Figure 9: FFT Fast Fourier Transform for evaluate the effect of throat lenght in cavitation dynamics behaviour.

5. Conclusion

In this paper, the influence of the throat section on the cavitation process for process intensification was investigated. It is understood that the unsteady process of cavitation is very complex and it depends on many factors. Using an FFT analysis it was possible to study the phenomenon of the re-entrant jet mechanism and

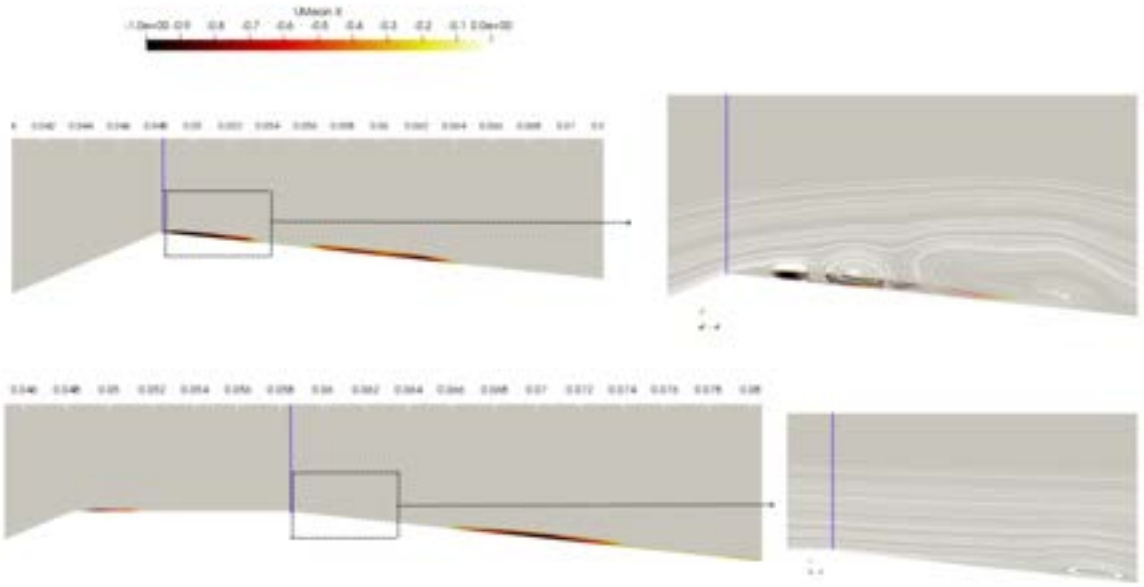

Figure 10: Average velocity field in which are compared the recirculation zone, the purple line represent the downstream throat section. On the left the streamline of the flow are plotted.

was found that an increase in throat section leads to a decrease in the oscillation frequency of cavities while a decrease in throat leads to a reduction in cavitation region extension. Despite the simplicity of the venturi device, there is no parameter to evaluate the effectiveness of the reactor for process intensification. For this reason, a specific term was developed to evaluate cavitation efficiency that was compared to the pressure drop within the cavitating device. Further experimental or numerical studies, are needed to determine the effect of varying the pressure at the outlet and keeping the same mass flow rate on the cavitation behaviour (at

a constant cavitation number). This forms the scope of future work.

Appendix A Model Validation

One of the critical aspects of cavitation models is to obtain reliable and accurate results. This is because especially empirical models or those based on Rayleigh-Plesset equations need a careful calibration process from the point of view of the numerical schemes and simulation settigs. from the point of view of the numerical schemes. For this work, since we do not have experimental data of the momentum field and volume fraction trend for the chosen geometry, we considered one of the most widely used test cases in the literature (Stutz and Reboud [12]) [12]) that offers experimental data on both the velocity field and volume fraction profile in the cavitation zone. Numerical settings are the same as those mentioned in the numerical setup section while a mesh of 100K hexahedral elements was made for the geometry. From the comparisons with the experimental data shown in graph 11, it can be seen that there is good agreement with the volume fraction and velocity profiles calculated with the developed model. The only differences are found at the first station where the mean value of volume fraction is overestimated, showing an inaccuracy in simulating the sheet cavitation region. While at the second station it is noticeable that the velocity profile calculated with cfd tends to underestimate the recirculation region. This is due to the URANS model used, in fact such models fail to totally capture adverse pressure gradients. A more detailed study of the velocity profile can be done using high fidelity approaches to evaluate the interaction between cavitating flow and turbulence. Comparison with experimental data showed how there is an error of about 4 percent in the calculation of cavitation length (48mm with numerics and 50 mm from experiment). For these reasons, the model was considered as validated.

Abstract:

This study investigates the heat transfer performance of a disc-shaped branched heat exchanger numerically. The numerical calculations have been conducted using the commercial computational fluid dynamics solver *ANSYS Fluent*, while three laminar and three turbulent cases are considered with Reynolds numbers of 100, 200 and 400 for the former; and 3000, 4000 and 6000 for the latter. Turbulence closure is achieved by employing the k-eps Realizable turbulence model, which uses Boussinesq approximation to model the eddy viscosity. The working fluid is water. Constant heat flux is applied at the bottom wall of the heat exchanger. The numerical method is validated by a previous experimental study. The heat transfer performance of the heat exchanger is evaluated by monitoring the temperatures at the outlet section, as well as the volume-averaged temperature of the solid part. It is observed that values of the heat transfer coefficient for the turbulent cases are much greater than that of the laminar case, whereas it is directly proportional with the Reynolds number, in general.

1. Introduction

The purpose of this study is to carry on with the determination of the most effective configuration for a branching heat exchanger that uses water as the coolant fluid and implement any necessary improvements.

Capata and Gagliardi [1] investigated the performance of branched heat exchangers working with organic fluids. An automotive refrigerant called glycol was used in experiments at two different concentrations (50 and 100 %). An organic fluid has also been employed and examined for heat transmission. After completing all the tests, the numerous dimensionless parameters that characterize the heat exchange have been determined, and a comparison analysis has been performed, in order to determine and suggest the optimal configuration for the branched heat exchanger.

Reis [2] investigated constructal theory and its applications to a variety of domains, including engineering, natural living and inanimate systems, social structure, and economics. A constructal approach offers an integrated structure to guide the creation of flow architectures in systems with fluid flow. The relationship between of constructal law and the thermodynamic optimization strategy for minimizing entropy generation is described. The constructal law is an independent principle separate from the Second Law of Thermodynamics. In addition, the relationship between the constructal law and other fundamental concepts, including the Second Law, the principle of least action, and the principles of symmetry and invariance, is discussed.

Capata and Beyene [3] investigated three distinct compact branched heat exchangers by assessing the thermal efficiency and pressure drop of each device. A performance comparison of several refrigerant fluids improves the generality of the understanding of phenomena. To provide an average constant flow speed throughout the exchanger, the channels in the first arrangement have been built with different inner diameters. In the second, a constant flow Reynolds number has been maintained inside the channels. According to Bejan Constructal Theory, the final configuration is constructed using the constructal diameter variation. The results of multiple comparative tests have been assessed to find the ideal exchanger for each refrigerant based on the gathered data.

Asgari et al [4] considered the simulation of phase change material solidification in a heat exchanger with branch-shaped fins. The thermal conductivity of phase change materials is studied in relation to the impacts of branch-shaped fins with varying thicknesses and lengths. The results demonstrated that fins considerably

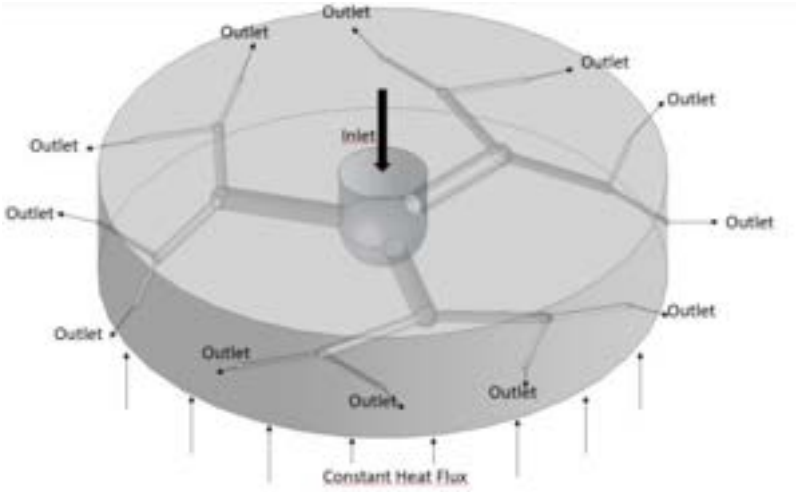
accelerate the solidification process, and simulation efficiency is maximized when thin, branch-shaped fins and nanoparticles with a volume fraction of 0.04 are utilized simultaneously.

Zhu and Jing [5] examined a numerical analysis of the thermal and melting performance of a horizontal latent heat storage unit with tree-like convergent fins. The paper presents a horizontal LHS unit embedded with branched tree-like convergent fins (BTCF) and statistically explores the influences of various geometric and structural characteristics of the BTCF. The results demonstrate that increasing N, m, and α values can efficiently enhance heat transfer between the fin and phase change material (PCM), speed up PCM melting, and increase energy storage.

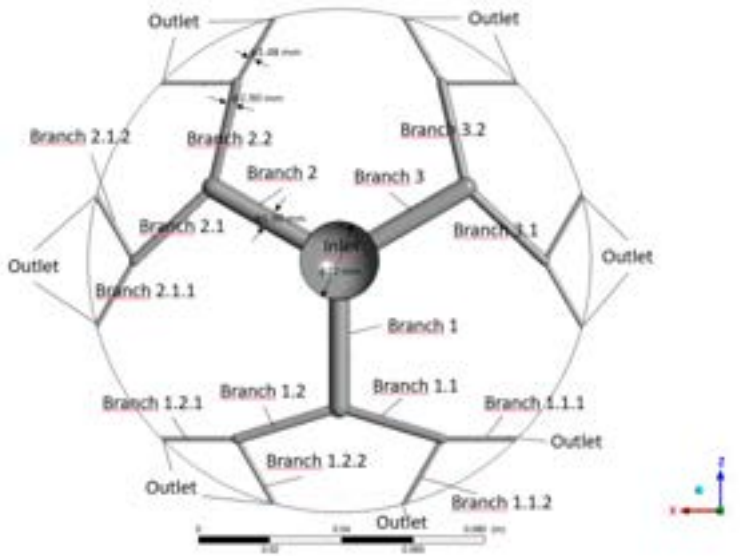
Huang et al [6] studied the heat transfer improvement of a latent heat storage unit using gradient tree-shaped fins, both experimentally and numerically. They examine two new LHS units with tree-shaped uniforms and gradient fins. The results indicate that tree-shaped fins promote heat diffusion from point to area, hence breaking the heat transport hysteresis in conventional LHS units and speeding the melting/solidification rate.

2. Numerical Method

This study investigates heat transfer characteristics in a disc shaped heat exchanger (Disc HEx), numerically. Steady, three-dimensional, and incompressible problem is modelled using commercial computational fluid dynamics (CFD) solver, *ANSYS Fluent*. Water as a heat transfer fluid for this study, enters disc heat exchanger through inlet section at temperature of 308 K with diameter of 22 mm which is located on the top of the disc heat exchanger. Diameter of branches are 5.9 mm, 2.9 mm, and 1.48 mm, respectively. Twelve outlets are located on sides of the disc and applied pressure outlet boundary condition, where static pressure is adjusted at zero gauge. Constant heat flux of 28294.212 W/m^2 is applied to the bottom of the disc for all cases. All surfaces of heat exchanger, except bottom surface where heat flux is applied, is considered adiabatic. Physical properties of water those of density, specific heat, heat conductivity and dynamic viscosity are assumed to be constant. Geometry description, branch definitions and boundary conditions are presented in Fig. 1 and Table 1.



(a)



(b)

Figure 1. *Geometry description and boundary conditions,* ***(a)*** *isometric view,* ***(b)*** *top view*

An unstructured mesh with approximately 3.5 million elements is generated for numerical calculations (Fig. 2). Reynolds number is calculated considering inlet diameter and inlet velocity (Eq. 1). In numerical calculations, three laminar cases with Reynolds number of 100, 200 and 400, and three turbulent cases with Reynolds number of 3000, 4000 and 6000 are considered, respectively. For turbulent cases, k-ε Realizable turbulence model with Enhanced Wall Treatment is employed. Coupled algorithm is utilized for pressure-velocity coupling.

$$Re = \frac{\rho V_o D_o}{\mu} \tag{1}$$

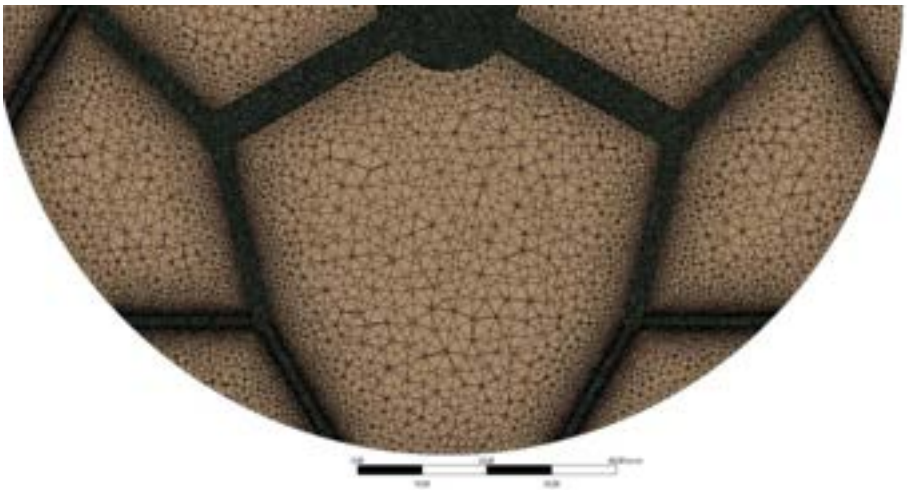


Figure 2. *The numerical grid used in this study*

Logarithmic mean temperature difference (ΔT_{lm}) is calculated according to Eq (2):

$$\Delta T_{lm} = \frac{\left(T_{wall,in} - T_{in}\right) - \left(T_{wall,out} - T_{out}\right)}{\ln \frac{\left(T_{wall,in} - T_{in}\right)}{\left(T_{wall,out} - T_{out}\right)}} \tag{2}$$

Where, T_{in} and T_{out} refer to inlet and outlet temperatures of certain branch, while $T_{wall,in}$ and $T_{wall,out}$ refer to solid temperature near inlet and outlet sections. Heat flux is calculated through the following equation:

$$q = \frac{\dot{m} c_p (T_{out} - T_{in})}{A_s} \tag{3}$$

In Eq (3), A_s is heat transfer area, while $\dot{m}$ and c_p are mass flow rate and specific heat. While mass flow rate is variable depending to Reynolds number, specific heat is assumed to be constant and 4182 J/kg K. Eventually, mean Nusselt number throughout each branch is calculated with Eq (4):

$$Nu_{m,i} = \frac{q D_i}{k\, \Delta T_{lm}} \tag{4}$$

Area-weighted average Nusselt number throughout whole disc for each case is calculated by Eq (5):

$$Nu_{m,ave} = \frac{\sum (A_s\, x\, Nu_{m,i})}{\sum A_s} \tag{5}$$

3. Results and Discussion

This study is validated with a previous experimental work of Capata and Gagliardi [1]. Solution parameters used in the previous experimental work are employed in numerical calculations, and obtained results are compared. Validation parameters are given in Table 1, and compared results are presented in Table 2. Results of the numerical and experimental studies agree very well, while the absolute percentage error in the estimated values of temperature is 1.35 % for volume-averaged temperature of the heat exchanger, T_{solid}, whereas error is less than 0.5% for outlet fluid temperatures, T_{out}. Thus, the numerical model is validated to be used for further investigating heat transfer characteristics of the disc-shaped heat exchanger.

Table 1. Solution parameters

Refrigerant	Inlet velocity [m/s]	Reynolds number	Inlet Temperature [K]
Water	0.253	3267	304
	0.505	6534	309
	1.263	16336	312

Table 2. Comparison of experimental and numerical results

$T_{solid, exp}$ [K]	$T_{solid, num}$ [K]	Error %	$T_{out, exp}$ [K]	$T_{out, num}$ [K]	Error %
320.00	320.84	0.26	309.50	308.97	-0.17
318.80	320.26	0.46	311.3	311.31	0.003
315.00	319.25	1.35	312.80	312.81	0.003

Figure 3 illustrates the temperature distribution on the horizontal mid-plane of the heat exchanger. Accordingly, cooling effect increases with Reynolds number, while the maximum temperature decreases. It is also observed that fluid temperature increases with each branching. This increase in temperature can be attributed to the vortex formation in the junctions due to the impingement of fluid on the junction wall, as is seen in Fig. 4. Apparently, this is the primary factor increasing the heat transfer rate from solid walls to the fluid for all cases. Also, streamlines shown in Fig.4 indicate that higher values of velocity are observed in Branch 1.1.1 than those in Branch 1.1.2, since Branch 1.1.1 deviates from Branch 1.1 with a smaller angle than Branch 1.1.2 does. Temperature contours on the branch walls for Re=200 and 3000 (Fig. 5) are in accordance with those shown in Figs. 3b and 3d, where the wall temperature drops gradually as the fluid travels through the branches.

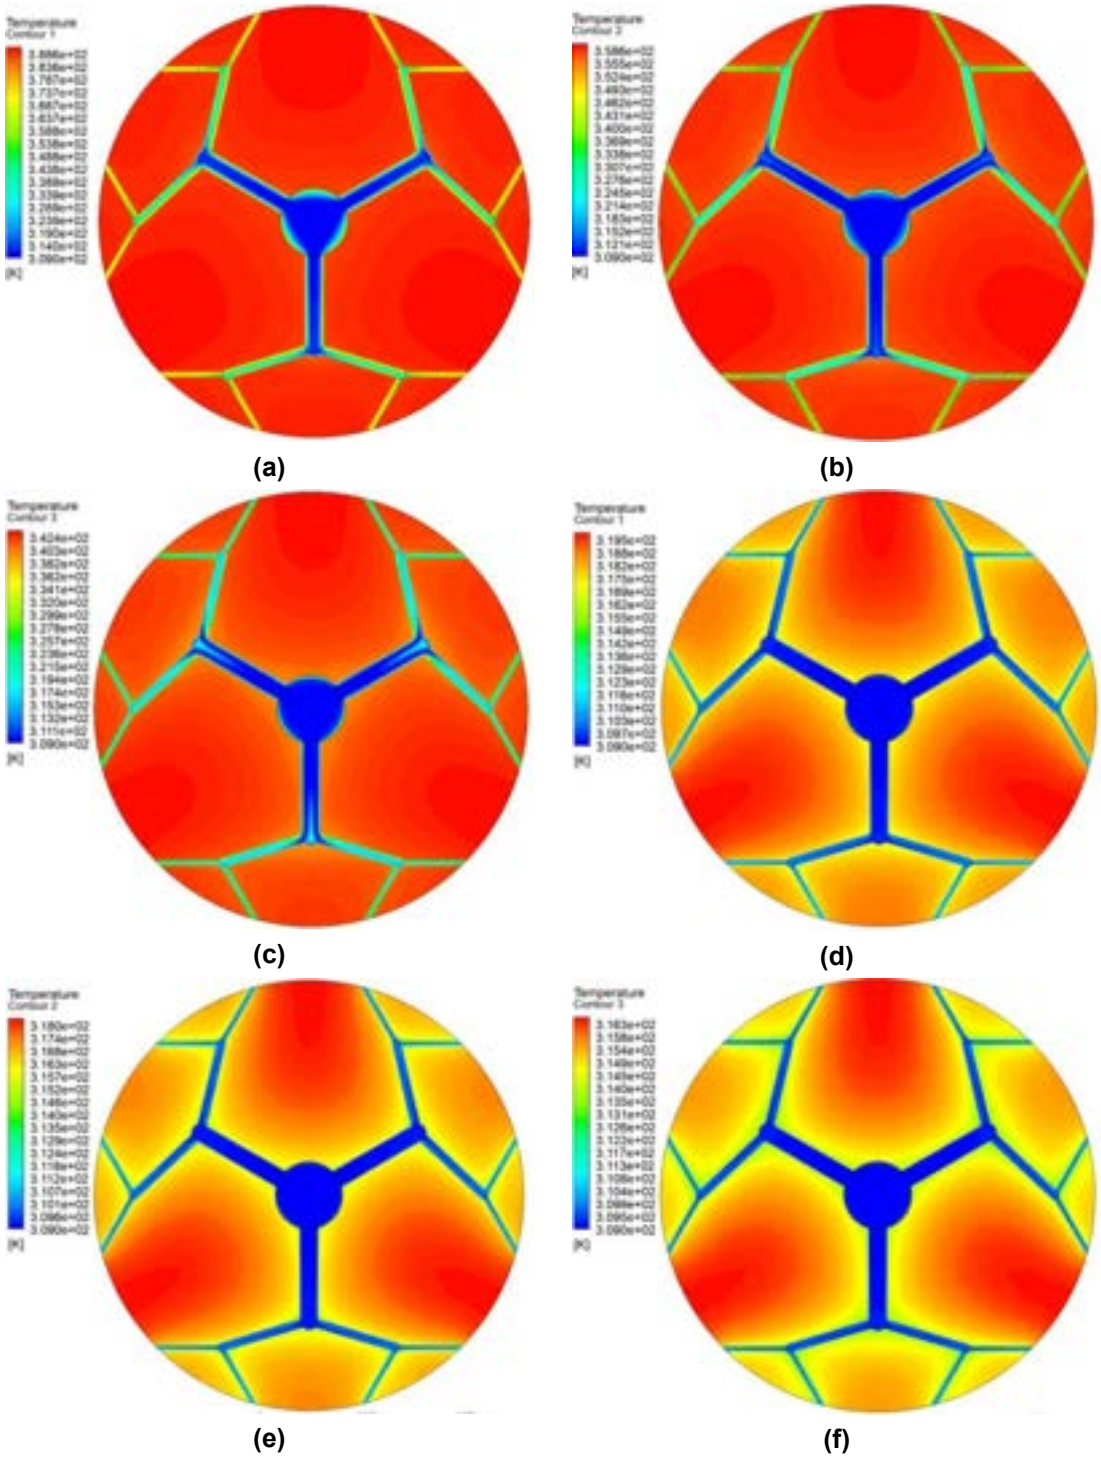

Figure 3. *Temperature distribution on mid-plane of the disc heat exchanger for* ***(a)*** *Re=100,* ***(b)*** *Re=200,* ***(c)*** *Re=400,* ***(d)*** *Re=3000,* ***(e)*** *Re=4000,* ***(f)*** *Re=6000.*

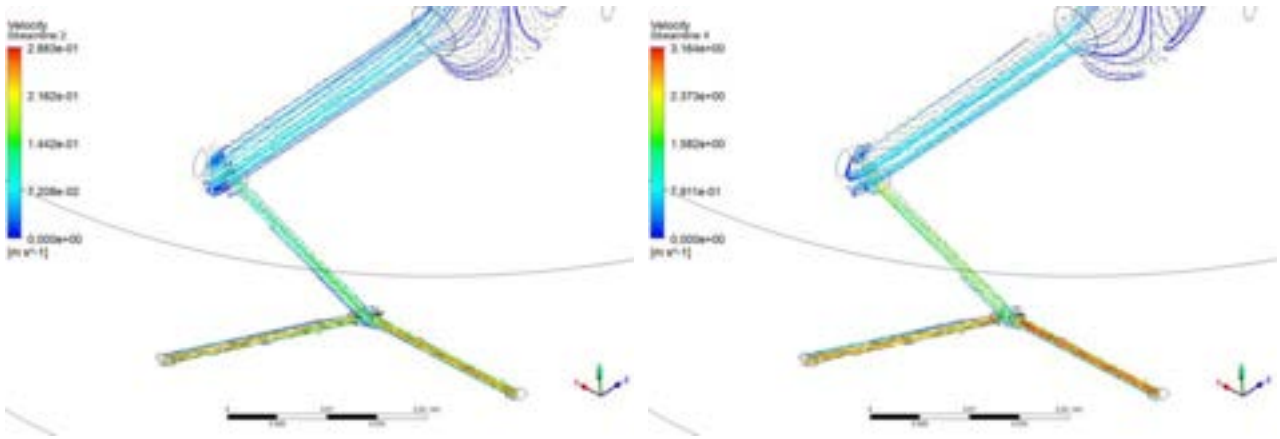

(a) **(b)**

Figure 5. *Temperature contours of the solid walls of the branches for* ***(a)*** *Re=200 and* ***(b)*** *Re=3000*

Variation of calculated mean Nusselt number with branching is presented in Fig. 6 for each Reynolds number. It is interesting to note that mean Nusselt number in Branch 1.1.2 is higher than that in Branch 1.1.1 in case of laminar flow, while it is the other way around for turbulent cases (Fig. 6). One reason for such a difference might be the difference in temperature distribution as seen in Fig. 7. A horseshoe-like temperature profile is evident throughout the branches which is thought to be caused by the vortices generated at the junctions due to the impingement.

Figure 8 shows variation in area-weighted average Nusselt number ($Nu_{m,ave}$) for the whole disc heat exchanger with Reynolds number. Accordingly, there is a linear variation in Nusselt number which can be expressed by Eq. (6) with a normalized root-mean-square error (NRMSE) less than 2%:

$$Nu_{m,ave} = 0.216Re + 7.205 \quad (6)$$

Variation in average fluid outlet temperature and volume-averaged solid temperature of the heat exchanger is presented in Fig. 9. Both the average fluid temperature at outlet and volume-averaged solid temperature exhibits an exponential variation with the Reynolds number. It should be noted that in high Re number limit the average outlet temperature approaches the inlet fluid temperature, i. e. 308 K.

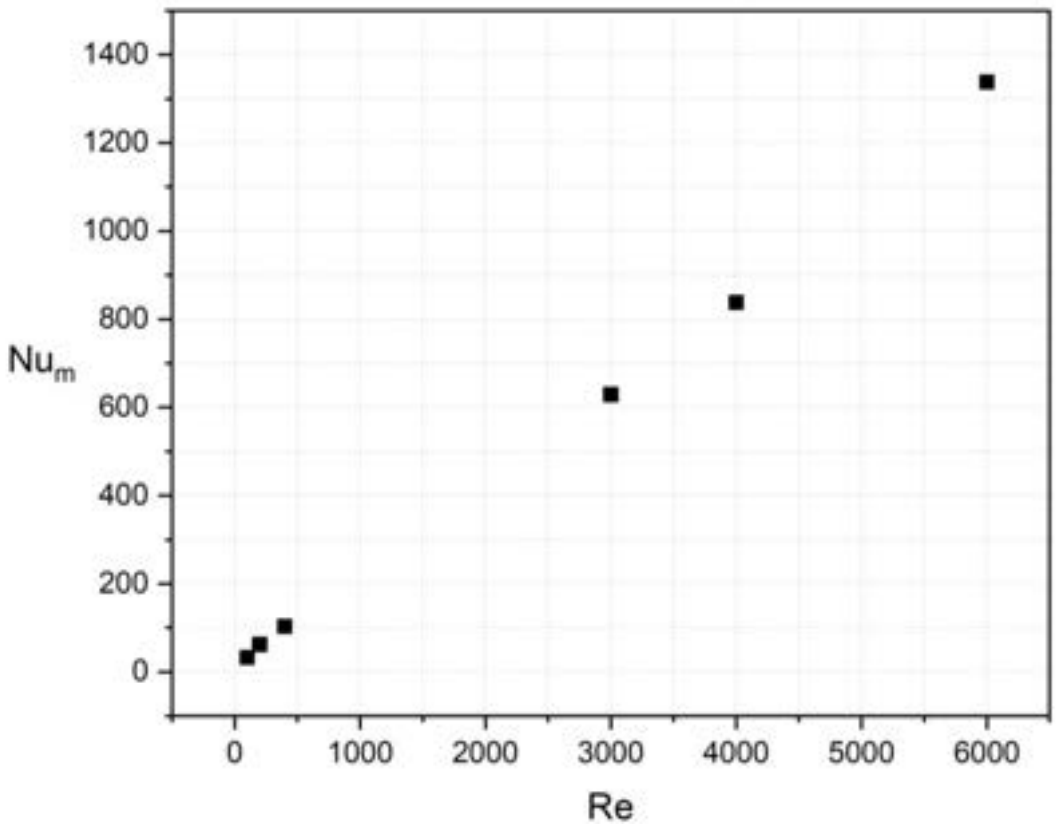

Figure 8. *Variation in area weighted average Nusselt number for the whole disc heat exchanger with Reynolds number*

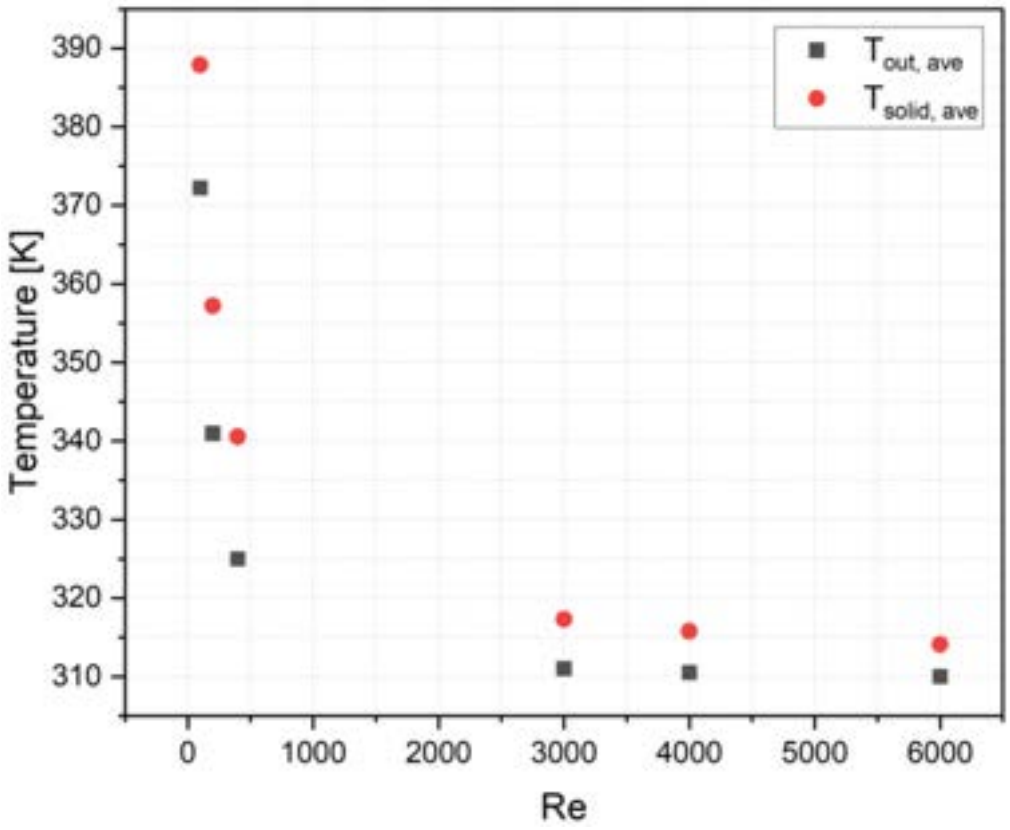

Figure 9. *Variation in average fluid outlet temperature and volume-averaged solid temperature with Reynolds number*

4. Conclusion

In this study, heat transfer characteristics of a disc-shaped branched heat exchanger is investigated for laminar and turbulent cases for Reynolds numbers of Re = 100, 200, 400, 3000, 4000 and 6000. The flow pattern and its effect on the heat transfer coefficient is discussed. According to the numerical results, mean Nusselt number for a given branch and the whole disc increases with the Reynolds number. The variation of the average Nusselt number for the whole disc with the Reynolds number is almost linear, a first order polynomial expression is offered which yields the average Nusselt number corresponding to a given Reynolds number with a maximum normalized root mean square error of less than 2%, for $100 \leq Re \leq 6000$. Extremely high values for volume-averaged solid temperatures are calculated for cases of relatively lower Reynolds number, which may exceed the design temperatures of device to be cooled. On the contrary, volume-averaged solid temperature of the heat exchanger approaches the inlet temperature of the coolant at high Reynolds numbers.

It is observed that the most significant factor affecting heat transfer coefficient of the disc-shaped heat exchanger is fluid impingement on the walls in junctions. This implies that a design allowing more effective impingement may provide higher heat transfer characteristics. However, although pressure losses are not considered in this study, a trade-off should be made between pressure loss and increase in heat transfer coefficient.

Abstract:

The current world energy context requires solutions to reduce energy demand and increase the energy efficiency of thermal power plants, which typically release heat into the ambient without a further useful purpose. Climate change, leading to higher temperatures and water scarcity, may make difficult heat rejection processes in power cycles. Hygroscopic Cycle Technology can become a relevant technology due to the increase in the cooling reflux temperature thanks to the incorporation of hygroscopic salts. This work analyzes the possibility of using the waste heat rejected from the cycle cooling reflux by developing a thermodynamic model with a lithium bromide-water (LiBr-H_2O) mixture as the working fluid. The model, validated with experimental tests performed at a pilot plant, was used to optimize cycle operating conditions regarding waste heat recovery potential without substantially decreasing the cycle efficiency. The increase in LiBr mass concentration led to higher cooling reflux temperatures, allowing for easier heat rejection and an increase in enthalpy and the cooling reflux mass flow rate. The effect of condensing pressure was found to have a relatively low impact on the mass flow rate and the potential heat recovery per unit mass flow. An exergy analysis revealed a decrease in potential physical exergy recovery as LiBr concentration increases. Concentrations between 30 and 50% seem the most suitable ones for maximizing the power output of the cycle, while maintaining a high enough heat recovery potential, with values of 0.6 kJ/kg for the optimum concentration of 45%. Finally, prospective uses for the waste heat are proposed, considering that current applications of the technology rely on the use of biomass fuels from olive oil production waste.

1. Introduction

Current environmental conditions and resource depletion trends are a worldwide challenge. In this context, electricity and heat generation represent the primary source of CO_2 emissions, reaching an all-time high of 14.6 Gt in 2022 [1]. Furthermore, electrical generation accounted for approximately 20% of global final energy consumption in 2021, with renewables contributing in 28% [2]. Moreover, the increasing electrification of the energy system and the growing population result in scenarios with significant increments in energy demand [2], requiring greater power generation capacities [3] while aiming for decarbonization and energy transition [4]. For this purpose, the Paris Agreement [5] aims for net-zero emissions by 2050 to prevent further rising of ambient temperatures and freshwater scarcity. In this sense, power generation, accounting for around 15% of freshwater withdrawal [6], plays a vital role, as the supply shortfall is expected to reach 40% by 2030 [7], while water consumption in the energy sector is predicted to rise 50% [8]. In this regard, energy supply reliability may be affected by droughts, as water stress hinders thermodynamic power cycles, which are key for the generation mix. Recent water shortage episodes have led to shutdowns and output disruptions. For instance, in France, the Chooz nuclear power plant was interrupted for two months in 2020 [2]. It is also estimated that India lost 14 TWh of thermal power generation in 2016 due to water shortfall [9]. In addition, rising ambient temperatures also lead to lower efficiencies of condensing and cooling systems, resulting in thermal processes being unable to respect discharge water temperature regulations. Lack of freshwater resources may also become problematic, with more significant desalination needs leading to greater energy demand. Hence, the viability of thermodynamic power cycles depends strongly on developing water-smart processes with

advanced cooling systems [8]. Ultimately, economic dependence on energy [10] and primary sources implies profound strategic and social implications. In this sense, stress over resources affects energy security [11], not only in reliability, stability and availability terms but also in affordability, with electricity rate increments [12], jeopardizing proper development of manufacturing industries, services and commodities. In this regard, worldwide policies are gradually turning towards sustainability through non-linear production and consumption models. Subsequently, circular economy [13] stands as the economic paradigm to minimize waste and pollution by extending the life cycle of products through reusing and recycling strategies in order to protect natural assets while ensuring secure and affordable energy supplies.

As per the state of the art, thermal efficiency and saving upgrade research has been intensely focused on recovering waste heat. Early analysis evaluated the introduction of regenerative-reheat processes within the Rankine cycle showing thermal efficiency increments of up to 14% [14]. Moreover, Tuantuan et al. [15] proposed a method for re-heat and regeneration stages optimization. Additional Rankine process stages have been further evaluated. In [16], the impact of close Feed-Water Heaters (FHWs) on the efficiency of a 200 MWe power plant was performed, resulting in a maximum efficiency enhancement of 10%. External source heat integration for water pre-heating has also been considered in the literature. Hu et al. [17] introduced the concept of Solar Aided Power Generation (SAPG) by replacing turbine steam bleed-offs for FWHs in regenerative Rankine with solar thermal energy. Prosin et al. [18] proposed a thermal power plant configuration in which secondary air flux was to be heated by solar thermal energy. Furthermore, Nsanzubuhoro et al. [19] considered geothermal energy as Low-Pressure Feed-Water Heaters (LPFHs) source. Solar thermal energy inclusion has been further evaluated. In this sense, Li et al. [20] examine the performance of Rankine cycles with a solar double re-heat system, observing a significant reduction in fuel consumption.

As energy demand grows, development has focused on cycles capable of operating with low-grade heat sources, which were technically unfeasible with previous systems [21]. In this regard, the Organic Rankine Cycle (ORC), Goswami Cycle (GC) and Kalina Cycle (KC) represent the most notorious power generation systems developed to work with low-grade temperature inputs [22], such as geothermal, solar thermal, waste heat and biomass combustion, by basing their operation on working fluids with boiling points lower than pure water. To date, most of the research efforts have concentrated on ORC, as it presents higher efficiency levels than those of GC and KC, which, although normally ranging between 10% and 18%, can reach peaks of up to 30% depending on the cycle parameters [22]. Moreover, ORC is generally more cost-effective due to its lower complexity and, consequently, lower capital and maintenance costs [23]. Additionally, ORCs can be easily adapted to a wide range of heat sources [24] and working fluids [25] while offering greater reliability due to its deeper study. Instead of rejecting heat into the environment, Combined Heat and Power (CHP) systems pose as an alternative for taking advantage of waste heat from power generation processes for practical applications, increasing thermal efficiency. As an example, Ballzus et al. [26] presented the Hellisheiði geothermal plant, which produces electricity (303 MWe) and hot water (133 MWt) for district heating [27] by harnessing thermal energy from the turbine exhaust steam.

Prevailing energy challenges require bold technical improvements in thermodynamic power systems to guarantee supply. In this context, the Hygroscopic Cycle Technology (HCT) [28], first developed in 2010 by Imatech, opens new prospects toward long-term power generation sustainability, posing as a Rankine cycle enhancement regarding efficiency, condensing and cooling terms. For this purpose, HCT operates with mixtures of water and hygroscopic compounds [29] as the working fluid, enabling to condensate turbine exhaust steam through absorption phenomena. As a result, HCT can optimize overall performance by working at lower condensing pressures for a given condensing temperature, effectively increasing the electrical power output of the cycle. Furthermore, absorption through hygroscopic compounds displays higher condensing temperatures [30], enabling the adoption of dry-cooling systems. In this sense, HCT can reject heat more efficiently, allowing the cycle to operate at high ambient temperatures, even over 45 ºC. Dry mode refrigeration advantages further expand as HCT is able to fully decouple power generation from water withdrawal, consequently expanding power plant availability while eliminating steam emissions. Low-concentration HCT has already been developed at an industrial scale. For example, HCT was implemented in Vetejar 12.5 MWe biomass power plant [31], successfully extending availability as the cycle was decoupled from disadvantageous climate conditions due to high external temperatures and water scarcity. Findings showed a 100% cooling water savings of 229,200 m^3/year, an additional 75 MWh/month power generation and a 150 MWh/month reduction of self-consumption due to high-efficiency dry-coolers. Other cases [28] like Baena 25 MWe biomass power plant and Industrias Doy 4.5 MWe cogeneration facilities emphasize the potential of HCT as it can be adapted [32] to any power generation range.

Despite the above improvements, HCT is subject to further enhancement, especially considering thermodynamic power cycles adaptation requirements toward circular economy principles and, subsequently, environmental protection [33]. In this sense, thermal efficiency improvement within HCT becomes relevant, especially with high hygroscopic concentrations where the thermal grade of the condensate flux is greater.

Currently, there are no HCT plants with implemented waste heat recovery systems. In this context, the work presented in this manuscript aims to evaluate the potential for waste heat recovery in high-concentration lithium bromide HCT (HC-HCT). With this objective, a thermodynamic model for evaluating the potential of waste heat recovery has been developed and validated with experimental tests. The final objective is to optimize operating conditions of the cycle regarding waste heat recovery potential without substantially decreasing the cycle efficiency. In addition, prospective uses for the waste heat are proposed, considering that current applications of HCT rely on the use of biomass fuels from olive oil production waste.

2. Methodology

To fulfill the objectives of this study, experimental tests were performed in the HCT pilot plant developed by Imatech in Gijón (Spain) to characterize the thermodynamic conditions at the condensing and cooling systems with high hygroscopic concentration. Then, the results were used to validate an analytical model capable of estimating the potential for the recovery of HCT waste heat.

2.1. Experimental methodology

The HCT pilot plant developed by Imatech in Gijón (Spain), used for performing the experimental tests of this work, is presented in Figure 1. In this work, the hygroscopic salt used is lithium bromide (LiBr) due to its several advantages: LiBr is highly hygroscopic but easily desorbed from water, non-flammable, non-toxic and chemically stable at typical cycle operating conditions.

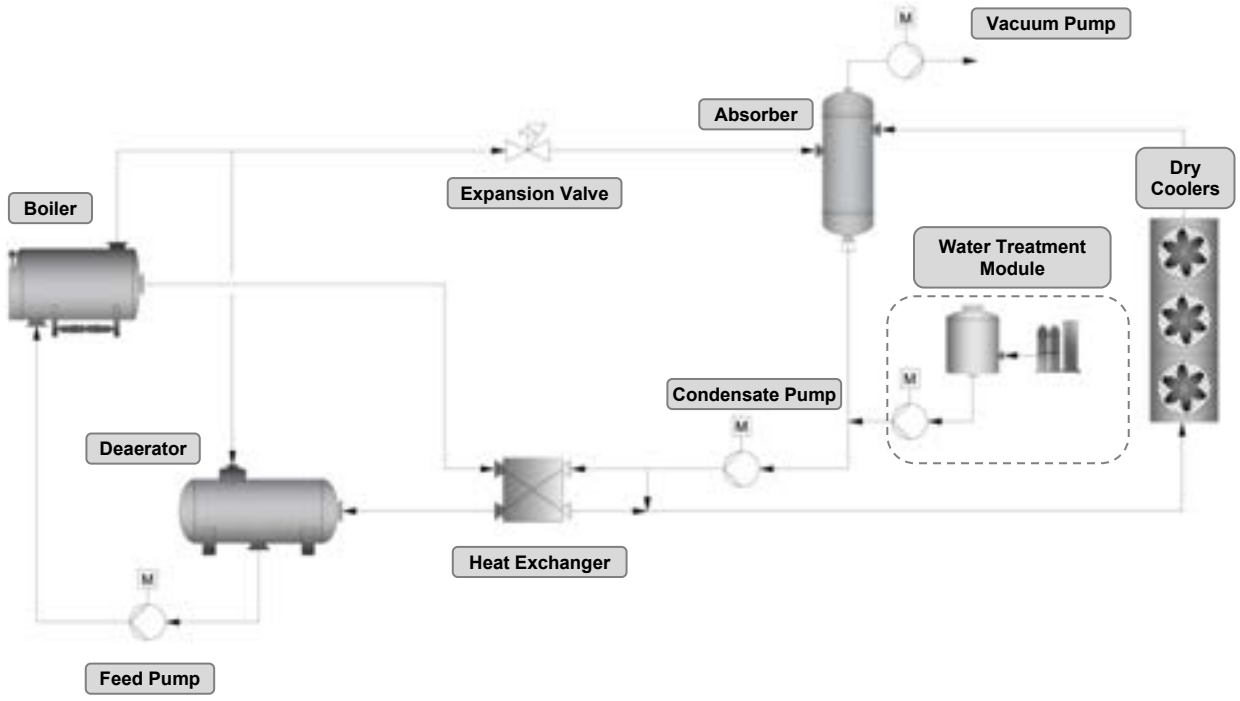

Figure 1. Operation process of HCT pilot plant.

The pilot plant is able to reproduce HCT power plant conditions by generating 100 kg/s of superheated steam at 14 bar and a maximum temperature of 200ºC. This steam is then led to an expansion valve that simulates the behavior of a 30 kW turbine-generator. The valve outlet steam then flows to the absorber, the key component of the HCT. In the absorber, the steam is condensed by absorbing a high-concentrated LiBr/H_2O cooling reflux coming from the dry cooling system that enters the absorber through nozzles to increase contact surface. Condensing pressure is controlled using a vacuum pump. The condensate then leaves the absorber, is pumped by the condensate pump and is separated into two flows: one continues to the boiler, while the other one is recirculated towards the dry coolers, releasing heat from the cycle, to be later reinjected into the absorber to provide the required salts for absorption to take place. A closed heat exchanger is used to recover thermal energy from boiler blowdowns to pre-heat the condensate water, which is then sent to a deaerator before entering the boiler, where LiBr salts are desorbed and purged. LiBr-H_2O mixtures are prepared and controlled via a 2 m^3 atmospheric tank and a demineralizing water module. Concentration values are derived from electrical conductivity measurements from samples taken from cycle purges.

The instrumentation used for performing the experiments is collected in Table 1. Data were collected using a Supervisory Control and Data Acquisition (SCADA) system developed by Siemens (SIMATIC S7, maximum uncertainty 0.004%).

Table 1. HCT pilot plant instrumentation.

Parameter	Instrument	Accuracy
Temperature	Endress+Haussser TR-61 platinum resistances PT100 RTD	± 0.1 °C
Absolute pressure	Aplisens PCE-28	± 0.5 %
Mass flow	Khrone OPTISWIRL-5080	± 0.5 %
Electrical conductivity	HANNA HI 98188-02	± 2.0 %

The parameters set for the different tests are collected in Table 2.

Table 2. HCT pilot plant working parameters.

Parameter	Value
Steam mass flow ($\dot{m}_S$)	100 kg/h
Steam temperature (T_S)	170 ºC
Condensing pressure (P_C)	3, 5, 7, 10, 15 kPa
LiBr concentration at the condensate (C_C)	45 %
Ambient temperature (T_C)	15 ºC
Temperature drop at dry coolers (ΔT_{DC})	7 ºC

2.2. Analytical model

2.2.1. Description of the model

Engineering Equation Software (EES, version V10.833-3D) [34] was used to develop a thermodynamic model of the condensing and cooling process of the HC-HCT, as represented in the scheme of Figure 2. The range of condensing pressure (P_C) studied was from 1 to 20 kPa.

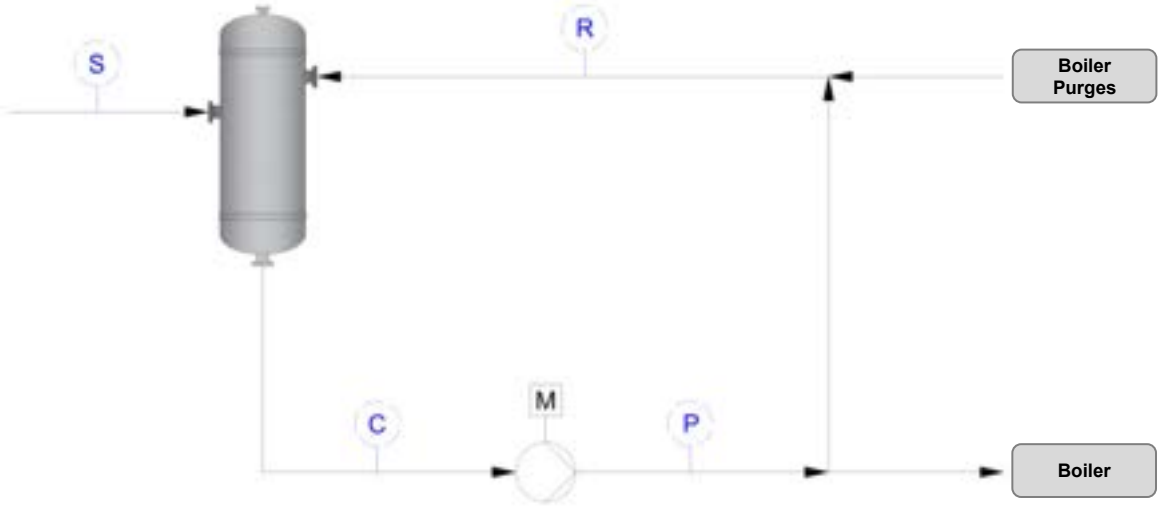

Figure 2. HCT condensing and cooling process model detail.

The following assumptions were considered to develop the model: kinetic and potential energy changes are negligible; the condensate pump only compensates for pressure losses in the pipes and equipment, which are perfectly insulated; and, since the cycle is closed, only the physical exergy is considered to estimate waste heat potential. The condensing process in the absorber is described by the mass, concentration and energy balances in Eqs. (1-3):

$$\dot{m}_S + \dot{m}_R = \dot{m}_C \quad (1)$$

$$\dot{m}_S \cdot C_S + \dot{m}_R \cdot C_R = \dot{m}_C \cdot C_C \quad (2)$$

$$\dot{m}_S \cdot h_s + \dot{m}_R \cdot h_R - \dot{Q}_D = \dot{m}_C \cdot h_C \quad (3)$$

The thermal power from the heat of dilution ($\dot{Q}_D$) depends on the difference between the concentration of the condensate (C_C) and reflux (C_R) streams. In this case, the correlations proposed by Yuan and Herold [35] were

implemented into the model. The LiBr concentration at the turbine outlet (C_S) was set to zero, being pure steam. The thermodynamic state at the condensate pump outlet was obtained from the isentropic efficiency of the pump (η_{CP}), considered 50%, according to industrial values from small centrifugal pumps [36]. Eqs. (4) and (5) determine the pump outlet properties:

$$\dot{m}_C = \dot{m}_P \tag{4}$$

$$\eta_{CP} = \frac{h_{Ps} - h_C}{h_P - h_C} \tag{5}$$

Once the energy analysis of the condensing and cooling process was finished, the physical exergy recovery potential (ex_{RCVY}) from the cycle cooling process was estimated with Eq. (6) as the difference between the physical exergy per unit mass of the flow before (ex_P) and after (ex_R) the heat rejection process, calculated with Eq. (7) [37]:

$$ex_{RCVY} = ex_P - ex_R \tag{6}$$

$$ex_i = (h_i - h_\infty) - T_\infty(s_i - s_\infty) \tag{7}$$

The reference environment or dead state for the exergy calculations was defined accordingly to the methodology proposed in [38]. The dead state temperature was set as the mean ambient temperature during the experimental tests, T_∞=15 ºC. The overall mass and volume of the cycle are constant, so no pressure equilibrium can be achieved with the exterior. Hence, the dead state pressure was set to the condensing pressure. The composition of the dead state was calculated at chemical equilibrium within the cycle, with the chemical potential of water in the LiBr-H_2O solution matching the Gibbs free energy of the water vapor, resulting in 0% of LiBr mass concentration for all the considered pressure values (over 1 kPa).

Finally, the heat per unit mass of cooling reflux rejected to the environment was corrected with the Carnot factor to study the influence of ambient temperature in the process, defined as:

$$\theta_{CP} = 1 - \frac{T_\infty}{T_{HR}} \tag{8}$$

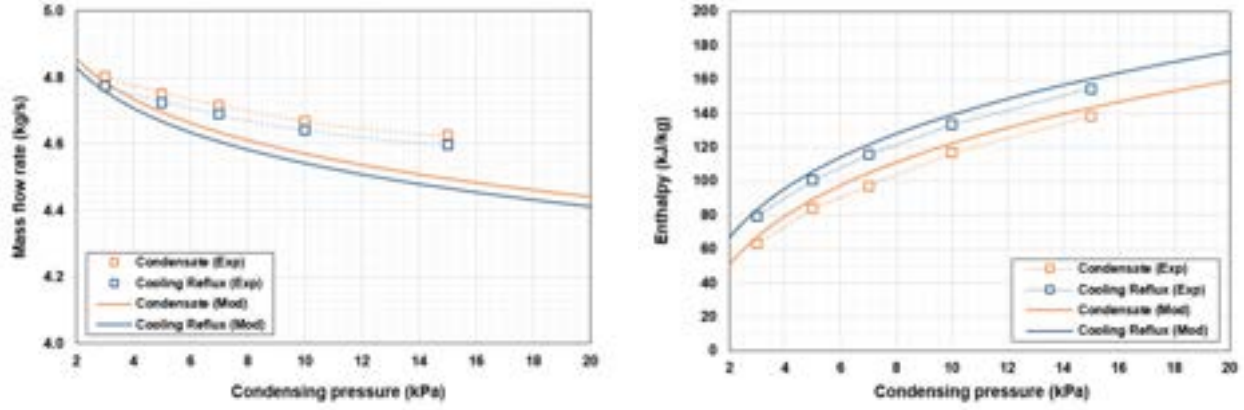
With the temperature at which the fluid rejects heat (T_{HR}) calculated as the logarithmic mean between the temperatures of the condensate pump outlet (T_P) and the cooling reflux (T_R) [27]:

$$T_{HR} = 1 - \frac{T_P - T_R}{log\left(\frac{T_P}{T_R}\right)} \tag{9}$$

2.2.2. Experimental validation

Figure 3a shows the condensate and cooling reflux mass flow rates calculated by the model alongside the experimental measured values for 45% LiBr concentration. It may be appreciated that the developed models are able to follow the tendency of the experimental results, with a slight underprediction in the mass flow rates that increases with the condensing pressure up to a maximum error of 3%.

Regarding the prediction of enthalpy values, Figure 3b depicts the contrast of the model with experimental results. The tendency of the evolution of enthalpy values with the condensing pressure is adequately followed by the model, with average errors of 5%. Therefore, the developed model may be considered as suitable for the analysis of the thermodynamic processes of the cycle under study.



a) Mass flow rate vs condensing pressure

b) Enthalpy vs condensing pressure

Figure 3. Experimental validation of the model

3. Results

Firstly, the results of the thermodynamic parametric analysis of the model are presented. Then, the selection of the most suitable operating conditions for the cycle are discussed and potential applications for the recovery of heat waste form the cycle are presented.

3.1. Thermodynamic parametric analysis

Figure 4 shows the evolution of the condensate temperature as a function of the LiBr concentration of the reflux and the condensing pressure. It may be observed that the increase in concentration leads to higher temperatures, with a slower increasing rate up to 30% LiBr concentration.

Above this concentration value, the slope of the temperature curves becomes much greater. The increase in pressure has an additional effect of increasing condensing temperature. The increase of the condensate temperature may be linked to higher temperature differences with the environment and thus an easier heat rejection from the cycle and possibly easier use of that waste energy. Nevertheless, it must be considered that, if the turbine power is kept constant and the heat rejected increases, more fuel consumption at the boiler will be required. Paralelly, if the heat input at the boiler is kept constant and the heat rejected increases, there will be less power delivered by the turbine and the cycle efficiency will decrease.

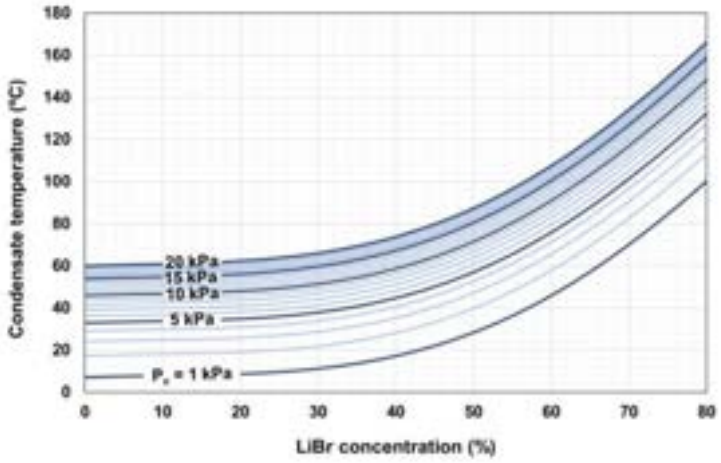


Figure 4. Condensate temperature as a function of LiBr concentration and condensing pressure

The results from the change of enthalpy with respect to LiBr concentration and condensing pressure are shown in Figure 5. A minimum for all curves may be found around 45% LiBr concentration, hinting to the selection of this concentration to minimize the enthalpy difference at the turbine and thus maximize the power delivered by the cycle. With concentration values up from this point, the condensate enthalpy increases very quickly, discouraging too high concentration values for the optimal performance of the turbine. Regarding the condensing pressure, it should be kept as lower as possible if the aim is to maximize cycle efficiency.

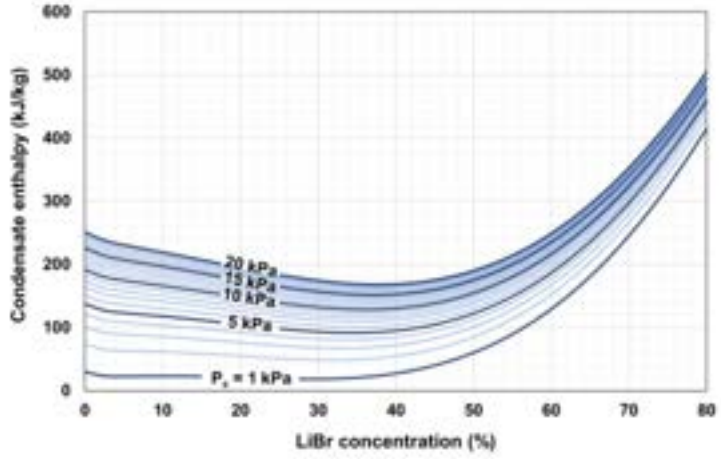

Figure 5. Condensate enthalpy as a function of LiBr concentration and condensing pressure

The cooling reflux mass flow rate shows an increasing trend with the increase of LiBr concentration, as shown in Figure 6. The effect of pressure in the ranges studied does not have a determining effect, becoming more important at intermediate LiBr concentration values. Nevertheless, for the sake of clarity, the results of all the pressure values studied have been averaged and represented as intervals with a 95% confidence level. It may be observed that the cooling reflux mass flow rate increases with the concentration, requiring a higher working fluid consumption and potentially leading to higher pumping requirements and pressure losses in the circuit. It seems sensible to keep the values of LiBr concentration below 50%, to avoid the steeper increase in the mass flow rate that comes with the increase of concentration.

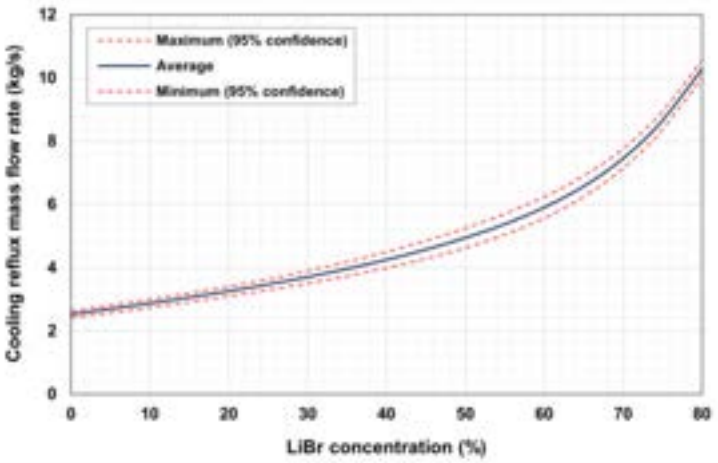

Figure 6. Average cooling reflux mass flow rate as a function of LiBr concentration

Regarding the heat recovery potential per unit mass of the cooling reflux, Figure 7 shows the results from the energy balance. Again, the effect of the pressure only becomes noticeable for intermediate LiBr concentration values, but it is minimal compared with the effect of LiBr concentration, so the values have been averaged and represented again as intervals with a 95% confidence level. A decreasing trend in the heat per unit mass is observed as the LiBr concentration increases, probably due to the increasing mass flows in the cycle. From these results, it seems sensible to try to maximize the heat per unit mass and avoid too high LiBr concentration values, which results in a lower energy density for potential applications.

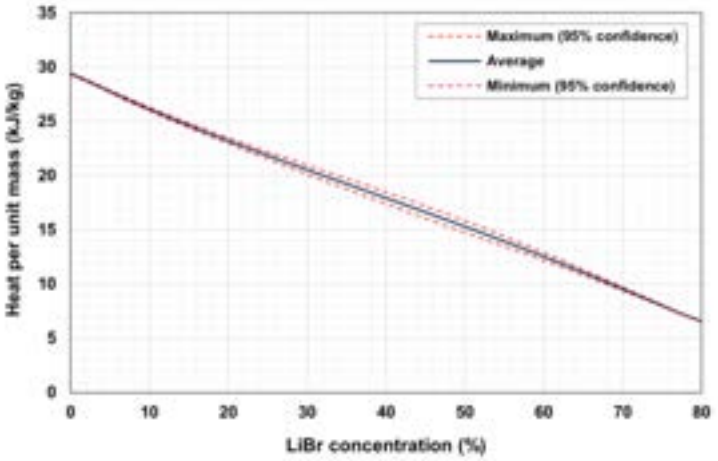

Figure 7. Heat recovery potential per unit mass of cooling reflux as a function of LiBr concentration

Finally, to evaluate the feasibility of the heat recovery process itself, the results from the physical exergy recovery potential per unit mass of cooling reflux mass flow, considering the dead state from the experimental conditions, are presented in Figure 8. In this case, the role of the condensing pressure cannot be overlooked, with higher condensing pressures leading to higher exergy recovery potentials. For the lowest condensing pressures, below 2 kPa, physical exergy increases with the increase in concentration. The negative values of potential recovery at these pressure conditions may be ascribed to the fact that the temperatures at the absorber would become lower than the dead state temperature. In addition, these lower pressures require higher-performance vacuum pumps, so there is no apparent reason to work at these operating conditions.

On the other hand, the global trend with the increase of LiBr concentration is the decrease of the potential specific exergy recovery. This decrease becomes more apparent for LiBr concentrations above 50%,

discouraging again the use of too high concentration values. The region between 30 and 40% shows a relatively smooth decrease with the increase in concentration, with similar potential recovery values. This advantage could be exploited for the stable operation of the heat recovery system.

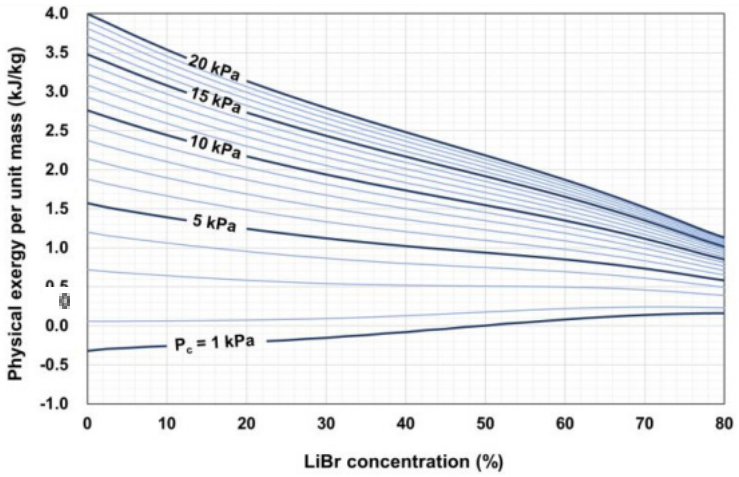

Figure 8. Physical exergy recovery potential per unit mass as a function of LiBr concentration

In summary, gathering all the results from the parametric analysis, it may be proposed to use concentrations of LiBr around 45% to maximize the enthalpy difference at the turbine. The exergy analysis has revealed that, at the dead state conditions of the experiment, the physical exergy recovery potential per unit mass of cooling reflux decreases sharply for values above 60%. On the other hand, concentration values lower than 30% may not achieve cooling reflux temperatures high enough for cycle heat rejection.

Regarding pressure values, selecting 5 kPa as the condensing operating pressure has several advantages. It increases the pressure difference at the turbine with respect to higher operating pressures, resulting in a higher turbine power output and in cooling reflux temperatures high enough to release heat from the cycle. In addition, it does not result in a significant effect regarding the cycle mass flow rates or the actual energy recovery potential per unit mass of cooling reflux. Apart from requiring higher-performance vacuum pumps, lower pressures are not justified in terms of the exergy analysis, while an operating pressure of 5 kPa has been verified in actual power plant operation.

3.2. Potential applications of waste heat recovery

After selecting a pressure of 5 kPa as the condensing pressure and 45% as the LiBr concentration for cycle waste heat recovery, the effect of the ambient temperature in the heat recovery potential per cooling reflux unit mass is depicted in Figure 9, to evaluate possible applications for the recovered waste heat.

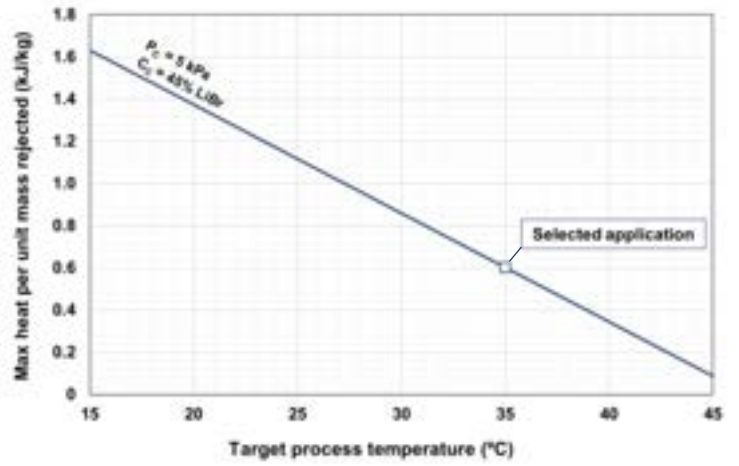

Figure 9. Heat recovery potential per cooling reflux unit mass vs ambient temperature.

Although desirable, it is not possible to reach conditions for pyrolysis (250ºC) or alperujo drying (100ºC) to treat the biomass and use it in the cycle boiler [39]. Nevertheless, there is enough potential for developing anaerobic mesophilic processes at 35ºC for biogas production [40] or compost for agriculture [41] with a

potential heat recovery of 0.6017 kJ/kg of cooling reflux. Considering typical industrial cooling reflux values of around 6000 t/h in HCT cycles, the potential heat that could be delivered to the biodigesters is in the range of 1 MW.

4. Conclusions

The current world energy context requires solutions to reduce energy demand and increase the energy efficiency of power plants. Thermal power plants typically release heat into the ambient without a further useful purpose. Climate change, leading to higher temperatures and water scarcity, may difficult heat rejection processes in power cycles. HCT can become a relevant technology due to the increase in the temperatures in the cooling reflux produced by the incorporation of hygroscopic salts, such as LiBr. In this work, it has been possible to analyze the possibility of using the waste heat rejected from the cooling reflux of the HCT by developing a thermodynamic model in EES and validating it with experimental tests. The main conclusions obtained are collected in the following paragraphs.

Firstly, the results from the thermodynamic parametrical analysis have revealed that the increase of LiBr leads to higher temperatures in the cooling reflux. This may be linked to easier heat rejection to the environment and thus an easier use of that waste energy, but the effect on the power delivered by the cycle and its thermal efficiency must also be considered. Regarding the enthalpy at the absorber outlet, a minimum value, linked to higher cycle power output values, was found to be around 45% LiBr concentration. With the increase of LiBr concentration up from this point, this enthalpy and the cooling reflux mass flow rate showed a steep increase trend. As these higher mass flow rates lead to higher pumping requirements and pressure losses in the pipes and equipment, values of LiBr concentration over 60% are strongly discouraged. On the other hand, the effect of condensing pressure was relatively small to the effect of LiBr concentration in both the mass flow of the cooling reflux and the heat recovery potential per unit mass of the cooling reflux. The increase of LiBr concentration was also linked to a decreasing trend in the heat recovery potential per unit mass and a lower energy density for potential applications.

The exergy analysis of the cooling process revealed a decrease in the potential physical exergy recovery with the increase of LiBr concentration, becoming more apparent with concentrations above 50%. Considering all the results obtained from this work, concentrations of LiBr around 45% seem the most suitable ones for maximizing the power output of the cycle, always working in the range between 30 and 50%. Regarding pressure values, 5 kPa of condensing pressure seems promising, finding a compromise between the pressure difference at the turbine and temperature high enough for heat rejection in the cooling reflux.

Finally, the results of evaluating the cycle with 45% LiBr concentration and a condensing pressure of 5 kPa for different ambient temperatures resulted in the identification of potential applications for the cycle. Sadly, pyrolysis or alperujo drying temperatures cannot be reached with this cycle configuration, preventing the use of this heat to treat olive residue as fuel in the biomass boiler of the circuit. Nevertheless, there is enough potential for developing anaerobic mesophilic processes at 35ºC for the production of biogas or compost for agriculture, with a potential heat recovery of 0.6017 kJ/kg of cooling reflux.

Acknowledgments

This work has been supported by the project *"Improvement of energy performance of the Hygroscopic Cycle for power production"* - PID2019-108325RB-I00/AEI/10.13039/501100011033 from the Agencia Estatal de Investigación - Ministerio de Ciencia e Innovación, Spain; and the *"Severo Ochoa"* grant program for training in research and teaching of the Principality of Asturias - Spain (BP20-176). The authors also want to acknowledge the contribution of the Spanish company Imasa Technologies S.L.U. (Imatech), owner of the Hygroscopic cycle pilot plant, as well as the support from the University Institute of Industrial Technology of Asturias (IUTA), financed by Gijón City Council, Spain. The help provided by Dr. María Rosario López is also highly appreciated.

Nomenclature

C	mass concentration, %
ex	physical exergy per unit mass, kJ/kg
h	enthalpy per unit mas, kJ/kg
$\dot{m}$	mass flow rate, kg/s
P	absolute pressure, kPa
Q	heat, kW
T	Temperature, ºC

Greek symbols

η	efficiency, %
θ	Carnot factor, %

Subscripts and superscripts

C	condensate
CP	Condensate pump
DC	dry cooler
HR	recovery heat
P	condensate pump outlet
R	cooling reflux
$RCVY$	recovery
S	steam
∞	dead state

Abstract:
The harmful environmental effects of fossil fuels and the variability in their prices are shifting attention away from conventional combined cycle power plants. Supply issues in islands are also a problem to be considered. The objective of this work is to evaluate the feasibility of integrating solar energy into a combined cycle power plant for fuel saving in insular subtropical climates. With this aim, a case study comprising a 93 MW combined cycle in Las Palmas de Gran Canaria (Spain) and the integration of solar energy in the gas upper cycle has been presented and analyzed with a thermodynamic model. The effects of incorporating solar heat before and after the cycle compressor were assessed, finding that injecting 35 MW of solar heat before the compressor resulted in savings of 49% of the original fuel consumption and an increase of 2% in the global cycle efficiency, but at the expense of reducing the net power delivered by 47%. On the other hand, incorporating the solar heat after the compression process resulted in an overall 16.2% increase in the cycle efficiency, while delivering the same net power as the original cycle and reducing fuel consumption in 22%. With the increase in the amount of solar heat added to the cycle, the difference between both options became greater, with the best option being injecting solar heat after the compressor. Estimations of the economic and environmental effects of the most suitable option are provided, resulting in potential overall savings of 7.14 million Euro per year and a yearly potential of 13.75 Mkg of CO_2 emissions avoided. The results of this work are expected to contribute to improve energy supply problems by using a renewable energy source and reduce fuel imports, providing more energy stability and security to the inhabitants of islands with similar climates as Las Palmas.

Keywords:
Integrated solar combined cycle power plants (ISCCs), fuel saving, insular subtropical climate, dynamic analysis, and CO_2 emission.

1. Introduction

Nowadays, there is almost no debate on the damaging effects that global reliance on fossil fuels holds for the future of the world. Fossil fuels (e.g., coal, natural gas, and oil), apart from being finite, entail several harmful effects in the environment, especially with CO_2 emissions increasing at an alarming rate. Over the past 12 years, global CO_2 emissions from energy combustion and industrial processes have increased by 4.2 Gt CO_2, to a value of 36.8 Gt CO_2 in 2022 [1]. CO_2 emissions from natural gas combustion increased by more than 215 Mt CO_2 in 2021, to reach an all-time high of 7.35 Gt CO_2, representing 22% of the total CO_2 emissions. On the other hand, the use of renewable energy sources increased by 3% in 2020, with a prime 7% growth in renewable electricity generation. Global renewable electricity generation increased from 27% in 2019 to 29% in 2020, reaching 30% in 2021 [1]. In this context, solar energy technologies represent one of the most mature options, with its share increasing from 1.08% in 2015 to 3.74% in 2022 [2].

Integrated solar combined cycle power plants (ISCCs) are one of the most promising solar hybrid configurations for power plants. ISCCs are composed of a concentrated solar power plant (CSP) and a natural gas-fired combined cycle (NGCC). The CSP plant is normally used either to produce additional steam for the combined cycle steam turbine [3, 4], or to preheat the compressed air in the gas turbine before entering the combustion chamber [5]. It has been estimated that the CSP contribution to global energy supply may reach 3-3.6% by 2030 and 8-11.8% by 2050 [6], alongside a drop in CSP costs to $0.05/kWh by 2050. Four main technologies exist for concentrating solar power in the CSP: parabolic trough collectors, solar tower, solar dish, and linear Fresnel systems, with parabolic trough collectors (PTC) being the most mature technology. These collectors, with high thermal efficiency, high performance systems, light structures, and low-cost technology,

can deliver up to 400 ºC. This temperature is generally high enough for most of industrial heating processes and applications. In addition, this technology is also suitable for low-temperature industrial applications, such as desalination and sterilization processes.

