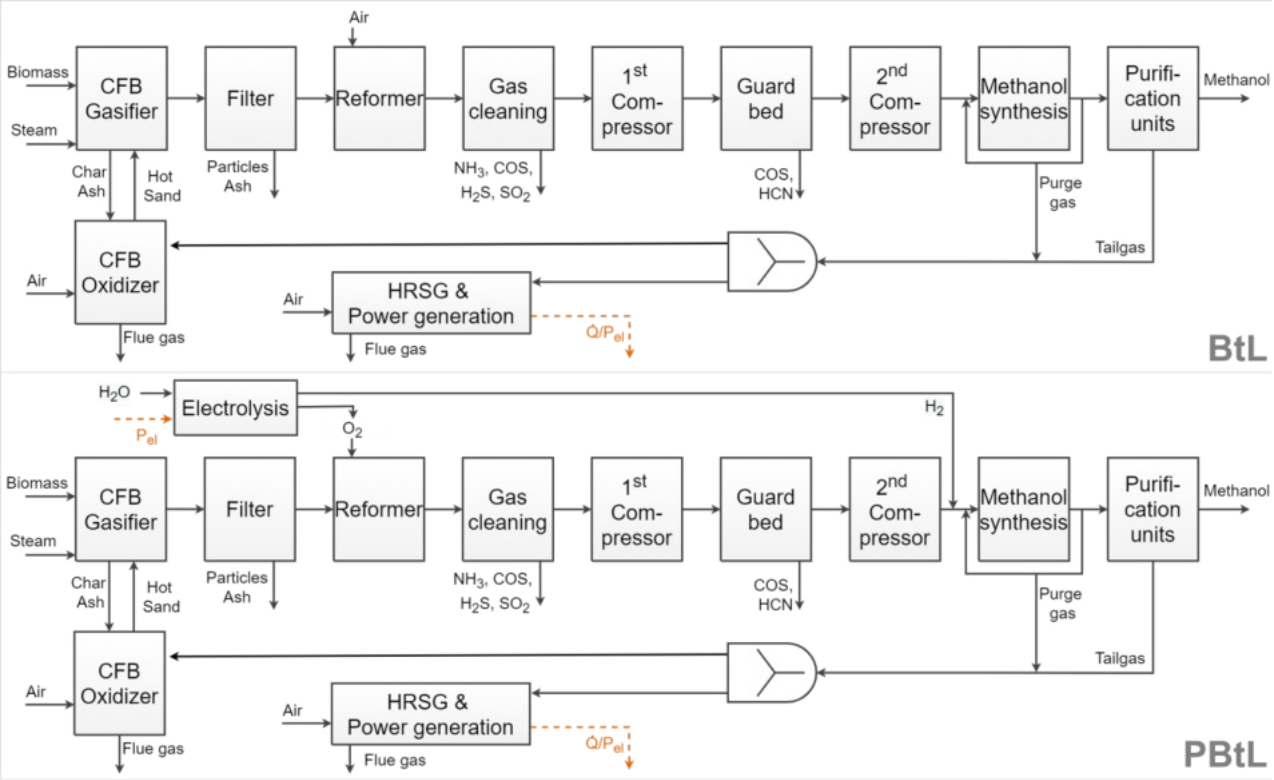

Figure 1. Process schemes for the biomass-to-liquid (BtL) and the power&biomass-to-liquid (PBtL) process.

2.2. Technical analysis

The process configurations are evaluated according to their ability to convert the stored energy of the biomass into the desired product methanol. To compare the different setups according to this performance indicator, the biomass-to-liquid efficiency is defined as follows:

Biomass-to-liquid efficiency: $$\eta_{PBtL} = \frac{\dot{m}_{CH_3OH} \cdot LHV_{CH_3OH}}{\dot{m}_{biomass}\, LHV_{biomass} + P_{el}}$$

2.3. Techno-economic analysis

The economic evaluation of the concept follows the approach of Peters, Timmerhaus, and West [26], which has been utilized in several previous techno-economic studies [15, 27, 28]. To apply this methodology, a database of reference equipment costs is needed to account for changes in the process configuration and its impact on capital and operational expenses. The AspenPlus® process model previously described is used to scale equipment sizes, as well as raw material and by-product streams, based on the material and energy flows. For the main equipment the cost functions of Maier et al. [10] are applied to the current biomass-to-methanol process concepts. The formulas utilized to calculate the production costs are listed below [15]:

- Equipment costs: $EC_i = EC_{ref,i} \cdot \left(\frac{D_i}{D_{ref,i}}\right)^{d_i} \cdot \left(\frac{CEPCI_{2020}}{CEPCI_{ref}}\right)$
- Fixed capital investment: $FCI = \sum_{i=1}^{m} EC_i \cdot \left(1 + \sum_{j=1}^{12} F_{eco,i,j}\right),\ TCI = \frac{FCI}{0.9}$
- Annualized capital costs: $ACC = FCI \cdot IR \cdot \left(\frac{(1+IR)^{PL}}{(1+IR)^{PL}-1} + \frac{1}{1-0.1} - 1\right)$
- Net production costs: $NPC = \frac{ACC + \sum OPEX_{ind} + OPEX_{dir} + N_P \cdot c_{labour}}{\dot{m}_{fuel}}$

The equipment costs are calculated by setting the actual unit capacity *D* into relation with a reference equipment capacity D_{ref} and its reference costs EC_{ref} and applying a defined digression factor *d* to it. To account for price differences between the reference and the base year the Chemical Engineering Plant Costs Index (CEPCI) is applied to the equipment costs. After including the Lang factors [26] for additional costs such as piping, engineering etc. the fixed capital investment (FCI) is estimated. To calculate the final net production costs, the direct and indirect operational expenditures (OPEX) are sum up together with the annualized capital costs and the labour costs. Finally, the whole yearly expenses are divided by the product output per year.

3. Results and discussion

Assessing the different process concepts regarding their biomass-to-methanol efficiency, it becomes clear that the power&biomass-based process routes yield in a higher energetic efficiency (Table 1). By enabling additional product formation, more biogenic carbon is converted to methanol, which increases the overall process efficiency. Furthermore, it can be seen, that the choice of the biomass feedstock has a significant impact on the technical potential of the process. Due to the higher ash content and higher oxygen content in the straw, the resulting syngas has a lower potential [10], since more hydrogen is required to remove the oxygen in form of water out of the system. Furthermore, due to the potential chlorine in the straw, the particle filter after the gasifier has to be operated at 550 °C which leads to further energy losses, since part of the reaction enthalpy in the autothermal reformer is used to heat the syngas up to 850 °C again. The disadvantageous composition is also the reason for the additional electricity demand in case of the straw-based PBtL concept, since more hydrogen is required to achieve the desired H/C ratio for the MeOH synthesis of 3.

Table 1. Technical results for the BtL and PBtL concepts with bark and straw as their feedstock

		BtL-B	PBtL-B	BtL-S	PBtL-S
Biomass moisture content	wt.%	50	50	12	12
Biomass input (mass flow)	kg/h	39.1	39.1	24.4	24.4
Biomass input (energy content)	MW_{th}	100	100	100	100
Electricity consumption	MW_{el}	14.6	103.9	15.8	121.4
Product output (mass flow)	kg/h	10,210	18,604	8,478	18,532
Product output (energy content)	MW_{th}	64.9	118.3	53.9	117.9
PBtL-efficiency	%	56.7	58.0	46.6	53.2

Compared to previous studies such as Peduzzi et al [4] the proposed biomass-to-liquid concept presents an 5% higher BtL efficiency for the bark case. The calculated efficiency for the bark-based PBtL case are in very good alignment with the work of [11], who estimated an efficiency of 57.5% for their process setup. Yet, the conducted analyses of this work highlight the potential of a power-enhanced setup for other biomass feedstocks. While for bark the PBtL efficiency has been increased by only 1.3%, the efficiency for converting straw into methanol can be increased by 6.6% which shows that especially for biogenic waste materials with a disadvantageous composition, the implementation of additional hydrogen generation is highly beneficial for its conversion rate.

To investigate the different concepts economically, the net production costs (NPC) are calculated (Figure 2) with the economic boundary conditions given in Table 2. With Germany as the selected region the biomass-to-methanol plant's costs are calculated for a country with relatively high raw material prices compared to other European regions such as Poland, Czech Republic or Slovenia [10].

Table 2. Economic boundary conditions.

Base year	-	2020	
Plant size	MW_{th}	100	
Interest rate (*IR*)	%	10	
Persons per shift (N_P)	-	10	
Full load hours (*flh*)	h/a	8260	
Plant lifetime (*PL*)	a	20	
Plant location	Germany		
Electricity costs/revenue (c_{EL})	€/MWh_{el}	106.5	[29]
Biomass costs ($c_{Bio,b}$)	€/GJ	8.4	[30]
District heating revenue (r_{DH})	€/MWh	21.0	[31]
Process steam revenue (r_{PS})	€/MWh	36.0	[31]
Labor costs (c_L)	€/h	29.0	[32]

Due to the process configuration, which contains an internal recycle within the methanol synthesis but no further re-activation of the process' tailgas, the process yields in a high amount of excess heat. Its utilisation is very dependent on the given boundary conditions. In the conducted techno-economic analysis, it is assumed that high pressure steam, as well as district heating can be provided. Hence, the methanol production costs can be decreased by achieving a quite high by-product revenue on the heat market. While the prices for

electricity and biomass are extracted from literature, the revenue for potential heat market products is calculated based on the assumption that they have to compete with a provision based on biomass- or natural-gas fuelled boilers. Therefore, the costs are calculated according to Ulrich et al. [31], where the price for the fuels is assumed to be the average between the local natural gas price and the biomass price [10].

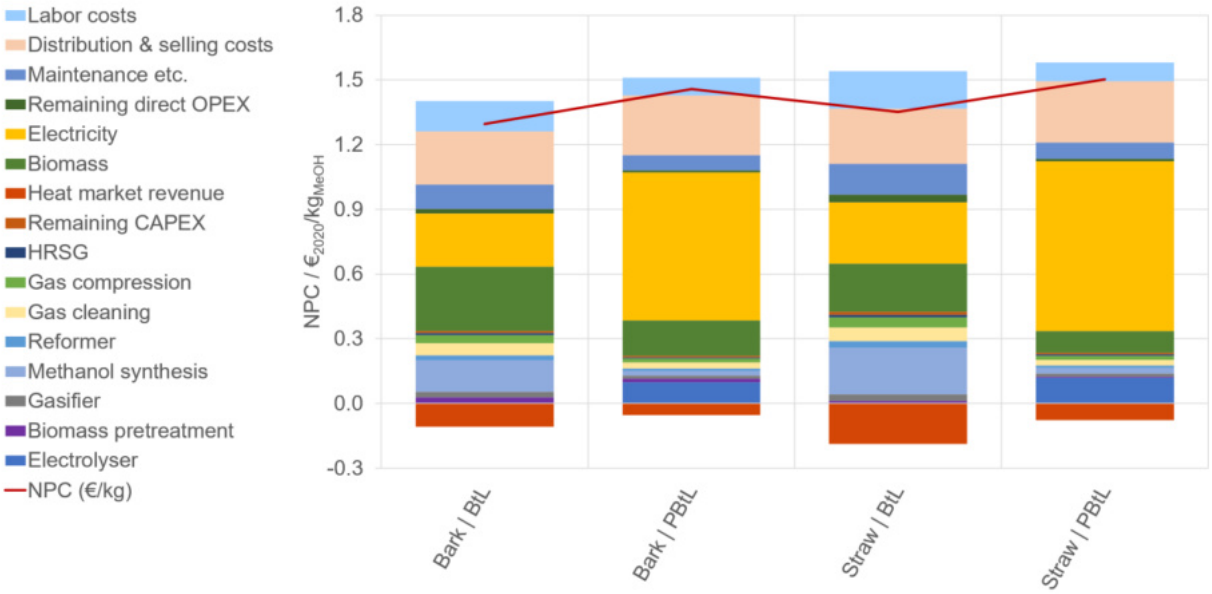

Figure 2. Net production costs for straw and bark for the two different process concepts biomass/power&biomass-to-liquid

In contrast to the prior technical results, the economic analysis of the concepts shows that the BtL process is more economic than the PBtL concepts. The main reasons can be found in the high additional expenses for the required electrical power and the additional investment for the electrolyser. The estimated NPC for all concepts differs within a range of 0.21 €$_{2020}$/kg$_{MeOH}$.

In order to identify at which conditions the PBtL concept might be able to compete with the BtL process, a sensitivity analysis with bark as feedstock is conducted and shown in Figure 3.

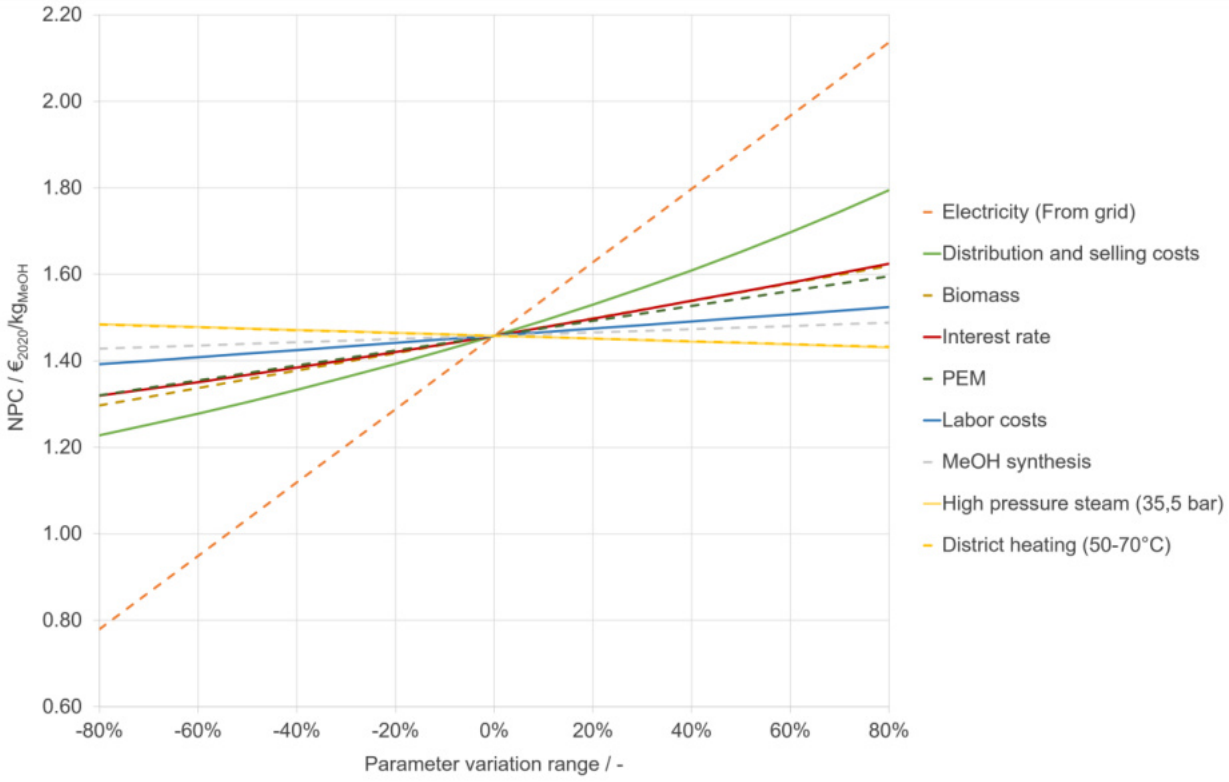

Figure 3. Sensitivity study for power&biomass-to-methanol concept using bark as feedstock

The presented sensitivity analysis is performed by varying each of the most relevant cost drivers within a range of -80% and +80%. Since the additional costs for distribution and selling of the product is dependent on the overall production costs and the interest rate affects the annualized capital costs their variations result in non-linear impacts on the net production costs. The remaining raw materials, utilities and equipment costs are having a linear effect on the calculated net productions.

In dependence on the electricity and biomass price, the PBtL concept gains more attraction. With a reduction of the electricity price, the productions costs can be reduced significantly. As it can already be seen in Figure 2, the electricity prices are the most dominant cost driver for the PBtL concepts, followed by the product distribution and the raw material: Biomass. In case of an electricity price of lower than 40 €/MWh_e, the production costs for the PBtL case are dropping below the methanol commodity prices of around 1 $€_{2020}/kg_{MeOH}$.

Figure 3 shows how the required subsidies for power demand or renewable methanol sales will change with feedstock and electricity costs. Future reduction of renewable electricity costs might favour the power-assisted biofuels production in the coming years. Furthermore, the increase of renewable energy in the electricity mix is required to achieve a positive environmental impact with the PBtL cases. Recent studies of Habermeyer et al. [27] and Weyand et al. [14] showed that utilizing the electricity from the German grid to generate the hydrogen, yields in an even higher greenhouse gas emission than using the fossil alternatives. Hence, PBtL concepts imply a potential alternative for an increased production of alternative fuels by an increased carbon efficiency but strongly depend on the availability of renewable and inexpensive electricity. Until then, only off-grid solutions may contribute to a reduction of the global warming potential or the exclusive use of biogenic waste materials as a feedstock together with a reduction of society's fuel consumption.

4. Conclusion and outlook

The study presented a promising approach for the production of sustainable methanol using two biogenetic waste materials, straw and bark. By combining highly efficient process units and by avoiding a recycle to the reformer stage, the equipment sizes can be kept small, while still achieving (power&)biomass-to-liquid efficiencies of up to 58.0%. An AspenPlus® flowsheet model was set up to model multiple process configurations which were evaluated using the DLR software-tool TEPET. Through automated heat integration, different process configurations were assessed, and a trade-off was identified between maximizing the BtL efficiency and minimizing net production costs. Even though the PBtL concepts come with high process efficiencies, the additional investment and costs for electricity lead to higher production costs in Germany in 2020. Furthermore, the shown work shows the potential of a hydrogen-enhanced biomass-to-liquid process especially for preliminary unattractive biogenic waste materials such as straw.

With an increasing investment into renewable energy sources and a ramp-up of cheap renewable electricity generation technologies, the PBtL concept might contribute to a carbon-neutral domestic transport by ensuring that the biogenic carbon is utilized best possible. To minimize the investment risk associated with the introduction of the technology, one approach could be to start the market introduction with biomass-to-methanol plants. These plants could then be expanded to include a hydrogen production plant and a second methanol synthesis reactor once a sufficient supply of renewable electricity is available.

Abstract:

The substitution of fossil fuels in current energy systems is essential on the path to carbon neutrality. In the building sector, different renewable and waste heat sources could be used in district heating systems to replace fossil-based heating plants. However, if new heat sources are integrated into multi-energy systems, the profitability of present heating plants could decrease. At the Forschungszentrum Jülich, the waste heat from a new high-performance computer is to be integrated into the local district heating system in order to reduce overall CO_2 emissions. This waste heat integration will have an impact on the holistic multi-energy system of the campus, which is mainly supplied by a combined cooling heat and power plant (CCHP). This paper investigates the described waste heat integration using a bi-objective optimisation approach. The proposed model optimises the operation of the overall multi-energy supply system with waste heat integration. Furthermore, the optimisation model allows for the optimal design of the required heat pump system and additional absorption chiller capacity that enable efficient CCHP heat usage despite the waste heat integration. In addition, the effects of lowering district heating temperatures and changed energy prices are studied. The results show that integrating waste heat reduces the overall CO_2 emissions of the multi-energy system and even more if the integration is combined with a lowering of district heating temperatures. Furthermore, the optimisation shows that a cost reduction is feasible by increasing the absorption chiller capacity that uses the produced heat of the CCHP.

Keywords:

Waste Heat Integration, Bi-Objective Optimisation, Multi-Energy System, CCHP, District Heating

1. Introduction

The endeavour to decarbonise the building sector offers great potential for achieving the European Union's climate targets. The heat supply is mainly based on fossil fuels such as gas or oil to supply boiler systems in buildings. However, also many district heating systems are supplied by fossil-based energy plants, like 74 % of the combined heat and power plants (CHP) in Europe are based on coal and gas [1]. As an important contribution to the overall energy transition, heating plants in district heating systems need to be replaced by sustainable heat sources in order to reduce carbon dioxide emissions in the building sector. Renewable energy sources such as solar or geothermal energy as well as (low-temperature) waste heat sources from industry or cooling processes are examples of sustainable heat sources. Depending on the quality of the waste heat, the utilisation of waste heat sources could reduce CHP operation and, thus, save fuel and operating costs [2]. However, replacing existing, operating heating plants with sustainable heat sources could be challenging for many reasons.

Most heating plants in district heating systems have large nominal thermal capacities that cannot be easily replaced since the potential heat sources for replacement have limited heat capacities, are geographically inconveniently located, or the heat availability fluctuates due to scheduled processes. Zhang et al. show the difficulties of waste heat usage by optimising the utilisation rate for a district heating system and a cooling process depending on the availability of heat and the seasonal demand. Furthermore, they also consider how many consumers can be supplied with the available heat capacity [3].

The economic constraints make it challenging to replace current heating plants, as the profitability depends on different boundary conditions, such as the fuel prices or the investment required to integrate the sustainable heat source. Dorotić et al. perform an economic assessment of waste heat utilisation in an urban area by investigating the available waste heat from supermarkets and power substations. They show that the costs

of waste heat integration into district heating systems depend not only on the waste heat process itself, but also on the waste heat temperature and the current temperature level of the district heating system [4]. In [5], the possibilities of integrating solar heat with the help of heat pumps into Helsinki's existing district heating system are examined and evaluated from an economic point of view. In this particular case, the operation of the CHP is less advantageous than the operation of the heat pumps due to the electricity price level. However, Durán et al. point out that the conversion of existing district heating systems towards sustainable systems is technically possible, but the substitution of CHP with sustainable heat sources is an economic challenge. Therefore, they propose to establish economic and political regulations to facilitate the economic realisation of such projects [6]. The challenging utilisation of sustainable heat sources depends on the boundary conditions of the respective use case.

Optimisation models are helpful in showing optimal adaptions of energy systems, from a design or an operational point of view, to e.g. enable the usage of sustainable energy sources. The consideration of different objectives is necessary in order to take into account ecological and economic interests. The objective functions of such mathematical optimisation problems can be the minimisation of emitted CO_2 emissions or the minimisation of total costs. Capone et al. develop a multi-objective optimisation model to optimise the operation of producers and consumers in a district heating system, taking into account different objectives, such as reducing CO_2 emissions or minimising the total costs [7]. However, the additional integration of sustainable heat sources in the existing district heating system is not considered.

The integration of a waste heat source into a fossil-fuelled district heating system takes place at the Forschungszentrum Jülich (FZJ), a research facility in Germany. On the campus of the FZJ, the integration of waste heat of an upcoming high-performance computer in the local district heating system is studied. However, the use of the waste heat source reduces the supply of the currently operated CHP units. Due to the fact that the CHP units are operated heat-led, the electricity production for the campus is lowered, which affects the economic profitability of the entire energy system. Therefore, the usage of the waste heat source in the energy system of the campus leads to ecological benefits, but may result in higher operating costs.

The impact of a possible waste heat utilisation at the FZJ is simulated for different shares of waste heat integration and evaluated for the ecological and economic effects in previous work [8]. In addition, [8] presents different measures on the energy system to improve the efficiency of waste heat utilisation are presented, such as lowering the district heating supply temperature and extending the absorption cooling production. However, as campus' heat and cooling demand fluctuates throughout the year, the operation of the existing energy plants is very dynamic, so the targeted waste heat utilisation could be further optimised. Therefore, we develop an optimisation model in this study to optimise the waste heat utilisation in the existing energy system design of the FZJ in order to show optimal system measures and optimal operation of the involved energy components under ecological but also economic aspects.

The paper is structured as follows: In Section 2., we first give an overview of the multi-energy system of the FZJ and describe the planned waste heat utilisation. Following, we describe the optimisation model and show the modelling approach of the energy components, which represent the different energy plants on the campus. Furthermore, we show the investigated scenarios and summarise the assumptions of the modelling approach. Section 3. shows the optimisation results for the different studied scenarios. After discussing the results and the limitation of the model in Section 4., Section 5. summarises the study.

2. Methods

In the following, we first explain the use case of waste heat utilisation on the FZJ campus. After that, we present the developed optimisation model and the objective functions. Thirdly, we show the scenarios studied and the corresponding boundary conditions.

2.1. Multi-energy system and waste heat utilisation

The campus of the FZJ is a research facility in North Rhine-Westphalia, Germany, with many buildings used as offices and laboratories. A local multi-energy system supplies the various energy demands on the campus with different energy components. The main energy plant of the multi-energy system is a gas-fired combined cooling, heat and power system (CCHP) consisting of three CHP units, two heat-only boilers (HOB) and an absorption chiller (AC). The CHP units supply electricity and heat to the campus and should operate at a high load for a cost-efficient operation. The electricity generated by the CHP is less expensive than the electricity supplied by the public power grid, which supplies the remaining electricity demand. The CHP units cover the heat demand in the base load. If the heat demand of the campus exceeds the capacity of the three CHP units, two HOB units support the heat supply. When the heat demand of the campus is low, the surplus heat from the CHP units is used to operate the AC to generate cooling for the campus. A district cooling network distributes the cooling to the buildings. Since the AC in the CCHP cannot meet the entire cooling demand of the campus, three additional compression chiller (CC) plants located on the campus also supply cooling to the

district cooling network.

A new high-performance computer is being built on the FZJ campus, which generates a lot of waste heat through its operation. This waste heat source is being integrated into the multi-energy system of the campus to partially replace the heat supply from the gas-fired heating plants in the CCHP. However, the emitted waste heat will be available at a low-temperature level. Therefore, a heat pump (HP) system is required to raise the waste heat temperature to a higher level to make it usable in the local district heating system.

Different measures are described in [8] to enable more efficient waste heat usage. First, the supply temperature in the district heating system could be reduced to improve the efficiency of heat pump operation for waste heat integration. Second, the possibility to utilise more high-temperature heat by the CHP in the AC for cooling production is presented. Integrating waste heat into the district heating system reduces the supplied heat by the CHP and HOB units. Suppose the CHP units decrease their operation because the produced heat is not used anymore. In that case, electricity production will also decrease, leading to higher electricity consumption of the public grid and, thus, to higher operating costs. The CHP workload could be maintained at a high level by using the CHP surplus heat for additional AC cooling production. In addition, the extended AC operation partially replaces the cooling supply of the CC plants, which reduces the electricity demand for the cooling supply. However, as the ability to extend the operation of the current AC is limited, the construction of additional AC capacities can improve the ability to utilise high-temperature heat by the CHP units.

The dynamic operation of the various components of the energy system, in combination with the integration of waste heat, can be improved by optimising the multi-energy system at the campus. Therefore, an optimisation model is developed that both optimises the CCHP operation and takes into account possible design adaptation, such as the installation of heat pumps for waste heat utilisation and the expansion of the AC cooling supply. In the following, we describe the developed optimisation model.

2.2. Optimisation model

The campus' current energy supply system forms the basis for modelling the multi-energy system. However, the district heating and cooling network are not considered in the optimisation model, as we want to investigate the effects of waste heat utilisation on the overall energy production in this study. The main objective is the utilisation of waste heat in order to reduce carbon dioxide emissions taking into account the economic profitability of the overall energy system. Therefore, we apply a bi-objective optimisation approach that optimises the global warming impact (GWI) and the total annualised costs (TAC) of the multi-energy system, which are described more in detail in Section 2.2.3.

We use the COMANDO framework, which is written in Python [9]. COMANDO is an open-source modeling and optimisation framework for modelling energy components and linking them to an holistic energy system. The resulting energy system model is passed to a solver that optimises the design or operation regarding the set objective functions. The model in this study is based on a two-stage stochastic programming, which allows the design of components and the simultaneous operation optimisation based on a few typical time steps, i.e. operating points [9]. The typical operating points are determined by a clustering approach (see Section 2.3.).

In Fig. 1, the structure of the FZJ multi-energy system is shown. The different energy components, represented by submodels, are described in the following section. First, we give an overview about the main formulations and assumptions of modelling, followed by a more detailed description of the existing components and optional components for waste heat utilisation.

2.2.1. General model formulations

All energy components in the multi-energy system are modelled in terms of their operation efficiency η_{part}, which determines the quantity of energy output as a function of the amount of consumed energy. The general formulation of the components' part load efficiency is

$$\eta_{\text{part}} = \eta_{\text{base}} \cdot \mathcal{P}(out_{\text{rel}}), \tag{1}$$

where the base efficiency η_{base} is multiplied with $\mathcal{P}(out_{\text{rel}})$ that approximates the part load behaviour using two polynomial equations. The polynomials are determined by the specific energy components and depend on the relative energy output out_{rel}, which refers to the nominal capacity.

The modelling approach of the part load behaviour (1) leads to non-linear equations that increase the computation time for solving. Therefore, the resulting efficiency formulations of the energy components are simplified by using piecewise linear functions if necessary. The output of the components is an operational variable, and so is the efficiency, since it depends on out_{rel}. Thus, the input-output correlation is a multiplication of two variables and results in a quadratic equation. Since this correlation is set as a constraint in the energy components, the resulting optimisation problem is a quadratically constrained program.

The existing energy plants are modelled according to the currently installed components on site. The optional components, i.e. the HP for waste heat utilisation and the additional AC, can be built or not and are, there-

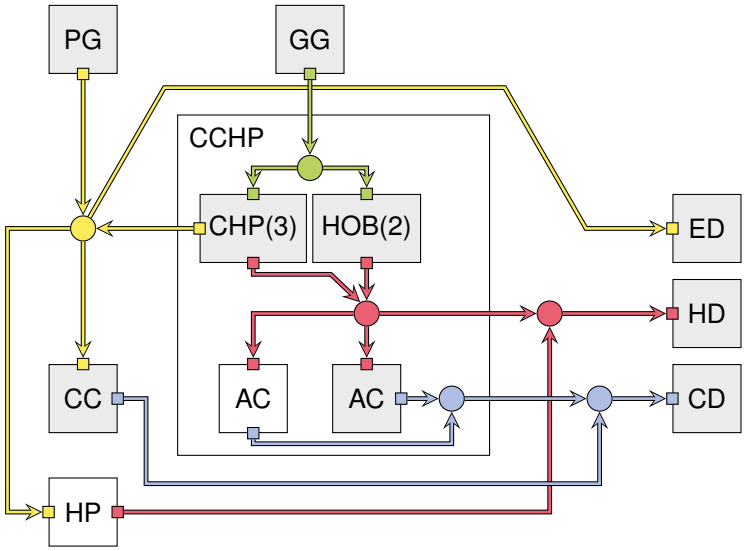

Figure 1: The different energy components of the multi-energy system are symbolised as grey boxes for existing and as white boxes for optional components. The CCHP includes three CHP units, two HOB units and an AC. The optional AC extension is shown as an additional AC in the CCHP. The CHP and HOB units are connected to the gas grid (GG). Electricity is supplied by the power grid (PG) and the CHP units to the CC and the electrical demand (ED) of the campus. The CHP and HOB units supply the heat demand (HD). The AC and the CC supply cooling to the cooling demand (CD). The AC is supplied by heat from the CHP units. A HP component is optional for waste heat utilisation, which consumes electricity from the PG and supplies heat to the HD. The waste heat source of the HP is not visualised.

fore, a design decision for the optimisation problem. In addition, the nominal output capacity of the optional components is a design variable.

For both existing and additional components of the energy system, the maintenance costs are taken into account through a maintenance coefficient and the initial investment of the component. The maintenance factors are based on [11].

2.2.2. Modelling of energy component

CHP

All three installed CHP units in the CCHP are identical in construction. The parameters set for the CHP model are based on manufacturer specifications. The nominal electrical output is 4.3 MW. At part load, the electrical efficiency decreases while the thermal efficiency increases. The manufacturer provides efficiency data for 100 % at full load (η_{heat}=0.437 and η_{el}=0.432) down to minimum part load of 50 %. The efficiency of the CHP between these operating points, with an additional available data point at 75 % part load, are linearly approximated.

HOB

The two HOB units in the CCHP have a nominal heat capacity of 16 MW each. The thermal efficiency is assumed to be constant at 80 % while considering a minimal part load of 20 %.

AC

The AC submodel is used for the installed AC in the CCHP and the optional AC capacity extension, i.e. an additional AC machine. For the already installed AC component, the design variable is set to one and the nominal cooling capacity to 5.7 MW. Furthermore, it is also considered that only the CHP units supply the AC, but not the HOB units.

The design variables for construction decision and dimensioning the nominal cooling capacity are used for the optional AC component. However, the minimal possible cooling capacity is set at 1 MW, as the investment for too small capacities is uneconomical for the studied energy system [12]. The part load efficiency of the AC components is modelled according to manufacture specifications, taking into account a minimal part load of 20 %. The specific investment of the AC is estimated following [12] at 200 EUR/kW.

HP

The waste heat utilisation in the multi-energy system is modelled as an optional HP. The HP increases the temperature of the waste heat to a sufficient level to integrate it into the local district heating system. Since the HP is not yet part of the multi-energy system, the HP component is a design decision subject to optimisation. In addition, the heat supply of the HP on the condenser side $\dot{Q}_{\text{HP,con}}$ is an operational variable to determine the

optimal amount of waste heat utilisation depending on the fluctuating demand.

The efficiency of the HP system is modelled by the coefficient of performance (COP). The COP of the HP COP_{HP} depends on the temperature difference between the heat source on the evaporator (eva) side, i.e. the waste heat source, and the heat sink on the condenser (con) side, i.e. the district heating system. The COP is calculated by

$$COP_{\mathrm{HP}} = \frac{T_{\mathrm{lm,con}}}{T_{\mathrm{lm,con}} - T_{\mathrm{lm,eva}}} \cdot \eta_{\mathrm{HP,system}} \cdot \eta_{\mathrm{HP,part}}, \tag{2}$$

where T_{lm} is the logarithmic mean temperature according to

$$T_{\mathrm{lm}} = \frac{T_{\mathrm{out}} - T_{\mathrm{in}}}{\ln T_{\mathrm{out}} - \ln T_{\mathrm{in}}}, \tag{3}$$

with the incoming (in) and outgoing (out) fluid temperature at the corresponding heat exchanger. The system efficiency $\eta_{\mathrm{HP,system}}$ is used to account for the system losses of the HP and is set to 0.5 [13]. The part load efficiency $\eta_{\mathrm{HP,part}}$ is based on [14] and linearised with the behaviour about 20 % part load. This linearised part load is considered down to the minimal set part load of 5 %. This is done, since the part load efficiency drops drastically below 20 % according to [14], however, the HP would not be operated in such inefficiently operating regimes in reality. The HP system is modelled as one component to reduce model complexity. In reality, however, the heat capacities required in this study would be realised by several HP units. The multiple HP units would allow for more efficient operation by avoiding the inefficient part loads under 20 %. Therefore, the linearised behaviour is used for the one HP system model.

The HP heat output $\dot{Q}_{\mathrm{HP,con}}$ is calculated by an energy balance and $COP_{\mathrm{HP}} = \frac{\dot{Q}_{\mathrm{HP,con}}}{P_{\mathrm{HP,el}}}$ to

$$\dot{Q}_{\mathrm{HP,con}} = \dot{Q}_{\mathrm{HP,eva}} + P_{\mathrm{HP,el}} = \frac{\dot{Q}_{\mathrm{HP,eva}}}{1 - COP_{\mathrm{HP}}^{-1}}, \tag{4}$$

where $\dot{Q}_{\mathrm{HP,eva}}$ represents the heat input of the waste heat source and $P_{\mathrm{HP,el}}$ the required electricity for operation.

Based on an anticipated waste heat capacity of 18 MW, a constant temperature level of the waste heat source at 44 °C [8], and the current supply temperature of the district heating system (see Section 2.3.), the upper limit of the design variable determining the thermal HP capacity is set to 22 MW. The lower limit of the HP capacity is set to 1 MW to avoid installing too small HP systems. The specific investment of the HP system is based on estimations by [15] and is set at 700 EUR/kW.

CC

The cooling demand of the campus is also met by three CC plants with a combined cooling capacity of 21 MW. Each CC plant comprises two or three CC units. In addition, no detailed manufacturer data of the individual chillers are available for these components. Since the district cooling network is not modelled and only the overall cooling supply is considered, all CC units on the campus are simplified into one CC component model. Therefore, a detailed analysis of the CC operational measurement data is performed to model the average behaviour of the summarised CC cooling supply.

The analysed measurement data of overall CC supply and consumed electricity for the CC operation does not show any significant correlation of the energy efficiency to the cooling load or the ambient temperature. The several CC units are from different years of construction, have various nominal capacities, and a control strategy for an optimal combined operation of the units is missing. Therefore, the analysed measurement data show a relatively constant COP over the year, which results from various superimposed COP characteristics of the individual CC units. Thus, the efficiency of the overall CC cooling supply is assumed to be constant and set at 3.7, as a COP formulation based on the temperature levels would not represent the actual CC operation on the campus.

The CC supply model consists of several small units, which is why the minimal part load of the comprised model is negligible. As no detailed information about the different CC units is available, the maintenance costs of the CC component are neglected.

GG, PG, ED, HD, CD

The external energy consumption by the GG and the PG (see Fig. 1) is modelled by considering specific energy prices and CO_2 factors that are defined in Section 2.3. Since the FZJ is not allowed to sell electricity to the grid, the energy flow from the PG model is limited to one direction. No restrictions on electricity and gas consumption are set for either grid model.

The demand models symbolise the consumption of the multi-energy system. The ED, CD and HD have a single input that represents the demand to be met (see Fig. 1). The energy demand symbolises the required

supply by the energy plants, as the distribution losses are not considered. The assumed data for the energy demand is described in Section 2.3..

2.2.3. Optimisation problem and objective functions

The defined optimisation model is solved considering two objectives, minimising the TAC and the GWI of the multi-energy system. The TAC is expressed as

$$TAC = \frac{(1+i)^n \cdot i}{(1+i)^n - 1} \cdot I + R, \tag{5}$$

with i for the interest rate of 0.7 %, n for the project duration of 20 a, I for the investment of HP installation and AC extension. The operational costs R are calculated according to the energy prices (see Section 2.3.) for energy consumption from the grids and the maintenance costs of the energy components. Gas is consumed to supply the CHP and HOB units, and electricity is consumed from the grid to cover the HP, CC and electricity demand of the campus that is not met by the CHP units.

Furthermore, the second objective GWI is formulated as

$$GWI = \dot{Q}_{\mathrm{GG}} \cdot CO_{2,gas} + P_{\mathrm{PG}} \cdot CO_{2,el}, \tag{6}$$

where $CO_{2,gas}$ and $CO_{2,el}$ represent the CO_2 emission factors for gas and electricity consumption supplied by the grids. The resulting bi-objective problem is solved by using the ε-constraint method.

The formulated energy system optimisation problem results in a Mixed Integer Quadratically Constrained Programming. The problem is passed to the Gurobi solver [16] via the implemented interface of COMANDO and solved for both objectives [9].

2.3. Studied scenarios

We define different scenarios for investigating waste heat utilisation in the FZJ multi-energy system. First, we optimise the energy system based on the current design without waste heat utilisation, i.e. an operational optimisation (Ref). Second, we consider the design option for an additional AC extension and HP installation for waste heat utilisation. Currently, the district heating network operates at high supply temperatures (HT) from 95 to 132 °C, controlled by a heating curve that depends on the ambient temperature. The first optimisation with optimal waste heat utilisation is carried out with these high supply temperature requirements at the HP system (WH_{HT}).

The HP operates much more efficiently if the temperature difference between waste heat and network supply temperature is reduced. Therefore, we investigate another scenario with lower supply temperatures (LT) in the district heating network of 80 to 100 °C (WH_{LT}). The technical feasibility of district heating operation and the sufficient heat supply to the connected consumers at these lower supply temperatures is already studied in [17].

In addition, we consider a changed energy price situation for gas and electricity consumption. As energy prices have changed significantly at the beginning of 2022, we estimate the changed energy prices for the FZJ supply ($WH_{HT,price}$ and $WH_{LT,price}$) in contrast to former energy prices used in [8]. Table 1 summarises all optimisation scenarios, including their considered option for waste heat utilisation, supply temperatures for HP operation and energy prices.

Table 1: Studied optimisation scenarios of the multi-energy system at the FZJ campus.

Scenario	Waste heat utilisation and AC extension	HP supply temperatures	Energy prices
Ref	No	95-132 °C	$c_{\mathrm{gas,old}}$ & $c_{\mathrm{el,old}}$
WH_{HT}	Yes	95-132 °C	$c_{\mathrm{gas,old}}$ & $c_{\mathrm{el,old}}$
WH_{LT}	Yes	80-100 °C	$c_{\mathrm{gas,old}}$ & $c_{\mathrm{el,old}}$
$WH_{HT,price}$	Yes	95-132 °C	$c_{\mathrm{gas,new}}$ & $c_{\mathrm{el,new}}$
$WH_{LT,price}$	Yes	80-100 °C	$c_{\mathrm{gas,new}}$ & $c_{\mathrm{el,new}}$

The energy prices in the period before 2022 ($c_{\mathrm{gas,old}}$=26.89 EUR/MWh and $c_{\mathrm{el,old}}$=149.54 EUR/MWh) are taken from [10] and used for the first scenarios. As the current energy prices of the FZJ were not made available, we estimate the energy prices increase based on the German gas and electricity prices of 2020 and calculate an average increase compared to December 2022. The average price increase for gas is calculated

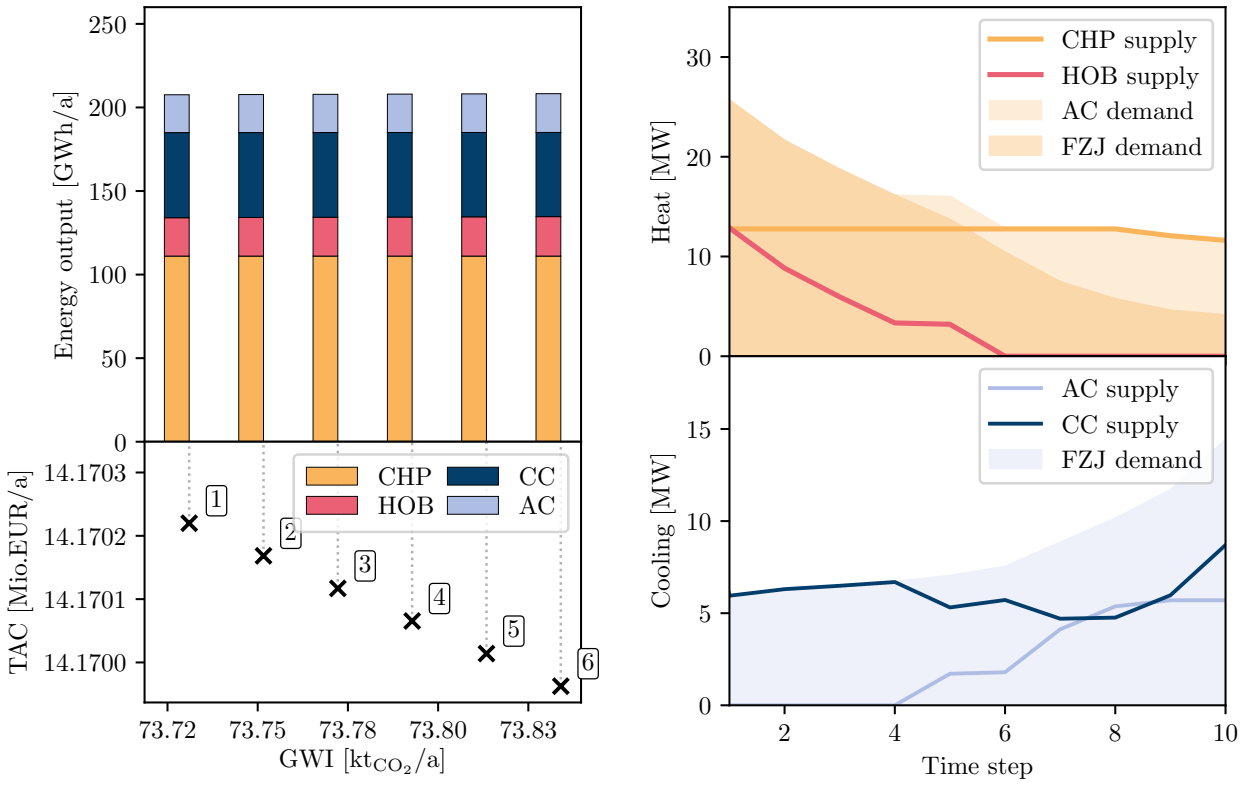
to 280 % [18] and to 126 % for electricity [19]. Thus, the increased energy prices for consumption from the energy grids are assumed to be $c_{gas,new}$=75.51 EUR/MWh and $c_{el,new}$=188.37 EUR/MWh, resulting in a lower price ratio between gas and electricity. Furthermore, the CO_2 emission factors are determined to $CO_{2,gas}$=201.24 kg/MWh for gas consumption and to $CO_{2,el}$=408 kg/MWh for electricity consumption [20, 21]. The energy demand data of the FZJ campus are taken from [10] since the consumption data from recent years are not representative due to the Corona-related basic operation with reduced on-site operation at the campus. Since the model is optimised for typical operating points that occur during one year of operation (see Section 2.2.), the demand data for heating, cooling and electricity are clustered. The demand data is clustered using the k-means algorithm [9]. The number of clusters is determined by the elbow-method, which evaluates the sum of squared errors within a cluster. Through this analysis, the number of clusters is set to ten. An additional cluster with a weight of zero represents the summed up nominal demand of the campus to account for the required design capacity [9]. The ambient temperature data, required for the district heating curve to calculate the HP condenser temperature, is matched to the identified clusters.

3. Results

We first present the optimisation results for the reference design of the multi-energy system. Then we show the results of waste heat utilisation with optional AC extension for both considered district heating supply temperatures. Finally, we show the influence of changed energy prices on the results of waste heat utilisation.

3.1. CCHP optimisation without waste heat utilisation

Figure 2a shows the multi-objective results of operational optimisation of the CCHP. The optimisation results are presented for both objectives resulting in multiple pareto-optimal solutions labelled as solution 1-6, with the resulting TAC on the vertical axis and the corresponding GWI on the horizontal axis. Solution 1 represents the minimal GWI, and solution 6 shows the minimal TAC. The energy output of the different energy components is presented in a stacked bar chart above each pareto solution.



(a) Pareto solutions (Ref)

(b) Operation over clustered time steps (solution 1)

Figure 2: Operational optimisation of the CCHP without waste heat utilisation (Ref); Pareto solutions (6) for GWI, TAC and the corresponding energy output of the components (2a); Campus demand and supply of energy components for heat and cooling over clustered time steps of pareto solution 1 (2b).

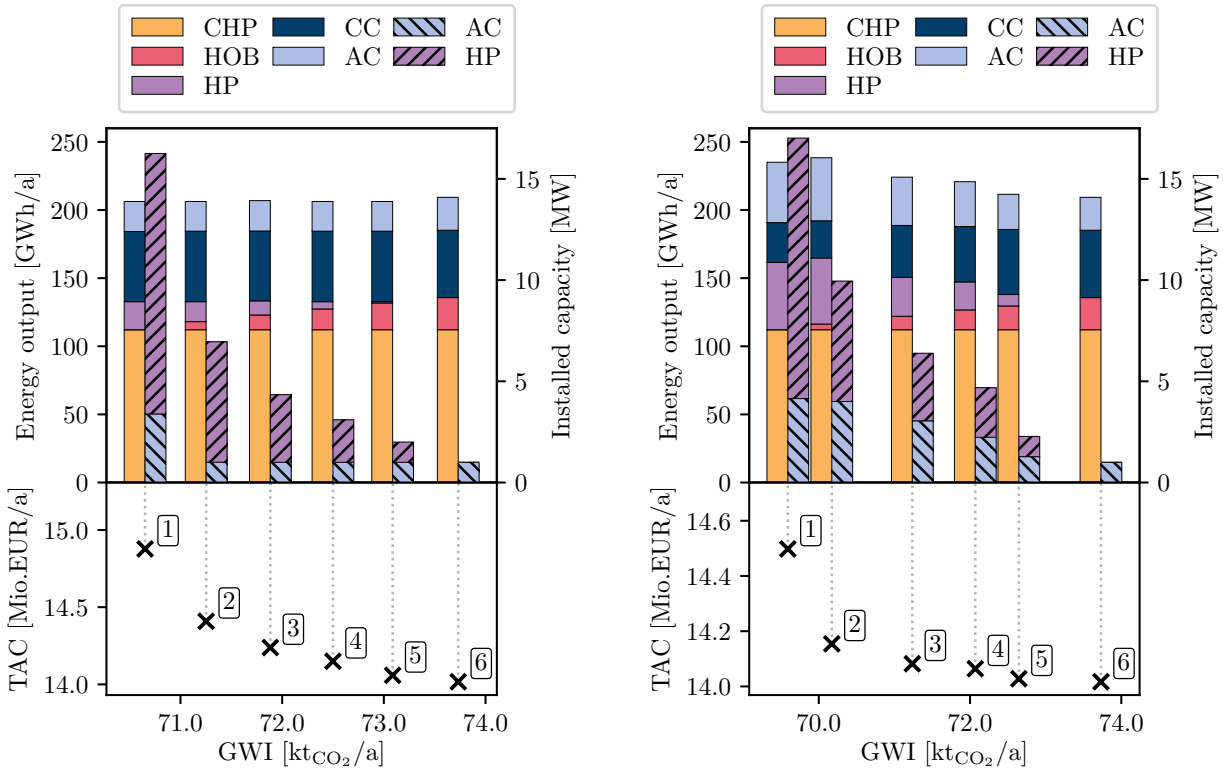
The bi-objective optimisation shows only minor deviations between the solutions (see Fig. 2a) and therefore

confirms that the current energy system is well designed to achieve the best economical and ecological result. Since the six solutions differ only minimally, the CCHP operational optimisation result is exemplary explained for solution 1.

In Fig. 2b, the energy demand of the campus and the energy supply of the different energy components over the clustered time steps are shown for solution 1. The clustered time steps are sorted from left to right by decreasing heat demand. The corresponding cooling demand is shown below the heat demand. The CHP units operate at full power to produce heat and electricity for the campus, while the HOB units cover the peak heat demands. Only in time steps 9 and 10 the CHP units operate in part load somewhat, as the heat demand of the FZJ and the AC demand are below the nominal heat output of all CHP units. The CC component covers the main cooling demand of the campus, especially when the heat demand is high. However, when the heat demand decreases, the heat from the CHP units is used to run the AC, which supplies cooling and replaces part of the CC supply (time step 7 and 8). In case the heat demand decreases and the cooling demand increases, the AC supply is extended as more CHP produced heat is available. At time step 8, the maximal cooling capacity of the AC is reached, so the CC cooling supply increases.

3.2. Waste heat utilisation and AC extension

The optimisation results for the additional waste heat utilisation, i.e. the optional HP installation and AC extension, are shown in Fig. 3a for the high supply temperature requirements at the HP system (WH_{HT}) and in Fig. 3b for the lowered supply temperatures (WH_{LT}). In addition, the installed system capacities for HP and AC extension are shown as stacked hatched bar charts above the corresponding solution.



(a) High-temperature requirements (WH_{HT})

(b) Low-temperature requirements (WH_{LT})

Figure 3: Optimisation of the CCHP with optional waste heat utilisation and AC extension.

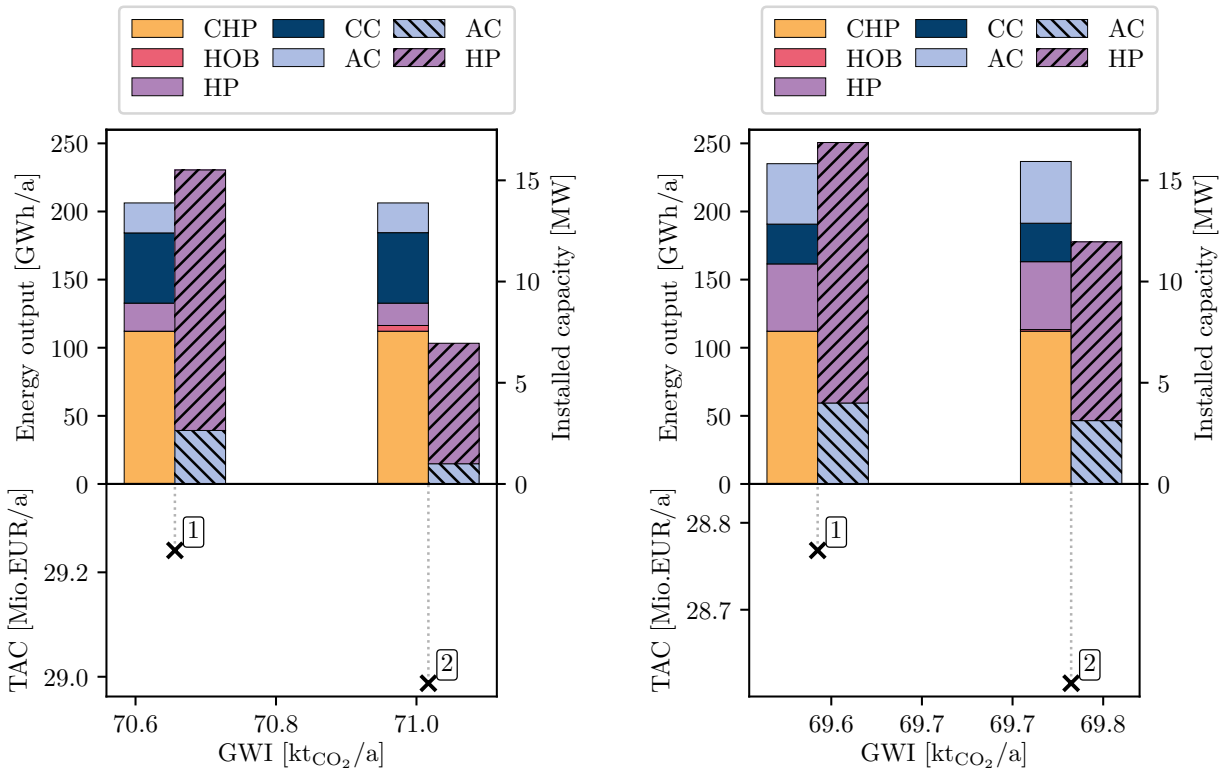
The pareto solutions 1-6 differ significantly for the high supply temperature scenario WH_{HT} in Fig. 3a. For the lowest TAC, no waste heat is used. However, compared to the Ref results (see Fig. 2a), an additional AC capacity of 1 MW is installed to allow higher AC cooling production. When the GWI is lowered (solutions 5 to 2), the HOB heat supply is reduced while the waste heat usage, represented by the HP, increases. The HP supply increases for lower GWI, leading to an increased HP capacity installation and, thus, to higher TACs. The minimal GWI is reached at the maximal TAC (solution 1), leading to the largest installed HP capacity and increased AC capacity extension. However, the HP heat supply in solution 1 is not much higher than in solution 2. From solution 2 to 1, the HP even replaces peak supply of the HOB, but therefore additional HP capacity is

needed to cover the highest peak demands. The waste heat utilisation at high temperatures enables a GWI reduction of up to 4.2 % while the TAC increases by 4.7 % compared to the Ref scenario. However, although the waste heat utilisation is expanded to reduce GWI, waste heat does not replace the CHP heat supply. This is due to the high CO_2 factor of the power grid, which is why the HP heat supply still leads to relatively high GWI compared to the more ecological combined electricity and heat supply of the CHP units.

For lower supply temperatures in the district heating network (WH_{LT}) and thus more efficient HP operation, the HOB heat supply is replaced by the HP supply much earlier (see Fig. 3b). Compared to the WH_{HT} scenario, the HP heat supply is much higher for lower temperature requirements and therefore results in lower GWI values in WH_{LT}. In addition, the AC cooling supply rises for lower GWI while the CC cooling supply decreases. The CHP units continue to operate at full load as they produce priceless electricity for the campus. The high-temperature heat is not used to cover the heat demand as the HP supports the supply and is therefore used to supply the AC. Lowering the supply temperatures of the district heating network therefore leads to a more efficient use of waste heat and, thus, to an extended HP supply, while the high-temperature heat generated by the CHP units is used to operate the extended AC capacity. Compared to the current energy system design (Ref), the waste heat utilisation at low supply temperatures (WH_{LT}) lead to a GWI reduction of 5.6 % while the TAC increases by 2.3 %.

3.3. Changed energy prices

For the results of the changed energy price situation ($WH_{HT,price}$ and $WH_{LT,price}$), we show only two solutions (minimal TAC and minimal GWI) for each investigated supply temperature since the solutions only differ slightly and the effects for reaching lower GWI are the same as described before. The optimisation results of the changed energy prices are presented in Fig. 4a for the high supply temperatures and in Fig. 4b for the lowered supply temperatures.



(a) High-temperature requirements $WT_{HT,price}$

(b) Low-temperature requirements $WT_{LT,price}$

Figure 4: Optimisation of the CCHP with optional waste heat utilisation and AC extension and increased energy prices.

In scenario $WT_{HT,price}$, waste heat is already used in the case of minimising TAC (solution 2), despite the necessary investment for HP installation, which indicates an uneconomic operation of gas-fired plants. However, the peak heat demand is still supplied by the HOB to avoid the installation of large HP capacities. Whereas for minimal GWI (solution 1), the peak heat demand is also partly covered by the HP, accepting the high investment

for the large HP capacity.

Lowering the supply temperatures in scenario $WT_{LT,price}$ also positively affects waste heat utilisation for increased energy prices (see Fig. 4b). For the minimal TAC (solution 2), a larger HP capacity is installed than in $WT_{HT,price}$ as the waste heat can be used more efficiently and, thus, already replaces the HOB heat supply to minimise the costs. To minimise GWI, the HP capacity installation is expanded to replace even the HOB peak supply (solution 1).

However, as the CHP units continue to operate at full load also for increased energy prices, the CHP heat is used to supply the extended AC. The AC capacity extension is more distinctive for lower supply temperatures, as waste heat utilisation is more efficient and, thus, more CHP heat is shifted to cooling production.

4. Discussion

The presented optimisation model confirms that the current CCHP is designed to operate at optimal ecological and economical performance, as the minimal TAC and GWI solutions are close to each other. The additional waste heat utilisation in the multi-energy system enables an increased ecological operation, as the waste heat replaces the HOB heat supply. However, the required investment for HP installation reduces the economic profit, as no waste heat is utilised for minimal TAC. Lowering the temperature in the district heating network has a positive effect on the efficiency of the HP, so that additional GWI and TAC savings can be achieved. Given the changed energy price situation, the waste heat is already being used for minimal TAC. As the gas price increases relatively more than the electricity price, the HP installation is more profitable for the HOB replacement in this price situation. Thus, the results show that a lower price ratio between gas and electricity strengthens the use of waste heat in the current energy system concept. To reduce the GWI, an extended HP heat supply becomes more attractive than a gas-fired heat supply. However, as the CHP units continue to operate at a high workload for producing electricity, additional AC capacity is installed to utilise the high-temperature heat of the CHP units. Thus, the option of AC extension enables continuous economic operation of the CHP units, as favourable electricity is produced, and the produced heat is used for cooling production and, thus, partially replaces the current CC supply.

The high CO_2 factor of the power grid leads to high emissions for waste heat utilisation, as the additional electricity for HP operation is supplied by the grid. In addition, the CHP produced electricity has a lower GWI than the electricity supplied by the power grid due to the assumed CO_2 factor. Thus, the waste heat does not replace the CHP heat supply, as the relative emissions of CHP produced heat and electricity, coupled with the cooling production via the AC, are lower than the emissions from the alternative supply by the HP and power grid. However, a changed electricity supply situation for the campus, e.g. through renewable electricity supply or a decreased CO_2 factor of the power grid, would reduce the emissions associated with waste heat utilisation and make the electricity supplied by the power grid more ecological than the electricity from the CHP plant. A more CO_2 neutral electricity supply by the grid could therefore increase the waste heat utilisation, as CHP operation would be replaced from an ecological point of view.

In the optimisation model, the CC component represents the total CC cooling supply from several individual CC units. The CC cooling supply model could be improved by collecting more detailed information about the installed CC units and parameterising several individual CC models to represent the different installed units. In this way, also the partially rather inefficient operation of the CC units on the campus could be improved. However, an adapted control strategy of the individual CC units, recommended by the optimisation, must be evaluated for a feasible district cooling operation, as the CC units are located decentrally on the campus.

5. Conclusion

In this study, we develop a model of a multi-energy system to optimise waste heat utilisation. Therefore, we model the existing components for heat, cooling and electricity supply and add an optional HP system to enable the usage of an available heat source. Additionally, we add the option to extend the AC cooling capacity to continue the CHP heat usage and, thus, maintain an economical CHP operation.

The optimisation model shows promising results for waste heat utilisation in the multi-energy system. To reduce the TAC, the CHP units operate at full load, and the HOB units cover the peak loads as these plants are already installed at the campus, and no investment is required. However, for minimal GWI, the waste heat utilisation by the installed HP system increases to replace the HOB heat supply. Lowering the district heating temperatures leads to a more efficient HP operation and, thus, to an increased waste heat usage to cover the heat demands of the campus. In contrast to the reference operation, the minimal GWI for the multi-energy system could be decreased by 4.2 % for high temperature requirements and by 5.6 % for lower supply temperature requirements at the HP system. The changed energy price situation leads to a smaller ratio between gas and electricity prices and strengthens the case of waste heat usage since, in this case, a HP installation is recommended to minimise costs as it replaces expensive gas-fired HOB heat supply.

With the developed optimisation model, different adaptations to the multi-energy system could be additionally studied to improve waste heat utilisation. For example, a more CO_2 neutral electricity supply to the HP system would favorise an expansion of waste heat usage. Overall, the model is applicable for investigating the general effects and possible measures for waste heat utilisation in an existing multi-energy system.

Nomenclature

c	Specific costs, EUR/MWh
CO_2	Carbon dioxide factor, kg/MWh
COP	Coefficient of Performance, -
GWI	Global warming impact, t_{CO_2}/a
i	Interest rate, %
I	Investment, EUR
n	Project time span, a
P	Electric power, W
$\mathcal{P}$	Factor part load behaviour, -
$\dot{Q}$	Heat flow, W
R	Annual operating costs, EUR/a
T	Temperature, K
TAC	Total Annualized Costs, EUR/a

Abbreviations

AC	Absorption Chiller

Abstract:

The energy crisis, global warming, and rising energy consumption have positioned renewable energy as a priority from national and international planning perspectives. Not only to reach the goals of the renewable energy mix, but also as part of overall energy security strategy. Rising energy prices and supply concerns have made the need for energy changes that are tangible for society and have increased public awareness of renewable energy. In order to achieve its renewable energy targets, Ireland has placed a focus on the development of offshore wind energy project, due to its massive potential. Other regions have already commenced the deployment of large-scale offshore wind farms and the technology is now competitive with fossil fuels. This work presents a comparison of Geographic Information System (GIS) applications and Multi-Criteria Decision-Making (MCDM) methods applied in the process of multicriteria site selection for Floating Offshore Wind Farms (FOWF). This work presents a reflection on current trends of FOWF site selection, the most suitable and efficient methods, and outlines critical limitations. Finally, the work attempts to map the next steps that shall be taken to improve the methodology.

1. Introduction

The energy crisis, global warming, and rising energy consumption have prioritised renewable energy from national and international planning perspectives. Not only to reach the goals of the renewable energy mix but also as part of the overall energy security strategy. Rising energy prices and supply concerns have made the need for changes tangible for society and have increased public awareness of renewable energy. In order to achieve its renewable energy targets, Ireland has begun to shift its attention to offshore wind developments, for a number of reasons. The government has introduced the new Maritime Area Planning Act [1] that streamlines the planning process. Other regions have already begun to deploy large-scale offshore wind energy projects. In January 2023, the Crown Estate signed Lease Agreements for six offshore wind projects, with a total capacity of 8.0 GW located in the waters around England and Wales [2]. The Scottish Government has even more progressive plans. The Net-Zero target has been set to 2045, five years before the consensus reached under the Paris Agreement [3]. To reach this ambitious target, in 2022 the Crown Estate Scotland conducted the ScotWind Leasing auction of 17 offshore projects with a total capacity of 24.8 GW, ten of those projects involve floating technology with a total capacity of 14.6 GW [4].

The energy crisis has accelerated the legislation and set new objectives dictating the pace of offshore wind development. In May of 2022, The European Commission defined the steps leading to independence from Russian fossil fuels before 2030. The Esbjerg Offshore Wind Declaration [5] signed in May of 2022 by representatives of Denmark, Belgium, Netherlands and Germany set out new targets of at least 65 GW by 2030 and 150 GW by 2050. The European region is not the only one to put offshore wind energy in the spotlight, ambitious objectives have been set out by the USA, China, South Korea, Vietnam, India and Brazil [6].

In 2021, 21.1 GW of offshore wind energy was connected globally to the grid [6] setting a new record. However, according to [7] to achieve Net-Zero before 2050, annual installations should increase to 28 GW by 2030 and then to 45 GW by 2050. The unprecedented shift towards offshore wind technology as one of the main renewable energy sources in the energy mix, and the new technology that must be implemented on a commercial scale to reach the targets, will bring new challenges that must be addressed. The vast majority of wind resources, estimated at about 80%, are located in waters deeper than 60 m [9]. From a technological development perspective, the fixed-bottom offshore wind turbine deployment is constrained to a water depth of approximately 60 m [7,8]. Hence to unlock the offshore wind potential and reach the ambitious objectives, the deployment of floating wind turbines on a commercial scale is inevitable.

The rapid growth of installed offshore wind turbines may, however, come at a price. Pressure to act quickly could potentially compromise stakeholders' interests and harm the natural environment, leading to conflicts and negative perceptions of offshore wind by society. In order to mitigate these potential issues, an efficient methodology and toolset to extract the most suitable locations for development projects is crucial. Site selection for the deployment of floating offshore wind farms off the Irish coast requires careful analysis. Careful site selection requires adequate technics that allow data integration with geographical location, analysis of data, and results visualisation. The Geographic Information System (GIS) addresses all of these requirements. Furthermore, it is widely used in spatial environmental studies since it supports the decision-making process by linking it with multicriteria evaluation methods [11]. Environmental and maritime spatial studies are complex and many interests must be considered. Therefore, sufficient criteria prioritisation and alternative comparison methods are highly desirable to implement alongside GIS.

A good example of how critical the preliminary site selection might be is the 400 MW offshore wind farm Anholt, located off the Danish coast on the Baltic Sea. This location was prioritised by authorities in the planning procedure. However, the risk of construction of the wind farm assessed by three potential bidders was so high, that two bidders gave up the race. As a result, only one offer was submitted with the price per kWh twice as high as for other offshore projects at the time [14]. Floating offshore technology is at a relatively early stage of commercialisation, the first commercial-scale floating wind farm, Hywind Scotland has been in operation since 2017; The farm consists of five floating wind turbines with a total capacity of 30 MW [13]. Another project of 3 wind turbines and total capacity of 25 MW called Windfloat Atlantic has operated since 2020 [12]. The largest operating floating wind farm is the Kincardine Offshore Windfarm located off the east coast of Scotland, consisting of five Vestas V164-9.5MW wind turbines and one Vestas V80-2.0MW wind turbine with a total capacity of nearly 50 MW [12].

2. Geographic Information System

2.1. Methods of spatial analysis

The Geographic Information System (GIS) is a data management and processing tool in the spatial domain. Hence, most researchers use GIS as the primary tool because it allows for the convenient organising of data in a spatial grid and its complex processing capability. It is also a flexible tool allowing advanced users to programme new features. Today, because of the large amount of available data, GIS plays an important role in many aspects of the modern economy. In principle, the vector or raster system of data analysis may be used in GIS. The chosen approach depends on the objectives, the results will differ depending on the chosen method [11]. The first common method of vector-based analysis is the conversion of the criteria to true or false values and then using Boolean operators. This approach leads to the results of a crisp spatial mapping of areas that are either included or excluded from a designated set [11]. This method is suitable to process hard constraints as an exclusion area. The second method is based on raster-based analysis where quantitative criteria are processed as continuous variables rather than simplified to a Boolean's true or false approach [11]. Very often two methods are applicable in one study. Examples of vector and raster methods application can be found in [11,17]. The constraints may have a form of exclusion areas like military zones or designated wildlife areas where offshore wind farm development is prohibited. Criteria can also be a continuous factor where development is not prohibited but less or more favourable because of other factors like wind speed, water depth, distance to the port and many others [11,14].

The key to effectively achieving the objectives is a proper definition of criteria that form the attractors and set the boundaries of the study. Criterion is the basis of decision-making; it represents the objectives and methodology and also serves as evidence of the reasoning behind the decision [22]. Hence, diligent criteria selection is a crucial part of the spatial assessment. Furthermore, the selection should also concern the appropriateness and quality of data they are based on.

2.2. State-of-the-art GIS applications

Due to open access to many valuable data sets and GIS tools, the usage of geographical information system in marine spatial planning has gained momentum. The importance of spatial planning is also acknowledged by authorities. In 2014 the European Commission adopted the directive establishing a framework for maritime spatial planning [15]. The main objectives of the directive are to support the sustainable development of the marine sector by consideration of economic, social and environmental aspects and applying the ecosystem-

based approach to ensure the coexistence of various activities and uses. Moreover, the marine spatial plans shall contribute to the sustainable development of the energy sector on the sea, transportation and fisheries with respect to the preservation and protection of the environment.

For the region of the Celtic Sea off the southwest coast of England and Wales, [16,17] have conducted an extensive GIS spatial analysis to identify project development areas to be offered on tender for Floating Offshore Wind Farm (FOWF) deployment. The central axis of the study was the engagement of the stakeholders at an early stage of the study to participate in the process. The study has a discrete structure that could be divided into five steps. In the first step, the authors defined the area of study and defined main assumptions that were implemented in GIS and visualised. In the second step, the hard constraints were defined. The hard constraints consist of nineteen criteria where only nine of them effectively influence the analysed area, and ten of them don't contribute to the model. Despite not ultimately contributing to the model it is important to acknowledge that they were considered in the study. Step three is the restriction model, based on soft constraints. It includes twenty-six criteria with only two of them not affecting the analysed area. Soft and hard constraints have been listed in Table 1 and Table 2.

Table 1 Hard constraints, exclusion zones

Study	[16, 17]		[18, 19]		[20]		[21]	
Criterion	Applied	Exclusion	Applied	Exclusion	Applied	Exclusion	Applied	Exclusion

Step four is based on the application and processing data applied to models in previous steps. As a result of running the exclusion and restriction models in the GIS, the map presenting more or less favourable to FOWFs deployment locations was created. The soft constraints criteria were organised into groups and subgroups and then pairwise compared. The analytic hierarchy process (AHP) was used to assess their relative importance and to calculate the weights of soft constraints. Finally, the weights were applied to the soft constraints model. The combined output has been normalised from 0 to 100 to reflect the percentage of constraints. Then the considered area has been divided into equal cells of the seabed. The constraints have been organised into ten groups ranging from the least constraints of 10% to the most constraint 90% and 100%. Cells constrained in 50% or less were chosen for further proceedings. Then neighbouring cells were organised forming five large areas representing 11,000 km^2, of potential FOWF sites, which will be a subject of a detailed study in step five which has not been completed yet. The selection of the project development areas (PDAs) is based on the assessment of technical risks, cost of energy and environmental and social impact. This step will identify smaller areas of the PDAs that will be offered on public auctions for particular FOWF projects. Therefore, a detailed study of technical risks and the cost of energy is required. To fully understand the technical challenges and cost of the energy the authors are aiming to:

- study wake effect to shape project parameters and forecast energy yield;
- recognise the relationship between the energy density, turbine layout and mechanical fatigue loading;
- analyse mooring and anchoring systems and their limitation in terms of geotechnical and met-ocean site characteristics;
- recognise energy export options and related costs as well as onshore grid reinforcement.

Finally, based on the information above fine tune Levelised Cost of Energy (LCOE) layer will be used in the final PDAs ranking.

For the region of the European Atlantic coast of Portugal, Spain and France the [18] has proposed an integrated GIS approach of multicriteria site selection for floating offshore wind farms. Researchers conducted the literature review in the field of offshore wind farms site selection based on GIS and Multi-Criteria Decision-Making (MCDM) methods and proposed their proprietary approach of an integrated GIS tool built using the Phyton language. The site selection is performed in three stages. In the first stage data from various regulatory bodies, like national marine spatial plans and issued concessions are collected and processed to feed the GIS model. The second stage is narrowing the area of search by the addition of hard constraints as a result of step one. The hard constraints or in other words exclusion zones can be divided in this study into two main categories. The first is the regulatory, infrastructural and maritime usage while the second is related to social-economic aspects reflected in wind speed, water depth and distance from shore. The locations with an average wind speed below 4 m/s at 10 m height are considered as not suitable therefore form the exclusion zone. As a suitable area to deploy FOWF the water depth range between 50 m to 1000 m has been considered as well as a minimum distance from shore in case of the regions where such regulations are in place. The third step of the study aims to assess the feasible locations defined in the previous step. Each site may have a different characteristic that shall be recognised and represented by the quantitative, objective measure to allow for choice of the best alternative from a technical and socio-economic perspective. To rank sites, a set of evaluation criteria or in other words soft constraints have been proposed by the researchers. With the help of industry experts and as per a review of existing studies, the twenty-three evaluation criteria grouped into six categories have been chosen and applied to the model. Soft and hard constraints have been listed in Table 1 and Table 2. As a result of the study, the forty-two locations suitable for floating offshore farms have been identified and evaluated. The area of potential FOWF development covers 7230 km^2. To ease site comparison, each site has been characterised by the fixed set of evaluation criteria like: average wind speed, wind potential, water depth and others. The researchers have also estimated the number of wind turbines and annual energy yield together with CO_2 and SO_2 reduction as well as direct and indirect job creation. The advantage of the procedure is its flexibility in terms of applied criteria and transparency however since there are just a few examples of operating small-scale floating wind farms, there is no reliable operational data that include the power curve changes and availability factors. Therefore, performance estimates have a large component of uncertainty and shall be treated just as an indication factor. In [18], no MCDM methods have been implemented.

In the follow-up article [19] written by the same authors, the site selection of forty-two potential floating wind sites has been supplemented with the MCDM method to ease and streamline the multi-criteria decision-making process. In that research, scholars utilised the twenty-three evaluation criteria formed in the previous study. The relative importance of each criterion has been estimated in a pairwise comparison process with the AHP methodology. The criteria's weights were assigned based on the opinion of five industry experts representing different fields of the offshore wind industry. The pairwise comparison method was used not only to weight criteria but also to evaluate alternatives which are in this case forty-two locations grouped by region. All feasible locations were compared concerning each criterion therefore with known criterion weight derived in the previous step the most suitable location in each group could be identified.

Castro-Santos et al. [20] have proposed the application of GIS for selecting the site for the floating offshore farm in the North-West of Spain. The GIS method is similar to the above studies and comprises two steps. The first is defining the exclusion zones, and the second step defines the soft constraints. As a hard constraint where development is not permitted or desirable the following restrictions are considered: fishing banks and grounds, navigation areas, Spanish marine development plans, environmental protection areas, underwater rocks and seismic fault lines. Noteworthy is the application of bathymetry as a hard constraint that can be adjusted to the given platform technology addressing different draft requirements. The area of the search will vary depending on the considered technology.

The soft constraints are based on local ports and shipyards' characteristics. The draft, storage area and lifting capability have been considered. In the case study described in [20], the ports and shipyards draft has been set between 3.0 m to 12.5 m which is suitable for installation vessels and tugboats but not for semisubmersible platforms where the draft oscillates around 20 m [10]. Low draft of the shipyards and ports that may not be suitable for towing to site some platform types or preassembled turbines on platforms. A higher draft and study of overhead clearance would contribute to the output of [20].

The final areas of interest are shaped based on hard and soft constraints as per desirable water depth or port and shipyard characteristics. As an output not only feasible areas of development are plotted but also the distance to the suitable port or shipyard and the economic indexes of internal rate of return, levelised cost of energy and others. The economic indexes are presented in the form of a heat map covering only areas that are resultant of the application of exclusion zones and soft constraints. The input parameters that are used to calculate the economic indexes have not been presented in [20]. No MCDM method has been applied in the study, however, the estimation of economic factors and depicture results on maps support decision-making based on economic criteria.

Nonetheless, due to the immaturity of floating wind farm technology, and other factors that have a significant impact on costs and energy yield, it is expected that large uncertainty is assigned to these factors. Therefore, they shall be considered as indications rather than precise values. Nonetheless, it is important to incorporate this information in the study as ultimately, it is one of the key decision drivers. Graphical presentation of economic indexes is a clear advantage of the study [20] and may be used as an input to GIS overlay analysis. However, the lack of clarity on how the indexes were obtained adds extra uncertainty to the results.

For the western part of the Irish coast, [21] has outlined a multiple attribute decision-analysis methodology for selecting the most suitable location to deploy the floating offshore wind farm. In order to limit the search area, researchers conducted a literature review, identified sites that are either developed or in planning procedure, investigated the grid connection possibilities and held meetings and consultations with experts in the renewable and legislation field. This procedure led to the selection of the area of interest of Shannon Foynes Bay off the coast of Galway. Instead of dedicated GIS software typically used in spatial analysis, researchers utilised Microsoft Excel. The Excel cells play the same role as the raster cells in GIS assessments. It allows the assignment of multiple attributes reflecting criteria to each cell and the application of Excel formulas. Usage of Excel where more suitable tools are available may not be the best choice. However, in cases where no high-resolution data are available or the research doesn't require a large spatial precision Excel may serve well. In [21] usage of proper GIS tools would contribute in a positive way to the conducted research. Here also criteria are divided into two main groups of hard and soft constraints. The nine hard constraints and thirteen soft constraints organised into three main groups have been identified. It is unclear if all of the listed constraints have contributed to the final output. After the limitation of the search area by the application of hard constraints the researchers with the help of five experts in the offshore wind industry prioritised soft criteria in the pairwise comparison procedure as a part of the AHP method. Then the MCDM method of Evidence Reasoning (ER) was applied. Soft and hard constraints have been listed in Table 1 and Table 2.

3. Multi-Criteria Decision Making

The Multi-Criteria Decision Making (MCDM) methods are used to support the decision-making aiming to achieve the objective by choosing the best alternative among all alternatives under multiple evaluation criteria. The increase in the number of MCDM methods took place in the 1970s, while the origins of modern MCDM date back to the 1950s [23]. Over one hundred MCDM methods have been developed, moreover, recently hybrid and modular methods are frequently used to eliminate the basic methods' drawbacks. An example is an application of fuzzy set theory to the Analytic Hierarchy Process (AHP), implemented in [29,30]. The MCDM methods are widely used in the financial sector, medical diagnostic, engineering, spatial planning, management and other fields where multiple criteria must be handled in the decision process. The choice of the method depends on the scenario that is analysed. Some of the methods are suitable for certain problem-solving, but there is no single universal method to address all scenarios [24].

3.1. MCDM methods used in site selection

A floating offshore wind farm site selection requires detailed consideration of multiple criteria in order to achieve the objectives. In FOWF site selection one of the most popular methods is the AHP introduced by Saaty in 1971 [25]. Application of AHP requires deconstructing problems in a hierarchical or network structure followed by the Pairwise Comparison (PC) of elements regarding their importance. To score relative importance, Saaty's fundamental scale has been applied as presented in Table 3. In the typical AHP process of site selection, the criteria would be pairwise compared to reaching the goal and separately the alternatives (feasible sites) concerning criteria.

The relative intensity of importance	Name	Explanation
1	Equal importance	Equal contribution
3	Moderate importance	Experience and judgment strongly favour one over another
5	Essential importance	Experience and judgment strongly favour one over another
7	Very strong importance	One is strongly favoured and its dominance is verified in practice
9	Extreme importance	Strong evidence exists in favour of one over another

2,4,6,8	Intermediate values	The comprise solution
Reciprocal	-	If *i* has one of the importance numbers when compared with *j,* then *j* has a reciprocal value of *i*

Table 3 The Saaty's fundamental scale [25]

The AHP is a relatively easy and transparent method, it introduces a structural and logical division of complex problems and a pairwise comparison of its elements step by step. It also allows for group decision-making and evaluation of quantitative and qualitative criteria as well as an application of subjective and objective measures.

Among the weaknesses of the method is a rapid increase in pairwise comparisons with criteria and alternatives to be considered [25]. The number of pairwise comparisons needed for a particular matrix of order *n,* is *n(n-1)/2* because it is reciprocal as well as its diagonal elements are comparisons of the same elements and therefore equal to one [25]. Let the A_1 , A_2 ,…, A_n , be the set of criteria. The comparison of criteria is represented by n-by-n matrix $A = (a_{ij})$, $ij = 1,2, \dots, n$. The quantified pairwise comparison on pairs of (A_i, A_j) is represented by numerical entries a_{ij} in matrix A [28]. The entries a_{ij} to (1) follow two general rules:

if $a_{ij} = a$, then $a_{ji} = 1/a$, $a \neq 0$;

and,

if relative importance intensity $A_i = A_j$, then $a_{ij} = 1$, $a_{ji} = 1$, as well as $a_{ii} = 1$.

The comparison matrix *A* has the form:

$$A = \begin{bmatrix} 1 & \cdots & a_{1n} \\ \vdots & \ddots & \vdots \\ \frac{1}{a_{1n}} & \cdots & 1 \end{bmatrix} \quad (1)\ [28]$$

Besides human error, bias, or subjectivity, the final result will also be influenced by the presentation of Saaty's scale, the number of degrees used (eg. five instead of nine) and their form of verbal degrees or numerical as well as the graphical presentation of scale. Also, the method of obtaining the judgments is important, whether as an administrated interview or without the influence of the researcher [26]. The main advantages and disadvantages of the AHP method are listed below.

Among the main advantages of the AHP method are:

- Relative simplicity and transparency [25];
- Useful for organising the complex problem into a structured hierarchy [25];
- Offer the possibility of application of quantitative and qualitative criteria as well as an objective and subjective evaluation of each on one scale [19];
- Support of group judgments [25];
- Consistency check allows for verification of errors in the pairwise comparison process [25,28].

However, the AHP method does have some disadvantages:

- It is based on experts' opinions therefore it may be subjective [27];
- Each group of elements that are pairwise compared should not exceed seven, therefore in the case of many criteria division in many subgroups is required [28];
- The number of pairwise comparisons increases rapidly with the number of criteria [25];
- Presentation of Saaty's fundamental scale and form of gathering expert's opinions may influence results [26];

The AHP procedure supported by GIS was used by The Crown Estate [17]. The pairwise comparison of criteria concerning their risk of achieving the objective was introduced. The criteria selection and weighting are a result of consultations with stakeholders and industry experts. Twenty-six soft constraints were identified and organised in the logic hierarchy. The soft constraints were relatively compared with respect to the risk posed to achieve a goal. Therefore, the higher the weight of the criterion then the higher the risk is. The result of this process is weights were normalised from 0 to 100 and divided into ten groups. Finally, they were fed to the GIS model as the attributes of raster cells, where weights were summed-up as an overlay of multiple data layers of each soft constraint. The higher the score the more constraint the raster cell is. The cells with a score of 50% or less were chosen for further proceedings followed by grouping neighbouring cells to form larger areas. In that manner, the areas with the lowest development risk were identified, so further assessment with the concern of the performance and costs of the FOWF can be conducted.

For the Atlantic coastal region of Spain, France and Portugal, Diaz and Guedos Soares [19], conducted an extensive multicriteria floating site evaluation. Their work comprises not only criteria weighting but also an

evaluation of forty-two sites that have been outlined as a result of the GIS procedure conducted in the preceding study [18]. The pairwise comparisons of constraints were conducted by five experts experienced and competent in broad offshore energy areas. Nonetheless, the evaluation of the importance of certain criteria varied between experts, which indicates the bias made by their area of expertise. The way of objectifying experts' input or at least the measurement of ambiguity and ignorance would contribute in a positive way to the study and assessment of the results. The authors also identified this downside and therefore explored other MCDM methods in the further studies [29].

To reflect the central tendency of the results of pairwise comparisons conducted by the experts, their judgments were averaged throughout the geometric mean. Unlike in [17] the criteria weights calculated in [19] are reflecting risks by minimising weight with the proximity to certain elements (eg. maritime routes) and the opportunities by maximising weight where higher wind speed occurs. The higher the combined weight the better the location is from an economic and risk perspective.

The AHP method assumes that the decision maker in the pairwise comparison process can select a clear winner which may not be the case in many situations. In these cases, the probabilistic approach would provide additional information [30]. Therefore, the AHP is not recommended for scenarios with high uncertainty of judgments. Also, if the final rank of alternatives is convergent, there are no statistical measures to differentiate alternatives and support decision-making [31].

To address issues inherently related to the application of AHP, the study [19] has been extended by Diaz et al. [29] with the addition of the Monte Carlo simulations and Fuzzy Set theory to determine the relative preference of wind farm locations. The fuzzy set theory applied to AHP forming the FAHP allows for ambiguity in decisions, where there are no clear boundaries therefore the decisions are closer to natural human decisions [29,30]. The application of the fuzzy set is executed by replacing the standard Saaty's scale with Triangular Fuzzy Numbers (TFNs).

The AHP and FAHP do not provide a measure for the imprecision and disagreement between decision-makers. The Monte Carlo Analytic Hierarchy Process (MAHP) provides information about the influence on results of judgment variability of decision-makers. The application of Monte Carlo simulation is recommended when there is a large uncertainty associated with the ranking of alternatives. However, the exact level of uncertainty over which the Monte Carlo Analytic Hierarchy Process (MAHP) outperforms the AHP is not clearly defined [31,32]. In [29] nine different locations were ranked based on twenty-three criteria resulting in twenty-three separate sets of pairwise comparisons for each location. Finally, the ranking of each location was performed with three methods: AHP. FAHP and MAHP. The same results were derived for locations ranked at first, second and third place. Seven out of nine locations were ranked the same by AHP and MAHP, the only differences being locations ranked as seven (Bilbao) and eight (Mutriku). Five out of nine locations were ranked the same by AHP and FAHP, where the highest difference in ranking is by two places, the location ranked by AHP is in seventh position while using the FHAP method is in ninth position. In All three methods, changes by one to two locations in the ranking occurred between Bilbao, Mutriku and San Vicente sites. The probability distribution derived from MAHP shows that the probability of ranking those three locations at the place of seventh, eighth and ninth is very close oscillating around 30%. That explains slight differences in final results between the three methods. Convergent results especially between the AHP and MAHP and slight variance between AHP and FAHP indicates that in the given example, the AHP method itself performs equally or if not better considering its simplicity than FAHP and MAHP. The clear advantage of study is application of MAHP resulting with an additional data to be used in interpretation of the results. The Table 4 lists the results of the [29].

Table 4. Comparison of AHP, FAHP and MAHP results from [29].

No.	Site name	Ranking			Probability of occurrence at a given ranking place					
		AHP	FAHP	MAHP	Ranking No.	Probability	Ranking No.	Probability	Ranking No.	Probability
1	Ribadeo	1	1	1	1	87%	2	6%	3	4%
2	Navia	2	2	2	2	40%	3	36%	4	10%
3	A Guarda1	3	3	3	3	35%	4	24%	2	21%
4	Huelva	4	5	4	4	24%	2	21%	6	20%
5	A Guarda2	5	4	5	5	33%	4	25%	6	22%
6	Santander	6	6	6	6	43%	5	29%	4	13%
7	Bilbao	7	9	8	9	32%	7	28%	8	28%
8	Mutriku	8	8	7	8	31%	9	30%	7	29%
9	San Vicente	9	7	9	8	32%	9	30%	7	29%

A slightly different approach to multi-criteria site selection of FOWF is presented in [21]. Researchers applied the AHP method to calculate weights of general and basic criteria and then employed the Evidence Reasoning (ER) method to rank the sites. The AHP method combined with ER is also named Multiple Attribute Decision Analysis (MADA). The ER is an evidence-based primary MCDM method developed in the early nineties. It applies to solving problems having quantitative and qualitative criteria [21]. Unlike in the AHP, the ignorance and uncertainty of decision-makers can be assessed. The downside of this method is its complexity, therefore non specialists may not be able to apply it or interpret results [33]. In [21] the MADA method was applied to rank forty-three sites of Shannon Foynes Bay off the coast of Galway. The utility ranking derived in the MADA method vary in the range of 0.6193 for the site ranked at first place to 0.5421 for the site at forty-third place which results in an average step per rank of 0.002. As a result of the study, the most suitable site has been determined along with other sites where five of the most suitable sites are adjacent. The site named F16 is the most favourable site among all forty-three sites explored. Furthermore, this site was ranked high in all three general criteria. However, site G14 ranked third position was ranked twelve and nineteenth in terms of the general criteria of met-ocean and facilities and environment but first in general criteria of logistics. The general criteria weighting has been distributed in [21] as follows: met-ocean 51.50%, facilities and environment 30.94% and logistic 17.56%. It is seen that combination weighting has a profound effect on the final assessment of site suitability [21]. The very small average step per place in rank and therefore high sensitivity to criteria alteration and resulting high uncertainty indicate that MADA method may not suit well in ranking adjacent sites of similar characteristics. To support the result interpretation, the ignorance and uncertainty of decision-makers shall be assessed in [21].

In [34] the researchers compared AHP and MADA methods. The comparison has been performed based on the case study of twenty-two feasible sites off the coast of Scotland and three sites off the Madeira Islands. The locations used in the case study were derived from other studies performed by Loughney et al. [35] and Diaz and Guedes Soares [18,19]. The final results of ranking sites off Scotland's shore show no substantial differences in location suitability assessment. Results up to eight in rank vary by one place. Results of ranking sites off the Madeira Islands are the same for the first place in ranking however the second and third places are reversed between AHP and MADA.

The weights range for the ranking of the Scottish sites is very narrow for the AHP method ranging between 0.9984 for the site ranked at first place to 0.9866 for the site ranked at the twenty-second place. It means that the average step of weight per place in the ranking is 0.0006. The range of weights derived in the MADA method vary in range of 0.7565 for the site ranked at first place to 0.6325 for the site at twenty-second place which results in an average step per rank of 0.006. The range of weights in the ranking of the Madeira Islands is wider than for Scottish sites the weights range from 0.697 to 0.567 in the AHP method and from 0.392 to 0.300 in the MADA method. Respectively the average step of weight per place of rank is then 0.065 and 0.046. The relatively narrow weight range in the case study of Scottish [35] sites are compared to Irish sites as in [21] which were also grouped in a relatively small area is probably the result of lower differentiation of sites' characteristics. The very small average step per place in rank, high sensitivity and resultant high uncertainty indicate that AHP and MADA methods may not suit well in ranking adjacent sites of similar characteristics.

The comparison shows that both methods are suitable to support multi-criteria decision-making and allow for the engagement of the industry experts and stakeholders considering all interests because both methods support group-decision making. The inherent subjectivity of preferences between criteria is one of the disadvantages of the AHP method. Limited involvement of experts in the final steps of the MADA method, which requires a detail study of criteria by the methodology developer, may reduce the influence of the subjectivity of the experts [34]. One of the advantages of the MADA method is its ability to measure ignorance, however this factor has not been estimated in reviewed studies. [21,34].

The AHP method requires less computations, is easier to implement, and more intuitive, therefore in this regard, it outperforms the MADA method. Because of this the AHP may be the preferred method to be applied where stakeholders and non-specialists are engaged in the process of site selection. Results indicate that the value of the weight across all sites is very similar, therefore there is no clear winner. In this case, the uncertainty of the results is high. This can raise confusion among stakeholders that no clear information for decision-making has been obtained as a result of the study. Ranking sites of similar characteristics using the AHP and MADA methods requires a diligent approach because of large uncertainty of the results.

4. Conclusion and further research

The complexity of this task is reflected in different sets of soft and hard criteria chosen by researchers as listed in Table 1 and Table 2. Some of the discrepancies in the criteria selection result from the methodology and some from the geographical region that is analysed but most of them are caused by lack of standardisation and immaturity of technology therefore lack of clear guidance that would set the framework to floating offshore farm site selection.

The methods of site selection are evolving and researchers use various GIS techniques, different criteria sets, as well as various combinations of MCDM methods. Very often the AHP method has been used to derive the criteria weights and rank sites.

The inherent disadvantage of the AHP method is its subjectivity and lack of possibility to measure ignorance and ambiguity of the expert's input. Some researchers applied a combination of the AHP method with other methods like fuzzy set theory, Monte Carlo simulations and evidence reasoning. A comparison of the results shows that there is no clear winner among those methods. Some of them like ER method add extra layers of complexity that its application is limited to advanced users and therefore would work as a black box for non-specialists. One of the advantages of the ER method is its ability to measure ignorance however this estimation has not been performed in reviewed studies [21,34].

The application of Monte Carlo simulations adds extra information to the site selection process. Despite its complexity, the probability distribution of rank place of various alternatives may be very important information in the decision-making process. However, very similar results between AHP and MAHP in the reviewed study [29] as presented in Table 4 together with the simplicity of AHP compared to MAHP are questioning the application of this method.

The application of MCDM methods to rank sites of very similar characteristics may result in convergent results for the sites, however, the uncertainty of the results is high and the final site ranking may be questionable. Therefore, the GIS and MCDM methods perform well in high-level spatial analysis over a large area on a national or international scale. While assessing adjacent sites on a local level different methods or at least different sets of criteria shall be considered.

Further research on site selection for floating wind farms should be focused on creating the standards reflecting the technical specification of floating platforms supported by operational data. That would decrease the level of experts' judgment subjectivity as well as allow for test robustness of various MCDM methods using the same criteria and possibly a quantitative comparison of them.

Future research shall also be conducted towards the economic aspects concerning the Levelised Cost of Energy (LCOE) from floating offshore wind farms. The success and pace of implementation of this technology are strongly correlated with this factor.

Abstract:

The sugarcane industrial sector is one of the main Brazilian economic activities due to its high efficiency and competitiveness, producing ethanol and sugar for internal and external markets. On the other hand, green hydrogen, produced from renewable energy, has emerged as a promising climate-neutral energy carrier over the last years; thus, several countries have published hydrogen roadmaps and are supporting the development of a hydrogen economy. Currently, hydrogen is produced mainly from natural gas through a reformation process; the refineries and the chemical industry are the main hydrogen consumers on the demand side. This hydrogen, produced from natural gas or methane without capturing the greenhouse gases made in the process, is classified as Grey hydrogen. In this way, in this study, the integration of Green hydrogen production into the conventional ethanol and sugar production process is proposed to use in the hydrotreatment of bio-oil produced via fast pyrolysis of sugarcane straw. Nevertheless, the sustainability and efficiency of the integrated process depend on the route adopted for hydrogen production. Thus, this study aims to perform an energy evaluation of different routes of hydrogen production and their integration into the ethanol and sugar production process from sugarcane. The different alternatives evaluated are: i) electrolysis using the surplus electricity in the process; ii) steam reforming of biogas produced from vinasse; iii) steam reforming of part of the ethanol produced. Furthermore, the impacts on the cogeneration system of the production process will also be evaluated.From the evaluated cases, ethanol reforming presented the lowest water consumption (14.1 L/t cane) and the lowest impact in cogeneration system (-6.3% in surplus electricity). Nevertheless Case III requires the consumption of 27.7% of the total ethanol produced in the mill.

Keywords:

Sugarcane; hydrogen; heat integration; hydrotreatment.

1. Introduction

In recent decades, debates have grown significantly about the use and dependence on fossil fuels as a result of the release of gases that intensify the greenhouse effect and global warming. Because of this, studies and research involving the use of alternative fuels have gained increasing prominence. Among these, hydrogen production has shown positive results and attracted the attention of the international market.

Hydrogen (H_2) has several advantages, such as its combustion only results in water, which makes its use especially attractive as a fuel since it is considered a clean energy. In addition, its heating value on a mass basis is significantly higher than that of fossil fuels, approximately three times that of fossil fuels [1], [2] . Given this, H_2 is an alternative energy source already widely studied, mainly for application in fuel cells. Moreover, H_2 is used as a reactant in the chemical and petroleum industries, for instance, ammonia production, petroleum processing and methanol production. However, H_2 is not found in free form in nature. Therefore, technologies such as water electrolysis, methane reforming and ethanol reforming have been

widely studied in order to obtain hydrogen. Another possibility for applying H_2 is upgrading biofuels, such as the pyrolysis bio-oil.

Mechanical harvesting of sugarcane increased the availability of straw in the field, which can be used as fuel in boilers or as raw material for second-generation biofuel production through biochemical and thermochemical routes. Regarding the thermochemical routes, the fast pyrolysis allows to production of bio-oil from sugarcane straw that can be used for heating applications. However, there are limitations to the use of pyrolysis bio-oils as fuel in the transport sector because of its high oxygen content (35–40 wt%), which gives bio-oil unwanted properties such as low energy content, corrosiveness, high viscosity and aging [3].

There are several technologies for bio-oil upgrading, according to Sharifzadeh et al. [4], these processes can be classified into physical and chemical technologies. Concerning the chemical processes, hydrodeoxygenation (HDO), also known as hydrogenation or simply hydrotreatment, is the leading technology for upgrading pyrolysis oils, moreover compounds contained in gasoline and diesel can be obtained through this process; however, significant amounts of hydrogen are required as well as high temperatures and pressures.

In the existing literature, there are several studies regarding H_2 production in sugarcane production plants; however, these studies do not compare technologies, nor evaluate heat integration between processes or impacts in the cogeneration system. Thus, this work aims to evaluate the possibilities and opportunities of integrating hydrogen production into the sugarcane processing plants to use the produced hydrogen to upgrade pyrolysis bio-oil aiming at the production of synthetic gasoline and diesel. For this purpose, three technologies for H_2 production were studied: water electrolysis, methane reforming and ethanol reforming. Thus, mass and energy balances were performed with the objective of analysing how much H_2 is necessary for the upgrading process, as well as how much it is possible to obtain through each technological route, from the raw materials available in sugarcane factories, in addition to the possibility of analysing the impacts within the sugar and ethanol production process. The novelty of this study is to present the potential of renewable H_2, from feedstocks available from a sugarcane processing plant, for the specific application of bio-oil upgrading in the context of a biorefinery, as well as investigating the opportunities of heat integration aiming at a more efficient and sustainable production process.

2. Hydrogen production processes and feedstocks

According to IEA [5], in 2021, almost total global H2 production came mainly from fossil fuels, 62% from natural gas without CCUS (Carbon Capture, utilisation and storage), 19% from coal, mainly in China and 18% as a by-product from naphtha reforming at refineries, approximately 0.7% from oil and approximately 0.04% from water electricity. Regarding the low emission H2 production, it accounted for less than 0.7%, almost all from fossil fuels with CCUS.

There are several technologies and routes for hydrogen production, which depends mainly on the material that contains the hydrogen (hydrocarbon or non-hydrocarbon), energy source and catalyst material. The selection of feedstock and production pathway determines the cleanness, cost-effectiveness, efficacy, and feasibility of hydrogen production [6]. The cleanness of a hydrogen production pathway depends on the GHG emissions associated with the life cycle of produced hydrogen determined through LCA (Life Cycle Assessment). Furthermore, some studies in the literature classify the hydrogen production pathways in colours based on their associated emissions. For instance, grey hydrogen is associated with dirty and polluting production, such as natural gas reforming without CCUS, blue hydrogen considers the use of CCS (Carbon Capture and Storage), while green hydrogen refers to renewable energy for hydrogen production.

This study focused the hydrogen production from renewable raw materials and energy sources that are products and by-products of sugarcane processing, such as ethanol, the biogas produced from anaerobic digestion of vinasse, and the surplus bioelectricity from cogeneration system that can be used for water electrolysis. Next, there is a summary description of the production routes that were assumed in this study:

2.1. Water electrolysis

Water electrolysis is the process responsible for the breakdown of the H_2O molecule into H_2 and O_2 from the application of a continuous current of electricity that, through redox reactions, dissociates the water. It is considered an endothermic process because energy is absorbed and converted into heat in the electrodes, subsequently converted into chemical energy resulting in gaseous H_2. This technology can be described by the reaction:

$$H_2O_{(l)} + \text{energy} \rightarrow H_{2(g)} + 1/2\ O_{2(g)} \quad (1)$$

The reactions that take place at the cathode and anode, respectively, are:

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad (2)$$

$$2OH^- \rightarrow 1/2\ O_2 + H_2O + 2e^- \quad (3)$$

According to [2], modern electrolysers have the capacity to reach an efficiency that varies from 75% to 90%, which is equivalent to a consumption of 4.0 to 5.0 kWh/Nm^3 of H_2.

2.2 Methane reform from biogas

Biogas is the result of the anaerobic digestion process, and their main components are methane (CH_4) and carbon dioxide (CO_2). Because of its high methane content (between 50 and 60 % in molar basis), biogas can be subjected to methane reforming to produce hydrogen. The methane reforming processes that can be applied for hydrogen production are: steam reforming, partial oxidation, autothermal reforming and dry reforming. Among them, steam reforming is one of the most used, representing 48% worldwide [7]. This process can be described globally through the following reaction:

$$CH_4 + H_2O \leftrightarrow CO + 3H_2$$

2.3 Ethanol reforming

Ethanol is considered a raw material with a strong potential to produce hydrogen. This is due to its well-established handling, transport and storage technologies, low toxicity and volatility characteristics, and economic and thermodynamic viability.

To obtain hydrogen from ethanol, steam reforming of ethanol is used. This is an endothermic process characterized by the reaction of ethanol with water when they are in the presence of catalysts. In this environment, the reactions will be intensified, producing a gas mixture (syngas) that contains H_2, CO and H_2O [8].

According to Teixeira et al. [8], the ethanol conversion into hydrogen has an efficiency of 93.7%, and the suitable temperature range for this process took place is between 800 K and 1000 K. However, the conversion depends on the physic-chemical characteristic of fuel and the conditions of temperature, pressure, fuel-steam ratio and reforming techniques.

Two stages mark the steam reforming of ethanol: steam reforming reactions and water-gas shift reactions, the first of which is characterized by high temperatures and the second by low temperatures.

The reactions below represent the two steps, respectively:

Steam reforming: $C_2H_5OH_{(v)} + H_2O \rightarrow 2CO + 4H_2$

Water-gas shift reaction (WGS): $2CO_{(g)} + 2H_2O \rightarrow 2CO_2 + 2H_2$

The reaction that encompasses the entire process can be written as follows:

Overall reaction: $C_2H_5OH_{(v)} + 3H_2O_{(v)} \rightarrow 2CO_2 + 6H_2$, $\Delta H = 207.7$ kJ/mol

The choice of catalysts and supports is an important factor to be considered since their choice will impact the amount of H_2 that will be obtained. According to [8], the combination of Cu and Ni achieved the best efficiency: 90% H_2.

3. Methods

In order to analyse the feasibility of hydrogen production in sugar and ethanol production plants, mass and energy balances were performed in order to quantify the amount of H_2 that is possible to produce from available inputs through the proposed methods. The first analysis focuses on the potential of H2 production. In contrast, the second aims to evaluate the amount of raw materials and energy necessary to produce a certain amount of H_2, which is needed for a hydrotreatment plant that upgrades the bio-oil produced from the fast pyrolysis of sugarcane straw.

3.1. Evaluated cases

3.1.1. Case 0 – Base case

The base case corresponds to the production process of sugar, ethanol and bioelectricity from sugarcane. In it, the starting point is the processing of 500 t/h of sugarcane. Mass and energy balances in this process were performed in previous research studies [9],[10]. Figure 1 shows the main flows of the production process.

In this process, it was assumed that 50% of total recovery sugars from sugarcane were sent to sugar production while the remaining was directed to hydrous ethanol production. Regarding the bagasse usage, from the total produced (136 t/h), 5% (6.8 t/h) is reserved for start-up operations, 5 kg/t cane, equivalent to 2.5 t/h, is used in filters, while the remaining (126.7 t/h) is used as fuel in the boiler of the cogeneration

system, which is based on a steam cycle with condensing extracting steam turbines (CEST) in order to maximise the electricity production; thus no surplus bagasse is obtained. The cogeneration system supplies steam and power to the production process (Fig. 1), and the main parameters of the cogeneration system are presented in Table 1.

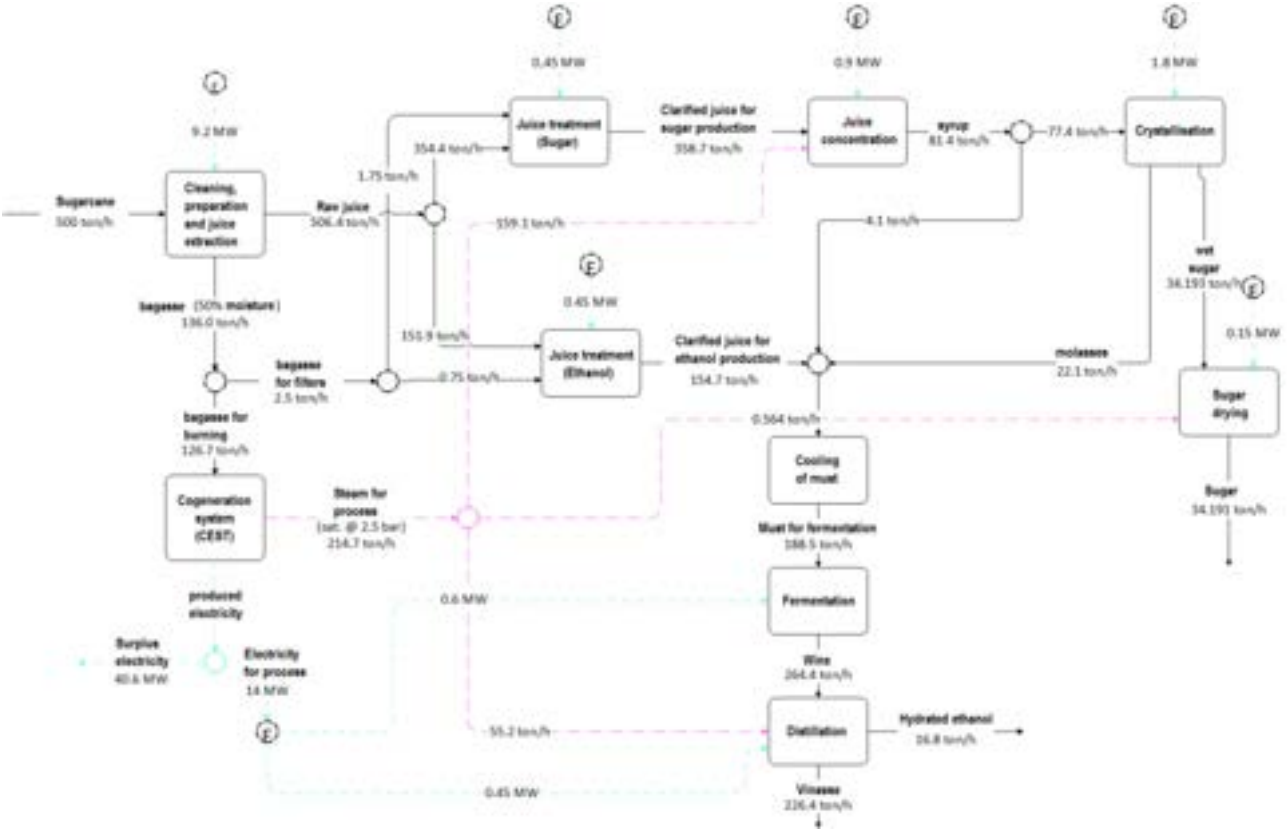

Figure. 1. Fowsheet of the conventional ethanol and sugar production process

Table 1. Main parameters of the cogeneration system of conventional process

Parameter	Value
Steam consumption, kg/t cane	437.6
Bagasse LHV (50% moisture content), MJ/kg	7.64
Electricity consumption in the conventional process, kWh/t cane	28
Boiler thermal efficiency, LHV basis,%	85
Isentropic efficiency of turbines and pumps, %	80
Condensing pressure, kPa	10
Temperature of live steam, °C	520
Pressure of live steam, bar	65
Process steam pressure, bar	2.5

Source: Palacios-Bereche et al. [10]

3.1.1. Case I - Water electrolysis

Table 2 presents the main parameters assumed for water electrolysis evaluation. The specific electricity consumption was assumed from the manufacturer Norsk Hydro A.S. according to [2] and [11].

Table 2. Main parameters of water electrolysis assessment

Parameter	Value
Energy consumption of electrolyser[a], kWh/Nm^3 of hydrogen	4.3
Ultrapure water requirement for electrolysis[b], L of water/kg of hydrogen	9
Cooling water requirement[b,c], (L/h) per MW of electrolyser capacity	400
Water recovery in standard filtration (pre-treatment)[b,d], %	98
Water recovery in polishing to ultrapure standard[b], %	75
Energy consumption in water treatment system [b,d], kWh/m^3 of water	2
Energy consumption related to cooling water system, kWh/m^3 cooling water	0.0465

[a]Norsk Hydro A.S., [b]Madsen [11], [c]For evaporative cooling tower, [d]For groundwater,

Concerning to the water treatment, it was assumed a pre-treatment with standard filtration and further polishing to achieve the ultrapure standard. Water consumption for electrolysis as well as make-up water for the cooling water system in an evaporative tower, were taken into account.

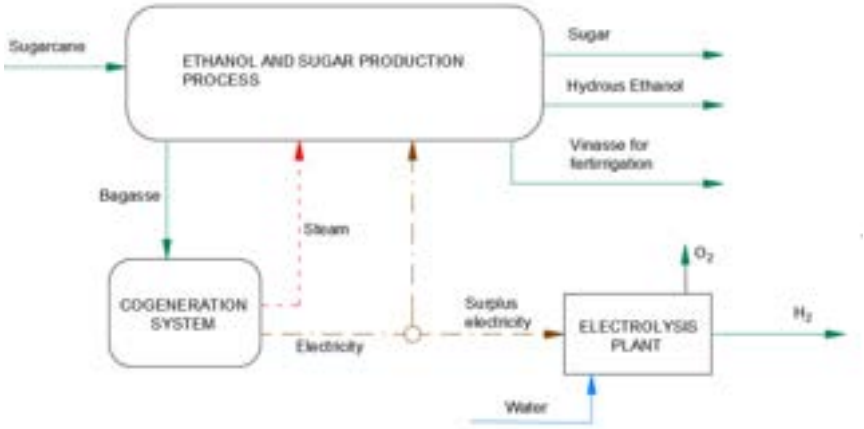

Figure. 2. Hydrogen production through water electrolysis using the surplus electricity of the mill

3.1.2. Case II - Biogas reforming

The biogas production from sugarcane was estimated according procedure presented in [10], which resulted in 2359.1Nm^3/h of raw biogas. In order to prevent reformer catalyst poisoning, a dessulphurisation system is necessary to remove H_2S; thus, a chemical scrubbing system (THIOPAQ system) was assumed in this study. Figure 3 presents a flowsheet for the H_2 production from biogas produced from vinasse biodigestion, while Table 3 shows the main parameters considered for simulation and evaluation.

Table 3. Main parameters assumed for biogas reforming

Parameter	Value
Biogas dessulphurisation	
Flow reduction in dessulphurisation process[a], %	15
Specific power consumption[a], kWh/Nm^3 of raw biogas	0.024
Biogas reforming[b]	
Reforming reactor temperature,°C	850
Reforming reactor pressure, bar	20.1
Steam/Carbon ratio in reforming (mol/mol)	2.87
Water-gas-shift reactor temperature[c], °C	400
Conversion of CO in WGS reactor[d], %	75
Efficiency of pumps and compressors, %	70
Hydrogen recovery in PSA (% of inlet H2)	75
H2 inlet concentration for PSA (% molar)	74
Temperature of preheated air, °C	315
Temperature of exhaust gases at burner outlet, °C	1400

[a]Flores-Zavala [12]; [b]Nakashima [13]; [c]Operating pressure 20.05 bar; [d]tese Peters

The desulphurised biogas composition was assumed in 64.4% of CH_4, 35% of CO_2, 0.6% N_2 and 40 ppm of H_2S in molar basis according to [12]. The biogas reforming process was simulated in Aspen Plus software

according to the flowsheet and specifications supplied by [13] and [14]. In order to maximise the hydrogen production, it was assumed that all available biogas would be sent to the reforming reactor while the heating requirements of the process were fulfilled by burning the off-gas from the PSA system with sugarcane bagasse. Heat integration through Pinch Analysis was applied in order to determine the minimum requirements of external utilities, thus minimising the amount of bagasse necessary.

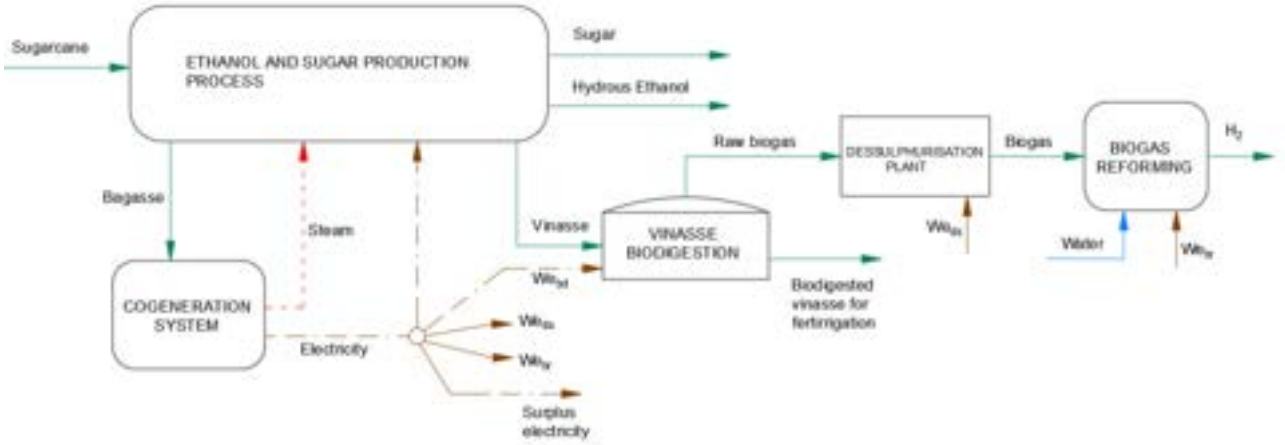

Figure. 3. Hydrogen production through biogas reforming

3.1.3. Case III - Ethanol reforming

Ethanol reforming was another technology analysed to obtain H_2. For this analysis, data from Souza et al. [15] was used to estimate the H_2 production and their energy requirements. In the same way, as in Case II, ethanol is sent to the reforming reactor, while the thermal energy demands were fulfil burning the off-gas from PSA and sugarcane bagasse. Using the simulation supplied by [15] performed in Aspen Hysys, it was possible to apply the heat integration procedure to determine the minimum amount of bagasse necessary. Figure 4 presents the flowsheet of H_2 production from ethanol, while Table 4 shows the main parameters adopted from [15] for evaluation

Table 4. Main parameters assumed for ethanol reforming [15]

Parameter	Value
Specific H_2 production from ethanol, kg H2/kg ethanol	0.219
Water consumption, kg water/kg ethanol	1.6
Additional heat supply, kWh/kg ethanol	1.25
Specific power consumption, kWh/kg ethanol	0.0441

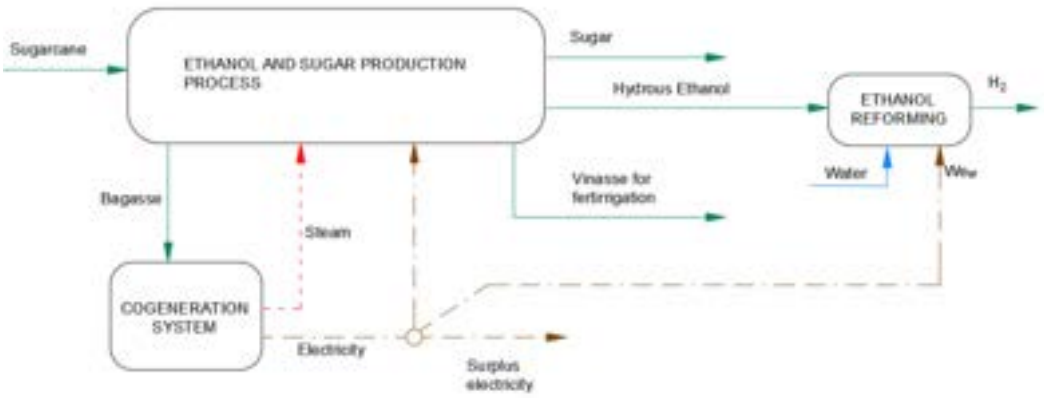

Figure. 4. Hydrogen production through water electrolysis using the surplus electricity of the mill

3.2. Hydrogen consumption in hydrotreating and hydrocracking

This analysis aims to evaluate the raw materials and energy requirements necessary to produce hydrogen for a bio-oil upgrading plant, which processes bio-oil produced from the fast pyrolysis of sugarcane straw. The fast pyrolysis of straw was simulated in Aspen Plus software in a previous study [16], while the hydrotreatment was simulated according to Peters [17]. Figure 5 presents the flowsheet of the hydrotreatment process followed by the distillation step with hydrocracking of the bottom product of the C-DIST2 column. Table 5 shows the main parameters assumed for hydrogen production analyses. Figure 5 shows that the organic phase produced in hydrotreatment is depressurized in a flash. The gaseous stream (FLSHGAS) has a significant amount of hydrogen recovered in a PSA system. This study assumed an H2 recovery of 85% in the PSA system; thus, hydrogen make-up results in 0.04651 kg H_2/kg bio-oil equivalent to 10,938 Nm^3/h.

Table 5. Main parameters assumed in the bio-oil upgrading system

Parameter	Value
Sugarcane straw recovery from field, %	50
Sugarcane straw processing rate in pyrolysis plant[a], t/h	47
Bio-oil produced in pyrolysis plant[b], t/h	21.1
Specific consumption of hydrogen in hydrotreatment[c], kg H_2/kg bio-oil	0.09
Specific consumption of hydrogen in hydrocracking[c], kg H_2/kg bio-oil	0.0032
Mass flow of FLSHGAS, kg/s	1.43
Hydrogen content in FLSHGAS, wt.%	22.6
Recycling rate of H_2 [d], %	55.8

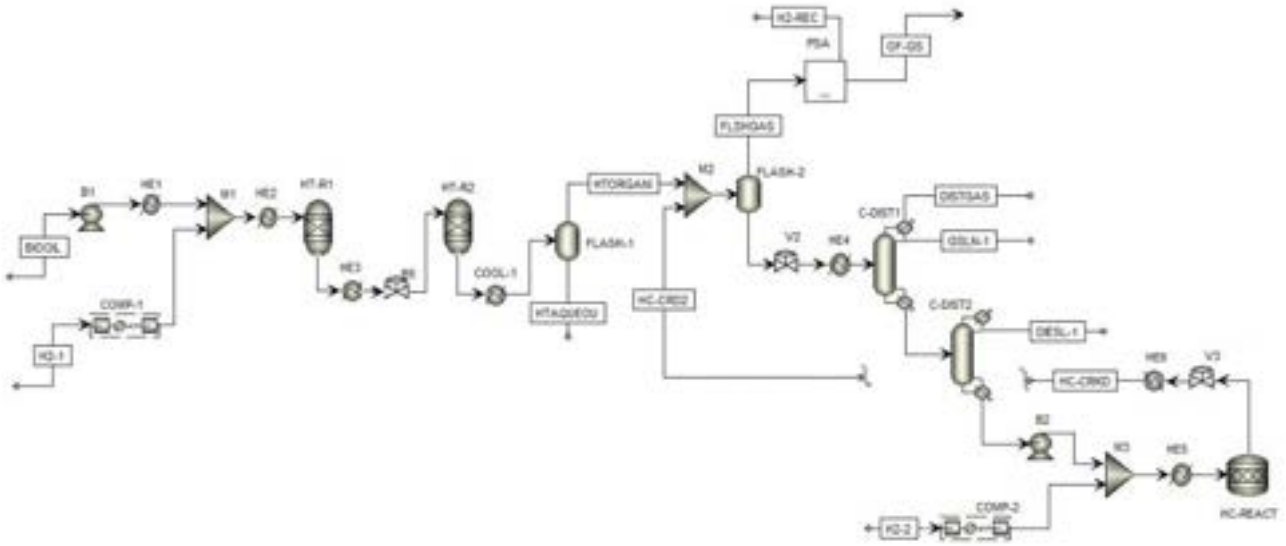

Figure. 5. Flowsheet of upgrading boi-oil plant in Aspen Plus software.

4. Results

4.1. Potential of hydrogen production from products and by-products of sugarcane processing plant

Figure 6 presents the results of hydrogen production from available inputs in the mill; it can be observed that only Case III (ethanol reforming) can supplied all the hydrogen necessary for hydrotreatment.

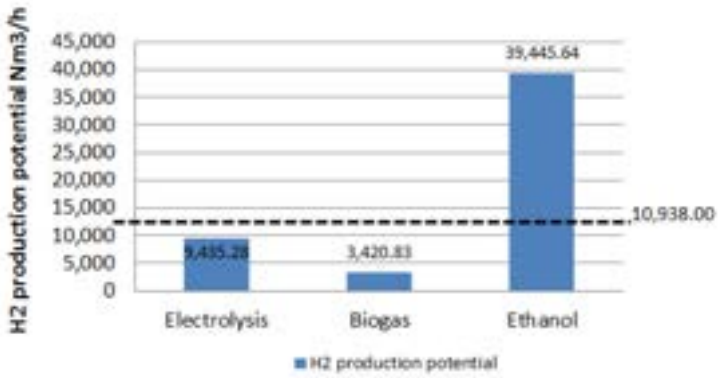

Figure. 6. Hydrogen production potential from available inputs in sugar and ethanol production process.

Thus, surplus electricity from the cogeneration system (40.6 MW) can produce 86.3% of the H2 necessary (Case I). Biogas reforming can achieve 31.3% (Case II) while considering all available ethanol produced in the plant (16.2 t/h), it is possible to produce 3.6 times the amount of hydrogen necessary (Case III). It represents a specific hydrogen production of 18.9, 6.8 and 78.9 Nm^3 of H_2 per t of cane for cases I, II and III, respectively. Regarding ethanol reforming, to produce the necessary hydrogen for hydrotreatment would be required only 4.5 t/h, which is equivalent to 27.7% of the ethanol produced in the mill.

Figure 7 shows the Grand Composite Curves obtained from Pinch Analysis for (a) biogas reforming (2,359.1Nm^3/h of raw biogas) and ethanol reforming (4.5 t/h of ethanol). Stream data for CC and GCC construction is presented in Appendix A

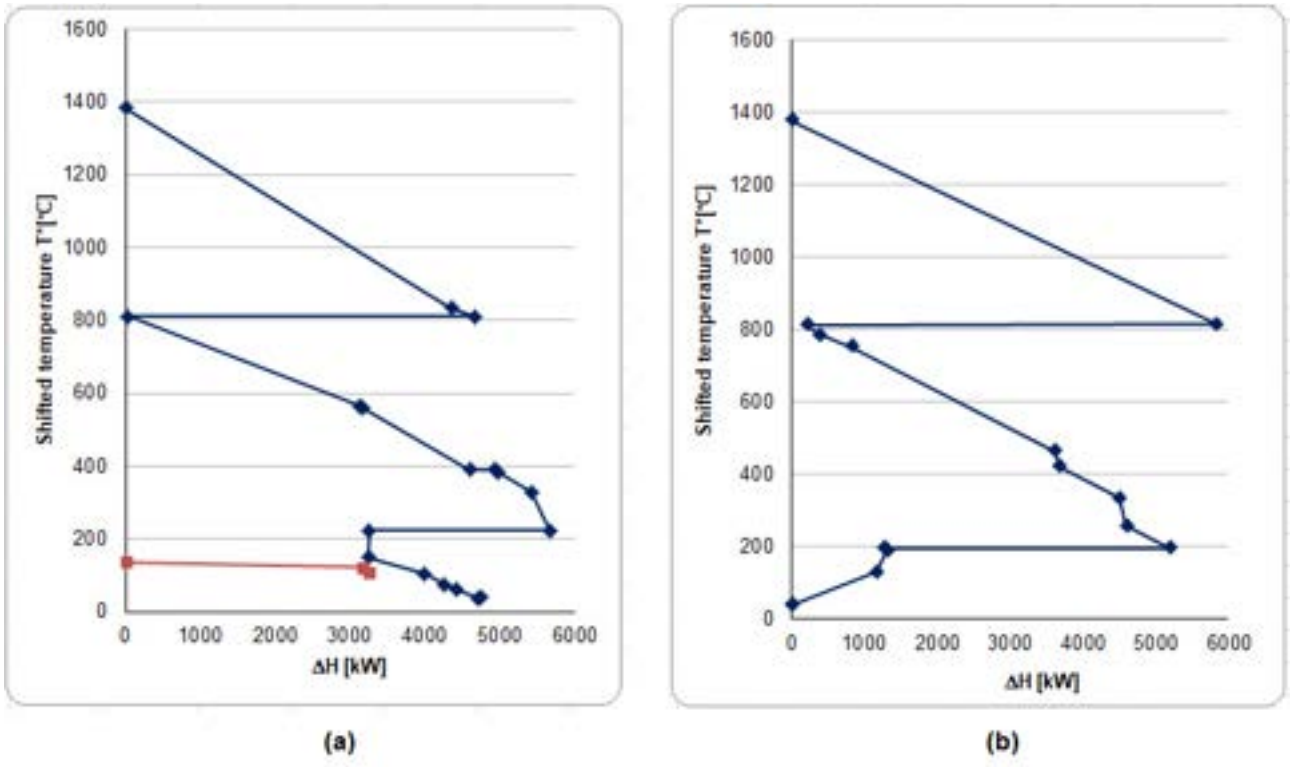

Figure. 7. GCC for (a) biogas reforming and (b) ethanol reforming process

From Fig. 7a, it can be observed that there is a significant amount of heat available at a relatively high temperature (below the reformer reactor temperature, 850°C); thus, it is possible to produce steam (at 2.5 bar and 127.4°C) and use it in ethanol and sugar production process, the red line in Fig. 7a represents this heat recovery potential. On the other hand, in Fig. 7b, better integration is observed because this configuration needs more heat at low temperatures (no hot and cold utilities are required for this case). Moreover, the heat integration procedure allows determining the amount of bagasse necessary to complete the heat demand in the reforming process for these cases. Table 6 presents the main results for these cases.

Table 6. Main results for H_2 production potential

Parameter	Case I	Case II	Case III
H_2 production, Nm^3/h	9,435.3	3,420.8	10,938.0
% of the total H_2 required	86.3	31.3	100.0

4.2. Production of H2 necessary for bio-oil upgrading plant and its impact in the cogeneration system

Table 7 presents the main results of this analysis. Regarding Case I, it would be necessary to buy from the electrical grid 6,466 kW (12.9 kWh/tcane) to achieve the required H_2 production. This electricity represents 11.8% of the total power produced by steam turbines of the cogeneration system. On the other hand, Case II requires an additional supply of 5,184 Nm^3/h of biogas or an equivalent of 2940.7 Nm^3/h of natural gas or biomethane (CH_4 content of 96.5% mol).

Regarding water consumption, biogas reforming presents the highest value, equivalent to 29.4L/t cane. According to Pina et al. [18], this value represents 7.1% of effective water collecting in the sugarcane processing plant (414 L/t cane). Finally, the case with the lowest impact in surplus electricity as well as water consumption is Case III; however, this case requires 27.7% of the total hydrated ethanol produced in the mill.

Table 7. Main results for H_2 production necessary to meet the bio-oil upgrading plant

Parameter	Case I	Case II	Case III
H_2 production, Nm^3/h	10,938.0	10,938.0	10,938.0

[a]Raw biogas; [b]Bagasse to fulfil the heat demand in the reforming process, 50% of moisture content, wet basis, [c]Saturated steam at 2.5 bar, [d]In comparison to the Base Case (surplus electricity of 40.6 MW).

5. Conclusions

Three routes of hydrogen production were evaluated in this study assuming as feedstock products and by-products available in sugar and ethanol production process aiming to match the hydrogen consumption of a bio-oil upgrading plant. Furthermore, its integration to the conventional sugar and ethanol production process was analysed as well as the impacts in cogeneration system. All evaluated cases presented feasibility; however there are advantages and disadvantages in each one. Case I (electrolysis) presented a significant impact in cogeneration system because the high electricity consumption of this technology. Case II (biogas reforming) presented the highest water consumption (29.4 L/t cane), while Case I presented the second highest (25.2 L/t cane), moreover, it would be necessary to acquire a significant amount of external biogas or natural gas, because the biogas available from anaerobic digestion of vinasse only can produce 31.3% of the required hydrogen for the upgrading plant. Case III (ethanol reforming) presents the lowest water consumption (14.1 L/t cane) and the lowest impact in cogeneration system (-6.3% in surplus electricity). Nevertheless Case III requires the consumption of 27.7% of the total ethanol produced in the mill, impacting significantly the revenues of the plant. In this way a more detailed analysis is needed, for instance an economic assessment or an exergoeconomic analysis to help in choosing the best proposal or proposals.

Abstract:

Second-generation biofuels are produced from non-food biomass such as the lignocellulosic residues of sugarcane processing, namely, bagasse and straw. Sugarcane processing is one of the most important economic activities in Brazil, producing ethanol and sugar for domestic and international markets. The use of these lignocellulosic residues would increase the second-generation biofuel production without increasing the sugarcane planted area. Among the second-generation technologies available nowadays, the fast pyrolysis is a thermochemical process that produces mainly bio-oil, which is a liquid that has several advantages in transportation, pumping, storage and handling, in comparison to solid biomass. Moreover, the bio-oil can be upgraded in order to obtain biofuels of higher added-value. Among feasible upgrading technologies for bio-oil, the hydrotreatment is one of the most promising for eliminating the reactive functionalities of the bio-oil by removing oxygen or cracking large molecules in the presence of hydrogen; however, the hydrogen consumption is significant. In this way, the aim of this study is to evaluate the biofuel production by means of fast pyrolysis of sugarcane straw, followed by a hydrotreatment to upgrade the produced bio-oil. The evaluation is performed through an energy assessment. The energy and mass balances of the processes were performed using the software Aspen Plus. Furthermore, the possibilities of the integration of the bio-oil production and upgrading into the conventional ethanol and sugar production process will also be evaluated. The final products of bio-oil upgrading plant showed a yield of 0.086 kg/kg of dry straw and 0.080 kg/kg of dry straw for renewable gasoline and diesel respectively. The heat integration of pyrolysis process, hydrotreating and hydrogen production process presented a significant potential for steam production. This could be integrated into the conventional sugar and ethanol production process, which could save 28.6% of steam and increase the surplus electricity in 6%.

Keywords:

Sugarcane; fast pyrolysis; bio-oil; hydrotreatment; energy analysis.

1. Introduction

The production of biofuels from lignocellulosic residues of sugarcane (bagasse and straw) is presented as a desirable alternative since it would increase the biofuel production without the need to increase the area planted with sugarcane. Thus, these biofuels diversify the Brazilian energy matrix and contribute to the reduction of greenhouse gases (GHG) emissions. In this context, the introduction of the fast pyrolysis of lignocellulosic residues into the conventional sugarcane process plant for bio-oil production, aiming at its further processing, can improve the productivity and sustainability indexes of the integrated process. Pyrolysis is the physico-chemical process of thermal degradation of a material in a non-oxidizing atmosphere, resulting in the formation of a solid residue rich in carbon (charcoal or char) and a volatile fraction composed of condensable organic gases and vapours. The proportions of these products depend on the pyrolysis conditions and the characteristics of the feedstock. Fast pyrolysis is characterised by low residence times in the reactor, high heating rate at moderate temperatures (400 to 600ºC). The formation of

bio-oil is prioritised, as it can be used as fuel for boilers or serve as raw material for the production of vehicles fuels. In the literature, some studies have already regarded the fast pyrolysis of lignocellulosic biomass, such as the study of Mesa-Perez et al.[1], where the oxidative fast pyrolysis of sugarcane straw in a fluidised bed reactor was analysed. In addition, Ferreira et al. [2] carried out a study to evaluate the influence of some parameters on the oxidative pyrolysis of sugarcane straw, while Alves et al. [3] experimentally evaluated and compared the fast pyrolysis of sugarcane straw and eucalyptus bark in a fluidised bed reactor at 500°C. Still, raw bio-oil is not suitable as fuel for the transport sector because of some undesirable characteristics such as low energy content, corrosiveness, high viscosity, incomplete volatility and chemical instability. These unfavourable properties are consequences of the high water content and oxygenated compounds [4]. Thus, the bio-oil requires upgrading and fine-tuning in order to achieve product specifications commensurate with existing transportation infrastructures. The upgrading methods aim at stabilising the crude bio-oil by removing its oxygen content and reducing its viscosity, ageing potential, and solid content [5]. Among the different available methods, the hydrodeoxygenation (HDO), also known as hydrogenation or simply hydrotreatment, is the main technology for upgrading pyrolysis oils due to its effectiveness. It was originally inspired by the hydrodesulphurisation (HDS) and hydrodenitrogenation (HDN) used in petroleum refineries. A catalytic reaction of crude bio-oil with hydrogen can significantly reduce the oxygenated compounds through the formation of water. The involved reactions in this process include hydrogenation, hydrodeoxygenation, decarboxylation, hydrogenolysis, hydrocracking, and dehydration. The optimal combination of these reactions requires significantly higher pressures (> 20 MPa) and moderate temperatures (around 400°C) [5]. HDO yields high quality hydrocarbon products for gasoline and diesel substitution, but requires important amounts of hydrogen at high pressure, which affects costs and energy balances. Process conditions and catalyst type have to be carefully adjusted in order to minimise hydrogen consumption and to achieve the desired product [6]. According to Sharifzadeh et al. [5], it is recommended to first stabilise the bio-oil through hydrogenation at a lower temperature, followed by more intense HDO at higher temperatures. Some studies regarding bio-oil upgrading can be found in the literature, for instance, Jones et al. [7] presented a report about process design and economic assessment for fast pyrolysis of woody biomass and bio-oil hydrotreating; in Zacher et al. [8], a study regarding technology advancements in hydroprocessing of bio-oils was accomplished, while Peters [6] evaluated the fast pyrolysis, including the bio-oil upgrading, for the production of second-generation biofuels from thermodynamic, environmental, and economic approaches.