1.1. Solar integration in combined power plants and research question

The first solar plant using parabolic trough technology was built in 1913 in Maadi, Cairo, Egypt. It was built for the purpose of power generation for pumping water for irrigation [7,8]. The technology of the ISCC system was proposed by Luz Solar International [9]. During 1980s, nine solar electric generating systems (SEGS) with a total capacity of 356 MW were installed in California desert, United States, where solar collectors capture and concentrate sunlight to heat a synthetic oil (Therminol), which then heats water to generate steam [10]. SEGS became one of the most important projects that paved the way for executing subsequent similar works. In 2000, the Global Environment Facility (GEF), an organization that supports developing countries' work to address the world's most pressing environmental issues, embraced the idea of encouraging the erection of ISCC power plants in developing countries with high solar irradiation, allocating up to $50 million for the construction of four ISCCs in the Middle East. This led to an increase in the interest in CSP technologies, especially in PTCs [11]. Consequently, wide research has been performed on this technology. Some works focus on studying system integration schemes between the PTC and the combined cycle, while others analyze the static or dynamic performance of the ISCC under different conditions. In 1997, the first technical and economic analysis of the ISCC was performed in Tunisia, where the authors clarify that ISCC system is more profitable than SEGS [12]. The performance of ISCC, SEGS and Combined Cycle (CC) power plants was studied, using IPSEpro and GateCycle software [13]. After comparing the three systems, they stated that ISCC technology had the best efficiency.

In 2013, the dynamic performance of a solar Rankine cycle and ISCC was compared with the solar thermoelectric components library in TRNSYS [14]. The results showed that ISCC had higher solar-to-electric efficiency values than the solar Rankine cycle. It was also found that using solar tower technology improved annual solar-to-electric efficiency by 21.8% with respect to PTC. One year later, ISCC and the conventional CC were compared, finding many advantages with ISCC, such as peak time efficiency and less carbon dioxide emissions [15]. Several configurations of solar integration with conventional CC plants were discussed later [16]. Results show that lower stack temperatures may be achieved, allowing for a better thermal match in the heat recovery steam generator (HRSG), so more feedwater may be circulated in the cycle. In 2018, ISCC power plant was compared with a thermal storage system and a conventional CC in thermo-economic and environmental terms, using a TRNSYS dynamic simulation [17]. Overall electrical efficiency improved by 1% compared to the conventional CC. A MATLAB dynamic model for the Hassi R'mel ISCC power plant in Algeria was validated under off-design conditions, finding that some factors could affect strongly the ISCC performance, such as wind speed and direct normal irradiance (DNI) [18]. In 2021, a dynamic model was developed of an ISCC power plant in Kuraymat, Egypt, using APROS software to evaluate the ISCC performance, limitations, and capabilities, validating the results with actual operational data [19]. The model was able to reproduce most of the operating parameters, such as pressure, temperature, mass flow rates and output power. An economic and performance assessment of the ISCC-PTC system in Hassi R'mel (Algeria), coupled with a new thermal storage system was performed [20]. Results revealed that a better grid stability was reached, increasing solar energy conversion and overall performance. The net solar thermal energy conversion ratio and the energy efficiency reached 14 and 56.06%, with natural gas consumption savings representing around $30 million. Finally, in 2022, different basic ISCC system models were compared with SEGS and gas turbine combined cycles (GTCC), presenting a method for assessing ISCC systems with different integration modes and solar operating temperatures [21]. Different integration points in the steam and gas cycles, as well as two working modes, "power boosting" and "fuel saving" were discussed. For the "power boosting" mode, solar energy is injected into the steam bottom cycle to heat up the gas turbine exhaust, the live steam, the reheated steam, or the feedwater. The main idea is to keep fuel consumption constant, while the output power increases as a consequence of the increase in the steam flowrate (mas flowrate boosting) or the enthalpy increase (parameter boosting). On the other hand, the "fuel saving mode" injects the solar energy in the upper Brayton cycle, heating the compressed air before entering the combustion chamber. This leads to a decrease in the fuel mass flowrate, leaving unaffected the operating conditions in the gas turbine and thus the bottom steam cycle.

The objective of this work is to evaluate the feasibility of integrating solar energy into a combined cycle power plant for fuel saving in insular subtropical climates and estimate its effect on the energy efficiency of the cycle, fuel saving, and possible economic savings and reduction of CO_2 emissions. With this aim, a case study comprising a combined cycle in the Canary Islands (Spain) and the integration of solar energy in the gas upper cycle has been developed and analyzed with a thermodynamic model. The results are expected to contribute to improve energy supply problems by using a renewable energy source and thus reducing fuel imports, providing more energy stability and security to the island inhabitants. After briefly reviewing the energy context in the Canary Islands, the methodology followed in this work is detailed. Then, the results are discussed, and finally the main conclusions of this work are presented.

2. Case study

The geographical nature of islands enforces them to have isolated energy systems unless a connection between their electricity power grid and another grid beyond its shores is developed. This entails a series of economic and environmental difficulties. Islands are highly dependent on imported fossil fuel, leading to high costs of fuel transportation, energy supply insecurity and higher electricity prices [22]. However, renewable energy resources (solar, wind & ocean waves) often exist in abundance in islands.

2.1. The energy context in the Canary Islands

The Canary Islands are a group of seven Spanish islands that are located off the African west coast. Around 84.2% of their energy demand was supplied from non-renewable energy sources in 2022, as shown in Figure 1. Combined cycle power plants have the highest share, 44.5%, while renewable energy resources contribute only with 15.8% [23]. Figure 2 shows the solar thermal capacity installed on each island, alongside the occupied area by thermal installations. The total thermal capacity of the archipelago is 88.7 MW, being Gran Canaria Island the highest contributor, with 38.7% of the total solar thermal energy installed in the Canary.

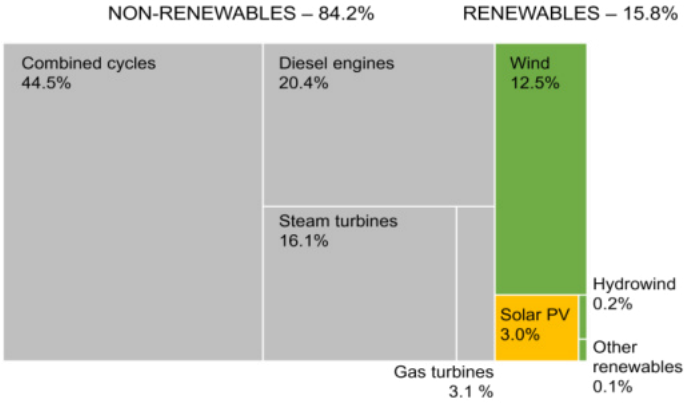

Figure 1. Canary Island electricity distribution in 2022 (Data source: [23]).

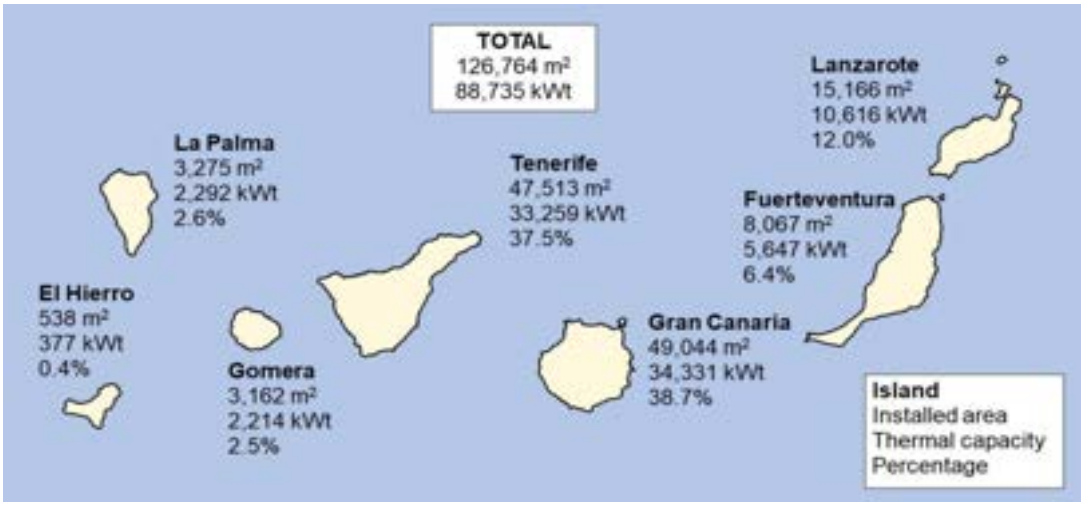

Figure 2. Installed solar thermal capacity in the Canary Islands on Dec 31st, 2021 (Data source: [24]).

The details of the energy system of the Canary Islands are collected in Table 1 [24]. The highest renewable energy sources (RES) share may be found in the island El Hierro, with 66.8%; however, this represents only 0.4% of the whole archipelago generation. The lowest RES capacity is found in La Gomera island, with only 0.4 MW. In this context, the study presented in this work may contribute to improve the energy supply network in the Canary Islands with a proposal based on renewable energy sources to integrate solar energy into existing combined cycles, providing more energy security to the islands.

2.2. ISCC in Las Palmas de Gran Canaria

The basic combined cycle power plant consists of an upper gas cycle, a bottom steam cycle, and a Heat Recovery Steam Generator (HRSG). The main characteristics of the CC, based on the power plant from Egyptian Petrochemical Company [25], with a thermal efficiency of 57.8% are shown in Table 2. In this work, two possibilities (Figures 3 &4) for the integration of the solar field within the CC, both working on a fuel saving scheme, have been studied and compared:

- Case A: solar field is integrated to preheat ambient air before the compressor inlet.
- Case B: solar field is integrated to heat up compressed air, before the combustion chamber inlet.

Table 1. Overview of the power system of the Canary Islands [24]

	Tenerife	Gran Canaria	Lanzarote	Fuerteventura	La Palma	La Gomera	El Hierro	Total

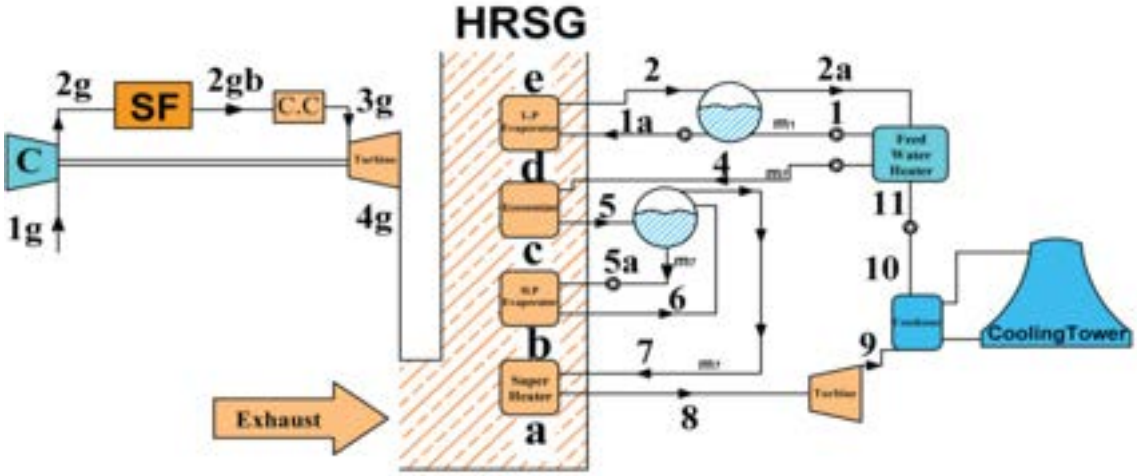

Figure 4. Case B: solar field integrated after gas cycle compressor.

3. Methodology

To fulfill the objectives of the study, a thermodynamic model has been developed in MATLAB with the Ideal Air code and the X Steam toolbox to obtain air and water properties for the upper gas and bottom steam cycles. The sequence of the methodology has been summarized in Figure 5, whereas the main thermodynamic equations used are discussed in the following subsections. A system of thermodynamic equations based on mass and energy balances in the cycle was solved, with the aim of calculating thermodynamic states, net power, efficiency, and air and fuel mass flows for the original CC and the two ISCC cases, allowing to estimate the amount of fuel saved, as well as economic savings and the reduction in CO_2 emissions. The values of solar heat integrated ranged from 0 to 35 MW. Pressure drop in the cycle was not considered, as well as the effect of inlet conditions in the isentropic efficiency of the compressor.

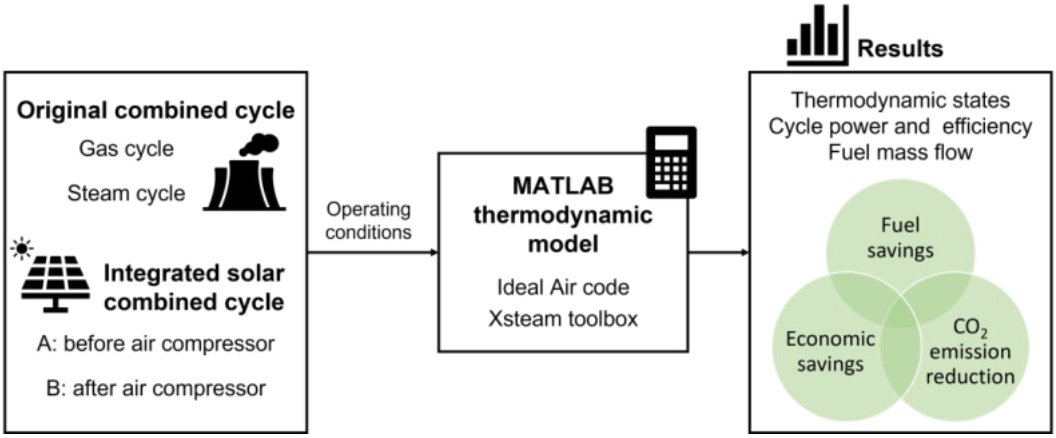

Figure 5. Methodology followed in this work.

3.1 Thermodynamic model of the original combined cycle

The upper gas cycle of the CC consists of three main components: compressor, combustion chamber and gas turbine. Ambient air (1g) is compressed to a higher pressure and temperature (2g). Then, it enters the combustion chamber, where fuel is added and burnt. The resulting high temperature gases (3g) enter the turbine and are expanded to ambient pressure (4g), producing useful work. Finally, exhaust gases are sent to the HRSG. The power of the gas turbine and compressor, the heat supplied in the combustion chamber and the net power of the gas cycle are calculated using the following equations:

$$\dot{W}_{GT} = \dot{m}_g \cdot (h_{3g} - h_{4g}) \quad (1)$$

$$\dot{W}_{comp} = \dot{m}_a \cdot (h_{2g} - h_{1g}) \quad (2)$$

$$\dot{Q}_{cc} = \dot{m}_f \cdot LHV = \dot{m}_g h_{3_g} - \dot{m}_a h_{2g} \quad (3)$$

$$\dot{W}_{G_{net}} = \dot{W}_{GT} - \dot{W}_{comp} \quad (4)$$

The bottom steam cycle of the CC comprises a steam turbine, a condenser, and a preheater. The steam that powers the cycle is generated in the HRSG with heat from the gas turbine exhaust gases. Energy balances in the HRSG yield the following equations (please refer to Figures 3-4 for the labels of thermodynamic states):

$$\dot{m}_g \cdot (h_a - h_b) = \dot{m}_7 \cdot (h_8 - h_7) \quad (5)$$

$$\dot{m}_g \cdot (h_b - h_c) = \dot{m}_7 \cdot (h_6 - h_{5a}) \quad (6)$$

$$\dot{m}_g \cdot (h_c - h_d) = \dot{m}_7 \cdot (h_5 - h_4) \quad (7)$$

$$\dot{m}_g \cdot (h_d - h_e) = \dot{m}_1 \cdot (h_2 - h_{1a}) \quad (8)$$

The steam turbine power is calculated as:

$$\dot{W}_{ST} = \dot{m}_7 \cdot (h_8 - h_9) \quad (9)$$

Hence, the total net power and efficiency of the CC power plant may be obtained as:

$$\dot{W}_{Total} = \dot{W}_{G_{net}} + \dot{W}_{ST} \quad (10)$$

$$\eta_{CC} = \frac{\dot{W}_{G_{net}} + \dot{W}_{ST}}{\dot{Q}_{cc}} \quad (11)$$

3.2 Thermodynamic model of the integrated solar combined cycle

The solar field has been integrated into the upper gas cycle, either to preheat ambient air before compression (case A), or to heat up compressed air before it enters the combustion chamber (case B). Gas turbine operating conditions (mass flow, inlet and outlet temperatures) are kept constant, so the steam cycle is virtually the same as the original one. In case A, the solar field generates a temperature rise before the compressor:

$$\dot{Q}_{Solar} = \dot{m}_{a_{new}} \cdot (h_{1gnew} - h_{1g}) \quad (12)$$

And the compressor power becomes:

$$\dot{W}_{comp_a} = \dot{m}_{a_{new}} \cdot (h_{2gnew} - h_{1gnew}) \quad (13)$$

On the other hand, in case B, heat is added after the compression process, leaving the compressor unaffected:

$$\dot{Q}_{Solar} = \dot{m}_{a_{new}} \cdot (h_{2gnew} - h_{2g}) \quad (14)$$

In both cases, the mass and energy balances in the combustion chamber are affected:

$$\dot{m}_g = \dot{m}_{a_{new}} + \dot{m}_{f_{new}} \quad (15)$$

$$\dot{Q}_{cc,new} = \dot{m}_{f_{new}} \cdot LHV = \dot{m}_g h_{3_g} - \dot{m}_{a_{new}} h_{2g_{new}} \quad (16)$$

And the total net power and cycle efficiency are modified accordingly, following Equations 10 and 11.

3.3 Estimation of economic and environmental effects of solar integration

Considering a natural gas price of 0.131 €/kWh [26], an estimation of the economic savings related to the amount of fuel saved may be performed using the following equation:

$$\text{Savings}_f = (\dot{m}_f - \dot{m}_{f_{new}}) \cdot LHV \cdot C_f \cdot \Delta t = \dot{m}_{f_{saved}} \cdot LHV \cdot C_f \cdot \Delta t \quad (17)$$

In addition, the introduction of solar energy reduces fuel combustion in the gas combustion chamber, leading to a reduction in CO_2 emissions. This reduction may be estimated from the lower heating value of natural gas (47,000 kJ/kg) [27] and the emission factor that relates natural gas and CO_2, 0.252 kg/kWh [28]:

$$\text{Savings}_{CO_2} = \dot{m}_{f_{saved}} \cdot LHV \cdot EF_{NG \rightarrow CO_2} \cdot \Delta t \quad (18)$$

4. Results

The results of the model show that the integration of solar heat into the combined cycle power plant results in a decrease in the fuel flow rate in cases A and B, with the air to fuel ration increasing accordingly. Table 4 collects the results from the three studied cycles when 35 MW of solar heat are added to the cycle.

Table 4. Original CC vs ISCC with 35 MW solar heat

Mass flow rates	**Original CC**	**ISCC (case A)**	**ISCC (case B)**
Air to fuel ratio	*50*	*99*	*64*
Turbine gas flow rate (kg/s)	*174.7*		
Air flow rate (kg/s)	*171.27*	*172.9*	*172.02*

Fuel saving (%)	*--*	*49*	*21.83*
Operating temperatures	***Original CC***	***ISCC (case A)***	***ISCC (case B)***
Compressor inlet (ºC)	*24*	*223.6*	*24*
Combustion chamber inlet (ºC)	*379*	*785*	*565*
Gas turbine inlet (ºC)	*1174*		
Gas turbine outlet (ºC)	*549*		
Solar heat integration	***Original CC***	***ISCC (case A)***	***ISCC (case B)***
Integrated solar heat (MW)	*--*	*35*	
Cycle efficiency	***Original CC***	***ISCC (case A)***	***ISCC (case B)***
Gas turbine cycle (%)	*39.84*	*25.2*	*51*
Combined cycle (%)	*57.8*	*60.4*	*73.9*
Cycle power breakdown	***Original CC***	***ISCC (case A)***	***ISCC (case B)***
Compressor (kW)	*62,450*	*106,601*	*62,450*
Gas turbine (kW)	*126,727*	*126,727*	*126,727*
Gas cycle (kW)	*64,277*	*20,722*	*64,277*
Steam cycle (kW)	*28,810*	*28,810*	*28,810*
Total net power (kW)	*93,000*	*49,087*	*93,000*
Specific work per unit fuel mass flow (kJ/kg)	*27,193*	*28,211*	*34,831*
CO_2 emissions saving (kg CO_2/kWh)	*-*	*0.0572*	*0.0166*

Option A results in a higher amount of fuel saving, 49%, whereas option B saves around 22%. However, the compressor power required increases by 70% with option A. Considering the changes in energy efficiency, option A results in a drop in the efficiency of the gas cycle of around 14.5%, although a slight increase in the overall combined cycle of around 2% is achieved, due to the reduction of heat supplied to the combustion chamber. Option B achieves the maximum cycle efficiency increase, around 11% for the gas cycle, leading to a 16.2% increase in the efficiency of the combined cycle. Therefore, option B seems the most beneficial option, delivering the same net power to the net with a substantial reduction on fuel consumption. The specific work per unit fuel mass flow rate reflects the superiority of case B over case A as 34,831 kJ could be delivered for each kg of fuel, while only 28,211 kJ for case A. CO_2 emissions avoided per net energy production is computed, where it is found that CO_2 emissions could be saved at a rate of 0.0572 and 0.0166 kg/kWh for case A and case B respectively.

Figure 6 shows the evolution of the cycle efficiency for the ISCC options studied as a function of the integrated solar heat, from 0 to 35 MW. It may be observed that integration of solar heat always results in better cycle efficiencies if it is done as proposed in option B, with the gap between options B and A increasing with further addition of solar heat. On the other hand, considering the fuel mass flow rates, depicted in Figure 7, and the reduction with respect to the original CC, shown in Figure 8, option A is the one that achieves the highest reduction in fuel consumption. From the original consumption of 3.42 kg/s, option A may save around 49% of the original fuel consumption if 35 MW of solar heat are added to the cycle, whereas option B can only reach around 21% savings. Nevertheless, it must not be forgotten that, although option A increases the cycle efficiency and reduces fuel consumption, the total net power delivered by the cycle is decreased with the integration of solar heat, as a consequence of the increase on the compressor power. Therefore, its use is not recommended. Option B does not have that disadvantage, as the integration of solar heat is performed after the compression stage. In addition, cycle efficiency increases more than with option A. Consequently, option B is the most adequate for integrating solar heat into the upper gas cycle of a CC.

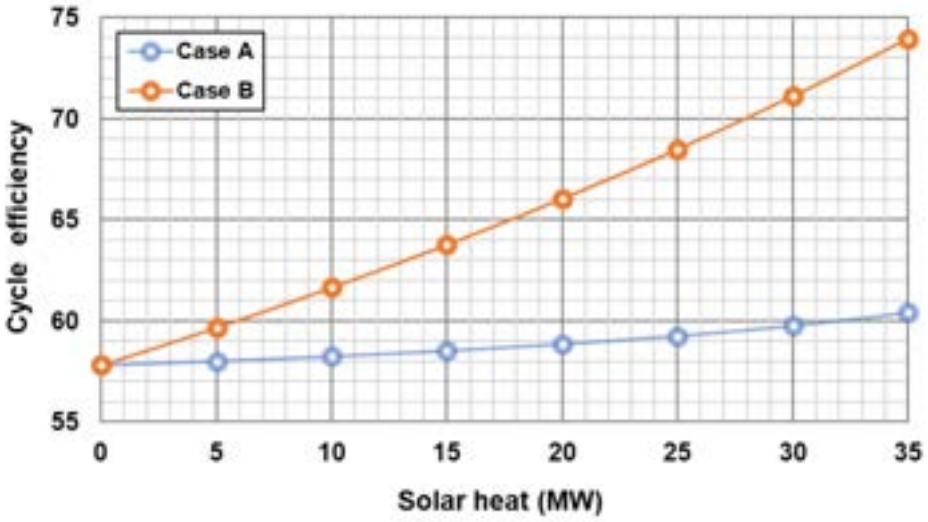

Figure 6: Combined cycle efficiency as a function of solar heat integrated into the cycle.

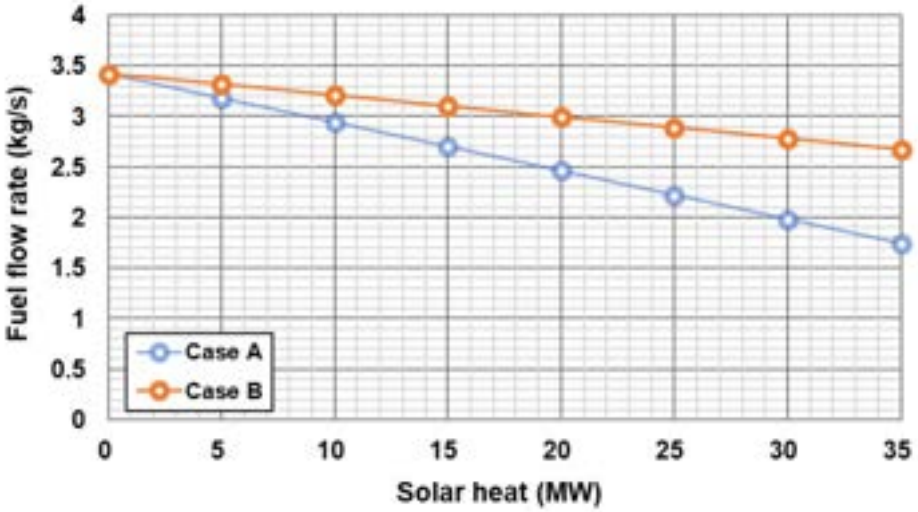

Figure 7: Fuel mass flow rate as a function of solar heat integrated into the cycle.

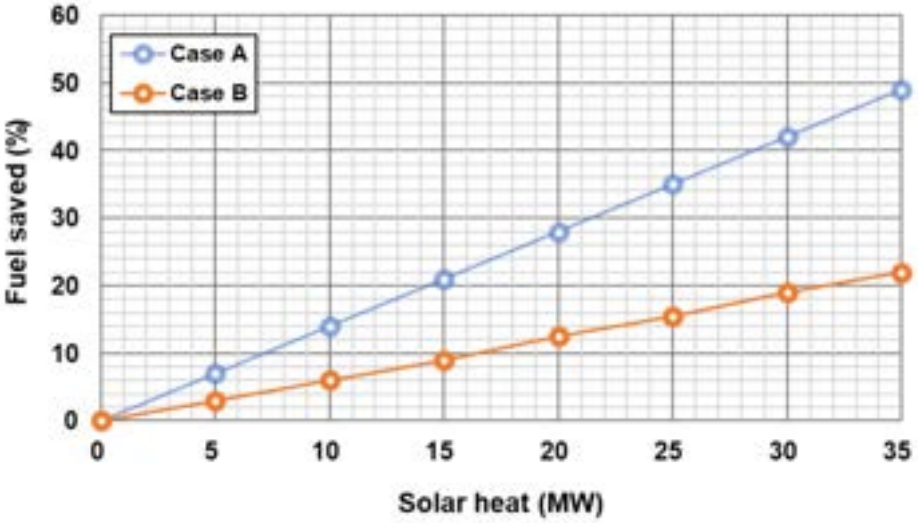

Figure 8: Fuel savings (%) as a function of solar heat integrated into the cycle.

Once it was been verified that option B is the most suitable one, in order to provide an estimation of the economic and environmental effects of solar heat integration, values from average solar irradiation in Las Palmas de Gran Canaria were considered. Figure 9 shows the monthly average daily global irradiation in Las Palmas, alongside the average heat power that could be provided by a 300,000 m^2 solar collector [29]. Maximum values of solar power are found in July, with 30,448 kW, while the minimum average solar heat is 15,597 kW, in December.

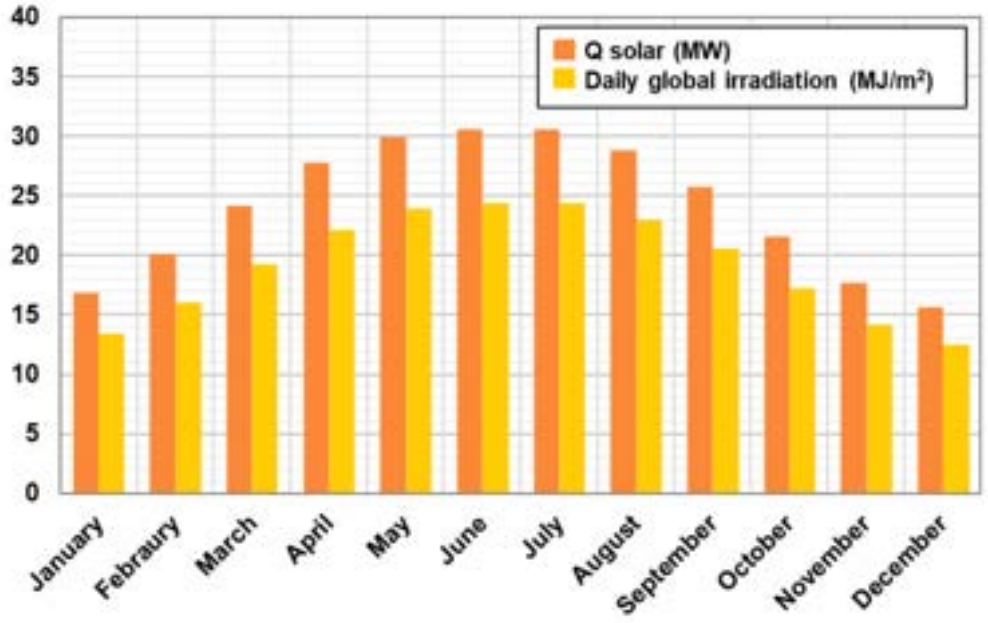

Figure 9: Monthly average daily global irradiation and solar heat power potential for a 300,000 m^2 collector in Las Palmas de Gran Canaria [29].

After the data from the solar heat power potential provided by the collector are introduced into the thermodynamic model of option B for the ISSC, the reduction in the fuel mass flow was calculated and translated into an estimation of the economic savings and reduction in CO_2 emissions. The results reveal a direct proportionality relation between the introduced solar heat power and the amount of fuel that may be saved. As shown in Figure 10, the highest savings may be achieved in July, of around 0.75 M€, while the lowest savings are reached in December, of around 0.38 M€. In all, if option B is integrated into the combined cycle, potential yearly savings of around 7.14 M€ might be achieved.

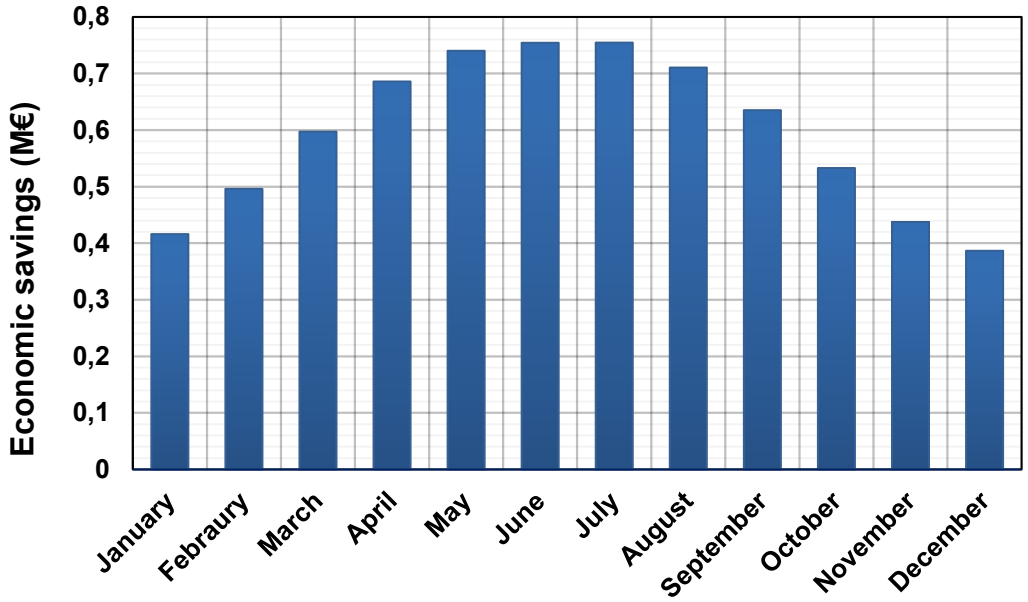

Figure 10: Monthly potential economic savings (M€) related to fuel consumption reduction.

Regarding the CO_2 emissions avoided by the integration of option B into the combined cycle, depicted in Figure 11, a direct proportionality with solar irradiance is found as well. Maximum values of potential reduction of emissions are found in July, of around 1.45 Mkg, whereas lowest values are found in December, of around 0.74 Mkg. In the aggregate, it has been estimated that incorporating option B into the combined cycle might lead to a total potential of reduction in CO_2 emissions of 13.75 Mkg per year.

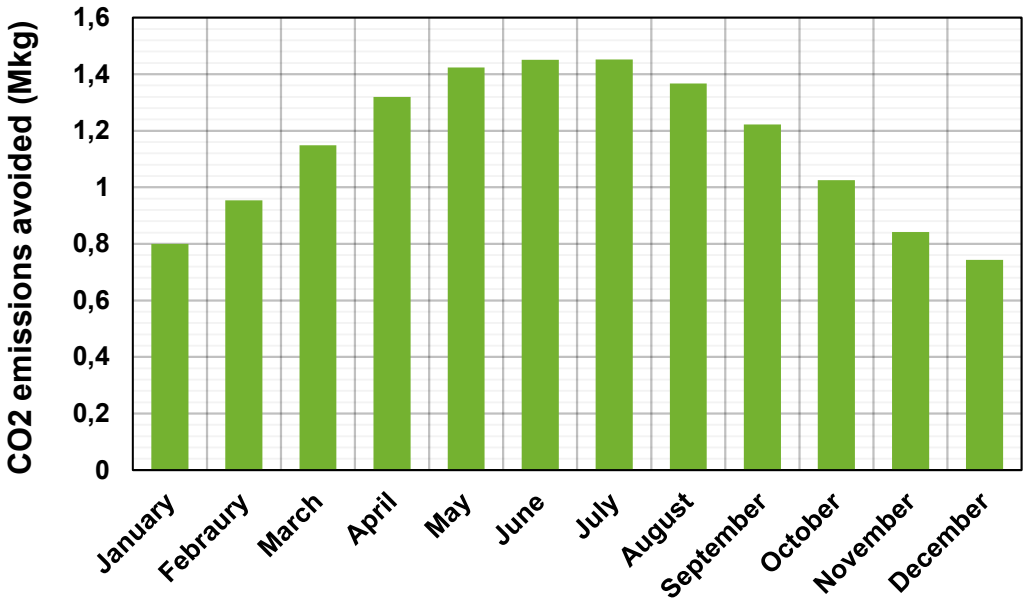

Figure 11: Monthly potential CO_2 emissions avoided (Mkg) related to fuel consumption reduction.

5. Conclusion

The overview of the power generation system in the Canary Islands reveals the important effect of renewable energy resources (especially, solar energy) to provide stability and reinforcement for power generation in thermal plants. The results from this work, which aims to evaluate the feasibility of integrating solar energy into a combined cycle power plant for fuel saving in insular subtropical climates, may contribute to improve the energy supply network in the Canary Islands, providing more energy security to the islands and reducing fuel imports. A thermodynamic model for solar heat integration into the upper gas cycle of the combined cycle was developed, studying the effects of injecting the solar heat before (case A) and after (case B) the compressor, before the combustion chamber.

It was found that the highest amount of fuel saved, 49% when injecting 35 MW of solar heat, was achieved when injecting the solar heat before the compressor (option A). However, this option resulted in a substantial increase of the compressor work due to the higher temperatures at the compressor inlet, reducing the net power of the cycle, although a global efficiency increase of around 2% was achieved. On the other hand, integrating the solar heat after the compressor (option B) had a very positive effect, with an overall 16.2% increase in the combined cycle efficiency when 35 MW of solar heat were introduced before the combustion chamber and. This option, in addition, can deliver the same net power with a substantial reduction of 22% in fuel consumption. The gap between the combined cycle efficiencies of both integration options became larger with the increase in the injected heat, with option B outperforming option A. Consequently, it may be argued that the most adequate for integrating solar heat into the upper gas cycle of a CC is right after the compressor and before the combustion chamber.

Combining the results from the energy analysis with the monthly solar irradiation distribution in Las Palmas de Gran Canaria and considering a solar collector of 300,000 m^2, it was possible to obtain an estimate of the economic savings and reduction in CO_2 emissions with the introduction of the solar field before the gas cycle combustion chamber. Oscillating between a minimum value of around 0.38 M€ in December and a maximum of 0.75 M€ in July, the integration of the proposed option may lead to potential savings of 7.14 M€ per year. Considering the CO_2 emissions potentially avoided with to the proposed solar heat integration, between 0.74 Mkg in December and 1.45 Mkg in July, it has been estimated that incorporating option B into the combined cycle might lead to a total potential of reduction in CO_2 emissions of 13.75 Mkg per year.

To conclude with, the integration of solar heat into a combined natural gas-fired cycle before the combustion chamber seems to be a very beneficial option for insular systems with solar irradiance values similar to Las Palmas de Gran Canaria. Substantial increases in the cycle efficiency, high potential economic savings, and a high reduction in potential CO_2 emissions are to be expected. Future works may focus on developing an exergoeconomic and environmental analysis of the studied alternatives, as well the study of other possible integration options of solar heat into the combined cycle.

Nomenclature

CC	Combined cycle
C_f	Fuel cost (€/kWh)
CSP	Concentrated solar power
DNI	Direct Normal Irradiance
$EF_{NG \to CO_2}$	Emission factor of natural gas (kg CO_2/kWh)
GEF	Global Environment Facility
GTCC	Gas turbine combined cycle
h_i	Specific enthalpy at state i (kJ/kg)
HRSG	Heat Recovery Steam Generator
ISCC	Integrated solar combined cycle power plant
LHV	Lower heating value (kJ/kg)
Mtoe	Million tonnes of oil equivalent
$\dot{m}_i$	Mass flow of fluid i (kg/s)
NGCC	Natural gas-fired combined cycle
PTC	Parabolic trough collectors
$\dot{Q}_i$	Heat transfer rate exchanged by component i (kW)
RES	Renewable energy sources
SEGS	Solar electric generating system
$\dot{W}_i$	Power of component i (kW)

Greek symbols

Δt	Time period (month)
η	Cycle efficiency

Subscripts

a	Air, case “A”
b	Case “B”
cc	Combustion chamber
CC	Combined cycle
$comp$	Compressor
f	Fuel
g	Gas
G	Gas cycle
GT	Gas turbine
new	New value (after solar integration)
ST	Steam turbine

Abstract:

A new Ericsson free-liquid-piston engine (FLPEE) configuration was previously presented. This consists of a U-shaped tube filled with water in its lower part, and whose two branches are closed by cylinder heads fitted with valves. The space between the surface of the liquid and the cylinder head of one of the branches constitutes the compression space, while this same space constitutes the expansion space in the other branch. The configuration studied operates in an open cycle. This system is able to produce compressed air which can be expanded in an external device to produce mechanical energy. This FLPEE is thought to be suited for the conversion of thermal energy such as solar energy, biomass or flue gases. In this communication, the experimental bench is presented in detail. In particular, the valve control system of the compression and expansion spaces, the various sensors and the data acquisition system are described. Various experimental results are presented, notably in the form of (p, V) indicator diagrams of the compression and expansion cylinders. These results confirm what the theoretical modelling had predicted, namely that it is possible to obtain a set of values of the operational parameters of the system leading to a stable operation of the free-piston system.

Keywords:

Free piston engine; Ericsson engine; Liquid piston, Experimental results.

1. Introduction

External heat engines such as Stirling or Ericsson engines [1] are proving to be a relevant technological solution for the valorisation of thermal energy such as solar energy, the energetic valorisation of hot gaseous effluents or the combustion of biomass, in order to produce low power mechanical or electrical energy. A major advantage of Ericsson engines over Stirling engines is that the heat exchangers are not dead volumes and can therefore be sized solely on heat transfer considerations [2]. This is particularly interesting in the case of hot sources with relatively low temperature or low transfer coefficient, such as flue gases. However, with regard to Ericsson engines, despite their interest and numerous theoretical developments [3-7], there is still little experimental work.

Liquid piston machines are particularly interesting because they ensure a perfect seal between the piston and the cylinder, while drastically reducing frictional forces. In addition, they can considerably improve heat transfer with the working fluid, for example to approach isothermal compression [8-10].

Free piston engines do not require a crank-connecting rod arrangement to transform reciprocating motion into rotary motion. Mechanical losses are therefore lower and the cost of the engine is reduced [11]. There are free piston internal combustion engines [12-15] or free piston Stirling engines [16-18] and free liquid piston Stirling engines, also known as Fluidyne. These engines, developed for pumping applications, have a poor efficiency [19-20].

In this paper, a totally new engine configuration combining the advantages of Ericsson engines, liquid piston machines and free piston engines is studied [21]. Dynamic simulation results of this engine have shown that it is possible to design a free liquid piston Ericsson engine (FLPEE) which, combined with a judicious choice of operational parameters, allows stable operation with interesting energy performance [22]. In particular, the FLPEE has a much better energy performance than the Fluidyne, which is the most similar configuration.

An experimental bench is being developed to validate the theoretical results. This bench is described and the first results are presented.

2. The test bench

2.1. The configuration under consideration

The configuration studied (Figure 1) consists of a U-shaped tube filled with water in its lower part, and whose two branches are closed by cylinder head fitted with valves.

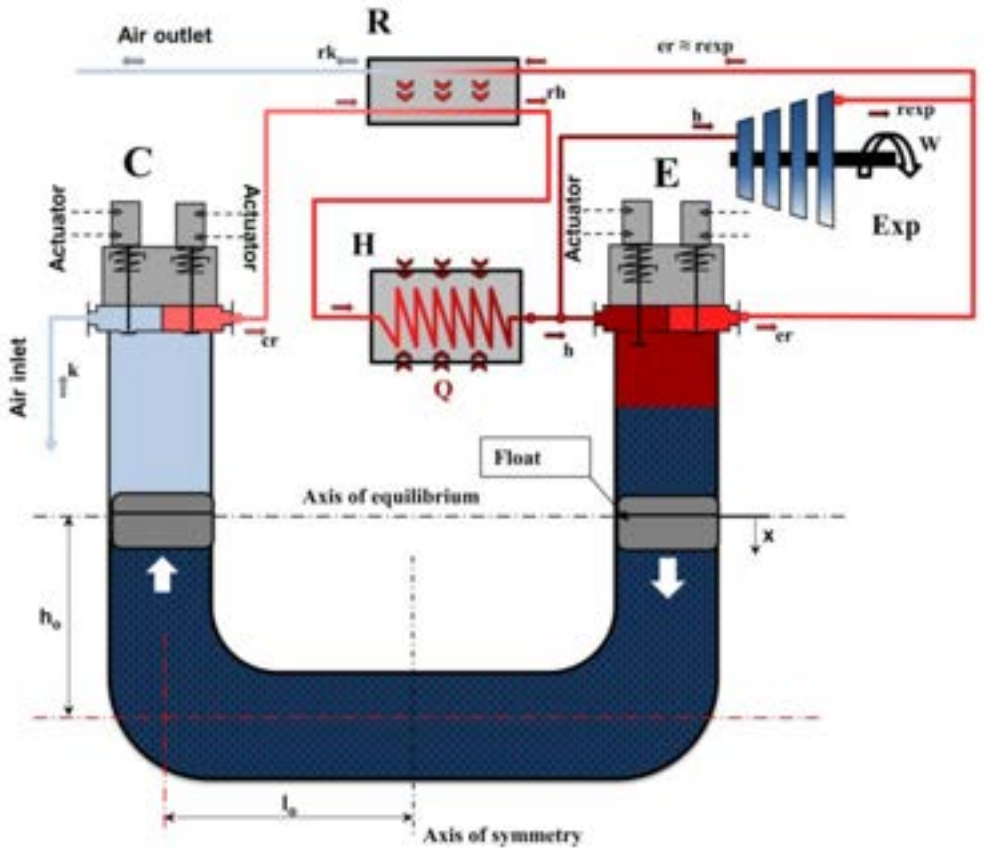

Figure 1. Schematic diagram of the free liquid piston Ericsson engine.

The space between the liquid surface and the cylinder head of one branch is the compression space C, while the same space is the expansion space E in the other branch. The configuration studied operates in an open cycle, with atmospheric air entering the compression space, being compressed by the liquid piston, then discharged to a heat recovery exchanger R and a heater H (hot source of the cycle) before being introduced into the expansion space E. The hot air expanded by the descent of the liquid piston is then discharged to the other branch of the heat recovery exchanger R, during the ascent of the liquid piston. In the case of the configuration studied, only a part of the air mass flow discharged by the compression space is introduced into the expansion space, the mass flow introduced being such that the expansion work exactly compensates for the compression work. In this configuration, the liquid piston and the compression and expansion spaces it defines are similar to a 'free piston gas generator', like the gas generator of the PESCARA engine [23-24]. The compressed air mass flow not admitted to the expansion space can be used as such, at the outlet of the compression space, the system being then a thermal compressor, or be taken after passing through the heat recovery R and heater H exchangers and be expanded in a machine operating in parallel to the liquid piston expansion space, if the objective is to produce mechanical energy (Figure 1).

2.2. The experimental set-up

Figure 2 shows the schematic diagram of the test bench, while figure 3 shows an overview of the experimental set-up. In order for the system to be tested in 'motored engine' mode, the device (Figure 2) is supplied with compressed air from the lab network (1). The compressed air from the external air compressor first passes through a pressure regulator (2) which allows the bench supply pressure to be adjusted, and then passes through a safety valve (3) which limits the downstream pressure to 3 bar, in order to avoid any risk of bursting the Pyrex tube (11). The valve (4) allows the compressed air in the test rig to be drained. A T-connection allows the expansion cylinder to be supplied from both the external compressor and the compression chamber of the liquid piston engine.

When the valves (1) and (5) are open, the compressed air from the external compressor pressurises the entire high-pressure branch of the device, including the two buffer tanks (8) and (15). The pressure line of the compression cylinder is pressurised and the engine can be started by opening the inlet valve of the expansion cylinder and introducing external compressed air.

When the valve (5) is closed, no more compressed air is introduced from the external compressor. A fluidic circuit is established which allows the bench to operate in "engine mode", i.e. the compressed air leaving the compression cylinder is divided into two flows: one part passes into the cold buffer (8), then through the heating cartridge (14) and the hot buffer tank (15) to be admitted into the expansion cylinder (11), and the other part passes into a back-pressure regulator (7) which makes it possible to keep the upstream pressure constant. The flow of air delivered by this back-pressure regulator can be measured by the float flow meter (6). This measurement allows the available air flow to be assessed for practical applications of the engine, such as the production of compressed air or mechanical power by adding an external expander.

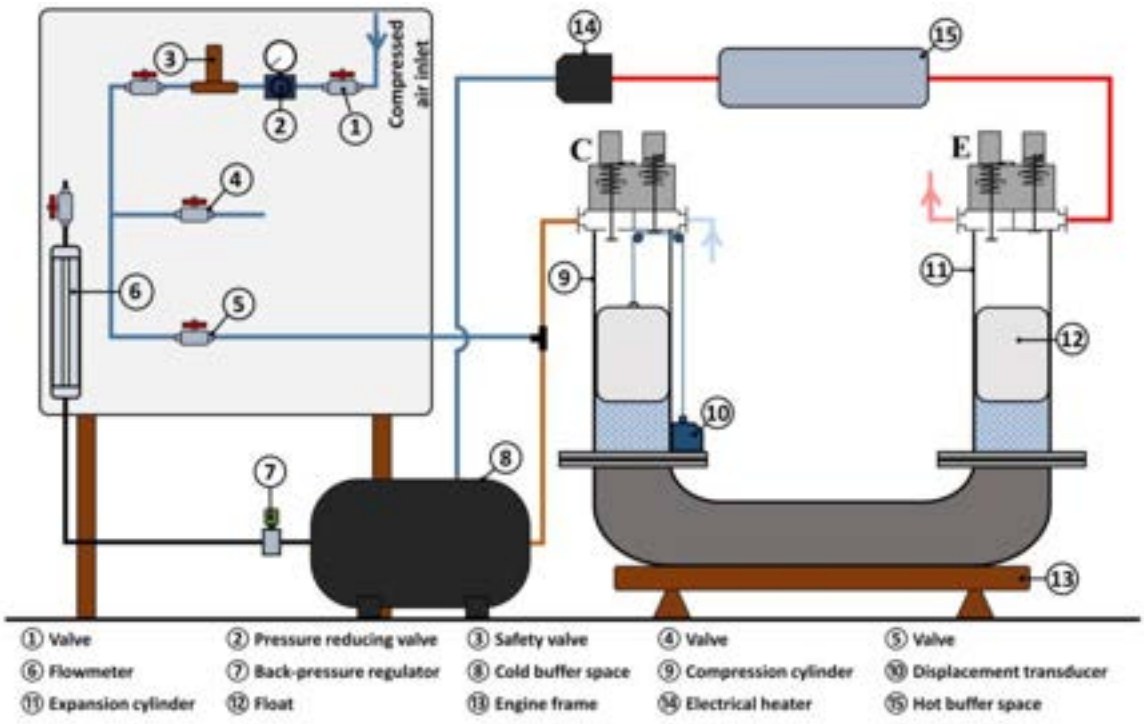

Figure 2. Schematic diagram of the test bench.

The lower part of the liquid piston system is made from commercial high-strength PN 10 pressure PVC pipe. The compression cylinder is made of stainless steel, while the expansion cylinder is made of Pyrex pipe with an external diameter of 180 mm, thickness of 8 mm, length of 500 mm. Two floats, with an external diameter of 156 mm and a length of 250 mm, are inserted in the cylinders. The length of the floats has been chosen to be at least equal to the maximum amplitude of movement of the liquid piston, so that water never licks portions of the wall of the expansion cylinder that would have been in contact with hot air. This reduces the evaporation of water from the liquid piston, as the nominal temperature of introduction of air into the expansion cylinder is 360°C.

Commercial YAMAHA XT500 motorbike engine heads are used to close the compression and expansion cylinders. The valves in these heads are operated by Festo 3/2-way quick-acting 1/4" valves, model MHE4-MS1H3/2G14K, and single-acting pneumatic cylinders, model AEN-40-8APA-S6, also from Festo. These valves are supplied with compressed air from the external air compressor.

The compressed air is heated before it enters the expansion workspace by an electric heating cartridge (item (14) in Figure 2), Osram Sylvania model SureHeat JET 074719, with a maximum power of 8 kW. A control box allows the supply temperature of the expansion cylinder to be set.

The test bench is equipped with K-type thermocouple temperature sensors with a measuring uncertainty of ± 1.5 °C, Keller-Druk PR23S and 23SY pressure sensors which have been calibrated beforehand and have a measuring uncertainty of ± 0.025 bar, and a micro-Epsilon WDS-300-P60-SR-I displacement sensor with a measuring uncertainty of ±0.25 %. This sensor (item (10) in Figure 2) is connected by a pulley system to the float of the compression cylinder. The measurement of the instantaneous pressure in each compression and expansion space is obtained by means of pressure sensors connected to the original location of the spark plugs in the cylinder heads. The sensors are connected to a National Instrument NI cDAQ 9172 modular

chassis data logger controlled by Labview. The sampling rate is 1 kHz. A control box operates the solenoid valves on the valve cylinders based on a comparison between the setpoints and the float position measured by the taut wire sensor.

Figure 3. Overview of the experimental set-up.

3. First experimental results

The first tests did not allow the system to operate autonomously [25], for reasons that will be explained later. The results presented here are therefore all related to a 'motored engine' mode, i.e. with consumption of compressed air from the network. In addition, according to the theoretical results, the displacement amplitude of the free liquid piston increases with the intake pressure of the expansion cylinder. However, in its current version, the amplitude is limited by the length of the tubes and the length of the floats. Therefore, the tests that have been carried out are limited to low pressure ratios. On the other hand, the frequency also depends on the inlet pressure of the expansion cylinder. Experience shows that above a frequency of about 3 Hz, the liquid-air interface no longer behaves satisfactorily. Due to its inertia, the float 'lifts off' from the liquid column and the interface breaks up into a multitude of droplets. For these reasons, the tests are limited to an absolute pressure of 1.6 bar at the inlet of the expansion cylinder.

3.1. Valves setting

The position of the liquid piston is denoted by x. The position $x = 0$ corresponds to the lowest bottom dead centre possible in the expansion cylinder (float on the bottom stop of the cylinder) and the highest top dead centre (TDC) possible in the compression cylinder (float in contact with the top stop of the cylinder). The position $x = 0.3$ m corresponds to the lowest bottom dead centre (BDC) possible in the compression cylinder (float on the bottom stop of the cylinder) and the highest top dead centre possible in the expansion cylinder (float in contact with the top stop of the cylinder).

The compression cylinder valves are supposed to simulate automatic valves, whereas the expansion cylinder valves are actuated valves whose opening and closing are governed by the values of the position of the liquid piston and its direction of movement.

The valves are actuated as follows:

- The inlet valve of the compression cylinder is open when the liquid piston moves downward and the in-cylinder pressure is lower than the atmospheric pressure.
- The outlet valve of the compression cylinder is open when the liquid piston moves upward and the in-cylinder pressure is higher than the pressure in the exhaust pipe.
- The inlet valve of the expansion cylinder is open when the liquid piston moves upward and $x >$ IVO or when the liquid piston moves downward and $x >$ IVC.
- The exhaust valve of the expansion cylinder is open when the liquid piston moves downward and $x <$ EVO or when the liquid piston moves upward and $x >$ IVC.

Figure 4 presents the valves setting of the expansion cylinder. Unless otherwise specified, the results presented here correspond to the following expansion cylinder valves setting:

- IVO = 0.16 m
- IVC = 0.1 m
- EVO = 0.03 m
- EVC = 0.16 m

Theoretically, with this valves setting, there should be an expansion process of the working fluid, since all valves are closed when the liquid piston moves downward from IVC = 0.1 m to EVO = 0.03 m, but there should be no re-compression of the dead space volume since the inlet valve opens at the same time as the exhaust valve closes: EVC = IVO.

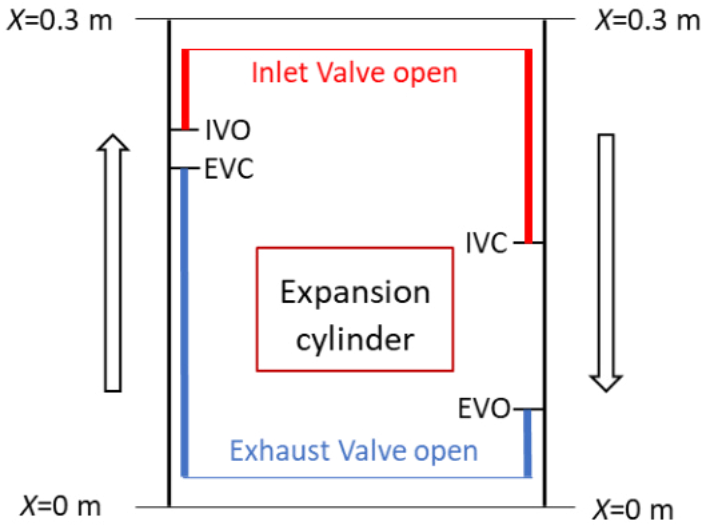

Figure 4. Valves setting for the expansion cylinder.

3.2. Cold tests

3.2.1. Frequency and stroke

Figure 5 shows the theoretical and experimental liquid piston displacement as a function of time, for a test duration of 20 s with a time step of 10^{-3} s. The expansion cylinder inlet pressure is set to 1.3 bar. There is good agreement between the theoretical and experimental data, both in term of frequency (about 2.2 Hz for the experimental and theoretical results) and stroke (about 124 mm for the theoretical results and 105 mm for the experimental ones, that is less than half the maximum possible travel between the stops).

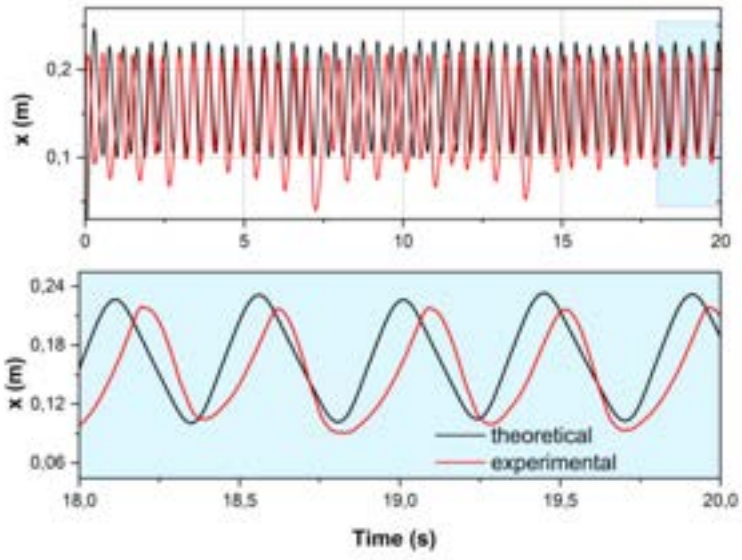

Figure 5. Liquid piston displacement as a function of time.

Figure 6 presents the frequency and the stroke as a function of the expansion cylinder inlet pressure. As the modelling has shown, it is not possible to vary the expansion cylinder inlet pressure without adjusting the valves setting. The experimental results shown in figure 6 are obtained by varying the pressure of the air admitted into the expansion cylinder from 1.15 to 1.5 bar. For the theoretical results, the model has been re-run, with the experimentally imposed pressure and valves setting, to allow comparison between the experimental and theoretical data. It can be seen that the theoretical frequency and stroke increases nearly linearly with the expansion cylinder inlet pressure. The experimental values are in fairly good agreement with the theoretical values, and the differences can be attributed largely to the fact that the experimental instantaneous pressure in the expansion cylinder is far from the theoretical pressure, due to pressure losses in the intake line, as will be shown below. The same applies to the compression cylinder, where the exhaust valve generates large pressure losses.

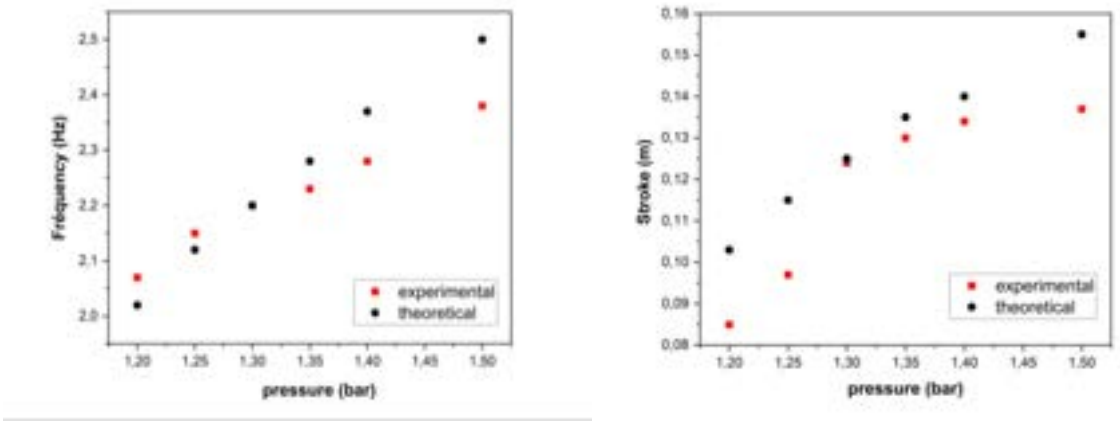

Figure 6. Frequency and stroke as a function of the expansion cylinder inlet pressure.

3.2.2. Instantaneous pressures

Figure 7 presents the instantaneous pressures measured at the expansion cylinder inlet (*p_admE*), in the compression cylinder (*p_C*), at the compression cylinder outlet (*p_echC*), in the expansion cylinder (*p_E*) and at the heater cartridge inlet (*p_Cart*), as a function of time for different expansion cylinder inlet pressures.

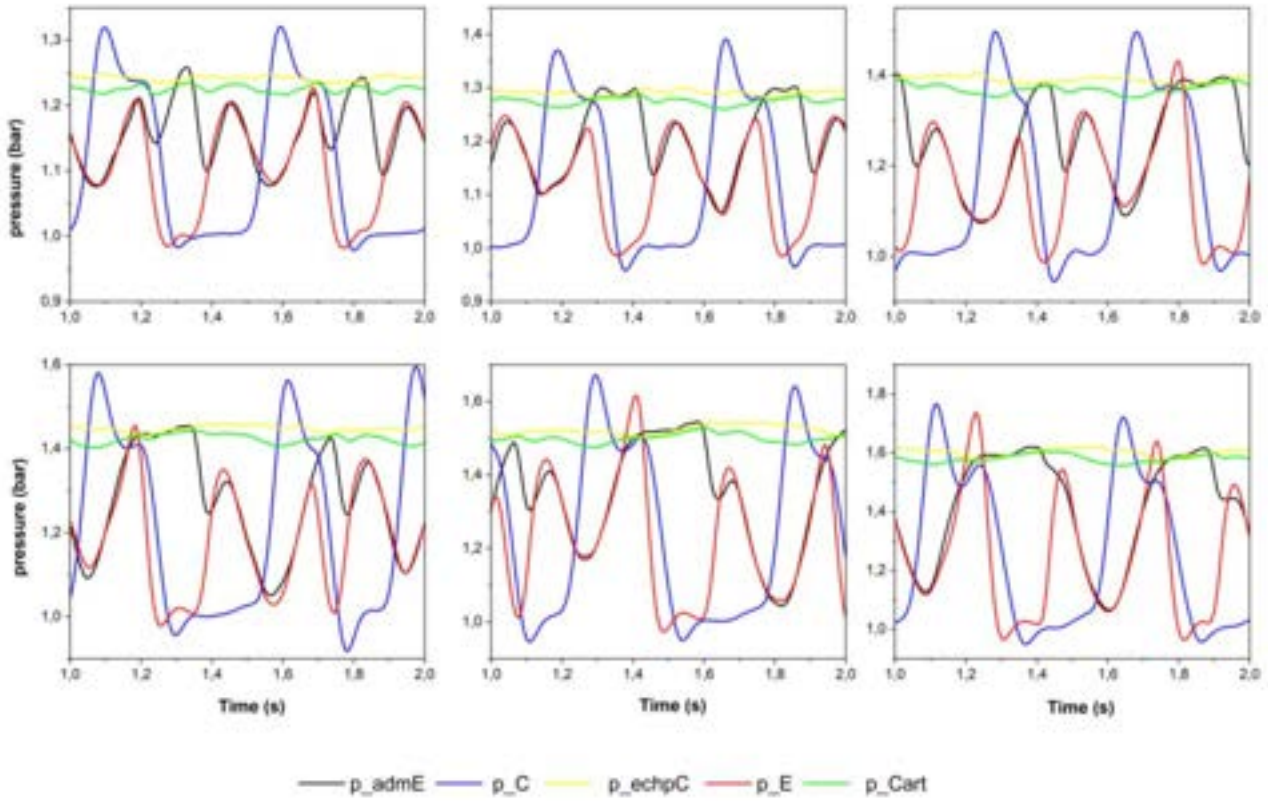

Figure 7. Instantaneous pressures as a function of time for different expansion cylinder inlet pressures.

It can be seen in Figure 7 that the pressures at the inlet of the heater cartridge *p_Cart* and at the outlet of the compression cylinder *p_echC* are almost constant, and almost identical, the pressure at the inlet of the

cartridge being slightly lower due to the greater pressure drop in the connecting pipe. In contrast, the expansion cylinder inlet pressure *p_admE*, which is supposed to be constant in the model, varies greatly when the inlet valve opens and closes. This is due to the high pressure drop generated by the pipe that connects the hot buffer tank to the expansion cylinder head. This line 'deflates' when the inlet valve opens and 're-inflates' to the cartridge inlet pressure when the inlet valve closes. The higher the pressure imposed by the compressed air in the high-pressure branch, the more pronounced this phenomenon becomes. This high pressure drop is the main reason why the engine has not yet been able to operate autonomously, without energy supply from the compressed air network. During the opening phases of the expansion cylinder intake valve, the pressure *p_E* in the cylinder is almost identical to the pressure in the intake pipe *p_admE*, proving that the pressure losses in the intake valve are negligible. However, these pressures are far from being equal to the constant pressure *p_Cart* as assumed in the model.

As far as the compression cylinder is concerned, it can be seen that when the free liquid piston moves up towards its top dead centre, the pressure in the cylinder *p_C* exceeds the pressure in the exhaust pipe *p_echpC* even though the exhaust valve is open, which indicates that the pressure losses generated by this valve are too high under these operating conditions.

3.2.3. In-cylinder pressures

Figure 8 presents the liquid piston displacement, the state of the valves (1 = open, 0 = closed) and pressure in the expansion cylinder as a function of time. For the valves setting considered, it can be seen that there is a time lag between the closing of the intake valve and the moment when the piston reaches its bottom dead centre. This should lead to an expansion of the fluid in the cylinder, which does not seem to be systematically observed. Similarly, it is also observed that the pressure in the cylinder increases when the liquid piston rises, while the exhaust valve is open, which seems to indicate that the exhaust valve generates significant pressure losses.

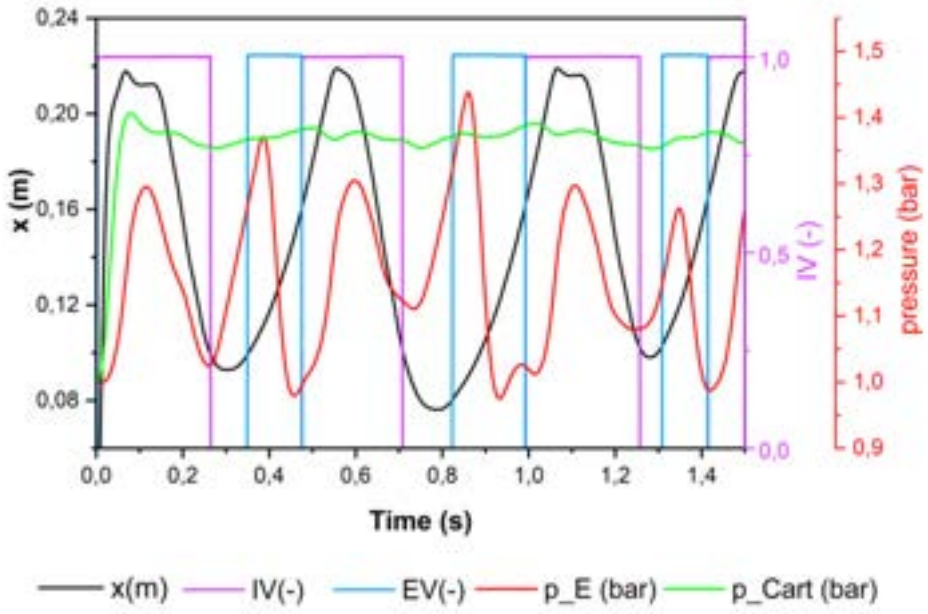

Figure 8. Liquid piston displacement, state of the valves and pressure in the expansion cylinder.

Figure 9 compares the experimental and theoretical pressure evolutions in the compression cylinder (Figure 9 (a)) and in the expansion cylinder (Figure 9 (b)). For the compression cylinder, it can be seen that the experimental pressure is slightly higher than the simulation pressure during the discharge phase, with a peak that is due to pressure drops around the exhaust valve. For the expansion cylinder (Figure 9 (b)), the theoretical results predict isobaric inlet, then isentropic expansion, followed by isobaric outlet and finally isentropic dead volume recompression. As mentioned earlier, the evolution of the experimental pressure *p_E* is significantly different, due to the pressure losses in the inlet line and in the valves, and the time needed for the complete opening and closing of these valves. Despite these problems, it can be seen that the theoretical cycle time corresponds to the experimental cycle time.

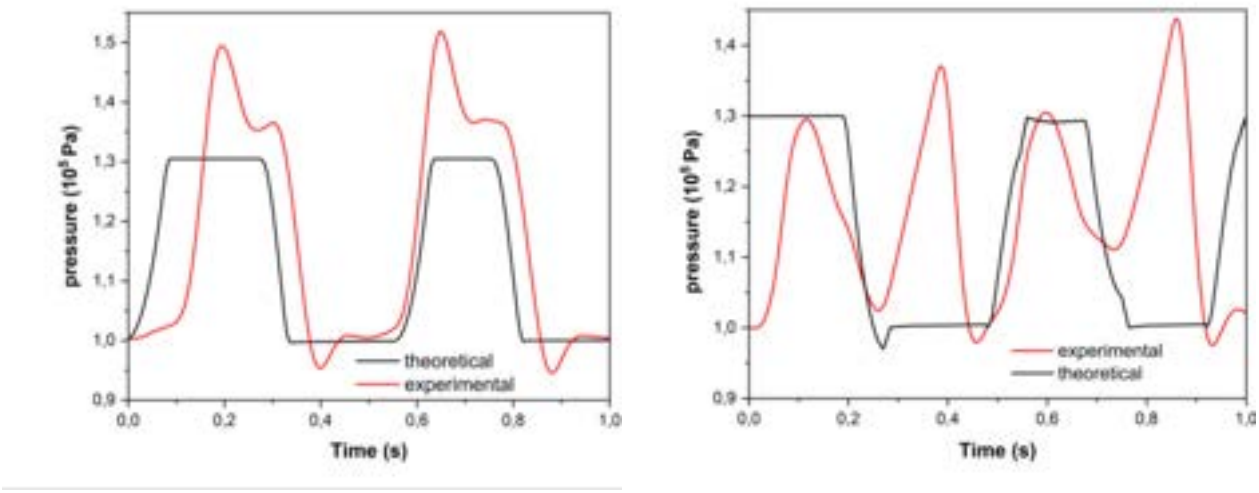

Figure 9. Instantaneous pressure in the compression cylinder (a) and the expansion cylinder (b).

3.2.4. Indicator diagrams

Figure 10 presents the (*p, V*) indicator diagram for the compression (blue) and expansion (red) cylinder. The area included in the closed curve of the (*p, V*) diagram corresponds to the work of the pressure forces on the liquid piston. A clockwise loop corresponds to a negative work, meaning that the working fluid produces mechanical work on the liquid piston, while a counter-clockwise loop corresponds to a positive work, meaning that the working fluid receives mechanical work from the liquid piston. Obviously, the two diagrams do not resemble the theoretical diagrams composed of almost isobaric and isentropic transformations. Normally, the compression cylinder indicator diagram should be a single counter-clockwise loop and the expansion cylinder indicator diagram should be an identical but clockwise loop.

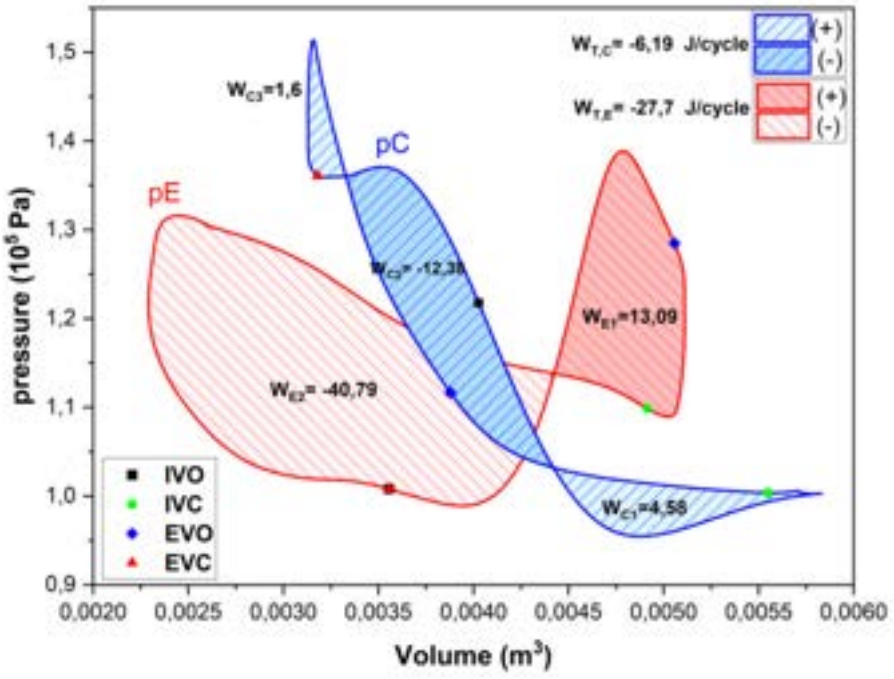

Figure 10. Compression (blue) and expansion (red) cylinder indicator diagram.

Experimentally, it can be seen that the working fluid in the compression cylinder globally gives up work to the liquid piston and the working fluid in the expansion cylinder receives mechanical work from the liquid piston during some phases of the cycle, around the BDC. There are many reasons for this.

As far as the expansion cylinder is concerned, at the moment when, simultaneously, the exhaust valve closes and the intake valve opens, the pressure *p_E* does indeed increase dramatically but with some delay, meaning that the inlet valve does not open instantaneously. But as the piston descends from its TDC towards its BDC, the pressure *p_E*, which should theoretically remain constant at its maximum value, decreases due to pressure losses in the intake line as mentioned above. When the intake valve closes, there should be an isentropic expansion of the fluid. However, the experimental pressure increases. This is due to the fact that the inlet valve

does not close instantaneously, meaning that compressed air goes on entering the expansion cylinder after the EVC point indicated on the red loop of figure 10. The liquid piston being nearly at rest around the BDC, the pressure increases dramatically. Similarly, when the exhaust valve opens around the BDC, the pressure *p_E* does not drop immediately to the value of atmospheric pressure, as would be expected in the theoretical cycle, but instead begins to rise and then gradually falls. This phenomenon is attributable firstly to the time required for the discharge valve to open fully, as it does not open completely instantaneously at the time shown in the diagrams, and secondly to the pressure drop generated by this valve.

As far as the compression cylinder is concerned, it can be assumed that the exhaust valve does not close instantaneously at the EVC point shown in the diagrams in figure 10. Compressed air would therefore enter the compression cylinder even as the liquid piston begins its stroke towards its BDC, leading to a cycle producing mechanical work instead of a cycle receiving mechanical work. In the case where there is no back pressure at the exit of the compression space (figure 11), the discharge of the compressed air is done towards the atmosphere. In figure 11, it can be seen that the indicator diagram (*p, V*) of the compression cylinder rotates counter-clockwise, which means that mechanical work is absorbed by the working fluid, and the expansion cylinder rotates clockwise, which means that mechanical work is supplied by the working fluid. However, despite the early opening of the compression cylinder exhaust valve, the pressure drops around this valve are significant, as the discharge is at a pressure *p_C* much higher than atmospheric pressure, especially when the piston has a high speed, around its mid-stroke. It can be seen that as the piston approaches its top dead centre, the pressure drop decreases and the pressure *p_C* falls towards atmospheric pressure. The mechanical work supplied by the expansion cylinder is more than twice as great as that absorbed by the compressor and the net work is 16.4 J/cycle at a pressure of just over 1.2 bar. The indicator diagrams of figure 11 confirms what the modelling has predicted, that is the possibility to design a free liquid piston Ericsson engine. Indeed the inertia of the liquid piston allows to achieve the compression of the air in the compression cylinder even when the pressure in the compression is higher than the one in the expansion cylinder, the liquid piston moving against the pressure forces.

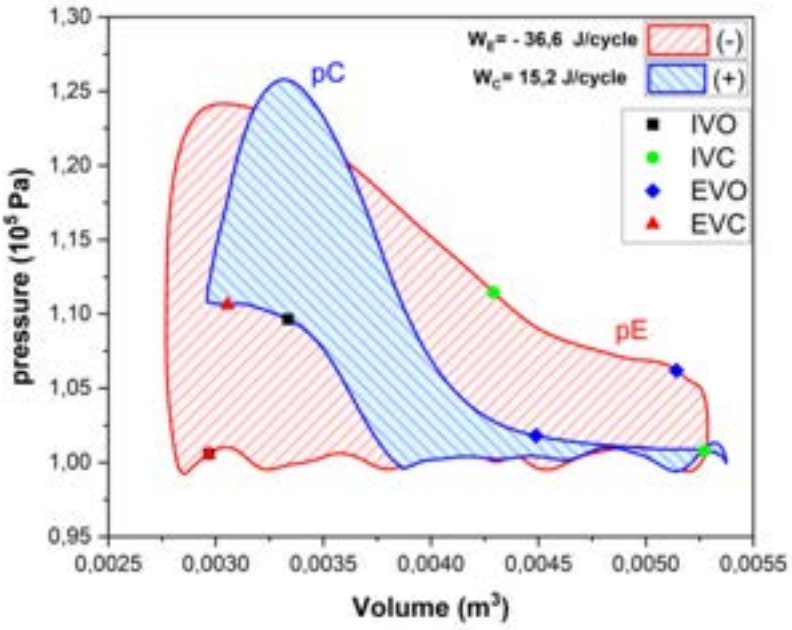

Figure 11. Compression (blue) and expansion (red) cylinder indicator diagram without back-pressure at the compression cylinder outlet.

Finally, it should be mentioned that, although the volumes swept by the liquid piston are obviously identical in the compression and expansion cylinders, the indicator diagrams in figure 10 and figure 11 show that there may be a very slight imbalance between the 2 branches of the liquid piston. The average volume of the compression cylinder is slightly higher than the average volume of the expansion cylinder, which means that the average height of the water in the E-arm of the engine is slightly higher than the average height in the C-arm.

3.3. Hot tests

Different tests were carried out at hot temperatures, up to 200°C.

The results of the experimental tests showed that the temperature does not affect the frequency or the stroke of the free liquid piston, as shown in figure 12, which represents the temporal evolution of the liquid piston displacement for different air inlet temperatures in the expansion cylinder, at the same inlet pressure of 1.3 bar. It can be seen that for the different temperature levels, the amplitude is almost the same. If, for example, we take the displacement for a temperature of 20°C and 190°C, we notice that it is almost the same stroke that is covered by the liquid piston, with the same cycle frequency, as predicted by the theoretical model.

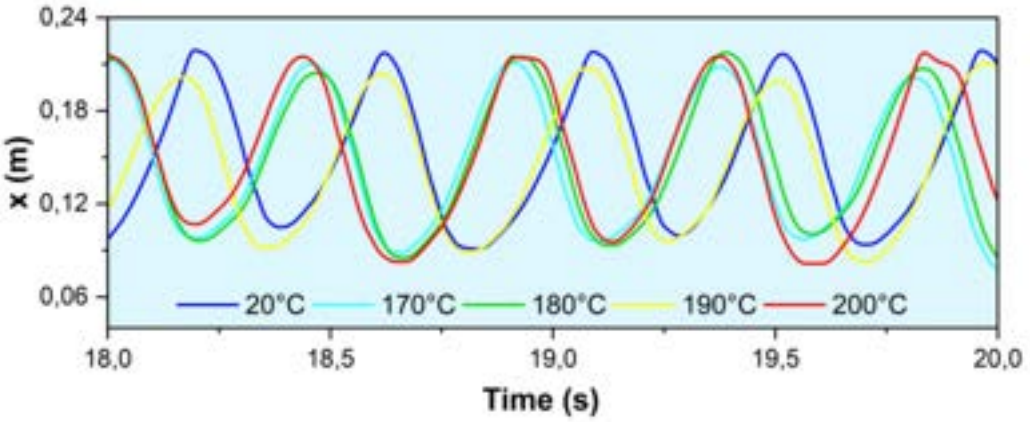

Figure 12. Liquid piston displacement for different inlet temperatures of the expansion cylinder.

The hot tests were carried out in a completely satisfactory manner, without any technical problems. At most, some fogging was observed on the wall of the Pyrex tube, due to the weak evaporation-condensation phenomena of the water in the liquid piston at high temperatures of the air admitted into the expansion cylinder.

4. Conclusion

The results of tests carried out on an original configuration of the Ericsson free liquid piston engine were presented. In its current configuration, the test bench did not allow for 'engine' operation. Tests in 'motored engine' mode using an external compressed air supply showed that it is possible to obtain stable engine operation, provided that the operational parameters (supply pressure, valve opening/closing settings) are carefully chosen. The oscillation frequency of the free piston and its stroke are in good agreement with the results of the theoretical model. The hot tests also demonstrated the good operation of the engine at high temperatures without encountering any technical problems. The examination of the experimental results highlighted the improvements to be made to the test bench.

Nomenclature

IV	state of the inlet valve of the expansion cylinder
IVC	inlet valve closure
IVO	inlet valve opening
EV	state of the exhaust valve of the expansion cylinder
EVC	exhaust valve closure
EVO	exhaust valve opening
p_admE	instantaneous pressure at the inlet of the expansion cylinder, bar
p_C	instantaneous pressure in the compression cylinder, bar
p_Cart	instantaneous pressure at the electrical heater inlet, bar
p_E	instantaneous pressure in the expansion cylinder, bar
p_echpC	instantaneous pressure at the outlet of the compression cylinder, bar
x	liquid piston instantaneous position, m

Subscripts and superscripts

C	compression space
E	expansion space
H	heater
R	heat recovery exchanger
T	external expander

Energy analysis of a hybrid top/bottoming ORC-based CHP configuration for residential applications

João S. Pereira* and José B. Ribeiro

Univ Coimbra, ADAI, Department of Mechanical Engineering, Coimbra Portugal,
joao.pereira@dem.uc.pt

Abstract:

The development of ORC-based micro-CHP systems to retrofit the current combi-boilers is receiving noticeable attention from research centres and companies due to the huge dimension of the potential market. Recognizing the importance that the evaporator has on the technological/ commercial success of these systems, and instead of avoiding the problem through the adoption of alternative restricting solutions (i.e.: indirect vaporization process), it seems reasonable to face the challenges associated with the development of a specifically designed ORC-evaporator capable to directly use the high-temperature combustion gases to perform the vaporization of the working fluid. In an attempt to overcome those challenges, that are believed to be preventing the widespread use of these systems, this paper presents and discusses some of its main design principles. From those principles emerged a hybrid (top/bottoming) CHP configuration in which the thermal energy is produced stepwise: firstly in the ORC condenser and then in a post-heater, that is integrated into the ORC-evaporator. A model of this configuration was developed to determine the fraction of the CHP water heating process performed in the post-heater that maximizes the primary energy savings and ORC net power output for a wide range of CHP operating conditions. When compared to a standard CHP configuration, this solution show benefits for the greater part of those conditions. Besides the performance benefits shown and solving the safety issue posed by the ORC-evaporator requirements, this configuration has an additional positive side effect: the decrease of the combustion gases' temperature before they reach the organic fluid heat-exchanger section in the ORC-evaporator that leads to a reduction of the risk its thermal degradation.

Keywords:

Organic Rankine Cycle, Hybrid CHP configuration, ORC-evaporator, Direct vaporization arrangement.

1. Introduction

The combined production of heat and power (CHP) is one of the major alternatives to traditional energy production systems in terms of energy savings and environmental conservation [1–3]. The most promising target for the micro-CHP systems lies in the residential sector given the huge dimension of the market [4,5]. At this scale, and for solutions attempting to retrofit the wall-mounted combi-boilers that are currently applied in residential dwellings, where the noise, vibrations, weight, dimension and reliability are crucial features, the Organic Rankine Cycle (ORC) based technology appears to be the most promising [6,7]. Even if it may seem surprising, in its basic configuration and from a thermodynamic point of view, an ORC is almost identical to a reverse refrigeration cycle in which the throttling valve is replaced by a pump, the condenser works as an evaporator, the compressor works as an expander and the evaporator as a condenser. From a technological point of view, the ORC-based micro-CHP system may share with the refrigeration devices their main component, the compressor (converted to an expander in the micro-CHP [8,9], while the pump and the condenser are off-the-shelf components of, e.g., coffee machines and HVAC systems, respectively [10]. This share of technology presents obvious benefits from the point of view of reliability, maintenance and cost that, partially due to the existence of alternative moving parts in Stirling Cycle and spark-ignited internal combustion systems, are envisaged to present less noise, vibrations and maintenance requirements [11,12].

Among the ORC-based micro-CHP main components, the evaporator is the only one that, due to its specificities (e.g. working with a vaporizing fluid at relatively high pressures, typically above 10 bar), cannot be found directly on the market or easily adapted from a mass production part of other appliances and needs to be specially designed and analyzed [13]. To partially avoid this question, the overwhelming majority of manufacturers and research centres choose to perform indirect vaporization of the working fluid. In those cases, an intermediate circuit with thermal oil, or slightly pressurized water, is commonly used to transfer the

energy from the high-temperature combustion gases to the organic fluid, being its vaporization performed in a plate-type heat exchanger [14,15]. In this way, it is not only possible to reduce the pressure but also to ensure the existence of a continuous liquid phase in the heat exchanger that is directly exposed to the high-temperature combustion gases, from which a significant reduction in the design requirements is obtained. Moreover, such a solution is expected to perform better control of the temperature of the working fluid vaporization process that can reduce the risk of its thermal degradation [16,17]. In comparison with direct vaporization, in which the phase change of the organic fluid occurs in the part of the evaporator directly exposed to the combustion gases, the aforementioned CHP configuration demands the inclusion of, at least, an additional heat-exchanger, a circulating pump, an expansion vessel, and the necessary tubes and accessories from which an increase of the system dimension and thermal inertial are expected. As an obvious consequence, such micro-CHP strongly reduces its ability to face the intermittence of the hot-water demands, with multiple short-time requests, that characterize one of the operation modes of the boilers [18].

Recognizing the importance that the evaporator has on the technological success of ORC-based micro-CHP systems, and instead of avoiding the problem through the adoption of restricting solutions (indirect vaporization [13]), it seems reasonable to face the challenges associated with the development of a specifically designed ORC-evaporator capable to directly use the combustion gases to perform the vaporization of the working fluid [19,20]. In an attempt to overcome those challenges and fulfil this technological gap, that is believed to be preventing the widespread use of these systems, this paper presents a solution for such evaporators. This solution leads to a hybrid (topping/ bottoming) CHP configuration in which the useful thermal energy is produced stepwise, firstly in the ORC condenser and then in a post-heater directly with hot combustion gases [21]. The benefits arising from its use, in what refers to the primary energy savings, cycle efficiency, net power output and risk of the organic fluid thermal degradation, are illustrated and discussed as a function of several CHP operating (design) conditions.

2. Direct vaporization ORC-evaporator

The gas burner with the characteristics required for the ORC-evaporator was promptly found in the market and is shown in Figure 1-a. Contrarily, the heat exchanger needs to be specifically designed. A schematic representation of its configuration can be seen in Figure 1-b. In this, the hot combustion gases flow around the tubes of the heat exchanger, within which is the organic fluid, in what can be described as a mixed counter flow/cross-flow arrangement. The use of high-temperature insulation material sleeves (presented in brown in Figure 1-b) prevents the energy transfer along the radial direction from the central combustion chamber to the helical coils to keep the counter-flow arrangement nature. Besides the mentioned characteristics, this configuration contains a water-cooled baffled sleeve to be used as a cold surrounding of the gas-burner head to ensure its proper and safe operation. In this, the water flows through the sleeve after being pre-heated in the ORC condenser, reducing the organic fluid condensing temperature in this component, which is beneficial for the cycle efficiency. In addition, this baffle sleeve can also reduce the risk of organic fluid thermal degradation because it decreases the combustion gases' temperature before they reach the ORC heat-exchanger part.

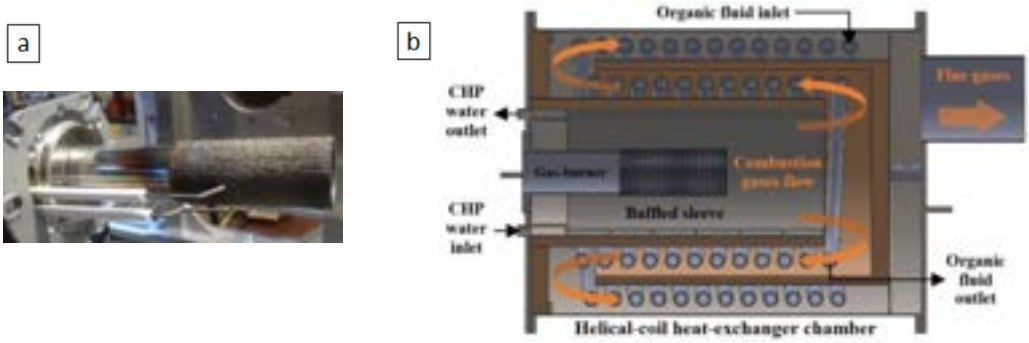

Figure 1: Photograph of the premix gas-burner head with the ignition spark and flame detector rod (a) and the schematic representation of the ORC-evaporator design with the water baffled sleeve (b).

3. Hybrid ORC-based CHP configuration

The schematic configuration of the micro-CHP system, derived from the integration of the newly designed ORC-evaporator, is shown in Figure 2. This can be described as a hybrid (topping/bottoming) CHP configuration [21] since the useful thermal energy is transferred to the water stepwise - before and after the production of work in the prime mover (expander).

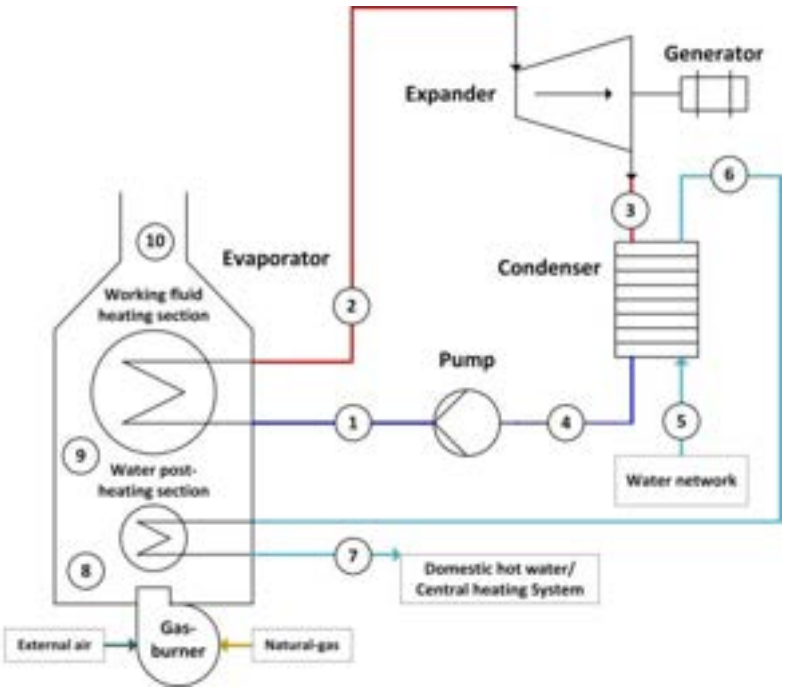

Figure 2: Schematic diagram of the hybrid CHP configuration with the new ORC-evaporator

The T-s diagrams of the hybrid and a standard ORC-based CHP configuration, including the combustion gases and water streams, can be found in Figure 3 using the organic fluid r245fa. For the same CHP outlet water temperature, the condensing pressure (and the temperature) of the ORC in this hybrid configuration may be significantly lower. The well-known advantages of such a decrease in the condensing pressure are an increase in the ORC specific power (net power per unit of working fluid mass flow rate) and an increase in the cycle efficiency. However, these advantages need to be considered against an inevitable reduction of the ORC working fluid mass flow rate that can partially, or totally, hinder them.

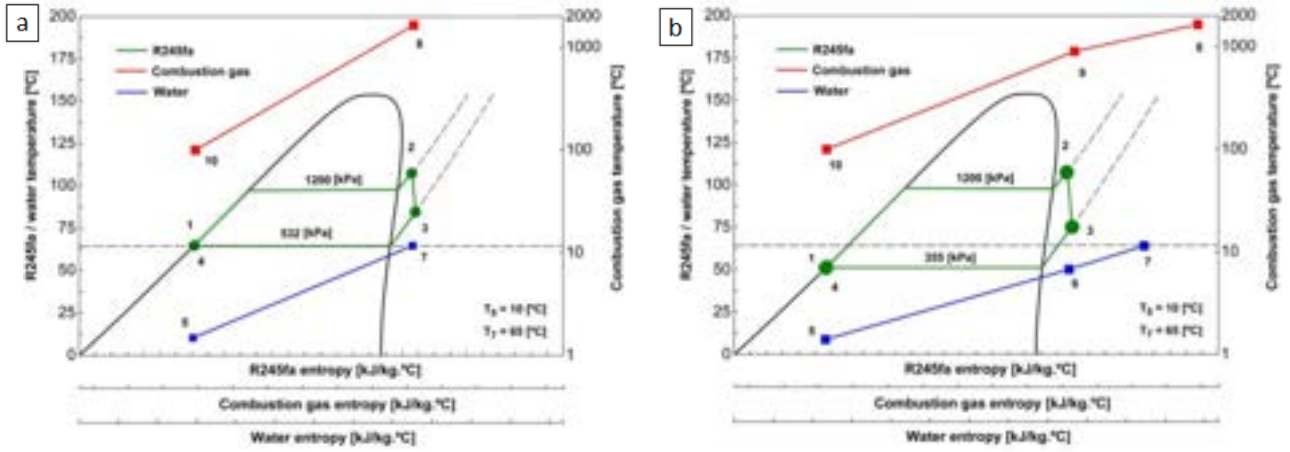

Figure 3: T-s diagrams of R245fa ORC-based CHP configurations: a) standard and b) hybrid

In this configuration, the amount of energy transferred to the water in the post-heating section is an additional design parameter that needs to be analyzed. This parameter can be defined by equation (1) where θ can be seen as the fraction of the water heating process that is done in the water post-heating section of the ORC-evaporator. To perform such analysis, a physical model, where all the main ORC components are considered working on their nominal conditions, was developed using Matlab® and REFPROP thermodynamic database [22]. The model assumes no heat or pressure losses as well as neglects the electro-mechanical inefficiencies for both the pump and expander generator.

$$\theta = \frac{T_7 - T_6}{T_7 - T_5} \times 100 \qquad (1)$$

The input parameters of this model, with the values used or the intervals within they are allowed to vary (in case of a parametric analysis), are listed in Table 1. Within the list of the input parameters is the water post-heating fraction (θ), defined by equation (1), which can be seen as the fraction of the water heating process that is done in the ORC-evaporator water post-heating section. A value of $\theta = 0\%$ refers to a standard CHP system in which all the water heating process occurs in the ORC condenser, while a value of $\theta = 100\%$ refers to a situation in which there is no cogeneration, or the ORC system is not working.

Table 1. Input parameters of the CHP physical model (based on [21]).

Model parameter	Symbol	Units	Value
Working fluid	-	-	R245fa
Expander isentropic efficiency	η_T	%	0,75
Pump isentropic efficiency	η_P	%	0,5
Condenser efficiency	η_{CHE}	%	0,98
Evaporator efficiency	η_{EHE}	%	0,9
Maximum ORC pressure	p_{max}	kPa	1200
Working fluid superheating degree	ΔT_2	^oC	10
Water pressure	p_w	kPa	300
CHP inlet water temperature	T_5	^oC	10 [a]
CHP outlet water temperature	T_7	^oC	65 [a]
Water post-heating fraction	θ	%	$[0, 50]$
End-user thermal power demand	Q_w	kW	25
Atmospheric pressure	p_{atm}	kPa	101,325
Combustion gases adiabatic flame temperature	T_{flame}	^oC	1540 [b]
Combustion gases' mass flow rate	$\dot{m}_{cg}$	kg/s	0,0137 [b]
Combustion products' mass fraction	m'_{cg_j} [c]	kg_j/kg_{fuel} [c]	[b, d]

[a] Isolated values were used to simulate a specific CHP operating condition (in accordance with the standard [23]) while the intervals were used to perform a system's parametric analysis. [b] The presented values were obtained for the complete combustion of natural gas with 30% of the excess air (according to the gas-burner manufacturer recommendation as shown in section 2.3). [c] $j = \{CO_2;\ H_2O;\ O_2;\ N_2\}$. [d] $\{m'_{cg,CO_2} = 0{,}123;\ m'_{cg,H_2O} = 0{,}093\ ; m'_{cg,N_2} = 0{,}734; m'_{cg,O_2} = 0{,}051\}$.

The way how the properties of the working fluid, the water or the combustion gases are evaluated at each of the CHP key points is presented in Table 2. To avoid problems related to the pinch-point in the ORC-condenser, the model assumes that the condensing temperature is limited (inferiorly) by the water temperature at the ORC-condenser exit (see Table 2 where, for point 3, at the expander exit, the pressure is equal to the saturation value defined by the water temperature at the condenser exit, point 6). The knowledge of the enthalpy at those key points allows solving the energy balance equations as they are shown, for each of the CHP main components, in Table 3 from which the CHP behaviour can be inferred and the usual performance indicators can be obtained.

Table 2. Evaluation of the thermodynamic properties at different CHP key points.

# [a]	$p\ [kPa]$	T [°C]	$h\ [kJ/kg]$	$s\ [kJ/kg]$	State [b]

[a] In accordance with Figure 2. [b] CL – Compressed liquid; SL - Saturated liquid; SH – Superheated vapour. [c] Correspond to an intermediate calculation for the isentropic thermodynamic condition.

Table 3. Power balance equations of the CHP system.

CHP component [a]	Stream	Power balance
Pump	ORC working fluid	$\dot{W}_{in} = \dot{m}_f \times (h_1 - h_4)$
Working fluid heating section (ORC-evaporator)	ORC working fluid	$\dot{Q}_{in} = \dot{m}_f \times (h_2 - h_1)$
	Combustion gases	$\dot{Q}_{cg_f} = \left(\dot{m}_{cg} \times (h_9 - h_{10})\right)/\eta_{EHE}$
Water post-heating section (ORC-evaporator)	Water	$\dot{Q}_{w_{PH}} = \dot{m}_w \times (h_7 - h_6)$
	Combustion gases	$\dot{Q}_{cg_{PH}} = \left(\dot{m}_{cg} \times (h_8 - h_9)\right)/\eta_{EHE}$
Expander	ORC working fluid	$\dot{W}_{out} = \dot{m}_f \times (h_2 - h_3)$
Condenser	ORC working fluid	$\dot{Q}_{out} = \dot{Q}_{w_{CHE}}/\eta_{CHE}$
	Water	$\dot{Q}_{w_{CHE}} = \dot{m}_w \times (h_6 - h_5)$
Hybrid CHP system	Natural gas/air mixture	$\dot{Q}_{CHP} = \dot{Q}_{cg_f} + \dot{Q}_{cg_{PH}}$
	Water	$\dot{m}_w = \dot{Q}_w/(h_7 - h_5)$
	ORC working fluid	$\dot{m}_f = \dot{Q}_{out}/(h_3 - h_4)$

[a] In accordance with Figure 2.

Among these indicators are the ORC efficiency (η_{ORC}), defined as shown in equation (2), the ORC net power output ($\dot{W}_{net}$), see equation (3), and the Primary Energy Savings (PES), as defined by the EU directive [24], that can be calculated using equation (4). In this, η_{REF_H} and η_{REF_E} are the harmonized efficiency reference value for separate production of heat (for the purpose of this paper was assumed 0,9 considering that the thermal energy produced is in the form of hot water from a natural-gas boiler manufactured before 2016 [25]) and the harmonized efficiency reference value for separate production of electricity (for this paper was assumed 0,445, considering that the electrical energy is produced in a natural-gas fueled power plant built before 2012 and an aggregated correction factor that includes the climatic specificities and the grid losses for low-voltage level end-users [25]). The values of η_{CHP_H} and η_{CHP_E}, that represents the thermal and electrical efficiencies of the CHP systems, respectively, are calculated by equation (5). Besides that, two non-dimensional parameters, the $rPES$ and the $r\dot{W}_{net}$, that relate the values obtained for the hybrid configuration (CHP system with $\theta \neq 0\%$) with those obtained for the standard configuration (CHP system with $\theta = 0\%$), see equation (6), and the reduction of the combustion gases temperature associated with the energy transfer in the water post-heating section of the ORC-evaporator ($T_8 - T_9$), are also retrieved from the model.

$$\eta_{ORC} = \frac{\dot{W}_{out} - \dot{W}_{in}}{\dot{Q}_{in}} \times 100 \quad (2)$$

$$\dot{W}_{net} = \dot{W}_{out} - \dot{W}_{in} \quad (3)$$

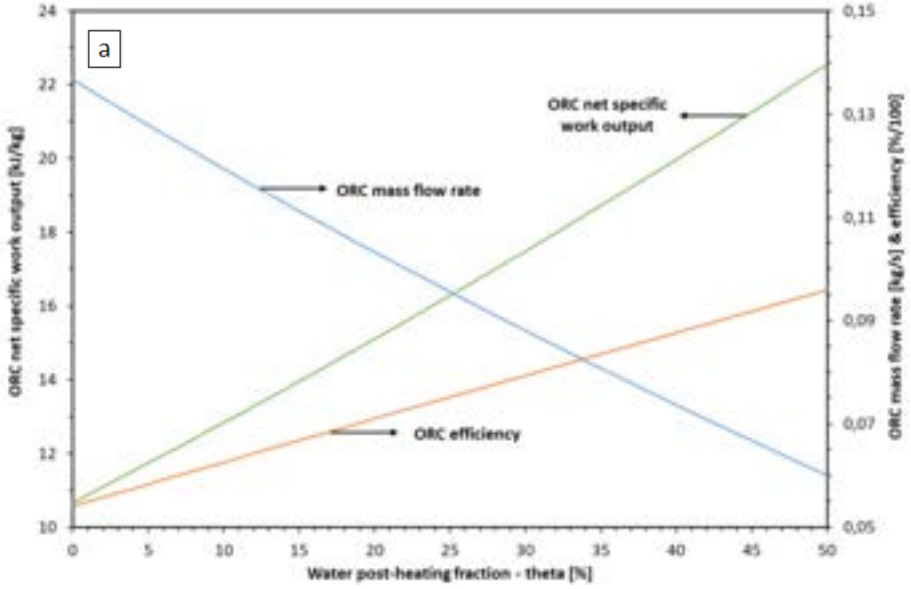
$$PES = \left(1 - \left(\frac{1}{\left(\frac{\eta_{CHP_H}}{\eta_{REF_H}} + \frac{\eta_{CHP_E}}{\eta_{REF_E}}\right)}\right)\right) \times 100 \quad (4)$$

$$\eta_{CHP_H} = \frac{\dot{Q}_{wPH} + \dot{Q}_{wCHE}}{\dot{Q}_{CHP}}, \qquad \eta_{CHP_E} = \frac{\dot{W}_{out} - \dot{W}_{in}}{\dot{Q}_{CHP}} \quad (5)$$

$$rPES = \frac{PES\ (\theta)}{PES\ (\theta = 0)}, \qquad r\dot{W}_{net} = \frac{\dot{W}_{net}(\theta)}{\dot{W}_{net}(\theta = 0)} \quad (6)$$

4. Model results

The variation's effect of θ over the net specific work, the efficiency (η_{ORC}) and the organic fluid mass flow rate ($\dot{m}_f$) is shown in Figure 4-a. As expected, mainly due to the increase of the pressure difference in the working fluid when passing through the expander, the net specific work and the efficiency increased with θ. However, since an increasing part of the water heating process is shifted from the ORC condenser to the post-heating section, an inevitable reduction of the working fluid mass flow rate is observed. The non-despicable result of these antagonistic variations is presented in Figure 4-b, where the values of the primary energy savings (PES) and the ORC net power output ($\dot{W}_{net}$) are shown as a function of θ. The maximum positive variations of PES and $\dot{W}_{net}$ are 23% and 7% for values of θ equal to 33% and 21%, respectively. The shifting of part of the water heating process from the ORC condenser to the post-heating section of the ORC-evaporator allows for solving a safety issue that will permit the adoption of a compact ORC-evaporator design and also induces positive effects in the CHP performance increasing not only the efficiency (an increase of PES) and economic (an increase of $\dot{W}_{net}$) figures in comparison with the standard configuration (for which $\theta = 0\%$).



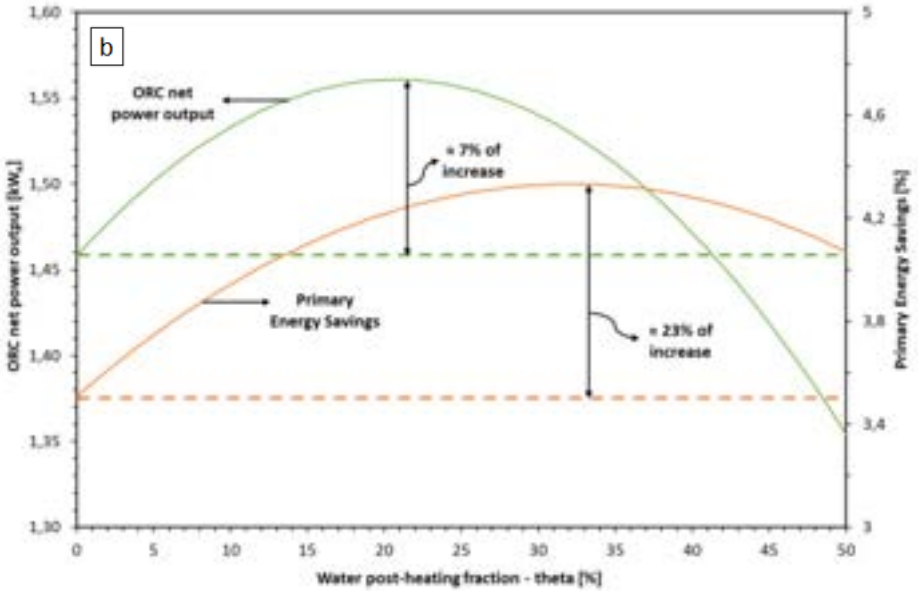


Figure 4: a) ORC net specific work, $\dot{m}_f$ and η_{ORC} as function of θ, b) PES and $\dot{W}_{net}$ as function of θ.

Moreover, the proposed hybrid configuration presents an additional advantage of reducing the risk of organic fluid thermal degradation that arises from a significant temperature reduction of the combustion gases on their passage through the water post-heating section of the ORC-evaporator. The temperature reduction for the value of θ that maximizes PES is about 420 ºC and for the value of θ that maximizes $\dot{W}_{net}$ is about 260 ºC. It is also important to mention that this value can be increased without any efficiency or net power output losses regarding the standard CHP configuration ($\theta = 0\%$) to more than 500 ºC if θ is increased to around 41%, as shown in Figure 5.

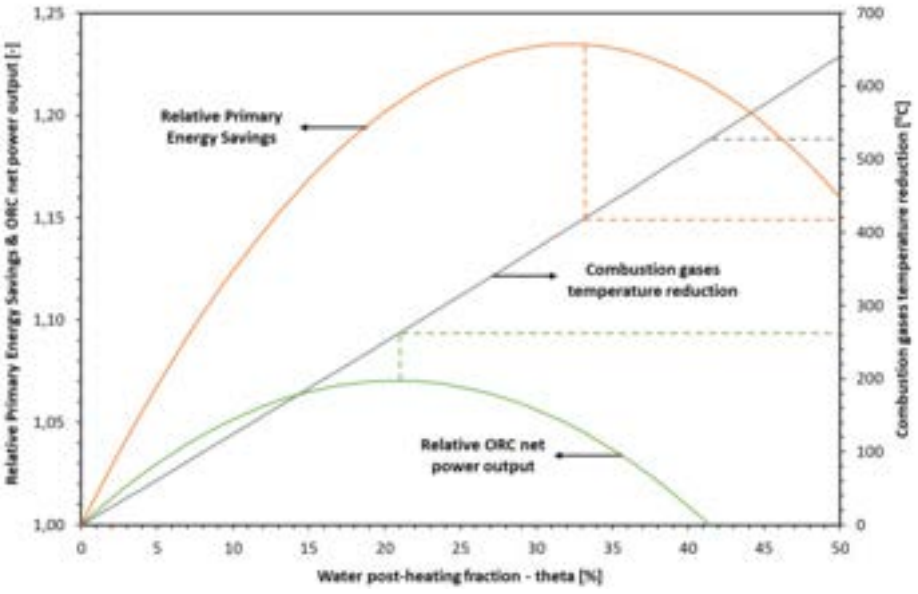

Figure 5: Relative value of $PES\ /\ \dot{W}_{net}$ and combustion gases temperature reduction as a function of θ.

5. Conclusion

The development of ORC-based micro-CHP systems aiming to retrofit the current combi-boilers demands small dimensions, high efficiency and high turn-down ratio evaporators. To achieve such requirements, the design principles of those ORC-evaporators should include: i) direct vaporization, ii) counter-flow arrangement and iii) pre-mixed gas burners. A solution for an ORC-evaporator accomplishing these specifications was presented. That solution showed the need for a cold surrounding on the gas-burner head. This last design principle led to the development of an ORC-evaporator where part of the energy contained in the combustion gases is transferred to the water before they reach the ORC working fluid heat exchanger. The integration of such ORC-evaporator in the CHP system gave origin to a hybrid configuration in which the useful thermal energy transferred to the water is done stepwise: firstly, in the ORC-condenser and then in

the water post-heating section of the ORC-evaporator. Such configuration, since it reduces the average temperature at the ORC-condenser, increases the cycle efficiency and the net specific work mainly because it increases the pressure ratio of the ORC cycle. Even taking into consideration the negative effect of the associated working fluid mass flow rate reduction, for a significant part of the CHP typical operating conditions, an increase of the primary energy savings by 23% and of the ORC net power output by 7% for values of θ equal to 33% and 21%, respectively, are shown for one of the most characteristic CHP operating condition (T_5 = 10 ºC, T_7 = 65 ºC). Furthermore, and for the same operating condition, the temperature reduction of the combustion gases in the water post-heating section of the ORC-evaporator can be as high as 520 ºC without no losses in the primary energy savings or the ORC net power output. This temperature reduction can help prevent, in a significant way, the occurrence of one of the major concerns associated with the direct vaporization of the ORC working fluid: the risk of thermal degradation. Therefore, the fraction of the CHP water heating process performed in the post-heater becomes a new design parameter that needs to be considered not only for the ORC-evaporator but for all of the CHP components which must be accordingly selected or designed.

The integration of part of the CHP water heating process in the ORC-evaporator led to a hybrid (topping/bottoming) configuration that not only solves a safety issue related to the gas-burner head overheating but also brings several (non-despicable) performance benefits and important reliability improvements for systems attempting to retrofit the current combi-boilers. Besides, this hybrid configuration applies to all the situations where the difference between the temperature of hot and cold sources is smaller as when water from non-pressurized biomass (or other fuels) boilers is used to power those CHP systems.

Nomenclature

h	Enthalpy, kJ/kg	EHE	ORC-Evaporator
θ	Tetha, %	f	ORC working fluid
η	Efficiency, %	flame	Combustion flame conditions
$\dot{m}$	Mass flow rate, kg/s	fuel	Related to the fuel used
$\dot{Q}$	Thermal power, kW	H	Thermal reference
$\dot{W}$	ORC power output, kW_e	*s*	Isentropic
m'	Mass fraction, kg_i/kg_{fuel}	in	Inlet conditions
PES	Primary Energy Savings, %	max	Maximum value
T	Temperature, ℃	Net	Net value
p	Pressure, kPa	ORC	Organic Rankine cycle system
$r\dot{W}_{net}$	Relative ORC net power output -	out	Outlet conditions
$rPES$	Relative Primary Energy Savings, -	P	ORC-Pump
s	Entropy, $kJ/(kg.℃)$	PH	Post heater
x	Quality, -	REF	Reference value
$\Delta T2$	Superheating temperature, ℃	T	ORC-Expander
		w	End-user water circuit
Subscripts and superscripts			
$\{1 \dots 10\}$	CHP locations	***Acronym***	
atm	Atmospheric conditions	CHP	Combined heat and power
cg	Combustion gases	EU	European Union
CHE	ORC-Condenser	GHG	Greenhouse gases
CHP	Combined heat and power system	HVAC	Heating, ventilation and air conditioning
E	Electrical reference	ORC	Organic Rankine Cycle

Abstract:
Current environmental goals to reduce greenhouse gas emissions impose a challenging thermal design scenario for power generation equipment in oil platforms. The low thermal efficiency seen in gas turbines and the large amount of wasted heat at plant systems are elements that need to be addressed in the next few years. In this context, the application of organic Rankine cycles (ORC) in oil platforms has been studied. However, given the intrinsic characteristics of the power plant and processing systems onboard, the ORC design must consider not only the thermal aspects, but also the operational conditions. In this paper, an ORC design methodology based on a fuzzy and particle swarm-based optimization algorithm (HORCAT) is proposed, where the design variables are the geometric parameters of the equipment and the organic working fluid. In addition, the generated designs are evaluated under part load conditions. Aiming at the simultaneous maximization of the ORC electrical power output and the minimization of the equipment volume, this method is applied for the ORC design for waste heat recovery from the exhaust gas of a GE LM2500+ gas turbine, whose model was calibrated accordingly with the performance of an equipment operating in an FPSO at the Brazilian Pre-salt. The results were evaluated from two perspectives: at a suboptimal condition and considering a highly optimized Pareto front. Although the former returned configurations that led to a maximum power output of 4.1 MW, 4 different working fluids and a large overall volume of the equipment, some solutions were not valid under partial loads. The results of the latter, all operating with toluene, were robust under part loads. Although the maximum electric power output was of 1.97 MW, all results remained valid and its thermal efficiency was not lower than 24% for all cases.

Keywords:
organic Rankine cycles, multi-objective optimization, particle swarm optimization, thermal design.

1. Introduction

The low thermal efficiency of power systems operating on oil platforms is a well-known challenge that has been evaluated over the years [1] [2]. Although this concern has been studied from a technical and economical perspective, today the solution of this problem has become mandatory, given its social and environmental impacts [3].

Taking into account the variety of equipment and thermal systems operating on the platforms, there are multiple sources of losses and, in addition, multiple options to increase the efficiency. From a detailed exergetic model of a North Sea platform, [4] identified the main sources of exergy destruction, being the loss at the gas turbine the most prominent, contributing with almost 50% of the total exergy destruction of the platform. The work of [5] presented the measurement of efficiencies at the main subsystems of four platforms operating in the North and Norwegian Seas. In addition, options for design and waste heat recovery were evaluated. The authors identified low thermal efficiencies in gas turbines, primarily due to their operation at partial loads. The authors also investigated WHR systems to be applied to the platform equipment studied, including an LM-2500 power plant. With focus given on the compression systems, the work of [6] presents a detailed review on the exergy destruction in a FPSO operating in Brazil. The study shows that the compressor system rearrangement could lead up to a reduction of 39% in the power consumption.

Therefore, gas turbines operating at oil platforms power plants offer an excellent opportunity to increase efficiency [7], given their typical operation at part loads and the massive exergy destruction seen in exhaust gases. Although heat recovery from these gases is an evident option for efficiency increase, the space for implementing the typical solutions such as HRSGs is extremely limited in platforms.

In this scenario, ORCs can be a preferable option, due to their smaller footprint and high flexibility in terms of design and working fluids. Reckoning with the need to increase the efficiency and reduce the footprint of the

power plant, multi-objective optimization techniques have been applied to the design of the system. Having as reference the power plant in a FPSO operating at Santos Basin, Brazil, [8] apply ORCs for the heat recovery of gas turbines. By using a model of the power plant and applying a genetic algorithm for optimization, the results obtained show that it would be possible to operate with only two gas turbines (instead of the original three) and achieve a maximum thermal efficiency of 47.3%. In their work, [9] developed a complete design methodology for ORCs for gas turbine WHR , taking into consideration its dynamic behavior and a multi-objective optimization is applied to generate potential designs. Also using multi-objective optimization, [10] used a combine heat a power unit at a platform operating in the Norwegian Sea for WHR at the gas turbines exhaust.

Considering the challenges in designing and applying ORC to real-life offshore conditions, this paper presents a new ORC design methodology based on a multi-objective optimization performed by a fuzzy-PSO algorithm. The algorithm is applied for the ORC design and waste heat recovery from a GE LM2500+ gas turbine with the typical configuration found in Brazilian FPSOs. Furthermore, the analysis is made by considering not only the gas turbine full load condition, but also its part load operation.

2. Methodology

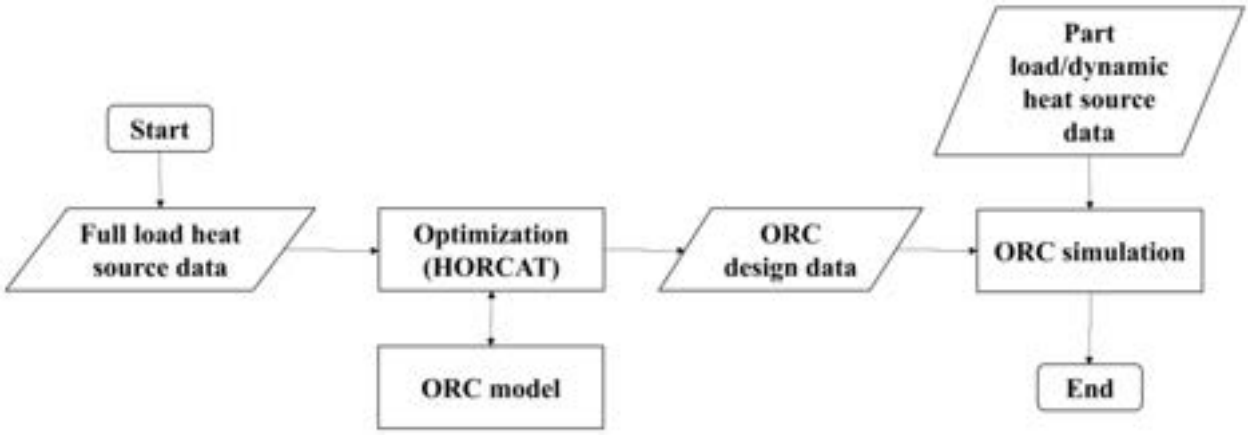
2.1. Overview

Since the methodology presented here was implemented in an ORC design computational system, it is important, firstly, to present and discuss its overall design process, which is shown in Figure 1. Initially, the parameters for the analysis are defined, including:

- The conditions of the heat source: if the data come from a model of data is read; if it operates at part or full load.
- The optimization constraints and limits for the optimized parameters.
- The optimization system parameters: number of iterations, population size, and particle swarm constants (initial values).

In the case presented in this work, the heat source model simulates a GE LM2500+ gas turbine, taking into account data from a real life equipment used for power generation in an FPSO [11]. Therefore, once the data from the heat source are available, the optimization system – HORCAT[1] – runs the design. The ORC model acts as an objective function that calculates the cycle thermal performance and returns the heat exchanger volume and the Rankine cycle electric power as outputs. Once the ORC design data have been defined, the proposed designs are evaluated and compared, given the part load data from the heat source. In the next subsections, HORCAT and the ORC model will be discussed in detail. In the case here studied, the ORC recovers heat from a single gas turbine.

Figure 1: Overall process of optimization and calculation for the ORC design.



The system was fully implemented in Python and the thermal properties are calculated using the CoolProp library [12].

The approach presented here is novel due to the application of a tailor-made optimization methodology for thermal systems. Notably, the use of part-load conditions to validate the optimization results, i.e., the proposed designs, is a new approach for the selection of ORC plants to be applied offshore.

[1] HORCAT - Hunting ORCs with *Asa-de-Telha*: *asa-de-telha* is the name in Portuguese for the Harris's hawk, a very common hawk in Brazil, which has the unusual characteristic of hunting in cooperative packs.

The approach here presented is novel due to the application of such optimization methodology and a tailor-made algorithm to thermal systems. Most conspicuously, the use of the part load conditions to validate the optimization results (i.e., the proposed designs) is a new approach for the selection of ORC plants to be applied offshore.

2.2. The optimization algorithm: HORCAT

The optimization-based design method applied to complex models such as the ORC model described in this work demands an algorithm that can deal with a highly nonlinear objective function, from which it is impossible to calculate its Jacobian or Hessian matrices and whose domain cannot be properly defined. This is a situation where heuristic optimization methods are typically employed [13]. Most specifically, due to its lightweight calculations and suitability to complex systems [14], the particle swarm method [15] is used as the core of HORCAT.

Two swarms (packs) are used, one for each objective to be evaluated, which means that, given the vector of objective functions, each pack optimizes a single function f_i, being

$$f(\overline{x}) = [f_1(\overline{x}), f_2(\overline{x}), \ldots, f_n(\overline{x})], \tag{1}$$

and

$$\overline{x} = [x_1, x_2, \ldots, x_m], \tag{2}$$

is the design vector.

Moreover, each pack cooperates in the global search by sharing the same results of "Elite" (Pareto optimal set) that, at the end of the search, comprise the Pareto front. In the specific case of the ORC design, two objective functions are calculated: the global equipment volume and the electric power output from the steam turbine, hence,

$$f(\overline{x}) = \left[Vol(\overline{x}), \dot{W}_{ST}(\overline{x})\right] \tag{3}$$

and

$$\overline{x} = [\text{fluid}, A_{ST}, p_{10}, L_{OTB}, A_C]. \tag{4}$$

Initially, Elite is defined as a matrix containing the best results,

$$\overline{E} = \begin{bmatrix} Vol_{1,1} & \dot{W}_{ST1,2} \\ Vol_{2,1} & \dot{W}_{ST2,2} \\ \vdots & \vdots \\ Vol_{m,1} & \dot{W}_{STm,2} \end{bmatrix}, \tag{5}$$

each result (f_k) from an evaluated design (an element of the pack, $\overline{x}_k$) is compared with each element of Elite. If f_k Pareto dominates any element of $\overline{E}$, this specific element is replaced by f_k elements, i.e., given

$$f(\overline{x}_k) = \left[Vol(\overline{x}_k), \dot{W}_{ST}(\overline{x}_k)\right], \tag{6}$$

if $Vol(\overline{x}_k) < \overline{E}(j,1)$ and $\dot{W}_{ST}(\overline{x}_k) > \overline{E}(j,2)$, then $\overline{E}(j,1) = Vol(\overline{x}_k)$ and $\overline{E}(j,2) = \dot{W}_{ST}(\overline{x}_k)$.

To prevent the results of the packs to stop converging to the best solutions, a Fuzzy Logic System (FLS) is coupled to the optimization loop. The aim is to dynamically change the PSO parameters (ω, c_1 and c_2) used to calculate the velocity of the particles, as shown in equation (7). This adjustment allows for a better balance between the particle best and the global best since it is fitted accordingly with the results already found.

$$v_i(t+1) = \omega v_i(t) + c_1 r_1 (\pi_i(t) - x_i(t)) + c_2 r_2 (\pi_G - x_i(t)). \tag{7}$$

If no change in the Elite is observed after a certain number of iterations, even with the action of the FLS, the entire population is replaced. Figure 2 presents an overview of HORCAT's components and its functional behavior.

Figure 2: HORCAT's optimization flowchart.

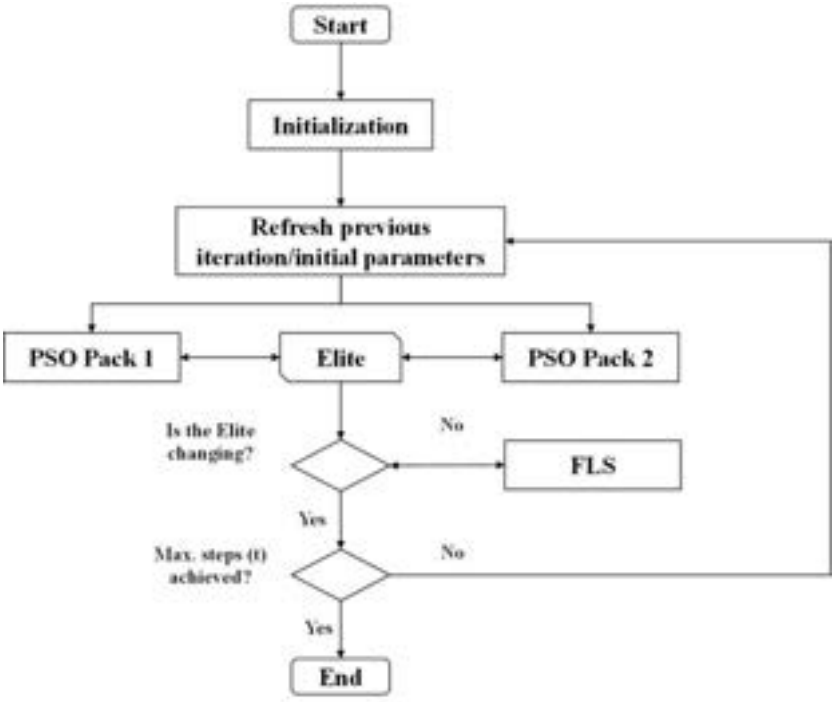


Figure 3: ORC equipment arrangement.

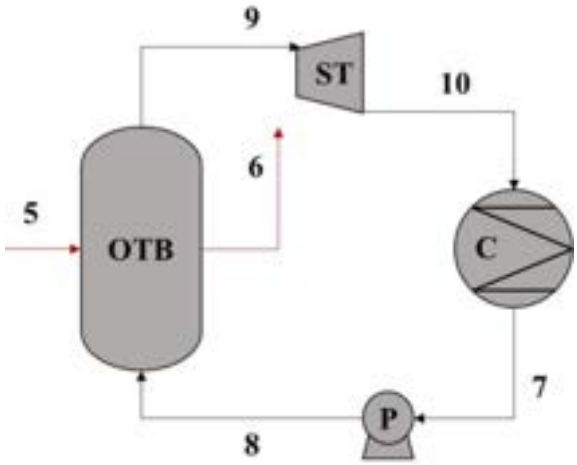


2.3. The ORC model

Given the design variables generated by HORCAT, the ORC thermal performance is calculated for each individual in the pack. The ORC arrangement is composed by an once-through boiler, a steam turbine, a condenser, and a pump, as presented in Figure 3. In general, mass and energy conservation equations are applied to each of these components. Constitutive equations are applied as discussed below.

The steam turbine model is based on the choked-nozzle model proposed by [16], where the mass flow rate at the inlet is given by,

$$\dot{m} = \rho_T a_T A_{ST}. \tag{8}$$

The electric power output and the isentropic efficiency are given by equations 9 and 10.

$$\dot{W_{ST}} = \dot{m}(h_9 - h_{10})\eta_M \tag{9}$$

$$\eta_{ST} = \frac{h_9 - h_{10}}{h_9 - h_{10s}} \tag{10}$$

The OTB model considers a two-step calculation. First, the NTU model is applied for the thermal calculation. The shell-and-tube heat exchanger design methodology presented by [17] and [18] is then applied to calculate the geometric parameters of the once-through boiler.

For a heat exchanger composed of finned tubes and in cross flow, the overall heat transfer coefficient and the effectiveness are calculated by [19]:

$$U_{global} = \beta \dot{m}_5^{\alpha}, \tag{11}$$

$$\varepsilon = 1 - exp\left\{\left(\frac{NTU^{0.22}}{C_r}\right)\left[-1 + exp\left(-C_r NTU^{0.78}\right)\right]\right\}, \tag{12}$$

where,

$$NTU = \frac{U_{global} A_{OTB}}{C_{min}} \tag{13}$$

and,

$$C_r = \frac{C_{min}}{C_{max}}. \tag{14}$$

Therefore, the energy balance is given by:

$$\dot{Q}_{max} = C_{min}\left(T_5 - T_8\right), \tag{15}$$

$$\dot{Q}_{OTB} = \varepsilon \dot{Q}_{max}. \tag{16}$$

For the pump, a simple fixed efficiency model is adopted, and for the condenser, a constant shell temperature model is applied.

3. Results and discussion

3.1. HORCAT validation

HORCAT was implemented following a novel approach in terms of methodology and application. Hence, before applying the algorithm to a thermal optimization and design problem, it was necessary to validate its robustness and suitability for the optimization of complex objective functions. Therefore, objective functions given in the literature to test multi-objective optimization algorithms were used, allowing the evaluation of the algorithm effectiveness when dealing with highly nonlinear conditions and non-continuous domains. Then, two test functions were applied: the (A) Binh & Korn function [20]; and (B) the Zitzler τ_1 function [21]. For the latter, the reference results were taken from Maghawry et al. [22].

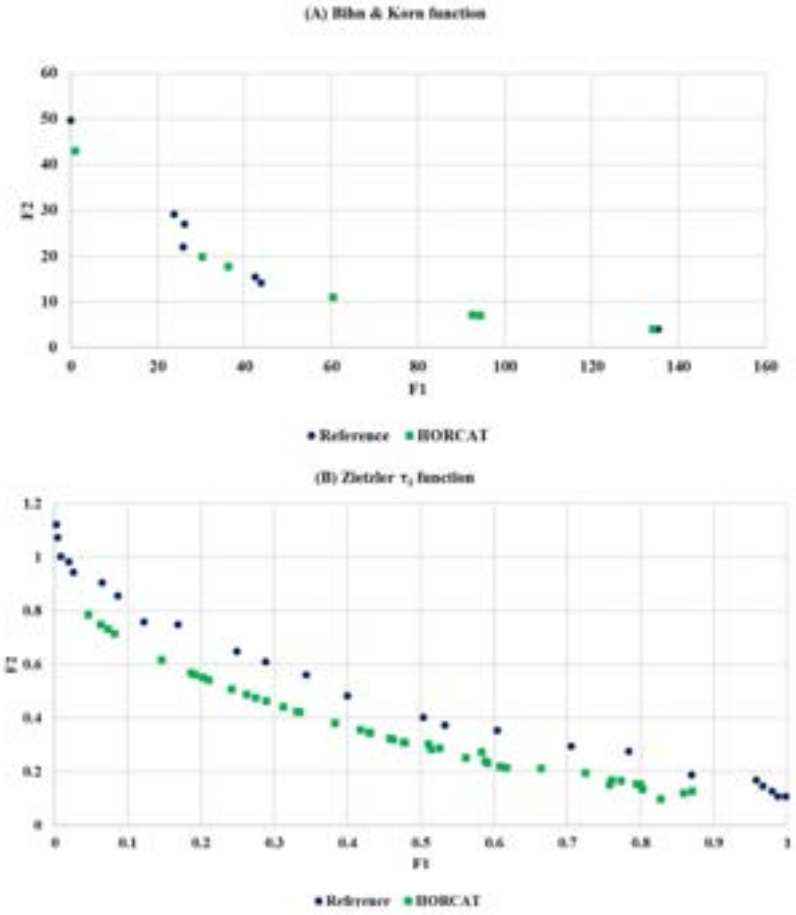
Figure 4 shows the optimization results , given in terms of Pareto fronts for both functions. It is important to mention that HORCAT discards similar designs, which leads to sparse Pareto fronts, but actual unique solutions. For both cases, HORCAT optimized results were similar (or even better) than the references given in literature. From the results obtained, it could be seen that the algorithm provides an effective optimization and is comparable with other algorithms given in the literature.

3.2. ORC design at full load

To generate ORC designs considering the gas turbine full load condition, the HORCAT setup considered two packs of 100 individuals. Two scenarios of results are shown in Figure 5: (A) after 3 iterations and (B) after 30 iterations.

In scenario (A), 10 valid designs were generated and, of a total of 18 organic fluids available for selection, only 4 resulted in the valid ORC designs. In this suboptimal condition, a wide ORC electrical power range (1.2 - 4.1 MW) can be seen, however, with large and unfeasible equipment volumes. There is a sensitive change in these conditions in scenario (B), where the effects of Pareto domination can be seen after several iterations and a higher power/volume ratio is obtained. In scenario (A), only toluene results as a valid design working

Figure 4: HORCAT validation against test functions.



fluid. In scenario (B), 16 valid designs were generated, with an ORC electric power range from 489 kW to 1.97 MW, which can lead to an increase of more than 8% in the power output when considering the gas turbine and the ORC combined. Furthermore, the Rankine cycle thermal efficiency of these valid designs is in the range 27-29%. The effect of Pareto dominance is evident when comparing scenarios (A) and (B). First, the lower number of valid designs in scenario (A) is a consequence of insufficient iterations so that the HORCAT packs were still unable to find a broader number of solutions that makes sense in terms of thermodynamic validity. As the number of iterations increases, more solutions are found in scenario (B). These solutions Pareto-dominate those found in scenario (A) and, additionally, there is a clear and expected migration of the Pareto front to the bottom (lower equipment volume) and to the right (lower power output) .

3.3. Comparative analysis of part load and design conditions

To test the ORC designs generated in scenarios (A) and (B) in load conditions typically found in FPSOs, the proposed solutions were simulated under part load conditions (50 and 75%) of the gas turbine. Figure 6 presents the Pareto fronts for scenario (A). Under part load conditions, the valid designs dropped from 10 to 8 cases, since the ORCs operating with n-dodecane were not able to operate at lower temperatures and remain thermodynamically feasible, given the geometry of the components that were designed for the full-load condition.

Regarding thermal efficiency, as seen in Figure 7, there is a significant drop under part loads for all fluids, with toluene having the lowest variation. It is important to highlight the case 5 as one example where the full load condition could not bring about a better solution. Although it presents the higher efficiency at full load, it also has the second worst performance at 50% load.

Comparative analysis considering part loads applied for scenario (B) returned more stable conditions compared to scenario (A). The number of solutions found after 30 iterations at full load did not drop under part load conditions, which can be explained by two factors: the highly optimized solutions and the suitability of toluene under such conditions. Figure 8 shows the Pareto fronts for each condition.

Moreover, as seen in Figure 9, the thermal efficiencies found for all cases remain high even under partial loads.

Figure 5: Optimization results for the ORC design considering only the gas turbine at full load. Scenario (A) is given after 3 iterations (valid designs for 4 working fluids) and scenario (B) after 30 iterations (only toluene resulting as working fluid).

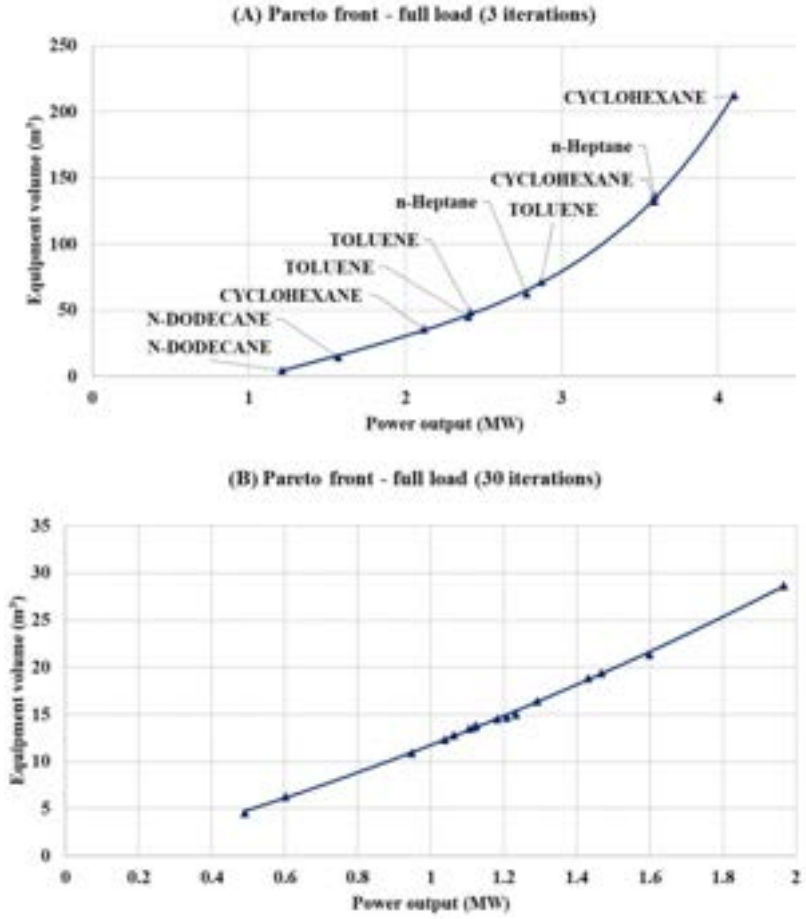


Figure 6: Pareto fronts for the scenario (A) proposed designs under the gas turbine loads of 50%, 75% and 100%.

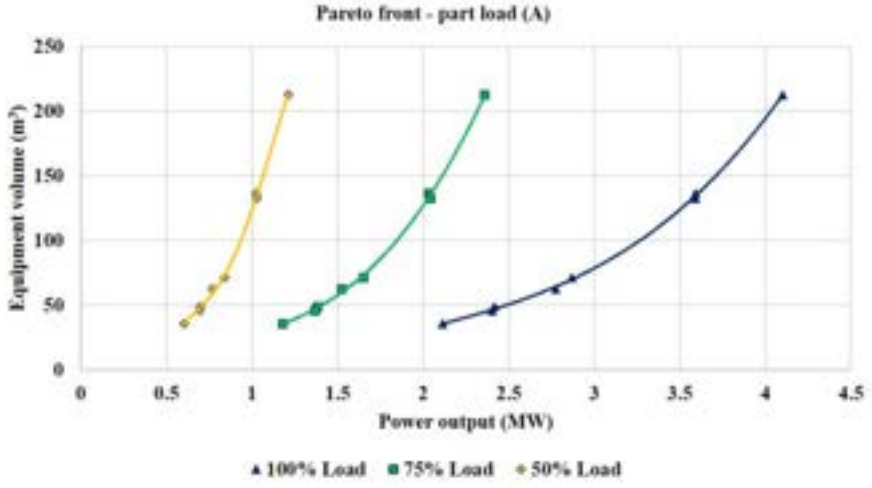

4. Conclusion

This work presented a new ORC design methodology for waste heat recovery application, which applies a fuzzy-PSO algorithm to find valid designs through a multi-objective optimization. HORCAT, the optimization algorithm, was validated against literature benchmark functions and was able to deal with the specific characteristics of the ORC model to be optimized.

Figure 7: Thermal efficiencies for each valid design under part load conditions - scenario (A).

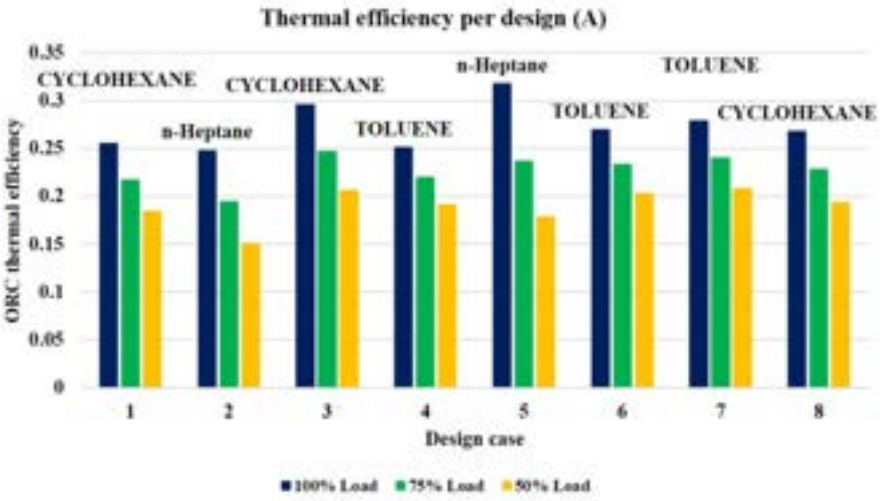

Figure 8: Pareto fronts for the scenario (B) proposed designs under the gas turbine loads of 50%, 75% and 100%.

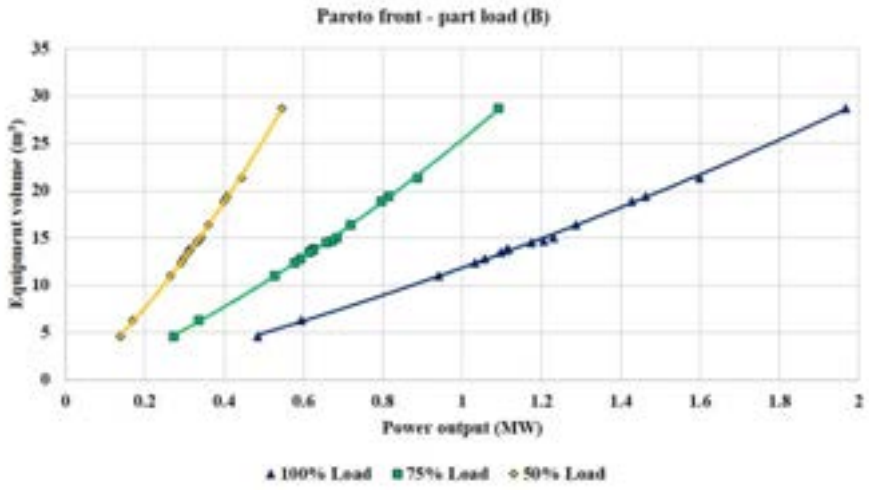

Figure 9: Thermal efficiencies for each valid design at part load conditions - scenario (B).

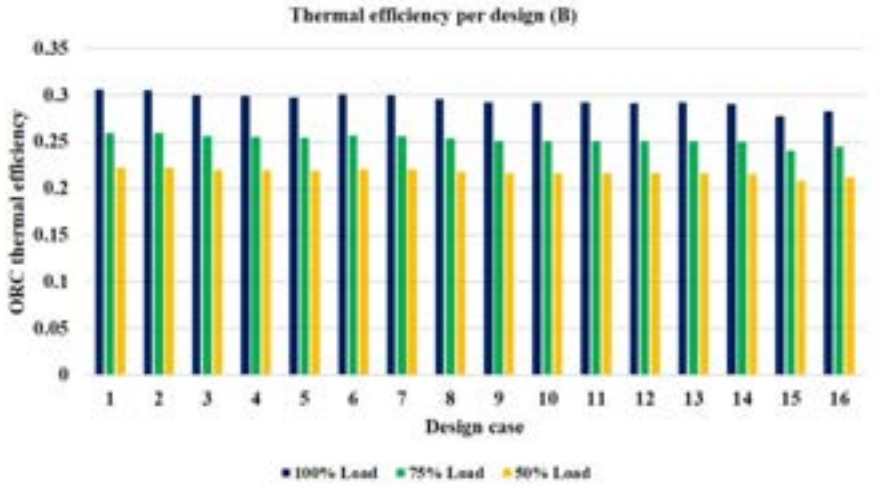

HORCAT was employed to provide optimized ORC designs for waste heat recovery from the exhaust gas of a gas turbine operating at an FPSO - using a single gas turbine coupled to a single Rankine cycle. To evaluate

the effect of suboptimal solutions on the thermal performance and, additionally, to analyze the impact of the part load operation of the given designs, the results were evaluated considering two scenarios: (A) after three iterations and (B) after 30 iterations.

In scenario (A), the results show that feasible ORC solutions decrease from 10 to 8 valid designs, when considering, respectively, the gas turbine at full and at partial loads. At full load, there were ORC designs providing up to 4.1 MW of electric power, however with an overall equipment volume that could make it impossible to be applied in FPSOs.

All the scenario (B) solutions were feasible at full and partial loads, showing that free optimization led to robust ORC designs. The electric power range of the solutions at full load for this scenario was from 489 kW to 1.97 MW, with a thermal efficiency range from 20 to 30%. Moreover, even at partial loads, the efficiency could be kept above 24% for all casess.

Finally, as verified in scenario (A), the analysis performed led to the conclusion that the full-load based design can provide unfeasible ORC solutions to oil rigs, most specifically because gas turbines at these facilities operate at part and unsteady load conditions. The approach proposed in this work shows that the optimal design needs also to consider both the near-optimal conditions and also part load scenarios in order to address the correct operational conditions at the platform.

Abstract:
To decarbonize our energy system, appropriate technology options must be established and applied at the right site. The investment decisions required for this are usually conducted based on techno-economic portfolio optimization. The presented research aims to optimize an energy system configuration for a district heating network of a global city located in Central Europe. The objective is to evaluate different configurations and determine the optimal combination for a fossil-free supply system. The energy system model is based on real district heating network data, including hydraulic restrictions, combined heat and power plants, heat-only boilers, heat storage, power-to-heat technologies, and fuel input options. Time series are heat demand, weather conditions, and exchange prices. Furthermore, investment costs and operating and maintenance costs are taken into account. Aristopy, a free and open-source Python-based framework, has been used to implement mixed-integer linear programming, which is solved by the state-of-the-art algorithm Gurobi. The model includes a time series aggregation to achieve accuracy and appropriate computation time. Multiple scenarios with different input data evaluate the robustness of each configuration. By assessing these configurations, the optimal system design is selected. The model succeeded in determining an optimal portfolio configuration and its operation. Simplification through time series aggregation has shown that the computation time can be shortened while providing the necessary accuracy. The scenario analysis shows the impact of the different input parameters and assumptions on portfolio planning. The presented methodology improves portfolio planning and operation of a real-world energy system. Simultaneously, license costs can be saved.

1. Introduction

The uncertainty and volatility of energy prices and fuel supplies have increased dramatically in recent developments within the energy market. This dynamic progress is also reflected in recent political and societal developments. The regulatory framework is an additional driver which impacts the operation and investments of power and heat generation units. The importance of scenario analysis is increasing due to the additional uncertainty. Optimization models are needed to find robust portfolios and analyze the impact of specific parameters. Within the presented research, the city, the district heating system, and the generation units under investigation are called by anonymous names.

In general, there are numerous research papers on energy system analysis, both on the level of methodological development and on the level of application-oriented research. Due to many works, only a relevant selection of overviews of the current state of research is compiled. DeCarolis et al. [1] conduct an extensive literature review to formalize best energy system optimization modeling practices. Kotzur et al. [2] note that many complexity drivers could be avoided a priori with a tailored model design. They review systematic complexity reduction methods for energy system optimization models and develop a guide for system modelers encountering computational limitations. Wirtz et al. [3] perform a comparison of different combinations of energy system model features: Piece-wise linear investment curves, multiple component resolution, minimum part-load limitations, part-load efficiencies, and start-up costs.

Decomposition approaches and approaches for optimization under uncertainty have also been proposed recently for energy system modeling. Wirtz et al. [4] present a Dantzig–Wolfe approach to decompose a mixed-integer linear program into multiple subproblems and a master problem. A realistic case study based on a district heating system was considered. They demonstrated that the proposed decomposition approach yields the same results attained by the original, not decomposed problem while achieving gains in scalability and computational times. Göke et al. [5] applied Benders decomposition to two-stage stochastic problems for energy planning with

multiple climatic years. With their approach they slightly increase solve time of the master-problem, but greatly reduce the number of iterations. Yue et al. [6] have identified four prevailing uncertainty approaches applied to energy system optimization models: Monte Carlo analysis, stochastic programming, robust optimization, and modeling to generate alternatives. They provided a critical appraisal of the use of these methods.

Studies focusing on the local district heating portfolio and dispatch optimization were published in the past. Jüdes et al. [7] and Christidis et al. [8] investigated the contribution of heat storage for the district heating network using large-scale optimization models developed and solved within the General Algebraic Modeling System (GAMS). The advantage of pressurized short-term heat storage for operating a district heating network was investigated by Hofmann et al. [9]. Gonzalez-Salazar et al. [10] present a district heating network portfolio optimization. Due to computation time restrictions, they use a merit order model instead of mixed-integer linear programming. Concerning the local portfolio of the city under investigation, it is clear that comprehensive portfolio analyses require further methodological development in model reduction while maintaining the same quality of results.

This research analyzes the energy system's behavior depending on the changing energy market scenarios. The purpose is to find a suitable optimization method with an appropriate computational load and framework to analyze different scenarios concerning the district heating grid and the future portfolio. Based on different input scenarios, portfolio options are presented, which can support investment planning.

The article is structured as follows: The next section summarizes the methods and tools applied here. The system analysis presents the technology options, input data, and boundary conditions taken into account. The portfolio optimization and sensitivity analysis results are discussed in Section 4., followed by the conclusions.

2. Methodology

2.1. Energy System Optimization

The current energy market is more volatile than ever, and the urge to transform the current energy system into a more climate-friendly portfolio is at its highest peak. Due to these reasons, it has become even more difficult for most energy suppliers to determine the future energy system configuration that fulfills economic and environmental objectives. Energy system optimization is an essential tool to address this challenge.

There are various approaches for energy system optimization depending on the question to be answered within the decision process. In all cases, the goal is to determine a set of decision variables so that the value of the objective function is maximized or minimized while fulfilling all constraints. The optimization objective can be the dispatch of individual generation units or a system configuration optimization where the entire grid is considered over the given period.

An overview of the available functionality and the specific advantages and disadvantages of the energy system modeling frameworks and open models are presented on the websites of the Open Energy Platform [11] or the Openmod Initiative [12]. Both platforms aim to actively exchange and initiate relevant energy system modeling topics, approaches, and data. Since the field of the energy system modeling is broadly diversified, and each tool has individual strengths and weaknesses, the community helps to enhance the quality and efficiency. In addition to those platforms, Groissböck [13] presents a general assessment of open-source energy system modeling.

This research uses the Python-based, objective-oriented framework Aristopy, which was developed under the research project "MINLP-Optimization of Design and Operation of Complex Energy Systems" and is presented in the following section.

2.2. Aristopy

Aristopy[1] is a free and open-source Python-based framework for the optimization of energy systems. In contrast to other frameworks, aristopy allows integrated time series aggregation methods that can be used directly within the model, see section 2.3. Aristopy uses the algebraic modeling language of Pyomo [14, 15]. The user can formulate individual restrictions and constraint which adapts to multiple programs such as LP, MILP, or MINLP. Various solvers can be utilized. For this research, the optimization problem has been solved using Gurobi [16]. For visualization of results, aristopy uses Plotter[2].