Thus, the present study aims at evaluating the biofuel production by means of fast pyrolysis of sugarcane straw, followed by its upgrading through hydrotreatment. The evaluation being performed through an energy assessment. The energy and mass balances of the processes were performed using the software Aspen Plus v12 [9]. Furthermore, the possibilities of integrating the bio-oil production and upgrading into the conventional ethanol and sugar production process will also be evaluated through the Pinch Analysis.

2. Biofuels production from fast pyrolysis of sugarcane straw

2.1. Fast pyrolysis of sugarcane straw

This section presents the main characteristics of the fast pyrolysis plant assumed in this study, whose flowchart is shown in Figure 1. This plant, receiving sugarcane straw as raw material, is comprised of the following components: reactor (1), cyclone (2), quench (3), condensers (4), heat exchanger (5), compressors (6), coal and synthesis gas combustor (7), heat recovery steam generator (HRSG) (8), fluidising gas preheater (9), and biomass dryer (10). In this configuration, the pyrolysis process is characterised as autothermal [10], burning the char and syngas to supply energy to the pyrolysis reactor. Furthermore, it is possible to produce steam in the HRSG (8), which is used in a Rankine cycle to produce electricity for the process. The bio-oil produced in this plant is then sent to the upgrading plant.

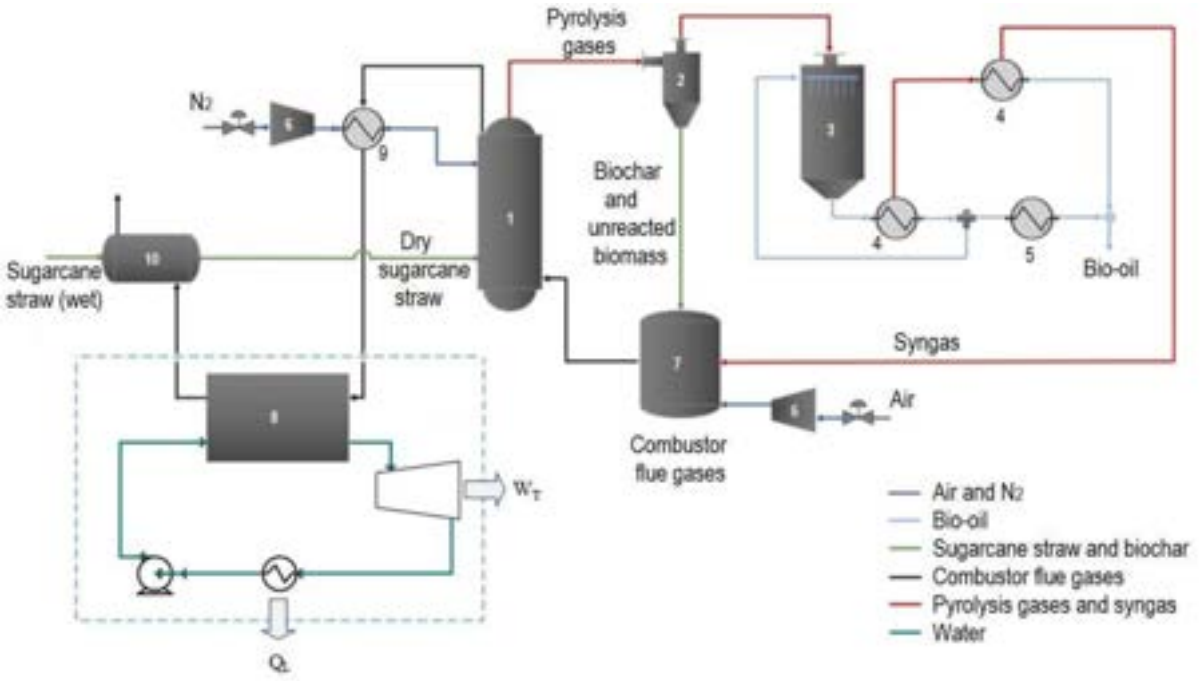

Figure. 1. Fast pyrolysis process diagram [10]

2.2. Bio-oil upgrading through hydrotreatment

The bio-oil upgrading plant was divided into three subsystems: hydrotreatment, distillation and hydrocracking, and hydrogen production. Figure 2 presents the flowsheet of the hydrotreatment section.

2.1. Hydrotreating section

The bio-oil supplied by the pyrolysis plant is pressurised in pump B1 and preheated in the heat exchanger HE1; after that, it is mixed with pressurised hydrogen in M1. The mixture is preheated in the heat exchanger HE2 before entering the first hydrotreating reactor HT-R1, whose operating conditions were assumed at 170 bar and 250°C, according to Peters [6]. This reactor aims at stabilising the bio-oil sufficiently to be suited for a more severe treatment in the second reactor. The product of HT-R1 is heated till 370°C and decompressed to 140 bar before entering the second hydrotreating reactor HT-R2. The operating conditions in HT-R2 were assumed at 370°C and 140 bar [6]. The aim of this second reactor is to deeply deoxygenate and stabilise the bio-oil up to an oxygen content of <2% [11],[12]. Both reactors HT-R1 and HT-R2 were assumed to operate with a standard Co-Mo catalyst, according to [6].

The product of HT-R2 is cooled to 137.4°C, in the heat exchanger COOL-1, before entering the flash tank, which operates at 35 bar, where the organic vapours (HTORGANI) are separated from the aqueous liquid phase (HTAQUEOU). The organic vapours are sent to the following subsystem (Distillation and Hydrocracking), while the aqueous stream enters the hydrogen production subsystem.

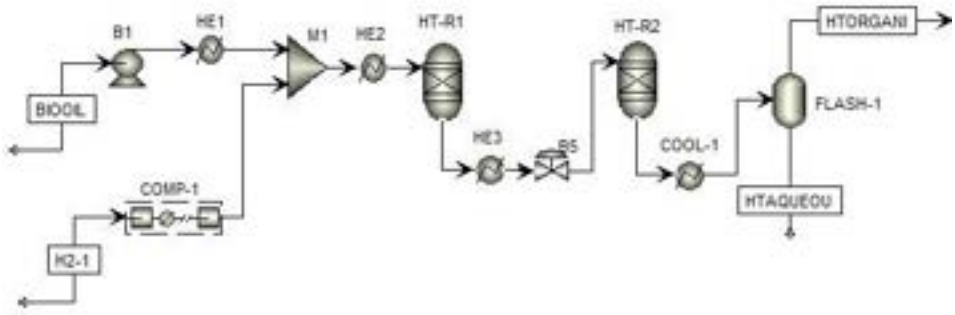

Figure. 2. Flowsheet of bio-oil hydrotreatment in Aspen Plus

2.2. Distillation and hydrocracking

Figure 3 presents the flowsheet of the Distillation and Hydrocracking subsystem. It can be observed that the products of the hydrotreatment step (stream HTORGANI) and the hydrocracking reactor (HC-CRD2) are mixed before being sent to a flash tank (FLASH-2) operating at 20 bar. The liquid phase is preheated in the heat exchanger HE4 and fed to the first distillation column (C-DIST1), while the gaseous phase, containing a significant amount of unreacted hydrogen, is sent to a PSA (Pressure Swing Adsorption) system for hydrogen recovery and recycling. This configuration was assumed according to Zacher et al. [8] and Jones et al. [7]. In this study, it was assumed that a part of the tail gas from the PSA system (OF-GS) is used as fuel in the utility system while the remaining is integrated into the hydrogen production system. In the first distillation column (C-DIST1), renewable gasoline is obtained at the top, while the bottom product is sent to the second distillation column (C-DIST-2). Moreover, in the top of C-DIST1, distillation gases (DISTGAS) are also obtained, which are used as fuel in the utility system.

In the second distillation column (C-DIST2), renewable diesel (stream DIESL-1) is obtained at the top, while the heavier product at the bottom is mixed with preheated hydrogen and sent to the hydrocracking reactor (HC-REACT). In the hydrocracking (HC) reactor, under severe conditions (677°C, 170 bar) and a hydrogen atmosphere, the heavy tar fraction is catalytically split up into smaller chain components, producing hydrocarbons in the range of C1-C18 [6].

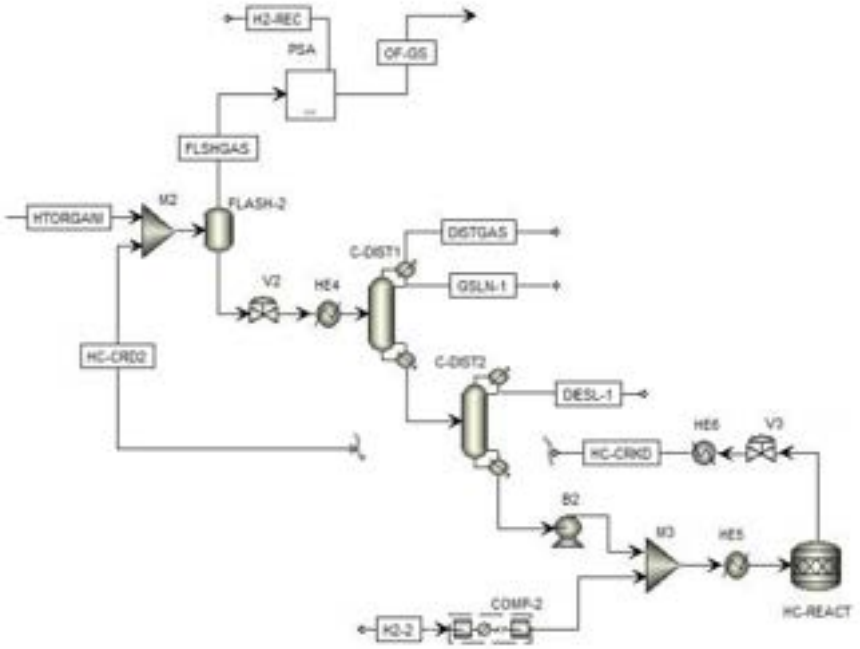

Figure. 3. Flowsheet of the distillation and hydrocracking processes in Aspen Plus

2.3. Hydrogen production

Figure 4 presents the flowsheet of the hydrogen production section. This study considered the steam reforming of desulphurised biogas (DS-BIOG1), produced from the anaerobic digestion of vinasse, in combination with external natural gas acquired from the grid (SRCH4EXT). The components removed together with some hydrogen lost in the PSA system are obtained as tail gas. Part of this tail gas (stream FLSHGAS2) is used as fuel to meet the energy requirements of the hydrotreatment and distillation sections, while the remaining (FLSHGAS3) is sent to hydrogen production. One part of the FLSHGAS3 stream is compressed till 50 bar and sent to the reform reactor, while the other part is used as fuel in a combustor (COMB), whose exhaust gases are used as hot utility to meet the heat requirements of the reformer. Furthermore, the aqueous liquid stream (HTAQUEOU) obtained in the hydrotreatment section is also sent to the hydrogen production system; where it is mixed with part of the condensate recovered (SRH2O-IN stream) in FLASH-3. Afterwards, the liquid mixture is pumped and heated in HE7 and sent to the reforming reactor (SR-REACT). Biogas and natural gas are sent to the reforming reactor as well. The feed of the reforming reactor is preheated in the heat exchanger HE8 till 500°C, the product of which is then cooled to 310°C and sent to the WGS (Water-Gas-Shift) reactor, which operates at 350°C and 48 bar. The product of the WGS reactor is then cooled to 77°C before entering the FLASH-3, which operates at 46 bar. The gaseous product of FLASH-3 is sent to the second PSA system (PSA-II) in order to separate the hydrogen from the other gases. The tail-gas from the PSA-II system (OFFGS stream), the gaseous product of the

distillation column (DISTGAS stream), and part of the tail gas from the PSA-I system (remaining part of FLSHGAS3) are preheated with combustion air in HE11 before entering to the combustor COMB to be burnt.

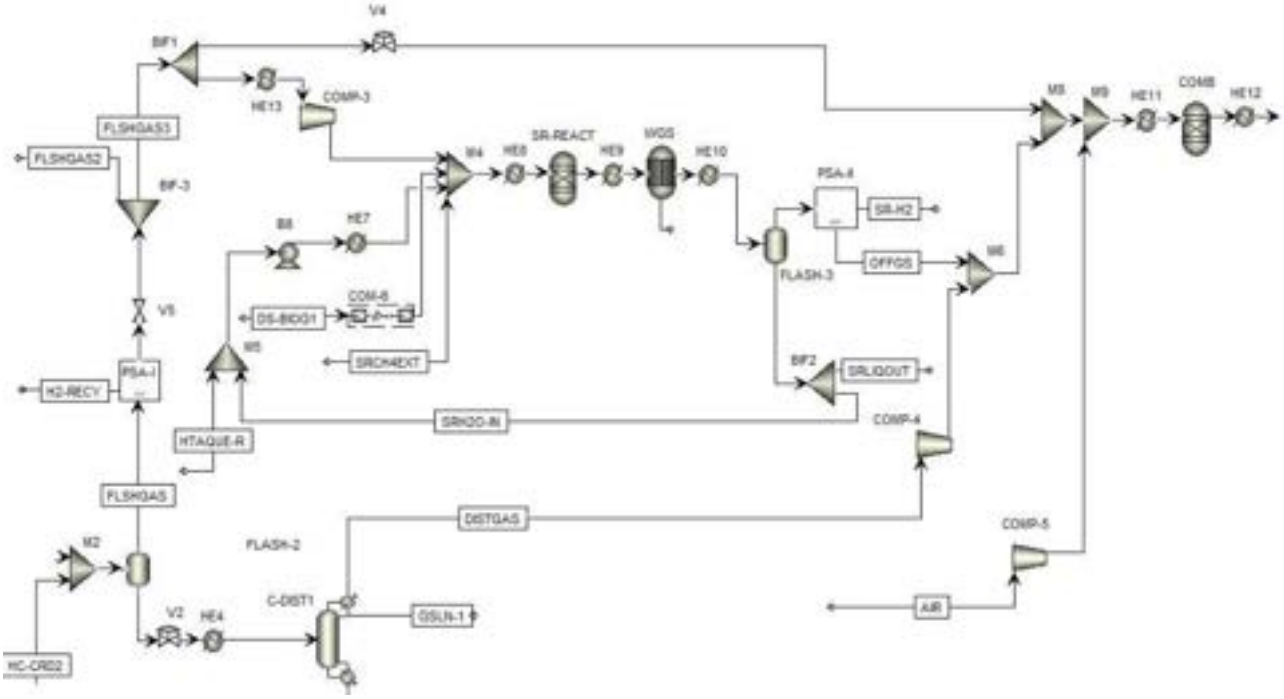

Figure. 4. Flowsheet of the hydrogen production process

3. Methods

3.1. Fast pyrolysis plant

The simulation of the fast pyrolysis plant using sugarcane straw as feedstock was performed in the Aspen Plus software, according to [10]. The Peng-Robinson equation of state with Boston-Mathias modification (PR-BM) was selected as the preferred method for properties calculation in the reactor and combustor system, while the NRTL method was selected in the separation system. A straw availability of 160 kg of dry matter per tonne of cane stalks [13] in the field was considered, the pyrolysis plant processing 50% of this total potential. The kinetic model developed by [14] was applied in this study. Table 1 presents the main parameters assumed in the simulation.

Table 1. Main parameters of sugarcane straw pyrolysis

Parameter	Value
Sugarcane straw, as received (15% moisture content), t/h	47.1
Sugarcane straw, dried (5% moisture content), t/h	42.1
Pyrolysis reactor temperature, °C	475
Pyrolysis reactor pressure, bar	1.5
Residence time, s	20
Fluidising gas and biomass ratio, (mass/mass)	0.5
Outlet temperature in first condenser, °C	75
Outlet temperature in second condenser, °C	25

3.2. Bio-oil upgrading plant

The bio-oil upgrading plant was simulated in the Aspen Plus software, according to the procedure presented in [6]. The composition of the bio-oil obtained in the fast pyrolysis simulation was adjusted in order to take into account the same components considered by Peters [6]; in addition, the Pen-Robinson with Boston-Mathias modification (PR-BM) method was selected [15], [16].

3.2.1. Hydrotreating section

In the hydrotreating section, the crude bio-oil from the pyrolysis process is upgraded in a two-stage catalytic hydrotreatment to almost oxygen-free hydrocarbon. Seeing as hydrotreating reactors were modelled as RYield blocks in the Aspen Plus software, the composition of reactor products were a necessary input. Since

there is not detailed information regarding the composition of hydrotreating reactors products from sugarcane straw, the composition presented by [6], who evaluated hybrid poplar wood chips, was taken as a reference. These values are based on a typical bio-oil hydrotreatment with Co-Mo catalyst, based on the literature [11]. In this way, taking into account these data and the specific bio-oil composition obtained in the pyrolysis simulation, a mass balance procedure was performed in MS Excel for each element present in the bio-oil, using proportionality factors, aiming at following a similar product distribution.

Table 2 presents the main parameters assumed in the modelling of the Hydrotreating section.

Table 2. Main parameters in the Hydrotreating section

Parameter	Value
Outlet pressure – pump B1, bar	170
Outlet pressure – compressor COMP-1, bar	170
Number of stages – compressor COMP-1	2
Outlet temperature – HE1, °C	100
Outlet temperature – HE2, °C	250
Operating pressure – hydrotreating reactor HT-R1, bar	170
Operating temperature – hydrotreating reactor HT-R1, °C	250
Outlet temperature – HE3, °C	370
Operating pressure – hydrotreating reactor HT-R2, bar	140
Operating temperature – hydrotreating reactor HT-R2, °C	370
Outlet temperature – COOL-1, °C	35
Operating pressure – FLASH-1, bar	35
Heat duty – FLASH-1, kW	0
Hydrogen consumption in hydrotreating section, kg H_2/kg bio-oil	0.09

3.2.2. Distillation and Hydrocracking section

Distillation columns were modelled as RadFrac blocks in the Aspen Plus software, while a stoichiometric block represented the hydrocracking reactor, and the reactions assumed thereof were adopted from [6]. In Table 3, the main parameters assumed in this stage for the modelling in the Aspen Plus software are presented.

Table 3. Main parameters for distillation and hydrocracking

Parameter	Value
Operating pressure in FLASH-2, bar	20
Outlet temperature in HE4, °C	212
Number of stages in C-DIST1	8
Reflux ratio (mass basis) in C-DIST1	1.2
Distillate to feed ratio (mass basis) in C-DIST1	0.48
Operating pressure in C-DIST1 (stage 1), bar	2.5
Condenser temperature[(a)], C-DIST1, °C	32
Number of stages in C-DIST2	7
Reflux ratio (mass basis) in C-DIST2	1.2
Distillate to feed ratio (mass basis) in C-DIST2	0.85
Operating pressure in C-DIST2 (stage 1), bar	0.01
Outlet pressure in pump B2, bar	90
Operating temperature in the hydrocracking reactor, °C	430
Operating pressure in the hydrocracking reactor, bar	90
Outlet pressure in valve V3, bar	36
Outlet temperature in HE6, °C	32
Hydrogen consumption in the hydrocracking section, kg H_2/kg bio-oil	0.0032

[(a)]C-DIST1 was assumed with a partial condenser, while in C-DIST2 there is a total condenser

3.3. Hydrogen production plant

The PSA systems (PSA I and II) were modelled as separators. Regarding the steam reforming assumed in this simulation, the reforming reactor considered a conventional nickel catalyst, as it is widely used in this type of reactors, and was modelled as a RGibbs reactor type in the Aspen Plus software, while a REquil type reactor was used in the modelling of the WGS reactor. The reactions within the WGS reactor were limited to the WGS reaction ($H_2O+CO<-->CO_2+H_2$), according to [6]. The temperature approach in the WGS reactor was adjusted in order to achieve a CO conversion in the range of 75%. The combustor COMB was modelled as a RGibbs reactor type as well. The mass flow of combustion air (AIR stream) was adjusted to achieve a temperature of 1500°C at the outlet of COMB, while the split fraction of stream SR2O-IN in the bifurcation BIF2, which determines the amount of liquid condensate recycled to the reforming reactor, was adjusted to achieve a Steam to Carbon ratio (S/C) of 4.5 (mol basis). The split fraction of the FLSHGAS stream specified in the bifurcation 1 (BIF1), which determines the mass flow of FLSHGAS destined for the reforming reactor, was determined from the energy balance. Thus, it was adjusted aiming at calculating the heat duty in HE12 to meet the required heat duty in SR-REACT, maintaining a ΔT_{min} of 30°C. Table 4 presents the main parameters assumed in the simulation of the hydrogen production plant. The composition of the desulphurised biogas was assumed as 35.4% CO_2 and 64.4% CH_4 (molar basis) [17], while the composition of the external natural gas was assumed as 3.5% CO2 and 96.5% CH4 (molar basis).

Table 4. Main parameters for the hydrogen production plant

Parameter	Value
Outlet pressure, valve V4, bar	2.3
Outlet pressure, compressor COMP-3, bar	50
Outlet pressure, pump B8, bar	50
Outlet temperature, HE7, °C	259.9
Outlet temperature, HE8, °C	500
Operating pressure, SR-REACT, bar	49
Operating temperature, SR-REACT, °C	950
Outlet temperature, HE9, °C	310
Operating temperature, WGS reactor, °C	350
Operating pressure, WGS reactor, bar	48
Outlet temperature, HE10, °C	77
Operating pressure FLASH-3, bar	46
H_2 recovery in PSA system, %	90
Outlet pressure, compressors COMP-4 and COMP-5, bar	2.2
Outlet temperature, HE11, °C	300
Operating pressure, COMB, bar	1.01325
Heat duty, COMB, kW	0

3.4. Integration into the conventional ethanol and sugar production process

The heat integration was accomplished according to the Pinch method [18], performing the following steps: data extraction from the evaluated processes, composite curves construction, evaluation of steam generation, and integration of the cogeneration system, which meets the heat and power demands of the processes.

4. Results

4.1. Bio-oil composition

Figure 5 shows the main components of bio-oil produced in the fast pyrolysis of sugarcane straw. The amount of sugar derived, which includes levoglucosan, hydroxyimethylfurfural, xilan and intermediate compounds derived from cellulose and hemicellulose represents almost 50% of the amount of bio-oil. This can be explained because the assumed kinetic model for fast pyrolysis only assumed primary reactions. In second place, the water content reaches 17.8%, followed by the aldehydes with 15.5%, which include

acetaldehyde, glyceraldehyde, formaldehyde, glyoxal, furfural, and acrolein. This composition presents a slightly divergence from the experimental data presented by [6] for bio-oil obtained from fast pyrolysis of pine wood, which contains sugar derived 33%, water 24%, and aldehydes and ketones 21%. Nevertheless, further research is needed in order to try taking into account secondary reactions.

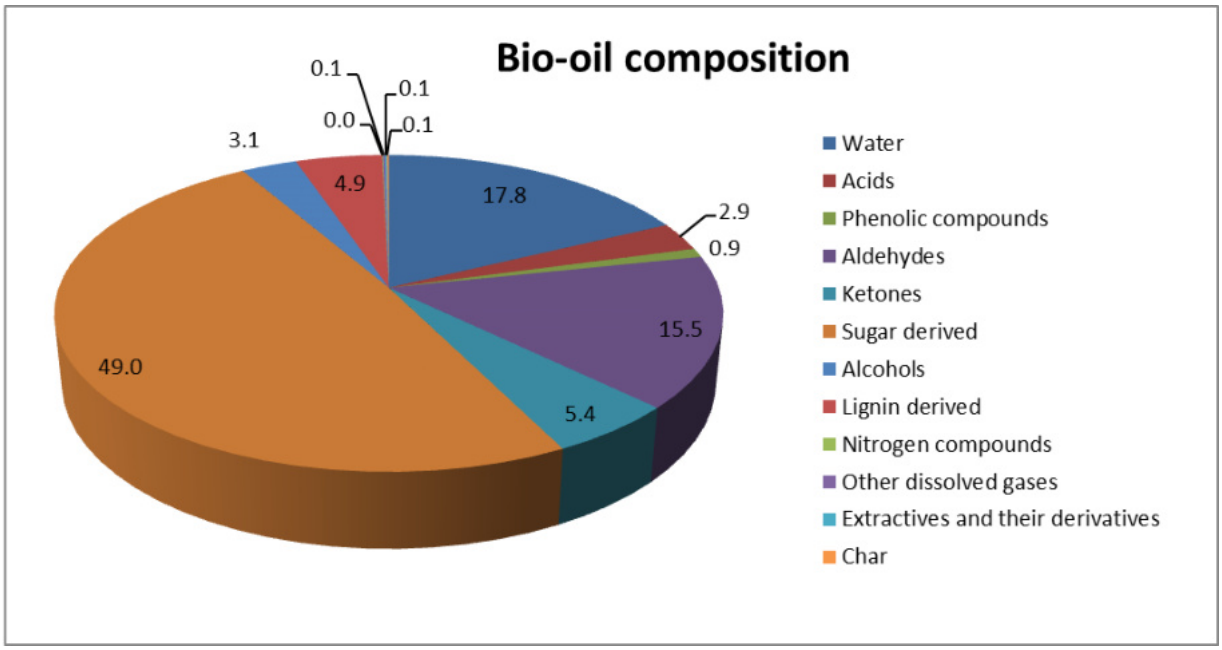

Figure. 5. Main compounds in bio-oil produced from fast pyrolysis

4.2 Bio-oil upgrading plant

This section presents the results of the bio-oil upgrading plant simulation. Table 5 presents the main results of this analysis.

Table 5. Main results of the hydrotreatment, and distillation and hydrocracking sections

Parameter	Value
Hydrotreatment	
Bio-oil production in fast pyrolysis plant[a], t/h	21.1
Hydrogen consumption in hydrotreatment, t/h	1.8
Water content at the outlet of HT1 reactor (mass basis), %	36.3
Water content at the outlet of HT2 reactor (mass basis), %	49.4
Organic phase stream (HTORGANIC) at the vapour outlet of FALSH-1, t/h	11.49
Water content in HTORGANIC stream (mass basis), %	0.1
Aqueous phase stream (HTAQUEOUS) at the liquid outlet of FLASH-1, t/h	11.43
Water content in HTAQUEOUS (mass basis), %	99.05
Power consumption in hydrotreatment section, kW	3,310.9
Distillation and hydrocracking	
Vapour product of FLASH-2 (FLSHGAS stream), t/h	5.11
Hydrogen content in FLSHGAS stream (mass basis), %	22.37
Hydrogen recovery in H2-RECY stream[b], t/h	0.97
Hydrogen consumption in Hydrocracking, t/h	0.28
Renewable gasoline (GSLN-1 stream)[d], t/h	3.45
Renewable diesel (DISEL-1 stream)[e], t/h	3.2
Power consumption in distillation and hydrocracking section, kW	125.4

[a]17.8% of moisture content; [b]85% of H_2 recovery in PSA system; [c]LHV at 15°C 34.4 MJ/kg; [d]LHV at 15°C 44.3MJ/kg; [e]LHV at 15°C 33.5MJ/kg

It can be observed, in Table 5, that the power consumption in the Hydrotreatment section resulted significantly higher in comparison to the Distillation and Hydrocracking section, because of the high power consumption in the hydrogen compressor COMP-1 (3.18 MW). The final products of the bio-oil upgrading plant showed a yield of 0.086 and 0.080 kg/kg of dry straw for renewable gasoline and diesel, respectively. The reboiler temperatures of columns C-DIST1 and C-DIST2 resulted 283.3°C and 254.6°C, respectively, these operating conditions being important for evaluating the heat requirements and heat integration opportunities. Regarding the hydrogen production, section Table 6 presents the main results.

Table 6. Main results of the hydrogen production process

Parameter	Value
External consumption of natural gas, (or biomethane)[a,b], kg/h	1232.7
Desulphurised biogas consumption[c,d,e], kg/h	2325.1
Water consumption in reforming process, t/h	18.1
Recirculation rate of SRH2OIN stream[f], %	55.9
Condensate sent to waste water treatment system (SRLIQOUT stream), t/h	5.4

Power consumption in hydrogen production process, kW	2,884.7

[a]96.5% of CH_4 (mol basis); [b]equivalent to 72.4 kmol/h; [c]produced from anaerobic digestion of vinasse; [d]64.4% of CH_4 (mol basis); [e]equivalent to 89.46 kmol/h; [f]split fraction of condensate recycled to reforming process specified in bifurcation BIF2; [g]split fraction of FLSHGAS specified in bifurcation BIF1; [h]Fraction of FLSHGAS3 stream; [i]LHV at 15°C of 34.4MJ/kg; [j]LHV at 15°C, 3.84 MJ/kg; [k]LHV at 15°C, 32.9MJ/kg

4.3 Heat integration results

Stream data adopted for heat integration is presented in Tables A1 and A2 of Appendix A, for the Hydrotreatment coupled with Distillation and Hydrocracking processes, and the hydrogen production process. Simulation results showed that the hydrotreating and the hydrocracking reactors are exothermic. In order to make use of this thermal energy, it was assumed that heat released from exothermic reactors is used to heat thermal oil that can be used as hot utility. Thus, these streams of thermal oil were taking into account for Composite Curves (CCs) and Grand Composite Curves (GCCs) construction. Because of the large amount of gaseous streams in the processes, the contribution to the ΔT_{min} was assumed to be 15°C for almost all streams. Process streams with phase change were divided into ranges in order to properly consider the available heat at different temperature levels. Figure 6a presents the GCC for the Hydrotreatment coupled with Distillation and Hydrocracking processes, while the GCC for the hydrogen production process is presented in Figure 6b.

According to Fig. 6a, the target of minimum hot utility consumption above the Pinch resulted in 1328.34 kW, thus, combustion gases with an adiabatic flame temperature of 1500°C were assumed as hot utility to meet this energy requirement using part of FLASHGAS as fuel. Considering that combustion gases are cooled till the Pinch temperature of 320°C, the fuel consumption resulted in 0.0486 kg/s (0.18 t/h) (mass flow of FLSHGAS2 stream in Fig.4).

On the other hand, both GCCs present available heat below the Pinch temperature that can be used to produce steam for the ethanol and sugar production process. The red lines in Figures 6a and 6b show these potentials. Since in Fig. 6a there is heat available at lower temperatures (below to 300°C), in comparison to Fig. 6b, the production of saturated steam at 2.5 bar (127.4°C) from available heat of hydrotreating and hydrocracking sections was assumed. On the other hand, the production of superheated steam at 500°C and 65 bar was assumed in Fig. 6b (represented by the red line). The steam mass flow resulted in 17.1 t/h and 20.9 t/h in Figures 6a and 6b, respectively. Moreover, from the superheated steam obtained in Fig. 6b, there is a power production potential of 3655 kW, using a back-pressure steam turbine. Thus, the exhaust steam from the turbine can be used to meet heat demands in the sugar and ethanol production process.

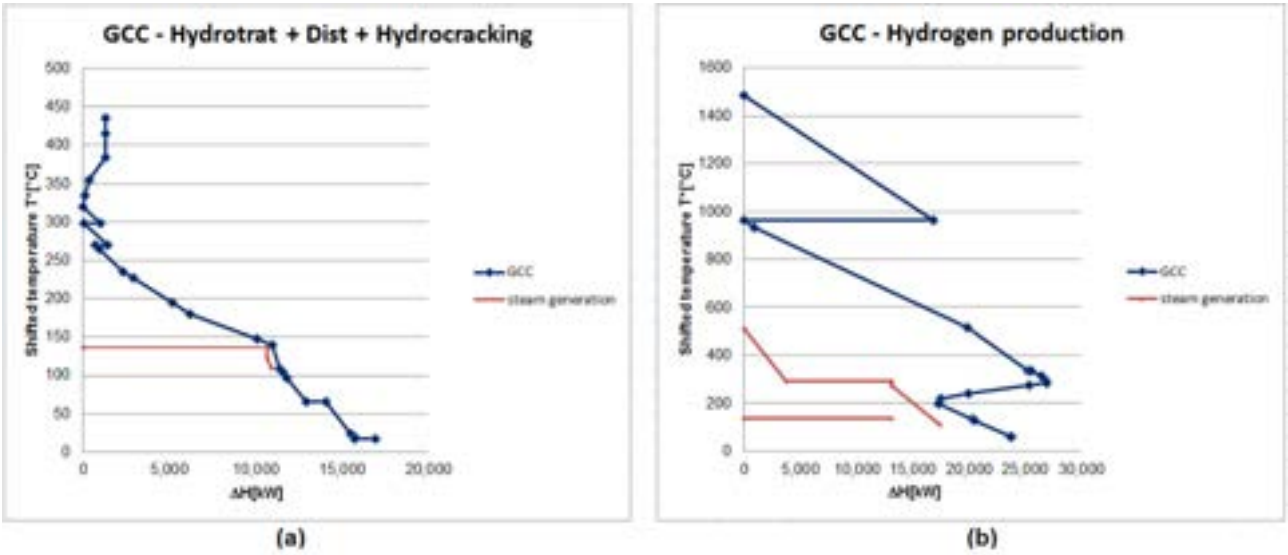

Figure. 6. Grand Composite Curves (GCC) for (a) the Hydrotreatment with Distillation and Hydrocracking processes, and (b) the hydrogen production process

Finally, Table 7 presents the impacts on the cogeneration system; detailed impacts regarding pyrolysis plant integration can be found in [19].

Table 7. Impacts on the cogeneration system

Description	Base Case	Integrated process
Steam consumption in cogeneration system, t/h	214.8	153.4
Steam produced in pyrolysis process, t/h	0	23.4
Steam produced in upgrading plant, t/h	0	38.0
Power consumption in pyrolysis process, kW	0	3,448.3
Power consumption in upgrading plant, kW	0	6,321.0
Power production in pyrolysis process, kW	0	2279
Power production in H_2 production process, kW	0	3655
Surplus electricity, kW	40,600.0	43,060.7

5. Conclusions

The modelling and simulation of a bio-oil upgrading plant was performed in this study; moreover, the integration of an upgrading plant into the sugar and ethanol production process was evaluated including the impacts on the cogeneration system. Bio-oil upgrading through hydrotreatment requires high amounts of hydrogen (4.16 kg of H_2/t cane for 50% of straw recovery from the field), and in this initial assessment, the steam reforming was assumed for H_2 production, taking the biogas produced from the anaerobic digestion of vinasse as feedstock. Nevertheless, from the hypotheses assumed (availability of vinasse in a plant that uses 50% of recoverable sugars in ethanol production), an additional methane source was necessary to complete the required H_2 production (2.47 kg/t cane of biomethane 96.5% mol). Regarding the energy assessment, the pyrolysis process, as well as the hydrotreating and hydrogen production process, presented a significant potential for steam production (28.6% of total steam consumption in the conventional mill), that can be integrated into the conventional sugar and ethanol production process. This could allow the reduction of process steam extraction in the cogeneration system of the conventional plant that operates with sugarcane bagasse as fuel. Thus, the electric energy production in the cycle that operates with condensing-extraction steam turbines would increase. After the power balance, it is possible to achieve a 6% increase in surplus electricity.

Abstract:

This work targets sustainable livestock farming, with the aid of cost-effective, novel renewable energy sources (RESs). A literature review showed that evaluating the energy consumption in the livestock sector is not straightforward. Therefore, a model was made to estimate the heating and cooling demands of a pig farm throughout the year. Various combinations of RES technologies are compared with respect to the current installation and an economic and ecological assessment is performed. The possible technologies are: PV panels, PVT panels, solar collectors, heat pumps, wind energy and batteries (both thermal and electrical). The assessment allows estimating the investment cost, life-cycle cost (LCC) and greenhouse gas (GHG) emissions from energy usage of different selections and sizes of renewable technologies. The boundary conditions for the studies are taken from an actual pig farm in Belgium. Autonomous energy creation with solar energy and/or wind generation in combination with a heat pump proves to be the most promising solution to reduce GHG emissions according to the model. The model and results will be evaluated with actual performance data by means of installing heat pumps, PVT panels and thermal storage at the pig farm.

Keywords:

Renewable energy, livestock, pig farm, energy optimization, economical assessment, prediction model

1. Introduction

According to Paris et al. [1], the livestock sector is one of the main energy consumers in the European Union (EU). A large part of this energy is still provided by fuel oils and natural gas. The goal of RES4LIVE[1], a project that received funding from the European Union's Horizon 2020 research and innovation program (grant agreement No 101000785), is to defossilize the livestock industry by researching the implementation of optimized designs and combinations of RES. Looking at the energy needs of different farms, an optimal solution based on investment cost, life-cycle cost (LCC) and greenhouse gas (GHG) emissions should be calculated. In the current work, the model developed for this purpose is explained and some initial results are presented.

The goal of Section 2. is to frame the energy consumption of livestock in the EU and Flanders (a region in Belgium). In 2021, a survey was held in Flanders about energy consumption in pig farming whose results can be found at the end of the section. In Section 3., the calculation model (made in Python) is explained as well as its application to a pig farm in Belgium called the 'Varkenscampus', together with the corresponding sensitivity analysis. At the end, some remarks about future work are presented.

2. Energy consumption in livestock

Even though the livestock sector is claimed to be one of the main energy consumers in the EU by Paris et al. [1], there is no standardized methodology to measure the energy usage in livestock. At the moment, the livestock's energy consumption pattern is derived from literature reviews or by performing analyses in a local environment. There is no detailed database available yet. In this section, the currently known energy usage in the livestock sector is discussed on three different levels. First, a literature review is performed to frame the energy consumption in livestock across the EU. Secondly, a biennial study performed by the Department of Agriculture and Fisheries about agriculture in Flanders (Belgium) is discussed. Thirdly, a recent survey was launched whose results are reported in this work.

2.1. Energy consumption in livestock across the EU

In Paris et al. [1], a literature review was conducted by the Agricultural University of Athens that gathered some papers on the subject. The review summarizes several direct and indirect energy uses from several livestock

[1] res4live.eu/

farms including dairy cattle, beef cattle, pigs, laying hens and broilers. Direct energy covers all energy used on the farm, while indirect energy refers to all outside usage, e.g. feed processing. To be able to equally compare energy consumption across all types of livestock farms, it is scaled per amount of end product produced by the farm. For all livestock categories, this is done per kg produced meat or eggs, except for milk production. To obtain similar values for milk, a unit is needed that takes into account the extra fat and protein production. The energy corrected milk production (ECM), expressed in kg, is the unit that fulfills this purpose. The total energy consumption can be roughly estimated by taking the mean of the results reported by Paris et al. [1] and multiplying these with the total production in Europe. This is done to obtain the total energy usage mentioned in Table 1.

Table 1: Estimation of the total energy consumption of different livestock farms across Europe in one year according to Paris et al. [1], the † indicates a number that could not be retrieved from Paris et al. [1] and was extracted from the Eurostat database [2] instead, with the mean weight of an egg assumed to be 60g.

Livestock type	Total production in the EU [10^9 kg]	Avg. energy per kg production [MJ/kg]	Total energy usage in the EU [10^{10} MJ]	Direct energy [%]
Dairy cattle	158	3.7	58	15-48
Beef cattle	7.9	49.9	39	60-70
Pork	23.8	19.3	46	20
Poultry meat	15.29	14.36	22	25
Laying hens	4.35 †	22	9.6	25-46

From the results reported by Paris et al. [1], it can also be concluded that the main contributor to energy consumption is the feed (indirect). In this paper however, the focus lies on the direct energy consumption. The percentage of direct energy consumption is indicated in Table 1. Although it is not as large as the contribution of the feed, it is still significant, especially in laying hens and beef production. A large share of this on-farm energy consumption is still produced by fossil fuels. Other energy sources are the electricity grid (still lacking green sources in many countries) and natural gas. By converting this direct energy consumption to renewable energy sources (RESs), a noteworthy improvement can be made in the climate impact of livestock.

2.2. Energy consumption in livestock across Flanders (Belgium)

In Flanders, the Department of Agriculture and Fisheries publishes an exhaustive report every two years about all agricultural related activities. Their most recent report [3] was written in 2017, but biannual updates can be consulted at [4]. In Fig. 1, a brief summary of the results concerning energy consumption in livestock is given. Pork, dairy and beef take up about 20% of the total energy consumption in Flanders. Poultry has been left out of this discussion due to insufficient data available.

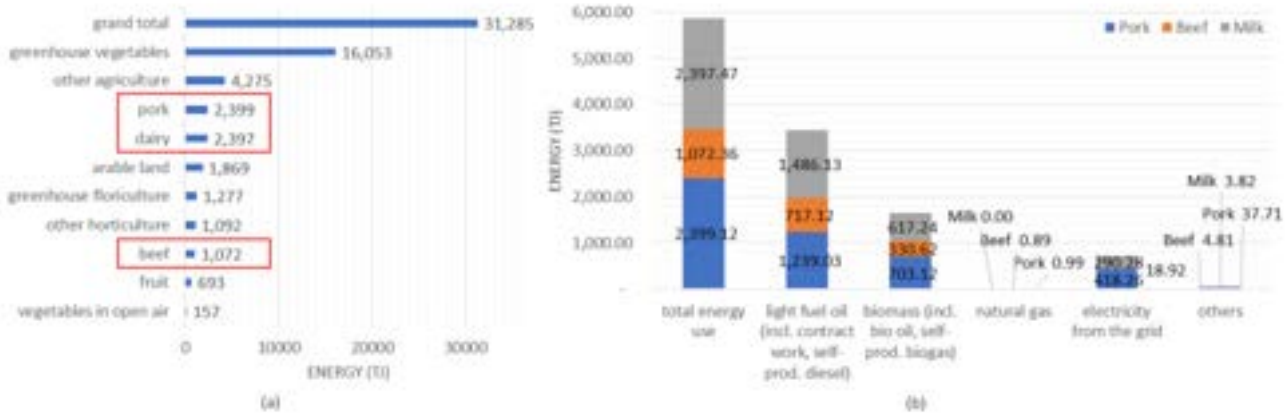

Figure 1: Results adapted from the Department of Agriculture and Fisheries [4] about (a) the energy consumption of agriculture in Flanders per sector with livestock indicated by red rectangles and (b) the energy consumption in livestock per carrier, poultry is not mentioned in this data since there is no detailed data available yet.

As can be seen in Fig. 1b, most energy comes from light fuel oils, such as gasoline and diesel fuel. The main consumers of these fuel oils are tractors for tillage. Another purpose is additional heating during winter by

e.g. heat canons. The latter is mostly for pigs, since cows do not need as much heat. Runner up is biomass, which shows that Flemish farmers have been making efforts in using cleaner energy. The energy balance [4] reported by the Department of Agriculture and Fisheries over the past 10 years, shows a rise of about 10 000 TJ in biomass energy generation across all agriculture. The biggest consumer of natural gas in Flanders is the pig industry. This phenomena can be attributed to the use of hot water systems for floor heating, providing the high heating needs for piglets, and sanitary hot water, used for cleaning and showers. According to Paris et al. [1], electricity from the grid is mainly used for ventilation, present in all livestock farms; heat lamps, appearing mostly in pig farms; and milk cooling for dairy cattle. Beef cattle requires the least amount of electricity. The Department of Agriculture and Fisheries [4] shows that during the last 10 years, the latter sector even produced a net amount of electricity by installing photovoltaic (PV) panels on their large roofs. Other energy sources are thus mainly solar panels, but can also be small wind turbines, heat pumps etc.

2.3. Energy survey in pig farming across Flanders

In 2021, a survey was launched by Flanders Research Institute for Agriculture, Fisheries and Food (ILVO) for Flemish pig farmers. This survey was meant to probe their current energy installations. There were 38 correspondents composed of 25 farrow-to-finish (farmers that have a sow herd to breed piglets and rear these from birth to slaughter - so the entire life-cycle of the pig), 11 fattening pig farmers (farmers that buy piglets and rear them until slaughter) and 2 sow farmers (farmers that have a sow herd to breed piglets and sell these piglets). In this subsection, the results are presented. Initially, the heating system of the participants' farms was asked. Heating is the main energy consumer in pig farming, since newborn piglets need a high temperature of about 35°C. In intensive pig farms, it is not unusual to have new piglets every three weeks meaning this high temperature demand is often required. Therefore, knowing the heating system offers valuable information about the energy consumption of the farm. The results about current installations can be found in Fig. 2. Most of the pig farmers still use fuel oil to heat up their farms. This result is in line with the literature review performed by Paris et al. [1]. It indicates that improvement is still possible in many farms. Almost all participants already took measures to reduce their energy consumption, especially on electricity.

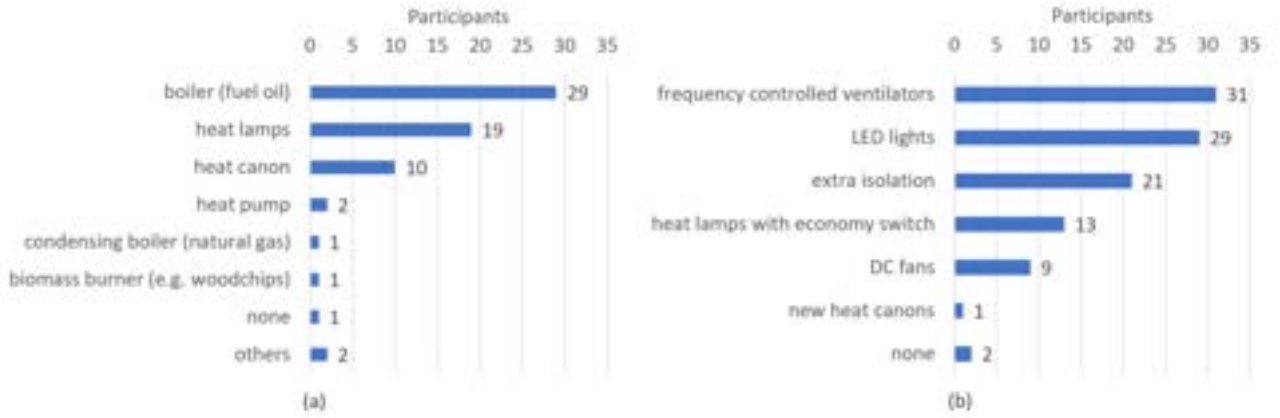

Figure 2: Survey results about energy consumption in pig farming with the horizontal axes representing the amount of participants (38 in total): (a) presents the currently installed heating systems on the participants farms and (b) which measures they already took to reduce their energy consumption.

In the next part of the survey, the participant's motivation about switching to renewable energy sources was questioned. All participants were asked to rate the importance of a project on introducing renewable energy in pig farming on a 5-point scale. The results of the survey were that 76.3% of participating pig farmers scores this type of project with an importance of 4 or 5 out of 5. Of the respondents, 92.1% thinks more energy saving measures are possible on their farm and 76.3% already owns a renewable energy source. These numbers conclude that switching to renewable energy is deemed important among pig farmers. Most of the farmers already made some efforts, but still think more energy saving measures are possible on their farms. This can also be concluded from the results in Fig. 3, in which their encountered difficulties were questioned. Lack of investment budget and insufficient knowledge about the needed capacity, system requirements and current legislation are the main obstacles for farmers.

From this section, it can be concluded that livestock in general has a high energy demand and a lot of improvement can still be made to convert to clean energy. In the residential and industrial sector, many optimized and adapted RESs are already present. The goal of this work is to evaluate these solutions for the livestock sector. A generally applicable calculation tool was created to optimize the combination and design of RESs

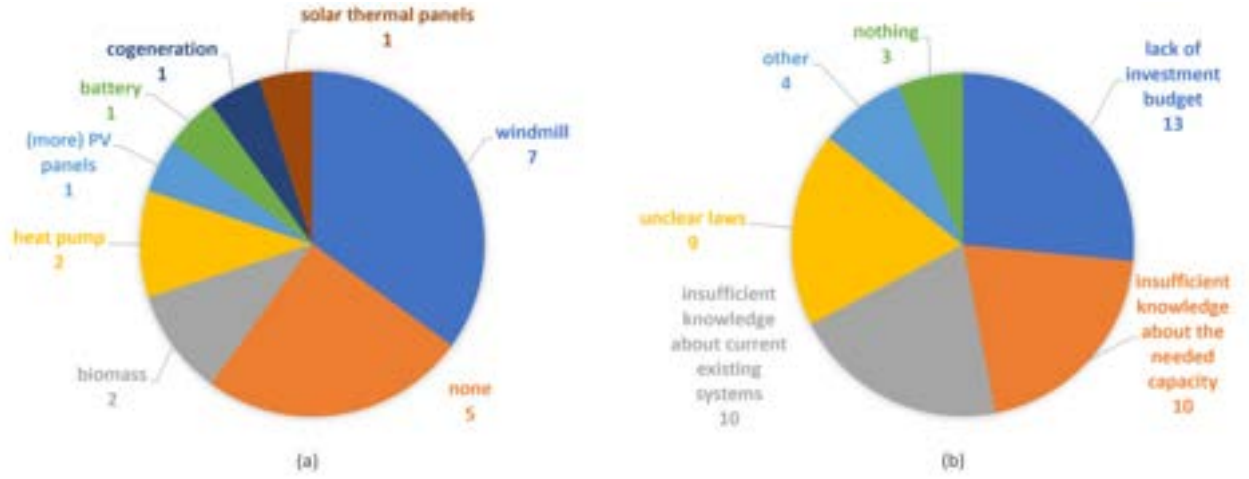

Figure 3: Survey results about energy consumption among pig farmers (38 participants): (a) which RESs the participants are considering and (b) the barriers they encounter to install (more) RESs.

for farm-specific cases. In the next part of this paper, the simulation methodology is explained and applied to a pig farm in Belgium, called the 'Varkenscampus'. The calculated parameters are investment cost, LCC and GHG emissions. Such a tool could fill the gap of insufficient knowledge about system requirements and needed capacities of RESs by livestock holders.

3. Calculation tool

A calculation tool was made in Python to find optimal combinations of RESs that are fine-tuned to the specific energy demands of livestock farms. A first version was made by Faes [5]. This paper expands further upon this tool and tests its sensitivity to several parameters. The calculation is based on the Varkenscampus, located in Melle (Belgium). This is a commercial farrow-to-finish pig farm with a maximum capacity of 136 sows, 576 piglets, 640 fattening pigs, 12 young sows and 2 boars. This puts the Varkenscampus into the category of a small to medium pork producer. Currently, the energy demand of the farm is provided by a connection to the grid and a condensing natural gas boiler. The electricity is mainly used for ventilation and heat lamps, while the condensing boiler provides hot water for floor heating, air heating and sanitary hot water. The tool takes into account past energy consumption patterns and satisfies this demand with predefined combinations of RESs. Subsequently, the investment cost, LCC and GHG emissions can be calculated for every combination. Finally, the optimal combinations are found by using Pareto optimization.

3.1. Explanation of the tool

The Python tool consists of multiple parts, each of which is explained below. The starting point is the construction of an hourly energy demand of the farm. These energy requirements must always be met, otherwise there would be discomfort for the animals. A reference case is obtained by implementing parameters of the current (existing) condensing gas boiler. Finally, the calculated output parameters of all the possible installations are scaled to this reference case.

3.1.1. Estimation of the energy demand

An hourly energy demand is required as input for the tool. To achieve this, the energy demand is separated into two flows: the electricity demand and the heat demand.

Electricity demand

The electricity demand profile of the farm is constructed based on monthly measurements at the Varkenscampus. The monthly usage was averaged out to obtain an hourly mean value. The total electricity demand of the farm in the year 2020 was 107 MWh.

Heat demand

The calculation of the heat demand is less straightforward since it cannot be measured directly and many factors need to be taken into account. These factors, among other things, consist of:

- The farm's building materials and isolation.
- The amount of pigs per compartment and their heat production.
- The complete heating system (sanitary hot water, air heating, floor heating etc.).
- The required heating and/or cooling for the pigs.
- Ventilation and relative humidity at which the pigs feel comfortable.

- The weather conditions outside.

In 2021, the calculations were performed by De Win [6] and eventually adjusted by Faes [7]. They created a steady-state model, which calculates the heat flow in and out of the barn. Documentation of the barn's building process provided the necessary information on the building's properties. From a literature study [8], the heat production and comfort requirements of pigs can be found. Subsequently, the hourly heating/cooling demands for air and underfloor heating can be estimated. This is done per compartment to take into account the occupation rate, age of the pigs and existing heating system. For example, some compartments have no air heating installed, while other ones require both air and floor heating. Different compartments will also have different ages of pigs at any time, which effects the heat production and comfort needs in that compartment at that moment.

In the end, two separate hourly heat demands were obtained: one for the high temperature water cycle (60°C) used for air heating (twin tubes), and one for the low temperature water cycle (40°C) used for floor heating. The high temperature heat demand is calculated by taking the required heat demand of every zone. It takes into account all of the above-mentioned factors. The low temperature heat demand is calculated with the characteristics of the heating mats in combination with the weekly occupation rate of newborn piglets of the farm in 2020. When piglets are present and they are younger than 4 days, the 16 available heating mats (each able to deliver 180W) are put at full power. When the piglets have the age of 4 to 7 days, the mats are put at half their power. In 2020, new piglets were born every 21 days. Consequently, the low temperature heat demand follows a periodic cycle of 21 days with 3 separate values per zone depending on the age of the piglets. In the end, the calculated heat demand in 2020 is about 212 MWh corresponding to an estimated consumption of 20,000 m^3 natural gas.

3.1.2. Selection of RES

In a next step, the model adds a selected combination of RESs to the current installation. These combinations are shown in Table 2. The currently installed natural gas boiler is included in the first row and taken as the reference point. The selection is made by taking the size of the Varkenscampus into account. As can be seen, the heat pump options are chosen in pairs indicated by a pair of brackets. Considering the two different heat demand profiles, it is more efficient to have two separate heat pumps with one operating continuously than one of a bigger size operating in on/off mode [6]. Running over every possible combination results in 123,480 possible scenarios, however not every scenario is sensible. Batteries are useless without an autonomous source of electricity and are therefore left out of the calculation if no such source is present in the scenario.

Table 2: Selection of energy systems to be calculated by the model, the square brackets are used to indicate a pair of heat pumps in the configuration, with first the high temperature heat pump (60℃), and second the low temperature heat pump (40℃).

Energy system	Unit	Options
natural gas boiler	kW	60
PV panels	m^2	$0 - 10 - 50 - 100 - 500 - 1000$
ST panels	m^2	$0 - 10 - 50 - 100 - 500 - 1000$
PVT panels	m^2	$0 - 10 - 50 - 100 - 500 - 1000$
heat pump(s)	kW	$0 - [60, 0] - [55, 15] - [30, 30]$
electrical battery	kWh	$0 - 2 - 5 - 10 - 100$
thermal storage (water)	liter	$0 - 250 - 800 - 1000 - 2500 - 3000$
wind turbines	kW	$0 - 15 - 30$

For every scenario, a steady-state model for the energy flow over a period of one year is performed. Besides the electricity and heat demand of the barn (see 3.1.1.) and the sizing of possible RESs combinations (Table 2), several other input parameters are needed. These include set parameters related to the steady-state model and weather parameters describing the boundary conditions of the RES (Table 3). The latter consists of the local solar irradiance (q_{sun} in W/m^2) and the wind velocity (v_{wind} in m/s). At the Varkenscampus, a weather station is installed that measures these at an hourly basis.

The RESs' hourly energy generating functions depending on the measured weather conditions are described by Eq. (1) to Eq. (5). Eq. (1) calculates the power P [W] generated by a surface size A [m^2] of PV panels. The model uses PV panels that generate 1 kWp per 7 m^2.

$$P_{PV} = q_{sun} \frac{A_{PV}}{7} \tag{1}$$

Table 3: Chosen parameters to create the steady-state model.

Parameter	Value
time step	1 hour
simulated period	1 year
boiler efficiency	95%
low temperature heating	40 °C
high temperature heating	60 °C
low temperature nominal COP	5
high temperature nominal COP	3.5
COP nominal temperature	17 °C
initial battery charge	0 kWh
initial thermal storage temperature	40 °C
maximal thermal storage temperature	90 °C

Eq. (2) describes the heat Q [W] generating profile of solar thermal (ST) panels. These panels generate 4 times the solar irradiance per surface size of 7 m^2, which results in an energy production of 500 $kWh/m^2/year$.

$$Q_{ST} = q_{sun}\ 4\ \frac{A_{ST}}{7} \tag{2}$$

For practical reasons, the generating profile of the photovoltaic thermal (PVT) panels is seen as a hybrid between PV and ST panels, relatively described by Eq. (3) and Eq. (4). They generate 80% of the electricity that PV panels would generate and 70% of the heat generated by the ST panels.

$$P_{PVT} = 0.8\ q_{sun} \frac{A_{PVT}}{7} \tag{3}$$

$$Q_{PVT} = 0.7\ q_{sun}\ 4\ \frac{A_{ST}}{7} \tag{4}$$

Finally the electricity generated by n small wind turbines with each a power P_{unit} of 15kW is given by Eq. (5). The measured wind speed at a height of 10m is multiplied by a factor 1.3 to correct for the height of the wind turbine's blades, which is 15m. The nominal wind speed at which nominal power is reached, is 7.8 m/s.

$$P_{wind} = n\ P_{unit}\ \left(\frac{1.3\ v_{wind}}{7.8\ m/s}\right)^3 \tag{5}$$

3.1.3. Simulation methodology

Starting from the energy demand mentioned in section 3.1.1., the tool tries to satisfy this demand in subsequent order:

1. Fulfill the heat demand by using heat pumps, if any are installed.
2. If PV, ST, PVT panels and/or wind turbines are installed, their energy is used to its full capacity. Without heat pumps installed, their produced energy goes to the heating or electricity systems of the farm. If heat pumps are present, their energy is first provided to the heat pumps. If the energy production exceeds the total demand, the excess is put back onto the grid or lost in case of heat excess. If the heat demand is not fulfilled, electricity is taken from the grid if heat pumps are present, else the condensing gas boiler is used.
3. If storage systems are present, they are filled to their maximum capacity before sending electricity to the grid or losing heat.

Subsequently, an hourly energy balance of all 123,480 scenarios can be calculated.

3.1.4. Cost and emission functions

The energy consumption pattern is now known for every scenario. Next, the parameters necessary to calculate the investment cost, LCC and GHG emissions are introduced in this subsection.

Investment cost

The investment cost is estimated from selling prices of local vendors. The condensing boiler and wind turbine are easiest to define since they exist as one unit. The prices chosen are:

- Condensing gas boiler: €15k (purchase price at Varkenscampus).
- Wind turbine: €60k (estimated from a commercial wind turbine [9]).

The other cost functions depend on the size of the installation. This phenomena can be attributed to the initial installation cost. They are represented by the functions in Fig. 4. To estimate these functions, the prices of several installation sizes were consulted. PV panel prices [10] and ST panel prices [11] were obtained from online sources. Prices of PVT panels are derived from these two and calculated with Eq. (6).

$$\text{PVT} = \text{PV} + \frac{\text{ST}}{2} \tag{6}$$

The heat pump prices were obtained from De Win's dissertation [6]. The prices for thermal storage tanks [12] and batteries [10] were also obtained online.

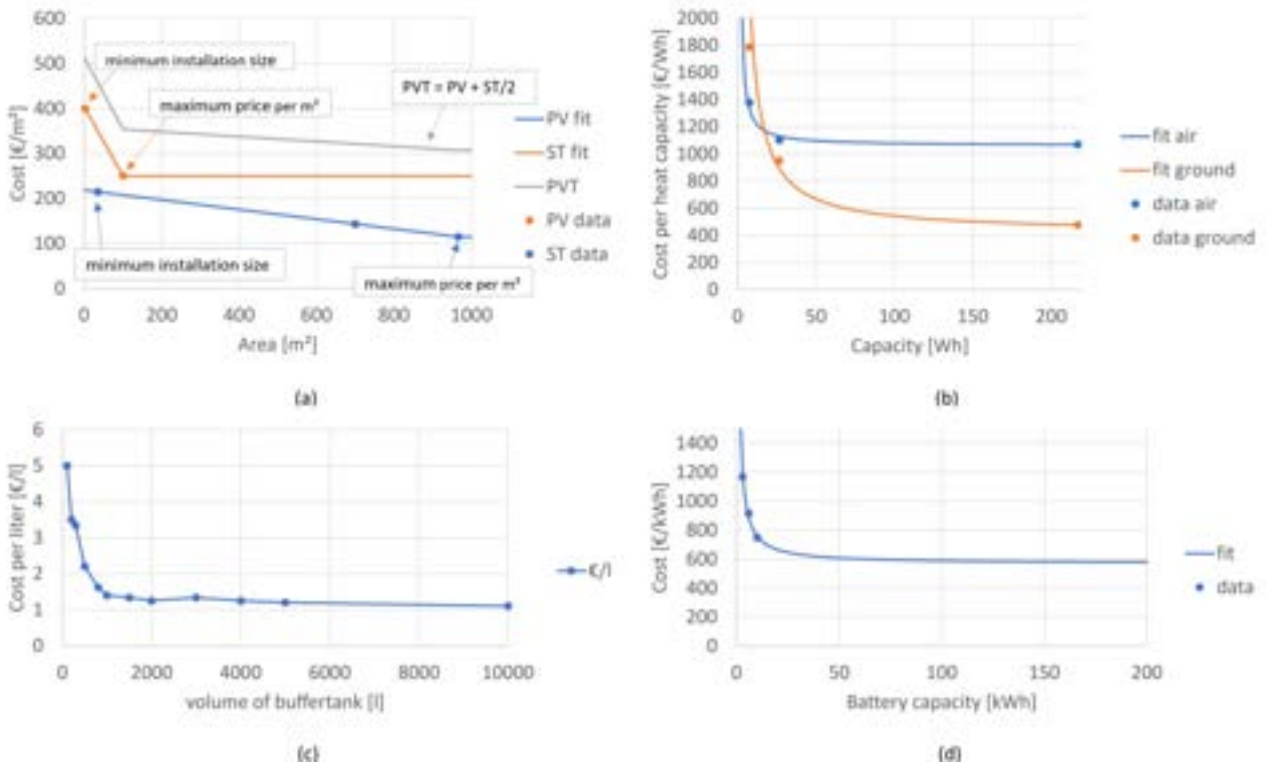

Figure 4: Cost functions of the renewable energy sources with prices depending on the size, the functions are interpolated from local vendor prices with (a) price function of PV panels [10], ST panels [11] and PVT panels according to Eq. 6, (b) heat pump prices [6], (c) prices of thermal storage tanks (water) prices [12] and (d) battery price function [10].

Life-cycle cost

The LCC takes into account the lifetime of the RES and their operational cost. When energy prices are high, it is self explanatory that autonomous energy generation would become more economical in the long run. The LCC is calculated using Eq. (7)

$$LCC = IC_0 + \sum_{i=0}^{n} \frac{EC_i + IC_i}{(1+r)^i} \tag{7}$$

The summation is done over a period of $n = 20$ years. Every year, the operational cost and potential replacement cost of the total combined system is calculated. IC_0 is the initial investment cost, calculated with the cost functions in Fig. 4. This cost reoccurs when the energy system's life is shorter than the 20 years, indicated in the sum by the term IC_i. In Table 4, an overview of the chosen lifetimes is given. Next in line is the operational cost, which is indicated by EC_i. It is calculated by multiplying the current energy tariffs and the yearly energy consumption resulting from the steady-state model. The energy tariffs can be found in Table 5 and were obtained from the VREG (Energy Regulator in Flanders) database [13]. At last, the reduction factor $\frac{1}{(1+r)^i}$ appearing in Eq. (7) represents the reduction in monetary value over the years. The parameter r is the internal rate of return and is chosen to be 6%.

Table 4: Lifetimes for the selected energy systems

Energy system	Lifetime (years)
condensing gas boiler	15
PV panels	25
ST and PVT panels	20
heat pump	20
electrical battery	8
thermal storage tank	20
wind turbine	20

Table 5: Energy tariffs in Flanders in 2022 [13].

Energy source	Cost [€/kWh]
electricity cost	0.5
gas cost	0.2
injection cost	-0.15

Greenhouse gas emissions
Just like the operational cost, the GHG emission is calculated by multiplying the energy demand from the steady-state model with the relevant parameters representing the GHG emissions. This is just a simple estimate without taking into account the GHGs emitted during the creation process of the RESs. For electricity from the grid and natural gas consumption, the equivalent CO_2 per kWh is given in Table 6 and were respectively obtained from the European Environment Agency [14] and Casasso et al. [15].

Table 6: Equivalent CO_2 emissions of the Belgian grid and the consumption of natural gas by a condensing boiler.

Energy source	Effective CO_2 [kg/kWh]
electricity grid	0.20 [14]
gas boiler	0.25 [15]

3.2. Results

In Fig. 5 the results of the calculation are shown. All three parameters are represented in this graph (i.e. investment cost, LCC and GHG emissions). To better investigate the results, an interactive version (in Plotly) was made to observe which RESs are present in a selected scenario.

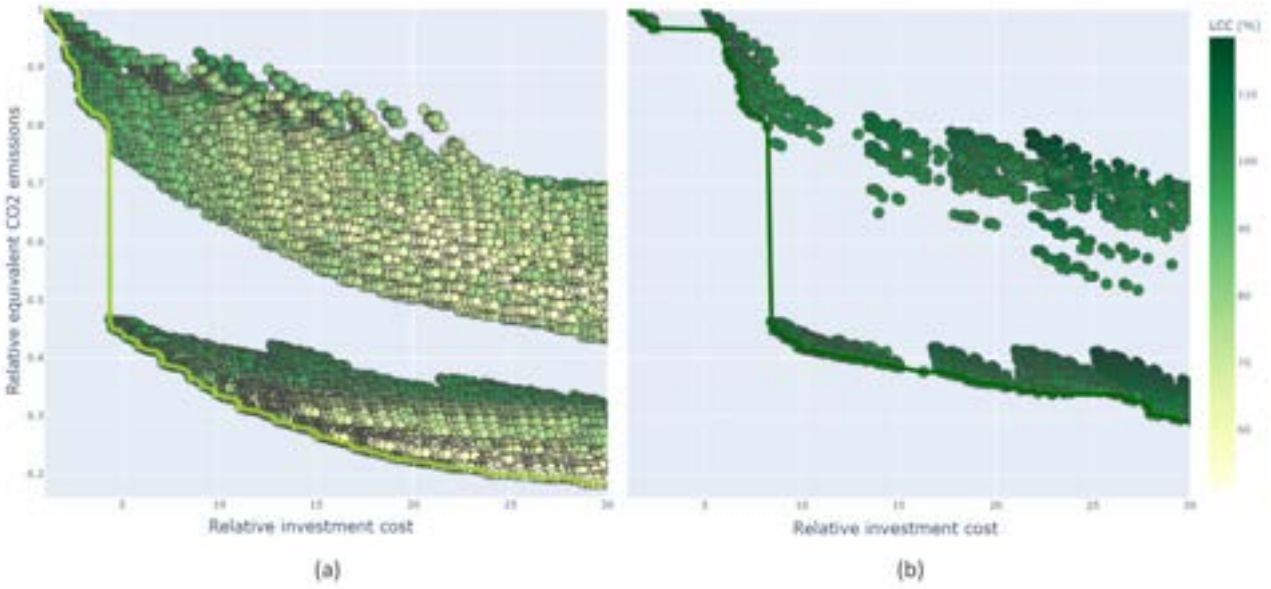

Figure 5: Scatter plots containing all 123,480 combinations from Table 2 with every dot representing a scenario for which the calculation was performed over one year, the results are expressed relative to the current installation which can be found at (1,1,1). In (a) results with a lower LCC compared to the current installation are plotted and in (b) those with a higher LCC, the optimal solutions can be found on the plotted lines (Pareto front).

A first observation is the separation into two clouds. The upper one has the most GHG emissions, but starts at the lowest investment cost compared to the lower cloud (only starting at a relative investment cost of 4 times the original scenario). This is due to a lack of heat pumps in the upper clouds, while the lower cloud

represents all scenarios where heat pumps are present. To find the optimized solutions, the Pareto front was calculated for GHG emissions and investment cost for the selection of results with a lower relative LCC (Fig. 5a) compared to the original installation (in other words LCC $<$ 100%) and with a relatively higher LCC (Fig. 5b). This division was made to take into account the third parameter, since the Pareto front is only calculated with two parameters. The principle is based on Pareto optimality in which two parameters are compared. If one parameter improves, it is imposed onto the other parameter that it cannot degrade. If one parameter improves to the detriment of the other one, the solution is discarded. This results in a front along the minima of both parameters, as can be observed in Fig. 5. By walking down this Pareto front, the optimized combinations can be recognized. For a lower LCC, the order is as follows:

$$PV > ST > PVT > \textit{thermal storage} > \textit{heat pumps} > \textit{electrical battery} > \textit{wind turbine}$$

and for a higher LCC:

$$PV > \textit{electrical battery} > PVT > ST > \textit{thermal storage} > \textit{heat pumps} > \textit{wind turbine.}$$

For clarity, these Pareto fronts are visualized in Fig. 6.

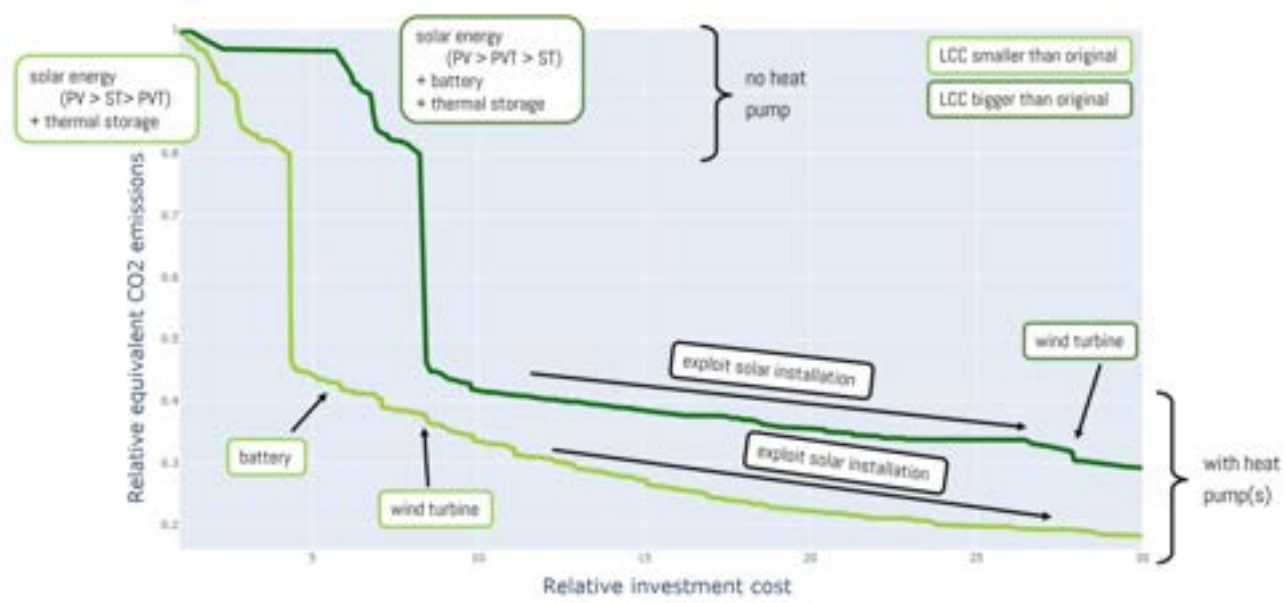

Figure 6: Pareto fronts representing an optimization of greenhouse gas emissions and investment cost, to take into account the third parameter (LCC) a separation was made between a relatively higher or lower LCC than the original installation at the Varkenscampus (natural gas boiler and grid connection), the boxes indicate the energy sources encountered in the configurations when walking along the fronts.

From these observations, it can be concluded that both Pareto fronts agree on installing solar panels first, preferably with heat production and storage. Taking this into consideration it seems that renewable energy systems are best integrated before installing a heat pump. Furthermore, installing a heat pump results into a large jump of 35% in the reduction of GHG emissions. Combining a heat pump with green energy, the GHG emissions are reduced by 55%. With the chosen parameters, the lower LCC Pareto front also results into the best case scenario for reducing GHG emissions compared to the higher LCC Pareto front. However, changing some parameters can cause the opposite to be true. This will be discussed in section 3.3. Batteries emerge sooner when walking along the front for higher LCC, which might be due to their short lifetime in the LCC calculation. Configurations with wind turbines appear last (starting at a relative investment cost of 8) on both fronts as their installation cost is the highest of all resources. However, they appear much sooner for lower LCCs indicating an economic advantage over longer periods.

3.3. Sensitivity analysis

A sensitivity study was made to see how the results behave when inserting different parameters. The changes are compared to a base case, for which the previously explained result is chosen. The adjusted parameters are shown in Table 7 with a variation in the relevant ranges. The influence of these variations on the optimized solutions can be derived from their influence on the Pareto fronts. This is shown in Fig. 7. The influence of the parameters corresponding to GHG emissions and energy costs will be discussed separately.

Table 7: Used alterations to the tweaked parameters.

parameter	[unit]	ref. case	variation in relevant range	%
CO_2-eq. emissions of the grid	[kg/kWh]	0.20	$\pm$ 0.05	25
CO_2-eq. emissions of the gas	[kg/kWh]	0.25	$\pm$ 0.05	20
electricity price	[€/kWh]	0.50	$\pm$ 0.25	50
gas price	[€/kWh]	0.20	$\pm$ 0.1	50
injection cost	[€/kWh]	0.15	$\pm$ 0.1	67

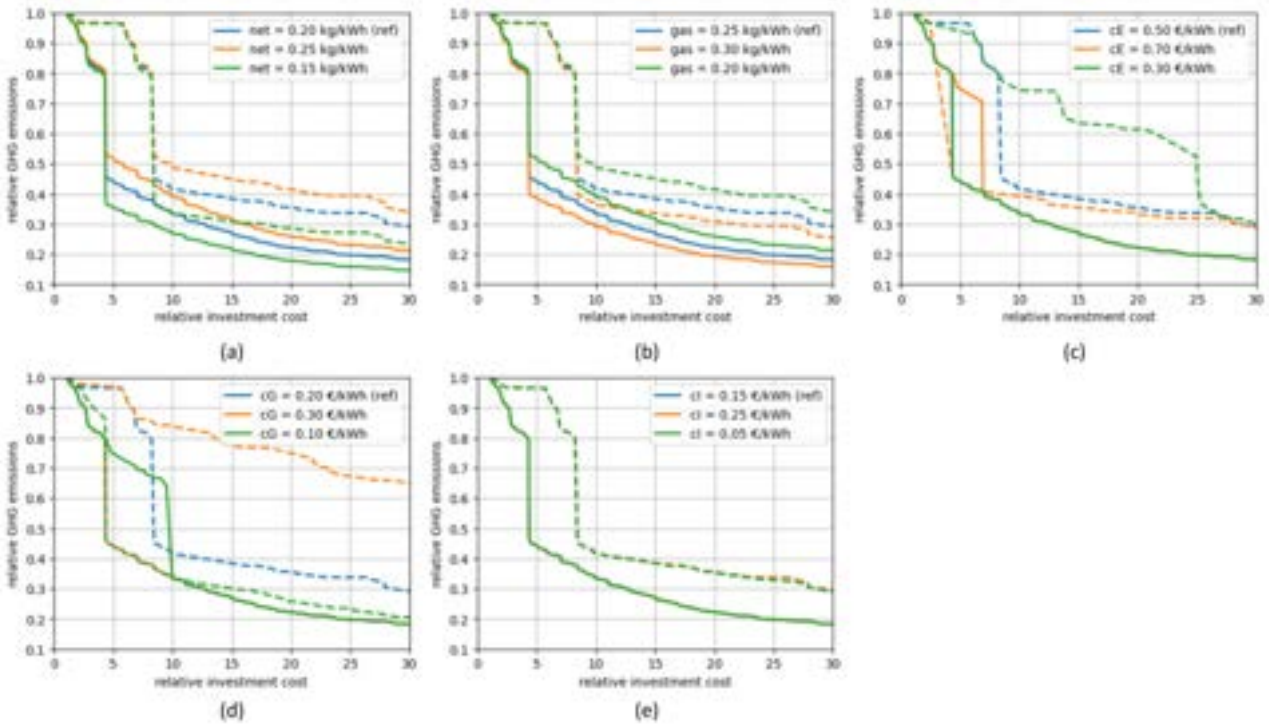

Figure 7: Influence of different parameters on the optimized solutions or Pareto fronts, the reference case from Fig. 5 is given in blue (in some cases, these blue lines are covered but they are the same everywhere), with a full line representing fronts with a lower LCC compared to the original scenario (where LCC = 1) and the dashed lines fronts with higher LCC, the studied parameters are (a) GHG emissions from the electricity network (b) GHG emissions from the natural gas boiler (c) electricity cost (d) gas price and (e) injection cost.

Influence of the equivalent CO_2 emission

The variation of the equivalent CO_2 emissions for the electricity and natural gas causes a vertical shift in the dispersion of the 123,480 scenarios. Their effect is inversely proportional. While a lower GHG emission factor for the grid (Fig. 7a) drives the clouds together, the opposite is true for the GHG emission related to natural gas burning (Fig. 7b). Therefore, these parameters additionally influence the reduction in GHG emissions when installing heat pumps. In the reference case, a reduction of 35% was seen. A variation of 20% on the electricity emission factor can cause this jump to reduce or increase by 8%. Further analysis indicates that a relative variation of the gas emission factor has a bigger influence on the data than the grid emission factor. The LCC and investment cost are left unchanged.

Influence of the energy prices

The variation in energy prices has a significantly higher effect on the results, especially on the Pareto fronts. Some variations even flip around the high and low LCC fronts, making configurations with a higher LCC more beneficial to reduce GHG emissions. This event occurs for high electricity prices (Fig. 7c: cE = 0.70 €/kWh) or low gas prices (Fig. 7d: cG = 0.10 €/kWh), causing a higher LCC for all scenarios containing heat pumps. The order encountered when walking along the Pareto fronts are the same as mentioned before (section 3.2.), but investing in a heat pump when electricity prices are high is detrimental for the LCC. This causes the front with higher LCCs to jump to heat pumps already at a lower investment cost than the front with lower LCCs. A higher investment cost is thus needed to make the reduction in GHG (by installing heat pumps) and simultaneously be beneficial to the LCC. When the electricity price is low (Fig. 7c: cE = 0.30 €/kWh) or the gas price high (Fig. 7d: cG = 0.30 €/kWh), the two Pareto fronts disperse until heat pumps no longer occur into the optimized

configurations with a higher LCC (the dashed line never reaches into the lower cloud at acceptable investment costs). In such scenario, heat pumps come out on top both economically and ecologically. Further analysis indicates that the influence of electricity and gas prices on the LCC is opposite: a low electricity price causes a generally higher LCC and vice versa. Again, a relative variation of the gas price a bigger influence on the results than the electricity price. The injection cost barely has any influence (Fig. 7e), since this cost only occurs for overproducing configurations and is relatively small compared to the other costs.

It can be concluded that realistically occurring changes in energy prices result in different optimal solutions. This is not very convenient if the tool is to be used to calculate economically optimized configurations. A solution could be to better predict the LCC by improving Eq. (7) and introducing life-cycle assessments. On a more positive note, the jump in GHG emissions owing to heat pumps is consistent throughout all parameter ranges.

4. Conclusion

A tool was made to calculate the influence of different combinations of RESs on livestock barns. From the simulations some preliminary conclusions can be drawn. The installation of a heat pump is most effective on GHG emissions when green energy sources are already present. This causes a reduction in GHG emissions of 55% compared to the current gas boiler installation at the Varkenscampus (reference case). Due to their high investment cost, scenarios containing heat pumps only start occurring at relative investment costs of 4 times that of the gas boiler or higher. However, with moderate energy prices they are beneficial to the LCC except when electricity prices are high or gas prices are low. All optimized solutions agree on investing in solar energy first, preferably with heat production and storage. This is a sensible result, since the Varkenscampus and pig farms in general, require a lot of heat. The best investment would be a wind turbine resulting in scenarios with the lowest LCCs. Unfortunately, they only come into the picture at a relative investment cost of 8.

Future work

The calculation tool requires further testing and fine-tuning. In the near future, two heat pumps, 50 m^2 PVT panels and a buffer tank of 800 liters will be installed at the Varkenscampus. This will be the calculation tool's first validation. Secondly, the tool needs to be expanded to other type of farms. As for the fine-tuning aspect, the cost and emission functions are pretty rough estimations at the moment. More sensitivity analyses must be performed on other parameters as well. It might be useful to connect the tool to energy price predictions on the web. Taking life-cycle assessments of the relevant RESs into account, would be an improvement as well. Many improvements are still to be made to the tool, but it already produces some sensible results. Fine-tuning, testing and adapting the tool to other farms can result into a positive contribution to the energy transition in livestock.

Acknowledgments

The RES4LIVE project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 101000785. Lastly, I would like to thank Robin Tassenoy, Jera Van Nieuwenhuyse and Petros Demissie Tegenaw for their useful inputs during our monthly discussions on the subject and for thoroughly proofreading this work.

Abstract:

The vinasse, produced as the bottom product of the distillation column of the ethanol production process, is the main liquid residue of this industry, whose disposition represents a problem for the industry because of its high production rate, which ranges from 10 to 15 litres of vinasse per litre of ethanol produced. In this way, the evaluation of technologies that could reduce the vinasse volume—either reducing its production during ethanol production process or its volume once already produced—is advantageous to the process and its sustainability, seeing as a lower amount of vinasse would allow a better and appropriate disposal of this effluent. This way, this work addresses the vinasse problem by a preliminary exergy cost analysis of two different technologies for vinasse volume reduction and a Base Case for comparison purposes; being the analysed cases: i) a Base Case (conventional production process), ii) the introduction of the VHG (Very High Gravity) fermentation with the use of ejectors as complementary refrigeration system, aiming at utilising a more concentrated most during fermentation to produce a wine with a higher ethanol content, thus reducing the amount of vinasse produced in the distillation step. The analysis aims at comparing the unitary exergy costs of the main products and by-products of the different alternatives, and identifying the processes with the highest irreversibilities associated, which resulted in the fermentation with distillation volume control, with values of 37.1% and 41%, for the conventional and VHG cases, respectively.

Keywords:

Vinasse; VHG fermentation; Exergy cost.

1. Introduction

The sugar and ethanol industry from sugarcane has an important role in the Brazilian agribusiness, being the ethanol demand quite significant in the Brazilian market [1], [2]; resulting in a desire of a more efficient ethanol production. Thus, seeing as the fermentation is a crucial step in ethanol production, where it is formed through a biochemical reaction lead by yeast, a more efficient fermentation process will lead, therefore, to an improved ethanol production. In this way, maintaining an adequate fermentation temperature is essential to favour ethanol production, as one of the most important parameters in this process. That being so, a low-temperature fermentation has been proved to result in higher ethanol yields since a more concentrated substrate can be used [3].

By lowering the fermentation temperature, a higher ethanol concentration in the wine is obtained, since the inhibition of organic acids and ethanol is reduced, and the flocculation and bacterial contamination is better controlled. In addition, a fermentation temperature lower than the conventional one, also allows the use of a high substrate concentration in the must, leading, in turn, to a Very High Gravity (VHG) fermentation, which is an emerging and versatile technology that offers great savings in process water and energy requirements during the distillation and fermentation steps, by reducing the size of distillation columns and decreasing the power consumption of yeast centrifugation, respectively, because of the higher concentrations of sugar in the

substrate, which leads to a higher final ethanol concentration in the medium. In addition, seeing as the ethanol content is higher in the wine, the amount of water and impurities is reduced, thus producing a lower amount of vinasse [3]–[5].

That being said, a cooling system is necessary to reach and maintain an adequate temperature. Since the fermentation process is an exothermic reaction, cooling towers have been conventionally used to control and maintain a fermentation temperature of around 34°C. Nevertheless, sometimes, the cooling water provided by cooling towers cannot achieve a temperature low enough to reach an appropriate fermentation temperature range because of adverse environmental conditions. In this way, alternative refrigeration systems are necessary when a fermentation with high sugar concentration in the substrate is applied.In this way, this work assesses the VHG fermentation against the conventional production process through a preliminary exergy cost analysis. In order to mantain the fermentation temperature in appropriate levels that make viable the VHG fermentation, a complementary refrigeration system based on ejectors was assumed for this case. Regarding the exergy cost assessment, this is a tool that aims at identifying the location, magnitude and source of thermodynamic losses (irreversibilities) in an energy system. Furthermore, it calculates the cost associated with the exergy destruction and exergy losses; besides assessing the production costs of each product in an energy-conversion system that has more than one product. The exergoeconomics is also used to compare technical alternatives and facilitates feasibility and optimisation studies [6]. Although the application of ejectors in cooling systems, as well as the assessment of the VHG fermentation, have already been regarded in the literature separately, there is a lack of studies either combining these technologies or evaluating the impacts of the VHG fermentation in the production and cogeneration systems; besides, studies evaluating these systems from exergy and exergy cost approaches are yet to be found.

2. Processes description and evaluated cases

2.1. Case i: Conventional fermentation – Base Case

A conventional fermentation was considered as a “Base Case,” according to Figure 1.

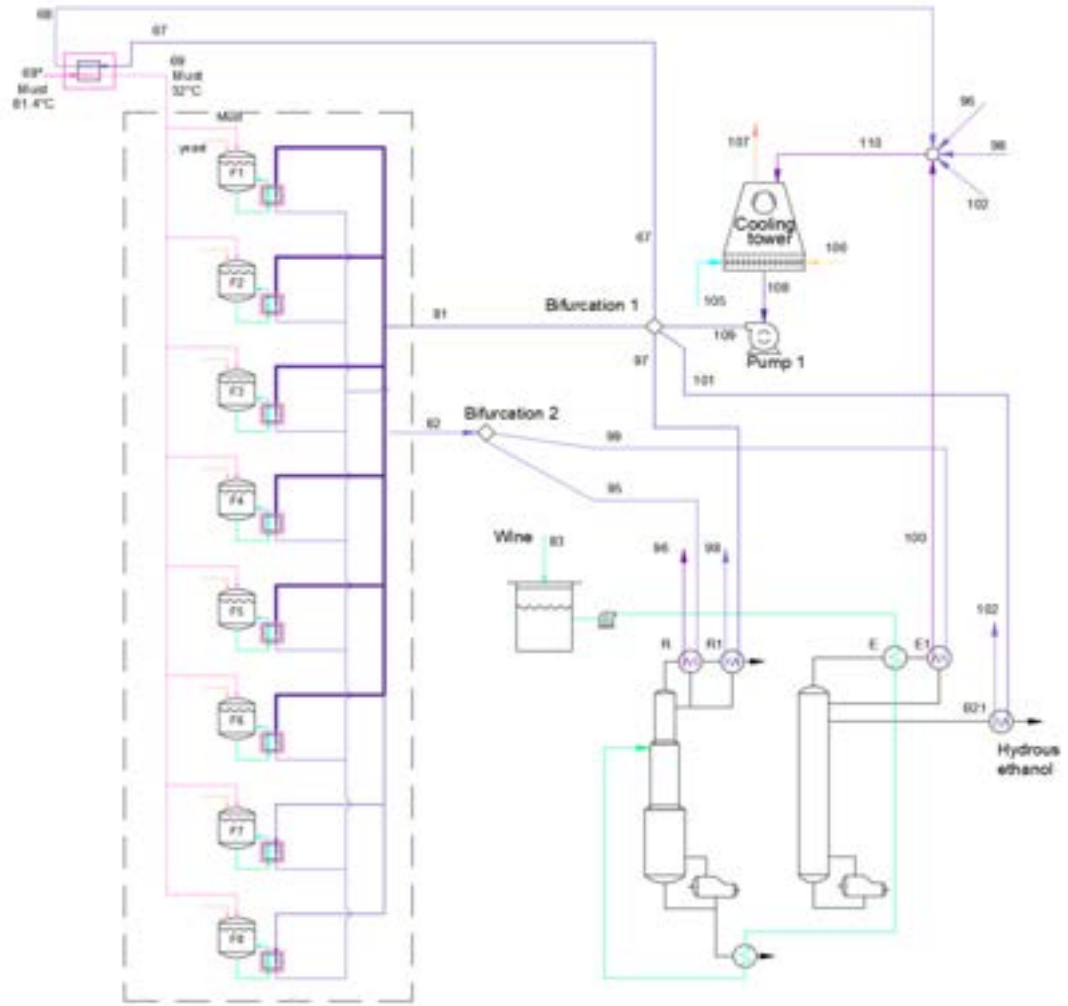

Figure. 1. Conventional fermentation operating with 8 fermentation vats, using water from the cooling tower as the only cold utility.

A cooling tower was adopted to supply water to meet the requirements of cold utilities in the plant, including removing the heat from the fermentation exothermic reaction, since this is a cooling system that is usually adopted in the industry. In this system, cooling water is used in the heat exchangers of fermentation vats, must cooling, and distillation system. A fermentation system operation with 8 vats was assumed, where 6 vats are being cooled simultaneously.

2.2. Case ii: VHG fermentation using an ejector system

Refrigeration systems based on the use of ejectors are an attractive alternative to compression vapour and absorption refrigeration systems because of their mechanical simplicity, which represents an easy maintenance and operation. Notwithstanding, some drawbacks of these systems include an increase in steam and energy consumption, as well as the high vacuum required in the evaporator [3]. In this study, a two-stage ejector system was chosen to aid the cooling tower, according to Figure 2. First, the chilled water (14°C) from the ejector system is used to refrigerate the fermentation vats and cool the must down to 28°C. Then, the cooling water that returns from the fermentation vats and must heat exchangers (stream 122) is mixed with the return water from the cooling tower (stream 121); this mixture is sent to a first flash tank at 20°C, where the first ejector is driven using steam at 9 bar. Next, the cooled water in this first stage is sent to a second flash tank at 14°C, whose low temperature is maintained by the vacuum generated by the second ejector. The chilled water is then sent to a buffer tank for storage before use. Afterwards, the steam at the ejectors' outlet (streams 119 and 120), at an intermediate pressure, is condensed in a barometric condenser. Finally, a fraction of this condensed water (stream 113) is sent to the cogeneration system of the mill, while the rest is cooled in the cooling tower. The fermentation operation assumed 8 vats, where 3 vats are cooled with chilled water and 3 are cooled with cold water from the cooling tower, simultaneously.

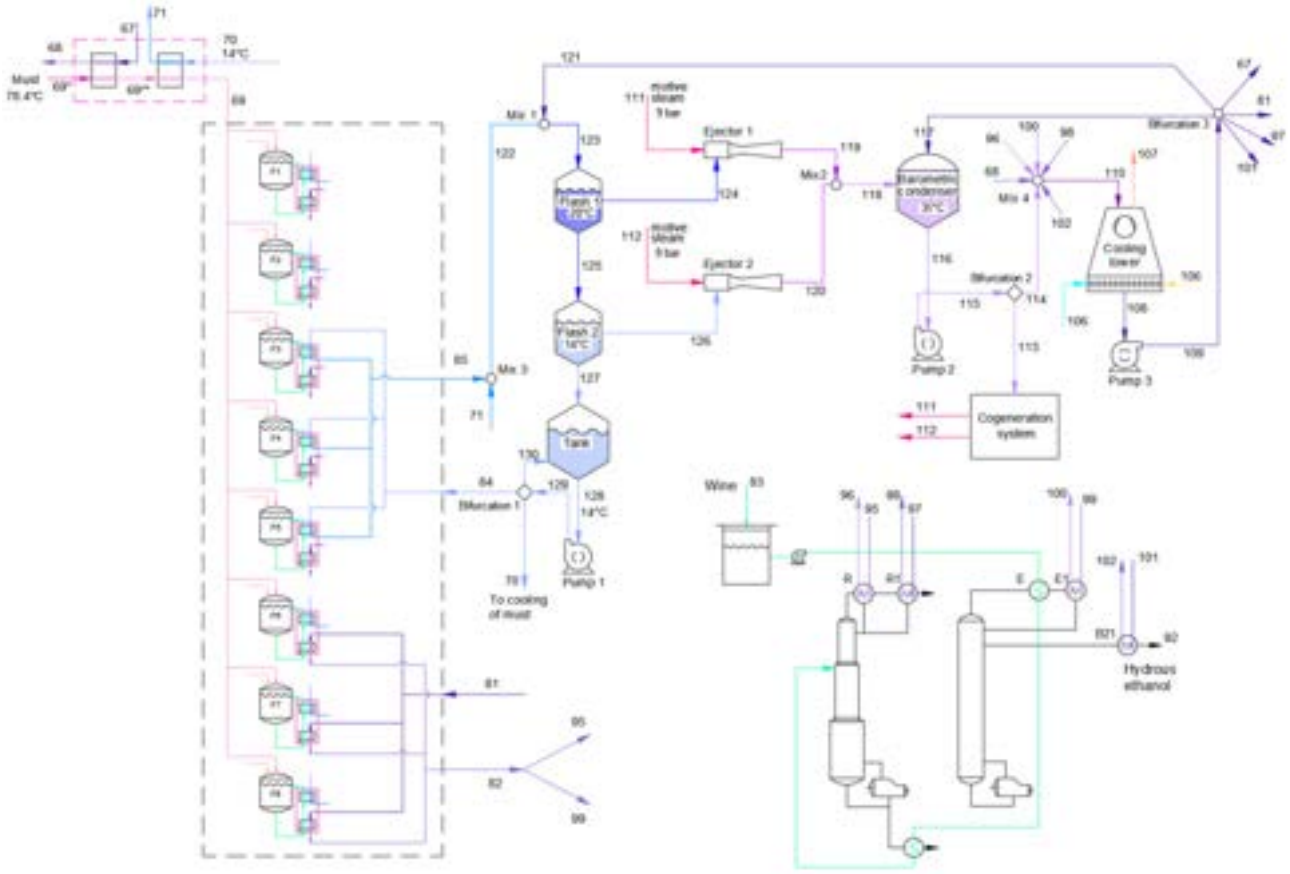

Figure. 2. Low-temperature fermentation operating with 8 fermentation vats, using cold and chilled water from the cooling tower and ejector system, respectively, as cold utilities.

2.3. Cogeneration system

The cogeneration system adopted was based on a Rankine cycle, considering back-pressure steam turbines, where the steam generation depends on the steam consumption of the overall production process. Figure 3 (a) presents a scheme of the cogeneration system for the conventional fermentation (Case i), while Figure 3 (b) shows a scheme of the cogeneration system when the VHG fermentation is considered (Case ii), where a steam bleed at 9 bar is needed to operate the ejector cooling system. The boiler pressure and temperature were

adopted at 65 bar and 520°C, according to [7], considering a boiler efficiency of 85%, according to [8], and turbine and pump efficiencies of 80%, as stated in [9].

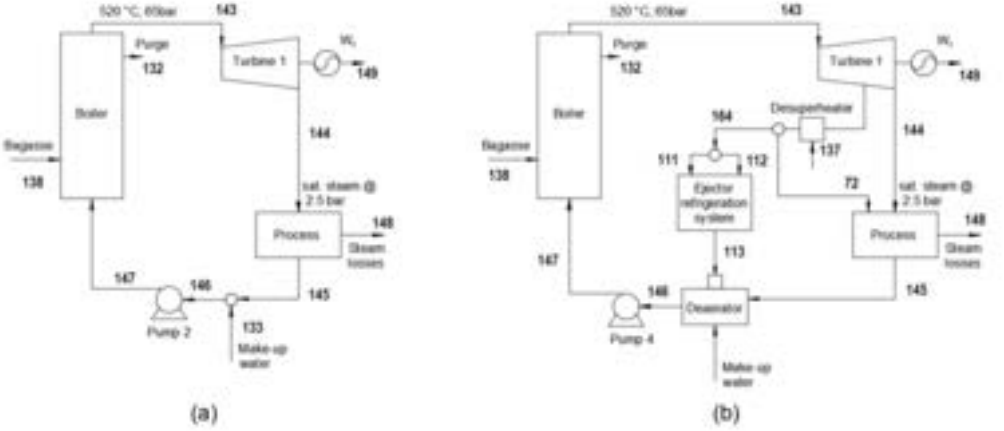

Figure. 3. Cogeneration system for (a) Case i and (b) Case ii.

3. Methodology

The main steps performed in the present work are listed below:

- Modelling and simulation of the conventional production process (Base Case), VHG fermentation integrated thereof, and cogeneration system;
- exergy analysis;
- exergy cost assessment.

3.1. Modelling and simulation

Two cases of a conventional ethanol and sugar production process were simulated using the software Aspen Plus v9 [10], according to [11], considering a sugar concentration of 16% and 35% (m/m) in the must for the conventional and VHG fermentation cases, respectively. Table 1 shows the main data assumed in the aforementioned simulation.

Table 1. Main parameters for the simulation of the ethanol and sugar production process.

Parameter	Value
Sugarcane processing rate, t/h	500
Bagasse production in mills, kg/t cane	272
Bagasse for filters, kg/t cane	5
Bagasse for self-consumption, %	5
Sugar production, kg/t cane	68.4
Hydrous ethanol, m^3/h	21.1
Vinasse production, m^3/h	247.8
Electricity consumption in conventional process, kWh/t cane	28
Steam consumption in conventional process, kg/t cane	437.6

Source: Palacios-Bereche et al. [11]

3.2. Kinetic modelling for conventional and VHG fermentation

First, the modelling of both, the conventional and VHG fermentation, was performed using the software Scilab. The kinetic model from [12] was chosen for the conventional fermentation, seeing that the best results were obtained since the model used a high cellular density and a cell recycle that were closer to the actual concentration used in the commercial process, which resulted in a better convergence than other models that used a low-cell concentration, and a more realistic modelling [12]–[17]. On the other hand, the kinetic model from [18] was used for the VHG fermentation, as this model was validated for very-high-gravity (VHG) fermentation conditions.

Then, an analysis of the heat exchanger of the fermentation vat was performed using the effectiveness approach, according to [19]. This method allows the calculation of the outlet temperatures of the heat exchanger for off-design conditions keeping constant the parameters R (relation of heat capacities) and P (effectiveness). In the conventional fermentation, these parameters (R and P) were calculated assuming the data from [20]. The temperature of the cooled wine that returns to the fermenter (T_{16}) is used as feedback for the energy balance in

the fermentation vat. Finally, the cold water mass flow is calculated through an energy balance in the heat exchanger. The same approach was assumed when the chilled water from the ejector system was used in the VHG fermentation case.

Finally, the ejector was modelled following the procedure presented in [21], due to its simplicity and the possibility of performing a thermodynamic analysis of the ejector system, without dimensioning the equipment. It is highlighted some design parameters that were considered for the simulations: a nozzle efficiency of 71.2% and 73.5%, a compression efficiency in the diffuser of 67.8% and 71.3%, and an efficiency of momentum transfer of 60.0% and 63.8%, all of them for ejectors 1 and 2, respectively. These values were used so that the steam consumption results obtained were similar to real systems that operate at the same thermal capacity.

Table 2 presents the fermentation parameters and initial conditions assumed for the fermentation process in the conventional and VHG fermentation processes.

Table 2. Main parameters for the fermentation modelling.

Parameter	Case i (Conventional)	Case ii (VHG fermentation)
Must feed		
Substrate feed volume rate, $\dot{F}$ [m^3/h]	67.1[*(a)]	42.0[*(a)]
Feed substrate concentration, S_in [kg/m^3]	169.7[(a)]	407.2[(b)]
Inlet must temperature, T_{18} [°C]	32.0[(a)]	28.0[(a)]
Specific heat capacity, cp_{in} [kJ/kg-K]	3.8[(c)]	3.34[(c)]
Density, ρ_{in} [kg/m^3]	1060.4[(c)]	1151.6[(c)]
Fermentation parameters		
Fermentation time, t [h]	8	15[(b)]
Feed time, t_{feed} [h]	4	5
Initial conditions		
Initial substrate concentration, S_0 [kg/m^3]	0	0
Initial ethanol concentration, P_0, [kg/m^3]	40[(b)]	26.96[(b)]
Initial cell concentration, X_0 [kg/m^3]	120[(b)]	52.08[(b)]
Initial temperature, T15_0 [°C]	32.0[(d)]	28.0[(d)]
Cooling		
Water temperature from the cooling tower, T_{cw} [°C]	28.0	28.0

[**] 1 hour of feeding

[***] The ejector was set to start operating two hours and a half after finishing the feeding time (7.5 h) until the end of the fermentation process.

3.3. Exergy calculation

The exergy of each stream of the evaluated processes was calculated according to previous studies [24], [25]. A reference level was chosen at 25°C and 1.01325 bar, according to [26]. The total thermal exergy (ex_{tot}) was calculated as the sum of the physical (ex_{phy}) and chemical (ex_{ch}) exergies [26]:

$$ex_{tot} = ex_{phy} + ex_{ch}. \quad (1)$$

The physical exergy was calculated according to (2), neglecting the potential and kinetic components:

$$ex_{phy} = h - h_0 - T_0(s - s_0), \quad (2)$$

where the subscript 0 indicated the reference level.

The chemical exergy is calculated, generally, considering the activity of the stream, as can be observed in (3), considering the standard chemical exergy of pure components (first term) and the losses of chemical exergy due to the dissolution process (second term), according to [26]:

$$ex_{ch} = \left(\frac{1}{\overline{M}}\right) \cdot \left[\sum_{i=1}^{n} y_i \cdot ex_i^{\circ} + \overline{R}_u \cdot T_0 \sum_{i=1}^{n} y_i \cdot \ln(a_i)\right]. \quad (3)$$

Nevertheless, other approaches were followed for certain streams. Thus, when sucrose-containing streams were contemplated (sugarcane, bagasse, juice, syrup, molasses, sugar), the specific exergy was calculated

according to the guidelines presented in [27]. On the other hand, for ethanol-containing streams, the guidelines in [28] were followed.

3.4. Exergy cost assessment

Since the exergy is an objective measure of the thermodynamic value of an energy carrier, it is also closely related to the economic value of said carrier, because users pay for the potential of energy to cause changes [6]. Thus, the exergoeconomic approach was utilised, since it integrates thermodynamic and economic analysis through the exergy costing, which is the assignment of costs to the exergy content of an energy carrier [6]. The Theory of Exergetic Cost [29] was followed to perform the exergy cost assessment in this study.

An exergetic cost balance was performed in each sub-system of the production process of the proposed cases (4), to calculate the exergetic cost of a flow:

$$\sum \dot{B}_{in} = \sum \dot{B}_{out}, \tag{4}$$

where $\dot{B}$ represents the exergetic cost of each flow that enters (*in*) to, and goes out (*out*) from the control volume.

According to [29], the exergetic cost of a flow ($\dot{B}$) is defined as the amount of exergy required to produce said flow (5):

$$\dot{B}_i = k_i \cdot \dot{E}x_i, \tag{5}$$

where the exergetic cost of an *i* stream is determined by its unit exergetic cost (k_i) and its total exergy $(\dot{E}x_i)$. The total exergy of a stream is calculated by its specific exergy (calculated in the previous section) and the mass flow of the stream, which is given by the process simulation.

Applying (4) to all the sub-systems of the production processes of all the considered cases results in a system of linear equations, where the unit exergetic cost (k_i) remains unknown. Thus, assumptions were made by following the propositions of the Theory of the Exergetic Cost [29], resulting in additional equations that are required to resolve the equation system.

- A unitary value is assigned as the unit exergy cost (k_i) of external inputs (sugarcane, freshwater, chemicals).

$$k_{externalinput} = 1. \tag{6}$$

- By-products of the control volume are assigned a unit exergy cost (k_i) equal to the input (P4a).

$$k_{by-product} = k_{input}. \tag{7}$$

As was the case of bagasse, molasses, phlegmasse, and vinasse, were the following were considered:

$$k_{bagasse} = k_{sugarcane}, \tag{7.1}$$

$$k_{molasses} = k_{syrup}, \tag{7.2}$$

$$k_{vinasse} = k_{phlegmasse} = k_{must}. \tag{7.3}$$

- If a control volume has two or more product streams, then the same unit exergy cost (k_i) is assigned to all of them (P4b).

$$k_{product1} = k_{product2} = ... = k_{productn}. \tag{8}$$

As in the case of second-grade ethanol and fusel oils, that were considered co-products and assigned an unit exergy cost equal to that of the hydrated ethanol

- The unit exergy cost (k_i) of the energy carrier (steam, condensates, vapour bleeds) is determined during its generation (at the boiler of the cogeneration system) and do not change throughout the process.

$$k_{live\ steam} = k_{processsteam} = k_{condensate} = k_{vapourbleeds}. \tag{9}$$

The cost of the irreversibility associated with the operation of the condenser in the cogeneration system, is added to the turbine control volume, thus increasing the unit exergy cost (k_i) of the electricity.

4. Results and discussion

In Table 3, the main results of the evaluated processes are presented, from which it can be highlighted the significant reduction of 60% in vinasse production when the VHG fermentation was considered, which can significantly reduce transport and disposal costs related to this effluent. In addition, this technology also allowed a reduction in the effective water withdrawal of 72%, which would lead to environmental and economic advantages. Still, the use of the VHG fermentation required an increased steam consumption at 2.5 bar, although not significant (0.8%), which can be explained due to the increased consumption during the concentration step, as more raw juice needed to be concentrated; in this way, even though there was a steam consumption was lower in the distillation stage, it could not compensate the juice concentration steam demand; moreover, there is an additional steam consumption at 9 bar for thermal juice sterilisation, a necessary step in the VHG fermentation, and for the ejector system (motive steam). Regarding the surplus electricity, an increase of 6.8% was observed in the VHG case, in comparison to the Conventional case, due to the higher steam consumption in the first one (the electricity produced in backpressure steam turbines is directly proportional to the flow of steam being expanded). Thus, there is an increase in fuel consumption in the boiler, which is reflected in a reduction of 52.6% in surplus bagasse in the VHG case, when compared to the Conventional case.

Table 3. Main results of evaluated processes

Parameter	Case i Conventional	Case ii VHG fermentation
Sugarcane, processed, t/h	500	500
Raw juice for sugar production, %	70	91.4
Sugar production, kg/t cane	68	68
Must for fermentation, kg/t cane	427.2	195.5
Must for fermentation, Brix	19.42	42.47
Ethanol content in wine, % (wt.)	6.15	12.37
Hydrated ethanol production[a], L/t cane	43.8	43.8
Steam consumption in process at 2.5 bar, kg/t cane	435.6	439.3
Steam consumption in process at 9 bar, kg/t cane	0	18.8
Vinasse production, kg/t cana	511.6	203.0
Vinasse production, L/L hydrated ethanol	12.8	5.1
Effective water collection, kg/t cane	418.7	116.2
Surplus electricity in cogeneration system, kWh/t cane	47.2	50.4
Surplus bagasse, kg/t cane	25.1	11.9

[a]At 35°C

Figure 4 shows the distribution and the connexion between the analysed subsystems in this study, for Cases I and II. In both cases, the fermentation and distillation processes were evaluated together, including the cold utility production system for these processes (cooling tower and chilled water) in the exergy and exergy cost assessments.

Table 4 presents the irreversibilities (kWh/t cane) calculated through the exergy balance in each sub-system considered in the analysis. The boiler subsystem presented the highest irreversibility for both cases, accounting for 62% and 60% of the total irreversibility for the Conventional and VHG cases, respectively, mainly due to the high irreversibilities in the combustion process. In second place, the Fermentation + Distillation subsystem represents 14.1 and 16.4% for the Conventional and VHG cases, respectively, this can be explained due to of the biochemical reaction in the fermentation process and the significant steam consumption in distillation columns; moreover, the cooling towers and the cooling ejector system in the VHG case were incorporated into this control volume. Next, the Juice extraction subsystem amounts to 12 and 10.9% for the Conventional and VHG cases, respectively, in this sub-system there is a significant power consumption in the mills. The following subsystem is the Juice treatment for sugar, which accounts for 4.7 and 6.8% for the Conventional and VHG cases, respectively. The following subsystems present a low irreversibility in comparison to the total.

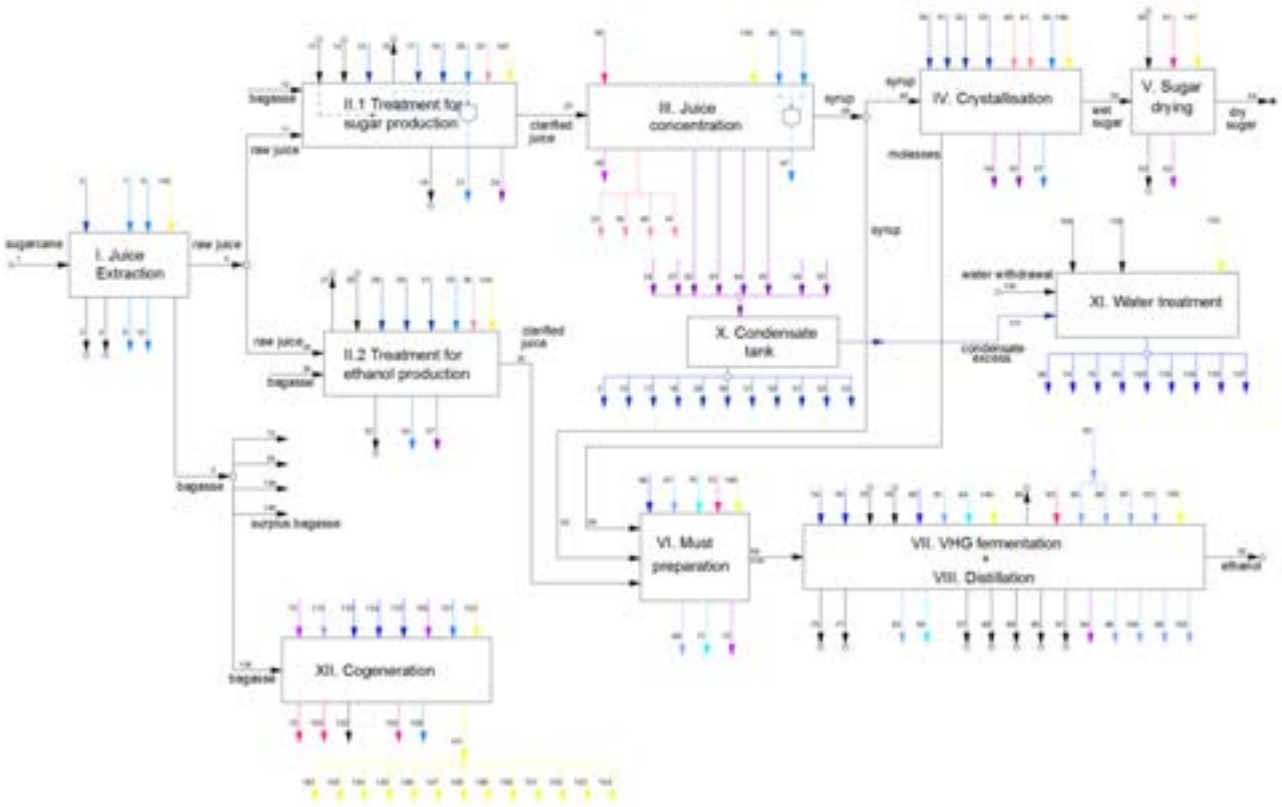

Figure. 5. Block diagram of the evaluated subsystems in the exergy and exergy cost assessments

Analysing the differences between the Conventional and VHG cases, an increase of 10.5% in total irreversibility can be observed, which can be explained by the additional requirements in the VHG case, such as the additional steam consumption in the must sterilisation in the fermentation process, and the steam demand in the cooling system based on ejectors. Moreover, there is a significant increase in the irreversibilities of the Juice treatment-sugar and Juice concentration subsystems, due to the larger amount of juice being concentrated and the layout assumed in this assessment.

Table 4. Irreversibilities in each sub-system for Conventional and VHG cases in kWh/t cane

Parameter	Case i Conventional (kWh/tcane)	Case ii VHG fermentation (kWh/tcane)
Juice extraction	91.4	91.4
Juice treatment - sugar	35.8	57.5
Juice treatment - ethanol	15.5	6.4
Juice concentration	14.9	19.5
Crystallisation	13.7	14.0
Sugar drying	1.6	1.6
Must preparation	4.1	2.9
Fermentation + Distillation	107.1	137.8
Water treatment	1.6	1.3
Boiler	472.4	504.8
Turbine	3.0	3.4
TOTAL	761.0	840.6

The results verification in the Base Case (Case i) can be done comparing results from other studies; however for VHG case verification of results was performed by calculating irreversibilities of the processes, in order to evaluate their thermodynamic feasibility from 2nd Law of Thermodynamic approach. In Figure 5,

the irreversibilities are presented in percentage, without taking into account the boiler, aiming at a better visualisation of the contribution of each subsystem.

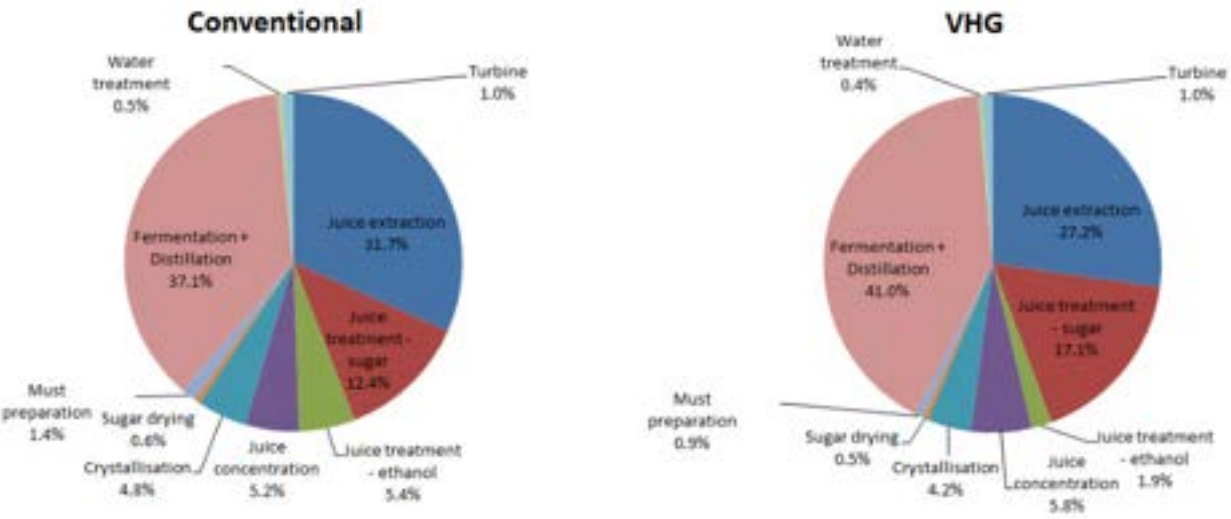

Figure. 5. Irreversibilities, in % without considering the boiler

Figure 6 presents the unitary exergy costs (kJ/kJ) of the main products and by-products of the analysed sub-systems for the Conventional and VHG fermentation cases. It can be observed that the highest unitary exergy cost corresponds to the hydrated ethanol because of the significant amount of processes required to produce it and the high irreversibilities associated to obtain this product; moreover, it can also be observed that the unitary exergy cost in the VHG case is higher than the Conventional case, mainly due to the higher costs of utilities produced in the cogeneration system, such as electricity and steam.

Regarding the other streams the difference between the Conventional and VHG cases is not significant (difference lower that 5.6%)

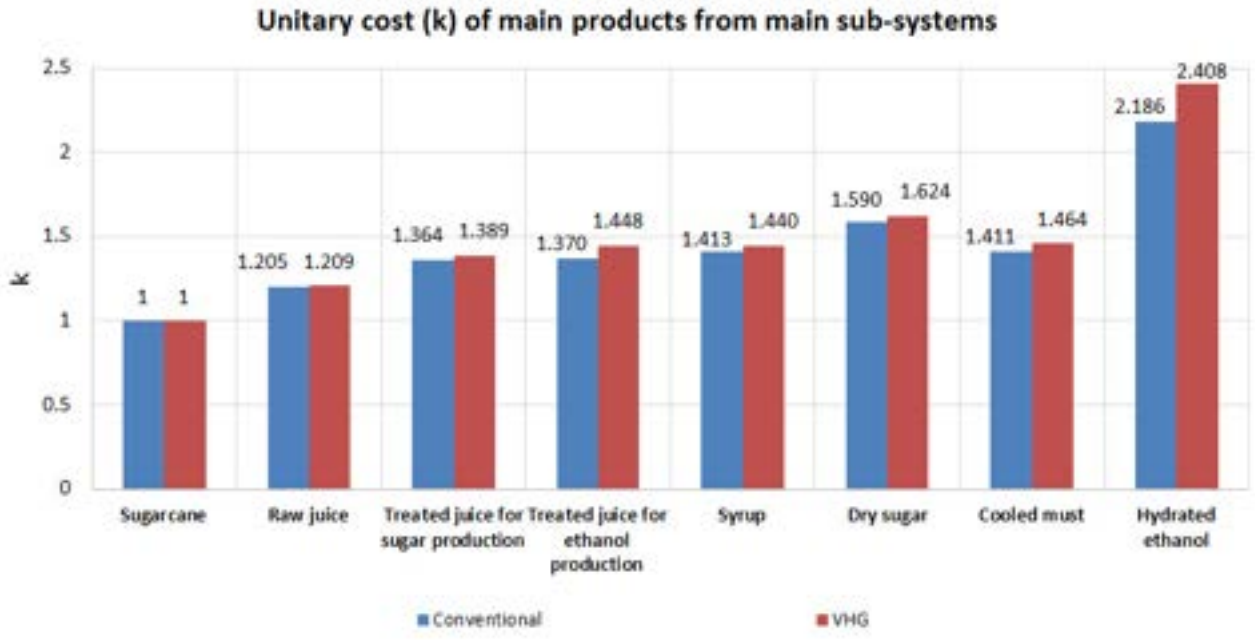

Figure. 6. Unitary exergy cost of main products and by-products for Conventional and VHG cases

Figure 7 presents the unitary exergy costs for the utilities produced in the process. It can be observed that the unitary exergy costs of steam, electricity and treated water are higher in the VHG case, in comparison to the Conventional case.

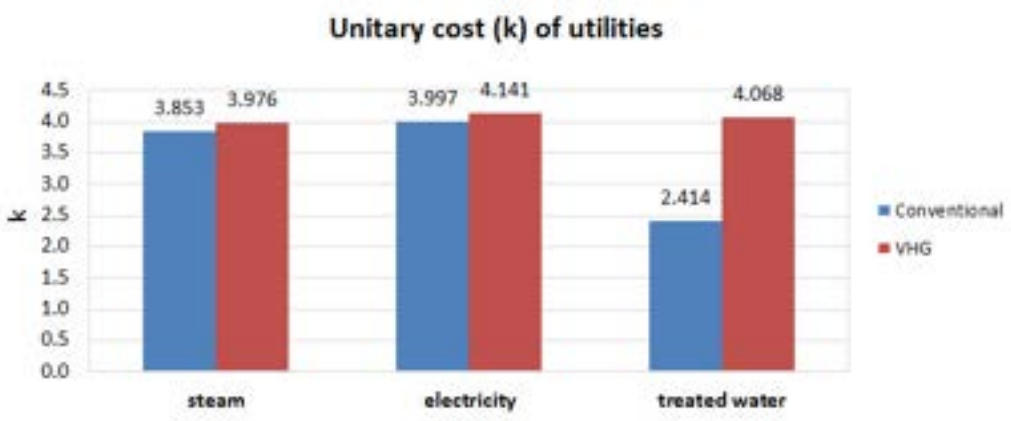

Figure. 7. Unitary exergy costs of the utilities produced in the process

Regarding the steam, its unitary exergy cost resulted higher in the VHG case, because the irreversibilities in the boiler, were the steam is produced, resulted higher as well, since more steam is necessary in this case, and more fuel is being burned. Regarding the electricity, the irreversibilities in the steam turbines are higher in the VHG case, as well; because more steam is being expanded through them; thus, the exergy cost to produce this electricity results higher as well. Concerning the treated water, although a smaller amount of water (33% of the total water use) is captured from the environment in the VHG case, in comparison to Conventional case (80% is captured in the conventional case), the exergy cost of the treated water was significantly higher (68.5%) in the VHG case. This can be explained by the fact that recycled and reused water streams come from the spray pond system and condensate tank, whose exergy cost was assumed equal to the steam ($k_{condensate}=k_{steam}$); in addition, the electricity consumption in the treated water system, where reverse osmosis membranes were assumed, had a specific energy consumption of 2.58 kWh/m^3 of water according to [30].

Conclusions

From the results, it is observed that the implementation of the VHG fermentation, using an ejector cooling system as auxiliary cooling utility, presents several advantages over the conventional production process, such as a significant reduction of the vinasse produced and a lower water withdrawal for the process, leading to economic and environmental advantages. Regarding the vinasse reduction, its volume could be further reduced when coupled with other technologies such as concentration by evaporation or incineration, or even membrane technologies; furthermore, the energy required in these technologies would be lesser than the energy needed when considering the volume and concentration of the vinasse produced in the conventional process. On the other hand, the exergy analysis revealed that the use of the VHG fermentation increased the irreversibilities of the overall process, besides impacting negatively in the cogeneration system, by increasing the unitary exergy costs of the utilities (steam and electricity), as well as increasing the unitary exergy cost of the hydrated ethanol. Moreover, even though there was an increase in surplus electricity, due to the higher consumption of steam, it leads to an also increased fuel (bagasse) consumption. Although the availability of bagasse surplus is desired when further processing of this residue is considered, such a production of second-generation ethanol, among others, further research and analyses are needed, in order to determine if the advantages here presented compensate this issue, such as economic and environmental assessments.

Abstract:

This manuscript presents a novel methodology for the design of Central Tower Receivers (CTR), which involves simplified models for optical and thermal calculations and evaluation of design constraints. The proposed methodology optimizes the total yearly energy production as the criterion, considering a multi-parameter analysis. This design is part of the AdInCCSol (Advanced Integration of Combined Cycles in Solar thermal power plants) project, which aims to integrate advanced thermodynamic cycles in solar thermal power plants to improve efficiencies and lower LCOE. Specifically, the manuscript presents the optimization of a 100 MW CTR plant based on a conventional cylindrical receiver that operates at an outlet temperature of 565 ºC. Unlike previous studies, the proposed methodology considers yearly calculations and takes into account most of the parameters that affect thermal and optical efficiencies, including tube diameter, receiver diameter, height, and the number of faces. The aiming strategy for each design was also optimized to achieve the best balance between optical and thermal losses while meeting stress and corrosion limits. The study was conducted using two in-house codes that integrate thermal and optic performance calculations and models for estimating design constraints, providing accurate results with low running times. The findings of the study indicate the presence of an optimal receiver area that optimizes the design for a target power of concentrated radiation flux density. Moreover, certain combinations of parameters yield similar yearly energy productions, enabling the development of designs with comparable performance and reduced costs.

Keywords:

Central Tower Receiver (CTR), aiming strategy, receiver design optimization, heliostat field

1. Introduction

This paper presents a study focused on designing an optimized central tower receiver for the AdInCCSol project. The objective is to analyze multiple parameters and optimize the receiver design in terms of yearly performance.

Designing a solar thermal power plant is a complex task that requires the integration of multiple models and tools from various multidisciplinary fields since the optimal solution depends on several parameters. One of the key challenges is that the optical and thermal performance cannot be optimized independently. Also, structural stresses or corrosion inside the tubes can cause receiver failure [1-3], while pressure drop and flow stability inside the tubes can lead to operational issues [2,4]. Therefore, it is essential to integrate all these calculations into the design process to achieve the desired performance.

The heliostat field design and aiming strategy are crucial for an optimal design. Firstly, it is important to establish the Allowable Density Flux (AFD) [5-6], to adapt the flux maps to this limit, maximizing thermal

performance and minimizing ray spillages. The strategy of adapting the aiming points of the heliostats can vary from different authors from more simple approximations [7] to more complex ones like the one based on Deviation-based Aiming Strategy (DBA) [8-9]. Again, the optimization of the aiming strategy involves the integrated analysis of the optical and thermal performances.

Over the last four decades, some algorithms have been developed oriented toward the optimization of the heliostat field [10]. However, up to the authors' knowledge, there are no studies that proposed a receiver design based on an optimization process coupling heliostat field and aiming strategy optimization with thermal performance analysis and considering stress and corrosion limits.

The present study describes the design of a solar thermal power plant with a standard configuration of 100 MWe in Seville. To achieve this, the power output is divided into two towers and their respective fields to avoid very large distances from the heliostats to the receiver that would be subjected to an important attenuation. In addition, the flexibility that adds a dual-tower system [11] is another aspect that can be considered in this project. Specifically, each tower is designed to produce 340 MW of concentrated radiation and 300 MWt of thermal output for the fluid, resulting in a Solar Multiple (SM) of 1.2. Doubling the tower produces an optimal SM of 2.4, which is suitable for 8 hours of storage [12].

Two already developed tools were adapted to this methodology and are described in section 2, while the methodology for the design is established in section 3. The results are introduced an analyzed in section 4 to obtain an optimum combination of design parameters and orientate the final design of the receiver.

This work represents a significant contribution to the field of Central Tower Systems (CTS) design for Concentrated Solar Power (CSP) by presenting an efficient methodology for designing CTRs and considering multiple parameters in the optimization. One of the novelties is the use of a Design of Experiments (DOE) methodology for the optimization, which contributes to having more information about the effect of the different parameters over the global performances.

2. Heliostat field and receiver modeling

In this project, two different tools have been used to facilitate the design process. One of the tools was specifically adapted for the optical optimization of the field and receiver aiming strategy. The other tool was dedicated to the thermal performance of the receiver and included integrated calculations to predict structural limits, flow stability issues, and pressure drops. By utilizing these tools in combination, a more comprehensive understanding of the solar thermal power plant design was achieved, allowing for an optimized solution that meets the requirements.

The subsequent sub-sections outline the models and tools utilized in the study, while the methodology section describes their integration and iterative process to obtain an optimal solution.

2.1. Optical modeling and optimization of the heliostat field. Aiming strategy.

Two software applications developed in Matlab 2022b have been employed.

- An application for optimizing the layout of heliostats.
- An application for optimizing the aiming strategy.

The first one, HRT (Homology Ray-Tracing) code is used for the optics optimization and is based on the yearly insolation weighted efficiency as a Function Of Merit (FOM), which according to [13] and [14], is given by Eq. (1):

$$\eta_{yearly\_w} = \frac{\sum_{d=1}^{365} \int_{orto}^{ocaso} \eta(t) \cdot IND(t)}{\sum_{d=1}^{365} \int_{orto}^{ocaso} IND(t)}, \quad (1)$$

where η (t) is the instantaneous optical efficiency and IND (t) represents the instantaneous beam insolation, Eq. (2).

$$\eta_{(t)} = \frac{\sum_{1}^{N} (\eta_{cos} \cdot \eta_{ref} \cdot \eta_{s\&b} \cdot \eta_{aa} \cdot \eta_{int})}{N}. \quad (2)$$

In general, the optimization code operates by proposing an array or pattern of heliostats in the field, according to parameterized expressions. These allow the location of each of the heliostats in the array to be determined within geometric limits on the horizontal plane, which are usually a function of the tower height and the geometry of the receiver [15, 16]. Typically, the proposed field layout comprises a greater number of heliostats than those required to reach the target power at the design point [13, 14, 17].

Next, the subset of heliostats of the proposed field is determined that, with greater optical efficiency, allows obtaining the target power on the receiver at the design point (autumn equinox at solar noon). Subsequently, operating with this subset of heliostats, the merit function is evaluated using multiple sample points. Since the initial field is as compact as possible, the overall efficiency can be improved, as significant losses due to

shading and blockages will occur, while the remaining elementary efficiencies (cosine factor, reflection, atmospheric attenuation, and interception) are very high. Then, the optimization code proposes another configuration or pattern, differing slightly from the previous one, and the calculations are repeated.

To reduce computation time, the code implements various resources, such as techniques to reduce the number of candidates in determining to shade and blocking performances [18], homographic techniques for determining interception and shading and blocking performance [19] and [20], or evaluating the merit function using numerical integration methods [21].

Starting from an optimized layout, the aiming strategy is optimized using the aforementioned second application. For this purpose, an iterative process is used, which consists of the following steps:

1. Several sample points are used to simulate in detail each of the heliostats in the solar field aiming at the receiver center and determine the power density matrices of each heliostat.
2. Correct the aiming in the vertical direction.
3. Recalculate the power density matrices and efficiencies of each heliostat.

In this case, a detailed Monte-Carlo Ray Tracing (MCRT) is used, with few simplifications. 10,000 rays per heliostat have been used. Other features of this ray-tracing include:

- Uses the MCRT methodology.
- Assumes that the surface of the heliostat has a rectangular shape and elliptical quadric curvature without holes or discontinuities (a spherical surface is considered in this case with on-axis cant).
- Incident rays are randomly generated following a Standard Solar Model (SSM). A Gaussian SSM with σ = 2.325 mrad has been considered.
- The incident rays are randomly generated uniformly over the surface of the heliostat.
- The optical errors (macroscopic and microscopic) associated with the reflecting surface of the heliostat are considered by using Gaussian distributions in both cases. Values of σ = 2.0 and 1.0 mrad for the macroscopic and microscopic, respectively, are used.
- The reflectivity of the heliostat, as well as the losses due to atmospheric attenuation, are applied in a non-deterministic manner.
- Both the methodology used for preselecting candidates for shading and blocking, as well as the methodology used for determining to shade and blocking, are defined in [19].

This sub-process dedicated to correcting the aiming in the vertical direction consists of the following steps: a ϕ_{obj} matrix of size m·n is defined, whose cells have the value given by Eq. (3).

$$\phi_{obj} = coef \cdot \frac{Total\ power\ over\ the\ receiver}{receiver\ area}. \quad (3)$$

Where *coef* is a user-defined value. The φ matrix of size m·n is initialized with null values, where m represents half of the number of vertical cells and n is the number of heliostats. An iterative process is started that goes through the n heliostats of the solar field ordered from highest to lowest total optical efficiency. The vertical location of the power density matrix of the i-th heliostat ϕ_i that minimizes the Root Mean Square (RMS) value is determined, by minimizing Eq. (4).

$$RMS = \sqrt{\sum_1^m \left(\sum_1^n \varphi + \phi_i - \phi_{obj}\right)/(m \cdot n)}. \quad (4)$$

Once the RMS is minimized the aiming vertical position for each heliostat is updated, using Eq. (5).

$$\varphi = \varphi + \phi_i. \quad (5)$$

The aiming vertical correction for the i-th heliostat is determined trigonometrically and stored. This is repeated for different values of coef.

2.2. Thermal modeling of the receiver

The thermal performance for a region of uniform absorbed radiation can be obtained using Eq. (6) [22].

$$\eta(x^*) = \frac{\eta_0 \cdot g'(Z)}{(1-g'(Z))} \cdot \frac{1}{NTU \cdot x^*} \cdot \left(e^{\frac{1-g'(Z)}{g'(Z)} \cdot NTU \cdot x^*} - 1 \right), \quad (6)$$

The thermal efficiency at the inlet denoted as η_0, is a key performance parameter for a thermal system. In this context, the derivative of the characteristic function, g'(z), and z, the variable of this function, are defined in [22], while NTU (Number of Transfer Units) is a characteristic parameter of the thermal system and x^* is the non-dimensional coordinate.

To model the system, external heat transfer coefficients are required to evaluate the different terms of the characteristic function. However, it should be noted that the heat transfer mechanisms at the receiver are

complex due to the non-uniform absorption of radiation. Consequently, a dense mesh is needed to precisely evaluate the temperature at the tube surfaces. Furthermore, the receiver tubes are exposed to ambient air at the front and are insulated at the back with a panel that is separated from them. As a result, the air can enter through the gaps situated among the tubes and refrigerate them. The complexity of the convective currents around the receiver tubes, the coupling with radiation, the large dimensions of the receiver, and its open configuration are some of the reasons that support the idea that to accurately capture convection heat transfer it is required to perform unaffordable simulations by Computational Fluid Dynamics (CFD). The radiation mechanisms are also complex because different sections of the surface have varying view factors concerning the sky, the heliostats, the ground, the neighbor tubes, or the insulation at the back part. In this study, it was decided to introduce some simplifications as the purpose is not to achieve precise results, but rather approximations that allow comparison of different designs with rapid yearly calculations to optimize the design. To this end, the following hypotheses are considered for radiation and convection heat transfer:

- The tube is painted with Pyromark, with a constant emissivity of 0.87 in the range of temperatures of the receiver, and a solar absorptivity of 0.96 [23].
- The front face of the tube exchanges radiation with an equivalent surface at ambient temperature.
- The back face of the tube is considered insulated.
- Heat transfer by convection is assumed to be constant and equal to 14 W/(m^{2}K), as it is proposed in [24] for the DELSOL code.