In aristopy, an optimization model is set up by creating the class EnergySystem. Within the class, five pre-defined components (Source, Sink, Conversion, Bus, Storage) can be used to describe different characteristics and behaviors of the energy system parts. All inputs and outputs of components are connected with a class Flow, which contains all variables and ensures energy transport. Figure 1 shows a simple illustration of an example energy system and the dependency of each component.

The Source component contains only one output, which provides fuel in the example. With the help of a Flow component, the fuel is transported to the Conversion component, where fuel is converted into thermal and

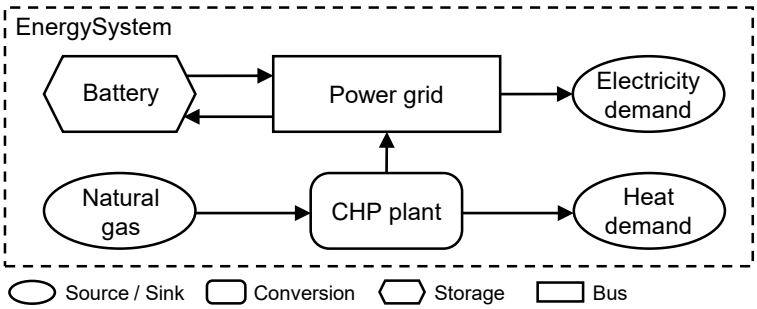

Figure 1: Simple example of generic model building using the class EnergySystem and the elementary component classes Source, Sink, Conversion, Bus, and Storage in the Python library aristopy. Translated adoption with permission from [17].

electrical energy. The energy flows are transported to a Bus component, where different streams of the same energy are gathered and transported to a Sink component. The Sink component, e.g., heat demand in the example, is the inverted component of Source. A Storage component (either battery or heat storage) can be added to the energy system, allowing more system flexibility. The storage can be directly integrated into the overall system or an individual grid by creating multiple Bus components.

Aristopy contains a particular class of photovoltaic or solar thermal collectors. An existing method from the Python library pvlib [18] is used for this. Furthermore, the built-in functions of add_variable, add_constraint, and add_objective_function_contribution are provided to add additional variables, constraints, and objective functions to the optimization model.

2.3. Time Series Aggregation

One of the biggest hurdles for an energy system optimization is the need to optimize numerous scenarios of possible future developments and the needed calculation time or computational capacity. Time series aggregation methods have been introduced for energy system optimization to reduce model complexity. Reviews are presented by Hoffmann et al. [19] and Teichgräber et al. [20]. This thesis uses the Python-based Time Series Aggregation Module (tsam) [21].

The concept of time series aggregation is to reduce an extensive and detailed data set into a representation with fewer time steps, ideally without loss of information by aggregating repetitive patterns. An appropriate method can reduce CPU and RAM requirements and make processing and analyzing extensive time series data sets efficient.

There are several time series aggregation methods. The most common is reducing the resolution by grouping the data into larger time intervals, from hourly time steps to days, weeks, or months. This method is called downsampling, which usually leads to underestimating the original times series' variances and the maximum and minimum values.

Besides the downsampling method, there is the segmentation method. It is a more complex but accurate method of aggregating time steps with similar characteristics to create an artificial time series replicating the original times series. There are different aggregation methods with their advantages and disadvantages. When this approach was introduced for energy system optimization, the heuristic method, where one representative day per month is selected, was a standard application. In the meantime, systematic aggregation methods are introduced, in which the time series is divided into particular periods of defined length and assigned to a cluster based on their similarity. The Euclidean distance function, see Eq. (1), is used to measure similarity. The equation is formulated for a one-dimensional distance where p and q represent two points on the real line.

$$d(p, q) = |p - q| \tag{1}$$

Three main methods exist to aggregate time series into groups with a single representative period. The most commonly used clustering method is the k-means algorithm. It belongs to the family of non-hierarchical cluster analysis methods where k random centroids are created in the feature space. All data points are assigned to the nearest centroid using the Euclidean distance function, which provides an initial cluster solution. Every data point is attached to one cluster, and the centroids are updated by finding the empirical mean of the features across all data points attached to that cluster. When the centroids are updated, the algorithm repeats the assignment of each data point to the next nearest (updated) centroid. The critical feature of a k-means algorithm is that the final centroids are not actual data points but a calculated mean of data points within that cluster.

Another algorithm called k-medoids chooses the final centroids from the actual data points, thereby allowing for greater interpretability of the cluster centers than in k-means. The "Partitioning Around Medoids" (PAM)

algorithm finalizes the point as a new centroid from the existing data points with a minimum loss. Besides k-means and k-medoid, there is the hierarchical clustering algorithm. In hierarchical clustering, each data point is grouped into a cluster tree by treating all data points as a separate cluster. When all data points are determined as individual clusters, the algorithm identifies two clusters that are closest together. Those two clusters will be merged into one cluster. As a result of this iterative process, all clusters are merged.

Since peak periods are not representative of a whole group or cluster of periods, the methods introduced for time series aggregation have the disadvantage of potentially cutting off so-called peak periods. An accurate energy system design must be able to meet all requirements. There are different approaches for identifying and mapping the extreme points. The append method adds the extreme periods as additional representative periods to the other representative periods. In contrast, the additional-cluster-center method sets the peak period as an additional new cluster center. The replace-representative-period method integrates the extreme value where the peak period is assigned as the new representative of the cluster.

For the analysis, it is essential to set the correct number of representative data points the user gives. Depending on the number of representative data points, the results can differ. Additionally, choosing the period length and the number of time steps per representative period is essential for the time series aggregation. Different energy systems behave individually depending on the preset of representative clusters. Usually, the aggregated time series are modeled individually, where the connection and correlation between those periods are not modeled accordingly. It can impact the integrated storage system, so it is suggested to choose more extended periods to model the impact of storage.

3. System Analysis

Figure 2 represents the example energy system generated for this research. The considered optimization problem represents an energy system where the coal capacities have been phased-out. By taking out the coal-firing capacities and providing each production site with various potential technology options, the solver can optimize the optimal portfolio configuration for the system and each production site.

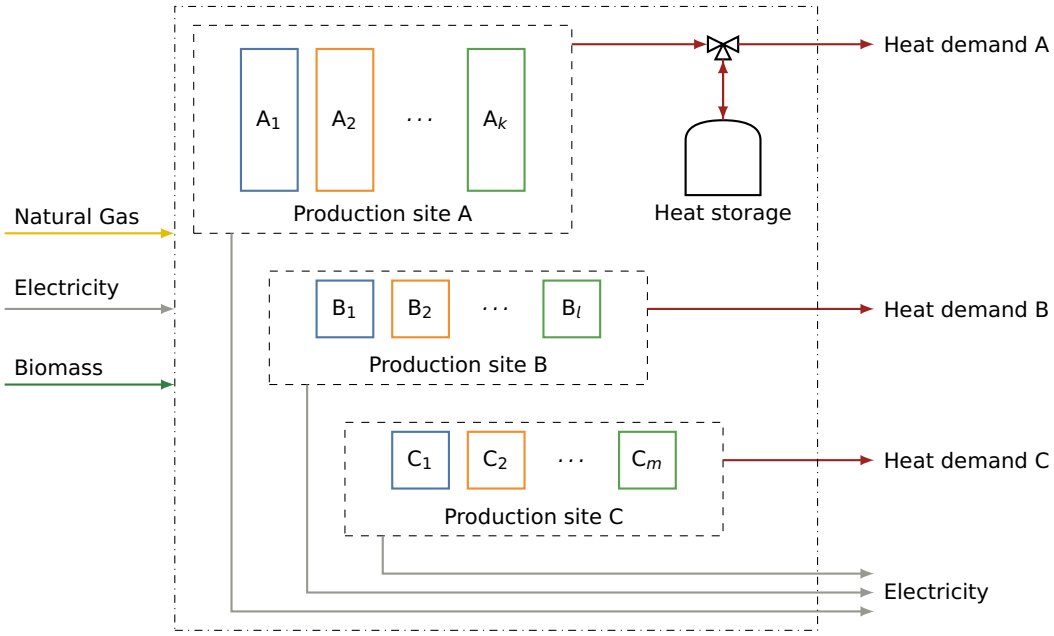

Figure 2: Simplified district heating system. Colors indicating recent and potential technology options at the sites.

As Figure 2 shows, the model is given with the possible fuel inputs, potential technology options, and the heat demand which must be met for each time step. The model considers portfolio options under various scenarios to find the most suitable and beneficial technology option for each site. The electrical grid is not given as a demand but as a market where the generation units can either sell or buy. The district heating grid can be divided into multiple sub-grids considering the geographical condition. Each generation site is assigned to a specific sub-grid to avoid significant heat losses and bottlenecks. The possibility of transferring heat from one sub-grid to nearby sub-grids is also modeled. Even though, it is physically possible to transport to the furthest sub-gird, it is very unusual considering the grid efficiency. Even when primary capacity fails, the heat-reserve boilers compensate for the capacity instead of transporting it from other sub-grids. The heat-reserve boilers are not set as a variable in this thesis but as given plants with extremely high operating costs.

The objective for the optimization is to maximize the net present value (NPV), see Eq. (2). The net present value measures the financial profitability of the portfolio. Equation (2) determines the difference between all revenues and expenses over the economic life of the investment.

$$\max NPV = -I + S + C \cdot k^{\mathrm{AF}} \tag{2}$$

In this equation, all expenses and revenues arising from the investment are discounted throughout the investment. As part of the input assumptions, various model parameters have been pre-determined.

All technology options are modeled with a fuel equation with technology-specific coefficients k_i and time-depending variables (Fuel rate $\dot{F}$, Electric power $\dot{W}_{\mathrm{el}}$, and heat rate $\dot{Q}_{\mathrm{th}}$); and if necessary (combined technology) with an additional $\dot{W}_{\mathrm{el}}$, $\dot{Q}_{\mathrm{th}}$-function.

$$\dot{F}_{\mathrm{f}} = \begin{cases} k_1 \cdot \dot{Q}_{\mathrm{th}} & \text{Heat pumps or heat-only boilers, } f = \{\text{Electricity, Bioenergy, } CH_4\} \\ (k_1 + k_2)^{-1} \left(\dot{W}_{\mathrm{el}} + \dot{Q}_{\mathrm{th}} \right) & \text{Gas turbines w/ or w/o heat-recovery boiler, } f = \{CH_4, H_2\} \\ k_1 \left(\dot{W}_{\mathrm{el}} + k_2 \cdot \dot{Q}_{\mathrm{th}} \right) + k_3 \cdot Y & \text{Combined heat and power plants, } f = \{CH_4, H_2\} \text{ and } Y = \{0, 1\} \end{cases} \tag{3}$$

Fundamental model parameters are given in Table 1. The complete model with all equations and specifications can be obtained from the authors. Note that due to corporate confidentiality, actual values can not be given.

Table 1: Fundamental model parameters and maximum heat rate per unit of the technology options

Parameter	Symbol	Unit	Value
Number of production sites	N	[–]	5
Economic lifetime	t	a	15
Future technology options (Abbreviation)	$\dot{Q}_{\mathrm{max}}$ [MW]		
Natural gas heat-only boiler (GHOB)			40
Combined cycle gas turbine (CCGT)			230
Gas turbine (GT)			120
Bioenergy heat-only boiler (BIOB)			100
River heat pump (HP)			50
Geothermal heat pump (GEOT)			50
E-Boiler (EB)			40

4. Results

4.1. Portfolio Optimization with time aggregation

As mentioned in the previous section, the total solution time increases with the additional complexity of the optimization problem. However, it is essential to analyze various scenarios with different assumptions to find the most robust portfolio for the future. With an average optimization duration of 5 to 6 hours for an optimization period of 15 years, the effort to investigate and analyze multiple scenarios is too high. The time series aggregation algorithm has been implemented to simplify this process and aim for similar results. For the analysis, different types of algorithms were used to analyze the impact of the aggregation methods. For the consistency of the result analysis, a similar scenario has been selected to compare different algorithms.

First, multiple combinations of representative periods and period lengths have been analyzed. Table 2 shows the average configuration variance with different representative periods and period lengths. The variance represents the percent difference compared to the original scenario result, optimized with hourly input data. The first column, Cluster Period, represents the combination selected for the optimization. The first number indicates the number of representative periods from the input data of 15 years and hourly resolution. The second number indicates the length of each period, represented as hours in full resolution. For the analysis, 18 representative periods and length variations have been optimized with the k-mean algorithm. The variance from the reference scenario has been filtered after technology types. As assumed, the number of representative periods and the length of the period drives the total solution time. The longer the period, the more optimized time steps, which leads to a longer solution time. Table 2 also shows that each technology option behaves differently depending on the variation of the cluster period. A significant variance can be seen for the gas heat-boiler option. The gas boilers have been utilized in the full hourly resolution, especially for peak shaving. By aggregating the time series, those continuous peaks of the heat demands have been relatively neglected, which makes the investment in gas boilers unnecessary. The analysis of the hourly resolution result is that the operation periods

of gas boilers are limited, but it is still economical to have the gas boiler as peak demand cover when the electricity generation is not beneficial for the operator.

Compared to the heat-only generation, the co-generation units show relatively low variance. Even though the solver could invest in the GT, which is also an option, the preferred investment is the CCGT technology. The CCGT has the lowest variance since the flexibility of such technology is higher and adaptable for almost any input assumptions. In the hourly resolution result of the original scenario, bio boilers were not preferred since the period where the bioenergy is more favorable compared to other technology options was significantly low. This relativity is underestimated by aggregating the time series, which leads to the solver investing in bioenergy-based heat generation units. Similar to the solution time, the impact of the number of periods and period lengths for the P2H technology is undoubtedly visible. Since the P2H technology is strongly dependent on the EEX price, which varies hourly in this energy system, the impact is significant. The more time steps are considered in the energy system, the more the error of over-investing or under-investing in P2H technology will decrease. As the analysis shows, the suitable representative periods are between 12 and 18 days concerning the accuracy of the configuration and the optimization duration. For the length of the period, the length of between 24 and 72-time steps is enough to expect a sufficient optimization result.

Table 2: Variance per technology and solve time for different representative periods and period lengths

Cluster Period	GHOB [%]	CCGT [%]	GT [%]	BIOB [%]	HP [%]	GEOT [%]	EB [%]	Solve time [s]

The results also showed that the capacitive variance differs depending on the technology and fuel type, but it still proves that the behaviors of the overall configuration are complementary. Interestingly, the natural gas-based technologies were relatively over or underestimated, even up to 100% underestimation. The overestimation and underestimation of different technologies also highly depended on the input scenarios, emphasizing the importance of input assumptions. The time series aggregation fulfills its requirement to assess numerous scenarios and various input assumptions. It is essential to acknowledge that optimization results for future configuration planning should be assessed in comparison and not as a stand-alone result. Due to the highly unpredictable and incalculable forecast data, the optimization serves the purpose of observing different behaviors of the technology, which can support a robust portfolio configuration.

Figure 3 compares *NPV* and *CAPEX* results for different time series aggregation algorithms. The k-medoids aggregation algorithm is excluded from this analysis due to the high aggregation time and computational load. With the given input assumptions, the solver could not build and aggregate the time series of 15 years with the k-medoids algorithms. However, the following section includes the k-medoids algorithm for shorter time series. As expected, the averaging algorithm is the most distanced result from the reference scenario. The relativeness of different input assumptions is neglected by averaging 140 256 time series into dramatically lower resolution, making the result not comparable with the reference scenario.

Figure 4 shows the variance of each aggregated optimization result filtered by technology options. Like the financial result, the k-medoids algorithm demonstrates each technology's least capacitive difference. It is

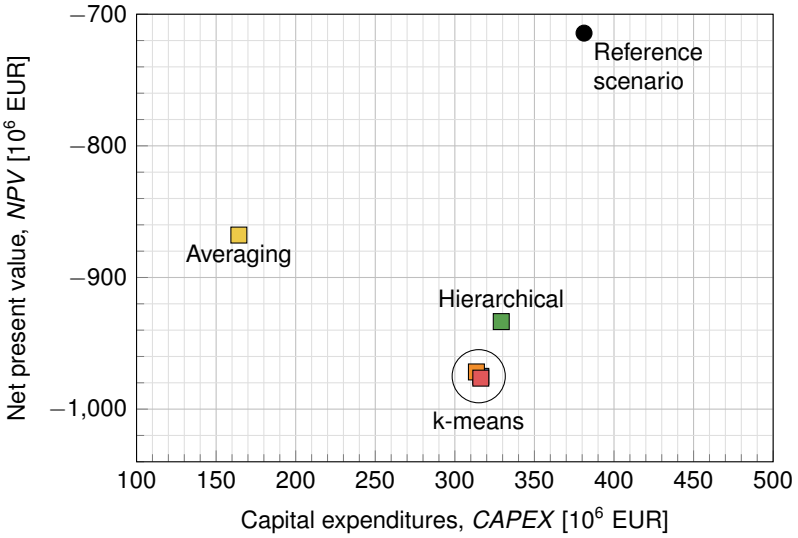

Figure 3: Net present value and capital expenditures for different time series aggregation methods

recognizable that the averaging method overestimates the capacities for each technology option and that the hierarchical method underestimates the capacity of heat pump technologies. The hierarchical algorithm ranked the heat pump technology lower than the other algorithms and assessed the gas turbine higher. The simplification of the input assumptions by the hierarchical algorithm is stronger than the other algorithms. Technologies with volatile dependencies can be underestimated in this algorithm, which makes it more difficult for technologies such as heat pumps or E-boilers to set the suitable representative period due to more unexpected developments. The capacitative overestimated technology options directly or indirectly depend on the most volatile input assumption. Even though the input energy of a geothermal plant depends on the power price, the constant heat source can level out the difference, elevating the value as a promising technology. The difficulty to optimize and the most discrepancy are shown for the gas-fired heat-only-boilers dispatched for the peak shaving. The number of representative periods is insufficient to express each peak demand, leading to higher variance in the GHOB result.

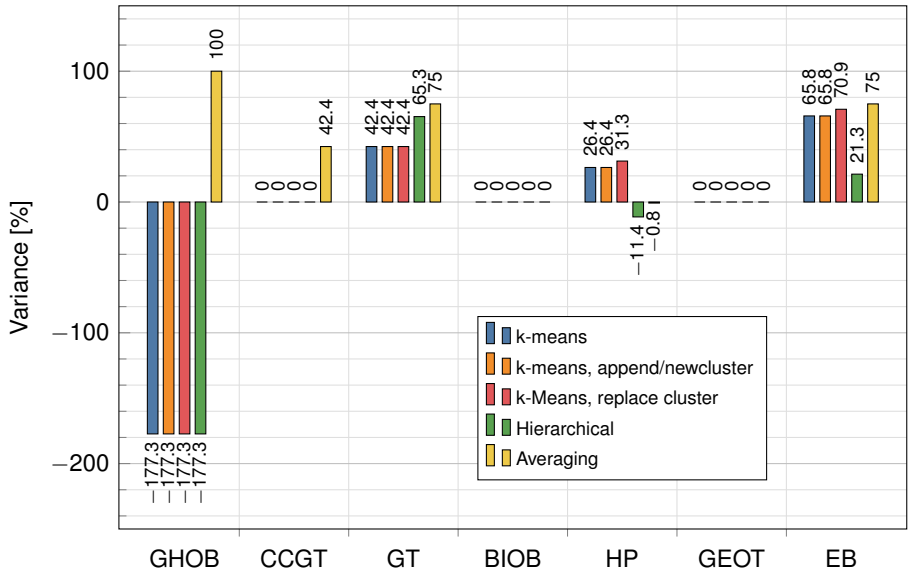

Figure 4: Variance comparison by cluster algorithm and capacity of technology

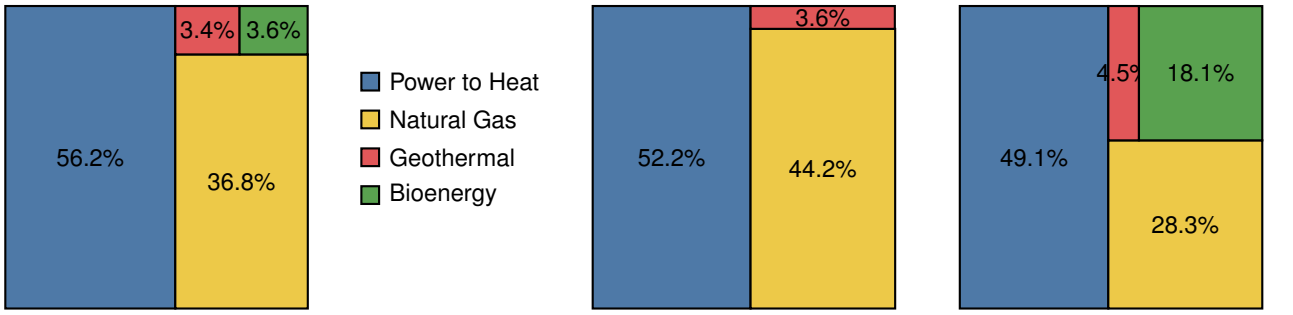
Overall, using the k-means or hierarchical algorithm as a clustering method is favorable for reducing the optimization problem's computational load. Keeping in mind that depending on the algorithm and the technology option, the particular capacitative result might be overestimated or underestimated. To reduce the computational load and shorten the optimization duration, the time series aggregation methods with appropriate periods can give sufficient indications for each portfolio configuration.

4.2. Sensitivity Analysis

Multiple activities exist to decarbonize gas-based power plants to realize a continuous hydrogen supply in the current gas grid. With enough supply for the required sectors, hydrogen will be the fastest way to decarbonize the gas-fired processes in Germany. Considering the significant increase of renewables in power generation, the potential of inland green hydrogen is considerable. This sensitivity analysis assumes that there will be enough hydrogen from 2040 onwards for the energy sector in Germany. Furthermore, green hydrogen combustion is counted as fossil-free fuel input, excluding the CO_2 certificate fee. For this analysis, the gas price ends in 2040 and is replaced by the hydrogen price from 2040 onwards. It assumes that there will be no natural gas in the grid from 2040, and the existing grid will be operated 100% with hydrogen. Besides the hydrogen price, all other input assumptions are equal to the original scenarios.

Figures 5a and 5b show the fuel mix of the portfolio for the H_2-integrated scenario and the original scenario. The apparent difference is the investment in bio boiler in the hydrogen integrated scenario. The share of gas/H_2-plants decreased, and the additional bio boiler and P2H plant compensated for the gap. The significant decrease in gas/H_2-based heat generation is recognizable from 2040. Due to the amortization of a plant, the bio boiler is invested from the beginning of the period. However, the high hydrogen price compensation can be seen by the increased heat generation of P2H and bio boiler from 2040. Even though hydrogen combustion relieves the CO_2 certificate fee, the hydrogen price is still too high to compete against power-based or bio-energy-based technologies.



(a) H_2-integrated reference case

(b) Reference case

(c) H_2-integrated reference case (hiearchical aggregation)

Figure 5: Scenario results showing fuel mix

Figure 5c shows the H_2 sensitivity analysis results compared to the aggregated results. As a result of the main portfolio optimization, the hierarchical algorithm was chosen for the sensitivity analysis. The results represent a higher variance of bioenergy and P2H share of total installed capacities. The higher flexibility of P2H technologies is preferable when the depths of the EEX price development are low. Increasing gas prices and switch to expensive hydrogen prices encourages the model for more investment in P2H technologies, and the increase in the CO_2 price also encourages investment in bio boilers despite the higher investment costs. Especially the discrepancy in bioenergy share is higher than in other fuel types. The main reason behind this result is the transition from natural gas to hydrogen. The non-aggregated scenario considers the yearly development and transition of fuel switch, making the natural gas capacities very attractive before the transition. However, the aggregated scenario emphasizes the higher price of hydrogen in the later years, which reduces the natural gas / H2-based assets and increases the alternatives.

5. Conclusion

Within this contribution, a simplified district heating system has been modeled as a case study with the Python-based optimization framework aristopy. The objective was to optimize the future district heating portfolio configuration and assess various impact parameters influencing the composition and operation of the portfolio. Additionally, the work analyzes the impact of the time series aggregation methods on portfolio planning to simplify and accelerate the comparison of different scenarios.

Potential technologies were analyzed to close the capacitative gap resulting from the coal phase-out. The existing district heating systems and recently commissioned power plants have been modeled with the optimization framework aristopy. Different technology options were implemented for each generation site for the future scenario comparison, considering the geographical and technological feasibility. The model identifies the main drivers for an advantageous portfolio configuration by comparing various scenarios with different input assumptions.

This contribution also showed that the right time series aggregation method could reduce the computational load and produce viable optimization results for portfolio planning. From the total optimization time of 3 to 8 hours for 15 years of considered time horizons, the time series aggregation could reduce the time to under 60 seconds with manageable optimization results. Comparing different clustering algorithms and representative periods, the hierarchical algorithm showed the most promising optimization results with a significantly shorter solution time. For clustering time series of 15 years, 12 to 18 representative periods with 24 period lengths were sufficient to indicate the configuration well.

An improvement potential is the time determination of the investment or refurbishment. The decommissioning process of existing coal-fired power plants is a long-term process, and decommissioning or refurbishing existing gas units into H_2-firing plants will also take time. By integrating the time factor as a variable for the investment, the optimized time for the construction and commissioning phase can be estimated considering the transformation plan of the portfolio. In addition to the time determination, various factors, such as government support schemes, change with a fixed factor over time. These factors are primarily key factors derived from the regulatory framework. Certain subsidies are given by the full-load operation hours, or efficiency goals reached every year. By aggregating the input assumptions, it is impossible to consider such subsidy types and goals, which depend on the generation unit's operation. Such considerations can improve portfolio planning but require detailed and accurate forecast data. The value of such optimization can be enhanced by integrating multi-objective or multicriteria optimization of an energy system. With more ambitious climate goals, the regulations for the energy sector will be stricter and more demanding. This means the government will require specific key indicators from the energy utilities. Key indicators such as primary energy factor, yearly renewable share in the system, or specific greenhouse gas emissions can influence the dispatch of each generation unit. The current aristopy framework allows the user to adjust the objective function, but each optimization problem must have only one objective function. By integrating multi-objective optimization, the user can plan a portfolio configuration that satisfies different regulatory requirements and maximizes the financial value of the portfolio. The downside of such optimization is the computational load. A multi-objective optimization comes with an exponentially higher computational load and solution time due to the multidimensional variables. However, when comparing various scenarios and the impact of the input assumptions, the additional computational load could be compensated by various methods, such as time series aggregation. When multi-objective optimization with an appropriate solution time and assessable granularity is possible, it can enormously enhance the planning of a portfolio configuration.

Abstract:

The present study presents the dynamic modelling in Dymola software of a vessel waste heat recovery Organic Rankine Cycle-ORC operating with R1233zd(E) that functions as a topping cycle of a cascade prototype also involving an Ejector Vapor Compression Cycle-EVCC as a bottoming cycle developed in the framework of the ZHENIT project. The ORC is designed to have a nominal thermal input of about 95 kW_{th} and is driven by Therminol VP1 oil at inlet and outlet temperatures of 150 ºC and 130 ºC while it includes two operating modes: 1) electricity-only, in which a recuperator is used and the condensation temperature is low and 2) combined heat and power (CHP), in which the recuperator is bypassed and the condensation temperature is raised to produce hot water. At the system design point, the evaporation temperature is 120 ºC, the condensation temperature 30ºC and 50ºC for electricity-only mode and CHP mode respectively, the superheating degree at expander inlet 10 K and the subcooling degree at condenser outlet 5 K. The system dynamic behavior is investigated considering a pump and expander reduction speed from 100% to 80% of the nominal. According to the results, the system has a fast response to the aforementioned disturbances.

Combined heat and power; Dynamic modelling; ECOS Conference; Electricity production; Organic Rankine cycle; Waste heat recovery.

1. Introduction

1.1. Basics of dynamic modelling

Organic Rankine Cycle (ORC) plays an important role in decarbonisation, especially in the field of waste heat recovery (WHR) in shipping, due to its effectiveness for the conversion of medium and high temperature waste heat into power [1]. ORC is an attractive WHR technology owing to its high reliability and simple design [2]. Because vessel engines operate extensively under variable loads, their waste heat has an intensely fluctuating profile (temperatures, flow rates), which poses technical challenges in the design and operation of ORC systems [3-4]. Therefore, dynamic modelling of ORC systems is necessary to predict their behavior and implement the essential control strategies for effective waste heat utilization, since dynamic models are able to trace the variation of the system operating parameters and detect critical points and outranges. In general, the dynamic behavior of a system including mechanical, electrical, fluid, thermal etc., can be described by a set of transient differential equations (ODE or PDE). The basic concepts that have to be known in dynamic modelling include system inertia, initial conditions, input stimulus variable and time constant [5].

1.2. Organic Rankine Cycles' dynamic operation

Dynamic behavior of ORCs is of interest during their start-up and shut-down and while their operating conditions are varied to respond to fluctuating boundary conditions (heat source, heat sink) to ensure their safe and efficient operation. The main investigated factors include [6]:

- the total system response time, overshoots, and identification of limitations and outranges
- recognition of the start-up and shut-down operation mode
- the part-load capability of the system

A prototype of the ORC system which is presented in this study is going to be developed in the context of the ZHENIT project, focusing on vessel engine WHR at different temperature levels to provide various on-board services. The present work presents the preliminary dynamic modelling of the prototype based on two operating modes: 1) electricity-only 2) Combined heat and power (CHP).

2. Methodology

2.1. System description

The prototype which is going to be developed within the ZHENIT project consists of a cascade ORC (topping cycle) integrated with an ejector-vapor compression cycle (bottoming cycle), utilizing heat sources of temperature levels ranging from 60 ºC (jacket cooling water) to 150 ºC (engine flue gas) for the production of electricity, heating and cooling. A micro-scale prototype (10 kW_e) will be constructed and demonstrated at lab-scale, along with other alternative proposed WHR solutions.

In the present study, only the topping cycle (ORC) of the aforementioned cascade system is presented, which operates under two modes: electricity-only and CHP mode and is driven by Therminol VP1 oil at a temperature of 150ºC. The two modes are simulated through Dymola software [7]. The layout of the system is illustrated in **Figure. *1***.

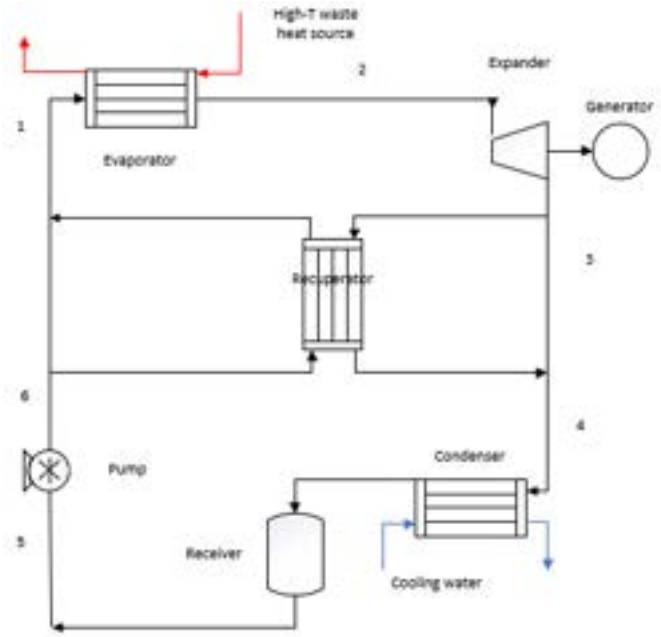

Figure. 1. ORC layout (2 first operating modes)

After a parametric study between three hydrofluoroolefins (HFOs), R1233zd(E) was proven to be the most suitable working fluid, considering its low environmental impact [low global warming potential (GWP) and ozone depletion potential (ODP)], following the regulations of Montreal [8] and Kyoto [9] protocol, as well as the F-gases regulations [10]. What is more, R1233zd(E) has no flammability, according to ASHRAE safety classification and relatively higher critical temperature, leading to higher cycle efficiency. The values of R1233zd(E) properties are mentioned in **Table 1**.

Table 1. R1233zd(E) properties

Working fluid	T_{crit} (°C)	p_{crit} (bar)	ODP	GWP	ASHRAE safety group
R1233zd(E) (ORC)	165.5	35.7	0	1	A1

2.2. System operating parameters and design point

The design point of the system was determined through a steady-state modelling methodology that is not elaborated in the present study. The values of the design point parameters are shown in **Table *2*Error! Reference source not found.**. In brief, the waste heat stream is Therminol VP1, which enters and exits the evaporator at 150 ºC and 130 ºC, respectively. The evaporation temperature (T_{evap}) for both modes was considered 120 ºC, while the condensation temperature (T_{cnd}) is 30 ºC in electricity-only mode (Mode 1) and 50 ºC in CHP mode (Mode 2).

The net electrical power output of the ORC ($P_{el,net}$) is defined as the gross electrical output of the expander ($P_{el,exp}$) minus the electrical power consumed by the pump ($P_{el,pump}$) and is given by the Eq. (1), considering also the expander-generator electromechanical efficiency ($\eta_{em,exp\text{-}G}$) and the pump motor efficiency ($\eta_{M,pump}$). The numeric subscripts (e.g. 2, 3) correspond to the points of the system layout in **Figure. *1***.

$$P_{el,net} = P_{el,exp} - P_{el,pump} = \dot{m}_{wf} \cdot \left(\eta_{em,exp-G} \cdot (h_2 - h_3) - \frac{(h_6 - h_5)}{\eta_{M,pump}} \right) \quad (1)$$

Table 2. ORC prototype design-point parameters

	Mode 1 (electricity-only)	Mode 2 (CHP)
Heat source mass flow rate (kg/s)	2.5 kg/s	
Heat source inlet temperature (℃)	150	
Heat source outlet temperature (℃)	130	
Expander isentropic efficiency	0.70	
ORC pump isentropic efficiency	0.65	
Expander-generator electromechanical efficiency	0.92	
ORC pump motor efficiency	0.95	
Superheating degree at expander inlet (K)	10	
Subcooling degree at condenser outlet (K)	5	
ORC working fluid	R1233zd(E)	
ORC evaporation temperature (℃)	120	
ORC condensation temperature (℃)	30	50
Cold stream temp. rise in recuperator (K)	20	-
Electrical power output (kW_e)	11.35	8.06
Heating output (kW_{th})	-	85.5
ORC electrical efficiency (%)	12.84	10.01

The heat input to the cycle ($\dot{Q}_{evap,ORC}$), is calculated according to Eq. (2), where $\dot{m}_{wh}$, $h_{wh,in}$ and $h_{wh,out}$ are the waste heat stream 's mass flow rate and enthalpies at the inlet and outlet of the evaporator respectively.

$$\dot{Q}_{evap,ORC} = \dot{m}_{wf}(h_2 - h_1) = \dot{m}_{wh}(h_{wh,in} - h_{wh,out}) \quad (2)$$

2.3. ORC dynamic modelling in component level

To develop a robust and concurrently a relatively fast dynamic model it is imperative to choose the proper components, correct initial conditions and to consider appropriate simplifying assumptions for the overall model. For instance, there are various types, sizes and modelling approaches for the heat exchangers, pumps, expanders etc. Consequently, in this point the types and the approaches of the models that were used in the model are described briefly.

2.3.1. Heat exchangers

The system heat exchangers (evaporator, condenser, recuperator) were modelled using the finite volume method, according to the available models that are included in the Thermocycle library [11]. In this method, the flow length of the heat exchanger is discretized into n equal volumes (cells), in which the equations of mass and energy conservation are applied.

The properties of the fluid for each volume can be calculated either at the mean states of the two nodes ("central scheme"), or it can be assumed that the properties of the fluid for each volume are equal to the properties of the fluid leaving the volume ("upwind scheme"). If the fluid flows only in one direction, the upwind scheme is more robust. The central scheme is more computationally intensive than the upwind scheme, but it deals better with discontinuities in the case of flow reversal. For the heat exchangers of the present study the upwind scheme was implemented. The properties of the fluid at the cell boundaries are represented by the symbol "*" in **Figure. 2**. The area of cell, volume of cell, temperature and enthalpy at each node are given by the following equations [Eq. (3), Eq. (4)] [12]:

$$A_i = \frac{A}{n}; \qquad V_i = \frac{V}{n}; \qquad i = 1,2,3,\dots,n \quad (3)$$

$$T_i = \frac{T_{i+1}^* + T_i^*}{2}; \qquad h_i = \frac{h_{i+1}^* + h_i^*}{2}; \qquad i = 1,2,3,\dots,n \quad (4)$$

The mass balance and the energy balance for each side and cell of the heat exchanger are given by Eq. (5) and Eq. (6) respectively:

$$\frac{d\dot{m}_i}{dt} = \dot{m}_i^* - \dot{m}_{i-1}^* \quad (5)$$

$$\frac{d\mathrm{U}_i}{dt} = (\dot{m}_{i-1}^* \mathrm{h}_{i-1}^* - \dot{m}_i^* \mathrm{h}_i^*) + \dot{Q}_i \quad (6)$$

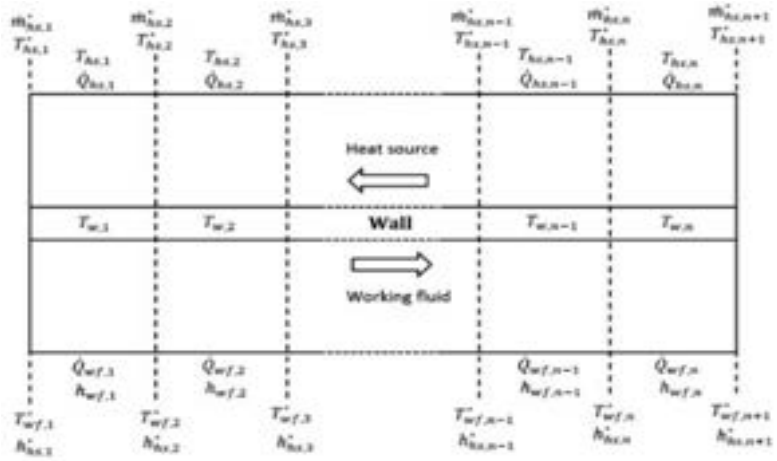

Figure. 2. Finite volume modelling approach of the heat exchangers [13]

Furthermore, for the modelling of the heat exchangers the following assumptions are considered:

- One-dimension fluid flow in the heat exchangers
- Constant heat flow per area unit and linear allocation of specific enthalpy in every control volume
- Negligible gravity forces in the fluid flow
- Negligible pressure drops in the heat exchangers and the pipes

2.3.2. Expander

For the dynamic modelling of the system a volumetric screw expander is used. The dynamics of the expander and the pump are very fast compared to those of the heat exchangers and are modelled at steady-state. Neglecting the heat loss, a volumetric expander can be modelled by its isentropic efficiency and filling factor, given by Eq. (7) and Eq. (8) respectively:

$$\eta_{exp,is} = \frac{\dot{W}_{exp}}{\dot{m}_{wf}(h_{exp,in} - h_{exp,out,is})} \tag{7}$$

$$ff = \frac{\dot{m}_{wf}}{\rho_{exp,in} V_{sw} N_{exp}} \tag{8}$$

The work output of the expander is given by Eq. (9):

$$\dot{W}_{exp} = \dot{m}_{wf}(h_{exp,in} - h_{exp,out}) \tag{9}$$

Expander boundary conditions are pressure and enthalpy at the inlet and pressure at outlet. In addition, the inlet and outlet are considered adiabatic.

Through the work of the expander, the net electrical power output and the waste heat energy as defined in Eq. (1) and Eq. (2) respectively, the ORC electrical efficiency is calculated and given by Eq. (10):

$$\eta_{el,ORC} = \frac{P_{el,net}}{\dot{Q}_{evap,ORC}} \tag{10}$$

2.3.3. Pump

Similarly, the dynamic response of the working fluid pump is very fast compared to that of the system heat exchangers. Hence, the pump is modelled by a steady-state lumped parameter model. In the present dynamic system, a centrifugal pump is used, whose role is to maintain the pressure and the mass flowrate of the working fluid. Usually for this type of pump the volume flow rate is a function of both the head and the rotational speed. However, in this model there is also the ability to define the mass flow as an input parameter. As a result, the pump power consumption and outlet temperature are calculated by the following equations [Eq. (11), Eq. (12)]:

$$P_{pump} = \frac{\dot{m}_{pump}(p_{out,pump} - p_{in,pump})}{\rho \eta_{is,pump}} \tag{11}$$

$$T_{out,pump} = T_{in,pump} + \frac{(1-\eta_{is,pump}) P_{pump}}{\dot{m}_{pump} C_{pump}} \tag{12}$$

2.3.4. Tank

A tank in an ORC system operates as a buffer storage for the working fluid to provide fluid or accumulate it during the transition phase of the system (start-up, part-load operation or shut-down). To calculate the working

fluid properties, the mass balance [Eq. (13)] and energy balance [Eq. (14)] are applied in the tank, while the tank level is calculated by Eq. (15), where V_0 is the initial total fluid volume in the tank.

$$\frac{d\dot{m}_f}{dt} = \dot{m}_{f,in} - \dot{m}_{f,out} \tag{13}$$

$$\frac{\mathrm{d(E)}}{dt} = \dot{m}_{in}h_{in} - \dot{m}_{out}h_{out} \tag{14}$$

$$H_{tank} = \frac{V}{V_0} \tag{15}$$

2.4. ORC system modelling

Based on the modelling of each individual component, the overall ORC system was modelled in Dymola through the Modelica language [14], as indicated in **Figure. 4** for Mode 1 and in **Figure. 3** for Mode 2.

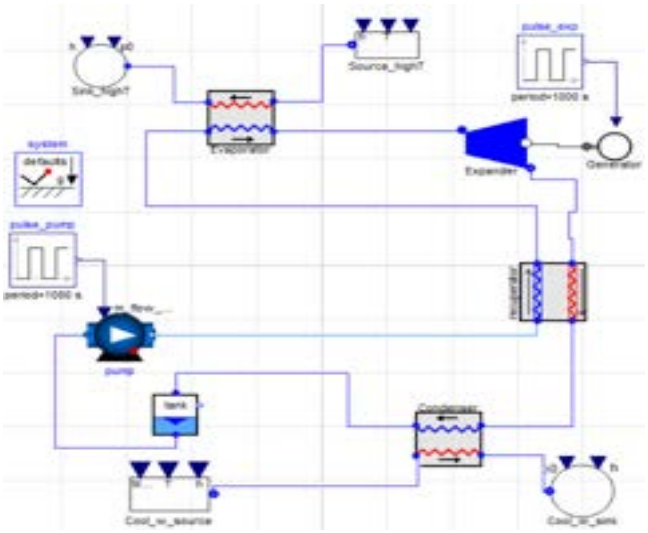

Figure. 4. Dymola ORC system layout (mode1)

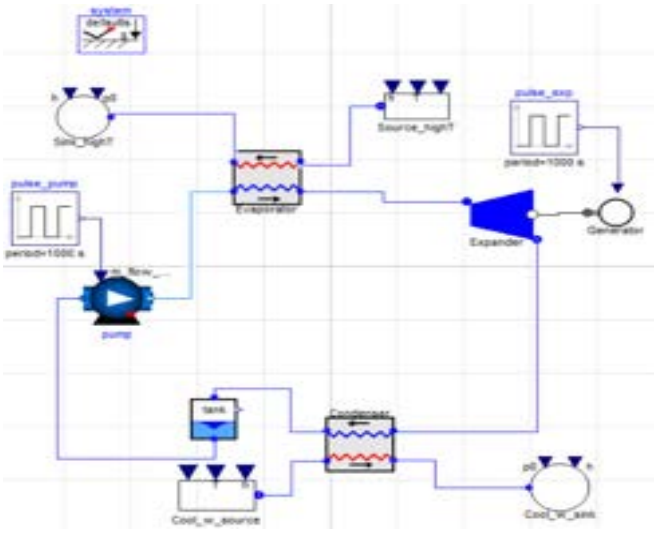

Figure. 3. Dymola ORC system layout (mode2)

During the modelling, the pressure drops of the pipes are omitted. Additionally, the system begins in steady-state (to avoid any discontinuities and consequent errors during the start-up) using initial conditions and then comes to a new steady-state after internal disturbances have been applied (heat transfer, mass flow etc). After that, a specific disturbance is imposed and the system results in a new steady-state. Two different scenarios regarding the type of the implemented disturbance are investigated, with alteration of the mass flow rate of the pump and change of the rotational speed of the expander. When the imposed disturbance ceases, the system returns to the initial steady-state. After a relevant investigation, it was inferred that a time period of 1000 s is well enough for the system to establish the steady-state. Thus, 1000 s is the time period that each disturbance lasts during the simulations.

3. Results and discussion

3.1. Initial conditions for the system

As mentioned before, the initial conditions of the system are selected so that the system reaches initially the steady-state at the design point. The two following scenarios are investigated for each mode:

Scenario 1: part-load operation of the system, reducing the pump mass flow rate at the 80 % of the nominal point and then bringing it back to the initial value

Scenario 2: part-load operation of the system, reducing the rotational speed of the expander at the 80 % of the nominal point and then bringing it back to the initial value

The initial conditions that have been defined for the system, after a relevant parametric analysis are presented in the **Table *3***.

For the simulations of Scenario 1 for both modes the pump mass flow rate is 0.435 kg/s for the first 1000 s, then it is reduced at 0.385 kg/s for the next 1000 s and finally it increases again at its initial value for the last 1000 s.

Likewise, for the simulations of Scenario 2 for both modes the rotational speed of the expander is 2400 rpm for the first 1000 s, then it is reduced at 1950 rpm for the next 1000 s and eventually it increases again at its initial value for the last 1000 s.

Table 3. Initial input conditions of the system

	Mode 1 (electricity-only)	Mode 2 (CHP)
Heat source mass flow rate (kg/s)	2.5	
Heat source inlet temperature (℃)	150	
Heat source outlet temperature (℃)	130	
Nominal working fluid mass flow rate (kg/s)	0.435	
Working fluid outlet temperature from the evaporator (℃)	130	
Working fluid outlet temperature from the condenser (℃)	25	45
Recuperator cold stream temperature rise (K)	20	-
Cooling water mass flow rate (kg/s)	3.94	3.94
Cooling water temperature inlet in condenser (℃)	15	25

Each simulation run is conducted for 3000 s with a time step of 6 s for each iteration and a tolerance of 0.0001 for the convergence of each iteration. Also, a noticeable feature is that it needs almost 170 s and 63 s in real time for the systems of Mode 1 and Mode 2 respectively to converge during the simulation.

3.2. Mode 1 results

To begin with, an important characteristic of the system is the temperature of the working fluid at the evaporator outlet, as, along with the pressure, it can be used for determining the superheating degree. The variation of this parameter for the scenarios of Mode 1 is depicted in **Figure. *5***. As it is illustrated in this diagram, initially the evaporator outlet temperature is 130 ºC for both scenarios, corresponding to the design parameter (120 ºC and 10 ºC superheating). During the disturbance, in the first scenario the examined temperature is increased, because, although the heat recovered from the heat source remains approximately the same [slightly lower due to reduction of the evaporator heat transfer coefficient (U)], the working fluid mass flow rate decreases and thus more energy is absorbed per working fluid unit mass. Furthermore, the fluctuation of the working fluid pressure in the evaporator is shown in **Figure. *6***. At the design point, the evaporator pressure is 15.7 bar, equal to the design evaporation pressure. On the contrary, when the disturbance occurs, in Scenario 1 the evaporator pressure decreases, as less working fluid mass passes through the expander, which has the same rotational speed. Thus, less pressure is required at the inlet of the expander in order for the working fluid to enter the expander. In the second scenario, in which the rotational speed of the expander is decreased, the evaporator outlet temperature is reduced. Inside the evaporator there is a constant volume of working fluid and while its density rises due to the pressure increase, there is more working fluid mass accumulated in the evaporator. The accumulated working fluid absorbs more thermal energy resulting in the reduction of the evaporator outlet temperature. Regarding the pressure, in Scenario 2 it increases, since the lower speed of the expander does not facilitate the passage of the working fluid, whose mass flow rate is imposed by the pump and remains constant. Hence, it needs to increase the pressure difference in the expander through higher pressure at its inlet. Furthermore, it is remarkable that in Scenario 2, although the pressure and subsequently the evaporation temperature rise, there is some liquid formed at the evaporator outlet reducing the temperature of the working fluid at the vapor saturation temperature (there is no superheating).

It is notable that the hypothesis of constant heat flow along the heat exchanger, which is implemented during the modelling of the heat exchangers, is validated by the fact that the inlet and outlet temperatures of the heat source are 150 and 130 ºC, while the evaporation temperature is 120 ºC. Thus, at the evaporator inlet and outlet there is an alteration of the temperature difference of the same order of magnitude. The impact of this hypothesis on the results is the easier convergence of the total system and the smooth temperature increase along the heat exchanger. What is more, as it is also shown in the following figure, the system response during the implemented disturbances is rapid, as the system reaches a new steady state quite fast.

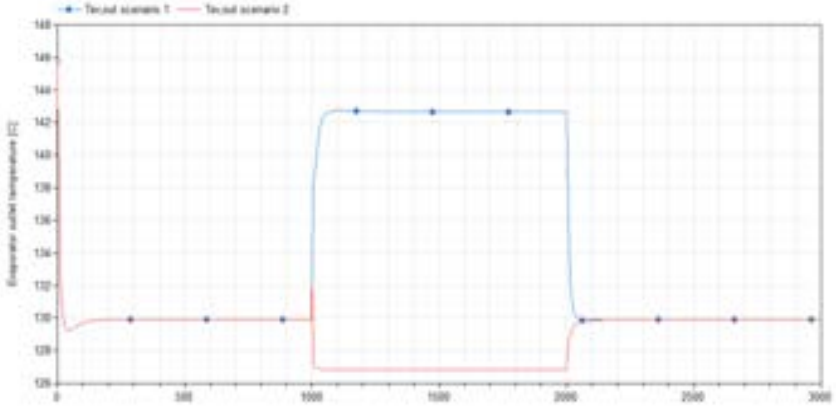

Figure. 5. Evaporator outlet R1233zd(E) temperature for scenarios 1 & 2 (Mode 1)

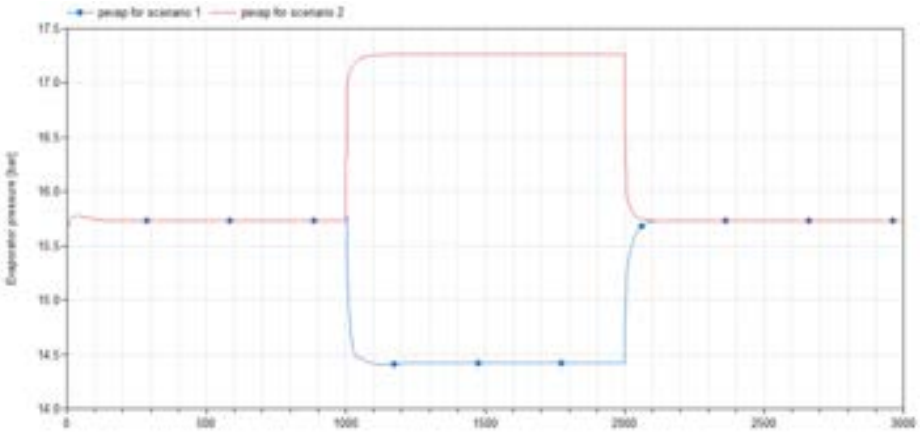

Figure. 6. Evaporator working fluid pressure for Mode 1

In **Figure. 7**, the inlet and outlet temperatures of the cold stream of the recuperator are shown. At the design point the temperature rise of the cold stream is indeed 20 K equal to the design parameter, while during the imposed disturbance, the system reaches fast to a new steady state. In Scenario 1 the cold stream temperature rise in the recuperator increases, while in Scenario 2 the respective value decreases. The heat transfer in the recuperator is described by Eq. (16).:

$$\dot{Q} = \dot{m}_{wf} c_p \Delta T \tag{16}$$

As a result, when the mass flow rate of the working fluid declines in Scenario 1 and the temperature of the fluid at the expander inlet rises, the thermal heat rate is increased. In this way, the temperature difference of the cold stream is increased so as to counterbalance the reduction of the mass flow rate. On the contrary, in Scenario 2, in which the rotational speed of the expander and its inlet temperature decline, the outlet temperature of the expander is also reduced, resulting in lower heat rate transferred to the cold stream. Thus, because the mass flow rate remains constant, the cold stream temperature difference decreases.

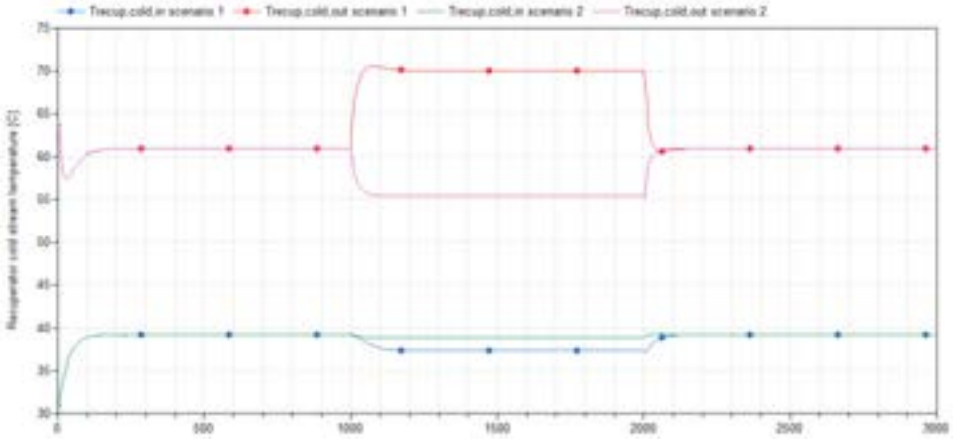

Figure. 7. Recuperator cold stream temperatures for scenarios 1 & 2 of Mode 1

The following diagrams demonstrate the working fluid temperature at the condenser outlet (**Figure. *8***) and the condenser pressure (**Figure. *9***) for the system of Mode 1 and the scenarios 1 and 2 respectively. As it is illustrated in the relevant diagram, during the dynamic modelling the working fluid temperature at the condenser outlet and at the design point, as well as the condensation temperature, is approximately 37 ºC, namely 7 ºC higher than the respective design point value. Similarly, the condenser pressure at the design point is 1.96 bar, higher than the design point condensation pressure. These significant differences are justified by the high complexity of the overall system and the fact that the design parameters of the heat exchangers, the expander and the pump have not been taken into account in the thermodynamic design of the system. In Scenario 1, the condenser outlet temperature of the working fluid and its pressure are reduced. This is due to the fact that the working fluid mass flow rate is decreased, while the cooling water mass flow rate and inlet temperature remain constant. Consequently, the working fluid is cooled in higher degree (lower outlet temperature and condenser pressure). In Scenario 2, the condenser outlet temperature and pressure remain stable, since the mass flow rate of the working fluid does not change and only the recuperator is affected by the reduced temperature at the expander outlet.

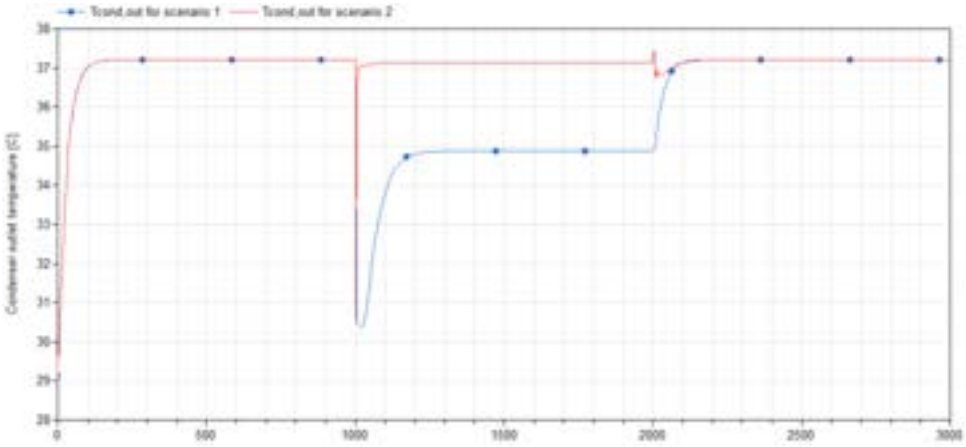

Figure. 8. Condenser outlet R1233zd(E) temperature for scenarios 1 & 2 (Mode 1)

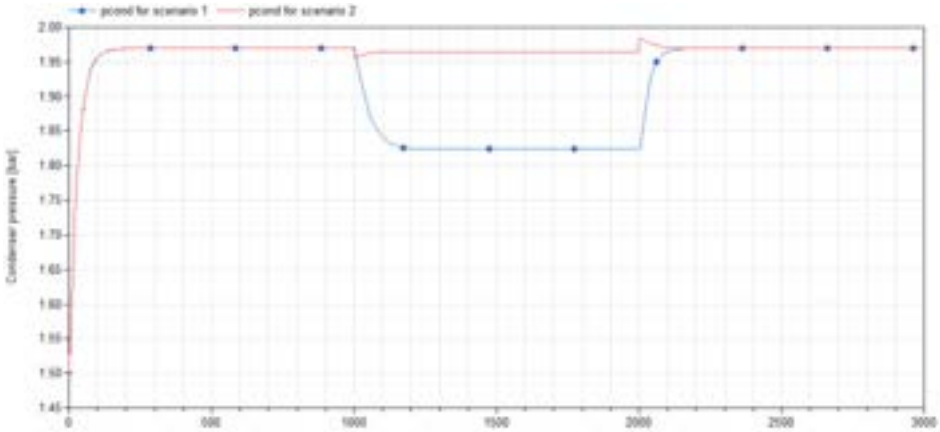

Figure. 9. Condenser working fluid pressure for Mode 1

As it is described in **Figure. *10***, the net electrical power output of the system for both scenarios at the design point is approximately 11280 W, almost equal as the design parameter of 11.35 kW (0.6 % lower). When the disturbance is imposed, in both scenarios the electrical power output is reduced because of the reduction of the working fluid mass flow rate (and lower expander inlet pressure and pressure difference as indicated before) and the rotational speed of the expander (lower evaporator outlet temperature and no superheating at expander inlet) respectively.

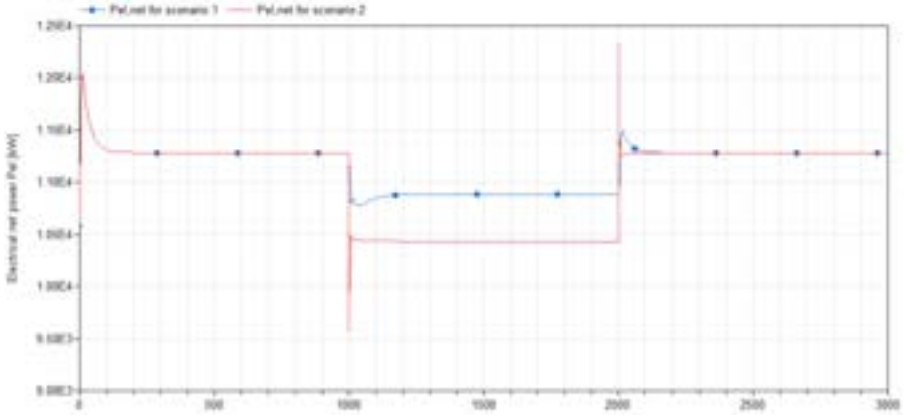

Figure. 10. System electrical net power (Mode 1)

It is worth pointing out that the heat source transfers 92.66 kW to the evaporator of the system at the design point. Therefore, the electrical efficiency of the system at the design point, according to Eq. (1), is 12.17 %, declining in 11.87 % and 11.40 %, due to the net electrical power output reduction, as long as the external disturbance lasts in Scenario 1 and 2 respectively. Moreover, as it is demonstrated from the diagrams of she system parameters for Mode 1, the system needs approximately 300 s in simulation time, to reach a new steady-state after an alteration in its parameters.

3.3. Mode 2 results

The temperature of the working fluid at the evaporator outlet for both scenarios of Mode 2 is demonstrated in **Figure. *11***, while the evaporator pressure for the correspondent cases is illustrated in **Figure. *12***. During the imposed disturbance, in the first scenario the examined temperature is increased, whereas in the second scenario the outlet temperature from the evaporator declines, following the trend of Mode 1 for similar reasons. At the design point the pressure is almost 15.7 bar, equal to the evaporation pressure. At the Scenario 1, the pressure of R1233zd(E) is reduced, as well as its mass flow rate, while lower expander rotational speed leads to the increase of the evaporator pressure in Scenario 2, for the same causes as in Mode 1.

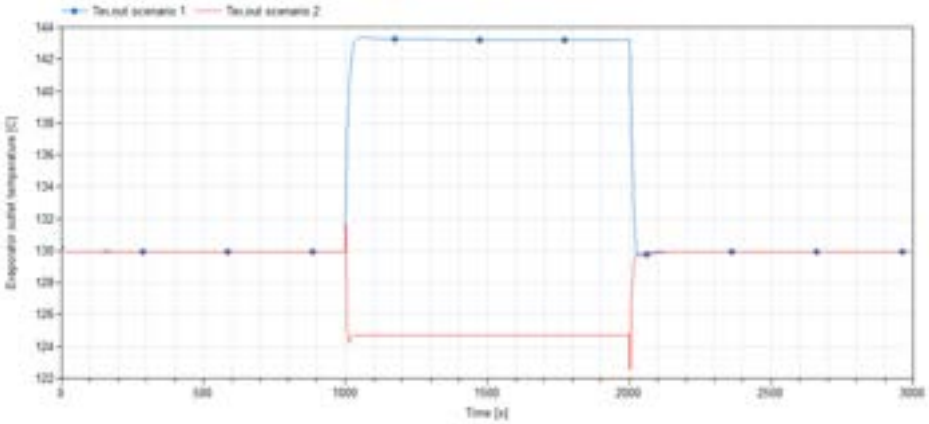

Figure. 11. Evaporator outlet R1233zd(E) temperature for scenarios 1 & 2 (Mode 2)

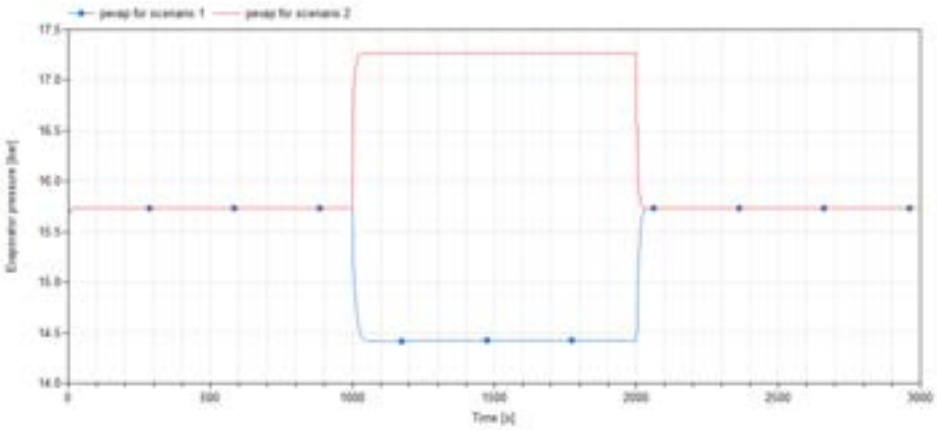

Figure. 12. Evaporator working fluid pressure for Mode 2

Moving to the condenser analysis, at the design point the working fluid outlet temperature (**Figure. *13***) is slightly lower than 50 ºC, which is the condensation temperature. In other words, R1233zd(E) exits the condenser lightly subcooled, being close to the saturation curve, but in the one-phase region along the whole simulation. During the disturbance, in Scenario 1 the temperature of the fluid after the condenser is lower for the same reason as it happens in the evaporator, while in Scenario 2, due to lower expander speed, the temperature at the expander outlet is lower, as mentioned above. Hence, because the cooling water parameters remain unchanged, the working fluid is cooled in a higher degree.

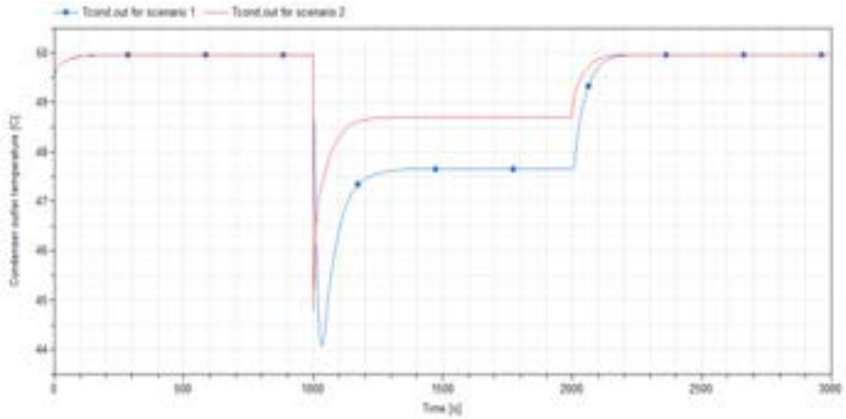

Figure. 13. Condenser outlet R1233zd(E) temperature for scenarios 1 & 2 (Mode 2)

Figure. *14* illustrates the condenser working fluid pressure, whose value at the design point is 2.93 bar just like the design parameter. During the disturbance, the pressure declines similarly to the working fluid temperature at the outlet of the condenser.

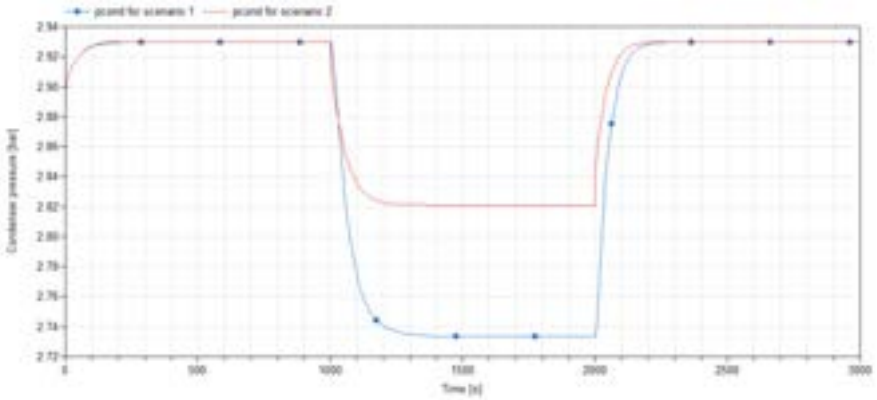

Figure. 14. Condenser working fluid pressure for Mode 2

Afterwards, in **Figure. *15*** the net electrical power output of the system is demonstrated. At the design point, the electrical net power is almost 7800 W, approximately 2.5 % lower than its design value. This deviation is owed to the fact that the design parameters of the system components have not been taken into account in the thermodynamic design, as well as because of the fact that R1233zd(E) was inserted in Dymola via CoolProp [15], which also contain some slight errors regarding its thermodynamic properties. In scenarios 1 and 2, the net power is reduced due to similar causes as in Mode 1.

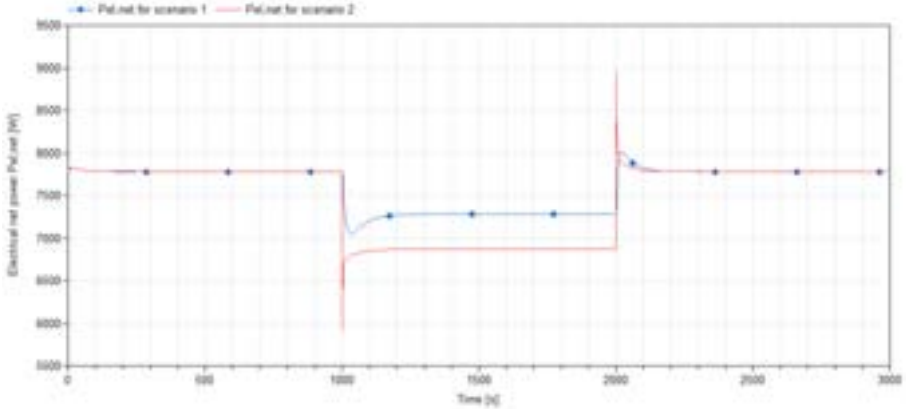

Figure. 15. System electrical net power (Mode 2)

It is notable that the heating output of the system of Mode 2 at the design point is 92.6 kW (higher than the design point value) decreasing in 89.44 kW and 87.03 kW in Scenario 1 and 2 respectively, while the heat source transfers 99.81 kW to the evaporator of the system at the design point. Therefore, the electrical efficiency of the system at the design point is 7.8 %, declining in 7.6 % and 7.4 % during the external disturbance in Scenario 1 and 2 respectively. The electrical efficiency arised from the dynamic modelling is lower than the design point ‘s one. The difference is owed to the same reasons as the deviation of the net electrical power. These are also the causes of the increased heating output of the system of Mode 2, which contribute to the reduced electrical efficiency.

4. Conclusions

The present study analysed the dynamic modelling of a vessel engine waste heat recovery Organic Rankine Cycle (ORC) system, which makes up the topping of a cascade ORC combined with an ejector vapor-cooling compression cycle (EVCC) and operates in two different modes: 1) electricity-only and 2) combined heat and power (CHP) via heat recovery by the ORC condenser. In the beginning, the basic concepts of dynamic modelling were mentioned briefly and the ORC system was described, as well as its main features and design point operating parameters. Furthermore, the modelling elements and methods at system component level were defined, whereas the total ORC system in Dymola and its simulations’ characteristics were highlighted. Eventually, after the presentation of the simulation results for the two modes and two different scenarios [1) reducing the pump mass flow rate at 80% of the nominal one and 2) decreasing the expander rotational speed at the 80% of the nominal one], it was demonstrated that the system, regarding most of its parameters’ values, during its steady-state at the design point parameters matches the values of the off design, resulting in net electrical power output up to 11.28 kW (Mode 1) with electrical efficiency of up to 12.17 % (Mode 1). What is

more, the system 's response to the disturbances ranges from 250 up to 300 s, whereas some slight deviations from the design point are owed to the fact that the design parameters of the system components have not been considered in its thermodynamic design.

Abstract:

Topics such as climate change and global warming that the world has been experiencing are increasingly a cause for alarm and concern which means that several goals must be achieved to avoid irreversible damages to the environment that interfere with its stability. For that aim, it is crucial to reduce emissions by discontinuing the use of fossil fuels, as an energy source to produce electricity, and replacing it with renewable energies. For a 100% renewable energy transition it is necessary to ensure dispatchability, flexibility, safety, and reliability of the electrical distribution grid. The main goal of this study is to evaluate the potential of a small-scale system using solar energy captured by Concentrated Solar Power (CSP) technology to produce electricity through an Organic Rankine Cycle (ORC). The System Advisor Model (SAM), one of the main tools for evaluating renewable energy projects, was used for system analysis. The CSP system implemented has gross installed power of 50kW$_e$ with 6 hours of Thermal Energy Storage (TES), whose main results are: production of 145529 kWh in the first year of operation, $559416.06 total investment cost and a Levelized Cost of Electricity (LCOE) of $0.3009/kWh. From the analysis of the results obtained, it can be seen the effect of economies of scale reflected in the LCOE value, which an expected consequence of scale reduction.

1. Introduction

The development of the humanity and society has brought, inherently, an energy dependence that is so naturally present in our daily life, almost like something previously acquired, that if for some reason there is a failure in the electricity distribution grid, there is no redundant system until that same failure is solved. This dependence coupled with the progressive increase in energy needs due, in part, to population growth and improvement in living standards, has led to an increase in the implementation of conventional electricity generation systems based on fossil fuels, resulting in increased greenhouse gas (GHG) emissions.

Topics such as climate change and global warming have emerged more frequently, more prominent and alarming, as they can result in irreversible damage to the environment. The use of renewable energy cannot be seen as a mere investment, but rather as a civil obligation, which implies a change of mindset to achieve carbon neutrality, a zero balance between GHG emissions and carbon retention. Knowing that this is a global problem with increasing emphasis among various organizations, several targets have been imposed and sanctions are applied to those who do not comply with them. For that aim, the member states of the European Union (EU) have stipulated and agreed to carry out, through the Paris Agreement (2015), three main goals [1] : limit the global average temperature rise below 2ºC compared to pre-industrial levels and pursuing efforts to keep it below 1.5ºC; increase the capacity to adapt to the impacts of climate change and foster climate resilience; make financial flows consistent with a pathway towards climate resilient and low-carbon development. Among the goals presented, the first is the most important since it could prevent irreversible damage to the environment that could put the population at risk.

In 2016, Portugal committed to ensuring carbon neutrality by the end of 2050 and developed the Roadmap for Carbon Neutrality (RNC2050) [1], which presents the main vectors of decarbonization and the path to follow for emission reduction, in conjunction with National Energy-Climate Plan (PNEC) [2], the main energy and climate policy instrument for the decade 2021-2030.

As can be seen from Figure 1, Portugal showed a growth in GHG emissions from 1990 until 2005, when it reached a peak, with a significant decrease from then on, in line with the targets for carbon neutrality. In 2017, there was a sharp increase in emissions related to the forest fires that occurred that year. An analysis of the evolution without considering emissions from Land Use, Land-Use Change and Forestry (LULUCF) shows a global trend of reducing GHG emissions.

Figure. 1. Evolution of Portugal's GHG emissions [3].

The electricity production sector, which will be target of analysis in this study, is one of the most potential for reducing emissions. The goal that Portugal has in this sector is clear, total decarbonization by 2050. The main drivers for decarbonisation in this sector are the transition from conventional electricity generation systems based on the use of fossil fuels to renewable energy systems, the discontinuation of use of coal by 2030 (already achieved) and natural gas by 2040, the development of new technologies that enable energy storage and ensure greater intelligence and flexibility of electrical distribution grid [1].

Investing in carbon neutrality will result in savings importing fossil fuels with a reduction in dependence on foreign countries. This result is of extreme importance for Portugal economy, as the acquisition of these fuels from other countries represents one of the main expenses. On the other hand, it would somehow attenuate fluctuations in the price of energy as it would be produced nationally, reducing the dependence on the availability of fossil fuels and external requirements or impositions.

In 2020, Portugal was the 11th country in the EU with the most energy dependence, with a value of 65.8%, while the European average was at 58%. The 8.4% decrease between 2020 and 2019 has three main causes: breakdown in energy consumption due to the COVID-19 pandemic; cessation of imports of coal for electricity production; increased production of energy from renewable sources at residential level [4]. The breakdown in consumption due to the pandemic leads the value of energy dependence in 2020 is not taken as a benchmark, since it is "artificially" low. The Figure 2 show the energy dependence in Portugal from 2000 until 2020, the latest data available.

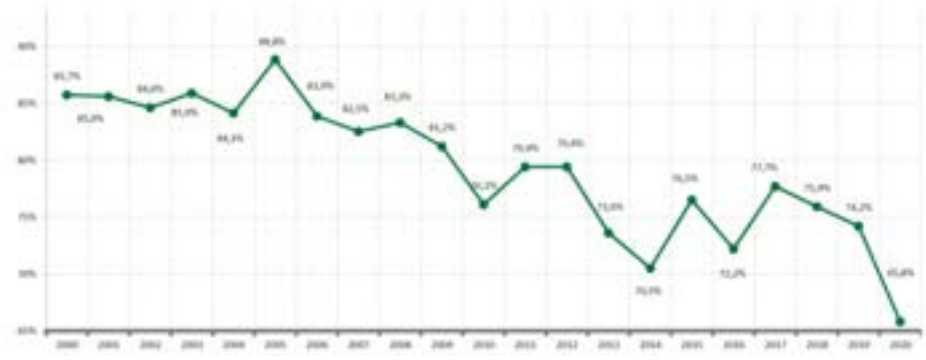

Figure. 2. Evolution of Portugal's energy dependence [4].

In recent years there have been large investments in photovoltaic (PV) and wind technology, but since their production is highly variable and depends on the availability of the resource, problems arise in terms of the dispatchability and stability of the electricity distribution network. As the goal is to ensure that 100% of the energy produced by 2050 comes from renewable resources, there will be a need to invest in other technologies that allow for some gap between the availability of the renewables and the production of electricity.

Following the development and investment in non-dispatchable electricity production technologies such as photovoltaic and wind, arises the need to create means of storage that allow a gap between renewable resource availability and electricity production. CSP technology emerges as one of the potential solutions to

ensure this gap. Its main advantage is the possibility of incorporating a TES system whose associated costs, as well as storage efficiency and environmental impact, make the technology favourable when compared to battery storage systems. Large-scale systems are well-known and mature but requires a very significant geographical area and a transport costs and losses due to a central electric production. Micro and mini-scale CSP – ORC systems integrated with TES can overcome the geographical limitation in a decentralized production.

1.1. Solar energy as a renewable resource

Solar energy is one of the most abundant renewable resources. Only 47% of the available solar energy reaches the Earth's surface (31% directly and the remaining 16% diffuse, through dust, water vapor and other molecules), with the remainder 53% of energy being divided into: 15% absorbed in the troposphere, 23% reflected by clouds, 7% reflected by the soil, 2% absorbed by the stratosphere and 6% of radiation diffused by the atmosphere, which does not reach the surface [5].

In Portugal, the implementation of renewable resources as a way of producing electricity has verified 3 main waves, each of which is represented by the development, growth and deployment of a given technology. The 80s and 90s were represented by the exploitation of water energy as a strong bet on electricity production, however, from the 2000s there is an increase in the use of wind energy and more recently the solar resource with a great potential for exploration and development [6].

The electricity consumption in Portugal has, in the last 10 years, an average value of 50 TWh/year, but only 2% of the total electricity production is made from solar energy [7], which reveals a fairly reduced value in relation to the potentiality it presents, however this technology is relatively recent when compared to the production systems from water and wind energy, which have a higher degree of maturity [8].

In assessing the potential of a zone for solar energy exploitation, radiation is the most important factor, being divided as: Direct Normal Irradiance (DNI), Diffuse Horizontal Irradiance (DHI) and Global Horizontal Irradiance (GHI).

Among several parameters, the one that has the greatest influence on the decision on the potential of a region to implement a Concentrated Solar Power (CSP) system is the DNI, which are considered more interesting and economically more viable when the value of the average DNI is equal to or greater than 2000 kWh/m^2.year [8,9]. Besides that, it is necessary to consider factors such as the level of nebulosity and dust since it decreases the fraction of available DNI.

Portugal is one of the countries in Europe with the highest availability of solar radiation, which, despite having a large variability in the distribution of the DNI, presents an annual average value across the national territory of 1800 kWh/m^2 [8], reaching 2200 kWh/m^2 in certain regions, with a number of annual hours of sun from 2200 to 3100 hours, which is much higher than the values of 1200 to 1700 hours presented by Germany [11], or 1750 hours of European average [12]. This makes Portugal one of the European countries with the greatest potential for exploiting this resource for national energy production. According to the study conducted in [9], CSP technology presents, in Portugal, the greatest potential among all renewable energies, namely: hydraulic, geothermal, biomass, wind, photovoltaic and waves / tide.

The DNI distribution in Europe and Portugal is presented in Figure 3.

(a) (b)

Figure. 3. DNI distribution in Europe (a) and Portugal (b) [11].

2. Concentrated Solar Power - CSP

The principle of operation of the CSP technology, presented in Figure 4, is based on the generation of electricity through a heat machine involving the concentration of solar radiation. Unlike PV technology that makes use of GHI, CSP technology only takes advantage of the DNI fraction of the radiation that, through solar concentrators, causes it to focus on a receiver, heating a Heat Transfer Fluid (HTF), thereby transforming solar radiation into thermal energy. The concentration of radiation makes it possible for the HTF to reach quite high temperatures, and this thermal energy can be used to produce electricity through a heat machine, usually with a turbine associated with a generator. on the other hand, to be stored to create a gap between solar radiation and electricity production, the concept of dispatchability.

The existence of Thermal Energy Storage (TES) allows thermal energy to be stored, creating a gap between solar radiation and electricity production, the concept of dispatchability. This makes it possible to create a more stable power distribution network, since most of the power generation systems are non-dispatchable, they produce and introduce electricity into the grid only when the primary resource is available. This inherent feature of CSP systems is one of its main advantages.

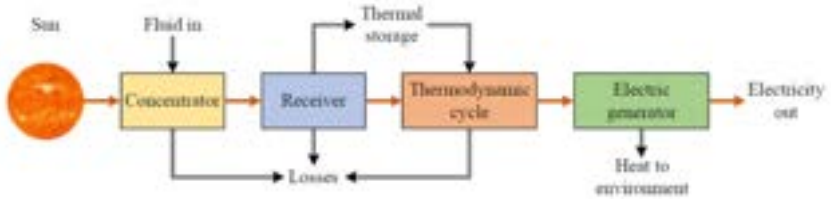

Figure. 4. Principle scheme of a CSP system [8].

2.1. CSP technologies

The aim of the solar field is to concentrate solar radiation in a receiver, converting it into thermal energy. The concentration of radiation causes the absorbed radiative density to be higher than that on the Earth's surface, so that, high temperatures are reached to operate a heat machine. The CSP technologies can be classified according to Figure 5. Despite having the same goal, they have forms and characteristics that distinguish them and that cause their application to be differentiated.

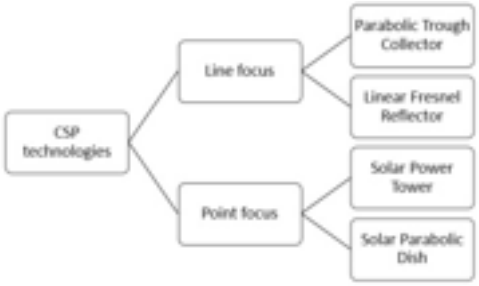

Figure. 5. Classification of CSP technologies

The aforementioned technologies are illustrated in Figure 6. A tracking system is implemented with the aim of making greater use of solar radiation, so that it constantly focuses the radiation on the receiver as the sun moves. Linear focus systems use single-axis tracking systems, while point focus systems are implemented with two-axis tracing systems. The orientation of the collectors is usually made in the longitudinal north-south direction with tracking east-west, as they ensure a greater amount of energy absorbed.

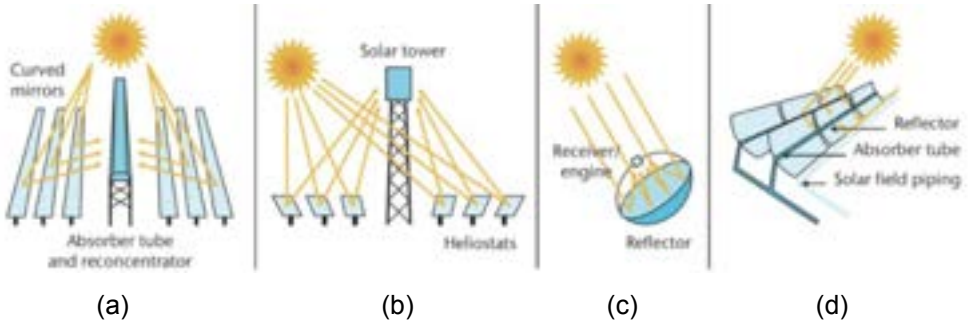

Figure. 6. Configuration of CSP different technologies: Linear Fresnel Reflector (LFR) (a); Solar Power Tower (SPT) (b); Solar Parabolic Dish (SPD) (c); Parabolic Trough Collector (PTC) (d) [12].

3. Thermal Energy Storage - TES

The production of electricity from renewable energies is not deterministic due to the variation of the natural resources' availability, as well as variation in electricity consumption demand. Given the intermittent availability, variability and limitation of certain natural resources, the existence of storage means becomes crucial to compete with the dispatchability that fossil-based electricity production systems offer, which has led to the development of different forms of energy storage, making them efficient and sustainable [13]. In general, the TES allows, not only the temporary storage of thermal energy for subsequent use of that same energy, compensating the intermittency of the solar resource or ensuring the dispatchability of the system, but also gives it thermal inertia, ensuring a greater stability of operation. Some of the advantages of its use are: increase the capacity factor (CF), ratio between actual energy produced during a certain period and maximum theoretical production in the same period, by 20-25%, without TES, up to 60-85% with TES; reduce the operation of the power cycle at partial load; and adjust production for peak hours [14].

3.1. Application of TES to CSP systems

The TES system can be classified, according to Figure 7, in Sensible Heat Storage, Latent Heat Storage and Chemical Energy Storage. The TES system can be characterized according to the following characteristics: capacity, charge and discharge power, efficiency, storage time, charge and discharge time and cost [13].

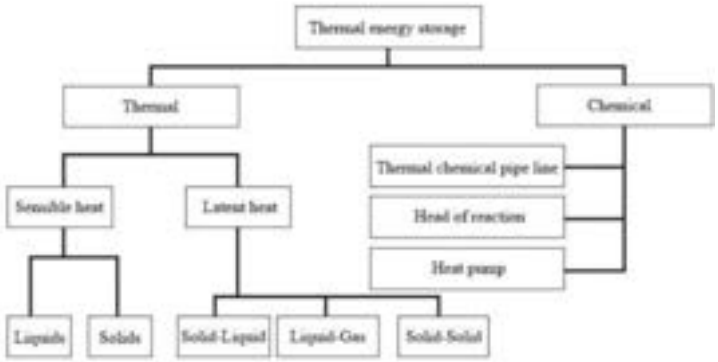

Figure. 7. Types of TES [13].

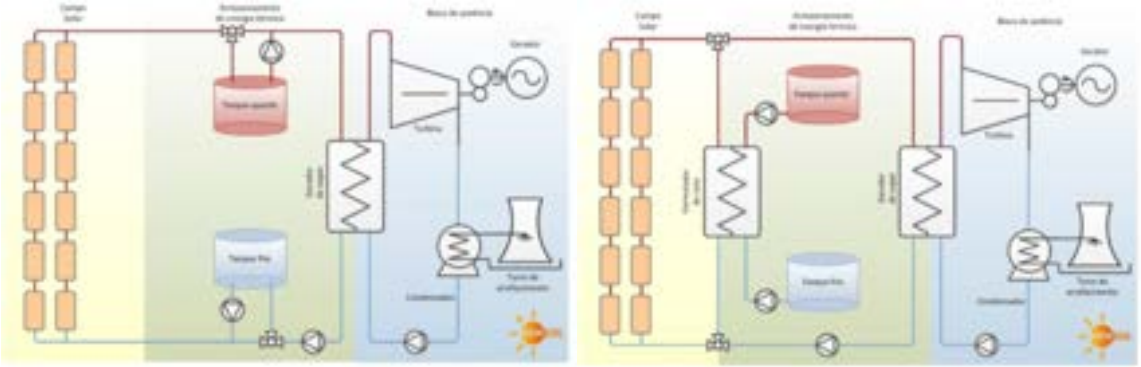
The development and choice of the TES system to be implemented requires knowledge of the heat flows between HTF and TES during the charge process and between TES and the heat machine in the discharge process [13]. Most CSP systems feature two types of TES configurations: two tanks and a single tank.

In the two-tank system the HTF is stored in two tanks with different temperatures, one of high temperature and another of low temperature, referred to as hot tank and cold tank, respectively. This type of TES can also be divided in direct, where the solar field HTF itself is used as a storage fluid, and indirect systems, where the HTF is different from the storage fluid, which requires the use of a heat exchanger that promotes energy exchange between the two fluids, as illustrated in Figure 8.



(a) (b)

Figure. 8. Configuration of a two-tank direct (a) and two-tank indirect (b) storage system [15].

In single tank storage systems is typically used thermocline technology, presented in Figure 9. The storage medium can be the HTF itself or be a solid medium, such as rock or silica. In the first case, the hot HTF remains at the top of the tank while the cold is at the bottom, with a dividing line called the thermocline gradient. The distribution of temperatures is guaranteed by the difference in material density at different temperatures. In the

second case, in the charging process, the hot solar field HTF enters the upper zone of the tank and goes out in the lower zone of low temperature, adding thermal energy to the solid medium, and the opposite happens in the discharge process [13]. This type of storage is suitable for small-scale applications as it allows a cost reduction compared to a two-tank system [16].

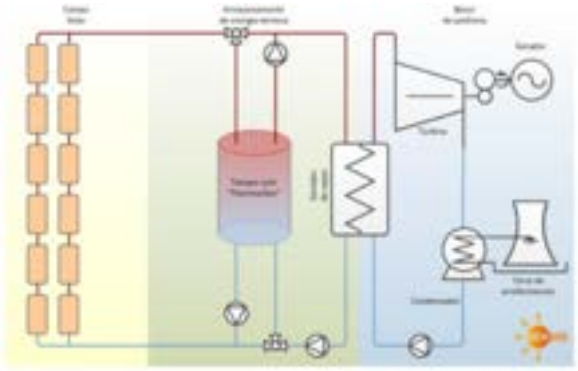


Figure. 9. Single-tank storage system [15].

4. Heat Transfer Fluid - HTF

The HTF is one of the key components of a CSP system with direct influence on its performance and efficiency [17]. According to Benoit et al. [18], the HTF should be compatible with the materials used and the storage medium and be able to operate in the required temperature range, receive and transfer heat easily and circulate well in confined spaces. Given the high amounts of HTF required in the system, since it can be used as a receiver and storage medium, it is necessary to minimize its cost while increasing performance [17]. In addition to having direct influence on overall system efficiency, the choice of the HTF determines the type of TES and the power cycle to be implemented, as well as the performance it can achieve [19]. Table 1 lists the main properties to be considered when choosing the HTF and its influence on the system.

Table 1. Influence of the HTF properties on the CSP system, adapted from [14]

Property	Related to
Solidification temperature	Minimum operation temperature
	Thermal protection needs
Thermal stability limit	Maximum operation temperature
Heat capacity	TES capacity
Viscosity	HTF pumping
Density	TES volume
Thermal conductivity	Heat transfer
	Heat exchanger

Improvement in the thermal properties of HTF is one of the most effective ways to improve the efficiency of CSP systems, as improvements in physical system have little potential since thermal losses are reduced [20]. The range of operating temperatures set by the HTF, and its thermal stability are the limiting factors in the overall system performance. The most used HTFs are water, gases, thermal oils, and molten salts.

5. Analysis of a small scale CSP system through the System Advisor Model (SAM)

CSP systems modelling is quite complex due to existing time fluctuations, resulting in transient effects on the system, unlike conventional power generation systems that operate much of the time at nominal conditions under a predominantly stationary regime [21].

The System Advisor Model (SAM) is a program developed by the National Renewable Energy Laboratory (NREL) from funding from the U.S. Department of Energy and is presented as: “free techno-economic software model that facilitates decision-making for people in the renewable energy industry”, namely, solar, water, wind, geothermal and biomass energy [22]. SAM is based on several series of the Transient System Simulation Program (TRNSYS) model that uses the program interface inputs as data to make the annual simulation with hourly system resolution.

SAM is currently one of the most widely used software for the techno-economic analysis of CSP systems worldwide. One of the main benefits of using SAM, in addition to the high reliability of results, is the possibility of making probabilistic, stochastic, and parametric analyses, with special emphasis on the latter, since it allows to make the optimization of the systems based on the change of certain parameters.

5.1. Implementation of the system in SAM

For the simulation of a model in SAM it is necessary, firstly, to choose the systems model and then the economic model that is intended to be used to carry out the analysis.

Due to the power cycle type being implemented and since it is the most mature technology and one of the most developed models in SAM, it was chosen the PTC system. Within the PTC option, the SAM have two distinct models: physical and empirical. The empirical model is based on correlations derived from data analysis obtained in systems already implemented, mainly from the Solar Energy Generating Systems (SEGS) in the United States of America, which makes the analysis of systems with distinct conditions more controversial and uncertain. On the other hand, the physical system uses concepts of heat transfer, thermodynamics, and fluid mechanics to characterize the system [23], so that, it was the model considered.

The economic model chosen was the Levelized Cost of Electricity (LCOE) Calculator, suitable for preliminary analysis of project feasibility, that is calculated using the Fixed Charge Rate method.

After base simulation, an optimization of the CSP system can be done. It involves choosing several parameters that result in a minimum LCOE value. If, on the one hand, the increase in the solar field area increases the electricity production, reducing the LCOE, on the other hand, in periods when the power cycle operates at maximum capacity and the TES is at maximum, the waste of energy increases, as well as the costs of installation, operation and maintenance. There is a turning point where the benefits of electricity production are overtaken by the remaining costs.

The system's layout to be implemented in SAM is presented in Figure 10.

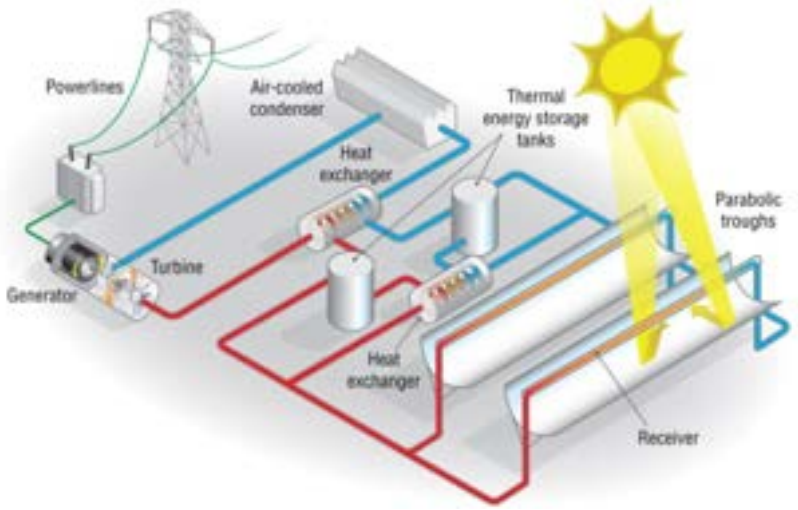

Figure. 10. Configuration of a CSP with PTC technology and a two-tank indirect TES [24].

5.1.1. Location and Resource

The SAM uses weather data from the National Solar Resource Data Base (NSRDB) developed by NREL.

Based on the levels of radiation that are potentially most viable for the implementation of a CSP system presented earlier, average values of DNI above 2000 kWh/m^2/year or 5.5 kWh/m^2/day, the region of Faro was chosen for the analysis of the system, since it is in the south of Portugal that is the region with the highest potential to implement CSP systems, exceeding the values presented above. The main values taken from the database with applicability in CSP systems are: DNI, average temperature and average wind speed and the values referring to Faro are 5.56 kWh/m^2/day, 18.5 ºC and 4.0 m/s, respectively.

5.1.2. System Design

The main system design parameters that determine the nominal capacity of the system are related with solar field, power cycle and TES, as presented in Table 2. Regarding the solar field, two crucial factor needs to be set: Solar Multiple (SM), design DNI.

The SM consists of the multiple of the area of the solar field required to operate the power cycle at its nominal capacity, in other words, a SM=1 represents the opening area of collectors that, when exposed to the design DNI, generates the exact thermal energy needed to operate the power cycle at nominal capacity.

The design DNI value is used to calculate the opening area of the solar collectors, which allows the power cycle to operate at the nominal capacity. Since the DNI varies over the course of the day and year, it is necessary to set a fixed value for the size of the solar field, knowing that its value depends on the geographical location and its value should be close, but lower, to the maximum value of annual DNI.

Table 2. Main system design parameters for SAM simulation [24].

Solar field	
Solar Multiple	2
Design point DNI	800 W/m^2
HTF	Pressurized water
Solar field inlet/outlet HTF temperature	100-150ºC
Power Cycle	
Design turbine gross output	50 kW_e
Estimated gross to net conversion factor	0.9
Cycle thermal efficiency	0.15
Thermal Energy Storage	
Hours of storage at design point	6 hours

5.1.3. Power cycle

The CSP system that comes implemented in SAM by default is the conventional Rankine cycle. SAM allows to use a custom power cycle, called User-Defined Power Cycle (UDPC), that uses data from a certain range of operating conditions to make a regression model. The performance of an ORC was modelled using actual operating data. The UDPC requires, as independent variables, the HTF temperature, HTF mass flow, and ambient temperature and, as dependent variables, gross electrical power generated and the thermal power entering the cycle.

5.1.4. Thermal Storage

The TES sizing is made based on the number of hours of storage of thermal energy that allow the power cycle to operate at the defined nominal power. In small-scale systems, the use of the thermocline tank has great potential, as it reduces costs and has high performance. According to Rodriguez et al. [16], the use of thermocline can represent a 33% reduction in TES costs when compared with a two-tank system with the same thermal storage capacity. SAM only allows to set two tanks direct and indirect storage system configurations, so that it was not possible to use thermocline in the simulation. The main parameters for TES are summarized in Table 3.

Table 3. Main parameters for TES system implementation [24].

Parameter	Value
TES type	Two-tank indirect storage system
TES fluid	Therminol VP-1
Hours of storage at design point	6h
TES thermal capacity	2 MWh_t
TES volume	109.04 m^3

5.1.5. Financial Parameters

The choice of the economic model, LCOE Calculator, leads to the need to introduce the relative installation costs as well as the fixed and variable operating costs. The relative installation costs were calculated through Power Purchase Agreement (PPA) economic model given that it allows to detail each of the system costs. The values used for installation costs are the values that SAM presents by default since they are an estimate of the NREL that best represents the typical costs of a CSP system. All standard values were kept except the cost of the power cycle which was adjusted to \$1000/kW_e to best represent the ORC under study. In Figure 11 the cost to install the CSP system is presented, where it is possible to verify that the solar field and TES system are the main costs, with shares of 31,5% and 22,2%, respectively.

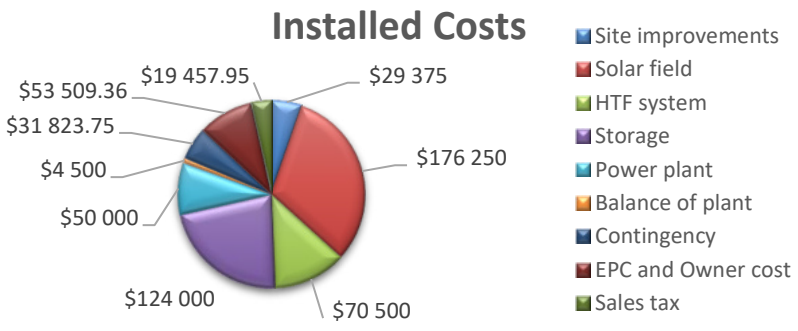

Figure. 11. CSP system installation costs [24].

5.2. Results

SAM offers several options that allow the analysis of the obtained data. The main results of the simulation are summarized in the Table 4 and a heat map is presented in the Figure 12. The implemented model has an annual electricity output of 145529 kWh for the gross installed power of 50 kW_e, which reveals a relative output of 3234 kWh/kW. The capacity factor of 36.9% is representative of the dispatchability that the system offers. The economic indicator obtained is the LCOE with a value of $0.3009/kWh which, when compared to the benchmark costs in the literature, $0.10-$0.20/kWh for large scale systems [8], is evident the effect of economies of scale of CSP systems.

Table 4. Main results of SAM simulation [24].

Metric	Value
Annual Net Electrical Energy Production	145,529 kWh-e
Annual Freeze Protection	618 kWh-e
Annual TES Freeze Protection	0 kWh-e
Annual Field Freeze Protection	618 kWh-e
Capacity factor	36.9%
Power cycle gross electrical output	163,673 kWh-e
First year kWh/kW	3,234 -
Gross-to-net conversion	88.9 %
Annual Water Usage	52 m^3
LCOE Levelized cost of energy	30.09 ¢/kWh

The heat map shows the system's electricity output over the first year of operation, which allows to identify the TES influence on the overall system performance. The period where the largest continuity of production occurs is between the 70th and 260th days of the year, between March and September, as expected. It is possible to verify the non-linear form as the system begins to operate in the early hours of the morning, which is in accordance with the relative movement of the sun during the year. Similarly, although the TES does not allow to see it, the system would also present a rounded shape in the afternoon. There are periods when the system presents negative power values, which is explained by the power required for the system to operate exceeds the power produced, such as the consumption of circulation pumps or tracking system.

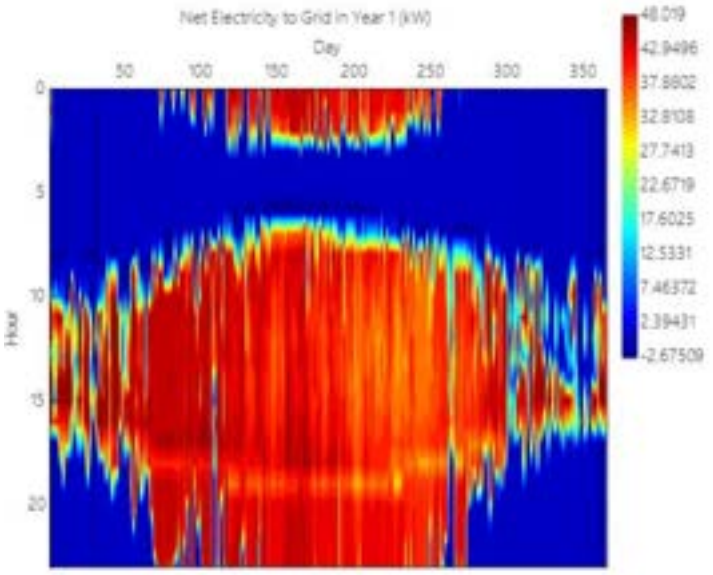

Figure. 12. Heat map of the system's electricity production in the first year of operation [24].

A comparison between the typical operation of the system on a winter day compared to a summer day is presented in Figure 13 and Figure 14, respectively. It is possible to verify that on winter days the system rarely operates at the design point as the available DNI is quite small and heavily affected by weather. All the energy that is captured in the solar field is used for power generation, there is no TES charging. On the other hand, in a typical summer day, a large amount of DNI is available which leads the system to a more stable operation at nominal capacity with great use of TES. The profile of the DNI on June 21 is perfect, which indicates that during that day the radiation does not face any obstacles to its passage, such as clouds.

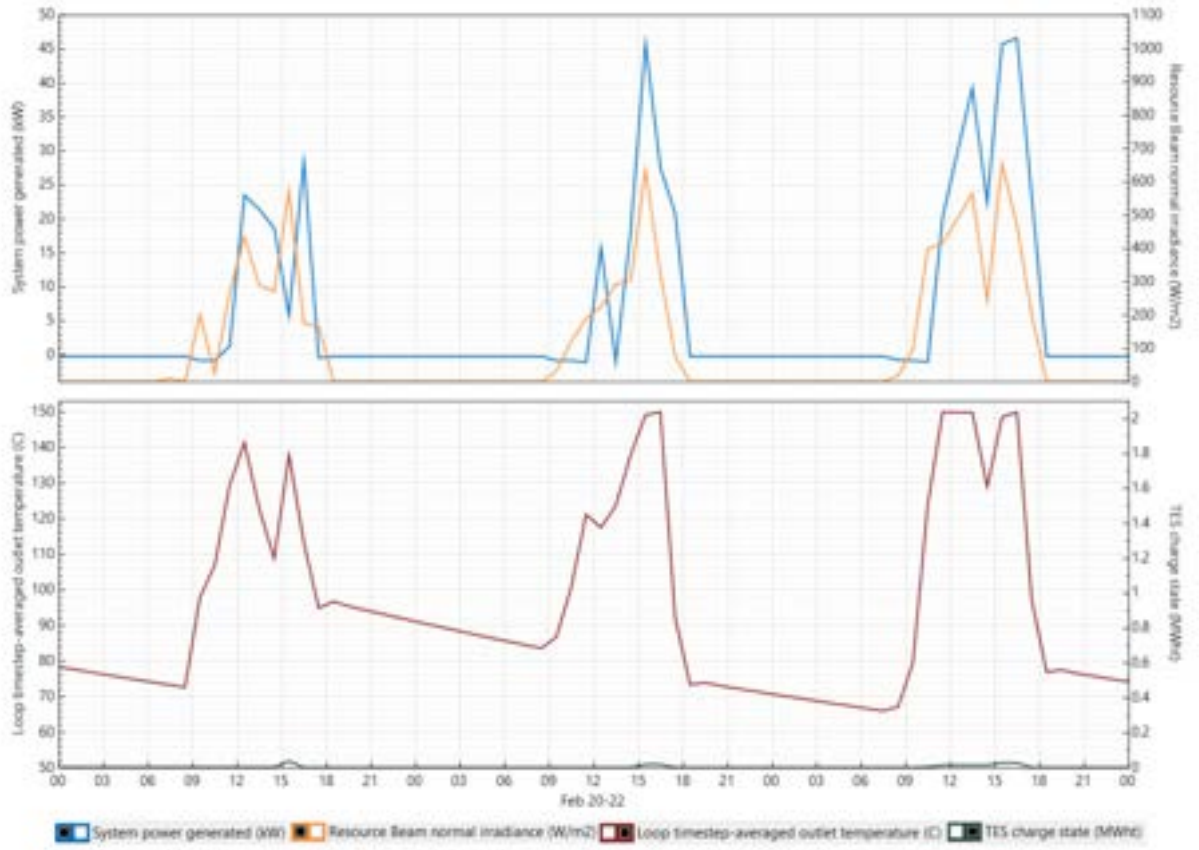

Figure. 13. System operation on a typical winter day [24].

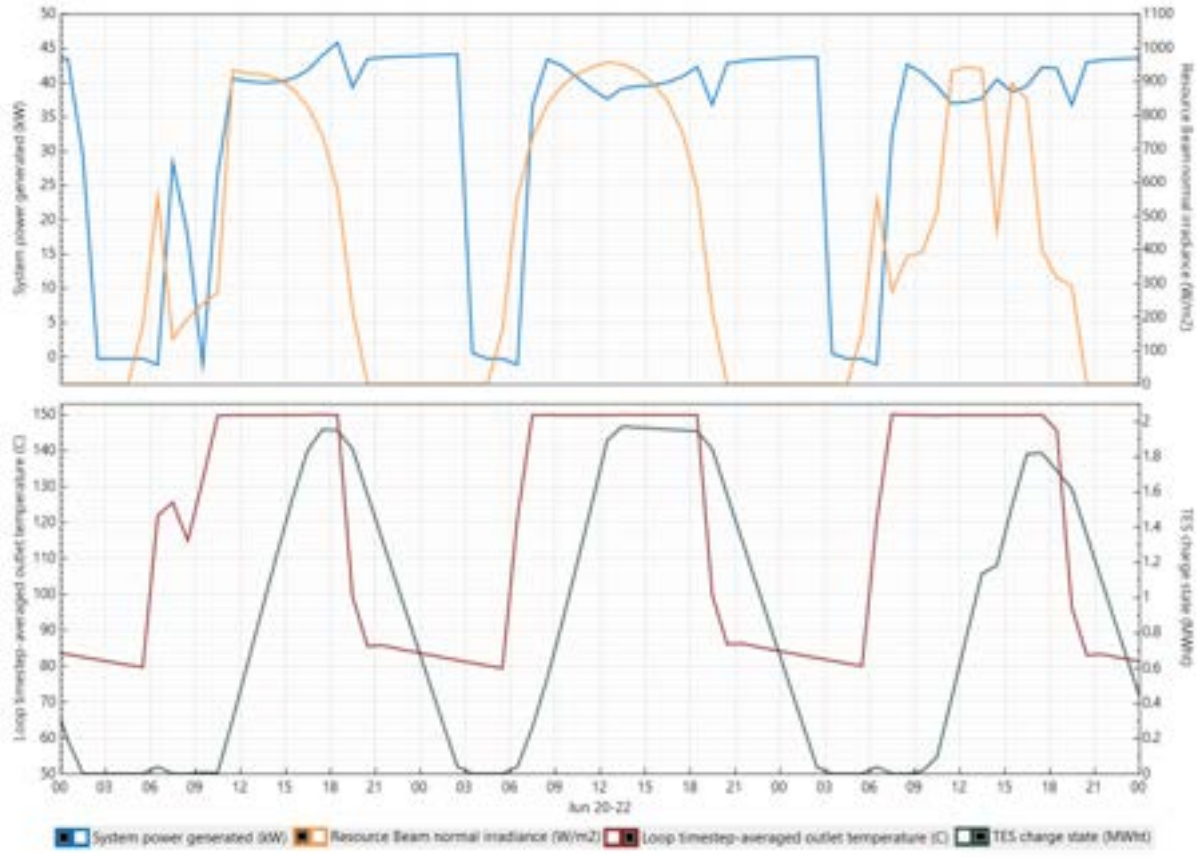

Figure. 14. System operation on a typical summer day [24].

Figure 15 presents the monthly production of energy throughout the year, where it is possible to prove that most of the production takes place between March and September. That profile results from the climate discrepancy between the seasons of the year in Portugal.

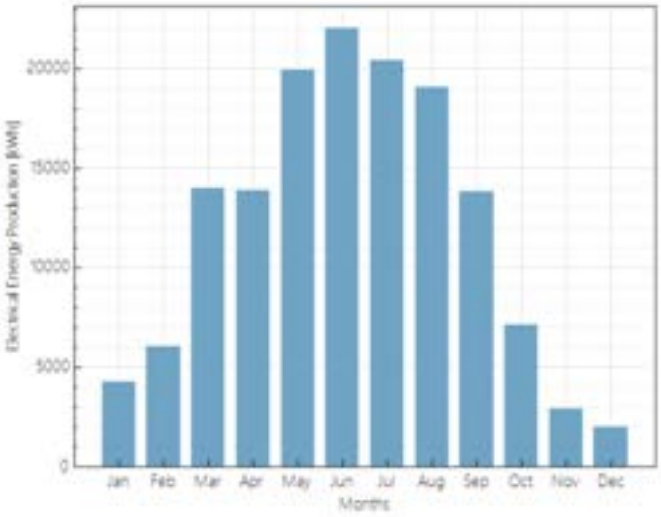

Figure. 15. Monthly electricity production in the first year of operation [24].

6. Conclusion

The shift in energy paradigm to reduce GHG emissions brings with it the need to replace the use of fossil fuels with renewable energies. In the power generation system, the transition to 100% renewable has some challenges to ensure the safety, reliability and dispatchability of the power grid. Following the development and investment in non-dispatchable electricity production technologies such as hydropower, wind, and PV, arises the need to create means of storage that allow a gap between renewable resource availability and electricity production.

CSP technology emerges as one of the potential solutions to ensure this gap. Its main advantage is the possibility of incorporating a TES system whose associated costs, as well as storage efficiency and environmental impact, make the technology favourable when compared to battery storage systems.

SAM is one of the leading tools for the techno-economic analysis of renewable energy systems, but its use for small-scale CSP systems analysis has proved challenging. Despite this, it was possible to implement a small-scale CSP case study that enabled the integration of an ORC actual data. The main results are: annual electricity production (145529 kWh), system cost ($559416.06), capacity factor (36.9%) and LCOE ($0.3009/kWh).

Even though SAM has several options that allow to create models with different characteristics and functions, it was found that it is not fully adapted for systems with such a small scale.

Abstract:
Waste heat recovery is one of the alternative energy sources that have been investigated by scientists in recent decades to address ongoing environmental problems, such as global warming. The organic Rankine cycle is a promising waste heat recovery technology to exploit industrial waste heat, even at low-temperature levels (<100^{o}C), for electricity production. The proposed study presents and compares two innovative organic cycle designs feeding with the same available heat source. The first cycle includes a nearly isothermal expander, where a small fraction of the supplied waste heat is continuously provided to the expander, aiming to approach a quasi-isothermal process instead of an adiabatic one, avoiding the temperature decrease due to the expansion process. The result is an increase in the cycle's thermal efficiency and greater power output production compared to the adiabatic expansion process. The second configuration is called the trilateral flash cycle, where the working fluid does not reach the saturated vapor state during heating at the heat recovery system, while it expands into the two-phase region of the fluid. The aforementioned cycles are investigated parametrically in terms of thermodynamics with a low-temperature heat source (80-100^{o}C) for different organic working fluids, such as the R1234ze(E), R1234yf, R1233zd(E), and R134a. Parametric studies are carried out through Aspen Plus software, while a techno-economic comparison of the organic cycle designs is conducted based on Aspen Process Economic Analyzer and literature data. According to the final results, R1233zd(E) seems to be the most proper working fluid thermodynamically, while the organic Rankine cycle with nearly isothermal expansion achieves higher values of both electrical and exergy efficiencies, reaching the maximum values of 10.51%, and 52.27%, respectively. In terms of finance, both cycles achieve similar payback period values, reaching the value of 1.56 years in the case of the trilateral flash cycle and assuming 8,000 operating hours per year. Finally, for the trilateral flash cycle, lower net present value levels of about 30% compared to the corresponding values for the other cycle, are determined despite its lower installation cost.

Keywords:
Trilateral Flash Cycle, ORC, isothermal expander, thermodynamic analysis, cost analysis, low-grade WHR.

1. Introduction

In recent decades, the increasing energy demand, economic, and population growth, as well as the high penetration of fossil fuels into the energy sector have led to significant environmental problems, such as air pollution, and global warming. Thus, the international community and scientists worldwide have promoted the utilization of alternative energy sources, such as the recovery of waste heat. In the industrial sector, considerable amounts of heat in various temperature levels depending on the processes, are rejected to the ambient, which can be recovered and further exploited to produce electricity or heating [1]. One of the most commercially available low-grade waste heat recovery technologies is the Organic Rankine Cycle (ORC). This cycle has a similar structure to the water-steam Rankine cycle but employs organic fluids with low saturation temperature levels. Thus, ORC can exploit low-temperature heat sources, even below 100^{o}C to produce electricity, while this kind of installation is highly reliable and easy to maintain [2].

Many researchers around the globe have focused on the performance of ORC modules. Indicatively, Eyerer et al. [3] analyzed experimentally the utilization of substances with low Global Warming Potential (GWP), such as R1233zd(E) and R1224yd(Z), instead of conventional fluids, such as R245fa. According to the final results, the maximum power output was achieved, when R245fa was used, which was 9%, and 12% higher than that of R1233zd(E), and R1224yd(Z), respectively. However, in the case of using the eco-friendly medium R1233zd(E), the thermal efficiency was enhanced by 2% compared to the other two fluid options. In the past few decades, the integration of the nearly isothermal expansion process in the ORC has been investigated. During the expansion process, heat is transferred to the organic medium maintaining the temperature at a higher level, compared to the conventional adiabatic process. Thus, the power output and thermal efficiency are expected to be enhanced [4]. Indicatively, Ziviani et al. [5] studied an ORC unit with liquid-flooded expansion and internal regeneration for different working media. In that case, a secondary fluid was ejected at the expander inlet being in thermal equilibrium with the organic fluid, to limit the temperature reduction due to the expansion procedure. So, the net electricity production and cycle efficiency could be increased by 20%, reaching up to 50% of the Carnot efficiency. Moreover, Kosowski and Piwowarski [6] performed the thermodynamic analysis of both a conventional ORC and an ORC with the ideal isothermal process. The incorporation of the isothermal process led to an increased cycle efficiency of up to 12% when the organic fluid reached the saturated vapor state, and up to 7% when the organic fluid reached the superheated vapor state.

In addition, another design has also gained attention and is called Trilateral Flash Cycle (TFC), which is a cycle similar to ORC. In TFC application, the working fluid reaches the saturated liquid state without evaporation and expands into the two-phase region. More specifically, Iqbal et al. [7] investigated in terms of energy a TFC system in comparison with a conventional ORC, considering a low-temperature heat source, up to 100^{o}C. According to this study, TFC could produce at least 50% further useful electricity compared to the conventional ORC for the same heat source and heat sink conditions. Ajimotokan [8] analyzed energetically and exergetically four TFC configurations, i.e. the simple TFC, the recuperated TFC, the reheat TFC, and the regenerative TFC. The results indicated that the aforementioned cycles could achieve thermal efficiencies of 21.97%, 23.91%, 22.07%, and 22.9%, respectively if the highest temperature of the cycle was equal to 473 K, and n-pentane was utilized as the working medium.

In parallel, many publications are concentrated on the comparison of different cycle designs. First, Zhar et al. [9] studied thermodynamically and economically three ORC configurations, i.e. the basic ORC, the reheat ORC, and the regenerative ORC, for different working fluids. According to the final outcomes, the regenerative ORC performed better energetically and exergetically, as the energy efficiency was enhanced by 13%, and the exergy destruction was reduced by 44%, contrasted to the basic ORC installation. From an economic point of view, all the configurations achieved similar payback periods and levelized cost of energy values. Furthermore, Kanno and Shikazono [10] carried out a thermodynamic comparison between a Rankine cycle, a TFC, and a supercritical cycle, taking into consideration different working media. Two different heat source cases were examined i.e. exhaust gas at a temperature level of about 400^{o}C, and hot water at a temperature level of about 80^{o}C. Assuming the 80^{o}C hot water as the heat source, the maximum exergy efficiency was determined based on the sink temperature for the TFC unit, using hydro-fluorocarbon refrigerants. Finally, for the 400^{o}C exhaust gas case, the ethanol supercritical cycle achieved the highest sink-temperature-based exergy efficiency.

According to the previous literature review, scientists are interested in the investigation of innovative organic cycle designs, such as the ORC with nearly isothermal expansion (ORC-NIE) or the TFC. Nevertheless, most of the aforementioned studies focus on a single design or compare these designs with other ones. There is a lack of research articles that compare these two configurations in terms of energy, exergy, and economics. So, the present work investigates the thermodynamic performance of both ORC-NIE and TFC, taking into account different working fluids. The heat source of both cycles is hot water with a temperature of up to 100^{o}C. Additionally, the two cycles are analyzed financially. The thermodynamic simulations are carried out in Aspen Plus software, while the cost estimation analysis is based on Aspen Process Economic Analyzer, and data from the literature studies [11,12].

2. Organic cycle designs' fundamentals

2.1. Organic Rankine cycle with nearly isothermal expansion

The proposed configuration includes the basic ORC devices, i.e. the pump, the heat recovery system, and the condenser. It is assumed that the organic fluid exits the heat recovery system as superheated steam, with a superheating level of 10 K. The subcooling level at the condenser is considered at 2 K. Additionally, the innovative element of this design, which is the incorporation of the nearly isothermal expansion process, has been decided to be modeled as a two-stage expansion, with intermediate additional heat input (Q_{heater}). It is also assumed that the fluid exits the first stage at an intermediate pressure level, then is heated up reaching the same temperature level as the one of the superheated steam at the heat recovery system outlet, and, finally, expands up to the condenser saturation pressure in the second stage. The intermediate pressure level (P_{med}) is defined taking into account the high (P_{high}) and the low-pressure level (P_{low}) as [13]:

$$P_{med} = \sqrt{P_{high} \cdot P_{low}}, \quad (1)$$

The ORC high pressure (P_{high}) is determined by taking into consideration a temperature difference of 10 K between the heat source inlet temperature ($T_{w,in}$) and the fluid temperature at the outlet of the heat recovery system. The main outputs of the ORC-NIE, which are the net electricity production ($P_{el,net,ORC\text{-}NIE}$), the electrical efficiency ($\eta_{el,ORC\text{-}NIE}$), and the exergy efficiency ($\eta_{ex,ORC\text{-}NIE}$), are described by the following expressions:

$$P_{el,net,ORC-NIE} = P_{el,exp,ORC-NIE} - P_{el,pump,ORC-NIE}, \quad (2)$$

$$\eta_{el,ORC-NIE} = \frac{P_{el,net,ORC-NIE}}{Q_{HRS,ORC-NIE}+Q_{heater}}, \quad (3)$$

$$\eta_{ex,ORC-NIE} = \frac{P_{el,net,ORC-NIE}}{E_{HRS,ORC-NIE}+E_{heater}}, \quad (4)$$

The exergy rate (E) due to a heat rate (Q) at a temperature level of (T), considering the reference temperature (T_0) of 25°C (298.15 K) can be defined as [14]:

$$E = Q \cdot \left(1 - \frac{T_0}{T}\right), \quad (5)$$

The model of the ORC-NIE in Aspen Plus is depicted in Figure 1.

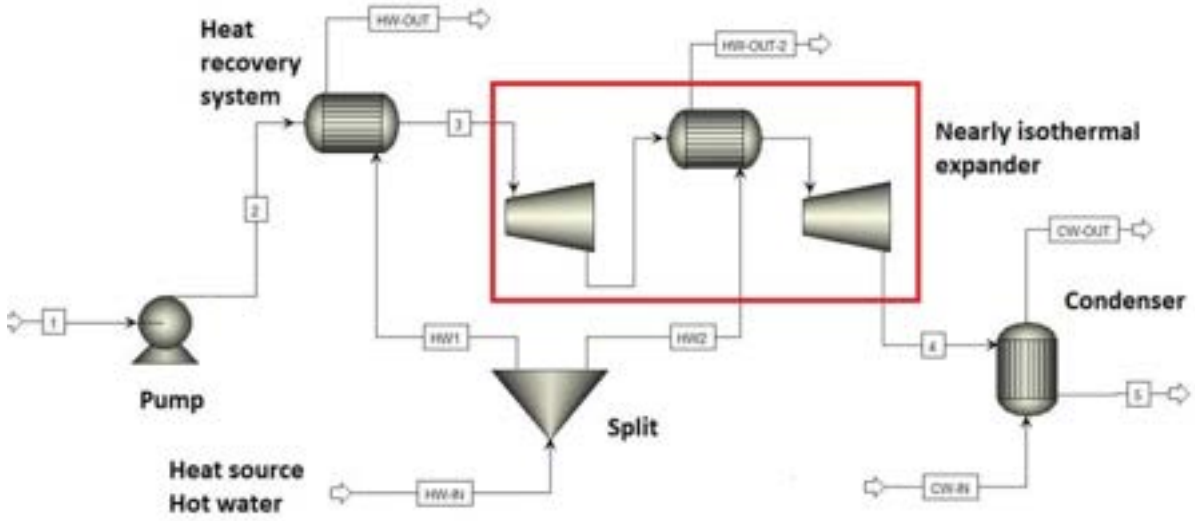

Figure. 1. Model of the ORC-NIE in Aspen Plus.

2.2. Trilateral flash cycle

The other examined design includes all the basic ORC devices, i.e. the pump, the heat recovery system, the expander, and the condenser. The main difference between the basic ORC module and the proposed one (TFC) is that the working medium exits the heat recovery system in the state of saturated liquid, without any evaporation or superheating. Subsequently, the fluid expands into the two-phase region of the substance. Additionally, the subcooling level at the condenser is considered at 2 K. The ORC high pressure (P_{high}) is determined by taking into consideration a temperature difference of 10 K between the heat source inlet temperature ($T_{w,in}$) and the fluid temperature at the outlet of the heat recovery system. The main outputs of the TFC, which are the net electricity production ($P_{el,net,TFC}$), the electrical efficiency ($\eta_{el,TFC}$), and the exergy efficiency ($\eta_{ex,TFC}$), are described by the following equations:

$$P_{el,net,TFC} = P_{el,exp,TFC} - P_{el,pump,TFC}, \quad (6)$$

$$\eta_{el,TFC} = \frac{P_{el,net,TFC}}{Q_{HRS,TFC}}, \quad (7)$$

$$\eta_{ex,TFC} = \frac{P_{el,net,TFC}}{E_{HRS,TFC}}, \quad (8)$$

The model of the TFC in Aspen Plus is depicted in Figure 2.

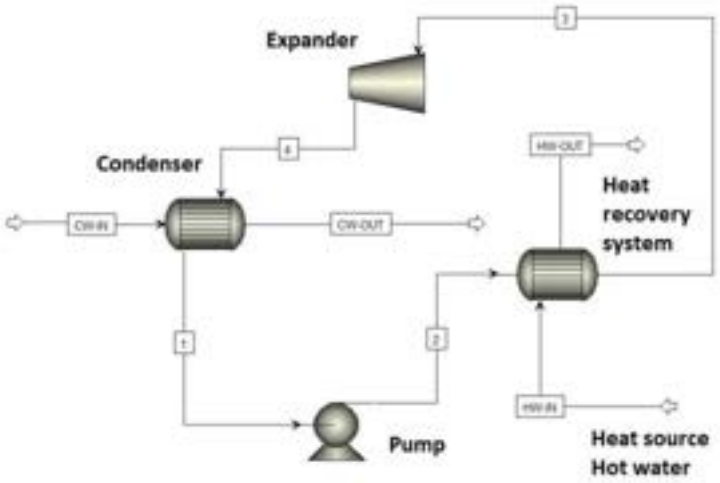

Figure. 2. Model of the TFC in Aspen Plus.

2.3. Techno-economic analysis

First, the investment cost (*IC*) of each cycle is defined taking into account the values that come from Aspen Process Economic Analyzer, and the literature studies [11,12]. In addition, the annual cash flow (*CF*) is defined considering the annual inflows and outflows. The annual inflows are consisted of the revenues from electricity selling, while the annual outflows include the operation & maintenance costs ($K_{O\&M}$). Taking into account the annual electricity production in kWh (Y_{el}), the operating hours per year (*hours*), and the electricity selling price in €/kWh (K_{el}), the annual cashflow is described by the following expression:

$$CF = Y_{el} \cdot K_{el} - K_{O\&M} = P_{el,net} \cdot hours \cdot K_{el} - K_{O\&M} \quad (9)$$

Then, the major financial indexes are defined. First, the payback period (*PBP*) is calculated as:

$$PBP = \frac{ln\left(\frac{CF}{CF - IC \cdot i}\right)}{ln\,(1+i)} \quad (10)$$

The net present value (*NPV*) is calculated as:

$$NPV = -IC + CF \cdot \frac{(1+i)^N - 1}{i \cdot (1+i)^N} \quad (11)$$

The aforementioned financial parameters are presented in Table 1.

Table 1. Parameters of financial analysis

Parameters	Values
Electricity selling price (K_{el})	0.2 €/kWh
Project lifetime (*N*)	20 years
Discount factor (*i*)	4%
Operation & maintenance cost ($K_{O\&M}$)	2% of the investment cost

2.4. Simulation methodology

First, the aforementioned cycles are studied parametrically in terms of thermodynamics in steady-state conditions through the developed models in Aspen Plus. More specifically, three main parameters are examined, the heat source inlet temperature ($T_{w,in}$), which strongly affects the cycle's high pressure (P_{high}), the condenser saturation temperature (T_{cond}), which strongly affects the cycle's low pressure (P_{low}), and the expander isentropic efficiency ($\eta_{is,exp}$). These values vary into a specific range to investigate their influence on the energetic and exergetic performance of the system. The heat source inlet temperature ($T_{w,in}$) ranges from 80 to 100°C, with a default value of 100°C, the condenser saturation temperature (T_{cond}), ranges from 10 to 40 °C, with a default value of 30°C, and the expander isentropic efficiency ($\eta_{is,exp}$) ranges from 0.4 to 0.8, with a default value of 0.7. Other parameters that remain constant during this analysis for both cycles are presented in Table 2. In parallel, the systems' operation is also examined for four different working fluids, which are depicted in Table 3. REFPROP is utilized as a proper method for refrigerants' properties [15]. Three of them (R1234ze(E), R1234yf, R1233zd(E)) are eco-friendly media with low GWP values, while R134a is a conventional refrigerant with a high level of GWP. All these fluids have zero Ozone Depletion Potential (ODP) and are selected as they have a critical temperature close to the examined heat source temperature levels. Then, the 2 designs are investigated financially. For this study, different values of

operating hours per year are assumed. All the defined thermodynamic and financial indexes (η_{en}, η_{ex}, *PBP, NPV*) are used to compare the aforementioned two cycles and specify the most techno-economically viable one when the two cycles are fed with the same heat source. Finally, it is important to mention that the two cycles are decided to be compared for similar heat input rates. That's why, a constant temperature difference of 20K and a constant flow rate is considered for the hot water stream.

Table 2. Constant parameters of both cycles.

Parameters	Values
Pump isentropic efficiency	0.7
Pump driver efficiency	0.93
Expander mechanical efficiency	0.95
Heat source (hot water) volume flow rate	75.5 m^3/h
Heat source (hot water) pressure	3 bar
Heat source (hot water) temperature difference	20 K

Table 3. Examined working fluids [14,16].

Working fluid	Flammability & Toxicity	P_{crit} (bar)	T_{crit} (°C)	ODP	GWP
R1234ze(E)	No	36.35	109.26	0	7
R1234yf	No	33.82	94.70	0	4
R1233zd(E)	No	36.24	166.45	0	4.5
R134a	No	40.56	101.03	0	1320

3. Results and discussion

3.1. Thermodynamic analysis

In this section, the results of the thermodynamic analysis are presented. More specifically, the influence of the three aforementioned parameters, i.e. the heat source inlet temperature the condenser saturation temperature, and the expander isentropic efficiency, on the electrical and exergy efficiency of both cycles for different organic working media, is examined.

Figures 3 and 4 indicate that both electrical and exergy efficiencies increase with increasing heat source inlet temperature for both cycles and all working fluids. The maximum achieved electrical and exergy efficiencies of the ORC-NIE are equal to 7.7% and 38.32% respectively, while the same values for TFC are found at 5.19%, and 25.82% respectively when the heat source inlet temperature is equal to 100°C and R1233zd(E) is used as the fluid.

On the other hand, the electrical and exergy efficiencies have a decreasing rate depending on the condenser saturation temperature for both cycles and all fluids, as shown in Figures 5 and 6. The lower the condenser saturation temperature, the lower the cycle's low pressure, so the cycle's useful work increases. The maximum electrical efficiency of the ORC-NIE and the TFC is calculated at 10.51% and 7.46%, respectively, for a condenser saturation temperature of 10°C and R1233zd(E) as the working medium. At the same temperature and for the same fluid, the exergy performance reaches the value of 52.27%, for the case of ORC-NIE, and 37.11%, for the case of TFC.

Moreover, the electrical and exergy efficiencies increase when the expander isentropic efficiency increases for both cycles and all the fluids, as it is illustrated in Figures 7 and 8. When the isentropic efficiency increases, the process is getting closer to the ideal isentropic one, leading to higher power output. The maximum determined electrical and exergy efficiencies of the ORC-NIE are equal to 8.79% and 43.72% respectively, while for TFC these values are defined at 6.08% and 30.26% respectively when the expander isentropic efficiency is equal to 0.8 and R1233zd(E) is the fluid used.

Consequently, according to Figures 3-8, in all cases, the electrical and exergy efficiencies of the ORC-NIE are higher compared to the corresponding values of TFC, as the energy content of the fluid at the expander inlet is greater for the case of the ORC-NIE, leading to higher power output. Furthermore, the most efficient fluid in terms of energy and exergy performance is R1233zd(E) for both cycles. At this point, it is important to mention that the influence of the working fluid type on the expander isentropic efficiency is not taken into account. It is assumed that the entire range of isentropic efficiency from 0.4 to 0.8 can be achieved utilizing all the examined working media.

The maximum achieved value of ORC-NIE electrical efficiency, which is equal to 10.51%, is similar to the corresponding optimized value calculated in the study [5]. For a heat source temperature of 100°C, the optimum efficiency was found at 9.6%. Moreover, according to one study [10], the TFC electrical efficiency reached the value of 7.4 %, when the heat source temperature was equal to 80°C. In the present study, the maximum defined level of TFC electrical efficiency is equal to 7.46%, which is close to the value in the literature.

The main thermodynamic results for both cycles at the default scenario conditions (heat source inlet temperature, the condenser saturation temperature, and the expander isentropic efficiency equal to 100°C, 30°C, and 0.7, respectively) and R1233zd(E) as the working fluid, including the main results of the heat exchangers, are presented in Table 4. The TFC condenser requires greater surface area as the condenser load is larger in this case compared to the case of ORC-NIE. Additionally, for the ORC-NIE a greater exchange area at the heat recovery system is needed to be installed, as in this case, three processes are taking place, which are the preheating, the evaporation, and the superheating of the working medium. On the other hand, TFC requires a heat recovery system with a smaller area, because the fluid reaches the state of saturated liquid.

In addition, the Sankey diagrams for the default case of each cycle are illustrated in Figures 9 and 10. It is important to mention that the available heat source load has been defined taking into account the temperature difference between the heat source inlet temperature and the reference (ambient) temperature. According to the Sankey diagrams, the pump and the condenser loads of TFC are greater than the ones of ORC-NIE, leading to poorer exploitation of the available heat source. In addition, a temperature-specific entropy (T-s) chart for both cycles is depicted in Figure 11. According to this diagram, it is obvious that the enclosed surface of the ORC-NIE, which represents the cycle's useful output, is larger compared to the case of TFC. Taking all of the above into consideration, the ORC-NIE is the most proper choice in terms of thermodynamics for low-grade heat sources.

3.2. Techno-economic analysis

In this section, the results of the techno-economic study are presented, which have been calculated taking into account R1233zd(E) as working fluid and the thermodynamic results of the default scenario, from the previous section. As it is shown in Table 5, the investment cost of the ORC-NIE is greater compared to the corresponding value of the TFC. It is considered a reasonable result, as the higher electricity production requires a larger expander size. Additionally, the ORC-NIE requires heaters with larger heat-exchanging areas, as shown in Table 4. The greater size of these components strongly affects the investment cost, leading to a significant increase. Additionally, the ORC-NIE achieves greater values of NPV for all the examined operating hours. NPV is equal to 299 k€ in the case of 2,000 operating hours per year, and 2,417 k€ for 8,000 operating hours. However, for the TFC, slightly lower values of PBP are calculated, which are determined from 1.56 years for 8,000 operating hours per year up to 7.68 years when the operating hours are equal to 2,000. Consequently, the TFC is more economically viable in terms of initial cost and achieves slightly lower PBP, but in terms of NPV, the ORC-NIE performs better financially. For the case of 8,000

operating hours per year, the main techno-economic results are presented in Table 5. The financial indexes for both cycles and different operating hours per year are shown in Figure 12.

Table 5. Results of techno-economic analysis

Costs	Values for ORC-NIE	Values for TFC
Investment cost	320,300 €	202,000 €
Investment cost per kW_{el}	2,466 €/kW_{el}	2,300 €/kW_{el}
Annual electricity production (8,000 operating hours)	1,039.1 MWh	702.1 MWh
Annual cash flow (8,000 operating hours)	201.4 k€	136.4 k€
Net present value (8,000 operating hours)	2,417 k€	1,651 k€
Payback period (8,000 operating hours)	1.68	1.56

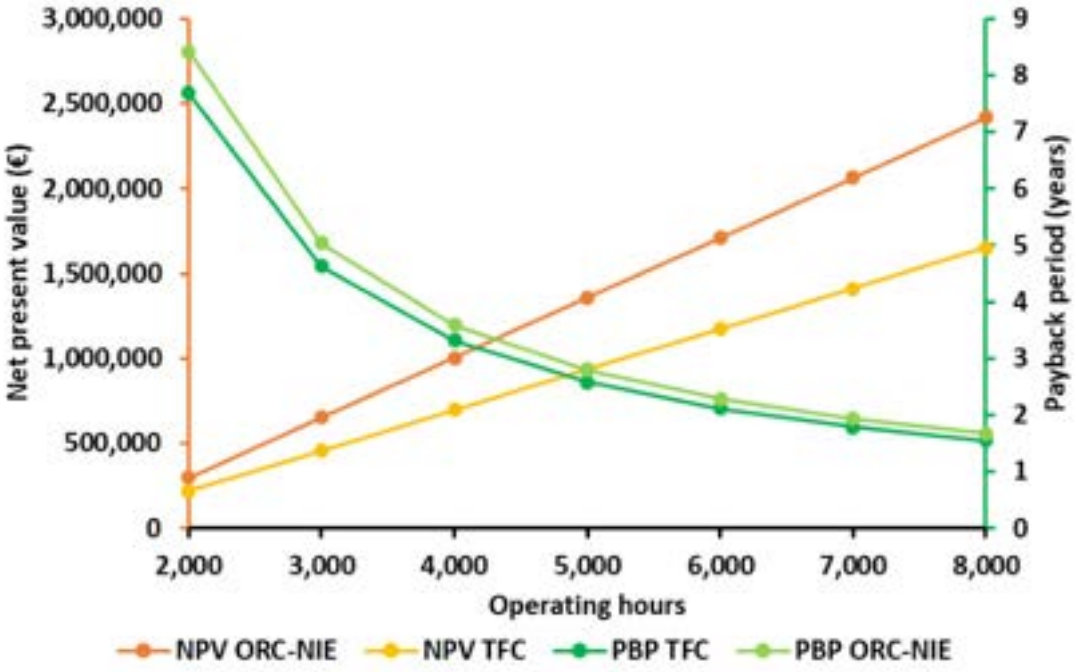

Figure. 12. Net present value and payback period for both cycles and different operating hours per year.

4. Conclusions

The present paper focuses on thermodynamic and techno-economic analysis and comparison of two organic cycle designs that are capable of operating at low-grade heat sources. For the comparison, the same available heat source conditions are assumed. The first one is similar to the ORC, but the expansion process approaches the isothermal conditions, and the second one is the TFC. The main conclusions are summarized below:

- R1233zd(E) seems to be the most proper organic working medium for both cycles in terms of thermodynamics.
- Both electrical and exergy efficiencies are enhanced with the increase of the heat source inlet temperature, and the expander isentropic efficiency while having a decreasing rate when the condenser saturation temperature increases.
- For the ORC-NIE, higher levels of electrical and exergy efficiencies are determined. The maximum achieved values are 10.51%, and 52.27%, respectively.
- For the case of TFC, lower investment costs and slightly lower payback period values are defined. The payback period can reach the value of 1.56 years when the annual operating hours are equal to 8,000.
- The ORC-NIE performs better in terms of net present value levels. On the other hand, TFC achieves net present values which are about 30% lower compared to the corresponding values of ORC-NIE.

The present work can be extended in the future, considering other organic cycle configurations, such as the recuperative ORC, and performing transient simulations.

Acknowledgments

This research has been co-financed by the European Regional Development Fund of the European Union and Greek national funds through the Operational Program Competitiveness, Entrepreneurship, and Innovation, under the call RESEARCH – CREATE – INNOVATE (project code: T2EΔK-00351). Moreover, this study has received funding from the European Union's Horizon Europe research and innovation program under grant agreement No 101058453 (FLEXIndustries - Digitally-enabled FLEXible Industries for reliable energy grids under high penetration of Variable Renewable Energy Sources (VRES)).

Abstract:

As a part of the transition of the energy system towards renewables, new technologies and combinations of technologies are emerging. These include utilization of medium temperature industrial processes or availability of surplus heat from renewables. For these applications, organic Rankine cycles may be cost efficient solutions, if both expander work and condenser heat may be utilized as valuable products. In this study, a solar powered organic Rankine cycle using a zeotropic mixture is investigated from a design perspective. Both an Exergy and Exergoeconomic analysis were conducted. The investigated unit is capable of co-producing approximately 30 kW electricity and 160 kW district heating with a exergetic efficiency of > 60 %. The unit is able to compete with existing renewable power generating systems in terms of specific cost of electricity.

Exergy, Exergoeconomic Analysis, Organic Rankine Cycle, Zeotropic Mixtures, District Heating.

1. Introduction

The climate crisis is the defining crisis of our time, and the escalation has been substantial in the last decade. The global threat is substantial and we as a society have the possibility of changing our current heading [1, 2]. In the last decade, the focus on finding new solutions to slow down or reverse our impact on the climate has been growing. This is also due to the heightened commitment from many governing bodies to pass laws and set goals that push the transition towards a carbon-neutral society. The European Union has published the Strategic Energy Technology Plan (SET-plan) which highlights 10 innovations and reaches areas that boost the progress to reach the goals set by the European Union [3]. The overall goal set by the European Union is to reduce the total emissions by 40 % between 1990 and 2030 [4]. In Denmark, the ambitions have been set high and goals of reducing the total emission by 70 % by 2030 and achieving net zero emissions by 2050 have been established by the Danish government. These goals will be achieved by increasing the supply of renewable energies and through energy optimisation. This will be guaranteed by investing in programmes such as the EUDP programme which focuses on research, development and demonstration (R&D) of new technologies related to renewable energy [5–7].

Due to their flexibility, safety, and low maintenance, ORC's appears to be a promising technology. They have favourable characteristics to exploit waste heat or low-temperature heat sources stemming i.e. from power-to-X or pyrolysis plants for conversion into work or electricity [8–10]. The combinations of heat source and ORC are many. However, in recent years extensive research has been carried out investigating solar-powered ORC systems. The use of solar irradiation as the driving force of the ORC shows great promise as a renewable energy technology due to the high compatibility between the achievable temperature of the solar collector matches well with the working temperature of the ORC cycle [8, 11, 12]. The Parabolic Trough Collector (PTC) is the most mature solar concentrating technology and is typically chosen due to their reasonable cost and relatively high efficiency. Furthermore, they perform well in lower solar resources and/or more cloudy climates [11–13].

The investigation of working fluids for ORC systems is covered in great length in literature where many have applied exergy analysis while fewer have performed an exergoeconomic analysis. The performance and economics of an ORC system are tightly linked to the working fluid. A higher efficiency may be achieved by choosing the correct working fluid, even with less expensive components [9, 14]. Many studies also consider the use of fluid mixtures as the working fluid. The great interest in fluid mixtures for use in power cycles stems from the possibility to reduce the irreversibility during a two-phase heat transfer process by utilizing the temperature glide of the working fluid mixture [14]. Rayegan and Tao [15] developed a methodology specifically for the selection of working fluids for solar-driven ORC systems. The method based the selection of working on several different parameters such as the molecular components of the fluids, temperature-entropy diagram and effects on the thermal and exergy efficiency. Tchanche et al. [9] investigated the performance of a low-temperature solar ORC based on thermodynamic criteria such as working pressure, mass and

volume flow of different working fluids. Isentropic working fluids proved favourable such as butane and n-pentane. R152a, R600a, R600 and R290 also resulted in attractive performances. Habka and Ajib [16] investigated the performance of zeotropic mixtures in a small solar-driven ORC for combined heat and power. They further compared the mixture with pure fluids. The results showed that the mixture R409A outperformed the pure fluid R134a and R245fa, and could reduce the production cost of the energy unit to 16.20%. In a similar study done by Wang and Zhao [17], a low-temperature solar-driven ORC using both pure fluid and zeotropic mixtures is investigated. They also introduced an internal heat exchanger (IHEX) to the ORC. The IHEX improves the overall efficiency of the cycle. They found that when superheating the zeotropic mixtures and introducing the IHEX, a significant increase in thermal efficiencies can be gained. Garg et al. [18] investigated hydrocarbons mixed with carbon dioxide for flammability suppression of the hydrocarbons in a medium-temperature concentrated solar-powered ORC. Their study showed that extending the heat recovery in the IHEX into the two-phase region resulted in higher efficiency and is advantageous. However, at the same time, an exergy analysis showed that irreversibility in the IHEX was caused by the shifting of the pinch point towards the warm end of the IHEX. With a mixture of propane and CO_2 a real cycle efficiency of 15–18% was achieved at a source temperature of 573 K.

Ashouri et al. [19] performed an exergo-economic analysis and optimization of a double pressure ORC with a solar collector and storage tank. Results show that system can reach the efficiency of 22.7%. The exergoeconomic analysis revealed that the solar collector has the highest $\dot{Z} + \dot{C}_D$ due to both high exergy destruction and high investment costs of the collector. Following the collector, the storage tank, condenser, turbine, recuperator and evaporators had the highest destruction. Le et al. [20] carried out similar thermodynamic and economic optimization of a subcritical ORC (Organic Rankine Cycle) using a pure (n-pentane and R245fa) or a zeotropic mixture working fluid (mixtures of the two). In the study, a maximization of exergy efficiency and minimization of the LCOE (Levelized Cost of Electricity) was found which showed that the n-pentane-based ORC showed the highest maximized exergy efficiency of 53.2% and the lowest minimized LCOE of 0.0863 $/kWh. Regarding ORCs using zeotropic working fluids, 0.05 and 0.1 R245fa mass fraction mixtures present comparable economic features and thermodynamic performances to the system using n-pentane at minimum LCOE.

In this study, a solar-powered ORC with a storage tank will be investigated. The sytem is designed to have a 200 kW heat input which is converted into 30 kW of electricity and 160 kW of district heating. The system is constrained to off-the-shelf components. The system will be evaluated based on thermodynamic performance, exergetic performance and exergoeconomic performance. Furthermore, three different working fluids will be investigated, one pure fluid and two mixtures. By conducting the various analysis, options for improvement of the design should be identified and ranked in terms of priority. The analysis differentiates from available literature as it focusses on medium scale (e.g. 100-1000 kW thermal) ORC systems to be coupled to solar thermal collectors, with the aim to supply both electricity and district heating. As the system is synthesized by off-the-shelf components, exergoeconomic analysis was used to differentiate the value of various improvement possibilities. The design of the system is part of a EUDP-project abbreviated Fullspec, which stands for full spectrum solar power.

2. Methods

This section covers the theory and working principles of the system and the methods used for performing an exergy analysis and exergoeconomic analysis.

2.1. System Description

The system investigated in this study is illustrated in Fig 1. The system can be dived into three main loops: 1) Solar loop, 2) ORC loop and 3) District Heating loop. The solar loop consists of the PTC field and storage tank. In the solar loop, a thermal oil is used as heat transfer fluid. In the analysis it is assumed that the thermal oil is heated to 250 °C in the PTC field and transferred to a stratified storage tank. The thermal oil is then used as a heat source for the ORC loop by transferring heat in the evaporator. The thermal oil used in the solar loop is Gobaltherm® Omnisol.

The ORC loop is a standard ORC configuration with an IHEX and a liquid receiver. Here the liquid working fluid from the receiver is pressurized through the ORC pump. In the IHEX heat is recovered to preheat the working fluid from state 2 to 3. The working fluid is evaporated in the evaporator and then expanded through the expander resulting in the production of electricity. Lastly, the working fluid condenses in the condenser, transferring heat to the DH water and hereby heating it.

Three different working fluids are investigated. The different working fluids in three cases are 1) pure iso-pentane, 2) iso-pentane/CO_2 (0.99/0.01) and 3) iso-pentane/undecane/CO_2 (0.89/0.10/0.01). Here all ratios are given regarding mass basis. This numbering of cases will be used onwards. Case 1 might be viewed as the base case. The two mixtures additionally investigated are due to a desire to 1) avoid vacuum with in the system when the system is offline, and 2) maintain or increase performance compared to case 1.

2.2. Thermodynamic Model

The modelling of the system was done using Engineering Equation Solver (EES) [21] where all thermodynamic properties were determined using REFPROP [22]. All parameters used for the modelling of the system is presented in Table 1. The system was modelled in a steady state where mass and energy balances were applied to control volumes for each

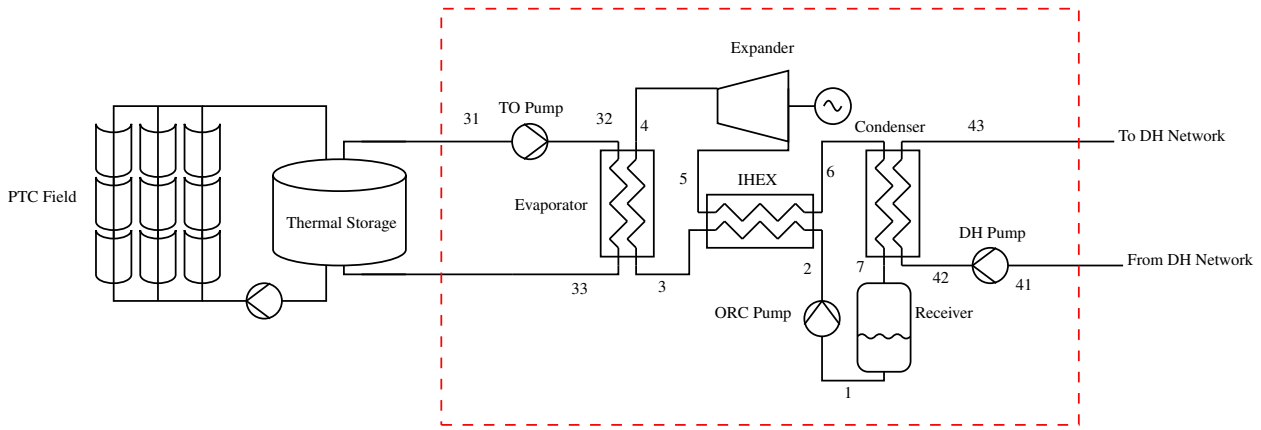

Figure 1: Schematic of the PTC powered ORC. The red dashed line mark the boundaries of the system investigated.

component using the general forms given in (1). Here, $\dot{m}$ is the mass flow rate, $\dot{Q}$ is the heat transfer rate across the control volume boundary, $\dot{W}$ is energy transfer by work, and h is enthalpy. The subscripts i and o denotes inlet and outlet streams, respectively.

$$0 = \sum_i \dot{m}_i - \sum_o \dot{m}_o \qquad \text{and} \qquad 0 = \dot{Q} - \dot{W} + \sum_i \dot{m}_i h_i - \sum_o \dot{m}_o h_o \tag{1}$$

Heat loss to the surroundings was neglected. However, the model did accounts for the pressure loss in the pipes and heat exchanger. The pressure loss through the heat exchanger is based on values from obtained heat exchanger manufactures. The pressure loss through the pipes is determined by the energy equation for pipe flows in (2) where the difference in velocity and height is neglected.

$$\Delta p = \frac{1}{2}\rho u^2 \left(f_f \frac{L}{D} + \sum K \right) \tag{2}$$

The power consumption of the pumps and gross power output of the expander are both determined using their respective isentropic efficiency, η_{pump} and η_{exp}.