The same set of hypotheses for the evaluation of thermal losses was considered and validated in [25], with the only difference of the values of the convective heat transfer coefficient that could vary.

Due to the non-uniform absorption of radiation in the receiver, the tube length is discretized into slices of 0.5 m where radiation flux density is averaged.

The fluid used is the "Solar salt", 60% $NaNO_3$ and 40% KNO_3, which thermo-physical properties are based on [1]. The fluid flow rate is adjusted to achieve the desired outlet temperature (565 ºC). However, under conditions of low absorbed radiation, the fluid flow may not be sufficient to adequately cool the receiver tube, leading to potential structural or corrosion limitations being exceeded. To prevent this, a threshold concentration of radiation at 160 MW (47% of the nominal value) has been established, below which the fluid flow rate is maintained at a constant value and the outlet temperature is allowed to vary accordingly.

The Direct Normal Irradiance (DNI) and temperature data for the location of Seville were obtained from the Typical Meteorological Year International Weather for Energy Calculation (TMY IWEC) database [26] and used as inputs in the simulations for all cases analyzed.

2.3. Design constraints

In concentrated solar power systems, receiver tubes are exposed to solar radiation and undergo thermal stresses that can lead to failure. The axial thermal stresses in the tubes can be eliminated with proper design. However, the temperature gradient in the tubes leads to maximum thermal stresses at the front or crown, estimated via a superposition of circumferential and radial gradients. Equation (7) has been adopted by multiple authors [4, 6-7].

$$\sigma_c = \gamma \cdot E \cdot \left[(\bar{T}_c - \bar{T}_w) + \frac{\Delta T_c}{2 \cdot (1-\nu)} \right]. \quad (7)$$

Where ν is the Poisson's ratio, γ is the coefficient of thermal expansion (mm/m·K) and σ_c is the thermal stress at the crown (MPa). The radial temperature difference at the crown (ΔT_c), the mean temperature at the crown (T_c), and the average tube temperature (T_w) are based on the local absorbed radiation and assuming that the backside temperature of the tube wall is the same as the working fluid temperature [4, 6-7]. These values are compared with Ultimate Tensile Strength (UTS) values for the tube material [27]. In this case Inconel 625 is selected for the tubes as it presents better performance to corrosion than, for example, Haynes 230, although this alternative presents better mechanical performance [7].

The corrosion of tubes is also a significant concern as it is accelerated by high temperatures. The material loss due to corrosion is limited to 0.5 mm over 10 years, and the temperature limit for corrosion of Inconel 625, used for the tubes, is 628 ºC [7]. These two limits are used to calculate the Allowable Flux Densities (AFD) for each node along the tube [7]. The radiation flux density at each node is compared to its allowable value, and the flux is reduced uniformly to meet this criterion. Although selective defocusing could be included in future studies.

Pressure loss is another critical factor, as a pressure of 20 bar is required to ensure correct solar field operation. Pressure losses are estimated for receiver tubes, headers, and elbows that appear in a standard, using the models proposed in [2].

Finally, downward flow inside the tubes may be subject to instabilities due to the upward buoyancy force, which tends to increase as flow velocity decreases. Perturbations in a downward-flow tube lead to the increased temperature inside the tube and buoyancy force, further decreasing the flow rate and potentially leading to

flow imbalance and operational problems in the receiver. The stability criterion proposed in [4] is included in the model to ensure that the downward flow inside the tubes is not subjected to instabilities. The criterion is expressed as follows, Eq. (8).

$$\frac{32 \cdot f}{\pi^2 \cdot d_i^5 \cdot \rho^2 \cdot g \cdot \beta} \cdot \dot{m}^2 / \Delta T \geq 1. \quad (8)$$

where f is the friction factor (-), di is the internal tube diameter (m), ρ is the fluid density in (kg/m3), $\dot{m}$ is the mass flow (kg/s), ΔT is the temperature difference (K), and L is the length of the tube (m).

3. Methodology

As was already introduced the proposed methodology was developed to optimize the heliostat field and receiver designs for a power plant located in Seville with a target thermal power of 300 MWt for each receiver, which implies a SM of 2.4. The design involves the analysis and optimization of three key parameters of the receiver, namely the receiver diameter (D), receiver height (H), and the number of faces (N). The optimization process is carried out in three steps. Firstly, the heliostat field is optimized for each of the receiver's diameters and heights using the code described in the previous section. Secondly, an appropriate aiming strategy is determined to maximize yearly energy production, and finally, a response surface is constructed and optimized using the results from all the simulations.

It is noteworthy that the effect of radiation flux densities changes from high to low temperatures, as shown in Fig. 1. The thermal performance for low temperatures due to a four-times reduction in radiation flux densities is found to be around 8%. In contrast, a two-times reduction for high temperatures leads to a significant reduction in performance, up to 20%. Thus, it is crucial to adopt a concentration level that optimizes thermal efficiency while avoiding optical losses for the operation over the whole year.

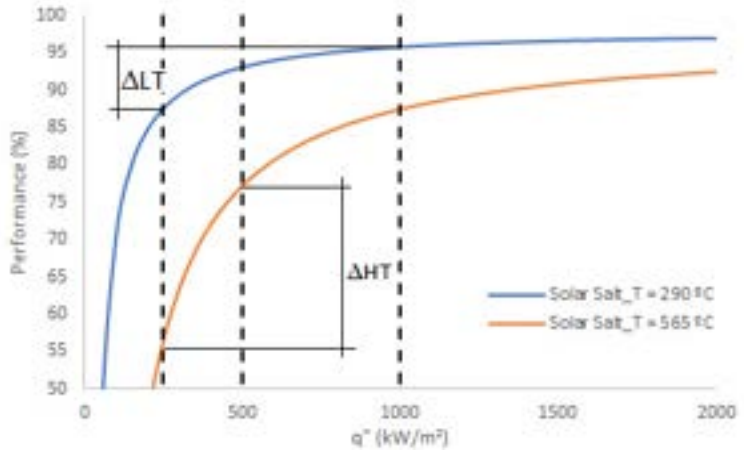

Figure 1. Thermal performance as a function of radiation flux density

To address the non-uniform distribution of the flux densities along the height of the receiver, a correction coefficient is proposed in this study, as described in section 2.1. This coefficient is designed in such a way that lower values indicate a tendency towards a uniform distribution (Figure 2 and Table 2). However, such uniformity can lead to an increase in optical losses due to ray spillage. On the other hand, higher values of the correction coefficient generate a narrower distribution with improved optical efficiency, but problems with the limits for tube failure. Thermal efficiency can increase or decrease depending on the shape of the distribution and receiver height. As a result, a search for the optimal value of this coefficient can be performed for a given set of parameters. Figure 2 shows the density flux maps for different values of the coefficient, while Table 2 summarizes the performance values of each of the maps.

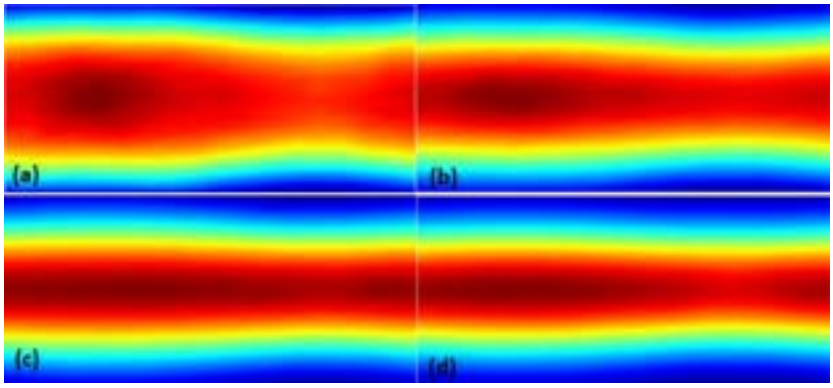

Figure 2. Density flux maps for different values of the coefficient

Table 2. Performance values for different coefficients in a general case

Coefficient	Thermal efficiency (%)	Optical efficiency (%)	Total efficiency (%)	Number of hours operation over the limit (h)
0.8	85.95	51.16	43.97	0
1.0	86.4	55.46	47.92	144
1.2	86.76	55.46	48.12	412
1.4	87.08	55.46	48.3	600

As it was said before, the operation over the tube failure limit is not permitted and radiation flux density is reduced for these instants, so the yearly energy produced would be diminished as this number increased, although optical and thermal efficiencies are greater. The operation under these conditions was limited to a maximum value of 10%, except in those cases with a small receiver, because the radiation flux density is very high. In any case, the influence of these cases on the optimization process is very limited, as It is shown in the next sections.

The optimization of the receiver design is carried out based on the yearly energy produced by the system, which is the main objective of this study. It is crucial to consider the system's performance under non-nominal conditions, as demonstrated in Fig. 1. The system's efficiency drops significantly when the absorbed radiation falls below a certain threshold, which is higher in the case of high temperatures.

The proposed methodology involves computationally expensive and time-consuming simulations. Therefore, the Design Of Experiments (DOE) methodology is preferred in this study due to its ability to reduce computational cost while providing a comprehensive understanding of the system's performance over a year. A face-centered central composite design algorithm is used to establish the case matrix which is composed of 15 cases (Table 3). The results of these cases are used to construct a second-grade polynomial function of three variables as a response surface for the yearly energy produced, which is then optimized.

Table 3. Case matrix from the face-centered central composite algorithm.

Cases	D (m)	H (m)	Number of faces	D tube (mm)	Gap (mm)	Number of tubes
1	8	10	10	36	0.9	670
2	15	10	10	22	1.06	2010
3	8	18	10	36	0.9	670
4	15	18	10	22	1.18	2000
5	8	10	18	57	2.4	414
6	15	10	18	34	1.2	1332
7	8	18	18	57	2.4	414
8	15	18	18	34	1.2	1332
9	8	14	14	46	0.85	532
10	15	14	14	28	1.28	1596
11	11.5	10	14	34	1.05	1022
12	11.5	18	14	34	1.05	1022
13	11.5	14	10	27	1.2	1260
14	11.5	14	18	43	1.38	810
15	11.5	14	14	34	1.05	1022

In all cases, the diameter of the tubes is established such that the mass flow velocity of the Heat Transfer Fluid (HTF) at nominal conditions is set at 3.6 m/s, with some margin from the maximum velocity. This is a critical factor that influences the overall efficiency of the system and needs to be maximized to achieve the highest possible thermal efficiency. So the tube diameter is a variable of our design which is previously established.

It can be observed that as the receiver diameter increases, the tube diameter decreases. This is because for lower receiver diameters, the radiation flux density is higher, and the total absorbed energy along the HTF path is also higher. An increase in tube diameter results in an increase in flow, which depends on the squared diameter, and an increase in the total amount of energy, which depends linearly on the tube diameter, so an increase in tube diameter tends to keep constant the temperature increment. The same principle applies to the number of faces; as this number increases, the length of the path that the HTF follows increases, and also does the total amount of energy, necessitating an increase in tube diameter to compensate for this.

The number of tubes primarily increases with the receiver diameter because the receiver is larger, and the tube diameter is lower. This number decreases as the number of faces increases since the tube diameter

increases and the receiver area only slightly increases. Meanwhile, the height of the receiver does not affect the number of tubes.

The gaps among the tubes are adjusted to cover the entire panel length with a minimum value to avoid tube contact.

The number of circuits considered for all the designs is 2 with no crossovers and the flow path for both circuits goes from N to S. This flow path reduces film temperatures and so the defocusing of the mirrors optimizing the yearly energy produced [2]. It is planned to analyze also these parameters in future works, but it is not expected important results modifications.

4. Results discussion and optimization

The heliostat field is optimized in the initial stage of the optimization process. For this purpose, heliostats of 12·10 m were considered and the optimized tower height was 250 m for all the cases. The layout for each case is summarized in Table 4.

Table 4. Heliostat layout for each case.

Cases	D (m)	H (m)	Number of faces (-)	Number of heliostats (-)	Number of rows (-)
1	8	10	10	6451	55
2	15	10	10	5644	51
3	8	18	10	5918	52
4	15	18	10	5390	48
5	8	10	18	6451	55
6	15	10	18	5644	51
7	8	18	18	5918	52
8	15	18	18	5390	48
9	8	14	14	6003	53
10	15	14	14	5451	49
11	11.5	10	14	5780	52
12	11.5	18	14	5390	48
13	11.5	14	10	5451	49
14	11.5	14	18	5451	49
15	11.5	14	14	5451	49

This layout only varies with receiver diameter and height.

Once the heliostat field is optimized for each case, the aiming coefficient is determined, which maximizes the yearly thermal energy output. As an illustration, an optimization example for case 12 is depicted in Fig. 3. The yearly energy production is normalized with the maximum value.

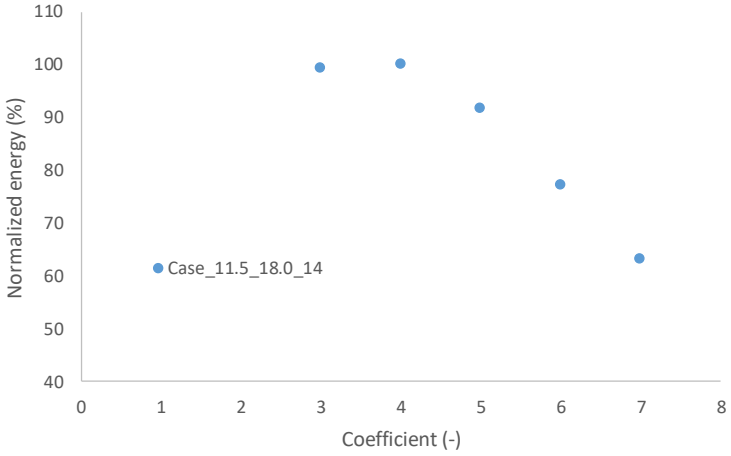

Figure 3. Normalized energy production for case 12

The results for, considering an optimum aiming strategy for each case are summarized in Table 5.

Table 5. Case matrix main results.

Cases	D (m)	H (m)	N. of faces (-)	Number of tubes (-)	Total energy (GWh/y)	η_{opt} (-)	η_t (-)	ΔP (bar)
1	8	10	10	670	497.60	47.28	81.33	1.14

15	11.5	14	14	1022	565.86	53.96	84.10	9.85

Only two cases have a greater pressure drop than the limit. This situation is considered for the optimum design.

It has been observed that the optical efficiency is optimized for each case, and the values are mostly similar, except for the cases with the lowest receiver areas. In such cases (i.e., cases 1, 5, and 9), the distribution is made more uniform to avoid exceeding the structural and corrosion limits at the radiation flux peak. As the area is small, spillage losses are high. As the receiver area increases, more rays hit the receiver with more uniform distributions, which helps avoid exceeding the structural and corrosion limits. For these cases, the thermal efficiency is high, and the slope of optical efficiency becomes lower with the growing area. However, if we continue to increase the receiver area, the radiation concentration is reduced, and thus the thermal efficiency drops, while the optical efficiency only marginally increases. Based on this analysis, it can be inferred that there exists a maximum yearly performance that is related to the receiver area (as shown in Fig. 4).

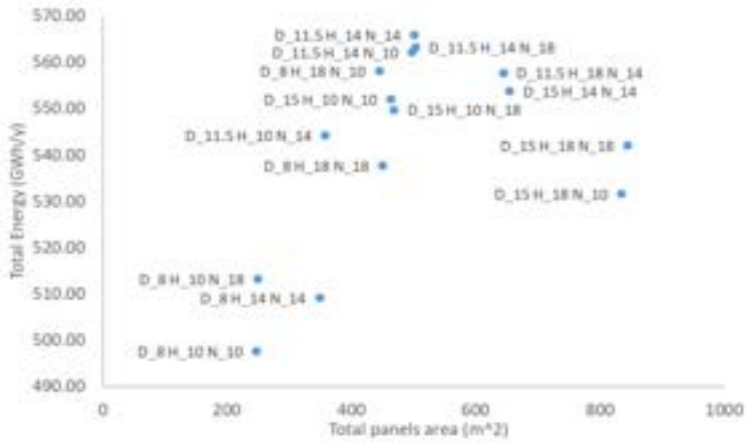

Figure 4. Yearly energy produced as a function of the receiver area.

It can be observed that the total energy produced increases with the total area of the panels up to the maximum value in the region near 500 m^2. For receiver areas greater than this value, the total energy drops. The result is not the same if the area is obtained with different combinations of values, as expected, it seems that, around the maximum value, it could exist some different combinations with similar yearly energy yield.

Once the results are obtained and analyzed, an expression that represents the yearly thermal energy as a function of the receiver diameter (D), height (H), and the number of faces (N) is obtained, Eq. (9).

$$f(D,H,N) = C_0 + C_1 \cdot D + C_2 \cdot H + C_3 \cdot N + C_4 \cdot D \cdot H + C_5 \cdot D \cdot N + C_6 \cdot H \cdot N + C_7 \cdot D^2 + C_8 \cdot H^2 + C_7 \cdot N^2 \quad (9)$$

The coefficients C_0 through C_9 are determined using the least squares method to fit the function to the data obtained from the DOE methodology. Once the coefficients are determined, this function can be potted to analyze the performance of the system as a function of the considered parameters. Figures 5(a), 5(b), and 5(c) depict the yearly energy production for cases with N = 18, N=14, and N=10, respectively. It can be noted that as the number of faces increases, the receiver height is higher and the receiver diameter is lower for the maximum value of the energy produced. So the receiver area tends to keep constant but with a different aspect ratio.

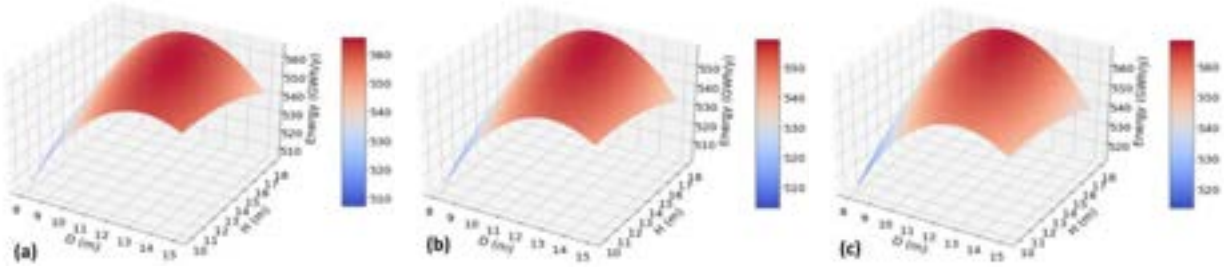

Figure 5. Total energy produced as a function of D and H for N = 18 (a), N=14 (b), and N=10 (c).

Figure 6 depicts a three-dimensional (3D) volume that displays the function value for each variable point within the considered range, represented by a color scale on the right. The volume illustrates the region where the function attains a maximum.

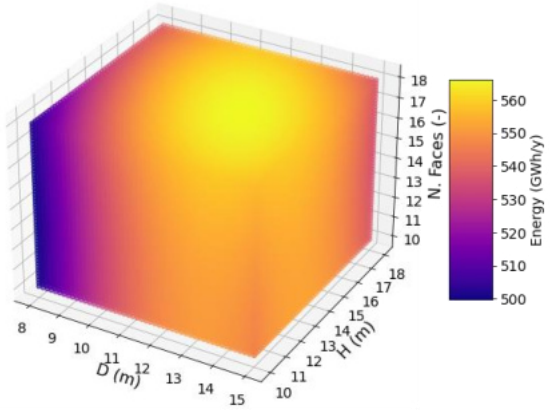

Figure 6. Total energy produced as a function of D, H, and N.

The function can be optimized to find the combination of the receiver parameters that yield the maximum yearly thermal energy. This optimization can be done using various optimization techniques, such as gradient-based methods or genetic algorithms, depending on the complexity and nonlinearity of the function. In this case, the Nelder-Mead method in Python was utilized to optimize the function within the specified range. The optimal values of the variables were determined to be (D = 12.63 m, H = 13.96 m, N = 18) which resulted in a total energy yield of 566.15 GWh/y and a receiver area of 550.3 m^2. This value is close to case 15 (D = 11.5 m, H = 14 m, N = 14), with a difference of only 0.05%. Figures 7(a) and 7(b) illustrate the areas where the response surface lies between this maximum value and yearly energy production that is 1% and 0.5% lower, respectively.

The optimal design resulting from the Nelder-Mead method would require a tube with a diameter of 40 mm and 972 tubes, which is less than the requirement for case 15. However, the receiver diameter is higher. It should be noted that the cost of the receiver is influenced by both the receiver diameter and the number of tubes required. Therefore, from a techno-economic analysis point of view, the response surface must be evaluated by taking into account the cost information to determine the optimal design. What is observed in Figures 7(a) and 7(b) is that there is an important number of combinations with similar yearly energy produced, so there is room to search for a design with a balanced cost and energy production which at the same time uses a nominal pipe size that can further reduce the costs and with a pressure drop less than 20 bar.

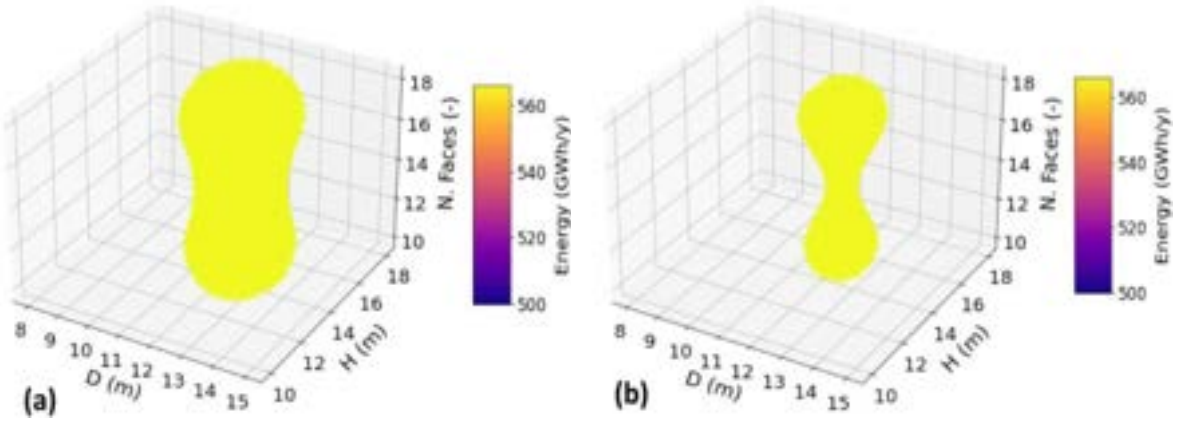

Figure 7. A volume that contains the combination of values that have yearly energy produced higher than 99% of the highest value (a) and higher than 99.5% of the highest value (b).

5. Conclusions

A methodology for the design of a CTR is proposed in this study, employing simplified models that encompass optical and thermal calculations, along with evaluations of other design constraints such as tube-failure predictions by stress or corrosion, and stable operation, which is ensured by limiting pressure drop and ensuring balanced flow among the receiver tubes. The methodology employs the yearly energy produced as the optimization criterion and considers the three primary parameters of receiver design, namely receiver diameter and height, and the number of panels. The tube diameter is predetermined for the optimization of thermal performance by controlling the HTF flow velocity.

The proposed methodology is developed in two steps, where the heliostat field is optimized for each design, followed by the optimization of the aiming strategy for the concrete heliostat field and receiver design. The employment of simplified models and DOE methodology to optimize the design enables the objective to be achieved within a reasonable time and with reduced computational resources. The response surface function obtained provides useful information for designing and optimizing solar receivers for maximum yearly thermal energy.

The results of the study indicate that for a target power of concentrated radiation flux density of 340 MWt (for one of the towers), the receiver area that optimizes the design is around 550 m^2, with an average value of 618 kWt/m^2. The results also reflect that some combinations of parameters will output similar yearly energy productions, thereby enabling the proposal of a design with similar performance and reduced costs.

Future work will include sensitivity analysis for the thermal-performance-related parameters to analyze their effect on the region for optimal designs. Furthermore, the inclusion of receiver costs as a function of the design parameters to obtain a response surface weighted by these cost estimations, oriented to reduce the Levelized Cost of Electricity (LCOE) for the optimized design will be explored. The implementation of more complex aiming strategies that can adjust heliostat aiming longitudinally in addition to vertically, to adapt the distribution to comply with the AFD without defocusing, will also be investigated.

A simple truncation criterion in CPCs using constructal theory

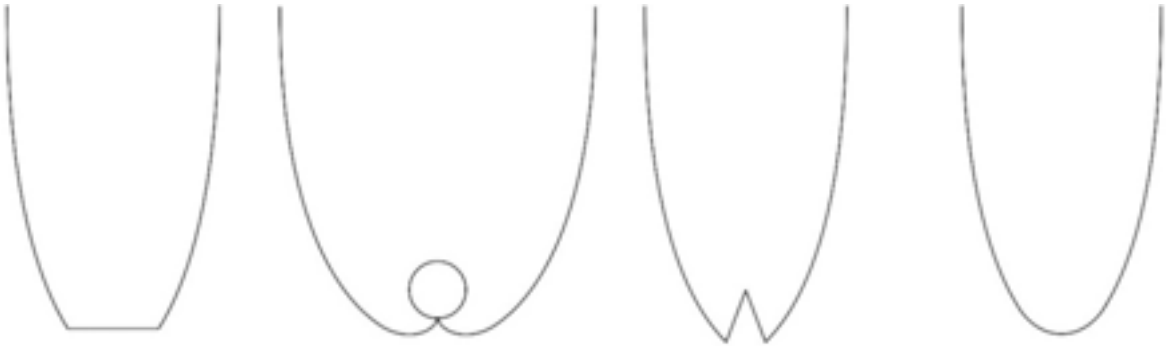
Abstract:
Compound parabolic concentrators (CPCs), whose origin dates back to the mid-1960s, gave rise to anidolic optics. Systems of this type allow the thermodynamic limit of solar concentration to be reached; however, in the case of CPCs, they involve systems with a very large height in relation to the aperture area (svelteness). Thus, arbitrary criteria have been proposed to reduce the height of the systems (truncation) and to be able to give them a real application. These truncation criteria establish the elimination of the upper part of the CPCs at a certain height in order to considerably reduce the height, but this has certainly undesirable consequences, since the geometric concentration (ratio of aperture area to receiver area) decreases with respect to the original design, which can limit the operating temperatures. Alternatively, a geometrical criterion has been proposed to truncate the CPCs without losing geometrical concentration, and still manage to reduce the height of the system by approximately 30%. This criterion consists of avoiding that the parabolic section mirrors do not block the incident rays that enter the aperture area with the maximum acceptance angle, thus defining an optimum truncation angle of 3 times the acceptance angle. However, now, with the help of the constructal law, it is possible to demonstrate that this angle is the optimum from a geometric viewpoint. Additionally, a new dimensionless number is defined for solar concentrating systems, relating the entropy generation distribution ratio, allowing to demonstrate that the Rincón criterion is the optimum for $C_g > 2.28$.

Keywords:
CPC truncation, entropy generation, étendue, constructal law

1. Introduction

The origin of compound parabolic concentrators (CPC) can be traced back to the mid-'60s by the developments of different researchers around the world: Baranov and Melinkov in the URSS [1], Ploke in Germany [2], and Hinterberger and Winston in the US [3], who independently described a novel optical system, unlike traditional systems, were based on the optimal transfer of radiation from the source to the objective, even if this implies forming aberrations and losing the shape of the source at the end of the system. This characteristic led to the coinage of the name non-imaging optics [4], to differentiate it from classical optics, where the image of the source must be conserved [5, 6]. As a result, in nonimaging optics, the light propagation is analyzed in terms of phase-space quantities and energy flow patterns This new optics has some advantages, but the possibility to reach the thermodynamic limit for solar concentrators systems is the principal [7]. Since mid-70s, their potential as collectors of solar energy was pointed out by Winston [8], and the widespread of this technologies has been fruitful.

Today, there is already a wide development of CPCs for solar applications, and several geometries have been generated that take advantage of non-imaging optics to concentrate solar energy on receivers of different shapes (circular, square, triangular, wedge, flat, elliptical...) [4, 9], Fig. 1 shows four typical CPC designs. All these geometries had been used for different purposes, like photovoltaics, solar heating and cooling, solar cooking, solar distillation, among others, that a complete summary of most of the works is out of the scope of the present paper, but several reviews [10–14] summarize some of the many developments, both experimental and commercial, that have been developed to date.



(a) Flat. (b) Circular. (c) Wedge. (d) Elliptical.

Figure 1: Different CPC receiver designs.

The main drawback of the CPCs, is that the ratio of height vs the receiver's area (svelteness) is too large, i.e. these concentrators are too high, and this ultimately limits their application even for fixed concentrators [4]. To overcome this problem, different truncation criteria have been proposed to decrease the total height [15–18] and consequently reduce the use of mirrors. These criteria had been developed from a purely geometrical perspective. Therefore, a formal analysis of the geometrical, optical, and thermodynamic aspects is necessary to establish which of the criteria is the most appropriate. This is fulfilled in the present work analyzing the original 2D flat receiver CPC with its geometric related parameters (height-aperture ratio and reflector area-aperture area ratio), optical-energy parameters (average number of reflections and étendue loss) and entropy related parameters (entropy generation number, optimum concentrator temperature and optimum efficiency) with the use of Bejan's constructal law [19, 20]. Although the analysis is done on a flat receiver CPC, the present work can be extended to any CPC design.

2. Brief description of the CPC

Regardless of the type of absorber the CPC may have, rays entering the concentrator with a maximum half acceptance angle θ_{max} (extreme rays), must be reflected by the mirror so that they are incident tangent to the absorber; while all rays entering with an angle θ less than the maximum half acceptance angle (i.e. within the angular full acceptance angle $2\theta_{max}$), are directed to the absorber after passing through the internal optics of the CPC (reflection or refraction).

With this definition, several receivers can be used, but only the flat receiver uses properly parabolas. In the present work, the flat receiver CPCs are considered. Equation 1 are the parametric equations to describe a flat receiver CPC with full height, schematically shown in Fig. 2., where it is assumed that the length of the trough CPC is l. The geometric parameters that define CPCs are the half-acceptance angle θ_0 and receiver size $2a'$. The subscript t stands for the truncated parameter.

$$\begin{cases} x(t) = \dfrac{2a'\,(1+\sin\theta_0)\cos t}{1-\sin\,(t-\theta_0)} \\ y(t) = \dfrac{2a'\,(1+\sin\theta_0)\sin t}{1-\sin\,(t-\theta_0)} \end{cases} \qquad t \in \left[0, \frac{\pi}{2}-\theta_0\right] \tag{1}$$

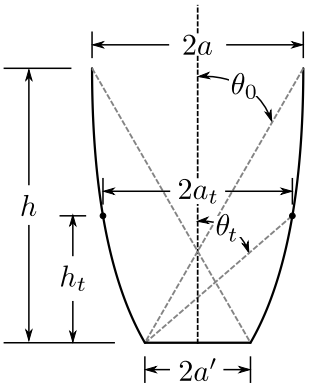


Figure 2: Schematic of the CPC with flat receiver.

From 1, it can easily be demonstrated that the concentration ratio (C_g) for a full CPC is simply:

$$C_g = \frac{A}{A'} = \frac{2al}{2a'l} = \frac{2x\left(\frac{\pi}{2} - \theta_0\right) - 2a'}{2a'} = \frac{1}{\sin\theta_0} \tag{2}$$

With the parametric equations given in 1, the svelteness Sv (height-aperture ratio) and the reflector area-aperture area ratio $r_{m,a}$ can be determined by.

$$Sv = \frac{y(t)}{2x(t) - 2a'} \tag{3}$$

$$r_{m,a} = \frac{\int_0^{t_{max}} \sqrt{x'^2 + y'^2}\mathrm{d}t}{2x(t) - 2a'} \tag{4}$$

2.1. Truncation of the CPC

As mentioned previously, one of the disadvantages of CPCs is the height of the concentrator; however, as seen in Fig. 2, the upper part of the mirrors does not contribute substantially to C_g. For this reason, it is recommended to remove a portion of the mirror to reduce height; this is known as truncation. While truncating the CPCs, material savings are achieved, but on the other hand, C_g will be reduced too since $2a_t < 2a$.

Winston, Rabl, and O'Gallagher recommend truncating the CPCs about half the fully developed height [7, 8, 17] (named Winston's criterion), while it can be found that some CPC can be truncated up to 2/3 the full height to reduce the loss in C_g. Independently, Rincón et al. [18] have proposed to truncate the CPCs to $3\theta_0$, because at this angle the mirror will not block light in the half-acceptance angle range $\pm\theta_0$ (Rincón criterion).

2.2. Optical energy related parameters

The thermal power that reaches the absorber can be described by a relation $\dot{Q}_u \sim G_b C_g \eta_o$, where G_b is the beam solar radiation and η_o is the optical efficiency, being a function of the average number of reflections n in the mirrors with reflectivity ρ as $\eta_o \sim \rho^n$. As can be seen, the lower the average number of reflections, the higher the optical efficiency and the higher the power that reaches the absorber.

Originally, Rabl [15] studied the average number of reflections , where it was shown that reducing the value of n led to an increase in the useful energy of the receiver. A summary of Rabl's equations for n can be found in [21]. Briefly, the average number of reflections in the CPC is a function of the type:

$$n = \max\left(F\left(\theta_0, x, y, t\right), 1 - \frac{1}{C_g}\right) \tag{5}$$

However, the most important parameter in optics is the étendue $\mathcal{E}$, defined as a geometric quantity that measures the amount of "place" available for light to pass [9], as a measure of the power transmitted along a beam of light. For 2D systems, the étendue is defined as [4, 9, 17, 22]:

$$\mathcal{E} = 2An_{ref} \sin\theta \cos\phi \tag{6}$$

where A is the area where the light passes, n_{ref} is the refractive index, θ is the solid angle where light enters in A and ϕ is the incidence angle. Recalling the concept of steady-state balance equations for any physical property ψ, the imbalance of the property can be determined as $\psi_{imb} = \psi_{in} - \psi_{out}$ [23, 24], where the subscript imb stands for the imbalance (destruction in the case of a negative value, generation for a positive value).

According to the definition of 6, if the rays enter an optical system with imperfections (the étendue is not preserved), then, at the output the rays will tend to scatter over the output area, consequently $\mathcal{E}_{out} > \mathcal{E}_{in}$, thus the imbalance term will be defined as scattered instead of generated. For full CPCs, the étendue is conserved [4, 9, 17, 22]. Any scattering in the étendue will cause the optics to fail to properly redirect the incoming light through the concentrator aperture, so the étendue scattering can be defined as:

$$\mathcal{E}_{sc} = \mathcal{E}_{out} - \mathcal{E}_{in} \tag{7}$$

or as a normalized scattering value as:

$$\mathcal{E}^*_{sc} = \frac{\mathcal{E}_{out} - \mathcal{E}_{in}}{\mathcal{E}_{in}} \tag{8}$$

which will have a value of 0, if there is no light scattering (perfect system, with conserved étendue); or 1 if the light is completely scattered (imperfect system, with non-conserved étendue).

2.3. Entropy related parameters

As described by Bejan [25], the minimization of the entropy generation rate implies the maximization of the useful power. In general, the entropy generation in a concentrating solar system, as in the thermal devices, will be due to the heat transfer process ($\dot{S}^{th}_{gen}$) and the fluid friction ($\dot{S}^{fl}_{gen}$) [25], but the étendue loss also contributes to an entropy generation $\dot{S}^{\mathcal{E}_{sc}}_{gen}$, so the total entropy generation has the basic form $\dot{S}^{total}_{gen} = \dot{S}^{fl}_{gen} + \dot{S}^{th}_{gen} + \dot{S}^{\mathcal{E}_{sc}}_{gen}$.
Considering an isothermal concentrator with no flow of mass on the concentrator (i.e., heating a plate), it is possible to eliminate the fluid friction entropy generation. The thermal entropy generation, as described by Bejan [25], includes the heat transfer coefficient U_r, the net solar transfer rate $\dot{Q}_s$ captured by the concentrator with an aperture A and receiver A' areas, the ambient temperature T_0, and the apparent sun temperature as an exergy source $T^* = \frac{3}{4}T_s$, as suggested by Petela [26], by:

$$\dot{S}^{th}_{gen} = \frac{U_r A' (T_r - T_0)}{T_0} - \frac{\dot{Q}_s}{T^*} + \frac{\dot{Q}_s - U_r A' (T_r - T_0)}{T_r} \tag{9}$$

The entropy generation for the etendue loss can be related trough the concepts of statistical thermodynamics, resembling that in general $S = k \log \Omega (E, V, N) + \text{const.}$ [27], and since the étendue is a measure of the transmitted power along a beam of light, a proper relation between this two variables can be developed. Winston et al. [28] have stated an entropy-étendue per photon relation as:

$$S^{\mathcal{E}} = k \log \mathcal{E} + \text{const.} \tag{10}$$

where the constant is related to a thermal quantity that can be set aside, since it applies only in the case of a wavelength shift [28, 29] or computed independently as done in 9, so the relation between entropy and étendue is firmly established. The entropy change for an irreversible process is equal to the entropy generation, so the entropy generation in terms of the étendue:

$$\dot{S}^{\mathcal{E}_{sc}}_{gen} = \dot{S}^{\mathcal{E}_{out}}_{out} - \dot{S}^{\mathcal{E}_{in}}_{in} = \dot{N}k \ln (1 + \mathcal{E}^*_{sc}) \tag{11}$$

where $\dot{N}$ is the number of photons per unit time that cross the aperture area of the concentrator. Note that under the numerical conditions of 8, the value of the entropy generation due to étendue scattering is always positive. The number of photons can be determined with $\dot{Q}_s$ and the average photon energy $E_{ph} \sim 10^{-19}$J as $\dot{N} = \dot{Q}_s / E_{ph}$.

Therefore, the total entropy generation rate in the concentrator is

$$\dot{S}_{gen}^{total} = \frac{U_r\,(2a')\,(T_r - T_0)}{T_0} - \frac{\dot{Q}_s}{T^*} + \frac{\dot{Q}_s - U_r\,(2a')\,(T_r - T_0)}{T_r} + \frac{\dot{Q}_s}{E_{ph}}\,k\ln\left(1 + \mathcal{E}_{sc}^*\right) \tag{12}$$

In view of this two discussed entropy generation terms, a dimensionless parameter relating the entropy (irreversibility) distribution ratio can be defined as $\dot{S}_{gen}^{\mathcal{E}_{sc}}/\dot{S}_{gen}^{total}$, with extreme values of 1 when the étendue scattering irreversibility dominates, 0 is the opposite limit at which irreversibility is dominated by heat transfer effects, and 0.5 is the case in which the heat transfer and the étendue scattering entropy generation rates are equal. In addition, when the entropy distribution ratio is zero, the étendue conservation condition is fulfilled. Thus, it is justified to define this parameter from the étendue concept and not from the heat transfer perspective.

Caution must be taken, since this relation can be confused with the Bejan number (Be) defined by Paoletti et al. [30] for the generation of entropy through heat and flow. This new relationship involves an optical parameter (the étendue) as an element that also generates entropy. This dimensionless parameter was originally proposed for entropy analysis in CPCs by González-Mora [31] but can be further generalized to any concentration geometry, since étendue conservation is a major concern when designing optical systems [4, 9, 22]. Consequently, it is suggested to call the entropy distribution ratio as Mo. The Mo number can then be expressed with the help of 12 as:

$$\mathrm{Mo} = \frac{\gamma\,(\theta_{max} - 1)\ln\left(1 + \mathcal{E}_{sc}^*\right)}{\theta^*\left[\theta_r^2 - 2\theta_r + \theta_{max}\right] + \theta_r\,(\theta_{max} - 1)\left[\gamma\theta^*\ln\left(1 + \mathcal{E}_{sc}^*\right) - 1\right]} \tag{13}$$

where $\theta_r = T_r/T_0$, $\theta^* = T^*/T_0$, $\theta_{max} = T_{r,max}/T_0 = 1 + \dot{Q}_s/U_r A' T_0$ and $\gamma = T_0 k/E_{ph}$. Furthermore, from 12 the optimal receiver temperature can be defined as the one that minimizes the total entropy generation rate, i.e. $\mathrm{d}\dot{S}_{gen}^{total}/\mathrm{d}\theta_r = 0$, resulting:

$$\theta_{r,opt} = \theta_{max}^{1/2} \quad \Leftrightarrow \quad T_{r,opt} = \sqrt{T_0\,T_{r,max}} \tag{14}$$

2.4. Constructal law

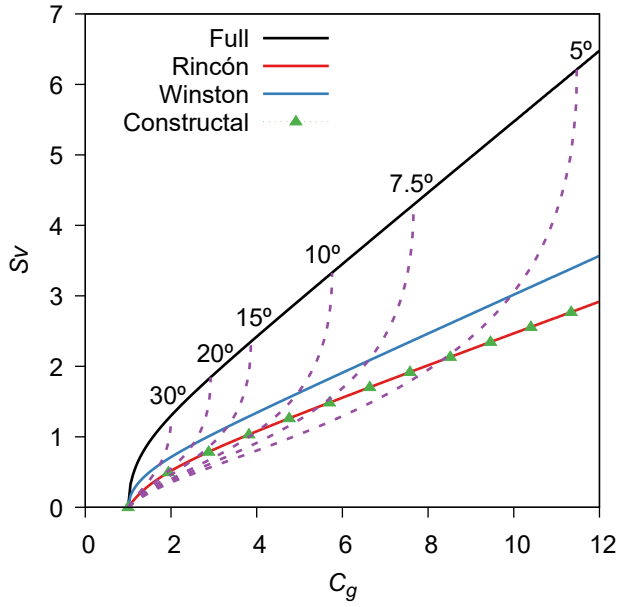
The aforementioned truncation criteria were established only through a purely geometrical approach. However, Rincón's criterion was recently demonstrated on a simplified parametric energy basis with a first approach of the constructal law [32]; while González-Mora [31] gave the first approach for entropy related parameters suggesting the evaluation of the so-called Mo number, as a response to several inquiries to rename the Rincón criterion. Therefore, a complete discussion of the geometric, optical and entropy parameters of CPCs is required for an objective comparison of the truncation criteria. To compare these criteria, constructal theory is used to define a constructal truncation criterion.

In 1997, Bejan [19] stated "For a finite-size system to persist in time (to live), it must evolve in such a way that it provides easier access to the imposed currents that flow through it", which is known today as constructal law, with a vast theory under it [20, 33]. The constructal law has been applied to various engineering systems [34], and recently in renewable energy systems analyzing a solar chimney and an oscillating water column [35], in addition to the first approaches in CPCs [31, 32], so the path for the constructal law in sustainable energy systems is clear and ongoing.

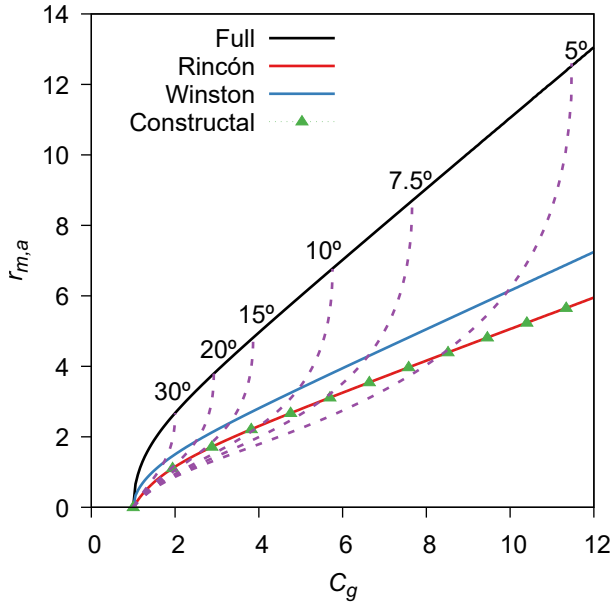
The fundamental concept of the constructal law is to establish the configuration that facilitates the flows in the system, by defining different parametric relations that establish the system degrees' of freedom and evaluating the behavior of the system with its proper restrictions. In the present analysis, the degrees of freedom are C_g and θ_r for the parametric relations that are described in the previous sections. Thus, accoring to the different truncation criteria, different configurations can be easily compared , where the main objective function is the Mo number described in 13.

3. Results

These results are shown graphically below, including the constructal law results applied with the PIKAIA genetic algorithm [36]. Although the objective function is the Mo number, all parameters were evaluated and discussed below. In all the plots, the same color palette is used: black for the full CPC, purple for the truncated CPCs, red for the truncated CPC under the Rincón criteria, blue for the truncated CPC under the Winston criteria, and green for the CPC results using the constructal law.



(a) Svelteness for different CPC designs.



(b) Reflector area-aperture area for different CPC designs.

Figure 3: Geometric results.

3.1. Geometric results

In Fig. 3, the svelteness Sv and the reflector area-aperture area $r_{m,a}$ are plotted as a function of the concentration ratio C_g. As can be seen, Winston's criterion (blue line) reduces the height of CPCs, but Rincón's criterion (red line) reduces the height even further compared to the full CPC (black line). Here, a remark must be done for this, and all the following plots, since Winston's criterion reduces the concentration ratio one must find the intersection of the blue curve with the green curves to read the desired parameter, while the Rincón criterion attains no reduction in concentration ratio since a new acceptance angle must be determined to keep the original C_g value, and parameters can be read directly.

When applying the constructal law to the geometric parameters (green line), the same result is obtained as the Rincón criterion. Therefore, from a purely geometric perspective, the Rincón criterion is a geometric result justified by the constructal law.

3.2. Optical-energy results

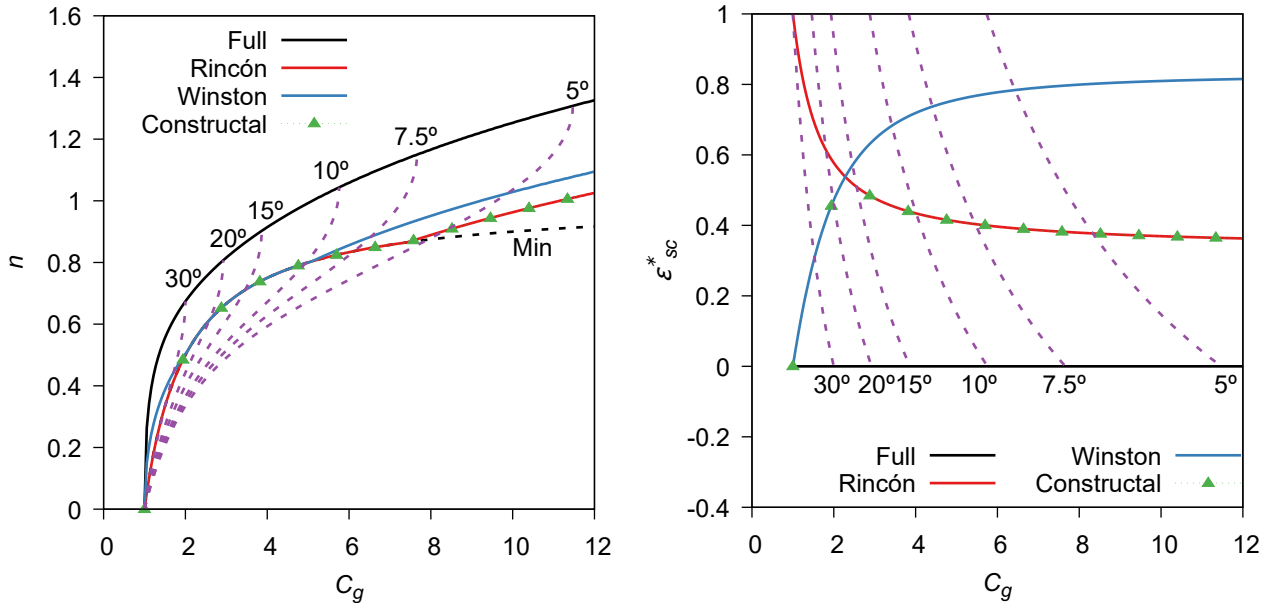
The average number of reflections and the étendue scattering are shown in Fig. 4 and can be read like the previous plots. As can be seen, the Winston criterion (blue line) considerably reduces the average number of reflections, but the Rincón criterion (red line) reduces even more the average number of reflections, being the same for C_g between 2.04 and 5.01; however, Rincón's criterion maintains an almost average value n close to the minimum average number of reflections. An interesting behavior occurs for the étendue loss, since the Rincón criterion results in beneficial results only for $C_g > 2.28$, otherwise the light will start to spread over the receiver. In view of these results, the optical efficiency will be maximum for the CPC that is truncated with the Rincón criterion due to a greater reduction of n and, in general a minimum loss of the étendue.

Similarly, the application of the constructal law (green line) to the optical energy parameters yields a curious behavior. For the average number of reflections, the results are in agreement with the Rincón criterion, but not so for the étendue scattering. The behavior of the truncation criterion according to the constructal law shows that the Winston criterion is beneficial up to C_g = 2.28, and subsequently, the Rincón criterion is the one that minimizes the dispersion of the étendue in the optical system for $C_g > 2.28$.

3.3. Entropy results

In this case, in addition to C_g, θ_r is another degree of freedom. Although a 3D surface could be generated, its interpretation would be complicated. The parameter θ_r is the dimensionless temperature of the receiver, so it is greater than 1, and necessarily less than θ_{max}, with the possibility of being $\theta_{r,opt}$. Under these constraints, in the present analysis θ_r is proposed as an average of these values.

The entropy parameters under the described conditions are shown in Fig. 5. As expected, for the full CPC (black line), Mo=0 regardless of C_g. In the case of the Winston criterion (blue line), Mo results lower up to



(a) Average number of reflections for different CPC designs.

(b) Étendue scattering for different CPC designs.

Figure 4: Optical-energy results.

$Cg < 2.28$, subsequently, the Rincón criterion (red line) presents lower values. Applying the constructal law (green line) gives a result very similar to the dispersion of the étendue, since the truncation of the CPC is optimized as a function of C_g. As can be seen in the graph of the optimum temperature, the Rincón criterion allows the optimum temperature of the complete CPC to be reached, just as if the constructal law were applied.

4. Conclusions

The CPC has several advantages for concentration systems; principally the possibility to get mid temperature ranges with a fixed concentrator, however, its height is the major drawback for its application. As a result, several truncation criteria had been proposed to increase its use, but, up to date, all had been justified by its height reduction, despite a first approximation with a simplified energy analysis.

Now, the analysis has been extended to include the rate of entropy generation, identifying that this production occurs by two factors: dispersion of the étendue and heat transfer process; leaving aside the entropy generation by fluid friction when considering only the heating of a flat plate for CPC with flat receivers. However, this analysis can be extended to any receiver geometry.

The present analysis has focused on comparing the behavior of the concentration ratio (C_g) for full CPCs with respect to truncated CPCs according to Winston's and Rincón's criteria and by applying Bejan's constructal law. This comparison is made by means of six parameters: two geometrical (svelteness and reflector area-aperture area ratio), two optical-energy (average number of reflections and étendue dispersion) and entropy (a new dimensionless group proposed Mo that relates the entropy generation distribution and the optimum receiver temperature).

When the study is carried out for different values C_g for the geometric parameters, the results of the constructal law and the Rincón criterion are optimal as Sv and $r_{m,a}$ decrease significantly to a value close to $1/3$ of the full CPC. With respect to the optical-energy parameters, the Rincon criterion and the construct law can be identified as the conditions for minimizing n; however, with respect to the dispersion of the étendue, the Rincon criterion is only beneficial for $C_g > 2.28$, for lower concentrations, the Winston criterion is a better choice, as shown by the constructal law. For the entropy results, again the Rincon criterion is only beneficial for $C_g > 2.28$, as shown by the constructal law; while for the optimal temperature, the Rincón criterion allows reaching the full CPC temperature.

In view of the results obtained, Rincón's criterion, although proposed from a purely geometric perspective, is practically a result of the construction law, provided that $C_g > 2.28$. This allows, without any doubt, to establish that, for the great majority of low- and medium-temperature applications, using the Rincon criterion allows obtaining the best performance in CPCs, as had been stated as an assumption (without a formal demonstration) in other previous works.

Alternative Methodology for Modeling Direct Steam Generation in Parabolic Collectors: A Study Case in Northweast Mexico

Eduardo González-Mora[a], Ma. Dolores Durán-García[a]

[a] Facultad de Ingeniería, Universidad Autónoma del Estado de México, Toluca, México, egonzalezmo@uaemex.mx

Abstract:

The possible implementation of direct steam generation (DSG) in parabolic troughs in the Northweast region of Mexico is very limited, since there are no analyses of this type to try to define a first proposal for a solar plant. Recently, a methodology has been implemented to eliminate the convective coefficient *h* in order to model the DSG process in a simpler way. This methodology has been validated with experimental data from the DISS results from PSA. This methodology allows to evaluate the temperature evolution along the loop, the pressure drop and the flow pattern in a short time and with low computational resources. This allows generating the first evaluation of a solar field with parabolic troughs. Additionally, by applying a new practical efficiency limit for the conversion of solar radiation into work, the exergetic efficiency of the installation is evaluated. The results show that this first evaluation, seems to be adecuate acording to the results suggested in the open literature.

Direct steam generation modeling, parabolic collector, flow pattern, heat transfer, boiling

1. Introduction

The consequences of the socioeconomic model based on the consumption of fossil fuels have been so dramatic in recent years that no one denies that the current energy model is in crisis and, therefore, in the process of a fast and unstoppable transformation [1, 2]. It is urgent to shift from the current centralized system based on fossil fuels toward a system that is distributed, and based on renewable energies [3]. Among the energies that should make up an important part of the world's energy mix, solar energy undoubtedly stands out. Solar energy is clean, environmentally friendly, and freely available over the planet.

Concentrating solar power (CSP) plants, also known as solar thermal, is a commercial alternative to non-renewable energy sources such as oil, coal and nuclear power for the production of electricity, mainly with the use of parabolic trough solar fields. Most CSP facilities to date have implemented synthetic or mineral oil as a working fluid in the solar field. The main limitation of thermal oil is that at 400°C it begins to degrade, thus imposing a limitation on the maximum operating temperature of the thermodynamics power cycle, generally a steam Rankine cycle [4–6].

Alternatively, thanks to DISS loop at Plataforma Solar de Almería [7–10], it has been demonstrated that it is possible to work with the concept of direct steam generation (DSG), in which steam is generated directly in the solar field and then redirected to the power block turbine. The DSG has some technical advantages that must be considered [5, 7, 11]:

- There is no danger of contamination or fire due to the use of thermal oil
- Possibility of raising the maximum temperature of the Rankine cycle above 400°C, which is the limit imposed by the thermal oil currently used
- Reduction of the size of the solar field, thus reducing the investment cost
- Reduction of operating and maintenance costs, as thermal oil based systems require a certain amount of oil inventory that must be changed every year, as well as antifreeze protection when the air temperature is below 14 °C

However, the DSG process have several problems. For example, Almanza et al. operated a parabolic trough collector (PTC) plant to feed a low-power steam engine, highlighting the deflection problems suffered by low-temperature systems and controllability of the flow pattern [12, 13]. It is therefore necessary to carry out simulations to understand the thermohydraulics of the process. Up to date, there is considerable progress in

DSG analysis [11, 14, 15]. However, they all resort to the concept of classical heat transfer with the calculation of the convective coefficient *h*, in combination with the friction factor *f*, to understand the thermo-hydraulic behavior of the installation, even in CFD models [16, 17].

Nevertheless, the use of these parameters demands high computational power because the methodology to obtain these parameters requires an iterative process [18]. In this work, we apply the recently proposed and validated methodology for the analysis of DSG in PTC [19], with low computational times and high confidence, in which the use of the convective coefficients *h* is eliminated. The analysis is performed on a 10 MW conceptual plant located in northwestern Mexico.

1.1. Structure and scope

This article is organized in two parts. The first part outlines the thermohydraulic model and, subsequently, its application to the case study. This allows us to identify that the proposed methodology can be used without complications in the analysis of solar plants for direct steam generation in parabolic troughs.

2. Thermohydraulic modeling for DSG in PTC

The model to be developed takes as a reference the one described by other authors [20–25]. The present, uses the typical 1D modeling technique based on a steady-state energy balance over the receiver. The receiver is divided into smaller parts called Heat Collector Elements (HCE). The balance equations comprises direct normal solar irradiation, optical losses, HCE thermal losses, and the working fluid gains. The distinction of this model lies for the use of the heat transfer methodology developed by Adiutori [26]. This methodology does not require iteration to solve the heat fluxes and associated temperatures in the thermal model.

2.1. Energy balance equations

The working fluid temperature increases as the energy is absorbed by the HCE. Heat losses will occur as a result of differences between the average fluid temperature in each cross section and the ambient temperature. With Fig. 1, the following balance equations can be written:

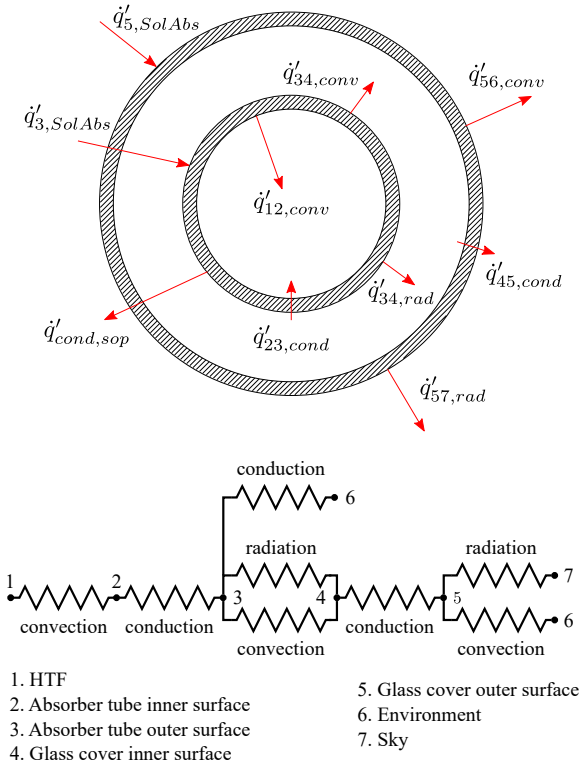

Figure 1: Heat fluxes over the parabolic trough.

$$\dot{q}'_{12,conv} = \dot{q}'_{23,cond} \tag{1a}$$

$$\dot{q}'_{3,SolAbs} = \dot{q}'_{34,conv} + \dot{q}'_{34,rad} + \dot{q}'_{23,cond} + \dot{q}'_{38,cond} \tag{1b}$$

$$\dot{q}'_{45,cond} = \dot{q}'_{34,conv} + \dot{q}'_{34,rad} \tag{1c}$$

$$\dot{q}'_{45,cond} + \dot{q}'_{5,SolAbs} = \dot{q}'_{56,conv} + \dot{q}'_{57,rad} \tag{1d}$$

$$\dot{q}'_{12,conv} = \frac{\dot{m}}{L_{HCE}} \left(h_{in} - h_{out}\right) \tag{1e}$$

For the five equations of 1, the radiation absorption phenomena in the absorber tube and the transparent cover are treated as surface heat fluxes. In addition, the temperatures, heat fluxes and all thermodynamic properties are uniform around the cross-sectional area (1D model) [27]. These simplifications lead to theoretical values larger than the real ones, but with adequate results [21]. Under these conditions, each heat flux can be expressed as:

$$\dot{q}'_{i,SolAbs} = \eta_o W G_{bn} \tag{2a}$$

$$\dot{q}'_{ij,cond} = \frac{2\pi k_{ij} \left(T_i - T_j\right)}{\ln\left(\frac{D_j}{D_i}\right)} \tag{2b}$$

$$\dot{q}'_{ij,rad} = \frac{\sigma\pi D_i \left(T_i^4 - T_j^4\right)}{\frac{1}{\varepsilon_i} + \frac{\left(1-\varepsilon_j\right) D_i}{\varepsilon_j D_j}} \tag{2c}$$

$$\dot{q}'_{ij,conv} = f\left(\Delta T\right) \tag{2d}$$

where $\eta_o = IAM\Gamma\rho\tau\alpha$ is the optical efficiency, W is the trough width, G_{bn} is the incident solar radiation in the normal direction, k is the conductivity, T is the temperature, D is the diameter, σ is the Stefan-Boltzmann constant, and ε is the emittance. The subscripts i and j allow us to identify each of the surfaces, according to Fig. 1.

Notice that 2d, omits the use of the convective heat transfer coefficient h, and a particular function of the temperature difference should be used. These functions must be obtained from the expressions of the Nusselt number, by means of a transformation of the dimensionless groups, as explained in [26].

The annulus formed between the absorber tube and the glass envelope is modeled as free convection between two cylinders because the receiver is evacuated. Between the glass cover and the environment the convection can be forced or natural. In the first case, the Žhukauskas equation is used, while the Churchill-Chu equation is adequate for the second case [28]. For the convection between the absorber tube and the heat transfer fluid, there are two cases: the Pethukhov or Gnielisnki equation [28] for the single phase fluid and the Gungor and Winterton correlation for the two-phase flow [29]. The transformation of the two-phase flow equation is described in [27], resulting in the following:

$$\Delta T = C_1 \dot{q}'_{12,conv} \left[C_2 \left(C_3 + C_4 \dot{q}'^{1.16}_{12,conv} \right)^2 + C_5 - \frac{C_6 \dot{q}'^{0.67}_{12,conv}}{C_7 \left(C_3 + C_4 \dot{q}'^{1.16}_{12,conv} \right)^2 - 1} \right]^{-1} \tag{3}$$

where each C_i is a functional parameter of the temperature, obviously positive ($C_i > 0$), which can be obtained from any database of thermodynamic properties. This equation can be used with confidence, as validated in [27] with data recovered from the DISS loop [10, 16].

3. Study case

A conceptual regenerative Rankine cycle with parabolic trough collectors using the DSG concept is under consideration. The power block is designed to produce 10 MW of net power output, fixing the conditions at the turbine inlet 100 bar and 673.15 K (400 °C), and 0.08 bar at the turbine outlet. A generic turbine with a nominal isentropic efficiency of 80% is selected, as it is a value suggested by other similar analyses [30]. The Rankine cycle employs two internal regenerations (see Fig. 2), which allow the inlet temperature of the solar field to be higher (496.121 K) and consequently the size of the parabolic trough loops to be smaller. The tubine steam extractions have been determined with the premise of minimizing the exergy destruction and consequently maximizing the second law efficiency. The process of this optimization can be found in [31, 32].

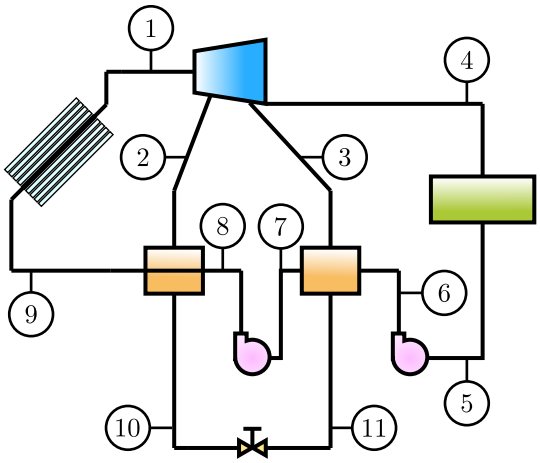

Figure 2: Schematic of the conceptual DSG Rankine power plant. Adapted from [31, 32].

With the operating conditions of the power block, 12.8058 kg/s of steam is needed to produce 10 MW of nominal power. Two conditions should be taken into account for DSG plants. The first is a mass flow rate that allows turbulent flow ($\mathrm{Re} > 2 \times 10^5$) to ensure an appropriate heat transfer between the absorber and the water/steam [9, 21]. Second, the annular flow pattern should be sought to avoid overheating in the absorber. However, at the beginning of the boiling process, the flow pattern may be intermittent and annular, as in the DUKE loop [33]. Dividing the mass flow rate into a certain number of loops allows us to fulfill the first consideration. At the end of the thermohydraulic characterization, the second consideration can be verified.

The analysis is carried out considering three days: June 21 (summer solstice), May 21 (highest insolation condition), and September 21 (lowest insolation condition). Therefore, there are a total of 24 simulations to be carried out. In all the cases, the HCE is fixed to 2 m. The weather conditions for the selected days in Agua Prieta (northwest Mexico) are described in Table 1. For the present analysis, the mass flow is divided into 8 loops; therefore, the mass flow rate per loop is 1.6007 kg/s, with Re = 3.699×10^5, fulfilling the first flow condition.

Table 1: Weather conditions for the selected simulation days in Agua Prieta, México. Data obtained from [34].

Parameter	21st june	21st may	21st september
DNI (W/m^2)	856.4815	889.6396	628.8580
Atmospheric pressure (bar)	0.886	0.884	0.885
Ambient temperature (K)	300.05	295.95	300.05
Sky temperature (K)	271.95	265.75	277.75
Wind speed (m/s)	4	4.1	3.2

For the two-steam extractions, the subcooled water must enter the solar field at 496.121 K. Once the fluid input conditions to the solar field are known, together with the normal weather conditions described in Table 1, it is possible to start with the simulations to thermo-hydraulically characterize the solar field, simultaneously solving 1. Knowing all the initial parameters and having defined the size of the HCE, the fluid starts its path along the loop, increasing its temperature and evidently suffering a pressure drop; until it reaches the saturated liquid condition. The fluid then undergoes a phase change from saturated liquid to saturated vapor in a non-isobaric process. An intermittent flow at the beginning of the boiling and annular in the rest of the process is expected. Finally, the fluid is superheated to a temperature of 673.15 K.

Figure 3 shows the temperature evolution along the loop. It is important to note that, as expected, the temperature during the phase change does not remain constant due to the pressure drop (as shown in detail in Fig. 4). The pressure drop decreases slightly the saturation temperature, which also affects the vapor-liquid mixture quality. It is evident that in the three days, the evaporation zone has a larger size since the phase change processes require a high demand of thermal energy to achieve this task.

As seen in Figure 4a, the pressure along the loop decreases until it reaches the required conditions at the turbine inlet (100 bar and 673.15 K). Figure 4b shows that the phase change region presents the highest pressure drop. It is important to note that the curve obtained shows an abrupt change in its slope, as occurs in the DISS loop [35].

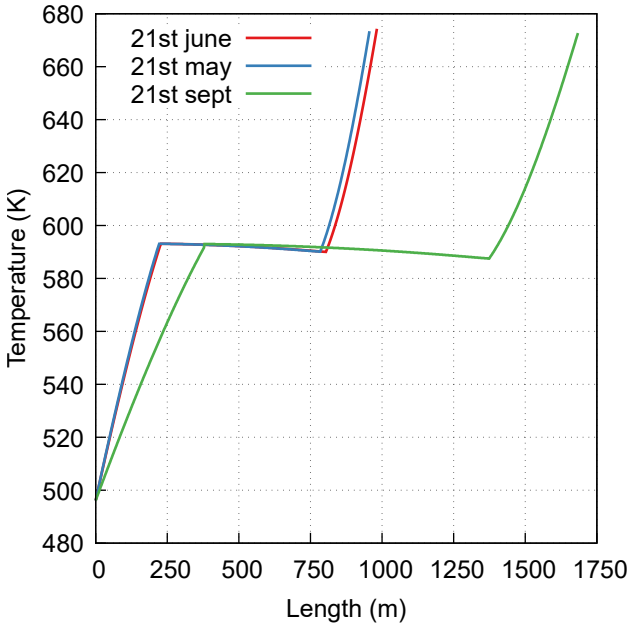

Figure 3: Evolution of the temperature increase along the loop.

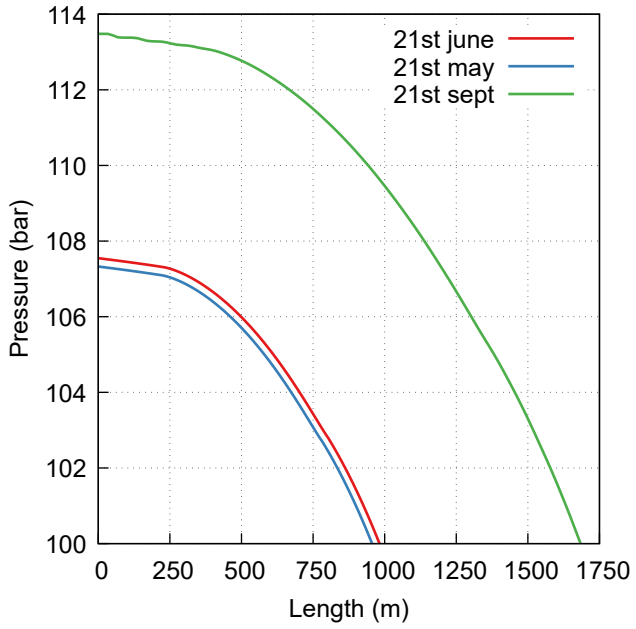
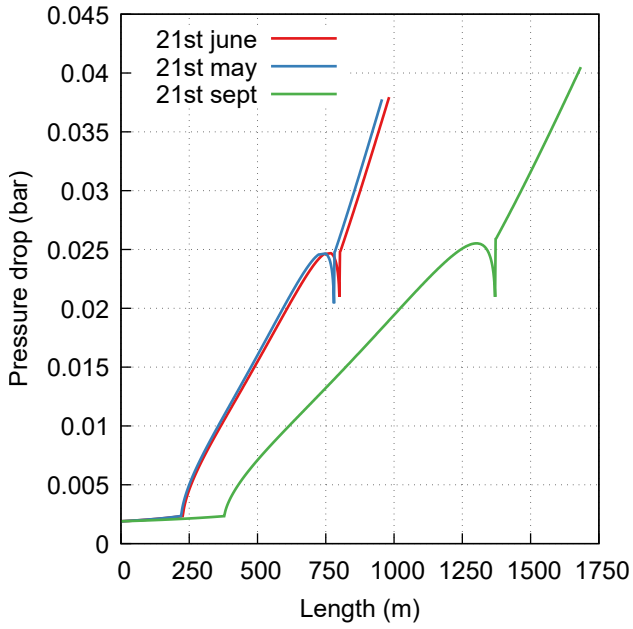


(a) Pressure evolution along the loop.



(b) Pressure drop along the loop.

Figure 4: Loop pressure characterization.

The flow pattern in the boiling process along the loop must be verified, as stated previously. Figure 5 shows the flow pattern in the two-phase flow region in the Taitel and Dukler flow map. While analyzing the graph for the Martinelli parameter X, an intermittent flow (high values of X) is present at the beginning of the boiling process, then changes to an annular flow as the steam quality increases (low values of X). Doing this verifies that the mass flow is adequate and meets the two established conditions: a high Re number to ensure a high heat transfer rate and a flow pattern that reduces overheating in the absorber.

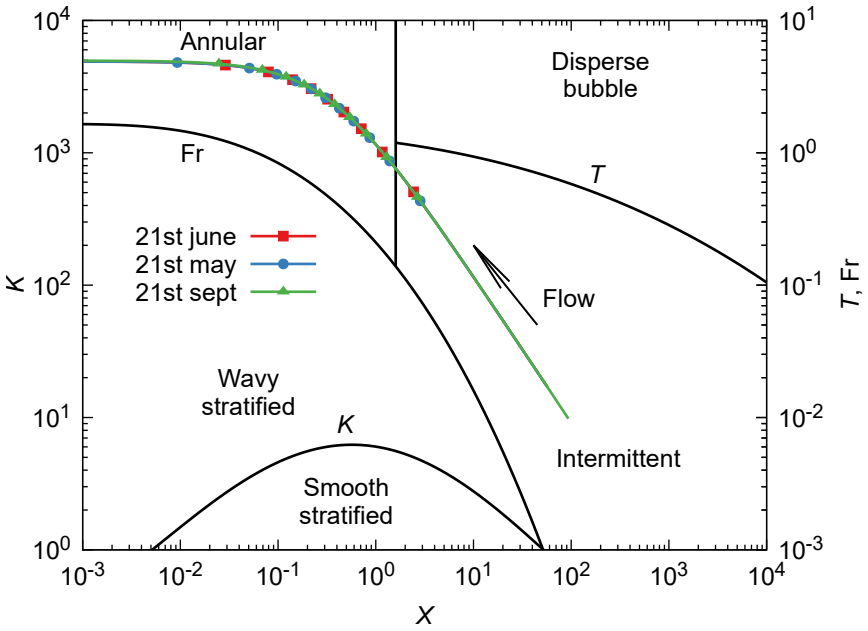


Figure 5: Flow pattern in the two-phase region.

When analyzing Figure 3, and as expected, the solar field has a longer length on the day of less insolation (September 21), being shorter for the day of greater insolation (May 21) although there is no substantial difference concerning the summer solstice (June 21). Since the total mass flow rate of the Rankine cycle was divided into eight loops, the total length of the PTC field must be multiplied by 8. It is possible to define the total concentration area for the solar field. These will allow us to define the type of arrangement of the loops in the solar field, since for areas greater than 40 ha, an "H" arrangement is recommended, while for less than 40 ha an "I" arrangement can be used [21, 36]. In Table 2, the precise loop length is shown, including the total area of the solar field, in addition, the pressure at the inlet of the solar field is also shown. In these three cases, the arrangement "H" is recommended.

Table 2: Solar field description.

Parameter	21st june	21st may	21st september
Preheater length per loop (m)	226	220	378
Evaportor length per loop (m)	578	570	1016
Superheater length per loop (m)	178	164	290
Total length per loop (m)	982	954	1684
Total concentrating area (ha)	4.53	4.41	7.78
Inlet pressure (bar)	107.55	107.33	113.48

The pressure evolution along the loop presents a similar behavior (Figure 4a). Since the September 21 loop is the longest, it will have higher pressure drops, so the solar field must be operated at a higher pressure (almost 114 bar). Figure 4b shows that the highest pressure drop occurs in the two-phase flow zone. The behavior at the phase change interfaces (saturated liquid and saturated vapor) presents an abrupt change in its slope (nondifferentiability condition), although as reported in [37], it is continuous.

Once all the operating parameters in the solar field (temperature and pressure) are known, it is possible to identify the flow pattern in the phase-change region. Although the loops have different lengths and pressure drops in the three cases of analysis, the flow at the beginning of boiling is intermittent. As the liquid transforms

into steam, the flow behaves as an annular. This behavior is desired in plants with the direct steam generation, so the feasibility of this loop is adequate.

Four additional parameters of great interest are usually computed for CSP plants: solar multiple (SM, 4), thermal energy storage size ($\dot{Q}_{TES}$, 5), energy (η_I, 6) and exergy (η_{II}, 7) efficiency of the PTC solar field. Considering that on September 21st, the loop is the largest, this day is considered as the design condition. If $SM > 1$, it is possible to include thermal energy storage (TES). For PTC, the SM must be below of 2 [6]. To date, there are no commercial TESs for DSG. However, a generic TES size system can be defined and rated accordingly. These four parameters are defined as:

$$SM = \frac{\dot{Q}_{solar\ field,design}}{\dot{Q}_{solar\ field}} = \frac{A_{ap} G_{bn}}{A_{ap,september} G_{bn}} \tag{4}$$

$$\dot{Q}_{TES} = (SM - 1)\, \dot{Q}_{solar\ field} \tag{5}$$

$$\eta_I = \frac{\dot{Q}_{HTF}}{\dot{Q}_{inc}} = \frac{\dot{m}\,(h_{out} - h_{in})}{A_{ap} G_{bn}} \tag{6}$$

$$\eta_{II} = \frac{\Delta \dot{E}x_{HTF}}{\dot{E}x_{inc}} = \frac{\dot{m}\,(ex_{out} - ex_{in})}{A_{ap} \dot{E}x_{solar}} \tag{7}$$

The exergy of solar thermal radiation is calculated with González-Mora formula [38]:

$$\eta = \left(1 - \frac{1}{\xi}\left[\frac{T_r}{T_{sun}}\right]^4\right)\left(1 - \frac{\lambda_c T_{amb}}{\lambda_c T_r + \xi\sigma T_{sun}^4 - \sigma T_r^4}\right) \tag{8}$$

where the optimum receiver temperature T_r must be obtained by solving $4\sigma^2 T_r^{11} - 8\sigma\lambda_c T_r^8 - 8\sigma^2\xi T_{sun}^4 T_r^7 + 4\lambda_c^2 T_r^5 - T_r^4\left(4T_{amb}\lambda_c^2 - 8\lambda_c\sigma\xi T_{sun}^4 - \lambda_c^2 T_{amb}\right) - \lambda_c^2 T_{amb}\xi T_{sun}^4 = 0$. In [38], it has been demonstrated that the exergy of solar radiation is $0.8391 G_{bn}$. Table 3 shows the solar multiple, the TES size, the energy efficiency and the exergy efficiency of the PTC solar field.

Table 3: Solar multiple and efficiencies of the solar loop.

Parameter	21st june	21st may	21st september
SM	1.72	1.77	1
TES (MW_t)	3.49	3.76	0
Energy efficiency (%)	70.38	69.49	56.05
Exergy efficiency (%)	40.71	40.78	32.23

4. Conclusions

The modeling of parabolic trough solar plants in direct steam generation remains crucial to understanding the operating behavior and, consequently, in their implementation. In this work, an alternative methodology for thermo-hydraulic characterization of these types of systems is used to characterize the solar field. The developed model, unlike other models, eliminates the use of the convective coefficient h and the friction factor f. This allows a fast computation, with confident results.

The thermohydraulic model was applied for the analysis of the conceptual direct steam generation plant in Agua Prieta (Northwestern Mexico). The 10 MW Rankine cycle was previously optimized to minimize the destruction of exergy. As a result, 12.8058 kg/s of steam at 100 bar and 673.15 K (400 °C) is required. With the restriction of maintaining a turbulent flow, the mass flow rate has been divided into 8 loops; each loop circulating 1.6007 kg/s of water/steam entering at 496,121 K, with a maximum pressure of 113.48 bar.

Three days have been analyzed for the conditions of highest insolation (21st may), minimum insolation (21st september) and the summer solstice (21st june), considering their respective weather conditions for each day. As a result, the total length of each loop has been defined first, where it turns out that the longest loop is for

21st september (1684 m, 7.78 ha in total). This loop is considered as the design field. Once the loop length has been defined, the flow pattern type in the two-phase zone has been characterized. It is identified that for the three days of analysis, the flow at the beginning of the boiling is intermittent and later evolves towards an annular flow, which is the one suggested in DSG plants.

Finally, the solar multiple has been calculated, showing that for the design condition, the solar multiple is not excessively large, so the loop is adequate, with a capacity of 3.76 MW. Similarly, the PTC energy efficiency has a maximum value of 70.38% (and 56.05% minimum), while the PTC exergy efficiency has a maximum value of 40.78% (and 32.23% minimum).

Abstract:

Energy consumption for metal extraction and beneficiation is substantial and is expected to keep growing due to increased demand. With rising worldwide energy prices and the continued energy crisis in South Africa, there is a need to decrease the dependence on the national energy grid. Among the refining processes, electrowinning is one of the most energy intensive unit operations. In the context of zinc, electrowinning can consume on average 2,900-3,300 kWh/t-zinc, approximately accounting for 60% of the total electricity consumption of refined zinc production. Industrial and economic growth, a major focus of Southern African countries, is positively correlated with zinc demand due to its role in general construction, electricity transmission, and telecommunications. South Africa is endowed with 14 Mt of zinc content within 200-300 Mt of zinc ore reserves and expanding internal zinc production capacity is a current focus. Since electrowinning units operate with low-voltage direct current, photovoltaic solar energy appears to be an applicable green energy source due to its electricity output also being low-voltage direct current. In addition, South Africa has an attractively high solar irradiance (220 W/m^2 compared with Europe's 100 W/m^2). Hence, an investigation into the technical and economic feasibility of substituting or supplementing the energy demand, using solar energy for the electrowinning unit of a theoretical zinc refinery operating in the Northern Cape of South Africa, is warranted. A high-level carbon footprint analysis is included. The findings from this study could assist in stabilising the energy supply for the beneficiation of zinc in South Africa, as well as contribute to the decarbonisation of the industry.

Keywords:

Zinc refining, electrowinning, solar energy, photovoltaic cells, South Africa

1. Introduction

The applications of metals within society are ubiquitous [1]. This continued, and increasing, demand for metals results in a substantial consumption of energy related to metal extraction and beneficiation. The embodied energy associated with metal production (mining, beneficiation and refining) can range from 20 MJ/kg refined metal (Pb, steel) to 200 MJ/kg refined metal (Al, Ni) and should be taken into consideration in conjunction with the annual production of metals when determining the total annual energy consumption per metal. While mining is reported to account for between 2-11% [2] (average reported value is 3.5% [3], [4]) of total global energy consumption, the energy consumption associated with metal refining processes (leaching, smelting, electrowinning etc.) typically far exceed that of mining activities. For instance, the following metals and alloys, namely copper nickel, zinc, lead, aluminium and steel, collectively consume approximately 6% of the annual global energy production, while depending on the source of energy production, they can account for up to 10% of the global greenhouse gas emissions [5], [6].

The following trends are the major driving factors for the increasing metal demand: population growth, increased urbanisation, electrification and renewable energy technologies [7], [8]. In conjunction with the United Nations prediction [9] that in the next 30 years the world's population may increase by 2 billion people, the World Bank [10] anticipates that the urban population will more than double by 2050. In order to accommodate this trend, there will be a focus on building infrastructure which will increase demand for certain metals, such as zinc (galvanised steel) [11]. In addition, societies focus on electrification, in the aim of achieving carbon neutrality, will not only increase demands for metals associated with green energy generation technologies but also on those for energy storage [12], [13]).

Several authors have already studied and predicted this increasing demand [14], [15], with Figure 1 illustrating the predictions from the last decades until 2100 [1]. Other authors have corroborated these trends with predictions for zinc [16] and copper [17] being of the same order of magnitude. This increased demand for metals will translate into increased metal production. However, one must ensure this is achieved in a 'sustainable' manner with due regard for the sources of energy used which will impact the industries' energy stability and carbon footprint.

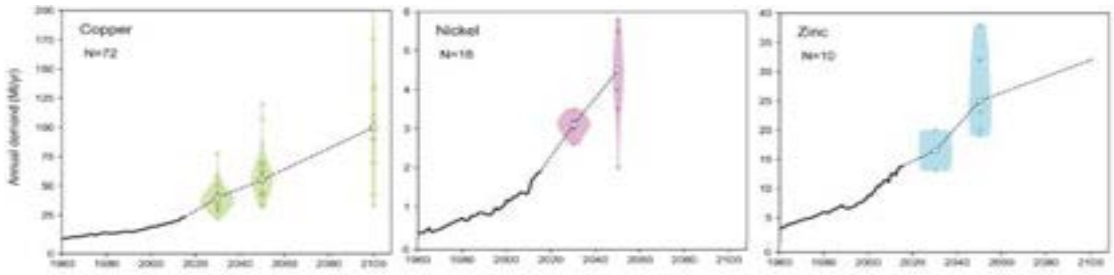

Figure 1. Historical and projected future outlook demand for copper, nickel and zinc from 1960 to 2100 [1].

To meet the demand created by electrification and population growth the global power consumption is also projected to increase by 50% between 2020 and 2050 [18], [19]. However, the world is currently in a Global Energy Crisis [7]. What started in 2021 as a supply and demand imbalance, emerging out of the COVID pandemic, has been exacerbated, primarily, by the invasion of Ukraine by Russia in February 2022. As Russia is seen as the world's largest exporter of fossil fuels and thus the interplay of sanctions and supply curtailment has exposed Europe's historic dependence on Russia for natural gas, oil and coal [7]. In some countries additional environmental factors such as droughts (Brazil and China) have also contributed to the crisis at a more local scale [20]–[22]. As a result of the current Global Energy Crisis there has been a high volatility in the prices for metals, gas and electricity. As a result of the high electricity prices, there are refineries in Europe which have been forced to either halt or reduce production capacity. The Budel refinery in Belgium, from the company Nyrstar, is one such example [23]. The IEA emphasised that this energy crisis is not a "clean energy crisis" as it believes the world should be relying on larger quantities of "green energy" to address this crisis and thereby creating more secure energy systems [7]. The hope is that this Global Energy Crisis will serve as a catalyst for policy makers and consumers to fast track the implementation of renewable green energy technologies.

Figure 2. Annual electricity generation (in thousands of GWh/yr) by source, in South Africa in 2020. Energy sources, other than coal and oil, are characterised further by % [7].

South Africa is also facing an energy crisis, although this crisis predated the current Global Energy Crisis. In 1998, a White Paper on the Energy Policy of the Republic of South Africa predicted that electricity demand would exceed generation capacity by 2007 [24]. As this warning was not heeded, the country started experiencing nationwide blackouts (referred to as load-shedding) in the latter part of 2007 and which continues to this day. Eskom is the state-owned utility company which has a monopoly on the electricity generation within South Africa, which is also highly centralised. The country has historically and continues to be primarily reliant on coal as its source of electricity generation [7]. As of 2020, coal represents 88% of energy generation, with nuclear and renewables representing 4% and 7% respectively (Figure 2). This is in comparison with the world average dependence on coal being 36.5% and renewable energies being 26% [25]. Despite South Africa's attractively high solar irradiance (220 W/m2 compared with Europe's 100 W/m2), solar PV only represents 1.5% of the electricity generation capacity at an estimated 3600 GWh/yr [24], [26]. The authors believe the application of solar PV within the local metals beneficiation and refining industries represents an opportunity for South Africa.

At the end of 2007, the National Energy Regulator of South Africa (NERSA) commissioned a Renewable Energy Feed in Tariff (REFiT), which was approved in March 2009, as a mechanism to promote the generation

of renewable energy within South Africa by creating certainty for investors. Effectively the REFiT was a purchase power agreement at fixed prices, which varied according to the renewable energy source. As of 2008, over 36 other countries (including Spain, Germany, certain states in the USA, Brazil, and even Kenya) had REFiT's [27], [28]. However, in 2011, the Department of Energy revised this scheme and replaced it with a more conventional procurement process, called the Renewable Energy Independent Power Producer Programme (REIPPP), which was based on a competitive pricing model, where independent power producers bid for the development of renewable power plants [28].. In particular, the application of Feed in Tariff (FIT) for small-scale embedded generation systems (SSEG) rests with the individual municipality / city. The City of Cape Town (CoCT) is one of the few South African cities which has successfully implemented a FiT for SSEG where households can receive approximately 0.04 $/kWh with the caveat that the household/business must be a net consumer of electricity (from the CoCT) over a 12-month period.

Load-shedding is a scheduled means of rotating the available electricity amongst Eskom's customers. The reason load-shedding is implemented is to prevent the entire electricity system from failing [29]. As a result, mining contracted by 9% in 2022 and many industries and companies are at the point of closure [30]. The need to stabilise the national energy system and ensure stability of energy availability is paramount to the minerals and metals industry. In response to their inability to provide a stable power supply and to incentivise private sector participation in addressing the continued load-shedding, in 2021 the South Africa government increased the embedded generation (self-generation) capacity licensing threshold from 1 MW to 100 MW [31].

While there are many metals which could be considered within the South African context, the refining of zinc has been chosen for this particular study. Zinc is the fourth most consumed metal globally [32] and as it readily reacts with oxygen, forming a protective zinc oxide layer, its primary use (>50%) is for galvanising of steel [33]. Other major uses include zinc-based alloys and brass production [33]. For the same aforementioned reasons that metal demand is expected to increase, the demand for zinc is also expected to increase. Zinc demand has been positively correlated with industrial and economic growth by White [34] and as both are key focus areas for Southern African countries the demand for zinc consumption is expected to increase. In order to obtain zinc at an economically competitive price, the focus on local production is expected to increase. South Africa is endowed with 14 Mt of zinc content [35] within 200-300 Mt of zinc ore reserves [36] which it is in the process of beneficiating (at Gamsberg with proposals to re-explore the Prieska Copper-Zinc Project). However, since the closure of Exxaro's Zincor Plant in 2011/2012, it no longer locally refines zinc metal. Zincor closed due to rising 'administrative costs', of which a contributing factor may have been the 2008/2009 zinc metal price depression [37] and in addition is speculated to have been due to rising electricity costs [34]. Given the renewed interest in exploring the refining of zinc and given the current energy supply crisis faced by the country, it is proposed to explore the potential application of solar PV within the zinc refining process within the context of South Africa.

The most energy intensive step in the traditional refining process (Roast-Leach-Electrowinning process) for zinc is electrowinning, which uses direct current (DC) to deposit zinc, typically from a purified zinc sulphate solution, onto cathodes. It consumes on average 2,900-3,300 kWh/t-zinc, accounting for approximately 60% of the total electricity consumption of refined zinc production [38]. As photovoltaic (PV) systems represent an established 'green' energy technology to produce DC electricity, it appears that a solar PV system is the most appropriate 'green' technology to generate electricity for this purpose. The application of solar PV for the provision of electricity for the zinc electrowinning unit operation would mean that losses in the electricity generation system would be minimised as no rectification from DC/AC is required, contributing to energy efficiency and loss minimisation, as well as contributing to the decarbonisation of the industry.

2. Case study

As previously mentioned, the Minerals Council of South Africa estimates that South Africa has 14 Mt of zinc content [35] within its 200-250 Mt of zinc ore reserves with the Northern Cape Province (specifically near the mining town of Aggeneys) containing significant deposits of these Lead-Zinc ores [39]. In particular the Gamsberg deposit, located approximately 30 km from Aggeneys, which is one of the largest zinc deposits in the world, is estimated to have approximately 12.8-13.9 Mt of Zinc content within its 214 Mt ore body (6-6.5% Zn) and a life of mine (LoM) of over 30 years [40]. As this one area accounts for nearly all the estimated zinc content within South Africa it is the most likely location for a future zinc refining facility and will thus form the focus area for this case study. This theoretical refinery, proposed in this study, would use the Roast-Leach-Electrowinning process, as this process accounts for 80-95% of all zinc production, with a production capacity of 50,000 tons of refined zinc per year. As zinc refineries can range in capacity from 30,000 tons refined zinc produced per year to 450,000 tons per year, the proposed 50,000 tons per year would be considered a small refinery.

Aggeneys is a copper, zinc, silver lead mining complex and was developed to service the Black Mountain Mine. Vedanta is the current majority owner of both Black Mountain and Gamsberg. With respect to climate Aggeneys is classified as semi-desert [41] and water is pumped from the Orange River (approximately 40 km away). In terms of Photovoltaic Power potential, Aggeneys is one of the world's prime locations with high solar irradiance (daily totals of 5.6 h corresponding to approximately 2,000 kWh/kWp) [42].

There is already a 46 MW (117 GWh/yr) solar PV power project which was commissioned in July 2020 in Aggeneys (Aggeneys Solar PV Park) and is designed to power 20,000 homes. It is owned by BioTherm Energy, cost $54.7m to build, and has a 20-year contract with Eskom under a power purchase agreement. It consists of 140,640 single axis tracking polycrystalline silicon PV modules and covers an area of 110 hectares [43]. This indicates the theoretical feasibility of designing and installing a solar PV plant in this location and the possibility of power purchase agreements with Eskom to possibly sell excess energy back to the grid if need be.

3. Methodology

Traditionally, solar resource / solar irradiance maps, which provide the average available hours of sun per day, were used for this purpose. However, there are now software packages available which can provide this and other important data, such as irradiance depending on the angle, azimuth, temperature, etc. Once the location, in this instance the Northern Cape, and other parameters such as the angle and azimuth are identified, it is possible to obtain the data monthly, daily, or even hourly. The software used in this project was the Photovoltaic Geographical Information System (PVGIS), provided as a free tool for the European Commission (EC) and the Joint Research Centre (JRC). As a general rule, solar PV installations located in the Southern hemisphere must face North (Northern hemisphere must face South) in order to maximise the amount of irradiation received. Furthermore, depending on the purpose of the installation, the slope angle must be equal to the latitude, or plus / minus 10º, depending on whether more irradiation is required in winter or summer.

For this study, the azimuth chosen is 180° (North facing), while the optimum angle, determined after a sensitivity analysis carried out, has been set up as 30°. This sensitivity analysis is shown in Figure 3, where it is possible to see the irradiation with different azimuth and angles. There are two figures which illustrate the best configuration in terms of azimuth. As can be seen, Figure 3a (left) has the least variance, having more or less the same irradiation during the whole year. Conversely, Figure 3b (right) shows an inverted Gauss bell, obtaining high irradiation (>265 kW/m2) during the summer months (from October to March), while in winter months (from April to September) the irradiation is very low (<20 kW/m2). Since the electrowinning plant is designed to work during the whole year, the most applicable configuration is Figure 3a (180° azimuth) which results in approximately the same amount of irradiation every month of the year (i.e. least deviation from the average irradiance value).

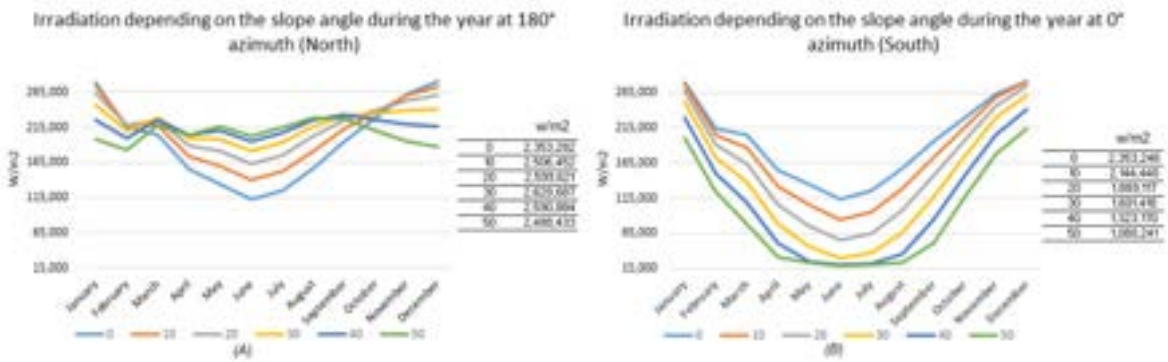

Figure 3. Annual irradiation in the Northern Cape, South Africa, with two different angles of azimuth chosen (180º and 0º). Tables on the right of the Figures summarize the total amount of irradiance per year depending on the slope of the solar panels.

Once the azimuth has been chosen, the angle of the solar panels needs to be determined. As aforementioned, this slope can vary according to the specifications of the facility. For the purpose of this study, the best configuration will be considered as the one with the highest irradiance. Thus, it has been decided to use all the irradiation for every hour in the year 2020, to obtain the cumulative irradiation at the end of the year. As it is possible to see in the data table included in Figure 3a, the highest irradiation occurs when the solar panels are inclined 30º. Therefore, and following this criterion, the configuration chosen for the solar plant is 180º for the azimuth, and 30º for the slope.

Different scenarios have been identified to analyse the performance of the solar plant according to the power installed and the operating time. Currently, the plant is assumed to be operating 24 h/day. However, this is not possible to carry out a 24h/day operation exclusively using solar PV technology as other technologies would be needed to supply electricity during the night, either as power generation (grid supply) or additional storage capacity (batteries).

Accordingly, two more scenarios have been analysed to determine the feasibility of the plant with respect to its hours of operation, while keeping annual zinc production the same. The first is operating the electrowinning plant for only 6 h/day. This operation time is designed around maximising the hours of sun per day that is possible to obtain, during wintertime. This means that even in winter it could be possible to produce the quantity

of zinc required, with the possibility of increasing the operation time in summer months, as more hours of sun per day are available. The second scenario is operating for 12 h/day and trying to strike a balance between maximising solar PV electricity generation while balancing the costs of storage capacity / alternative energy sources. In this way, it has been proposed that there will be three different operating durations for the electrowinning plant: 24 h/day, 12 h/day, and 6 h/day.

The electrowinning plant is designed to achieve a production of at least 50,000 tons per year, which is the current production, operating 24 h/day. For all scenarios considered, this annual production value must be reached by the end of the year, irrespective of whether operation times change. For that purpose, if the operation times are reduced, the capacity of the electrowinning plant must be increased, being multiplied two times if the operation time is reduced to 12 h/day and four times if the plant is reduced to 6 h/day. With the above three different operating time scenarios, an energy and economic assessment will be carried out taking into account that the scenarios are applied in the following cases: 1) Grid tie only (basis for comparison as this is the benchmark), 2) Solar plant and grid tie, 3) Solar Plant and Batteries (off grid), 4) Solar Plant with no Batteries (off grid).

3.1. Grid tie only

Electrowinning units worldwide are typically connected through a country's national / regional electricity grid. Grid tie is therefore the benchmark for all other scenario comparisons detailed below. Since no additional technologies (additional energy generation nor energy storage) are used in this option, the electrowinning process will be designed to operate 24 h/day. The capacity of the plant would be costed for a production of 50,000 tons refined Zn/day. The economic assessment in this case, in terms of electricity cost, would be simply multiplying the electricity demanded by the electrowinning plant with the current price of the electricity. Operating the electrowinning plant 12 h/day or 6 h/day would result in an unnecessary doubling and quadrupling of the capacity of the electrowinning unit, if the same annual production is to be achieved. In this event, the economic assessment would be calculated similarly to the 24 h/day case, however, additional electrowinning capacity would be needed (increased CAPEX costs), solely increasing the final economic costs without any perceived financial gain.

3.2. Solar PV plant and grid tie

This scenario is the most widespread when supplementing electricity supply with solar PV, in particular for households and businesses that are located in close proximity to the grid. This scenario combines a new solar PV plant with the traditional way of obtaining electricity from the grid. One of the main reasons to keep the connection to the grid, is to ensure that in principle there will always be electricity for the plant. This assumes there is no load-shedding. The grid connection mitigates a scenario where there is a drop in embedded generation due to cloudy and rainy days and accommodates for during the night without the necessity to invest in storage capacity or other power generation technologies. It is anticipated that all three operation times are applicable and achievable with this configuration. When the operation times are reduced, the capacity of the electrowinning plant must increase in order to reach the required production throughput. In addition, the power capacity of the proposed solar PV plant must increase in order to produce the increased electricity supply required to maintain annual production. Therefore, the CAPEX of the additional electrowinning units and the increased size of the solar PV plant must be included and added to the final price calculated. This scenario is therefore about balancing the increased capital expense of an increased electrowinning plant and increased solar PV plant with a lower payment for electricity from the grid. The break-even point of each of these scenarios would need to be determined.

3.3. Solar PV plant and batteries

There are currently limited technologies available for storing energy at large scale. The largest being dammed hydroelectricity, however, this application is location specific requiring the available land and water to make it viable. As Aggeneys is classified as semi-desert, dammed hydroelectricity production does not appear to be a viable option. Another option which is starting to make an appearance within the mining industry is the production and storage of hydrogen with excess electricity which can then be converted back to electricity when needed. This should be explored further in future studies, particularly for large scale projects. Although batteries are capable of storing a certain amount of energy, they are widely used in small (household) solar plants. They are unfortunately still very inefficient, since batteries based on lead cannot be discharged more than 40%, while those based on lithium it is possible to use up to 80% [44]. Depending on the type of battery utilised, some metals used for their manufacture are classified as ‘critical’ and may therefore be expensive due to limited supply. Despite their high cost, batteries were deemed by the authors to be the simplest storage option for this study.

There are different technologies in batteries that can be applied to store energy. The most known are the based on lead-acid (considered the traditional) and those based on lithium [44]. The batteries based on lead-acid are very inefficient since they cannot be discharged more than 40%, otherwise the lifespan could be shortened, being already not very long, since the best technology for this kind of batteries is gel, with a lifespan lower than 750 cycles [44]. On the other side, batteries based on lithium have an efficiency higher than 80%,

spotting the LTO (variation of the crystalline structure), which has a lifespan higher than 5,000 cycles [44]. The main disadvantage of this battery is that is very expensive (six more times than lead-acid), and this can increase the initial investment. However, this study, lithium batteries have been chosen due to them being the most efficient energy storage system. However, other options should be explored in future studies.

3.4. Solar PV plant with no batteries

This option would only make sense for the configuration of the lowest operation time, namely 6 h/day, since 12 h/day and 24 h/day would inherently require a storage capacity or an alternative source of energy supply because the sun is not available for that length of time. Running an electrowinning plant solely with a solar plant must therefore be carried out during the day, when the sun is shining. The reason for proposing this scenario is due to the well-known fact that batteries (energy storage) represent a significant cost and therefore the feasibility of operating without storage capacity was proposed. However, given that solar irradiance fluctuates within a day and with the seasons, it is already known that a consistent throughput is impossible to maintain. The authors are not anticipating that this scenario will be technically feasible to achieve without a more detailed design where throughput can be increased during the peak solar irradiance hours.

4. Design and performance of the plant

4.1. Power of the solar PV plant

The capacity of the solar plant will dictate the amount of electricity which can be generated. For this study, the solar plant must be designed to achieve the production expected at the end of the year, namely 50,000 tons of refined zinc. The first step to start the design is calculating the power capacity. To that aim, it is needed to convert the zinc generated at the end of the year into power units. It has been taken from the literature review the specific energy to produce 1 ton of zinc in an electrowinning cell, being a range from 2,900 kWh to 3,300 kWh. 2,900 kWh was chosen as the best-case scenario for the initial investigation. If these values are multiplied by total annual tons of zinc produced and divided by the total hours working during the year (the current operation time is 8760 h/yr), it is possible to determine the power needed in 1 h (see Equation 1).

$$Power\ Demand = \frac{50{,}000\ tons\ Zn \times \frac{2{,}900\ kWh}{tons\ Zn}}{8760\ h} = 17\ MW \quad (1)$$

This means that it is necessary to install a solar plant of 17 MW to achieve the specified zinc production. However, and for the reasons explained in the next section, this power must be higher due to losses incurred, as well as the fluctuating electricity produced during the day and depending on the season. To determine the most appropriate power capacity for each of the three operation times proposed, Figure 4 has been presented.

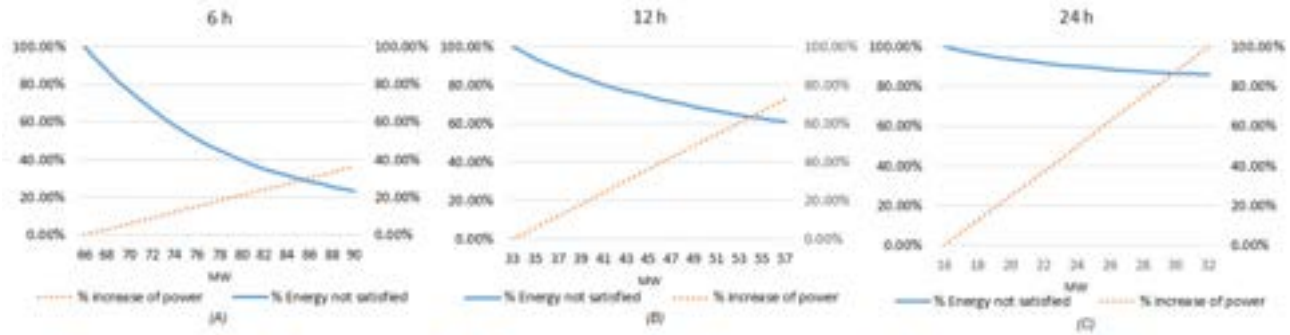

Figure 4. Comparison between the increased power capacity of the solar PV plant (left axis) with the electricity demand not-satisfied by the solar plant as a % (right axis).

As shown, the power required for 24 h operation starts with the 17 MW calculated, while for the 12 h and 6 h are 33 MW and 66 MW, respectively. From these power capacities, as a starting point, the power capacity will be linearly increasing and compared with the electricity not-satisfied from the solar plant, starting at 100% and being reduced when the power installed increases. The electricity not-satisfied can be defined as the electricity needed to supply from another alternative source, either from a green energy or from grid, due to the solar plant not being able to supply all the electricity demanded at certain times.

Although it would make sense to choose the best/optimal power capacity of each solar PV plant as the point at which a % increase in power capacity is no longer greater or equal to the % decrease in energy not-satisfied, given the curvature of the graph, this point is reached very quickly with the 12 h scenario and is never possible with the 24 h scenario. The optimal/best power capacity was therefore chosen as the intersection point between the curve for energy not-satisfied and the line for increasing power capacity of the solar PV plant. The authors felt that for this high-level study this approach balanced the increasing CAPEX association with increasing the power capacity of the proposed solar PV plant while still achieving a reasonable electricity production.

In this way, it is seen that for the 24 h operation time it is needed to increase the power by 90%, to 30 MW, to reduce this electricity by approximately 20% (i.e., 80% of the energy requirements are still not-satisfied). In the case of the 12 h operation time, the power must be increased by 60% approximately to decrease the electricity not-satisfied by 40%. The last chart could be the most interesting option, in terms of electricity exploitation, since increasing the power installed only 25%, the electricity not-satisfied can be reduced by 75%.

This could be explained by the fact that the solar plant works only 6 h, most of the time is running when the sun is out. This means that the exploitation of the solar plant could have a higher efficiency with this operation time. Nevertheless, since an assessment of the performance and economic will be carried out with all scenarios, it has decided to choose the best power for each operation time, being 30 MW for 24 h, 55 MW for 12 h and 85 MW for 6 h, as can be seen in Figure 4.

4.2. Electricity generation

The performance of the solar plant electricity production depends on the power installed and how this electricity can be used to supply the energy to the electrowinning plant. Once the irradiance has been calculated for the specific location and the power selected for the different operation times, it is necessary to know the specifications of the solar panels to install. For this analysis, solar panels from a local supplier were chosen, with the details summarised in Table 1, and the electricity generated per hour calculated with equation 2.

Table 1. Specifications of the solar panels.

Type	Lifetime	Power	Surface	Efficiency
Monocrystalline	25 years	400 W	2 m^2	21%

$$Electricity\ Generated = Irradiance \times Surface \times Efficiency \quad (2)$$

By cumulating the electricity generated every hour of the year (determined using Equation 2), it is possible to analyse the quantity of energy which can (1) be produced, (2) is self-consumed and (3) the excess electricity. Figure 5 and Table 2 summarise the above data, calculated for the different operation times proposed.

Figure 5. Performance of the solar PV plant designed according to the operation times.

As can be seen in Figure 5, the highest electricity generation (due to solar PV) is produced when the operation time is smaller since the power capacity installed is higher. This makes sense as the higher the power capacity installed, the more panels have been installed and therefore the surface to absorb the irradiance from the sun is larger which translates into higher electricity generation. However, in order to see the performance of the three different operation times, it is important to check how much electricity is not being satisfied by the solar plant. While the demand is constant for the three scenarios, it is shown that the electricity not-satisfied is increasing when the operation time is longer. This is explained by the fact that there is an electricity demand when it is dark with the operation times of 12 h and 24 h. These numbers can be seen in Table 2, where the energy not-satisfied from the total demand is 26.68 % and 62.41 %, for 12 h/day and 24 h/day, respectively. On the other hand, this number drops to less than 5 % when it is operated 6 h/day. Therefore, it is not possible to accomplish these requirements for 12 h/day and 24 h/day with the solar plant alone, so an alternative energy source is required to supplement the electricity demand and keep the electrowinning unit operating.

One of the most important disadvantages of running the electrowinning plant for only 6 h/day is the amount of excess energy generated. Since the plant is only working for 6 h, there are hours during the day that some electricity is being produced and cannot be used, so it would either be (1) wasted, (2) stored in batteries, or (3) sold back to the grid. This is reflected in the self-consumption data being the lowest of the three cases analysed.

Table 2. Annual data calculated according to the solar PV power capacity installed.

Operation time	Power installed	Energy generated	Excess Energy	Self-consumption	Energy not-satisfied	Energy not-satisfied
6 h/day	85 MW	215,845 MWh	77,250 MWh	64.21 %	4.42 %	6,408 MWh
12 h/day	55 MW	139,662 MWh	33,352 MWh	76.12 %	26.68 %	38,690 MWh
24 h/day	30 MW	76,179 MWh	21,670 MWh	71,55 %	62.41 %	90,491 MWh

The following should be noted for the 6 h/day operation. For the combination of solar PV and grid tie backup power, it can be seen from Table 2 that very little energy is needed from the grid (4.42%) to supplement electricity supply and given that excess energy far exceeds the energy not-satisfied (77,250>>6,408 MWh) that the plant is actually likely to be a net provider of electricity to the grid. A Feed in Tariff (FiT) would need to be negotiated with Eskom or the local municipality. There is a similar situation with batteries, as opposed to grid tie, in that excess energy significantly outweighs energy not-satisfied at all times of the year. Therefore, the addition of battery storage capacity should comfortably allow the operation of the electrowinning plant for the 6 hour/day operational schedule. Unfortunately, as there is no tie to the grid, the excess energy which does not need to be stored will be wasted unless an alternative use can be found. It is recommended that further studies investigate lowering the power capacity installed (<85 MW) and increase battery capacity to minimise energy losses. Finally, with respect to solar only (no batteries and no grid tie) unfortunately at this specific power capacity it is unable to entirely meet demand. This is evident by the fact that there is a % of energy not-satisfied. The only way to still meet the annual demand for zinc is firstly to increase the power capacity of the plant ensure the total energy is always satisfied, however this will increase the excess energy which is wasted. The other alternative is to increase the capacity of the electrowinning unit such that during the middle of the day the throughput can be increased to compensate for lower throughput at the beginning and end of the day. However, the economic feasibility of this trade-off would need to be explored in a further study.

The following should be noted for the 12 h/day operation. For the combination of solar PV and grid tie backup power, it can be seen from Table 2 that the energy not-satisfied is fairly significant at 26.68% and electricity from the grid is therefore essential to maintain operations. In addition, as the energy not-satisfied is similar, although still slightly larger than the excess energy (38,690>33,352 MWh), the plant will be a net importer of electricity from the grid. A negotiated FiT is still encouraged to minimise the expense of buying energy from the grid. When using batteries as a storage capacity it can be seen that there is insufficient excess energy generated to be able to be stored and resupplied by the batteries to the plant. The power capacity of the solar plant would need to be increased (at least by 3 MW) above the proposed 55 MW and would also need to account for losses involved in storing the DC energy in the DC batteries. Luckily the high losses associated with DC/AC conversion can be avoided in this process. A solar only supply is unfeasible as can be seen by the aforementioned 26.68%.

The following should be noted for the 24 h/day operation. For the combination of solar PV and grid tie backup power, it can be seen from Table 3 that the energy not-satisfied is high at 62.41% and significantly greater than the excess energy (90,491>>21,670 MWh) meaning that once again the plant is a net importer of electricity from the grid. At the current power capacity of 30 MW, the battery scenario is therefore unfeasible and would require at least an additional 30 MW of capacity to generate sufficient electricity to charge at the batteries. Once again, the scenario with a stand-alone solar operation is unfeasible due to the large amount of energy not-satisfied within the system.

Table 3. Summary of the technical feasibility of the various scenarios under the current constraints**.**

	Electrowinning operating hours and solar PV power capacity (if applicable)		
	6 h/day (85MW)	12 h/day (55 MW)	24 h/day (30 MW)
Grid Only	N/A	N/A	✔
Grid + Solar	✔	✔	✔
Solar + Batteries	✔	?	X
Solar Only	?	N/A	N/A

N/A= not applicable / scenario not investigated; ✓ = technically feasible; ? = not technically feasible under the current conditions, however, requires further investigation as technical feasibility was borderline; X = not technically feasible under the current conditions.

4.3. Key assumptions and limitations of the study

The following key assumptions have been made during this investigation. The plant operates for 365 days a year with no down time and the effect of loadshedding is not taken into account. Electricity use within the zinc plant, other than electrowinning, is not included. The cost of electricity was assumed to stay constant

throughout the day and year. A 25-year lifespan was assumed for all economic calculations. Lastly, it is assumed that the quality of zinc will be unaffected if the electrowinning unit runs for only 12 h/day or 6 h/day. It is acknowledged that if some of the above parameters were altered the results may be affected and that further investigations with sensitivity analyses are needed to determine the effect that each assumption has on the results.

5. Economic assessment

The aim of this study is to determine the most economically feasible option(s) of the aforementioned scenarios. To be able to implement an economic assessment, certain factors must be included, such as the price of solar panels and batteries, the capital cost of an electrowinning unit at different scales, electricity price from the grid, price for the compensation of extra energy being fed back into the grid (Feed in Tariff) etc. In addition, the methodology of Levelized Cost of Energy (LCOE) has been applied. This methodology was applied in order to obtain a value to measure the average cost of generating one kilowatt hour (Megawatt hour in this case, MWh) of electricity over the lifetime of a generating asset. The LCOE takes into account the costs associated with a system, including installation, operation, maintenance, and fuel. The average cost per year (over 25 years) has also been determined in Table 5 to provide the easiest comparison amongst the scenarios.

As obtaining electricity solely from the grid has been deemed the benchmark, this value will be calculated first. It must be noted that the price for the power supplied from the grid (Eskom) is assumed to remain constant (no peak hour costs), even though it varies in quantity amongst the different operating times. Based on this, it has been calculated that the electricity cost (OPEX) associated with obtaining electricity solely from the grid is $ 10,585,000 ($ 10.585 M) for the 2022/2023 year. Further Eskom electricity price increases are expected as outlined in Table 4.

The capital cost of the zinc electrowinning unit was estimated using capital cost data from a copper electrowinning unit [45]. The CAPEX for the solar PV plant was taken as the 2021 worldwide estimate for solar installations which is $ 857 per kW [46] which was comparable to the $/kWh value quoted by Green Pro Consulting of $ 778/kWh [47]. The prices applied to the various scenarios, are summarised in Table 4.

Table 4. Costs associated with the various solar PV plant designs.

Price of grid (Eskom) supplied electricity [39]	FiT (based on CoCT) [48]	CAPEX associated with different scales of the Electrowinning Unit			CAPEX for Solar PV plant [46]	CAPEX for battery storage (Lithium)
		6 h/day (85 MW)	12 h/day (55 MW)	24 h/day (30 MW)		
$ 73 / MWh*	$ 18 / MWh	$ 150 M	$ 75 M	$ 35 M	$ 857,000 / MW	1,005 $/kWh

The final LCOE price is determined by the power installed, as the more power installed the more panels are needed. Accordingly, it is also necessary to include the operation and maintenance (O&M) costs, which is usually calculated as the 10% per year of the capital cost. Using these values and the LCOE method, to calculate the feasibility of the design for a 25 years of lifespan, it has been calculated that the LCOE price for the 6 h/day, 12 h/day and 24 h/day are $ 80.66 /MWh, $ 65.77 /MWh and $ 57.87 /MWh, respectively (without taking into account the batteries). Although the price calculated for the 6 h/day scenario is higher than the price from the grid in 2022, it should be noted that once the proposed 18% price increase takes effect, all scenarios will be cheaper ($/MWh) than the grid-only price. In addition, having the embedded generation capacity (through solar PV) provides additional advantages compared with solely relying on the grid connection for electricity supply. As discussed in the introduction, as South Africa continues to experience load-shedding it results in interrupted power supply on almost a daily basis which is affecting the production of all industries including mining and refining of metals. Having an independent embedded electricity generation capacity will therefore reduce / eliminate this situation while also having the advantage of decreasing the pressure on the national grid. If excess “green” electricity can be returned to the grid it will also have an added benefit to the stabilising of the grid as well as contributing to meeting renewable energy targets.

Table 5. Summary of the average total cost per year (25 years) for the various scenarios [million $/year].

	Electrowinning operating hours and solar PV power capacity (if applicable)		
	6 h/day (85MW)	12 h/day (55 MW)	24 h/day (30 MW)
Grid Only	N/A	N/A	10.59
Grid + Solar	13.79	10.38	9.79
Solar + Batteries	1,045	6,230	14,555
Solar Only	14.79	N/A	N/A

The most economical configuration is therefore operating a solar plant for 24 h/day with a combination of grid and solar energy supply. It should be noted that the grid only price of $ 10.59 million/year is expected to increase to $ 12.47 million/year in 2023/2024 as an 18% increase is expected and to $14.07 million/year by 2025 when a further 12% increase is expected. The Eskom supplied electricity cost is expected to continue to increase. With this understanding one can see that all solar and grid options will become more economical than only being supplied by the grid over the 25-year life of the project. With respect to different operating times, the grid and solar option at longer operating times makes more economic sense as it requires less additional capital expenditure in the form of additional electrowinning capacity and additional solar capacity. As can be seen, under no circumstances is the scenario of solar and batteries economically feasible. However, in this scenario it can be seen that, as expected, shorter operating times results in a smaller capital cost (less batteries required) and thus is more economical than longer operating times. Lastly, the reason the solar and grid combination for 6 h/day is more economical than solar stand alone is the benefit gained from selling electricity back to the grid.

6. Conclusions

A stable (and economical) electricity supply is one of the key necessities that society (households and companies) requires. Unfortunately, there are a number of factors which are generating volatility in terms of the supply and cost of electricity. Globally, a major factor in the increasing price of electricity is the Russian-Ukrainian war, with some European countries experiencing an increase of up to 200%, while on a local scale South Africa is struggling with insufficient generation capacity, ageing infrastructure amongst other factors. The hope is that globally and at the local level, these challenges will promote the implementation of increasing quantities of alternative (renewable) energy sources to alleviate dependence on fossil fuels and or countries' national energy grids.

Different scenarios were analysed to determine the optimal incorporation of solar PV for the electricity substitution for zinc electrowinning, namely: grid only, solar and grid supply, solar and battery storage, and a stand-alone solar supply. Although the ideal would be to maximise reliance on embedded generation capacity, it needed to be determined as to where this optimal point currently is. It should be acknowledged that this optimal may change over time. In addition, the operational times were varied (24h, 12h and 6h) in order to determine the trade-off between increased capital costs associated with increasing the size of electrowinning units and solar plant power capacity as the operational time decreased) and the increased costs of energy storage (as operational timeless increased). Accordingly, it has been demonstrated that the best orientation for the solar panel is facing South with a slope of 30º, obtaining the highest electricity production within a year, and ensuring similar monthly generation.

With this configuration, the most promising scenario to maximise reliance on embedded energy generation, is running the electrowinning plant for 6 hours per day. The reason being that it had the lowest energy not-satisfied (< 5% of the total electricity demanded in a year), while the 12 h and 24 h scenarios resulted in 27% and 64% energy not-satisfied. In addition, since the power installed in 6h case is higher than the other scenarios, there will also be excess energy that can be introduced into the grid which may assist in stabilising the grid while the company owning the zinc plant may derive economic benefit. While the 6 h/day solar can feasibly be combined with a grid or battery supply to cover the energy not-satisfied, under the current solar power capacity of 85 MW, running on a stand-alone solar PV plant (no batteries) is not feasible. The power capacity of the solar PV plant would either need to be increased or there would need to be an increase in the capacity of the electrowinning plant to allow for a higher throughput during peak irradiation hours.

The most economical configuration is operating a solar plant for 24 h/day with a combination of grid and solar energy supply. Further studies should investigate how varying only the size of the solar plant will affect the economics in this scenario. Under no circumstances was the solar and battery scenarios economically feasible with the current price of lithium batteries. Future studies should explore alternative energy store options.

One of the main disadvantages of installing solar plants is the amount of land that is needed to produce the electricity expected. For the best-case scenario (6 h/day), from an energy generation perspective, the land use would be 0.425 km2, taken into account only the panels. This number can increase from 30-50%, up to 0.64 km2 after adding the separation between panels and rest of equipment. Choosing the option of installing the lowest number of panels (30 MW plant operating for 24 h/day), the land use can still be in excess of 0.25 km2, which is still significant. However, compared to the existing 46 MW solar PV plant in Aggeneys, which is 110 hectares (1.1 km2) the proposed land area per MW installed is significantly less. In addition, Aggeneys as a town not pressurised for space (i.e., it is not densely populated), therefore the space requirements are not anticipated to be problematic.

One benefit from this study is that the approach can be applied to similar industries/unit operations where the electricity is needed in direct current form, which avoids additional losses incurred when converting from DC to AC and vice versa. For instance, it could be applied to electrowinning plants for other metals located in other areas such as Europe. Other locations may have advantages or face different challenges, for instance in

Europe although there are established FiT schemes, the solar irradiance is significantly lower and there may be more space constraints.

This study has demonstrated that the incorporation of solar PV into the energy supply mix for a zinc electrowinning plant can be beneficial. To that end, governments such as South African government must incentivize the continued investigation and investment into solar PV and other renewable energy sources which can improve the energy stability of the country as well as meet the increasing worldwide expectations on decarbonation within the minerals and metals industry.

Abstract:

The objective of this study is to design an optimal vertical axis wind turbine (VAWT) for electric generation on a high-density urban highway in Cochabamba, Bolivia, taking into account the special functional conditions due to the characteristics of the high altitude area. Based on the literature, it was initially determined that the Banki cross-flow turbine is the most suitable VAWT for use on highways. An in-situ measurement of the wind velocity spectra was conducted to assess the typical wind characteristics along the highway using statistical analysis and selected optimal values for testing and optimization. The diameter of the Banki wind turbine was then determined and fixed considering the width of the space between the two lanes of the highway as a limitation. Three geometrical aspects were assessed as variables for finding the optimal power coefficient; attack angle, number of blades and height. Computational fluid dynamics (CFD) simulations were carried out with every turbine combination to determine the optimal characteristics. From C_p and TSR values obtained from the simulations a multivariate analysis was carried out optimizing these values. The response of C_p and TSR were obtained, prioritizing C_p results. Finally, an ultimate design for the Banki wind turbine is proposed. The optimized Banki cross flow turbine has 11.5495° attack angle, 12 number of blades and 0.9 m of height.

Keywords: Vertical Axis Wind Turbine, Energy harvesting, Highway wind turbine, Banki Cross-flow

1. Introduction

Nowadays, the world is facing an energy crisis resulting from a shortage of traditional energy resources. As a result, many countries have started to shift their focus towards renewable energy alternatives such as solar thermal and photovoltaic energy, hydro energy, geothermal energy and wind energy to generate power.

Recent technological advances and diversification of types of wind turbines show a reduction in the risk of these installations and present more efficient systems in electrical conversion. Nevertheless, wind energy generation has shown to be a risky investment for the development of an interconnected power grid due to wind energy variability and uncertainty, its effect on power fluctuations, voltage drops, and as a consequence, grid instability.

The trend within wind turbines falls on a horizontal configuration of their axes or HAWT (horizontal axis wind turbine), mainly due to their large generation capacities within a specific area. However, horizontal-axis wind turbines are complex projects that cannot compete in micro-scale markets due to demanding operating conditions, large investments and studies, and high maintenance costs. A more relegated but no less important technology is the vertical axis wind turbine or VAWT (vertical axis wind turbine), which has an increased demand due to the need to take advantage of resources in limited environments. These turbines allow easy integration into the market of products for electricity generation and installation in urban areas for micro-generation and self-sustainability of products. The VAWT stands out due to the possibility of self-starting the generation as well as the omnidirectional capacity to harvest winds; factors that are limiting for horizontal axis wind turbines. In addition, new studies consider the use of sets of VAWTs in different configurations to increase efficiency or new types of airfoils with the same purpose, taking advantage of fluid mechanics and phenomena occurring during their operation.

In the literature, the principal focus of the research on VAWTs is the geometrical design, consequently, the VAWTs are continually being adapted and redesigned to achieve maximum benefits in power generation. Geometrical design of a Nautilus wind turbine [1], a comparison between helical and straight blades [2] and a

nature-inspired shape blades proposal for a VAWT [3] are some examples. Likewise, VAWTs have been researched to suit specific applications, such as subsidized houses [4] and highways [5], [6]. On highways, the authors are exploring the possibility of using VAWTs for electricity generation and street lighting, with certain types of turbines, with the cross-flow Banki wind turbine appearing to be the most effective option. Recent developments have also focused on enhancing the efficiency of arrays of vertical wind turbines [6], [7], [8]. Moreover, wind deflectors or guiding vanes are being studied as a solution to the performance challenges of some turbines [9]. Additional details and discussion on the state-of-the-art of VAWTs can be found on a recent review done by Alave-Vargas et al. [10].

In this sense, the present article will propose the design of an optimal Banki-type vertical axis wind turbine according to specific wind conditions and data analysis of in-situ measurements of the location within Blanco Galindo highway in Cochabamba, Bolivia; a city that is located at 2558 m.a.s.l., which implies a high altitude condition that has effects on the viscosity and density of air. The experiment consists on the geometrical design based on the angle of attack, height, and the number of blades of the turbine. The experiment will be carried out on computational fluid dynamics (CFD) recording moment and angular velocity to perform an efficiency analysis, obtaining an optimal Banki wind turbine that can be used in-site.

2. Types of vertical axis wind turbines

Although horizontal axis wind turbines have been extensively studied and are currently used as the prime wind energy generation turbine in the world, new advances and studies have emerged related to the construction and application of vertical axis wind turbines and emphasize the optimal values of tip-speed ratio (TSR), power coefficient (C_p), thrust coefficient (C_t) and the cut-in speed at which the turbine starts generating [1].

The values of TSR for VAWTs are determined by the turbine geometry, installation conditions and required power output. TSR is defined as the relation between the blade tip velocity and the wind speed. A high TSR value means higher power output, but it can cause mechanical issues. The C_p measures the turbine's efficiency converting the kinetic energy of the wind into electrical energy, and its maximum value occurs at a specific TSR value. The calculation of C_p is defined by Eq. (1). The C_t also measures the efficiency of the turbine extracting energy from the wind, and depends on the thrust force produced by the turbine, air density, wind speed, and swept area of the turbine, this value is represented by Eq. (2). A high C_t value indicates higher efficiency, but it could cause the turbine to fail mechanically as suggested by [11] and [5].

$$C_p = \frac{P}{\frac{1}{2}\cdot\rho\cdot S\cdot V^3}, \tag{1}$$

$$C_t = \frac{\tau}{\frac{1}{4}\cdot\rho\cdot S\cdot V^2\cdot D_1}, \tag{2}$$

The types of vertical axis wind turbines, according to recent literature, can be divided on:

2.1. Darrieus turbine

Darrieus rotors were invented in the third decade of the 20th century in France. They consist of 2 or 3 blades parallel to the axis of the rotor [12]. Regarding sub-types, there are Darrieus turbines with straight blades, with H rotor and with curved blades. They are considered the most efficient vertical-axis turbines [5], [6], and also very trustful [13].

The Darrieus turbines generate power from the lift produced by the rotating airfoils and have a higher power coefficient than the Savonius turbine [14]. They are recommended for use in areas with high and constant wind speeds without noticeable variations [15].

2.2. Savonius turbine

The Savonius turbine is used for variable wind flows in different ranges and requires a minimum wind speed to start working [15]. Despite being less efficient than the Darrieus turbines, it has been shown to have higher starting torque and good starting performance [5], [13].

2.3. Banki turbine

The Michell-Banki or Banki turbine is a cross-flow wind turbine type. Experiments have shown that it outperforms the Savonius and Darrieus vertical axis turbines in certain conditions and on highway applications [16]. It has a low autostart of around 1.2 m/s, relatively high torque and a rigid structure [13]. The remarkable efficiency of this turbine is due to the fact that the wind passes through two stages. In the first stage, the wind enters the turbine hitting the blades facing the wind and in the second stage, it leaves the turbine hitting the blades facing backwards. A large number of blades gives the turbine the ability to have low connection speed and high starting torque [11].

The construction of Banki turbines adapted for wind applications can be designed following a series of guidelines and equations, proposed by Al-Maaitah [11]. They define the maximum efficiency or C_p of the turbine

for the given context, where the geometry of the exposed blades is specifically designed using a velocity triangle as shown in Figure 1.

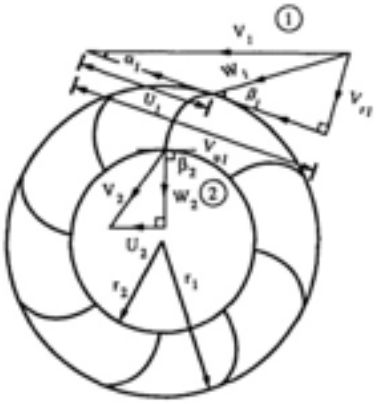

Figure. 1. *Velocity triangle diagram of wind input and output of the rotor* [11].

Through a geometric analysis of the velocity triangles of the input speed (system 1) and the output speed (system 2), Eq. (3) and Eq. (4) are obtained, where r_2 corresponds to the inner radius, r_1 is the outer radius, α_1 represents the angle of attack, and β_1 represent the input blade angle.

$$\left(\frac{r_2}{r_1}\right)^4 + 4 \cdot \left(\frac{r_2}{r_1}\right)^2 \cdot tan^2(\alpha_1) - tan^2(\alpha_1) = 0, \tag{3}$$

$$tan\ \beta_1 = 2 \cdot tan\ \alpha_1, \tag{4}$$

With the definition of the radius, Sammartano et al. [17] proposed the Eq. (5) and Eq. (6) to calculate the radius of curvature of ρ_b and degree of curvature of the blade δ, this geometry is shown in Figure 2.

$$\rho_b = \frac{D_1}{4} \cdot \left[1 - \left(\frac{D_2}{D_1}\right)^2\right] \cdot cos\ (\beta_1)^{-1}, \tag{5}$$

$$tan\left(\frac{\delta}{2}\right) = \frac{cos(\beta_1)}{sin(\beta_1)}, \tag{6}$$

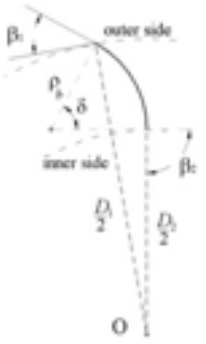

Figure. 2. *Blade geometry* [17].

3. In-site wind resource analysis

In order to carry out a design based on real conditions, wind speed measurements were taken on the Blanco Galindo highway in the city of Cochabamba, Bolivia. This avenue has a double lane with one lane going east and the other going west, and a space of 1.86 m separating the lanes of opposite circulation.

The data collection was carried out at 3.5 km of the highway, 460 metres from the distributor of another important avenue, Beijing avenue (the exact location can be seen in Figure 3). The criteria for determining the location for data collection were based on the observation of high vehicular flow, circulation of trucks and heavy vehicles coming from the distributor, and the absence of traffic lights within a radius of at least 400 metres.

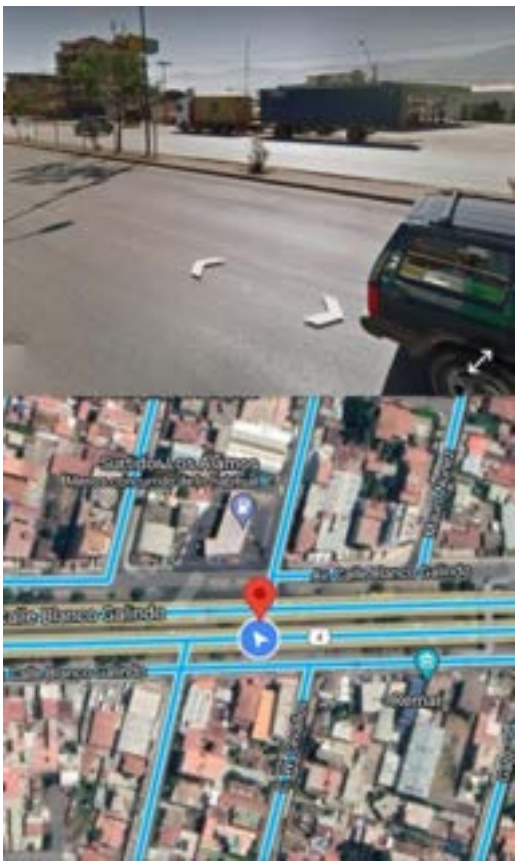

Figure. 3. *Location of the data gathering point (-17.393004, -66.188506).*

Wind data were collected for four days at different periods, taking into account high traffic periods caused by rush hours. During the measurement days, there was no rain or significant variations in temperature and humidity. Anemometers with data loggers and Bluetooth were used with a collection frequency of 1 data/s. The data was measured at 1 m from the ground; this selection is based on a study by Al-Aqel et al. [18]. They concluded that the maximum recorded wind speed is found at that height because of the formation of trailing vortices behind and at the sides of vehicles. The results obtained for periods, in terms of maximum wind speeds and average speeds, are shown in Table 1.

Table 1. *Summary of wind speed data.*

Period	Day	From	To	Maximum wind velocity north side, m/s	Maximum wind velocity south side, m/s	Average wind speed north side, m/s	Average wind speed south side, m/s
Period 1	Wednesday	08:58 am	10:00 am	7.29	3.49	1.598	1.226
Period 2	Wednesday	11:47 am	12:55 pm	7.64	7.63	2.237	1.898
Period 3	Thursday	08:58 am	09:58 am	6.31	6.35	1.305	1.445
Period 4	Thursday	12:06 am	01:08 pm	5.94	4.42	1.806	0.655
Period 5	Friday	08:22 am	10:00 am	10.14	0.00	2.050	0.000
Period 6	Friday	12:04 pm	01:08 pm	9.47	4.42	2.180	0.655
Period 7	Friday	04:09 pm	05:01 pm	7.23	6.17	1.494	1.722
Period 8	Saturday	07:42 am	08:45 am	7.75	5.79	2.622	0.938

For a better understanding of the data, Table 2 presents the percentage of data that corresponds to a specific range of wind speed.