The net electrical power output of the system is defined as the gross electricity production where the required electricity of the all pump are subtracted.

$$\dot{W}_{\text{net}} = \eta_{\text{gen}} \dot{W}_{\text{exp}} - \dot{W}_{\text{ORC,pump}} - \dot{W}_{\text{TO,pump}} - \dot{W}_{\text{DH,pump}} \tag{3}$$

The work required by the thermal oil pump accounts for the pressure loss through evaporator and pipes back and forth to the thermal storage.Similar, the worked required by the district heating pump accounts for the pressure loss through the condenser and the pipes connecting to the district heating network. The district heating pump does not take into account the loss through the overall district heating network.

The electric net efficiency of the system is defined as

$$\eta_{net,el} = \frac{\dot{W}_{net}}{\dot{Q}_{evap}} \tag{4}$$

The UA-value of each heat exchanger is determined based on a discretisation of the overall heat transfer in the heat exchangers. For each control volume, the following is applied assuming the cold side of the heat exchanger:

$$\dot{Q}_n = \dot{m}_{n,c} \left(h_{n,o,c} - h_{n,i,c} \right) \tag{5}$$

$$\dot{Q}_n = UA_n \Delta T_{\text{lmtd},n} \tag{6}$$

The overall UA is then determined by

$$UA = \sum_{j=1}^{n} UA_j \tag{7}$$

2.3. Exergy Analysis

To perform exergy analysis and exergoeconomic, the exergy destruction rate ($\dot{E}_{\text{D},k}$) for each component k was determined, using the theory described in [23].

Table 1: System parameters used in the present study

Parameter		Value	Parameter		Value
Thermal Oil Loop			*ORC Loop*		
TO inlet temperature	T_{31}	250 °C	Evaporator heat input	$\dot{Q}_{\text{evap}}$	200 kW
TO outlet temperature	T_{33}	200 °C	Expander inlet temperature	T_4	225 °C
TO inlet pressure	p_{31}	500 kPa	Expander isentropic efficiency	η_{exp}	225 °C
District Heating Loop			Expander inlet pressure	p_4	3000 kPa
DH outlet temperature	T_{43}	70 °C	Pinch temperature in IHEX and condenser	ΔT_{pinch}	5 K
DH inlet temperature	T_{41}	40 °C	Expander generator efficiency	η_{gen}	0.98
DH inlet pressure	p_{41}	500 kPa	Condenser outlet quality	x_7	0
Overall					
Pump isentropic efficiency	η_{pump}	0.7			

In this study, only the physical part of the exergy is accounted as no changes in chemical composition occurs due to the implied steady state assumption, the system being a closed cycle and no splitting of streams with respect to the working fluid. The physical exergy is determined from (8) where the difference in velocity and elevation has been neglected.

$$e^{\text{PH}} = (h - h_0) - T_0(s - s_0) \tag{8}$$

For the exergy analysis, the fuel and product for each component were used to evaluate the performance of each individual component and the entire system. The general definitions of fuel and product are given by Bejan, Tsatsaronis, and Moran [23] and are presented in Table 2 for relevant components.

From the exergy rate of fuel and product, two exergy destruction ratios and the exergetic efficiency:

$$y^*_{D,k} = \frac{\dot{E}_D}{\dot{E}_{D,\text{tot}}} \qquad \text{and} \qquad \epsilon_k = \frac{\dot{E}_P}{\dot{E}_F} \tag{9}$$

Here y_D is the exergy destruction with a component with respect to the overall fuel input, y^*_D is the exergy destruction with a component with respect to the overall exergy destruction in the system and ϵ is the exergertic efficiency.

2.4. Exergoeconomic Analysis

The exergoeconomic analysis is, as the name implies, the combination of exergy analysis and the economics regarding the system. Prices for components within the ORC for all three cases along with the price for solar collectors, storage and district heating connection are based on offers collected from suppliers. Prices will not be presented due to confidentiality. Furthermore, price for each component with the ORC are adjusted such that the sum of prices of components matches with the actual retail price of the ORC unit. The actual retail price is based on a fixed percentage of profit desired for the sale of a ORC-unit. Parameters used for the exergoeconomic analysis is presented in Table 4. The exergoeconomic analysis is based upon the cost balances known from conventional economic analysis. In conventional economical analysis, the cost balance will typically be formulated for an entire system, whereas in the exergoeconomic analysis, they will be formulated for each component. The cost balance for the k'th component is given by

$$\dot{C}_{P,k} = \dot{C}_{F,k} + \dot{Z}^{\text{CI}}_k + \dot{Z}^{\text{OM}}_k \tag{10}$$

where $\dot{C}_{P,k}$ is the cost rate associated with the product, $\dot{C}_{F,k}$ is the cost rate associated with the fuel, $\dot{Z}^{\text{CI}}_k$ is the cost rate associated with the capital investment and $\dot{Z}^{\text{OM}}_k$ is the cost rate associated with operation and maintenance (O&M). The capital investment and O&M were be combined to $\dot{Z}_k = \dot{Z}^{\text{CI}}_k + \dot{Z}^{\text{OM}}_k$. The cost balance states that the cost rate associated

Table 2: Fuel and product definitions for various components. Subscripts c and h refers to the hot and cold stream in a heat exchanger

Parameter	Pumps	Expander	Heat Exchanger
Product, $\dot{E}_P$	$\dot{E}_o - \dot{E}_i$	$\dot{W}$	$\dot{E}_{o,c} - \dot{E}_{i,c}$
Fuel, $\dot{E}_F$	$\dot{W}$	$\dot{E}_i - \dot{E}_o$	$\dot{E}_{i,h} - \dot{E}_{o,h}$

with the product must be equal to all expenditures used to generate the product. Similar to the definitions of fuel and products presented in Table 2, definitions of the cost rate associated fuel and product is also created. Furthermore, auxiliary equation are needed. Both are presented in Table 3. The cost rate associated with capital investment of the component is determined based on the lifetime of the component and the yearly operational hours which yields in

$$\dot{Z}_k^{\mathrm{CI}} = \frac{CI_k}{t_{\mathrm{OP}} Y_k} \tag{11}$$

where Y is the expected lifetime of the component in years, t_{OP} is the yearly operation of the system in seconds. Furthermore, the cost rate associated with O&M of each component is assumed to be 5% of the capital investment for the given component and is then determined from the yearly operation.

$$\dot{Z}_k^{\mathrm{OM}} = \frac{0.05 CI_k}{t_{\mathrm{OP}}} \tag{12}$$

2.5. Exergoeconomic Performance Parameters

Based on the thermoeconomic properties previously introduced, several performance parameters were defined. The three employed performance parameters are 1) the cost of exergy destruction, $\dot{C}_{D,k}$, 2) the relative cost difference, r_k and 3) the exergoeconomic factor, f_k.

The cost of exergy destruction does not directly show itself from the cost balance previously presented. However, from the exergy balance and cost balance, one will be able to obtain the cost of exergy destruction of the k'th component, which describes as

$$\dot{C}_{D,k} = c_{F,k} \dot{E}_{D,k} \qquad \text{or} \qquad \dot{C}_{D,k} = c_{P,k} \dot{E}_{D,k} \tag{13}$$

As seen the cost of exergy destruction may be defined in two different ways. The first definition assumes that the rate of product ($\dot{E}_{P,k}$) is fixed and that the unit cost of fuel ($c_{F,k}$) is independent of the exergy destruction. The second definition assumes that the rate of fuel ($\dot{E}_{F,k}$) is fixed and that the unit cost of the product($c_{P,k}$) is independent of the exergy destruction. In general, the first definition gives a lower estimate and the second definition gives a higher estimate with the actual value of $\dot{C}_{D,k}$ being in-between.

The relative cost difference r_k for the k'th component is defined by

$$r_k = \frac{c_{P,k} - c_{F,k}}{c_{F,k}} \tag{14}$$

The relative cost difference displays the relative increase in average cost per exergy unit between product and fuel. The relative cost difference also highlights whether the increase in the cost of the product stems from the price of fuel or the price associated with capital investment and O&M for the component.

Lastly, the exergoeconomic factor is defined for k'th components as

$$f_k = \frac{\dot{Z}_k}{\dot{Z}_k + c_{F,k} \dot{E}_{D,k}} \tag{15}$$

The exergoeconomic factor expresses a ratio which enables one to highlight whether the increase in cost rate from fuel to product stems from non-exergy-related cost or not. In the denominator of (15) $\dot{Z}_k$ is associated with non-exergy-related cost and $c_{F,k}\left(\dot{E}_{D,k} + \dot{E}_{L,k}\right)$ is associated exergy-related cost. A low value of the exergoeconomic factor for a component indicates that the increase in cost is due to high exergy destruction within the component and vice versa. Often the value of the exergoeconomic factor varies dependent of the component type. For compressors or turbines, the value is typically between 0.35 and 0.75, heat exchanger typically have a value below 0.55 and pumps tend to have a value above 0.7.

Table 3: Cost of fuel and product definitions for various components. Subscripts c and h refers to the hot and cold stream in a heat exchanger

Parameter	Pumps	Expander	Heat Exchanger
Product, $\dot{C}_P$	$\dot{C}_o - \dot{C}_i$	$\dot{C}_w$	$\dot{C}_{o,c} - \dot{C}_{i,c}$
Fuel, $\dot{C}_F$	$\dot{C}_w$	$\dot{C}_i - \dot{C}_o$	$\dot{C}_{i,h} - \dot{C}_{o,h}$
Auxiliary equation	None	$c_i = c_o$	$c_{i,h} = c_{o,h}$

2.6. Levelised Cost of Electricity

The levelised cost of electricity (LCOE) is a measurement that enables one to assess and compare alternative methods of energy production. The LCOE of an energy-generating system should be seen as the average total investement and O&M cost of the system per unit of total electricity generated over an assumed lifetime. Alternatively, the LCOE can be seen as the average minimum price at which the electricity generated by the system is required to be sold to break even with the total costs of building and operating the system over its lifetime [24]. The overall assumptions used for the calculation of LCOE is presented in Table 4. The LCOE is determined by

$$\text{LCOE} = \frac{\sum_{y=1}^{Y} \frac{CI_y + O\&M_y}{(1+r_r)^y}}{\sum_{y=1}^{Y} \frac{W_y}{(1+r_r)^y}} \tag{16}$$

where CI is the capital investment per year, O&M is the cost of the operational and maintenance per year, W is the electricity production per year and r_r is the discount rate. No fuel term is used as the solar input is assumed to be free of charge. The value of O&M in year 1 is estimated as 5% of the investment cost of entire system, equal to the definition used in the exergoeconomic analysis. After year 1 the cost of O&M increases with r_{OM} percent per year. This yields in

$$O\&M_y = O\&M_1 \, (1 + r_{\text{OM}})^y \quad \text{for} \quad y > 1 \tag{17}$$

The yearly production of electricity is determined by

$$W_y = \dot{W}_{net} t_{\text{OP}} \quad \text{for} \quad y = 1, 2 \ldots Y \tag{18}$$

3. Results and Discussion

A comparison between the different cases has been carried out and the main thermodynamic findings are presented in Table 5. The overall electrical efficiency of the system is greatest for the third case, followed by case 1 with the second highest. This relates to the output of the expander. As the inlet conditions of the expander are equal for all three cases, outlet conditions determine the possible output of the expander. Here lower outlet pressure contributes to more power output. This also means that one should strive to find working fluids that allow for a lower condensation pressure. On the other hand, case 2 has the greatest overall efficiency due to a higher district heating output. However, as electrical efficiency is valued highest, Case 3 is promising as the electrical efficiency of the system increases compared to case 1 while avoiding vacuum in a non-operational state. The gained efficiency does come at a price as the sizing of heat exchangers is influenced by the choice of the working fluid. Compared to case 1, the UA-values of the condenser and IHEX in case 3 are $\approx 38\,\%$ and $\approx 127\,\%$ greater, respectively. One of the reasons that increases in UA-values are observed for mixtures is the temperature glide occurring in the condensation phase which affects the temperature differences. This is quite evident when comparing the process in the condenser for cases 1 and 3. As seen Fig 2, a larger temperature difference can be clearly seen the in the condenser (state 6-7) for case 1 to case 3 and even though $\dot{Q}_{\text{cond}}$ is smaller than in case, the UA-value needed is still greater. The temperature glide of the mixtures and the desired $\Delta T_{\text{pinch}} = 5[\text{K}]$ in the condenser and IHEX further results in condensation starting in the IHEX. This means that two-phase flow will exit the IHEX and enter the condenser. Especially in case 3, where a large portion of the process is in the two-phase region. These conditions should be taken into account when building the system as it might lead to maldistribution in the condenser.

Table 4: Economical parameters used for the exergoeconomic analysis and determination of LCOE. All components are assumed to have equal expected lifetime.

Parameter		Value
Expected lifetime	Y	20 years
Discount rate	r_r	5%
Yearly increase of O&M	r_{OM}	0.25%
Yearly operation	t_{OP}	6000 hours

3.1. Exergy Analysis

The results of the exergy analysis are presented in Table 6. There are four major components that stand for 98 % of all the exergy destruction in the system and they are the heat exchanger and expander. This also shows that the pumps are almost neglectable. Based on the analysis, the expander is in all three cases the component associated with the largest amount of exergy destruction, followed by the evaporator, condenser, IHEX and pumps. The expander stands for 37 % to 43 % of the overall exergy destruction. The high exergy destruction in all three is related to the relatively low isentropic efficiency of the expander. The expander also has the lowest exergetic efficiency of major components. This combination of high exergy destruction and low exergetic efficiency could suggest that the expander would be the first component to optimize in order to reduce the exergy destruction.

The large amount of exergy destruction within the evaporator is mostly due to the specification of the system, where thermal oil must return at 200 °C. This creates large temperature differences throughout the heat exchanger. A lower outlet temperature could be considered with the goal of reducing exergy destruction as the evaporator is a heat exchanger with the greatest amount of exergy destruction.

It is quite interesting to note that case 3 has the highest exergetic efficiency for all heat exchangers. This also highlights the benefits of utilizing the temperature glide which allows lower temperature differences and therefore, lower exergy destruction. The mixture of case 3 has a quite significant temperature glide, as seen from Fig 2. The effects of the temperature glide are particularly clear in the condenser where both case 2 and 3 have lower exergy destruction and higher exergetic efficiency compared to case 1. However, for case 2 the benefit of the mixture is only present in the condenser as lower exergetic efficiencies are seen in the evaporator and IHEX compared to case 1.

When investigating the overall performance of the system, case 3 has the best performance of the three cases with a system exergetic efficiency of 64.1 % and a total exergy destruction of 35 kW. Case 2 results in the lowest thermal efficiency of the 3 cases. However, opting for case 2 to obey the no-vacuum criteria will only result in a 1.0 % decrease in exergetic performance while opting for case 3 will result in a 4.4 % increase in exergetic performance. As expected a small difference is observed in the overall performance, due to the two cases being almost identical.

3.2. Exergoeconomic Analysis

The main findings of the exergoeconomic analysis is presented in Table 7. The exergoeconomic parameters will be evaluated based on the procedure suggested by [23]. Here the analysis starts by investigating the value of $\dot{Z} + \dot{C}_D$ and ranking the components based on their value. This couple with firstly evaluating the value of r and secondly, evaluating

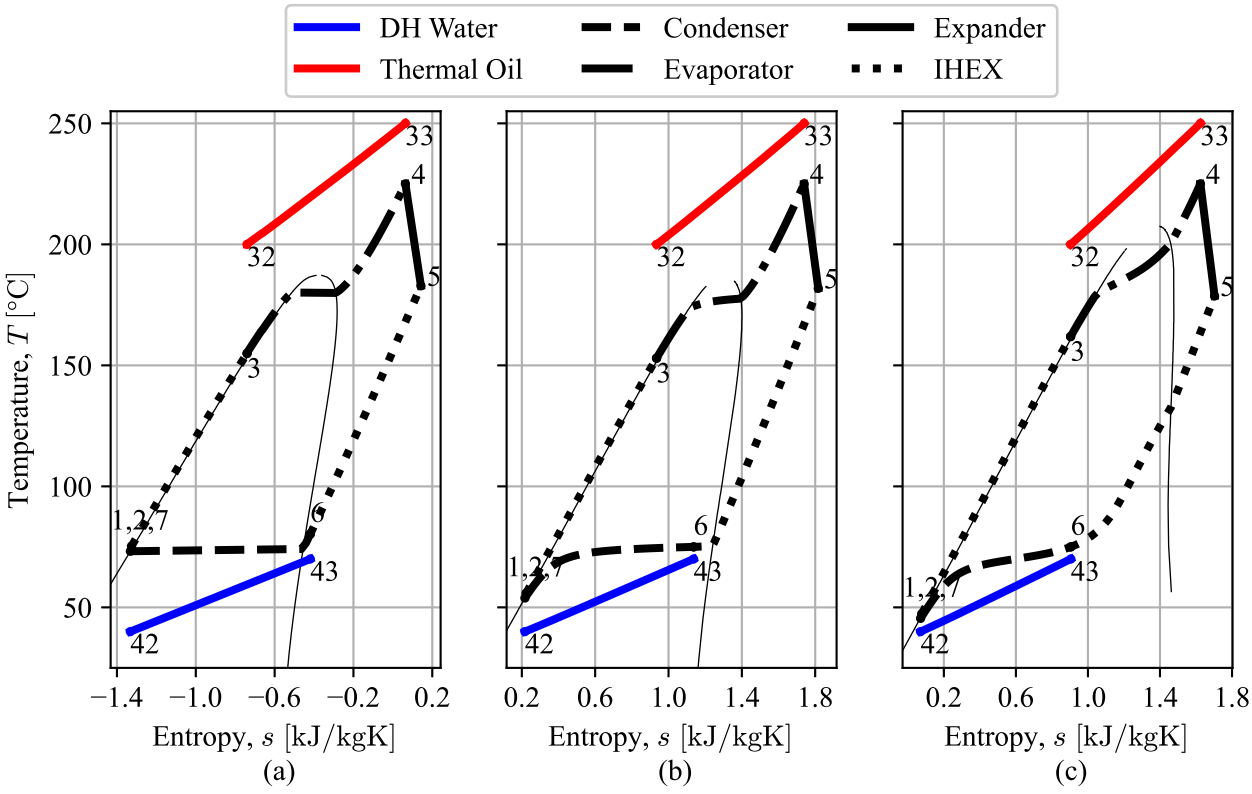

Figure 2: T,s-diagram for (a): Case 1, (b): Case 2 and (c): Case 3. It should be noted DH water and Thermal oil is used for visualisation and entropy is only for the working fluid

the value of f.

The expander is in all three cases the component with the greatest value of $\dot{Z} + \dot{C}_D$ and the value is more than 3 times greater than that of other components. However, this is expected as the expander is the most expensive component of all, coupled with having the highest exergy destruction. This indication suggests that the expander would be the first component where design changes or choice of expander type should be considered. For the rest of the components, the

2	0.83	0.33	0.05	0.65	0.16	0.98	0.99
3	0.82	0.49	0.08	0.62	0.26	0.98	0.99

three cases differ with regards to the ranking of highest to the lowest value of $\dot{Z} + \dot{C}_D$.

When further investigating the relative cost difference, r, for the expander, a value above 1 can be observed. This indicates that a majority of the increase in the cost of the product stems from the price of the capital investment and O&M, rather than the price of the fuel. The same conclusion can be made for all pumps. Especially for thermal oil pump and district heating pump, the value of r is very high. On the contrary, the increase in the cost of the product for all heat exchangers stems from the price of the fuel rather than capital investment and O&M. The fact that all the more mechanically complicated component have a higher value of r, is as expected due to the much higher price of components such as turbo machinery and pump compared to heat exchangers. Furthermore, components which do add much thermodynamic value to the system also then to have high values of r. This is seen from both the thermal oil and district heat pump. The pump does not have to overcome high pressure differences and should mainly ensure flow, hereby having close to zero exergy destruction associated with these components. Therefore, a high value of r is inevitable.

Last, the exergoeconomic factor, f, is investigated. This factor should ideally be 0.5, meaning that the cost is evenly distributed between the cost of capital investment and O&M and the cost of exergy destruction. However, the value tends to depend on the type of component. The exergoeconomic factor for the pumps and expander for all cases is above 0.5. Therefore, it could be cost-effective to decrease the capital investment of these components at the expense of their efficiency. Especially, the values for the pumps as their values are quite close to 1. The value of the expander may be over 0.5 but as the value for an expander is between 0.35 and 0.75, a value of 0.65 is quite acceptable. Therefore, the expander may not be the right component to optimize as few economical benefits would stem from it. As expected, it would be beneficial to increase the capital investment for both the evaporator and condenser as most of the cost is associated with the cost of exergy destruction. Especially, the evaporator which also relates to the high exergy destruction and the boundary conditions set for the system. The value of f for the IHEX is greater compared to the evaporator and condenser. In case 1 and 2, a greater investment could be beneficial but the IHEX in case 3 is very close to the optimum of 0.5.

When comparing the exergy analysis and the exergoeconomic analysis, similar conclusions may be drawn for some components, whereas conflicting conclusions can be drawn from others. The pumps in the system would not harm the exergy efficiency of the system greatly if the pumps were downgraded to cheaper models with lower efficiencies due to their low contribution to the overall exergy destruction. In most cases, both the exergy and exergoeconomic analysis indicates that more could be invested in the heat exchangers which would reduced to exergy destruction and benefit the system. Here the exception is the IHEX in case 3 as the exergoeconomic factor is 0.49. The expander is a component that stands out in all cases as the exergy analysis would suggest improving it as it is the greatest contributor to the exergy destruction of the system. However, it would not be cost effective to improve the expander as shown by the exergoeconomic analysis.

3.3. Levelised Cost of Electricity

Lastly, LCOE may also be used to compare the three systems. The LCOE is presented in Table 8. Here the lowest value of LCOE is found for case 3 with a value of 0.87 DKK/kWh and 1.69 DKK/kWh. Even though, the ORC-unit is more expensive in case 3 compared to case 1 because of the larger heat exchangers needed, the increased performance of the system results in a lower LCOE. Compared to another renewable technology photovoltaics (PV), the LCOE for case 3 is slightly above the LCOE for PV but within the price range of PV systems with battery storage when looking at the ORC-unit isolated. However, when including the solar collectors and storage, the price slightly exceeds to LCOE of PV with battery storage. However, the ORC benefits from producing district heating as well. Therefore, an additional source of income will also be associated with the ORC system.

Table 8: LCOE for all three cases. LCOE are given for the ORC-unit isolated and including the solar field and storage

Parameter	Case 1	Case 2	Case 3
$LCOE_{\text{ORC}}$ [DKK/kWh]	0.89	0.92	0.87
$LCOE_{\text{ORC+Solar}}$ [DKK/kWh]	1.79	1.84	1.69

4. Conclusion

The current study investigates a 200 kW heat input solar driven ORC-unit based on thermodynamic, exergetic and exergoeconomic performance. The study has been investigating three different ORC working fluids, one pure fluid and 2 mixtures. The mixtures are chosen to ensure an offline pressure of 1 atm Iso-pentane is the pure fluid and the two mixture are iso-pentane/CO_2 (0.99/0.01) and iso-pentane/undecane/CO_2 (0.89/0.1/0.01). The greatest electrical net efficiency of the ORC was found for the last mixture at 14.18 % which is a 9.5 % improvement compared to the pure fluid. The first mixture performed worst with an efficiency of 12.73 %. The improvement from pure fluid to second mixture does require greater heat exchangers compared due the temperature glide of the mixture ensuring lower temperature differences. Similar, results are seen from the exergy analysis. Here the second mixture has the smallest overall exergy destruction 34.96

kW and the highest exergetic efficiency of 64 % due to the utilization of the temperature glide. The expander was in all three cases the component with the largest amount of exergy destruction.

The exergoeconomic factor of the exergoeconomic analysis highlighted the pumps in the system as the components where capital investment should be greatly reduced as it would benefit the overall system economically. For all three cases, the analysis suggested that a greater investment for both the condenser and evaporator could be made improving the components and hereby being both exergetic and economically beneficial. The exergoeconomic analysis illustrated IHEX and expander are two components that are close their optimal operational state with regard to capital investment and thermodynamic efficiency. Even though, the expander is associated with the greatest amount of exergy destruction, no economical benefits will be the result of improving the component.

With the current layout and specific choice of components, the ORC unit isolated will be able to produce electricity at LCOE of 0.87 DKK/kWh which is within the range of PV systems with battery storage but the LCOE of 1.69 DKK/kWh for combined system with the ORC unit, solar field and storage slightly exceeds that of PV systems with battery storage. However, this is without accounting for the extra revenue generated by the district heat.

Nomenclature

Roman Letters

$\dot{C}$	Cost rate [DKK/s]
c	Average cost per unit of exergy [DKK/kJ]
D	Diameter [m]
$\dot{E}$	Exergy flow rate [kW]
f	Exergoeconomic factor [−]
f_f	Friction Factor [−]
h	Specific enthalpy [kJ/kg]
K	Minor Losses [−]
L	Length [m]
$\dot{m}$	Mass flow rate [kg/s]
p	Pressure [kPa]
$\dot{Q}$	Heat transfer rate [kW]
r	Relative Cost Difference [−]
r_r	Discount rate [−]
$\dot{S}$	Entropy flow rate [kJ/(Ks)]
T	Temperature [°C]
t	Time [s]
u	Velocity [m/s]
$\dot{W}$	Power [kW]
Y	Lifetime [year]
y^*	Exergy desctruction ratio [−]
$\dot{Z}$	Non-exergy related cost rate [DKK/s]

Greek Letters

η	Efficiency [−]
ν	Kinematic viscosity [m^2/s]
ρ	Density [kg/m^3]

Subscripts

k	Component
0	Reference state
[1;43]	State points
c	Cold Side
D	Destruction
F	Fuel
gen	generation
h	Hot Side
i	inlet
L	Loss
o	Outlet
P	Product
pinch	Pinch point
s	Isentropic
tot	Total system
y	Year

Superscripts

CI	Capital Investment
OM	Operation & Maintenace
OP	Operational
PH	Physical

Acronyms

DH	District heating
IHEX	Internal heat exchanger
LCOE	Levelized cost of electricity
O&M	Operation and Maintenance
ORC	Organic Rankine Cycle
PTC	Parabolic Trough Collector
TO	Thermal Oil

Abstract:

Global warming has increased the use of renewable energy in energy systems. In this regard, the present work presents an innovative polygeneration system to produce power, ammonia, and process steam using solar, biomass, wind, and geothermal energies. By using a solar-syngas hybrid boiler, steam has been created in two high-pressure (HP) and low-pressure (LP) levels, and the HP steam is used for the gasification process. Syngas produced from biomass gasification process produces ammonia with the nitrogen obtained from an air separation unit by going through water gas shifting and carbon capture processes. Power consumption in the mentioned sections is produced by wind turbines. A Brayton cycle with ammonia and hydrogen hybrid fuel has been used to produce power and heat. The integration of supercritical CO_2 and organic Rankine cycles with the hot flue gas output from the Brayton cycle has reduced heat losses and increased power generation. The presented renewable system has been analysed from the point of view of energy, exergy, exergeoeconomic, and exergoenvironmental (4E) methods. The overall results indicate that the total energy and exergy efficiencies are 31.33% and 38.53%, respectively. Also, the cost rate and environmental impacts of the whole system are calculated as 3222.35 $/h and 53.16 Pts/h, respectively. Meanwhile, the levelized cost and environmental impacts of electricity are equal to 0.18 $/kWh and 0.003 Pts/kWh, and the presented system is capable of producing 297.86 ton/day of ammonia.

Keywords:

Ammonia synthesis; Solar and biomass; Wind energy; Geothermal; Polygeneration.

1. Introduction

In the field of energy, there are various crises that indicate the importance of using renewable resources as a sustainable solution for energy production. These crises include rising prices of fossil fuels, decreasing levels of oil production, increasing air pollution, and the effects of desertification and global warming. In addition to the existing crises in the field of energy, energy production is also facing environmental crises. The use of fossil fuels leads to an increase in greenhouse gases and climate change, which has serious effects on life globally. Also, the use of fossil fuels causes air pollution and an increase in respiratory-related diseases. Biofuel production has been considered as a sustainable solution for energy production due to its biological properties. Biofuel is obtained from renewable sources such as plants, agricultural waste, and other organic materials and reduces greenhouse gases and air pollution [1]. In 2020, more than 80% of the installed power capacity worldwide was supplied by renewable sources [2]. This percentage will likely increase due to the increasing growth of the renewable industry.

One of the famous examples of biofuels is ammonia. Ammonia is one of the most widely used chemicals in the world. Ammonia synthesis from natural gas reforming [3], or ammonia production with syngas is one of its production methods [4]. Recently, the idea of creating an alternative fuel for fossil fuels has arisen, hydrogen can be converted into ammonia and then ammonia can be used as a fuel [5]. In addition, producing ammonia and replacing it with fossil fuels has advantages, including reducing air pollution and generating energy [6]. Furthermore, considering that hydrogen is not easily accessible and its storage is not necessarily easy, producing ammonia from hydrogen as an alternative approach has many advantages. In this regard, Aziz et al [7]. showed in their research that ammonia can be used in internal combustion engines, combustion for gas turbines, and direct ammonia fuel cells due to its high efficiency. Also, Lamb et al [8]. proposed hydrogen storage by ammonia production as a suitable way to transport and store it. Tinoco Caicedo et al [9]. conducted a study using biofuels in tri-generation systems to meet the energy demands of an instant coffee plant located in Guayaquil, Ecuador. The results show an increase in exergy efficiency from 51.9% to 84.5%

The use of renewable energies such as wind, solar, geothermal, and biomass is highly justifiable due to the countless benefits they have in the fields of energy, economy, health, and the environment [10]. Although each of the renewable energies individually creates many possibilities for us, the integration of these energies can significantly improve efficiency and reduce energy production costs [11]. Mousavi Rabati et al [12]. have proposed an integrated multi-generation system based on renewable energy sources such as solar and biomass for the production of power, heat, freshwater, and hydrogen. Their analysis results show that for Municipal Solid Waste (MSW) fuel, the overall energy and exergy efficiencies of the multi-generation system are 39% and 32.01%, respectively. The flexibility of renewable energy systems allows us to have the most efficient energy production systems in any condition. Borhanazad et al [13]. showed the potential of using wind, solar, and water energy well for two states in Malaysia to provide electricity. In these two states, due to the high potential of solar radiation, they can produce 3182 kW and 6317 kW through 18 and 22 sites, respectively. During their research in Europe and Latin America, Bersalli et al [14]. observed the positive impact of using renewable energy sources on reducing the economic costs of energy production. Khani et al [15]. demonstrated a multi-technology solar-based energy production system, which integrates gas and steam turbine cycles, organic Rankine cycle (ORC), and carbon dioxide capture, Humidification-dehumidification (HDH), showing that electricity production can be increased from 37.3% (in winter) to 59.41% (in summer) by integrating solar energy.

There are different solutions for integrating energy systems, for example, cogeneration and polygeneration systems can be used [16]. The Brayton cycle is one of the processes in cogeneration, in which electricity and heat are produced using a fuel such as ammonia. The goal of using renewable fuels is to reduce the environmental impact of using fossil fuels [17]. Also, the Supercritical CO_2 (S-CO_2) cycle is a power generation technology in which supercritical carbon dioxide is used as the working fluid in a closed-loop system. The supercritical carbon dioxide cycle offers several advantages over traditional steam-based cycles in energy systems, such as higher efficiency, lower footprint, lower capital costs, and lower greenhouse gas emissions [18]. The economic and environmental characteristics of a multi-generation system are very important. Multi-generation production systems can be used in various industries, such as freshwater production [16]. Diyoke and Ngwaka [19], integrated a gasifier, a syngas electric motor, connected to an absorption refrigeration system, and a wind turbine generator. They observed that the overall energy efficiency and exergy efficiency were 0.48 and 0.25, respectively, and major exergy destruction of about 95% for this system in this system, wastes are first collected and separated, and then sent to processes for energy production [20].

Despite extensive research in the field of renewable energy systems, the dependence of these systems on fossil fuels is still felt to create stability. Therefore, presenting a system that is entirely based on renewable energies requires further research. In this regard, the present work focuses on utilizing solar, biomass, and wind energies to produce ammonia as an alternative fuel for energy systems. The ammonia produced as a biofuel is then used in the Brayton cycle to generate sustainable power. The integration of S-CO_2 cycles and ORC in this system has increased power production and improved the efficiency of the studied system. Finally, by conducting energy, exergy, economic, and environmental analyses for the studied system, the feasibility of operating such a system has been examined in more detail. A series of innovations carried out in the present work are as follows:

- Ammonia production has been done using the integration of solar, wind, and biomass energies.
- The gas turbine cycle with a combined fuel of ammonia and hydrogen has been analyzed.
- The integration of S-CO_2 and ORC with the Brayton cycle based on ammonia has been investigated.
- Machine learning has been used to analyze and model parts in the processing unit.

2. System description

In this work, a polygeneration system based on solar, wind, geothermal, and biomass renewable energy is proposed to produce ammonia, power, and heat (process steam). This system has been analyzed for the city of Tehran in Iran. Tehran is located at 51° 6' to 51° 38' east longitude and 35° 34' to 35° 51' north latitude. The solar irradiance in Tehran is about 1800 to 2200 kilowatt-hours per square meter per year. The average wind speed in this city is around 4.5 meters per second [21], and the geothermal source in Tehran can provide heat up to 110 degrees Celsius for the energy systems. Also, the biomass used in the system is municipal solid waste (MSW), and its annual production in Tehran is around two million tons on average. The designed system consists of sections for ammonia synthesis, CO_2 capture, water gas shift (WGS), gasification process, ORC (R123), S-CO_2 cycle, and Brighton cycle. Their explanations are given below. Based on Figure (1), which illustrates the schematic of the designed system, it can be stated that after the water makeup, steam is produced at two pressure levels, LP and HP, from a hybrid solar-syngas boiler using syngas as fuel. The produced LP steam is used as a process steam, while the HP steam is fed into the gasification reactor for the production of synthesis gas using the air-steam gasification agent. The chemical reaction that occurs in the gasifier is as follows:

$$CH_\alpha O_\beta N_z + wH_2O + m(O_2 + 3.76N_2) \rightarrow x_1H_2 + x_2CO + x_3CO_2 + x_4H_2O + x_5CH_4, \quad (1)$$

In the boiler, water is initially preheated by the heat of the syngas outlet from the gasifier and the heat resulting from its combustion in the boiler, and exits the system from the stream (4) and by solar energy, it loses its latent energy and enters the boiler and the LP steam leaves the stream (8). In the same way, another part enters and leaves the boiler with a higher pressure (HP) to enter the gasifier and produce syngas. The use of solar energy has been used as an aid to produce steam in the boiler. The second section of the syngas stream, which is the stream (21), enters the WGS stage to convert the CO in the syngas to CO_2. Its reaction is reported in relation (2):

$$CO + H_2O \leftrightarrow CO_2 + H_2, \quad (2)$$

The final synthetic gas, devoid of CO, is directed into a CO_2 capture process. Using an air separator unit (ASU), nitrogen is added to the exhaust gas from the CO_2 capture to produce ammonia with higher and more suitable efficiency, and gas rich in nitrogen and hydrogen enters the ammonia synthesis stage. In this section, the ammonia reaction takes place through two converters with a conversion efficiency of 25%, operating at a temperature and pressure of 350 ℃ and 30 bar, respectively [4, 22]. The ammonia reaction is as follows:

$$N_2 + 3H_2 \leftrightarrow 2NH_3, \quad (3)$$

The produced ammonia with a purity of 99% is removed from the separator, and a part of it is stored while the other part is used to maximize the use of the system designed for burning in the Brayton cycle, which is coupled with a PEM electrolyzer (PEMEC) to provide hydrogen for the combustion chamber. Hydrogen is added to ammonia to increase the fuel's calorific value. It is also noteworthy that the power required for the operation of the PEMEC and ASU in the CO_2 capture section is supplied by renewable wind energy through wind turbines. The wind turbine used is LTW77 and has a capacity of 1MW [23]. The required heat for the S-CO_2 cycle and ORC is supplied from the exhaust temperature of the gas turbine, which is high to reduce losses, recover heat, and generate power. The working fluid used in the Rankine cycle is R123, which utilizes geothermal energy to change the phase of the output water stream (55). Assumptions used in the proposed system:

- The system has been studied in a steady state, and kinetic and potential energies in all flows have been neglected.
- There is enough time to carry out the gasification reaction, so this equilibrium process is carried out
- Gasification pressure is considered constant.
- The production of tar and char in gasification has been disregarded.
- Heat losses in all heat exchangers have been disregarded.
- The temperature and working pressure of WGS reactors are 450 ℃ and 14.4 bar, respectively, and their fractional conversion is 88.2 [22].
- Ambient temperature and pressure are considered to be 25 ℃ and 1.01 bar, respectively.
- The collectors used are PTC and their model is ET100 [24].
- The temperature and pressure are assumed to be constant in the PEMEC, equal to 80 ℃ and 1 bar, respectively [25].
- The production of nitrogen oxides, sulfur, chlorides, etc. in the syngas products has been disregarded.

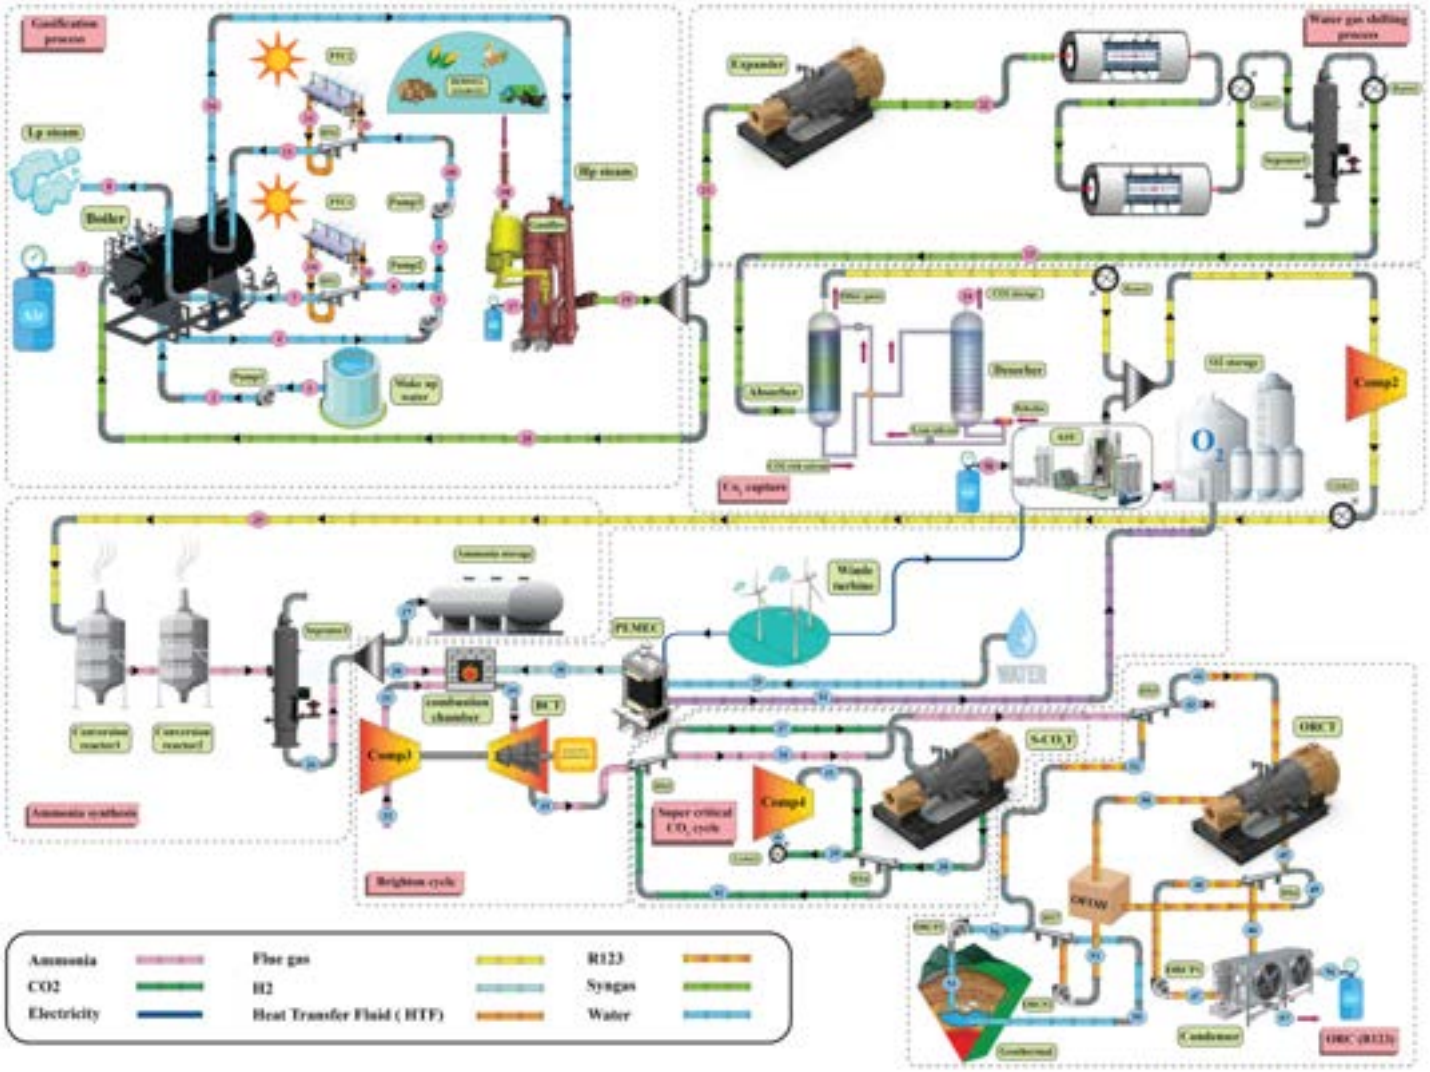

Figure. 1. Schematic of polygeneration system based on solar, wind, geothermal, and biomass renewable energy to produce ammonia, power, and heat

3. Governing equations

To calculate the heat and power exchanged by an energy system in a steady state, the mass and energy balances can be calculated based on the first law of thermodynamics, and the equations are as follows [26]:

$$Q - W = -\sum_{i=1}^{n} m_{out}\left(h + \frac{V^2}{2} + gz\right)_{out} - \sum_{i=1}^{n} m_{in}\left(h + \frac{V^2}{2} + gz\right)_{in}, \quad (4)$$

$$\sum_{i=1}^{n} m_{out} = \sum_{i=1}^{n} m_{in}, \quad (5)$$

In equation (4), Q is the heat transfer rate, W is the power transfer rate, and m_{in} and m_{out} are the input and output mass flow rates. Also, each input and output flow has parameters g gravity, h specific enthalpy, v velocity, and z height. It should be noted that in flows where the potential and kinetic energy values are negligible, these terms are disregarded. However, for inflows such as the inflow and outflow of wind turbines where the kinetic energy is important, this term is included. By using the conventional principle of state and knowing two independent thermodynamic variables, it is possible to calculate other thermodynamic variables. Writing the energy and mass balance for all equipment is not enough because these equations consider the system in a closed state and only check the input and output flows to this system. If necessary, to investigate mass transfer, heat transfer, and other important parameters in equipment, additional equations must be involved for each piece of equipment. For example, in PTC, energy transfer is not the only issue and the required collector surface is also important, so it is necessary to use heat transfer equations to calculate it. Also, in a gasification reactor, it is necessary to balance the molar flow rates based on equilibrium constants to calculate the molar coefficients on the reactant side. For process systems such as ASU and ammonia production, writing the energy and mass balance and modeling these systems is very complicated. The equipment in these systems all have equations related to energy and mass balance, and each piece of equipment can also be divided into several sub-systems. As there are feedback currents in these systems, modeling them, like other components of the system, will be very time-consuming and complex. Therefore, machine learning or faster alternative methods are suggested for these systems. In the present work on the gasification system, ASU, and ammonia production, machine learning has been used, and the equations governing these systems have been extracted. The equations are extracted by simulating or modeling each of the mentioned systems in software. For ASU, it was simulated in Aspen Plus software according to the reference [27]. For ammonia production, it was simulated in Aspen Hysys software based on the reference [22]. For gasification, modeling was performed using MATLAB software based on the article by Sirinivas et al [28]. After that, the validation was done and the data bank was formed by repeated calculations to extract comprehensive relationships by Python software. For analyzing and investigating other equipment such as PEMEC, equations from the reference [25] have been utilized. For wind turbines, references [23, 29] were employed. For PTC, references [24, 30] were used, and for gasification, reference [28] was employed. In the current work, exergy analysis, exergoeconomic analysis, and exergoenvironmental analysis have been utilized for a more precise investigation and better evaluation of the system. The analysis of entropy production, irreversibility, and measurement of energy system deviations in ideal operational conditions can be easily achieved by employing the second law of thermodynamics to more accurately investigate and evaluate the energy systems. Equation (6) shows the exergy balance [31]:

$$Ex_Q + \sum_i m_i ex_i = \sum_e m_e ex_e + Ex_w + Ex_D, \quad (6)$$

Where Ex_Q, Ex_w, Ex_D, ex_i, and ex_e correspond to the exergy caused by heat transfer, exergy caused by power transfer, exergy destruction, and exergy caused by mass flow rates of the inlet and outlet streams, respectively. Other necessary equations for this analysis are mentioned in reference [31].

Exergoeconomic and exergoenvironmental analyzes have been reviewed to check the economic and environmental performance of the system, and its balance is as follows [32]:

$$C_Q + \sum_{in}(c.Ex)_{out} + Z_k = C_w + \sum_{out}(c.Ex)_{out}, \quad (7)$$

$$B_Q + \sum_{in}(b.Ex)_{out} + Y_k = B_w + \sum_{out}(b.Ex)_{out}, \quad (8)$$

Z_k, b, c, and Y_k respectively represent the investment cost of each piece of equipment, environmental impacts of the flow, flow cost, and environmental impacts of each piece of equipment over its lifetime. Other necessary equations have been mentioned in reference [32]. The constants used in this study are: an interest rate of 10%, a maintenance factor of 1.06, and a 20-year lifespan for the power plant and operating hours considered are 3500 hours for PTC, 6000 hours for wind, and 8000 hours for other equipment [32]. In addition, references [12, 32] have been used for capital investment cost and equipment weights in economic and environmental calculations. Environmental analysis using LCA. LCA, as a technique, searches, evaluates, and examines the environmental impacts of a product or equipment from manufacturing, transportation, use, disposal, and important environmental impact aspects are analyzed.

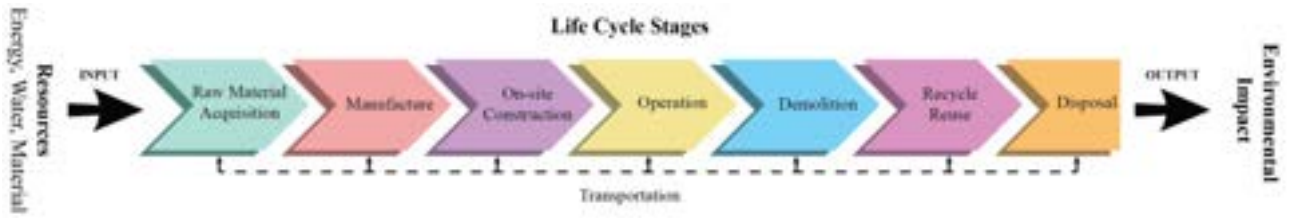

Figure. 2. Life cycle Assessment stages [33]

4. Results

Figure (3) shows the results of the energy analysis of the proposed system in a block form. In this figure, it is possible to observe the relationship between the different parts of the proposed system and the exchanged energies within the system.

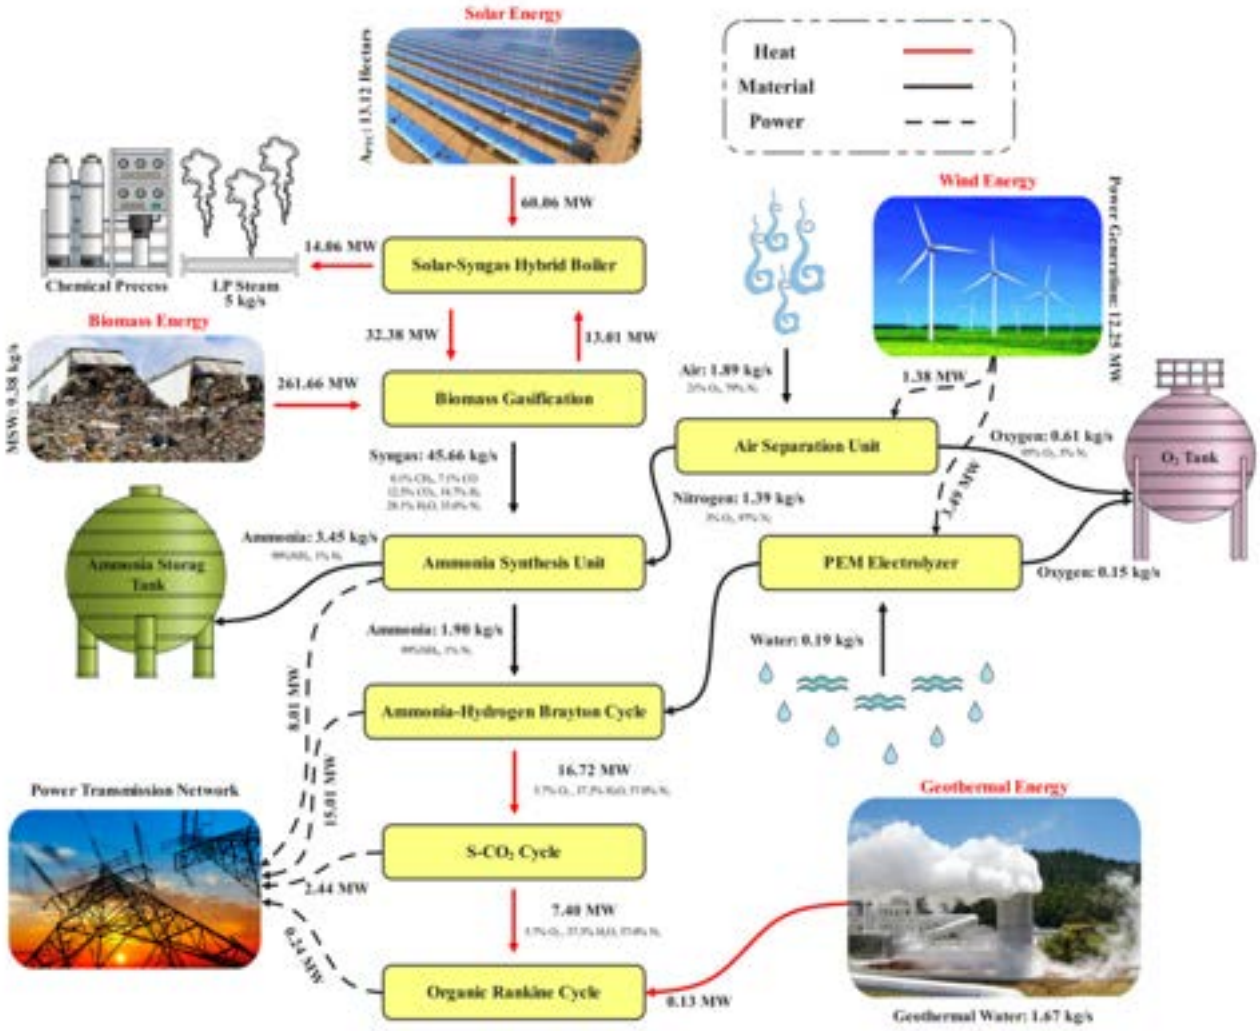

Figure. 3. The block diagram of the proposed system.

For a more detailed analysis of the proposed system, energy, exergy, economic and environmental analyzes have been performed on the system and its results have been discussed. The highest exergy efficiency is related to the expander equipment for power generation from syngas. The lowest exergy efficiency is related to the wind turbine farm. The highest investment costs in the studied system are related to the solar farm with a cost of 0.46 $/s and the wind farm with a cost of 0.22 $/s, respectively. The highest environmental impacts have been caused by the S-CO_2 turbine, and it is necessary to modify this equipment to reduce the environmental impacts. According to Table (1) which shows the 4E results on the proposed system, it can be stated that the Net power generation, Total exergy destruction, Overall polygeneration exergy efficiency, Total cost rate of polygeneration system, and Total environmental impact rate of polygeneration system are 17.93

(MW), 553.31 (MW), 38.53 (%), 3222.35 ($/h), and 53.16 (Pts/kWh), respectively. The pie diagrams in Figures (1a), (1b), (1c) represent exergy destruction, cost destruction, and environmental impact destruction of the system, respectively. It is clear that the ASU is more destructive in terms of exergy destruction, cost destruction, and environmental impact compared to other parts of the system. One reason for this is that the system involves deep cooling processes which require high energy consumption. Therefore, the exergy destruction, cost destruction, and environmental impact of this unit are very high, and corrective measures need to be taken to improve the system. The ammonia production unit has high exergy destruction after ASU due to high energy consumption and high losses. It is necessary to recover these losses in the system to reduce exergy destruction. In the gasification unit, because many chemical reactions occur and the production of entropy is high, its exergy destruction is also significant. The use of solar energy for the boiler has reduced the environmental impact of the equipment, but on the other hand, it has increased the cost of destruction of this equipment. The reason for the significant amount of exergy destruction, cost, and environmental impact in the Brayton cycle is the presence of chemical reactions and the release of a large amount of energy in the combustion chamber. Improvements must be made in the direction of improving this system. Wind turbines have a noticeable level of exergy destruction, but it is well observed that in Figures (1b) and (1c), the destruction cost and destruction environmental impact of this unit is minimized as much as possible. This shows that wind farm can be very effective in reducing costs and environmental impacts.

Table 1. overall result of 4E analysis of the proposed system.

Parameters	**value**
Net power generation (MW)	17.93
Net ammonia flow rate production (ton/day)	297.86
Mass flow rate of LP steam generation (kg/s)	5
Mass flow rate of oxygen generation (ton/day)	52.30
Overall polygeneration energy efficiency (%)	31.33
Total exergy destruction (MW)	553.31
Overall polygeneration exergy efficiency (%)	38.53
Total cost rate of polygeneration system ($/h)	3222.35
Total environmental impact rate of polygeneration system (Pts/h)	53.16
Levelized cost of electricity ($/kWh)	0.18
Levelized environmental impact of electricity (Pts/kWh)	0.003
MSW mass flow rate consumption (kg/s)	9.38
Geothermal mass flow rate consumption (kg/s)	1.67
Number of wind turbines (model: LTW77)	35
Area of PTC (model: ET-100) in the solar field (Hectares)	13.12

5. Validation

The thermodynamic validation of the proposed system, which includes the Brayton cycle, S-CO_2 cycle, ORC, ammonia production, PEMEC, PTC, wind turbine, and gasification sections, has been verified by credible articles. It should be noted that the cases of PEMEC and gasification have been validated in the work of Mousavi Rabeti et al [12]. and PTC has also been validated in the research conducted by Khoshgoftar Manesh et al [30]., who are among the authors of this study. It has been refrained from including them due to limitations in this section. In addition, the cases of the S-CO_2 cycle, ORC, Brayton cycle, and wind turbine have been validated by modeling in MATLAB software, and their results have been validated with the articles of [23, 34-36]. Ammonia production has been simulated in Hysis software and validated with the article by Ishaq et al [22]. The performed validations have been compared with articles and their results have the least errors, so the performed validation is correct. The average validation error has been reported to be below 5%.

6. Conclusions

This article has presented a new polygeneration system with the driver of solar-biomass-wind-geothermal energy to produce power, heat (steam), and ammonia for the city of Tehran in Iran. MSW gasification has been used for ammonia synthesis. A part of produced ammonia along with hydrogen has also been used as biofuel to produce electricity in Brayton, supercritical CO_2, and organic Rankine cycles. Modeling of the proposed system has been done using energy, exergy, exergeoeconomic, and exergoenvironmental (4E) analyses. The general results of polygeneration system modeling show that this system has an average energy and exergy efficiency of 31.33% and 38.53%. The results of the economic and environmental analysis show that the overall cost rate and environmental impacts rate of the entire system are 3222.35 $/h and 53.16 Pts/h, respectively. Other main results are as follows:

- Production of ammonia and process steam is equal to 297.86 ton/day and 5 kg/s, respectively.
- Using biomass and solar energy to produce products in the proposed system is more than other energies.
- The most destruction of exergy, destruction of costs, and destruction of environmental impacts is related to the air separation unit.
- The highest investment cost is related to the solar and wind field sectors.

In the end, this system can be integrated with other energy systems, such as a variety of thermal desalination systems, in order to have more flexibility in producing products while having low environmental impacts. Conducting more investigations including dynamic analysis and optimization can better evaluate the performance of such a system.

Acknowledgments

This research has been co-funded by ERDF funds, INTERREG MAC 2014-2020 programme, within the ACLIEMAC project (MAC2/3.5b/380). No funding sources had any influence on study design, collection, analysis, or interpretation of data, manuscript preparation, or the decision to submit for publication.

Abstract:

The much-needed energy transition brings special focus on fuel cell micro-combined Heat and Power (mCHP) systems for residential uses, one of which is a Solid Oxide Fuel Cell (SOFC), fed by natural gas, designed to provide continuously 1.5 kW_{el} with an associated amazingly high expected Low heating Value (LHV) electrical efficiency of 60%. Fortunately, this power output can be modulated as desired down to 500 W_{el}. With this machine, heat can also be recovered to partially contribute to the heat demand of the household. One main advantage of this appliance is that the heat recovery system is designed to be purely optional and it can be shut down, removed or added as desired, even if the machine is running. The machine is driven and completely monitored by the manufacturer remotely.
This system has been installed in a laboratory environment and has been specifically instrumented in order to evaluate its performance at thermal loads (according to the electrical output power controlled remotely by the manufacturer). In this paper, focus is brought on the resulting thermal output and efficiencies, both thermal and electrical, which have also been modelled with great goodness of fit. With several electrical power outputs between the 500-1500 W_{el} range, this study shows total High Heating Value (HHV) total efficiencies up to 88-89% at minimal return temperatures (around 20°C) in the heat recovery circuit. Maximum LHV electrical efficiency has been found to be equal to 57% at nominal output power (regardless of the thermal loads), which is close to the manufacturer's target of 60%.

Experimental, Fuel cell, Micro-CHP, Efficiency, Model, Part-load

1. Introduction

In its latest Sixth Assessment Report in 2022, the Intergovernmental Panel on Climate Change (IPCC) has reported a maximum carbon budget of 890 $GtCO_2$ that humanity can emit from January 1st 2020 in order for global warming to likely remain under the +2°C widely acknowledged limit compared to preindustrial temperature levels [1]. Even at residential scales, this much-needed decarbonation brings focus on cleaner power sources such as fuel cells combined heat and power (CHP) systems [2, 3, 4].

One system, already commercialized and tested in inhabited dwellings in field-test applications [5], is a Solid Oxide Fuel Cell (SOFC) fed by natural gas, designed to provide 1.5 kW_{el} of nominal output power with an amazingly high announced Low heating Value (LHV) electrical efficiency of 60%, along with a heat recovery of 0.6 kW_{th} representing a LHV thermal efficiency up to 25%. The output power can be modulated down remotely (by the manufacturer, upon the owner's request) as wanted in the 0.5 - 1.5 W_{el} range, affecting those announced efficiencies, but it is not advised to completely shut it down. Indeed, the thermal cycles that would be induced would imply too intense temperature gradients, which are known to contribute to degradation by opening micro-cracks and delaminations (failure mode for which materials fracture into layers) [6]. It is known that start-up and shut-down procedures require appropriate control to ensure fuel cell durability [7] and it is believed that in this case, this is the reason why start-up operations have been reported in the user manual to last up to 30 hours.

The purpose of this paper is to report the laboratory test campaigns that have been conducted in the facilities of the University of Liege on this SOFC system. This study aims to verify the electrical and thermal efficiencies announced at nominal output power, as well as to investigate how part-load operations affect them, which have not been extensively studied in literature with commercialized mCHP fuel cells. In addition, a wide range of operating temperatures for the heat recovery system of the SOFC have been tested and reported in this paper. The novelty of this work also lies in the performance models that have been computed from the experimental results and that can be easily integrated in building simulation tools.

2. Description of the system and the test bench

Discarding its chimney, the system has approximately the same size as a dishwasher, as it can be seen in Figure 1. Its internal schematics has not been disclosed but has been discussed in a previous publication [5], based on observations of the system and cogeneration SOFC literature. Amongst other particularities, the reforming process of the inlet natural gas (into hydrogen) is not only internal, i.e. directly onto the stack, at the anode (allowed with high operating temperatures occurring with that fuel cell technology [8]), but it also uses an external steam reformer upstream of the stack (called 'pre-former' [5]).

Figure 1. Tested mCHP SOFC in ULiege laboratory facilities

The test bench, presented in Figure 2, has been described in a previous publication [9]. It has been designed to control the heat recovery flow rate, through a variable speed circulator, and the operating temperatures, through a high-capacity cooling heat exchanger bypassed by a thermostatic three-way valve [9].

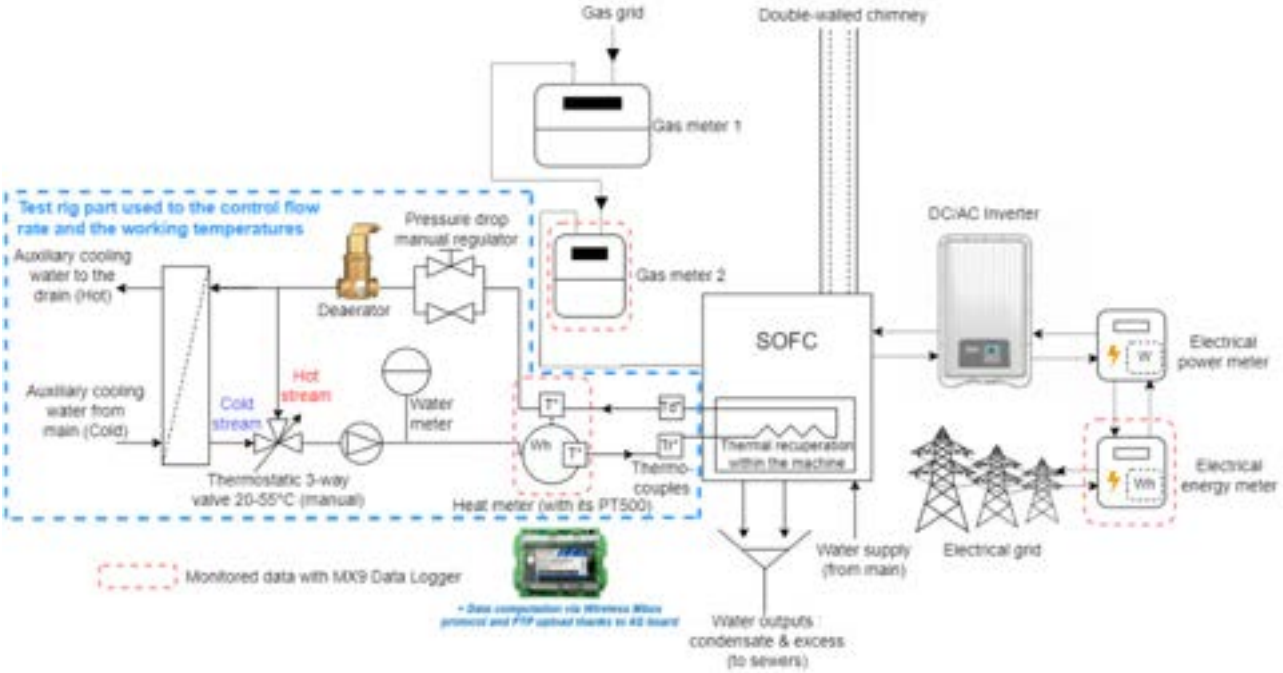

Figure 2. Schematics of the SOFC test bench described in this paper

2.1 Measurement devices

The test bench has also been designed to offer redundancy of the sensors required to compute electrical and thermal efficiencies: gas, electrical and heat meters (consisting of flow rate meters and temperature probes) have indeed all been doubled with field-test monitoring sensors connected to a Wireless M-bus (Meter-bus) data-logger [10]. It is worth mentioning that the same Wireless M-bus sensors have been implemented in a parallel field-test study on the same mCHP SOFC [5]. Therefore, the purpose of adding the same sensors as in the field-test study was to correlate the measurements and subsequently validate the field-test measurements. Main sensors used in the test bench for efficiency computation are shown in Figure 3 and Figure 4. Their references, accuracy and resolution have been reported in Table 1.

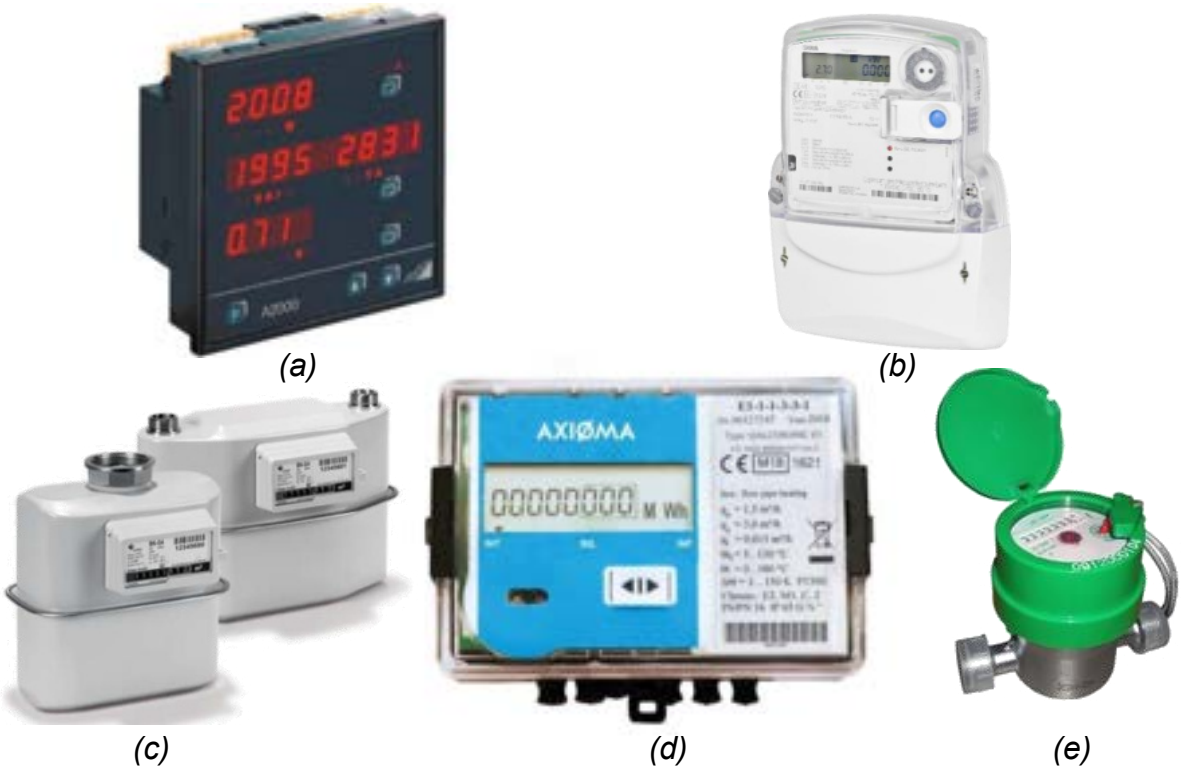

Figure 3. Metering sensors used on the test bench: a) electrical power, electrical energy meter, c) gas meters, d) heat recovery meter (that computes supply and return temperatures as well as the flow rate).

Table 1. Specifications of the main sensors used to compute efficiency laboratory results

Sensors	Reference	Resolution	Accuracy
Recovery heat rate (and flow rate)	Qalcosonic E1 Qn2,5 qi=0.025m³/h | L=130mm	1 W_{th}* 1 L/h*	<5% Accuracy Class 2 [11]

** Data logger included* *** Assumed from Class B* [13]*, highest tolerance figure for most common PT500*
**** For redundancy of the heat rate calculation*

The field-test electricity meter is a Iskraemeco MT174, shown in Figure 3(b). It computes two indexes of electrical energy (for production and consumption). Electrical power is not directly provided and must

be established by taking the derivative of the energy index. The electrical power meter, which is shown in Figure 3(a), is an A2000 bidirectional electrical power meter that shows both the net electrical power consumed and generated.

It is important to mention that the generated power exported to the grid is reduced by the power consumed by the operation of the SOFC itself. In electrical production mode (which occurs for all the test conducted in the laboratory), no electrical consumption is measured: the system provides for its own auxiliaries, except for the circulator of the (optional) heat recovery circuit, that is external to the SOFC and could be sized and chosen independently.

The field-test heat meter sensor is a Qalcosonic E1, shown in Figure 3(d). It is preferably placed on the return line (as close as possible to the heating appliance to reduce the impact of thermal losses). It is composed of flow rate ultrasonic sensor combined with two PT-500 temperature probes to implement power calculations according to the first thermodynamics principle. One of those probes is included in the main body part of the sensor (where the flow rate measurement occurs) whereas the other probe has to be mounted in separate valve body (to place on the depart line as close as possible to the heating appliance). A commented photograph of this separate temperature probe assembly is presented in Figure 4(a).

The Qalcosonic sensor also provides the flow rate and temperature it measures. It also computes an energy index (by integration of the power measurement).

The heat meter is correlated to a specific combination of independent water flow rate and temperature measurements. On the one hand, 'type-T' thermocouples are placed in specifically manufactured immersion sleeves, as shown in Figure 4(b). Those are located at the recovery circuit return and depart (close to the PT-500 probes of the Qualcosonic E1 heat meter). The thermocouples are insulated after installation to ensure that the collected data to avoid the influence of radiation or convection with other sources. On the other hand, the water flow rate of the heat recovering circuit is also measured thanks to a DHV 1300 water meter, shown in Figure 3(e). It computes the volume of water that is passing through the sensor (thanks to the displacement of a rotating piston). It provides 10 pulses every litre so a frequency meter can be implemented to generate an analog signal. A specific calibration process allows for converting its frequency signal into the desired flow rate measurement.

Both gas metering diaphragm sensors reported in the test bench are BKG4T (temperature compensation implemented). They are shown in Figure 3(c).

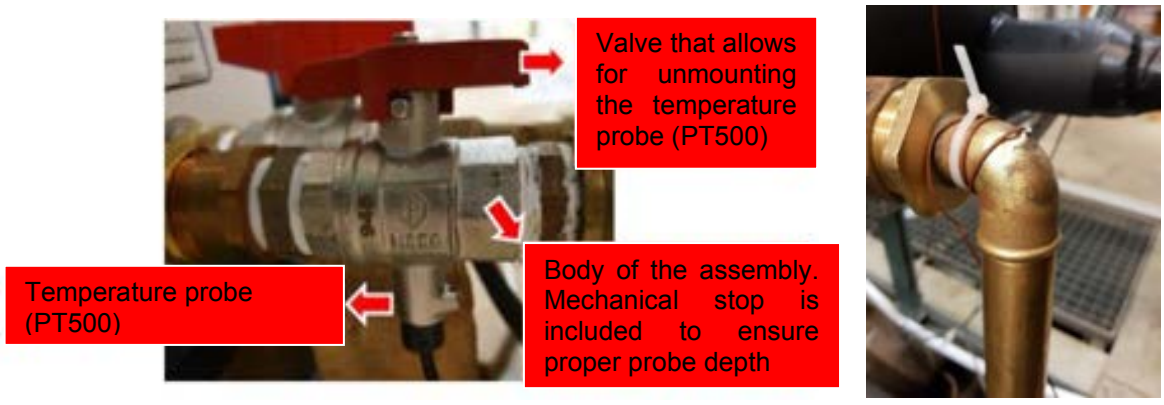

Figure 4. Temperature measurements required to establish the heat recovery rate: a) separate PT-500 probe assembly required for the Qualcosonic E1 heat meter, b) thermocouple elbow immersion sleeve associated with the DHV1300 water meter.

2.2 Testing procedure

As explained, one purpose of the laboratory test campaigns is to evaluate the heat recovery performance according to the electrical power output of the SOFC (set remotely by the manufacturer and measured in the test bench). The heat recovery performance is studied related to the working temperature levels (it suffices to only control and measure the return temperature) and related to the heat recovery flow rate (also controlled and measured).

It has been chosen to discretize the net electrical output range into three: nominal (maximum) power (1500 W), minimal power (500 W) and an intermediate power setting (1000 W).

The flow rate range is also discretized into three. The chosen discretized flow rates are about 230 L/h, about 160 L/h and about 90 L/h. They correspond to the three positions of the chosen manual variable-speed circulator ('Yonos Para 15/6' by Wilo) and therefore cover its whole operating range.

The minimal return temperature that could be obtained depends on the auxiliary heat exchanger efficiency (and the temperature of the water mains which it is supplied from). At the time of the test campaign (September 2021), it was not possible to go lower than about 18°C. Maximum temperature of the return line is obtained by bypassing the auxiliary heat exchanger completely and depends on the thermal losses of all the heat recovery circuit to the air of the room (that can be considered at a constant temperature and humidity). At the time of the test campaigns, it was difficult to obtain return temperature higher than 47°C (corresponding to about 50°C of depart/supply temperature), especially for low output power setting (and therefore low heat recovery capacity). Beyond those extremes, it was then chosen to conduct the tests with 8 additional intermediate temperature levels: each temperature step is about 3 or 4 K.

For each tested operating conditions, one has waited at least 15 minutes to ensure for the system to be considered at steady-state.

2.3 Equivalent energy contained in the consumed gas

It is worth mentioning that all the laboratory tests were conducted in three separate days over two weeks in September 2021, allowing the electrical power output to be changed in between.

Natural gas consumed on the test bench comes from the grid. Its HHV has been provided hourly by the gas provider and the daily average values have been reported in Table 2.