Table 2. *Range wind speed percentage.*

Wind speed range , m/s	Data percentage north side, %	Data percentage south side, %
0.1 - 1.1	27.20	57.58
1.2 - 2.1	41.01	27.52
2.2 - 3.1	19.97	12.26
3.2 - 5-1	7.920	2.540
5.2 - 10.2	3.900	0.100

As shown in Table 2, the entirety of the collected data is concentrated between 0.1 and 2.1 m/s, with at least 68% of the measurements on both sides falling within this range. There are some variations between the south and north side measurements, with higher values consistently recorded on the north side. However, while the data is consistent, the measured wind speeds are limited to specific periods and have a low magnitude, which limits their potential as a good wind resource [13], [18]. Therefore, for the purpose of obtaining an optimal turbine design, a higher wind speed value will be used. During the Saturday measurements, higher wind speeds were recorded on the north side, with every measurement greater than 5 m/s, with a mean value of 6.15 m/s. The first measured speed on the north side with this value has a 1.98 m/s speed on the south side. These two values were used for the development of all CFD simulations.

4. Experimental design

To obtain the most efficient turbine possible, a series of parameters and limitations must be defined. Since the turbine must be located in the middle of the highway and the maximum width is 1.86 m, the diameter will be limited to 1.4 m, taking into consideration safety factors to prevent risking human lives during its operation. Other considerations for the site include the local density and viscosity of the air, which were extracted from the EES software library, corresponding to the air pressure at 2,558 m.a.s.l. with a value of 0.8913 kg/m^3 and 1.82E-5 m^2/s, respectively. The experiment will not focus on power production and will analyse the optimal turbine with the dimensionless coefficient C_p. This parameter will enable the comparison of turbines with different configurations and give an idea of the raw power they can produce [5], [19] , [20]. Since the experiment will be conducted on a double duct wind tunnel, the defined TSR concept will be adapted to consider wind speed as the sum of the speed in both lanes; C_t and C_p will have a similar variation using the sum of wind speeds as the parameter. Finally, a factorial statistical analysis will be carried out using the peak values obtained from the parameters of each turbine to obtain the optimal values for each turbine's geometrical parameters.

4.1. Turbine type selection

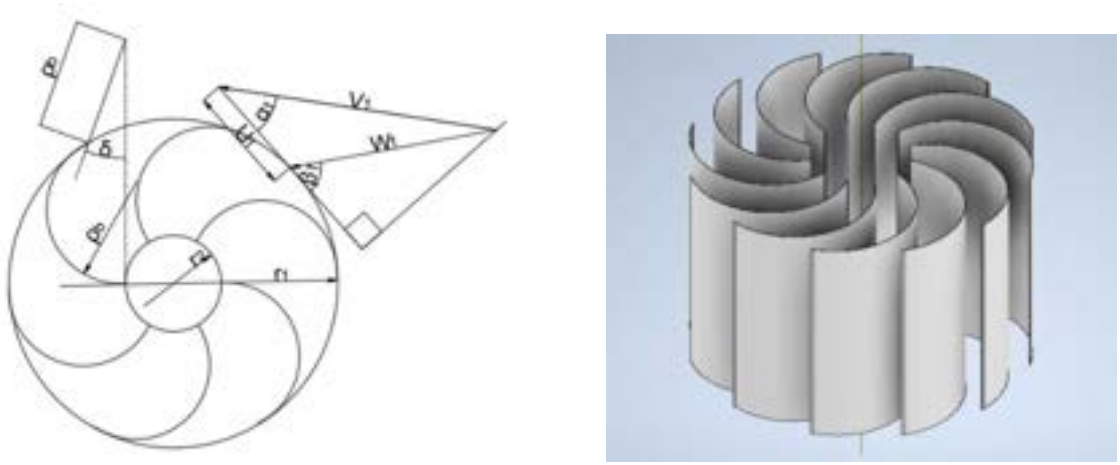
Many types of turbines have been studied, each with its advantages and disadvantages in different situations and wind characteristics. Highways have a wind resource that is not related to climate phenomena and has high turbulence and a mixture of air, as well as short bursts of air that require the use of low-starting torque turbines. Tian et al. [6] conducted a study comparing the Savonius, Darrieus, and Banki turbine designs for highway energy recovery applications. The results showed that the Banki wind turbine is the most efficient for energy production on a turbine situated on a highway due to its drag characteristics, which allow it to perform at low wind speeds and high torque. This is why in the current study, this turbine will be analysed and used for highway energy recovery.

Considering that there is an interest in building a functional prototype of the wind turbine, the material selection was carefully considered. While many authors utilize models with aluminium or composite materials, these materials can be both high-density and expensive. To mitigate these issues, a solid polyvinyl chloride (PVC) with a density of 1.4 g/cm³ was chosen for its ease at manufacturing, natural material resistance, low cost, and availability in the local Bolivian market. This choice of material allows for the turbine's geometrical properties to be easily constructed while still maintaining its functionality [21], [22], [23].

4.2. Geometric design parameters

After selecting the Banki wind turbine for simulation to find the geometric design parameters for the operating conditions, parameters such as height, angle of attack, and number of blades for Banki turbines with similar characteristics are presented. Tian et al. [6] used 18 blades, a radius of 0.25 m, and a height of 0.21 m for the Banki turbine design. Al-Maaitah [11] used an angle of attack of 16°, a height of 1 m, and 8 blades. However, Ushiyama et al. [24] suggest that the turbine must have a minimum of 12 blades to be more effective. Andrade et al. [25] have demonstrated through experiments that the angle of attack can vary from 7° to 23°. On the other hand, Sammartano et al. [17] use a design with 35 blades, an angle of attack of 22°, and a height of 1 m.

Based on these experiences, it was decided to establish three angles of attack (6°, 10°, and 14°), rotor heights of 0.9 m and 1.1 m, and numbers of blades of 12, 16, and 20. Therefore, 18 possible turbine designs were created. For all these combinations, calculations were made using the proposed equations for Banki turbine design. The outer radius r_1 was defined based on the available space of 1.86 m where wind speed measurements were taken, with a fixed value of 0.7 m. Equation (3) was used to calculate the inner radius r_2 and Eq. (4) to obtain the blade angle β_1. The geometric parameters that complete the blade geometry, the radius of curvature and the curvature angle, were calculated using Eq. (5) and Eq. (6). The geometrical design parameters are shown in Figure 4a and the computer model of a specific Banki turbine is illustrated in Figure 4b.



a) *b)*

Figure. 4. *a) Geometric design parameters for a Banki wind turbine, b) 3D model of the Banki turbine.*

For the 18 turbines geometries, using 3D computer design software with the selected material, their mass and moment of inertia were obtained. These results for all possible combinations are presented in Table 3.

Table 3. *Design parameters.*

With the 18 possibilities of wind turbines a multivariable analysis will be carried out. The study will analyse the influence of the angle of attack, number of blades, and height in power production; correlating these parameters to the C_p and TSR of the turbine. From this analysis, an optimal geometrically designed turbine will be obtained. Integer steps were proposed to evaluate a high number of transient analyses, covering a broad range of values. While smaller steps in all variables would increase the precision of the statistical analysis allowing us to reach more specific values, there are limitations to do it without increasing the length of the study.

4.3. Performance simulations

4.3.1. Numerical methods and computational domain

A CFD simulation has been conducted using Ansys Fluent. The numerical simulation was performed with a k - ε turbulence model due to its accuracy; the enhanced wall treatment condition was applied. The simulations used dynamic mesh and included the mass and inertia data from each turbine to generate the movement in the respective flow. A pressure-based solver was chosen and velocity inlets were defined, with inlet 1 having a value of 6.15 m/s and inlet 2 having a value of 1.98 m/s with their disposition shown in Figure 5. Both outlets were pressure based with a gauge pressure of 0 and assumed no loss [26].

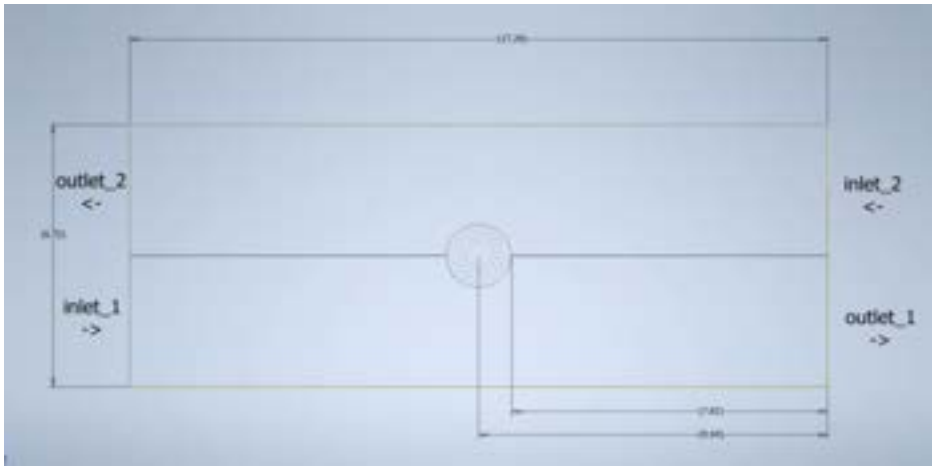

Figure. 5. *Computational domains for CFD simulations (dimensions are m).*

For the current analysis, the turbine was isolated from interaction with vehicles, and a separator in the middle was used for the flows to develop completely. This separator is a thin wall 20 mm thick, allowing the turbine to be analysed without mixing the flows and obtaining the optimal design based solely on performance under similar conditions to those on the highway, not including elevated turbulence of air. Creating an adequate computational domain is necessary to generate real results from the data input into the simulation. When the computational domain is too short, the flow does not resemble a real flow, and when it is too large, the duration of the computational process is considerably long [20]. The computational domains are analogous to Toudasrbari et al. [20], and consist of a rectangle of 17.28 m x 6.72 m. The values were decreased from other studies due to the crossflow characteristics of the domain as shown in Figure 5. The thin wall that separates both flows and avoids interaction between them before reaching the turbine is 7.82 m from the lateral wall, allowing a small gap that generates the resultant mixture of air due to the turbine interacting with the flow. The domain is 1.5 m tall since it is not necessary to analyse the flow in the y-axis.

4.3.2. Mesh generation and simulation setup

The meshing type and size are crucial in every CFD simulation to generate good results and accuracy. The meshing generation uses multizone generation for the wind turbine, where the resultant mesh has a free mesh type of tetrahedral elements and hexa/prism elements for the whole domain. As shown in Figure 6, the number of elements has a higher density over the turbine to correctly calculate the flow and to resemble a real one. On average, the whole domain has approximately 362240 nodes. This value fluctuates for every turbine and geometrical model, but the pre-set is the same for every evaluation. To further increase the quality of the results, an inflation layer was generated for the blades of the turbine, further diminishing the size of the mesh and gaining precision in the calculation.

Figure. 6. *Mesh of tetrahedral elements over the turbine.*

As a final step previous running the simulations a time step must be defined. To avoid long computational processes and according to Tourdarbi et al. [20], a series of time steps must be defined as a translation of angle: $\Delta\theta = 1°$, $\Delta\theta = 0.5°$ or $\Delta\theta = 0.25°$. This is translated into the simulation as a time step of 0.005 s [20]. Another parameter for the simulation is limiting the number of iterations to 50 which allows the solver to converge into a result.

4.3.3. Simulation results and final selection

CFD simulations were carried out for the 18 generated models, and the graphical results obtained for the TS-01 simulation are shown in Figure 7.

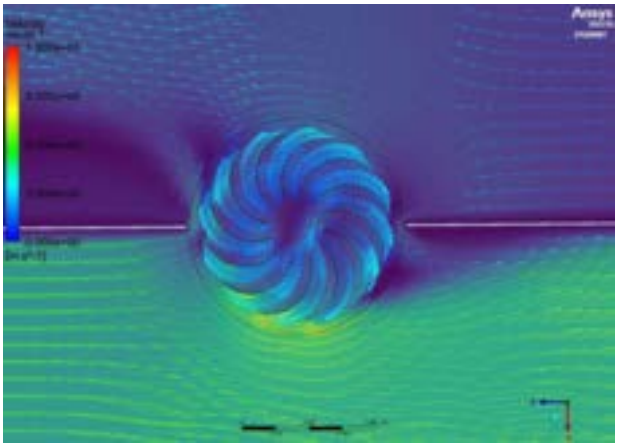

Figure. 7. *Velocity and vector contour for TS-01 model.*

Reports were generated for all simulations for the analysis of the relevant parameters in MatLab. The speed of the turbine's tip was obtained through CFD and the no-slip boundary condition, while the moment was obtained through FEA (Finite element analysis). From these simulations, TSR, C_t, and C_p were calculated with the assistance of Eq. (1) and Eq. (2).

The turbines were grouped by attack angle to show the graphed results in Figure 8 and Figure 9. The maximum C_p value of the 6° angle group was obtained with TS05 at 0.0594 and a TSR of 0.2456. In the group of 10° angle, the maximum C_p was 0.5686 from TS07 and a TSR of 0.2903 and from the 14° angle group the maximum C_p was 0.0583 with a TSR of 0.3094 corresponding to TS13. Overall, the C_p and C_t values show low efficiency, but high starting torque, which is a good value for the current wind resource measured in-site. The generated vortices in the turbine show unbalance and indicate the need for higher structural resistance. The crossflow functionally of the turbine is neglected and instead, the re-entry angle becomes sharper, inducing a lower efficiency of the turbine.

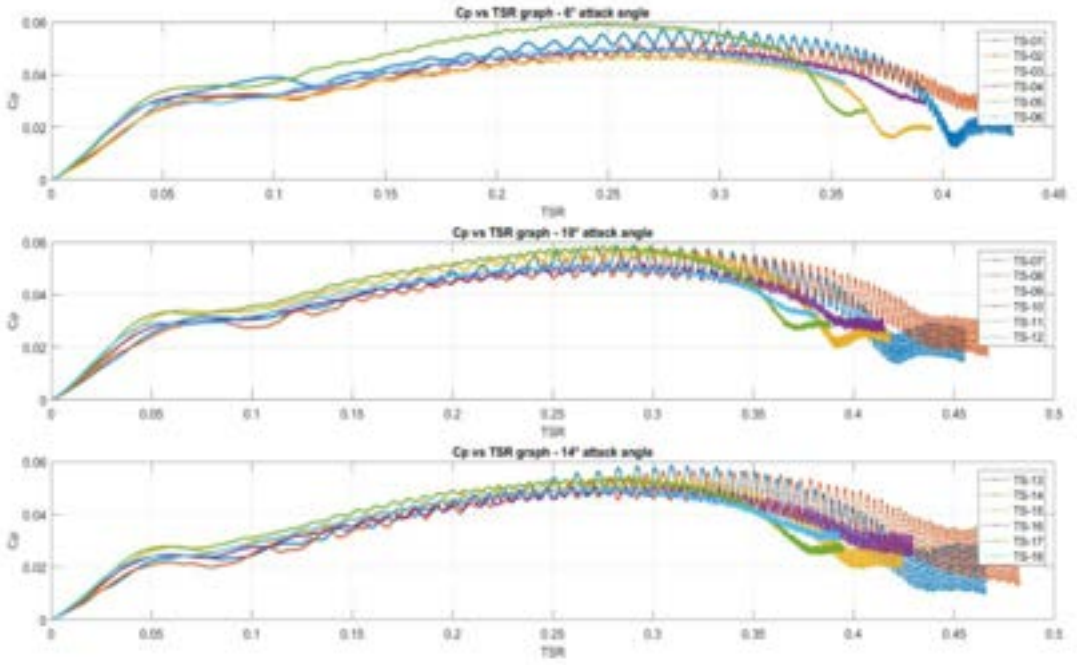

Figure. 8. *Resultant* C_p *vs TSR plot grouped by attack angle.*

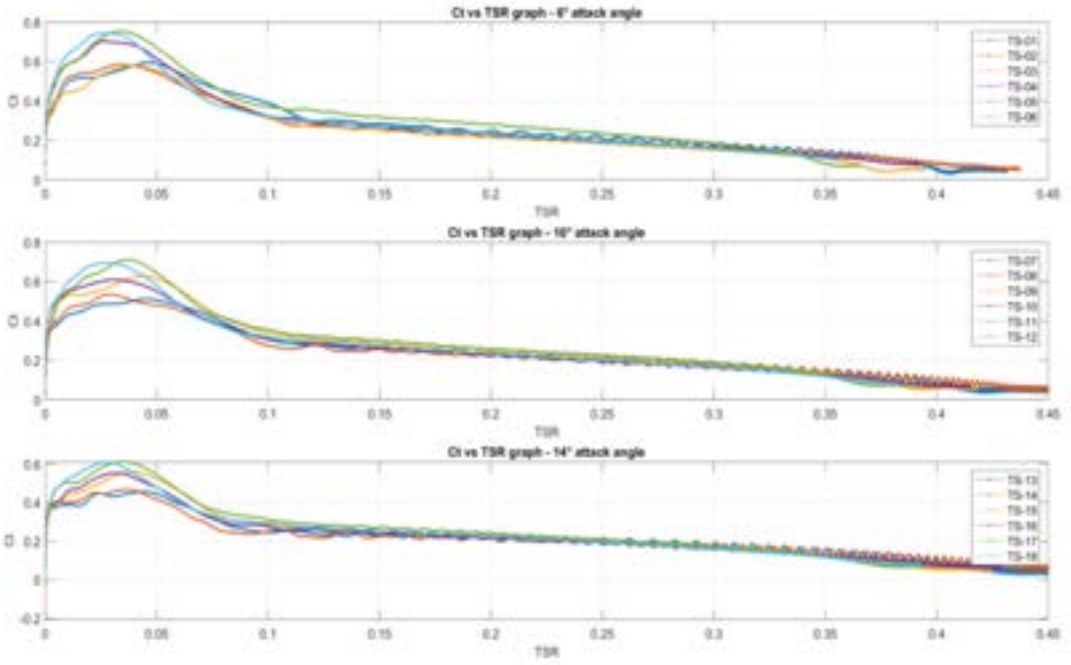

Figure. 9. *Resultant* C_t *vs TSR plot grouped by attack angle.*

From all these values a multivariate statistical analysis was carried out with C_p and their related TSR. The data input is given in Table 4. The software STATGRAPHICS 19 Centurion was used to carry out the multivariate analysis.

Table 4. *Data for factorial analysis.*

Part name	Angle of attack α_1	Number of blades	Height, m	C_p	TSR
TS-01	6°	12	0.9	0.0570	0.2742
TS-02	6°	12	1.1	0.0520	0.3161
TS-03	6°	16	0.9	0.0474	0.2456
TS-04	6°	16	1.1	0.0505	0.2701
TS-05	6°	20	0.9	0.0594	0.2456
TS-06	6°	20	1.1	0.0500	0.2639
TS-07	10°	12	0.9	0.0586	0.2903
TS-08	10°	12	1.1	0.0566	0.3002
TS-09	10°	16	0.9	0.0580	0.2973
TS-10	10°	16	1.1	0.0518	0.2868
TS-11	10°	20	0.9	0.0583	0.2755
TS-12	10°	20	1.1	0.0511	0.2542
TS-13	14°	12	0.9	0.0583	0.3094
TS-14	14°	12	1.1	0.0564	0.3202
TS-15	14°	16	0.9	0.0545	0.2871
TS-16	14°	16	1.1	0.0512	0.3006
TS-17	14°	20	0.9	0.0537	0.2834
TS-18	14°	20	1.1	0.0502	0.2763

The first conducted analysis was the optimization for C_p, where the desired behaviour is to maximise this value. Table 5 summarises the obtained values and optimization results. The optimal geometrical properties for energy production were found to be an angle of attack of 11.5495°, a minimum height of 0.9 m and a number of blades of 12.0058, resulting in a C_p prediction of 0.05944. Although the recorded values are low for the given wind speed, this behaviour may be expected due to the lower air density and the definition of TSR and C_p, where the global speed is considered to be the sum of each lane's speed. The surface plot resembles a saddle-back, indicating that higher C_p values may exist on the extreme ends of the number of blades and near 10° attack angle.

Table 5. *Optimization results for* C_p.

Factor	Lower limit	Upper limit	Optimum value
Angle of attack α_1	6°	14°	11.5495°
Number of blades	12	20	12.0058
Height, m	0.9	1.1	0.9

After obtaining the C_p analysis, a similar analysis was performed for TSR, trying to minimise this value due to the low wind speed present in the selected location. This analysis didn't provide any interesting results. So, an additional analysis was carried out considering both responses. Table 6 shows the resultant values to minimise the TSR and maximise the C_p. The height is the same as for the optimal results in Table 5, but the condition to minimise TSR imposes a higher blade number of blades and lower attack angle, obtaining the value of 20 and 6.4656° respectively. From the response analysis, the predicted C_p is 0.05725 and a TSR of 0.49881.

Table 6. *Optimization results for multiresponse analysis.*

Factor	Lower limit	Upper limit	Optimum value
Angle of attack α_1	6°	14°	6.46562°
Number of blades	12	20	20
Height, m	0.9	1.1	0.90075

Figure 10 shows the response surface and has a similar shape as the one generated for C_p, but shifted to benefit higher blade numbers and with a sharper slope. The resultant height is the mean between both values, upper and lower limit. This is the default option from the software to avoid dependence of the third variable and since the response from the height is not significant the figure is valid and represents the correct behaviour of the system.

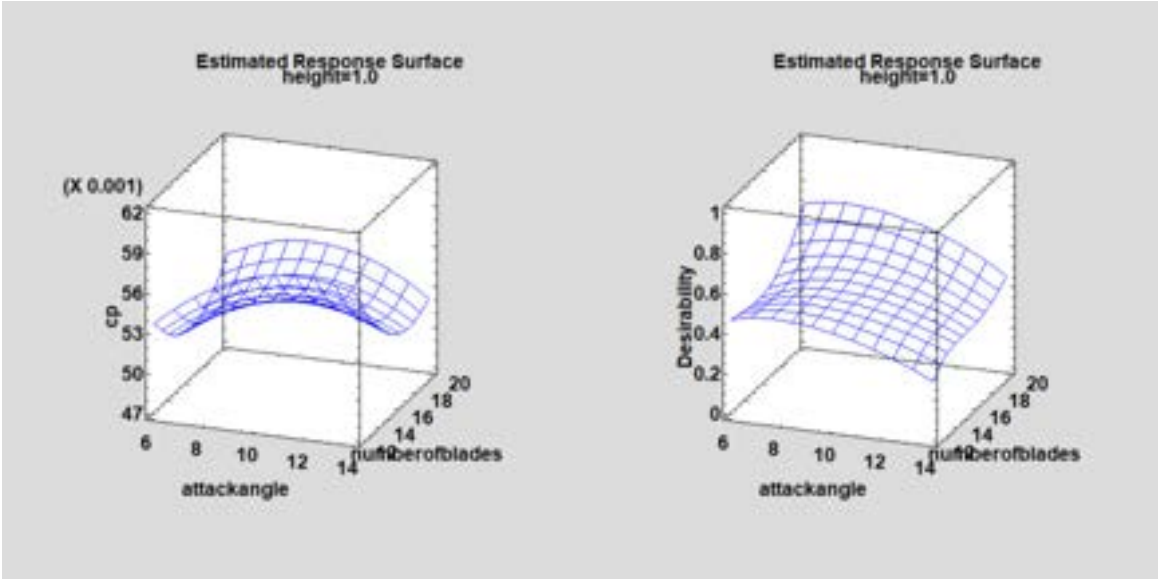

Figure. 10. *Estimated response surface for* C_p *optimization and Multiresponse analysis at height 1 m.*

5. Conclusions and recommendations

The design and simulation of a Banki cross-flow wind turbine for highways under high turbulence and high altitude conditions was developed in this work. The results include the following conclusions:

- The number of blades, attack angle and height were optimized for maximum energy production. The results indicate that the number of blades should be 12 and the attack angle and height should be 11.55° and 0.9, respectively.
- The predicted maximum C_p value is 0.05944, which indicates low efficiency. Results that could be improved with the addition of concentrators. The TSR value for this maximum C_p must be minimised to improve turbine performance at lower wind speeds, which is important considering the location and high altitude conditions.
- The optimal value for the combination of the Cp and TSR fluctuates in terms of blade numbers, where higher values indicate higher starting torque and lower self-start speed of the turbine, resulting in a higher Cp shortly after the turbine's cut-in speed. The predicted C_p, in this case is 0.05735 and the optimal blade number is 20 and 6.46° angle.

- The attack angle seems to have a maximum efficiency point for the conditions where the most beneficial angle for energy production appears to be in the middle of the considered parameters. Overall and considering that the difference between C_p's in both analysis is low, the optimal geometrical designs for the turbine are the ones related to the C_p analysis.

The design of the turbine was successful and has a similar approach to other authors in the literature regarding limitations and parametrical design. Nevertheless, we have some recommendations and future work to do:

- The results must be improved with better instruments of measurement and larger intervals of wind speed measurements in order to obtain a more accurate prediction of the resource and to assess the feasibility of installing the turbine over the Blanco Galindo highway.
- The construction of a prototype is also recommended. The prototype should be made from a durable material with a high Young modulus that will enable the turbine to operate correctly. Composite materials offer an advantage in this regard.
- Also, in order to increase the reliability of the study a more realistic CFD analysis should be carried out taking into account the aerodynamics of a moving vehicle, with a higher number of elements and better-quality meshing for a group of turbines (energy harvesting). Moreover, future studies could also consider wind deflectors or other passive elements to increase turbine efficiency.

It is also important to mention that the next steps in this work include manufacturing a couple of prototypes to validate their performance in different conditions and to gather information from at least two sites where the altitude is a predominant factor for eolic generation efficiency. The construction and manufacturing of these prototypes would involve a improvement on Bolivia's renewable energy matrix and distributed generation. The sites chosen for the next stage of the project are the Blanco Galindo Avenue in Cochabamba, Bolivia (2558 m.a.s.l.) and the El Alto - Mallasilla road in La Paz, Bolivia (3500 m.a.s.l.).

Nomenclature

ρ	air density, kg/m^3
α_1	angle of attack, °
β_1	blade angle, °
δ	degree of curvature, °
D_2	inner diameter, m
r_2	inner radius, m
D_1	outer diameter, m
r_1	outer radius, m
P	output power from the turbine, W
S	projected area of the turbine, m^2
c_p	power coefficient
ρ_b	radius of curvature, m
c_t	thrust coefficient
TSR	tip-speed ratio
V	wind speed, m/s

Abstract:

In the recent years, European Countries are paying more and more attention to the issue of greenhouse gases emissions due to the road transport sector. In particular, the fuel consumption due to the heavy road transport is one of the most relevant issues both for the weight and the long distances that they cover. In addition, the cost of the natural gas dramatically increased in many European countries due to recent international crisis. Thus, finding alternative ways of producing natural gas from renewable sources would be of great economic and environmental impact for the current global asset. In this work, a dynamic thermoeconomic analysis of a plant producing bio liquefied natural gas (bio-LNG), driven by renewable sources, to meet the fuel demand of a fleet of heavy trucks is proposed. The plant consists of a plug flow reactor digesting the organic fraction of municipal solid wastes in mesophilic conditions. The biogas upgrading model and the biomethane liquefaction models are in detail developed in MATLAB. The whole system is integrated in TRNSYS for dynamic simulation purpose. Then, the bio-LNG is used to meet the fuel demand of heavy trucks which cover relevant distances all over the region of Campania, in the South of Italy. The environmental impact related to the avoided emissions due to the use of bio-LNG is analysed together with the economic feasibility of the proposed system. The results of the thermoeconomic simulation show that the system has high capital costs, close to 85 M€ despite the fundings granted for bioLNG trucks purchasing. However, the fundings for the biomethane production and selling are enough to guarantee a remarkable economic feasibility with a Simple Payback period of less than 2 years and a Net Present Value of 402 M€. Furthermore, the solution proposed is effective for the pathway of the green mobility, with a Primary Energy Saving of 91% and a reduction of CO_2 emissions by 86%.

Keywords:

Liquefied biomethane; plug flow reactor; renewable energy; heavy-duty truck; Linde cycle.

1. Introduction

To achieve the goal of the climate neutrality by 2050, the European Commission of the European Union (EU) issued several directives that must be mandatorily attended by all the EU Countries [1]. To this scope, a first key set of proposals to revise EU Legislation was signed in 2021, known as "fit for 55" package [2]. The main purpose of this package is to reduce by 55% CO_2 emissions by the end of year 2030, compared to the year 1990. The proposals include a significant revision in EU policies on energy taxation, carbon border adjustment mechanisms and emissions trading systems. In this framework, particular attention was paid to the transport sector, which is still responsible for over 25% of greenhouse gases (GHG) emissions, by including a strict alternative fuels infrastructure regulation [3]. Nowadays, there are 13.4 million of alternative fuel road vehicles in the EU, around 5% of the total number, but estimations predict an exponential increasing trend of alternative fuels spreading in the next 20 years [4]. More specifically, large attention is paid to the installation of alternative refuelling points on the main roads, to allow vehicles, especially heavy-duty trucks, to circulate throughout the EU countries [5].

The environmental impact of the heavy-duty trucks is indeed widely acknowledged and the main reason lies behind the ever increasing spreading of worldwide freight shipments [6]. The current globalized market allows the trade of products among the most remote parts of the world by means of containers which carry out tons of consumer goods. These goods are then overwhelmingly land transported by heavy trucks for internal moving among the ports of the same country [7]. Unfortunately, the sustainability of this market is jeopardized by the increasing connections of ports for the exchange of containers, that comes with the increase of the number of

heavy-duty trucks for road transport of containers. In this framework, among the proposals for the EU Legislation revision for a sustainable development, the installation of alternative fuels refuelling stations in the busiest seaports was indeed considered [8]. This strategy mainly involves electric batteries recharging, but the usage of liquefied natural gas (LNG) is also taken into account. Unfortunately, latest directives in terms of road transport vehicles circulation are aiming to the utter replacement of internal combustion engine vehicles with electric vehicles by 2035 []. However, these directives are still under discussion since several EU Countries are concerned that this pathway is not at all the most efficient and sustainable for the road to the full decarbonisation. In fact, cutting-edge solutions for the progress towards a green mobility not only include electric road transport [9], but also hydrogen vehicles [10] and vehicles fuelled with compressed natural gas (CNG) and liquefied natural gas (LNG), even produced starting from biomass, respectively named bio-CNG and bio-LNG. In fact, the scientific literature shows an increasing number of studies involving produced emission analyses and economic feasibility of these solutions compared to Diesel fuelled heavy trucks [11]. A case study with real drive cycles was conducted in British Columbia [12] and it was estimated that CNG trucks emit 15% less CO_2 than Diesel trucks, primarily depending on drivetrain technology rather than operating conditions. The same results is found in similar works [13].

However, what is mostly catching the eye nowadays is the possibility of exploiting the biomasses to produce fuels that are utterly eco-friendly [14]. In fact, electric road transport is a solution which is still not sustainable as a unique for the advancement towards the “green mobility” and alternative solutions are increasingly pursued. This, in particular, is shown by the ever and ever growing interest for the study of power-to-fuels (PtF) technologies [15]. The anaerobic digestion (AD) process for the production of biogas from the municipal wastes is a well-known technology and it is suited for PtF systems. In fact, it allows one to combine the urban waste recycling and the necessity of producing natural gas from renewable sources. The biogas produced by the AD is a gaseous compound mainly consisting of methane (CH_4) and carbon dioxide (CO_2), with other minor impurities [16]. After a process of clean up, required for the poisoning components included in the biogas, this gas may undergo an upgrading process to separate, with a high grade of purity, the CH_4 from the CO_2 [17].

On the one hand, the most commonly adopted solution for the biogas upgrading is the membrane separation process [18]. This solution provides biomethane with a still significant gas purity (around 95%) and is the less expensive, so it is vastly adopted for the production of CNG. On the other hand, the biogas upgrading process with the highest percentage purity of the final biomethane obtained as by-product is the liquefaction [19]. The LNG is mainly obtained by means of the cryogenic separation process. However, this process is high-energy demanding since the biogas must be compressed up to 20 MPa and cooled down to -161°C [20]. Naquash et al. [21] provided an energy and exergy analysis of the biomethane liquefaction process with mixed-refrigerant followed by CO_2 solidification. The process simulated in Aspen and validated with experimental data showed a 68.6% of energy saving with respect to the case in absence of CO_2 solidification. Furthermore, a beneficial specific consumption of 0.49 kWh/kg was observed with respect to the base case where 1.57 kWh/kg were required. The greatest exergy rate is due to the cryogenic heat exchangers. In [22] the authors compare two different upgrading options, namely cryogenic separation and ammine absorption, combined with liquefaction for LNG production. Models were simulated in Aspen and optimized for minimization of energy consumption. In case of cryogenic upgrading, the specific consumption resulted of 2.07 kWh/kg whereas for ammine absorption, a value of 3.35 kWh/kg was obtained, also considering the heat required for regenerating the ammines. In reference [23], a comparative energy, environmental and economic analysis is proposed for the biogas upgrading and distribution of CNG and LNG. As a result of the analysis, it was obtained that differences among different biogas upgrading and biomethane liquefaction technologies, using a life cycle analysis, are marginal, especially in case of long-distance transportation of the gas. However, the longer the distance to the customer, the more convenient the bio-LNG with respect to the bio-CNG.

The aim and novelty of the work here proposed can be summarized in the following points:

- Development of an innovative layout based on a plug flow reactor fed by organic fraction of municipal solid waste for the production of biogas, equipped with biogas upgrading unit and biomethane liquefaction unit
- Adoption of a solar PV system with lithium-ion battery for analysis of the specific energy consumption for the production of the bio-LNG
- Thermoeconomic analysis of the model in dynamic operating conditions with specific case study for meeting the fuel demand of a fleet of heavy-duty trucks

2. Layout

The layout of the system is shown in figure 1.

In the proposed system configuration, the whole liquefied biomethane production is based on the anaerobic digestion (AD) of the organic fraction of municipal solid wastes (OFMSW) within a plug flow reactor (PFR). The PFR is fed by the biomass, converted in biogas by the AD process. The biogas production is almost constant in rated operating conditions and a buffer is equipped downstream the PFR to ensure constant operating

conditions of the biogas upgrading unit [24]. The thermal demand of the digester is partially met by evacuated tube solar collectors (ETC), the integration occurs by means of a biomass-fed auxiliary boiler.

The biogas upgrading unit is a hollow fiber three-stage membrane compression system which separates the methane from the carbon dioxide. The three-stage compression is intercooled by means of sea water heat exchangers, so the inlet temperature from the cold side continuously changes. Thus, the energy consumption of the process is not constant despite the constant operating flow rate of biogas. The biomethane obtained as a by-product from the separation of the carbon dioxide is supplied to the liquefaction unit, operating according to the Linde industrial process [25]. Details of the models are discussed in the following section. Here only the final result of the process is explained. In fact, the biomethane is cooled down to the saturation temperature at ambient pressure and the liquid phase is separated from the steam phase. The former one is captured and sold as LNG, the latter is instead used to refill the process and repeat the cycle. The precooling of the biomethane is realized by means of an ammonia electric chiller, then a lamination valve realizes the final cooling. This whole cycle of biomethane production and liquefaction is also equipped with a PV system and a Lithium-Ion battery (LIB). This equipment is considered to partially meet the energy demand of the process and increase the share of renewables in the overall bio-LNG production. The PV system coupled with the LIB is responsible for meeting the load of the upgrading unit and the liquefaction unit, together with the auxiliary electricity-driven devices.

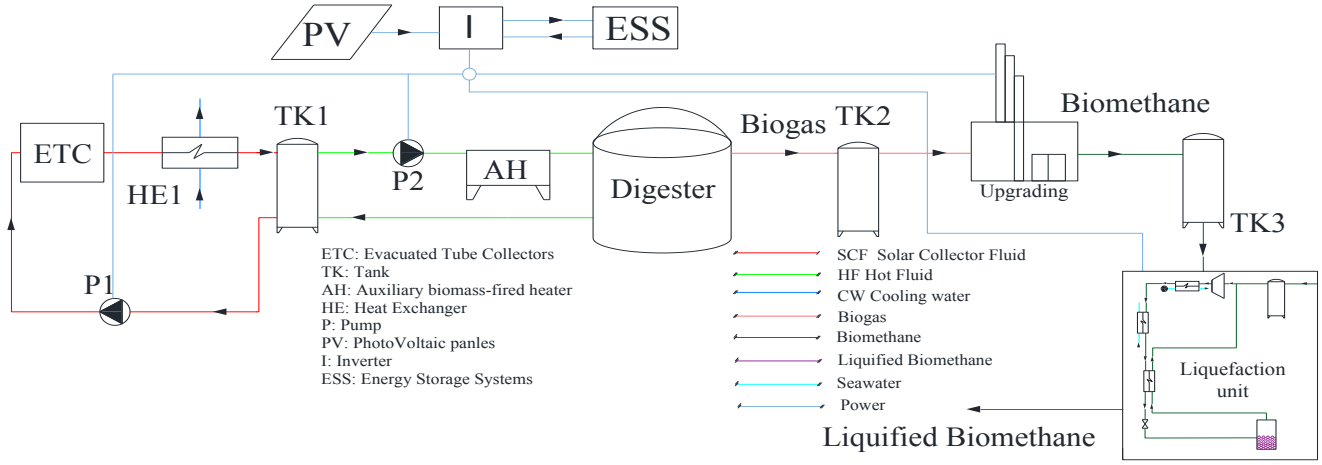

Figure. 1. Layout of the plant.

3. Model

In this section the main models developed by the authors are shown and discussed. The models are first developed in MatLab and then integrated in TRNSYS environment to perform the dynamic simulation of the plant including all the technologies proposed. Furthermore, the thermoeconomic model adopted to perform the energy, environmental and feasibility analysis of the solution proposed is shown. The following models are proposed by the authors and discussed in this work:

- Plug Flow reactor for the biogas production
- Membrane separation for the biogas upgrading
- Biomethane liquefaction

3.1. Plug Flow reactor

The plug flow reactor (PFR) model here developed is based on the discretization of the system of partial differential equations for the anaerobic digestion and the heat transfer phenomena occurring in the reactor. The model has been widely explained by the authors in previous works [26], together with its validation. The biological model is based on the anaerobic digestion model n.1 (ADM1) with some simplified assumptions on the number of species taking part to the process, eq.(1) [26]. The thermal model is instead based on the well-known heat transfer equation for heat exchangers, eq.(2) [27]. In addition, the thermal balance between the digester and the environment is considered, see eq.(3) to understand how dynamically varies the thermal demand basing on the heat loss to the ambient. The main equations involved in the model are thus the following:

$$\frac{dC_{w,i}}{dt} = \frac{\dot{V}_{w,in}}{V_w}\left(C_{w,i,in} - C_{w,i}\right) + \sum_j \rho_j \nu_{i,j} \tag{1}$$

$$\dot{m}_{wat} C_{p,wat} \left(T_{in,wat} - T_{out,wat} \right) = n U_{HE,n} A_{HE,n} (\overline{T}_{in,wat} - \overline{T}_{react}) \tag{2}$$

$$\dot{m}_{OFMSW} C_{p,OFMSW} T_{in,OFMSW} + \dot{m}_{wat} C_{p,wat} \left(T_{in,wat} - T_{out,wat} \right) - \dot{m}_{dig} C_{p,dig} T_{react} + \\ -\dot{m}_{biogas} C_{p,biogas} T_{react} - \dot{Q}_{loss} = \rho_{OFMSW} V_{OFMSW} C_{p,OFMSW} \frac{dT_{react}}{d\vartheta} \tag{3}$$

Where $C_{w,i}$ is the concentration of the bacterial species considered, $V_{w,in}$ is the input waste volumetric flow rate, V_w is the volume occupied by the biomass in the digester, $C_{w,i,in}$ is the concentration of the i-th species in the input flow rate. The last term is the sum on the j-th process of all the kinetics terms times the reaction coefficient of the i-th biochemical species involved in the j-th process. The temperature at which the kinetic terms of the biological process are iteratively calculated according to the thermal balance on the digester and the heat exchange with the inner water heat exchanger.

3.2. Membrane separation

The biogas upgrading process is based on a three-stage hollow fiber membrane compression unit in which each stage includes a double stage compression with inter-refrigeration by means of seawater heat exchangers, see figure 2.

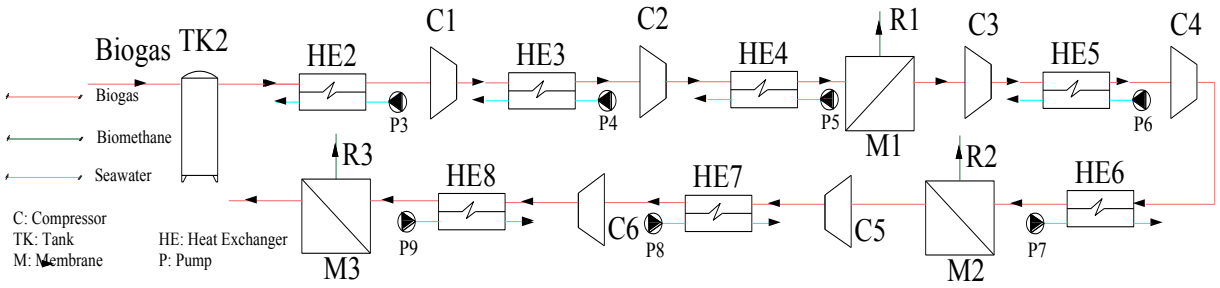

Figure. 2. Membrane separation unit.

The gaseous compound compressed is sent to the membrane at the end of each stage and the different permeability of CH_4 and CO_2 at a given operating pressure and temperature drive the separation process. In fact, due to the different permeability of the gases, two different streams are obtained, one rich in CH_4 (retentate) and one rich in CO_2 (permeate) [28]. The detailed model of the system of equations describing the process is discussed in [29].

3.3. Biomethane liquefaction

The biomethane obtained from the biogas upgrading process is the liquefied by means of a Linde cycle where the biomethane itself is the working fluid, see figure 3.

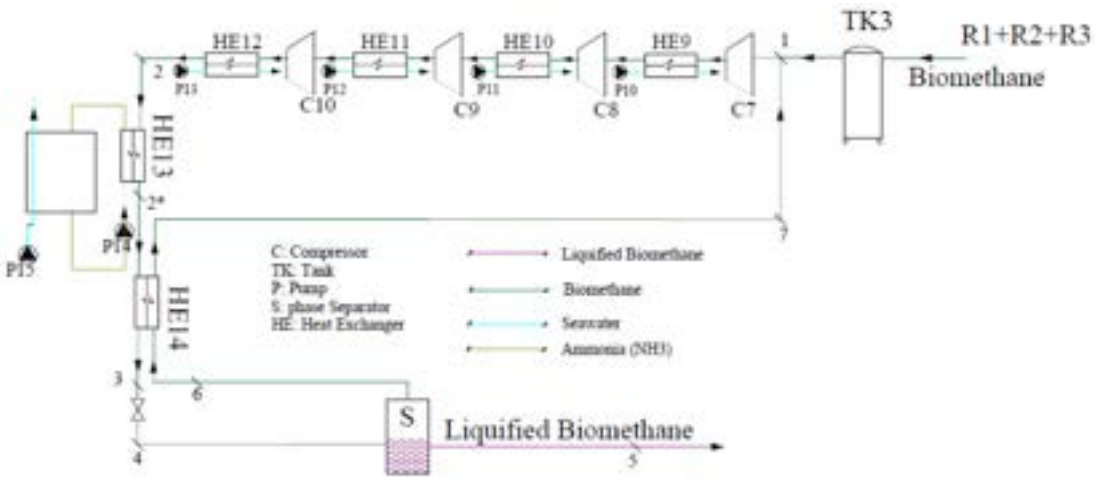

Figure. 3. Biomethane liquefaction unit.

The biomethane first undergoes an inter-refrigerated multi-stage compression up to the rated operating pressure of the cycle of 20 MPa. Here, the temperature is still the ambient temperature, T = 25°C. Then, the biomethane is cooled down to the temperature of -50°C through the evaporator of an ammonia electric chiller.

This heat exchanger HE13 is pivotal to drive the operation of the cycle in the transient conditions, since after this precooling the biomethane is furtherly cooled down by means of the regenerative heat exchanger HE14. After this, a throttling valve is used to decrease the pressure of the biomethane down to the ambient pressure and obtained saturated steam. The liquid fraction of the biomethane is spilled and stored, whereas the steam is used as cold fluid for the HE14 and then as a refill for the cycle. The model is developed in MatLab and iteratively calculates the variables T_3, T_7 and x_4 by means of the following system:

$$\begin{cases} h_4 = h_6 x_4 + h_5 \cdot (1 - x_4) \\ \dot{Q}_{HE14} = \dot{m} \cdot x_4 \cdot (h_7 \cdot - \cdot h_6) \\ \dot{Q}_{HE14} = \dot{m} \cdot (h_{2^*} \cdot - \cdot h_3) \end{cases} \quad (4)$$

Where Q is the heat transfer rate and h is the enthalpy of a specific state point.

There is no direct validation of these models against experimental data but each of them is based on well-known and globally accepted equations for the calculation of the biogas production, the membrane separation, and the Linde cycle. Therefore, the model as a whole can be considered intrinsically valid, since all the results are also consistent with data available from literature.

3.4. Thermoeconomic model

The thermoeconomic analysis is based on a widely adopted approach which allows to evaluate the energy, environmental, and economic performance of the proposed system (PS) with respect to the reference system (RS) by means of few key performance indicators [30]. The RS in this case is the one including the heavy-duty trucks equipped with Diesel engines, with the fuel provided by the GPL stations. In the PS, the heavy-duty trucks are equipped with LNG engines whose fuel demand is partially met by the renewable plant described. The Primary Energy Saving (PES) is calculated as $\Delta PE/PE_{,RS}$ where ΔPE is:

$$\Delta PE = PE_{RS} - PE_{PS} = \left(M_{Diesel} LHV_{Diesel}\right)_{RS} - \left[\frac{E_{el,fromGRID} - E_{el,toGRID}}{\eta_{el,grid}}\right]_{PS} \quad (5)$$

Where $\eta_{el,grid}$ is the efficiency of the national electric grid, $M_{LNG,dem}$ is the fuel demand of the heavy-duty trucks adopting LNG engines and $M_{LNG,prod}$ is the LNG produced by the renewable plant proposed. The CO_2 emissions saved are calculated according to the emissions factors of electricity and diesel consumed [31]:

$$\Delta CO_2 = CO_{2,RS} - CO_{2,PS} = \delta_{trucks} f_{trucks,D} - \left(E_{el,fromGRID} - E_{el,toGRID}\right) f_{EE} \quad (6)$$

Where δ_{trucks} is the total distance covered by the heavy-duty trucks and $f_{trucks,D}$ is the CO_2 equivalent emission factor for Diesel fuel trucks [31].

The economic feasibility is instead evaluated by means of the cost savings due to the PS:

$$\begin{aligned} \Delta C &= C_{RS} - C_{PS} \\ &= (V_{Diesel} c_{u,Diesel})_{RS} - (E_{el,fromGRID} c_{u,EE} + M_{wc} c_{wc} + E_{el,toGRID} p_{u,EE} - CIC + M)_{PS} \end{aligned} \quad (7)$$

Where the term M represents the maintenance costs whereas CIC is referred to the fundings granted by the Italian Government for the production of biomethane from municipal organic wastes [24]. More precisely, for the calculation of the operative costs for both the RS and the PS, the carbon tax for the CO_2 emissions due to fossil fuels consumption is considered [32].

The capital cost of the system includes the cost for the replacement of the trucks, the digesters, the collectors, the photovoltaics, the storage units, the liquefaction units, the membranes, the heat exchangers, and all the auxiliary components. The correlations for the costs of all of the components can be found in previous works of the authors [33]. From the values calculated, is possible to calculate the main thermoeconomic indicators such as the Primary Energy Saving (PES), the Simple Payback (SPB), and the Net Present Value (NPV) [24]. Table 1 shows the main parameters used for the thermoeconomic analysis. More information about the costs of the components can be found in previous works of the authors [33].

Table 1. Parameters used in the thermoeconomic analysis.

Parameter	Description	Value	Unit
$c_{u,EE}$	Electricity purchasing cost	0.20	€/kWh
$p_{u,EE}$	Electricity energy exporting cost	0.05	€/kWh
c_{wc}	Woodchip purchasing cost	0.06	€/kg
$c_{u,Diesel}$	Diesel purchasing cost	0.805	€/L

LHV_{Diesel}	Diesel lower heating value	12.67	kWh/kg
LHV_{wc}	Biomass lower heating value	3.70	kWh/kg
LHV_{LNG}	LNG lower heating value	15.33	kWh/kg
LHV_{biogas}	Biogas lower heating value	5.86	kWh/Sm^3
J_{ETC}	Evacuated thermal collectors unit capital cost	300	€/m^2
J_{PV}	PV panels unit capital cost	1000	€/kW
J_{LIB}	Lithium-ion battery unit capital cost	200	€/kWh
J_{CH-NH3}	Ammonia chiller specific cost	2076	€/kW
J_{mem}	Membrane unit capital cost	50	€/m^2
J_{D2LNG}	Replacement unit cost from Diesel to LNG truck	84.72	k€/truck
M_{plant}	Plant yearly maintenance	1.5	%/year
K_{mr}	Membrane replacement price	25	€/m^2
v	Replacement rate	0.25	1/year
$\eta_{el,Grid}$	Electric efficiency of the public power grid	0.46	-
$\eta_{th,boiler}$	Thermal efficiency of the auxiliary heater	0.95	-
f_{EE}	Electric energy equivalent CO_2 emission factor	0.483	$kgCO_2$/kWhel
$f_{trucks,D}$	Diesel truck equivalent CO_2 emission factor	0.942	$kgCO_2$/km
CIC	Certificate of release for consumption	375	€/CIC

4. Case study

The techno-economic analysis of the proposed system is evaluated for a case study in the region of Campania, in the South of Italy. More specifically, the liquefied biomethane produced with the layout described is supposed to fully meet the fuel demand of a fleet of heavy-duty trucks. The trucks considered for the case study are the ones that everyday transport the containers (TEU) arriving as freight shipments in the port of Naples. The TEU are handled in the port and transported by means of heavy-duty trucks to the several distribution points where other TEU are withdrawn, in a continuous back-and-forth trading. According to the latest report of the Port System Authority [34], the total number of hinterland TEU daily handled in the port of Naples in 2022 was around 1440 TEU/day. The assumption of the model proposed is that half of these are incoming and half are outgoing, thus for each trade considered the trucks move one TEU from Naples to the distribution point and viceversa. On the base of this assumption, 720 heavy-duty trucks everyday take part to this trading system. The distribution points considered for the reference year are the cities of Caserta, Benevento, Isernia, Frosinone, Latina, and Salerno, see figure 4.

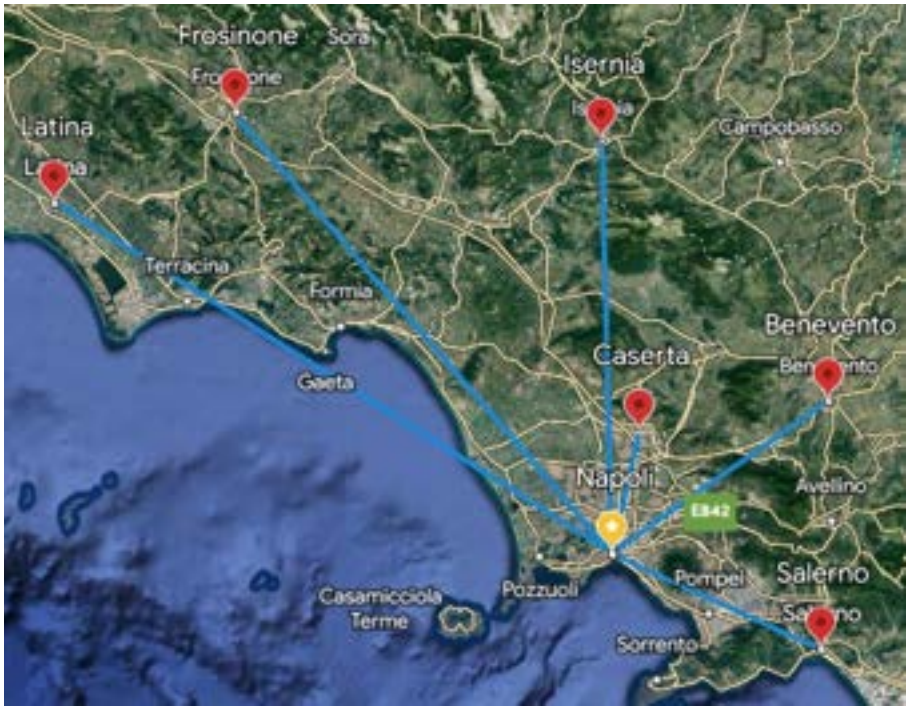

Figure. 4. Distribution map of the heavy-duty tracks transporting the containers.

Each truck runs for an average of 200 km every day mainly on highway roads, which means that the total distance daily covered by the fleet is 144´000 km/day. To cover this distance in the RS, 90´000 L/day of Diesel fuel are required, given a specific fuel consumption of 0.623 L/km [31]. According to data in table 1 and table

2, this fuel demand is equivalent to roughly $3.5x10^8$ kWh of primary energy, which is equivalent to roughly 23´000 tons/year of LNG. To meet this demand with the PS, the necessary amount of OFMSW needed is roughly 353´200 tons/year. According to data discussed in the "Report on Management of Municipal Waste in Campania" [35], around 625´000 tons/year of OFMSW are harvested, 65% of which come from the area of Naples, Caserta, and Salerno. Therefore, the biomass demand is fully met by the region and the collection points are possibly located very close to the TEU distribution points. In this case, 5 massive bio digestion plants are supposed to be dislocated in these areas, neglecting the energy costs for the fuel displacement due to the position with respect to the trucks displacements. Each plant is composed of 4 parallel PFRs of 2´580 m^3 operating with 2´016 kg/h of biomass and producing an average of 1´231 Sm3/h of biogas each. The biogas is then collected and sent to a membrane upgrading unit of roughly 2´850 m^2. Each plant is thus able to produce an average of roughly 530 kg/h which is sufficient to fully meet the LNG demand of the fleet. Detailed data regarding the case study are shown in table 2 and table 3.

Table 2. Main technical features of the case study proposed.

Parameter	Description	Value	Unit
δ_{trucks}	Distance covered by trucks	200	km/day
$Cs_{,Diesel}$	Diesel fuel truck specific consumption	0.623	L/km
ρ_{Diesel}	Density of the Diesel fuel	0.85	kg/L
M_{Diesel}	Mass of Diesel fuel required	27´922.5	tons/year
M_{LNG}	Mass of LNG required	23´077.5	tons/year
X	Rated quality of Linde Cycle	0.58	-
M_{bioCH4}	Rated flow rate of biomethane	6´272	kg/h
M_{OFMSW}	Organic municipal waste harvested in Campania	625´000	tons/year

Table 3. Technical data of the digesters.

Parameter	Description	Value	Unit
$\dot{m}_{OFMSW}$	Mass flow rate of OFMSW	2016	kg/h
ρ_{OFMSW}	Density of OFMSW	750	kg/m^3
$C_{p,\,OFMSW}$	Specific heat of OFMSW	2.72	kJ/(kg K)
$\dot{m}_{W,\,in}$	Mass flow rate of the inlet hot water range	1400÷9000	kg/h
T_{amb}	Ambient temperature range	-2 ÷ 35	°C
$T_{W,\,in}$	Inlet hot water temperature range	40 ÷ 60	°C
HRT	Hydraulic Retention Time	30	days
T_{dig}	Digester temperature	38	°C
H_{react}	Height of digester	10	m
n_{react}	Number of reactors operating in parallel	4	-
n_{plant}	Number of plants in operation	5	-

4. Results

The hourly, monthly, and yearly results of the simulation are presented and discussed in this section. Figure 5 shows the dynamic results for the electricity flow rates.

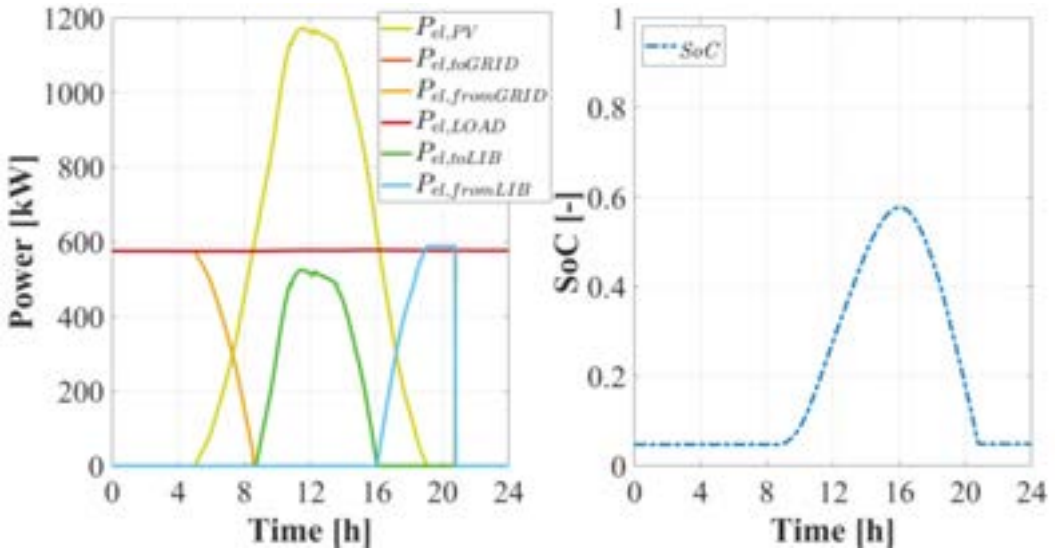

Figure. 5. Dynamic results for power flow rates.

The electricity flows shown here regard a single plant with 4 digesters operating with the biogas upgrading unit and the liquefaction cycle. The load of the plant is almost constant due to the possibility of operation in rated conditions, as it is common for optimal management of these technologies [29]. The day shown in figure 4 is a summer day so the electricity demand is met by the PV for large part of the day – 5 AM to 5 PM – with a remarkable fraction integrated with the battery in the other hours. In fact, the PV excess is relevant and the battery is filled up to roughly 60% allowing to extend the share of renewable power until 9 PM.

Figure 6 shows the monthly results of the simulation considering the total amount of energy for all the plants proposed.

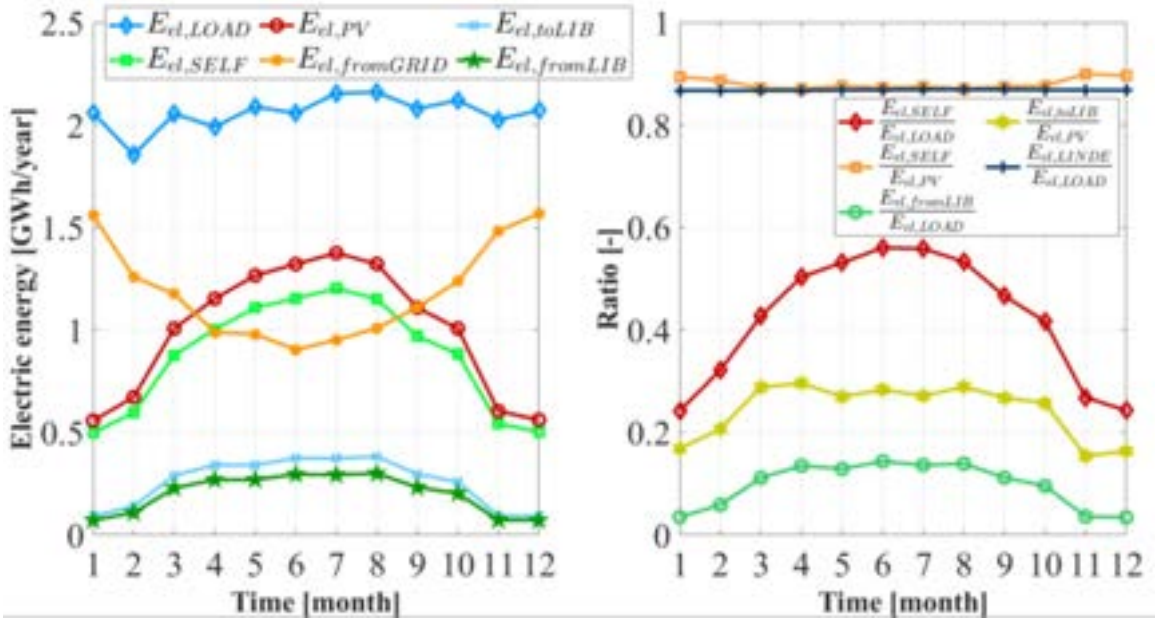

Figure. 6. Monthly results for the electric energies.

In the proposed system, the usage of the battery is pivotal to increase the share of renewables, since almost 30% of the PV energy is collected by the battery each month. The renewable fraction with respect to the PV energy, in fact, is constantly higher than 85%, see $E_{el,SELF}/E_{el,PV}$, and it reaches a peak of roughly 60% with respect to the total load in the summer period, see $E_{el,SELF}/E_{el,LOAD}$. The dynamic trend is thus confirmed and the battery is almost always fully exploited, with just a slight energy dispatching of few kWh in the summer period. However, the electricity sent to the grid is always negligible. This result is crucial since the production of bioLNG with this PS does not affect the electric grid and allows a great reduction of fossil fuel energy consumption. Furthermore, monthly trends also show that large fraction of the energy consumption is due to the liquefaction cycle, see $E_{el,LINDE}/Ee_{l,LOAD}$, as it was expected.

The trends discussed are confirmed by the results shown in Table 4. Furthermore, yearly results show a great economic feasibility of the solution presented.

Table 4. Results of the yearly analysis.

Parameter	Value	Unit
$E_{el,Upgrading}$	3.24	GWh
$E_{el,Linde}$	21.44	GWh
$E_{el,LOAD}$	24.71	GWh
$E_{el,fromGRID}$	14.22	GWh
$E_{el,toGRID}$	0.00	GWh
$E_{el,self}$	10.49	GWh
$E_{el,PV}$	11.95	GWh
$E_{el,toLIB}$	3.08	GWh
$E_{el,fromLIB}$	2.42	GWh
$E_{el,self}/E_{el,LOAD}$	0.424	-
$E_{el,fromLIB}/E_{el,LOAD}$	0.098	-
$E_{el,fromGRID}/E_{el,LOAD}$	0.575	-
$E_{el,toGRID}/E_{el,PV}$	0.000	-
$E_{el,self}/E_{el,PV}$	0.878	-
$E_{el,Upgrading}/E_{el,LOAD}$	0.131	-
$E_{el,Linde}/E_{el,LOAD}$	0.868	-
PE_{RS}	353.78	GWh
PE_{PS}	30.91	GWh
ΔPE	322.87	GWh
PES	0.91	-
$CO_{2,RS}$	49511.5	tons/year
$CO_{2,PS}$	6868.5	tons/year
ΔCO_2	0.86	-
$M_{biomethane}$	$5.5\ 10^7$	kg/year
M_{LNG}	$2.3\ 10^7$	kg/year
$M_{LNG}/M_{LNG,demand}$	1.00	-
C_{inv}	84.19	M€
C_{RS}	26.44	M€/year
C_{PS}	-20.33	M€/year
ΔC	46.77	M€/year
SPB	1.80	years
NPV	402.22	M€
PI	4.78	-

The primary energy consumption in the RS, when the Diesel fuel required is considered, is by far larger than the one of the PS. In fact, in this case only the amount of electricity withdrawn from the grid is responsible for fossil fuel consumption since the bioLNG produced meets all the fuel demand of the fleet of trucks, and the PES is equal to 91%. At the same time, the CO_2 emissions are reduced by 86%, also due to the fact that the thermal energy demand of the digesters is fully met by renewables, ETC and auxiliary biomass-fed boilers.

The economic feasibility is due to strong incentives both for the usage of bio-fuelled trucks and the production of biomethane from organic municipal wastes. In fact, Italian Government provides double fundings both for the purchase of bioLNG trucks and the dismissal of old Diesel fuelled trucks, and for the production and selling of “advanced” biomethane produced from organic wastes. In this case, the relevant capital costs of such a proposed solution, higher than 84 M€, are widely justified by the great reduction of the operative costs which lead to a yearly money saving of 46.77 M€/year. The fundings due to the CIC for biomethane vastly overcome the extra costs necessary for the maintaining of the plants and the withdrawal of electricity form the grid. The outstanding result in terms of profitability of the solution is highlighted by the NPV which is equal to 402 M€, almost five times the initial investment.

Figure 7 shows a parametric analysis considering different prices for the purchasing of urban waste for the disposal. In fact, Government may pay the ones who assume the responsibility of the urban wastes disposal.

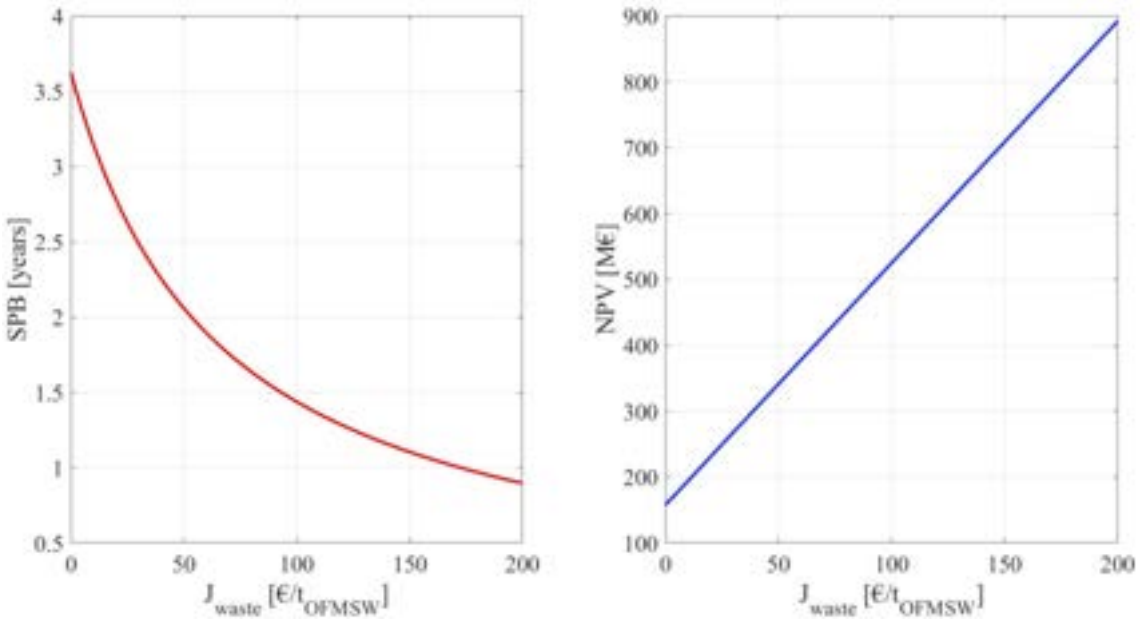

Figure. 7. Dynamic results for power flow rates.

The purchasing price for the disposal (J_{waste}) ranges from 0 to 200 €/ton of waste, treated to be used as biomass for the anaerobic digestion plants. In this case the CIC were not considered in the calculation of the economic indexes since with CIC the biomethane produced is already paid twice because of the treatment of the organic fraction of municipal solid wastes. In this case the SPB of the system could be even more profitable when the value of J_{waste} is greater than 70 €/ton. The same occurs for the NPV, with a constantly linear increase. It is worth noting that further increasing of J_{waste} over 250 €/ton would not come with relevant beneficial effect on the SPB of the system.

5. Conclusion

This work proposed a thermoeconomic analysis of a liquefied biomethane production plant proposed for several cities in the region of Campania, in the South of Italy. The proposal of these plants was to meet the fuel demand of a fleet of Diesel fuelled heavy-duty trucks which transport containers back and forth from the port of Naples. The main results obtained from the dynamic simulation and thermoeconomic analysis of the model proposed are the following:

- Five plants each one including four plug flow reactors operating 2016 kg/h of organic fraction of municipal solid wastes are able to fully meet the fuel demand of the fleet, equal to roughly 23000 tons/year of liquefied biomethane.
- The system proposed has large share of renewables since the thermal demand of the digesters is met by evacuated tube collectors and biomass fed boilers. In fact the Primary Energy Saving is remarkable and equal to 91%. At the same time the CO2 equivalent emissions avoided are equal to 86%.
- In addition, the system shows also great economic feasibility due to the grants provided by the Italian Government for the production of biomethane. Furthermore, relevant discounts are offered for the purchasing of green trucks, resulting in a Simple Payback of 1.8 years. The profitability is also shown by the Net Present Value equal to roughly 422 M€.
- Considering a premium tariff for the purchase of the urban wastes would increase the profitability of the system even more than the incentives for the selling of biomethane. In this case the Simple Payback and the Net Present Value would be even higher with a value of this tariff greater than 70 €/ton of waste.

Abstract:

Due to climate change and worldwide policies, the importance of renewable energy sources is increasing significantly. Increasing its share of total energy consumption is essential to reduce CO_2 emissions and achieve energy independence. A commonly available source of heat is solar energy, which can be efficiently used and converted using a specific technology. For the generation of medium and high-temperature heat, CSP technologies are used, with parabolic trough collectors (PTC) being the most mature. In heat industrial power, this technology is used on a reduced scale, with a smaller aperture. The scale-down of the geometry and the lower temperature stage compared to traditional high aperture PTCs provides opportunities for optimisation and the use of alternative materials. As the temperature and heat flow parameters change in different sections of the absorber, it is optimal to introduce different methods in different areas of the solar loop. This article presents the optimization results of the use of non-selective but highly absorptive and cost-effective solar coating and twisted tape inserts in solar loop sections. The research was conducted for a case study which was a medium-sized industrial facility with a heat demand of a maximum of 250 °C. A numerical model was used for this study, validated by a previously performed experiment using a solar simulator. The results showed that both methods lead to an intensification of heat absorption, almost 45% of the absorbers can have a low-cost non-selective coating and twisted tapes with a twisted ratio of 1 and 2 can be applied inside the absorber pipes. The maximum efficiency gain was 1.3%.

Keywords:

solar energy; parabolic trough collectors; renewable energy; heat absorption; concentrated solar power.

1. Introduction

The development of renewable energy sources in parallel with energy storage is necessary to increase energy independence from fossil fuels, the availability and price of which have been strongly influenced by international policy in recent years [1,2].Due to rising raw material prices, the profitability of most technologies previously not considered due to their relatively high cost and the long payback period is increasing [3]. Another but extremely important aspect in favour of increasing the share of low- and zero-carbon sources is the positive impact on the environment [4]. Energy requirements can be roughly divided into two, in the form of electricity and heat [5]. Considering only solar energy as a clean energy source, for electricity generation the most common sources are photovoltaic panels. Heat can be generated using PV panels and heat pumps, but this solution is mainly considered for small domestic installations [6].

The greatest need for heat is in industry, which uses it in various processes. Depending on the characteristics of the company, heat can be used for manufacture of food and dairy products [7,8], drying and sterilization [9], steam production [10]. Heat, in the temperature range up to about 300 °C, can be efficiently generated by parabolic trough collectors with a low concentration ratio. It is a mature technology that has recently been scaled down and adapted to produce heat at lower temperature levels [11,12].

Reducing the temperature level opens up opportunities to increase the efficiency of these installations and reduce their manufacturing cost. It is therefore necessary to look for solutions that can be easily applied to this scaled-down version of a mature technology. These treatments are intended to increase the popularity of solar technologies mainly in the industry sector.

The methods proposed in this article for intensifying heat absorption can be divided according to their location of application: outside and inside the absorber. The first is the use of the no-selective and cost-effective coating in the individual preliminary sections of the absorber, in such a way as to increase efficiency and reduce the investment cost of the installation. The proposed coating differs from the regularly used one

in that it is not selective, so radiation losses are high but are compensated by the extremely high absorptivity of this coating. The methodology associated with such a coating application has been presented in previous work [13]. A second method of heat intensification is the use of twisted tape inserts, which is a fairly popular and mature research topic [14–16]. Twisted tapes have been tested experimentally and numerically for a wide range of parameters [17,18]. Solutions that modify traditional twisted tapes, such as the application of perforation [18] or peripherally cut [19] as well as double application [20], are also analysed. However, the literature provides no sufficient data on the application of twisted tapes for low-concentrated parabolic trough collectors, which are characterised by different boundary conditions, such as radiation distribution, temperature range or mass flow.

In this analysis, a numerical study supported by experimental results has been carried out, where we propose to use the two previously described methods sequentially in an absorber loop. The research questions that this article answers are as follows.

- Does the application of the two proposed methods increase the efficiency of the installation?
- How can both methods of heat intensification be used optimally?

2. Methods

An analysis of the combination of the two heat intensification methods developed was carried out using a mathematical model and the results of numerical tests and experimental study. Figure 1 shows the assumptions accompanying the analysis. Three absorber configurations were tested in the absorber loop. The case 1, also called the reference case, was the use of tubular absorbers with a selective coating throughout the whole absorber loop. Case 2, involved included partial application of non-selective, but cost-effective coatings in part of the absorbers in such a way that the efficiency of the installation did not decrease. Case 3 shows the addition of twisted tapes inserts to the previous (from case 2) results. In summary, the analysis first aimed to determine the number of absorbers that could be covered with a no-selective coating and then to add an additional method of intensifying heat collection through twisted tapes applied inside the absorber.

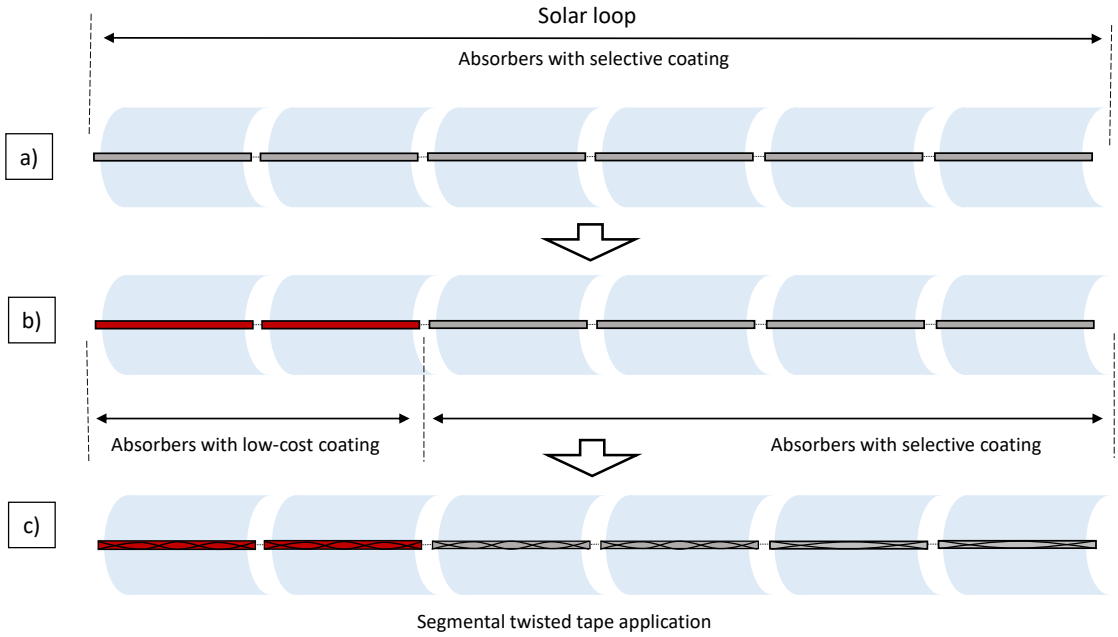

Figure. 1. Coating and twisted tapes application strategy: a) refence CASE 1 (all absorbers covered by selective coatings), b) CASE 2 with no-selective and selective coatings, c) CASE 3: combination of coatings applications and segmental twisted tapes coatings (in configuration as case 2).

2.1. Analysis assumptions

The following section outlines the assumptions that were used in the model.

2.1.1. Parabolic trough collector – geometry and operation parameters

The analysis considers a low-concentration parabolic trough collector that can produce heat for industrial applications. The geometric and optical parameters are shown in Table 1, and the most important ones which are particularly important are: aperture width 1800 mm, absorber length 1000 mm, absorber external diameter 33.7 mm. The assumed parameters are based on parabolic trough collectors manufactured serially [21].

Table 1. Geometrical and optical parameters of analysed parabolic trough collector.

Parameter	Symbol	Value	Unit
Focal length	f	0.647	m
Aperture width	W_{ap}	1.8	m
Absorber length	L_{abs}	1	m
Absorber external diameter	$d_{abs,e}$	33.7	mm
Absorber internal diameter	$d_{abs,i}$	30.7	mm
Absorber wall thickness	th_{abs}	1.5	mm
Glass env. external diameter	$d_{c,e}$	56	mm
Glass env. internal diameter	$d_{c,i}$	51	mm
Glass env. wall thickness	th_c	2.5	mm
Transmittance of glass envelope	τ_c	0.93	-
Clean mirror reflectance	η_{ref}	0.9	-
Dirt factor	η_{dirt}	0.96	-

The installation was assumed to consist of 90 absorbers connected in series, with an inlet temperature of 60 °C and a maximum outlet temperature depending on weather conditions but not exceeding 250 °C. For the analyses, the mass flow was assumed to be constant at 0.3 kg/s.

2.1.2. Heat transfer fluid

The heat transfer fluid used in the analysis was Therminol VP-1, an Eastman product widely used in solar installations and successfully used in our previous publications [22]. The operating temperature of this fluid is 12 – 400 °C. In the analysis, the data of this fluid as a function of temperature was used, based on the manufacturer's data [23]. Table 2 presents, as an example, the fluid parameters for extreme temperatures occurring in the system, i.e. 60 °C and 250 °C.

Table 2. Example Therminol VP-1 parameters [23].

Temperature, °C	Density, kg/m^3	Heat capacity, kJ/kg	Thermal conductivity, W/(m·K)	Viscosity, mPa·s
60	1032	1.662	0.1323	1.76
250	867	2.181	0.1055	0.288

2.1.3. Coatings assumptions

The analysis examined the effect of two coatings on the absorber surface. The first one was selective coating reported by Lu et al. [24] as suitable for SHIP installations. It has high absorptivity and low emissivity which reduces radiation losses. The alternative coating analysed is Pyromark 2500, which is a non-selective coating but with extremely high absorption [25]. Due to its lack of selectivity, the emissivity of the Pyromark is also high, but it is characterised by low cost and very simple application. The parameters of both these coatings are shown in Table 3.

Table 3. Coatings parameters.

Coating type	Coating name	Absorptivity	Emissivity
Selective	Mo/Al_2O_3	0.9	0.08
No-selective	Pyromark	0.965	~0.8

2.1.4. Twisted tapes

Two geometries of twisted tapes were analysed in this work, first one with twisted ratio (Tr) 1 and the second one with 2, the width of each twisted ratio was assumed equal to 28 mm and thickness 1 mm. The material used is steel. The insert is assumed to be centred on the axis of the absorber, which in reality can be realised by a specially shaped handle that centres the twisted insert. The study analysed inserts with a low twisted ratio to find the limit for which there is a benefit to its use. The twisted ratio was defines as Eq. (1):

$$Tr = H/d_{abs,i} \quad (1)$$

where, H is 180° turn length and $d_{abs,i}$ is internal diameter of absorber.

2.2. CFD model

Numerical calculations were performed in ANSYS Fluent using a discretised 3D domain. The analysis was performed for the steady state. CFD tests were performed in the heat transfer fluid region, where constant mass flow and inlet temperature were assumed. It was assumed that twisted tape is used as a swirl flow forming element and is not involved in heat transfer. In the analysis, the k-ω SST turbulence model listed in the literature as the most optimal for this type of analysis was used [26]. To determine the influence of the numerical grid on the results, a grid independence test was performed, analysing five grids with the parameters shown in Table 4.

Table 4. Analysed numerical meshes.

Grid no.	Number of elements	Average Nusselt number
1	244 283	273.6
2	1 320 067	286.6

The results showed that the difference between grids 3 - 5 is about 0.2%, so it was decided to choose grid number 4, which is shown in Figure 2.

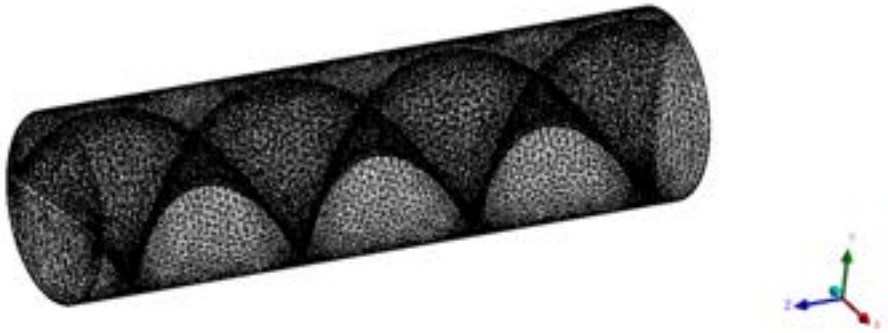

Figure. 2. Mesh used in CFD for absorber and twisted tape.

The parabolic trough collector is an installation based on a tracking system which makes it possible to utilise direct solar radiation during operation. Thus, the concentrated radiation reaching the surface of the absorber is not uniform. In CFD studies, this factor should be considered and a polynomial described distribution of radiation should be introduced by using a defined function. To obtain this distribution, optical studies were performed using the Monte Carlo Ray Tracing Method in APEX software, which has been successfully used in our previous studies [27]. An absorber with applied radiation distribution is shown in Figure 3.

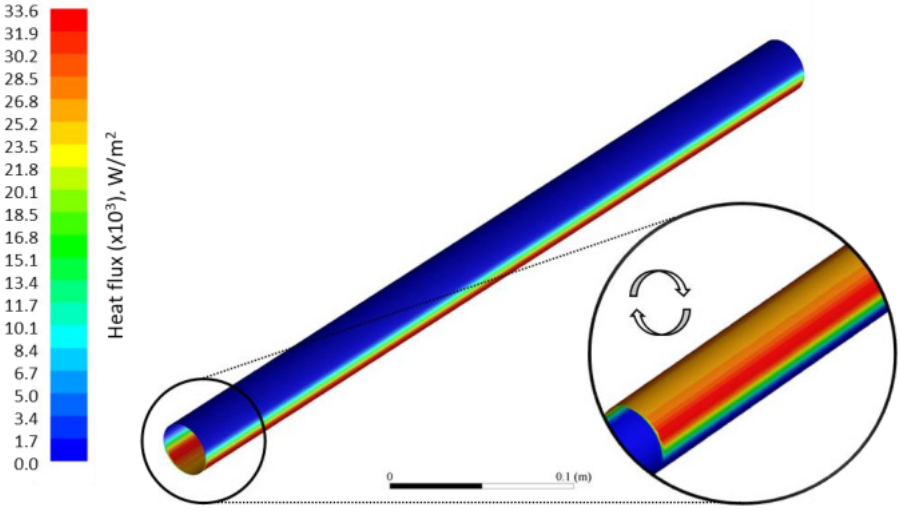

Figure. 3. Heat flux distribution on external absorber surface.

2.3. Mathematical model

In this study, a previously developed mathematical model of a parabolic solar concentrator was used, which is described in detail and validated in publication [13]. The distinguishing feature of this model from others available in the literature of the subject is the separation of heat absorbed by concentrated radiation and direct radiation (which was not reflected from the parabolic mirror). This radiation passes through a different pathway, therefore the efficiency must be calculated separately. For the high aperture PTC analysis, the influence of this factor is small, but for the low concentrated PTC, the contribution of direct radiation is more significant. The heat absorbed by the absorber is defined as Eq. (2) – (4):

$$Q_u = \dot{m} \cdot c_p \cdot (T_{out} - T_{in}), \tag{2}$$

$$Q_u = (Q_{u,CSP} + Q_{u,SP}) - Q_{loss}, \tag{3}$$

$$Q_u = ((A_{ap} - d_{abs,e} \cdot L) \cdot G_B \cdot \eta_{opt,CSP} \cdot cos\,\theta \cdot IAM + (d_{abs,e} \cdot L) \cdot G_B \cdot \eta_{opt,SP}) - Q_{loss} \tag{4}$$

where, $\dot{m}$ is mass flow rate, c_p is specific heat, T_{in} and T_{out} are inlet and outlet temperatures, $Q_{u,CSP}$ is the concentrated solar energy, $Q_{u,SP}$ is the non-concentrated solar energy, Q_{loss}- energy losses, A_{ap} is the aperture surface area, $d_{abs,e}$ is the absorber external diameter, G_B is the direct solar irradiance, $\eta_{opt,CSP}$ is the optical efficiency for CSP, θ is the incident angle, IAM is the incidence angle modifier, L is absorber length, $\eta_{opt,SP}$ is the optical efficiency for solar power. The individual efficiencies for concentrated irradiance and non concentrated irradiance, their components and how they are calculated are presented in a previous paper [13].

Furthermore, when twisted tapes are used, it is necessary to consider the effect of the pressure drop on the requirements of the circulating pump. For this purpose, efficiency of PTC is defined as Eq. (5):

$$\eta_{PTC} = \frac{Q_u - \frac{W_p}{\eta_{el}}}{Q_s} \tag{5}$$

where, W_p is required pump power, Q_s is heat from sun and η_{el} is average reference electricity production efficiency. For purposes of this analysis, the value 32.7% is selected [28].

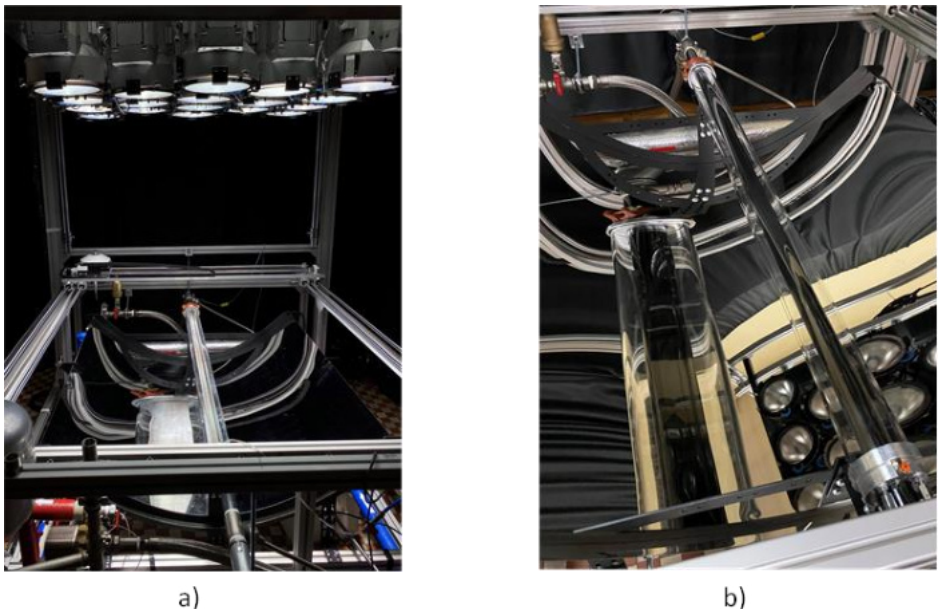
A pumping work demand for the fluid movement is calculated as Eq. (6):

$$W_p = \frac{\dot{m} \cdot \Delta P}{\rho} \tag{6}$$

where, ΔP is pressure drop, ρ is fluid density. The pressure drop was determined using the Darcy-Weisbach equation.

2.4. Models validation

Validation of the numerical model presented in section 2.3 was performed using the solar radiation simulator test rig and parabolic trough collectors presented in previous publications [29] and conference presentations [30]. The test stand is shown in Figure 4.



a) b)

Figure. 4. Experimental test stand: a) solar simulator and parabolic trough collector under experimental campaign, b) linear absorber covered by Pyromark coating in collector focal length.

The test rig consists of 18 metal halide lamps, each with a nominal power of 575 W, and a parabolic solar concentrator with aperture and length of 1000 mm, and absorber with diameter of 33.7 mm covered by Pyromark coating with glass envelope and vacuum in between. For temperature incensement for plane absorber the RMSD was 1.02, for absorber with twisted tape with twisted ratio 3.8 RMSD was 1.43. For pressure drop measurement RMSD was as follows: plane absorber RMSD = 5.8, absorber with insert Tr = 3.8 RMSD = 7.5.

Validation of the mathematical model presented in section 2.4 was performed using experimental data provided by the National Renewable Energy Laboratory (NREL) [31] and indicated an RMSD of 2.54 for absorber temperature and 3.52 for heat loss, which confirms its agreement with reality.

3. Results and discussion

The first part of the analysis was to determine the maximum number of absorbers in preliminary sections of the solar loop that would not result in a reduction in efficiency compared to the reference value (all absorbers covered with selective coating CASE 1). Tests were carried out for various values of direct radiation and the results are shown in Figure 5. For $G_B \geq 300$ W/m^2, the potential for partial replacement of absorbers with low-cost coatings is clearly visible. For $G_B = 300$ W/m^2, the maximum number of absorbers with Pyromark coating that can be used is 40. For higher radiation values, the possible number of absorbers increases, but assuming a worst-case scenario, a value of 40 was chosen for further consideration.

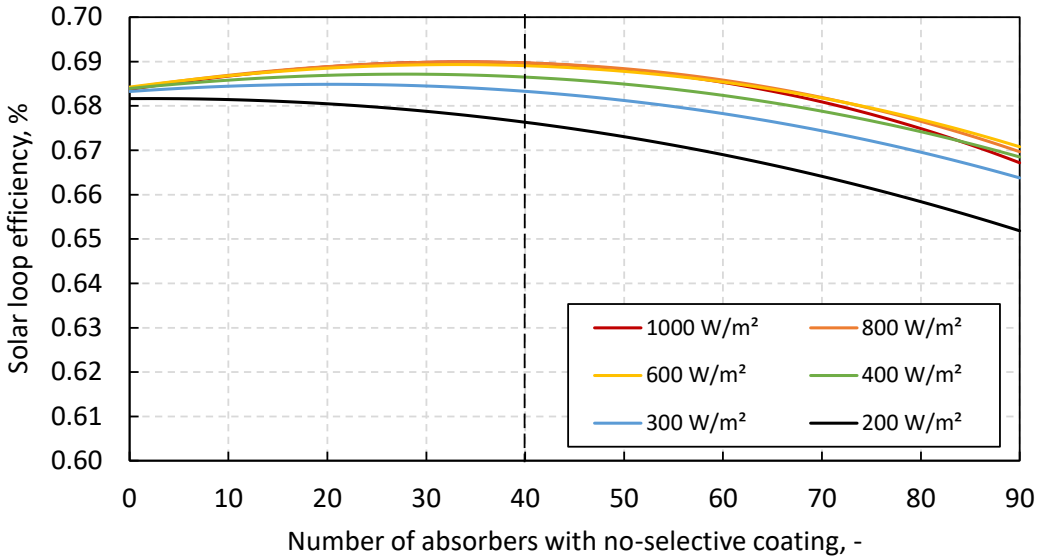


Figure. 5. Absorber loop efficiency as a function of absorber numbers with no-selective coating.

The next stage of the analysis was to test the effect of twisted tapes on increasing the intensity of heat absorption by the fluid. Twisted tapes cause swirl flow, which intensively mixes the fluid inside, resulting in an increase in velocity and thus in the number of Reynolds and an intensification of heat absorption. What is more, this flow character results in a reduction in the temperature difference at the absorber surface, which reduces material stress and increases the life span of the installation. However, the placement of any element inside the tubular absorber results in increased pressure losses which force higher own energy needs to drive the circulation pump.

Considering the pumping demand (Eq. (6)) in the efficiency of the PTC loop (Eq. (5)), it is possible to determine the efficiency increment resulting from the use of an insert with a specific twisted ratio. Fig. 6 shows the increase in efficiency ratio relative to the reference case for a specific thermal fluid temperature. The graph highlights two data series, for twisted ratio 1 and 2. It can be seen that the use of both these inserts results in an efficiency gain relative to the reference case. However, it was observed that for fluid temperatures above 200 °C the efficiency of PTC with twisted ratio 1 decreases significantly. This is due to the high velocity and relatively high-pressure drop relative to the increased intensification of heat absorption and the increased power requirement of the pump. It was therefore decided that for temperatures up to 200 °C it was appropriate to use tape with ratio 1, and above this temperature tape with ratio 2.

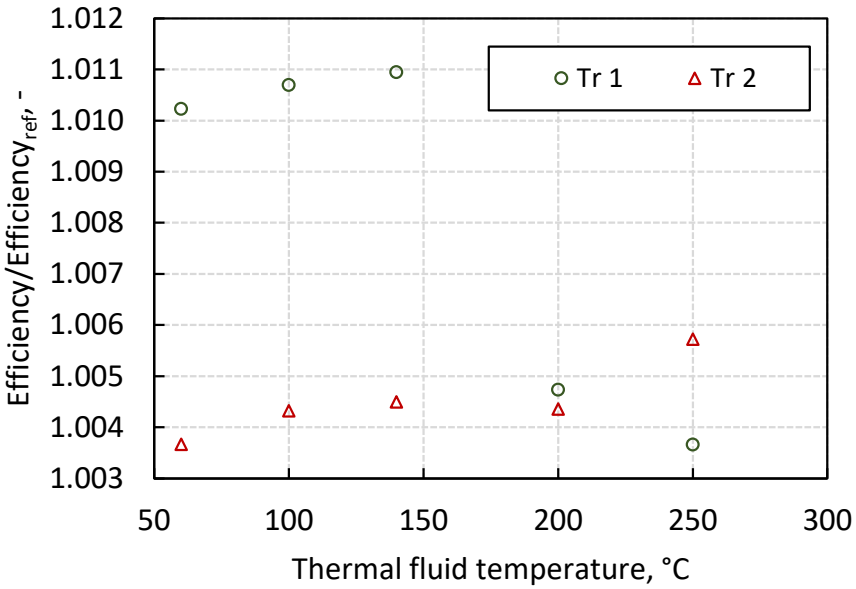

Figure. 6. Efficiency with twisted tapes to reference efficiency ratio as a function of heat transfer fluid temperature for different twisted ratio inserts.

As the application of twisted tapes has to be done for specific sections of the PTC, the next part of the analysis was, for a predefined sequence of specific absorber types, to determine where to apply which type of twisted tape. For this purpose, it was determined that a temperature above 200 °C of fluid would occur in the furthest sections of the absorbers for the case of the highest radiation value. The efficiency of absorber loop and thermal oil temperature along loop length were therefore determined and presented in Fig. 7. Based on the results, it was determined that defined temperature in the absorber loop, consisting of 90 absorbers, could occur after the 60 absorbers, so it was decided to use inserts with twisted ratio 1 in preliminary 60 metres. After the 60th absorber, twisted tape with Tr = 2 was used.

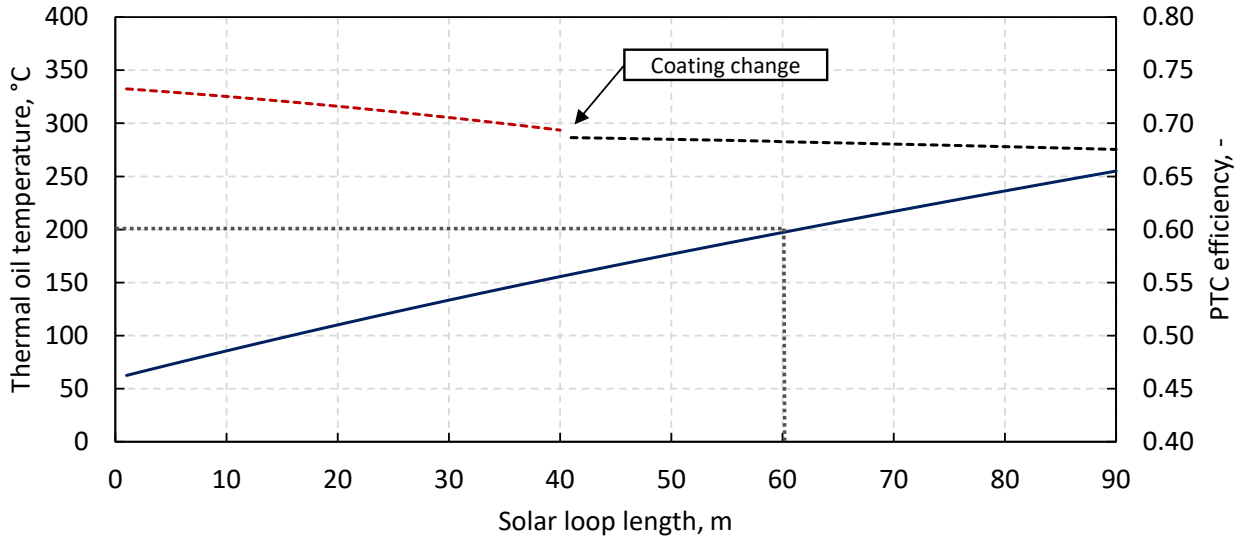

Figure. 7. Thermal oil temperature and efficiency along solar loop for G_B = 1000 W/m^2 and T_{amb} = 23°C.

To directly compare the results, a wide-parameter analysis was performed for G_B ranging from 300 to 1000 W/m^2, T_{amb} from 2 to 35 °C and wind speed of 0.1 - 5 m/s while maintaining a constant mass flow of 0.3 kg/s and T_{in} 60 °C. Case 1 has the lowest efficiency, but the most constant curve. As the parameter represented on the x axis increases, the efficiency slightly decreases. Each of the methods analysed intensifies heat absorption and increases the overall efficiency of the installation. By using absorbers with a high absorptivity value, the highest efficiency gains when the installation is operating in high solar radiation is visible. The increased absorptivity along the length of the installation largely contributes to increased heat collection and efficiency. Emission losses are largely compensated by the high absorptivity. For periods with low insolation and temperature, there is no increased heat absorption and losses to the environment are high, but no greater than the reference case. The use of twisted tapes has the effect of intensifying heat absorption throughout the whole analysed range. In periods of high solar radiation, swirl flow reduces the

temperature of the absorber wall and intensively mixes the heat transfer fluid. During periods of low insolation, twisted tape has the effect of increasing the velocity and the Reynolds number and increases heat extraction. Using only the method related to the coatings, the maximum efficiency gain will be around 0.7%, for using both methods in the configuration presented, the efficiency gain is between 0.3% and 1.3%.

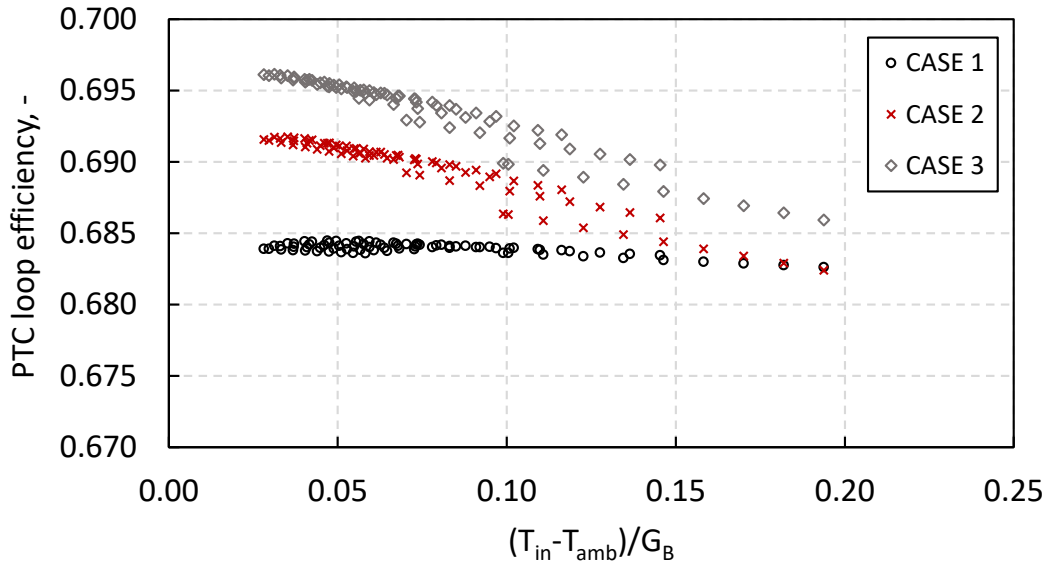

Figure. 8. PTC loop efficiency curves for 3 analysed cases.

4. Conclusions

This paper presents two methods to intensify heat absorption: externally by using a highly absorptive coating, and internally by using twisted tapes to increase flow turbulence. The following conclusions can be drawn.

- Both of the proposed methods intensify the heat collection in the absorber.
- It has been shown that it is optimal to cover 40 of the 90 absorbers with a no-selective coating.
- Besides the increased heat uptake of the absorber in this configuration, it is possible to reduce investment costs due to the low price and simplicity of the Pyromark coating application.
- Numerical tests have shown that both inserts analysed increase the heat absorption efficiency and that up to a temperature of heat transfer of 200 °C it is optimal to use an insert with twisted ratio 1, above this temperature with twisted ratio 2.
- Analysing the entire solar loop consisting of 90 absorbers, the following parameter combinations were determined: non-selective coating up to 40 absorbers, from 41 absorbers selective coating, insert with twisted ratio 1 up to 60 absorbers, from 61 absorbers twisted ratio 2.
- Efficiency increment after proposing Pyromark coatings increased from 0% to 0.7% with both methods, from 0.3% to 1.3%.

Abstract:

The deficient utilisation of the solar spectrum in conventional hybrid concentrating photovoltaic-thermal (CPV-T) technologies leads to a detrimental decrease in PV efficiency due to elevated temperatures. Solar spectral beam splitting (SBS) is an advancement in PV-T system design, which aims to use the full solar spectrum with minimal optical losses. The implementation of fluid-based SBS designs is economically feasible, with optical features that can be tuned by selecting suitable nanofluids with a desired concentration. Fluid-based SBS filters are advantageous over other filters for PV-T systems due to their ability to operate simultaneously as thermal storage as well as heat transfer media in these systems. In the present study, we report on the optical and thermophysical properties of a novel water-based Ag-ZnO hybrid nanofluid. The filter is synthesised by adding Ag to ZnO nanoparticles by a wet chemical method for improved stability. Silver (Ag) allows visible light harvesting (down conversion of UV to the visible region of the solar spectrum) and good optical properties in the visible and near-IR regions. An Ag shell can be embedded into the core of zinc oxide (ZnO) nanoparticles for improved stability. The presence of ZnO enables excellent optical properties, including high visible transmittance and high UV absorption. The presence of structural defects in ZnO induces colour centres which are deep traps emitting in the visible. Ag-ZnO nanofluids with different nanoparticle concentrations were tested to measure absorbance and transmittance using UV spectroscopy. These nanofluid filters can be used for full spectrum utilisation (by SBS) which helps in achieving: (i) down conversion in the UV region, (ii) transmit visible and near IR (NIR) region (desired wavelength of Si PV cell optoelectronic efficiency) ,and (iii) absorb (filter) the IR region of the solar spectrum (for downstream thermal use/applications).

1. Introduction

In the 21st century, the energy crisis and climate change are both among the most pressing global issues. Fossil fuels derived from carbon are responsible for both problems. In the future, energy demand will undoubtedly increase, so how to balance energy supply and CO2 emissions will become a global concern. In this case, it's essential to focus on emerging technologies involving new energies and decarbonization. As one of the most important renewable energy sources, solar power could play a crucial role in solving the energy crisis and cutting down on pollution. It may be utilised in two important ways, namely through direct production of electricity via photovoltaic conversion (PV) and through the conversion of heat i.e. photothermal (PT) conversion. Solar photovoltaic panels use only a small fraction of the solar spectrum for the generation of charge carriers, while the remainder causes undesirable heating of the panels, reducing their efficiency [1]. A hybrid photovoltaic-thermal (PV-T) system was therefore proposed in which the heat generated by the PVs is dissipated by a heat exchanger fluid, commonly called a coolant, thus resulting in a PV-T hybrid system [2]. The hybrid system is also more energy-efficient than individual photovoltaic or thermal systems. The performance of PV-Ts has improved significantly with the emergence of alternative heat exchange fluids

[3]. However, the emerging spectral splitting PV-T technology can produce greater fluid temperature and higher total efficiencies by separating the PV and thermal units.

In the spectral splitting method, the part of sunlight that cannot be converted into electricity is filtered out before it reaches the PV cells. Solar radiation is split into ultraviolet (UV), visible, and infrared (IR) spectrums by this technique, which requires matching the spectral bands of the cells and the wavelengths absorbed by the filter. A solar PV system uses the visible spectrum to produce electricity, while UV and IR spectra are absorbed and collected elsewhere as heat. It has been reported in previous studies that fluid-based spectral beam splitters (SBS) are more efficient than other kinds of splitters, such as interference filters and holographic filters [4]. Furthermore, fluid based SBS can be implemented economically, and its filtering features can be easily altered by choosing suitable by varying fluid properties. The fluid-based filter is also advantageous over other filters for PV-T systems since it can simultaneously serve as a thermal storage medium and a heat transfer medium. There have been experimental studies conducted with water as a filter for PV-T collectors in the past. Water is a common liquid, used conventionally in such systems and has excellent thermal and optical properties. There has been evidence that water improves the performance of PV-T, and many researchers have explored the ability of traditional fluids to absorb solar irradiance not effectively utilised by PV cells [4,5], including water, inorganic salts, glycols, and oils. Pure fluids can only absorb a portion of the infrared light, while they perform poorly in the UV region of the solar spectrum, so PV-T systems with pure fluid filters are inefficient.

Water-based nanofluids have been recommended by many studies as beam splitters in PV-T systems [6,7]. PV modules will heat up unnecessarily when they are exposed to wavelengths that are outside of their spectral ranges, thereby reducing efficiency. Nanofluids may solve the challenges discussed above because of their tunable optical properties. A nanofluid comprises a stable suspension of nanoparticles in a base fluid (e.g., water). In addition, nanoparticles allow the splitter to adjust its bandwidth and absorption peak continuously according to the amount of bandgap energy needed for converting solar energy into electricity [8]. Several experimental studies have so far investigated the performance of nanofluid filtered PV-T systems. This led to an ideal nanofluid filter for a particular solar cell [4, 5]. An interesting method for improving nanofluid beam splitting involves plasmonic metal nanomaterials. Plasmonic nanoparticles that manipulate, guide, and localise the incident light. Silver (Ag) is among the most important metals for plasmonic particles, it has demonstrated capabilities for visible light harvesting [9] as well as support in the visible and near-infrared spectrum. A silver nanofluid is highly effective in both thermal and electrical conversions in previous studies involving beam splitting applications such as- Silver nanoparticles are also highly suitable for industrialization and commercialisation. Zhang et al. [10] conducted an indoor experiment to optimise the heat/electricity production of a PV-T system filtered by Ag/water nanofluid. The results confirmed that arranging the nanofluid above PV modules is beneficial for heat collection and cell temperature regulation. The performance of a PV-T system with nanofluid filter consisting of silver-silica nanoplates as visible light absorbers and silica-coated gold and gold-copper nanorods as infrared absorbers was evaluated through an indoor test [9]. The results showed that the c-Si PV cells based PV-T system with Ag-SiO2 nanofluids achieved the highest combined efficiency of 40%, while the electrical efficiency was only 6%. Han et al. [11] developed a high-performance optical filter using water-based Ag-CoSO4 nanofluid for SBS PV/T systems. The measured transmittance indicated that water-based Ag-CoSO4 nanofluid is superior to Ag/water nanofluid in terms of performance. A PV-T system with water based rGO-Ag nanofluid filters was experimentally investigated by Abdelrazik et al. [12]. As a result of the experimental results, the proposed system showed better performance than a PV system with only PV cells, and the electrical efficiency was generally less than 10%, whereas the thermal efficiency ranged between 24-30%. Despite these advantages, the readily oxidising nature of silver in air restricts its use. This drawback may be overcome by embedding Ag nanoparticles into stable oxides such as zinc oxide (ZnO). As an optoelectronic material, ZnO exhibits excellent optical properties like transmittance, suggesting the possibility of using it with Ag nanoparticles [13,14].

This work presents plasmonic silver metal with ZnO nanoparticles, made using simple wet chemical methods. The hybrid material has excellent spectral splitting properties that can be used in PVs to harvest visible light and convert it into electrical power. The narrow bandwidth of transparency (400-1000 nm) also leads to heat absorption by filtering UV and infrared rays. The water-based Ag-ZnO nanofluids has been assessed with optical transmission measurements, whereas Ag-ZnO hybrid nanomaterials is examined about structure, morphology, and chemical composition, which helps confirm the observed optical properties with those of the material. The preliminary results reported could be useful in providing a better insight in the optical and thermal processes that leads to SBS. Localised surface plasmons of Ag nanostructures are observed in the visible region (400 nm), ZnO band edge absorption is observed above 375 nm, and IR absorption, particularly for low-energy photons, is observed. More work is required for selection of the nanofluid filter parameters, including nanoparticle type, size, mass fraction, base fluid type, etc. Nevertheless, the results are promising to demonstrate a spectral beam splitting with environment friendly, benign and economical composition.

2. Experimental details

2.1. Materials

Zinc nitrate hexahydrate [$Zn(NO_3)_2.6H_2O$, mol. wt. = 297.49 g/mol, 99.99% pure, from Sigma Aldrich], Silver nitrate [$AgNO_3$, mol. wt. = 169.87 g/mol, 99.90% pure, from Sigma Aldrich], PVA [mol. wt. = 96800 g/mol, degree of polymerization = 2000, from Fischer Scientific], ammonia solution (NH_4OH, conc. 25%, from Merck), and sucrose ($C_{12}H_{22}O_{11}$, mol. wt. = 342.30 g/mol, 99.95% pure, from Merck) were used for the synthesis of ZnO -Ag hybrid nanoparticles.

2.2. Synthesis method

The process of synthesis of *Ag coated ZnO hybrid nanoparticles* has been shown in Fig 1. There were two main stages in the synthesis procedure of ZnO:Ag nanoparticles. In the first stage, Zn^{2+}-PVA-sucrose precursor powders were created by a chemical reaction between aqueous solutions of Zn^{2+} salt and PVA-sucrose polymer, as described in reference [15–18]. The next step involved further processing the precursor powders to create ZnO:Ag core-shell nanoparticles. A comprehensive explanation is given below.

In synthesis, 1:10 mass ratio of PVA and sucrose was mixed in water at reaction temperature of 60–65 ^oC with continuous magnetic stirring to disperse 0.2 M aqueous Zn^{2+} salt solution. The PVA-sucrose used in this process acts as a surfactant and offers a stable medium for the nanoparticles'-controlled growth through encapsulation in polymer micelles [19,20]. The sucrose additive improves the average viscosity of the reaction solution. It was noted that in the solution, the salts had an endothermic reaction with the PVA-sucrose molecules. By adding NH_4OH solution in the required quantity to support the hydrogenation of Zn^{2+} ions in the reaction solution, the pH of the mixed solution was maintained at 9 throughout the reaction. Following the reaction, the mixture was cooled to room temperature and aged at 20-25 °C for 24 hours before the transparent, colourless top layer of PVA-sucrose was decanted out. To obtain the fluffy, voluminous, whitish mass of polymer capped precursor powders, the obtained precipitate was dried at a controlled temperature of 50–60 °C after being washed with methanol to remove any unreacted residual PVA–sucrose. After pulverising the polymer precursor powders in a mortar and pestle, they were heated for two hours at 400–600 °C to produce refined ZnO nanoparticles. The final size of the particles is largely controlled by the heat treatment temperature.

In the next step, 5.0 g of the dried ZnO precursor powders were mixed with 100 ml of a 0.25 M solution of $AgNO_3$ in water. This was done in the dark at 60 °C under constant stirring. After about 30 minutes of reaction time at this temperature, the powders were recovered by decanting the $AgNO_3$ solution, washing them at least twice in hot water, and then drying them under low pressure (10 to 100 mbar) at 25 °C. The dried powders were then heated for 2 hours in ambient air at 500 °C. Followed by recrystallization, the ZnO nanoparticles are encapsulated by a stable, thin layer of Ag.

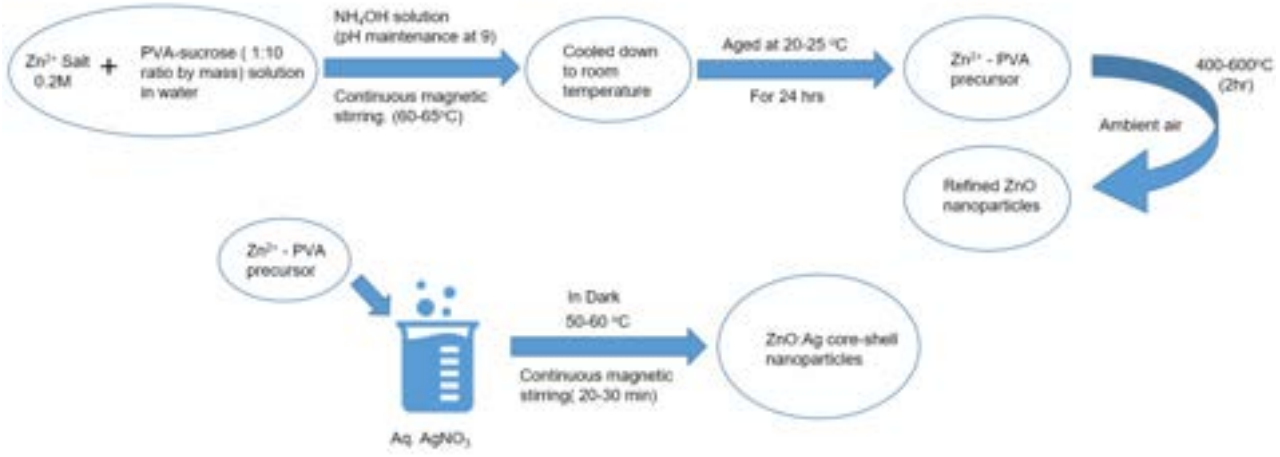

Figure 1. *Synthesis route of Ag coated ZnO hybrid nanoparticles.*

2.3. Characterisation

The crystalline nature and structure of synthesised Ag coated ZnO hybrid nanoparticles was examined under Bruker D8 powder X-ray diffractometer using Cu K_α source of radiation wavelength 1.5406 °A in the range 5 ° to 90 ° with a step size of 0.02 °. The particle morphology and elemental composition of the samples was analysed using FEI Nova Nanosem 450 Field Emission SEM equipped with Energy Dispersive X-ray spectroscopy (EDS). The individual particle morphology was investigated with FEI Tecnai G2 sprit Bio-Twin TEM at an accelerated voltage of 120 kV. To probe at the local structures of the chosen regions under investigation, an in-situ study of electron diffraction from selected areas (SAED) and high-resolution TEM imaging was carried out with FEI Tecnai G2 F30 S-Twin TEM at an accelerated voltage of 300 kV. The Raman spectra were captured on a Horiba Jobin

Vyon LabRam HR Raman by exciting with a 532 nm laser at room temperature. The optical transmittance spectra of the sample were taken in aqueous solution at room temperature with Perkin Elmer Lambda 950. The sample was sonicated for 30 minutes for well dispersion of nanoparticles in water. ZnO:Ag/Water nanofluids of mass fractions 50 ppm, 30 ppm, 15 ppm, and 5 ppm were made. Transmittance and absorption spectra were taken in the cuvette of 10 mm optical length.

3. Results and discussion

Figure 2 (a) shows the XRD pattern of the as-prepared ZnO-Ag sample. The pattern shows broad and distinct peaks which marks the nanocrystalline nature of the sample. The pattern is indexed to the hexagonal wurtzite type (space group P63mc) crystal structure of ZnO [JCPDS card # 036-1451]. Three distinct peaks corresponding to metallic silver of face-centred-cubic (fcc) crystal structure [JCPDS card # 04-0783] have been identified. The same have been marked as Ag with given (*hkl*) indices. The peaks are sufficiently broad in either case, which denotes the small particle size.

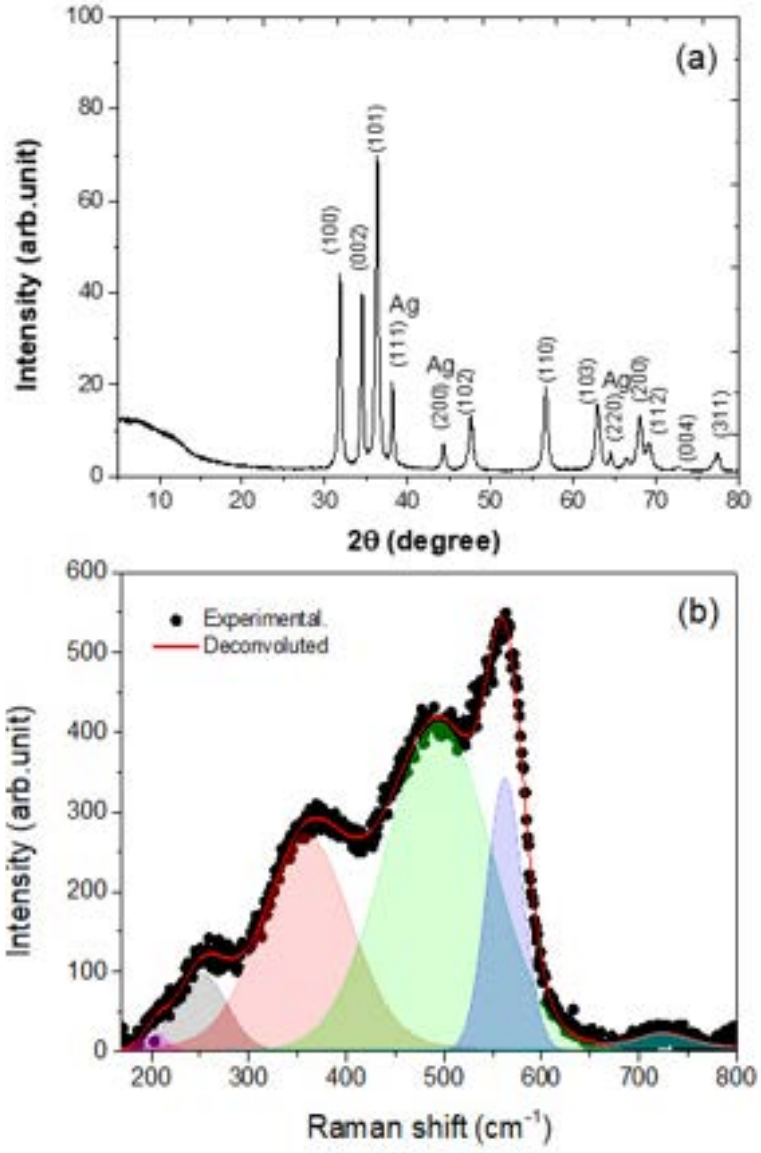

Figure 2. *(a) X-ray diffraction patterns, and (b) room temperature Raman spectrum of Ag-ZnO hybrids.*

The room temperature Raman spectra of Ag-ZnO as shown in Figure 2(b). The spectrum shows five distinct peaks that are listed in Table 1 along with their probable assignments [21–23]. Overall, from the comparison of observed data with that of reported literature, it can be observed that the Raman modes are significantly broadened in the present sample and the usual high intense peak of 438 cm^{-1} $E_{2(high)}$ is suppressed and the 563.2 cm^{-1} peak is observed to rise which is often ascribed to either high oxygen defects, substitutional impurities [21] or even lower particle sizes. [22] In this case, the smaller crystallite size along with presence of Ag additives may have resulted into such highly dispersive Raman absorption bands.

Table 1. Comparison of observed Raman peaks and probable modes reported in literature.

Peak position (cm^{-1})	Probable mode
205.1	2 $E_{2(low)}$ at 210 cm^{-1}
252.8	Not found
357.3	$E_{2(high)}$-$E_{2(low)}$ at ~340 cm-1 and E1(TO) at ~380 cm^{-1}
493.9	$E_{2(high)}$ at 440 cm^{-1}
563.2	A_1(low optical) or E_1 (low optical)) at 576 cm^{-1}

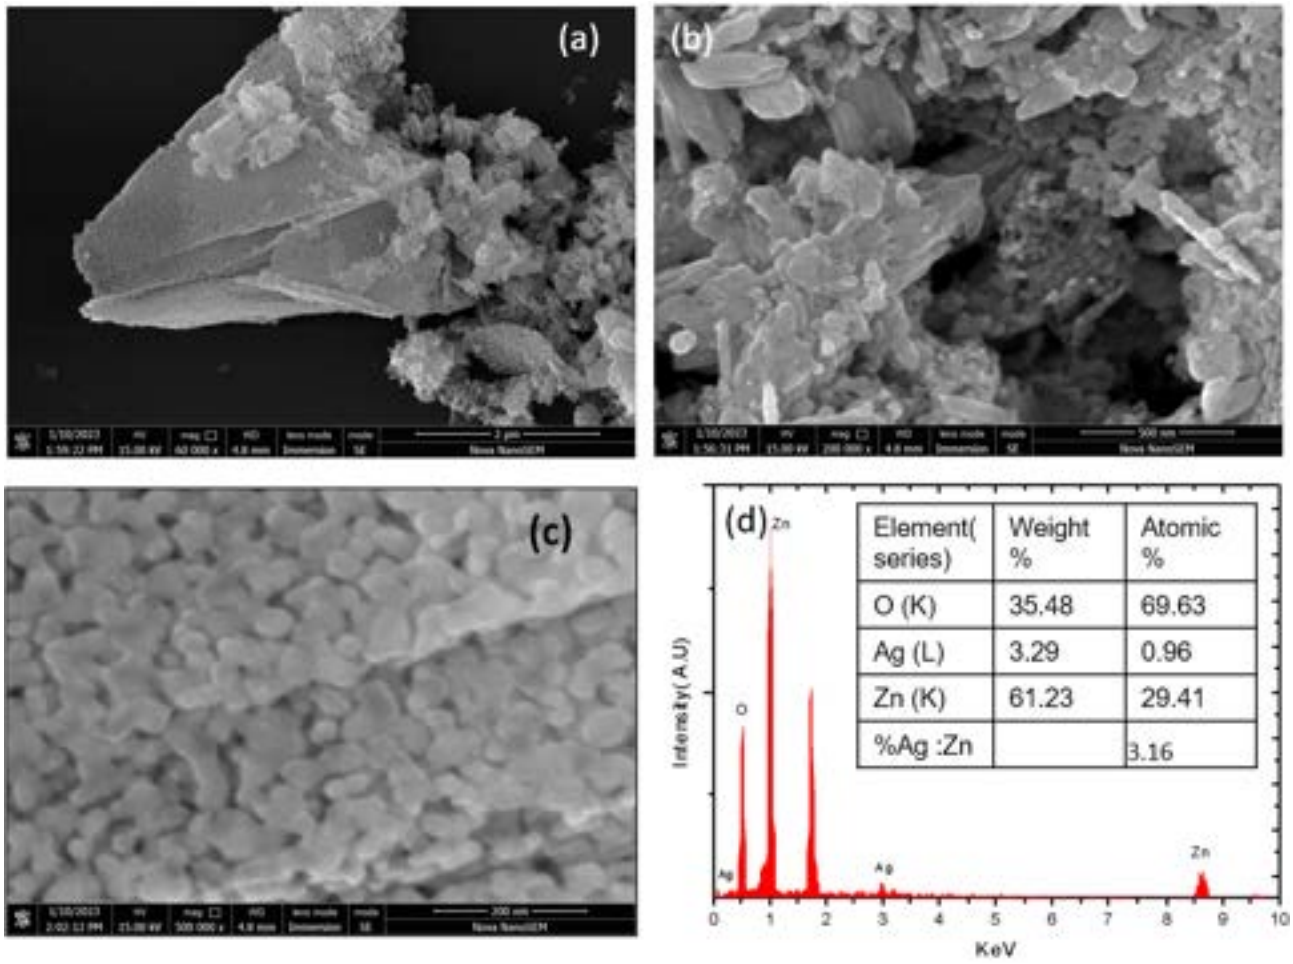

Figure 3. *Scanning electron micrographs of Ag-ZnO hybrid at: (a) low ,and (b, c) high magnifications showing the nanoscale particles (~50 nm). (d) energy dispersive spectrum of the Ag-ZnO sample with the quantification shown inset.*

Figure 3 shows the FESEM images of Ag-ZnO hybrid nanoparticles synthesised at 500 °C after heating the precursor for 2h in air. The loose agglomerates can be seen in the micrographs of the sample (Figure 3 a, b). In the particle clusters, a magnified view (Figure 3. b) reveals particles arranged in petal-like structures. Figure 3(d) depicts the elemental composition of the Ag-ZnO nanoparticles obtained at 500 °C. The presence of Zn, O, and Ag elements is confirmed in the samples, according to the EDS spectrum. The quantitative analysis indicates that Zn and Ag elements have atomic contents of 29.41%, and 0.96%, respectively.

Figure 4 shows the typical TEM images (a-d) and HRTEM (e) of Ag-ZnO nanoparticles. Figure 4 shows well dispersed particles. The average particle size was calculated from a histogram shown in Figure 4(f) and it is found to be 25–30 nm, with a narrow size distribution (±20 nm). The high-resolution TEM (HRTEM) image of a single particle is shown in Figure 4(e) it reveals that the particles may have facets with regular shape which gives them a thickness contrast. Nevertheless, the hexagonal shape is evident from Figure 4(a) also. The visible lattice reflections are close to an interplanar spacing of 0.27 nm (as shown in Figure 4 (e)). The results demonstrate the Ag along with ZnO nanoparticles. A typical selected area electron diffraction pattern (SAED) of nanoparticles is provided in Figure 4(g). It is made up of ZnO and Ag lattices that look like separate, concentric rings with spots in between. There are six characteristic rings of d_{hkl} values 0.2851 nm, 0.2503 nm, 0.1938 nm, 0.1659 nm, 0.1503 nm, and 0.1394 nm that correspond to the (100), (101), (102), (110), (103), and (112) planes of ZnO respectively, and the two characteristic rings of d_{hkl} values 0.2099 nm and 0.1112 nm correspond to the (200) and (222) planes of Ag. The d_{hkl} values derived from the SAED pattern and those

derived from the X-ray diffractograms are in close agreement. Due to the lower intensity of the diffraction spots, some reflections of ZnO and Ag could not be distinguished.

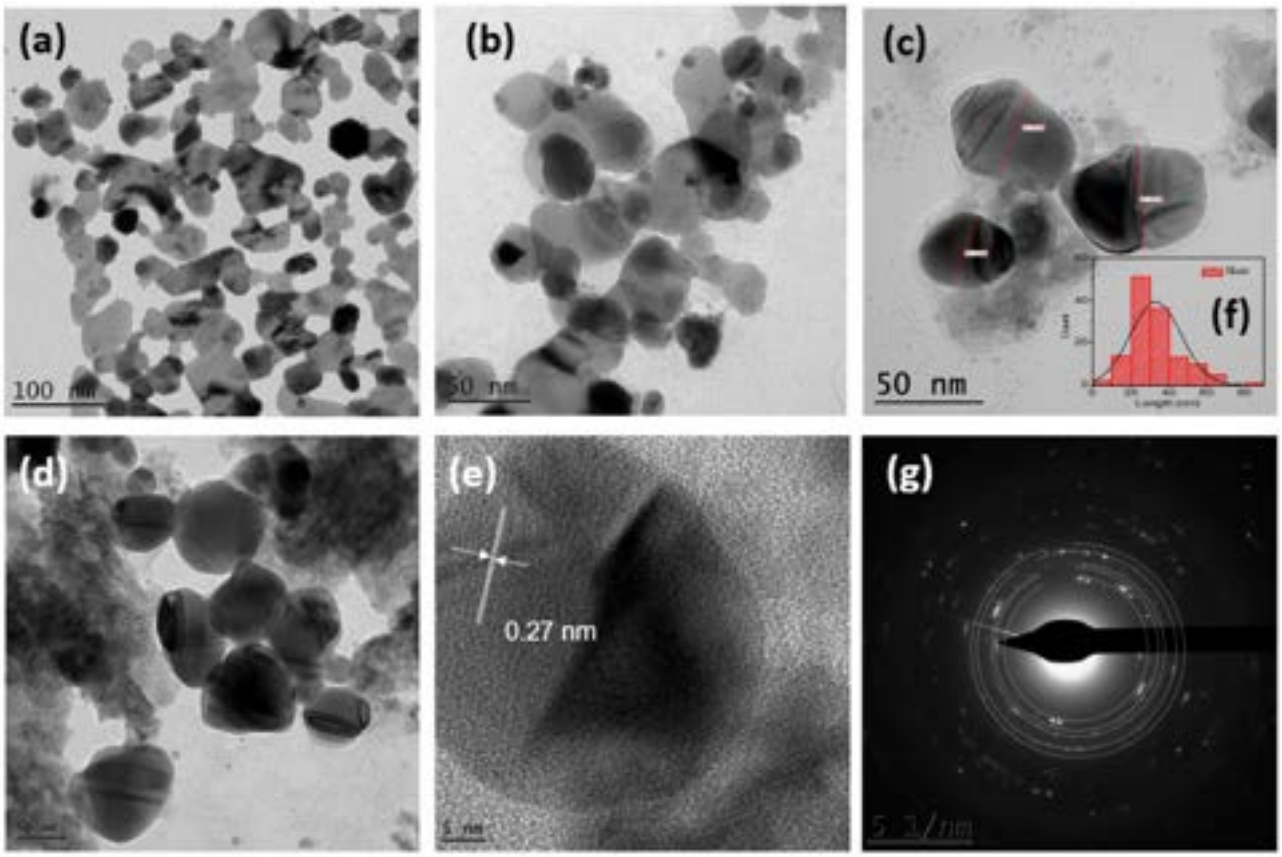

Figure 4. *Transmission electron micrographs of the Ag-ZnO showing: (a-d) the typical morphology of the powder at nanoscale, (e) high-resolution image of the individual nanoparticles, (g) selected area electron diffraction pattern, and (f) the size distribution histogram.*

Figure 5 shows the optical transmittance of Ag-ZnO/Water nanofluid with four mass fractions: 50 ppm, 30 ppm, 15 ppm, and 5 ppm. As the concentration of Ag-ZnO increases from 5 to 50 ppm in the nanofluid, the transmittance in the UV region of the spectrum decreases. The effect of the mass fraction of the nanofluid is found to be insignificant in the 400–1100 nm range. The majority of spectral energy between 400 nm and 1100 nm can pass through the Ag-ZnO /water nanofluid, while the remaining energy is absorbed. As a result of this nanofluid's ability to absorb spectral energy that is not used by the solar cell, heat harvesting has improved. Therefore, it may be regarded as a suitable optical nanofluid for PV-T systems that use spectral splitting, as the working area of PV/T systems is reported to be between 400 nm and 1200 nm.

ZnO has a wide bandgap of nearly 3.3 eV in bulk. In nanoscale morphologies this may increase slightly depending on the size, shape, etc. Because of this band gap, the absorption edge of ZnO is 3.3 eV which corresponds to about 375 nm [24]. Therefore, ZnO absorbs significantly in the UV region and the peak is observed near band edges that decreases gradually on either side. ZnO may be completely transparent in the wavelength below 400 nm if there exist no energy states within the gap [23]. These gap states usually arise because of donors for n-type (or acceptors for p-type) which lie just below the conduction band (or above valence band for p-type). ZnO shows intrinsically n-type character due to unintentionally doped oxygen vacancies and zinc interstitials [21, 25]. These crystal defects have low formation energies in the ZnO lattice and hence readily nucleate. Zinc interstitial (Zni) lies just below conduction band whereas oxygen vacancies depending on their charged state can lie shallow or deep within the gap. These states are referred to as gap states and they may lead to photo-absorption and emission of energies equivalent to the difference between the defect state and the valence band maximum. Therefore, they may increase the visible emission as their energies are 1-2 eV above valence band maxima.

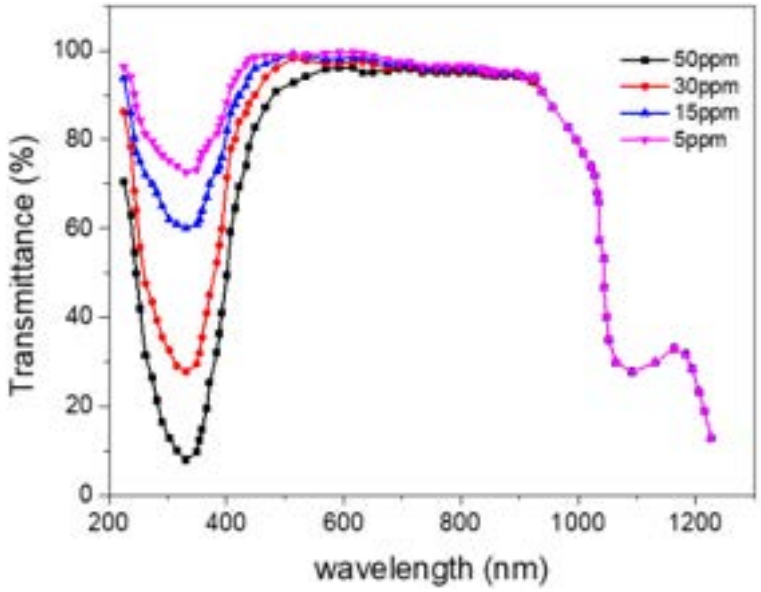

Figure 5. *UV-visible transmittance spectra of the Ag-ZnO nanoparticles at different dilutions in water.*

On the other hand, the silver lattice may show significant absorption that is usually caused in noble metals due to presence of surface plasmon resonance (SPR). The SPR is called collective oscillations of the free electron in metals which is the result of excitation due to electromagnetic radiation of appropriate energy (frequency); For Silver, this absorption mostly occurs at about 400 nm. Therefore, the corresponding amount of energy is called the plasmon absorption energy. In this case, the work function of Ag (fermi level is only slightly smaller than that of ZnO). Thus, any electron excited to a virtual SPR level is higher in energy that conduction band of ZnO and hence the charge transfer from Ag to ZnO is highly likely. This configuration of Ag-ZnO not only allows the absorption of near UV regions but may also result in visible emission as the charges transferred to ZnO may undergo a radiative transition and emit photons of smaller energy which happens to be in the visible region. Thus, this offers a win-win situation where the Ag absorbs the near UV and ZnO emits the visible light. This Additional visible light emitted can be beneficial to the PV sell and enhance the efficiency.