Table 2. Average HHV and LHV figures on the day of the test sequence

AC Electrical power output of the test sequences	HHV (given by the gas provider)	LHV (assuming HHV/LHV ratio of 1.1085 [16])
1500 W_{el}	11,5762 kWh/m³	10,4431 kWh/m³
1000 W_{el}	11,5885 kWh/m³	10,4542 kWh/m³
500 W_{el}	11,6133 kWh/m³	10,4766 kWh/m³

It must be stated that the HHV figures of Table 2 have been measured by the gas provider in reference conditions (1 atm and 0°C), which are different from the gas delivery conditions. Therefore, the metered gas volume must be corrected to be applied to those HHV or LHV figures, following the method described in a previous publication [17]. Since the atmospheric pressure was not measured at the laboratory facility, it has been computed considering an assumed pressure at sea level of 101325 Pa and an ambient temperature of 15°C (see reference [17] for explanatory details).

The uncertainty levels of the HHV-LHV figures of Table 2 have not been given by the gas provider. Therefore, since the laboratory facility is receiving type 'H' natural gas ('rich' gas, as opposed to 'lean' gas, called type 'L' gas), the uncertainty level of those heating values can be assumed equal to ±234 Wh/m³, i.e. the same uncertainty level considered in the already referenced field-test study [5] for the site that also receives type 'H' gas.

3. Results

It is worth mentioning that the measured output power fluctuated in a range of only ± 3 W around the power output setting set remotely by the manufacturer (i.e. ± 0.6% in the worst case), not affected by the working temperature of the heat recovery system (nor its flow rate). Similarly, the gas consumption was observed to be very stable according to the output power setting and therefore not to depend on neither the temperature nor the flow rate of the heat recovery system. Indeed, it was observed to vary at worst in the ± 0.5% range. Those fluctuating ranges are even in the same order as the accuracy of the corresponding sensors, as shown in Table 1. Therefore, it has been established that electrical efficiency (not considering the power consumption of the circulator of the heat recovery system) also only depends on the output power setting (and is not affected by the state of the heat recovery system). Since the state of the heat recovery system affects the temperature of the flue gases, which heat up the incoming air required for the fuel cell reaction through the double-walled chimney (Figure 2), it could have indeed been imagined that it might have affected the electrical efficiency of the stack. However, it is not the case and one can assume that the internal heat management of the system is robust enough so the state of the heat recovery circuit only impacts the thermal efficiency of the system.

Indeed, only the thermal efficiency has significantly varied in all the laboratory test campaigns. So, the system's thermal efficiency dependency related to working temperature and flow rate of the heat recovery circuit is presented in Figure 5, Figure 6 and Figure 7, according to the electrical power output setting (respectively 1500 W_{el}, 1000 W_{el} and 500 W_{el}).

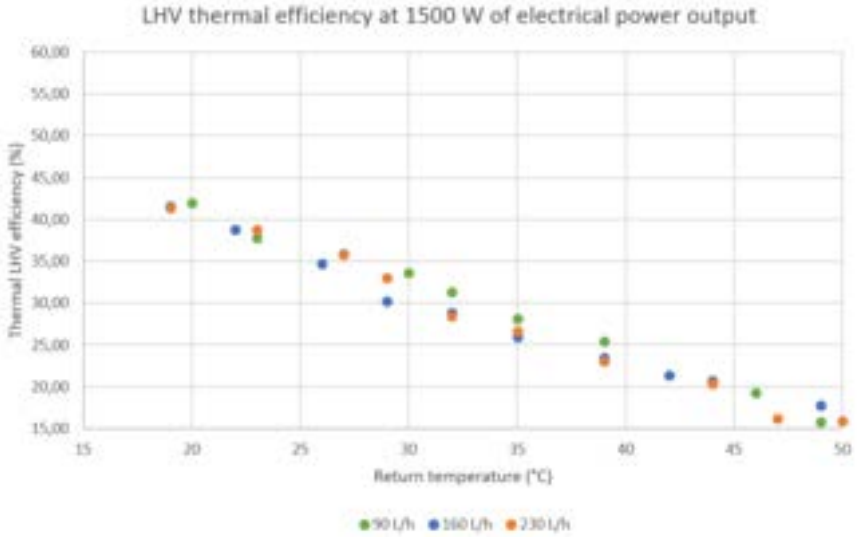

Figure 5. LHV thermal efficiency of the SOFC related to working temperature (and water flow rate) at 1500 W of power output. LHV electrical efficiency has been found constant and equal to about 57%.

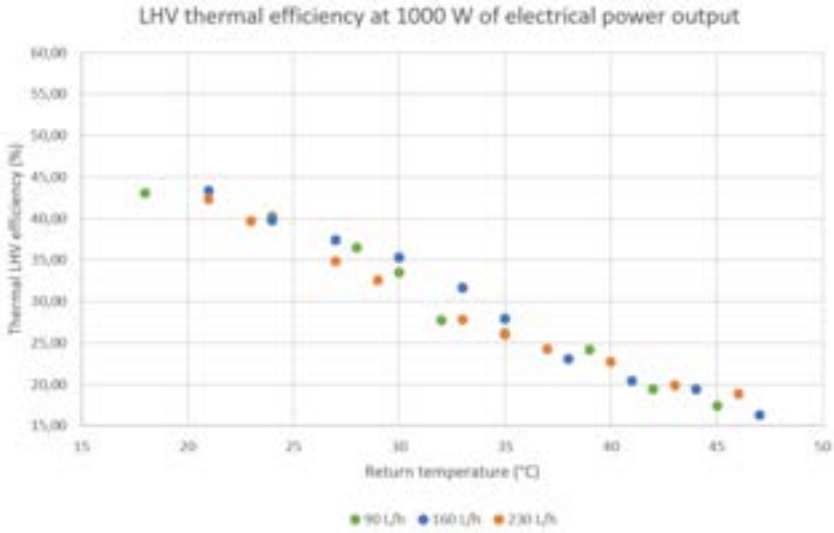

Figure 6. LHV thermal efficiency of the SOFC related to working temperature (and water flow rate) at 1000 W of power output. LHV electrical efficiency has been found constant and equal to about 55%.

It is clear that the flow rate, in the tested range, has no significant influence on thermal efficiency. On the contrary, the efficiency decrease according to increased working temperatures is always noticeable and quite linear. It even increases (exponentially) as the electrical output power setting is lowered. Indeed, over similar tested working temperature ranges (of about 30°C each time), at 1500 W, the decrease in thermal efficiency is about 26 percentage points; at 1000 W, it is about 28 percentage points and at 500 W, it is about 35 percentage points. This exponential trend can be explained by the exponential relation between thermal efficiency and electrical output power, observable in Figure 8, which highlights efficiency results according to the power output setting. It also compares directly the results gathered in this particular experimental study with the one previously published by the manufacturer [18] (all obtained at a return temperature of 30°C). It is worth mentioning that those previous results have been presented in 2011 and might be relevant for a previous version of the system.

As shown in Figure 8, total LHV efficiency is always about or above 80%. Figure 8 also shows that the laboratory efficiency variations between nominal electrical output power and 1000 W of output power is

not significant. On the other hand, working at minimal power brings significant total efficiency decrease (explained by the 17 percentage points decrease in electrical efficiency, which is not balanced by the slightly higher thermal efficiency). It is quite trivial that partial load functioning leads to lower electrical and total efficiencies (mainly due to higher heat losses than at design operating conditions because the internal temperature must be kept constant [19]). Therefore, it is also quite normal that, as electrical efficiency increases, thermal efficiency decreases. This has been verified in literature for many CHP systems [20], as demonstrated with Figure 11, for which the experimental results of the BlueGen system reported in Figure 8 have been added for comparison.

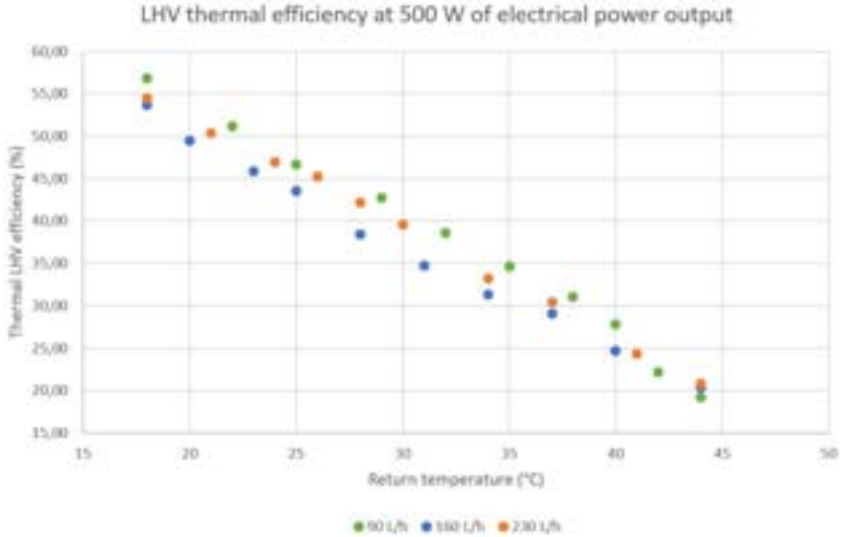

Figure 7. LHV thermal efficiency of the SOFC related to working temperature (and water flow rate) at 500 W of power output. LHV electrical efficiency has been found constant and equal to about 40%.

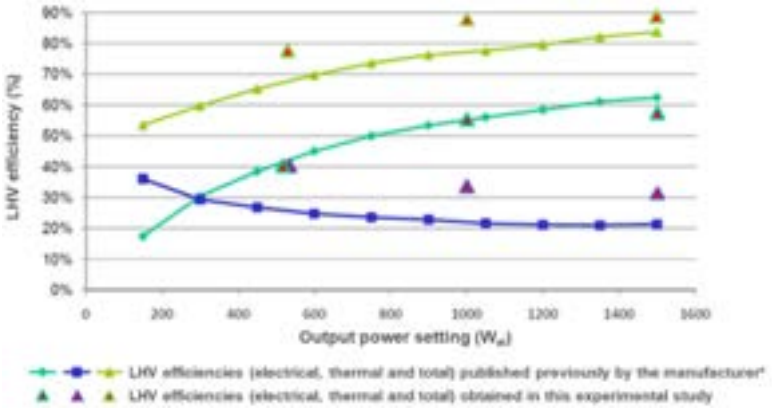

**Reference :* [16]

Figure 8. LHV efficiency results obtained in this laboratory study superposed on reproduced ones previously published by the manufacturer [18] (all obtained with a return temperature of 30°C). System's version in the results published by the manufacturer has not been disclosed, neither as the way efficiencies have been measured or computed (which might explain the few differences).

4. Performance models

Based on those results, the system has been modelled in two main steps with the Matlab software, starting with the thermal efficiency and finishing with the electrical efficiency.

As stated, the thermal efficiency of the system does not depend on the water flow rate of the heat recovery circuit. Therefore, the only influencing parameters for the thermal efficiency are the electrical output power $\dot{W}_{el}$ and the working temperature of the heat recovery circuit (which influence has been studied through its return temperature T_R). The resulting LHV thermal efficiency model (with its tremendous goodness of fit) is presented in Figure 9. It consists of a polynomial regression of the second order on both axes of all the results presented in Figure 5, Figure 6 and Figure 7, independently of the water flow rate of the heat recovery circuit. Between electrical power output $\dot{W}_{el}$ of 500 and 1500 W_{el}, this LHV thermal efficiency $\eta_{th,model}$ model is defined by Equation (1), whose parameters are

provided in Table 3. Equation (1) has been nondimensionalized in Equation (2). Equation (2) is therefore expressed in terms of load factor λ, i.e. the nondimensionalized ratio between the electrical output power and the nominal power, equal to 1500 W_{el} in this case ($\lambda = \dot{W}_{el}/1500W_{el}$).

$$\eta_{th,model}(\%) = f(\dot{W}_{el}, T_R) = p_{00} + p_{10}\dot{W}_{el} + p_{01}T_R + p_{20}{\dot{W}_{el}}^2 + p_{11}\dot{W}_{el}T_R + p_{02}{T_R}^2 \quad (1)$$

$$\eta_{th,model}(\%) = f(\lambda, T_R) = p_{00} + 1500p_{10}\lambda + p_{01}T_R + 1500^2p_{20}\lambda^2 + 1500p_{11}\lambda T_R + p_{02}{T_R}^2 \quad (2)$$

Table 3. Parameters of the LHV thermal efficiency model of the SOFC of Equation (1) and Equation (2), valid between electrical power output $\dot{W}_{el}$ of 500 W_{el} and 1500 W_{el}

Thermal LHV efficiency model parameters	p_{00}	p_{10}	p_{01}	p_{20}	p_{11}	p_{02}
Values	97.52	-0.03938	-1.699	9.855e-6	4.257e-4	3.249e-3

It must be stressed that this thermal efficiency model is valid on the tested heat recovery water flow rate. It is likely that higher heat recovery flow rate will not affect the model (because efficiency of the thermal exchange within the system seems to have reached its maximum asymptote). However, extremely low heat recovery flow rate will trivially reduce the efficiency of the exchange within the machine. It would therefore be considered as good practice to ensure at least 90 L/h of water flow rate in the recovery heat circuit (or to ensure that lower flow rates will not affect the thermal efficiency of this system). The model is likely to be valid in real applications since 90 L/h of water flow rate has been obtained at the 'lowest position' of the variable speed circulator used in the test bench (see Figure 2). Lower water flow rates could only occur with unlikely great pressure losses on the heat recovery circuit.

It is worth mentioning that goodness of fit can indeed be studied easily with the Matlab software thanks to RMSE and R-square values. The following explanations have been provided by the Matlab Software support regarding those fitting variables :

- R-square: This statistic measures how successful the fit is in explaining the variation of the data. Put another way, R-square is the square of the correlation between the response values and the predicted response values. R-square can take on any value between 0 and 1, with a value closer to 1 indicating that a greater proportion of variance is accounted for by the model.
- RMSE: This statistic is an estimate of the standard deviation of the random component in the data. RMSE value closer to 0 indicates a fit that is more useful for prediction.

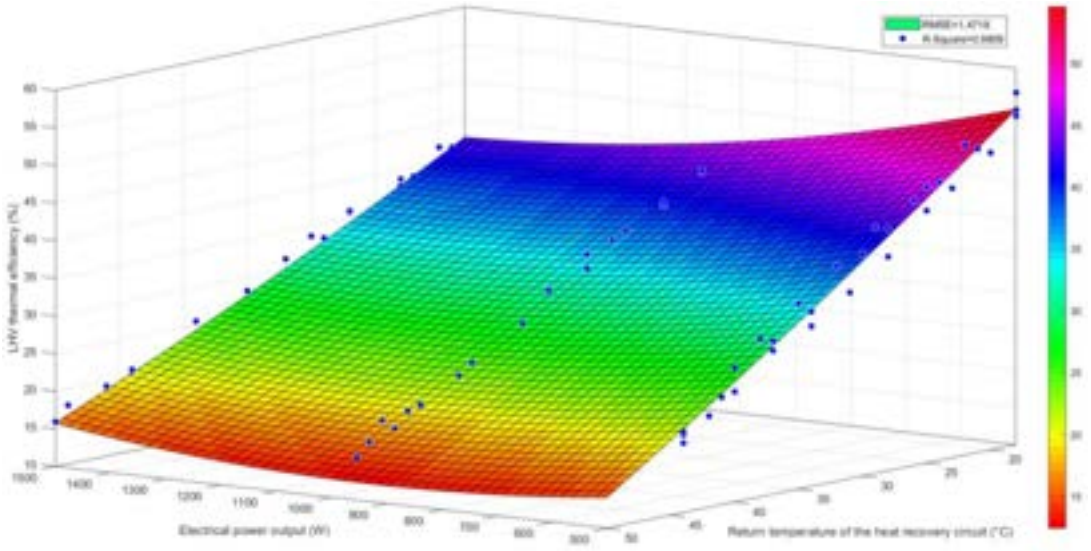

Figure 9. Model of the laboratory BlueGen LHV thermal efficiency according to return temperature of the heat recovery circuit and electrical output power

Modelling the LHV electrical efficiency is simpler as it does not depend on the return temperature of the heat recovery circuit (nor on its flow rate, as it was already the case with the thermal efficiency).

Again, the Matlab software has been used on all the results presented in Figure 5, Figure 6 and Figure 7. The resulting model is defined by the exponential Equation (3), which has been nondimensionalized in Equation (4). Equation (4) is therefore expressed in terms of load factor λ, i.e. the ratio between the electrical output power and the nominal power, equal to 1500 W_{el} in this case ($\lambda = \dot{W}_{el}/1500W_{el}$). Model parameters and goodness of fit indicators are given in Table 4.

$$\eta_{el,model}(\%) = f(\dot{W}_{el}) = a \times \dot{W}_{el}{}^{b} + c \quad (3)$$

$$\eta_{el,model}(\%) = f(\lambda) = a \times 1500\lambda^{b} + c \quad (4)$$

Table 4. Parameters and goodness of fit indicators of the LHV electrical efficiency model of the SOFC of Equation (3) and Equation (4)

Electrical LHV efficiency model parameters	a	b	c	RMSE	R-Square
Values	-7.491e8	-2.82	57.64	0.1687	0.9996

5. Discussion

5.1 Comparison with previously published results

LHV electrical efficiency at nominal power is about 3 percentage points behind the manufacturer target (one has obtained 57% experimentally and not 60% as stated in the Introduction) and this could be explained by the intrinsic statistical difference between production units and/or simply by the natural ageing of the stack (as shown in Figure 10). At lower electrical power (1000 W and 500 W), the laboratory electrical efficiency results seem to be relevant with the 2011 results of Figure 8 [18]. On the other hand, it seems that heat recovery has been significantly improved since the earlier manufacturer's publication in 2011, probably achieved with the use of an internal recovery heat exchanger of larger size.

By deduction of Figure 5, the 25% LHV thermal efficiency announced by the manufacturer (as stated in the Introduction) is relevant with a return temperature of 40°C, which is sufficient in some DHW production applications as well as if the SOFC was directly connected to high-temperature terminal units (in older dwellings, for example). This SOFC mCHP performance has been compared with other well-known cogeneration technologies in Figure 11 [20]. It confirms that fuel cells (especially SOFC's) allow for achieving much higher electrical efficiencies than other technologies.

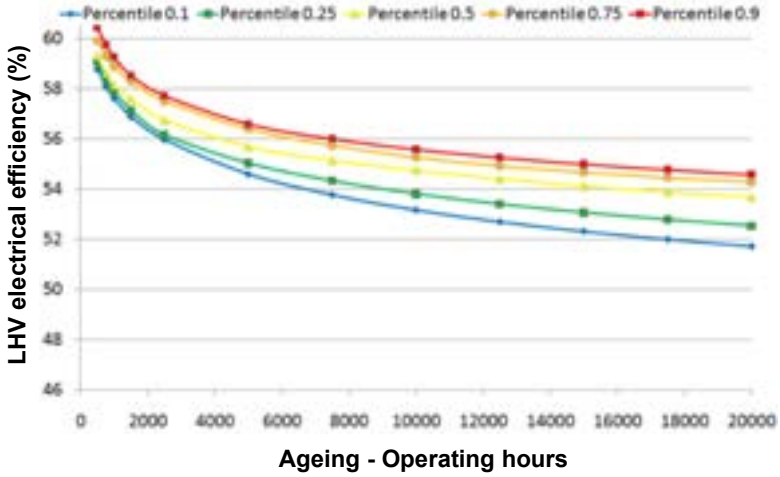

Figure 10. Statistical analysis of production systems back in 2011 [18] expressed in terms of LHV electrical efficiency decay over time at nominal output power (1500 W_{el}). System's version in the results published by the manufacturer has not been disclosed. Reproduced from reference with the addition of this study's laboratory results.

5.2 External weather conditions

At the time, it was decided not to monitor the external temperature and humidity during the test campaigns. Looking at the outcomes published in this paper, there are no unexpected results that are significant enough to be related to any weather variation that has occurred during the test campaigns. Therefore, with such a SOFC system, with tremendously high internal temperatures around 800°C [21], it could be considered that moderate external temperature and humidity variations (typical of Western Europe's climate) have no significant influence on the efficiencies of the system. It is worth mentioning that there were also neither any significant influence of external weather conditions that could have been inferred from the field-test study previously published about that particular SOFC system [5].

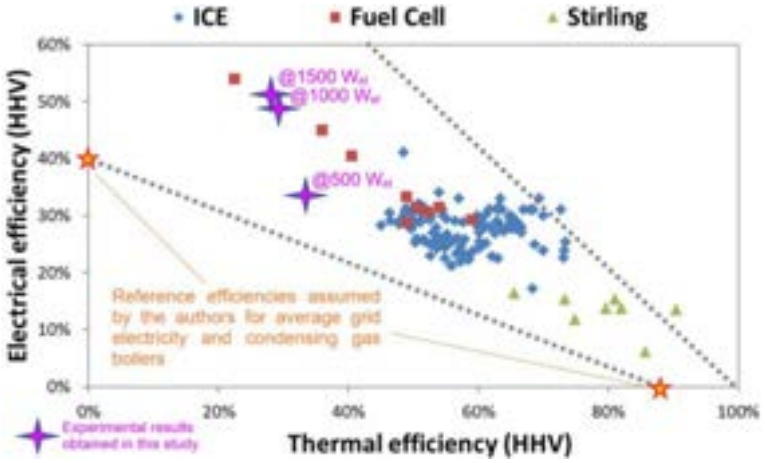

Figure 11. Market study on reported efficiencies for three different groups of micro-CHPs: Internal Combustion Engines (ICE), Fuel Cell based micro-CHPs and CHP based on Stirling principle. The efficiencies are put in perspective with a line (lower dotted one) representing the reference conventional power that the micro-CHPs must beat (i.e. the average grid efficiency for electrical generation and the gas condensing boiler for heat production). Average efficiency of the grid electrical mix is considered to be at 40 % HHV (as comparison, the one of UK in 2013 was about 38.6% LHV, i.e. 34.8% HHV [22]). Reference thermal efficiency of condensing gas boiler is considered to be at 90% HHV (as comparison, yearly HHV efficiency figure of field-tested gas condensing boiler have been reported in the 82-89% range [23] whereas the Walloon energy regulator in Belgium has stated, based upon field-test studies, that reference state-of-the-art gas condensing boilers have efficiencies of 90% LHV, i.e. 81.2 % HHV [24]). The maximum physically possible upper limit corresponding to total HHV efficiency of 100% is represented by the upper dotted line. Reproduced and adapted from reference [20]. The experimental results of this SOFC system at 30°C of return temperature reported in Figure 8 according to the output power setting have been added considering a 1.1085 HHV to LHV ratio [16]. The efficiency results over the upper line (total efficiency results over 100% HHV) are most likely due to measurement uncertainty, especially regarding how the HHV is accounted for [17].

5.3 Water consumption (and evacuation)

As explained in the field-test study previously published about that particular SOFC [5], the system consumes water (discontinuously, a few times a day) from the mains in order to (filter and) store water that could later on help provide steam for methane reforming purposes. Even though a water meter was placed on the test bench (at the water mains connection), in such steady-state tests, the water consumption can hardly be related to the operating conditions as water withdrawals are only executed periodically (a few times a day). Indeed, generally, no water consumption was observable while conducting the test procedure for one particular set of operating conditions. For example, water withdrawal occurred a couple hours later, while the test campaign was finished or while conducting the test for other operating conditions.

However, from 20th September 2021 to 16th February 2022, the SOFC was turned on in the laboratory facilities and has provided (continuously, mostly at its nominal power output) 5048 kWh_{el} of electrical energy and 1434 kWh_{th} of heat. During that time, the system consumed 6274 L of water from the grid. This accounts for a water consumption of 1.24 L/kWh_{el}. This figure can be considered as in the upper range related to this SOFC system because, in the laboratory facilities, the heat recovery circuit was turned off most of the time (except during the three days of the actual test campaigns). Therefore, the return temperature was generally not cooled down and water in the flue gases was less likely to condensate and be fed back to the internal tank, which would have reduced the water consumption from the mains [5].

As shown in Figure 2, the system has two water outlets to the sewers (that have not been instrumented as water evacuations are quite sporadic). The first outlet evacuates brine water from a reverse osmosis filter [25] that cleans the water supply (from the mains) and feeds an internal tank (with cleaned water required for steam reforming processes of the inlet fuel, that is subsequently processed by the fuel cell stack) [5]. With such a two-chamber filter (separated with a filtering membrane), the water impurities concentration in the periodical inlet water volume becomes too high compared to the pressure used for the reverse osmosis. Thus, the remaining inlet water (with high levels of impurities) has to be thrown

away for another periodical grid fresh water inlet to take place (and to be submitted to the reverse osmosis filter). The more water is consumed from the grid, the more brine water will be evacuated.

As mentioned here above, flue gases are ideally cooled down by the optional heat recovery circuit and the condensates, which are not required to be processed in the reverse osmosis filter, are recovered and fed to the internal water tank [5]. However, this latter might be full so a second water outlet to evacuate its potential excess has been implemented [5].

Thus, enabling the heat recovery circuit and allowing for more processed water recovery (from the flue gases) will increase the probability of water excess in the internal tank (and water evacuation from the second outlet), but it will more importantly reduce water consumption from the grid and the resulting brine water evacuation (from the first outlet).

6. Conclusion

Electrical and thermal performance (efficiencies) models of the studied SOFC mCHP system are demonstrating great goodness of fit. Its electrical power output is tremendously stable and corresponds quite accurately to the output power setting as well as to the performance announced by the manufacturer (especially considering ageing). Along with the stable gas consumption, this leads to very stable electrical efficiencies. The electrical efficiency (and power output) is not altered at all by changes in working temperature of the heat recovery circuit (nor by potential change in heat recovery flow rate). In the tested range (corresponding to the range of a variable speed regular space heating circulator), thermal efficiency is almost not altered by the heat recovery flow rate.

Thermal efficiency is affected by the working temperature of the heat recovery circuit quite linearly and it decreases as working temperature increases. The slope of that linear decrease increases exponentially as electrical power output decreases. Indeed, at nominal electrical power output (1500 W), the thermal efficiency increase between about 50°C and 20°C of return temperature is about 26 percentage points. And, over a similar temperature range at minimal electrical output power (500 W), the thermal efficiency decrease reaches 35 percentage points. At nominal electrical power output (1500 W), highest LHV thermal efficiency is about 42% whereas it increases up to about 55% at minimal electrical power output (500 W).

The efficiency results at 1000 W of electrical power output are really close to the one obtained at 1500 W of electrical power output (for both electrical and total efficiency). However, lowering the electrical power output down to 500 W mainly reduces the electrical efficiency, which is not balanced by the increase of the thermal efficiency, meaning that the total efficiency still decreases compared to higher power output settings. Total LHV efficiency is indeed about 78% at 500 W of electrical power output whereas it comes close to 90 % at 1000 W and 1500 W of electrical power output.

The LHV thermal efficiency of 25% at nominal electrical output power of 1500 W announced by the manufacturer seems to correspond to a return of 40°C, which is relevant for many residential DHW applications. This corresponds to about 600 W of heat recovered. Residential DHW represents thus a suitable way of recovering the heat provided with the system. As explained, lowering the return temperature (without significantly reduce the heat recovery flow rate below the operating range of the variable speed circulator that has been used) would even increase the amount of heat recovered (and the thermal efficiency of the system) but at temperature lower than 40°C, it would no longer be convenient for DHW production.

Compared with CHP literature, this SOFC technology demonstrates quite high electrical efficiencies and satisfactory thermal efficiencies. In fact, no commercialized CHP system exhibiting higher electrical efficiencies than this system have been found by the authors of this paper.

How to Choose the Best Refrigerant in Heat Pumps from an Ecologic Perspective? Analyzing the Influence of the Evaluation Method

Christoph Höges[a,*], Lennard Wissing[a], Christian Vering[a] and Dirk Müller[a]

[a] Institute for Energy Efficient Buildings and Indoor Climate, Aachen, Germany
** CA, christoph.hoeges@eonerc.rwth-aachen.de*

Abstract:

Heat pumps are one of the key technologies to reduce CO_2-emissions and reach a net zero building stock. However, heat pumps still induce CO_2-emissions, which split up into direct and indirect emissions. Direct emissions result from leakages on site and indirect emissions mainly relate to the power consumption. In particular, the refrigerant choice influences both direct emissions due to its global warming potential, and indirect emissions due to the efficiency of the heat pump. Thus, the refrigerant choice is crucial to minimize the overall emissions of heat pumps. When selecting a proper refrigerant, several evaluation methods exist in the state of the art. In this work, we analyze the influence of the evaluation method on optimal fluid selection. Four methods are employed: Efficiency-based method using the seasonal coefficient of performance (*SCOP*), Total Equivalent Warming Impact (*TEWI*), Life Cycle Climate Performance (*LCCP*), and Life Cycle Assessment (LCA). The study includes ten refrigerants. For method comparison, the study includes refrigerants with either a high GWP or an ODP greater zero also to account for the sensitivity with respect to the evaluation method. The investigation shows only minor differences between the studied refrigerants when comparing the results of *SCOP*, *TEWI* and *LCCP*. The refrigerant ranking is not influenced by the assessment method. Main reason is the high share of the indirect emissions and thus, the dependency on *SCOP*. Using the LCA, the main difference occurs for refrigerants with an ODP. Using current regulations (zero ODP, GWP < 150), we conclude, *SCOP* comparison is a sufficient evaluation criterion when selecting refrigerants.

Keywords:

Fluid selection; TEWI; LCCP; LCA; low-GWP refrigerants.

1. Introduction

In the context of climate change, global greenhouse gas (GHG) emissions have to be reduced in all sectors. In the building sector, the provision of heating and cooling in the building sector is responsible for approximately 19 % of global CO_2-emissions [1]. To achieve the goal of a CO_2-neutral building stock, heat pumps are considered a key technology to replace conventional technologies. Typically, heat pumps use electricity to upgrade ambient heat and thus provide useful heat for heating purposes. Thereby, the emissions of heat pumps are divided into indirect and direct emissions [2]. Indirect emissions are related to the energy demand to operate the system. Most heat pumps use mechanical energy to lift the temperature level and match heat supply and demand. In Germany, the necessary energy is mostly provided by power plants that emit CO_2 and thus, leads to emissions not at the place of the heat pump but at the power plant. For a user-specific heating demand, the emissions depend on electric power demand and thus, on the cycle efficiency of the heat pump. Direct emission originates to refrigerant leakages on site. All currently used refrigerant have a non-zero global warming potential (GWP). Therefore, their leakage supports the greenhouse effect. The main contributor to direct emissions is the used refrigerant, its charge, and its respective GWP. To reduce the overall emissions of heat pumps, direct and indirect emissions need to be reduced.

Besides the GWP, the overall cycle efficiency depends on the choice of refrigerant [3]. Thus, selecting a proper working fluid is crucial regarding low emissions. The refrigerants, however, are subject to increasingly strict political regulations that lead to maximum allowed limits for the GWP, refrigerant charges, and include bans on specified characteristics of refrigerants [4]. In search for possible alternatives that satisfy the political restrictions, the current research focuses on natural refrigerants and hydrofluoroolefins (HFO) since both have near zero GWP values [5–8]. However, selecting the optimal refrigerant is complex and depends on many boundary conditions. Thus, evaluation criteria exist comparing and evaluating refrigerants. In addition

to conventional energetic assessment metrics like seasonal coefficient of performance (*SCOP*), multiple evaluation methods estimate the environmental impact at different levels of complexity: The *Total Equivalent Warming Impact* (*TEWI*) [9], the *Life Cycle Climate Performance* (*LCCP*) [10] and the *Life Cycle Assessment* (LCA) [11]. However, to the authors' knowledge it is unknown how different ecologic evaluation methods influence the results regarding the refrigerant selection and whether the high complexity of the evaluation is necessary within the selection process. Thus, this work aims to analyze the influence of the evaluation method on the optimal refrigerant selection. In the evaluation, the *SCOP*, the *TEWI*, *LCCP*, and LCA are evaluated for ten refrigerants. The refrigerants are mainly low-GWP refrigerants, e.g. propane (R290). Additionally, conventional refrigerants such as R410A, R134a and R404A are included as well as R22, which has an ozone depletion potential (ODP) to include multiple environmental aspects and derive general conclusions.

The paper is structured as follows: Sections 2 describes and discusses the simulation model. We investigate three refrigerant cycle flowsheets since the flowsheet strongly influences the energetic performance of refrigerants. Additionally, the calculation methods of the assessment criteria are presented. Section 3 shows the results and highlights the differences of each evaluation method. Section 4 discusses the impact of the evaluation method on refrigerant selection and Section 5 draws the overall conclusions and give a suggestion for future work.

2. Method

This section describes the overall method and assessment criteria. Section 2.1 presents the heat pump modeling approach. Section 2.2 shows the evaluation of the energetic assessment criteria of the seasonal coefficient of performance. Sections 2.3 to 2.5 describe the evaluation of the ecologic criteria *TEWI*, *LCCP* and LCA. Finally, section 2.6 shows the selected parameter and the case study.

2.1. Heat pump modeling approach

In the present investigation, we evaluate three heat pump cycle configurations. For each cycle configuration a thermodynamically consistent modeling approach is used. A short description of the selected approach is presented. A detailed description is given in [12]. The modeling approach follows an optimization procedure using the *Python* scipy package [13]. Equation (1) shows its formulation.

$$\begin{aligned} &\max_{\vec{x}} COP(\vec{x}) \\ &s.t.\ \ g\left(\vec{x},\vec{\theta}\right) \geq 0 \\ &\qquad \vec{x}_{\min} \leq \vec{x} \leq \vec{x}_{\max} \end{aligned} \tag{1}$$

In the optimization, the coefficient of performance (*COP*) is maximized by adjusting the process parameters $\vec{x}$. The process parameters depend on the individual cycle configuration and are presented below. For each process parameter, the optimization considers box-bounds. Additionally, the optimization is subject to inequality constraints $g\left(\vec{x},\vec{\theta}\right)$. The inequality constraints depend on the process parameters $\vec{x}$ and on the temperatures of heat sink and source. The constraints ensure a physical and technical feasible operation and include (1) wet compressor prohibition, (2) subcritical operation and (3) minimal approach temperatures for all heat exchangers to satisfy the 2nd law of thermodynamics. The heat exchanger modeling uses a minimum approach temperature $\Delta T_{\min} = 2$ K. The expansion valves are assumed isenthalpic. Losses due to friction in the pipes, pressure losses, and heat losses to the surroundings are neglected.

For the compressor, a loss-based compressor model of a reciprocating compressor is used to evaluate refrigerant and operating point dependent isentropic and volumetric compressor efficiencies [14]. The model includes multiple loss mechanisms within a compressor and combines them to a single definition of the compressor efficiency. Thereby, losses due to friction of the piston, flow losses at the compressor valves, electrical losses of the inverter, and heat losses to the environment are included. Additionally, the model scales all effects for a predefined heat flow rate in the condenser. In this work, we consider a 10 kW heat pump for a residential building at the design point -10 °C ambient air temperature and a sink temperature of 55 °C. Thus, the size of the calculated heat pump does not vary between fluids, and a general comparison is possible. A fluid-dependent and operating point-dependent calculation is crucial since the compressor is the component with the highest irreversibilities in the cycle, and an inaccurate calculation can lead to significant differences between the fluids [15].

To account for the influence of the cycle configuration, the study includes three different flowsheets. All models are implemented in *Python* and use *REFPROP* version 10.0 [16] to calculate the fluid properties of all refrigerants. **Figure 1** shows the flowsheets.

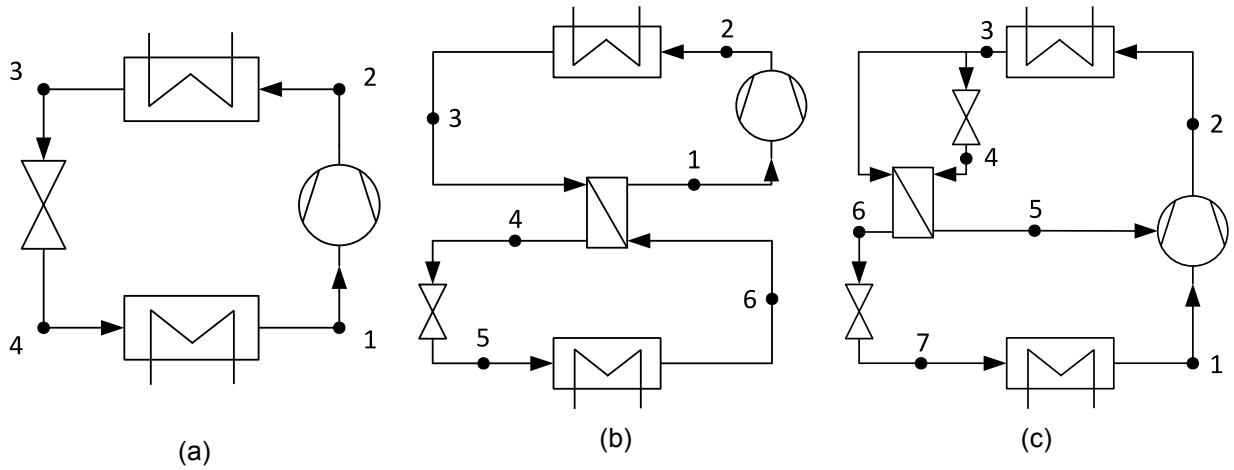

Figure 1: Selected heat pump cycle configurations for the case study.

The simple flowsheet (**Figure 1**a) consists of the four basic components. During the cycle calculation, the optimizer adjusts four optimization variables that specify the simple cycle. Equation (2) shows the optimization variables for the simple cycle.

$$\vec{x}_{\text{simple}} = \vec{x}_{\text{ihx}} = [p_{\text{eva}};\ p_{\text{con}};\ \Delta T_{\text{SH}};\ \Delta T_{\text{SC}}]^T \tag{2}$$

Thereby, the amount of superheating at the compressor inlet ΔT_{SH}, the amount of subcooling at the condenser outlet ΔT_{SC}, the evaporation pressure p_{eva} and the condensation pressure p_{con} are optimized. For each parameter set, the cycle efficiency *COP* is evaluated by equation (3).

$$COP_{\text{simple}} = \frac{\dot{Q}_{\text{con}}}{P_{\text{el}}} = \frac{h_2 - h_3}{h_2 - h_1} \tag{3}$$

The second flowsheet uses an internal heat exchanger (**Figure 1**b). The amount of superheating is shifted from the evaporator to the internal heat exchanger, recuperating heat from the high-pressure side. Thus, the evaporator outlet is saturated vapor. Within the used modeling approach, the internal heat exchanger provides heat for the necessary amount of superheating only and the calculation of the efficiency *COP* in the ihx-cycle is similar to the simple cycle stated in equation (3).

The third cycle uses vapor injection to increase the overall cycle performance (**Figure 1**c). For the vapor injection (vi), a two-stage compression model is used. After the first stage, a partial mass flow rate $\dot{m}_{\text{inj}}$ (state 5) is injected into the compressor. The injected mass flow rate arises from the expansion of a partial mass flow after the condenser to an intermediate pressure level and the heat transfer within the economizer (state 5). Due to the vapor injection, the cycle includes two additional degrees of freedom: (1) The intermediate pressure p_{int} of states 4 and 5 and (2) the injection ratio *y*, which is the ratio of injected vapor $\dot{m}_{\text{inj}}$, and total mass flow rate in the condenser $\dot{m}_{\text{con}}$.

$$y = \frac{\dot{m}_{\text{inj}}}{\dot{m}_{\text{con}}} \tag{4}$$

$$\vec{x}_{\text{vi}} = [p_{\text{eva}};\ p_{\text{con}};\ \Delta T_{\text{SH}};\ \Delta T_{\text{SC}};\ p_{\text{int}};\ y]^T \tag{5}$$

The injected mass flow rate at state 5 is assumed saturated vapor. Due to the two-step compression and vapor injection into the compression chamber, the cycle efficiency calculation is more complex than the simple heat pump cycle. Equation (6) shows the definition of the *COP* for the vi cycle.

$$COP_{\text{vi}} = \frac{h_2 - h_3}{(1-y)\cdot \Delta h_{\text{com,step,1}} + \Delta h_{\text{com,step,2}}} \tag{6}$$

Thereby, $\Delta h_{\text{com,step}\,i}$ is the specific enthalpy difference due to the compression in step *i*. Since the mass flow within the evaporator and thus, the first compression step only includes a partial mass flow rate.

2.2. Seasonal coefficient of performance

To evaluate the annual energy consumption of a single-family house, we evaluate the seasonal coefficient of performance (*SCOP*). In this work, a weighting approach is used that divides a whole test reference year (TRY) into representative clusters. Here, we use the *k-medoids* clustering method [17] and a TRY of the city Aachen in Germany provided by the German Weather Service. A building energy model from the *AixLib* Modelica library calculates the heating demand of a defined operating point [18]. The building has a heating

demand of 9.7 kW at nominal ambient air temperature. Equation (7) shows the resulting formula of the *SCOP*.

$$SCOP = \frac{\sum_i \dot{Q}_{\mathrm{heating},i} \cdot \omega_i}{\sum_j \frac{\dot{Q}_{\mathrm{heating},j}}{COP_j} \cdot \omega_j} \tag{7}$$

Here, the indices *i* and *j* indicate the selected cluster, ω_i is the weight of the cluster in hours, $\dot{Q}_{\mathrm{heating},i}$ is heating demand of the building and thus, the condenser heat flow rate of the heat pump and *COP* is the evaluated *COP* for the defined flowsheet at the operating point of the cluster.

The temperatures of the source and sink, describing the operating point of the heat pump, are derived from the ambient air temperature given by cluster *i*. Additionally, a heat curve of a radiator system is coupled, using a nominal design temperature of 55/45 (supply temperature in °C / return temperature in °C), which is a common heating system in the German building stock. Thus, the heat pump operates at different working and load conditions.

The annual electricity demand $W_{\mathrm{el,annual}}$ can be calculated using equation (8).

$$W_{\mathrm{el,annual}} = \sum_j \frac{\dot{Q}_{\mathrm{heating},j}}{COP_j} \cdot \omega_j \tag{8}$$

2.3. Total Equivalent Warming Impact

In addition to the energy evaluation, selected refrigerants and flowsheets are evaluated with regards to their environmental impact. Different approaches exist in the literature for this purpose. A comparatively simple estimation allows the calculation of the *Total Equivalent Warming Impact* (*TEWI*). The *GWP* evaluates refrigerants in terms of their direct emissions to the environment. This value indicates the global warming potential of the refrigerant, but does not take into account the actual amount of refrigerant released into the environment in case of leakage. In addition to the GHG emissions from refrigerant leakage, the *TEWI* also takes into account the GHG emissions from the electricity used to operate the heat pump. Thus, the *TEWI* considers direct and indirect emissions [9]:

$$TEWI = GWP \cdot m_{\mathrm{ref}} \cdot (L_{\mathrm{annual}} \cdot n + EOL) + (W_{\mathrm{el,annual}} \cdot EM_{\mathrm{GWP}} \cdot n) \tag{9}$$

Where L_{annual} is the annual refrigerant leakage, m_{ref} is the refrigerant mass, *n* is the system lifetime, *EOL* is the end of life refrigerant leakage, $W_{\mathrm{el,annual}}$ is the annual electricity demand, and EM_{GWP} is the CO_2-emission factor of the electricity grid. The *TEWI* provides an approximation of the actual CO_2-emissions caused by a heat pump. However, this assessment method only covers the use phase and neglects further climate-relevant life cycle phases.

2.4. Life Cycle Climate Performance

To include further life cycle phase, an extension to the *TEWI* is the *Life Cycle Climate Performance* (*LCCP*). Compared to the *TEWI*, the *LCCP* includes further sources of equivalent GHG emissions. Like the *TEWI*, this is composed of direct (equation (11)) and indirect emissions (equation (12)) [19, 20].

$$LCCP = LCCP_{\mathrm{DE}} + LCCP_{\mathrm{IE}} \tag{10}$$

$$LCCP_{\mathrm{DE}} = m_{\mathrm{ref}} \cdot (n \cdot L_{\mathrm{annual}} + EOL) \cdot (GWP + Adp.GWP) \tag{11}$$

$$LCCP_{\mathrm{IE}} = n \cdot W_{\mathrm{el,annual}} \cdot EM_{\mathrm{GWP}} + \sum_{i=1}^{n} \left(m_{\mathrm{new},i} \cdot MM_i\right) + \sum_{j=1}^{m} \left(m_{\mathrm{rec},j} \cdot RM_j\right) + m_{\mathrm{ref}} \cdot (1 + n \cdot L_{\mathrm{annual}}) \cdot RFM + m_{\mathrm{ref}} \cdot (1 - EOL) \cdot RFD \tag{12}$$

Here the additional variables stand for:

- *Adp.GWP*: *GWP* of the atmospheric decomposition products
- m_{new}: mass of the new material of the heat pump unit
- m_{rec}: mass of recycled material of the heat pump unit
- *MM*: emissions per kg of virgin material of the heat pump unit
- *RM*: emissions per kg of recycled material of the heat pump unit
- *RFM*: emissions from the production of the refrigerant
- *RFD*: Emissions from disposal of the refrigerant

The metric follows the so-called cradle-to-grave approach so that GHG emissions are captured regarding the entire life cycle. In addition to the GHG emissions captured by the *TEWI*, GHG emissions from energy contained in product materials and for refrigerant production, and disposal are also included. The additional parameters introduced in the *LCCP* supplement the *TEWI*, but account for only a small proportion in the overall analysis. However, *TEWI* and *LCCP* use equivalent GHG emissions and do not account for further assessment criteria that might be of importance to avoid misleading the fluid choice.

2.5. Life Cycle Assessment

The Life Cycle Assessment (LCA) includes all life cycle stages of a heat pump and introduces several assessment metrics. To utilize this method, first the overall goal of the assessment must be defined. In this case, the goal is the environmental evaluation of heat pumps and refrigerants in a single-family house in Germany. The LCA aims to investigate the influence of the refrigerant on environmental impact caused during the life cycle of a heat pump. Thereby, the environmental impact is divided into different environmental categories.

This work investigates the life cycle of an air-to-water heat pump (cf. section 2.1 and 2.6). The investigation focuses on the production of refrigerants and heat pump, the operation of the heat pump and the disposal (including a possible recycling). The function of the air-to-water heat pump is to provide space heating and domestic hot water over an observation period of 20 years, matching the heat pump's lifetime (cf. **Table 3**).

This study comprises four main environmental impact categories: global warming (GW), ozone depletion (OD), Photochemical Ozone Formation (POF) and Acidification (A). Overall, their normalized values (normalized by the maximum of each category) are weighted (cf. **Table 1**) and summed to one single LCA-value.

Table 1: Weighting factors for each environmental impact within the LCA.

Environmental impact	Weights in %
Global Warming (GW)	40
Ozone Depletion (OD)	30
Photochemical Ozone Formation (POF)	15
Acidification (A)	15

Since this work aims to compare multiple evaluation methods using the same overall technology, in this case the heat pump, these are the main environmental impact categories. In case different technologies should be compared, however, further impact categories are necessary to provide a full LCA and, thus, a proper ecologic comparison.

2.6 Case study

Within the present case study, we consider ten refrigerants of different fluid groups (hydrocarbons, hydrofluoroolefins, hydrofluorocarbons and chlorofluorocarbons) to account for several effects when evaluating the ecologic parameters. **Table 2** presents the selected refrigerants and their fluid properties.

Table 2: Properties of the investigated refrigerants [16, 21].

Refrigerants	Safety	GWP	Adp. GWP	ODP	T_{crit} in °C	ΔT_{g} in K
R436A	A3	3	0	0	115.89	7.2
R32	A2L	675	0	0	78.11	0
R1270	A3	2	0	0	91.06	0
R290	A3	3	0	0	96.74	0
R22	A1	1760	0	0.055	96.15	0
R410A	A1	1920	0	0	71.34	0.1
R454C	A2L	146	0	0	85.67	7.5
R134a	A1	1300	1.6	0	101.06	0
R404A	A1	3940	0	0	72.12	0.4
R1234yf	A2L	4	3.3	0	94.70	0

In addition to the refrigerant properties, further parameters for the ecologic assessment are necessary. Thus, **Table 3** provides an overview of the constant parameters.

Table 3: Parameters for ecologic assessment. [2]

Parameter	Value
Temperature difference of source	5 K
Lifetime of heat pump (*n*)	20 a
Annual leakage rate (L_{annual})	2 %
Refrigerant mass (m_{ref})	2.5 kg
End of life leakage (*EOL*)	20 %
Heat pump mass (simple cycle)	150 kg

Due to missing data within the literature, the emissions due to the disposal of the refrigerants (*RFD*) are neglected, which is a similar approach to Wan et al. [20] and Yang et al. [2]. For the emissions due to refrigerant production (*RFM*), values of Hwang et al. [10] are used.

The heat pump itself has an assumed constant mass of 150 kg for all refrigerants. However, additional mass is added for the ihx and the vi cycle due to additional piping and further components (e.g. internal heat exchanger). The mass of the basic configuration (simple cycle) of the heat pump is split into four main materials: steel, aluminum, copper, and plastic. **Table 4** shows their share of the total heat pump mass in the basic configuration, their recycling material percentage, and their emissions during production. The additional mass for the more complex cycle configurations consists of copper (piping) and steel (heat exchanger) only.

Table 4: Share of materials with in the heat pump and their individual emissions during production [2, 10].

Material	Share of heat pump in %	Recycling percentage in %	Emissions virgin materials in $kg_{CO2\text{-}eq}/kg$	Emissions recycled materials in $kg_{CO2\text{-}eq}/kg$
Steel	46	29	1.8	0.54
Aluminum	12	67	12.6	0.63
Copper	16	40	3.0	2.46
Plastic	23	7	2.8	0.12

Lastly, equation (13) defines the specific grid emissions for the main investigation. The curve was derived by using the specific emissions of the German grid of the last ten years and predict the general trend for the next 20 years.

$$EM_{\mathrm{grid}} = 405 \cdot 0.9542^{year} \text{ in } g_{CO2}/kWh_{el} \tag{13}$$

In the equation, *year* represents the current lifetime of the heat pump starting with one. Besides equation (13), two constant values are used for section 3.5 to analyze the sensitivity of the results in section 3.2 to 3.4. Here, zero emissions and 50 g/kWh are selected to account for a grid that has no emissions at all and a grid that uses only solar generated power.

3. Results

The following section presents the results of the conducted case study (cf. section 2.6). Section 3.1 shows the results of the energetic assessment for all three investigated flowsheets. Afterwards, sections 3.2 to 3.4 show the results for the ecologic assessments using the energetic assessment of the ihx flowsheet. Finally, a sensitivity analysis is conducted to evaluate the influence of specific parameters on the ecologic assessment results.

3.1. *SCOP*

Figure 2 shows the results of the energetic assessment using the seasonal coefficient of performance (*SCOP*) of all three mentioned flowsheets using the boundary conditions stated in section 2.6.

For the simple cycle (grey bars), the pure fluid R32 shows the highest efficiencies with 3.82, whereas R1234yf shows the lowest efficiencies with 3.29. Besides R1234yf, the pure refrigerants show significantly higher efficiencies than the investigated mixtures. For the flowsheet with vapor injection (vi – blue bars) the absolute values for the efficiencies increase. Overall, the efficiencies increase by a mean value of approximately 6 %. The improvements mainly result from reduced throttling losses since only a partial mass flow rate must overcome the whole pressure difference. Additionally, the mean temperature in the condenser is reduced, leading to reduced losses due to heat transfer in the condenser.

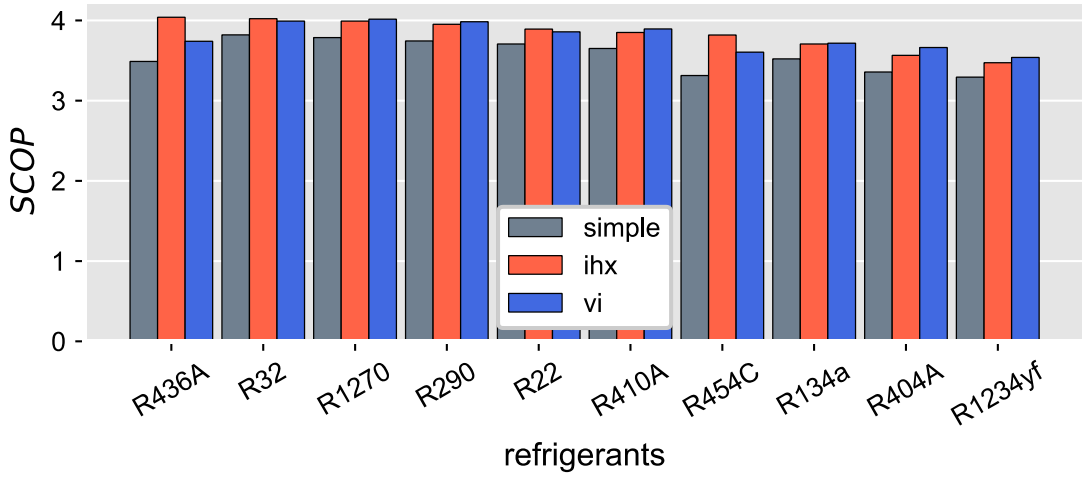

Figure 2: *SCOP* evaluation for the selected refrigerants within all three investigated cycle configurations. The refrigerants are sorted by their highest value in the ihx cycle.

In the vi cycle, the mixtures (e.g., R454C) show higher improvements (approx. 8 %) compared to the pure fluids (4 %). Nevertheless, the overall refrigerant ranking does not vary. Thus, R32 still shows the highest efficiency in the vapor injection cycle.

The ihx cycle (red bars) lead to the overall highest *SCOP* value. Additionally, the ranking of the refrigerants changes. Compared to the simple and vi flowsheet, R436A shows the highest efficiency of 4.04. Overall, the improvements range from approx. 16 % (R436A) to 5 % (R22) with much higher values for the zeotropic mixtures (e.g., R454C and R436A). Main reason for the higher improvements of zeotropic mixtures is the temperature glide (cf. **Table 2**) in combination with an internal heat exchanger. In the simple and vi flowsheet, the pinch point in the evaporator is located at the refrigerant outlet due to the amount of super heating necessary for a safe heat pump operation. Thus, the temperature glide of the zeotropic mixtures leads to a decrease in the mean temperature during heat transfer, increasing heat transfer losses and thus, lowering the efficiency. In the ihx flowsheet, however, the amount of superheating is shifted into the internal heat exchanger. Thus, the pinch point shifts to the evaporator inlet resulting in higher evaporation pressures and overall, higher efficiencies. For zeotropic mixtures, the increase in pressure can exceed the improvements of pure refrigerants due to the temperature glide, especially if the temperature glide matches the temperature difference of the heat source. Therefore, the observed improvements are higher for zeotropic mixtures following findings within the literature [12].

Since the highest differences occur when using the ihx cycle due to the utilization of the temperature glide of zeotropic mixtures, *SCOP* values of the ihx cycle are used in the following ecologic assessments to exploit the full potential of fluid choice. Additionally, the refrigerants will be sorted by their energetic ranking in the ihx cycle, starting with R436A with the highest *SCOP* and ending with R1234yf with the lowest.

3.2. *TEWI*

Figure 3 shows the results for the *TEWI* evaluation of the mentioned refrigerants separated by their cause. For the operational evaluation, the results of the *SCOP* using the ihx cycle are selected.

Similar to the energetic evaluation, R436A shows the best performance and leads to the lowest emissions with overall 18.950 kg_{CO2eq} emissions during the heat pump's lifetime. Additionally, the main contributor to the *TEWI* are the emissions related to the energy demand and thus, are proportional to the *SCOP* (cf. section 3.1). For the low-GWP (<150) refrigerants, the share of the emissions due to energy demand is 99 % and higher, proving that the direct emissions are negligible. For refrigerant with high GWP (e.g. R404A with a GWP of 3.940), the share is 75 %. Due to the high influence of the emissions due to the energy demand and thus, the influence of the indirect emissions due to the power generation in Germany, the additional categories do not lead to changes in the refrigerant ranking regarding the optimal refrigerant choice. Considering the ban on high-GWP refrigerants, the *TEWI* evaluation shows similar results compared to the assessment of the energetic efficiency *SCOP*. Thus, the *SCOP* is sufficient when selecting a refrigerant compared to the *TEWI* evaluation in case low-GWP refrigerants are studied that satisfy current regulations.

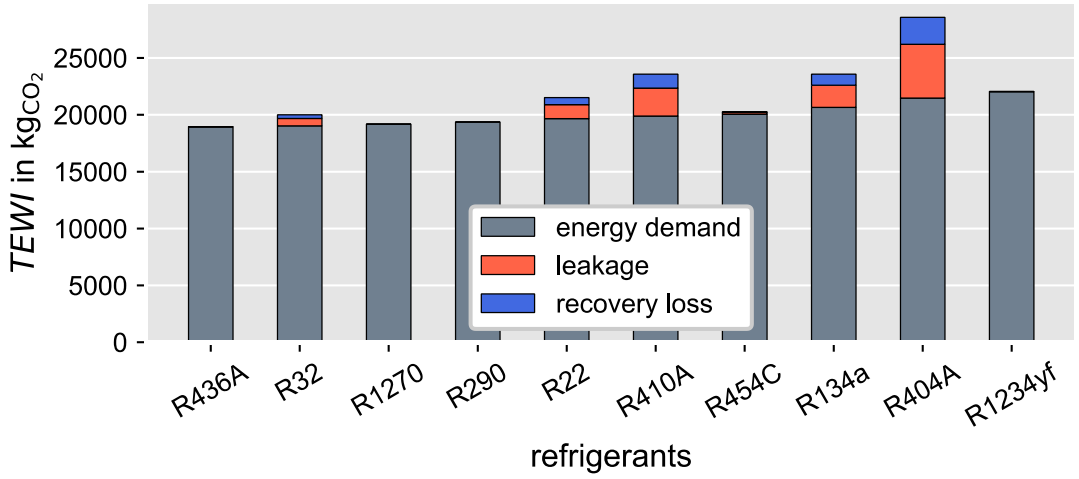

Figure 3: *TEWI* values for the investigated refrigerants. The value is split into each share regarding the emissions related to energy demand, leakage and recovery losses. The refrigerants are sorted by their *SCOP* value within the ihx cycle.

3.3. *LCCP*

Figure 4 shows the results of the *LCCP* evaluation. The results are divided into their individual categories and compared to the *TEWI* (cf. section 3.2).

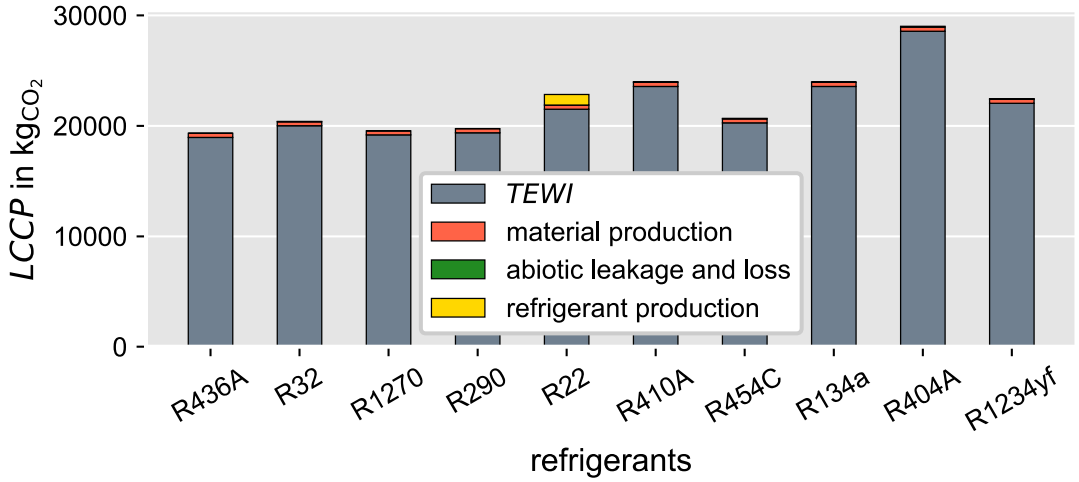

Figure 4: *LCCP* values for the investigated refrigerants. The bars show the share of the *TEWI* and the additional factors within the *LCCP* analysis. The refrigerants are sorted by their *SCOP* value within the ihx cycle.

Compared to the *TEWI*, the *LCCP* accounts for the CO_2-equivalent emissions of the lifecycle *cradle to grave*. However, the main differences between the *TEWI* assessment (grey bars) and the *LCCP* occurs for R22 since the production of R22 and the chemical reactions required have a high energy consumption as well as byproducts with high GWP values. The production of the materials of the heat pump shows only a minor influence on the *LCCP* of a heat pump with a defined refrigerant. Additionally, the composition and weight of a heat pump do not vary between the refrigerants in the current modeling approach leading to identical values. However, the differences in materials due to a refrigerant change and possible bigger components (e.g., larger heat transfer area) is negligible since the influence of the materials of a 150 kg heat pump is already below 1 % of the total emissions. Therefore, a significant influence regarding the CO_2-emissions is unlikely.

Overall, the *LCCP* results are similar to the *TEWI* and *SCOP* results especially for the low-GWP refrigerants. Thus, the more complex evaluation method is not required during a low-GWP refrigerant comparison. Additionally, the figure shows the results for the ihx cycle only. However, the total ecologic assessment conducted for this paper included the evaluation of all three flowsheets. The comparison of the selected

flowsheets leads to the conclusion that the emissions due to additional components within the heat pump are negligible, if improvements in the energy efficiency occur. Thus, more complex flowsheet are always beneficial from a CO_2-emission related point of view as long as the *SCOP* improves.

Besides the CO_2-emissions, the construction and operation of a heat pump influences further environmental impact categories. Thus, the following section presents the results of the LCA, which accounts for multiple environmental impacts.

3.4. LCA

Figure 5 shows the results of the LCA analysis. The LCA value of a refrigerant is the sum of all normalized values in the individual environmental impact category multiplied with the weights in **Table 1**.

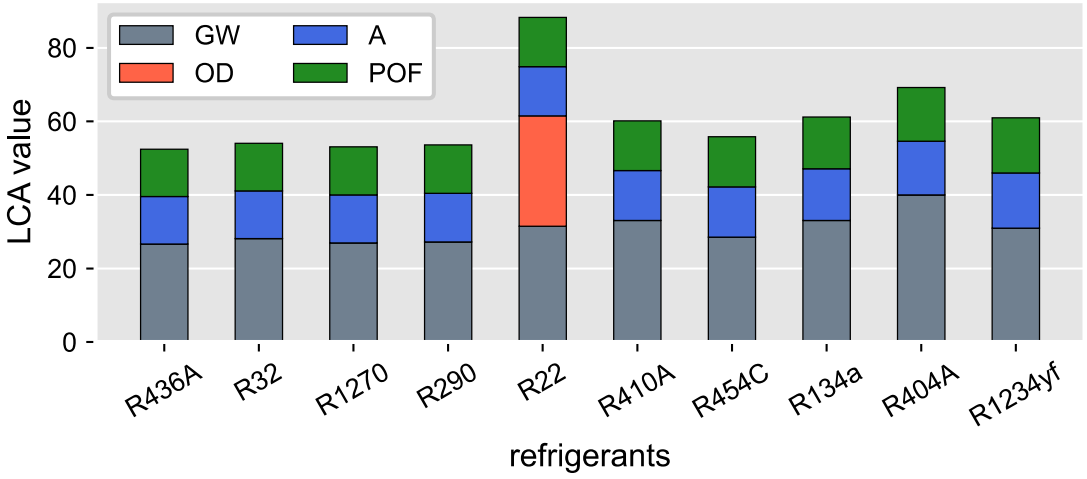

Figure 5: LCA values for the investigated refrigerants. GW: global warming, A: acidification, OD: ozone depletion, POF: photochemical ozone formation.

The most apparent difference compared to the previous results is the huge discrepancy between R22 and the other refrigerants due to the ozone depletion bar (OD – red). Since all other refrigerants have an ODP of zero the differences are to be expected and within the current regulation. Regarding the other impacts, no huge differences occur between the refrigerants. R436A still shows the lowest overall environmental impact and thus, is still favorable. The photochemical ozone formation (POF) and the acidification (A) of the refrigerants are mainly related to the power generation. Thus, the influence of the *SCOP* increases further.

To demonstrate the overall influence of the *SCOP* and the dependency of the environmental assessment criteria, **Figure 6** shows the normalized environmental functions (*TEWI*, *LCCP*, LCA) and the *SCOP*. Additionally, linear functions are included within the figure to show the overall trend.

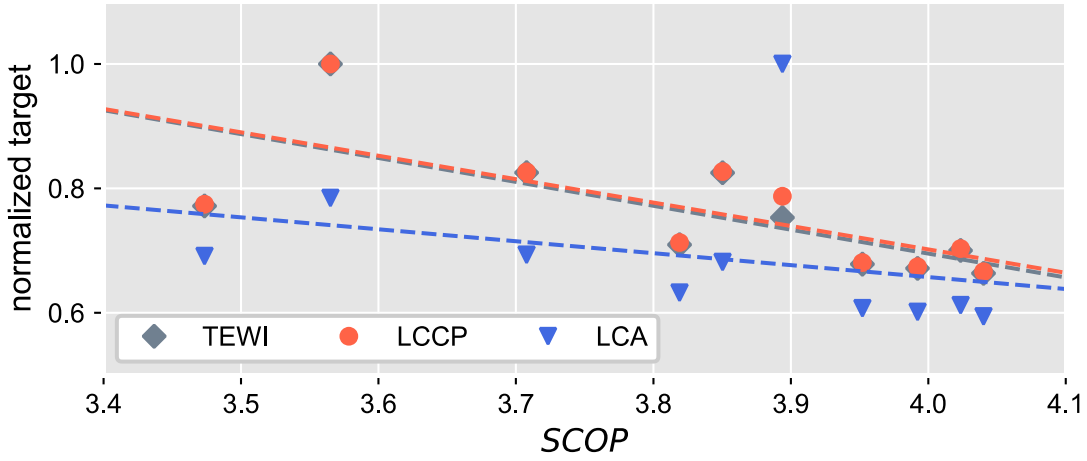

Figure 6: Correlation between the *SCOP* and the ecologic assessment parameters *TEWI*, *LCCP* and LCA. The ecologic parameters are normalized using the maximum value of the present investigation.

The figure shows that the ecologic assessment criteria strongly depend on the *SCOP* and follow a linear curve. The highest differences occur for R22 in the LCA assessment since R22 has an ODP, which is not assessed within the *SCOP* and the energy demand related emissions. Nevertheless, all three linear regression curves offer a good fit for low-GWP and zero ODP refrigerants. Hence, using the *SCOP* offers an accurate assessment criterion when selecting a refrigerant under current regulations (ODP = 0 and GWP < 150).

Table 5 summarizes the results of a refrigerant selection in dependency of the investigated targets. The best performing refrigerant does not vary when the target function is adjusted. However, the ranking of the other refrigerants is offset.

Table 5: Overview of the refrigerant ranking in dependency of the target function.

	SCOP		***TEWI***		***LCCP***		**LCA**	
Ranking	Ref.	$\Delta SCOP$	Ref.	$\Delta TEWI$	Ref.	$\Delta LCCP$	Ref.	ΔLCA
1	R436A	0 %	R436A	0 %	R436A	0 %	R436A	0 %
2	R32	-0,4 %	R1270	1,2 %	R1270	1,2 %	R1270	1,2 %
3	R1270	-1,2 %	R290	2,2 %	R290	2,2 %	R290	2,2 %
4	R290	-2,2 %	R32	5,5 %	R32	5,6 %	R32	3,0 %
5	R22	-3,6 %	R454C	6,9 %	R454C	7,0 %	R454C	6,4 %
6	R410A	-4,7 %	R22	13,5 %	R1234yf	16,3 %	R410A	14,7 %
7	R454C	-5,5 %	R1234yf	16,3 %	R22	18,2 %	R1234yf	16,3 %

9	R404A	-11,8 %	R134a	24,4 %	R134a	24,1 %	R404A	32,0 %
10	R1234yf	-14,0 %	R404A	50,7 %	R404A	50,1 %	R22	68,3 %

Since the energy demand related emissions strongly depend on the emissions during the power generation, the influence of the emissions factor is evaluated in the following section.

3.5. Influence of the power related emissions

The results of the ecologic assessment show that the environmental impact of a heat pump is mainly influenced by the energy demand. Thus, in the following the influence of the specific emissions related to the power generation is evaluated. Since the energy demand dominates the emissions due to the production and disposal of the heat pump for the German grid emissions (with average values of approx. 290 g/kWh – cf. equation (13)), **Figure 7** shows the influence of lower specific emissions on the *LCCP*.

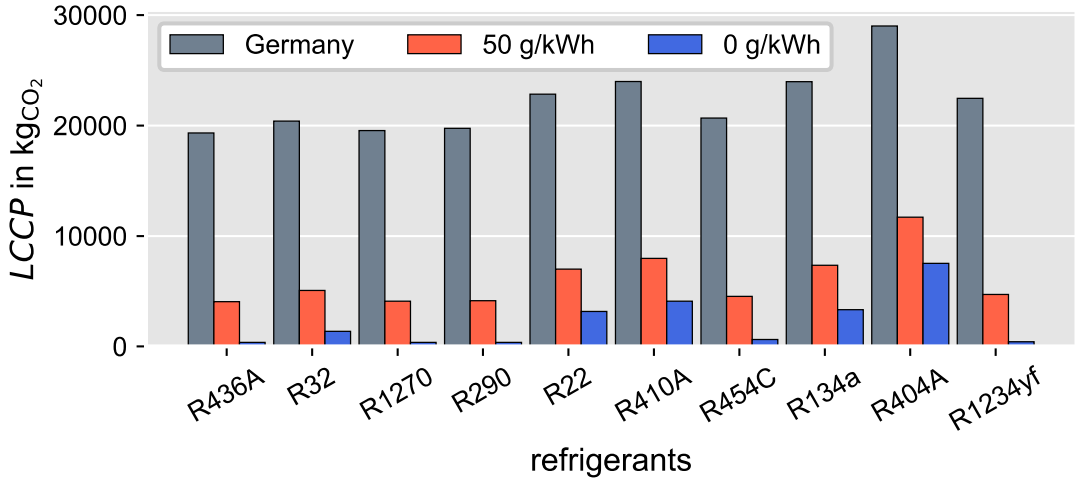

Figure 7: *LCCP* values for all investigated refrigerants using different specific grid emissions. The refrigerants are sorted by their *SCOP* value within the ihx cycle.

The grey bars show the results mentioned in section 3.3. When using a lower power with a lower specific emission ratio which results from the usage of only solar power (red bars – 50 g/kWh), the lifecycle related emissions decrease significantly due to the high influence of the energy related emissions. For most refrigerants, the decrease is similar to the reduction in grid related emissions (approx. 80 %). However, the best performing refrigerant does not change since R436A has a single digit GWP value (3) and the emissions related to material productions are similar for all refrigerants. Thus, the ranking does not change and, the *SCOP* has significant influence on the ranking due to the low GWP of most refrigerants.

Reducing the emissions to a net zero (blue) bars, the dependency on the *SCOP* is lost since no emissions occur due to the energy demand. Thus, the GWP is the main influencing parameter. However, current regulations demand low-GWP refrigerants leading to quite low emission rates. Due to the low energy related emissions, the impact on the environmental impact category of climate change is close to zero whereby other environmental impact categories become more dominant – e.g., material and water usage. Thus, for a zero-emission grid, ecologic assessment criteria based on CO_2 emissions only are insufficient. Nevertheless, there is no country currently with a net zero power grid. Therefore, the authors suggest that the *SCOP* is a sufficient evaluation category when selecting low-GWP refrigerants for a heat pump application.

4. Discussion

The investigations in section 3 show that a correlation between the environmental impact of a heat pump and its individual *SCOP* exists. Thus, the authors conclude that the *SCOP* is a sufficient evaluation criterion when comparing different refrigerants and heat pump systems for residential applications using current regulations regarding a low-GWP (<150) and a zero ODP. Since most electric grids over the globe have emissions higher than 100 g_{CO2}/kWh, which also will not change significantly within the upcoming decade, the described trend will be similar soon. Additionally, the effect increases for electric grids that have higher significantly emission rates than the mentioned 100 g_{CO2}/kWh, reducing the influence of leakages and production even further. Even for lower values (cf. section 3.5), the energy related emissions are more significant still compared to production and leakage related emissions. On top of that, a zero-emission electric grid does not imply that the systems efficiency (*SCOP*) can be neglected since lower efficiencies lead to higher power demand and thus, bigger infrastructure, which once again leads to emissions and the usage of other resources.

Besides the impact on global warming, there are further environmental impact categories of a heat pump, e.g., the mention resource usage. Within the conducted LCA, four out of 16 commonly used environmental categories were used and weighted individually. The results strongly depend on the selected weighting factors and thus, should be investigated further. Additionally, future studies should include further categories to assess the whole impact on the environment. Nevertheless, the selected categories show the strong impact of the *SCOP*.

In this regard, future investigations should include the analysis of more complex flowsheets that improve the cycle efficiency. The present study shows that the impact of the additionally components due to the more complex flowsheet is negligible as long as the cycle efficiency increases. However, additional target functions such as costs must be included in future analysis to assess the energy efficiency, environmental impact, and the economic aspects for a feasible transition towards a net-zero building sector.

Overall, the refrigerant R436A, which is a zeotropic mixture of propane (R290) and isobutane (R600a) shows the best ecologic performance when using a flowsheet with an internal heat exchanger. Additionally, the hydrocarbons R290 and R1270 lead to high efficiencies and thus, low environmental impacts. Furthermore, hydrofluoroolefins (HFO) show lower efficiencies than the hydrocarbons leading to a bigger environmental impact. Additionally, most HFOs lead to the formation of trifluoroacetic acid (TFA) when leaked into the atmosphere. The impact of TFA on the overall lifecycle performance was neglected within the study due to insufficient data. Thus, the actual ecologic performance of HFO will decrease when TFA formation is included in the lifecycle. Thus, the authors conclude that hydrocarbons pave the way towards long-term environmentally friendly solutions in residential heat pumps. Due to their high flammability (A3), however, additional safety measures must be implemented that might worsen the overall ecologic performance. The influence of the additional factors should be investigated in future studies.