Conclusions

In this paper, results were presented relating to the use of Ag-ZnO nanofluids (nanoparticles suspended in water as the base fluid) for spectral-splitting PV-T applications. Ag-ZnO nanoparticles were synthesised by the solvothermal method. Several characterization techniques were utilised, including electron microscopy, X-ray diffraction and Raman spectroscopy. The XRD patterns revealed that Ag may coexist with the ZnO nanoparticles and these may have poor crystalline nature. The presence of Ag has also been confirmed by energy dispersive spectroscopy. The optical properties of the proposed nanofluids were investigated over a range of concentrations. The nanofluids exhibited a high degree of spectral selectivity, in the UV and IR regions which were absorbed or reflected respectively. In the visible region, a good transmittance was observed, which promotes higher PV cell efficiencies. In future work, visual inspection and dynamic light scattering techniques will be applied to evaluate the long-term stability of these nanofluids.

[b] Thermal Area of the Laboratory of Quality Control of Buildings of the Basque Government; Aguirrelanda 10, Vitoria-Gasteiz, Spain

Abstract:
The energy consumption of buildings is constantly increasing and not only impacts on resources, but also emits polluting gases into the atmosphere. For this reason, there is a great commitment to integrate renewable energies, as well as to renovate and hybridize the energy facilities of existing buildings. Spain has a large potential to exploit solar energy and this is reflected in the PV integration in buildings, as PV self-consumption has risen to 1,203MW installed. However, buildings still have a high potential for improving photovoltaic applications and can help to increase the exploitation of renewable resources. Following European recommendations and Spanish directives, the Basque Government is analysing how to conduct the renovation of the existing public housing stock to achieve more sustainable housing and take into account the quality of life of the users. To this end, the project Plan ZERO-Plana, led by ALOKABIDE "Public institution of the Basque Government", was developed to, among others, increase renewable energy implementation for self-consumption. This work takes a step forward and analyses the photovoltaic potential of the public building stock of the Basque Country based on a GIS application. The objective is to, on the one hand, account for the PV potential in each of the public housing units themselves and, on the other hand, to analyse the possibility of implementing energy communities in the Basque Country to supply the energy use of these buildings, as well as to compare the viability of both options.

Keywords:
ALOKABIDE; PV potential; energy community; Vitoria-Gasteiz; QGIS; renewable energy; rooftops.

1. Introduction

Spain, due to its climate and geographical location, has a significant number of sun-hours during the year, which allows the exploitation of clean energy with significant potential to meet energy needs. Given that a large part of the world's population is concentrated in cities, it is necessary to establish urban plans to ensure the sustainable development of urban environments, using available human resources and technology. In addition, Buildings are responsible for approximately 40% of the energy consumption of the European Union (EU) [1]. Residential buildings in particular accounted for the 27% of the final energy consumption of the EU in 2020 [2], so one of the options is to produce energy through solar technology, such as placing photovoltaic panels on building rooftops. Therefore, this work assesses the solar potential of the city of Vitoria-Gasteiz, as a geographical area with suitable characteristics for the installation of solar panels and the possibility to create different energy communities in this area.

1.1. State of the art

Accordingly, some studies have identified areas of high population density, such as urban centres, as places with high potential for solar production, such as Ávila and Zamora [3], Miraflores de la Sierra (Madrid, Spain), Gassar and Cha [4] in Geneva (Switzerland), Guevara [5] (Perú) and Haegermark and Dalenbäck [6] (Sweden).

In terms of feasibility analysis, analysis is frequently restricted to figuring out solar radiation, although the environment is still crucial. In addition, the study can be further detailed, as it is done in the case of housing in Valencia (Spain), Aparisi [7], where the orientation of the roof and the adjacent buildings are taken into account, as well as the tilt of the roof. On the other hand, the polytechnic school of engineering in Gijón studied photovoltaic feasibility in Asturias (Spain), Guerrero [8].

The PV potential can be estimated by using different models or methods. In this study, the method used is based on a Geographic Information System (GIS). This method or tool has been employed in numerous studies for various purposes, including the estimation of PV potential in rooftops. Examples include Quiros-Tortos et al.'s [9] consideration of various factors when integrating GIS data sources in a PV analysis and Khan and Arsalan's [10] use of the GIS tool to determine the best rooftops for solar PV applications in Karachi. Baiocchi et al. [11] also uses this tool to study the effect of defining different PV criteria, and Davybida et al. [12] uses GIS to design a PV system for a built-up roof in Poland, which generates an electrical power of around 100 MWh/year.

Moreover, this tool can be used to determine the influence of different elements on PV solar energy generation, and Silveire Júnior et al. [13] uses GIS to determine the influence of aerosol in the state of Goiás (Brazil).

Apart from GIS there are different models that can be used to analyse the PV potential of an area. For instance, of Mohajeri et al. [14], used Machine Learning to classify urban characteristics for solar applications, including the impacts of different roof shapes on annual solar PV electricity production.

The electricity obtained from the PV installation can be used in different ways. Current policies are promoting the combination of technologies such as heat pumps or solar thermal collectors, and these possibilities have been studied in articles such as Wang et al. [15]. This last work analyses three different configurations to supply the heating and DHW demands of a dwelling (ST, PV/T and PV with ASHP). Herrando et al. [16] analyses the possibilities of using solar thermal collectors to meet the heating and DHW demands of a dwelling (ST, PV/T and PV with ASHP), and Ayadi and Al-Dahidi [17] compares how to implement heating and cooling in a building with solar thermal and solar electric power.

In addition, some countries are also promoting energy communities, which is a relatively new concept. Frieden et al. [18], Jeriha [19] and Gjorgievski et al. [20] reviewed the current regulatory framework and analyse the social arrangements, technical designs and impacts of an energy community. As it is known, with energy communities the heating, cooling and electrical demand can be assessed, so this could be a great opportunity for the public house stock of Vitoria-Gasteiz to introduce this kind of initiative into work, due to its geographical and distributional situation.

1.2. Regulatory framework

This section briefly explains the European, Spanish and regional regulatory framework.

1.2.1. European framework

In Europe, the recent directives are seeking to promote new roles for citizens who produce and use energy by promoting local energy markets and introducing the concept of energy communities.

One of the most remarkable directives, is the Directive (EU) 2018/2001 of the European Parliament and of the Council of 11 December 2018 [21], on the promotion of the use of energy from renewable sources. This directive defines Renewable Energy Communities (REC) as "*A legal entity; which, in accordance with the applicable national law, is based on open and voluntary participation, is autonomous, and is effectively controlled by shareholders or members that are located in the proximity of the renewable energy projects that are owned and developed by that legal entity;. The shareholders or members of which are natural persons, SMEs, or local authorities, including municipalities; the primary purpose of which is to provide environmental, economic, or social community benefits for its shareholders or members or for the local areas where it operates, rather than financial profits*.".

This directive establishes that the Renewable Energy Communities (RECs) have the right to produce, consume, store, or sell renewable energy, or to share what is generated by producing units owned by that community and to access all energy markets. It also mandates member states to provide a framework to encourage and facilitate the development of RECs, as well as to guarantee the right of consumers to participate in a REC.

Another remarkable directive is the Directive (EU) 2019/944 of the European Parliament and of the Council of 5 June 2019 [22], which defines the common rules for internal market for electricity in Citizen Energy Communities (CEC) as follows. "*A legal entity that: is based on voluntary and open participation and is effectively controlled by members or shareholders that are natural persons, local authorities, including municipalities, or small enterprises; has for its primary purpose to provide environmental, economic or social community benefits to its members or shareholders or to the local areas where it operates rather than to generate financial profits; and may engage in generation, including from renewable sources, distribution, supply, consumption, aggregation, energy storage, energy efficiency services or charging services for electric vehicles or provide other energy services to its members or shareholders*."

This directive establishes the obligation for member states to provide a favourable legal framework for CECs that ensures that: (1) participation in CECs is open and voluntary; (2) the distribution system operator cooperates, in return for fair compensation, to facilitate the transfer of electricity between different CECs; (3) CECs are subject to procedures and charges that ensure that they contribute adequately and in a balanced way to the overall sharing of system costs.

These two directives are included in the “Clean Energy Package” [23], which proposes an adaptation of the European energy policy framework to facilitate the transition away from fossil fuels toward cleaner energy.

1.2.2. Country framework

In Spain, the most recent regulations related to electricity self-consumption are “*Real Decreto-ley 15/2018*” [24], which establishes urgent measures for energy transition and consumer protection, and “*Real Decreto-ley 244/2019*” [25], which regulates the administrative, technical and economic conditions for electricity self-consumption, promoting the consumption of km0 energy.

In addition to these regulations, the Spanish state proposes the "*Plan Nacional Integrado de Energía y Clima 2021-2030*" [26], which describes several measures for the penetration of renewable energies and energy efficiency, as well as introduces local energy communities and the importance of citizen participation in the energy field. For the latter, lines of action are set out to develop the appropriate regulatory framework to define these legal entities and encourage their development.

In addition to this national plan, the Spanish government in 2020 proposed the document "*Estrategia de Descarbonización a Largo Plazo 2050*" [27] with the aim of becoming a climate neutral country by 2050 by transforming the energy and economic system in a stable and joint manner with the help of citizens.

1.2.2. Regional framework

In the Basque Country, there are different regulations and strategies that establish guidelines to favour the use of renewable energies and sustainable development.

This is the case of Ley 4/2019, of 21 February [28], on energy sustainability in the Basque Autonomous Community and its development decree, “*Decreto 254/2020”*, of 10 November [29], whose objective is to promote energy saving and efficiency measures, and the promotion and implementation of renewable energies. The spatial planning guidelines, approved by “*Decreto 128/2019”* of 30 July [30], state that renewable energies must be increasingly incorporated into the construction of our territory.

The Basque Energy Strategy 2030 [31] identifies, after a full analysis of the surrounding, elements that will be key to the transition towards a sustainable energy system in the Basque Country. This analysis includes: energy saving and efficiency; renewable energies; infrastructures and networks; distributed energy, self-consumption and energy cooperatives; non-conventional gas; energy and environmental taxation; policy integration; governance; adaptation to climate change in the energy system; and the importance of health co-benefits.

2. Case study

This work examines 157 sections of 31 public housing buildings, managed by ALOKABIDE, in the city of Vitoria-Gasteiz (Basque Country, Spain), with an average age of 16-year-old. In addition, 84% of the 31 buildings have a D and E labels in primary energy consumption or CO2 emissions [32], which means they have relatively low values.

This analysis focuses on electrical consumption and considers the available data obtained from previous works. Therefore, after averaging the number of households and consumption in Vitoria-Gasteiz, we obtain the average monthly consumption profile of a household, see Figure 1. It is also taken into account that 21 out of 31 buildings already have renewable energy solar thermal systems installed, but there is still space to expand the facility and increase the renewable production.

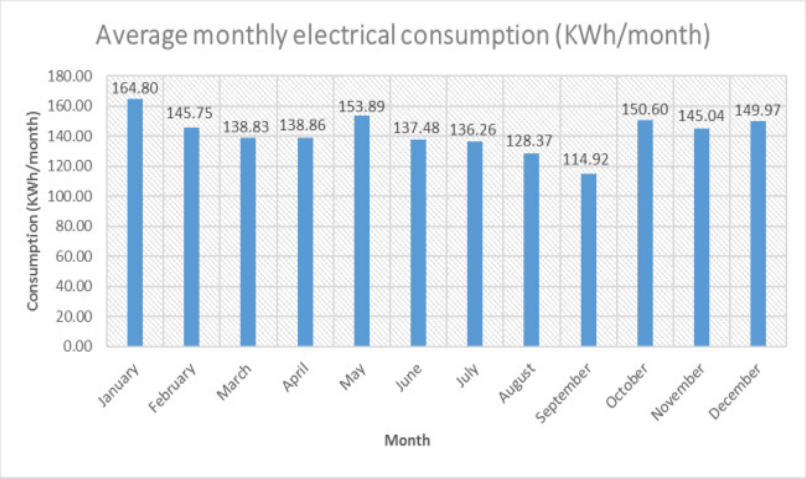

Figure. 2. Average monthly electrical consumption of the buildings studied in Vitoria-Gasteiz.

Due to technical limitations, only a specific number of buildings will be analysed in this work, which are collected and depicted in Figure 2. The analysis of the rest of the public building stock can be done in an analogous way.

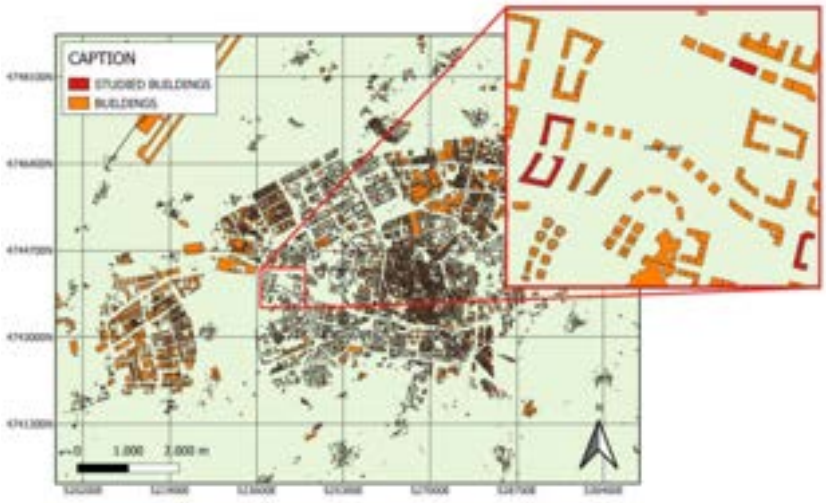

Figure. 2. Buildings studied in Vitoria-Gasteiz.

3. Methodology

QGIS Georeferencing Software (Open Access Geographic Information System) has been used for studying solar radiation from the rooftops of public buildings in Vitoria-Gasteiz. This tool organizes large volumes of data from a particular place in the world, allowing data to be stored, manipulated, analysed and modelled.

3.1. Data

Topographic data have been obtained from GeoEuskadi [33], which collects data from the entire Autonomous Community of the Basque Country. These are LIDAR (L*aser Imaging, Detection, And Ranging*) type and are obtained by optical remote sensing through a laser light. That is, with accurate x-y measurements, they define a compact sample of the Earth's surface as in cartographic applications of aerial laser images. These data contain cadastral information on all the localities of the Basque Country, such as buildings, urban centres, rural areas, railway lines, roads, etc., as well as data on the boundaries of each municipality. It also contains other data on the DSM sheets (Digital Surface Model) representing all the elements of the soil surface, such as vegetation, buildings, infrastructure, and soil itself.

3.2. Methods and indicators

Once the topographic data have been obtained and downloaded into the software, they are assigned a reference system of type ETRS89/UTM zone 30N, and are also assigned to the other layers of QGIS.

Between these layers, radiation accumulates by means of a device called Potential Incoming Solar Radiation. This device simulates accumulated radiation over a time-period, taking into account the type of radiation selected. In the case of this study, a period of one year, 2018, has been set by months, with a 7-day and 1-hour jump, and takes into account total or global radiation, i.e., the sum of direct, diffuse, incident, reflected and absorbed radiation. Therefore, monthly layers are obtained, for example, the total radiation of August and December is gathered in Figure 3 and Figure 4.

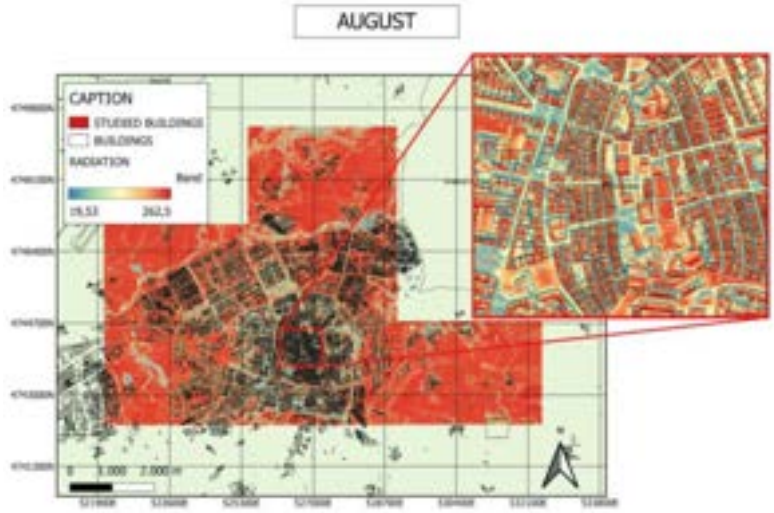

Figure. 3. Accumulated radiation during August.

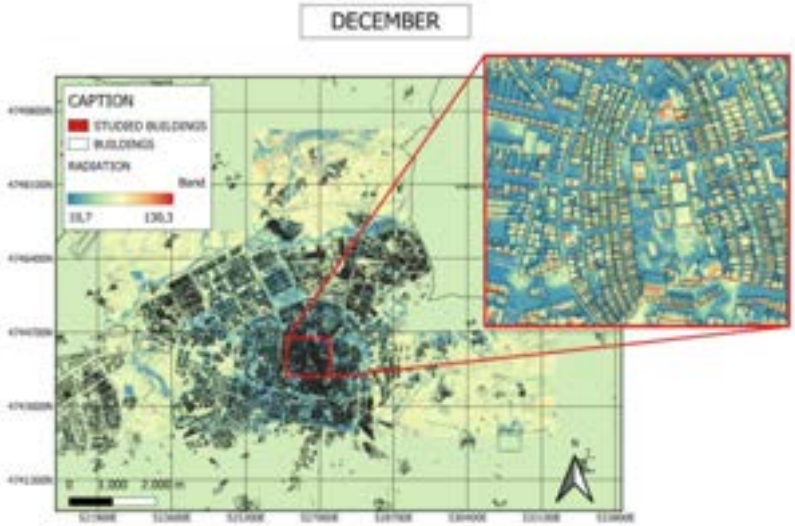

Figure. 4. Radiation accumulated on December.

As it can be seen, there is a huge difference between the maximum and minimum total radiation reaching the layers in both months of August and December.

The layer of the same size as the DSM simulation sheet is then cut to collect only radiation data consistent with buildings (public houses); see figure 5.

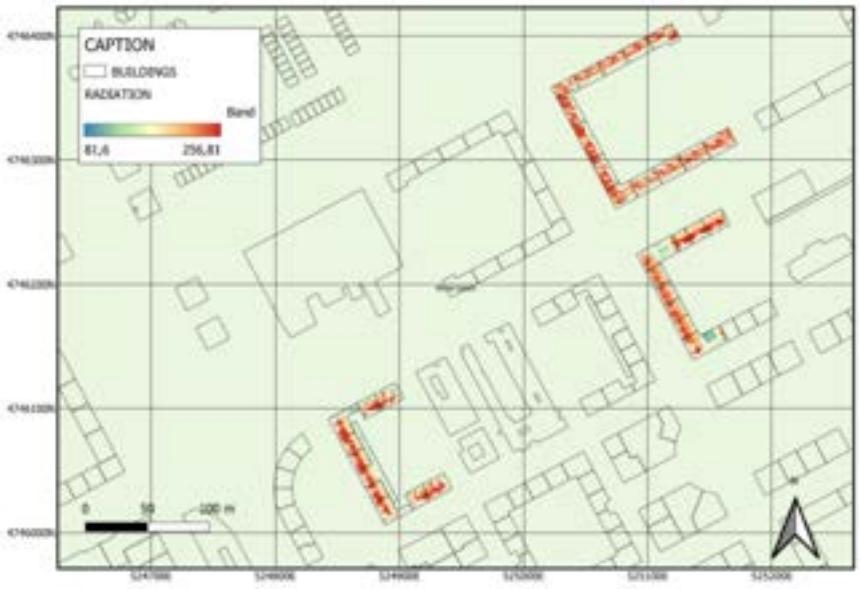

Figure. 5. Radiation accumulated on building rooftops.

Thus, once the radiation potential of residential rooftops has been achieved, three criteria are proposed to identify the suitable rooftops, as Delphine Khana mentions [34]:

- C.1) The rooftops must contain at least 65 kWh/m^2 of accumulated solar radiation in one month.
- C.2) The slope of suitable roofs must be less than or equal to 45 degrees, as steep slopes tend to receive less sunlight. The 45 degree limit is defined according to the latitude of Vitoria-Gasteiz, which is 42.85 °, since the optimal inclination is ± 10 ° compared to the local latitude.
- C.3) The rooftops, which are oriented north and receive less sunlight, are rejected.

Once the appropriate rooftops are identified and their radiation potential is obtained, the next step deals with analysing the possibilities of establishing energy communities, taking into account the location of the buildings of the public houding stock, since the consumption points must be at a maximum distance of 500 metres from the production point. Following these instructions, seven energy communities are proposed in Figure 6.

Figure. 5. Energy communities proposed in Vitoria-Gasteiz.

From now on, considering the seven energy communities, only 134 buildings out of the original 157 will be analysed (since the rest are outside of the circles), and for this analysis, several indicators have been determined to better understand the analysis:

- Optimal surface of section rooftops [m^2]

Indicates the appropriate surface of the PV panel installation rooftop according to the predefined criteria.

- Percentage of optimal surface [%]

It is the ratio between the optimal surface of the building and the total.

$$Percen.opt.surf.(\%) = \frac{Opt.surf.\ (m^2)}{Total\ surf.\ (m^2)} \quad (1)$$

- Photovoltaic efficiency [%]

It relates the photovoltaic capacity of each section to the electrical consumption. This indicator allows a detailed analysis of the context of each building.

$$PV\ eff.(\%) = \frac{PV\ capacity\ (KWh)}{Elec.consumption\ (KWh)} \quad (2)$$

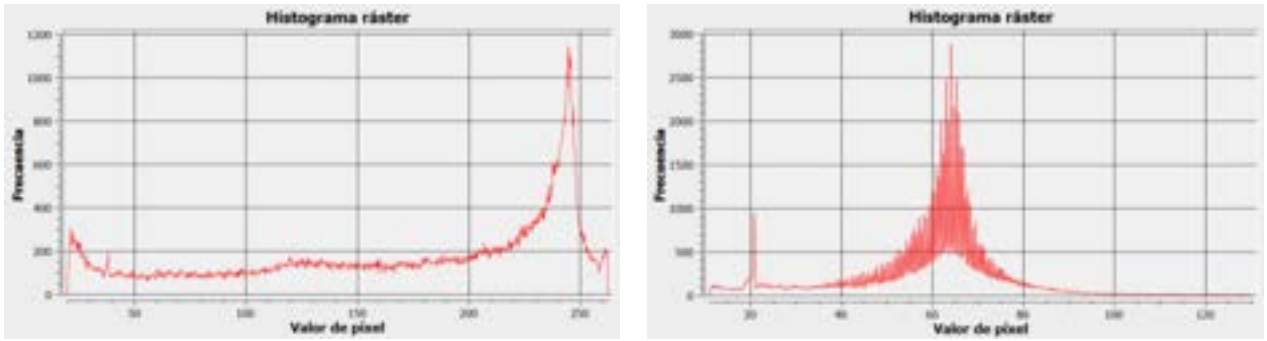
4. Results

The most significant results are related to the following:

- Histograms of radiation based on the first calculation.
- Optimal surface of the buildings, after applying the three criteria to the rooftops.
- Radiation percentage of each cover for the introduction of a PV facility.
- Photovoltaic efficiency of the proposed energy community.

4.1. Histograms

Accordingly, Figure 6 shows the histograms of August and December associated with the buildings of Figure 5, where the most repeated value of the accumulated radiation in August is around 240 kWh/m^2 and in December around 65 kWh/m^2.



(a) (b)

Figure. 6. Histogram of the accumulated radiation: a) August, b) December.

4.2. Optimal Surface

As it has been said, each building is examined according to three criteria (C.1, C.2 and C.3) to identify suitable rooftops. A building-by-building analysis has been carried out and the global results are gathered in Table 1.

Table 1. Summary based on three criteria

Optimal surface (m^2)	Total surface (m^2)	Percentage (%)
25,076.20	52,804.88	47.49

Consequently, only 47.49% of the total roof capacity is considered adequate for installing PV panels.

But what is more, some parts of this area are not suitable for installing a photovoltaic panel, since there are also areas with obstacles, such as chimneys, antennas, etc. Because of that, the results are afterwards filtered and analysed more precisely in order to identify the specific areas of the rooftop detecting the obstacles, according to the following three criteria:

- C.4) Buildings with an adequate area of less than 25% are excluded.
- C.5) Buildings with an optimal surface area of less than 30% and an optimal surface area of less than 100 m^2 are eliminated.
- C.6) Suitable areas of less than 10 m^2 are excluded.

Based on these extra criteria (considering C.1-C.6), the number of the optimal percentage falls from 47.49% to 47.10%, as shown in Table 2.

Table 2. Summary based on all six criteria

Optimal surface (m2)	Total surface (m2)	Percentage (%)
24,871.76	52,804.88	47.1

4.3. Including PV facility

In addition, on the one hand, only 25% of the optimal surface can be covered with photovoltaic panels (in order to avoid panel loss of shadow, inclination, structure, space for maintenance, etc.). On the other hand, photovoltaic panels are estimated to have 15% performance and 86% PR (Performance Ratio). Thus, the monthly electricity contribution on public residence decks has been calculated with this equation:

$$Elec.production\ (KWh) = Surf_{opt} \cdot 0.25 \cdot Rad_{mean} \cdot 0.15 \cdot 0.86 \quad (3)$$

Accordingly, the results of electricity PV production of the selected public buildings of Vitoria-Gasteiz are shown in Table 3.

Table 3. Monthly electricity production

Month	Electricity produced (kWh)
January	43,940.12
February	66,805.28
March	139,575.64
April	191,039.39
May	226,364.23
June	242,116.29
July	235,092.65
August	206,475.89
September	161,275.77
October	110,118.26
November	59,850.77
December	27,482.56

Once the PV electricity production of each of the roofs has been calculated, the electricity consumption of each dwelling and the number of dwellings in each of the buildings need to be considered in order to obtain the percentages of electricity that could be self-consumed.

4.4. Energy Communities

Apart from that and going further, seven energy communities are proposed, which take into account the proximity of the buildings and the criterion of 500 metres (mentioned in section "*3.2 Methods and indicators"*).

As the same conclusions are obtained for all energy communities, and because of technical limitations, only the most representative one will be analysed in this paper, the one shown in Figure 7.

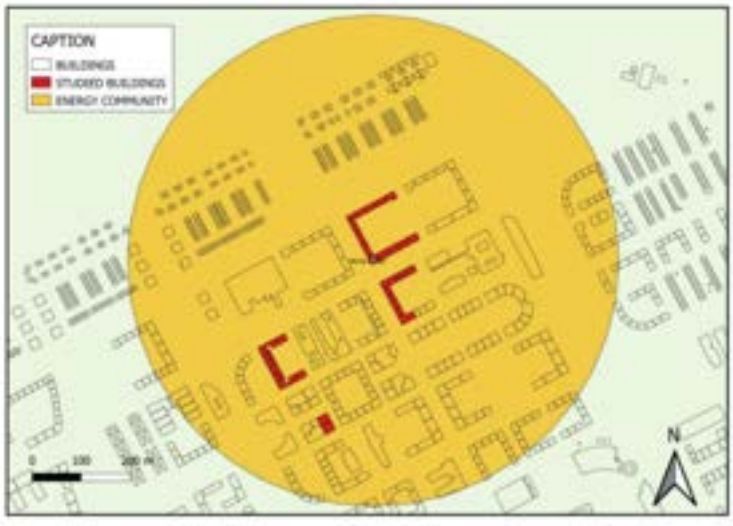


Figure. 7. Selected energy community.

The chosen energy community has the characteristics shown in Table 4:

Table 4. Energy community characteristics

Description (name of the building)	Number of households
Lakua 30	30
Lakua 110	110
Lakua 90	90
Ibaiondo 228	228

Moreover, the monthly electricity produced in the corresponding rooftops (obtained from the previous analysis) and the consumptions of the households (calculated with the corresponding consumption data of 2018) of this energy community are shown in Table 5 and is graphically represented in Figure 8:

Table 5. Production vs Consumption

Month	Total production (KWh)	Total consumption (KWh)	Photovoltaic efficiency (%)
January	7,924.77	75,478.25	10.5
February	15,676.17	66,751.97	23.48
March	28,054.36	63,586.10	44.12
April	38,414.26	63,597.44	60.4
May	45,512.82	70,480.53	64.58
June	48,704.16	62,964.97	77.35
July	47,276.88	62,408.82	75.75
August	41,509.91	58,794.55	70.6
September	32,450.38	52,632.10	61.66
October	21,996.25	68,973.49	31.89
November	11,048.48	66,429.19	16.63
December	5,462.89	68,684.48	7,95

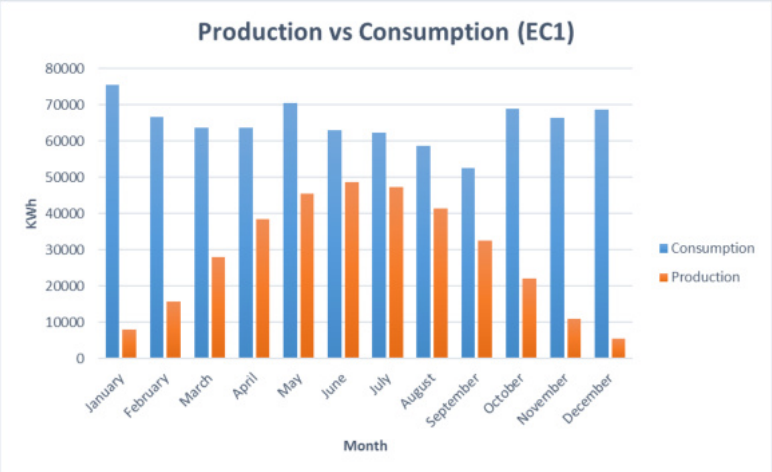

Figure. 8. Production vs Consumption in the selected energy community.

As it can be seen, the selected energy community, composed only by the public residential buildings, is not capable of supplying the total electricity demand in any of the months of the year, although it does supply part of the demand.

Without making an economic analysis of the study, it is too early to conclude whether it is economically viable or not, but at least it can be seen that in the central months of the year the installation of PV panels and the concept of the energy community is an option to be taken into account.

5. Conclusions and next steps

In summary, the study determines that 47.1% of the total roof surface area of the social housing buildings in Vitoria-Gasteiz is suitable for a photovoltaic installation. Furthermore, by adding the criterion that only 25% of the optimum surface area can be used for photovoltaic installations, it is still possible that all these potential PV installations together could produce more than 1,700 MWh per year, see Table 6.

Table 6. Summary table

Percentage of optimal surface (%)	Electricity production (MWh)
47.1	1,710.14

Furthermore, if an energy community is proposed, the electricity consumption cannot be completely compensated or supplied by the PV electricity production. However, PV production could be increased by adding more buildings' roofs to these communities, following the 500 metres criterion, such as other public tertiary-use buildings.

Therefore, the main conclusions of this study are, on the one hand, that introducing photovoltaic panels in social housing buildings is a viable option, and on the other hand, that implementing energy communities in Vitoria-Gasteiz could be an interesting option but requires further analysis, being the beginning of a community or municipality with a vision towards the future of sustainability.

Considering all this, the next steps would be, at first, to make an economical study of the energy community proposed, and then, to evaluate the possibility of making a hybridization between PV panels and heat pumps, to benefit from their potential as energy storage.

6. Acknowledgments

The authors would like to thank the Basque Government's Laboratory for the Quality Control of Buildings and ALOKABIDE SA for the provided information and help for this study.

Abstract:

An alternative powerplant layout to the commonly applied flash technology is proposed for the geothermal location of Monte Amiata, Italy. The reservoir conditions correspond to a pressurized brine field, with relevant contents of CO_2, acid gases/contaminants, and dissolved salts. The present solution avoids flashing the brine stream, proposing instead to install a borehole pump capable of maintaining pressurized conditions. By applying this solution, the amount of non-condensable gases released when reaching the ground level with reduced pressure can be conveniently limited; the gas stream is recovered, compressed and reduced in liquid conditions, suitable for complete reinjection into the reservoir. The necessity of a gas treatment section is thus completely avoided. The heat recovered from the hot brine, placed at ground level, is transferred to the supercritical CO_2 cycle. Different CO_2 cycle configurations were considered. Exergy and exergo-economic analyses of the whole system are carried out. The optimal calculated exergy efficiency of 45.5% was achieved for the recuperative cycle with intercooling and reheat configuration and the lowest obtained produced cost of electricity was 7.4 c€/kWh for the recuperative cycle configuration. Furthermore, the influence of the pressure losses to the heat exchanger has been assessed, allowing evaluating of the loss in efficiency for each cycle.

Geothermal energy; binary cycle; sCO2; Exergo Economic; Electricity production cost

1. Introduction

The energy demand has increased exponentially in recent years due to the strong increase in economic development and population growth. This led to an increased concern on sustainability issues and environmental deterioration [1]. The exploitation of renewable energy technologies has therefore bloomed, allowing an increase in the efficiency of the conversion systems. Among renewables, geothermal energy has the advantage of having the highest resource availability, not depending on the weather conditions. Geothermal energy systems exploit the heat content of the earth's interior, as the earth is slowly cooling down. The total global output of the Earth's heat flow is over $4x10^{13}$ W [2], which is four times higher than the actual energy consumption; however, only a small part of this heat flux can be exploited. Geothermal power plants can be categorized in shallow geothermal and deep geothermal. The first exploits low temperature heat sources at the surface, with a maximum of well drilling in the range of 250 m and are suitable for low temperature heat generation. On the other hand, deep geothermal is considered when wells are drilled deep, from 1 to 5 km within the Earth, or even deeper with the newest drilling technologies. Deep geothermal allows reaching higher temperature, which enables the conversion of the geothermal heat in electricity. Another way to categorize geothermal power plant is to classify it on the enthalpy content of the flow: low, medium or high enthalpy. Medium and high enthalpy resources are the most common exploited and have almost reached its maximum potential, while low or moderate enthalpy fields are still yet to be fully utilized. Typical power plant for the exploitation of medium high temperature fields are single, double and triple flash power plants (for a water dominant reservoirs) and direct steam power plants (for vapor dominant reservoirs). These power plants have several advantages, such as relatively high conversion efficiencies, several years of operation which led to a solid know-how, well-known safety measures which are not critical thanks to low pressure and temperatures involved, and economic feasibility. On the other hand, they present a significant disadvantage when considering the environmental sustainability; indeed, a relevant documented issue is the release of non-condensable gases NCGs (mainly CO_2 plus several kind of contaminants) to the environment [3, 4]. The current solution to reduce the environmental impact of geothermal power plant is the utilization of AMIS

technology in Italy, developed by ENEL GP [5]. This allows reducing the Hg and SO_2 content from the NCGs stream, and thus the environmental impact of the power plants. Several studies have been developed on the environmental sustainability of geothermal energy conversion systems though the application of life cycle assessment [6]. In [8] a 20 MW single flash power plant is evaluated and compared with similar size power plants operating with wind and solar. It was found that the geothermal power plant, which includes the AMIS technology, performs well against other renewables, and has only a slightly higher environmental footprint, due to larger values of the global warming category (Recipe 2016 Midpoint). In [9] enhanced geothermal systems (EGS) were considered, estimating several design scenarios and compared to other renewable energies environmental impacts. The results indicated that EGS power plant environmental footprint is in the same range of other renewables and it was confirmed that the highest contribution to the environmental impact comes from the drilling of the wells, in particular by the diesel burned in the drilling process. In [10], the environmental impact of a combined heat and power double flash geothermal power plant was estimated. Their studies confirmed that the drilling process is the main responsible for most of the impact category results. However, it was also found that the global warming and acidification category are significantly affected by the operation phase. Indeed, during the operational lifetime of the power plant, continuous emissions of CO_2 and H_2S provide a significant environmental impact. In [11] the definition of harmonized LCA guidelines for the comparison of geothermal power plant have been drought. Particularly, the aim of their study was to increase the comparability of the results of LCA studies on geothermal system, by proposing a consistent methodology with several indications of the critical aspects of the analysis.

From the above mentioned studies, it seems that only the use of binary cycles (like ORCs, Kalina or trans-critical and super critical CO_2) coupled to the complete reinjection of NCGs could give a valuable answer to the improvement of sustainability of geothermal power plants, particularly in the operational phase [12]. ORC and Kalina cycles work with novel and environmentally friendly fluids (low GWP), which are adapt for the exploitation of low temperature resources. Several studies on the coupling of ORC or Kalina cycles with low temperature or medium-high temperature [13-17] geothermal resources have been performed. These studies involved the optimal selection of the working fluid [18], including zeotropic mixtures [19], the optimal configuration of the power plant [20, 21], as well as thermo-economic analysis [22]. In [23] an energy and exergy analysis is carried out for a dual fluid ORC. Isobutane and Isopentane were selected as working fluids, allowing a production of almost 3.5 MW of electricity, almost equally shared between the high temperature isopentane cycle and the low temperature isobutane cycle. The most critical components for this power cycle configuration were found to be the low and high pressure vapor generators, due to the not optimal match of the heat curves. An interesting study on the profitability of geothermal electricity production from several ORC configurations have been carried out in [24]. In their study, an optimization of cycle configurations, working fluid selection and thermodynamic conditions was carried out in order to investigate the most performing configuration, based on levelized cost of electricity, return of investment and payback period. They performed the analysis taking into account for the economic calculation the corporate tax rates and the average electricity prices of 20 countries and found that is the country with the highest return of investment due to the high electricity price. A focus on the design and optimization of the evaporator for ORCs for low temperature geothermal application has been developed in [25]. In their study a Pareto front solution has been found in order to assess the proper compromise between costs and pressure drop in the heat exchanger; finally evaluating the performance of the ORC.

While several studies on ORC and Kalina cycle for geothermal applications have been developed, on the other hand, few studies on the coupling of super critical CO_2 cycles with geothermal energy resources have been carried out. In [26] a trans critical power cycle for low temperature geothermal power plants has been investigated, with a particular focus of the influence of the recuperator performance in both design and off-design operation. It was found that the recuperator allows an improvement in the off-design performance of the system, particularly enhancing the performance of the CO_2 pump.

In [27], an innovative supercritical CO_2 cycle configuration was evaluated, and its performance compared to a ORC working with R245fa or R1233zd(E). The cycle configuration exploits the thermosiphon concept, therefore utilizing the CO2 both as heat medium in the reservoir and as the working fluid in the power cycle. The results obtained indicated that the ORC cycle with R245fa as working fluid allowed the highest power production for one year of operation (8% more than the sCO_2 thermosiphon cycle). In [28] a low temperature geothermal case study, the Sidirokastron field in Greece was studied with the objective of coupling a super critical CO2 power plant. Particularly, the maximum temperature achieved by the geothermal fluid is of 75°C, which is a very low value, hindering the thermodynamic efficiency. In these conditions, the sCO_2 cycle achieved a maximum thermal efficiency of over 6%. Another interesting study by [29] deals with the thermodynamic analysis of a low temperature geothermal power plant utilizing a mixture of SF_6 and CO_2 as working fluid. The maximum achieved efficiency of the binary geothermal cycles was found to be 15% with a 20% SF_6-80% CO_2 composition, with a resource temperature of 160°C. The results therefore indicated that the utilization of zeotropic CO_2 mixtures could allow to increase the thermal efficiency of the sCO_2 power plants for geothermal applications.

While few studies were focused on the coupling of super critical CO_2 cycles with low temperature geothermal application, on the other hand several studies are available in literature dealing with high temperature applications, like solar power generation [30], coal fired power plants [31] or waste heat recovery [32,33]. This is due to the very good behaviour of the CO_2 for high temperature applications, nonetheless, it seems that further studies are needed to provide a clear assessment on the application of CO_2 cycle to low temperature resource. Indeed, the selection of CO_2 as working fluid is a due to its main characteristics, such as non-toxic, non-flammable, not suffering any thermal degradation at high temperature (unlike ORCs fluids) and optimal environmental traits, with a nil ODP and a GWP of 1. Furthermore, in the supercritical region, the high density of the CO_2 allows a smaller and more compact design of the components, which could allow a "miniaturize" design of geothermal power plants. Finally, for variable temperature heat source, super critical CO_2 allow a better match of the profiles, guaranteeing a higher efficiency of the heat exchange and thus reducing the exergy destructions in the heat exchanger.

1.1. A Case study for a sustainable Geothermal Energy power plant (Mount Amiata, Italy)

The properties of the geothermal resource are variable depending on the location in terms of pressure, temperature, state of the fluid, and amount and composition of NCGs as well as of dissolved mineral salts. The nature of contaminants released by GECS usually includes H_2S, NH_3, CH_4, and in some cases Hg [34 – 36]. Each potential location deserves careful study, possibly leading to different issues when selecting the best available technology.

The area of Mount Amiata, Italy, represents a significant challenging application. This region of Southern Tuscany is historically one of the reference sites for the development of geothermal conversion systems; currently, about 120 MW of geothermal electricity are installed there. The Amiata reservoir is water-dominant type [37]; the current conversion technology applies single or double-flash power plant layouts, in one case also combined to an ORC to recover the energy content in brines. The composition of the geofluid includes relevant amounts of NCGs (CO_2, H_2S, NH_3, CH_4), mercury sulphide, HgS and dissolved salts (mainly stibnite and silica salts). The reservoir is located at 3000–3500 m depth, thereby determining supercritical pressure conditions (p >250 bar); however, the fluid is not in critical conditions, since the reservoir temperature is in the 300–350 °C range. Consequently, flashing in the well takes place at a depth between 600 and 1500 m, with two-phase flow in the upper section. In the current technology, a throttling valve/separator assembly is located at the wellhead [38, 39]. Despite the attractiveness of the region in terms of energy generation potential, local opposition is present in the area against further development of geothermal energy. The main concerns of the opponents are long-term sanitary effects (mainly traceable to Hg and H_2S emissions, even after the introduction of catalytic gas treatment [5]), as well as the water balance and the greenhouse gas emissions. Within this context, even if the resource can be classified as high-enthalpy and therefore traditionally converted using flash power plant solutions, it makes sense to explore different possible options, investigating the potential to mitigate these specific issues.

1.2. Reference case

As a specific reference case, the available data from the Bagnore 3 power plant were considered. A flow rate of 122 kg/s is assumed to be available at an enthalpy level of 1200 kJ/kg, corresponding to about 275 °C at 250 bar, which are the estimated reservoir conditions for the deep reservoir in the Mt. Amiata region at a depth z>3000 m. The CO_2 content of the brine is evaluated at 2% mass fraction [40]. The current power plant applies a wellhead separator set at 20 bar, determining a saturated steam flow rate of 36 kg/s (with 7% CO_2 content), while a hot brine (enriched with salts causing considerable scaling problems) of about 86 kg/s is directed to reinjection. The power plant is a single-flash unit equipped with an ORC recovery section on a secondary (low-pressure) flash of the brine, providing a total power output of about 23 MWe (actually, at present 3 MWe less because a smaller ORC unit is installed, with incomplete heat recovery from the reinjection brine). The separator setting determines the flash conditions inside the well, which take place at a depth of about 600 m. The considerable amount of CO_2 in the flash steam is accompanied by minor contaminants (H_2S, Hg and NH_3 with minor traces of CH_4); while the steam is condensed in the steam cycle, the NCGs are discharged to the atmosphere; however, before the final release, the emissions treatment is applied, with extensive capture of H_2S, Hg and NH_3. The following emissions levels were calculated: e_{CO2} = 396 g/kWh; e_{H2S} = 1.21 g/kWh; e_{Hg} = 1.3 g/kWh; these figures correspond to measurements taken by the pollution control authority. It should be underlined that the CO_2 emissions are of natural origin; however, they are of similar level to those obtained by the most advanced fossil fuel power plants and could be avoided if the resource was not extracted from the reservoir.

For the above reasons, a number of improved solutions were developed, leading finally to identifying guideline the complete reinjection of NCGs in the reservoir as a possible best practice to exploit this geothermal resource [40].

To summarize, the literature review and the analysis of the presented case study has indicated a significant gap in the study of supercritical CO_2 cycle for the exploitation of geothermal resources.

Specifically, in the present study a relatively simple solution is proposed, inspired by the guideline of completely avoiding the practice of flashing the geothermal stream by the means of a borehole pump located at suitable depth, coupled to an advanced (supercritical) binary cycle.

The aim of this study is therefore to **evaluate the energy, exergy and economic performance** of the proposed advanced CO_2 power plant, which guarantee a relevant step ahead in the environmental behaviour of the geothermal powerplants, but they could result into a not economically viable options if compared to the current single and double flash technologies.

The main goal of this study is, therefore, the investigation and comparison of optimized solutions adopting supercritical CO_2 cycles configurations to the selected case study, in order to assess the *most suitable ones to compete with the current single flash +ORC power plant,* either from thermodynamic and exergo-economic points of view. Figure 1 presents the schematic of the current power plant and table 1 summarizes its main performance parameters.

Table 1. Bagnore 3 single flash + ORC power plant performance parameters

Parameter	Value
First Law efficiency η	0.19
Second Law efficiency η_{II}	0.46
Net power output W_{net}	20
Cost of energy €/kWh	0.04

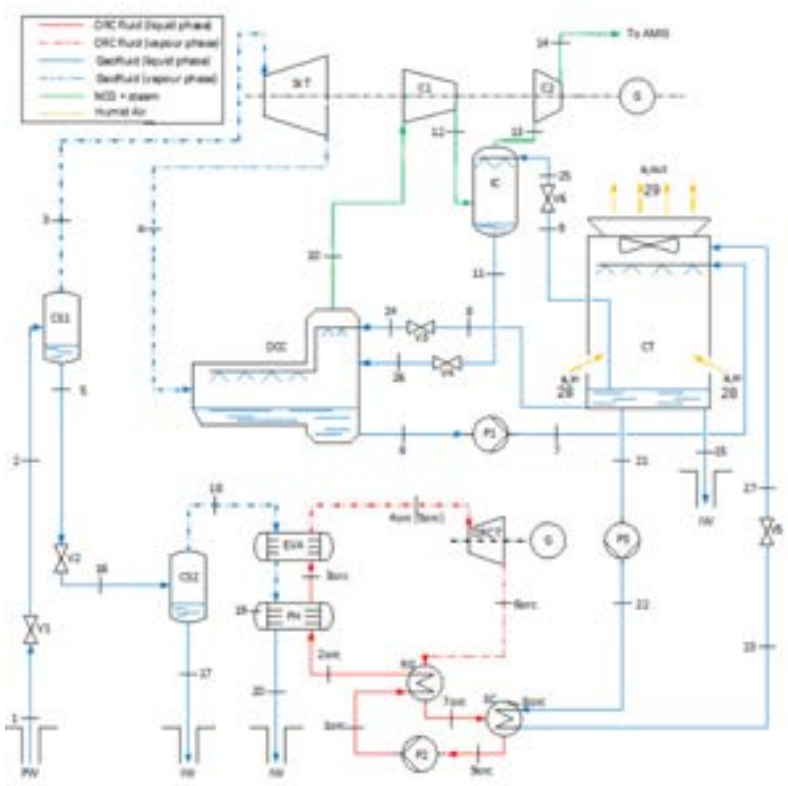

Figure 1. Schematic of Bagnore 3 power plant [40]

2. Methodology

The Amiata geothermal field was selected as a case study because of the difficulties encountered in using the local resource with flash power plant technology. The brine is particularly rich in antimony sulphide (Stibnite), which precipitates in the flash drain at temperature below 140°C and is responsible for the scaling of the ducts, causing drastic reductions of the passage sections. In order to prevent the scaling of Stibnite, the introduction of a borehole pump upstream the flash point located inside the well at 800 m depth from the ground level was proposed, thereby maintaining the geothermal fluid under pressurized liquid conditions, from the extraction to the re-injection reservoir. The required pump head and power were calculated modelling the friction and heat losses in the geothermal fluid extraction duct. The pressurized fluid, after having delivered its sensible heat to the working fluid, is re-injected at a fixed 150°C temperature, in order to avoid any sedimentation of stibnite while ensuring, at the same time, a correct management of the geothermal field. A guideline applied in this research is to maintain the geothermal fluid under pressurized liquid conditions: this includes the modelling of the well thermo-fluid dynamics and of the borehole pump. A model was thus developed in EES [41] in order to calculate the heat transfer and pressure losses, while the fluid (geothermal brine in liquid conditions) is ascending the well duct. A steel cladding is included only in the first 500 m from the surface. Once the geometry is fixed, the head losses, which must be overcome by the borehole pump in order to maintain the geothermal fluid in liquid phase were calculated; the same was done for the heat losses. The Colebrook formula for the

calculation of the friction factor was utilized. The temperature of the ground is assumed to vary linearly with a gradient of 50°C per km of depth, from the starting value of the ambient temperature of 285 K.

Table 2 and Figure 2 show the main thermodynamic and performance parameters and the configuration of the borehole pump respectively.

Table 2. Main borehole pump parameters

Parameter	Value
η	0.8
W_{bp}	0.87 [MW]
T_{inBH}	273 [C]
P_{inBH}	5758 [kPa]
T_{outBH}	274.6 [C]
P_{outBH}	10258 [kPa]

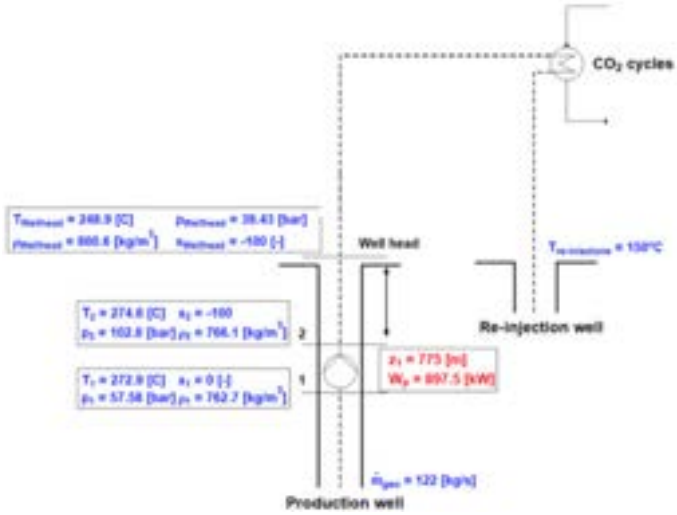

Figure 2 Borehole Pump schematic

2.1. Power plants schematic

In these work several power plant configurations were considered in order to evaluate the optimal power plant layout to be applied to the investigated medium temperature geothermal resource. Clearly, it is general for many different aspects, so that it may be representative of many other cases of exploitation of medium – high temperature geothermal resource with trans and supercritical CO2 binary cycles. Figure 3 shows the analysed configurations and figure 4 represents the corresponding temperature-entropy diagrams. Particularly, the assessed configurations comprehend a recuperative cycle, a recuperative cycle with reheating, a recuperative cycle with reheating and intercooling, a precompression cycle, a recompression cycle with two recuperation and a recompression cycle with one recuperator.

For each developed power plant, it was assumed that: (i) the cycles work in steady state conditions; (ii) the geothermal fluid is modelled as pure water; (iii) the difference in kinetic and potential energy between the input and output of turbomachines and heat exchangers is ne-glected; (iv) the isentropic efficiency of turbomachines is fixed.

The real fluids thermodynamic properties were evaluated from EES internal libraries [41].

For each component, mass end energy balance equations were applied, as displayed in Eqns. (1)-(2).

$$\sum \dot{m}_{in} = \sum \dot{m}_{out} \qquad (1) \qquad \dot{W} + \dot{Q} = \sum \dot{m}_{out} h_{out} - \sum \dot{m}_{in} h_{in} \qquad (2)$$

The first law efficiency was then defined, as shown Eq. (3).

$$\eta_I = \frac{\dot{W}_{net}}{\dot{Q}_{in}} \qquad (3)$$

2.2. Exergy and exergo-economic analysis

Exergy is the ability of a system, a flow of matter or an energy interaction (such as heat, work or potential energy) to produce work as a result of interaction with the environment. For a completely reversible system, the maximum obtainable work is equal to the total exergy of the initial thermodynamic state.

Exergy is, therefore, the combination of the First and Second Laws of Thermodynamic, which allow to properly assess the energy efficiency of a system and to correctly identified the associated irreversibilities [42].

Exergy analysis is considered as one of the most robust method for the design and assessment of energy systems [43]. Indeed, the concept of exergy allows to estimate the effective thermodynamic values of energy flows. In the present work, the exergy is calculated at each point of the system by Eq (4).

$$\dot{E}x_j = \dot{m}_j[(h_j - h_o) - T_o(s_j - s_o)] \qquad (4)$$

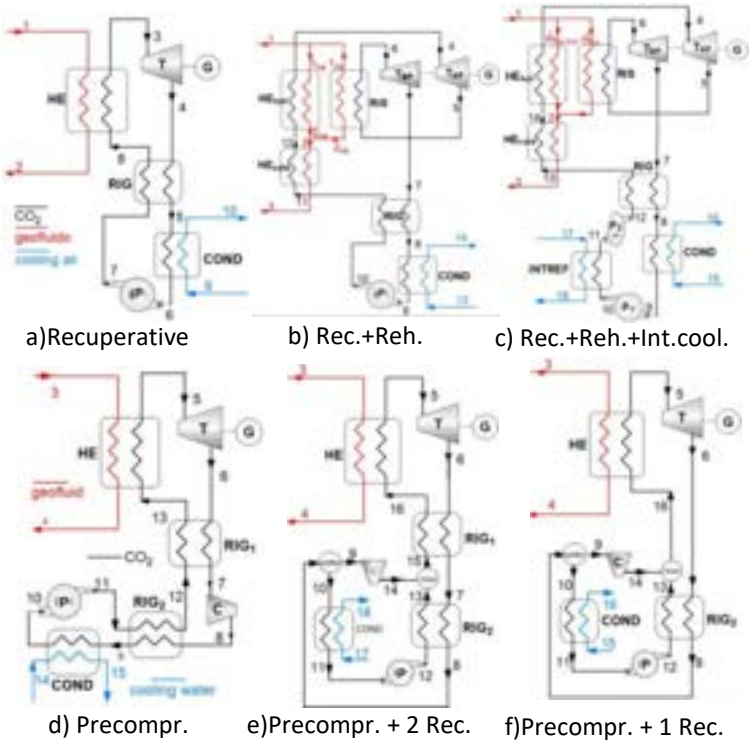

Figure 3 Schematic of super critical cycles

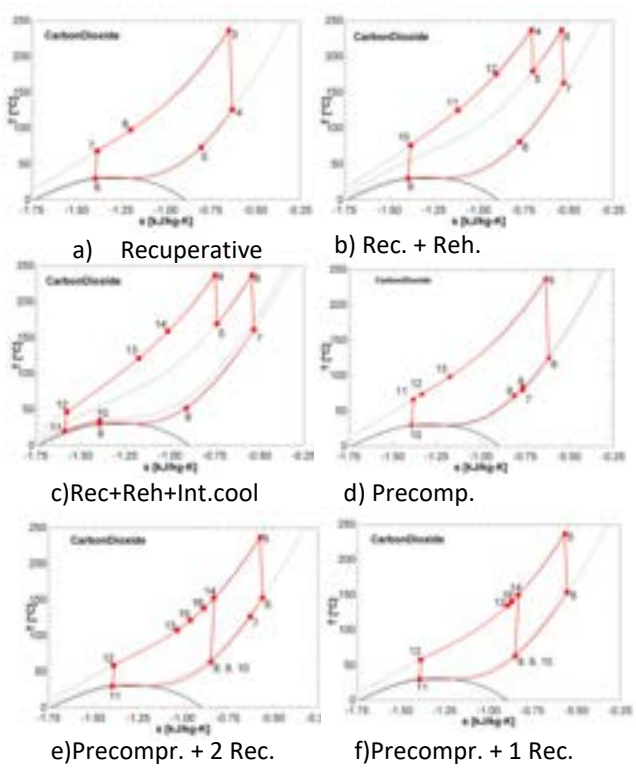

Figure 4 T-s diagram of super critical cycles

Combining the economic and exergy analysis (e.g. exergo-economic methodology) allows providing an efficient evaluation of the power plant and components cost-effectiveness, by introducing the costs per exergy unit [44]. The exergo-economic approach outlined in [45] was applied in this work by defining, for each component k, a cost balance equation, expressed in the following equations (5).

$$\dot{C}_{P,k} = \dot{C}_{F,k} + \dot{Z}_k$$
$$c_{P,k}\,\dot{E}x_{P,k} = c_{F,k}\,\dot{E}x_{F,k} + \dot{Z}_k \qquad (5)$$

Where:

$\dot{C}_{P,k}$ and $\dot{C}_{F,k}$ are the cost rates associated with exergy products and fuels respectively

$c_{P,k}$ and $c_{F,k}$ are the costs per unit of exergy of product or fuel respectively.

$\dot{Z}_k$is the sum of cost rates associated with investments and O&M for the k-th component.

In order to determine the investment and O&M costs ($\dot{Z}_{tot}^{CI} + \dot{Z}_{tot}^{OM}$) of the two proposed power plants, an economic analysis was carried out. The cost functions applicable to the system components were obtained from [46, 16]. Costs were actualized to 2019 values, by using the CEPCI indexes [47]. The Operation and Maintenance costs (O&M) of each component were determined following the best practises in literature [48, 16].

Finally, Table 2 summarizes the exergo-economic balances and the auxiliary equations [44], which are logic statements that allow defining the missing number of conditions to solve the cost equations applied to each component for the recuperative cycle.

Table 2. Exergo-economic balance equations of power plant components for the recuperative configuration

	Recuperative
Borehole pump	$c_{21}\cdot\dot{E}x_{21} = c_{20}\cdot\dot{E}x_{20} + c_{Wp_{kJ}}\cdot\dot{W}_{BHpump} + \dot{Z}_1 \qquad c_{Wp_{kJ}} = c_{Wt_{kJ}} \qquad c_{20} = c_{fuel_{kJ}}$
Condenser	$c_6\cdot\dot{E}x_6 + c_{10}\cdot\dot{E}x_{10} = c_5\cdot\dot{E}x_5 + c_9\cdot\dot{E}x_9 + \dot{Z}_2 \qquad c_9 = 0 \qquad c_{10} = c_9$
Recuperator	$c_8\cdot\dot{E}x_8 + c_5\cdot\dot{E}x_5 = c_7\cdot\dot{E}x_7 + c_4\cdot\dot{E}x_4 + \dot{Z}_3 \qquad c_4 = c_5$
Heater$_{geo}$	$c_2 * \dot{E}x_2 + c_3 * \dot{E}x_3 = c_1 * \dot{E}x_1 + c_8 * \dot{E}x_8 + \dot{Z}_4 \qquad c_1 = c_{21} * \frac{\dot{E}x_{21}}{\dot{E}x_1} \qquad c_1 = c_2$
Turbine	$c_{Wt_{kJ}}\cdot\dot{W}_T + c_4\cdot\dot{E}x_4 = c_3\cdot\dot{E}x_3 + \dot{Z}_5 \qquad c_4 = c_3$
Compressor	$c_7\cdot\dot{E}x_7 = c_6\cdot\dot{E}x_6 + c_{Wp_{kJ}}\cdot\dot{W}_{pump} + \dot{Z}_6$

3. Results

3.1. Power Cycles Optimization

The main parameters influencing the cycles efficiency are the maximum pressure and temperature. Specifically, a very wide range of maximum cycle pressures was investigated, with a wider range for the recuperative cycle with reheating and intercooling, in order to assess the optimal configuration of the power plants. On the other hand, the maximum temperature of the cycle was defined by the geothermal source at 249 °C, therefore the ΔT approach was varied in order to investigate its influence on both efficiency and cost.

Figure 5 shows the behaviour of the first law efficiency and unit electricity exergo-economic cost at variable maximum pressure (a and b) and ΔT approach (c and d) of the investigated power cycles configurations reported in figures 3 and 4. The figures clearly show that the recuperative configuration with reheating and intercooling is the highest efficiency one, followed by the recuperative and reheating configuration. For all the proposed cycles, an optimizing efficiency range of maximum pressure exists. It is essentially due to the variable shape of the cycles at different p_{max}, which is rather remarkable in the range of 15000 to 30000 kPa. On the other hand, the First Law efficiency and unit energy cost are less sensitive to ΔT approach, with the costs monotonically decreasing with increasing ΔT, due to the dominant effect of heat exchanger cost on the slightly improved performance at low ΔT. The efficiency of the cycles also shows a slight optimization at ΔT in the 3 to 8 degrees, because of the increase of the compressors work for very low ΔT approach due to the increase of the exchange area (and therefore of the pressure losses) of the heat exchanger.

Conversely to the efficiency behavior, the lowest exergo-economic cost is achieved from the less efficient configuration which, however, is also the simplest one, namely the recuperative layout. This was expectable, as the other configurations allow indeed improved performance, but not so high to counterbalance the increased costs due to the additional required equipment. This is more remarkable for the recompression configurations, allowing a modest increase of efficiency at the price of much larger exergo-economic costs. Another interesting feature of the recompression configurations, is their optimal efficiency at lower maximum pressures, while the recuperative and the precompression layouts require higher maximum pressure in order to achieve high cycle efficiencies and low exergo-economic costs.

The performance data of the optimized power cycles are summarized in table 4. The considered configuration allows a 249°C geothermal fluid temperature at the inlet of the main HE, also considering the temperature increase given by the pumping process. The geothermal fluid is re-injected at 150°C in order to avoid the precipitation of stibnite while guaranteeing, at the same time, a correct management of the geothermal field. The best performing thermodynamic cycle is the recuperative with reheating and intercooling, which achieves an efficiency, even including the pumping power from the borehole pump and the heat losses of the ascending geothermal fluid in the well close to that of the currently installed single flash unit (19%). However, the maximum achievable power is much lower than the reference case, with a dramatic 40% reduction in power output. Indeed, all the configurations loose an amount of power output between 40 and 50% when compared to the traditional flash solutions.

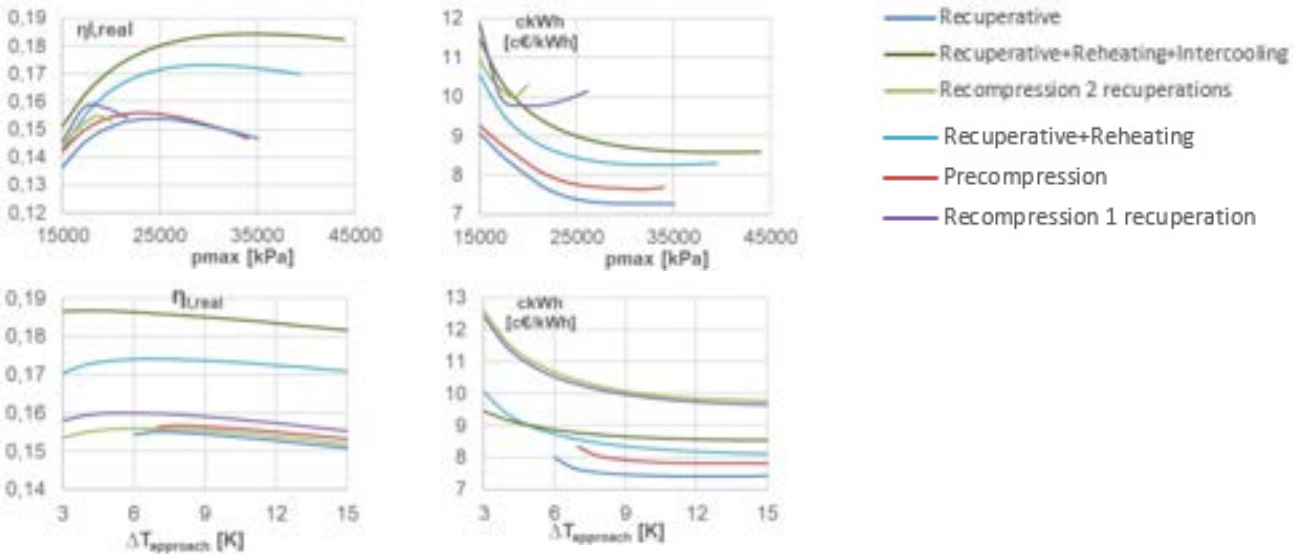

Figure 5 Efficiency and produced energy unit cost as a function of max pressure and $\Delta T_{approach}$ with geothermal fluid

The largest gross power production was achieved with the recompression cycles. However, these layouts have the main drawback of requiring the highest compressor power, exceeding 12 MW, which is almost double than

all the other configurations. These ones, however, guarantee the lowest maximum pressure of the cycle at 18.9 and 18.6 [MPa] respectively, for the configurations 1 and 2 with recuperation.

Finally, the recuperative cycle is the one generating the lowest amount of power, and therefore it is also the less efficient one. It should be remarked that the considered overall power plant efficiency takes into account the heat losses in the ascending well pipe. If the analysis was carried out from the well-head input, the overall efficiency would be closer to the cycle efficiency, and therefore higher than the reference case with flash.

Table 4 Performance comparison of each supercritical CO_2 cycle configuration

Performance Parameter	**Recuperative**	**Recuperative with reheating**	**Recuperative with reheating and intercooling**	**Precompression**	**Recompression with 2 recuperations**	**Recompression with 1 recuperation**

3.2. Exergy analysis: results

Figure 6 shows the non-dimensional exergy destruction and losses of each components of the power cycles. The exergy input from the geothermal resource, was fixed at the same value for each thermodynamic cycle. As it is evident from figure 6a, the highest exergy loss comes from the production well (29%). Indeed, this loss is common to all the considered cycles and cannot be avoided. On the other hand, the exergy losses at the condenser to the environment, are not the main contributors to the inefficiency of the cycles, as they are in the range of 2%. These levels of losses are clearly related to the largely different exergy value of the two heat losses.

The source of highest exergy destruction is differently located for the considered cycles: for example, in the recuperative and precompression cycles the highest values belong to the main heater (HE). Furthermore, the exergy destructions in the condenser represent the second main contributor to the inefficiency of the cycles, with values higher than 7.5% for all the configurations except the recuperative one with reheat and intercooling, as it allows a further heat recuperation from the exhaust stream of the turbine.

From the sum of the exergy destructions, it is possible to address the best and worst performing power cycles configurations. The highest exergy efficiency (45.4%) belongs to the recuperative cycle with reheat and intercooling, as clearly shown on figure 6b. As clear from the comparison of the exergy destruction sources in the different cycles, this is mainly due to the lower values found in the heaters and the condenser. Moreover, the good coupling of the fluids heat capacities (water and CO_2) allows achieving a satisfactory value of exergy efficiency in the main HE for this power plant layout. On the contrary, for the same reason (e.g. the weak coupling of heat capacities in the main HE) the recuperative cycle configuration shows the lowest overall value of exergy efficiency.

3.3. Exergo-economic analysis: results

The cost of electricity generation for the proposed power plant configuration can be obtained from an exergo-economic assessment. The levelized cost of electricity for geothermal power plants project installed (or in progress) between 2007 and 2021 varies depending on technology and size. Particularly, for binary cycle configuration the cost of electricity varies between 4 c€/kWh for very big power plants (>300 MW), to values close to 14 c€/kWh for power plants with a nominal capacity of 1 MW. The mean range value of electricity production from geothermal power plants is between 6 and 10 c€/kWh [49].

In the here presented power plant case studies, the range of installed power is between 10 and 15 MW. These lead to a relatively high cost of electricity for some of the investigated configurations (recompression), but still very close or in line with the expected electricity production values. Particularly, the lowest electricity cost (7.42 c€/kWh) was achieved with the recuperative configuration. On the contrary, the highest electricity cost (9.98 c€/kWh) was obtained for the recompression cycle layout with one recuperation level. The configuration achieving the highest efficiency (recuperative with reheating and intercooling) achieves electricity production at 8.6 €/kWh, which is a proper value for this power range. However, if we compare the obtained electricity costs with the reference power plant (Bagnore 3, single flash + ORC), the costs are doubled and the power produced is lower. This kind of power plants can be nonetheless attractive, as they can achieve an almost zero environmental impact configuration during the operation phase. Figure 7 summarizes the calculated electricity cost for all the analysed power cycles.

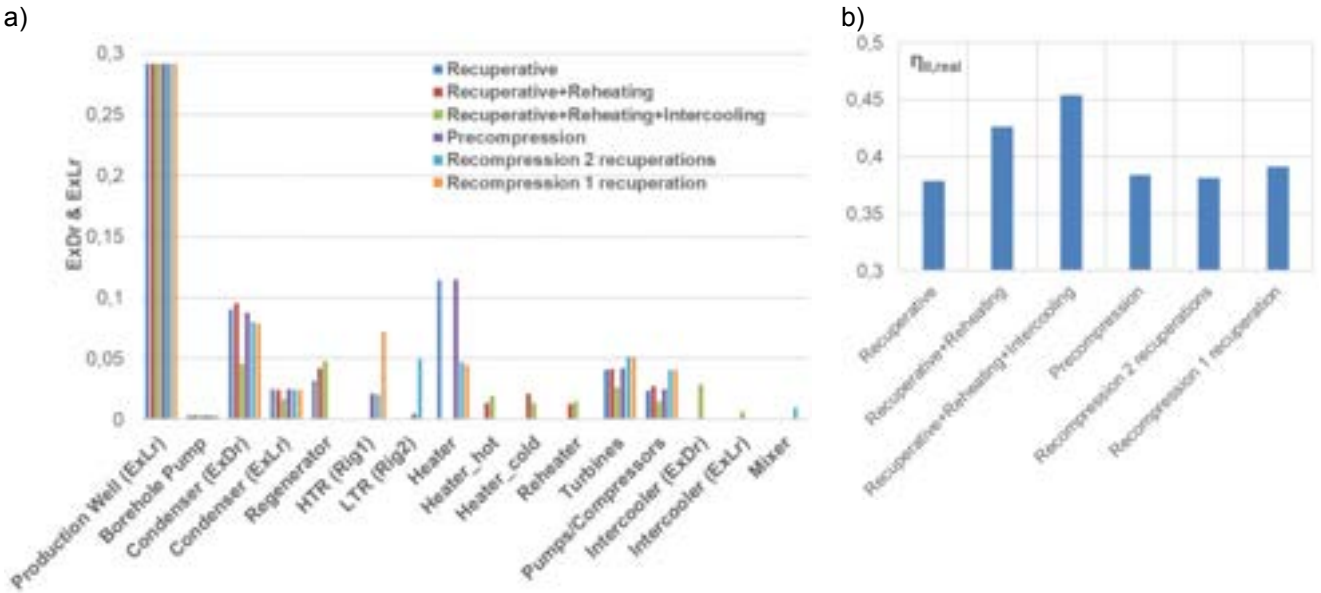

Figure 6 a) comparison of components exergy destruction of the different configurations overall; **b)** comparison of overall Second Law efficiency of the different configurations

3.4. Influence of heat exchangers pressure losses on cycles performance and electricity cost

Finally, given the primary importance of the heat exchangers performance, size and cost on the cycle efficiency and electricity cost, the influence of the pressure losses of the heat exchangers was carried out. In fact, when dealing with heat exchangers network in power cycles, the counteracting effects of their efficiency, generally enhanced with high specific area per unit volume with the induced enhanced pressure losses, negatively affect the cycle performance. Indeed, here the recent very efficient and compact Printed Circuit Heat Exchangers (PCHE, [50 – 52]) were considered, so deserving an accurate addressing of the pressure losses against their high heat transfer performance. The results presented so far included the evaluation of the pressure losses within the circuit, calculated through the developed model of the heat exchangers. The influence of the heat exchangers pressure losses is, on the whole, not negligible, as they reduce the efficiency in a relevant amount, especially for the recompression cycles where the efficiency drops by almost 5 percentage points, as clear from Figure 8.

The drop in efficiency is directly related to the increase of the produced electricity cost. Indeed, as can be grasped from Figure 9, the associated increase of the produced electricity cost is more remarkable for the recompression cycles, because of the relevant decrease in efficiency due to friction pressure losses, leading to an increase of costs higher than 1 c€/kWh. On the other hand, the lowest increase in electricity cost due to HX pressure losses belongs to the recuperative cycle configuration, as it is the simplest one from this point of view.

Conclusions

In this study an exergo-economic assessment of different supercritical CO_2 power cycles configurations for the exploitation of water dominant geothermal resources in place of traditional flash based technologies was carried out by the means of energy, exergy and exergo-economic analysis. The proposed power cycle configurations adopted the efficient PCHE which, on the other hand, may negatively affect the cycle

performance due to their possible relevant pressure losses. The results confirmed that the supercritical CO_2 cycles may be valuable binary cycles solutions for the exploitation of low temperature geothermal resources, as the produced cost of electricity is in line with the existing binary cycle costs [49].

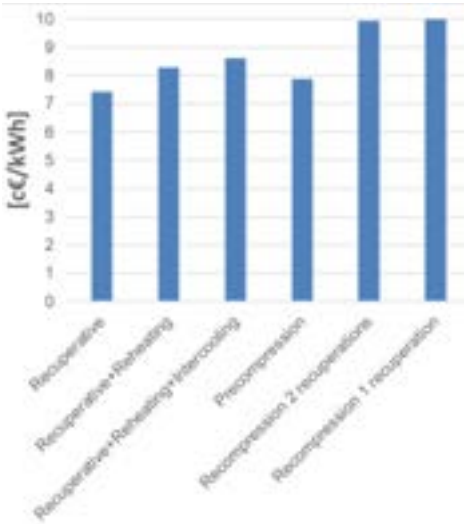

Figure 7 Comparison of electricity costs for the analysed power plants

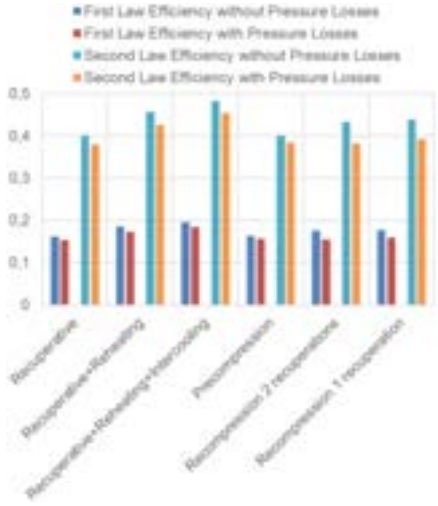

Figure 8 Sensitivity of first and second low efficiencies of the proposed cycles to the pressure losses in the heat exchangers (bars with and without considering them).

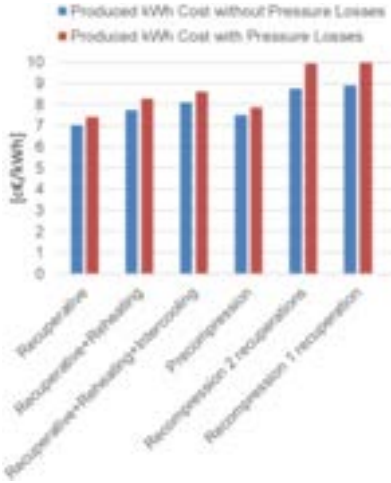

Figure 9 Sensitivity of electricity cost of the proposed cycles to the pressure losses in the heat exchangers (bars with and without considering them)

The most remarkable outcomes from the present research are the costs of electricity related to the adoption of supercritical power cycles under six different configurations, exploiting the same fixed geothermal resource:

- The lowest cost of electricity was achieved for the simplest recuperative cycle configurations, at 7.4 c€/kWh, which is in line with the level of current geothermal binary cycles.
- The configuration allowing the highest thermodynamic efficiency was the recuperative with intercooling and reheating, which gave First and Second Law efficiencies of 18.5% and 45.4% respectively. However, due to the increase in complexity of the power plant configurations, especially related to the “heavier” heat exchangers network, the cost of electricity becomes slightly higher (8.092 c€/kWh), even though still competitive with that of current binary cycles.
- The recompression configurations are hindered by the high required compressors work, having therefore the highest produced electricity costs and the lowest efficiencies. Nonetheless, it should be remarked that these configurations guarantee the lowest maximum cycles pressures (around 190 bar).
- All the binary configurations show lower performance when compared to the currently adopted single flash +ORC power cycle, with a reduction of the power output in the range of 40-50% and an almost doubled cost of the electricity. On the other hand, these CO_2 power plants could guarantee an almost zero environmental impact during the operation phase.

As a concluding remark, this analysis well addresses the importance of including the effect of pressure losses in the heat exchangers, also considering the fact that the high efficiency and compact PCHE were adopted, where this issue may be typically relevant. It is shown, here, that this aspect might lead to a significant increase of the produced electricity costs, related to the entailed drop of power cycles efficiency, especially in the most complex configurations.

The results of this research introduce, in the context of known configurations of CO_2 based binary cycles to exploit geothermal resources, the novelties related to two main aspects which are missing in literature:

1) The accurate evaluation and comparison of electricity production costs by the means of exergo-economic methodology;
2) This methodology was applied to cycles equipped with PCHEs, which is a novel proposal in these applications, particularly for the aspects addressing the influence of the related pressure losses on the cycle's performance.

Abstract:

Hydropower (HP) has played an important role in Europe in recent decades, offering a unique combination of safe, low-cost and clean power generation. Today, it is still one of the largest renewable energy sources (RES), accounting for about 35% of RES electricity generation and its share is estimated to reach 50% by 2025. However, grid stability is threatened by the increasing amount of unregulated energy (wind and solar). Flexibility and dynamics such as energy storage and rapid response are urgently needed to achieve EU policy goals. In such a context, HP can play a key role, not only as a provider of regulated renewable energy, but also due to its ability to balance a renewable energy system in the short term (seconds to minutes) and in the medium/long term (months or even years) through the use of pumped storage technology. All these aspects underline the new role of hydropower, which aims to strengthen grid stability and power supply resilience, and to enable higher penetration of volatile RES.

The study provides an overview of the preliminary results obtained by the working groups of the COST Pen@hydropower action. In particular, it presents a first assessment of the flexibility offered by hydropower today at the European level, focusing on different geographical areas, and confirms the key role of hydropower in future scenarios (30% of the flexibility demand at all time scales met by hydropower). An overview of the digitalization solutions and innovative technologies that support the growth of a new generation of sustainable hydropower and the modernization of existing hydropower plants is also provided.

Keywords:

Hydropower; Energy; Sustainability; Flexibility; Digitalization.

1. Introduction

Many countries in the world have introduced specific installation targets and financial incentives for further wind and solar power development, but few have policies to support the sustainability of existing and facilitate the addition of new hydropower plants (HPPs). However, hydropower is the most appropriate technology to provide the future power systems at RES with the emission-free flexibility they need. This new, crucial role that hydropower is expected to play in future power systems should be recognized by governments, energy stakeholders, and society, and reflected in long-term expansion targets and investment plans.

The sustainable use of water resources for hydropower to support this new role is the goal of some initiatives and international associations, such as the Technology Cooperation Program on Hydropower of the International Energy Association [1], which is a working group of some member countries and organizations from Europe, the Americas, and Asia; the International Hydropower Association [2], whose members are hydropower developers, operators, and manufacturers from many countries around the world, and the Joint Research Program on Hydropower of the European Energy Research Alliance [3], which consists mainly of universities and research organizations in Europe.

In this sense, the main objective of the Pen@hydropower Cost Action [4] is to build and establish a Pan-European network for sustainable, digitalized and flexible hydropower in order to contribute to the Clean

Energy Transition (CET) and climate change mitigation, and to promote the development of a sustainable society. Pen@hydropower engages members on a more personal level and aims to create an interdisciplinary consortium that brings together researchers, scientists, and other stakeholders from engineering, social, economic, legal, and environmental sciences who will work towards the above goal through various activities. A key objective of the Action is to engage and build the capacity of many young researchers to bridge generations and prepare the hydropower experts of tomorrow.
To achieve this goal, there are some recognized challenges and identified barriers that need to be addressed and overcome. First, EU support for the scientific environment of HP is low. Over the past 15 years, only about 15 HP projects have been funded [5], and today only about 0.7% of EU funding for RES development goes to HP to improve the performance, efficiency, and flexible operation of hydropower plants, to support the use of other RES and electricity storage, and to address important environmental issues related to river hydraulics and ecology. As a result, there are few technological innovations to promote sustainability and resilient operation of old and new power plants to meet the increasing demands of power systems and environmental and social requirements.:

- Research coordination objectives that include a scientific support framework for HP producers and investors, a platform for collaboration among scientists and stakeholders from different disciplines, mapping of current EU legislation, market and CET scenarios, and identification of policy gaps and barriers to create a unique knowledge base currently lacking in the scientific community, and to develop a novel holistic scientific HP community strategy with new approaches to support sustainable development.
- Capacity building objectives to expand the existing technical network by incorporating additional disciplines (engineering, ICT, environment and climate, hydrology, social, finance, etc.), promote career development of young scientists through joint PhD programs, knowledge transfer, and training schools, and increase awareness among policy makers and industry of the importance of HP in the energy mix.

The Pen@Hydropower management committee consists of members from 33 European countries, including 20 COST Inclusiveness Target Countries (ITC), and there are more than 160 members in the 5 working groups, ranging from young researchers and early career investigators (ECI) to experienced researchers. During the 4-year duration of the project, several funded activities are planned for researchers or innovators from all fields HP. Each year, a training school for PhD students and ECI will be organized in different European regions to broaden their knowledge and deepen their teamwork in the field of hydropower. This year, the training school will be organized in Timisoara, Romania (May 9-12, 2023), on the topic of "Sustainable Hydropower" [6].

Researchers can also apply for short-term scientific missions to visit and work at a host institution in another country to gain new knowledge or access equipment or techniques not available at their home institution. In addition, the Action offers conference grants that enable young researchers to attend international conferences, as well as grants to attend high-level conferences to present their activities and results under this Action and to establish new contacts and potential future collaborations [7].

This article presents some initial results of the Pen@Hydropower working groups since the launch in September 2022. These results provide for the first time a pan-European overview of the hydropower technology status from an holistic perspective, exploiting information and data collected among stakeholders spread in several different Countries. Section 2 discusses the future flexibility requirements for power systems in different European countries with a time horizon from 2030 to 2050 and the contribution of hydropower to meet these needs. Section 3 then presents some technical innovations and digitization technology that can be used to modernize the existing HP power plant fleet and to design new plants so that they can more effectively support the power systems of the future.

2. The flexibility of hydropower in the European context

It is well known that transitioning our energy system to one dominated by renewable energy sources is an increasing challenge. This includes volatile renewable energy sources (VRE), which increase the demands on the system to balance supply and demand. For example, the increasing use of power converters to generate solar and wind energy is reducing grid inertia and challenging traditional approaches to limiting and restoring frequency. The Australian Energy Market Operator (AEMO) has found that a lack of frequency limiting by conventional power plants leads to difficulties in managing frequency and scheduling system reserves [8]. Similarly, the California Independent System Operator (CAISO) experienced a progressive degradation of its frequency containment and restoration performance: the frequency response measure (FRM) decreased by 122 MW /0.1 Hz in 4 years [9].

In Europe, forecast scenarios for the 2030 horizon show that effective management of large-scale VRE, flexibility on multiple time scales from short-term to seasonal, as shown in Figure 1.

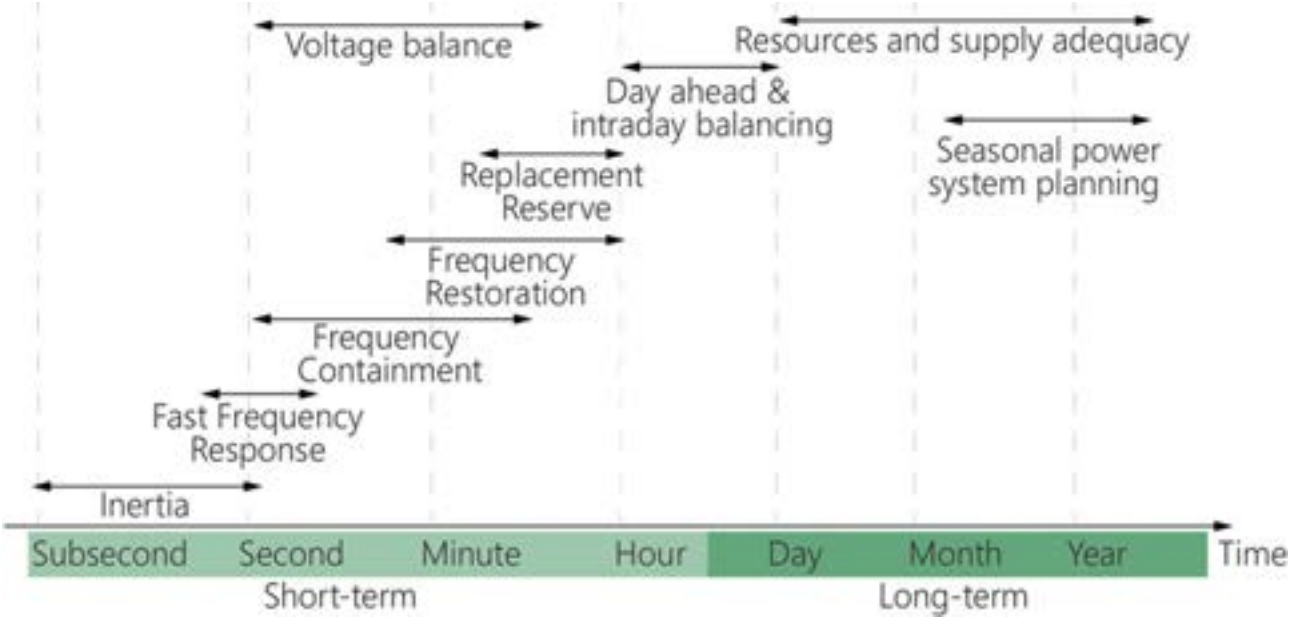

Figure. 1. Time-horizon of the flexibility services that hydropower can provide. Adapted from IEA [10].

In particular, the simulations projected the residual load curve in 2030 in the European Union (EU), which serves as a parameter for assessing flexibility requirements [11]. As can be seen in Figure 2, the residual load curve has a peak in the morning and evening, which coincides with hours of increasing demand, and a significant drop in the midday when solar production increases. By measuring and predicting this parameter, the flexibility demand can be quantified in terms of energy per day, week, and month. Figure 3 shows the daily flexibility demand per country in Europe in 2021, 2030, and 2050. The daily flexibility demand will be 288 TWh in 2030 and will increase by an average of 133% between 2021 and 2030 in all countries. Weekly and monthly flexibility needs are lower (258 TWh on a weekly basis and 173 TWh on a monthly basis), but they increase faster over the next decade: weekly flexibility is projected to increase by 166% and monthly flexibility by 300%. From these results, it is clear that flexibility must be used in all areas of the power system, from power generation to stronger transmission and distribution systems to storage and more flexible demand.

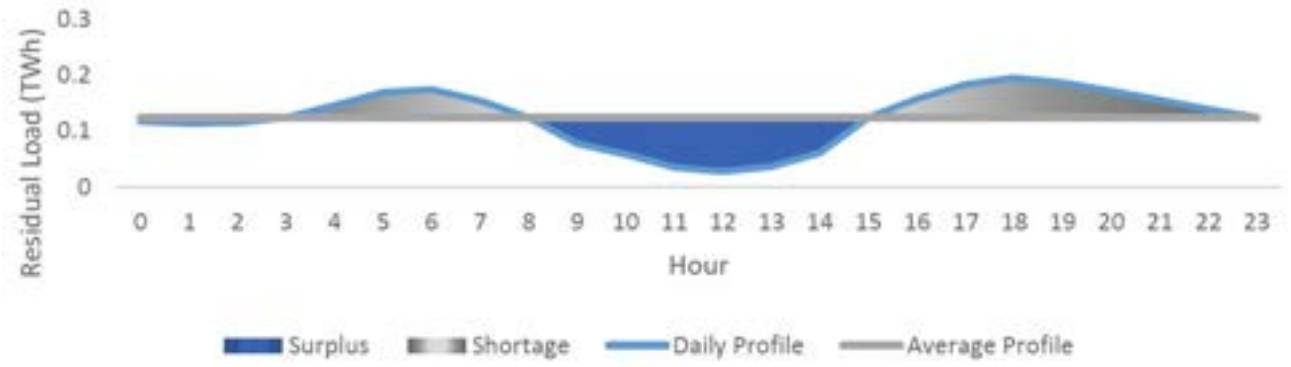

Figure. 2. Flexibility requirements based on hourly-averaged daily EU residual load curve in 2030 (Source: Joint Research Centre [11])

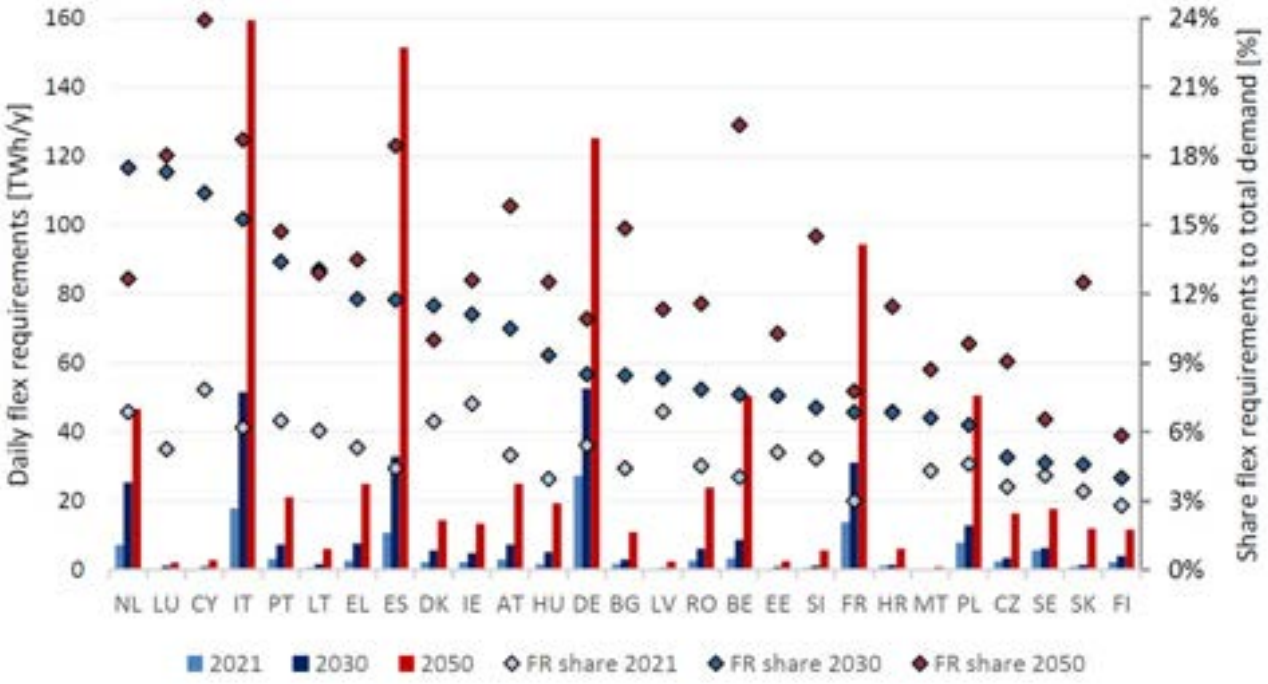

Figure. 3. Daily flexibility requirements in 2021, 2030 and 2050, ordered by 2030 flexibility requirements share to total demand (Source: Joint Research Centre [11])

With dispatchable power generation and high potential for storage capacity, hydropower is already providing these essential services to the grid. Even though the simulations predict a decrease in the share of hydropower in these services by 2050 (about -7% for hydropower including pumped storage), this technology will be needed to meet the increasing demand for these services, which will require higher flexibility of hydropower plant (HPP) operation, higher availability, and higher electricity capacity and storage capacity of the hydropower fleet. In the 2030 scenario for the European Union, more than 30% of the flexibility demand at all time scales is met by hydropower. Another study on the optimization of storage needs and market profitability has shown that, considering the previous scenario for 2030 and excluding gas-fired power plants from the options, the optimal additional capacity of pumped storage is 1.3 GW (and + 14.5 GW batteries), with an additional storage capacity of 62.2 GWh, of which 7% comes from hydropower.

A study conducted by the IEA [12] presents several case studies around the world in which hydropower contributes to power system flexibility by demonstrating its ability to support almost all the systems studied at the different time horizons, from short-term grid services to long-term storage. In the selected countries in Europe (Germany, Norway, Switzerland and Finland), the share of hydropower depends on the country, as it is a geographically limited resource. This also reflects a different market structure, which seems to be particularly pronounced in the countries where the share of hydropower is highest, such as Norway and Switzerland, even for short-term sub-hourly services.

According to these studies, it is clear that hydropower is a key resource to enable the energy transition and achieve the 2030 and 2050 sustainability targets. Therefore, there are new opportunities for this technology in terms of market participation and further increasing its production. This requires, for example, an increasing share in the auxiliary services under the hour, by increasing the availability of balancing energy of the hydropower plant with multiple units, if available, both in generation and pumping mode.

3. Technological Evolution through Innovation & Digitalization

As explained above, flexible operation is one of the challenges facing hydropower, and technological development to achieve this goal and others (e.g., related to increasing sustainability in terms of river hydraulics and ecology) must come through advances in digitalization and innovation. The PEN @Hydropower action has a working group dedicated to these aspects, with the aim of raising awareness of digitalization and other innovative technologies, sharing experiences between operators, manufacturers and universities, and imagining the new generation of hydropower plants.

In the first grant period, one of the objectives of Pen@Hydropower is to identify trend technologies and the needs of the hydropower sector in terms of digitalization, flexibility and efficiency. To this end, a survey will be conducted to identify the current situation of members in their countries in terms of technological

developments and common practices. This survey, described in detail below, can be considered representative of the European context and the different disciplines, as the PEN @Hydropower working group has 97 members from 27 different countries (70% of the members are under 40 years old and 12% of the members are female), whose expertise spans a wide spectrum that includes electrical, mechanical, environmental, computer science and civil disciplines.

3.1 Methodology

Surveys are used to gather information from respondents to answer research questions. Conducting surveys is a very convenient way to gather information from a large number of people in a given period of time. Due to the locations of the respondents, an Internet survey is chosen as the survey type. A conceptual framework consisting of innovative technologies and digitalization in hydropower is constructed. Many of the questions are prepared as closed-ended. Some of the questions in the survey are asked as open-ended questions. The choices in closed-ended questions are determined based on the experience of the preparers. The questionnaire is validated through sharing the questionnaire with the experts in the COST Action before publishing the questionnaire. The questions in the survey were created to understand the technological level of hydropower plants in the different European countries and to identify what technological advances the new investments in hydropower plants should include.

The structure of the questionnaire was optimized to facilitate completion by members from different disciplines. The final form of the questionnaire is shown in Figure 4, and its explanation with the survey results is given in the following section. There are some open-ended questions as well as most of the closed-ended questions.

Participant's Information • Name • Surname • Country Unmanned Operation of Hydropower Plants • 0% • Below 10% • 10% to 25% • 25% to 50% • Above 50% Presence of Modern SCADA Systems • 0% • Below 10% • 10% to 25% • 25% to 50% • Above 50% Number of pumped storage hydropower plants • 0 • 1-5 • 6-10 • 11-20 • Above 20 Fish friendliness of hydropower plants • There exist fish passages • The turbine design is fish friendly • Not fish friendly Presence of variable speed operated hydropower	Presence of any hydropower plants in drinking water supply system for pressure energy recovery or any projects related to hydropower plant in drinking water supply system • Yes/No If yes, typical output of recovery units? • Below 10 kW • 11-100 kW • 101 – 500 kW • more than 500 kW The average age of hydropower plants • 0-10 • 11-20 • 21-35 • 36-50 • Older than 50 The percentage of the hydropower plants have technical documents in digital media • 0% • Below 10% • 10% to 25% • 25% to 50% • Above 50% Presence of any recent hydropower installations or major hydropower refurbishments, any installation of significant technological innovations or adopting up-to-date digitalization approaches.

plant or any project on variable speed operation • Yes/No	Any (realistic) plans for building new hydropower in near future, any plans to adopt digitalization approaches or any major technological innovations.

Figure 4. Questionnaire Structure

3.2 Results and Discussions

During one of the regular meetings of the Working Group, the questionnaire is explained to members of the group and the questionnaire link is shared with the members through the data sharing platform. The questionnaire is open before the submission of the manuscript. So far, ten respondents from nine different countries fill the questionnaire.

It is well known that unmanned operation increases operational efficiency in hydropower plants and protects plant operations from human error, but it also requires an advanced control system that collects all sensor data on site. It also requires a communication infrastructure with a reliable communication protocol. The control algorithms of the hydropower plant should be sophisticated enough to allow the control system to operate the plant satisfactorily even when there is no operator on site.

The first question aims to analyze the prevalence of unmanned operation of hydropower plants in Europe. The respondents are experts and academicians who give consultancy to plant owners and operators in their countries such that they are aware of the general situation in their countries. The results are shown in Figure 5. 60% of the respondents indicate that at least 50% of the power plants in their country are operated unmanned. On the other hand, 30% of the respondents indicate that at most 10% of the power plants in their country are operated unmanned. This question shows that the unmanned operation of the hydropower plants is quite high among the participants.

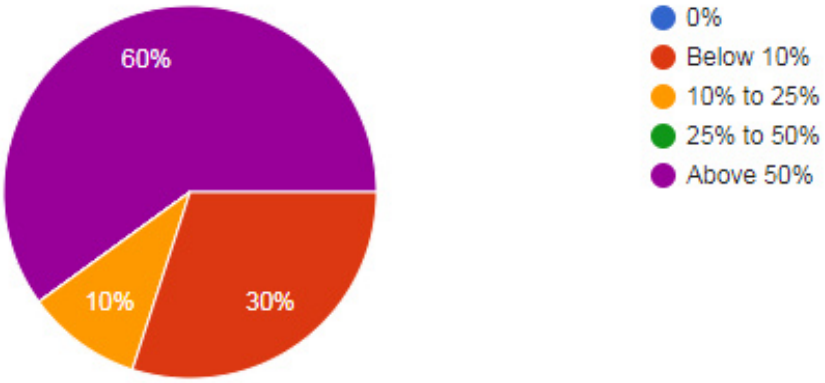

Figure 5. Distribution of Unmanned Operated Hydropower Plants

Unmanned operation requires that the facility's communications infrastructure and other control algorithms are set up accordingly. Supervisory Control and Data Acquisition (SCADA) systems are used to collect information from sensors in the plant, log that information, visualize it based on trends, and list it as alarms and events. The operator monitors and controls the plant remotely or on-site via man-machine interfaces. Regarding this aspect, it appears that the majority of hydropower plants have modern SCADA systems, as shown by the results in Figure 6, which perfectly reflect the results of the first question (Figure 5): 60% of the respondents say that at least half of the power plants in their country have modern SCADA systems, while 10% of the respondents say that up to 25% of the hydropower plants in their country have modern SCADA systems. These results show that most hydropower plants are unmanned and have modern control systems. This situation will allow the hydropower industry and developers to access historical data in a structural way

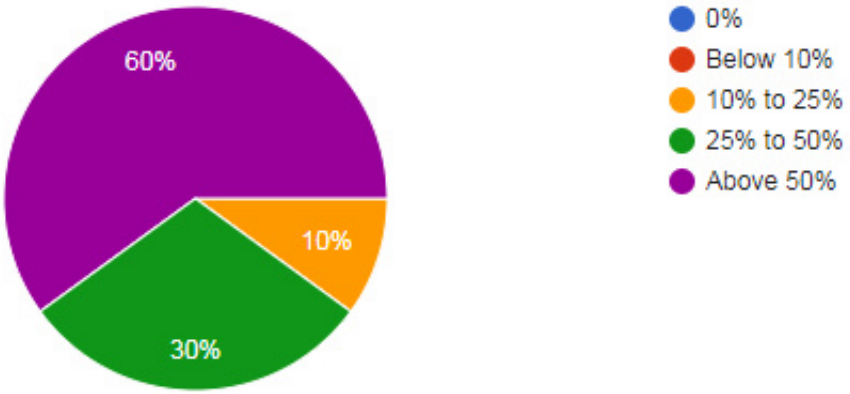

Figure 6. Presence of Modern SCADA Systems in Hydropower Plants

A pumped storage power plant is an efficient way to store electrical energy by pumping it to a higher reservoir when demand is low and by generating power to a lower reservoir during peak periods when demand is high. The next question asks about the presence of pumped storage power plants and the results are shown in Figure 7. 20% of the respondents have more than 20 pumped storage power plants in their country. On the other hand, 40% of the respondents have 1 to 5 pumped storage power plants in their country and 20% of the respondents have none. This question shows that the number of pumped storage power plants is variable and there is no common installation in the different countries when looking at the numbers.

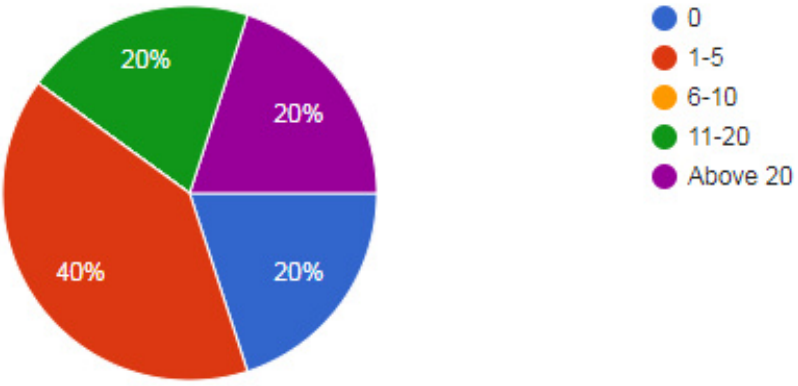

Figure 7. Number of pumped storage hydropower plants

Regarding the interaction between hydropower plants and the environment, new approaches have been developed in recent years to ensure accurate and rapid monitoring of fish. The use of digital tools combined with machine learning and artificial intelligence algorithms (e.g. convolutional neural networks) for automatic image-based detection and classification of species in different environments has been a breakthrough. Deep neural networks have already been successfully applied in various fields for fish monitoring [13]. In addition to image-based detection systems, molecular techniques such as environmental DNA have emerged as a tool for monitoring various aquatic species, particularly fish [14]. For example, a single eDNA study at the Spjutmo hydropower plant (Sweden) detected twice as many fish species as several electrofishing studies [15].

Fish-friendliness is a must for sustainable hydropower. To this end, there are many ways to provide fish safety, including fish passages, turbine designs, and fish tracking. When asked about the fish-friendliness of hydropower plants in their country, most of the respondents confirmed the presence of a fish passage in their country's hydropower plants. Few of them also indicated that the turbine design is fish friendly, and only a small proportion of respondents indicated that the hydropower in their country is not fish friendly. It can be concluded that most of the hydropower plants care about fish passage.

Regarding the presence of variable speed operation, which is extremely efficient in pumping mode, it was found that this is common throughout Europe. 60% of the respondents confirmed the introduction of variable speed operation in their country. The use of variable speed turbines is not very common in the hydropower industry in Europe.

Hydropower in the drinking water system is an untapped potential for green and sustainable cities. In the questionnaire, respondents are asked about the existence of hydropower plants in the drinking water supply for the recovery of pressurised energy or about the existence of projects related to hydropower plants in the drinking water supply. 90% of respondents indicate that there is a hydropower plant in the drinking water system in their country. As can be seen in Figure 8, the typical capacity of recovery plants ranges from 11-100 kW. This suggests that while the majority of countries have hydropower facilities in their drinking water systems, the potential of hydropower in the drinking water system needs to be explored more thoroughly.

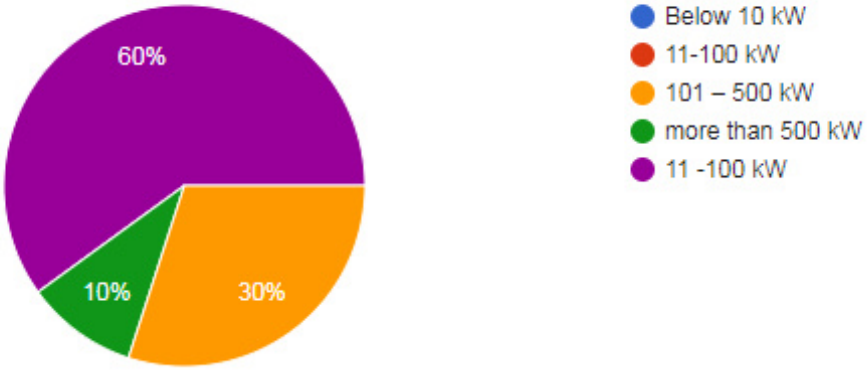

Figure 8. Typical Outputs of Recovery Units

The average age of the hydropower plant fleet can give an indication of the future potential for refurbishment in a country. When power plants are modernized, new technologies can be easily adapted and integrated into the newly modernized system. The results summarized in Figure 9 show that for 50% of the respondents, the power plants in their country are on average between 21 and 35 years old, while for 20% they are over 50 years old. 30% of the respondents indicate that the average age of the hydropower plants in their country is between 36 and 50 years. These results show that the hydropower fleet in Europe is quite old and the hydropower industry should develop new solutions based on innovation and digitalization for refurbishment.

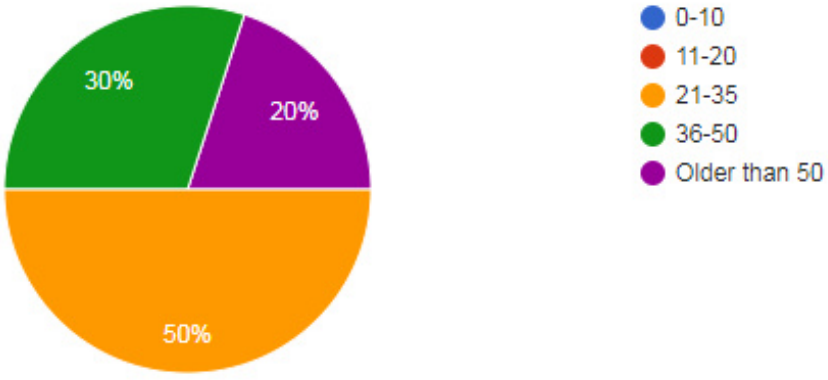

Figure 9. Average age of Hydropower plants

In the context of digitization, technical documents are stored and organised on digital media in order to digitise them. The last question asks respondents how much of the technical documents in their countries' hydropower plants are stored in digital media. As shown in Figure 10, 40% indicate that more than 50% of the technical documents of the hydropower plants in their countries are stored on digital media. On the other hand, 30% of the respondents indicate that this rate is less than 10%. This confirms that the hydropower

industry and developers need to spend more time to digitise the technical documents for technological progress, such as the digital twin.

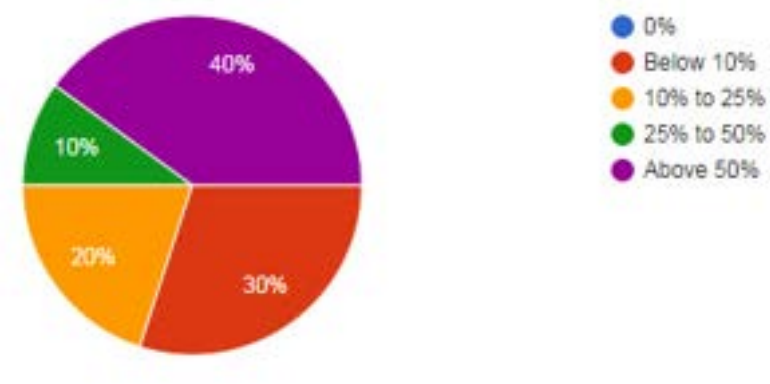

Figure 10. Technical documents in digital media

In the open-ended questions, respondents refer to major modernization works, including hydropower plants with an installed capacity of more than 500 MW. There are some power plants that are being renovated to make them compatible for variable speed control.

4. Conclusions

The PEN @Hydropower action laid the foundation for a pan-European collaborative platform of scientists and stakeholders from different disciplines, whose initial goal was to map the current state of the hydropower sector in Europe.

This study summarizes the results of the first activities carried out in the framework of PEN @Hydropower. In particular, we focused on the European energy framework and on the challenges of the Clean Energy Transition. Several studies have confirmed that one of the key requirements for the successful implementation of this zero emissions scenario is flexibility in all areas of the energy system, from power generation to stronger transmission and distribution systems, storage and more flexible demand. In this context, the key role of hydropower has been highlighted by several authors, along with the technological advances that are still needed for hydropower to play this role successfully. One of the most important is certainly to increase sustainability to make these advances technically feasible and economically viable, minimize environmental impacts, and increase society's awareness of the importance of hydropower technology to the CET.

This technological development must occur through advances in digitization and innovation, the mapping of which was the second short-term goal of PEN @Hydropower. Using its multidisciplinary network (engineering, ICT, environment and climate, hydrology, social, financing, etc.), the state of hydropower technology was studied, with some interesting results. The European hydropower sector confirms a good level of digitalization, but this is not fully exploited for technological advances. The latest technological solutions do not seem to have been uniformly adopted across European countries, confirming the need for knowledge transfer between stakeholders. For instance, the unmanned operation of hydropower plants has to be improved in Turkiye, Crotia, Albania and Bosnia Herzegova. Another figure to improve is the number of pumped storage type hydropower plants, e.g. there is no pumped storage type hydropower plant in Turkiye and Albania. Moreover, the fleet is quite old, which offers a great opportunity for promoting innovative refurbishment strategies to increase the sustainability of hydropower worldwide.

Abstract

The main objective of this study was to develop a prediction model using artificial neural networks (ANNs) and analyze the performance indicators of a green electric energy generation process based on the gasification of Brazilian biomass residues. The recovery of energy from renewable resources is a promising avenue for efficiently delivering valuable products. To achieve this, sugarcane and orange bagasse, residues from the sugarcane harvest, sewage sludge, residues from the corn harvest, coffee residues, eucalyptus residues, and municipal urban waste were used in the proposed process. The Aspen Plus software was used to generate simulation data to predict the energy conversion for each biomass, and a three-layer feed-forward neural network algorithm was employed to build the model. The developed model showed good training and test data accuracy, with an R^2 greater than 0.993. Regarding the performance of the generation plant, the gasification unit provided a maximum of 18.12 MJ/kg of HHV for sewage sludge. Urban and orange waste had the highest cold gas efficiency at 82.21% and 80.66%, respectively. Meanwhile, in the gasification process, sugarcane bagasse and orange residue showed the highest carbon conversion efficiency at 92.88% and 91.17%, respectively. The results indicated that eucalyptus waste gasification could generate more electricity at 12.86 MW. In overall, the study highlights the potential of using ANNs to predict energy conversion and analyze the performance of gasification-based green electric energy generation processes using Brazilian biomass residues.

Keywords:

Biomass gasification, Artificial neural network, Power generation, Exergy analysis.

1. Introduction

Biomass is a significant source of renewable energy that has the potential to reduce fossil fuel dependence and CO_2 emissions. Biofuels have accounted for almost 70% of renewable energy production globally, and biomass was responsible for 25.5% of Brazil's domestic energy supply [1]. Brazil has enormous biomass potential, and biomass wastes could be converted into valuable energy products like hydrogen, ammonia, and electrical energy. This way, energy consumption and greenhouse gas emissions could be reduced, along with waste disposal costs and environmental impact. Brazil has a vast biomass potential, including sugarcane bagasse, orange bagasse, corn, and coffee residues that could be used to produce bioenergy.

Waste-to-energy systems produce electrical and thermal energy using a variety of processes, including combustion, gasification, and power cycles [2]. Sapali and Raibhole [3] examined the combination of air separation and biomass gasification techniques. Because it uses less energy, the low-pressure column's pressure is close to the surrounding atmosphere's pressure of around 1.2 bar, while the high-pressure column operates at about 4 bar. To use less energy than the standard procedure, Wu et al. [4] also modeled a multi-column cryogenic air separation (i.e., high-pressure, low-pressure, and mixed fluid cascade columns) in combination with LNG regasification.

Banerjee et al. [5] also demonstrated a biomass gasification system under various oxygen and vapor ratio circumstances. Five biomass types, including pine, corn, coffee, maple, and straw, were used as fuel for the gasification unit. The fluid bed's gasification temperature was 800°C. Dhanavath et al. [6] have conducted various tests on corn straw, sawdust, and sunflower shells in a fixed bed reactor to study the gasification with stea. The outcomes were contrasted with the process modeling in Aspen Plus. They concluded by reporting that increasing the gasification temperature to 1000ºC produced cold gas with an efficiency of 95% for all inputs. A combined floatation gasification unit and power generation system were described by Lan et al. [7]. They discovered that gradually raising the gasifier's temperature boosted the hydrogen and methane output. In any case, the synthesis gas stream's carbon dioxide content decreased, but the amount of carbon monoxide produced grew considerably.

Artificial neural networks (ANNs) are one of the alternative modeling techniques most utilized at the moment; when compared to other techniques, they may be used to forecast and optimize system outputs in a shorter amount of CPU (Central Processing Unit) time [8]. Although ANN may learn and predict non-linear correlations between the output and input parameters, memorizing the data for training should be avoided [64]. A well-developed ANN model requires careful consideration of the transfer function, training algorithm, and model structure. A powerful and popular analytical technique for the non-linear model is the multi-layer network structure and feed-forward ANN with the backpropagation method [9]. Many studies have adopted ANN models because of their superior effectiveness in predicting the parameters associated

with the gasification process. An ANN model was created by Mikulandric et al. [10] to forecast gasification process parameters, and the findings demonstrated a good correlation with experimental research. The study realized of Serrano et al [11], used an artificial neural network model to predict gas composition and gas yield in a biomass gasification process in a bubbling fluidized bed. The effect of different bed materials was included as a new input, and different network topologies were simulated to determine the best configuration. The developed models were able to predict gas composition and gas yield accurately, indicating that this approach is a powerful tool for efficient design, operation, and control of bubbling fluidized bed gasifiers with different operating conditions, including the effect of bed material.. An ANN model for a combined biomass gasifier-power system was utilized by Safarian et al. [12] to evaluate power output utilizing the features of the biomass and gasifier operation. An ANN model was used by Sozen et al. [13] to look into the energy losses of the heat transformer.

Integrating neural networks and Aspen Plus models present a promising approach to improving the accuracy of power generation predictions. Neural networks can learn complex patterns from operational variables and historical data, making them helpful in predicting generated power. With that in mind, the primary goal of this research was to convert Brazilian waste biomass into renewable energy using waste-to-energy systems, including gasification plants and combined cycles. An Aspen Plus simulation program was used to simulate the bubbling fluidized bed gasifier and combined cycle to achieve this goal. This simulation generated data on the gasification and power generation process, which were used to create a general artificial neural network (ANN) pattern. Some of the significant contributions of this study include proposing a new method for evaluating cycle power generation, implementing machine learning methods on simulation data, and calculating performance indicators as crucial parameters. Finally, the study achieved a new method for generating renewable electricity from waste biomass by integrating these concepts.

2. Methods

2.1. Hypotheses for simulation

In this study, the combustion of volatile and biomass materials is assumed to occur with complete mixing. The Gibbs reactor is used to simplify the simulation, assuming that the gasification reactor is in equilibrium. These assumptions and the software's capabilities allow for accurate predictions of chemical process behaviour, including the physical and chemical properties of mixtures under various operating conditions.

It is important to note that utilizing Aspen Plus for process simulation has limitations. For example, the software cannot account for every factor, such as pressure drops in pipelines or other equipment, and all process-related calculations. However, despite these limitations, Aspen Plus is a powerful and valuable tool for predicting the behaviour of chemical processes, and its use is widespread in the industry.

Also, the following assumptions are considered in the simulation:

1. The system is in a steady state operating condition.
2. Kinetic energy and potential energy changes are neglected.
3. All heat exchangers are assumed to have counter-current flow.
4. Biomass only contains carbon and ash.
5. The volatile materials in the final product of the gasification process are mainly composed of carbon dioxide, carbon monoxide, hydrogen, methane, and water.
6. The pressure drop in the pipelines and other simulation equipment and process-related calculations are ignored.

2.2. Drying and milling process

The flow rate data used in this study were collected through a bibliographic review and data provided by the Basic Sanitation Company of the State of São Paulo [14]. The simulations assumed a constant biomass mass flow rate of 26,400 kg/h, which was kept the same across all simulations, including those performed using neural network analysis.

Figure 1 illustrates the production route that was proposed and analyzed in this study. The process begins with a rotary dryer that removes moisture from the biomass, consuming approximately 15 kWh per wet ton of biomass [15]. The dryer reduces the water content of the biomass to 7% [16]. Following the drying process, the biomass is chipped, and the specific electricity consumption required for the grinding process to obtain 0.5 mm particle diameters [17] was estimated to be approximately 3% of the thermal input of the biomass, based on its lower heating value.

2.3. Waste gasification process

Moving on to the next stage, shown in Fig 1, the gasification unit model was employed using the ultimate and proximate biomass analyses, as illustrated in Table 1. The gasifier model proposed by Battelle Columbus Laboratory (BCL) [18]–[20] was utilized, which is based on an indirect gasification process carried out at atmospheric pressure. This process prevents dilution between the nitrogen present in the produced syngas and the combustion gases. The combustion and gasification processes are carried out separately in a double-column system, with steam serving as the gasification medium.

During the combustion process, a portion of the char produced in the biomass pyrolysis step provides the heat necessary for endothermic drying, pyrolysis, and gasification reactions. Once these reactions are complete, the syngas exits the gasifier, and the produced tar undergoes thermal catalytic cracking. The syngas is then cooled to 400°C and scrubbed with water to remove any impurities that could affect downstream equipment. Finally, the syngas is compressed to 30 bar.

Table 1: Proximate and Ultimate analysis used for different biomass (dry basis) %

Biomass	M_{db}	FC_{db}	VM_{db}	Ash_{db}	C	H	N	S	Cl	O	REF.
Sugar cane bagasse	50.00	14.32	83.54	2.14	46.70	6.02	0.17	0.02	0	44.95	[21]
Sewage sludge	18.40	7.60	64.90	27.50	33.90	6.30	5.88	0.67	0.21	25.50	[22]
Sugar cane straw waste	31.30	12.80	20.60	13.00	49.00	5.60	0.80	0.30	0	44.00	[23]
Coffee waste	8.88	14.48	75.85	0.79	49.33	5.86	0.66	0.04	0	43.24	[24]
Eucalyptus waste	7.73	16.38	74.91	0.98	48.65	6.16	0.28	0	0	44.91	[25]
MSW	49.16	13.94	71.83	14.23	42.04	5.90	0.66	0.10	0	29.87	[26]
Orange bagasse	9.23	13.20	30.60	6.20	46.40	5.54	1.70	0	0	40.15	[27]
Corn waste	60.29	12.62	84.22	0	47.54	6.33	1.32	0.08	0	42.22	[28]

M, moisture content; VM, volatile matter content; FC, fixed carbon content; db, dry basis.

The base of gasification is composed of sequential process pre-treatment (dryer and chipping), pyrolysis, reduction, and combustion processes. Besides, the moisture removal simulation uses a FORTRAN subroutine [18]. To estimate the yield rates of H_2, CO, CO_2, methane, tar, char, and water in the pyrolysis reaction, step one uses empirical correlations reported in the literature as a function of temperature [29]. For this, it is employed an Aspen-embedded Excel spreadsheet.

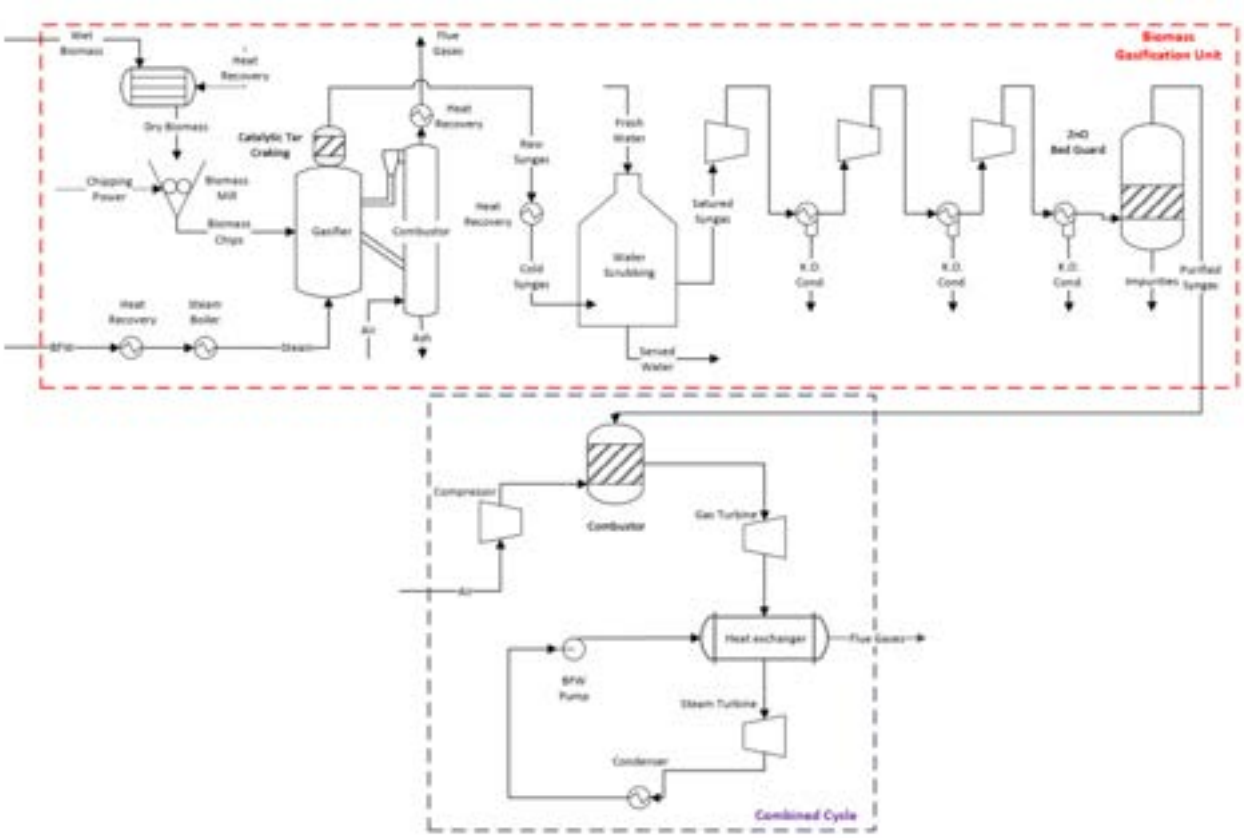

Fig. 1. Superstructure used in the process power conversion of the biomass-based.

2.4. Combined cycle

Figure 1 presents a comprehensive diagram of the combined cycle, depicting the various stages involved. The gas turbine utilized in this system is designed to simulate a Brayton Cycle and is based on the Alstom GT11N2 engine. The specifications for this turbine include mass flow, temperature, and pressure ratio. The steam turbine, on the other hand, operates using a conventional Rankine Cycle, with the simulation parameters being outlined in Table 2. It's worth noting that the same set of assumptions utilized by Silva Ortiz [30] and Medeiros et al [31] have been employed in this study.

To achieve a desired total exit flow rate of 400 kg/s, it is necessary to determine the mass flow rate of air based on the design specifications. The syngas produced during the gasification process serves as the inlet stream in the combustion chamber, where the air and syngas streams are directed to a RStoic reactor for combustion at a prescribed pressure ratio and constant pressure, as presented in Table 2. The gas turbine is designed to maintain the outlet temperature at 526°C. Once the steam temperature is attained, the output gases from the turbine undergo heat exchange with a compressed liquid water stream. Posteriorly, the steam follows to the steam turbine, that operates at an 83% isentropic efficiency and an outlet pressure of 0.1 bar, follows the previously stated pressure and isentropic efficiency assumptions [48, 49]. Ultimately, the water will be cooled in a heat exchanger and pumped back to start a new cycle.

Table 2: Combined cycle variables

Variable	Unit	Value
Compressor pressure ratio	-	15.9:1
Temperature after the gas turbine	°C	526
Pressure after the gas turbine	bar	1
Flue gas temperature	°C	~130
Temperature entering the turbine	°C	510
Pressure entering the turbine	bar	81
Isentropic efficiency of steam turbine	-	83
Pressure after steam turbine	bar	0.1

2.5. Validation

In this study, gasification represents a critical unit operation, given its significant impact on the quality of the final product. To validate the results obtained from the gasification system, It was utilized parameters from Almond shell biomass. Specifically, It was compared our findings with those from a previous study conducted by Marcantonio et al. [32]. and the comparative results are presented in Table 3. The most notable deviation was observed for CO_2, with a discrepancy of approximately 2.13%. However, the deviations for the other substances were relatively minor, with CH_4 showing a deviation of only 0.52%.

Table 3: Gasification results validation.

Parameter	Experimental results [32]	Simulation results	Standard deviation
Proximate analysis (%)			
FC	18.2	18.2	0.00
VM	80.6	80.6	0.00
Moisture	12	12	0.00
Ultimate Analysis (%)			
C	47.9	47.9	0.00
H	6.3	6.3	0.00
O	44.27	44.27	0.00
N	0.32	0.32	0.00
Ash	1.2	1.2	0.00
Volume Fraction (% vol)			
CO	28	29.35	0.95
CO_2	18	14.99	2.13
H_2	44	46.44	1.69
CH_4	10	9.27	0.52

2.6. Artificial neural network

A three-layer feed-forward neural network was employed to model the process of connecting each layer to the one below it. Unlike feedback neural networks, the information in this architecture flows only in one direction, from the input to the output layer. It was assumed that the data gathered accurately represented the system under investigation, a common assumption when working with neural networks. The neural network follows the same structure as described in the work of Cavalcanti et al. [33], with modifications to the inputs and outputs.

To represent the category or categorical-quantitative input variables, one-dimensional zero-arrays were used with a composition value of the component other than zero. This means that nine input neurons were used to represent a proximate and ultimate analysis of biomass, as well as temperature and steam biomass ratio. The ANN design was then expanded to include four neurons in the hidden layer, resulting in 11 input neurons and one output neuron.

To adjust the data, it was used the *NeuralNet package* available in the R software environment [34]. The package trains an ANN by estimating the weights between two neurons in successive layers, which simulate synapses. During training, information is transferred from one neuron to another. The ANN is trained using a sufficiently large dataset to compare its predictions. The training procedure stops when all partial derivatives of the error function E/w concerning the weights are smaller than a specified tolerance, such as 0.01. To compute the error function, it was summed the quadratic errors between observed and predicted values by the ANN.

To mitigate the impact of variable magnitudes on the model predictions, we pre-processed the data using min-max normalization, scaling their values between 0 and 1. The dataset was then randomly split into two subsets: 20% for the

test set, which was solely used to evaluate the ANN's performance, and 80% for the training set, which was used to estimate the ANN weights.

It is important to note that the test data used to evaluate the performance of the ANN must be representative of the same data domain used for training to avoid extrapolations that may result in uncertain predictions. In our case, the ANN included a bias neuron that served as an intercept with sigmoid activation characteristics.

The Resilient Backpropagation with Weight Backtracking (RPROP+) algorithm was used to train the network. Unlike the conventional Backpropagation algorithm, RPROP+ uses a different learning rate for each weight and can be modified during training. This allows for setting a global learning rate suitable for the entire network. RPROP+ only uses the sign of the gradient to update the weights instead of their magnitude, ensuring that the learning rate has an equal impact on the entire network. Weight backtracking refers to erasing the previous weight iteration and adding a smaller value to it in the subsequent step, preventing repeatedly jumping over the minimum. It is important to note that this algorithm is designed to avoid overfitting and improve the model's generalisation ability.

The number of neurons in the hidden layer (NH) was determined to prevent overfitting using the k-fold cross-validation procedure. This technique aims to run the ANN calculations multiple times with different training and test dataset combinations to identify the NH value that results in the lowest mean squared error (MSE) for the test set. This approach helps to ensure that the data used in the analysis are suitable for the ANN model, considering that all data from the articles were employed for training the ANN [35]. The MSE is calculated using Eq. 1.

$$\mathrm{MSE} = \frac{\sum_{i=1}^{a}(P_i - R_i)^2}{a} \tag{1}$$

where for the calculation of MSE; a is the number of data, P_i and R_i are the predicted and real values of the model, respectively.

The topology of the ANN used in this study is shown in Figure 2. The ANN comprises one input layer, one hidden layer with four neurons (NH=4), and one output layer. The inputs to the ANN are gasification temperature (labeled as "temperature" in °C), steam biomass ratio (labeled as "s/b ratio" in %), ultimate analysis of biomass (labeled as "moisture," "volatile material," "fixed carbon," and "ash"), and proximate analysis of biomasses in wt% (labeled as "carbon," "hydrogen," "nitrogen," "sulfur," and "oxygen"). In total, there are 11 input neurons and one output neuron. The ANN topology was generated using the *neuralnet* package available in the R software environment [34]

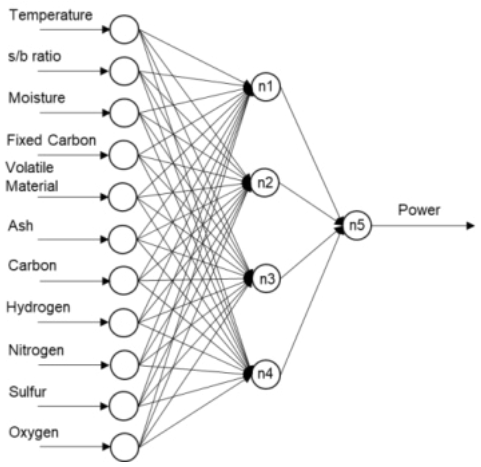

Figure 2. Three-Layer Feedforward Neural Network employed in this work

It is worth noting that none of the covariates directly affect the bias neurons (whose initial value is equal to one) existent to the intercept. The estimated weights calculated during the training phase are also presented in Table 4, where the "From" column indicates the source neuron and the "To" column indicates the destination neuron, as shown in Figure 2.

2.7. Performance indicators

To assess the overall performance of production plants [20], [36], two performance indicators are proposed by Florez-Orrego et al [37] to allow systematic comparisons among the different designed setups: rational and relative exergy efficiencies. The rational efficiency is defined according to Eq. (2), and the relative efficiency by Eq. (3).

$$\eta_{rational} = \frac{B_{useful\,,output}}{B_{\,input}} = 1 - \frac{B_{Dest}}{B_{\,input}} = 1 - \frac{B_{Dest}}{B_{biomass} + W_{input}} \quad (2)$$

$$\eta_{relative} = \frac{B_{consumed\,,ideal}}{B_{\,consumed,actual}} = \frac{B_{power}}{B_{biomass} + W_{input}} \quad (3)$$

where, B is the exergy flow rate (kW) and B_{Dest} represents the exergy destroyed rate, while W is the electrical power input to the plant.

The efficiency of a gasifier is typically investigated in terms of two types of efficiency: carbon conversion efficiency and cold gas efficiency. The carbon conversion efficiency (η_{cc}) (Eq. (4)) is defined as the ratio of the reaction carbon ($\boldsymbol{M}_{c_{re}}$) to the feed carbon in the gasifier ($\boldsymbol{M}_{c_{in}}$).

$$\eta_{cc}(\%) = \frac{\boldsymbol{M}_{c_{re}}}{\boldsymbol{M}_{c_{in}}} \quad (4)$$

The higher heating value (HHV) of fuels, including coal, coke, biomass, and municipal wastes, emanates from the heat released from the complete combustion of a unit of mass of fuel at a specific temperature and pressure [38]. Based on HHVs, the cold gas efficiency (η_{cg}) (Eq. (5)) is also expressed as the ratio of the chemical energy of the gas products released from the gasifier to the chemical energy of the input biomass.

$$\eta_{cg}(\%) = \frac{HHV_{syngas} \times M_{syngas}}{HHV_{biomass} \times M_{biomass}} \times 100 \quad (5)$$

The evaluation of each flow's thermodynamic properties and the mass, energy, and exergy balances of each operating unit are evaluated using the Aspen Plus® V8.8 software [39] . Compressors and pumps are modeled using 60% and 80% isentropic efficiencies, respectively. Furthermore, pressure and heat losses are not considered in any process. The ratio of specific chemical exergy (b ^{ch}) to the lower heating value is calculated employing the correlation proposed by [40] for solid fuels with specified mass ratios, Eq. (6)

$$\beta = \frac{b^{ch}}{LHV} = \frac{1.0438 + 0.1882\frac{y_H}{y_C} - 0.2509(1 + 0.7256\frac{y_H}{y_C})}{1 - 0.30350.1882\frac{y_O}{y_C}} \quad (6)$$

where the biomass lower heating value (LHV, MJ/kg) is estimated based on the correlations reported by [41] in Eq. (7)

$$LHV = 349.1y_C + 1178.3y_H + 100.5y_s - 103.4\,y_O - 15.1y_N - 21.5y_{ashes} - 0.0894h_{lv}y_H \quad (7)$$

and y_i are the mass fractions of carbon (C), hydrogen (H), sulfur (S), oxygen (O), nitrogen (N), and ashes (A) in the dry biomass and h_{lv} is the enthalpy of evaporation of water at standard conditions (2442.3 kJ/kg).

Finally, the biomass higher heating value (HHV, MJ/kg) is estimated based on the correlations reported by Parikh et al. [42] in Eq. 8

$$HHV = 0.3536\text{FC} + 0.1559\text{VM} - 0.0078\text{ASH} \quad (8)$$

where FC (%dry basis) is the fixed carbon, and VM is the volatile matter (%dry basis) ASH (%dry basis). The lower heating, high heating, and chemical exergy of biomasses are shown in Table 5.

Table 5: Calculated lower heating value (LHV) and specific chemical exergy value (b^{CH}) for selected materials and fuels streams.

Biomass	HHV (MJ/kg)	LHV (MJ/kg)	b^{CH} (MJ/kg)
Sugar cane bagasse	16.89	15.25	19.50
Sewage sludge	20.28	18.12	16.13
sugar cane waste	16.43	14.89	19.28

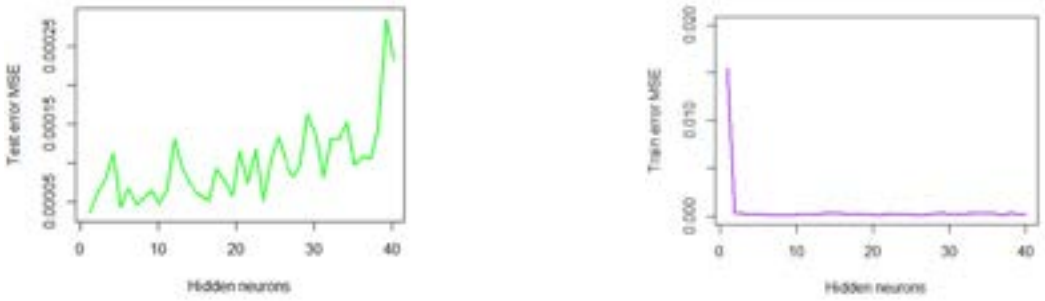
eucalyptus waste	17.19	15.54	21.75
MSW	18.92	17.08	18.32
Orange bagasse	16.79	15.20	20.26
Corn waste	17.87	16.13	19.93

3. Results and discussion

To determine the number of neurons in the hidden layer of the ANN, the data were divided into ten sets using the k-fold cross-validation technique. Each set was then used for training and testing purposes. The mean squared error (MSE) for the testing set was plotted against the number of neurons in the hidden layer (NH), as shown in Fig. 3a. The graph indicates that the MSE value drops to its lowest point at NH = 4 before rising and oscillating, which could be due to overfitting.

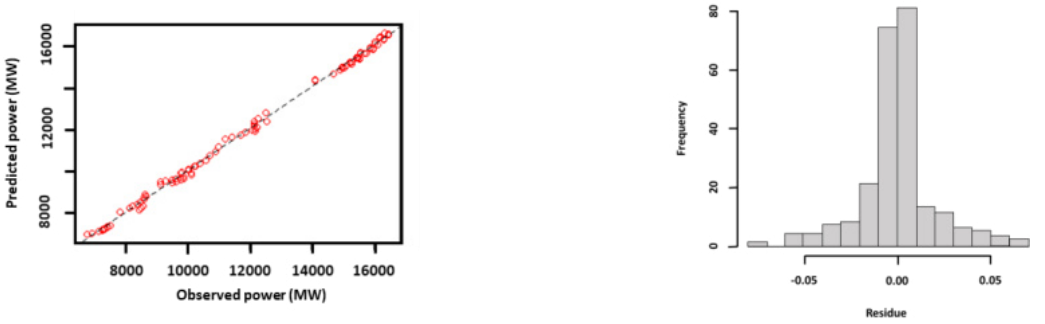
Based on the prediction graphs, it was decided that four neurons were sufficient for the ANN hidden layer without compromising the system representation performance. It should be noted that the MSE value for the training set (Fig. 3b) tends to decrease as more neurons and parameters are added to the model, resulting in model overestimation.



(a) (b)

Figure 3. Mean squared error versus the number of neurons in the hidden layer (a) for the testing set and (b) for the training set.

The training procedure converged after 3309 steps, resulting in an error of 0.04368 for the ANN weights. The accuracy of the ANN model for the training set can be seen in Fig. 4a, which shows an excellent match to the data, as indicated by the high R^2 value of 0.996. The mean square error (MSE) between the observed and projected values was 0.000366. The training set consisted of 80% of the overall dataset, and these data were used to estimate the ANN weights, explaining the good values for R^2 and MSE. Moreover, the residues histogram (Fig. 4b) displayed typical behaviour with an average of roughly zero, further confirming the high agreement between the observed and predicted values.



(a) (b)

Figure 4. (a) Comparison between prediction and observed power conversion values for the training set (b) Histogram of residues for the training set.

Fig. 5a demonstrates that the ANN model was validated using the test set. The results indicate that the network can accurately predict data not used in weight estimation, with an R2 value of 0.994 and an MSE of 0.00909. While these metrics are slightly worse than those obtained from the training set, they still reflect a highly credible performance. The corresponding histogram of residuals for this validation, as shown in Fig. 5b, reveals a more significant normal distribution with a less frequent zero-centred average compared to the training set, further corroborating the accuracy of these results.

(a) (b)

Figure 5. (a) Comparison between prediction and observed power conversion values for the testing set (b) Histogram of residues for the testing set.

The results presented in Fig. 6 are based on the entire dataset. A residuals histogram displaying a standard shape and an R^2 value of 0.993 and MSE of 0.00172, indicating a good match between predicted and observed values without any noticeable bias in the fit. These performance metrics lie between those obtained from the training and testing sets but are closer to the former, given that the training set contained 80% of the total data and was used to estimate the ANN parameters. Overall, the ANN model exhibits good predictive ability across the entire dataset.

To investigate the gasification unit's performance with different fuels, the reactor's initial biomass mass flow rate (26,640kg/h), temperature (850°C), s/b ratio (0.5), and operating pressure were kept constant. The quality of the produced synthesis gas for each fuel was then compared by examining the quantity of its main constituents: H_2, H_2O, CO, and CH_4. Fig. 7 displays the mole fraction of hydrogen and carbon monoxide, the two primary syngas components, in the gasifier's output stream for each fuel. The results reveal that corn waste and sewage sludge produce a high amount of hydrogen but a low mole fraction of carbon monoxide compared to the other biomass fuels.

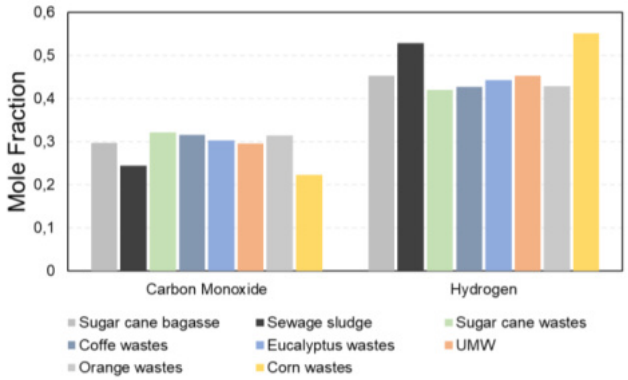

Figure 7 Comparison of syngas quality by the mole fraction of hydrogen and carbon monoxide.

Fig. 8 provides valuable insight into the net power production of different waste materials after the gasification process. The graphic shows that eucalyptus waste, sewage sludge, and sugar cane bagasse have the highest power production potential in the gas turbine section, with 15.86 MW, 15.06 MW, and 14.73 MW, respectively.

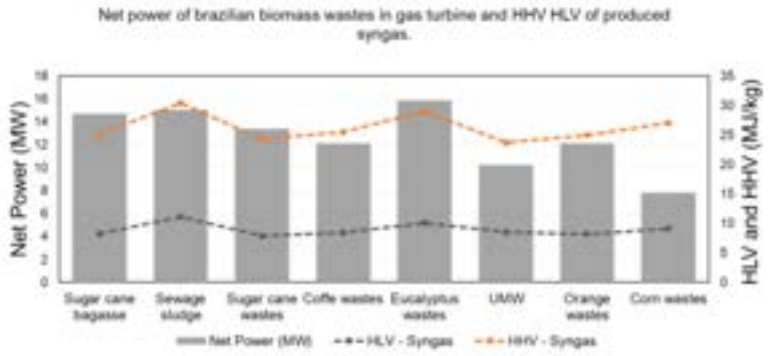

Figure 8. Net power of Brazilian biomass wastes in combined cycle and HHV and LHV of produced syngas

This highlights the importance of utilizing these waste materials as potential energy sources, which can generate significant amounts of power. Additionally, Fig. 8 suggests that the higher the HHV (Higher Heating Value) and LHV (Lower Heating Value) of the produced syngas, the greater the power output from the gas turbine. This underscores the importance of selecting appropriate waste materials for gasification, as those with higher HHV and HLV values can provide greater energy yield and efficiency. Moreover, it is crucial to note that using waste materials for energy production can positively impact the environment by reducing greenhouse gas emissions and mitigating the negative impacts of waste disposal.

Based on the information provided in Fig. 9, It can observe that urban municipal waste has the highest cold gas efficiency (82.21%) among all waste materials studied. This indicates that a significant proportion of the energy content of the waste

material is converted into syngas during the gasification process. On the other hand, sugar cane bagasse exhibits the highest carbon conversion efficiency (92.88%), indicating that most of the carbon content in the waste material is converted into syngas during gasification.

It is important to note that cold gas efficiency (CGE) is affected by various factors, such as the HHV and mass flow rate of waste and syngas. As depicted in Fig. 9, there is a positive correlation between the HHV of syngas and CGE, implying that waste materials with higher HHV values can result in more efficient gasification processes. However, it is also worth mentioning that coffee waste has the lowest cold gas (61.88%) and carbon conversion (72.35%) efficiencies among the waste materials studied. This highlights the need to carefully consider the waste material selection for gasification to ensure optimal efficiency and energy yield.

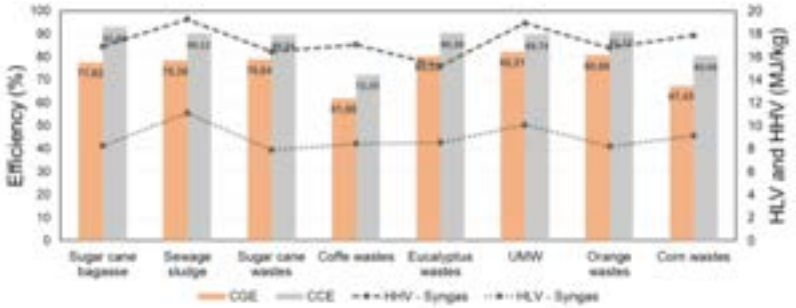

Figure 9: LHV and HHV of syngas, cold gas efficiency (CGE), and carbon conversion efficiency (CCE) of Brazilian biomass wastes in the gasification process.

Figure 10 presents a more detailed view of the destroyed exergy, considering each residual biomasses' leading equipment and processes. Thus, when analyzing these data, it can be noted that the gasifier and the combustor of the combined cycle contribute the largest share of the destruction compared to all biomasses. In addition, it is worth remembering that the syngas' grinding, drying, scrubbing, and compression are also processed internally by the gasification unit. However, compared to the gasification process, they present a small share in the contribution of the exergy destruction of the unit. In addition, it is worth citing the works of Florez-Orrego et al. [18], where the gasification of sugarcane bagasse was studied, and Domingos et al. [19], studying black liquor, obtained similar results.

Observing only the gasifier for the different waste biomasses, the process representing the highest exergy destruction was via RMU, with 68.79%, followed by coffee waste and orange bagasse, with 67.53% and 65.78%, respectively. On the other hand, gasification via sugarcane bagasse had the lowest exergy destruction rate, approximately 58.61%. Also, the combustion process of the combined cycle corresponds to a variation of 22.95% to 30.63% of the exergy destroyed by the entire power conversion process. In other words, exergy destruction in the gasifier is caused by the reactions that decompose the large biomolecules into smaller gas molecules presenting the most considerable exergy destruction compared with combustor burning only syngas.Another essential point to be highlighted is the compression systems, which present intermediate values of exergy destruction. These systems are divided into 3 parts: compression of syngas typical to all conversion plants, air compression of the gas cycle, and pump for the Rankine cycle. The highest proportion of exergy destruction was located in the sewage sludge (2.78%). This happened because the flow rate of syngas after the gasifier is the biggest one compared with other biomasses.

A way to help reduce the amount of exergy destroyed in biomass-based production plants is to employ better technologies to remove the bagasse moisture, hot catalytic cleaning of the syngas, and increase gasifier pressure [43].

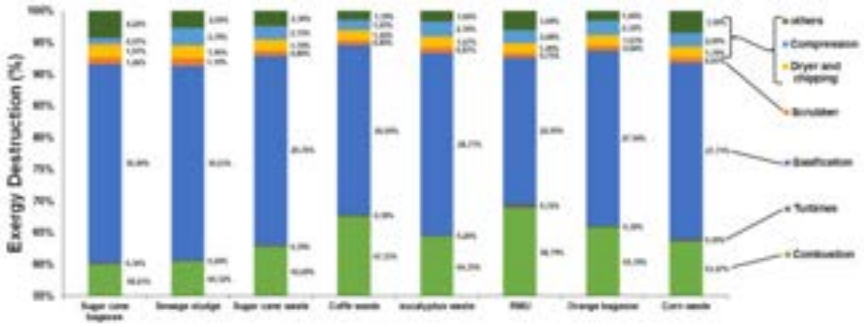

Figure 10: Exergy destroyed by equipment or conversion processes for different biomass waste selected types.

Fig. 11 presents the calculated plantwide efficiencies for different waste materials, revealing that the relative exergy efficiencies ranged from 24.42% for sugar cane straw waste to 42.57% for sugar cane bagasse. Similarly, the rational exergy efficiencies ranged from 23.71% for coffee waste to 39.09% for sugar cane bagasse. These results highlight the significant variability in the energy efficiency of different waste materials. However, it is worth noting that the performance of different biomasses was impaired, likely due to differences in the proximate and ultimate analysis of the waste materials.

Factors such as moisture content and volatile materials can significantly affect the gasification process, leading to variations in energy efficiency. Therefore, it is essential to thoroughly analyse the waste materials before selecting them for gasification to ensure optimal performance and energy yield. By understanding the composition of the waste materials strategies can be developed to optimize the gasification process and improve the energy efficiency of the overall plant.

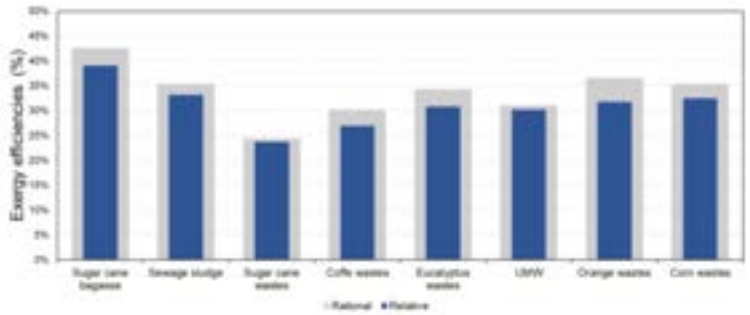

Figure 11. Comparison between the exergy efficiencies of conversion processes for different types of selected biomass.

4. Conclusions

The current research aimed to develop a predictive model using artificial neural networks (ANNs) to analyze the performance indicators of a green electric energy generation process based on the gasification of Brazilian biomass residues. The results indicated that the highest cold gas and carbon conversion efficiencies were achieved using urban municipal waste and sugar cane bagasse with 82.1% and 92.89%, respectively. On the other hand, coffee waste had a relatively low carbon conversion efficiency of about 72.35%, with cold gas efficiency of 61.88%. Eucalyptus waste was found to have the highest renewable power capacity, with 12.86 MW. The relative and rational exergy efficiencies were determined for different waste types, ranging from 24.42% to 42.57% for sugar cane straw waste and sugar cane bagasse, respectively, and from 23.71% to 39.09% for coffee waste and sugar cane bagasse. Furthermore, the study demonstrated the effective use of environmental resources by mapping the exergy destruction reaction to produce a clean and valuable energy source. The study's findings provide important insights into the sustainable utilization of environmental resources by mapping exergy destruction reactions for producing a clean and valuable energy source. These outcomes can be used to guide future research and improve the performance of similar models. However, further studies are necessary to enhance the robustness of ANN models in predicting power generation. More research should be reported in the literature to develop more reliable models. It is worth noting that the ANN model developed in this study exhibited high accuracy in predicting power generation, with R^2 values greater than 0.993 for both training and test datasets. Finally, using neural networks and Aspen Plus models provides a viable solution to improve power generation predictions and reduce computational costs. Applying these methods in this study demonstrates the potential of waste-to-energy systems to generate renewable electricity from waste biomass, promoting a more sustainable energy future.

Abstract:

A Radiative Collector and Emitter (RCE) is a device which combines solar collection and radiative cooling functionalities to provide both heat and cold from renewable sources. In solar collection mode, fluids are heated up using the incoming solar radiation. In radiative cooling mode, it takes advantage of the atmospheric window transparency to dissipate infrared radiation towards the outer space at nights, allowing to cool down fluids circulating through it. However, the heat production of the RCE is about 10 times higher than the cold production, and the cold water can only be produced a few degrees below ambient temperature (4-8 ºC). An evolution of the RCE, the adaptive RCE (ad-RCE) is capable to adapt its behaviour to the energy requirements, producing either heat or cold during daytime, as well as cold during night-time. To further enhance the cooling potential, we suggest coupling the ad-RCE with a compression heat pump (HP) that utilizes the cold produced by the ad-RCE as a heat sink for the condenser. In this study, we numerically estimate the performance of a water-to-water compression heat pump coupled with an ad-RCE. Our results indicate a yearly average improvement of the coefficient of performance (COP) of 3.89%, which translates to an annual electricity savings of 3.70%.

Keywords:
radiative cooling, solar thermal collection, adaptive energy production, renewable energy, heat-pump, COP.

1. Introduction

The building sector is considered to have a significant impact on energy consumption, with estimates indicating that it accounts for 40% of final energy consumption in Europe and generates 36% of CO_2 emissions [1]. Space conditioning, including DHW, cooling, and heating, constitutes the largest share of 80% of the total energy consumption in buildings. This trend is expected to continue, with rising global temperatures and heat waves leading to increase the energy consumption for refrigeration in households. Unfortunately, this will contribute to a vicious cycle of CO_2 emissions, further exacerbating the problem.

While renewable energies have become more important in recent years, cooling comfort is still achieved through electricity consumption [1]. However, new technologies based on radiative cooling have emerged in recent years, enabling the production of cold in a renewable way [2–4]. Radiative cooling (RC) is the process by which terrestrial bodies reduce their surface temperature by emitting infrared radiation towards outer space, taking advantage of the transparency of the infrared atmospheric window at certain wavelengths (7-14 μm). The low effective temperature of the space makes it possible to cool down below ambient temperature [5]. At the beginning, it was only possible to achieve RC during the night, in absence of solar radiation. New materials, called Daytime Radiative Cooling (DRC) materials, have been developed in the last decade, which enable the achievement of RC during daytime hours [6–11]. These materials reflect most of the incident solar radiation [10–12], thus the surface is able to cool down. This phenomenon, which is known as all-day radiative cooling, has been achieved using low-cost materials in recent years [13, 14].

Radiative coolers present low cooling rates, between 20 and 80 W/m^2 with peak values of 120 W/m^2 [15], which represent an order of magnitude lower than those that can be achieved in solar heating, representing a limitation of this type of technology. In order to make the technology attractive to markets, Vall et al. [15]

introduced the Radiative Collector and Emitter (RCE) as a novel technology that integrates, in a single device, solar collection and radiative cooling to produce both heat and cold through renewable means. The RCE operates by circulating a heat transfer fluid through pipes that are in contact with a radiative surface. During the day, the radiative surface heats up and transfers heat to the fluid. At night, the heat from the fluid is transmitted back to the radiative surface and radiated away. By using this technology, the dependence on fossil fuels can be greatly reduced, leading to a smaller carbon footprint.

The integration of radiative cooling systems with the built environment is still a field under study. One of the proposal is that the low power rates of cold generated in the RCE can be used to improve the performance of a water-water heat pump by increasing its coefficient of performance (COP), thereby decreasing electricity consumption. Goldstein et al [16] showed electricity savings up to 21% in an office building when a heat pump was combined with radiative cooling. In 2023, Vilà et al. [17] presented a study that simulated different configurations of RCE coupled with heat pumps, where the RCE produced cold during the night in combination with the heat pump, while during the day the RCE was decoupled and used to produce DHW independently by means of solar heating. The study examined various cities and climates and found an improvement in the system performance. However, the hot water production during solar heating mode far exceeded the domestic hot water (DHW) demand.

To minimize the underutilization of the solar collection mode while increasing the production of cold water, we propose an evolution of the RCE, the adaptive RCE (ad-RCE). The RCE takes advantage of the above-mentioned DRC materials to modify its behaviour to produce hot or cold water during the day and cold water during the night, as required. By reducing the solar heating mode to 1 or 2 hours, the ad-RCE can optimize cold production during the day.

This study builds upon the previous research conducted by Vilà et al. by implementing the advanced version ad-RCE. The aim of this study is to present a preliminary evaluation of the improvement of the COP of a water-water heat pump coupled with an ad-RCE in the condenser's side. In this study, we evaluate the performance of the combined system ad-RCE+HP integrated in a hotel in Brisbane (Australia) to cover the cold and DHW requirements of the building. The results are compared with a reference case of a conventional heat pump, and the potential energy savings are discussed.

2. Methodology

2.1. Description of the configurations

2.1.1. Studied case: ad-RCE+HP

An ad-RCE was coupled to the condenser of a water-to-water compression heat pump (**Figure *1***). The proposed configuration consisted of two modes of operation. In the first mode, the radiative cooling mode, the heat transfer fluid was initially pre-cooled through an air-water heat exchanger where its temperature decreases close to ambient temperature. The fluid was then circulated through the ad-RCE circuit, where it was further cooled, and finally, it was used as the condenser heat sink. In the second mode of operation, the heating mode, the ad-RCE field was disconnected from the heat pump. During the day, the heat transfer fluid was circulated through the ad-RCE field, heating up the fluid, and directly supplying the DHW demand.

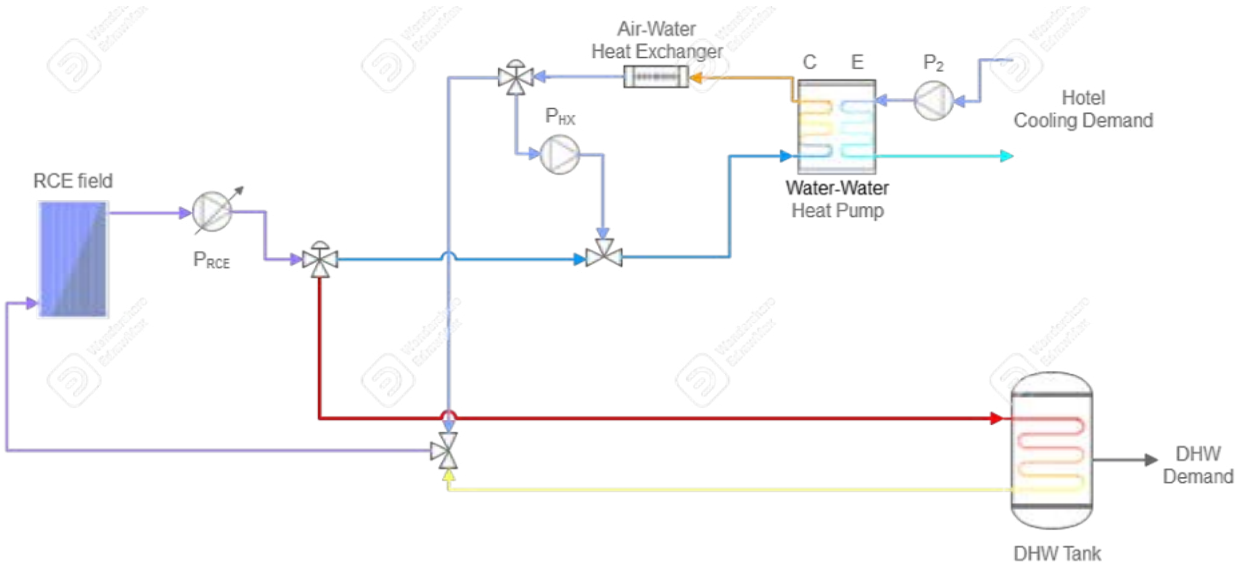

Figure 1. Conceptual scheme of the proposed configuration of an ad-RCE field with a water-to-water heat pump.

2.1.2. Reference case: water-to-water heat pump

The conventional cooling circuit, which employs a water-to-water heat pump, was used as the reference case to assess the improvement provided by the ad-RCE (**Figure 2**). The condenser side comprised a closed circuit with a single speed pump and an air-water heat exchanger. The heat transfer fluid was cooled down to temperatures close to ambient in the heat exchanger (5 ºC above the ambient), releasing the heat of condensation in the heat pump to the surrounding air.

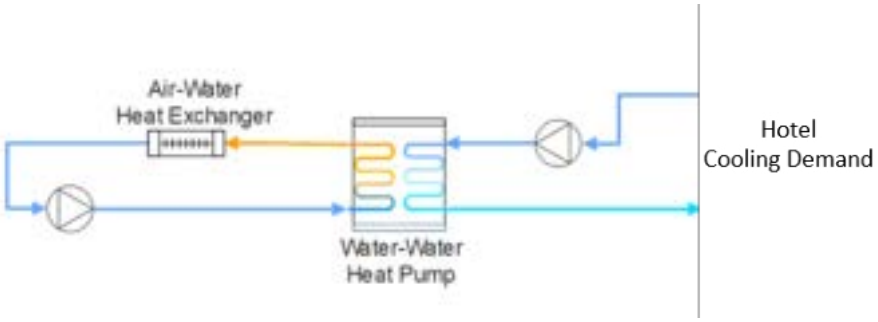

Figure 2. Conceptual scheme of the reference case of conventional water-to-water heat pump.

2.2. Building Load Demands and simulation condition

The studied facilities were designed to meet the load demand for cooling and DHW of a small hotel located in Brisbane (Australia). To determine the energy demands, numerical simulations were conducted using EnergyPlus software [33]. The building models used in the simulation were adapted from those published by the US Department of Energy (DOE). The small hotel consisted of a rectangular floor plant spanning 4 floors, with a net conditioning area of 4,013.6 m^2 and a roof area equivalent to 1,003.4 m^2 (**Figure *3***). The hotel's facades were oriented towards each of the four cardinal points, and the set point temperature was set at 25 ºC. Brisbane's climate is classified as Cfa in the Koppen-Geigger classification, which is characterized by relatively high temperatures and evenly distributed precipitation throughout the year.

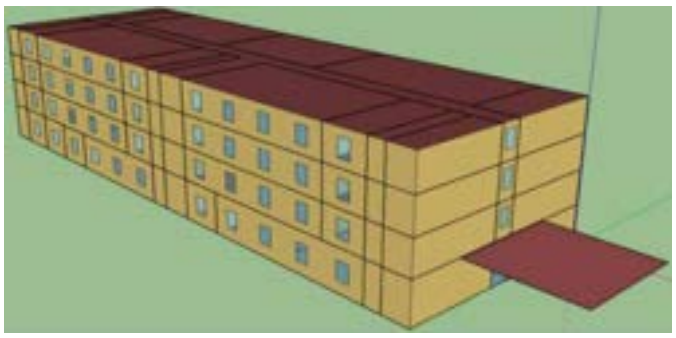

Figure 3. Small hotel simulated in EnergyPlus.

Prior to evaluate the integration of the heat pump system, an extensive energy analysis was conducted through a year-long numerical simulation to assess the building's energy requirements. Results were organized on a monthly basis. As shown in **Figure *4***, the cooling demand greatly surpasses the DHW demand in almost all the months, except for the months of June, July, and August in Brisbane, which is worth noting that are the winter months in Australia. January, December, and February have peak values of cooling demand, exceeding 30,000 kWh. In contrast, the DHW demand remained barely constant throughout the year, with an average of around 10,000 kWh per month. This finding emphasizes the importance of focusing on cooling demand in the design and implementation of the system.

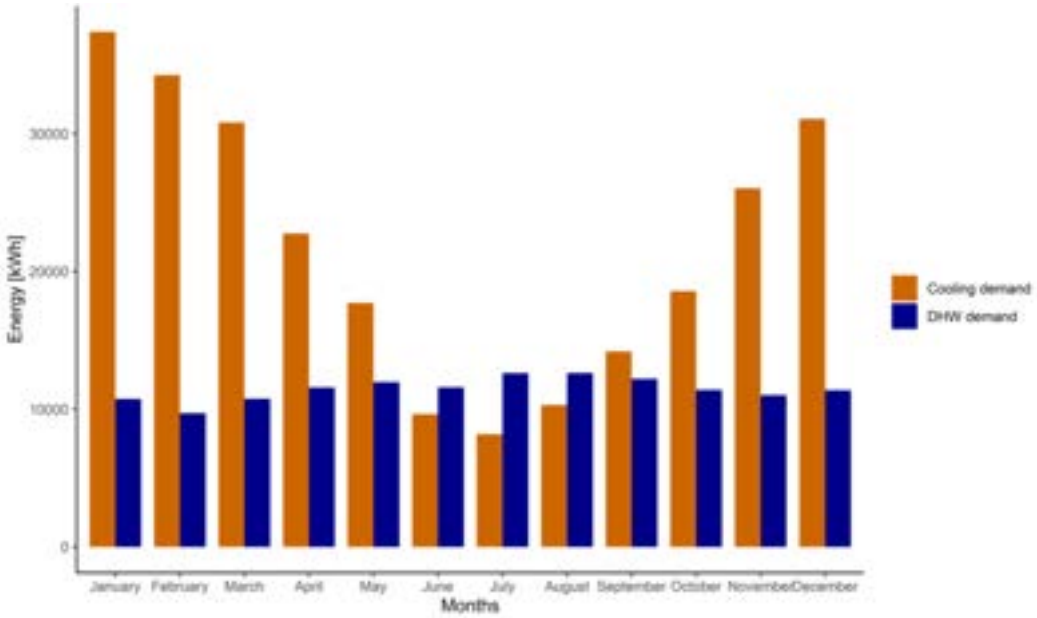

Figure 4. Yearly energy loads (cooling and DHW) in a small hotel in Brisbane.

2.3. Sizing

In the present study, an ad-RCE was considered which could switch its optical properties perfectly between each of the two modes. During the solar heating mode, the devices absorbed the totality of the incoming solar radiation while blocking the long-infrared radiation. During the radiative cooling mode, the device was able to reflect the totality of the incoming solar radiation, while perfectly emitting in the 7-14 μm range (atmospheric window). For the calculations, the following assumptions were also made:

- A steady-state model was used.
- The efficiency of the ad-RCE accounted for the conductive and convective losses.
- The tilt angle for the ad-RCE was assumed horizontal, maximizing the cold production.

The number of ad-RCE installed on the horizontal roof was determined by the required water flowrate for the case when the maximum cooling was demanded. 349 ad-RCE were used which corresponded to a total surface (A) of 698 m^2, representing 69.5% of the total roof area. All the months produced the required DHW from 11 a.m. to 12 a.m., except from April to September, when an additional hour was added (from 11 a.m. to 13 a.m.); the remaining hours were dedicated to radiative cooling mode.

The heat pump was sized so that its evaporator could match the peak value of the year demand, which corresponded to 93.9 kW. The flowrate for the RC mode was set to 5.84 kg·s^{-1}, while a lower flowrate of 4.17 kg/s was set for the solar heating mode. As both modes had different design parameters, the different flowrates were represented by a variable speed pump in the diagram.

2.4. Heating Mode

To determine the DHW production, the hourly Global Horizontal Irradiance (GHI) data was used along with the efficiency of the ad-RCE in solar collection mode, which is calculated using Eq. 1. This method of calculating solar collector efficiency is widely accepted and it takes into account various inefficiencies of the system, including optical and thermal losses. In line with previous research [15], an annual average efficiency η_{sc} of 0.6 was used in the calculations.

$$P_{solar,net}\left[\frac{W}{m^2}\right] = GHI \cdot \eta_{sc} \quad (1)$$

Once the average thermal power for each hour of the year was calculated, the next step was to determine the amount of energy produced. This was done by multiplying the average thermal power by the time step of 1 hour. To calculate the daily DHW production, the values obtained for each hour of the day were integrated over the course of a day. This allowed for a more accurate determination of the DHW production on a daily basis. The monthly production was then calculated by integrating the daily production values for a month. The formula used to calculate monthly production is presented in Eq. 2.

$$E_{solar,month}\left[\frac{Wh}{month}\right] = A \cdot \sum_{month} P_{solar,net} \cdot \Delta t \quad (2)$$

2.5. Cooling Mode

The maximum achievable RC power was determined using Eq. 3, which takes into account the infrared atmospheric radiation (Q_{atm}) and the absorbed radiation from the Sun (Q_{sun}) - both available in the weather data file- the radiation emitted on the surface of the ad-RCE (Q_s) – expressed in Eq.4., and the conductive and convective heat transfer. The approximation was made that the conductive and convective transfer were included in the efficiency parameter of the ad-RCE and therefore were assumed to be zero in Eq. 3. To determine the useful cooling power (Eq. 5), an efficiency of 60% was used.

$$Q_{net}[W] = [Q_s(T_s) - Q_{atm}(T_{atm}) - Q_{sun}(T_{sun}) - Q_{cond} - Q_{conv}] \cdot A \quad (3)$$

$$Q_s\left[\frac{W}{m^2}\right] = \varepsilon_s \sigma T^4 \quad (4)$$

$$P_{RC,net}[W] = Q_{net} \cdot \eta_{RC} \quad (5)$$

The temperature at the outlet of the ad-RCE (T_{out}) was calculated with the Eq. 6, where T_{in} represents the inlet temperature, $\dot{m}_{in}$ is the inlet flowrate and C_p is the water specific heat. The temperature at the inlet (T_{in}) was assumed to be equal to the pre-cooled temperature in the heat exchanger, which was set 5 ºC above the ambient temperature.

$$T_{out}[°C] = T_{in} - \frac{P_{RC,net}}{\dot{m}_{in} \cdot C_p} \quad (6)$$

A correlation was developed to model the performance of a water-to-water heat pump in TRNSYS. The correlation, expressed in Eq. 7, calculates the coefficient of performance (COP) of the heat pump as a function of the inlet temperature of the condenser (T_{cond}), assuming a constant evaporator temperature of 12 ºC.

$$COP = 7.45 - 0.116 \cdot T_{cond} - 0.00234 \cdot T_{cond}^2 + 0.0000852 \cdot T_{cond}^3 - 6.67 \cdot 10^{-7} \cdot T_{cond}^4 \quad (7)$$

The *COP* was calculated, for each time-step, both for the reference configuration and the ad-RCE+HP configuration. In the ad-RCE+HP configuration T_{cond} was set to be the same temperature as the outlet of the RCE (T_{out}). In the reference case, T_{cond} was assumed to be equal to the temperature at the outlet of the heat exchanger (5 ºC above the ambient temperature). The electrical energy of the compressor (E_{comp}) was determined using the energy supplied by the evaporator (E_{evap}, cooling demand) and the COP (Eq. 8).

$$E_{comp}[Wh] = \frac{E_{evap}}{COP} \quad (8)$$

3. Results and discussion

3.1. Heating Analysis

In **Figure *5***, the DHW production from the ad-RCE and the DHW demand of a small hotel are presented. As mentioned earlier, the DHW production is limited to two hours per day from April to September and one hour per day during the remaining months. On average, the system can produce 12,233 kWh of DHW per month. From April to September, the DHW production from the ad-RCE is higher than the hotel's demand. During the rest of the year, although the demand exceeds the potential production, the system has been sized to ensure a coverage of at least 80% of the demand, with actual coverage ranging from 85.25% to 95.52%.

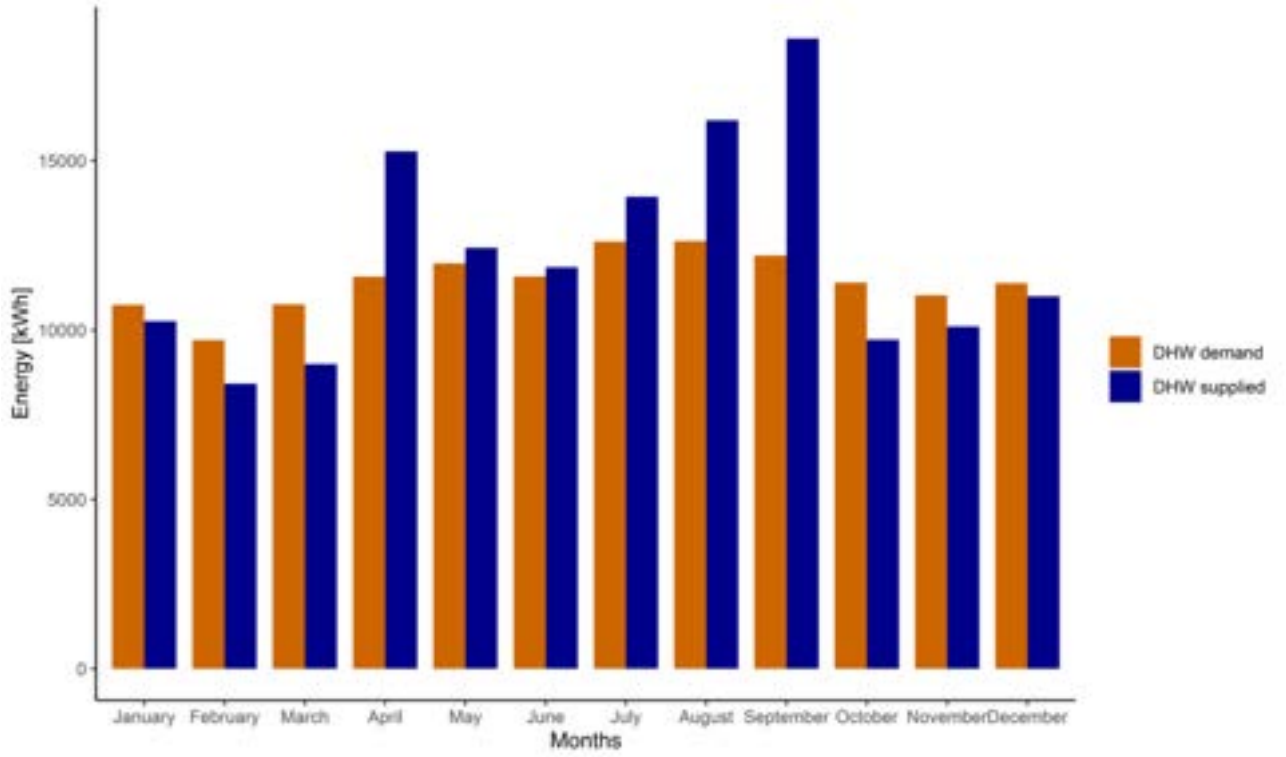

Figure 5. DHW energy loads in a small hotel in Brisbane and DHW produced in the ad-RCE.

3.2. Cooling Analysis

Through the implementation of radiative cooling, the average reduction in the temperature at the condenser inlet of the heat pump is found to be 1.4 ºC. The highest decrease is recorded in June with a value of 1.49 ºC, while the lowest reduction is observed in May, with a value of 1.31 ºC. A graphical representation of the monthly average temperature decrease at the condenser inlet is presented in **Figure *6***.

Additionally, the integration of the ad-RCE system with the heat pump leads to an increase in the yearly average coefficient of performance (COP) from 4.15 to 4.42 (**Figure *7***). The greatest improvements are observed during the winter months in Brisbane (**Figure *6.*** Temperature difference between inlet and outlet temperature in the ad-RCE over a year (orange) and improvement of the COP in the new configuration (blue). Cooling of water by more than 1.3 ºC is achieved in all the months.). The average increase in performance is 3.89%, with relatively constant values throughout the year ranging from 3.64% to 4.10%, as demonstrated in **Figure 6**.

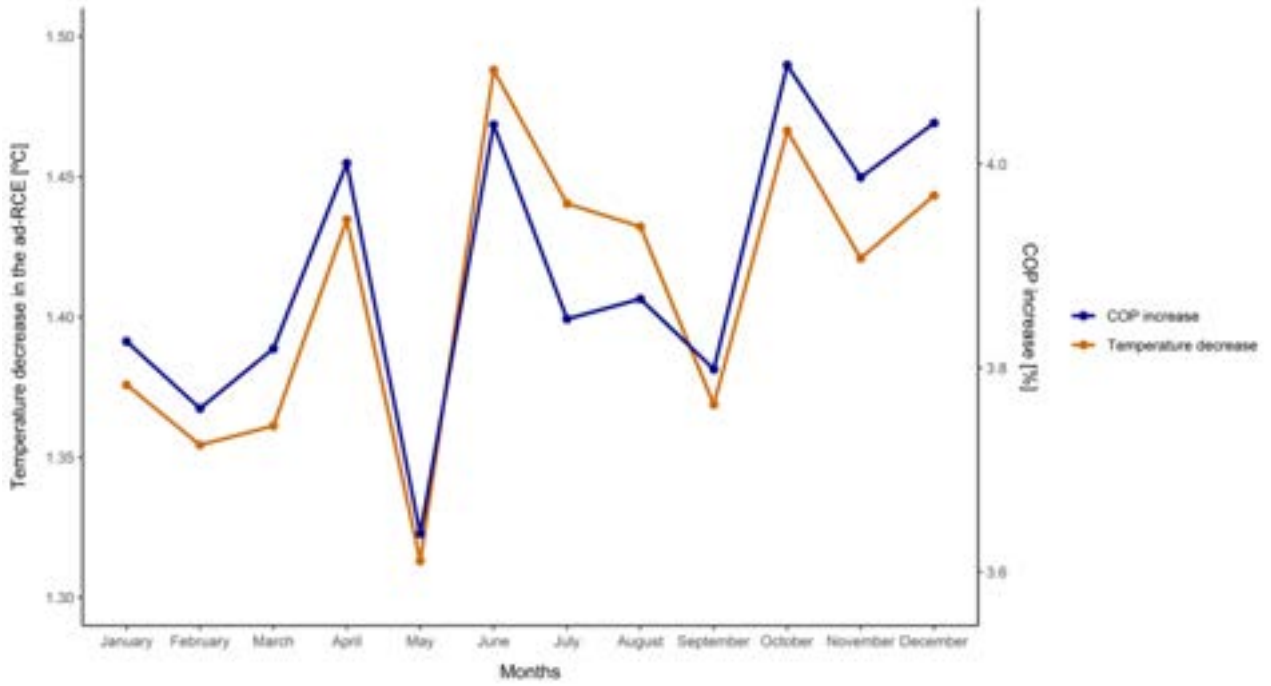

Figure 6. Temperature difference between inlet and outlet temperature in the ad-RCE over a year (orange) and improvement of the COP in the new configuration (blue). Cooling of water by more than 1.3 ºC is achieved in all the months.

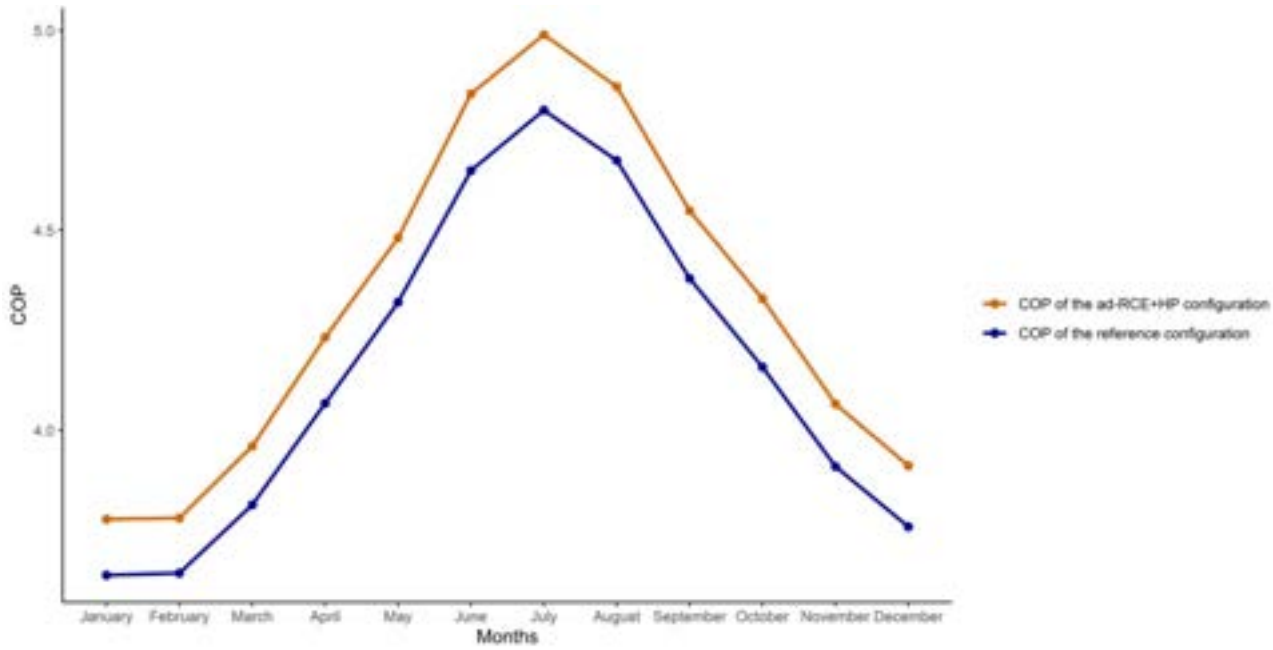

Figure 7. Evolution of the COP of the reference configuration and the studied configuration.

The integration of the ad-RCE with the heat pump system resulted in estimated total electricity savings of 2,533.3 kWh per year, which represents a reduction of 3.7%, the greatest savings are found during the summer months in Brisbane (**Figure *8***). This finding is consistent with literature reports which suggest that electricity consumption of a heat pump is reduced by approximately 3.5% for every degree Celsius reduction in the condenser's temperature [18]. In our study, the average reduction in the inlet temperature achieved with the ad-RCE is 1.4 ºC, resulting in a slightly lower condenser temperature. The monthly energy savings remained relatively constant throughout the year, ranging between 3.34% and 3.92%, which could contribute to a decrease in fossil fuel dependency of the system.

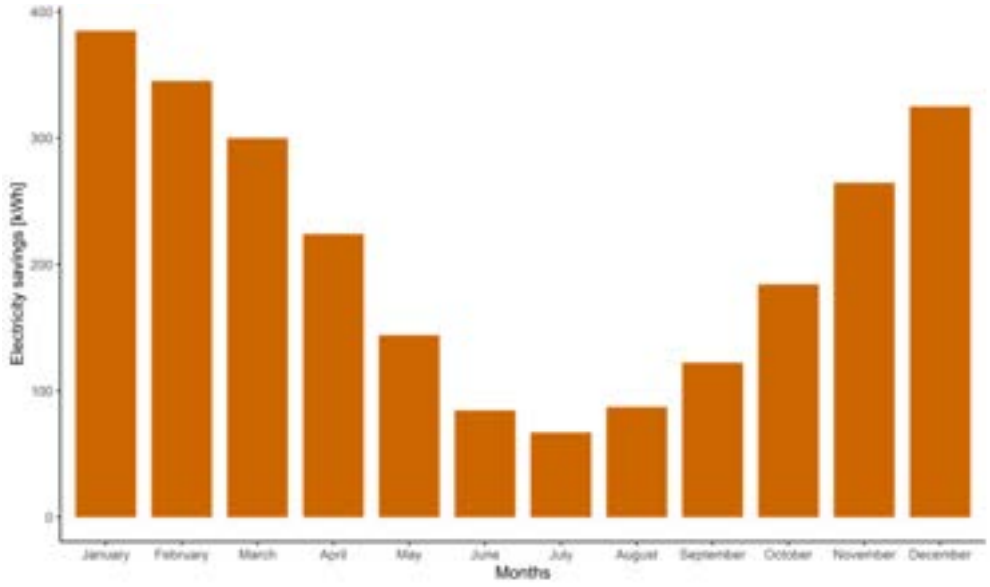

Figure 8. Electricity savings in the ad-RCE+HP configuration.

These results are preliminary estimates, and future work involves developing a validated ad-RCE model, similar to the RCE model previously developed [19] – and implementing effective control strategies to maximize energy savings. Additionally, a promising approach to improve energy savings would be to develop an efficient control system that anticipates the energy demand and operates the ad-RCE during optimal radiative cooling conditions. Another potential strategy is to integrate storage tanks, such as sensible heat water tanks and latent heat phase change materials tanks, to store the cold produced by the ad-RCE during favourable radiative cooling periods for later use during less favourable weather conditions. These strategies will be investigated in detail in the following stages of our research.

4. Conclusions

In this paper, we present a numerical analysis of the performance improvement of a water-to-water compression heat pump when combined with an adaptive Radiative Collector and Emitter (ad-RCE). The ad-RCE is an advancement of the Radiative Collector and Emitter (RCE), a device capable of producing hot water by solar thermal collection during the day and cold water by radiative cooling at night. The ad-RCE is a redesigned version of the RCE that offers users the option of selecting either daytime radiative cooling mode or solar collection mode, depending on the daily energy demands. By coupling the heat pump with the ad-RCE, higher COPs can be achieved compared to conventional heat pump reference systems. Our results demonstrate an average yearly COP improvement of 3.89% in a small hotel in Brisbane (Australia), leading to annual electricity savings of 3.70%.

Abstract:

The building sector is one of the main consumers of energy, being the heating and cooling, as well as the Domestic Hot Water (DHW), the highest demands. The Radiative Collector and Emitter (RCE) is a renewable technology capable of providing both heating and cooling in a single device. This innovative technology reduces the dependency on fossil fuels, as well as diminishes the carbon footprint. An evolution of the RCE, the adaptive RCE (ad-RCE), which allows night-time radiative cooling and either daytime solar collection or daytime radiative cooling is presented for a single-family house in Johannesburg, South Africa. This new concept is capable to adapt its behaviour to the energy requirements, producing either heat or cold during daytime, as well as cold during night-time. Thus, the production of heat and cold adapts to the demands of the building. By means of numerical simulation, the relation between cooling and Domestic Hot Water (DHW) demands are compared with the renewable energy produced by the ad-RCE to determine the suitability of such technology to cover the energy demands of buildings by means of renewable energy. Results show that with a proper decision on the number of hours in solar collection mode and the rest for daytime or night-time radiative cooling, the ad-RCE field could yield to annual coverages of the cooling demand of 83% and of 100% for the DHW.

Keywords:

Radiative cooling, solar thermal collection, adaptive energy production, renewable energy, energy demand, single-family house.

1. Introduction

In the European Union, 40% of the final energy consumption and 36% of the CO_2 emissions are associated to the building sector [1]. The Eurostat [2] concludes that space heating represents 64.1% of the total consumption in buildings, Domestic Hot Water (DHW) 14.8%, and space cooling 0.4%. Although space cooling is a small fraction in the total energy consumption of households, [3] predicts that refrigeration demands will triple worldwide by 2050 if no action is taken. Today, the operating refrigeration systems account for 18.5% of the world's electricity consumption [4]. Most current cooling systems run on compression cooling cycles, consuming a lot of electricity, especially in the summer heat peaks. Typically, space heating and domestic hot water is produced by natural gas in households, whereas space cooling is all achieved by electricity consumption [5]. Both natural gas and non-renewable electricity production, contributes negatively to climate change and an alternative renewable production of these energy needs should be fostered.

The Radiative Collector and Emitter (RCE) is a renewable technology capable of providing both heating and cooling in a single device [6]–[8]. This innovative technology reduces the dependency on fossil fuels, as well as diminishes the carbon footprint. It combines in a single device the ability of solar collection during the day and radiative cooling (RC) during the night. Solar thermal collectors are a mature and commercially implemented technology to produce hot water from renewable energy. They rely on exposing an absorber to solar radiation to heat up a fluid circulating through different internal pipes [9]. On the other hand, radiative coolers are not mature yet. RC is the process by which a surface reduces its temperature by emitting thermal radiation (long wave) into the deep space, taking advantage of the transparency of the infrared atmospheric window at certain wavelengths (7-14 μm). The low effective temperature of the space makes it possible to cool down below ambient temperature [10]. Initially, RC was only possible at night, since the energy balance during the day resulted in gains due to solar radiation, but with the appearance of new materials it is also possible to

cool a surface during the day by RC [11], [12]. Several papers have been published recently proposing different types of materials for daytime radiative cooling (DRC), such as nanoparticles, metamaterials, bio-inspired materials, photonic structures, and hierarchically porous polymers [15]. However, these new materials do not allow to take advantage of solar energy during the day.

Vall et. al [6] showed how the RCE device could be integrated in several residential and commercial building types and in various cities located in different Köppen-Geiger climate classification regions over the world, covering most of the DHW usage. However, with the RCE surface sized for this DHW coverage, the covered fraction of the cooling demands was modest, being below 25% in 10 of the 15 climates studied. Besides, a not realistic 100 % efficiency for the radiative cooling mode was applied in this maximum cooling potential study, so even less cooling production and less coverage is expected for a real RCE prototype. The production of cooling could be increased mainly with two different strategies. On the one hand, the RCE efficiency should be substantially enhanced, as the achieved experimental values in a RCE prototype are only in the order of 25%, with peaks of 32%. This means that most of the cooling power generated in the RCE emitter is not used to cool down the circulating water but cools down the surrounding air and surfaces. On the other hand, the above mentioned daytime radiative cooling materials could be exploited, generating cold water also during the day. In summertime, when cooling is more necessary, DRC could reach a three-fold increase of the number of cooling hours.

An evolution of the RCE, the adaptive RCE (ad-RCE), which allows night-time radiative cooling and either daytime solar collection or daytime radiative cooling is presented in this study for one of the cities and one of the buildings used in [6]: a single-family house in Johannesburg (Africa). This new concept is capable to adapt its behaviour to the energy requirements, producing either heat or cold during daytime, as well as cold during night-time. Hence, this new equipment, which is still under development, avoids over-sizing the installation while maintaining high levels of energy coverage.

In this study, both the feasibility of the ad-RCE and the improvement it offers, compared to its predecessor, (RCE) is analysed. With this objective, this work presents a simple methodology to estimate the minimum operating hours of solar heating mode needed to cover DHW demands and for determining the hourly, daily and monthly production of heat and cold with the ad-RCE. As expected, the increase of cooling hours within a day thanks to daytime RC predicts a significant raise in annual cooling coverage, reducing the dependency on traditional CO_2 emitting cooling and heating systems.

2. Evolving the concept of RCE to ad-RCE

Figure 1 shows the conceptual differences between the original Radiative Collector and Emitter (RCE), which produces cold water during the night by radiative cooling and hot water during the day by solar thermal collection (Figure 1, a), and the evolution to the adaptive RCE (Figure 1, b) with a new design capable of producing both solar heating and radiative cooling at daytime, together with night-time radiative cooling. Thus, during the day the user can decide to apply it to heat up water or cool it down, adapting to variable energy demands of the building. The RCE concept has already been demonstrated experimentally with a prototype [7] and a model has been validated [8], whereas the ad-RCE is still under development. We aim to develop and validate a new ad-RCE model and to design, build and test a new ad-RCE prototype in the following 2 years.

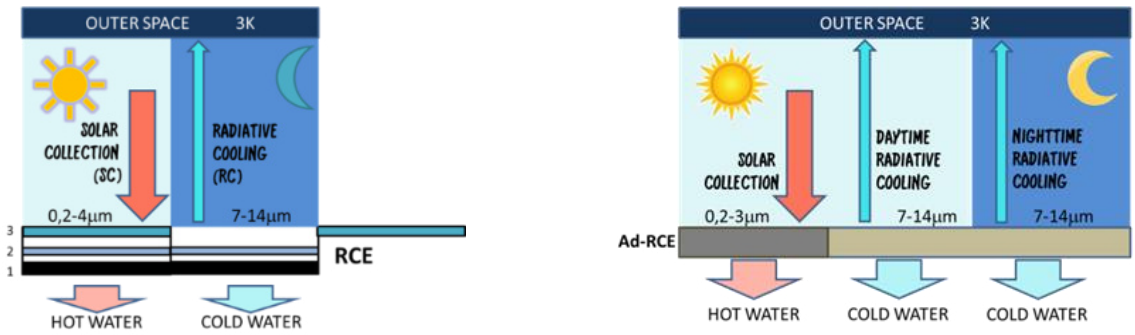

Figure. 1. Conceptual differences between the RCE (a) and the ad-RCE (b), which includes DRC.

3. Methodology

A simple steady state method was used to estimate the DHW and cooling production of the ad-RCE for a whole year in Johannesburg. The house energy demands were obtained from a whole-building energy simulation. Daily productions and demands were used to calculate the daily and monthly coverages of the ad-RCE.

3.1. Calculation of DHW and cooling building demands

Meteorological information for Johannesburg was obtained from the Meteonorm database [16], which corresponds with the radiation period 1991-2010 and the temperature period 2000-2009. The DHW and cooling demands for the simulated single-family house were obtained from the EnergyPlus building energy simulation software. The single-family house (Figure 2) is a template taken from the USA Department of Energy, DOE [17]. It consists of a two-floor, pitched gabled roof, detached house with a net conditioned area of 223.1 m^2. The original house model was modified to include additional active and passive strategies such as set point temperature schedules at 25ºC, summer night ventilation and overhangs. The same procedure as the presented in [6] was followed.

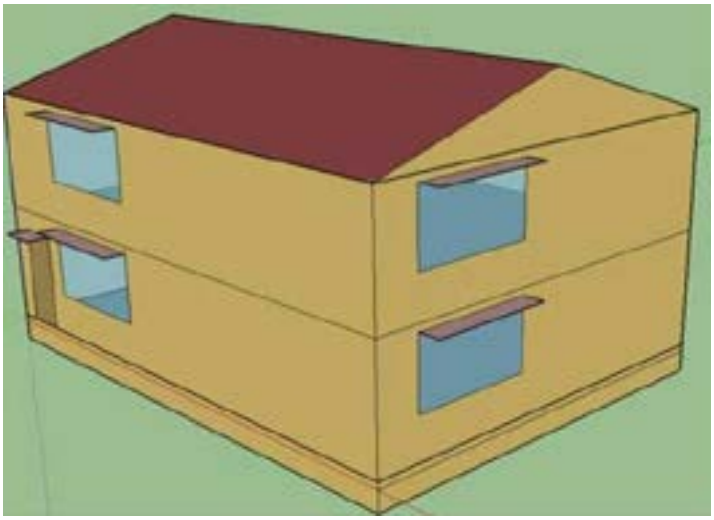

Figure. 2. Simulated single-family house in Johannesburg.

3.2. ad-RCE production

A very similar procedure to the one explained in [6] has been applied in this paper. A summary of the assumptions for the production of DHW and cooling, used both in [6] and in this work, is presented as follows:

- Steady state model.
- Conductive and convective losses are included in the ad-RCE efficiencies.
- Tilt angle for the ad-RCE is assumed horizontal, for maximum production of cooling.
- Wind-shield cover for solar collection mode with 100% transmittance in solar spectrum and 0% transmittance in the thermal spectrum is considered.

Contrary to the previous work, the daytime RC capability of the ad-RCE forces the wind-shield cover in DRC mode to have 100% reflectivity in solar spectrum and 100% transmittance in the thermal spectrum.

The DHW production thanks to solar collection was determined considering the hourly Global Horizontal Irradiance (GHI) given in the data file and the RCE efficiency in solar collection mode (Eq. 1). The solar collector efficiency is a common methodology and considers in a single parameter all the inefficiencies of the system (solar collector efficiency, losses due to inclination and shadows, etc.). The same annual average efficiency η_{sc} of 0.6 used in [6] was applied in this work for the solar collection calculations.

$$P_{solar,net}\left[\frac{W}{m^2}\right] = GHI \cdot \eta_{sc} \quad (1)$$

The average thermal power calculated for each hour of the year is then converted into energy produced simply multiplying by the time step (1 hour). The integration of these values along a day will determine the daily DHW production and along a month, the monthly production. Eq. 2 presents the calculation of this monthly production:

$$E_{solar,month}\left[\frac{Wh}{m^2 \cdot month}\right] = \sum_{month} P_{solar,net} \cdot \Delta t \quad (2)$$

The assumed efficiency for cooling production by daytime and night-time RC in the ad-RCE is also 60%. The justification for this value is that it is expected that the achieved 32% efficiency in the first prototype could be improved with better design that reduces the heat gains by conduction and convection to the emitter. This RC efficiency η_{RC} is defined as the cooling power achieved by the circulating water and the maximum cooling power achieved on the surface of the radiative cooler. This maximum cooling power can be calculated as an energy balance on the radiative surface, as presented in Eq. 3 and in Figure 3:

$$Q_{net} = Q_s(T_s) - Q_{atm}(T_{atm}) - Q_{sun}(T_{sun}) - Q_{cond} - Q_{conv} \quad (3)$$

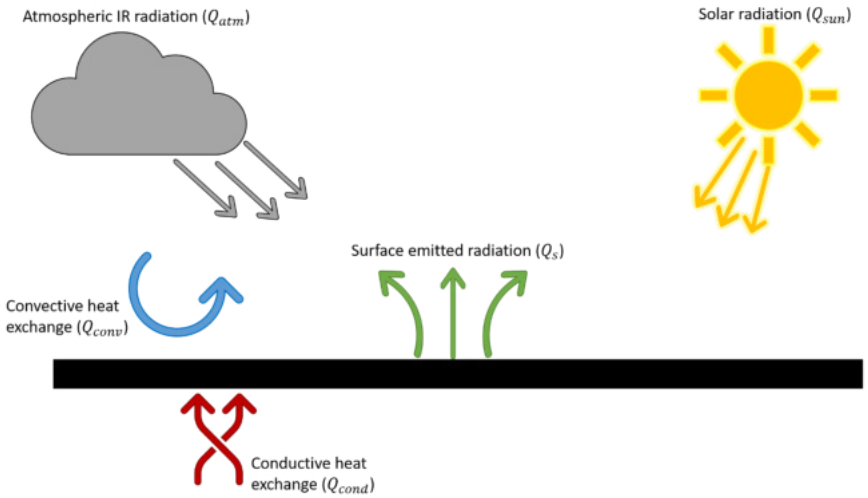

Figure. 3. Scheme of the thermal exchanges between the radiative surface (black) and its surroundings.

For this calculation, heat gains/losses by conduction Q_{cond} and convection Q_{conv}, are taken as 0. The infrared radiation coming down from the atmosphere Q_{atm} and the absorbed radiation from the Sun Q_{sun} are direct readings from the weather file, as the absorptivity of the surface is assumed equal to 1 in this study.

The amount of energy emitted from a surface with an average emissivity ε_s (in this study equal to 1) is given by Eq. 4.

$$Q_s = \varepsilon_s \sigma T^4 \quad (4)$$

Eq. 5 gives the useful cooling power given to the water, as the product of Q_{net} and the RC efficiency η_{RC}:

$$P_{RC,net}\left[\frac{W}{m^2}\right] = Q_{net} \cdot \eta_{RC} \quad (5)$$

The integration of the $P_{RC,net}$ values along a day will give us the daily cooling production and along a month, the monthly production. Eq. 6 presents the calculation of this monthly production:

$$E_{cool,month}\left[\frac{Wh}{m^2 \cdot month}\right] = \sum_{month} P_{RC,net} \cdot \Delta t \quad (6)$$

The energy coverage is calculated as the ratio between the cooling or heating energy produced in a day divided by the daily demand. If this ratio is over 1 (or 100% in percentage), we take a coverage percentage of 100% for that day. When there is an excess of daily energy production, this excess is lost; it is not used in the following days. The monthly coverage is the average of the daily coverage. Note that this simplified approach, without considering energy storage tanks, is underestimating the potential maximum coverage. So, we are on the safe side of the coverage predictions. A correctly designed thermal energy storage system would slightly raise the coverage figures presented next in the results section.

All the meteorological data processing, all the above hourly calculations and the daily and monthly integrations are carried out with the Rstudio, version 1.3R.

3.2. ad-RCE sizing

A similar approach as the one proposed in [6] is followed in this work. Indivisible units of 2 m^2 are assumed for the ad-RCE and the number of ad-RCE installed on the roof should cover at least 75% of the DHW demands. In the case of Johannesburg, the RCE sizing resulted in 4 m^2 of surface area and 2 units of RCE, with 2 m^2 each [6]. Thus, in this study, 2 ad-RCEs of the same area used. However, an additional degree of freedom is available with the ad-RCE that was not present in the traditional RCE [6]. The number of solar collection hours during the day can be reduced while increasing the RC hours. Starting at 11.00 h, we have increased the number of hours of solar collection (and decreased the RC hours) until all the months had at least 80% DHW coverage with the ad-RCE. In this case study, running in solar heating mode from 11.00 h to 17.00 h is enough for the target DHW coverage for all the months, but May, June and July (winter months in Johannesburg), which need 12 h of solar heating instead of 6 h, from 7.00 to 19.00 h. The remaining 18 h (12 h for the latter three months) of the day are dedicated to RC, both in daytime and nighttime, increasing the cooling production with respect to pure night RC.

3. Results and discussion

Figure 4 shows the comparison of the DHW monthly demand with the ad-RCE monthly hot water energy production over one year in the selected single-family house in Johannesburg. As explained in the previous section, the DHW production is realized only during 6 hours with high insolation, in the middle of the day, from 11.00 h to 17.00 h (12 hours for May, June and July). The rest of the time the ad-RCE works in RC mode, producing cold water both at daytime and night-time thanks to the use of advanced daytime radiative cooling materials. The fine-tuned optical properties of these materials make them capable of reflecting barely all sunlight and emitting, almost as a black body, to the deep space. In most of the months, the monthly supplied DHW production surpasses the monthly demands, with the only exception of April, July and August, where the fraction of demand not supplied by the ad-RCE is small (in the range 1-10%). DHW demands are relatively constant in the house, ranging from 250 and 315 kWh/month. The expected increase in DHW demand in winter months due to the lower water grid temperatures is compensated by the above-mentioned increase in the number of hours in solar mode. Adding up the monthly demands and productions of DHW and making the ratio, the annual coverage reaches 108%. However, this coverage is an upper limit for the actual coverage as a non-realistic, large DHW tank, would be necessary to store all the excess heat that is not used in a particular day.

Regarding the cooling demand and supply, Figure 5 presents the cooling covered by the ad-RCE each month of the year. For months with modest, or almost inexistent cooling needs, the ad-RCE cooling generation clearly exceeds the demands. On the other hand, in the months with the highest cooling demands (January, February, March, November and December), the ad-RCEs cooling productions are well below the house cooling needs, being the monthly productions between 26 and 60% of the monthly demands. Adding up the monthly demands and productions of cooling and making the ratio, the annual coverage reaches 83%. The 37% yearly cooling coverage obtained in [6] for the same single-family house in Johannesburg with normal RCEs is clearly surpassed with the same surface of ad-RCEs. This is achieved due to the extra hours of DRC offered by the ad-RCE. However, more surface of ad-RCEs should be necessary if a higher percentage of RC fraction is targeted for the hot summer months.

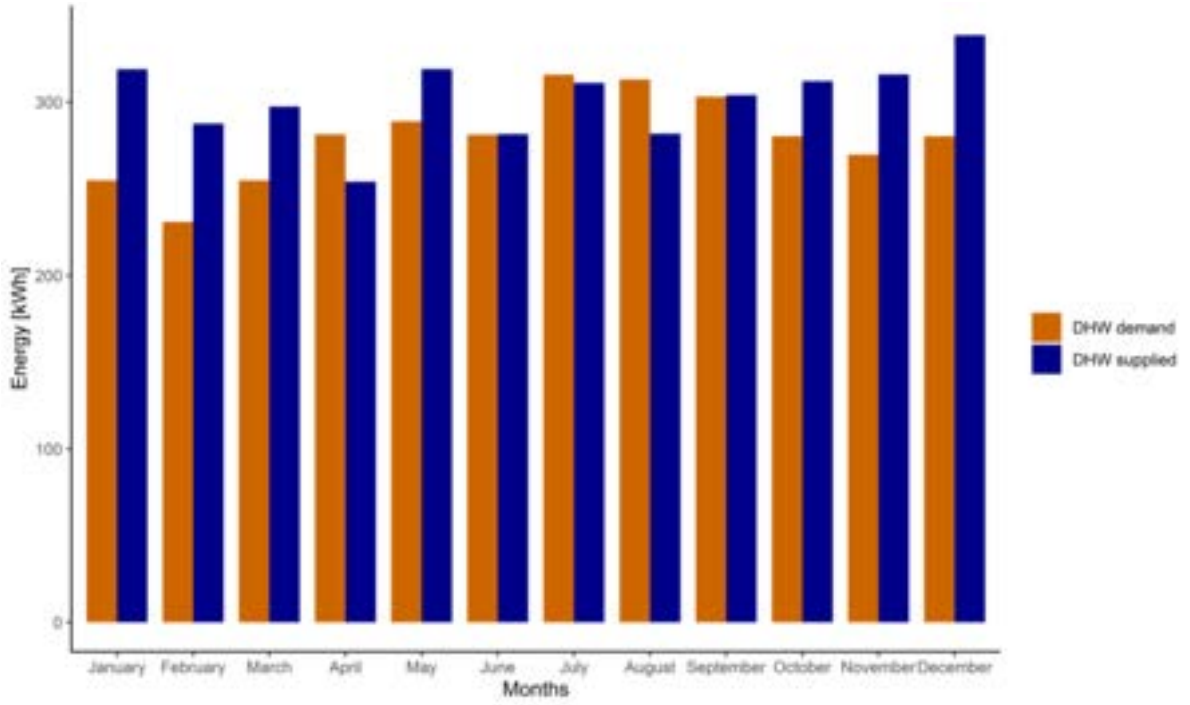

Figure. 4. Comparison of monthly DHW demand versus RCE DHW production.

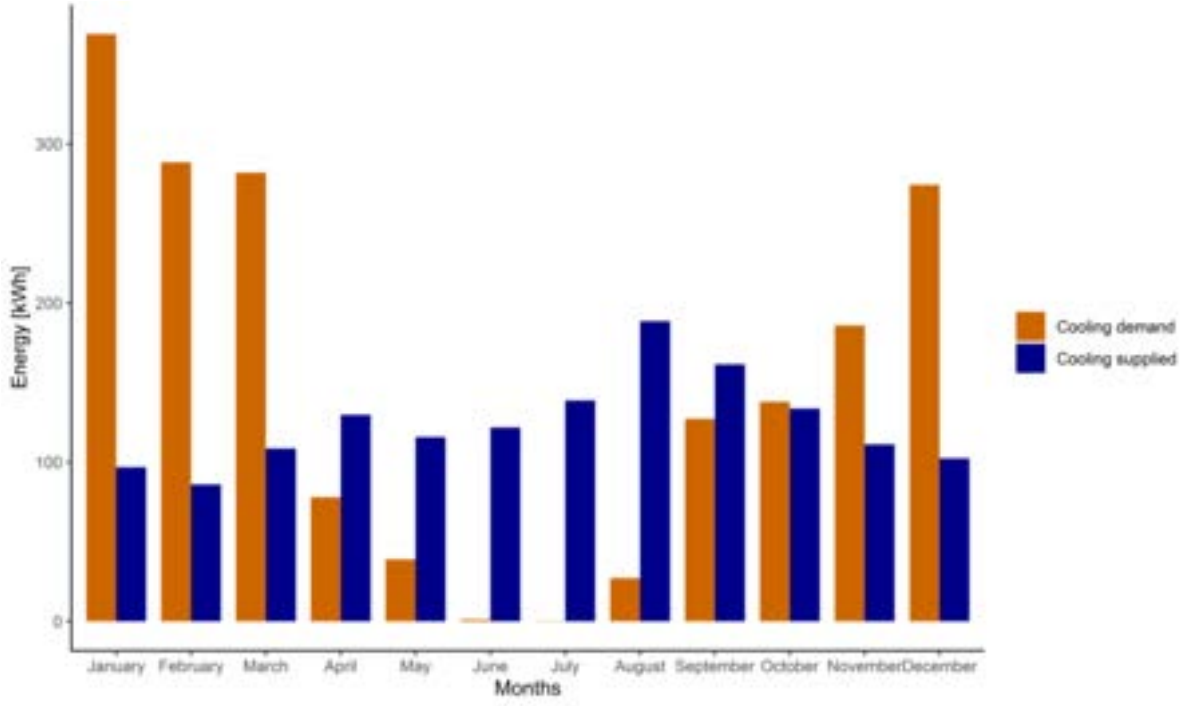

Figure. 5. Comparison of monthly cooling demand versus RCE cooling production.

It is important to note that these comparisons of Figure 4 and Figure 5 of annual demands over annual productions are overestimating the real coverage because we are assuming that any excess production of one day can be used in the following days of the month. Next, we will compare the monthly coverages as the average of the daily coverages, which is the lower end of the estimation, as the excess production of one day is not used in the following days of the month. In a real situation, with DHW and cooling storage tanks, the actual monthly coverage should be between these two extreme values.

The monthly energy coverage for both DHW and cooling is shown in Figure 6. These coverages are calculated as the average of the daily coverages. DHW coverages lie in the range 83-94%, meaning that, even in the sunny summer months, there may be some cloudy days when the DHW demand is not reached. As for the

cooling, the coverages are above 90% in the central cold months (May, June, July and August) and it goes down to 32 % for February, the month with the lowest cooling coverage. Note that an easy strategy to increase the cooling coverage in summer months, without increasing the ad-RCE total surface, may be the reduction of the number of hours in solar collection mode, sacrificing in that way the DHW coverage. Nevertheless, it is out of the scope of this study the optimization of the number of operating hours per day to minimize the house operating costs and/or the environmental impacts of the consumed energy.

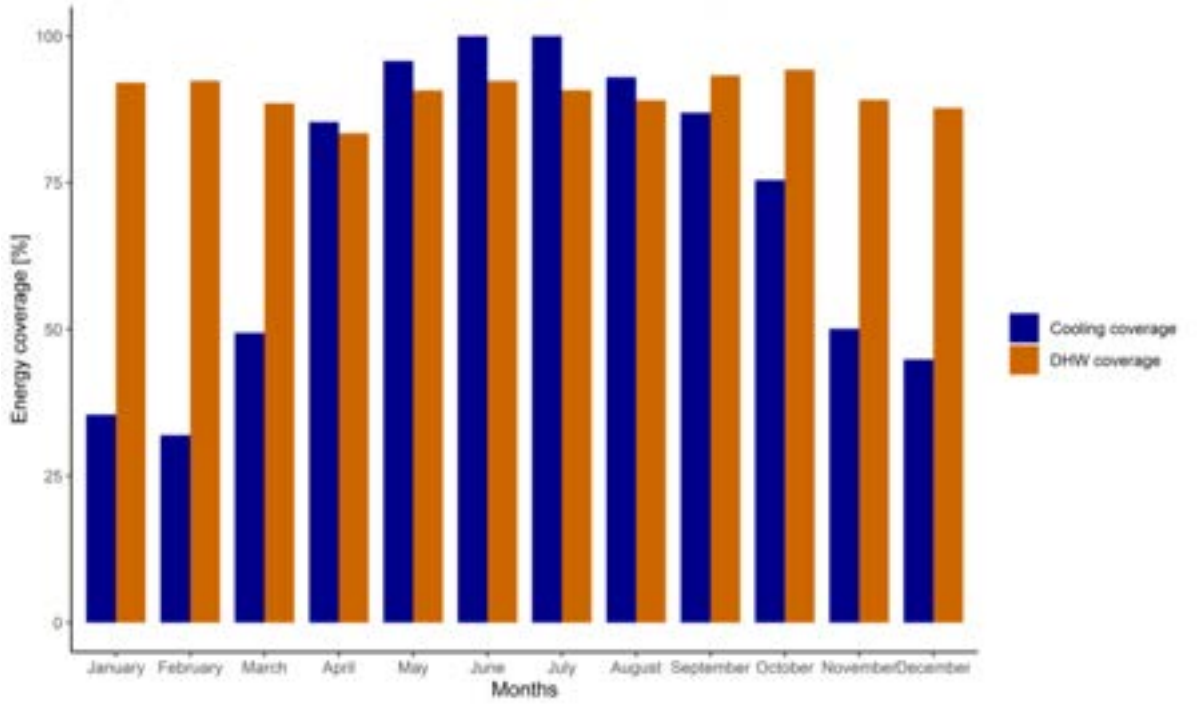

Figure. 6. DHW and cooling coverage of demands achieved by the ad-RCE.

Figure 7 illustrates the substantial increase in cooling coverage thanks to the substitution of normal RCEs by new ad-RCEs. In the hottest months of the year in Johannesburg, where the cooling is more needed, the growth in cooling production is in the range of 65-70%. This implies an increase in cooling coverage between 36 and 56%. These increases could even be higher for locations in the world where the difference of daily and night hours in summer are more pronounced than in Johannesburg.

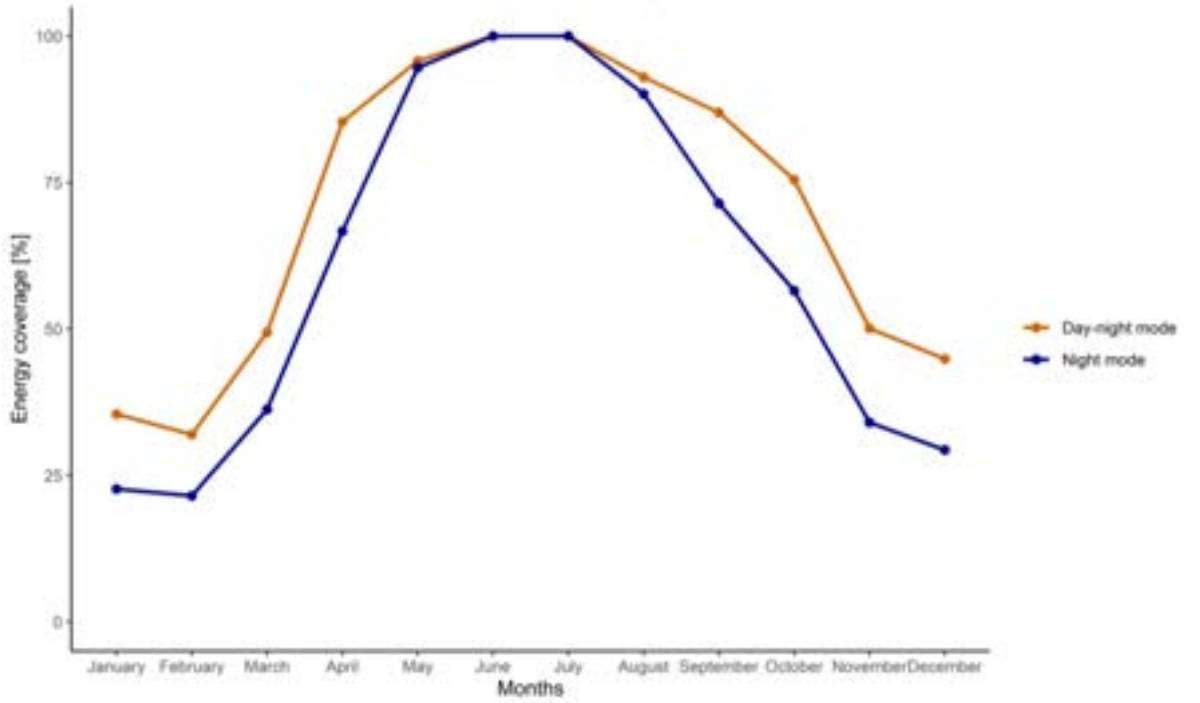

Figure. 7. Cooling coverage of ad-RCE with DRC and NRC, and normal RCE with only NRC.

4. Conclusions

In this study a new renewable energy device, the ad-RCE, is presented. The ad-RCE is an evolution of the Radiative Collector and Emitter (RCE), which is a single device able to produce cold water by radiative cooling at night and hot water by solar thermal collection at daytime. The ad-RCE is a new redesign of the RCE that enables the user to choose between daytime radiative cooling mode and solar collection mode, depending on the daily demands. The new ad-RCE is integrated in a house in Johannesburg, South Africa, to analyse the level of DHW and cooling monthly coverages for the house. Energy plus is used to calculate the DHW and cooling demands of the house and R studio is applied for the dynamic hourly simulation of the ad-RCE. The increased hours of radiative cooling in daytime enables a better match between the demand and production of cooling, increasing the annual production by 66%, while keeping the DHW coverage above 80%.

Abstract:

Since the recognition of self-consumption in Spain in 2019, self-consumption photovoltaic installations have experienced significant growth. This fact, together with a rise in energy prices, has allowed the development of both individual and collective distributed photovoltaic generation. Collective installations allow several consumers to benefit from a single photovoltaic installation. The use of dynamic distribution coefficients of the photovoltaic energy among the different consumers for each hour of the period is allowed and can be determined according to the criteria considered most appropriate by the participants. This article makes a technical and economic study of a photovoltaic installation for collective self-consumption of a group of houses located in Tafira - Gran Canaria, with different possibilities of photovoltaic energy distribution coefficients, both fixed and dynamic, to study the profitability of the different energy distribution and optimize the energy distribution, taking into account the different consumption curves and electricity contracts of each of the consumers. Eight cases of energy sharing are studied, the most characteristic and with which the best results are the cases with coefficients based on previous consumptions and current consumptions (in situ).

Keywords:

Shared Self-Consumption, Photovoltaic Energy, Renewable Energy.

1. Introduction

The Canary Islands are rich in natural resources, especially the wind and sun. The Canary Islands has abundant hours of light that allow the production of a photovoltaic panel installation to be much higher than in other areas, photovoltaic energy in the Canary Islands is an opportunity for the economy since, the installations of photovoltaic panels in hotels or other establishments provide savings and companies can offer more competitive prices.

Anthony Roy [1], Jean-Christophe Olivier, François Auger [1], Bruno Auvity [1], Salvy Bourguet [1], and Emmanuel Schaeffer [1] mention that collective self-consumption is especially useful in places that lack lands such as the Canary Islands, the Balearic Islands, large cities such as Madrid and Barcelona, or industrial estates. Thanks to this mode of self-consumption, consumers can benefit from a shared investment, which means that many consumers can have clean electricity at an affordable price. On the other hand, with collective self-consumption, you can obtain savings of up to 70% in the electricity bill, and reduce greenhouse gas emissions, and emissions of polluting gases, therefore, the carbon footprint of consumers. In addition, this type of facility will allow us to move towards a market of real flexibility, cleaner, decentralized, and less dependent on fossil fuels.

The collective self-consumption of photovoltaic solar energy has great advantages for the consumer, however, there are many unknowns when executing a project of this type. For example, the calculation and allocation of the distribution coefficient β among final consumers, which represents the proportion of the net energy generated that corresponds to each consumer.

On April 5, 2019, Royal Decree 244/2019 was approved, which regulates electricity self-consumption in Spain. This Royal Decree recognized collective self-consumption for the first time [2]. This change in the regulations allows several people to join and consume from the same generation plant. Royal Decree 244/2019 provides for the existence of coefficients to distribute energy in collective self-consumption. The value of these partition coefficients depends on the agreement between the participants, with the only requirement that they be constant values. These criteria and coefficients must be included in the agreement between the participants

and each consumer must send to the distributor or through its marketing company. The annex I of Royal Decree 244/2019, of April 5, establishes that: [2]

"The value of these coefficients may be determined according to the power to be billed by each of the participating associated consumers, the economic contribution of each of the consumers for the generation facility, or any other criterion provided that there is an agreement signed by all the participants and provided that the sum of these coefficients β i of all consumers who participate in collective self-consumption is the unit. In any case, the value of these coefficients must be constant" In addition, on November 15, 2021, Annex I was modified, which allows each participant to have a dynamic energy distribution coefficient under any criterion, as long as all consumers agree.

Villalonga [3], Serrano [3], Riquellme [3], Alvarez [3] and Roldan [3] mention that despite the fact that this normative represents ¨an advance over the previous regulatory framework, this new regulation introduces a series of inefficiencies with respect to the criteria for sharing the energy produced by the collective generation system. These inefficiencies are associated with an economic cost for the members of the collective self-consumption community, which to a certain extent may discourage its deployment, with the consequent negative impact on the development of renewable energies and the achievement of climate objectives´´.

That said, taking into account Royal Decree 244/2019 and order TED/1247/2021 [4] , an analysis is carried out to determine the different benefits that can be obtained with permanent and dynamic energy distribution coefficients for the case of collective self-consumption of 15 homes located on the Island of Gran Canaria (Spain). Using these homes, the economic viability and benefits of each of the dwellings obtained from different methods of distributing the PV energy generated will be analysed.

2. Methodology:

In this work, a technical economic study of a photovoltaic installation for collective self-consumption in a housing development with 15 houses located in Tafira - Las Palmas De Gran Canaria (Spain) is carried out.

For this study, 2 main scenarios have been considered. The first scenario assumes that the neighbours decide to invest in a self-consumption installation individually. Each one contracts the same installation company. In turn, as it is individual self-consumption, each house will have its own single-phase inverter and photovoltaic panels.

The second scenario is collective self-consumption, in which all the neighbours make a joint investment in photovoltaic solar panels and a connection inverter for all the installed power. Making a joint investment could reduce costs since the purchase and installation is cheaper the larger the investment.

In order to carry out this work, a series of steps were followed. First, we obtained the actual consumption of the fifteen houses, hour by hour during the period of one year. After this, we studied the consumption profiles, from which we obtained the percentage of consumption in hours of sunshine, the houses with the highest percentage will take more advantage of the energy produced by the photovoltaic panels.

In each of the houses, we chose to study their annual energy consumption and the availability of the roofs to estimate the peak power installed in the individual case. In the case of collective installation, an identical installation was simulated for each house. In order to study the electricity generation obtained in each installation, the photovoltaic production is estimated based on the solar radiation of the area. Table 1 shows the peak power that would correspond to each house according to the annual energy consumption, both for the individual case and the cases of collective self-consumption.

Table 1. Summary peak power to be installed in each home in the case of individual and collective self-consumption.

House N.º	Consumption Annual (kWh/year)	Hsp	P. Peak individual (kW)	P. Peak Collective (kW)
House 1	9948	2025	5.46	3.51
House 2	6000,6	2025	3.51	3.51
House 3	5397	2025	3.12	3.51
House 4	4599	2025	2.8	3.51
House 5	5610	2025	3.12	3.51
House 6	3361	2025	2.34	3.51
House 7	7970	2025	4.68	3.51
House 8	5610	2025	3.12	3.51
House 9	5610	2025	3.12	3.51
House 10	3361	2025	2.34	3.51
House 11	9948	2025	5.46	3.51
House 12	4599	2025	2.8	3.51
House 13	5610	2025	3.12	3.51
House 14	5610	2025	3.12	3.51
House 15	5610	2025	3.12	3.51
Total consumption	88844		51.23	52.65

Once the peak photovoltaic power for each case study has been estimated, we use the data obtained in the weather stations installed by the University of Las Palmas de Gran Canaria in the city of Las Palmas. From these data, the electrical energy produced using the described model is calculated. [5] [6] [7]

On the other hand, the different types of electricity billing that the owners had, according to the electricity market, which can be free market or regulated market (PVPC) were studied. The difference between these two markets is that the free market allows having a constant energy price during the contracting period, while in the regulated market the price of electricity changes hour by hour and day by day according to the supply and demand between the producers and marketers. In addition, the compensation price of surpluses also depends on the type of contract of the owner, in the same way as the purchase price of energy.

For the calculations, the data for the purchase and sale of electricity in the regulated market were obtained from the Sistema De Información Del Operador Del Sistema (eSios) website [7], while for the free market, a fixed purchase price of 0.16 €/kWh and a fixed sale price of 0.06 €/kWh were established. Once all these data were obtained for each of the homes, different cases of coefficients of distribution of energy generated by collective self-consumption were studied. From these coefficients, the calculations of the net energy balance were made in each hour, surplus (€) and network consumption (€) with which we will study the profitability of the installation in each case. In addition, other terms of the electricity bill such as power or electricity tax were studied, in order to make an approximate calculation of the price of this for each home in order to determine the savings in the electricity bill. In order to decide the best installation in each case, budgets were made, the economic feasibility study (NPV) and the results obtained were analyzed.

3. Cases of study

According to [2] "the net hourly energy generated individualized of those subjects 'i' that carry out collective or consumer self-consumption associated with a nearby installation through the network, ENG h, 'i' it Will be:

$$\boldsymbol{ENGh, i = \beta i . ENGh}$$

$ENGh$: total net hourly energy produced by the generator(s).

βi: Coefficient of distribution of the energy generated among consumers who participate in collective self-consumption.

For each consumer '*i*' participant of collective self-consumption, this coefficient will take the value that appears in an agreement signed by all consumers participating in collective self-consumption and notified to the distribution company as responsible for reading consumption. The value of these coefficients can be determined with any criterion, provided that there is a signed agreement for all participants and provided that the sum of the beta coefficient of all consumers participating in collective self-consumption is unity."

The generic formula established by the royal decree to find the coefficient of energy distribution is as follows:

$$\beta i = \frac{Pci}{\sum Pcj}$$

Pci: Maximum power contracted to the associated consumer i.

∑PCJ: Sum of the maximum powers contracted by all consumers who participate in collective self-consumption.

Based on the above, the following cases of energy distribution coefficient are proposed:

1. **Individual Self-consumption with surplus and Compensation (ISC):** Each owner of a home invests in a photovoltaic self-consumption installation individually, that is, each home will have its own single-phase inverter and photovoltaic panels.
2. **Collective self-consumption with distribution coefficient according to the number of houses (CFC-NH):** In this case, it has been decided that the beta energy distribution coefficient will be the same for all houses at all times of the year and the criterion is the total number of houses that will participate in self-consumption (15 dwellings), the way to calculate it is as follows:

$$\beta i = \frac{1}{15} = 0.06666666667$$

3. **Collective self-consumption with a distribution coefficient based on the contracted power in the electricity bill (CFC-PEB):** In this case, the criterion for choosing the beta coefficient of energy distribution will be according to the contracted power that each of the 15 dwellings has in the electricity contract, in this way each dwelling will have its own beta coefficient that will be the same for each hour of the year. The formula for calculating the beta coefficient is as follows:

$$\beta i = \frac{contracted\ power\ i}{\sum contracted\ power\ of\ the\ dwelling\ j}$$

4. **Collective self-consumption with distribution coefficient according to peak installed (CFC-IPP):** For this case study it has been decided that the criterion for calculating the beta coefficient will be the peak installed power of each of the dwellings, this power will be the same as that used for the case of individual self-consumption. In this case, the formula used for calculating the beta coefficient for energy distribution is the following:

$$\beta i = \frac{PV\ power\ installed\ i}{\sum \text{PV power installed of the dwelling } j}$$

5. **Collective self-consumption with dynamic distribution coefficient according to monthly consumption ex ante (CFC-MCE):** As mentioned in section No. 5, on November 15, 2021, Annex I of RD 244/2019 [3] was modified. Said modification allows the use of dynamic distribution coefficients, these coefficients may be different for each hour of the billing period as long as the coefficient βi is unity. The ex-ante monthly consumption is the criteria selected to determine the dynamic allocation coefficient.

   The term ex-ante means "before the event", in the case of collective self-consumption it will be a coefficient of distribution prior to the energy consumption. For calculating this coefficient we have decided to take the monthly consumption ex-ante for two months. The coefficient will be constant for all the hours of the same month but will adopt a different value for each month.

   It is taken as ex-ante data for two previous months because normally the billing comes every two months. In this way, the process for the new allocation of the betas coefficients would not be delayed every month. The formula to find the ex-ante dynamic allocation coefficient is:

$$\beta i(marzo) = \frac{January\ dwelling\ consuption\ i}{\sum January\ dwelling\ consuption\ j}$$

   The previous formula indicates that if we want to know what the coefficient βi is for the month of March I will have to use the consumption for the month of January.

6. **Collective self-consumption with distribution coefficient according to hourly consumption ex-ante (CFC-HCEA):** This coefficient is similar to the dynamic monthly ex-ante with the difference that there will be a different distribution coefficient for each hour. For the calculation of this coefficient we have decided to take the ex-ante hourly consumption two months prior to the month for which we want to calculate the coefficient, i.e., if we want to find the distribution coefficient in January, we will use the hourly consumption for the month of November. The formula to find the dynamic ex-ante allocation coefficient is:

$$\beta i = \frac{hourly\ ex\ ante\ consuption\ of\ dwelling\ i}{\sum hourly\ ex\ ante\ consuption\ of\ dwlling\ j}$$

7. **Collective self-consumption with distribution coefficient according to hourly consumption ex-post (CFC-HCEP)**: Despite the current regulation does not allow using these distribution coefficients, as a study, this work will calculate the ex-post dynamic coefficient in order to compare them in the future with the other cases of energy distribution coefficients and see which of them is more convenient for collective self-consumption. The term ex post refers to consumptions based on real and on-site readings. The calculation will be the same as the one used to find the dynamic distribution coefficient ex with the only difference that we take the hourly consumptions of the same hour from which we want to calculate the coefficient, i.e., if we want to find the distribution coefficient at 13 o'clock we will use the consumptions of that same hour 13. The formula to find the dynamic distribution coefficient ex-post is:

$$\beta i = \frac{hourly\ home\ consuption\ per\ hour\ i}{\sum hourly\ home\ consuption\ per\ hour\ j}$$

8. **Collective self-consumption with distribution coefficient according to hourly consumption ex-post with consumption improvement in a dwelling (CFC-IMP):** Solar energy generation occurs during daylight hours, so it is crucial to self-consume as much of the energy produced as possible since surplus energy is not paid for at the same price as the energy purchased. Therefore, the best option is to use as much of the energy produced by solar panels as possible.

   In order to demonstrate that consumers adapt their consumption to sunny hours the results will improve. For the demonstration, we have chosen house No. 1 for the ex-post sharing coefficient case.

   .

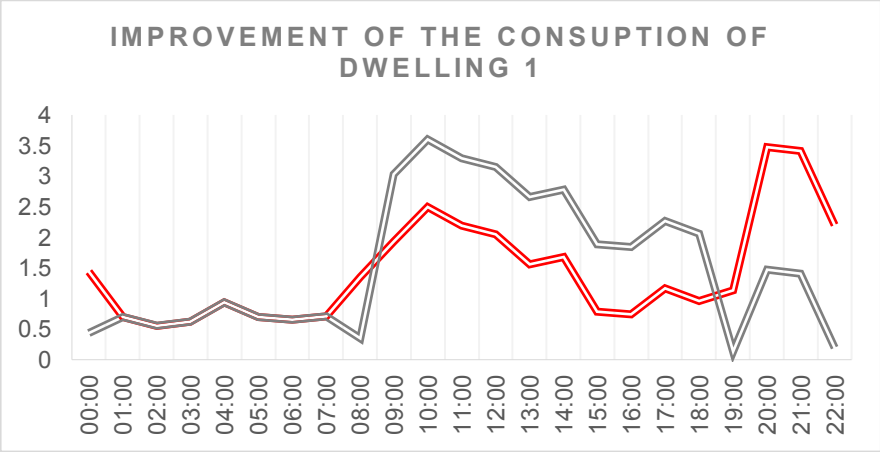

Figure. 1. Consumption before (red) and after (grey) the improvement of the consumption of dwelling No. 1 for 02/28/2021.

In the case of the ex-post dynamic distribution coefficient, as house 1 will adapt its consumption to the hours of sunshine, its beta coefficient will be higher compared to the rest of the houses. This will result in a higher energy distribution, a decrease in grid consumption, an increase in surpluses and an increase in the percentage of self-consumption over total consumption.

4. Economic study

4.1. Electricity bill

The changes suffered by electricity bills if the photovoltaic installation is carried out will be analyzed in order to visualize the economic savings that it would mean for the owners in each of the cases studied. As mentioned above, the electric bill has fixed terms that will be present even with no electricity consumption. The variable term is where the economic savings for self-consumption are visualized. Greater self-consumption translates into a decrease in the energy purchased from the grid, and therefore lower cost. In addition, to the variable term is added the fact that if there are surpluses of the photovoltaic generation they can be compensated in the monthly bill.

The term variable shall adopt the following formula:

- No photovoltaic installation:

  Variable term= Network consumption (kWh) x Price (€/kWh)

- With photovoltaic installation:

  Variable term= Network consumption (kWh) x Price (€/kWh)- Compensable surplus (€/kWh)

For the estimation of the annual bills of the houses, the following price assumptions have been used:

Table 2. Data used for electricity bills on the regulated market

Electricity tax	5.11%
Canary Tax	7.0%
Power	0.083 €/kWh
Energy Price	eSios
Compensated energy price	eSios

The regulated market prices correspond to the year 2021 and, as mentioned above, were obtained from the website of Red Eléctrica [8] de España eSios [9]. While the data used for the free market electricity bill are shown in Table 3.

Table 3. Data used for the free market electricity bill.

Electricity tax	5.11%
IGIC	7.00%
Contracted power	0.083 €/kWh
Energy Price	0.168662
Compensated energy price	0.0663 €/kWh

4.2. Investment

An estimated budget is made for the case of individual installation and collective self-consumption. In addition, ways to distribute investment in cases of collective self-consumption are proposed.

The economic distribution is made as follows:

$$\boldsymbol{Individual\ investment\ for\ fixed\ coefficents\ \beta i} = \textbf{total}\ \boldsymbol{investment\ x\ \beta\ fixed\ i}$$

$$\boldsymbol{Individual\ investment\ for\ dynamic\ coefficents\ \beta i} = \frac{\boldsymbol{total\ investment}}{\boldsymbol{\sum dwelling}}$$

in the following table, we can see a summary of the investment for each case and each home.

Table 4. Summary of the investments of each of the houses for the different case studies.

House N.º	CASE 1	CASE 2,5,6,7	CASE 4	CASE 3
House 1	9.454 €	4.621 €	7.763 €	4.666 €
House 2	7.841 €	4.621 €	4.683 €	4.666 €
House 3	7.810 €	4.621 €	4.212 €	4.243 €
House 4	6.738 €	4.621 €	3.589 €	4.243 €
House 5	7.810 €	4.621 €	4.378 €	4.874 €
House 6	6.473 €	4.621 €	2.623 €	4.243 €
House 7	8.579 €	4.621 €	6.219 €	4.874 €
House 8	7.810 €	4.621 €	4.378 €	4.874 €
House 9	7.810 €	4.621 €	4.378 €	4.874 €
House 10	7.810 €	4.621 €	4.378 €	4.874 €
House 11	9.454 €	4.621 €	7.763 €	4.666 €
House 12	6.738 €	4.621 €	3.589 €	4.243 €
House 13	7.810 €	4.621 €	4.378 €	4.874 €
House 14	7.810 €	4.621 €	4.378 €	4.874 €
House 15	7.810 €	4.621 €	4.378 €	4.874 €

5. Results

Several conclusions can be drawn from the cases studied, either from an economic point of view, referring to the NPV, or from the point of view of savings in the electricity bill, which will depend on several factors such as consumption, type of market or contracted power.
In order to be able to understand the reason for the results, Table 5 shows the data for each house, which will be used to identify them and see their main differences:

Table 5. Summary of characteristic data of the dwellings

House N.º	Annual consumption (kWh/Año)	% Sun Hours Consumption	Contracted power (kW)	Electricy market	Electricity Bill no PV (€)
House 1	9948	48%	5.5	Free	2084
House 2	6000	61%	5.5	Regulated	1481
House 3	5397	61%	5	Regulated	1338
House 4	4599	52%	5	Regulated	1143
House 5	5610	54%	5.75	Free	1272
House 6	3361	56%	5	Regulated	938
House 7	7970	63%	5.75	Free	1719

The importance of the % consumption in hours of sunshine was mentioned previously since the consumers who have a higher percentage will benefit more because they will consume more energy from the photovoltaic panels than energy from the electric grid. House No. 7, 2 and 3 have the highest consumption in sunlight hours; on the contrary, houses No. 1, 4, 5 and 6 have a slightly lower percentage, meaning that they consume more energy at night than during the day.

5.1. Economic feasibility

Several economic parameters were studied to determine the feasibility of each case, such as NPV, ERP and savings obtained in the electricity bill. Below, we can see the results obtained for the houses with the highest consumption (1;11) and the houses with the lowest consumption (6;10)

***Table* 6.** Summary of economic results obtained from housing 1 and 6.

Colours scale from worst to best.

Nº DWELLING	1	6	1	6	1	6
	NPV €		SAVINGS%		ERP	
Cfc-Nh	10048	4835	55%	52%	9	9
Cfc-Peb	9511	6687	40%	71%	6	8
Cfc-Ipp	8679	9655	38%	66%	6	6
Cfc-Mce	9501	5581	53%	52%	7	6
Cfc-Hcea	15329	3633	56%	53%	4	10
Cfc-Hcep	14604	4530	54%	58%	4	9
Cfc-Imp	13724	4410	48%	57%	5	9

Table 6 shows that cases with fixed coefficients benefit homes with higher consumption, while houses with low consumption obtain better benefits with fixed distribution coefficients.

5.2. Percentage of distribution of electrical energy over the total produced

This percentage indicates the electrical energy that corresponds to each dwelling annually as agreed. The following table shows how the distribution of energy improves or worsens according to the distribution coefficients adopted. The homes that have a higher percentage mean that it corresponds to more photovoltaic energy.

Table 7. Percentage of distribution of photovoltaic energy of each dwelling part of the total energy production of the installation.

% PV allocation energy/ Total PV production						
	CFC-NH	CFC-PEB	CFC-IPP	CFC-MCE	CFC-HCEA	CFC-HCEP
House 1	7%	7%	11%	11%	10%	9%
House 2	7%	7%	7%	8%	8%	8%
House 3	7%	6%	6%	7%	7%	7%
House 4	7%	6%	5%	5%	6%	6%
House 5	7%	7%	6%	6%	6%	6%
House 6	7%	6%	4%	4%	4%	4%
House 7	7%	7%	9%	9%	11%	11%
House 8	7%	7%	6%	6%	6%	6%
House 9	7%	7%	6%	6%	6%	6%
House 10	7%	6%	4%	4%	4%	4%
House 11	7%	7%	11%	11%	10%	9%
House 12	7%	6%	5%	5%	6%	6%
House 13	7%	7%	6%	6%	6%	6%
House 14	7%	7%	6%	6%	6%	6%
House 15	7%	7%	6%	6%	6%	6%
Total	100%	100%	100%	100%	100%	100%

We can see that the CFC-NH case is the same for everyone, this is because the distribution is made equally. The CFC-PEB case depends on the contracted power that each house has, we can see that there is not much variation, the reason is that all houses have a very similar power (between 5 to 5.75 kW).

$$\uparrow \boldsymbol{Contracted\ power} \uparrow \%\ \boldsymbol{PV\ energy\ allocation}$$

In the case of CFC-IPP, if we can see the difference, the houses that have greater installed power will have a higher percentage.

$$\uparrow \boldsymbol{Power\ installed} \uparrow \%\boldsymbol{PV\ energy\ allocation}$$

The CFC-MCE case benefits more households with the highest monthly consumption. House 1 has the highest consumption in all months of the year, which is the reason why this house corresponds to a higher percentage of photovoltaic energy.

$$\uparrow \boldsymbol{Monthly\ consumption} \uparrow \%\ \boldsymbol{PV\ energy\ allocation}$$

For the cases CFC-HCEA and CFC-HCEP the order of preference that will define whether a house corresponds to more or less a percentage of the distribution of photovoltaic energy will be:

1. Houses with high consumption and also do it on sunny hours.
2. Houses with high consumption, but do most of it at night
3. Houses with low consumption, but make most of it in sunny hours

5.3. Percentage of self-consumption over total consumption

Having a higher percentage of self-consumption means having greater savings in the electricity bill, since the consumption of the network is reduced, in addition, knowing that the compensable energy is paid worse than the price of energy from the network, the importance of everything generated is self-consumption is visualized and surpluses are avoided. The table below shows the percentages of self-consumption, these percentages correspond to the fraction of total consumption that is consumed during the hours in which the PV system is generating energy and the remaining percentage is obtained from the grid.

Table 8. Percentage of self-consumption for each of the case studies

	CFC-NH	CFC-PEB	CFC-IPP	CFC-MCE	CFC-HCEA	CFC-HCEP	CFC-IMP
House 1	35%	33%	32%	35%	38%	35%	39%
House 2	40%	38%	38%	35%	44%	46%	50%
House 3	42%	42%	41%	43%	40%	33%	50%
House 4	43%	47%	46%	4%	42	46%	46%
House 5	41%	42%	40%	40%	41%	47%	44%
House 6	43%	47%	30%	44%	43%	45%	47%

5.4. Overall results

In view of the results of the investments shown in Table 5, it can be concluded that opting for any case of collective self-consumption is more economical than individual self-consumption since savings of up to 50% can be made on the investment.

The cases with fixed coefficients, especially CFC-NH and CFC-PEB are the ones that benefit less to houses with high consumption because the distribution is made in equal parts without taking into account the consumption of the house, in these cases, it can happen that while a house with low consumption produces surpluses, another with high consumption will need to consume from the electricity grid.

We have taken the consumption and energy distribution of houses 1 and 6 for case 2, in this case, the two houses have the same amount of energy, house 6 has more energy than it consumes and house 1 needs to consume energy from the grid to meet its demand. This is the reason why these cases obtain the lowest savings in the electricity bill. The houses with low consumption, which in turn consume energy during sunlight hours, tend to have better results with fixed coefficients.

Table *9*. Comparison of houses 1 and 6 for Cfc-Peb case.

House	Hour	Hourly Consumption (kWh)	Cast Fv (kWh)	Net Balance (kWh)	Energy Price (€/kWh)	Compensation Price (€/kWh)	Network (€)	Surplus (€)
House	10	2.21	1.79	-0.41	0.168662	0.0663	0.07	0
House	10	0.25	1.79	1.54	0.22122	0.08266	0	0.128

Table 9 compares a house with high consumption versus a house with low consumption for the cases with fixed coefficients, it is observed that the house with low consumption is supplied with photovoltaic energy and even has surpluses. On the contrary, house 1 has a higher consumption and cannot be supplied with photovoltaic energy, so it has to consume energy from the electric grid.

Houses with a higher percentage of sunshine hours will obtain greater benefits with dynamic distribution coefficients. Since they have a higher beta coefficient compared to the rest of the houses and, therefore, they have a higher energy distribution.

consumers who adapt their electricity consumption to the hours of sunshine will be able to achieve a higher percentage of self-consumption and therefore greater savings. In addition, they will obtain better economic results and will recover their photovoltaic investment in less time. The study was carried out in the months of January and February with house 1.

The results are shown in Table 10, comparing the case of self-consumption with ex-post coefficient without improvement versus ex-post with improvement in the months of January and February.

Table 10. *Comparison of the results obtained before and after the improvement in consumption.*

House 1	January		February	
	No Improvement	With improvement	No Improvement	With improvement
Consumption Month (kWh)	1305	1305	999	999
Energy Distribution (kWh)	792	1235	837	1241
Mains consumption (kWh)	861	615	584	389
Surpluses (kWh)	25	545	29	630
% Self-consumption	32%	53%	40%	61%

Energy consumption through the grid decreased by 30% in both January and February. However, surpluses increased by 31% due to the increase in energy sharing. In addition, energy sharing increases because the sharing coefficient increases. Table 11 shows the variation of the energy sharing percentage, while for house 1 it increases from 12.59% to 19%, and for the rest of the houses it decreases

Table 11. photovoltaic energy allocation percentage before and after the improvement of the consumption of house 1.

% Energy Distribution		
	No Improvement	With improvement
House 1	12.59%	19,00%
House 2	6.09%	5.98%
House 3	5.48%	5.14%
House 4	5.38%	5.1%
House 5	4.86%	4.35%
House 6	4.66%	4.15%
House 7	14.45%	14.01%
House 8	4.86%	4.35%
House 9	4.86%	4.35%
House 10	4.66%	4.15%
House 11	12.59%	12.21%
House 12	5.38%	5.1%
House 13	4.86%	4.35%
House 14	4.86%	4.35%
House 15	4.86%	4.35%
Total	100%	100%

6. Conclusions

In view of the economic results, it is concluded that opting for collective self-consumption is an economically more beneficial decision than individual self-consumption.

The cases with dynamic coefficients are better than permanent coefficients. Because dynamic coefficients take into account the consumptions of the houses, then the distribution of energy will be done in an efficient way. On the other hand, fixed coefficients distribute the energy equally, without taking into account this important aspect.

The cases of collective self-consumption with permanent distribution coefficients are suitable for houses with low consumption during sunlight hours. If the consumptions are very low, these houses will have many surpluses and this will not be convenient because the purchase price of these surpluses is very low. On the other hand, houses with high consumption do not benefit from this coefficient because the distribution of energy is not very efficient since, while the houses with low consumption produce surpluses, the houses with high consumption will have to consume from the grid.

The problem of the efficient distribution of consumption is solved with the dynamic coefficients, these coefficients optimize the allocation of energy that corresponds to the different consumers. For example, they allow adjusting the distribution of photovoltaic energy to different casuistry, for example, to adjust to different daily consumption habits.

In addition, if consumers adapt their electricity consumption to the hours when the installation is generating energy, it is found that self-consumption increases and therefore the savings on the electricity bill is higher.

The results obtained in this study will help communities of neighbours to make a decision on which distribution coefficient to choose. However, the ex-post coefficient is recommended because the distribution of energy is made according to instantaneous consumption, thus, if a house increases its consumption in sunny hours, it will obtain greater energy savings.

The acceptance of dynamic coefficients is an important step towards the ecological transition in Spain. Even so, governments must continue to take measures and seek solutions to encourage photovoltaic self-consumption if they Xant to meet the targets set.

Evaluation and possible direct utilization of low- to medium-enthalpy geothermal resources for the sustainable development of the African continent

Claudio Zuffi[a-b], Luca Socci[a], Andrea Rocchetti[a], Giampaolo Manfrida[a] and Daniele Fiaschi[a]

[a] Department of Industrial Engineering, University of Florence (Italy),
[b] claudio.zuffi@unifi.it, CA

Abstract:

Low- and high-enthalpy geothermal resources exist throughout the African continent, but their utilization is still minimal. The rift valley area includes several high-enthalpy resource manifestations, but numerous medium- and low-enthalpy resources characterize the mainland. Geothermal resources offer a large energy potential suitable for several users. The main goal of this article is the assessment of the energy potential of the geothermal resources in Africa for direct use. The analysis of different types of medium- and low-enthalpy resources is carried out. The use of absorption cycles for cold production is considered here. A parametric analysis of the resource conditions, with special reference to the temperature level, allowed the estimation of the cooling power potential connected to the low to medium geothermal energy resources available in the African continent. On the other hand, possible end users of this resource are identified cold room storage and building cooling. The present study covers several aspects, from thermodynamic modelling to environmental analysis. The mathematical model allows the simulation of the cooling system and, through parametric analyses, the most suitable cycle characteristics are determined in compliance with the potential of the available geothermal resource. The Life Cycle Assessment (LCA) methodology is adopted for the sustainability analysis and the assessment of environmental compatibility of the proposed solutions. A parametric Life Cycle Inventory (LCI) is developed, modeling the components according to the required size for each use. The main outcome of the present work is that the low enthalpy Geothermal available in the African continent can offer significant energy savings and large environmental benefits, which may play a fundamental role in the sustainable development of this area.

Keywords:

Geothermal energy, direct use, Absorption Refrigeration System, Life Cycle Assessment

1. Introduction

Geothermal energy is acknowledged as a renewable source with a very relevant potential, and technologies to exploit it are at a rather advanced stage of development [1]. The use of this source is mainly classified into two categories: *indirect*, in which electricity is produced by power plants; direct, which directly exploits the geothermal heat flow for several applications, from residential to industrial heating [2]. Over the years, the installed geothermal powerplant capacity has grown extensively. In 2000, the worldwide installed capacity was 7.97 GWe producing about 49.30 GWh/y [3], while at 2020 the installed capacity had roughly doubled to 15.95 GWe producing about 95.10 GWh/y electricity [4]. The currently available technologies for electricity production are dry steam, flash steam and binary cycles, usually for medium-high enthalpy resources ranging from 120° C to 350° C. On the other hand, in a 20 years range period, the direct use of the resource has also grown extensively, from 15.14 GWt in 2000 to 107.73 GWt in 2020 installed capacity, with a growth in the produced heat from 1.9E+5 TJ/y to 1.02E+6 TJ/y at worldwide level [5]. The direct heat uses can vary widely, often involving space heating and cooling for building or industrial applications: Heat pumps, Heat Exchangers, Absorption cooling and refrigeration, greenhouses, agricultural drying, fish farming and others. The choice is highly related to the temperature level of the resource and to that required for the specific applications [6]. Generally, the direct heat use technologies belong to medium-low enthalpy resources, usually ranging between 20° C and 150° C.

The African continent, and in particular the East Area where Rift valley is located, has a very high geothermal potential (over 15 GW) but the exploitation of this resource is still limited to extremely low fractions [7]. In 2020, data on the installed geothermal power in Africa amounted to 830 MWe, of which 823 MW in Kenya and 7 MW in Ethiopia. On the other hand, direct use of geothermal heat in the African continent is about 198 MWt, shared between several countries. Direct use applications are more equally distributed across the entire continent (Algeria, Burundi, Egypt, Ethiopia, Kenya, Madagascar, Malawi, Morocco, Nigeria, South Africa and Tunisia) [5].

In this context, investigating direct-use applications of geothermal heat for low to medium-enthalpy resources in the African scenario is of relevant interest. In the 40 – 150 °C heat range, the Absorption Refrigeration System (ARS) is economically and environmentally promising [8]. Several studies were conducted considering different conditions of the geothermal resource. Tugcu et al. analysed an ARS with ammonia-water mixture fed by a geothermal resource at 133°C [9]; Kairouani et al. evaluated an ARS with a mixture of ammonia and water and the geothermal resource in a range between 72°C and 75°C [10]; Velàzquez et al. have designed a single- and double-effect ARS which utilises a geothermal resource at 80°C and 163°C respectively [11].

Similarly, some paper in literature analyse the sustainability of geothermal heat for refrigeration and chilling, evaluating the coupling of the generator to different renewable sources with the Life Cycle Assessment methodology. Solano-Olivares et al. and Bukoski et al. evaluated an absorption cycle coupled with a solar system for building cooling [12], [13]. Hamedani et al. analysed the energy and environmental aspects through LCA of a biomass-fuelled heating and cooling system [14]. On the other hand, Maione et al. and Chaiyat, assessed the environmental impacts of coupling the ARS to a geothermal resource [15], [16].

In numerous regions of Africa, electricity is not easily accessible and distributed. As a result, geothermal energy plays a crucial role in the country's development. Thus, investigating systems that harness the existing heat from geothermal resources facilitates the implementation of multiple systems that would be considerably more challenging if powered by electricity. The objective of this work is modelling and evaluating the thermodynamic behaviour and the environmental impact of an ARS for different possible geothermal conditions. It is designed to cover the cooling load of a cold room (for food storage or other industrial use) or a building. The thermodynamic performance of an absorption cycle with a mixture of water and ammonia under different geothermal resource conditions have been evaluated. At the same time, the environmental impact assessment of the investigated ARS has been carried out by the means of Life Cycle Assessment (LCA), considering the construction and operation phase of the system.

This work is done in the framework of the European Horizon 2020 project Long-Term Joint EU-AU Research and Innovation Partnership on Renewable Energy *(LEAP-RE)* [17].

2. Materials and methods

The analysed ARS is an absorption cycle with a mixture of water and ammonia (NH_3/H_2O mixture) for the refrigeration of a cold room or cooling of a building. The proposed mathematical model of the ARS takes into account the chemical characterization of the mixture, the mass and energy balances. In order to realize a model suitable and easily applicable to different conditions of the African continent, several wide range variable parameters were considered. The parametric analyses focused on condensation temperature (T_{cond}), evaporation temperature (T_{evap}), mass ratio of NH_3 to the whole mixture (y), and finally the temperature of the geothermal resource (T_{geo}).

An environmental analysis was performed by the Life Cycle Assessment of the ARS, following the ISO 14040 and ISO 14044 standards [18], [19] The regulations define 4 key steps in this analysis: Goal and scope definition, Life Cycle Inventory (LCI), Life Cycle Impact Assessment (LCIA), Interpretation. In this work, the focus was on the second step, consisting in the development of a parametric LCI representing the construction phase of the absorption cycle. The goal is to provide the assessment of materials needed for construction in relation to the cooling power of the ARS, refereed to the installed kW unit. In addition, some parameters used in the thermodynamic model are set to evaluate the operation phase as well. Then, by combining the results obtained from the thermodynamic model and using them as inputs of the LCA model, it is possible to perform a comprehensive analysis of system performance and sustainability. This is done by varying the external conditions such as outdoor temperatures T_{air}, and target temperatures T_{aim}. The next sections describe the thermodynamic model and the LCA model of the considered plant, outlined in Figure 1.

The mathematical model of the absorption cycle was implemented in Engineering Equation Solver (EES) software [20], whereas the environmental analysis was conducted with OpenLCA software [21] and Ecoinvent 3.7 datatbase [22].

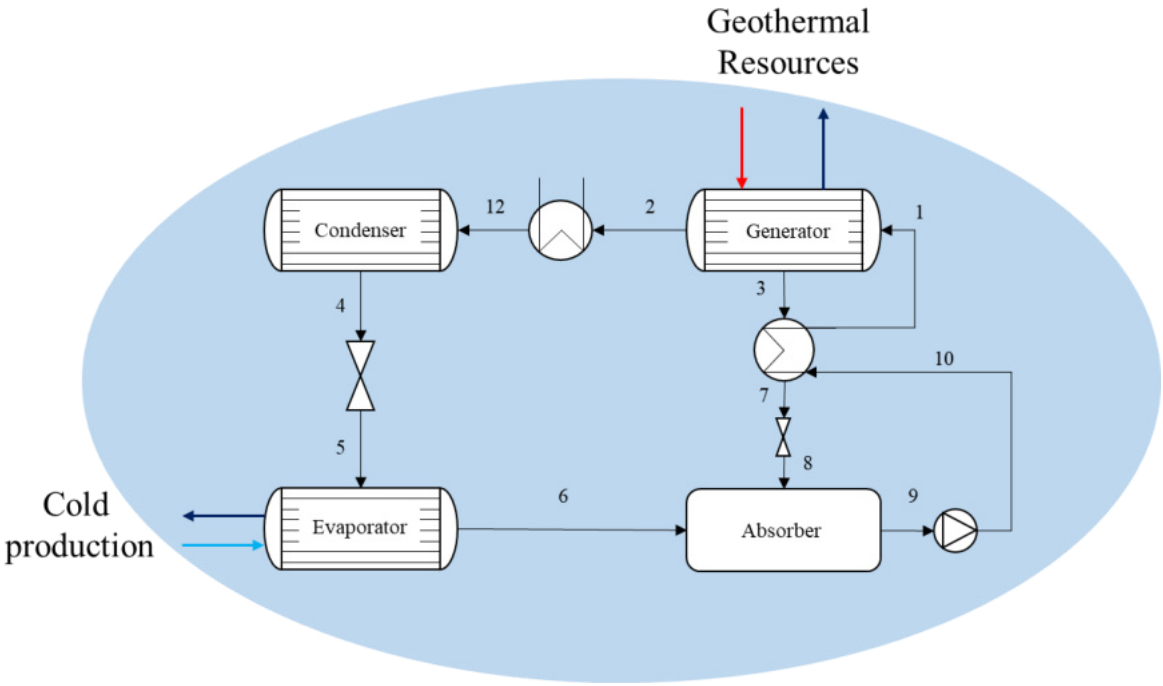

Figure 1 - Geothermal absorption cycle for refrigeration, with a mixture of water and ammonia

2.1 Energy modelling

The ARS is a single-effect cycle, mainly consisting of generator, desuperheater (DSH), condenser, evaporator, absorber, and heat recovery unit (RH). The system is shifted in two lines, differently modelled according to the working fluid. At the generator outlet, from point 2 to point 6, the working fluid is pure ammonia starting as superheated vapor in 2, saturated vapor in 12, saturated liquid in 4 and saturated vapor in 6. From the generator outlet at point 3 (line 3-8) and the absorber outlet at point 9 (line 9-1) the working fluid is in the liquid state, consisting in a mixture of NH_3/H_2O at the concentration y. The working fluid is at a high concentration y in line 9-1 (strong solution), corresponding to the design concentration of the cycle, and at low concentration

in line 3-8. With reference to the external conditions, two parameters mainly influence the cycle, namely the temperatures at point 4 (T_{cond}) and the NH_3 mass ration at point 9 (y), as they set the two pressure levels of the cycle:

- High pressure corresponding to the saturation pressure of ammonia at T_{cond};
- Low pressure corresponding to the saturation pressure of the mixture evaluated at temperature T_{cond} with mass ratio y.

T_{cond} is determined by the external conditions (1), hence the environmental air temperature, while y is set and evaluated at different level. The reason for setting the temperature T_9 equal to the temperature T_{cond} is that the absorber exchanges heat with the outside air. T_{evap} is evaluated from the low-pressure level as the saturation temperature at low pressure and also defines the aim temperature (T_{aim}) achievable in the cold room or in the building (e.g. cold utility temperature) (2). Thus, these parameters uniquely set the cycle and a changing one of them leads to a variation in temperatures and pressures of the other components (Figure 2 - Temperature-pressure graph with constant water-ammonia concentration curves of the Absorption Refrigeration System), as will be seen in the Results section.

$$T_{cond} = T_{air} + \Delta T_{cond} \quad (1)$$

$$T_{evap} = T_{aim} + \Delta T_{evap} \quad (2)$$

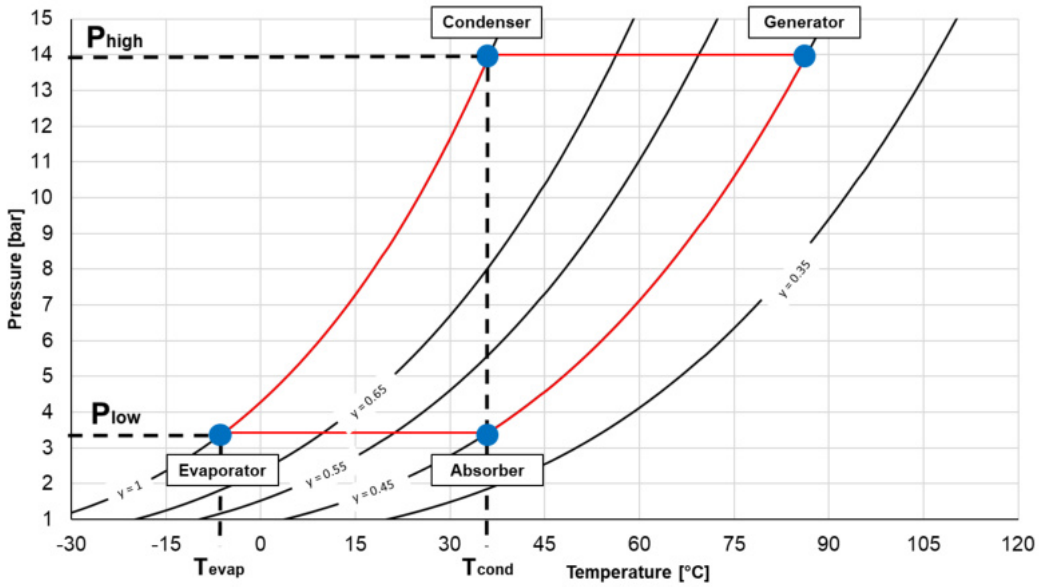

Figure 2 - Temperature-pressure graph with constant water-ammonia concentration curves of the Absorption Refrigeration System

The whole cycle is calculated around these two fixed pressure levels. In Point 1, the water-ammonia mixture enters into the generator, which is heated by the geothermal resource. The temperature level at the generator output (point 3) is evaluated according to equation (3), where T_{geo} is the temperature of the geothermal resource entering the generator.

$$T_2 = T_3 = T_{geo} - \Delta T_{gen} \quad (3)$$

Thus, from point 2 the ammonia in the superheated vapour state passes through the desuperheater (DSH) and successively condenses at point 4. Downstream the isenthalpic throttling valve (4-5), the ammonia evaporates into the evaporator (5-6), providing the required refrigeration effect. At the same time, in point 3 the weak water / ammonia solution under the liquid state releases heat (thus recovered) to the NH_3/H_2O strong solution from the absorber. The regeneration level R of this recuperator is defined in equation (4).

$$R = (h_3 - h_7) / (h_1 - h_{10}) \quad (4)$$

The equations governing the energy balances of the main points of the cycle are given below from (5 to 14).

$$Q_{geo} = \dot{m}_{geo} * (h_{15} - h_{16}) \quad (5)$$

$$Q_{geo} = \dot{m}_2 * h_2 + \dot{m}_3 * h_3 - \dot{m}_1 * h_1 \quad (6)$$

$$Q_{DSH} = \dot{m}_2 * (h_{12} - h_2) \quad (7)$$

$$Q_{cond} = \dot{m}_2 * (h_{12} - h_4) \quad (8)$$

$$Q_{evap} = \dot{m}_2 * (h_4 - h_6) \quad (9)$$

$$Q_{abs} = \dot{m}_2 * h_6 + \dot{m}_3 * h_8 - \dot{m}_1 * h_9 \quad (10)$$

$$\dot{m}_1 * (h_1 - h_{10}) = \dot{m}_3 * (h_3 - h_7) \quad (11)$$

$$Q_{abs} = \dot{m}_2 * h_6 + \dot{m}_3 * h_8 - \dot{m}_1 * h_9 \quad (12)$$

$$W_p = \dot{m}_1 * (h_{10} - h_9) \quad (13)$$

$$COP = {Q_{evap}}/{(Q_{geo} + W_p)} \quad (14)$$

The model relies on some fixed parameters set during the analysis, while other ones are allowed to vary. Table 1 shows all fixed and variable parameters and their values or ranges. T_{cond} and T_{evap} are evaluated to analyse their influence on the Coefficient of Performance (*COP*) of the whole system. The sensitivity analysis to the NH3/H2O solution concentration *y* is carried out to determine the most suitable ammonia concentration for the cycle in relationship to the available low-temperature level of the geothermal resources. Finally, T_{geo} allows defining the performance level achievable referred to the heat input to the system.

Table 1 - Range of parameters used in the parametric analysis of the system

Name	***Parameter***	***Unit***	***Value /range***
Hot-cold side temperature difference at the condenser	ΔT_{cond}	°C	10
Hot-cold side temperature difference at the evaporator	ΔT_{evap}	°C	5
Hot-cold side temperature difference at the generator	ΔT_{geo}	°C	5
RH regeneration level	*R*	-	0.8
Condenser temperature	T_{cond}	°C	25 – 50
Evaporator temperature	T_{evap}	°C	-10 – 0
Mass fraction Ammonia/mixture	*y*	kg $_{NH3}$/kg $_{mixture}$	0.3 – 0.8
Geothermal mass flow rate	m_{geo}	kg/s	0.5 – 10
Temperature of resources	T_{geo}	°C	50 – 120

2.2 LCA Modelling

The surface plant for refrigeration defines the system boundaries of the analysis. Geothermal wells or the drawdown point are not considered because they are strongly site dependent. The cold room or the building are as well not considered at the analysis, as out of the focus of this work. The electricity consumption of the pumps is taken into account, and it's impact is modelled using Kenya's electricity energy mix as a reference. The assumed functional unit is 1 kW of installed cooling power.

The parametric LCI consisted in two basic steps:

- Finding a reference process representative of the construction materials of the absorption cycle;
- Finding enough data to establish a relationship between the installed cooling capacity and the weight of the device.

For the first step, a literature review was conducted, and several LCIs were compared [12]–[16]. It turned out that many of them were either incomplete or referred directly to secondary processes in the database. For this reason, to consider a consistent reference, the process of the Absorption cycle provided by the Ecoinvent 3.7 database [22] was adopted as a reference model. This process was the starting point to obtain the typical composition of materials for the devices of the case study. Indeed, by neglecting the materials not closely related to the construction phase of the devices, a relative mass fraction (%) of construction materials was made per each considered unit. The second step was finding reliable catalogues of Absorber manufacturing companies. The purpose of this step is achieving information on weight and cooling power. Once obtained the necessary data, a distribution of points outlining the relationship between the weight of the devices and the nominal ARS cooling power (kW) may be traced. The *World Energy Absorption Chillers Europe Ltd* catalogues available online[23] were used which allowed to obtain 140 number of points.

With the distribution of this data in hands, it was possible to achieve a satisfactory second-degree polynomial fitting function. The second-degree function was selected in order to limit its complexity, increasing with the polynomial degree, without entailing an appreciable reduction of the uncertainty. Figure 3 shows the point distribution and the related 2nd degree polynomial power-weight fitting function.

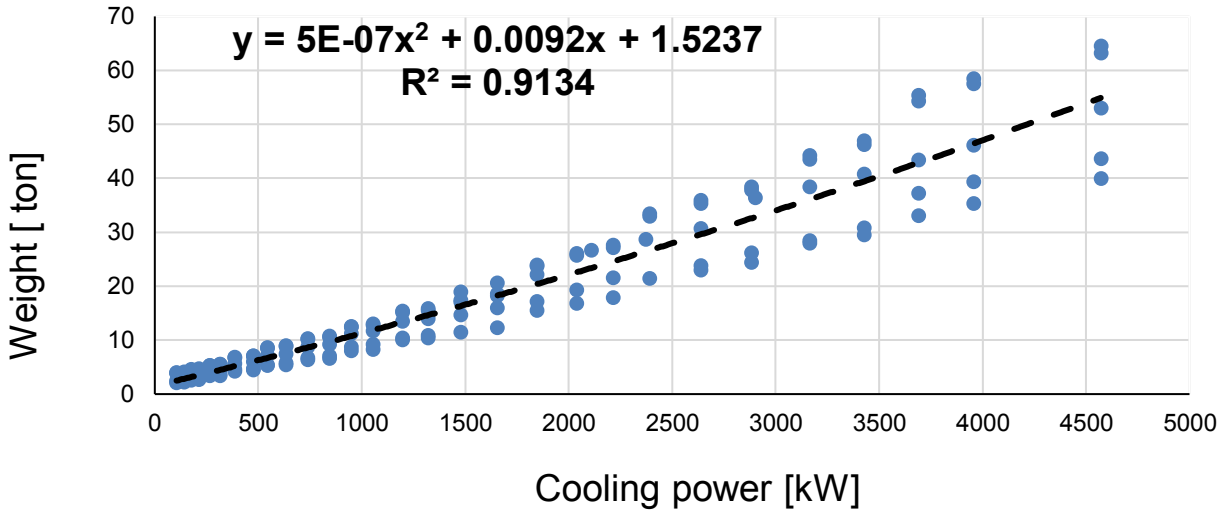

Figure 3 - Descriptive function of installed cooling power-weight trend

The conducted analysis adopts the Environmental Footprint (EF) 3.0 methodology, adapted to the Ecoinvent database. Specifically, the analysis develops on two levels: (i) Analysis of the environmental indicator Climate Change (CC) in terms of kg CO_2 equivalent emitted and (ii) analysis of the single score in terms of Environmental Points (Pt). The latter is achieved following normalization and weighting of all indicators evaluated by EF3.0, therefore it represents the overall environmental impact of the system.

3. Results

In this section, the results coming from energy parametric analysis and LCA study are presented. In particular:

- The parametric analysis shows the sensitivity of the absorption refrigeration cycle to the ammonia concentration in the mixture, condensation temperature and geothermal resource temperature.
- The LCA study shows the contributions analysis of the environmental indicator Climate Change (CC), as well as an analysis of the most impactful categories at single score level.

3.1 Effect of ammonia concentration

Figure 4 shows the temperature trend of the NH_3/H_2O mixture at the generator inlet T_1 and the evaporation temperature T_{evap} with respect to different y_1 levels. In this case, the analysis was carried out by keeping the T_{geo} set at different temperature levels: a) 120°C; b) 100°C; c) 80°C; d) 60°C. The y analysis highlights a key aspect of low-, and medium-enthalpy geothermal resources and the target temperature. The first aspect that results is that as y_1 increases, the temperature T_1 decreases and T_{evap} increases. Respecting the constant

concentration curves of the ammonia-water mixture shown in Figure 2, it is denoted that as the selected curve in the Aborber-Generator stream varies, the temperature levels at the generator and evaporator also vary. This means that increasing y_1 allows geothermal resources to be exploited at lower temperatures. However, it must be considered that the refrigeration effect for cold room can be obtained at most for T_{evap} in the order of 5°C while, for the cooling of a building, T_{evap} must be higher than this level. As a reference, it must be considered that a satisfying refrigeration effect for a cold room can be obtained for T_{evap} not higher of 5°C (while, for the cooling of a building, Tevap could be higher). Taking this graph into account, it is easy to identify the NH_3/H_2O concentration y_1 which allows the required performance to be obtained with respect to the temperature of the geothermal resource. There is a grey area in the graphs, the low side of this area represents the temperature level of geothermal resource. This implies that the T_1 profile is not acceptable when it crosses this area and it can only assume values below that level. For low-temperature resources, the variation of y_1 is very limited and therefore also the terminal uses forcing only one type of application such as the cooling of buildings. Conversely, for higher temperature levels, such as a) and b), it is possible to choose both applications of cold storage and building cooling.

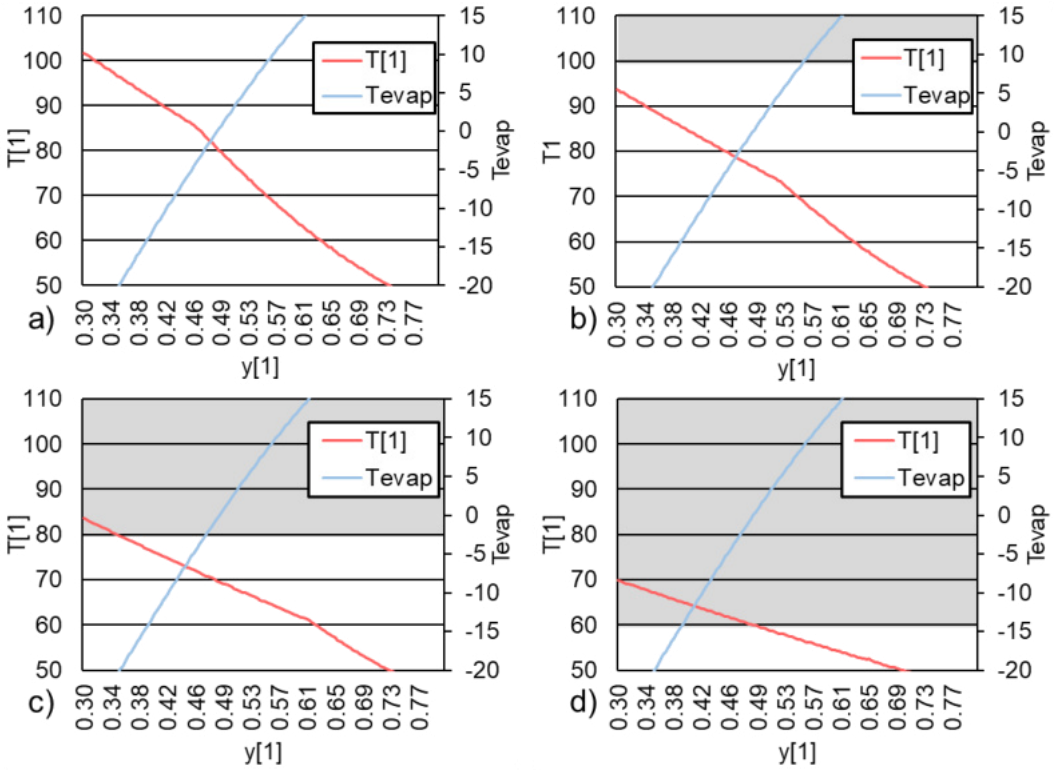

Figure 4 - Parametric analysis of T_1 and T_{evap} as a function of y_1 at different level of T_{geo}: a) T_{geo} =120°C; b) T_{geo} = 100°C; c) T_{geo} = 80°C; d) T_{geo} = 60°C.

3.2 Effects of condensation temperature

Through the parametric analysis of T_{cond}, the trend of the system's COP)is investigated using a function that is also dependent on y_1. In order to explore various T_{cond} variations, T_{geo} was set to its maximum level of 120°C. Figure 5 illustrates the relationship between COP and T_{cond} at different levels of y_1. It can be observed that at lower levels of y_1, higher COP values are achieved with lower T_{cond}, but as y_1 increases, the system's performance tends to decline.

However, for higher levels of y_1 ranging from 0.5 to 0.6, it appears that T_{cond} has minimal influence on COP. Since T_{cond} is influenced by external air temperatures, this indicates that these particular cases are minimally affected by external temperature changes, maintaining their performance almost unchanged within the typical temperature ranges of the African continent. Conversely, for cases where y_1 is below 0.45 to 0.35, variations in external temperatures significantly impact the system's performance, leading to a drastic drop in COP.

Another consideration is that the different y_1 levels correspond to a specific T_{evap} level, which are presented in Table 2. The cases relevant to refrigeration purposes focus on y_1 = 0.5. Realistically, considering the outdoor temperatures commonly encountered in East Africa, the design T_{cond} would fall within the range of 30-40°C [24], where the COP exhibits a declining phase. Furthermore, it should be noted that a slight increase in T_{evap} can slightly enhance the system's performance, but it may require applications beyond refrigeration, such as building cooling. Thus, considering all the aforementioned factors, the performance of the system is highly

dependent on its final application, as well as the external temperatures prevailing at the specific African site where the geothermal resource is located.

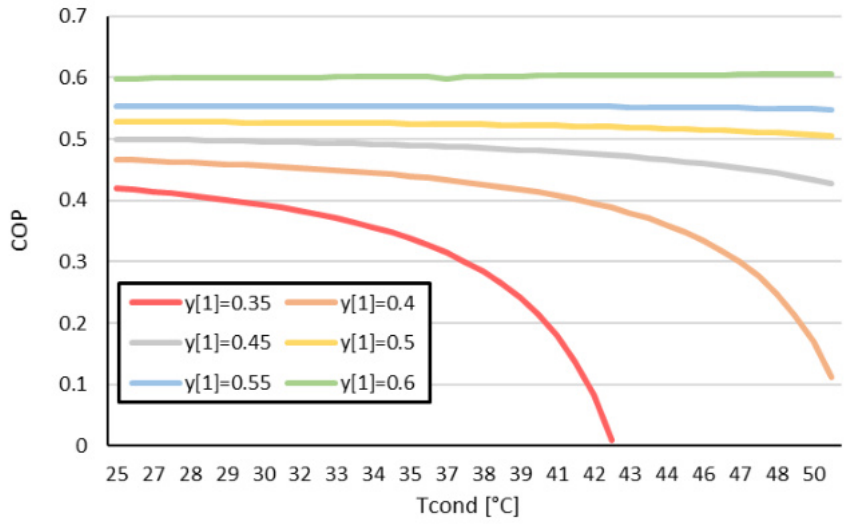

Figure 5 - Parametric analysis of COP as a function of T_{cond} and T_{evap}

3.3 Geothermal resource

The parametric analysis performed on the geothermal resource explores the trends of the COP at various y_1 levels. Figure 6 depicts the overall pattern, characterized by a substantial performance increase until reaching the temperature that maximizes COP, followed by a gradual decline. The lowest point of each curve corresponds to the geothermal resource temperature at which the absorption cycle initiates operation.
Considering the values presented in Table 2 and setting y_1 to 0.5 as the threshold for applications related to food refrigeration, it becomes evident that the minimum geothermal resource temperature is 83°C (lowest point of y_1 = 0.5 curve). As y_1 increases, corresponding to lower T_{evap} temperatures, the required geothermal resource temperature approaches the maximum value at a medium-low enthalpy level. In essence, lower y_1 levels in the cycle necessitate higher geothermal resource temperatures. This highlights the fact that refrigeration-type applications demand minimum temperatures around 80°C, which are only available in select regions of Africa, particularly in the East Africa Rift Valley (EARV) area.
Conversely, for higher y_1 levels, corresponding to higher Tevap temperatures, lower-temperature resources can be exploited, which are present in both the EARV and North Africa (e.g., Algeria and Morocco).
Hence, it is crucial to determine the optimal ammonia concentration, y_1, that maximizes COP as a function of the geothermal resource. For this reason, Table 2 provides the respective COP_{max} and T_{geo} values for each y_1 level.

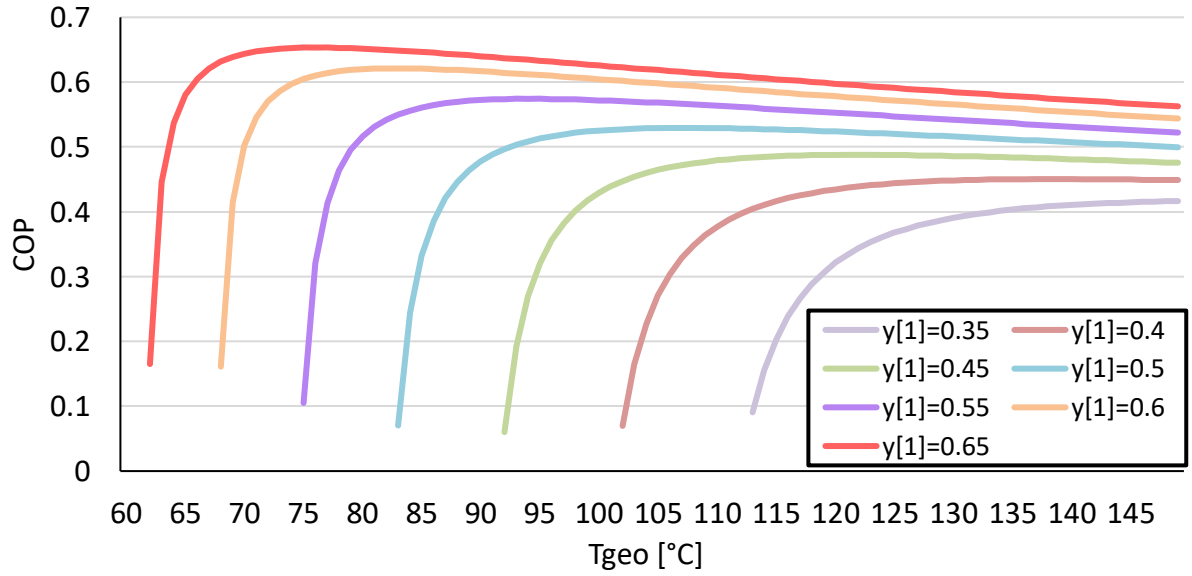

Figure 6 - Parametric analysis of COP as a function of T_{geo} and y_1

Table 2 - Evaluation of the maximum COP with respect to the temperature of the resource and the resulting cooling power

	y_1						
	0.35	**0.40**	**0.45**	**0.50**	**0.55**	**0.60**	**0.65**
T_{geo} [°C]	140	137	121	106	94	83	76
T_{evap} [°C]	-20.00	-12.56	-5.34	1.50	7.85	13.60	18.63
COP_{max}	0.41	0.45	0.48	0.52	0.57	0.62	0.65

3.4 Final application

Two cases are taken as reference: a) the first has the conditions set at y_1=0.5 and therefore T_{evap}=1.5° C for the refrigeration of a cold room for food storage purposes; b) the second has the conditions set at y_1=0.6 and therefore T_{evap}=13.60° C for the cooling of a building. In Figure 7 an analysis is shown on the heat loads of the main components, as the geothermal resource variations. As the two graphs show, for the cooling of the building it is possible to exploit a resource at temperatures above 70°C, while for the cold room it must be above 85°C. Analysing the point at which COP is maximum for both configurations show that for case a) the cold load is 21.34 kW while for load b) it is 22.27 kW.

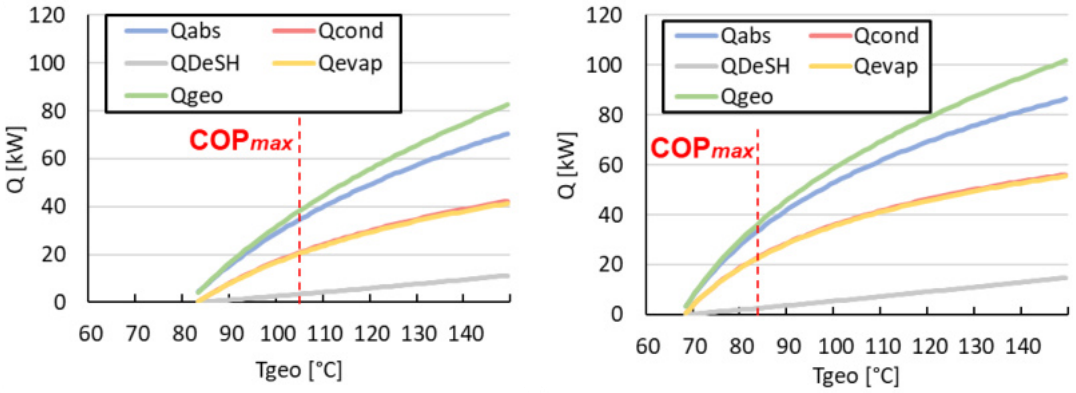

Figure 7 - Evaluation of heat level of two different cases: On the left a) for the application of a cold room, on the right b) for the cooling of a building

A preliminary dimensioning of a cold room was carried out to evaluate the output of the refrigeration and cooling system. Using equation 15 to estimate the annual cooling energy ($E_{cooling}$) in terms of kWh/y in a cold room for food storage. Where CF_a is the total number of hours per years of about 8000 [25], and F_r is a reduction factor of about 0.5. The results obtained for the reference case is approximately 85.360 MWh. Given data from literature 73 kWh/m^3 per year [26] for cold room is required, so a hypothetical cold room that is met by this system is 1169 m^3. At the same time, approximately 0.21kW/m^2 of cooling power is required for cooling a building with an internal temperature of 23°C [27]. Therefore, it can be estimated that with the analysed system a building of approximately 106 m^2 can be cooled. To make a point in support of these results, consider the case of the cold room. Taking as reference the results obtained from Evans et al. 2014 [28], an estimation can be made that suggests the consumption of around 56 kWh/m3 per year for cold room. It is crucial to emphasize that the availability of electricity poses challenges in numerous African regions, which underscores the necessity to devise a system that ensures access to electricity. In this context, the utilization of the geothermal resource in Africa assumes even greater significance.

$$E_{cooling} = Q_{evap} * CF_a * F_r \quad (15)$$

3.5 Life Cycle Impact Assessment

The analysis carried out on the environmental indicator CC, is shown in figure Figure 8. Here it is shown that the larger the installed cooling power of the device, the more CO_2 eq per kW of installed cooling power is reduced. In particular, the largest contribution of the impact comes from the electricity consumption of the operation phase, which is in the range of 60-65 % of the impact. In addition, the ammonia mixture makes a very low contribution ranging from 1.6-3.5 % of the impact. The construction phase results in approximately 1.94E+02-1.89E+021 kg CO2/kW, contributing 33-36% of the impacts.

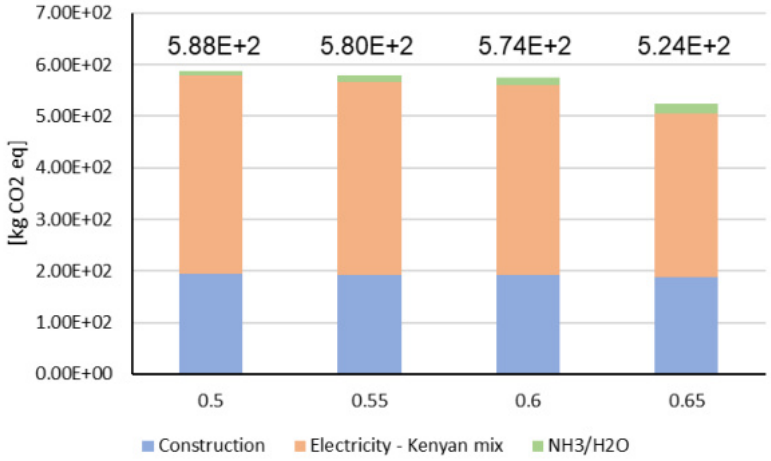

Figure 8 - Climate change evaluation

Finally, a single score analysis is shown in Figure 9, highlighting the contribution of the most impactful categories. The trend that was achieved for the CC indicator also persists at the overall system level. In fact, even at single score there is a decrease in impacts for systems with higher ammonia concentrations in the working fluid. Furthermore, globally, the most impactful categories are Resource use, minerals and metals, which impact in the range of 55-52%%. Two other indicators such as CC and Ecotoxicity, freshwater have a significant weight of about 9-11% and 11-12% respectively. While acidification, Particulate matter and Resource use, fossil impact about 3-6%, while the other indicators have negligible impact percentages.

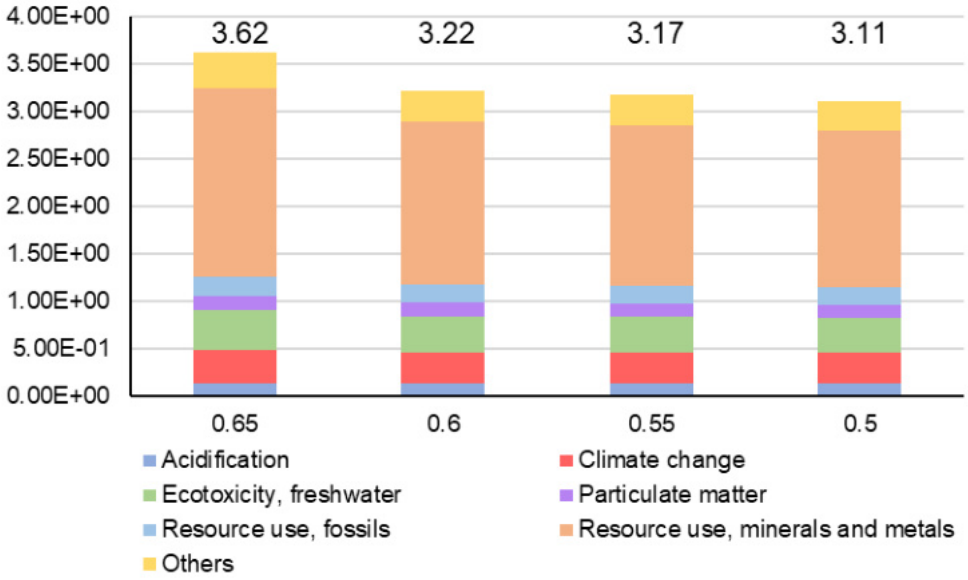

Figure 9 - Single score evaluation

4. Conclusion

In this paper, an application of direct use of the geothermal resource for medium and low enthalpy is analyzed. In particular, an absorption refrigeration system using a mixture of NH_3/H_2O is taken as a reference system for col room or building cooling. The analysis that has been conducted aims to highlight aspects concerning achievable thermodynamic performance and aspects concerning sustainability. For this reason, a thermodynamic model of the system was developed using the EES software to assess the performance of the cycle with several parametric analyses. From the analysis of the ammonia concentration, it can be deduced that increasing y_1 decreases the temperature of the mixture feeding the generator but at the same time increases the temperature level at the evaporator. This makes it possible to exploit a geothermal resource at a lower temperature but to increase the target temperature. The condenser temperature analysis shows that for low y_1, the increase in T_{cond} strongly reduces COP performance, whereas, for higher levels of y_1, the cycle is not influenced by these effects. The range of air temperatures in Africa limits T_{cond} to the 30-40°C range where the COP trend is decreasing. From the analysis of the geothermal resource, the minimum temperature values T_{geo} are set at different values of y_1. Furthermore, it is possible to evaluate the T_{geo} that maximizes the COP for each type of application. In particular, for refrigeration purposes, concentrations below 0.5 are required and COP_{max} is obtained for temperatures above 106°C. For the purposes of building cooling, on the other hand, y_1 greater than 0.55 is preferred and allows resources to be exploited at temperatures below 94°C. The results obtained dimension a cold room of 1169 m^3 at 5°C, using a resource at 106°C, and a building to be cooled of 106 m^2 at 23°C, with a resource at 86°C. To analyze the sustainability of the considered system, an LCA was conducted developing a parametric LCI to represent the construction and operation phase of the system. It was used OpenLCA software and the EF3.0 methodology adapted to the Ecoinvent 3.7 database. LCA uses the cooling power installed of the system as functional unit. Only the cooling system is analyzed, neglecting the entire system outside it (geothermal resource extraction point, cold room, building).

The outputs obtained from the thermodynamic model, in terms of cooling power, energy consumption, mass flow rate of ammonia mixture, are taking as input for the parametric LCI. The analysis of the environmental indicator CC shows a reduction in impacts corresponding to the increase in installed cold power of the system. The main contribution comes from electricity consumption and accounts for about 60-65%, while the construction phase of the device accounts for 33-36%. The single score analysis determines the same trend as for CC, and it is also established that the environmental indicator with the highest impact is Resource use, minerals and metals for about 52-55%. The environmental impact of CC accounts for 9-11%.

Abstract:

In the last decade, biomass consumption for thermal and electrical energy generation presented significant growth, as part of the plan to reduce greenhouse gas emissions through the gradual substitution of fossil fuels for renewable sources. In Brazil, although coal burning is still allowed in thermal power plants, the environmental demand is imminent for its substitution for less polluting sources and financial institutions already take a stand against coal investments, rising the pressure over existing consumers. This paper intends to identify and model coal-based power generation plants and compare its performance to that of different types of biomass available in Brazil – wood chips, wood pellets, sugarcane bagasse pellets – which are candidates to substitute coal in a large scale. Energy and exergy approaches are used to assess the full life cycle efficiency of these fuels, with a focus on the fuel combustion for steam generation, enabling the identification of inefficiencies and the selection of the most interesting operational opportunities. Despite of the life cycle specific energy consumption of biomass being higher than that of coal, its environmental performance is highly advantageous, drastically reducing fossil CO_2 emissions in the combustion process. When comparing pellets to dry wood chips, under the aspect of life cycle specific energy, biomass pellets result in a significantly higher specific energy consumption compared to dry wood chips, due to the thermal energy demand of drying and pelletizing stages. Such distinction between the performance of different types of low moisture biomass may only be detected if the life cycle approach is utilized. From the perspective of life cycle energy efficiency, the use of less processed types of biomass such as dried wood chips is preferrable over pellets.

Keywords:

Biomass; Thermal power plants; Coal substitution; Exergy analysis.

1. Introduction

Climate changes have encouraged efforts worldwide to reduce greenhouse gas emissions through the gradual insertion of renewable energy sources in substitution of fossil fuels, among which coal stands out as a major emitter to be controlled.

Coal substitution is an alternative to the reform of existing coal-based power plants for controlling NOx and SOx emissions limits, which tends to be an expensive solution, or even to their shutdown. Required investment for NOx and SOx control might be prohibitive and force these plants to interrupt operation [1].

Large scale power plants in the European Union have stricter atmospheric emissions limits to attend in the current decade, as described in BREF – Best Available Techniques Reference Documents – regarding not only CO_2 emissions, but also NOx and SOx emissions. IEEFA [1] shows that, from a sample of 600 solid fuel based power plants with capacities higher than 50 MW, more than 43% are not in conformity with new limits for SOx (180-320 mg/Nm³) and 69% were considered in non conformity with new limits for NOx (150-175 mg/Nm³).

In that context, as it is reported by Escobar [2], since 2010 biomass consumption in the European Union has presented significant growth. In opposition to the intermittent behavior of solar and wind-based power generation, biomass is adequate as a fuel for base load power plants.

In the United Kingdom, for instance, Drax power plant is one of the largest base load units, with an installed capacity of 4.0 GW, originally coal-based. From this total, approximately 2.6 GW have been converted to burn biomass pellets, which are mostly wood-based and imported from North America [3]. Other examples of

coal to biomass conversions are reported by boiler manufacturers and contractors such as Mitsubishi Power [4], Hofor [5] and AET [6], which also list well succeeded conversions in Denmark, Finland and Canada.

By sharing physical characteristics with coal, biomass might be applied in existing coal-based power plants after adaptations in the fuel storage and combustion systems, which would result in a significant impact in the Brazilian electricity matrix. Although mineral coal represents a small fraction of the Brazilian matrix, it causes the highest specific CO_2 emissions for each MWh of generated electricity [7].

The Brazilian electricity matrix currently reports 6 operational coal-based pure power plants, with capacities ranging from 350 MW to 720 MW, and 3 coal-based cogeneration plants, with capacities from 75 MW to 104 MW [8], [9]. These plants are concentrated in the southern region, for which coal is mainly provided by national mines, and in the northern coast, for which coal is imported from Colombia and the USA.

At least since 2009, there have been reports pointing out that coal substitution or co-firing with biomass would be a promising alternative for clean electric generation in Brazil [10], but until this time there have not been yet registers of coal-based cogeneration or pure power plants to have firmly migrated to biomass. In the meantime, however, the potential of utilizing biomass for energy purposes has been extensively reported, usually highlighting *Eucalyptus* chips or pellets [2], [11], sugarcane bagasse pellets [12], [13] and straw pellets derived from many sources, such as rice, soy and corn [11].

The objective of this work is to compare the processes of electricity generation by coal combustion and biomass combustion, in several forms, in order to identify and quantify the potential of utilizing biomass as an energy source to substitute coal. This analysis uses energy and exergy approaches to evaluate the performance of the technological route for each fuel, as well as calculating CO_2 emissions resulting from their life cycle. This study should assess what are the impacts of substituting coal for biomass and what are the resulting efficiencies in each case.

2. Materials and methods

The simulations of typical thermal power plants are carried out in PowerFNESS® software [14], which contains a thermodynamic database for the working fluids used in power cycles and acts as an equation solver for mass and energy balances, given the inputs for equipment efficiencies and operational boundary conditions (flow, pressure and temperature).

The software is based on the construction of thermal cycles consisting of equipment, nodes and lines. The nodes represent boundary conditions and the union or separation of flow currents; in each node, fluid properties are calculated and updated on every simulation step. The lines serve as connections between nodes, which correspond mainly to the pipe sections and connections from the real system. When running the model, mass and energy balance equations are linearized and solved by the finite element method, until convergence to a steady state flow condition is reached.

A model description is presented in the following sections.

2.1. Process modeling

Typical plants for power and heat cogeneration or pure power generation are presented in Figure 1. Energy and exergy efficiencies will further be calculated based on these configurations.

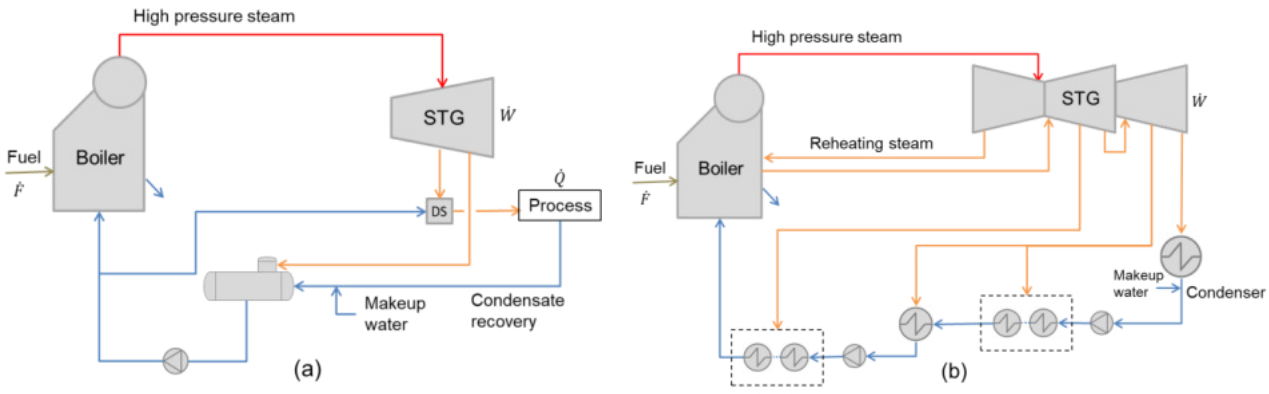

Figure 1. Thermodynamic cycles for power generation plants: a) Cogeneration of power and heat; b) Pure power generation.

Table 2. Main operation parameters for cogeneration and pure power generation configurations.

Process parameter	Unit	Cogeneration Plant	Pure Power Plant
Boiler			
Type	-	Circulating Fluidized Bed / Pulverized Fuel	Pulverized Fuel
Operating steam pressure	bar a	85	170
Operating steam temperature	°C	485	540
Thermal efficiency	%	91	93
Turbogenerator			
Exhaust steam pressure	bar a	15	0.085
Thermal efficiency	%	84	86
Generator / Reductor losses	%	3	2
Process heat demand			
Steam flow	t/h	500	-
Steam pressure	bar a	15	-
Steam temperature	°C	210	-
Condensate Recovery			
Recovery rate	%	90	100
Temperature	°C	100	43
Makeup water			
Temperature	°C	25	25

Since 2 out of the 3 coal-based cogeneration plants listed by the Brazilian National Electric Power Agency are part of alumina refineries [8-9], in the Cogeneration scenario it is assumed that the process demands low pressure steam at 15 bar a, as this is representative of such refineries [15].

Regarding the boiler technology, typical configurations for Brazilian coal-based plants considered in this study are equipped with pulverized coal boilers, whose full conversion to biomass is arguably viable and has been applied in the previously mentioned cases [4], [5], [6]. The same premise could not be adopted for fluidized bed or grate boilers. Biomass has lower carbon content than coal, therefore producing less CO_2 in combustion, which is a gas that highly contributes to radiation heat exchange. Since grate boilers are the most dependent on radiation heat exchange, their performance would be the most harmed after fuel migration. Also, good performance in fluidized bed boilers is deeply related to fuel ash content, which is much lower for most types of biomass when compared to coal. Fluidized bed boilers that were originally designed to burn coal, exclusively, would hardly be able to maintain design bed temperature and achieve design capacity after the conversion to biomass.

2.2. Fuel characterization

Both *Eucalyptus* and sugarcane bagasse derived fuels are selected as substitute fuels for coal, given their abundancy as residues and potential to be grown in large scale sustainable forest plantations [2], [11].

Elemental compositions and moisture content for each fuel are presented in Table 2.

Table 2. Elemental composition of the selected fuels (dry basis).

Element	Coal	*Eucalyptus [16]*	Sugarcane bagasse [16]
C	72.7%	47.5%	46.5%
H	4.4%	6.1%	6.2%
N	1.1%	1.5%	1.2%
O	8.0%	43.8%	44.4%
S	2.4%	0.0%	0.0%

Ashes	11.4%	1.1%	1.8%
Moisture	12.0%	15.0% (dry chips) 7.0% (pellets)	7.0% (pellets)

Ambient conditions are $T_0 = 25$ °C and $p_0 = 1$ bar.

Regarding fuel chemical exergy, Szargut [17] expressions for solid fuels are utilized, taking as inputs fuel LHV, moisture content and elemental composition:

$$b_{q,biom} = \beta.\left(LHV_{fuel} + x_w.h_{lv}\right) + x_w.b_{q,H2O,l} + x_S.\left(b_{q,S} - LHV_S\right) + x_{ash}.b_{q,ash} \quad (1)$$

Factor β varies according to mass composition of the respective fuel. The following correlations are established: any solid fuel, Eq. (2); coal, Eq. (3); wood, Eq. (4).

$$\beta = \frac{1.044 + 0.016(H/C) - 0.3493(O/C)[1 + 0.531(H/C)] + 0.0493(N/C)}{1 - 0.4124(O/C)} \quad (2)$$

$$\beta = 1.0437 + 0.1896\left(x_{H_2}/x_C\right) + 0.2499\left(x_{O_2}/x_C\right) + 0.0428\left(\frac{x_{N_2}}{x_C}\right) \quad (3)$$

$$\beta = \frac{1.0412 + 0.216\left(x_{H_2}/x_C\right) + 0.2499\left(x_{O_2}/x_C\right)\left[1 + 0.7884\left(x_{H_2}/x_C\right)\right] + 0.045\left(x_{N_2}/x_C\right)}{1 + 0.3035\left(x_{O_2}/x_C\right)} \quad (4)$$

From Eq. (1) to Eq. (4) and elemental compositions presented in Table 2, the chemical exergy for each fuel is calculated, as shown in Table 3, as well as the chemical exergy to LHV ratio.

Table 3. LHV and chemical exergy for each selected fuel.

Property	**Unit**	**Coal**	***Eucalyptus* dry chips**	***Eucalyptus* pellets**	**Sugarcane bag. pellets**
Moisture	%	12%	15%	7%	7%
Bulk density	kg/m³	900	350	657	726
LHV (per mass)	MJ/kg	25.6	14.8	17.2	18.3
LHV (per vol.)	MJ/m³	23040	5180	11300	13311
$LHV_{biomass}$ / LHV_{coal} (per vol.)	-	-	22%	49%	58%
bq	MJ/kg	28.4	15.7	18.0	19.1
bq/LHV	-	1.110	1.061	1.045	1.043

Aiming for operating the boilers at their original design capacities, substitute fuels shall have heating values and densities as close as possible to those of coal. The volumetric energy density of solid fuels has impacts both to the storage system design and to the boiler itself, whose furnace volume defines how much fuel can be introduced and how much heat can be generated. This hinders the utilization of *in natura* biomass at high moisture, due to its lower volumetric energy density. Dry wood chips at 15% moisture content were selected so that their LHV and density properties would be closer to pellets and coal. The necessary heat for drying wood chips from 40% down to 15% will further be considered in its life cycle analysis, as discussed in section 3.2. Wood chips would not serve as an alternative fuel for pulverized fuel boilers, but only for circulating fluidized bed boilers.

As presented in Table 3, all three types of biomass resulted in low values of chemical exergy to LHV ratio, ranging from 1.043 to 1.061, which is caused by their low moisture content. *In natura* wood chips with moisture content up to 40% would result in even higher ratios, up to 1.17, which would significantly harm the exergy efficiency of power plants.

Although dry wood chips and pellets are types of biomass with relatively high energy densities, they are still less dense than coal and would require the expansion of fuel storage, handling systems and the adaptation of burners, in the case of pulverized fuel boilers. Fuel silo (or bunker) and the pulverizing mill shall be adapted, as well as forced and induced air fans, since flue gas flow is expected to rise for higher moisture content fuels.

2.3. Efficiencies

In cogeneration plants, both electric power and useful heat for process consumption are considered when calculating the plant efficiency, as shown in Eq. (5):

$$\eta_e = \frac{\dot{W} + \dot{Q}_u}{\dot{F}} \tag{5}$$

In which:

- $\dot{W}$ is gross electric power
- $\dot{Q}_u = \dot{m}_{stm}(h_{stm} - h_{mup})$;
- $\dot{F} = \dot{m}_{coal}.LHV_{coal}$ or $\dot{F} = \dot{m}_{bio}.LHV_{bio}$

In analogy, exergetic efficiency is calculated as in Eq. (6):

$$\eta_b = \frac{\dot{W} + \Delta\dot{B}_f}{\dot{B}_q} \tag{6}$$

In which:

- $\dot{W}$ is gross electric power
- $\Delta\dot{B}_f = \dot{m}_{stm}(b_{stm} - b_{mup}) = \dot{m}_{stm}[(h_{stm} - h_{mup}) - T_0.(s_{stm} - s_{mup})]$;
- $\dot{B}_q = \dot{m}_{coal}.b_{q,coal}$ or $\dot{B}_q = \dot{m}_{bio}.b_{q,bio}$

2.4. Life Cycle Analysis

2.4.1. Coal route

Figure 2 shows the most relevant stages in mineral coal life cycle, as well as resources consumed and gas effluents produced in each stage. As a premise in this study, only existing power plants will be evaluated, therefore both the plant construction and decommissioning are excluded from the routes considered.

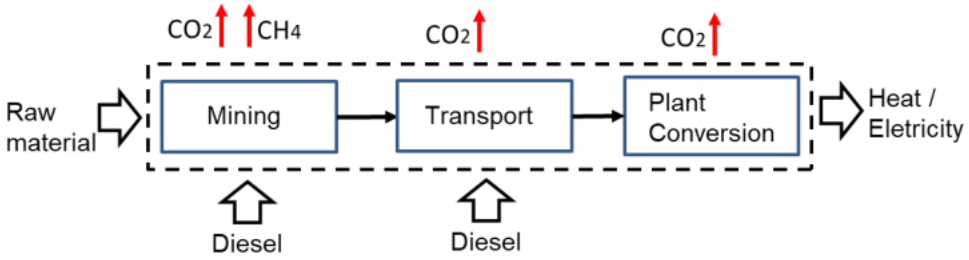

Figure 2. Mineral coal route to be consumed in existing power plants. Adapted from [18].

Figure 2 shows that, besides CO2 resulting from coal combustion and Diesel consumption in transportation vehicles, it is also relevant to count CH_4 emissions in mining stage. Methane is produced during coal formation process and is gradually liberated to the atmosphere as coal layers shatter and gas deconfines. Methane contribution in total equivalent CO_2 emissions equals 1% to 9% [18].

The tracking of mineral coal allows to calculate specific energy consumption rates and CO_2 emissions in terms of electric power generated as the final product of the power plant.

The following premises are considered [18]:

- Power plant life time: 30 years;
- Transportation logistics: road transport, 100 km radius;
- Equivalency from CH_4 to CO_2: 21 kg CH_4 / 1 kg CO_2 (100 year period);
- CH_4 contribution in total equivalent CO_2 emissions: 3%.

2.4.2. Biomass route

Figure 3 shows the most relevant stages in biomass life cycle. After wood extraction and chipping, wet wood chips are dried to 15% before being transported to the power plants. Both for wood and sugarcane bagasse pellets, not only the material is dried, but also compacted to pellets. Besides Diesel consumption in extraction and transport stages before reaching to the power plant, drying and pelletizing stages also demand relevant heat and electricity.

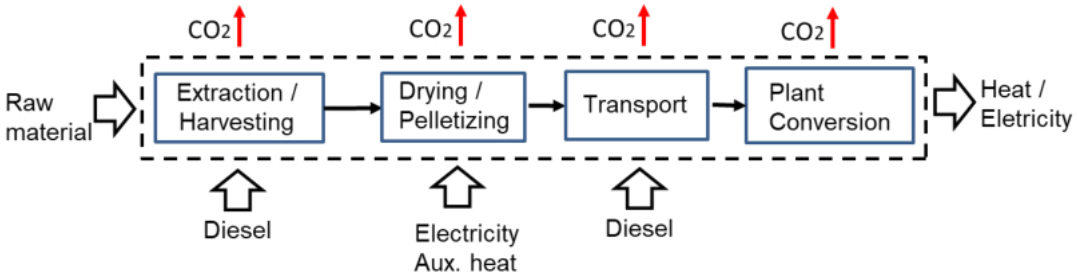

Figure 3. Biomass route to be consumed in existing power plants. Adapted from [19].

Premises for energy consumption and CO_2 emissions along biomass life cycle are the following [19]:

- Extraction executed by field harvesters, forwarders and chargers;
- Transportation logistics: road transport, 100 km radius;

As commented by [19], since silvicultural activities have a low level of mechanization compared to biomass extraction, harvesting and transport, then Diesel consumption at that stage is assumed to be not relevant to this analysis. Silviculture is therefore omitted from the biomass route illustrated in Figure 3.

3. Results and discussion

3.1. Thermal power plants

Table 4 shows the calculates efficiencies for each fuel and both plant configurations.

Table 4. Calculated efficiencies for each configuration.

Process parameter	Unit	Coal	Dry wood chips	Wood pellets	Sugarcane bag. pellets
Cogeneration Plant					
Fuel consumption	t/h	60.3	104.3	90.0	84.5
Fuel energy	MWh	430.2	428.8	429.8	429.7
Fuel exergy	MWh	475.5	454.9	449.2	449.1
Electricity generated	MWh	52.3	52.3	52.3	52.3
Steam to process	t/h	500.0	500.0	500.0	500.0
Thermal energy	MWh	338.5	338.5	338.5	338.5
Thermal exergy	MWh	136.6	136.6	136.6	136.6
Energy efficiency	%	90.9%	90.9%	90.9%	90.9%
Exergy efficiency	%	39.7%	41.5%	42.1%	42.1%
Pure Power Plant					
Fuel consumption	t/h	125.6	218.1	187.7	176.4
Fuel energy	MWh	896.6	896.6	896.6	896.6
Fuel exergy	MWh	991.0	951.2	937.2	936.9
Electricity generated	MWh	365	365.0	365.0	365.0
Energy efficiency	%	40.7%	40.7%	40.7%	40.7%
Exergy efficiency	%	36.8%	38.4%	38.9%	39.0%

The calculated values shown in Table 4 refer to gross electric power generation and energy efficiency, therefore not considering impacts on electricity consumption by auxiliary systems within the power plants, such as fuel milling before pulverization or induced and forced draft fans. Although it is expected that the fans demand will increase due to higher flue gas flows resulting from wet biomass compared to coal, such impact would represent less than 0,1% of total power generation and may be neglected in this preliminary approach. Auxiliary systems electric load and general losses in a pulverized fuel fired power plant would typically represent up to 10% of gross electric power generation, therefore resulting in a net energy efficiency of 35% to 37% [18], which is consistent with the calculated gross energy efficiency of 40.7% as shown in Table 4. Analogously, exergy efficiency for pure power plants would be reduced to the range between 33% and 35% when net electricity generation is considered.

Impacts on boiler efficiency due to biomass moisture content were minimized in this study due to the selection of low moisture (<15%) types of biomass, but this would be a major factor in the case of *Eucalyptus* and sugarcane bagasse *in natura*, harming the efficiency and making it not viable to convert and still preserve the boiler design capacity.

From the exergy approach, the advantage is clear for the use of dry types of biomass instead of coal. As shown previously in Table 3, all three types of biomass with low moisture content resulted in close values of chemical exergy comparing their own LHV, which positively affects the exergy efficiencies. Energy and exergy losses due to the process of drying biomass are not detected in the thermal plant analysis, making it necessary to analyze the fuel life cycle to correctly quantify its influence.

Regarding the cogeneration configuration, exergy efficiencies are remarkably lower than energy efficiencies, as expected, since exergy approach calculates process steam as a low value stream, with low potential for electric power generation (15 bar a, 210°C).

3.2. Fuel life cycle

Coal and biomass life cycle performances are presented in Table 5. Each line shows the contribution of the most relevant energy sources consumed – Diesel (as fuel for extraction, handling and transportation vehicles), heat (for biomass drying), electricity – at specific energy consumption rates and equivalent CO_2 emissions along the fuel cycle from extraction stages to electricity conversion process.

Specific energy is calculated as the energy input to the energy output ratio, which is the inverse of the efficiency. The CO_2 emissions for coal and biomass life cycles are calculated according to [18] and [19], respectively, as the sum of direct, indirect and life cycle emissions.

Table 5. Calculated energy consumption and CO_2 emissions for each configuration.

Life cycle stage	Unit	Coal	Dry wood chips	Wood pellets	Sugarcane bag. pellets
Diesel					
Specific Energy	MJ/MWh	389	319	293	220
CO2 emissions	$kgCO_2$/MWh	28.2	22.4	21.2	16.0
Heat					
Specific Energy	MJ/MWh	0	969	1681	3778
CO_2 emissions	$kgCO_2$/MWh	0	0.3	0.5	1.1
Electricity					
Specific Energy	MJ/MWh	1590	766	571	403
CO_2 emissions	$kgCO_2$/MWh	2.2	1.1	0.8	0.6
Fuel					
Specific Energy	MJ/MWh	10073	10286	10286	10286
CO_2 emissions	$kgCO_2$/MWh	905.0	0.3	1.4	1.3
Total specific energy	MJ/MWh	12052	12340	12831	14687
Total CO_2 emissions	$kgCO_2$/MWh	935.4	24.0	23.9	18.9

Energy consumption and equivalent CO_2 emissions due to fuel extraction and distribution stages highly depend on the characteristics of the mining area (in the case of coal) and the distances to the power plant sites. The premises presented in section 2.3 are estimations based on the main Brazilian power plants, but they should be revised when studying specific cases. In any respect, such values represent a small fraction of total energy and emissions, therefore not harming final conclusions here stated.

As Table 5 shows, biomass processing stage (chipping, drying, compaction) represents a significant fraction of total specific energy consumed, from 8% in the case of dry wood chips to 25% in the case of sugarcane bagasse pellets, resulting in higher values of total specific energy consumption than that of coal. Although an economical study is beyond the scope of this paper, it is relevant to mention that biomass processing also implies in higher production costs, which may inhibit the selection of dry versions of biomass. Conversions of this type will most probably take place in cogeneration and power plants which must preserve and guarantee the current heat and electric power generation capacities in the future scenarios. Otherwise, wet versions of wood and sugarcane bagasse would be acceptable, even if requiring an expansion in the storage area or causing derating in the boiler thermal capacity.

Both for coal and biomass, the energy conversion stage is dominant in the life cycle, representing from 70% to 84% of total energy consumption. This indicates that the biggest efforts to achieve higher efficiencies should be focused on this stage, through the correct evaluation and selection of the burner technology, biomass properties and operation routines.

In contrast to the energy efficiency performance, the environmental performances of all three types of biomass show significant benefits when compared to coal performance. Table 5 shows that wood chips, wood pellets and sugarcane bagasse pellets emit from 19.0 to 24.0 equivalent kg CO_2 for each electric MWh generated, which represents less than 3% of mineral coal specific emissions. When multiplying this difference for the annual coal-based electricity generation in the Brazilian matrix in 2022, of 15327 GWh [40], it results in avoiding up to 14.0 equivalent Mt CO_2 each year, when converting 50% of the total installed coal-based capacity. Although coal currently represents only 3.3% of Brazilian electricity generation, it is responsible for around 24.4% of CO_2 emissions in that sector. The conversion of 50% of coal-based installed capacity to dry types of biomass would result represent an annual reduction of around 12% in annual CO_2 emissions in the electricity generation sector.

4. Conclusions

Under the global tendency of reducing CO_2 emissions and adhering to net-zero targets, it is expected that large scale coal-based systems will have to be converted to the use of renewable fuels, at least partially. In that decision, long term technical and environmental impacts need to be evaluated. This paper approaches the life cycle assessment of coal and different types of biomass when applied in typical configurations of the main coal-based power plants and cogeneration installed in Brazil.

Empirical correlations found in literature were utilized to calculate the chemical exergy of coal and biomass, reassuring that the resulting exergies for low moisture fuels deviate less from their LHV, which slightly increases the exergy efficiency of the thermal power plants from 38,4% to around 39,0% when comparing dry wood chips to pellets. Nevertheless, under the aspect of life cycle specific energy, biomass pellets result in a 19% higher specific energy consumption compared to dry wood chips, due to the significant thermal energy demand of drying and pelletizing stages. Such distinction between the performance of different types of low moisture biomass may only be detected if the life cycle approach is utilized, since energy efficiency within the power plant cycle may be very similar among them.

The analysis of large scale coal-based plants shows that the conversion to dry types of biomass (up to 15% of moisture content) is viable and demands relatively low intervention in the existing infrastructure for coal, as it has been previously demonstrated mainly in European plants. Particularly in Brazil, this kind of conversion is greatly motivated by the high availability and diversity of biomass residues and land for sustainable plantation. From the perspective of life cycle energy efficiency, the use of residues and less processed types of biomass is highly preferrable over pellets.

Abstract:

The use of evaporative cooling techniques for pre-cooling the inlet air of a condenser used in air conditioning applications has proven to be very effective in improving its performance. Ultrasonic techniques constitute a promising alternative to improve the design of evaporative pre-cooling systems. Compared to direct spray cooling applications, not only they eliminate the pressure loss induced in the inlet air stream but also, they are capable of generating smaller droplet sizes with reduced power consumption than a high-pressure spray nozzle. This paper deals with an experimental investigation of an ultrasonic spray atomiser used to pre-cool the air entering to the condenser of a heat pump used in air-conditioning applications. A set of 12 experimental tests were conducted on a test bench consisting of a subsonic wind tunnel with an ultrasonic spray atomiser installed in the test section. The influence of the air velocity and mass flow rate of sprayed water (depending on the number of active atomisers) on the performance of the system was investigated. The results of the study show the pre-cooling capacity of this system, under different operating conditions, through several performance indicators: evaporative cooling efficiency (saturation efficiency), temperature drop, wet bulb depression and evaporated water efficiency. The highest values of evaporative cooling efficiency occur in the low speed range of the tested airflows, for configurations of the atomisation system with a high number of active atomisers, and it has been found that the evaporative pre-cooling process is not homogeneous throughout the airflow for some operating conditions.

Keywords:

Evaporative cooling, ultrasonic spray atomiser, cooling efficiency, air conditioning

1. Introduction

Evaporative cooling techniques applied to the condenser of a refrigerating machine represent one of the most effective and immediately applicable solutions for improving the efficiency of domestic and commercial air conditioning systems worldwide. With these techniques it is possible to reduce significantly, mainly in countries with hot-dry climates, the energy demand and the high consumption peaks. Energy savings contribute to reducing the dependence on fossil fuel in any country and have a direct impact on its economic development and growth, as well as decreasing greenhouse gas emissions.

A considerable amount of studies in the literature show the benefits of pre-cooling techniques applied to different air conditioning systems. There are different strategies to reduce the temperature of the air entering the condenser. The most widely studied systems can be classified into: evaporative packings or pads and spray or mist generators. For direct evaporative coolers, Martínez et al. [1] investigated how different thicknesses of cooling pads influenced the energy performance of a split-type air-conditioner. They found that the highest increase of 10.6% in the overall coefficient of performance (COP) was achieved by a thickness of about 100 mm. The main drawback of pre-cooling systems based on evaporative pads is the additional pressure drop produced in the condenser air stream. Furthermore, this effect is present even if pre-cooling is not activated. Pressure drop causes a reduction in the air flow rate through the condenser and a decrease in its ability to reject heat to the environment. This means an increase in the condensation pressure, an additional compressor consumption and a reduced cooling capacity of the air-conditioning system, [2]. When water is sprayed over the evaporative pads and pre-cooling is activated, the temperature drop of the intake air to the condenser far outweighs both effects, the pressure drop and the air flow rate reduction, and results in savings of energy consumed by the compressor. However, when the water injection is not activated, the evaporative pads still generate a pressure loss that penalises the energy consumption in the compressor. Compared with direct evaporative coolers, mist or deluge systems give further installation flexibility because of their low profile piping network and provide negligible flow resistance to the air stream. Yu et al. [3] analysed the cooling effectiveness of mist in pre-cooling condenser air for an air-cooled chiller. In a subtropical climate, pre-cooling the condenser air by mist brought an increase of 0.36–8.86% and 0.34–10.19% in the coefficient of performance of the chiller

under the normal mode (conventional head pressure control) and the VSD mode (variable speed control for the condenser fans), respectively. However, the use of water spray or deluge can cause corrosion, scaling, and fouling on the heat exchanger bundles if water droplets are carried by the airstream to the heat exchanger bundles of the condenser. To avoid this, the system is required to evaporate all water in the airstream to prevent water droplet contact with the heat exchanger surface. Special wet media or spray nozzles may be required to meet the requirement. High-pressure nozzles provide small water droplets but at a higher cost. Water quality affects the performance of the nozzles and their maintenance cost, [4]. In view of the drawbacks found in current techniques for pre-cooling, a search for alternatives seems appropriate.

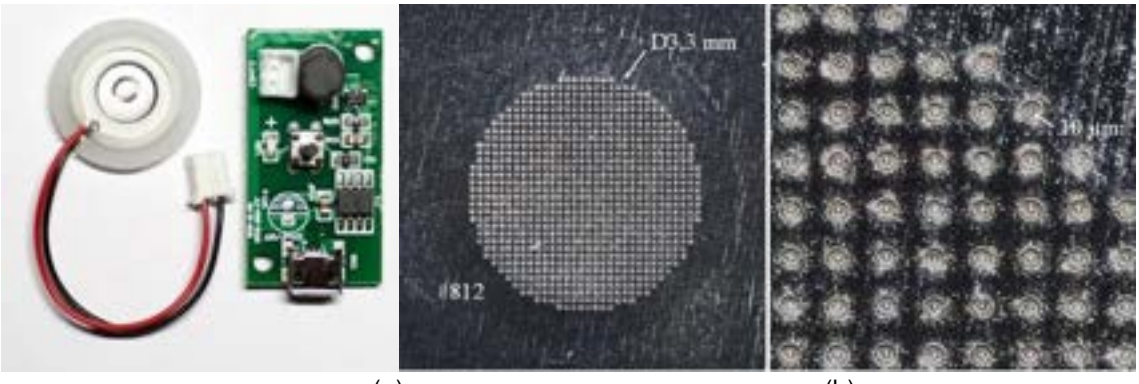
Applications of ultrasonic energy to enhance a wide variety of processes or to improve system efficiency have been explored in recent years. Yao [5] reviewed the studies addressing the applications of ultrasound as a new technology in the field of Heating, Ventilation and Air-Conditioning (HVAC). The author claimed that, from a general point of view, all the effects produced by ultrasound could be interesting in applications involving heat or mass transport, decreasing both the external and internal resistance to transport. Yao et al. [6] presented a review of the state-of-the-art of high-intensity ultrasound and its applications. However, the authors did not specifically cite evaporative cooling as an application of ultrasound, denoting the little attention they have received to date. Up to the knowledge of the authors, the studies conducted by Ruiz et al. [7] and Martinez et al. [8] were the first attempt to apply ultrasonic techniques (mist generator) to pre-cool the air entering the condenser in an air conditioning application. The authors experimentally analysed the performance of an ultrasonic mist generation system in [8]. Its thermal performance and its water mist production capacity were assessed in terms of the mass flow rate of atomised water and size distribution of the droplets generated. A CFD model of an ultrasonic mist generator specifically designed for HVAC applications was reported in [7]. The model was validated using the results obtained in [8], and the authors conducted a parametric analysis including some physical variables involved in the cooling process, and, finally, carried out an optimisation process regarding the overall cooling performance of the ultrasonic generator.

However, although the tests were satisfactory and their scientific interest has been revealed by the recent publications achieved, there are still many aspects related to the search for the optimal design of the pre-cooling system based on ultrasound techniques (reduce wet length and water power consumption). In conclusion, the works referring to the pre-cooling of the inlet air with ultrasonic atomisation techniques have been reviewed and it has been observed that this technique has received limited attention for this application, with few references found in the literature to date. Despite this, it has been proven that ultrasound technology constitute a promising method to improve the design of evaporative pre-cooling systems. Therefore, the main objective of this paper is to study the performance of an ultrasonic spray atomiser used to pre-cool the air entering to the condenser of a heat pump used in air-conditioning applications. The influence of the air velocity and mass flow rate of sprayed water (number of atomisers) on the performance of the system was investigated.

2. Materials and methods

2.1. Experimental test facility

To evaluate the performance and cooling capacity of the water mist produced by the ultrasonic atomiser, a set of tests has been conducted on a redesigned test bench specifically adapted for this purpose. The test rig mainly consists of two components: ultrasonic spray atomisers and a subsonic wind tunnel where evaporative cooling takes place.



(a) (b)

Figure 1: (a) Used ultrasonic spray atomisers and an oscillator circuit PCB. (b) Microscopic image of the water outlet holes in the spray atomisers used.

The device used in the system is a ultrasound spray atomiser (Fig. 1 (a)). This is composed of a ceramic piezoelectric, which surrounds a porous metallic membrane, and an oscillator circuit PCB that generates a pulse signal at a frequency of 108 kHz for the spray atomiser. When the current is supplied, the piezoelectric initiates an expansion/contraction cycle. This oscillation allows the water to pass through its microscopic holes (around 10 μm, Fig. 1 (b)) , and pushes the drops forming a column of water spray. The mass flow rate is approximately $1.95 \cdot 10^{-5}$ kg s^{-1}. This component is characterised by having a low cost and consumption (1.3 W). Table 1 shows the operating conditions and technical specifications of a spray atomiser.

Table 1: Spray atomiser technical specifications.

Magnitude	Value
Disc diameter	15.5 mm
Ceramic core diameter	8.5 mm
Porous membrane diameter	3.3 mm
Microscopic Holes Diameter	10 μm
Input voltage	DC 5 V
Power	1.3 W
Resonance frequency	108 kHz
Mass flow rate	$1.95 \cdot 10^{-5}$ kg s^{-1}
Exit speed of the drops	2.5 m s^{-1}

In this research, several atomisers work at the same time, therefore, a hydraulic installation was built to supply several units at the same time. For this, an ABS plastic body was used for the connection of the atomisers with a system of flexible silicone pipes. On the other hand, to avoid creating bubbles in the pipes, it was decided to use a low-flow pump (RS PRO 20) for the recirculation of the water. It has a maximum flow rate of 650 ml min^{-1} and a consumption of 5 W. Fig. 2 shows a schematic representation of the configuration of 5 $\times$ 5 atomisers (rows $\times$ columns) with which the experimental tests were carried out.

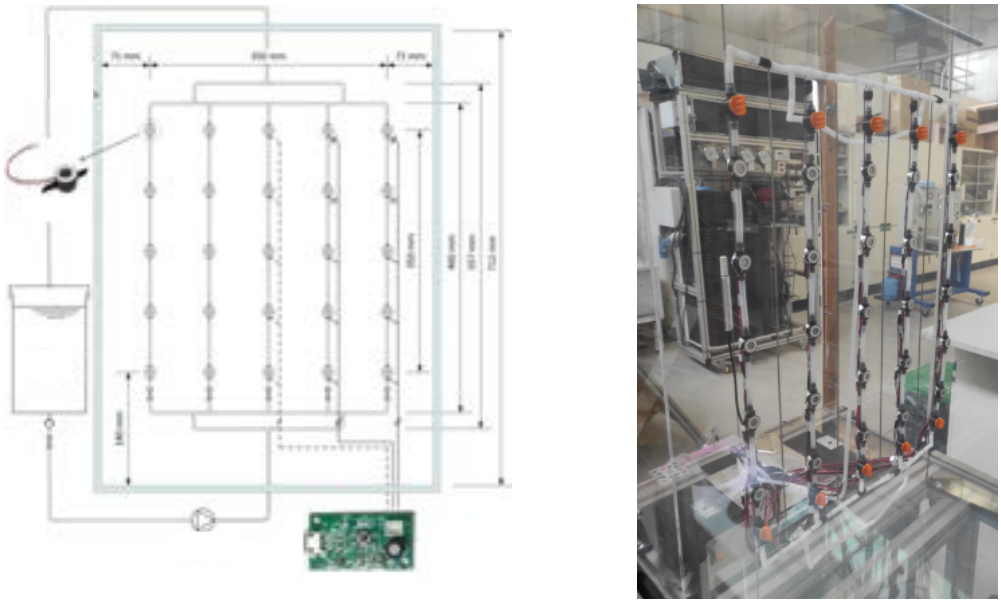


Figure 2: Scheme of the distribution of the spray atomisers in the form of a 5 $\times$ 5 manifold.

To carry out the experimental tests of ultrasonic evaporative cooling, the open-circuit subsonic wind tunnel shown in Fig. 3 was used. To ensure stable and uniform velocity profiles of the air flow, a nozzle was used along the honeycomb baffle (anti-turbulence screen), which was adapted for the tunnel entrance (leftmost part). It is not shown in the Fig. 3 because it is removed when modifications are made to the atomiser system. This nozzle has dimensions of 1.2 $\times$ 1.7 m^2 (cross-sectional) and a length of 1.55 m. While the test section of the wind tunnel has a cross section of 0.492 $\times$ 0.712 m^2 and a length of 5.3 m. A axial fan of 0.55-kW has been used to create the air flow inside the tunnel, which is located at the tunnel exit. This is associated with a variable-frequency drive that allows different air flows to be configured (from 0–3 m s^{-1}). The maximum

volumetric air flow rate allowed by the fan is 3783 m^3 h^{-1}. A detailed description of the wind tunnel can be found in [9, 10].

Figure 3: Subsonic wind tunnel facility in which the experimental tests are carried out.

2.2. Experimental procedure

A number of tests have been carried out to evaluate the performance of the ultrasonic spray system. Firstly, the flow rate of atomised water that the system is able to supply as a function of the number of working ultrasonic transducers has been studied by means of a gravimetric measurement method. A photographic technique with digital image processing has also been used to determine the size, emission speed and distribution of the droplets generated in the atomisation process. Finally, the pre-cooling capacity of atomised water when sprayed into an air stream has been evaluated as a function of both air flow velocity and atomised water flow rate (depending on the number of atomisers).

In order to reproduce in the wind tunnel the real operating conditions of the atomisation system when used to pre-cool the inlet air to a condenser of a conventional split-type air-conditioning system, tests were carried out with four different air flow rates covering the usual range of flow rates of this type of equipment: 0.5 m s^{-1}, 1 m s^{-1}, 1.5 m s^{-1} and 2 m s^{-1}. Different flow rates of atomised water were used in the tests using three configurations of the ultrasonic atomisation system with 5, 15 and 25 active atomisers, respectively, in order to determine the performance of the system in terms of water consumption and taking into account the power consumption of the ultrasonic transducers. Counting the different configurations of the atomisation system and the air flow velocities established in the wind tunnel, a total of 12 tests were carried out.

For each test, dry bulb temperature and relative humidity were measured at various positions along the central axis of the wind tunnel, as can be seen in Fig. 4, which shows a schematic of the location of the different sensors installed in the wind tunnel. On the other hand, a set of nine thermo-hygrometers was used to record the temperature and relative humidity distribution in a measurement cross section. T_{ms} and ϕ_{ms} refer to the average temperature and relative humidity at the measurement section. Finally, a hot-wire anemometer was used to measure the airflow peak velocity (v_a) at the centre of the wind tunnel. By means of a calibration test of the air flow through the tunnel, an experimental correlation was obtained to determine the mean velocity and the volumetric flow rate from this central peak velocity.

Table 2 shows the technical specifications and accuracy of the test bench probes used in both the wind tunnel calibration tests and during the experimental characterization tests of the ultrasonic spray atomiser. All measurements were recorded with a Keysight DAQ970A data acquisition unit incorporating two Keysight DAQM901A 20-channel multiplexer modules.

In accordance with UNE-EN 13741 [11], steady-state conditions were maintained throughout the wind tunnel tests. A maximum variation of ± 0.2°C at each of the temperature probes during a continuous measurement recording period of 5 minutes was set as the steady-state criterion for the tests. The temperature of the water supplied to the atomisation system was maintained in the same range of variation. Before the start of each test, all the equipment and instrumentation is started up with a stabilisation period of at least 20 minutes during which measurements are taken to correct the zero error of the temperature and relative humidity probes. In order to guarantee the repeatability of the measurements, each test lasted approximately 40 minutes, during

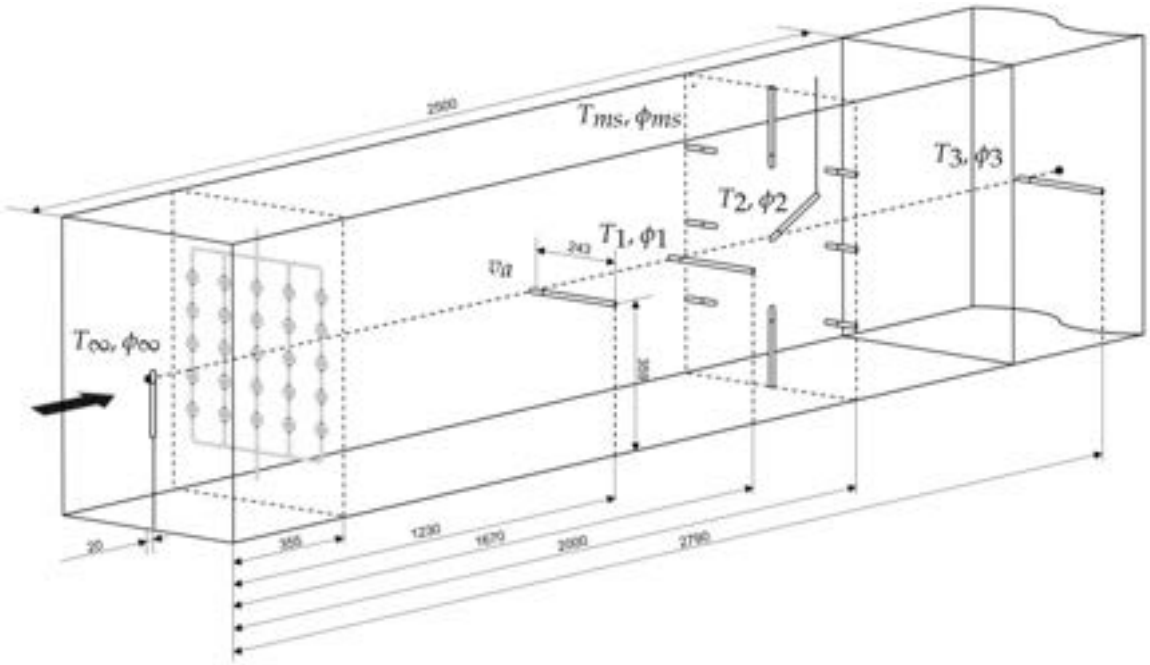

Figure 4: Schematic layout of the ultrasonic atomisation system and location of the probes and the measuring section in the wind tunnel.

Table 2: Specifications and characteristics of the test bench probes used during the experimental tests

Measurement	Measuring device	Brand	Model	Measuring range	Output signal	Accuracy
Air temperature	Thermohygrometer	E+E Elektronik	EE210-HT6xPBFxB	-20 to 80 °C	4–20 mA	± 0.2 °C

Water weight	Benchtop scale	PCE Instruments	PCE-TB 3	0–3 kg	4–20 mA	± 0.1 g

which measurements were taken every 7 seconds.

The atomised water flow rate was determined using a gravimetric method, measuring the initial and final mass of water supplied during each test with a benchtop scale and recording the time elapsed during the test. The average power consumption of the ultrasonic transducers was also determined by averaging the instantaneous power measured every 5 minutes.

3. Results and discussion

3.1. Measurement of water droplet size and spray emission speed

To determine the average size of the water droplets produced by the ultrasonic spray atomiser, a technique of high-speed photography and subsequent digital image processing has been used, similar to the method described by Ramisetty et al. [12]. A Pentax K-1 DSLR camera with a shutter speed of 1/8000s and a Tamron SP AF 90 mm F2.8 Di Macro 1:1 lens were used to measure the size of the droplets produced in the ultrasonic atomisation process. Due to the micrometric size of the droplets, it was necessary to attach an 18 cm extension tube to the lens to achieve a higher magnification of the captured images. The lighting was performed with a Pentax AF-360 FGZ automatic flash in TTL mode to achieve a t.5 peak duration time of approximately 1/20000 s.

Shots were taken over a reference atomiser, by placing the plume of atomised water between the lens and the flash and using a remote shutter release. The light emitted by the flash was filtered through a honey comb and then passed through a 3 mm grid to create a narrow illumination plane and thus reduce the number of drops that appear in each shot, as only the drops that cross the illumination plane are captured by the camera. An f-stop number of f/2.8 was used to provide a pronounced defocusing of the out-of-focus drops, so that some drops are isolated from others, which simplifies further digital processing.

The pictures taken with the camera were then processed with a graphic editor to increase contrast and acutance. An image analysis technique was used to measure the diameter of the droplets with both ImageJ and Fiji software. Fig. 5 shows an example of a high-speed shutter photography in which the movement of the droplets is frozen and diameter measurements can be made.

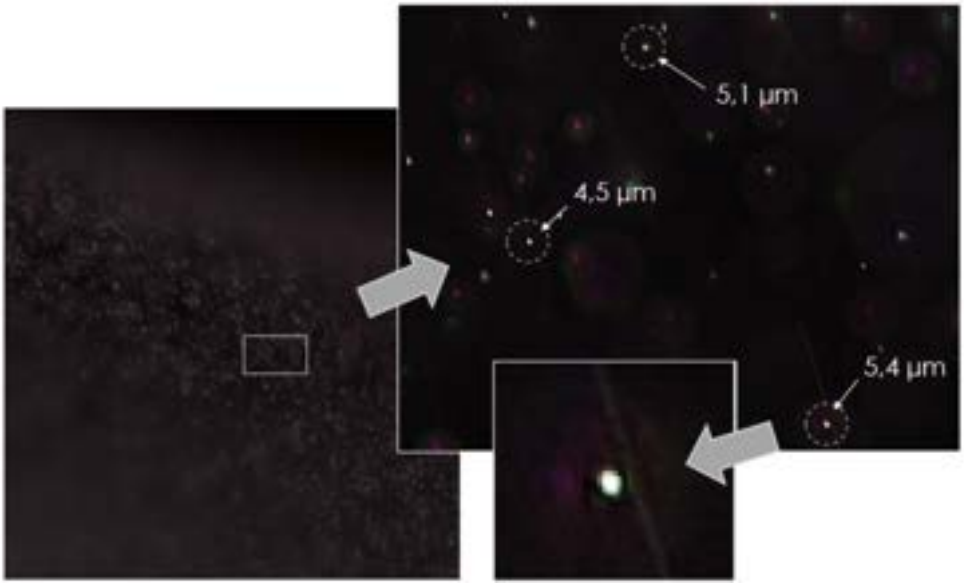

Figure 5: Example of a digitally processed high-speed photograph showing droplet diameter and size distribution.

The arithmetic mean diameter ($D_{1,0}$) and Sauter's mean diameter ($D_{3,2}$) of the droplets produced by the ultrasonic atomiser have been calculated according to the following general equation of the mean diameter:

$$D_{p,q} = \left[\frac{\sum_{i=1}^{N} n_i d_i^p}{\sum_{i=1}^{N} n_i d_i^q} \right]^{\frac{1}{p-q}} \tag{1}$$

where n_i stands for the number of droplets with a diameter d_i.

Finally, the arithmetic mean diameter of the droplets emitted by the ultrasonic atomiser under the test conditions is approximately $D_{1,0}$ = 5.0 μm and the Sauter mean diameter is $D_{3,2}$ = 5.2 μm. The uncertainty of this measurement method was calculated by considering a $\pm$1 pixel variation in the droplet diameter measurement by digital image processing. Taking into account the native camera resolution of 7360$\times$4912 pixels and the lens magnification factor, the maximum uncertainty was estimated to be $\pm$1.6 μm.

With this photographic technique it was also possible to measure the emission speed of the droplets generated in the ultrasonic atomisation process. From high-speed images showing the starting sequence of the atomised water injection (see Fig. 6), an approximate spray emission speed of 2.4 m s^{-1} was determined. This value is important to be able to perform a CFD simulation of the process and to determine the boundary conditions of the numerical model.

3.2. Thermal performance of the ultrasonic spray system

Table 3 summarises the operating conditions and configuration of the ultrasonic atomisation system in the conducted thermal performance tests and the experimental measurements obtained by the probes.

Based on the measurements obtained, a first study of the thermal behaviour of the atomisation system was carried out, taking into account the temperature drop reached in the air flow as it moves longitudinally through the wind tunnel. In this case, the temperature measurements obtained by the T_∞, T_1, T_2 and T_3 probes located on the central axis of the wind tunnel have been considered. A visual inspection of the water mist plume was also carried out during the tests to approximately determine the degree of evaporation of the supplied water flow, since as long as it is visible it indicates that there are still non-evaporated droplets that may be able to produce additional evaporative cooling within the air flow.

Fig. 7 shows the results of the longitudinal evolution of the temperature drop for the three configurations of 5, 15 and 25 active atomisers and for the different levels of air flow velocity considered in the tests. These graphs

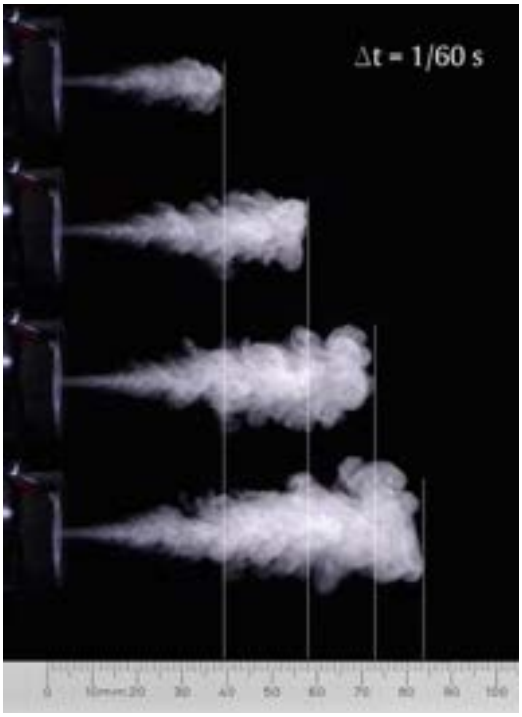

Figure 6: High-speed images showing the initial sequence of atomised water injection used to determine the spray emission speed.

show, as expected, that the largest temperature drops occur at lower levels of air velocity, since low velocity leads to an increase in the residence time of the water droplets in the air, which allows a higher transfer of sensible and latent heat between the water and the air.

For low air velocity levels (0.5–1 m s^{-1}), the largest longitudinal temperature drop occurs in almost all cases at probe T_1, the first one downstream of the atomisation section. From that moment on, the temperature drop of the air evolves along the tunnel, slightly decreasing its value. This effect is caused by the fact that the volume of atomised water is more concentrated at the centre of the tunnel and, therefore, this is where the evaporative cooling of the air is most intense, whereas at points away from the centre, the air temperature does not decrease as much. Far away from the atomisation section, a progressive temperature equilibrium is established in the air flow, which causes the temperature value measured at the central axis to be closer to the average temperature of the air flow cross-section at that location. The resulting non-homogeneity in the atomisation process is the reason for the longitudinal decrease in temperature drop observed in the graphs for the different levels of air velocity.

On the other hand, for higher air velocities (1.5–2 m s^{-1}) the highest temperature drop occurs at a distance further away from the atomisation section, between the probes T_1 and T_2, because at these velocities the droplets travel a longer distance before evaporating completely.

In the results for the configuration of 5 active atomisers, some anomalous behaviours are observed, such as a sharp drop in the temperature drop at the end of the tunnel for the velocity of 0.5 m s^{-1}. This may be due to

the lack of uniformity in the generation of atomised water, which is more pronounced the smaller the number of active atomisers.

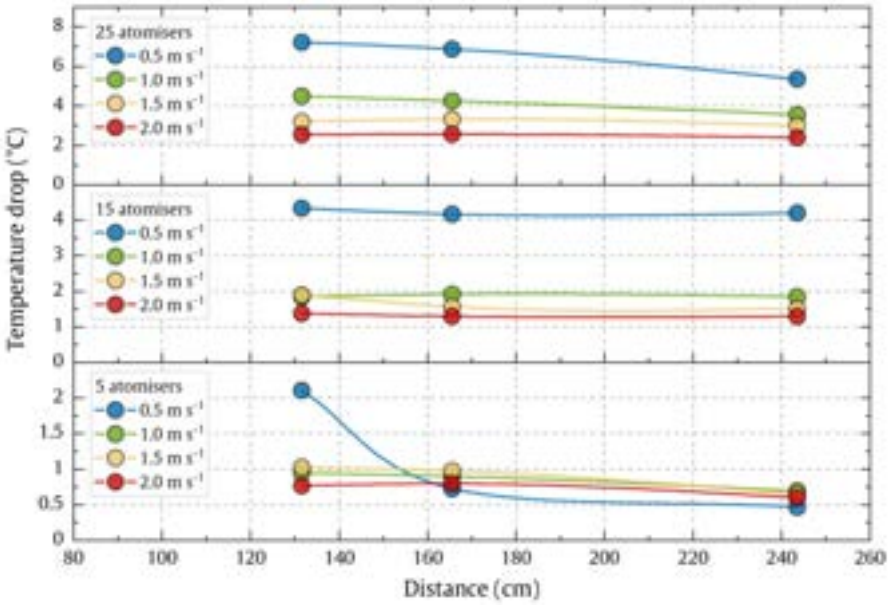

Figure 7: Temperature drop measured by the thermo-hygrometers located on the longitudinal axis of the wind tunnel, as a function of the distance of the probes from the atomisation section and the velocity of the air flow.

A study of the thermal behaviour of the atomisation system was then carried out, centred on a measurement cross-section in which a total of 9 thermo-hygrometers were installed to record the level of homogeneity of the evaporative cooling caused in the air flow. Table 4 and Fig. 8 show the values of the temperature drop recorded in each of the thermohygrometers that constitute the measurement section, for the three configurations of the atomisation system (5, 15 and 25 active atomisers) and for the four levels of air flow velocity.

Table 4: Temperature drop (°C) recorded on the 9 thermo-hygrometers located in the measuring cross-section of the wind tunnel, as a function of the active number of atomisers and the different levels of air flow velocity.

	Air flow velocity											
	0.5 m s^{-1}			1 m s^{-1}			1.5 m s^{-1}			2 m s^{-1}		
25 atomisers	1.0	3.8	2.8	1.6	0.8	2.3	0.9	0.4	1.2	0.9	0.3	1.3
	6.1	6.9	6.0	2.6	4.3	3.6	1.9	3.3	2.6	1.7	2.6	2.1
	6.4	7.2	6.5	1.6	3.6	2.1	0.8	2.1	0.9	0.6	1.6	1.0
15 atomisers	0.3	0.5	0.7	1.2	1.3	0.9	0.3	0.3	1.5	0.4	0.1	1.3
	3.8	4.2	4.8	2.0	1.9	2.1	1.1	1.6	1.9	0.9	1.3	1.4
	4.3	5.0	4.9	1.2	2.4	1.9	1.0	1.2	1.0	0.9	1.1	1.1
5 atomisers	0.2	0.1	0.4	0.5	0.4	0.2	0.2	0.1	0.1	0.4	0.1	0.2
	0.4	0.7	1.2	0.9	0.9	0.4	1.0	1.0	0.3	0.3	0.8	0.4
	2.7	2.7	2.9	0.7	1.7	0.3	0.3	0.9	0.4	0.3	1.1	0.5

From the temperature drop measurements, it can be seen that, for low velocities, very significant temperature drops are obtained in all the tests. However, as the number of active atomisers decreases, the temperature drop registered on the upper thermo-hygrometers and those located in the central area decreases. A lack of uniformity in the temperature drop can also be observed and, for example, the temperature drop in the upper right area of the measurement section is usually higher than that obtained in the upper left area. This situation may be caused by non-uniform atomisation of water or also by the development of turbulent vortices in the air flow. For all three configurations of the atomisation system, as the velocity increases, the temperature drop in the measurement section decreases, because the air mass flow rate is higher.

Fig. 9 shows a comparison of the calculated average values of the evaporative cooling efficiency or saturation efficiency (η_{sat}) and the wet bulb depression (WBD) for the three configurations of the atomisation system and

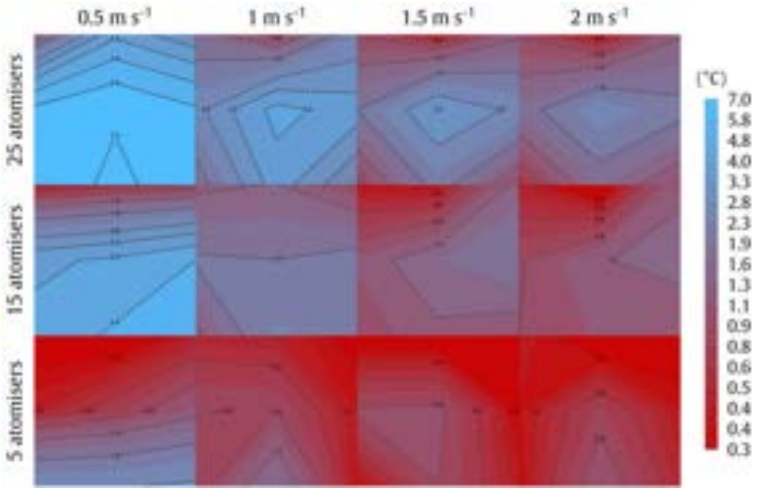

Figure 8: Contour plot of data presented in Table 4.

as a function of different air flow velocities. The saturation efficiency and the wet bulb depression have been calculated from the following expressions:

$$\eta_{sat} = \frac{\omega_{ms} - \omega_{\infty}}{\omega_s^* - \omega_{\infty}} = \frac{T_{\infty} - T_{ms}}{WBD} \tag{2}$$

$$WBD = T_{\infty} - T_{wb} \tag{3}$$

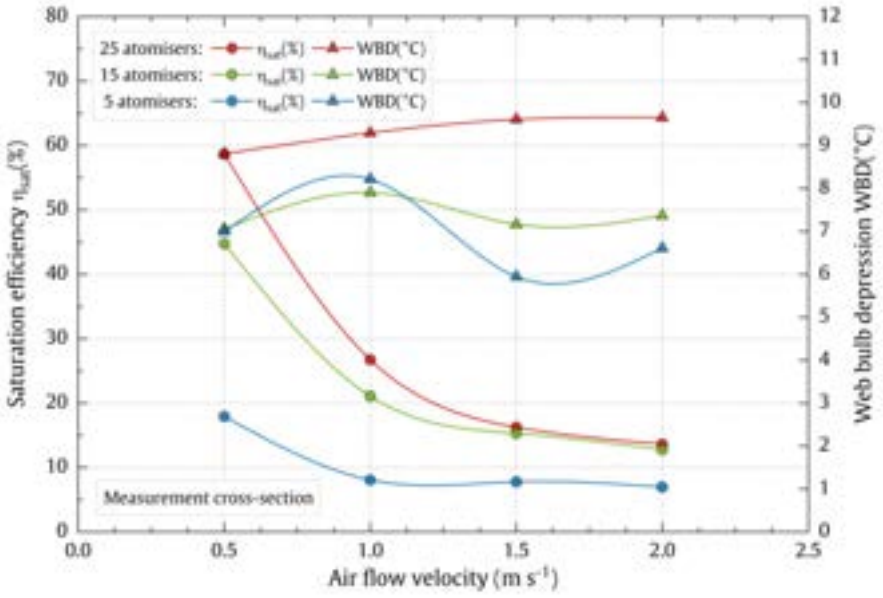

Figure 9: Comparison of the saturation efficiency (η_{sat}) and the wet bulb depression (WBD) for the three configurations of the atomisation system and as a function of different air flow velocities.

In Fig. 9 we can see that for high air flow velocities (1.5 m s^{-1} and 2 m s^{-1}) the results are very similar in the configurations of 25 and 15 atomisers. However, the saturation efficiency alone may be insufficient to obtain a clear interpretation of the evaporative cooling phenomenon taking place and it is necessary to include in the graph the wet bulb depression, which represents the largest possible temperature drop, i.e., the difference between the dry bulb temperature of the incoming air and its wet bulb temperature. Thus, if we compare the configurations of 15 and 25 atomisers for high air flow velocities we can see that, although they have a very similar saturation efficiency, as the web bulb depression is higher in the case of 25 atomisers, this implies that the temperature drop will also be higher for the configuration of 25 atomisers.

Finally, Fig. 10 shows a comparative study for the configuration of 25 atomisers of the evaporative cooling achieved in the measurement cross-section with respect to the maximum cooling that could be obtained if the entire flow of atomised water were evaporated before reaching the measurement cross-section. For this study, a novel performance indicator called evaporated water efficiency (η_{evap}) was considered, that denotes the extent to which the temperature in a particular region of the air flow (T_{ms}) approaches the minimum temperature (T_{min}) that would be reached if all the atomised water evaporates, defined as:

$$\eta_{evap} = \frac{T_\infty - T_{ms}}{T_\infty - T_{min}} = \frac{T_\infty - T_{ms}}{\frac{\dot{m}_w h_{fg}}{\dot{m}_a c_{pma}}} = \frac{1}{r_w} \frac{c_{pa} + \omega_a c_{pv}}{h_{fg}} (T_\infty - T_{ms}) \tag{4}$$

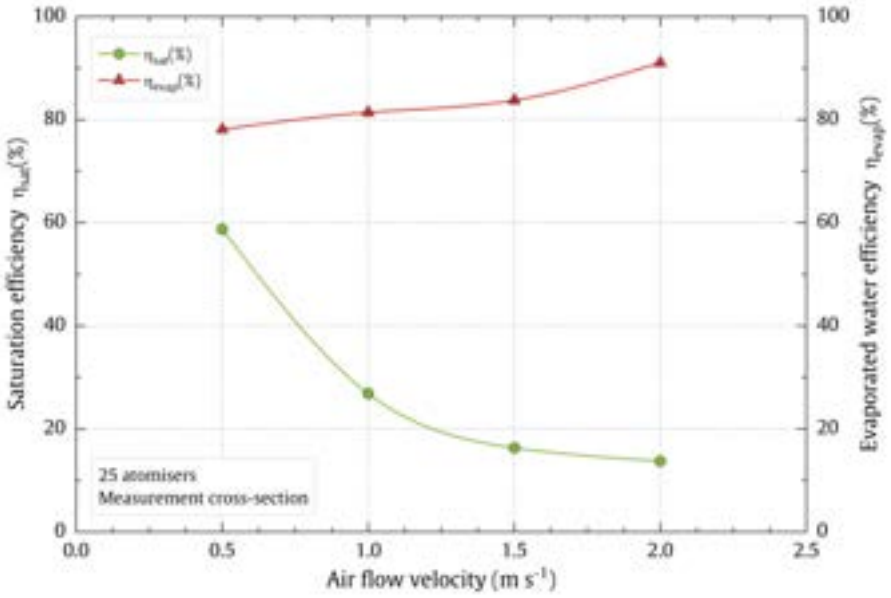

Figure 10: Comparative study of the saturation efficiency and the evaporated water efficiency for the configuration of 25 atomisers. Values close to η_{evap} = 100% indicate a more uniform distribution of the evaporative cooling effect.

The evaporated water efficiency can be used to identify the operating conditions of the atomisation system that lead to the most uniform and homogeneous evaporative cooling (η_{evap} = 100%) throughout the air flow, with complete utilisation of the supplied water.

4. Conclusions

In this article, an experimental study of the operating conditions and thermal behaviour of an ultrasonic atomisation system for evaporative pre-cooling of the inlet air of a condenser in air conditioning applications has been carried out.

Firstly, a measurement of the water droplet size and the emission speed of the atomiser was conducted using a high-speed photography technique and digital image processing to determine the average size of the water droplets produced by the ultrasonic atomiser and the emission speed of the atomiser. As a result, it has been obtained that the arithmetic mean diameter of the droplets emitted by the ultrasonic atomiser under the test conditions is approximately $D_{1,0}$ = 5.0 μm, the Sauter mean diameter is $D_{3,2}$ = 5.2 μm, and the approximate spray emission speed is 2.4 m s^{-1}.

An experimental study of the thermal behaviour of the atomisation system was then carried out in a wind tunnel to determine the longitudinal and transversal evolution of the temperature drop, specific humidity and saturation efficiency at different locations along the central axis of the wind tunnel and at a specific cross-section downstream of the atomisation section. The results of this study have provided information on the configurations of the atomisation system and the air flow velocities that provide the greatest potential of pre-cooling.

A maximum temperature drop of 7.2℃ was obtained for a configuration of 25 atomisers and 0.5 m s^{-1} at the temperature probe T_1, located at 131.5 cm from the atomisation section. Under the same operating con-

ditions, the maximum saturation efficiency, calculated from the 9 thermo-hygrometers in the measurement cross-section, was 58.7% and the wet bulb depression value was 8.8°C.

It has been noticed that the lowest air velocities lead to the highest saturation efficiencies in the measurement cross-section. Furthermore, it has been found that for velocities of 0.5 m s^{-1} and 1 m s^{-1}, and for a configuration of 25 atomisers, the supplied water is almost completely evaporated when the air flow reaches the measurement cross-section, located 164.5 cm downstream of the atomisation section.

Finally, it has been found that the evaporative cooling process is not homogeneous throughout the air flow under many operating conditions, so a new performance indicator called evaporated water efficiency (η_{evap}) has been defined to specifically evaluate this phenomenon.

From the results of this study, it is concluded that an ultrasonic atomisation system is a promising alternative to conventional evaporative cooling systems that can be used to pre-cool the incoming air flow into a condenser with the following advantages: no pressure loss in the air flow; no maintenance, cleaning or replacement of evaporative pads and no accumulation of salts; no recirculation or storage of a large volume of water. However, there are a number of issues that still need to be addressed in future research, such as optimising the energy consumption of the ultrasonic transducers and increasing the evaporation rate of the droplets to reduce the wet length and reduce the potential impact of droplets on the condenser heat exchanger. A final issue to be solved is the optimisation of the atomised water distribution to ensure a more homogeneous pre-cooling throughout the air flow.

Abstract:

The efficiency of a Concentrated Solar Power (CSP) plant strongly depends on the temperature at what the steam is condensed. To date, the conventional systems used to remove the heat from CSP plants are either water (wet) or air-cooled (dry). The use of wet cooling in CSP plants results in the best plant performance. This efficiency increase, however, comes at a high cost: huge water use. This fact is crucial since CSP plants are, in general, located in arid areas where water is scarce. Dry cooling eliminates the water use but suffers from lower efficiency when ambient air temperature is high. Those hot periods are often the periods of peak system demand and higher electricity sale price. A combined cooling system (combination of dry and wet cooling) offers the advantages of each process in terms of lower water consumption and higher electricity production. The ultimate goal of this research is to model and optimise the performance of a CSP plant operating alongside with a combined cooling system in terms of water consumption and net power generation. This paper focuses on the wet cooling tower modelling validated with experimental data from a pilot plant. In this sense, two different models are compared: the Poppe model and an artificial neural network (ANN). Both models are compared in terms of performance prediction (water outlet temperature and water use), experimental requirements and applications. Although both models are reliable (for outlet water temperature, R^2 = 0.97 and RMSE= 1.01°C with the ANN, and $R^2 \approx 1$ and RMSE$<$ 0.36°C for with the Poppe model), it was found that depending on the variable, each model had its strengths and weaknesses.

1. Introduction

Concentrated Solar Power (CSP) plants use mirrors to concentrate the sun's energy to drive steam turbines that create electricity. This technology currently represents a minor part of renewable energy generation in Europe. Only approximately 5 GW are installed globally (of which 2.3 GW in Europe, concentrated in Spain). However, the potential for growth is significant given the capability of CSP to provide renewable electricity when needed, unlike other technologies that are dependent on the availability of the energy source. This dispatchability is possible thanks to in-built energy storage and enables plants to respond to peaks in demand, continue production even in the absence of sunlight, and provide ancillary services to the grid. According to the International Energy Agency forecasts, CSP has a huge potential in the long term, ranging from the 986 TWh by 2030 up to 4186 TWh by 2050 according to the Sustainable Development hi-Ren scenario (Energy Technology Perspectives 2014), meaning CSP will account for 11% of the electricity generated worldwide and 4% in Europe. As the technological leader in the sector, the EU has much to gain from such expansion. To remain a global leader, the European industry needs to stay ahead with more advanced, competitive technologies. CSP plants are, in general, located in arid areas, where water is scarce. The efficiency of these plants strongly depends on the temperature at what the steam is condensed. To date, the conventional systems used to remove the heat from CSP plants are either water (wet) or air-cooled (dry). The lowest attainable condensing temperature is the wet-bulb temperature (wet system). This efficiency increase comes at a high cost: huge water use. Dry cooling eliminates the water use but suffers from lower efficiency when ambient air temperature is high. Those hot periods are often the periods of peak system demand and higher electricity sale price.

There are different types of innovative cooling systems that can reduce the water consumption: those that integrate the dry and wet cooling systems into the same cooling device, which are called hybrid cooling systems [1–3] and those that combine a dry and a wet cooling system, which are called combined systems. In the last case, different configurations can be found.The most proposed in the literature is the one considering an Air

Cooled Condenser (ACC) in parallel with a Wet Cooling Tower (WCT) [4, 5]. In this case, the exhaust steam from the turbine is condensed either through the ACC or through a surface condenser coupled with the WCT. Another configuration, recently proposed in Palenzuela et al. [6] is a wet and a dry cooling tower (type air cooled heat exchanger) sharing a surface condenser. In this case, the exhaust steam from the turbine is condensed through the surface condenser and the heated cooling water is cooled either through the WCT or through the dry cooling tower. Combined systems are the most suitable option for a flexible operation as a function of the ambient conditions, allowing to select the best operation strategies to achieve an optimum water and electricity consumption [7]. To optimise the operation of this kind of refrigeration systems, modelling each one of its components is required as a first step.

Regarding WCT modelling, two kind of models can be distinguished: those based on physical equations and black-box model such as artificial neuronal networks (ANN). The analysis of wet cooling towers through modelling (physical equations) has its origin in [8], where the theory for the performance evaluation of wet cooling towers was developed. The author proposed a model based on several critical assumptions to reduce the solution of heat and mass transfer in wet-cooling towers to a simple hand calculation. Because of these assumptions, however, the Merkel method does not accurately represent the physics of the heat and mass transfer process in the cooling tower. Bourillot [9] stated that the Merkel method is simple to use and can correctly predict cold water temperature when an appropriate value of the coefficient of evaporation is used. In contrast, it is insufficient for the estimation of the characteristics of the warm air leaving the fill and for the calculation of changes in the water flow rate due to evaporation. These quantities are important to estimate water consumption and to predict the behaviour of plumes exiting the cooling tower. Jaber and Webb [10] developed the equations necessary to apply the effectiveness-NTU method directly to counterflow or crossflow cooling towers. This approach is particularly useful in the latter case and simplifies the method of solution when compared to a more conventional numerical procedure. The effectiveness-NTU method is based on the same simplifying assumptions as the Merkel method. Poppe and Rögener [11] developed the Poppe method. They derived the governing equations for heat and mass transfer in a wet cooling tower and did not make any simplifying assumptions as in the Merkel theory. Predictions from the Poppe formulation result in values of evaporated water flow rate that are in good agreement with full scale cooling tower test results. In addition, the Poppe method predicts the water content of the exiting air accurately.

Although the theoretical analysis of WCT has demonstrated successful results with not excessive complexity, black box models based on experimental data are also available in the literature. Numerous authors have designed ANN models for WCT with different objectives, such as performance prediction, simulation and optimisation. One of the first works in this area is the one described in [12] where an ANN model was developed to predict the performance of a forced-counter flow cooling tower at lab scale. In this case, the input variables were the dry bulb temperature, relative humidity of the air stream entering the tower, the temperature of the water entering the tower, the air volume flow rate and the water mass flow rate. The outputs of this model were the heat rejection rate at the tower, the mass flow rate of water evaporated, the temperature of the water at the tower outlet and the dry bulb temperature and relative humidity of the air stream leaving the tower. The results obtained with a 5-5-5[1] ANN demonstrated that cooling towers at lab-scale can be modelled using ANNs within a high degree of accuracy. At lab-scale there are also ANN models for Natural Draft Counter-flow Wet Cooling Towers (NDWCT) such as the one proposed by [13]. In this case, the authors used a 4-8-6 ANN structure and considered some additional variables, such as air gravity, wind velocity, heat transfer coefficients and efficiency as outputs. All these works at lab-scale can be useful to validate the model development methodology but may fail predicting the performance of WCT at larger scale. In this sense, special attention deserves the study carried out by [14] where an 8-14-2 ANN model was proposed to predict the performance (the cooling number and the evaporative loss proportion) of NDWCTs at commercial scale. The model is based on 638 sets of field experimental data collected from 36 diverse NDWCTs used in power plants. It is a very challenging work since it covers samples from a wide range of tower sizes and capacities but the results show that the Mean Relative Error (MRE) is below 5%. From the ANN models found in the literature, it can be concluded that these computational models are able to predict WCT performance with satisfactory results, but it is necessary to deepen and reflect when it is convenient to develop models of this type or to use others, either based on experimental data or based on physical equations. In the literature, comparisons between ANN and Response Surface Methodology (RSM) models for WCT can also be found [15], such as the case of where ANN model is compared with one obtained with the RSM. Although the results obtained show that ANN model predictions are better than RSM model, the study is based on data from a WCT lab-scale system, with only one output (the cooling temperature) and no ambient conditions variability.

Based on the previous discussion, the ultimate goal of this research is to optimise the operation of combined cooling systems integrated into CSP plants in terms of water consumption avoiding a penalty in the plant performance . This paper presents a comparison between the Poppe model (based on physical equations) and

[1] The notation n_1-...-n_l represents the architecture of the ANN model, where l is the number of layers and n_i are the nodes in each one of the layers.

a model based on an ANN for performance evaluation of wet cooling towers. For the calibration of the physical model and for the development of the neural network model, experiments have been performed in a 200 kW_{th} WCT integrated into a combined cooling system pilot plant, located at Plataforma Solar de Almería (PSA). The comparison between models not only evaluates the outputs accuracy obtained with both models, but also discusses other aspects such as required inputs/outputs and parameters, minimal number of experiments and possibility of applying these models for different purposes.

This paper is organised as follows: section 2. contains the description of the experimental facility, the mathematical modelling, and the experimental procedure for the performance tests. Next, the results obtained in the tests are presented and discussed in section 3. Finally, the the most important findings of the research are summarised in section 4.

2. Methodology

2.1. Description of the pilot plant

The pilot plant of combined cooling systems located at PSA (see the layout in Figure 1) consists of three circuits: cooling, exchange and heating. In the cooling circuit (see a picture in Figure 2), refrigeration water circulating inside the tube bundle of a Surface Condenser (SC) can be cooled through a Wet Cooling Tower and/or a Dry Cooling Tower (type Air Cooled Heat Exchanger), both with a designed thermal power of 204 kW_{th}. In the exchange circuit, a saturated steam generator of 80 kWth (on the design point), generates steam at different pressures (in the range between 82 and 200 mbar), which is in turn condensed in the surface condenser that has a thermal power at design conditions of 80 kW_{th}. In this way, the steam transfers its latent heat of condensation to the refrigeration water, that is heated. Finally, in the heating circuit, a solar field with a thermal power of 300 kW_{th} at the design point, provides the energy source required by the steam generator, in the form of hot water. It is a unique, very flexible, fully instrumented and versatile facility, able to operate in different operation modes: series and parallel mode, conventional dry-only mode (all water flow is cooled through the dry cooling tower) and wet-only mode (all water flow is cooled through the wet cooling tower). For this work, the wet-only operation mode has been used, in which the cooling water (FT-003) is pumped by Pump 1 from the basin of the WCT to the surface condenser, circulating through Valve 2 position I up to the entrance of the WCT where water is sprayed. The velocity of air going through the tower is regulated by variable frequency drive (SC-001). The water losses by evaporation in the tower are replaced by demineralised water (FT-004) when the basin level decreases. The sensors used in this operation mode and their characteristics in terms of errors are shown in Table 1.

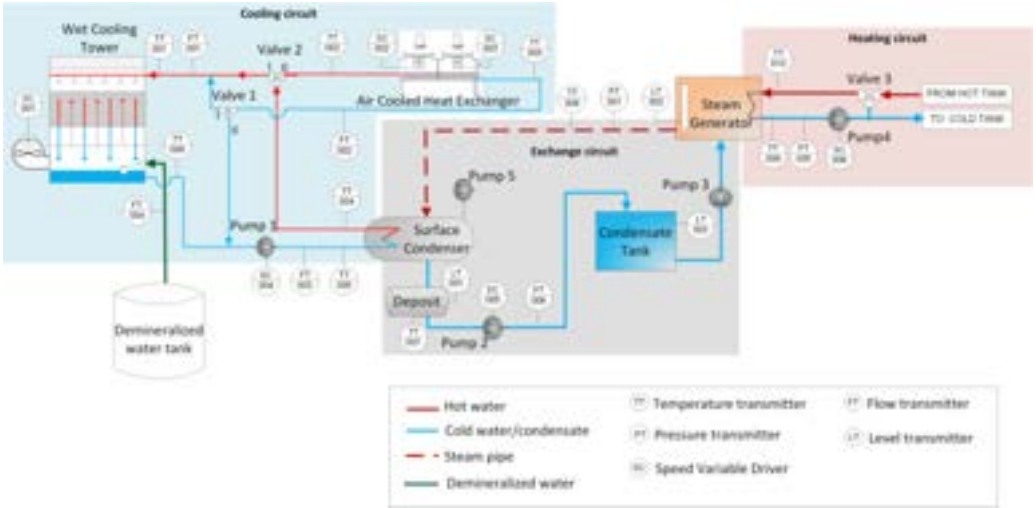

Figure 1: Layout of combined cooling systems pilot plant at PSA.

2.2. Experimental campaign

As mentioned in section 1., two models have been developed for performance evaluation of a WCT: the Poppe model (based on physical equations) and ANN (based on experimental data). With the aim of calibrating and validating both models, 19 experimental tests were performed at the combined cooling pilot plant located at PSA. The physical model focuses on the calculation of the Merkel number, which according to the literature depends on the water-to-air mass flow ratio ($\dot{m}_w/\dot{m}_a$). Therefore, the experimental camping has been designed to cover different water-to-air mass flow ratios. This criterion is also valid with the neural network model, since varying $\dot{m}_w/\dot{m}_a$ allows obtaining different operating points, which helps in collecting information from different

Figure 2: Picture of the cooling circuit in the combined cooling pilot plant at PSA.

Table 1: Characteristics of instrumentation ([a] value of the temperature in °C, [b] of reading, [c] full scale, [d] mean value).

Measured variable	Instrument	Range	Measurement uncertainty
Water temperature, TT-001, TT-006	Pt100	0 - 100°C	$0.3 + 0.005 \cdot T^a$
Cooling water flow rate, FT-001	Vortex flow meter	9.8 - 25 m^3/h	$\pm$ 0.65% o.r.[b]
Water flow rate, FT-004	Paddle wheel flow meter	0.05 - 2 m^3/h	$\pm$ 0.5% of F.S[c] + 2.5% o.r
Ambient temperature	Pt1000	-40 - 60°C	$\pm$ 0.4 @20°C
Relative humidity	Capacitive sensor	0 - 98%	$\pm$ 3 % o.r @20°C
Air velocity	Impeller anemometer	0.1-15 m/s	$\pm$ 0.1 m/s + 1.5% m.v.[d]

scenarios that can occur in tower. At the experimental facility, $\dot{m}_w/\dot{m}_a$ can be modified in two ways, with Pump 1 ($\dot{m}_w$) and with the fan frequency SC-001 ($\dot{m}_a$). Both variables were varied within the allowable range for plant operation. In the case of the water flow, it ranged from 8 to 22 m^3/h. The air mass flow rate was modified by changing the frequency from 12.5 to a maximum of 50 Hz. Therefore, the experimental values of $\dot{m}_w/\dot{m}_a$ obtained were in the range 0.5-5. The thermal load was $\approx$ 170 kW_{th} in all tests conducted.

The standards UNE 13741 "Thermal performance acceptance testing of mechanical draught series wet cooling towers" [16] and CTI "Acceptance Test Code for Water Cooling Towers" [17] were taken as a reference to evaluate that stationary conditions were achieved during the tests, in which it is established that the duration of the test should not be less than one hour. During the test, the maximum deviation of circulating (or cooling) water flow rate, heat load and range cannot be more than 5%. For the wet-bulb temperature and dry-bulb temperature, the linear least-squares trends should not exceed 1°C and 3°C, respectively. Both variables shall not have a deviation greater than $\pm$1.5°C and $\pm$4.5°C, respectively. Finally, it must be verified that the average wind velocity did not exceed 4.5 m/s throughout the test and punctually (for a minute) the 7 m/s.

2.3. Modelling

The models presented in this section have been developed to predict two main outputs, the water temperature at the outlet of the WCT, $T_{wct,out}$, and the water consumption, $\dot{m}_{wct,lost}$. As inputs, both models require five variables: the cooling water flow rate ($\dot{m}_w$), inlet water temperature ($T_{wct,in}$), ambient temperature (T_∞), ambient relative humidity (ϕ_∞) and the frequency level of the fan (f_{fan}) (or the air mass flow rate[2] ($\dot{m}_a$).

2.3.1. Poppe model

The well-known Merkel number is accepted as the performance coefficient of a wet cooling tower, [18]. This dimensionless number is defined in Equation 1, and it measures the degree of difficulty of the mass transfer processes occurring in the exchange area of a cooling tower.

[2]ANN uses as input f whereas Poppe's model uses $\dot{m}_a$.

$$\mathrm{Me} = \frac{h_D a_v V}{\dot{m}_w}, \tag{1}$$

where the variables and parameters involved are described in the Nomenclature Section.
The Merkel number can be calculated using the Merkel and Poppe theories for performance evaluation of cooling towers. The Merkel theory [8] relies on several critical assumptions, such as the Lewis factor (Le) being equal to 1, the air exiting the tower being saturated with water vapour and neglecting the reduction of water flow rate by evaporation in the energy balance. For this reason, the Poppe theory [11] is usually preferred. In this theory, the authors derived the governing equations for heat and mass transfer in the transfer region of the cooling tower (control volume shown in Figure 3, one dimensional problem). The detailed derivation process and simplification of the previously-mentioned governing equations can be found in [18]

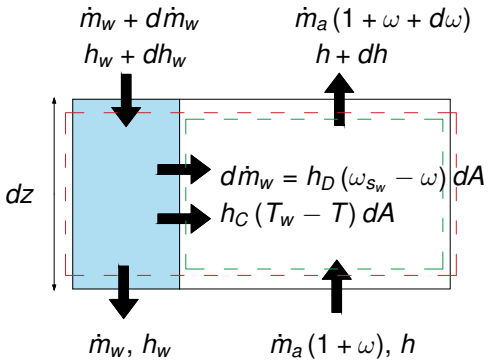

Figure 3: Control volume in the exchange area of a wet cooling tower for counterflow arrangement.

According to the Poppe theory, the major following equations for the heat and mass transfer are obtained:

$$\frac{d\omega}{dT_w} = \frac{c_{p_w}\frac{\dot{m}_w}{\dot{m}_a}\,(\omega_{s_w} - \omega)}{(h_{s_w} - h) + (\mathrm{Le} - 1)\,[(h_{s_w} - h) - (\omega_{s_w} - \omega)\,h_v] - (\omega_{s_w} - \omega)\,h_w} \tag{2}$$

$$\frac{dh}{dT_w} = c_{p_w}\frac{\dot{m}_w}{\dot{m}_a}\left[1 + \frac{(\omega_{s_w} - \omega)\,c_{p_w}\,T_w}{(h_{s_w} - h) + (\mathrm{Le} - 1)\,[(h_{s_w} - h) - (\omega_{s_w} - \omega)\,h_v] - (\omega_{s_w} - \omega)\,h_w}\right] \tag{3}$$

$$\frac{d\,\mathrm{Me}}{dT_w} = \frac{c_{p_w}}{(h_{s_w} - h) + (\mathrm{Le} - 1)\,[(h_{s_w} - h) - (\omega_{s_w} - \omega)\,h_v] - (\omega_{s_w} - \omega)\,h_w} \tag{4}$$

where Me in Equation 4, is the Merkel number according to the Poppe theory. The above described governing equations can be solved by the fourth order Runge-Kutta method. Refer to [18] for additional information concerning the calculation procedure.

2.3.2. Neural Network model

Machine learning algorithms are unique in their ability to obtain models and extract patterns from data, without being explicitly programmed to do so. They are more effective with large volumes of data but can also be applied for steady state modelling with fewer information. Artificial neural networks are part of this set of algorithms and, as the name suggests, have a behaviour similar to biological neurons. Its structure is formed by a succession of layers, each one composed by nodes (or neurons) and receiving as input the output of the previous layer. With this input a calculation is performed and its output is fed as the input for the subsequent layers.

The training process was done making use of the *Neural Network Toolbox* of MATLAB, using the Lavenberg-Marquardt BP algorithm [19]. Several ANN architectures were tested varying the number of hidden layers between 1 and 2 and the number of neurons in each layer between 1 and 10. The transfer function adopted in the hidden layers was the *logsig*, whereas the one employed in the output layer was the *purelin*. The optimal architecture was selected according to the performance function (Mean Square Error, MSE).

2.4. Procedure

Figure 4 schematically depicts the steps taken to perform the comparison procedure. Different tests are carried out with a variety of values in the system inputs (mainly cooling water mass flow rate and fan speed), while the system timeseries outputs are monitored and stored. The processing of the experimental data is done

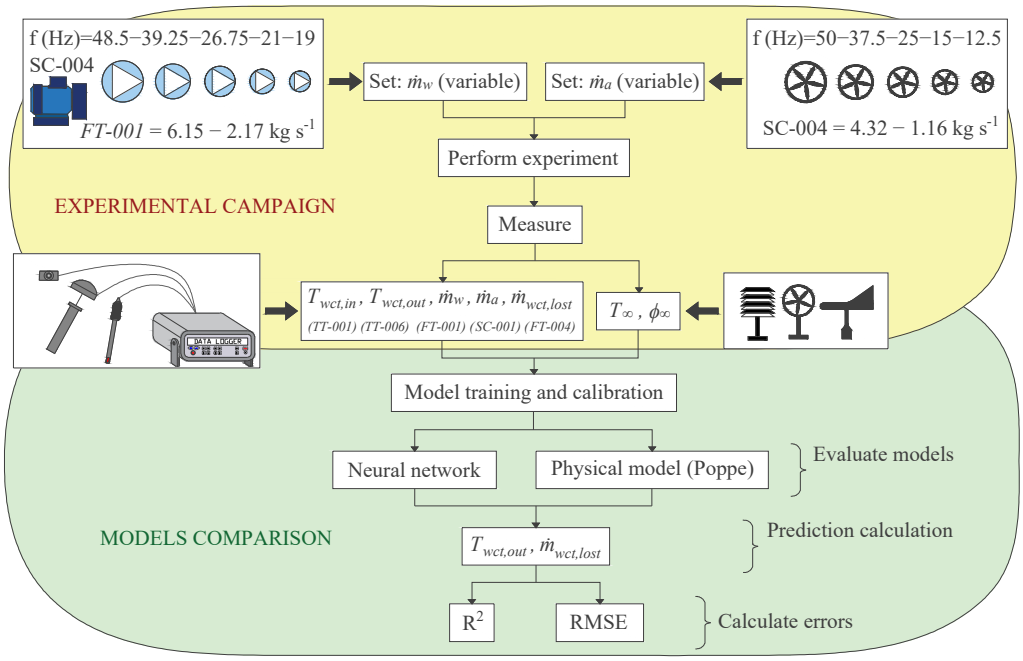

Figure 4: Methodology scheme for experimental procedure and model calibration and evaluation.

as mentioned in subsection 2.2., when the plant achieves steady state conditions according to UNE 13741 specifications.

Once the experimental campaign is done and the steady state operation points identified, different case studies are presented. Each case study takes the available operation points and divides them in two subsets: one is used for calibration/training of the modelling approaches and the second one for testing their performance. The case studies start with a low amount of points selected for training while the remaining are used for validation and increase up to a maximum, to have a minimum of 5 points for validation.

The performance metrics used to evaluate the fitness of the models to the experimental data are the Root Mean Square Error (RMSE) and R-squared (R^2). RMSE is a statistical measure of the difference between the values predicted by a model and the observed values. It is calculated as the square root of the mean of the squared differences between the predicted and observed values:

$$\text{RMSE} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}$$

where y_i is the measurement variable for the $i-th$ data point, $\hat{y}_i$ is the estimated value of the same variable and N is the number of data points.

R-squared [20] is a statistical measure that represents the proportion of the variance in the predicted variable that can be explained by the independent variable in a regression model, the measured output in this case, with value equal to 1 indicating the best fit. It is calculated as follows:

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2},$$

where $\bar{y}$ is the mean value of the experimental values.

3. Results and discussion

Table 2 shows the average values of the variables required by both models, which were obtained from the experimental campaign described in subsection 2.2.. As can be observed, the range of air and water mass

flow rates are 1.16-4.32 kg/s and 2.17-6.15 kg/s, respectively. Regarding the environmental conditions, these were quite similar for all tests: high ambient temperatures (ranging between 32°C and 41°C), and low ambient relative humidities (between 13% and 40%) since it was carried out during the summer season. The table also lists the output variables: $T_{wct,out}$ and $\dot{m}_{wct,lost}$.

Table 2: Averaged values in the experimental test runs.

Test	Q_{pump} (m^3/h)	f_{fan}(%)	T_∞ (°C)	ϕ_∞ (%)	T_{wb_∞} (°C)	$T_{wct,in}$ (°C)	$T_{wct,out}$ (°C)	$\dot{m}_a$ (kg/s)	$\dot{m}_w$ (kg/s)	$\dot{m}_{wct,lost}$ (kg/s)

3.1. Poppe model

Figure 5 shows the variation of the Merkel number as a function of the water-to-air mass flow ratio ($\dot{m}_w/\dot{m}_a$) for two case studies. It can be seen that the expected trend is observed: decreasing Me for increasing $\dot{m}_w/\dot{m}_a$ values (linear trend on log-log scale).

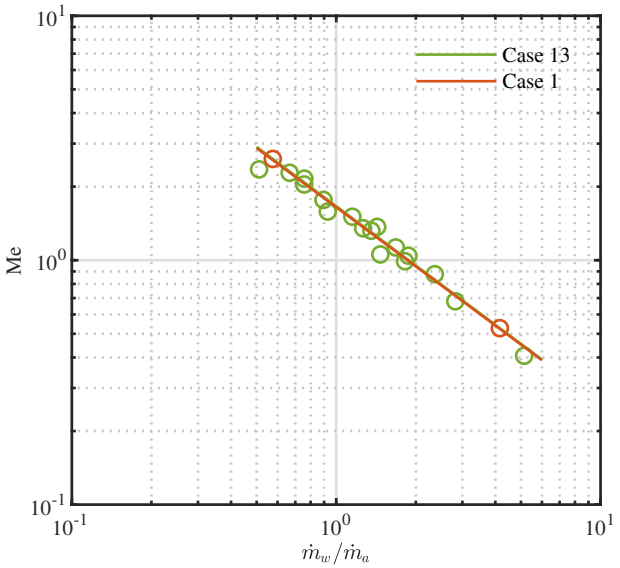

Figure 5: Experimental results for the Me number as a function of $\dot{m}_w/\dot{m}_a$.

The model based on the physical equations (Merkel number) can be obtained by correlating the values of Me with the water-to-air mass flow ratio as an independent variable, described by an equation of the form $\text{Me} = c\,(\dot{m}_w/\dot{m}_a)^{-n}$. Constants c and n in the previous equation have been calculated for the different case studies. In the Case 1, only 2 tests are considered for the fit (solid red line in Figure 5). Subsequently, more

tests are progressively added for the fit, up to a total of 14 tests in Case 13 (green series). These data are presented in Table 3.

As can be seen in the Figure 5 and in Table 3, the fit is practically the same for cases 1 and 13. This suggests that not much tests will be needed to get a reliable model of the tower. To evaluate the goodness of the correlation, the differences between the data calculated with these correlations and those measured experimentally for the outlet water temperature and water consumption of the tower can be verified. The results of the comparison for both models is presented in subsection 3.3..

3.2. ANN

In Table 3 - Topology column, the configuration of the best obtained networks for each case study are shown. In the first case study, the data available for training the neural network were too sparse to obtain significant results, but it was still done to show the strengths of the model based on the first principle. More interesting results are obtained for the latter case studies that make use of more data for its training, even though better results could be obtained with a more extensive campaign and thus obtaining more points to work with. For all of them, one hidden layer was always the best design, which is in accordance with results from literature [12–15] since there is not enough data to adjust a more complex ANN. Also, the number of neurons tends to be low, though the most performant networks make use of a higher number of neurons in the hidden layer (10). As expected, the optimal network, considering as optimal the one that performs best with the available data, is the one using the maximum amount of available data for training, while leaving enough points for testing. A high error is obtained for the scarce available data networks.

Detailed parameters for the best obtained model are shown at Table 4. It is composed of five inputs, one hidden layer containing ten neurons, and two outputs. It is a feedforward neural network (FFNN) that can be described as 5-10-2 and its predicted output expression is: $\hat{Y} = \Phi_{(2)}(LW_{(1)}\Phi_{(1)}\left(IW_{(1)}x + b_{(1)}\right) + b_{(2)})$, where Φ_i is the layer i transfer function, b the bias matrices, LW and IW are the layer weight matrices (output and input respectively), x is the network input and $\hat{Y}$. The subscripts corresponds with the notation used in the table.

3.3. Comparison between both approaches: prediction, abilities and requirements

3.3.1. Prediction

Table 3 shows the results obtained with both models. Each row shows a case study, which corresponds to a number of data used for the training (or calibration) of the models. As one progresses through the case studies, the number of data used for calibration increases. For each case the performance metrics (*RSME* and R^2) are calculated. Looking at the case of study with the best results (case study 16), the error obtained in the prediction of the water outlet temperature ($T_{wct,out}$) is almost null using the Poppe model ($R^2 \approx 1$ and RMSE = 0.36°C) whereas the error with ANN model is slightly higher (R^2 = 0.97 and RMSE = 1.01°C). This comparison is also observed in Figure 6 (b), where the perfect fit is depicted together with the results obtained with both models. On the contrary, in the case of the water consumption, the results with the ANN model are better than those provided by Poppe's model, being the RMSE with ANN model less than half that obtained with Poppe's model (0.25 to 0.55 l/min). This is because Poppe's model predicts the water lost by evaporation during the process, but it does not consider the water lost as drift (emission of droplets into the atmosphere) nor other losses such as windage , splash-out, leaks or overflow.

Table 4: Best performing network parameters.

Input weight matrix $IW_{(1)}^{(10x5)} = \begin{pmatrix} 0.0016 & 0.0418 & 0.1239 & 0.1353 & -0.1324 \\ 0.0011 & -0.0348 & -0.1022 & -0.1104 & 0.1098 \\ 0.0064 & -0.0066 & -0.0297 & -0.0294 & 0.0334 \\ -0.0015 & 0.0252 & 0.0697 & 0.0740 & -0.0748 \\ -0.0056 & 0.0109 & 0.0389 & 0.0394 & -0.0430 \\ 0.0035 & 0.0454 & 0.1362 & 0.1494 & -0.1452 \\ 0.2361 & 0.1815 & 0.4889 & 0.3339 & -0.4397 \\ 0.0209 & 0.0641 & 0.1763 & 0.1930 & -0.1823 \\ -0.0079 & -0.0505 & -0.1457 & -0.1602 & 0.1539 \\ 0.0024 & -0.0319 & -0.0953 & -0.1023 & 0.1026 \end{pmatrix}$

Hidden layer bias vector $b_{(1)} = \begin{pmatrix} 0.0041 \\ -0.0062 \\ -0.0040 \\ 0.0064 \\ 0.0048 \\ 0.0022 \\ -0.2480 \\ -0.0086 \\ -0.0001 \\ -0.0066 \end{pmatrix}$

Output layer weight matrix $LW_{(1)}^{(2x10)^T} = \begin{pmatrix} 0.1648 & -0.1636 \\ -0.1349 & 0.1351 \\ -0.0335 & 0.0430 \\ 0.0922 & -0.0908 \\ 0.0467 & -0.0540 \\ 0.1814 & -0.1799 \\ 0.6502 & -0.5160 \\ 0.2428 & -0.2231 \\ -0.1969 & 0.1897 \\ -0.1246 & 0.1265 \end{pmatrix}$

Output layer bias vector $b_{(2)} = \begin{pmatrix} -0.0051 \\ -0.1031 \end{pmatrix}$

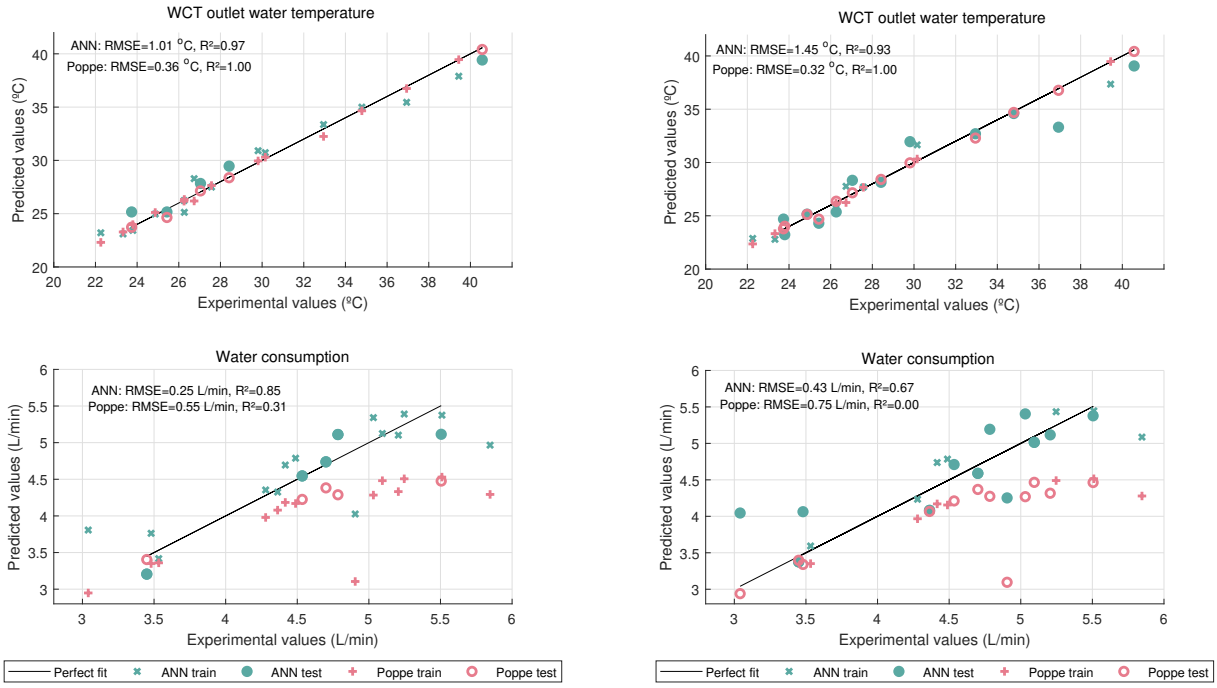
3.3.2. Experimental requirements

As previously mentioned, Table 3 shows the results obtained varying the number of training experimental points. Regarding the water outlet temperature ($T_{wct,out}$), it can be seen that the error is almost null for the Poppe model even using the lowest number of train points ($R^2 \approx 1$ and RMSE = 0.33°C), whilst is not the case for the ANN one ($R^2 = -0.19$ and RMSE = 5.23°C), as expected. This is reflected in Figure 6 (a), there is not enough information to adjust the weights and biases in the network and therefore it is unable to capture the system dynamics. By increasing the available information during training, the results get better obtaining the best results explained in subsubsection 3.3.1.. In the case of the ANN model, this trend is similar for ($\dot{m}_{wct,lost}$) predictions; increasing the training point, the results improve (RMSE decreases more than 80% and R^2 changes from being negative to approaching 1). With the Poppe model and the $\dot{m}_{wct,lost}$ predictions, it can be observed that, increasing the number of tests, the prediction improvement is low (RMSE decreases less than 27 % and R^2 changes from being negative to 0.31). Therefore, while the ANN model benefits from as much data as possible, the Poppe model is already able to produce satisfactory results with just two properly selected points. These two points are easy to identify in advance because they are related to the maximum and minimum $\dot{m}_w/\dot{m}_a$ ratio. In the practice, to minimise the error prediction, ≈5 points are often used.

Regarding the instrumentation, Poppe's model requires measurement of the air flow rate at the outlet of the WCT, while the ANN model uses as input the frequency of the WCT fan. In addition, to improve the water consumption estimations provided by Poppe's model, it would be necessary to carry out an experimental campaign to measure the water losses due to drift.

3.3.3. Scalability, operating and weather conditions

One important advantage of the Poppe model is its adaptability to large scale systems, as long as the system configuration remains the same. This allows to study and analyse pilot scale plants and extrapolate the results to industrial sized plants. In addition, the model obtained is also capable of accurately predicting the behaviour of the WCT in conditions that have not been tested (different environmental conditions or inlet water temperatures). It would even be valid for unknown $\dot{m}_w/\dot{m}_a$, although the reliability of the model will be lower if this ratio moves away from those experimentally used for calibration. This is not the case for ANN models that are only applicable to the system and operating ranges they are trained for. Even though there are techniques to create new ANN models from previously trained ones [21], this is not as straightforward, requires expertise and additional experimental data.



(a) Larger set for training. Case study: 13

(b) Scarce train data. Case study: 6

Figure 6: Models performance comparison with different dataset distribution.

3.3.4. Implementation

In the recent years and due to the increase popularity of artificial intelligence, there are many libraries of easy access for most common programming languages, which makes the development and implementation of ANN models achievable by non experts or specialised teams. The need of extensive data can be mitigated if an online steady-state identification is implemented [22], which allows updating the model with a growing dataset. In the case of the Poppe model, although the number of tests is not a problem, it is necessary to know the governing equations described in the subsubsection 2.3.1.. Solving the system of differential equations requires a non linear solver, which nowadays it is not a problem since there is a wide variety of software tools and packages available to face it.

3.3.5. Execution time

The execution time in the case of the ANN model is very low (in the order of milliseconds) and independent of the input conditions. This is not the case for the Poppe model because it depends on the non-linear solver used. This issue can have an impact in optimisation applications, such as the determination of optimal operating conditions to minimise the water consumption of combined cooling systems for CSP plants.

4. Conclusions

In this study, a comparison between an artificial neural network and Poppe model for wet cooling tower performance prediction in CSP plants has been performed. The results obtained during the investigation can be summarised as follows:

Both models reported good results predicting the outlet water temperature, since the errors were quite low (R^2 = 0.97 and RMSE= 1.01°C for the best case with the ANN, and $R^2 \approx 1$ and RMSE$<$ 0.36°C for all cases with the Poppe model). However, the Poppe model reached confidence levels with only 2 tests, while the ANN needed the maximum number of points available.

For the measurements of water consumption, it was shown that the Poppe model does not accurately predict this magnitude (R^2 = 0.51 and RMSE= 0.51 l/min for the best case), since it does not account for the water lost by drift or other losses. On the other hand, the ANN does present good results in this aspect (R^2 = 0.85 and RMSE= 0.25 l/min for the best case), since it only depends on the results measured in similar tests.

The strengths and weaknesses of each model have also been compared. As for the Poppe model, it is capable of predicting the operation of the tower, regardless of the tested conditions. It is also possible to adapt it to large-scale systems, as long as the system configuration remains the same. Unlike the ANN model that can only be used for the conditions and the tower for which it was developed.

As for the ANN model, it has the advantage of being able to be developed and implemented by non expert or specialised teams (who do not know the physical process that takes place in a cooling tower). Another advantage is in the execution time, the ANN model is faster and more constant independently of the input conditions (in the order of milliseconds for simple networks like the ones presented in this work).

As future lines of work, drift measurements could be carried out on the tower so that the prediction of $\dot{m}_{wct,lost}$ can be improved for the Poppe model. Another way could be to parameterise and adjust this model output to reduce the error. Other possible lines of work would consist of checking other output variables ($\phi_{a,o}$ and $T_{a,o}$) or evaluating the models under different conditions (other seasons). Finally, these models will be used for optimisation purposes in combined cooling systems for CSP plants.

Abstract:
An optimized inverter sizing depends on the installed photovoltaic capacity, the azimuth and zenith of the panels, the latitude and the efficiency curve of the inverter. Simplified inverter sizing rules are generally used and can be narrowed to two rules of thumb. The first rule aims a maximum PV-production and uses an inverter according to the PV power, the second rule aims a maximum self-sufficiency and uses an inverter size ratio of 0.7. Simulations are performed to quantify the production loss or self-sufficiency loss when the rule of thumb is used instead of the optimized inverter power for a load profile with only household appliances. In a second part, the energy system is extended with a heat pump, a battery or both combined. This study checks if the refurbishment of residential PV systems with heat pump and/or battery still can use the same rules of thumb or is a new sizing method preferred to replace the inverter. Detailed models for load, PV-inverter, battery and battery-converter are developed. The PV-production and the self-sufficiency are determined for 6 azimuths and 7 zenith positions. A final evaluation of the rules of thumb is made.

Inverter, Photovoltaics, renewable energy, electrical storage, heat pump

1. Introduction

The energy transition is progressing and boosts the sales of photovoltaic solar systems (PV). Between 2015 and 2021, the installed PV capacity in Belgium is more than doubled[1]. The heat pump market grew with factor 10[2] and in 2021 the number of installed home batteries exceeded 11000 units where in 2020 hardly 337 units were installed[3].The inverter is an important component of the PV system. Since several years, the Flemish government advises to size the inverter power on 70% of the installed PV power at standard reference conditions to get a maximum self-sufficiency [4-6], the Walloon government advises 70 to 100%[7], the Brussels region advises 80% [8]. Belgium's neighbouring countries do not give an unambiguously advice. In France, the government advises 80% [9], in the Netherlands 90 to 110% [10] is advised to have a maximum production and in Germany [11] 100% for maximum production and 70% for maximum financial benefit. All those rules of thumb can be narrowed to two rules. When a maximum PV production is the target, the inverter is sized with an inverter ratio of 1[12]. When a maximum self-sufficiency or self-consumption is targeted, the inverter ratio is 0.7.The optimized inverter power to get a maximum PV production is described by Burger [13], Nofuentes[14] and Van Der Borg [15]. They investigated the inverter power for different zeniths and azimuths to maximize the PV production. Their results show that the ideal inverter power, for maximum PV production vary from 0.3 to 1.1. The rules of thumb give just one fixed figure, namely a ratio of 1. What is the production loss if the rule of thumb is used? Maximizing the self-sufficiency or self-consumption is another target to optimize the inverter power[4] .The previous target, maximizing the PV production, is maximizing the energy output of the inverter which is independent of the loads connected to the inverter. Once maximizing the self-sufficiency becomes the main objective, the load profile of the energy user becomes an extra parameter. Since every end user has a different consumption profile, different equipment, different PV technologies, orientations, inverters etc. it is impossible to state that there is one optimal inverter power. This includes that the resulting optimized inverter power in this case is indicative and can state a trend. Although the authors could not trace the original documents that formed the basis of the rule of thumb where 70 to 80% of the installed PV power is used, in each case this rule was made when heat pumps and batteries were not frequent applied [16], now they are. Adding a heat pump to a residential energy system will increase the energy use during the winter

and mid-season, just in the period that less solar energy is available. The load profile of the heat pump is even the opposite of the PV production profile. It can be questioned if it is not better to optimize the inverter for the energy use during winter. A similar question can be asked in case of adding a battery to the residential energy system. The battery can take energy during the full period with daylight. As long as there is daylight a battery can charge energy. The battery can be considered as a load that can take energy during the moments with maximum solar radiation. Is a larger inverter power beneficial in that case? Optimized inverter sizing to maximize the PV production is described by different authors [13-15, 17] but optimized inverter sizing to maximize the self-sufficiency related to orientation and panel zenith or the impact of a heat pump, or battery, on the optimized inverter power is not yet described. In this study the different rules of thumb are investigated for residential buildings in the Belgian climate. Different scenarios are investigated starting with a reference case with only household appliances, called ‘appliances’ in this paper. Next, the energy system is extended with a heat pump and/or a battery. Evaluating the impact of the heat pump and the battery on the optimal sizing of the inverter compared to the rules of thumb is the main contribution of this research. The optimized inverter is determined for the full range of both, zenith and azimuth. For each case the maximum self-sufficiency, using the optimized inverter power, is compared to the self-sufficiency obtained by using the rules of thumb.

2. Methodology

2.1. Residential energy system

The reference case (case 1) is a realistic example of a standard family in Belgium. The family counts 4persons. The energy system is used for a residential house where space heating and domestic hot water production is realized with fossil fuel combustion technology. The energy use for the appliances is 5000kWh/a. A PV system of 5 kWp is installed. The optimized inverter power is determined for this system as reference for a panel zenith of 0° to 90° in steps of 15° and 6 orientations are considered with steps of 60°. Case2 to case 4 are based on this reference case where the system is extended with a heat pump, a battery or the combination of the two. Case 5 is similar to case 1 but with an high efficiency inverter (Table 1). In each case, the PV production and self-sufficiency obtained with the optimized inverter power is compared to the one resulting with the rule of thumb inverter power.

2.2. Components overview

2.2.1. Photovoltaic panels

The power output of a PV area is simulated in Trnsys, using type 94. The simulations were performed with the technical specifications of the polycrystalline solar panel type Q.Plus-G4.1 275. The power P_{pv} , in Watt is a function of:

$$P_{pv} = f\left(n, \mathrm{W}_p, \Phi_{solar}, T_{module}\right) \quad (1)$$

2.2.2. Inverter

The inverter transforms the DC-voltage coming from the PV panels to AC 230V which can be used by the appliances. The inverter efficiency varies with the load. Faranda [18] presented a few typical inverter curves. Two of them are used in this study (see Fig. 1). ’ Inverter 1’ has a pronounced efficiency drop for low part loads. ‘Inverter 2’ has a significant higher efficiency in that part. The impact of a high efficient inverter will be evaluated. Each curve is characterized by two sections. A low part load ,below 10% of the nominal power, results in a low inverter efficiency due to the relative high self-consumption losses compared to the input. Once the load is above 10% of the nominal power, the efficiency reaches maximum values of up to 96%. The inverter efficiency curves presented in Fig. 1contain already the information to predict the trend which can be expected as end result:

- An inverter sized too small will have high part loads with high efficiency but the limited inverter power will not be able to handle the loads above the nominal inverter power. The load will be limited to the nominal inverter power and the overshoot becomes an extra production loss.
- An inverter sized too large will result in small part loads which gives a low inverter efficiency

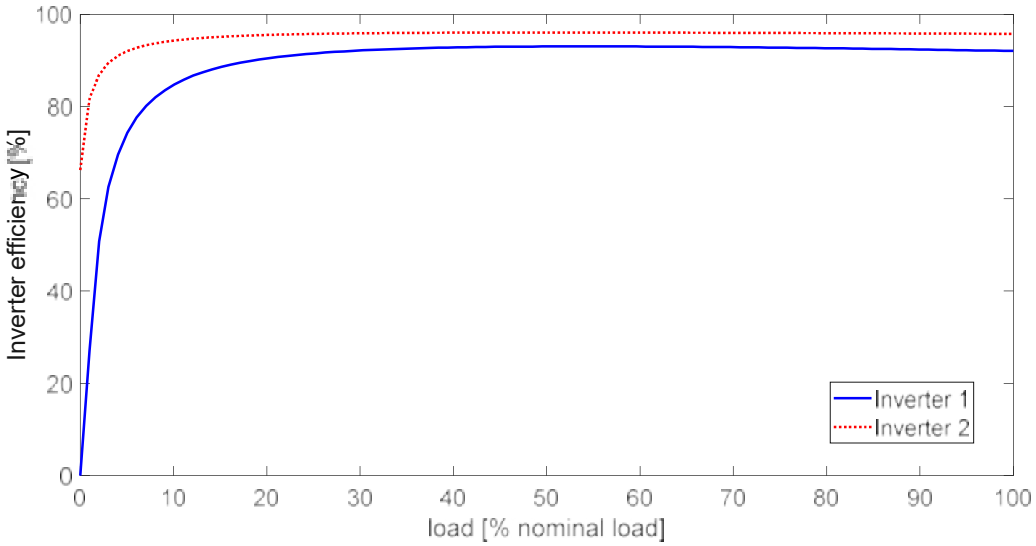

Figure. 1. Typical inverter efficiency curves from different manufacturers[18]

The presented inverters have a maximum efficiency between 90 and 96%. New technology is already available with 99% inverter efficiency [19, 20]. The simulations are made with inverter model 1. Inverter model 2 is used as alternative to check the influence of a high efficient inverter. Adding a heat pump to the system for space heating and domestic hot water makes that the winter period will have the highest energy use, just when the PV production is lower and where the efficiency of the inverter at low part load becomes more important. The results show the impact of the heat pump on the inverter selection.
The power of an inverter is therefore a function of:

$$P_{inverter} = f(\eta_{eff}, P_{pv}) \tag{2}$$

2.2.3. Heat pump

The heat pump is an air to water inverter system used for space heating and production of domestic hot water. The heat pump model calculates the needed energy input for the given outdoor temperature, heating curve and needed capacity for space heating. Manufacturer data is used to make the model. The start-up sequence and switch off sequence of the heat pump is integrated into the model to get realistic electric peak loads in the load profile. Each 3 minutes, the part load ratio can increase or decrease with 10% to get a balance with the energy demand. The minimum part load ratio is 30%. The production of domestic hot water always happens on full load.

$$P_{hp} = f(PLR_{HP}, T_{outdoor}, T_{lwt}) \tag{3}$$

2.2.4. Battery converter

The battery converter is characterized by its efficiency curve and its capacity. The same considerations as for the PV inverter are applied. The efficiency curve presented by Weniger [21] is used with a nominal capacity of 5kW. Previous simulations showed that the self-sufficiency achieved with a converter power of 5kW reaches an optimized point within the range of 0.5% loss due to not optimized battery converter for the considered load profiles, PV area and different PV panel positions.

$$P_{batt\ conv} = f(E_{bat\ conv}, PLR_{bat\ conv}) \tag{4}$$

2.2.5. Battery

A battery model described by Brivio [22] is modelled in Matlab to calculate the battery performance. The model is represented by a RC circuit. The R and C value is related to the state of charge. The model calculates the available charge or discharge capacity which is function of the C-rate. The battery is determined by its nominal capacity, the maximum depth of discharge (80%), maximum state of charge90%, self-discharge 3%/month, charge capacity factor 0.5kW/kWh and discharge capacity factor0.55kW/kWh.

$$P_{batt} = f(E_{bat}, C_{bat}, C_{dr}, R_f, SOC, E_{loss}) \tag{5}$$

2.2.6. Grid

The generated PV energy is converted by the inverter to be used by the appliances and/or the battery system. The surplus of energy is supplied to the grid. In case the PV system nor the battery can deliver enough energy, the deficit is supplied by the grid. It is assumed that there is no feed-in limitation.

$$\frac{d\,E_{bat}}{dt} = P_{inverter} + P_{grid} - P_{appliances} - P_{hp} \tag{6}$$

2.3. Load profiles

2.3.1. Appliances

A synthetic load profile is developed for a household of four persons, one full time working parent, apart-time working parent, a student and a young child. The load profile of the base case only contains appliances, assuming that space heating and DHW is done with fossil fuels. A probability curve is used to identify the start of use of 19 different appliances [23] [24]. Reinhardt measured the energy use of different appliances , for several actions, on a 1 second timestep [25]. His results are the building blocks of the synthetic profile. The energy use profiles are composed out of appliances with different measured performances to get a load profile of 5000kWh/a. The synthetic load profile is generated with a 1 sec time step and rescheduled to a 3 minute time step. The synthetic profile is verified with the results of measured data. Fig. 2 shows 4 load duration curves of load profiles of 5000kWh/a. All curves are presented on a 3 minute time step. One measured profile is a similar household measured in the Lineas project[26] with time step 15 minutes. The second verification is the average of 50 load profiles of 5000kWh/a from the distribution network operator Fluvius. The synthetic profile is presented with a time step of 15 minutes and also with a time step of 3 minutes. The different curves show that the 15 minute time step synthetic profile matches the average values. The 3 minutes time step synthetic profile shows more peak loads. The larger the time step the more that peak loads disappear in the average values.

2.3.2. Domestic hot water

The daily DHW-profile of the European Directive EU813/2013 is used (Medium user profile - 3XS user profile Ecodesign)) [27]. To use a maximum of solar energy, the charging of the DHW buffer is programmed to start at 14h00.

2.3.3. Heating demand

An archetypical Belgium dwelling[28] is used to calculate the heating demand. The heating demand is simulated in Trnsys[29] for a south oriented building. The air infiltration is simulated with Trnflow[30].The resulting heating demand includes the inertia of the building mass and the under floor heating. The appliances and the persons (presence is coupled with the probability determination used for the load profile) are considered as an internal heat gain and are assigned to a specific room. A predefined heat gain factor is used per appliance to deduct the not used energy such as the hot water drain of a laundry machine.

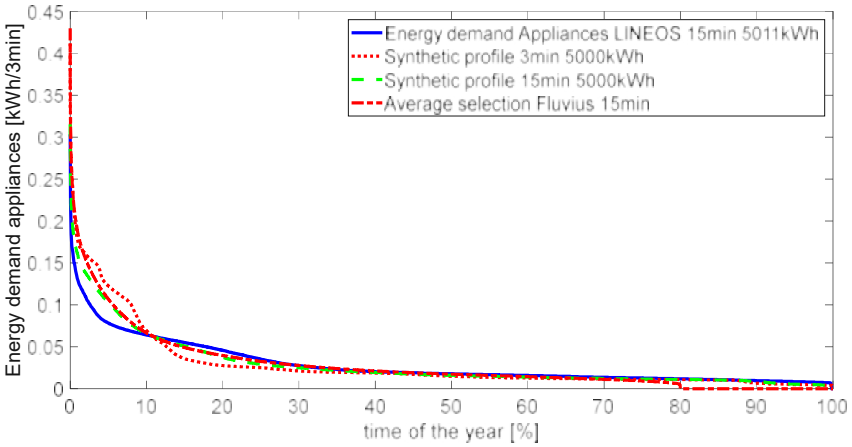

Figure. 2. Load duration curves of different load profiles

2.4. Climate data

The Meteonorm climate data of the reference year of Uccle (Belgium), time step 1 hour, is used to simulate the PV performance and the heating demand. The PV generation and the heat demand is simulated in Trnsys

using the Meteonorm data using interpolated time steps of 3 minutes. To check the impact of 3 minute interpolated time steps using 1 hour data compared to 3 minute time step, measured data with time step 1 minute is used. The self-sufficiency calculated with the interpolated data had a maximum difference of 0.6% compared to the self-sufficiency calculated with 3 minute data. Using the 3minute interpolated hourly climate data gives no significant difference when 3 minute appliance data is used.

2.5. Simulation method

The simulations of the energy flows between the different components are performed in Matlab. Several authors investigated the impact of the time step [31] [32] [33] [34] and conclude that a time step of less than 5 minutes reduces the error to 2% and even less than 1% in case a battery is used. All inputs (PV production, electrical load, heating demand, domestic hot water production) are on a 3 minute time step. All simulations are done for a full year. To investigate one case, 7 inverter powers are simulated for 7 zeniths and 6 orientations. The load is determined by the sum of the energy use of the appliances and the energy use of the heat pump if available. If there is renewable energy available, it is first used to compensate the energy demand of the appliances and the heat pump, a shortage is supplied from the grid, a surplus is supplied to the battery (if available) as far as the battery can take the surplus in quantity and power. The leftover is supplied to the grid. All efficiencies (inverter, converter, battery) are calculated per time step.

2.6. Case study selection

The 5 selected cases could be a timeline of one residential energy system starting with a PV system that can cover the energy use of the appliances. The following cases could be the refurbishment of the energy system, namely adding or a heat pump, or a battery, or both. For each case the results are checked to see if the inverter has a different power as in the reference case. The reference case is an energy system with only appliances (5000kWh/a) with 5kWp PV, no heat pump, no battery. The optimized inverter is calculated for the targets of the two main rules of thumb, namely maximum PV production and maximum self-sufficiency. The results are compared with the rules of thumb.

Table 1. Overview cases

Case	Appliances	Heat pump	Battery	Inverter model
1	5000 kWh/a	no	0 kWh	1
2	5000 kWh/a	no	8 kWh	1
3	5000kWh/a	yes	0 kWh	1
4	5000 kWh/a	yes	8kWh	1
5	5000 kWh/a	no	0 kWh	2

Two solar panel positions are picked out to follow up each case, respectively due south (azimuth 0°) and azimuth -120°.

3. Results

3.1. Case 1

3.1.1. Maximum PV production

To maximize the PV production, the rule of thumb advises to use an inverter ratio of 1. The maximum PV production is evaluated at the output of the inverter. This is the sum of used PV energy in the residential energy system and the energy supplied to the grid.

$$0 = P_{inverter} + P_{grid} - P_{appliances} \quad (7)$$

This is only evaluated for case 1 but is equal for all other cases. Fig. 3 gives the resulting inverter output in kWh/a in relation to the inverter power for different zeniths with 0° azimuth and a PV area of 5kWp. Each curve is characterized by a fast decreasing inverter output for an inverter power lower than 4 kW and a slightly decreasing efficiency above an inverter power of 4 kW. The fast inverter output decrease in the left side of the curve is caused by the peak shaving due to the limited inverter power. All produced energy above the nominal capacity of the inverter is a loss. The slow decreasing right part of the curve is caused by the low efficiencies during small part loads. The larger the inverter power the more the inverter will operate in the region of the low part loads which results in low inverter efficiency. The 90° zenith has less high irradiation than the 0° zenith. The lower irradiation is a lower part load of the inverter and results in a lower inverter efficiency. Over-sizing the inverter power is less critical than under-sizing. The best performing PV panel position (due south, zenith

between 30 and 60°) gives an ideal inverter ratio of 0.99 and 1.01. For this positions, the rule of thumb is perfect. The 90° zenith gives an optimized inverter ratio of 0.81. Using the rule of thumb is a 19% oversizing but results in a loss of 0.6% of the yearly production.

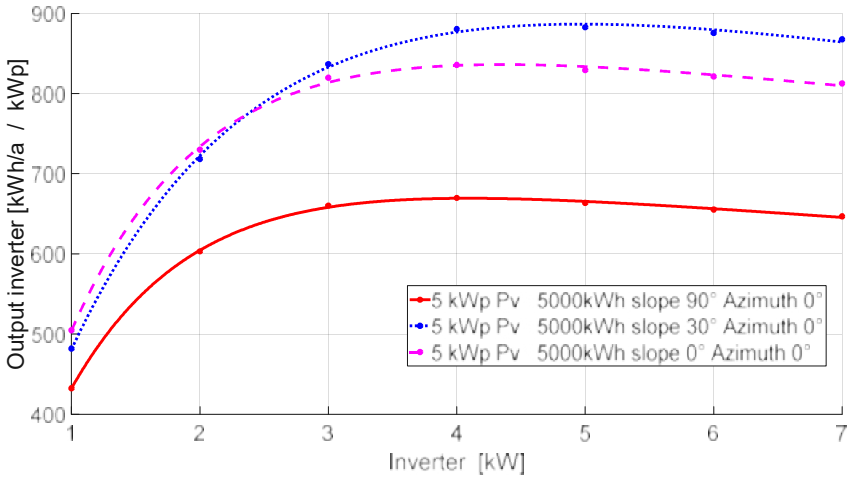

Figure. 3. Output inverter for inverter model 1, 5kWp PV, no heat pump, no battery, azimuth 0°

Table 2 gives the optimized inverter power per kWp installed PV at reference conditions to get the maximum yearly production. In case of azimuth -120° and a 90° zenith, the optimized inverter power is0.54kW/kWp instead of 1kW/kWp (rule of thumb). The optimized inverter ratio 0.54, results in 3.7%more PV production. Due to the lower irradiation, a smaller inverter is needed.

Table 2. Optimized inverter power kW/kWp for maximum energy production, inverter model 1, 5kWp PV, no heat pump, no battery

azimuth	-180	-120	-60	0	60	120	180
zenith							
90	0,30	0,54	0,78	0,81	0,78	0,54	0,30
75	0,35	0,61	0,89	0,93	0,88	0,61	0,35
60	0,38	0,67	0,94	0,99	0,93	0,67	0,38
45	0,41	0,72	0,96	1,01	0,95	0,71	0,41
30	0,56	0,77	0,95	0,99	0,94	0,76	0,56
15	0,74	0,82	0,92	0,95	0,91	0,81	0,74
0	0,87	0,87	0,87	0,87	0,87	0,87	0,87

Most rules of thumb advice 1kW inverter power/kWp to get the highest production. The results show that the rule of thumb fits for a south orientation. Deviating from the best zenith decreases the inverter power for the south direction up to 20%, changing the azimuth to east or west can decrease the inverter power up to 50%. The mentioned design rules can be considered as a good first estimation. Using the simulated optimum as design criteria can bring an extra production up to 3.7% (azimuth between 120° and -120°)and gives an additional saving due to the lower inverter power to be installed. A pure north orientation, zenith 90° , results in a loss of 8.8%. North facing solar panels are rare but there is a growing interest, especially for building integrated PV panels [35] [36] [37].

3.1.2. Maximum self-sufficiency

To maximize the self-sufficiency, the advised inverter ratio is 0.7. Fig. 4 show the self-sufficiency for different inverter powers and zeniths for azimuth 0. The optimized values are listed in Table 3. If the aim of the PV system is to maximize the self-sufficiency, an optimized inverter size ratio of 0.7 to 0.77is calculated for azimuth 0° . The azimuth -120° has enough with an inverter size ratio down to 0.33.A higher self-sufficiency for the same PV capacity means that the energy production is better fitting with the energy demand. The chosen load

profile is for a standard family with standard behaviour. This means an average daily energy demand profile is characterized by a peak in the morning and a peak in the evening. The PV production peak at noon happens most of the time during a low energy demand which makes that the high inverter power is not needed for the high peaks at noon. In contrary the high inverter power makes that the low PV generation in the morning and the evening is transformed at a lower inverter efficiency. A lower inverter power brings the average inverter efficiency to a higher level when the solar energy can be used. In case an inverter ratio of 1 is used (gives the maximum PV production) when a maximum self-sufficiency is targeted, less PV energy can be used. The maximum extra loss is 6.2% when the inverter ratio 1 is used and the 0.7 inverter ratio gives a maximum extra loss of 3% (see Table 4).

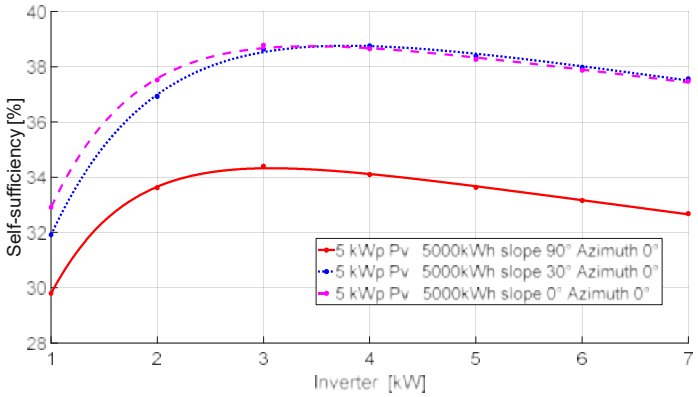

Figure. 4. Self-sufficiency load inverter 5000kWh/a, inverter model 1, 5kWp PV, no heat pump, no battery, azimuth 0°

As long as the azimuth is between -60° and 60° , the loss in self-sufficiency remains smaller than 1%using the 0.7 inverter ratio.

Table 3. Optimized inverter power kW/kWp in function of azimuth and panel zenith for maximum self-sufficiency, load 5000kWh/a, inverter model 1, 5kWp PV, no heat pump, no battery

azimuth	-180	-120	-60	0	60	120	180
zenith							
90	0,23	0,33	0,49	0,61	0,54	0,32	0,23
75	0,29	0,38	0,56	0,70	0,62	0,38	0,29
60	0,32	0,42	0,62	0,75	0,68	0,44	0,32
45	0,36	0,48	0,66	0,77	0,71	0,50	0,36
30	0,46	0,55	0,69	0,77	0,72	0,58	0,46
15	0,59	0,63	0,70	0,74	0,72	0,64	0,59
0	0,69	0,69	0,69	0,69	0,69	0,69	0,69

Table 4. Evaluation loss caused by rules of thumb

sizing method		ideal inverter	inverter ratio 0,7		inverter ratio 1	
Azimuth	zenith	Self-sufficiency [%]				
		Result	Result	% Loss	Result	% Loss
-120°	0°	38,7	38,7	0,0	38,3	1,1
	30°	31,6	31,1	1,6	30,3	4,2
	90°	27,9	27,0	3,0	26,1	6,2
0°	0°	38,7	38,7	0,0	38,3	1,1
	30°	38,8	38,7	0,0	38,5	0,7
	90°	34,4	34,3	0,3	33,7	2,1

Considering each target, the rule of thumb is in both cases a good robust sizing method for a load profile with only residential appliances.

3.2. Case 2

Case 2 is the energy system of case 1 with an extra battery of 8kWh useful battery capacity. The nominal battery capacity is 11.4kWh with a maximum state of charge of 90% and maximum depth of discharge of 80%. Adding a battery will not change the maximum PV production but will increase the self-sufficiency from 40% to 68% for azimuth 0° zenith 30° . Table 5 gives the optimized inverter ratio for the this extended energy system.

$$\frac{d\,E_{bat}}{dt} = P_{inverter} + P_{grid} - P_{appliances} - 0 \tag{8}$$

Table 5 shows that the optimized inverter power to maximize the self-sufficiency is between 0.5 and 0.77 for the values of azimuth -120° to +120° . This brings the average inverter power value on 0.64 instead of 0.6 for the values of azimuth -120° to +120° , so 6% closer to the rule of thumb of 0.7.

Table 5. Optimized inverter power kW/kWp in function of azimuth and panel zenith for maximum self-sufficiency, load 5000kWh/a appliances, inverter model 1, 5kWp PV, heat pump 1691 kWh/a, 8kWh battery

azimuth	-180°	-120°	-60°	0°	60°	120°	180°
zenith							
90°	0,30	0,50	0,65	0,68	0,68	0,49	0,30
75°	0,35	0,51	0,67	0,71	0,70	0,51	0,35
60°	0,38	0,51	0,66	0,69	0,69	0,52	0,38
45°	0,40	0,51	0,64	0,68	0,67	0,53	0,40
30°	0,42	0,52	0,62	0,65	0,63	0,52	0,42
15°	0,49	0,54	0,59	0,60	0,60	0,54	0,49
0°	0,57	0,57	0,57	0,57	0,57	0,57	0,57

Table 6 gives the relative increase of the optimized inverter power of case 2 compared to case 1. Zeniths above 45° have a significant increase of the inverter power up to 53%, zeniths below 45° have a smaller inverter power up to 19% smaller. The vertical installed panels have the largest increase. Without battery, the inverter is determined by the match between solar production and energy demand. Using a large battery, produced energy can be used as long as the battery is not full charged. This means that the vertical panel has only a short period of the day that beam irradiation can be captured. The lower the zenith the larger the period of the day that beam irradiation can be captured which can even result in a smaller optimized inverter power.

Table 6. Increase of inverter power in percentage case 2 compared to case 1

azimuth	-180°	-120°	-60°	0°	60°	120°	180°
zenith							
90°	33	53	33	12	26	51	33
75°	20	36	19	1	13	34	20
60°	17	22	7	-8	2	20	17
45°	11	7	-3	-13	-6	4	11
30°	-9	-6	-11	-16	-12	-11	-9
15°	-17	-14	-16	-19	-17	-16	-17
0°	-17	-17	-17	-17	-17	-17	-17

Adding a battery to the energy system brings for most positions the optimized inverter power closer to the inverter ratio of the rule of thumb. The energy loss due to a not optimized inverter power is even smaller.

3.3. Case 3

Case 3 is case 1 extended with a heat pump. Table 7 shows the percentage increase of the inverter power compared to the base case.

$$0 = P_{inverter} + P_{grid} - P_{appliances} - P_{hp} \tag{9}$$

The orientations influenced by the rising sun have a small increase of inverter power, the orientations influenced by the sunset have a small decrease of inverter power. The morning has the coldest temperature of the day and will make that the heat pump is more activated which makes that the resulting load during the morning will be higher. When the solar panels are oriented to the west makes that they only have diffuse irradiation during the morning. A smaller inverter power will increase the efficiency of the small part loads that occur in the morning. On the level of sizing can be concluded that the extra load of the heat pump does not influence the optimized inverter power significant. For example azimuth -60° , zenith 75° , brings the optimized inverter from 0.56kW/kWp to0.62kW/kWp. Adding a heat pump makes the loss smaller when the rule of thumb is used.

Table 7. Percentage increase of inverter power, case 2 compared to case 1

azimuth	-180°	-120°	-60°	0°	60°	120°	180°
zenith							
90°	1	5	11	2	1	1	1
75°	0	7	9	0	0	1	0
60°	0	9	7	0	0	-1	0
45°	1	8	5	0	-1	-1	1
30°	0	4	3	0	-2	-1	0
15°	0	2	2	-1	-1	-1	0
0°	0	0	0	0	0	0	0

3.4. Case 4

In case 4 the energy system is extended with a heat pump and a battery.

$$\frac{d\,E_{bat}}{dt} = P_{inverter} + P_{grid} - P_{appliances} - P_{hp} \tag{10}$$

Table 8 shows the optimal inverter for maximum self-sufficiency for the reference system extended with a heat pump and a battery. Most values come even closer to the rule of thumb value of 0.7.
Table 9 gives the relative increase of the optimized inverter power of case 4 compared to case 1 in percentage. The increased load due to the added heat pump and the extra battery that charges the surplus makes that a larger inverter power can be used for zeniths which have a limited time to capture beam irradiation. The orientations having larger periods access to beam radiation have more time to charge the battery resulting in a smaller inverter power. Case 4 combines the effects of case 2 and case 4: decrease for zeniths below 45° and increase for zeniths above 45° , increase for sunrise sensible positions and decrease for sunset sensible positions. The statements are mentioned in case 2 and case 3.

Table 8. Optimized inverter power kW/kWp in function of azimuth and panel zenith for maximum self-sufficiency, load 5000kWh/a appliances, inverter model 1, 5kWp PV, heat pump 1691 kWh/a, 8kWh battery

azimuth	-180°	-120°	-60°	0°	60°	120°	180°
zenith							
90°	0,30	0,52	0,69	0,72	0,69	0,50	0,30

3.5. Case 5

Case 5 is equal to case 1 but using a more energy efficient inverter (see Fig.1). Inverter model 1 has an EU-efficiency of 91.1%, where inverter model 2 has an EU-efficiency of 95.6%. Table 10 shows the optimized inverter power for inverter model 2 to maximize the self-sufficiency. In the previous cases the inverter power is often reduced to limit the inverter losses during low part loads. The higher the inverter efficiency during low part load the less there is a need to reduce the inverter power. The rule of thumb is in this case an under-sizing for the south orientation. The loss in self-sufficiency is maximum0.2%.

Table 10. Optimized inverter power kW/kWp in function of azimuth and panel zenith for maximum self-sufficiency, load 5000kWh/a appliances, inverter model 5, 5kWp PV, no heat pump , no battery

azimuth	-180°	-120°	-60°	0°	60°	120°	180°
zenith							
90°	0,32	0,43	0,63	0,77	0,70	0,43	0,32
75°	0,35	0,48	0,72	0,86	0,79	0,49	0,35
60°	0,37	0,52	0,78	0,90	0,84	0,56	0,37
45°	0,39	0,60	0,82	0,92	0,87	0,65	0,39
30°	0,57	0,69	0,84	0,91	0,88	0,73	0,57
15°	0,73	0,78	0,85	0,89	0,87	0,80	0,73
0°	0,83	0,83	0,83	0,83	0,83	0,83	0,83

4. Conclusion

The optimized inverter power is determined for a reference system without battery or heat pump, as well as for the extended systems with heat pump and battery. Adding a battery, or adding a heat pump, or both, results in a different optimized inverter power but the gains compared to the inverter power determined by the rule of thumb are small.

Two rules of thumb to select the inverter power are used by contractors in Belgium, namely 70% and100% of the installed PV power expressed in kWp regarding the standard conditions. The 70% rule aims a maximum self-sufficiency, the 100% rule aims a maximum PV production. The results show that the rules of thumb are valid for the ‘best’ orientation in Belgium, namely due south and 30° zenith. A deviation of this position results in an extra loss of self-sufficiency or extra loss in production. Those losses are smaller than 1%. Adding a heat pump, a battery or both gives a small shift to a larger or smaller inverter power depending the orientation and zenith. Even with a changing load profile by adding heat pump and/or battery, the rule of thumb remains a good selection method of the inverter power. For an azimuth out of the range [-60°,60°] the optimized inverter will have a smaller power as the one determined by the rule of thumb and will reduce the investment with a better performance on top.

Nomenclature

C_{bat}	charge/discharge rate of the battery [h^{-1}]
C_{dr}	Capacitance of the battery cell in function of the open circuit voltage [F]
E_{bat}	Nominal capacity battery [kWh]
E_{loss}	Capacity loss of the battery in function of the SOC [kWh]
n	number of solar panels
$P_{appliances}$	Power of all appliances [W]
P_{batt}	Power charge/discharge battery [W]
$P_{batt\ conv}$	Power battery converter [W]
P_{grid}	Power supplied by the grid [W]
P_{hp}	Heating power heat pump [W]
$P_{inverter}$	Power output of the inverter [W]
P_{pv}	Power generated by the solar panels [W]
$PLR_{bat\ conv}$	Part load ratio battery converter [%]
PLR_{HP}	part load ratio heat pump [%]
R_f	Resistance of the battery cell in function of the open circuit voltage [mOhm]
SOC	State of charge of the battery [%]
T_{lwt}	Leaving water temperature heat pump [K]
T_{module}	Temperature of the solar panel [K]
$T_{outdoor}$	Outdoor temperature [K]
W_p	peak power of the solar panel at standard conditions [W/panel]
Φ_{solar}	Solar irradiation [W/m²]
η_{eff}	Efficiency of inverter [%]

Abstract

The current energy transition goals set by Spain in the PNIEC 2021-2030 anticipate a photovoltaic (PV) installed capacity of 39 GW by 2030, against the installed capacity of about 9 GW in 2020. The global improvement of PV systems' cost-effectiveness coupled with the current escalation in energy prices and the high annual solar energy potential of Spain are positive drivers. Thus, there has been an acceleration in the deployment of PV in the country, where the installed capacity has increased by 72% in the last two years, up to 15 GW. To study the potential contribution of residential rooftop PV systems in the future Spanish electricity mix, a data-driven multi-regional tool has been developed in Python. The hourly net electricity production-consumption balance is obtained for one year by using specific hourly solar irradiation data and real hourly electricity consumption data for each of the 8,131 municipalities in Spain. Furthermore, the economic potential of such installations is evaluated with the consideration of different electricity market scenarios as well as surplus electricity compensation policies. The analysis of the results shows a capacity for self-consumption which is 3 to 4 times higher in rural areas than in urban areas when energy storage is not considered. Furthermore, the current compensation policies may negatively affect the economic profitability of PV systems in the areas with the most significant PV potential.

Keywords

Data-driven tool; Regional analysis; Rooftop photovoltaic; Self-consumption potential; Techno-economical assessment.

1. Introduction

According to *PNIEC 2021-2030* national plan [1], Spain aims to deploy 39 GW of PV power by 2030 in the country, a significant increase from the 9 GW capacity in 2020. To encourage self-production of energy through PV systems in the residential sector, legal changes and fiscal measures have been implemented recently, including a law passed in 2019 to regulate surplus energy fed into the grid [2] and subsidies announced in 2021 to cover a percentage of the cost of new installations [3]. These measures, combined with the improving cost-effectiveness of PV systems and rising electricity prices [4], have led to an increase in PV system installations for self-consumption in Spain of 72% over the past two years [5].

Spain has a heterogeneous population distribution, with 16% residing in rural areas and occupying 84% of the land, while 84% live in urban areas and occupy 16% of the land [6]. According to [7-10], this distribution will affect the deployment of PV systems in the country, as some areas have low population densities but large surface areas to install PV while others have high population densities but small surface areas to install PV. Therefore, challenges remain in optimizing the deployment and integration of solar PV systems into different regional energy systems. Decision-makers in Spain need to address key questions, including the contribution of individual PV systems to the energy transition, promotion of larger-scale solutions such as energy communities, and how solutions should differ in rural and urban areas.

Previous studies have examined the potential of solar PV systems in specific regions of Spain, such as the Canary Islands. One study [11] found that the islands' potential solar fraction (i.e., percentage of the total energy demand satisfied by solar energy) is about 150%, meaning that there will be an overproduction of energy from PV compared to current demand. The same study concludes that PV systems would be economically profitable on the islands even without policies to compensate for electricity surpluses. Another recent study [12] focused on Gran Canary Island examined a theoretical hybrid energy system based on PV, offshore wind turbines, and energy storage to support local electricity self-consumption, with positive results. However, its analysis of future electrification scenarios showed that the optimal weight of solar PV generation systems decreases as electricity demand increases in contrast to wind turbines.

Moreover, other studies have focused on PV self-consumption capacity at the municipal scale in urban areas of Spain, such as the cases of Seville [13], Irun [14], and Valencia [15]. In Seville, PV systems installed on the roofs of buildings (residential, services, and industrial) could virtually meet the electricity demand of the city.

However, in Irun, only 59% of the city's demand could be covered by PV on building rooftops due to the prevailing climatic conditions. The study presented a sensitivity analysis of PV systems' economic profitability under three different surplus compensation policies: sole self-consumption, net-metering, and electricity transactions between buildings. The results showed that to achieve an investment return rate below 12 years, 27% to 71% of the roof surface area would need to be used, depending on the compensation policy. Meanwhile, the study of Valencia developed a multiple linear regression model to determine the economic payback of PV installations on residential buildings. The model identified shadow losses and power unit cost as the main factors affecting the payback period, which ranged between 7 and 15 years in most cases. High electricity demand buildings with low surpluses were found to be more profitable than those with large surpluses, due to the low economic compensation when injecting surplus electricity to the grid. The study suggested the promotion of energy communities to improve the profitability of PV systems.

At the national level, Gomez-Exposito et al. [16] evaluated Spain's potential for sustainable energy systems based on rooftop PV systems. The study highlighted the model's limitations due to the lack of hourly resolution energy demand data although it showed promising possibilities regarding a greener future in Spain.

With a careful review of the previous works on self-generation of electricity through PV systems, no work is yet to assess the impact of current Spanish surplus compensation policies on economic profitability and adoption. Additionally, no regional-level study has been conducted on the self-consumption capacity of the residential sector using massive data of real electricity consumption with hourly resolution. To address this gap, this work proposes a novel data-driven method to analyze the economic profitability and electricity self-production capacity using PV modules on residential rooftops, considering different compensation policies and flexible electricity prices. The analysis uses real hourly electricity consumption data from individual smart meters for all municipalities in Spain, allowing for higher resolution energy balances and individual analyses for each municipality. This enables the assessment and comparison of the capacity and profitability of rooftop PV between rural and urban areas.

2. Material and methods

Data from online databases are used to estimate the average electricity demand, rooftop surface availability, PV generation capacity, and solar fraction at different scales and regions. An economic analysis is conducted to find the optimal PV investment, calculating Net Present Value, Total Annual Cost, and Payback Period at the dwelling scale. Sensitivity analyses are performed for different scenarios of electricity prices and surplus electricity compensation policies. A Python-based software is developed to extract and process data automatically and generate tabular and graphic outputs for ease of analysis.

2.1 Architecture of the solution

Figure 1 illustrates the four main steps of the workflow: 1) Data collection, 2) Pre-processing, 3) Modeling, and 4) Analysis and visualization. Input datasets such as electricity consumption data, cadastral data, weather data, PV performance data, and economic data are collected in step one. Step two involves cleaning, filtering, and normalizing the collected data. In step three, the normalized datasets are combined to build the energetic and economic models. Finally, the techno-economic indicators are computed for all regions in Spain at the municipality level at hourly resolution.

2.2 Data processing

Hourly electricity demand per dwelling: Equation (1) can be used to obtain the Average Electricity Consumption per Dwelling, E_{dw}, by assuming one electricity contract per dwelling. E_{dw} is derived from the hourly electricity consumption in a municipality, E_T, and is influenced by the number of consumers in the area, C.

$$E_{dw} = \frac{E_T}{C}. \quad (1)$$

Rooftop availability per dwelling: The average amount of available rooftop surface per dwelling in square meters has been determined for each of the 15 typical housing clusters proposed by [17] in Spain. This calculation utilized the "void fraction coefficient," "shadowing fraction coefficient," and "facility coefficient" proposed by [18]. These coefficients consider factors such as empty space, shading, and obstacles in rooftops.

Hourly solar irradiation per square meter: Hourly solar irradiation data G in kWh·m^{-2} is obtained from the PVGIS platform [19]. Municipalities are reduced to one point (latitude and longitude) for simplicity when retrieving data. Solar PV modules are assumed to be installed horizontally to simplify the model by discarding the dependency of irradiation on the panel's azimuth angle and considering the associated decrease in efficiency for this configuration.

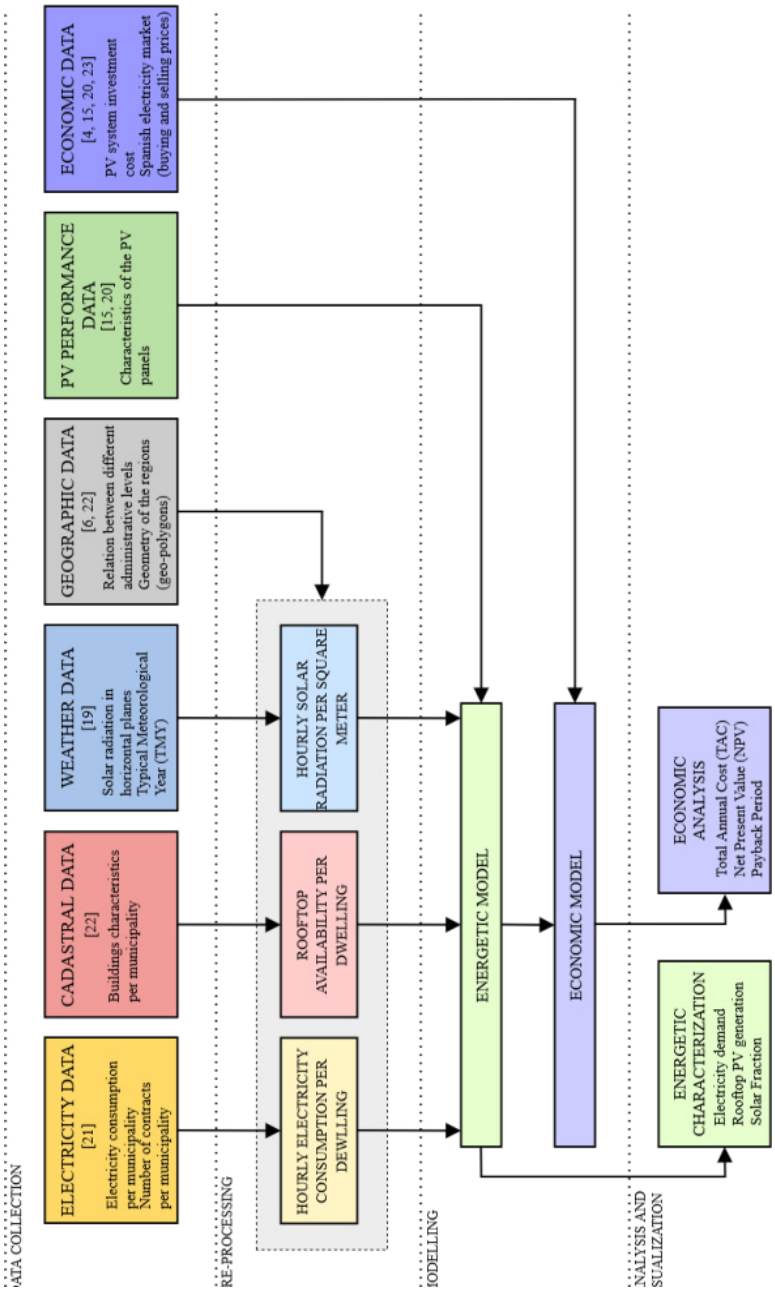

Figure 1. Workflow of the proposed method.

2.3 Techno-economic model

PV potential generation per dwelling. The PV potential per dwelling (in kWh) is determined by the percentage of rooftop surface (S_{PV}) covered by solar modules (load factor), hourly solar radiation (G) in kWh·m^{-2}, and the PV system performance factor (η). In the developed model, the rooftop load factor (α) ranges from 0% (no PV module) to 100% (full coverage of available roof surface). Equation (2) calculates the PV potential per dwelling (in kWh) for each observed hour i.

$$E_{PV,i} = G_i \cdot \alpha \cdot S_{PV} \cdot \eta. \quad (2)$$

Solar Fraction. The Solar Fraction represents the proportion of the annual energy demand that can be met by solar energy. Typically, this balance is calculated using annual average data of demand and PV production. However, studies have shown that analyzing the balance using hourly average data can provide valuable insights into the region's self-consumption estimation [16]. This study includes both methods: the one based on annual averages (SF_a, Eq. 3) and the one based on hourly averages (SF_h, Eq. 4).

$$SF_a = \frac{\sum_{i=1}^{j} E_{PV,i}}{\sum_{i=1}^{j} E_{d,i}} \cdot 100\%. \quad (3)$$

$$SF_h = \frac{\sum_{i=1}^{j} \frac{E_{PV,i}}{E_{d,i}}}{j} \cdot 100\%. \quad (4)$$

where $E_{d,i}$ is the hourly electricity demand (in kWh) at each hour *i*, $E_{PV,i}$ is the hourly PV electricity production (in kWh) at each hour *i*, and *j* is the total number of hours in a year.

Net money flow. The hourly money flow (C_h) in EUR is determined in Eq. (6) at each hour *i* according to the price of electricity and the net hourly energy balance (E_h), calculated in Eq. (5) as the difference between electricity consumed (E_d) and produced (E_{PV}) in an hour. When the net hourly energy balance (E_h) is positive, the purchase price (P_p) is used in Eq. (6); but when the balance is negative, selling price is used (P_s).

$$E_{h,i} = E_{d,i} - E_{PV,i}. \quad (5)$$

$$C_{h,i} = \begin{cases} E_{h,i} \cdot P_p \ \ if E_{h,i} > 0 \\ E_{h,i} \cdot P_s \ \ if E_{h,i} < 0 \end{cases}. \quad (6)$$

Accordingly, the monthly money flow (C_M) in EUR is an aggregate of all the hourly money flows for the month for the number of hours *I* observed in that month:

$$C_M = \sum_{i=1}^{I} C_{h,i}. \quad (7)$$

Total Annual Cost TAC The Total Annual Cost (*TAC*) for a PV system in EUR includes the annualized costs of owning, operating, and maintaining the system. *TAC* is the sum of Investment Annual Cost (*IAC*) in EUR and operational cost (C_{ope}) in EUR, as shown in Eq. (8):

$$TAC = IAC + C_{ope}. \quad (8)$$

The *IAC,* as given by Eq. (9), is the result of the *TIC* after applying the Capital Recovery Factor (*CRF*) which is given by Eq. (10):

$$IAC = TIC \cdot CRF, \quad (9)$$

$$CRF = \frac{ir \cdot (1+ir)^n}{(1+ir)^n - 1}. \quad (10)$$

where *IAC* is the Investment Annual Cost in EUR; *TIC* is the Total Investment Cost in EUR; *CRF* is the Capital Recovery Factor; *ir* is the Interest Rate in %; and *n* is the lifetime of the project in years. In Eq. (8), C_{ope} refers the cost of electricity consumption, i.e., the electricity bill, where C_{fix} is the Monthly fixed costs in EUR by using Eq. (11):

$$C_{ope} = \sum_{y=1}^{12} \left[(C_{fix,y} + C_{M,y}) \cdot (1 + VAT) \right]. \quad (11)$$

It is worth mentioning that each state, region, etc., has its own policies and laws on surpluses that may affect Eq. (11). For instance, in the current Spanish scenario, the monthly money flow (C_M) is restricted to be a positive value [2].

Total Investment Cost TIC The total investment cost for one PV system includes the cost of all the hardware, the installation cost, and the maintenance cost, in Euro per peak watt (EUR/Wp) and it is obtained by using Eq. (12):

$$TIC = (1 + F_{ind}) \sum_{k=1}^{K} \left[C_c \cdot (1 + FNPV_k) \cdot \left(1 + F_{m,k}\right) \cdot (1 + VAT) \right]. \quad (12)$$

where:

- F_{ind} — Factor for the indirect costs of the project (e.g., engineering cost) and it is estimated as 0.2 [20].
- FNPV — Net Present Value Factor for the possible repositions of components during the lifetime of the project.
- F_m — Factor for installation and maintenance costs and it estimated as 0.01 [20].
- VAT — Value-added tax (specific for each country)
- K — the number of all the different components of in system

Net Present Value NPV. The Net Present Value for one PV system (in EUR) as determined by Eq. (13), gives the time value of money invested and the economic risk of the project.

$$NPV = -TIC + \sum_{y=1}^{n} \frac{C_Y}{(1+ir)^y} \quad (13)$$

where C_Y is the Net Money Flow for one year in EUR.

3. Case study

This methodology was applied to assess the PV potential and self-consumption capacity in all 8,131 municipalities in Spain, covering both rural and urban areas. The study estimated the net energy balance over one calendar year and evaluated the economic profitability of PV systems over a 20-year projection. Hourly electricity demand data for 2019 was obtained from the Datadis database [21] for each municipality, while solar radiation data was collected from meteorological data series from 2006 to 2015 [19]. The availability of rooftop surface was estimated using the latest data from the INE database (dated 2011) [22]. Electricity prices were based on trends in the Spanish wholesale electricity market from 2015 to 2021 [4], while the performance and investment costs of the PV system were based on up-to-date global benchmarking reports and other referential works [14,15,20].

It should be noted that complete data on electric demand and housing stock is not available for all 8,131 municipalities in Spain. 326 municipalities, mostly with populations under 500 and representing 0.79% of the country's population, lack complete electricity demand data for 2019 [21]. Meanwhile, 138 municipalities representing 0.09% of the population have no statistical data on the housing stock [22].

In order to facilitate the analysis, all municipalities have been classified into 11 hotspots based on their population size, as shown in Table 1.

Table 1. Population distribution of the municipalities in Spain.

Number of municipalities	Size of the municipality (Number of inhabitants)
1233	< 100
2521	101 to 500
968	501 to 1,000
848	1,001 to 2,000
931	2,001 to 5,000
548	5,001 to 10,000
499	10,001 to 20,000
110	20,001 to 50,000
84	50,001 to 100,000
57	100,001 to 500,000
6	> 500,000

3.1 PV systems' parameters

Table 2 presents the PV system performance parameters used in the techno-economic analyses, including peak power per square meter, system efficiency, and lifetime.

Table 2. Performance parameters of the PV systems considered for the analyses.

PV performance parameters	Value
PV system output peak power	200 W_p/m^2 [20]
PV system efficiency	20 % [20]
PV system lifetime	20 years [13,14,20]

Table 3 summarizes the economic parameters considered in the analysis, including the cost in EUR per peak watt installed, the operation and maintenance costs in EUR per watt per year, and the VAT rate.

Table *3.* Economic parameters of the PV systems considered in the analyses.

PV economic parameters	Value
Residential PV system cost (VAT excl.)	1.6 EUR/Wp [14,15,20]
O&M cost (VAT excl.)	0.02 EUR/W·year [20]
VAT	21%

3.2 Electricity market scenarios

Table 4 outlines the proposed hybrid tariffs for electricity prices, which are based on REE's Active Energy Billing Term of the Voluntary Price for the Small Consumer (PVPC) [23] and the average prices in Spain from 2015-2021 [4]. The prices are divided into three hourly sections during the week with no differentiation on weekends. Three scenarios are considered: a downward trend, average trend, and an upward trend price.

Table 4. The three scenarios of hourly electricity prices considered in the analyses.

Period of the day (hours)	Downward trend (EUR/kWh)	Average trend (EUR/kWh)	Upward trend (EUR/kWh)
0-8	0.06	0.12	0.17
8-10; 14-18; 22-24	0.10	0.18	0.26
10-14; 18-22	0.14	0.24	0.34
Weekends	0.06	0.12	0.17

3.3 Surplus compensation policy scenarios

In Spain, the self-production surplus policy restricts profits from selling excess production as the monthly money flow (C_M) cannot be negative [2]. This means compensation for surplus sale cannot provide economic gains to consumers. To account for this constraint, Eq. (11) is redefined as Eq. (11b). However, to evaluate the impact of this policy on PV system profitability, both equations are computed, and their results compared.

$$C_{ope} = \begin{cases} \sum_{y=1}^{12}\left[(C_{fix,y} + C_{M,y}) \cdot (1 + VAT)\right] \; if \; C_{M,y} > 0 \\ \sum_{y=1}^{12}\left[(C_{fix,y} + 0) \cdot (1 + VAT)\right] \; if \; C_{M,y} < 0 \end{cases} . \quad (11b)$$

4. Results and discussion

4.1. Hourly electricity demand

Figure 2 displays the average electricity demand per dwelling per year (E_{dw}) in kWh for 7,828 municipalities in Spain. These municipalities were categorized into 11 population groups using Table 1 in Section 3.1. The average daily electricity demand in Spain is 7.6 kWh per dwelling per day, increasing to 8.5 kWh during winter and decreasing to 7.3 kWh during summer. Urban areas with over 30,000 inhabitants exhibit similar consumption patterns as the average. However, rural areas tend to have lower consumption, likely due to factors such as electrification levels and local alternative energy availability.

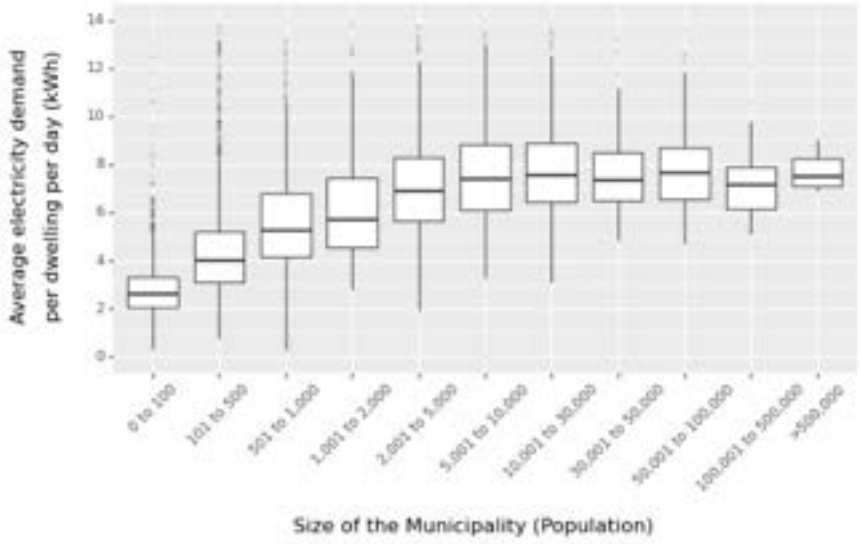

Figure 2. Average electricity demand per dwelling per day, in kWh, in the 7,828 municipalities in Spain with available data (>99% population representativity) grouped by population.

4.2 PV rooftop potential

Figure 3 displays the estimated useful rooftop surface to install PV per dwelling for the 7,828 municipalities with available data in Spain, calculated using the methodology described in Section 2.2. Small rural

municipalities (less than 5,000 inhabitants and 12% of the total population) have a consistent 10 m^2 of surface per dwelling in average, while larger urban areas (over 100,000 inhabitants and 40% of the population) have only between 3 – 4 m^2. This is due to a higher concentration of single-family buildings in rural areas compared to urban areas, where the proportion of multi-story housing blocks is significantly higher. Expressed in PV power terms, smaller rural areas can accommodate up to 5 solar panels per dwelling in average, equivalent to around 1.5 – 2.0 kWp of installed power, while larger urban areas can only accommodate up to 2 solar panels per dwelling in average, approximately 0.8 – 1.2 kWp. These results will be further discussed in the next section in relation to electricity demand.

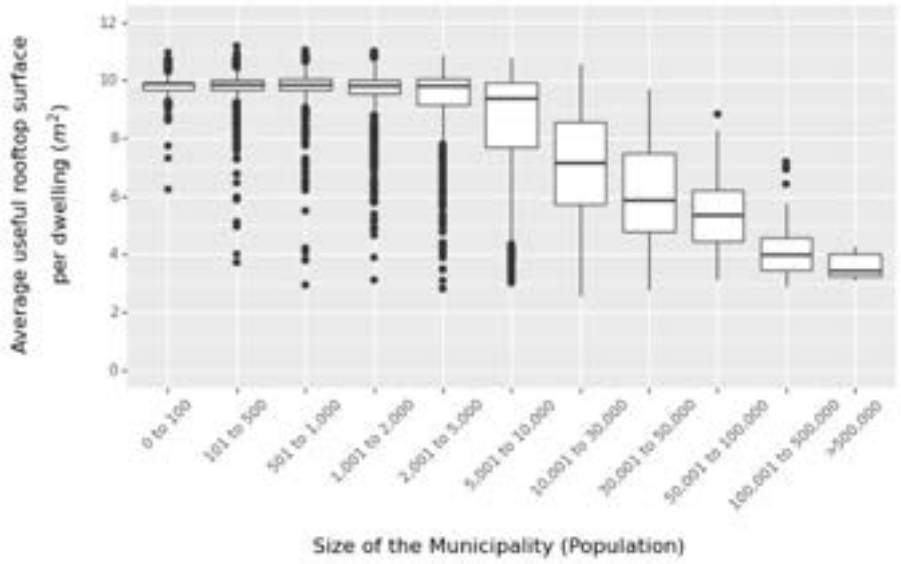

Figure 3. Available rooftop surface per dwelling, in square meters, for the installation of PV panels in the 7,828 municipalities in Spain with available data (>99% population representativity) grouped by population.

4.3 Solar Fraction

When estimating the solar fraction for municipalities in Spain, the annual balance method driven by Eq. (3) assume that surplus solar energy can be stored for on-demand use. However, this is not realistic due to current storage technology limitations. Therefore, a more practical approach is determined by using the hourly balance method driven by Eq. (4), which only considers immediate consumption. Figure 5 shows the results using this method, which demonstrate a decrease in self-production capacity for all municipalities compared to the annual balance method (Figure 4). With the hourly method, rural areas are no longer 100% self-sufficient, and all municipalities will remain between 30 and 55% solar fraction. Specifically, large urban areas experience a 30% drop, while rural areas see a 50 – 75% drop.

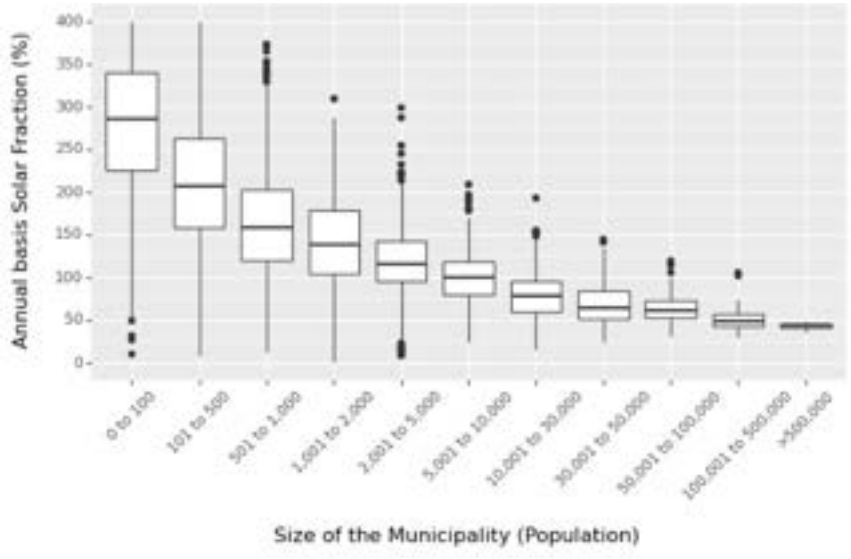

Figure 4. Solar fraction per dwelling (%) obtained with the annual balance method in the 7,828 municipalities in Spain with available data (>99% population representativity) grouped by population.

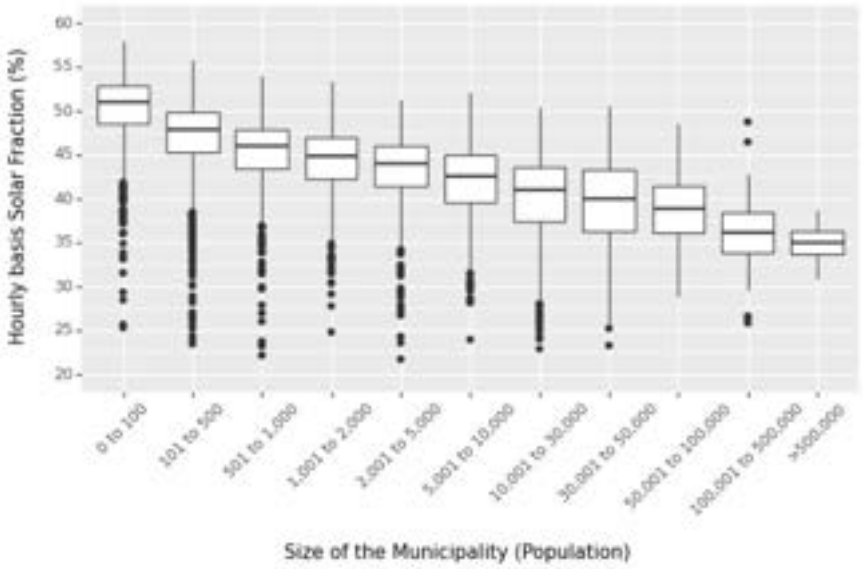

Figure 5. Solar fraction per dwelling (%) obtained with the hourly balance method in the 7,828 municipalities in Spain with available data (>99% population representativity) grouped by population.

4.4 Economic analysis

The economic optimization of 7,828 municipalities was conducted employing Total Annualized Cost (TAC), Net Present Value (NPV), and Payback Period (PBP) as key metrics. Figure 6 illustrates the outcomes for a selection of six municipalities distributed across various regions and diverse population sizes, thereby enabling a comparative study between urban and rural morphologies and also between different prevailing climate conditions. This selection encompasses Bilbao and Sopuerta in the north, Madrid and Ajalvir in the center, and Sevilla and Pruna in the south. Each pair of cities symbolizes urban and rural morphologies, respectively. Three distinct electricity price scenarios, as outlined in Table 4, were assessed, in conjunction with two surplus compensation policies, elucidated in section 3.3. The outcomes are portrayed for green (downward trend), orange (average trend), and red (upward trend) electricity price scenarios. The compensation policies considered include one that permits economic gains and another that aligns with the current Spanish regulations, devoid of economic incentives. The x-axis signifies the percentage of rooftop occupancy or load factor, which ranges from 0% (indicating no PV system installation) to 100% (indicating full occupancy). For this analysis, an interest rate of 3% and a projected lifespan of 20 years were presumed. Neither inflation nor owners' risk factor were considered in the study.

The TAC results, as shown in the first row, demonstrate that all six municipalities could obtain economic benefits from the installation of solar panels. However, the optimal rooftop load factor is subject to variations on the size of the municipality and the surplus compensation policy considered. Large urban municipalities such as Bilbao, Madrid, and Sevilla, generally have less rooftop surface availability compared to their rural counterparts, Sopuerta, Ajalvir, and Pruna. This constraint in urban areas diminishes the PV potential capacity, and consequently, the potential economic gains, as depicted by the marginal decrease of TAC with increasing load factor. Furthermore, the limited PV potential implies that surplus in urban municipalities are inadequate to reap the benefits of more generous compensation policies for PV system owners. Hence, both policy scenarios exhibit similar behavior. In contrast, rural municipalities, with generally larger rooftop surface availability per dwelling, yield superior economic performance and more significant surpluses. Consequently, they stand to gain the most from a hypothetical, more favorable surplus compensation policy.

The second row presents the NPV values, which supplement the TAC analysis by suggesting the optimal rooftop load factor for PV investment. The Payback period values also exhibit variability, dependent on the size of the municipality, electricity prices, and compensation policy. It is evident that current compensation policies could potentially hinder the complete deployment (100% load factor) of PV in rural areas. In an average market scenario, a dwelling in the rural areas could attain a PBP between 8 and 10 years under the current compensation policy. However, this could be reduced to between 6 and 8 years if a more favorable policy were implemented.

In summary, the analysis indicates that all municipalities could profit economically from the installation of solar panels. However, the optimal rooftop load factor and investment return timing are subject to multiple influencing factors. Moreover, current compensation policies negatively impact dwellings with more than 6 – 8m2 of available surface for installing PV.

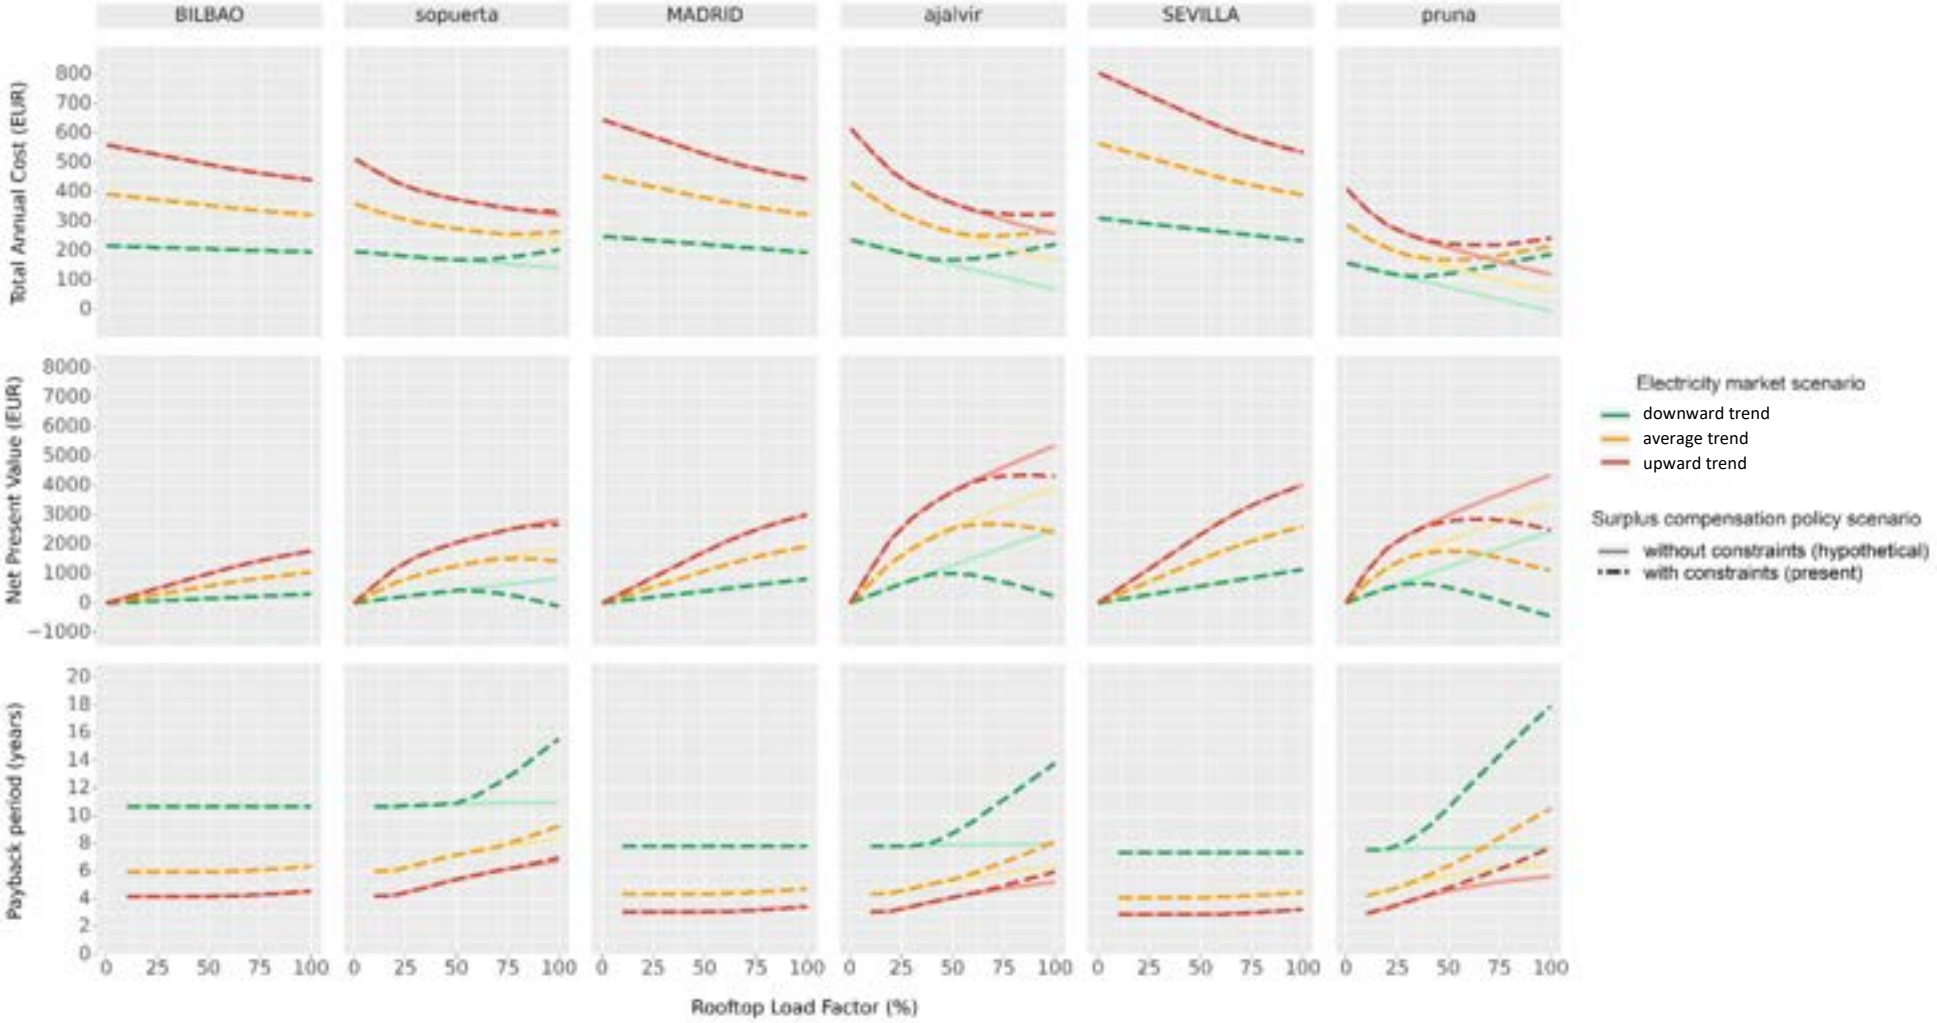

Figure 6. Total Annual Cost, Net Present Value, and Payback Period associated with installing solar panels on residential rooftops in different regions of Spain, under different electricity market and surplus compensation policy scenarios. Capitalized municipality names indicate urban morphology municipalities, while lowercase names indicate rural morphology municipalities.

5. Conclusions

This study introduces a new hourly data-driven method to assess the feasibility of residential solar PV systems for electricity self-consumption in Spain. The method employs mathematical models to estimate the electricity demand, self-consumption capacity, and economic profitability of rooftop-based PV systems at the municipal level, considering different surplus compensation policies and flexible electricity prices. The most relevant conclusions of this work are presented below:

- Rural areas have up to three times more rooftop surface per dwelling than urban areas, resulting in higher rooftop PV generation capacity. This correlation is linked to population size and rooftop availability per dwelling in a municipality.

- High-resolution hourly data is crucial for estimating self-consumption capacity when planning PV deployment. Analyzing hourly data reduces the potential by up to 75% in rural and 30% in urban municipalities compared to yearly data analysis.

- Current policies do not fully compensate for surplus electricity generated by PV systems, limiting potential investments in residential PV systems by 40 – 60% of their maximum capacity and reducing economic profitability.

Abstract:

Rural areas are strategic assets to ensure sustainable energy transition due to their potential to implement renewable energy production. In this context, the EU seeks to promote synergies between renewable energy deployment and rural development, through several funding programs and supporting policies that benefit both parties. Consequently, the number of rural Energy Communities is increasing, and researchers are focusing on optimizing their designs. In this regard, one critical aspect when simulating the energy demand of Energy Communities is the use of weather data which are mostly not available for specific locations. In these cases, data from nearby urban centers are typically used, if available. But these data may not be representative of the typical weather conditions of the specific rural area under study which will negatively affect such design. In this context, this paper studies the impact of using urban areas' weather data when designing Energy Communities in the nearby rural areas. Therefore, the case study of the Tarragona province in Spain is presented, driven by 43 weather stations homogeneously distributed across the region. Findings reveal higher correlation in temperature and solar irradiation between local data and province's capital data than with third-party data, despite climatic differences. Heating degree day analysis indicates third-party's data closer to reality. Given Spain's heating demand, accurate data is crucial for HDD, therefore, when local data is unavailable, third-party data is recommended, despite lower correlation.

1. Introduction

Increasing global energy demand and costs have been catalyzed by growths in global population and in the technological input required to drive economies [1]. This is also projected to be amplified by the rising global temperatures due to global warming. Resultant effects have been seen in rising energy prices due to the domination of energy supply from non-renewable resources. International agreement was reached, with clear road maps to reduce the emission of greenhouse gases (GHGs) with clean and renewable energy resources [2]. The UNEP Emissions Gap Report 2022 [3] indicates that to attain the goal outlined in the Paris Agreement [4] to reduce global temperatures increase to below 1.5 ^{o}C, the current global emissions of GHGs must be cut by 45%. This calls for greater penetration of cleaner energy into the global energy scenario. Following this, the European Union (EU) has committed to the attainment of 32 % renewable energy inclusion in its member states by 2030 [5]. An even bolder commitment of attaining 42% inclusion of renewable energy inputs into its nation energy mix by 2030 has been made by Spain [6]. Realizing these goals will require paradigm shift in all sectors, especially in electricity production as the supply of electricity drives many sectors (industrial, residential, services, transportation, etc). Hence, there is a need to deviate from the traditional centralized system of power generation to a distributed one which is capable of flexibly accommodating inputs from complimentary renewable energy sources. The creation of energy communities has been demonstrated to be a viable approach to meeting energy targets in the EU [7]. The EU in its Green deal commitment to meet emission targets, recognizes and supports Renewable Energy Communities (RECs) as essential components of energy transition [8]. This energy model also has the potentials of promoting self-consumption, reducing energy cost to consumers, and job creation. Thus, a demand is placed on member states to develop national policies and legal frameworks to promote participation of their stakeholders. However, the current Spanish energy regulatory framework has limited widespread roll-out of these RECs [9-10].

To maximize self-consumption and stabilize the national electricity grid, different types of renewable systems can be combined into a hybrid renewable energy system (HRES) [11]. Spain possesses vast renewable energy potentials which places it at advantage of benefiting from the HRES scenario [12]. On the other hand, the building sector accounts for about 43% of the total final energy consumption with about two-thirds of this from the residential buildings [13]. According to the International Energy Agency (IEA), the Spanish residential sector reliance on energy from fossil fuels still accounts for more than 50% of the sectors' final energy consumption [14]. This is even more prominent in the rural areas of the country. Therefore, energy transition efforts from the angle of the building sector are crucial. To this end, the EU directive 2010/31/EU and its amendment 2018/844/EU are legislative frameworks binding on member states to improve the energy efficiency of their buildings. Apart from participating in the energy demand side, buildings are also expected to participate in the supply side through the incorporation of available renewable energy technologies [15]. The idea is to achieve nearly zero energy buildings (NZEBs) or even positive energy buildings (PEBs) [16]. The excess energy generated by a PEB may then be consumed by another member of its HRES or exported to the national grid.

Dynamic numerical simulation has for some time, been an indispensable tool for HRES and NZEB researchers/designers in improving buildings' and HRES' energy efficiencies. The energy models utilized are usually run with weather data generated for the climatic conditions around the facility and they are often with some measure of uncertainties [17]. Different procedures have been used to construct typical annual weather data by statistically processing a multi-year (usually 10 years or more) actual weather data set as means of forecasting future weather conditions [18]. The Typical Meteorological Year (TMY) method was developed by Hall et al. [19] at Scandia laboratories, using Filkenstien-Schafer method, was modified into TMY2 and later, TMY3, by the National Renewable Energy Laboratory (NREL). The American society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) commissioned the International Weather Energy Calculations (IWEC) which was later updated to International Weather Energy Calculations 2 (IWEC2) [20]. The International Organization for Standards (ISO) also presented a procedure (ISO 15927-4:2005) for constructing a reference year of hourly values of meteorological data [21].

The reliability of the results obtainable from a building's or/and HRES' energy performance simulation depends on the accuracy of the weather data file utilized for the corresponding facility's location. The weather data used to compute typical weather conditions are typically obtained from historical measurements from weather stations which are usually situated at capital cities or airports. Since rural communities are usually far from such locations, their climatic conditions may differ from those around the weather stations. This will introduce errors when assessing energy performances in the rural areas [22]. However, generating the weather data for a specific location through any of the established procedures can be very demanding. A simpler alternative is to patronize the services of a third-party company which will generate the needed weather files while specifying the preferred meteorological model and the geographic location of concern.

In summary, the constitution of energy communities in the rural areas requires a precise evaluation of the energy performance of the involved buildings. However, according to the literature reviewed, no studies have yet to specifically investigate the impact of utilizing non-local meteorological data on these communities' design. This paper, therefore, seeks to fill this research gap by examining the implications of using data from various common sources, such as the capital city of the region or third-party providers, in comparison to employing local weather data in the design of rural energy communities.

2. Methodology

2.1. Data gathering and preparation.

The multi-year weather data supporting this work have been recorded by the weather stations owned by METEOCAT (Meteorological Service of Catalonia) during the period 2010 - 2019 at the 12 different locations around the province of Tarragona in Spain. The locations and main characteristics of these are presented in Figure 1.

The METEOCAT weather dataset include among others, 30-minutes measures of the following meteorological variables: dry-bulb temperature, wind velocity, relative humidity, global solar irradiance, maximum dry-bulb temperature, minimum dry-bulb temperature, maximum relative humidity, and minimum relative humidity. Despite the good quality of these measured weather data, it contained small gaps of usually a few hours, mainly in the wind speed data. Therefore, the linear interpolation technique was employed to fill in the missing data.

In building energy simulation, typical meteorological year weather data is usually a synthesized single year of weather data that represents multiple years of historical weather data. The collected weather data were then used to construct typical weather years according to the TMY. This method extracted a monthly weather dataset each, for all the calendar months, which typifies the weather characteristics of each location, from the historical data. The twelve selected typical months, which do not necessarily belong to the same year, were then concatenated to create a typical year.

municipalities	population	altitude	latitude	longitude
Amposta	**21317**	**3 m**	**40.7078**	**0.6321**
El Perelló	2846	179 m	40.8729	0.7158
El Vendrell	38891	59 m	41.2155	1.5212
Falset	**2724**	**359 m**	**41.1537**	**0.8195**
Horta de Sant Joan	1138	515 m	40.9513	0.3056
L'Espluga de Francolí	3717	446 m	41.3924	1.0989
Prades	**602**	**926 m**	**41.3148**	**0.9816**
Roquetes	8159	1055 m	40.797	0.3182
Tarragona	**135436**	**5 m**	**41.1039**	**1.201**
Vila-rodona	1299	287 m	41.3073	1.3626
Vinebre	427	53 m	41.185	0.5938
Vinyols i els Arcs	2193	29 m	41.0802	1.0666

Figure. 1. A map of the province of Tarragona, indicating the locations of the weather stations analyzed in this study and their key characteristics. The four stations examined in this paper are highlighted for reference.

The TMY methodologies build upon the original method by Hall et al. [23] which utilizes the following nine parameters that are considered with daily frequency: minimum, maximum and mean values of dry bulb air temperature (ºC) and dew point temperatures (ºC); maximum and mean values of the wind speed (m/s); and the cumulative global horizontal solar radiation (Wh/m^2). The weather data obtained from the different meteorological stations did not include the data for dew point temperature but this was determined from the data for relative humidity and dry bulb through psychrometrics.

In the TMY procedure, the Finkelstein-Schafer (FS) [24] statistic was calculated to determine the typical weather months for a calendar year. The FS statistic defines the absolute value of the difference between long-term data and each of the historical candidate months. That is, for each weather data month, all historical months were evaluated and the month which matched most statistically to the long-term weather pattern was selected. The procedure is summarized below.

a) The daily means $\bar{p}$ were calculated from the parameter *p* values of the data series.

b) For each calendar month, the cumulative distribution function ($CDF_{p,m,i}$) of the daily means for all the years in the dataset was calculated by sorting all the daily means values in increasing order and then ranking them using Eq. (1):

$$CDF_{p,m,i} = \left(\frac{K(i)}{N+1}\right), \quad (1)$$

where *K*(*i*) is the rank order of the *i* values of the daily means of a month *m* in the total data set and *N* is number of days for the month in the total data set.

c) For each year of the dataset, the cumulative distribution function ($CDF_{p,m,y,i}$) of the daily means within each month was calculated by sorting all values for that month *m* and year *y* in increasing order and then ranking them using Eq. (2),

$$CDF_{p,y,m,i} = \left(\frac{J(i)}{n+1}\right), \quad (2)$$

where *J(i)* is the hierarchical order of the values *i* of the daily means within that month and year while *n* the number of days in the specific month.

d) For each month, the FS statistic were then calculated for each parameter according to Eq. (3) & (4):

$$FS_{(p)} = \frac{1}{n}\sum_i^n \delta_i\,, \quad (3)$$

where δ_i is absolute difference between the long-term data CDF and the historical candidate month data CDF, and *n* is the number of readings in a month.

$$\delta_i = \sum_{i=1}^{n}\left|CDF_{p,y,m,i} - CDF_{p,m,i}\right| \quad (4)$$

e) The TMY procedures introduced a weighted sum of the single FS statistics calculated for every parameter for each month as in Eq. (5). The weighting factors W_p attributed to each of the nine weather parameters vary according to their importance on building energy demandand are presented in Table 1. The month with minimum weighted sum of FS displays the most similar weather pattern to the long-term historical weather.

$$WS_p = \sum W_p * FS_{(p)} \quad (5)$$

The hourly weather data belonging to the minimum WS were then used to fill up the corresponding month of the twelve-month weather file.

Table 1. Weighting factor used for each meteorological parameter.

Meteorological Parameter	**TMY** [24]
Maximum dry-bulb temperature	0.042
Minimum dry-bulb temperature	0.042
Mean dry-bulb temperature	0.083
Maximum dew point temperature	0.042
Minimum dew point temperature	0.042
Mean dew point temperature	0.083
Maximum wind speed	0.083
Mean wind speed	0.083
Global horizontal solar radiation	0.500

Also, the TMY for each of the 12 municipalities were obtained with the Meteonorm software which has a database with information from more than 7700 weather stations distributed around the world. The main advantage of the Meteonorm software is its ability to generate weather date for user-defined locations by interpolating data from nearby weather stations in combination with data obtained from satellites [25, 26].

2.2. Data analysis

The four locations selected for this study, are each considered to be representative of the 12 different climatic typologies of the province. Tarragona's (the capital) station is coastal, Amposta stations is pre-coastal, Falset is inland at 259 meters above sea level, and Prades is also inland but at the highest altitude of about 926 meters. It should also be noted that the weather station at Prades usually records the lowest temperatures during winter in the province.

A correlational analysis of weather parameters (ambient temperature, relative humidity and total solar irradiation) from the TMY of Tarragona, which was determined from historical data; the TMY for each of the three locations as determined from their historical data and also the TMY obtained for each location from Meteonorm, was performed. The Taylor Diagram provides a second approach for comparing weather data from the on-site weather station, Meteonorm, and the province capital's weather station. This method uses statistical metrics, such as the Pearson correlation coefficient (R), the centered root-mean-squared error (RMSE), and the normalized standard deviation (σ), to visually represent how closely a weather parameter sample matches the local observation.

A comparative study of the Heating Degree Days (HDD) and the Cooling Degree Days (CDD) were then conducted for the municipalities. The HDD relative to a base outdoor temperature of 18 ^{o}C were integrated from mid-October to mid-April, while the CDD relative to a base outdoor temperature of 24 ^{o}C were integrated from mid-April to mid-October. For each municipality, the values of the HDD and the CDD obtained from the TMY built using the climatic data of its meteorological station were compared with the TMY of the capital (Tarragona) and with the TMY obtained from the Meteonorm software. The method used for calculating the degree days are as defined in [27].

3. Results and discussion

3.1. Typical Meteorological Months

Table 2 shows the monthly weather data that were selected to assemble the typical meteorological year for each of the location considered in this study, based on the TMY procedure.

Table 2. Selected typical months for the different locations based on the TMY procedure.

Location	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Amposta	2018	2013	2014	2016	2012	2018	2013	2015	2016	2012	2016	2012
Falset	2015	2015	2014	2016	2012	2016	2013	2017	2016	2019	2016	2014
Prades	2013	2015	2014	2018	2014	2016	2013	2015	2016	2015	2016	2012
Tarragona	2013	2013	2014	2016	2016	2018	2010	2015	2016	2019	2016	2012

3.2. Taylor Diagram

The Taylor diagram is a useful graphical display of the statitiscal summary of how different models' performances match each other in terms of correlation, root-mean-square difference and ratio of variance [28].

The weather data from on-site weather stations, the province capital's weather station, and third-party software (Meteonorm) are compared using the previously introduced statistical metrics and displayed in a Taylor diagram for each of the three selected municipalities (Amposta, Falset, and Prades), based on three meteorological variables (temperature T, relative humidity RH, and global horizontal irradiance GHI).

In Amposta (Figure 2), T and GHI from the province capital's weather station have higher correlation with the on-site data (R=0.92 and R=0.93) than the Meteonorm's data (R=0.82 and R=0.73) obtained for the location.

RH however, generally showed much lower correlation (R=0.65 for the capital and R=0.21 for Meteonorm). The standard deviations are similar in all cases, below the 10% compared with the reference, except for the T of Meteonorm's data, around 21%.

In Falset (Figure 3) and Prades (Figure 4), T and GHI from the province capital's weather station also have higher correlations with the on-site data than Meteonorm's data, while RH has lower correlations. In these two locations, the standard deviation for all parameters is within acceptable values in all cases, less than 20% different from the reference data. It is noteworthy that Meteonorm's data are worse than the province capital's data in all locations, despite significant climatic differences between some of the municipalities. Although it is expected that Amposta and the province capital would have similar data, as they are both located on the coast with a Mediterranean climate, Prades and Falset have different climates and are located at higher altitudes than the capital.

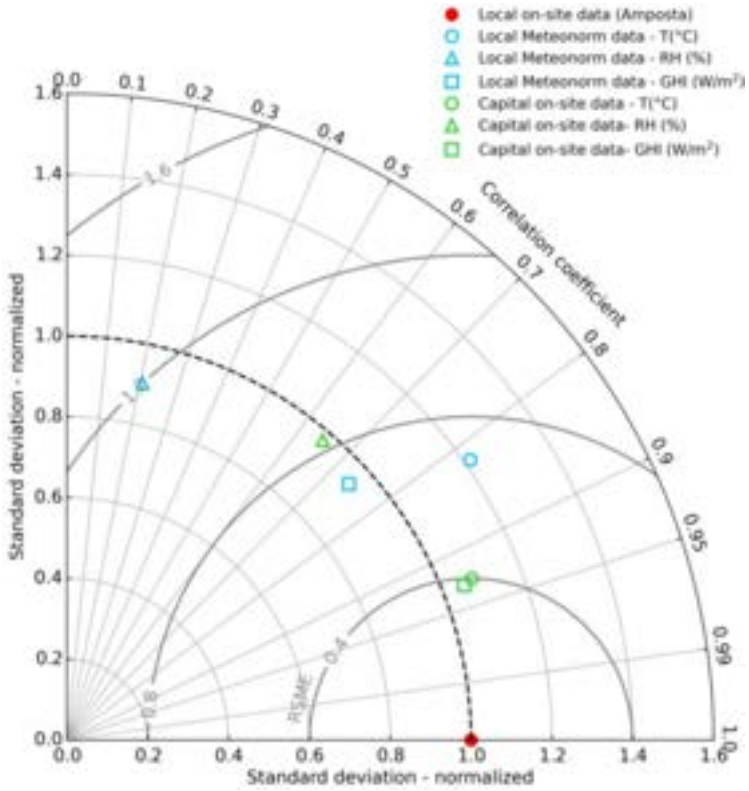

Figure. 2. Normalized Taylor Diagram for Amposta municipality, which compares the Amposta on-site weather station data (as reference) with Amposta third-party Meteonorm data, and with the province capital's weather station data for the TMY 2010-2019.

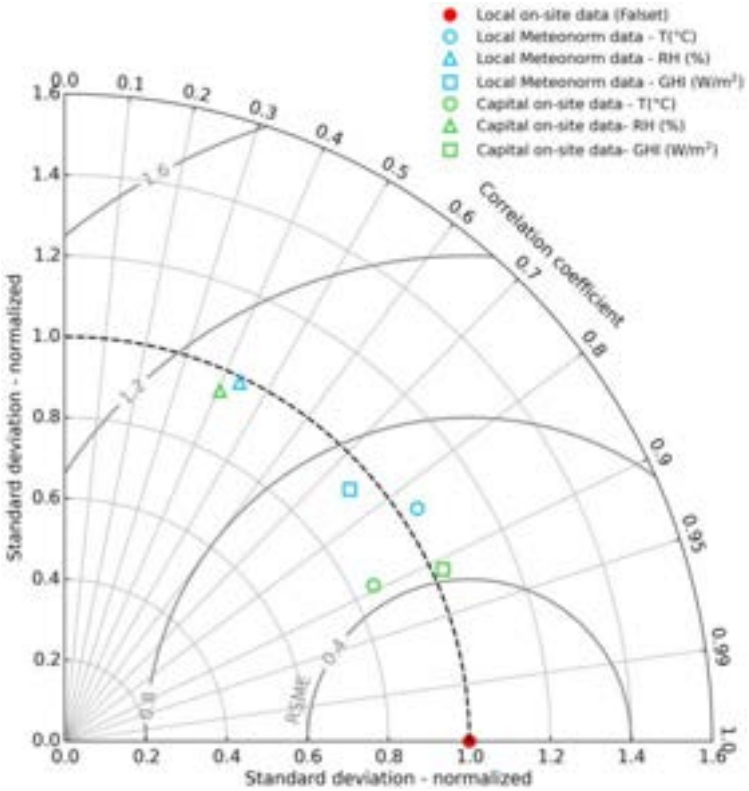

Figure. 3. Normalized Taylor Diagram for Falset municipality, which compares the Falset on-site weather station data (as reference), Falset third-party Meteonorm data, and the province capital's weather station data for the TMY 2010-2019.

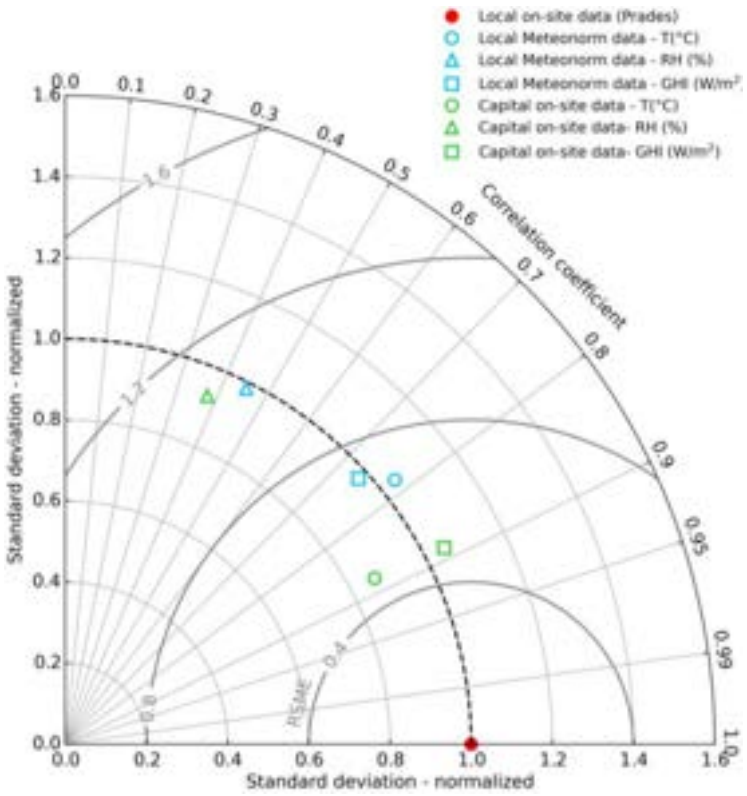

Figure. 4. Normalized Taylor Diagram for Prades municipality, which compares the Prades on-site weather station data (as reference), Prades third-party Meteonorm data, and the province capital's weather station data for the TMY 2010-2019.

3.3. Heating degree days (HDD) and Cooling degree days (CDD)

To evaluate the impact of typical weather data sources on building energy demand prediction for the three locations (Amposta, Falset, and Prades), it is crucial to analyze the representative Cooling Degree Days (CDD) and Heating Degree Days (HDD) of the different weather datasets. To this end, Figure 5 presents a comparison of the HDD and CDD values obtained from the TMY built using climatic data from each local weather station (On-site TMY), the TMY built using climatic data from the province's capital weather station (Capital TMY), and the TMY generated for each location using the Meteonorm software (Meteonorm TMY).

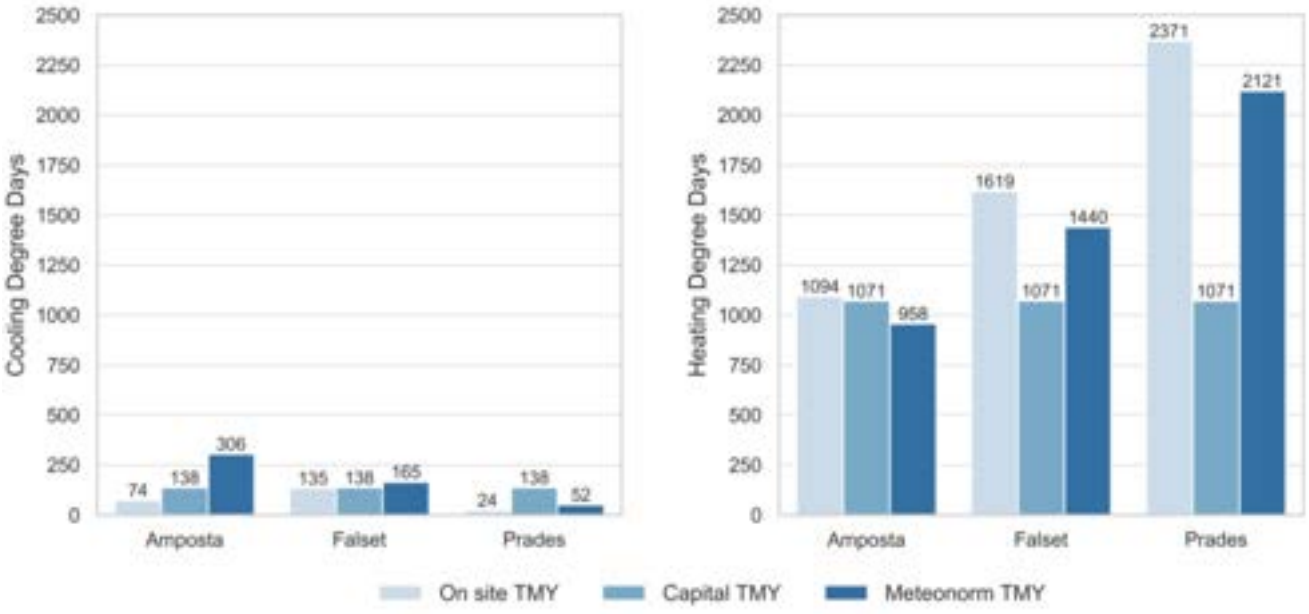

Figure. 5. Cooling Degree Days (left) and Heating Degree Days (right) for the 3 municipalities in the study (Amposta, Falset and Prades), computed from 3 different TMY 2010-2019 datasets: on-site weather station data, province capital's weather station data, and third-party Meteonorm data.

For the coastal municipality of Amposta, which is assumed to be more climatically similar to the provincial capital, the CDD values show significant deviations. Specifically, the onsite weather dataset resulted in CDD

which deviated from those from Tarragona's weather dataset by -86%, and even larger deviation of -300% from those given by the Meteonorm weather dataset. With respect to HDD, the onsite weather dataset minimally deviated from Tarragona's weather dataset by +2% while significant deviation of +12% from the Meteonorm's dataset is observed. These deviations are consistent with the Degree Days presented on the METEOCAT website for Amposta and Tarragona [29]. Concerning the implications for building energy demand, using the weather datasets from both the capital or Meteonorm would result in a large overestimation of cooling energy demands of buildings in summer. On the other hand marginal underestimation of heating demand of buldings in winter would result from the use of weather dataset from the capial while significant underestimation would result with the use of Meteonorm's dataset.

The CDD from the onsite weather dataset at Falset, which is located inland and at an altitude of 359 meters, are similar to those resulting from the capital's dataset with a minor deviation of about -2% while a larger deviation of about -22% resulted compared to the Meteonorm's dataset. However, the onsite weather data HDD show a larger deviation of about +34% from the capital's dataset and about +11% from the Meteonorm's dataset. This imply that using weather dataset from Meteonorm will result in significant overestimation of buildings' cooling demands in summer while datasets from both the province's capital and Meteonorm will result in significant underestimation of buildings' heating demands in winter.

Finally on Prades, which experiences considerably colder winters than the other locations (as evidenced by the onsite HDD values in Figure 5), the onsite weather dataset's CDD deviates with +475% and +116% with respect to the capital's and Meteonorm weather datasets respectively. The HDD from the onsite weather dataset on the other hand, deviates with +55% and +11% from the capital's and meteonorm's datasets respectively. Therefore, there is the risk of significantly underestimating buildings' heating demands during winter if the local weather dataset are not utilized, especially by using the weather dataset from the provincial capital. Additionally, significant overestimation of buildings'cooling energy demands will result from using weather datasets from both the province's capital and Meteonorm in summer.

Overall, and considering that in the period between 2010-2020, heating accounted for 41.5% of the total energy consumption in the residential sector in Spain, while air conditioning only accounted for 1% [31], it is crucial to properly size the heating system as opposed to the cooling system. Thus, in cases of extreme winter temperatures, it is more advisable to use Meteonorm data instead of relying on data from the provincial capital.

3.4. Conclusions

The objective of this research is to show the impact of using approximate meteorological data instead of using real local weather data in the design of rural energy communities. The study was conducted in twelve rural municipalities in the province of Tarragona, which have on-site data from local weather stations, with focus on three of them. Thus, for each location, the data from the local Typical Meteorological Year (TMY) computed from the on-site data were statistically compared, in terms of correlation, root-mean-square difference and ratio of variance, with data from the TMY of the province's capital and the TMY obtained using third-party software, Meteonorm. Additionally, the typical cooling and heating demands in buildings at each location were estimated using Cooling Degree Days (CDD) and Heating Degree Days (HDD) for the three meteorological datasets: referencial on-site data, province's capital data, and Meteonorm's data. The results show that, in all three case studies, the correlation of temperature and solar irradiation parameters between the local data and the data from the province's capital was higher (R=0.85-0.90) than with those from Meteonorm (R=0.70-0.85). This is despite the apparent climatic differences between the capital, in the coast, and the inland municipalities of higher-altitude. It should also be noted that the relative humidity data had correlation values lower than R=0.5 with respect to both the province's and Metenorm's data, indicating that they are unreliable for replacing the on-site data in any case. Furthermore, the analysis of CDD indicates that the data from the provincial capital is closer to the real local data than the data provided by Meteonorm. However, for HDD, the opposite is true, as the data from Meteonorm was found to be closer to real data, with deviations of 11%, compared to the deviation of 34-55% with the data from the provincial capital. Given that the heating energy demand in the residential sector in Spain represents 41.5% of energy consumption in average, while cooling demand barely reaches 1%, it is vital to use the data that best approximates reality with respect to HDD. Therefore, when local meteorological data is not available, third-party data yields better results in HDD analysis than the weather data of the provincial capital, though with low worse correlation. However, it is advisable to study to what extent the deviations found affect the definition of specific building design parameters for rural energy communities.

Abstract:
Marca Ambiental is a Brazilian company that collects and treats solid waste from Grande Vitória, state of Espírito Santo, since 1997. In order to recovery this waste energy, mainly the landfill biogas, the company installed a steam power plant, in 2008, generating 1 MW of electricity. A study showed that greater efficiency and electric power, by recovering the landfill biogas energy, would be possible using internal combustion engines (ICE). This first repowering has already occurred using three internal combustion engine gensets, generating more than 3 MW of electricity. This work carried out a thermo-economic analyse for this plant new repowering, using organic Rankine cycle (ORC) systems. The energy and exergy balances showed that, although more than 40% of the biogas energy is converted into electricity, more than 54% is lost through exhaust gases (27.2%) and cooling water (27.4%), which represent, respectively, 14.13% and 4.12% of the biogas total exergy. The simulation and economic evaluation of this repowering, using ORC systems, shows technical and economic feasibility, respectively, for 400 kW and 300 kW of additional electricity generation.
Keywords:
Energy Efficiency, Repowering, Exergy Balance, Energy Recovery.

1. Introduction

According to [1], in 2021 the Brazilian electric energy demand was 497 TWh, an increase of 4.6% in relation to the year of 2020. In the same period, the participation of thermoelectric power plants in electricity generation was 23.5%. Nowadays, thermoelectric generation is mostly using fossil fuels. The use of landfill biogas from Urban Solid Waste (USW) landfills may be one of the alternatives to improve this scenario. One of the technologies for thermoelectric generation is Internal Combustion Engines (ICE). According to [2], the waste heat energy from these engine gensets, due to the cooling system (of the engine block, lubricating oil and intercooler) and exhaust gases, is generally rejected to the atmosphere. This waste heat, from exhaust gas and cooling water can be effectively recovered, for the system efficiency improvement and repowering.

Repowering is defined by [3] as an important alternative to achieve improvements in systems and thermoelectric generation. Among the improvements, there are: reduction of the specific fuel consumption and/or costs, reduction of the emissions and least cost option for increasing generation capacity. The repowering methodology presented by [3] is summarized with the following steps: determine the generation system goals; identify the generation system information and restrictions; identify the candidates repowering technologies; Evaluate and select the most feasible technology. In consideration of repowering thermal power plants through the usage of waste heat, a study was conducted by [4] in order to survey waste heat recovery technologies for power plants equipped with internal combustion engines (ICE) aiming at increasing the produced net power and overall efficiency. Among the alternatives, the following were chosen as interesting based on commercial availability and low impact on engine operation:

- Combined cycle with Conventional Rankine Cycle (CRC).
- Combined cycle with Organic Rankine Cycle (ORC).
- Combined cycle with Kalina Cycle (KA).
- Absorption cycle for intake air cooling.

The results of a study by [4] showed that the Organic Rankine Cycle, using the exhaust gases heat from an ICE) presented the best performance for repowering purposes, considering the maximum power produced, achieving 5.3% in additional power produced. According to [5] ORC involves the same components of a conventional Rankine cycle: evaporator, expander, condenser and pump. One study [6] affirmed ORC is considered a simple technology because most of the heat addition and rejection happens during the phase change of the working fluid in the evaporator and condenser, respectively. The fundamental difference between CRC and ORC is the working fluid. As seen in [6], in ORC the fluid is an organic compound characterized by a lower boiling temperature than water, allowing power generation using heat sources with lower temperatures than in the conventional Rankine cycle. [8] affirms that, consequently, for low temperature waste heat recovery, ORC is a more suitable technology. One study [4] claims that organic fluids are high molecular mass fluids, compared to water, which allows compact equipment and low pipe diameter, for higher mass flow and higher isentropic efficiency of the expander.

In [5], parameter optimizations were performed, considering evaporation and condensation temperature, evaporator pinch-point and different types of organic fluids, as decision variables, in two configurations of ORC systems (simple and regenerative) to recover waste heat from an internal combustion engine. Considering the lowest specific costs for the power generated, as objective function, the best working fluid were selected, Toluene for waste heat recovery from engine exhaust gases and R141b for engine cooling water recovery. In [5], the maximum increase in efficiency and additional power generated was about 7%.

A study [6] was conducted to compare the efficiency of different working fluids in the heat recovery of exhaust gases from an internal combustion engine operating with biogas. The study examined pure organic fluids as well as their mixtures. The findings revealed that the Organic Rankine Cycle (ORC) system operating with toluene demonstrated the highest net electrical energy production, achieving an efficiency of 19.9%. In a related study [7], the use of toluene and cyclohexane in recovering waste heat from the flue gas of a reheat furnace was compared. The results indicated that under similar conditions, the ORC system with toluene exhibited a lower gross electricity production of 30 kW, but a higher energy efficiency of 17.08%. It is worth noting that neither of these studies explored the heat recovery potential from engine cooling water nor conducted an economic feasibility analysis of implementing the ORC technology.

With this in mind, the present work aims to recover both waste heat from the exhaust gases and cooling water of gensets in a Brazilian company involved in the collection and treatment of municipal waste. This company operates a thermal power plant based on three internal combustion engine gensets for landfill biogas energy recovery, generating over 3 MW of electricity. This paper outlines the procedures and discusses the results of a thermo-economic assessment of organic Rankine cycle systems for repowering applications in this landfill biogas power plant. The main contribution and novelty of this work lie in conducting an economic analysis of this plant under Brazilian conditions, as well as utilizing the engine cooling water as an input for a secondary ORC system.

To perform the energy and exergy balance analysis of the gensets, Engineering Equation Solver (EES) software was employed. IPSEpro was used for simulation purposes, and Excel was utilized for the economic evaluation of the ORC systems. Importantly, this work proposes advancements in the utilization of residual heat from an engine by providing a detailed explanation of the economic analysis using Brazilian economic conditions. Furthermore, the utilization of engine cooling water as a heat source is investigated in a real plant setting, with actual operating conditions that have not been previously explored.

2. Case Study Description

Marca Ambiental is an urban solid waste (MSW) recovery company, which has been collecting and treating municipal waste from Grande Vitória, in the state of Espírito Santo, Brazil, since 1997. According to [8], the urban solid waste is deposited in the landfill and then covered with layers of soil from the site itself, isolating it from the environment. Chambers are then formed, in which microbial activity, mainly of anaerobic bacteria that, through their metabolism, transform organic matter into combustible products, such as methane gas and released leachate. The slurry is captured through pipes and drained into treatment tanks.

In 2011, the company installed a steam cycle thermal power plant, generating 1 MW of electric power. Later, as shown in Figure 1, the original system was replaced by three ICE gensets (Genset 1, 2 and 3), generating more than 3 MW of electric power. Figure 1 shows the pipelines for capturing the biogas and directs it to the three engine-generator sets (EG's). There is a forecast for the future installation of two more generator groups. Nowadays, the thermoelectric plant has 3 ICE gensets modules, Jenbacher J416 GS models, 4-stroke Otto engines with mixture compression and exhaust gas turbocharging.

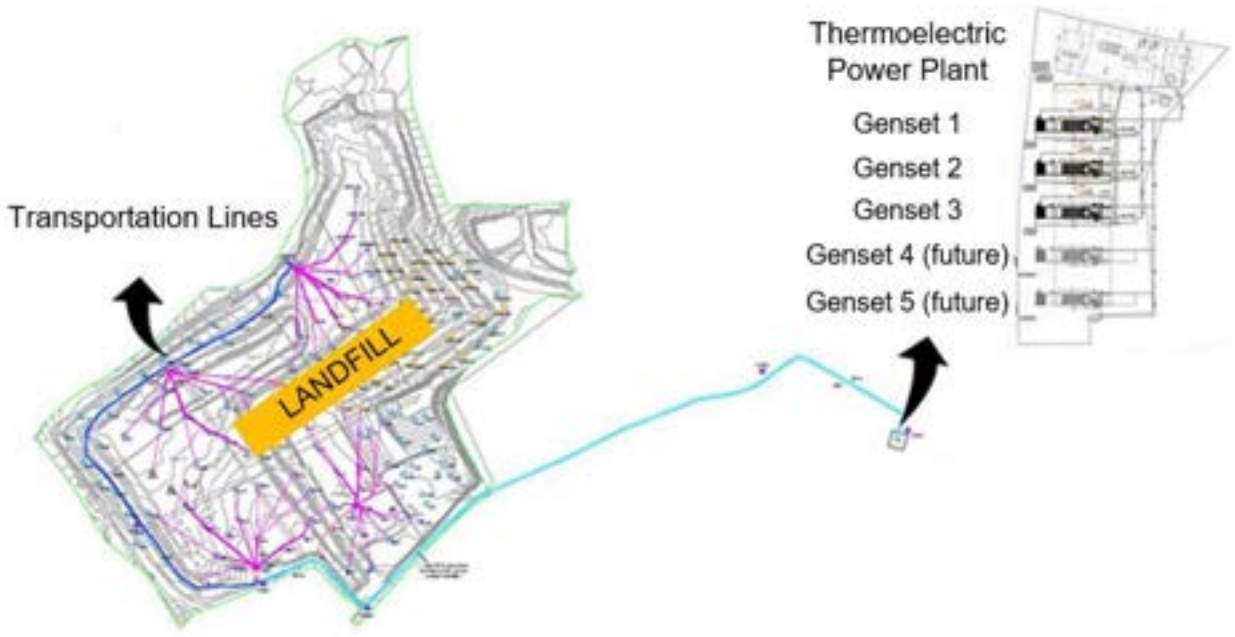

Figure 1 - Marca Ambiental's Biogas Capture and Thermoelectric System.

The average chemical characterization of the biogas generated at the Marca Ambiental landfill is shown in Table 1, as well the air composition, considering the average onsite conditions (25°C, 1 atm and 60% RH).

Table 1 - Biogas Characterization and Environmental Conditions.

Parameters			Value	Unit
Biogas Composition	CH_4		47.57	%
	CO_2		47.34	
	N_2		4.02	
	O_2		1.07	
	Heating Value	Lower (LHV)	12,753	kJ/kg
		Higher (HHV)	14,153	
Onsite Average Conditions	Pressure		1.013	bar
	Temperature		25	°C
	Relative Humidity		60	%

2.1. Gas Exhaust System

Each genset releases exhaust gases through the stack at a temperature of approximately 457 °C and a mass flow rate of 1.54 kg/s. This is the main source of heat with the potential to be recovered. It is important to stress the fact that there is a limit temperature for cooling the exhaust gases in their recovery process, due to the possible presence of sulfur in the fuel composition, which is considered 180ºC, in this work. The molar composition of the exhaust gases, shown in Table 2, was previously calculated with the aid of Engineering Equation Solver (EES) software using a complete combustion model with excess of wet air.

Table 2 - Molar Composition of the Exhaust Gases.

CO_2 (%)	H_2O(%)	N_2(%)	O_2(%)
12.85	14.49	67.57	5.09

2.2. Engine Cooling System

The cooling system of the generating units is done by means of demineralized water in two closed circuits, high temperature (HT) and low temperature (LT), with very low makeup during operation. The heat removed from the two aftercoolers, the lube oil and jacket water must be dissipated in a cooling system in order to allow the closing of the circuit. In the case of the thermoelectric plant, the cooling method adopted, depending on environmental conditions and water availability, is the use of a bank of radiators, with each generator set having two radiators. A thermal scheme of the cooling system, with water, biogas and exhaust gas flow values, can be seen in the engine flowchart, collected from the company documents, in Figure 2.

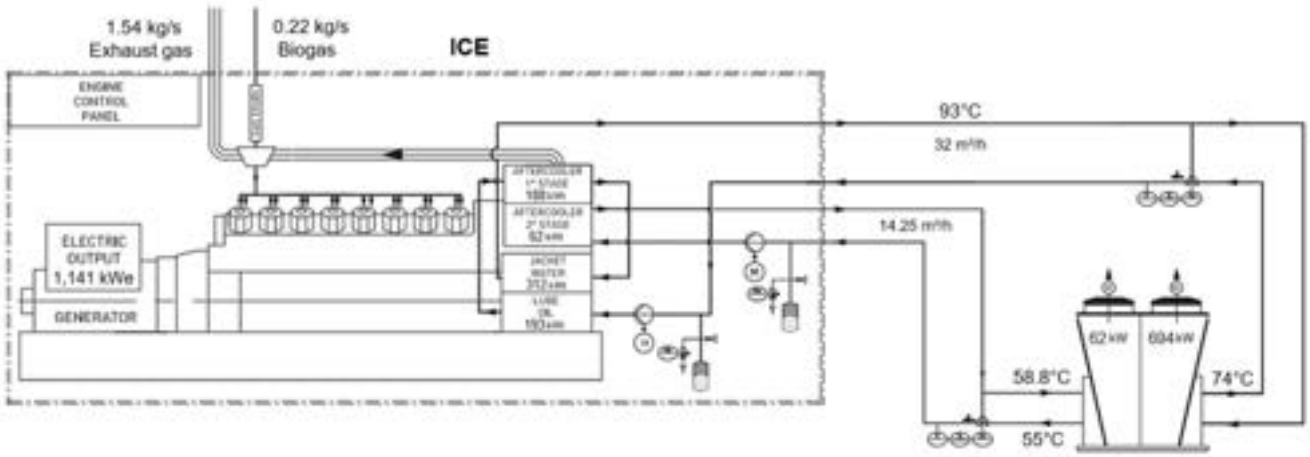

Figure 2 - Engine Flowsheet.

3. Engine Energy and Exergy Balance Methodology

The biogas energy rate is expressed by Eq. (1), as function of lower heating value (*LHV*) and mass flow ($\dot{m}_b$). The exergy rate of the biogas is calculated by Eq. (2), where $\dot{n}_b$ is the molar flow rate of the fuel, e_i^{ch} is the standard specific chemical exergy of each element, $\bar{R}$ the universal gas constant on a molar basis and T_0 is the reference temperature (dead state) in Kelvin scale.

$$\dot{Q}_b = \dot{m}_b \,.\, LHV \tag{1}$$

$$\dot{Ex}_b = \dot{n}_b \left(\sum_{i=1}^{j} y_i e_i^{ch} + \bar{R} T_0 \sum_{i=1}^{j} y_i \ln y_i\right) \tag{2}$$

The recoverable heat of each engine cooling water circuit is expressed by Eq. (3), where h_O and h_i are the specific enthalpy of the outgoing and incoming water stream, respectively. The sum of the two circuit recoverable heats, due to the two cooling water circuit, is the total recoverable cooling water heat ($\dot{Q}_{cw}$).

$$\dot{Q}_i = \dot{m}_i \,.\, (h_o - h_i) \tag{3}$$

The exergy of each engine cooling water flow is expressed by Eq. (4). The sum of the two circuit recoverable exergy is the total exergy loss, due two both cooling water circuit ($\dot{Ex}_{cw}$).

$$\dot{Ex}_i = \dot{m}_i \,.\, (\Delta h_i - T_0 \Delta s_i) \tag{4}$$

The energy contained in the exhaust gases ($\dot{Q}_{eg}$) is calculated using Eq. (5) Where $\dot{n}_{eg}$ is the molar flow rate of the exhaust gases, y_i is the molar fraction of each component in the exhaust gases, and $\Delta\bar{h}_i$ the variation of the specific enthalpy between the standard state and the state of interest.

$$\dot{Q}_{eg} = \dot{n}_{eg} \,.\, \sum y_i \,.\, \Delta\bar{h}_i \tag{5}$$

To calculate the exergy of the exhaust gas, its chemical and physical parts are calculated ($\dot{Ex}_g^{ch} + \dot{Ex}_g^{phi}$) represented by Eqs. (6) and (7), respectively, where y_i^e represents the molar fraction of the component in the air.

$$\dot{Ex}_g^{ch} = \dot{n}_b \, \bar{R} T_0 \sum_{i=1}^{j} y_i \ln \frac{y_i}{y_i^e} \tag{6}$$

$$\dot{Ex}_g^{phi} = \dot{n}_b \sum_{i=1}^{j} y_i (\Delta h_i - T_0 \Delta s_i) \tag{7}$$

$$\dot{E}x_g = \dot{E}x_g^{ch} + \dot{E}x_g^{phi} \quad (8)$$

Since the mechanical power is pure exergy, then the exergy of this stream is represented by $\dot{E}x_M$. Finally, the overall energy and exergy balance are represented by Eqs. (9) and (10) respectively.

$$\dot{Q}_b = \dot{W}_M + \dot{Q}_{cw} + \dot{Q}_{eg} + \dot{Q}_l \quad (9)$$

$$\dot{E}x_b = \dot{E}x_M + \dot{E}x_{cw} + \dot{E}x_{eg} + \dot{E}_d \quad (10)$$

In Equations 9 and 10, $\dot{Q}_l$ is other heat losses from the internal system and $\dot{E}_d$ is the destroyed exergy involving engine irreversibility and other losses.

4. Recoverable Waste Heat using Reversible Bottoming Cycles

The heat available to be used by each heat source in an engine if the minimum recoverable temperature is reached is shown in Table 3, considering that the heat sink temperature ranges from 27 °C to 32 °C.

Table 3 - Amount of heat available at each source to be recovered.

Range Temperature of the Recoverable Heat Source	Total Heat (kW)
Exhaust Gases (457 °C – 180 °C)	511
Cooling Water HT (93 °C – 74 °C)	694
Cooling Water LT (58.8 °C – 55 °C)	62

In an optimist scenario, where the heat addition line of the bottoming cycle is very close to the hot source line and the heat rejection line is close to the heat sink, one has the maximum technical potential presented in Table 4, considering that the recoverable would be converted into net power using a total reversible cycle.

Table 4 - Maximum Technological Potential of Repowering.

Range Temperature of the Recoverable Heat Source	Net Power (kW)
Exhaust Gases (457 °C – 180 °C)	250
Cooling Water HT (93 °C – 74 °C)	105
Cooling Water LT (58.8 °C – 55 °C)	5

It can be seen that the LT cooling circuit has a small flow rate and temperature variation compared to the remaining heat sources, so this water flow has a very small heat amount. Therefore, only the HT circuit heat source is chosen to be model for repowering purposes using the ORC with cooling water hot source.

4.1. Proposed Heat Recovery Thermal Scheme

The configuration of the ORCs coupled to the ICEs is proposed by joining the flows of the 3 gensets units and proposed to model one ORC for each of the available recoverable heat sources, as shown in Figure 3.

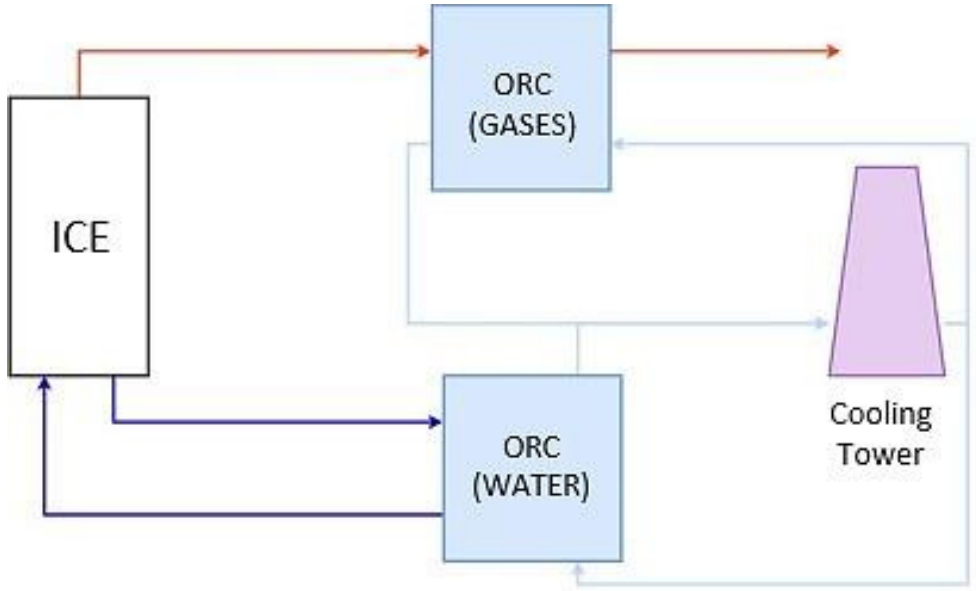

Figure 3 - Configuration of the ORCs to be coupled at the Marca Ambiental Thermal Power Plant.

5. Thermo-Economic of the ORCs

From the optimization data of [5], which caried out a similar case study, the implementation of the simple ORC was defined. This same study tested several working fluids for the different heat sources for recovery and reached a conclusion that in terms of power production with the lowest specific cost, the best fluids were Toluene and R141b, for the cycle recovering exhaust gases heat source and for the cycle recovering cooling water heat source, respectively. Based on that work, other parameters were taken into account to start modeling the ORCs, such as evaporation and condensation temperature and isentropic efficiencies of turbines and pumps, for each modeled ORC. These parameters are presented in Table 5.

Table 5 - ORC parameters.

Parameter	Fluid	
	Toluene	R141b
T_{evap} (ºC)	242.60	62.63
T_{cond} (ºC)	57.45	38.35
η_b (%)	71.54	71.10
η_t (%)	81.52	86.27

With the set of equations of the mass and energy balance of the Organic Rankine Cycle it was possible to obtain all the thermodynamic properties (pressure, temperature, enthalpy and entropy) of each state of the cycle, which was obtained as described, according to the configuration represented in Figure 4.

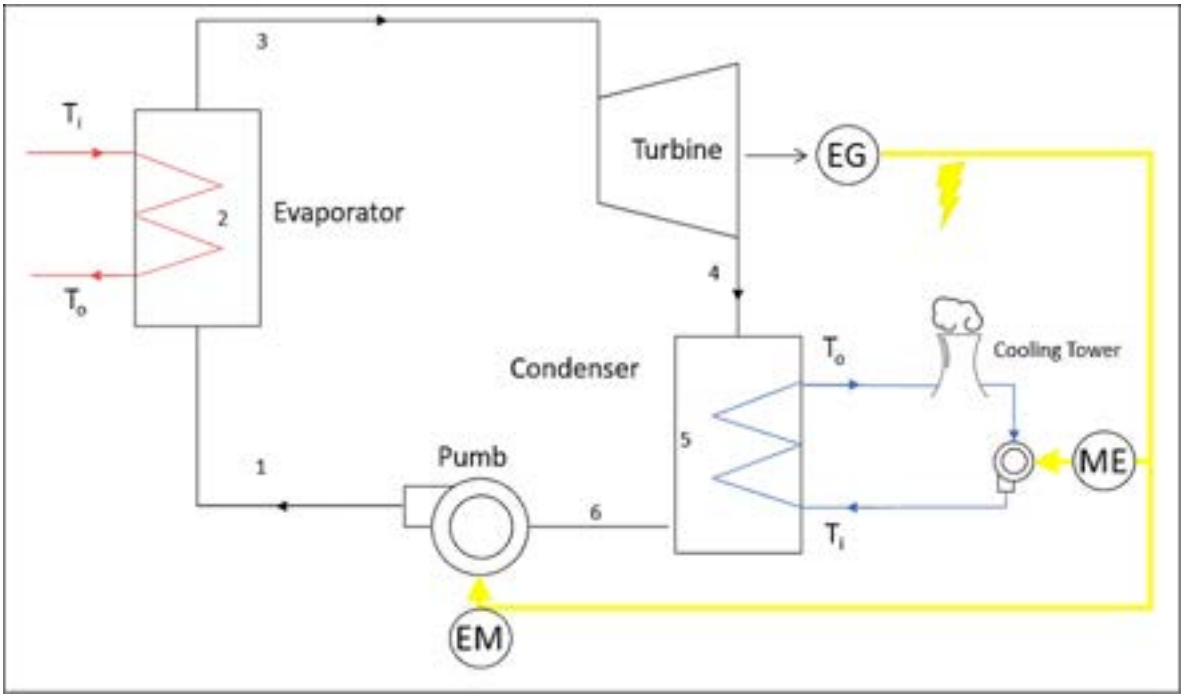

Figure 4 – ORC System Flowsheet.

The successful completion of a thermal design project requires estimation of the major costs involved in the project. Therefore, good cost estimation is a key factor in successfully completing a design project, as shown in [11]. There are many types of capital cost estimations and various methods often provide different results. The economic evaluation in this work is performed according to the module costing technique (MCT), extensively used for preliminary cost estimates of plants by [12]. This technique relates all direct and indirect costs to the purchased equipment cost evaluated for base conditions (C_{PE}) at ambient pressure, and carbon steel construction expressed by Eq. (11), where K_i are constants depending on the equipment type and A is the capacity or size parameter.

$$log_{10} C_{PE} = K_1 + K_2 log_{10}(A) + K_3[log_{10}(A)]^2 \quad (11)$$

Deviations from these base conditions are handled by multiplying pressure (F_P) and material (F_M) factors. The pressure factor is given by Eq. (12), where P is the pressure and c_i are constants depending on equipment type.

$$log_{10} F_P = C_1 + C_2\, log_{10}(P) + C_3[log_{10}(P)]^2 \quad (12)$$

The additional direct and indirect costs are considered through the bare module factor (F_{BM}) in the module costing technique. The bare module cost is the sum of all direct and indirect cost and can be calculated by Eq. (13).

$$C_{BM} = C_{PE} \cdot F_{BM} \quad [US\$] \quad (13)$$

The values of the bare module cost factors are given for different types of equipment. For heat exchangers and pumps the expression of the bare module cost factor is given by Eq. (14), where B_i are constants depending of the heat exchanger or pump type.

$$F_{BM} = B_1 + B_2 \cdot F_P \cdot F_M \quad (14)$$

For other components the F_{BM} is directly given as a multiplier that accounts for equipment type, operating pressure and construction material. The coefficients for Eq. (11) to (14) are obtain from [12] for carbon steel turbines, pumps and shell and tube heat exchangers. The parameters to estimate the cost of the colling tower was not considered in [11]. Thus, for this equipment, the methodology by [13], was employed in this work, as shown in Equation (15).

$$C_P = C_{ref,i} \cdot \left(\frac{X}{X_{ref}}\right)^m \quad (15)$$

For modifications and expansions of existing thermal systems, there are also other costs that need to be accounted for, like taxes and contingencies costs. According [14] when there are no other recommendations, these costs are 3% and 15% of the bare cost module respectively. Adding these remaining costs, the total module cost is calculated by Eq. (16), where *n* represents the number of the project equipment.

$$C_{TM} = 1.18 \cdot \sum_{i=1}^{n} C_{BM,i}\ [US\$] \quad (16)$$

All the data available in [12] are referenced in 2001. According to [14] the calculated cost updated is made through an appropriated cost index. The cost index is an inflation indicator used to correct the cost of equipment items, material, labor, and supplies to the date of the estimation. For thermal design projects the Chemical Engineering Cost Index (CEPCI) is recommended for total plants, or groups of components. It's adopted the CEPCI of 2022 ($CEPCI_{2022}$ = 821.3). Thus, the correct total cost is given by Eq. (17), where the $CEPCI_{2001}$ is 397.

$$C_{Total} = (C_{TM})\ \frac{CEPCI_{2022}}{CEPCI_{2001}}\ [US\$] \quad (17)$$

6. Results and Discussions

The thermodynamic evaluations of the repowering alternative were carried out on energy and exergy basis aiming at providing more support to the analysis, since exergy efficiency, exergy losses and irreversibilities allow a better understanding of the improvement opportunities in the waste heat recovery for power production, once that power is pure exergy. Exergy allows the evaluation of waste heat according to its maximum potential for power conversion, which is not possible using only an energy evaluation, as it overestimates the available heat potential for recovery and repowering. The economic evaluation allows the estimation of the specific capital cost for the repowering technology.

6.1. Recoverable Waste Heat

Based on the balances performed on the engine, the equations were implemented in the EES software. Thus, the results were found for a Jenbacher J416 GS engine of the EG of the Marca Ambiental Thermal Power Plant (TPP). In Figure 5 are the energy and exergy balances of an engine. The available heat energy is 54.60% of the energy provided by the biogas. However, the exergetic heat potential is 18.25% only.

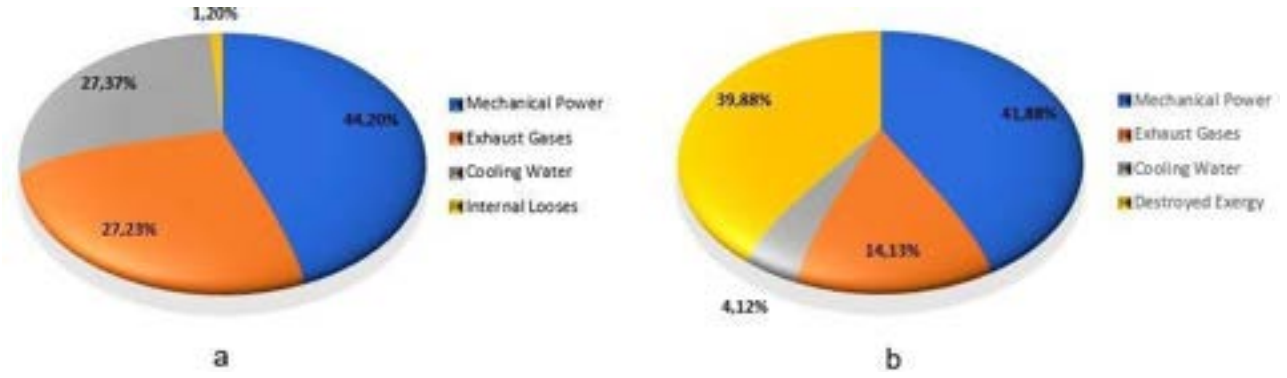

Figure 5 - UTE Marca Ambiental EG balances: a) energy balance, b) exergy balance

6.2. ORC Utilizing the Exhaust Gases Heat

Given the thermodynamic properties of toluene calculated in the EES it is possible to plot the T x s plot of the cycle, as seen in Figure 6. the values of the properties for each point are shown in the Table 6. The cycle has a net electric power production of 300.87 kW. In Table 7 there are the capacities and costs of each equipment.

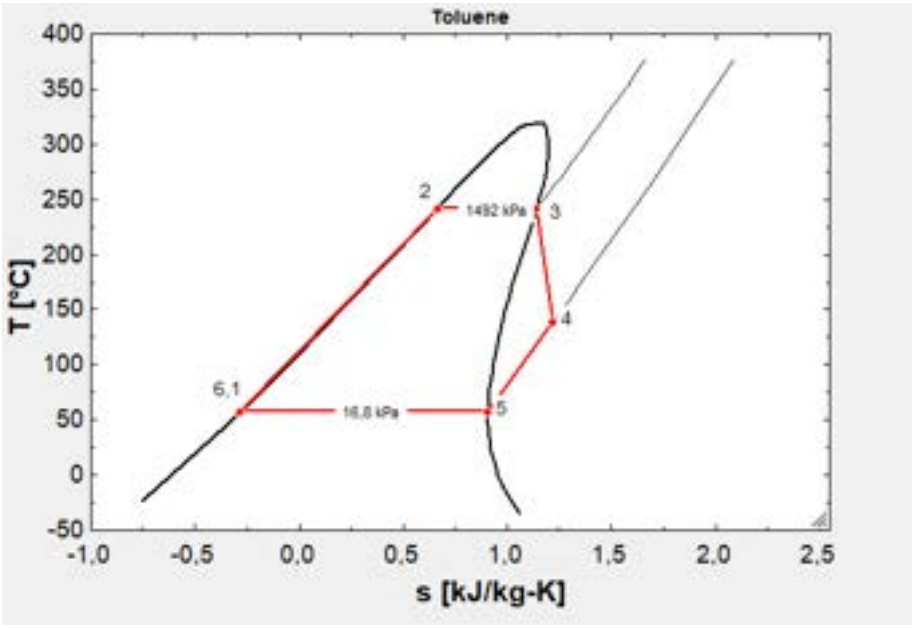

Figure 6 - Toluene T x s Diagram.

Table 6 - Thermodynamic Properties of Toluene at the ORC State for 2.38 kg/s of Mass Flow.

State	Temperature (°C)	Pressure (kPa)	Enthalpy (kJ/kg)	Entropy (kJ/kg.K)
1	58.2	1492.4	-98.8	-0.281
2	242.6	1492.4	301.7	0.667
3	242.6	1492.4	545.7	1.140
4	139.0	16.8	407.9	1.218
5	57.5	16.8	292.8	0.908
6	57.5	16.8	-101.3	-0.283

Table 7 - Capacity and Cost of Each Equipment.

Equipment	Capacity [unit]	C_{BM} [US$]
Evaporator	46.85 [m²]	149,190.03
Condenser	99.52 [m²]	203,466.40
Turbine	328.03 [kW]	543,019.03
ORC Pump	5.90 [kW]	13,469.85
Condenser Pump	2.06 [kW]	10,681.43
Cooling Tower	3.48 [m³/min]	29,867.1

Inserting the fees and updating the values to 2022 the total cost of the project is US$ 2,318,339.01.

Starting from the total cost of the project, we can apply some methods of economic feasibility analysis, such as: payback, NPV (Net Present Value) and IRR (Internal Rate of Return). For this we need the interest rate per year on the investment, the value of the electric energy and the life time of the project. The interest rate of the investment which was adopted is 12% and the life time of the equipment adopted was 20 years. Unitary Variable Cost (UVC), that is, the cost of selling electricity to the grid was US$ 0.130/kWh. The obtained payback was 15.36 years, showing that the initial investment will be paid, even if it is in a time close to the useful life of the equipment of 20 years. The IRR is was approximately 13.38%, greater than 12%.

6.3. ORC Utilizing Cooling Water

Faced with the thermodynamic properties of toluene calculated in the EES it is possible to plot the T x s plot of the cycle, as seen in Figure 7. the values of the properties for each point are shown in the Table 8.

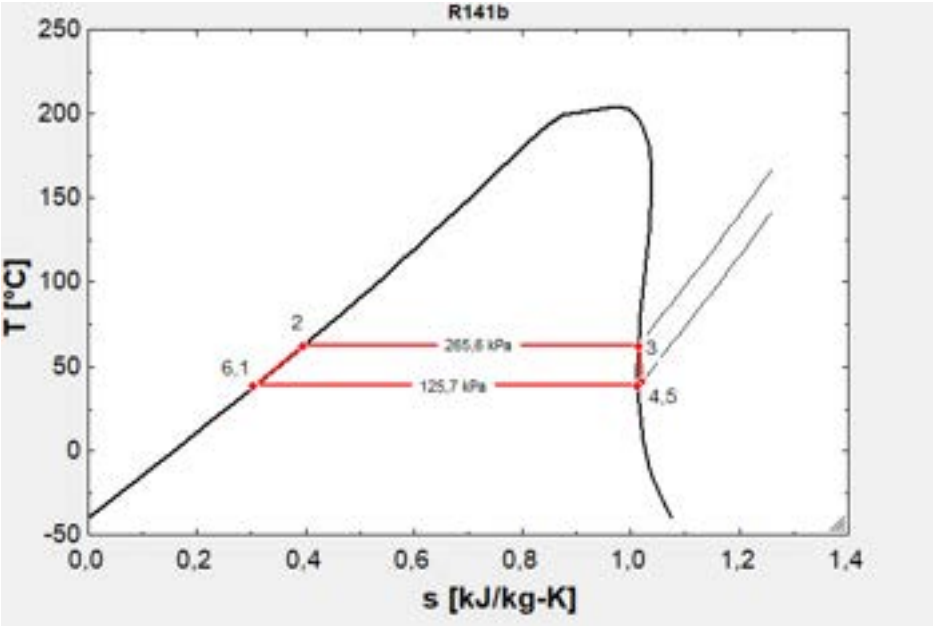

Figure 7 - R141b T x s Diagram.

Table 8 - Thermodynamic Properties of R141b at the ORC State for 8.35 kg/s of Mass Flow.

State	Temperature (°C)	Pressure (kPa)	Enthalpy (kJ/kg)	Entropy (kJ/kg.K)
1	38.50	265.59	83.27	0.306
2	62.63	265.59	112.86	0.397
3	62.63	265.59	320.09	1.014
4	41.58	125.74	306.10	1.021
5	38.35	125.74	303.52	1.013
6	38.35	125.74	83.09	0.305

The cycle has a net electric power production of 100.42kW. In Table 9 re defined the capacities and costs of each equipment.

Table 9 - Capacity and Cost of Each Equipment.

Equipment	Capacity [unit]	C_{BM} [US$]
Evaporator	300.71 [m²]	106,597.48
Condenser	891.53 [m²]	143,471.47
Turbine	116.74 [kW]	284,450.35
ORC Pump	1.47 [kW]	10,231.25
Condenser Pump	3.07 [kW]	11,462.07
Cooling Tower	5.34 [m³/min]	45,830.55

Inserting the fees and updating the values to 2022 the total cost of the project is US$ 1,469,673.82.

In this case, the ORC system is not able to return the money invested within the useful life of the equipment of 20 year. The find the IRR, which was approximately 4.06%, comparing to the MARR of 12 %, it can be stated that the IRR rate is extremely lower than the MARR, show the unfeasibility of the project.

7. Conclusions

This paper aimed to perform the thermodynamic modeling of ORC systems, and then analyze the additional power generated, repowering performance, in order to carry out an economic feasibility analysis of the implementation of the ORC systems, using some economic indexes: payback, Net Present Value (NPV), Internal Rate of Return (IRR). Two separately ORC system was simulated for this repowering purpose.

Firstly, energy and exergy balance were performed in order to evaluate the thermodynamic repowering potential, obtaining more than 43% of repowering potential. However, it is important to notice the limitations of the recoverable waste heat sources, which make the repowering potential drop down to approximately 32%. Additionally, it was observed that the LT colling water circuit has a very small repowering potential, representing approximately 5% of the HT cooling water circuit or 1% of the exhaust gas repowering potential.

Bearing this in mind, an ORC system was modeled for the exhaust gases from the 3 engines, operating with toluene as working fluid, generating 300.87 kW, which represents almost 8.8% of repowering. Another ORC was modeled for the HT colling water circuits heat of the 3 engines, operating with R141b as working fluid, generating 100.42 kW of additional electric power, representing 2.9% of repowering. The net efficiencies obtained for each cycle were 20.99% for exhaust gases ORC system and 5.83% for the cooling water ORC.

The economic analyses indexes obtained demonstrated the economic feasibility for the exhaust gases heat ORC system only, with total investment cost of US$ 2,318,339.01 and payback of approximately 15.5 years.

Acknowledgments

The authors would like to thank the Federal University of Espírito Santo (UFES), the Eficácia Consultoria, the Marca Ambiental, this study was financed in part by the Coordenação de Aprefeiçoamento de Pessoal de Nível Superior – Brasil (CAPES), the Support Foundation of Espírito Santo Research (FAPES), Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) and Rodrigo Guedes for the technical revision and formatting of the article.

Nomenclature

Symbols

A	capacity or size parameter, kW, m² or m³/min
B	bare module factor coefficient
C	pressure factor coefficient
E	exergy rate, kW
h	enthalpy, kJ/kg
K	equipment type coefficient
$\dot{m}$	mass flow rate, kg/s
P	pressure, bar
$\dot{Q}$	energy rate, kW
s	entropy, kJ/(kg.C)
T	temperature, °C
$\dot{W}$	power, kW
y	mole fraction
η	efficiency

Subscripts and superscripts

BM	bare module
cond	condensation
b	biogas
cw	cooling water

evap	evaporation	i	in
eg	exhaust gases	o	out
ex	exergetic	wf	working fluid
ge	generator efficiency