5. Conclusions

In the present paper, the influence of the evaluation method with focus on ecologic assessment criteria on the selection of a refrigerant for heat pump systems is investigated. We apply four evaluation methods (*SCOP*, *TEWI*, *LCCP* and LCA) and study ten refrigerants, ranging from high to low-GWP refrigerants. The investigation shows that the main influence on the ecologic performance of a heat pump in a residential building in Germany is the energy demand and the related emissions. Thus, the *SCOP* is the key metric that is sufficient for the ecologic assessment. The key findings of the investigations are:

1. Since *TEWI* and *LCCP* assess CO_2-equivalent emissions only, they strongly depend on the energy demand related emissions and thus, the *SCOP*.
2. When using low-GWP and zero ODP refrigerants, the *SCOP* is a sufficient assessment criterion when selection a refrigerant for a heat pump application.
3. Adjustments in the cycle configuration or the selected flowsheet that improve the *SCOP* are recommended since the overall emissions of the heat pump can be reduced. This effect is valid for specific power grid emissions of 50 g_{CO2}/kWh and higher.
4. The hydrocarbon zeotropic mixture R436A shows the overall best performance in combination with an internal heat exchanger flowsheet.
5. Further research regarding the influence of TFA and a more detailed LCA are necessary to validate all findings of the present work and over a proper comparison to other technologies, e.g., hydrogen related systems.

Abstract:

Heat pumps have emerged as key technology to pave the way for a sustainable heat supply in buildings. However, the ongoing shortage of trained experts counteracts the current heat pump trend. Increasing the capacity of experts, services like Fault Detection and Diagnosis (FDD) can support the identification of malfunctions and integration of methods for predictive maintenance. The primary objective of FDD is to detect faults, diagnose their causes, and possibly enable correction to prevent efficiency losses as well as system damage or downtime. This involves a comparison between a fault-free reference case and the real system. In research, machine-learning methods like Artificial Neural Networks (ANN) show the capability to learn the behavior of fault-free systems. In practice, however, the implementation of ANN is limited due to missing data in operation for training. Therefore, it is common to utilize physically simulated data for pre-training.

One way to achieve high efficiency in heat pumps is to maximize heat transfer in the evaporator. Fouling within this component therefore leads to significant performance degradation and reduced system lifespan. As a result, this work introduces and evaluates an extendable FDD method for evaporator fouling in air-to-water heat pumps. To detect evaporator fouling during operation using an ANN, a transient model of a refrigerant cycle provides the training data. Based on literature, the fouling effect is emulated afterwards, serving the data for the reference system considering faulty operation. Applying the present concept, we reveal a reduction in *COP* due to evaporator fouling of approximately 3 % over a whole year, while our fault detection methodology detects 55.65 % of the faults within the given heat pump model. Overall, this study provides insights into the performance of FDD methods for evaporator fouling in air-to-water heat pumps, which can help to improve the efficiency and reliability within the system lifespan. The results of this study demonstrate that the concept of FDD offers the potential to be applied in practice, and proposes recommendations for future perspectives about ANN within FDD in heat pump systems.

1. Introduction

As part of the agreements of the Paris Climate Convention, a sharp decrease in greenhouse gas emissions is enforced [31]. This also affects the building sector. One of the objectives of the German government is to achieve a nearly climate-neutral building stock by 2045 and thus a sustainable energy supply for the building sector [32].

Most renewable energy is available as electric energy, which can only be converted into commonly used forms such as methane with significant energy losses. Thus, sector coupling by electrification seems to be essential for decarbonization in the building sector. Heat pumps represent a key technology in this field and offer a good possibility to replace fossil fuel-based heat production with electric power [33]. Due to a limited availability as well as high demand for renewable energies, a reduction of primary energy consumption through increased efficiency is also necessary for the success of the energy transition. [35]

The heat pump efficiency is thereby strongly dependent on a fault-free operation of the system. The rising challenges such as the ongoing lack of technicians, the gas crisis or the increasing demand due to the decision of the *Heat Pump Summit 2022* in Germany carries the risk that the vast number of new installations and maintenance of heat pumps cannot be handled. The consequences are, that specialized companies will be overwhelmed, system efficiency decreases and comfort is reduced. [4] [36]

A promising approach to face these challenges is the integration of Fault Detection and Diagnosis (FDD) methods. The development in technology and sensor devices provides a basis for embedding continuous system monitoring and thus implementing such algorithms [6]. FDD is about detection and identification of the reduced functionality or performance within a component at an early stage, as well as localization and determination of the causes [10]. In technical systems, the goal of Fault Detection and diagnosis (FDD) is to guarantee the quality, safety, and efficiency of operation. One way to achieve this is the automated detection of faults in operation, so the fault can subsequently be resolved rapidly [1]. Thus the integration has the potential to minimize system installation/control errors, detect performance degradation during operation, avoid unnecessary visual inspections and component replacement as well as reduce maintenance costs and downtime [37]. Madani et al. [37] furthermore states that already small modifications in heat pump systems can reduce size and costs caused by the fault. Their suggested framework *Smart Fault Detection and Diagnosis* (SFDD) system is capable of Detection and Diagnosis of possible faults in installation and operation phases in order to reduce maintenance costs and system down time.

FDD is a well-established research field with broad utilization. These fields include, for example, the aviation, automotive, chemical, and power plant industries. In contrast, FDD is still in an early stage for the building sector. This can also be seen in the lack of consistent terminology. [2] [28]

Isermann [29] differentiates the following notions in the context of FDD:

- **Fault Detection** - Determination of faults in a system and the time of their detection.
- **Fault Isolation** - Determination of the type, location and time of detection of a fault via evaluation of its symptoms; follows after Fault Detection.
- **Fault Identification** - Determination of the impact and evolution of a fault over time.
- **Fault Diagnosis** - Determination of the type, impact, location, and time of detection of a fault via evaluation of its symptoms; follows after Fault Detection and includes Fault Detection, Fault Isolation, and Fault Identification.

A considerable amount of FDD methods have been developed for building energy systems in the last decades, such as for air handling units, chillers, or HVAC system levels [9]. Only a small part of FDD methods relates to heat pump systems. Bellanco et al. [11] have summarized several common faults and their effects on system performance from literature for different types of heat pumps; some of them are stated in Table 1. Particles or impurities such as rust can lead to clogging or deposits in the filter, affecting the refrigerant mass flow. Consequently, the superheat increases and the cooling capacity decreases in cooling mode [13]. However, this effect is negligible for moderate fault level, when using units with thermostatic expansion valves [13]. This also applies to refrigerant undercharge, which represents a fault of the design phase [40]. The effect on system performance like *COP* due to refrigerant overcharge, though, seems to be more significant [41]. [14] and [30] refer that refrigerant leakage, which occurs especially due to broken valves on the suction and discharge line of the compressor, can negatively affect the *COP* of vapor compression systems in particular [11]. According to Kocyigit et al. of [12], fouling of the outdoor unit (e.g. by fallen leaves) has a major influence on the *COP* in cooling mode for air-to-air systems. Primarily caused by an increased thermal resistance at the fin heat exchangers due to fouling as well as a decrease of the external air flow rate, whereby the former shows a more significant impact on the *COP*. While the emulation of common faults for experimental validation such as refrigerant leakage [15] or liquid line restriction [39] are complex studies in some cases, fouling is frequently conducted in the literature by simply blocking the area of the heat exchanger with paper or cardboard [15] [16] [39]. Therefore the present work focuses on evaporator fouling.

Table 1. Common faults in heat pump systems [11].

Faults type	System	Effect	Reference
Outdoor unit fouling (FO)	Air-to-Air (cooling mode)	*COP* decreases 9 % Capacity decreases 14 %	[12]
Indoor unit fouling (FI)	Air-to-Air (heating mode)	*COP* remains	[39]
Valve leakage (VL)	Air-to-Air (heating mode)	*COP* decreases 4.4 %	[39]
Ref. overcharge (RO)	Air-to-Water (heating mode)	*COP* decreases 3.4 %	[38]
Ref. undercharge (RU)	Air-to-Water (heating mode)	*COP* decreases 1.2 %	[38]
Liquid line restriction (LL)	Air-to-Air (heating mode)	*COP* and Capacity remains	[12]

Typically, FDD methods are integrated as follows: The calculations of a simulation model representing the fault-free state of the device are compared to the behavior of the system in which a fault has been injected [17]. There are two modeling techniques in order to represent the fault-free behavior. First-principle models are (partly) based on physical knowledge of underlying physical phenomena to describe the system. Unfortunately equations describing real systems are complex and usually difficult to solve. For this reason, data-driven models are attracting more and more attention [17], using experimental or simulative data to learn the relationship between the inputs and outputs of the system to build both linear and nonlinear models. Apart from established methods like Support Vector Machine (SVM) [18] or Partial Least Squares (PLS) [19], Artificial Neural Networks (ANN) [7] [8] revealed comparatively better results [sources]. [6]

Few references dealt with the study of air-to-water heat pump systems in heating mode, although this is one of the most common heat pump systems in the building sector with further increasing interest in the future [3]. To bridge this research gap, this paper proposes the development of FDD for air-source heat pumps. For implementation, we include an ANN-model that simulates the fault-free operation of the plant and calculates the *COP* (Section 2). The actual fault is then injected in a further (physical) simulation for simplicity reasons and compared with the *COP* of the fault-free calculation. Based on the deviation between the two simulation models, a methodology for Fault Detection in case of evaporator fouling is developed (Section 3), and the results are presented (Section 4). Finally, the main conclusions are given in Section 5.

2. Methodology

The methodology used within this paper for FDD can be isolated based on Figure 1 (red section). Here, Melgaard et al. [20] aggregated from [23] a generic framework for engineering systems. In a first step, the real system or device is monitored metrologically to detect any abnormal conditions. The data is subsequently analyzed and evaluated in the process of Fault Detection (FD), Fault Isolation (FDD), and Fault Identification (FDD). In case a fault is detected, a notification is provided (FD). The FDD also provides information about the location, time and length of the fault occurrence as well as the fault's level. In a final step, the fault is evaluated in terms of the level and significance of its impact on system performance (e.g. costs, energy consumption and other performance indicators). The Fault Evaluation allows to make a decision about the further procedure and handling of the fault inside the fault tolerant control. [23] Within the scope of this work, as first step, fault detection (FD) without further evaluation is carried out (red section), which serves as a basis for future developments.

2.1 Modeling

An essential part of FDD is typically a model, which in case of data-driven based methods can represent either a classifier or a regressor. Classification methods described for example in [9] provide a simple approach to detect and diagnose faults. However, a major disadvantage of this technique is the necessity of large labeled datasets (subdivided into faulty and fault-free modes) for the training procedure. This means the fault behavior must be emulated experimentally, which may cause high costs and efforts. Regression-based methods as used in [24] compare a simulated variable (obtained e.g. from a trained ANN) with the measured variable of the real system in order to detect and/or diagnose a fault by comparing both. Therefore, the model learns in a preceding training process the fault-free behavior of the system with measured features, which are ideally not affected by the fault itself. Thus, only fault-free operation must be modeled, which is why this approach is addressed within this work (section 3).

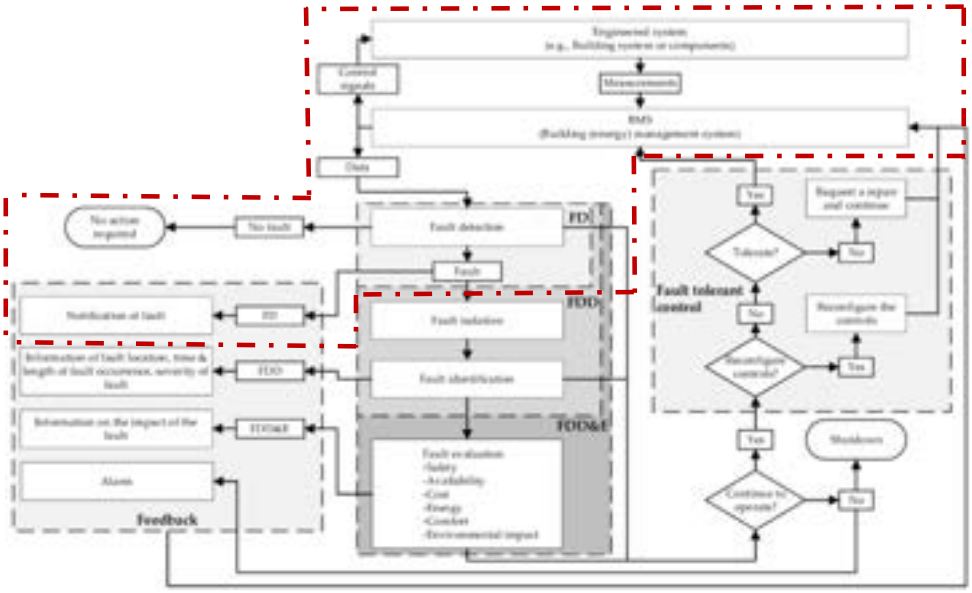

Figure 1: Generic FDD framework for building energy systems according to [20]. The marked red section describes the scope within this work.

2.2 Notification of faulty operation

A further important aspect is the implementation of a subsequent method, which detects the fault as reliably as possible depending on the described comparison between the real system and the ANN. Keliris et al. [21] introduced a simple threshold-based approach using the residual of the real and simulated system (Figure 2). Essential and subject of current research is the selection of a proper threshold for the residual from which a fault is detected. This strongly depends on the model, the real system and the use case. Within this work, the threshold is subsequently adjusted according to the fault level (section 4).

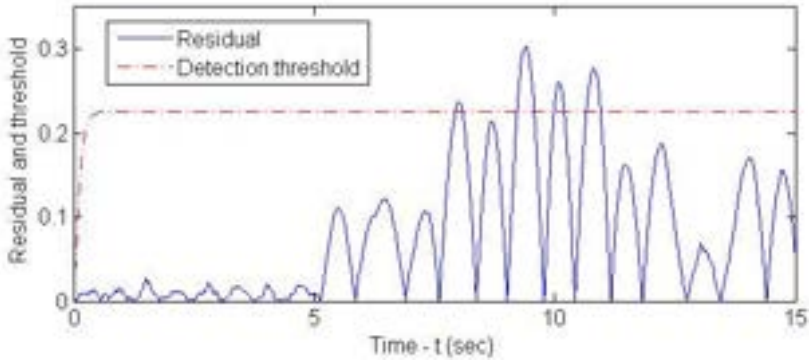

Figure 2: Example of a threshold-based method for a Fault Detection and Diagnosis using the residual [21].

2.3 Evaluation of FDD method

To evaluate the proposed FDD method, the literature suggests a classification into the following parameters, as shown in Table 2. The False Alarm Rate (FA) may be the most serious for FDD, since it could be trigger service being done on a properly working system. Although the algorithm or protocol does not trigger any unintended operations by services in the case of Missed Detection Rate (MD), the failed fault detection can lead to further subsequent faults and performance degradation in the long term. [22]

Yuill et al. [22] also take into account the fault intensity when evaluating the algorithm or protocol. The key parameters within this paper are the FA and MD parameters. However, this is because the intensity of the fault is not considered and the FDD focuses solely on the fault of the evaporator fouling. A Missed Diagnosis can thus be excluded as well as No Response.

Table 2: Evaluation parameter of FDD methods [22].

Parameter	Declaration
False Alarm Rate (FA)	Algorithm returns fault notification during fault-free operation.
False Negative Rate or Missed Detection Rate (MD)	Algorithm fails to detect faulty operation.
No Response (NR)	No response from algorithm.
Missed Diagnosis Rate (MDI)	Algorithm diagnosed wrong fault.

3. Modeling of Artificial Neural Network and reference system

The literature shows great potential for the using ANN, especially for fault detection in complex HVAC systems, improving the results compared to other data-driven methods [25]. The ANN in the context of this work is intended to represent the fault-free state of the system, the dataset used for training and the reference case as well as the hyperstructure of the model is explained below. The investigation period covers one year with an hourly resolution.

3.1 Simulated reference system

In order to consider the effect of the air flow rate on the evaporator capacity, this paper uses the TiL-Suite [34] to model the heat pump. This allows a detailed and transient simulation of the refrigerant cycle. The heat exchanger in the evaporator is designed as fin tubes in crossflow mode and is based on the finite volume approach. We use a simple refrigeration cycle and the medium is propane. The *COP* is then obtained from an energy balance of the evaporator, condenser and compressor. This model is applied in section 3.2 in order to train a fault-free ANN.

To simulate evaporator fouling, the external air flow rate in the evaporator needs to be decreased. In this paper, a gradual reduction of the fan speed is implemented using tangens hyperbolicus (Eq. 1), motivated by [26]. n_{fan} is the fan speed with its maximum value of 15 Hz, t the time and t_{half} the time at half a year in hours. The assumption in this context is that fault-free operation correlates to a fan speed of 15 Hz (Figure 9).

$$n_{\mathrm{fan}}(t) = 15Hz - 7.5Hz \cdot tanh\left(\frac{\pi}{2} \cdot \frac{t}{t_{\mathrm{half}}}\right) \quad (1)$$

3.2 ANN model for fault-free operation

The selected hyperstructure of the ANN is shown in Figure 3 and will be used within this work to represent the fault-free mode of the reference heat pump. The structure is a result of a predefined hyperparameter optimization beforehand and consists of two hidden layers and a total of 176 neurons to calculate the *COP* ("signal"). The input variables ("features") represent compressor speed n_{comp}, discharge temperature T_{dis} from the compressor and refrigerant mass flow $\dot{m}_{\mathrm{ref}}$. The feature selection is a result of an optimization using ADDMo [27], a tool developed by the Institute for Energy Efficient Buildings and Indoor Climate at RWTH Aachen University. This tool automatically calculates the correlation of different features to the signal based on the Pearson correlation coefficient.

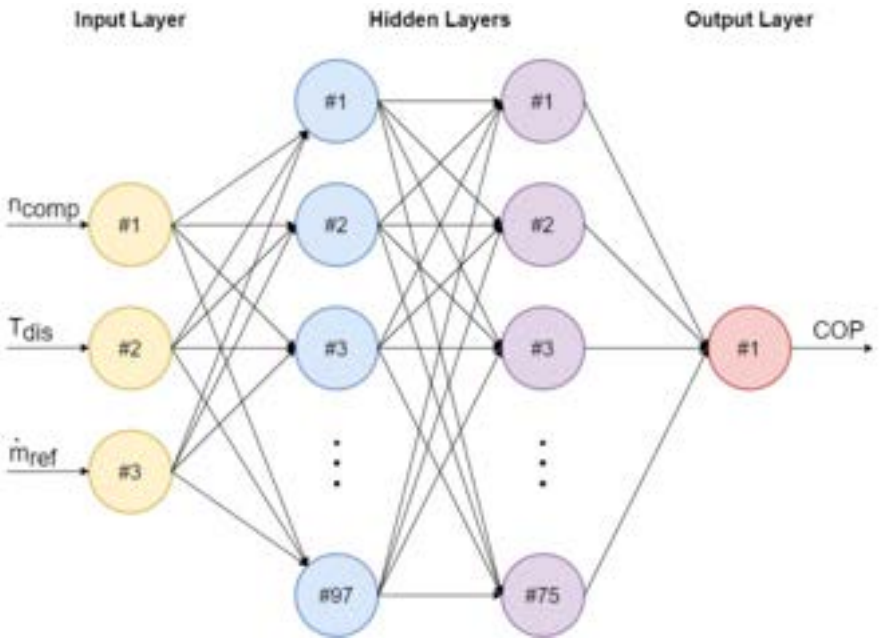

Figure 3: ANN hyperstructure used within this work for calculation of *COP* in fault-free operation. The model's features are the compressor speed, the discharge temperature of the compressor, and the refrigerant mass flow rate.

4. Results

In this section, the fault detection results obtained from the described methodology (section 2) using simulated data (section 3.1) and the ANN model for training and testing (section 3.2) are presented and discussed afterwards.

4.1 Validation of *COP* model

In order to train an ANN for fault-free operation, the relevant simulation data for one year is presented below for validation. For simplification, we assume an operation of the heat pump over the whole year. The data are subsequently shuffled to obtain a heterogeneous and randomly spread data set for the training of the ANN. The result is shown in Figure 4; the *COP* ranges between about 3.5 and 6.

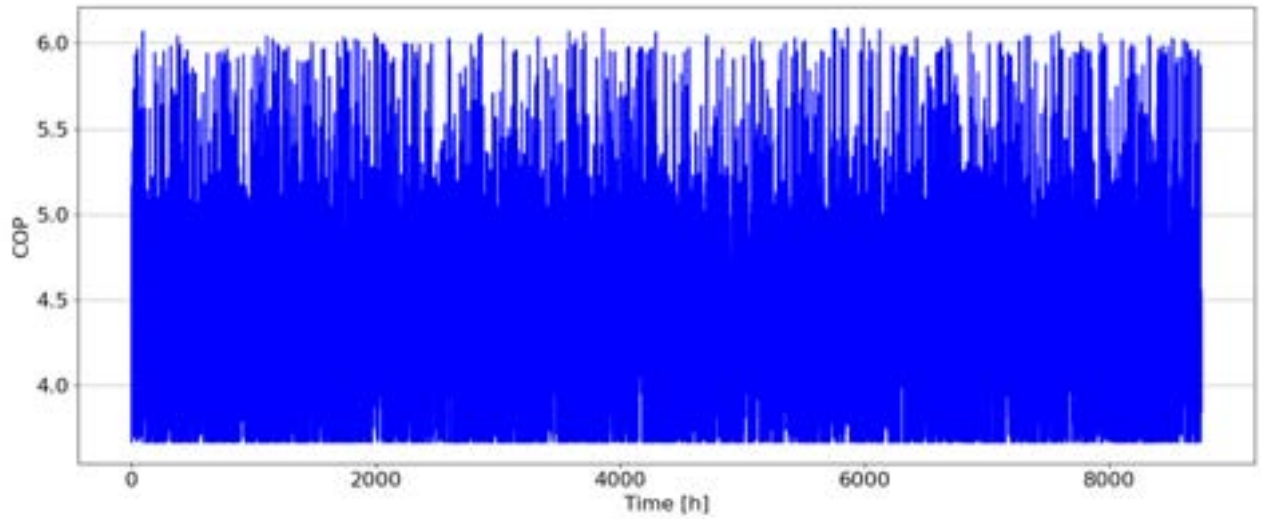

Figure 4: Shuffled dataset of *COP* within the yearly simulation and an hourly resolution.

Figure 5 provides a part of Figure 4, which is used for training (400 hours) and testing (100 hours). This corresponds to a 75 to 25 % split. The majority of the data points are below a *COP* of 5, similar to Figure 4. In addition, Figure 6 shows the test data set used to validate the ANN based on *COP* comparisons to the reference model. The result is an RMSE of about 0.03 for mapping fault-free operation by the ANN.

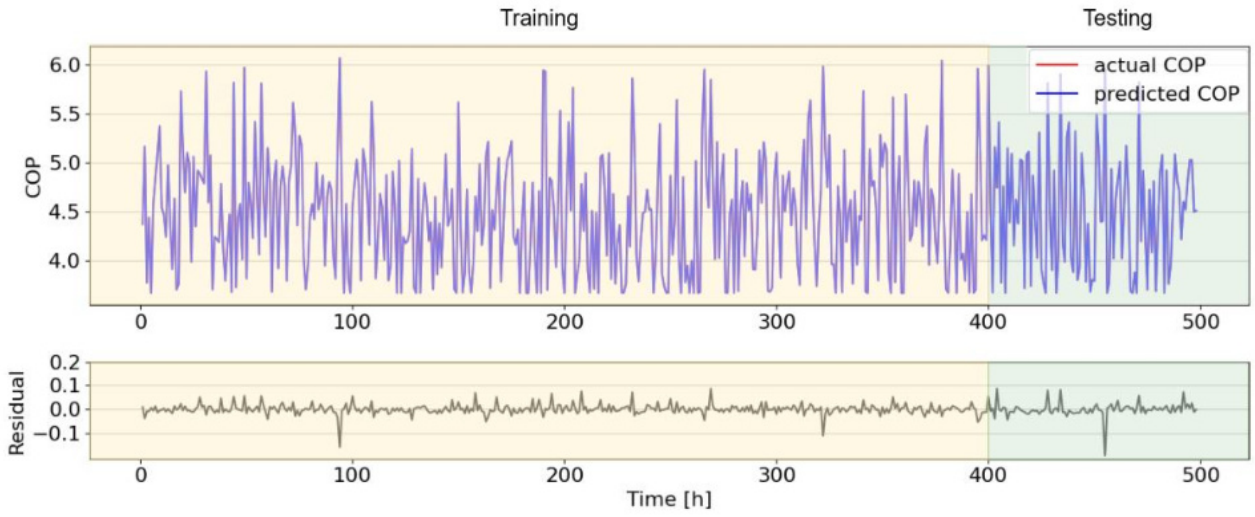

Figure 5: Shuffled dataset of Training and Testing period for ANN Validation.

In Figure 7 we compare the predicted *COP* from ANN and the reference system from the simulation with TiL-Suite (section 3.1) in fault-free operation combined with the residual of both. An RMSE of 0.023 is obtained, hence the ANN seems to be able to model the *COP* quite well. The residual is significantly higher in the summer period compared to winter. This might be due to the composition of the training data set (Figure 5), where the amount of data coming from the winter period is higher, even after shuffling the data. This can be observed as well in the histogram of Figure 8.

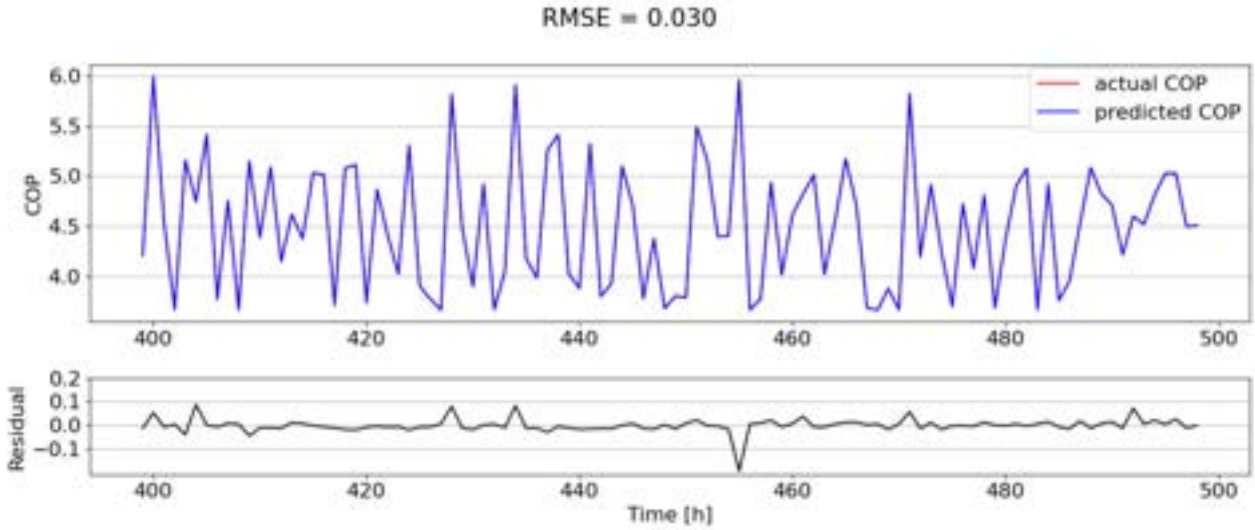

Figure 6: Testing period for ANN Validation from Figure 5.

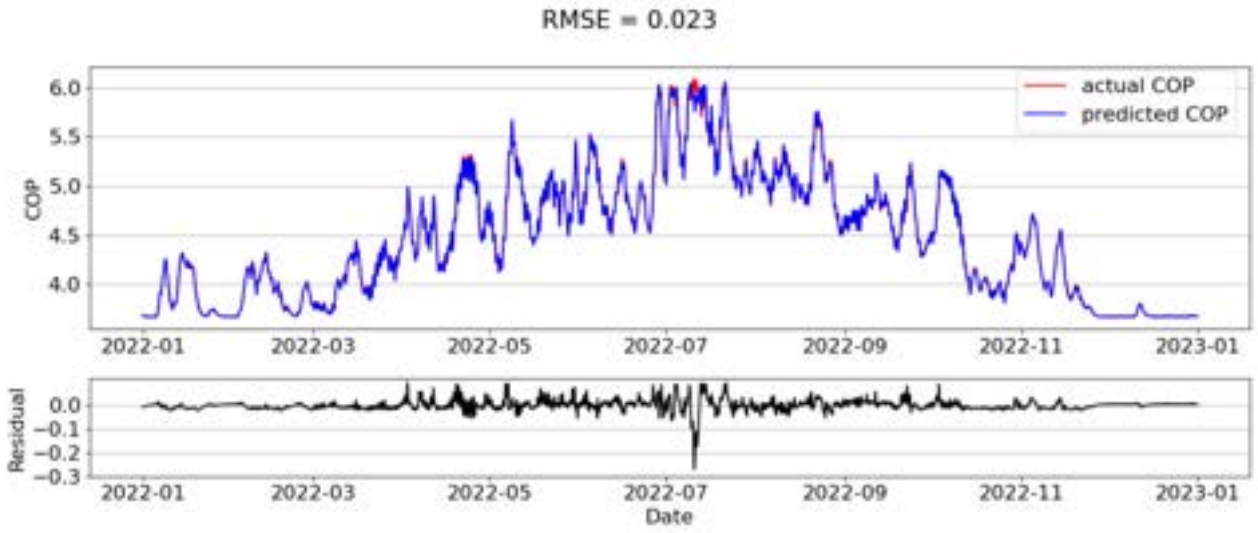

Figure 7: Above: Predicted *COP* with ANN (blue) and *COP* of reference system (red) within the study period. Below: Residual of predicted and actual *COP*.

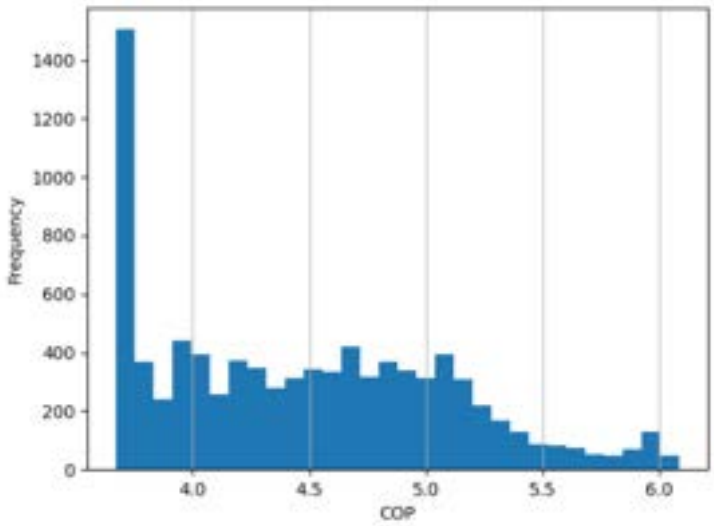

Figure 8: Histogram of occurred *COP*s in the Simulation.

4.2 Model tests for Fault detection

In Figure 9, we again show the *COP* of prediction from ANN and the reference system (with injected fault) from the simulation with TiL-Suite (section 3.1) combined with the residual of both. The green plot demonstrates the fault intensity, which increases according to equation 1 from 0 to 100 %. The maximum fault indication is limited to a reduction of the fan speed by 50 %. The residual increases significantly from April and hence a fault intensity of around 70 % (fan speed accordingly corresponds to 10.5 Hz) on average. It can be observed that the residual increases from April and thus an error intensity of around 70 % (fan speed thus corresponds to 10.5 Hz) on average. The *COP* does not seem to be affected significantly at lower fault intensities. This seems to be partly due to the problem described in section 4.1 above, where the ANN is generally poorer at representing the *COP* in the summer periods, but an increased residual compared to Figure 7 can be detected clearly as well.

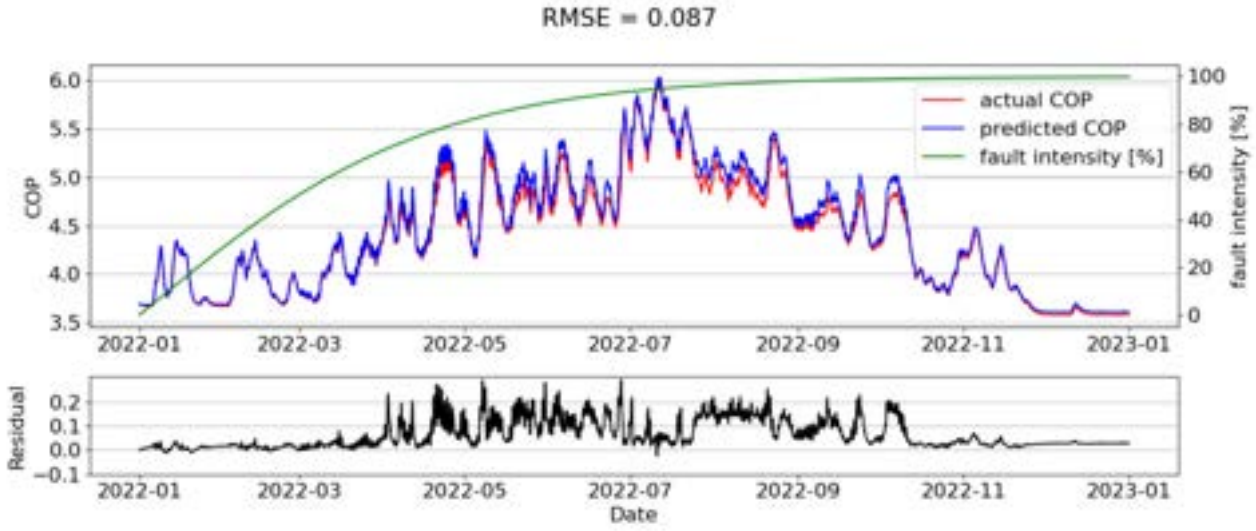

Figure 9: Above: Predicted *COP* with ANN (blue) and *COP* of reference system (red) within the study period including the fault injection. The fault intensity is shown in green. Below: Residual of predicted and actual *COP*.

Based on the results shown in Figure 7 and Figure 9, the threshold value, which serves the basis for fault notification, is defined to be a residual of 0.05. Exceeding this value leads to a notification and in this case to a MD of 44.35 % and FA of 1.35 % (Evaluation is carried out starting from a fault intensity of 70 %).

4.3 Limitations of the work

Within the scope of this work, all results were obtained from simulation data in order to emulate the effect of evaporator fouling. The associated model has not yet been completely validated, but has been compared with similar results from the literature. Hence, a validation based on real experiments, focusing the effect of evaporator fouling, is necessary in the future. For evaluation the threshold value (Section 4.2) has a significant impact on both the MD and the FA. The divergence in model accuracy between the winter and summer periods of the ANN leads to a significant increase in MD starting from early October. A further decreasing of the threshold may help here, but leads to an increase of FA, thus a pareto-optimization is necessary. Thus, this work has demonstrated the importance of training data selection for data-driven model performance. For future work, we expect better accuracy of the fault detection results by using a confidence interval instead of a threshold approach. Moreover, a valid benchmark for the evaluation of FDD methods by e.g. MD and FA is missing in the literature so far and needs to be elaborated.

5. Conclusion

This paper provides a first proof of concept for FDD using Artificial Neural Networks (ANN) to detect any abnormal behavior like evaporator fouling in air-to-water heat pumps early on. The early detection of faults like evaporator fouling is essential in maintaining the efficiency and performance of air-to-water heat pumps. Fouling causes a decrease in heat transfer, which reduces the system efficiency and increases energy consumption. Fault detection enables the scheduling of maintenance before significant performance degradation or system downtime occurs. For this purpose, an ANN is trained to predict the *COP* representing the fault-free operation of an annual simulation. The training data is obtained based on a transient simulation of a refrigerant cycle from the TiL-Suite, which also represents the reference system for fault injection. By gradually reducing the fan speed in the model, the heat transfer within the evaporator is decreased, thus emulating the fouling effect. Subsequently, using the residual of the ANN and the reference model, the deviation of *COP* correlates to the fault and a notification is provided based on a predefined threshold value. This way we are able to detect 55.65 % of all occurring faults and a false alarm is raised only in 1.35 % of the cases.

In future work, instead of using simulation data, we intend to apply experimental data to monitor and detect the effect of fouling and other faults more accurately. Furthermore, we will extend the fault notification method by including a confidence interval and further examine the selection and effect of training data to the ANN. Another crucial aspect in this paper is that a reduction of *COP* is no indication for a specific type of fault. Thus, a key for further development towards fault diagnosis in the future will be the identification of decoupled features which indicate specific fault characteristics or at least isolate potential fault types.

Abstract:

High-temperature heat pumps represent a valuable technology to decrease fossil fuel consumption in industry, as they can use renewable electricity to cover a given heat demand. Conventional heat pumps provide heat at temperatures around a maximum of 80 °C. Nowadays, heat production up to 150 °C can be achieved with high-temperature heat pumps. For higher temperatures between 150 °C and 250 °C, specialized designs, such as Brayton heat pumps, are required. This paper aims to investigate the transient response of the DLR's CoBra prototype, an innovative Brayton-cycle heat pump intended to provide heat above 250 °C and currently under commissioning at the DLR facility in Cottbus, Germany. First, a comprehensive transient thermodynamic model of the system is developed, accounting for heat exchangers and piping thermal inertia. Furthermore, a control logic is presented that ensures safe operation throughout off-design conditions and start-up manoeuvres. In particular, several control parameters are considered to avoid potential operational issues, such as critical temperature gradients, compressor surge, and critical mechanical vibration phenomena due to resonance. The performed simulations aim to reduce start-up time and energy consumed during start-up. Results show that with the help of the described controller, the system can reach design operation via a transient trajectory safely and quickly. Therefore, the capability of the CoBra prototype to flexibly supply high-temperature heat is demonstrated.

1. Introduction

Heat provision accounts for over 50 % of the final energy consumption, with about 25 % for domestic purposes and space heating and 25 % for industrial processes [1]. For industrial processes, the great majority of this energy demand is met by fossil fuels. High-temperature heat pumps represent one of the most efficient options to abate emissions in this sector, as such technology may use renewable electricity to recover heat from low-temperature sources. To date, the market for industrial high-temperature heat pumps offers machines with up to 150 °C heat delivery temperature and COP values up to 5 [2–4]. Primarily fields of applications comprise the food, chemical, paper, and textile industries. Nevertheless, recent studies reported that a significant heat demand at higher temperatures currently exists in Europe [5,6], suggesting it could be addressed through heat pumps in the case higher sink heat temperatures are achieved.

Nowadays, heat pump development is limited by economic and technical barriers [2,4,7]. Economic barriers primarily consist of the long payback periods and the high ratio of electricity to gas costs. Conversely, the technical ones are related to the limited heat sink temperature and the lack of eco-compatible refrigerants performing well and safely at higher temperatures. In their investigation on the heat pumps potential for high-temperature process heat supply, Zühlsdorf et al. [3] suggest that with the proper technology, for instance, by adopting equipment already available within the oil and gas industry, sink temperatures of up to at least 280 °C can be met with heat pumps, both from a technical and economic perspective. Therefore, their scope of applications in the industry may extend.

Most heat pumps are based on the thermodynamic Rankine cycle [2]. However, other cycles can be advantageous depending on the temperature profile or the plant where they are used. In their analysis of different industrial heat consumers, Gai et al. [8] found that sometimes the transcritical, Brayton or Rankine cycle is optimal depending on the process under consideration. In particular, Brayton-based heat pumps may

offer more versatility in design and operability when processes characterized by large temperature glides are considered, as they use single-phase operating fluid and exchange sensible heat with the temperature sink and source [3]. Nevertheless, such systems generally offer a more straightforward construction than the Rankine or hybrid ones and also allow for partial power recovery leveraging turbo expanders. Possible processes include the food industry, with the heating of thermal oil or frying needed, hot air processes like baking or drying, paper and pulp and chemical industries but also thermal energy storage systems where Brayton heat pumps offer the advantage of supplying very high temperatures and also sub-ambient cold temperatures [9,10]. However, systems must be developed, built, and integrated into the relevant industries. Furthermore, they should be compact and provide flexibility in operation to replace or supplement current state-of-the-art gas boilers in brownfield applications. Hence, new concepts should allow for quick start-up times and load changes, ideally at high efficiencies, whilst ensuring safe operation.

To date, few Brayton-based prototypes have been proposed and developed for industrial applications [11–13], whilst most of the research focused on the energy storage field, where several projects and developers are already present on the market [14,15]. Although several research may be found in the literature discussing the cycle optimization or analysing the system behaviour in design conditions, only a few works analyse the dynamic behaviour of such plants, especially when critical operations such as start-ups are considered. In this regard, Frate et al. [16] analyzed the dynamics of a Brayron PTES during warm start-up and off-design operations. Despite not optimizing the gas turbine speed ramp for quick start-ups, a start-up time of around 30 min was reported. Smith et al. [17] presented the design of a laboratory scale pumped thermal electricity storage demonstration plant in order to test the control strategies and demonstrate the system operability and criticalities. Start-up times of around 1.38 h and 2 h were reported depending on the compressor recycle valve opening. Furthermore, Oehler et al. [12] developed and analyzed a control strategy to safely perform a cold start-up of an air-based Brayton heat pump for industrial purposes. A start-up time of more than 2.5 h and a turbine bypass valve was used to avoid compressor surge. However, the control inputs used to drive such maneuver were not designed to optimize the start-up of the system. Faster start-ups are then possible.

To further investigate in this regard, the present work analyses the transient capabilities of the Brayton heat pump proposed in [12] while undergoing a cold start-up manoeuvre. A closed-loop control system is developed and presented in the following to determine whether the system can achieve faster start-up times safely. Results aim to provide useful insights into the system's behaviour and limitations and help design an optimised procedure for quick start-ups.

2. Prototype overview

The CoBra (Cottbus Brayton Cycle) heat pump is currently under development by the German Aerospace Center (DLR) in Cottbus. Figure 1 shows the schematic and thermodynamic cycle of the heat pump.

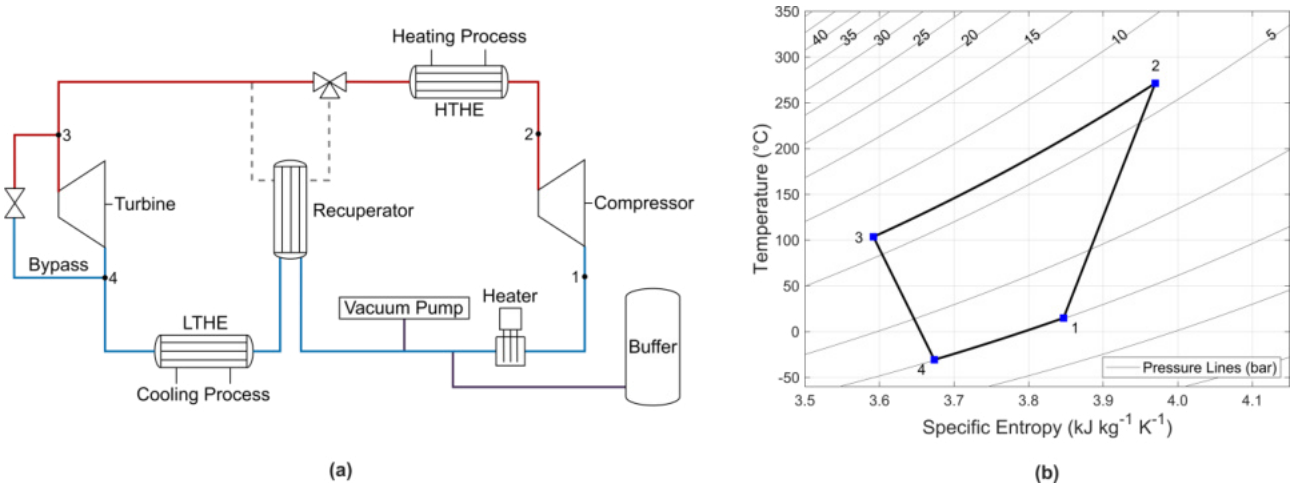

Figure. 1. CoBra heat pump: (a) system layout; (b) T-s diagram.

As a closed-loop Brayton cycle heat pump, the CoBra features a three-stage turbo compressor with pressure ratios of up to 7. The compressor raises the pressure and temperature of the working gas, which is primarily dry air but can also use other media such as argon or CO_2. With the available pressure ratios, the heat pump can achieve heat sink temperatures of 250 °C and more. After rejecting heat to a high-temperature heat sink (e.g. industrial process heat or thermal energy storage), the gas is expanded using an axial two-stage turbine, which recovers power and cools the gas to sub-ambient temperatures. A turbine bypass valve can be opened to increase the mass flow rate in the heat pump, thereby stabilizing the compressor flow. In the low-temperature heat exchanger, the gas absorbs heat from a heat source before returning to the

compressor. An internal recuperator may leverage the remaining temperature difference between the heat exchanger outlet flows to raise the temperature at the compressor inlet. All three heat exchangers are shell-and-tube heat exchangers. The heat pump cycle is nearly hermetically sealed, thus enabling load variation via injection or air removal. Using valves and pressurized buffer storages, the system pressures and, consequently, the load can be controlled [11].

3. Dynamic modelling methodology

A transient model of the CoBra heat pump was developed through the Simulink® environment of Matlab® R2022b [18]. In particular, the Simscape™ libraries were used as they provide built-in models for all the main components constituting the plant. As for the system fluid, dry air was considered and treated as real gas. Its thermophysical properties were retrieved through RefProp [19].

3.1 Turbomachinery

The compressor and turbine were modelled from a system level by using custom components available in Simscape™. The mathematical model of each element comprises continuity equations, such as mass and energy balances. In particular, mass is conserved such that:

$$\dot{m}_{in} + \dot{m}_{out} = 0, \tag{1}$$

where $\dot{m}_i$ are the inlet and outlet mass flow rates, respectively. In a similar fashion, energy balance is computed as:

$$\dot{\Phi}_{in} + \dot{\Phi}_{out} + \dot{W}_{fluid} = 0, \tag{2}$$

where $\dot{\Phi}_i$ are the inlet and outlet energy fow rates, and $\dot{W}_{fluid}$ is the power delivered to/done by the operating fluid (e.g., $\dot{W}_{fluid} = |\dot{W}_{fluid}|$ in case of a compressor, and $\dot{W}_{fluid} = -|\dot{W}_{fluid}|$ in case of a turbine), defined as:

$$\dot{W}_{fluid} = \dot{m}_{in} \frac{\Delta h_{is}}{\eta_{is}}, \tag{3}$$

where $\dot{m}_{in}$ is the inflow mass flow rate, Δh_{is} is the specific enthalpy isentropic variation, and η_{is} is the turbomachine isentropic efficiency. Compressor and turbine mechanical powers are respectively computed according to Eq. (4) and Eq. (5):

$$\dot{W}_c = \frac{\dot{W}_{fluid}}{\eta_m}, \tag{4}$$

$$\dot{W}_t = \eta_m \dot{W}_{fluid}, \tag{5}$$

where η_m is the turbomachine mechanical efficiency. As for the design and off-design modelling, performance maps were used, therefore establishing the relationship between the machines inlet conditions (e.g., mass flow rate, temperature, and pressure) and quantities such as pressure ratio and isentropic efficiency. Figure 2 reports the performance maps considered in this work. Corrected parameters, defined as in Eq. (6), were used to account for variations at the machine inlet:

$$\begin{cases} \dot{m}_{corr} = \dfrac{\sqrt{T_{in}/T_0}}{p_{in}/p_0} \\ n_{corr} = \dfrac{n}{\sqrt{T_{in}/T_0}} \end{cases}, \tag{6}$$

where $p_0 = 101325$ Pa and $T_0 = 288.15$ K. Furthermore, turbomachines were assumed adiabatic with neglibile volume. Their thermal dynamic was therefore neglected. Conversely, inertial effects were considered by accounting for the compressor, turbine, motor, generator, and transmission moments of inertia. Inertial torques were therefore computed as:

$$\tau = J\dot{\omega}, \tag{7}$$

where J is the moment of inertia of the component, whilst $\dot{\omega}$ is its angular acceleration. Finally, coupling between compressor and motor, as well as turbine and generator, was assumed ideal. Hence, gearboxes losses due to backlash and friction were neglected.

3.2. Heat exchangers

Similarly to the turbomachinery, the shell-and-tube heat exchangers were modelled through Simscape™ Fluids library components. Heat exchangers were assumed adiabatic with and a fixed-volume construction to capture variations in fluid mass flow rates due to compressibility. Therefore, mass is conserved along the tube/shell side of the exchanger such that:

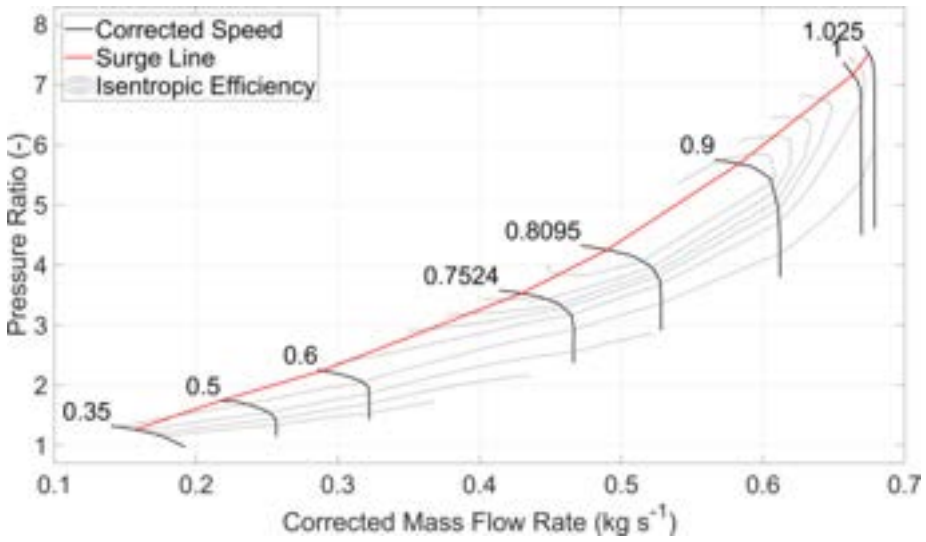

Figure. 2. Compressor map.

$$\left[\left(\left(\frac{\partial \rho}{\partial \mathrm{p}}\right)_u \frac{d\mathrm{p}_I}{d\mathrm{t}} + \left(\frac{\partial \rho}{\partial \mathrm{u}}\right)_p \frac{d\mathrm{u}}{d\mathrm{t}}\right] \mathrm{V} = \dot{\mathrm{m}}_{\mathrm{in}} + \dot{\mathrm{m}}_{\mathrm{out}}, \tag{8}$$

where $\dot{\mathrm{m}}_{\mathrm{i}}$ are the mass flow rates at the inlet/outlet of the tube or shell side, whilst ρ, p_I, u, and V are the gas mass density, pressure, specific internal energy, and volume, respectively. Pressure losses were modelled as:

$$\Delta \mathrm{p} = \left(\frac{\rho_{\mathrm{nom}}}{\rho}\right)\left(\frac{\dot{\mathrm{m}}^2}{\dot{\mathrm{m}}_{\mathrm{nom}}{}^2}\right)\Delta \mathrm{p}_{\mathrm{nom}}, \tag{9}$$

where the subscript $_{\mathrm{nom}}$ refers to the thermophysical quantities evaluated when the system operates at nominal conditions. Furthermore, energy is conserved such that:

$$\left[\left(\left(\frac{\partial \mathrm{U}}{\partial p}\right)_{\mathrm{T,V}} \frac{d\mathrm{p_I}}{d\mathrm{t}} + \left(\frac{\partial \mathrm{U}}{\partial \mathrm{T}}\right)_{\mathrm{p,V}} \frac{d\mathrm{T_I}}{d\mathrm{t}}\right] = \dot{\Phi}_{\mathrm{in}} + \dot{\Phi}_{\mathrm{out}} + \dot{\mathrm{Q}}, \tag{10}$$

where $\dot{\Phi}_{\mathrm{i}}$ are the energy flow rates at the tube or inlet/outlet, $\dot{\mathrm{Q}}$ is the heat transfer rate exchanged between the two fluids, and $\mathrm{p_I}$, $\mathrm{T_I}$, and U are the pressure, temperature and internal energy of the gas volume, respectively.

As for the heat transfer through the heat exchanger, it was determined according to the ε-NTU method. At each simulation step, the number of transfer units (NTU) was therefore computed as:

$$\mathrm{NTU} = \frac{1}{\mathrm{C_{min}R_{overall}}}, \tag{11}$$

where $\mathrm{C_{min}} = \min\left(\mathrm{c_{p,tube}}\dot{\mathrm{m}}_{\mathrm{tube}}; \mathrm{c_{p,shell}}\dot{\mathrm{m}}_{\mathrm{shell}}\right)$, whilst $\mathrm{R_{overall}}$ is the overall thermal resistance defined as:

$$\mathrm{R_{overall}} = \frac{1}{\alpha_{\mathrm{tube}}\mathrm{A_{tube}}} + \mathrm{R_{foul,tube}} + \mathrm{R_{wall}} + \mathrm{R_{foul,shell}} + \frac{1}{\alpha_{\mathrm{shell}}\mathrm{A_{shell}}}, \tag{12}$$

where α_{i} are the convective heat transfer coefficients of the fluids flowing within the tube/shell, $\mathrm{A_i}$ are the aggregate heat transfer surface areas, $\mathrm{R_{foul,i}}$ are the fouling resistances, and $\mathrm{R_{wall}}$ is the wall interface thermal resistance. The heat exchanger effectiveness was then computed as a function of the NTU value through correlations based on the heat exchanger type [20].

In order to capture the thermal transient due to the heat exchangers mass, the wall thermal mass was defined as:

$$\mathrm{C_{wall}} = \mathrm{c_{p,wall}}\mathrm{M_{wall}}, \tag{13}$$

where $\mathrm{c_{p,wall}}$ is the wall specific heat, and $\mathrm{M_{wall}}$ is its inertial mass. Therefore, the heat transfer rate exchanged across the heat exchanger was determined according to:

$$\dot{\mathrm{Q}}_{\mathrm{tube}} = \varepsilon\dot{\mathrm{Q}}_{\mathrm{max}} + \mathrm{C_{wall,tube}}\dot{\mathrm{T}}_{\mathrm{wall,tube}}, \tag{14}$$

$$\dot{\mathrm{Q}}_{\mathrm{shell}} = \varepsilon\dot{\mathrm{Q}}_{\mathrm{max}} - \mathrm{C_{wall,shell}}\dot{\mathrm{T}}_{\mathrm{wall,shell}}, \tag{15}$$

where $C_{wall,i} = \frac{C_{wall}}{2}$ is the thermal capacity evenly divided between the two sides of the heat exchanger, $\dot{T}_{wall,i}$ is the rate of change in temperature in the wall half (positive if the temperature increases, negative when it drops), and $\dot{Q}_{max}$ is the ideal heat transfer rate. Finally, to improve simulation accuracy, each heat exchanger was modelled as a series of ten components characterized by the mathematical model described above. Hence, nominal gas volumes, heat transfer surface areas, as well as pressure losses have been evenly distributed among the elements.

3.3. Piping

As piping represents a non-negligible fraction of the gas volume of the system volume, it was considered and distributed throughout the model according to the actual plant layout. Similarly to the heat exchangers, pipe components conserve energy as in Eq. (10), whilst mass is conserved such that:

$$\left[\left(\left(\frac{\partial M}{\partial p}\right)_{T,V}\frac{dp_I}{dt} + \left(\frac{\partial M}{\partial T}\right)_{p,V}\frac{dT_I}{dt}\right]\right. = \dot{m}_{in} + \dot{m}_{out}. \quad (16)$$

Momentum balance was determined by assuming the pipe in half. Hence, the momentum flux and the viscous friction of each half were computed as:

$$p_i - p_I = \left(\frac{\dot{m}_i}{S}\right)^2\left(\frac{1}{\rho_i} - \frac{1}{\rho_I}\right) + \Delta p_{iI}, \quad (17)$$

where the subscripts $_i$ and $_I$ refer to the pipe inlet/outlet and gas volume nodes, respectively, S is the pipe cross-sectional area, and Δp_{iI} are the pressure losses due to viscous friction, computed accordingly to the flow regime. As for the heat transfer occurring throughout the pipe, it was modelled as:

$$\dot{Q} = \dot{Q}_{conv} + \dot{Q}_{cond}, \quad (18)$$

where $\dot{Q}_{conv}$ is the convective heat transfer between the pipe wall and the gas volume, whilst $\dot{Q}_{cond}$ denotes the heat transfer within the pipe material. By assuming an exponential distribution along the pipe, the convective heat transfer was computed as:

$$\dot{Q}_{conv} = \left|\dot{m}_{avg}\right| c_{p,avg}\left(1 - \exp\left(-\frac{\alpha_{avg} A}{\left|\dot{m}_{avg}\right| c_{p,avg}}\right)\right)(T_{wall} - T_{in}) + -\frac{k_I A}{d_h}(T_{wall} - T_i), \quad (19)$$

where $\dot{m}_{avg}$ is the average mass flow, $c_{p,avg}$ is the specific heat evaluated at the average gas temperature, α_{avg} is the convective coefficient computed by considering the gas thermal conductivity at average temperature (k_{avg}), A is the pipe surface area, d_h is hydraulic diameter, and T_{wall}, T_i, T_{in} are the wall, gas volume, and inlet mass flow rate temperatures, respectively. Finally, the heat transfer due to the conduction within the pipe metal was computed as:

$$\dot{Q}_{cond} = 2\pi k_{mat} L\left[\frac{(T_{mat} - T_{in})}{\ln\left(\frac{d_{avg}}{d_{in}}\right)} + \frac{(T_{out} - T_{mat})}{\ln\left(\frac{d_{out}}{d_{avg}}\right)}\right] + c_{mat} M_{mat} \dot{T}_{mat}, \quad (20)$$

where L is the pipe length, k_{mat}, c_{mat}, M_{mat}, $\dot{T}_{mat}$ are the thermal conductivity, specific heat, inertial mass, and temperature of the pipe material, d_i are the pipe inner, mean, and outer diameters, and T_i are the respective metal temperatures.

3.4. Valves and other equipment

The transient model also accounted for the ancillary equipment reported in Figure 1a. Hence, valves were modelled as adiabatic variable restrictions with negligible volume. In particular, the three-way valve was modelled through two inversely linked valves, such that opening one valve results in the closing of the other. Furthermore, valve geometry was characterized based on manufacturer data, and a linear flow characteristic was considered. As for the heater, only pressure drops were accounted for and modelled as in Eq. (9).

3.5. Controls

Two independent control loops were implemented to simulate the system in transient conditions, namely:

- anti-surge controller;
- temperature controller.

The anti-surge controller was designed to prevent the compressor from operating within critical regions in proximity to the surge line. With reference to Figure 1a, compressor surge was avoided by manipulating the turbine bypass opening, thus increasing the primary mass flow rate. The valve opening was regulated by a

variable-gain PI feedback controller based on the surge margin error. In the present work, the surge margin was defined as:

$$\mathrm{SM} = \left(\frac{\mathrm{PR_{surge}}}{\mathrm{PR_{op}}} - 1\right)_{\dot{m}_c}, \tag{21}$$

where $\mathrm{PR_{op}}$ is the actual pressure ratio, while $\mathrm{PR_{surge}}$ is the surge line pressure ratio evaluated at the same reduced flow. Controller gains were determined to provide a pure proportional action at high errors to ensure a prompt response in case of critical operating conditions. An integral control action was gradually added at low errors for setpoint tracking.

On the other hand, the temperature controller varies the compressor shaft speed in order to control the compressor outlet temperature. As discussed in [12], the control requirements were set as follows:

temperature slopes of no more than 2 K/min to avoid critical thermal stresses at the heat exchangers;

fast crossing of critical low speeds to avoid resonance effects of the compressor shaft.

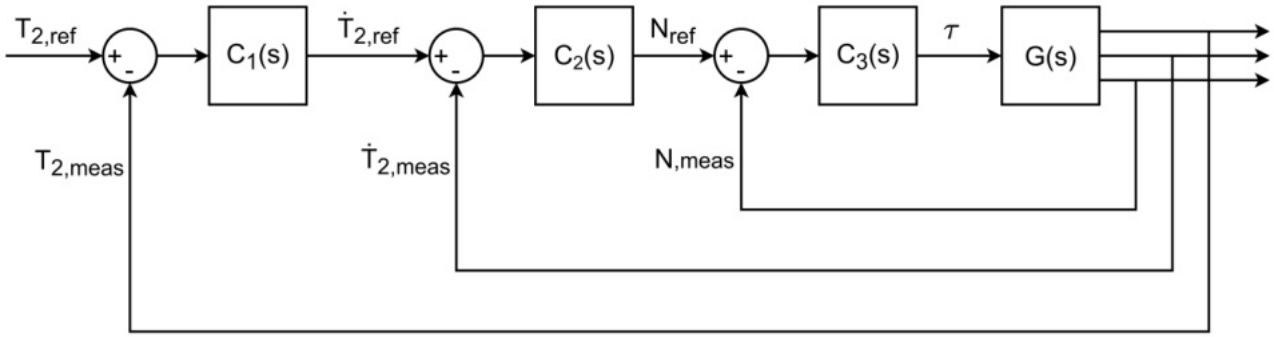

Figure. 3. Simplified temperature control schematic.

A cascade control architecture, made of three nested loops, was found suitable for the given requirements. The compressor outlet temperature was chosen as the primary controlled variable, as measuring the temperature inside the heat exchanger is a non-trivial task. As shown in Figure 3, the outer regulator uses the temperature error to determine a setpoint for the compressor outlet temperature slope. Here, the slope setpoint is limited to a maximum value of 2 K/min. Subsequently, the intermediate control loop processes the temperature slope setpoint and compares it with the actual measurement/estimation to provide a motor speed setpoint. Similar to the outer loop, the speed setpoint is limited to values within the compressor's operating range. Finally, an inner loop determines the motor torque based on the difference between the reference and measured motor speed.

It is worth mentioning that sensor and controller dynamics are negligible as they are faster than the ones characterizing the system under analysis. Nevertheless, standard anti-windup techniques were employed to manage the undesired effects related to the interaction between the controllers' integral actions and the saturations characterizing the physical system and the control schemes.

3.6. Transient simulation

The model outlined in the previous sections was used to investigate the system's transient behaviour during the start-up, aiming at determining the characteristic time and the significant criticalities that occur while performing such a manoeuvre.

At first, a cold start-up manoeuvre was simulated while imposing a maximum temperature slope of 2 K/min. The start-up time was assumed to be when the system provides heat at a temperature with an absolute error of less than one degree with respect to the design value. Secondly, a sensitivity analysis was performed by varying the maximum allowed slope in the 2−50 K/min range to investigate how the start-up time of the system is affected by the temperature slope limit.

Each simulation scenario was initialized through the same initial conditions. In particular, initial conditions were computed such that the system had enough mass to reach nominal conditions at the end of the start-up. Therefore, the initial system pressure was assumed to be almost 2 bar, whilst the initial fluid and metal temperatures were set between 15−20 °C. Mass flow rates on the secondary side of the cycle heat source and sink heat exchangers were considered constant throughout the simulation and were already at their nominal values. The turbine and generator were supposed to rotate at their respective design speeds. Conversely, the motor and compressor were assumed to rotate very slowly (~3 % of the nominal speed) to avoid numerical instability during the transient initialization of the model. Finally, control actuators such as the heater and the recuperation valve three-way were not considered during the start-up manoeuvre. In particular, the three-way valve was set such that the primary mass flow exiting the high-temperature heat

exchanger went directly to the turbine inlet. Therefore, the recuperator was disabled and a non-regenerated configuration of the plant was assumed.

4. Results and discussion

4.1. Cold start-up

During the cold start-up, the system goes from steady conditions to nominal ones based on the control inputs determined by the temperature and anti-surge regulators. Control input and outputs are reported in Figure 4.

At the beginning of the simulation, the system is at an ambient temperature at a pressure of 2 bar. As the compressor rotates at low speeds, corrected flow is negligible. The surge margin is less than 10% (e.g., minimum allowable value), and the bypass valve is fully open due to the anti-surge controller action (Figure 4a). Moreover, as the compressor outlet temperature is lower than 271 °C (e.g., the desired setpoint), the temperature controller causes the motor/compressor to accelerate (Figure 4b). Consequently, the compressor outlet temperature increases, as reported in Figure 5a, whilst the turbine inlet temperature remains constant as heat is absorbed by the high-temperature heat exchanger. Since the bypass is fully open, part of the primary mass flow does is not expanded by the turbine, and only a minor temperature drop

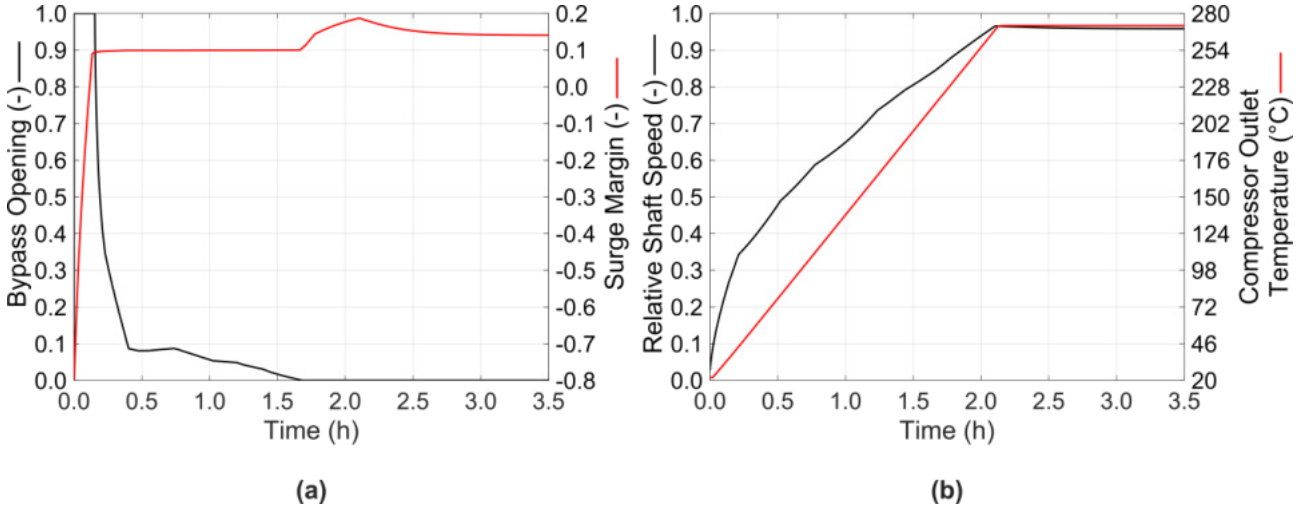

Figure. 4. Control signals (in blue) against controlled variables (orange): (a) surge margin controller ($SM_{ref} = 10\%$); (b) compressor outlet temperature controller ($T_{2,ref} = 271°C$).

occurs through the valve. The system operates in the abovementioned configuration for almost ten minutes. In such a period, the compressor keeps accelerating, increasing its outlet temperature and reducing the surge margin. As a result, the operating point slowly moves toward higher speeds and efficiencies on the right of the compressor map at an almost constant pressure ratio (Figure 6).

At t = 9 min, the surge margin becomes greater or equal to the minimum allowable limit. Since the compressor keeps accelerating, the anti-surge regulator gradually closes the bypass valve to maintain the setpoint surge margin. In more detail, the bypass valve goes from 100% open down to around 10 % open at t = 23 min, and it is fully closed after t = 1.67 h, as shown in Figure 4a. Due to the bypass closure, part of the primary mass flow expands through the turbine, and consequently, the temperature at the turbine outlet starts to decrease (Figure 5a). Also, the pressure ratio progressively increases because of the higher rotational speed (Figure 5b). As a result, the operating point moves toward higher speeds and efficiencies parallel to the surge line.

At t = 1.67 h, the anti-surge controller fully closes the bypass valve as the system operates safely away from the surge line. On the other hand, slightly after two hours, the compressor outlet temperature reaches the design value, and the temperature regulator stops accelerating the compressor. The system operates close to the design conditions at this point, providing a heat flow rate of 115 kW at around 262 °C. From here to the end of the simulation, the temperature controller provides only minor adjustments. In particular, the motor/compressor speed slightly decreases as a consequence of the stabilization of the system temperatures, which is not instantaneous due to the thermal inertia of the system (e.g., T_3, T_4 and T_{wall}). This can also be observed in Figure 6, where the compressor operating point remains almost in the same position on the map, experiencing only a minor displacement toward higher efficiencies and pressure ratios as the temperatures settle.

It is worth noting that, during the transient, the compressor outlet temperature increases at a constant slope, which is maintained below the maximum allowable value by the temperature controller. Limiting the compressor outlet temperature helps contain the temperature gradients within the heat exchangers. For

instance, by looking at Figure 5a, it can be observed that the metal temperature at the high-temperature heat exchanger inflow shows a similar trend after a delay of almost 12 min caused by the thermal mass of the piping and the first element of the heat exchanger. A significant delay can also be noted in the turbine inlet temperature as it increases only after 40 min with respect to the compressor outlet temperature. Here, the delay magnitude is higher as it accounts for the thermal inertia of the complete high-temperature heat exchanger and the piping connecting the heat exchanger with the expander. Furthermore, as the temperature slope is determined based on the capability of the heat exchangers to sustain thermal stresses, it can be stated that their design represents a critical constraint for quick plant start-up.

It can be further noted that the motor/compressor speed increases quickly, especially at the lower values, ensuring the compressor never operates at critical speeds for an extended amount of time, thus avoiding potential deleterious effects related to compressor shaft vibrations. Moreover, the motor/compressor acceleration is continuously modulated as a reaction to the bypass valve closure, thereby denoting interaction and the goodness of the developed control system.

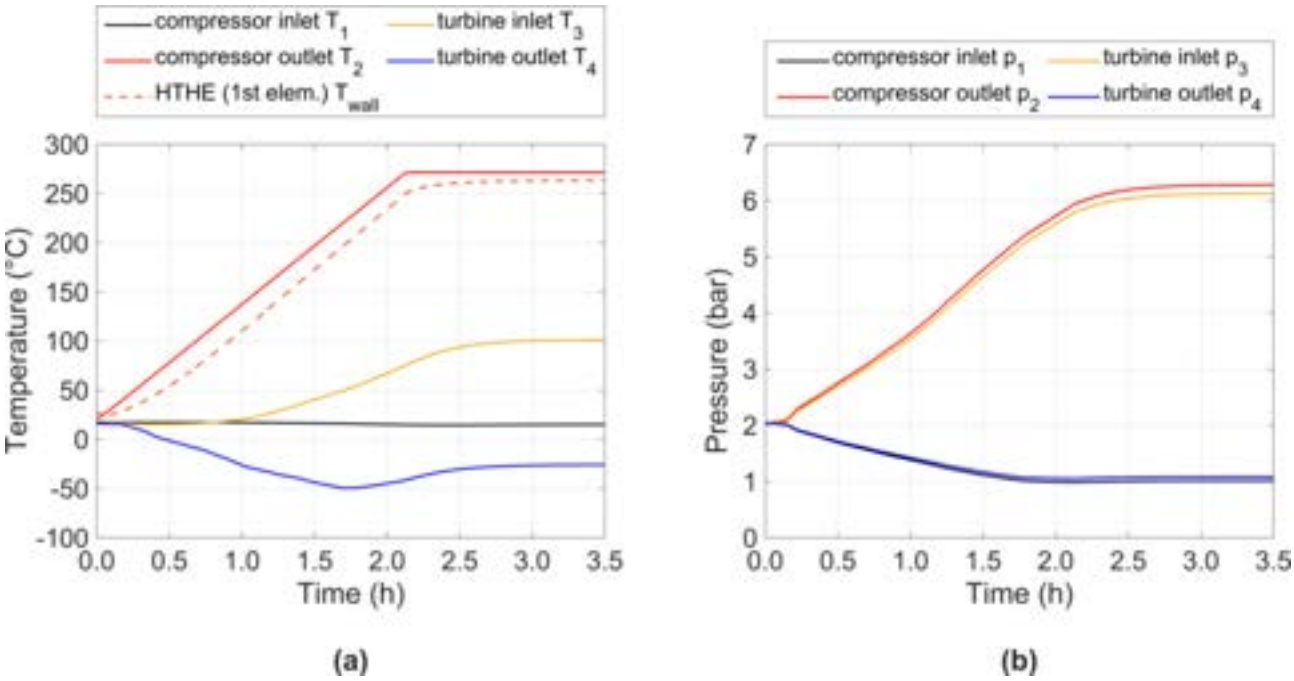

Figure. 5. System transient response during a cold start-up: (a) cycles temperatures and HTHE first element average wall temperature; (b) cycle pressures.

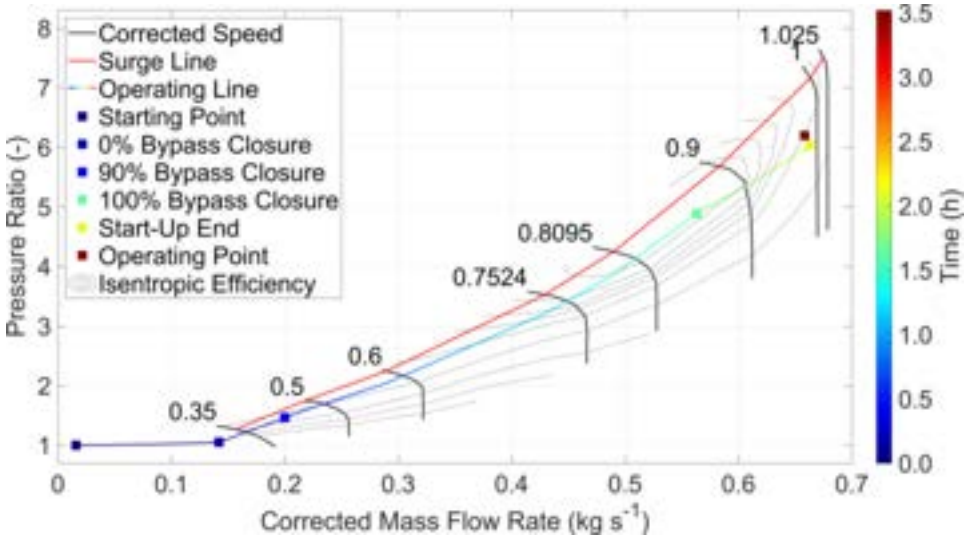

Figure. 6. Compressor operating line during the start-up.

4.2. Sensitivity analysis

The previous section showed that the thermal stresses sustainable by the heat exchangers mainly constrain the start-up time of the system. Hence, a sensitivity analysis was performed to further investigate such a relationship. The system's start-up was simulated by varying the maximum allowable slope at the compressor outlet temperature in the 5−50 K/min range with a 5 K/min step. Each simulation was initialized as discussed in Section 3.6. Results are summarized in Figure 7, which reports the start-up times and system power consumption as a function of the maximum allowable slope of the compressor outlet temperature.

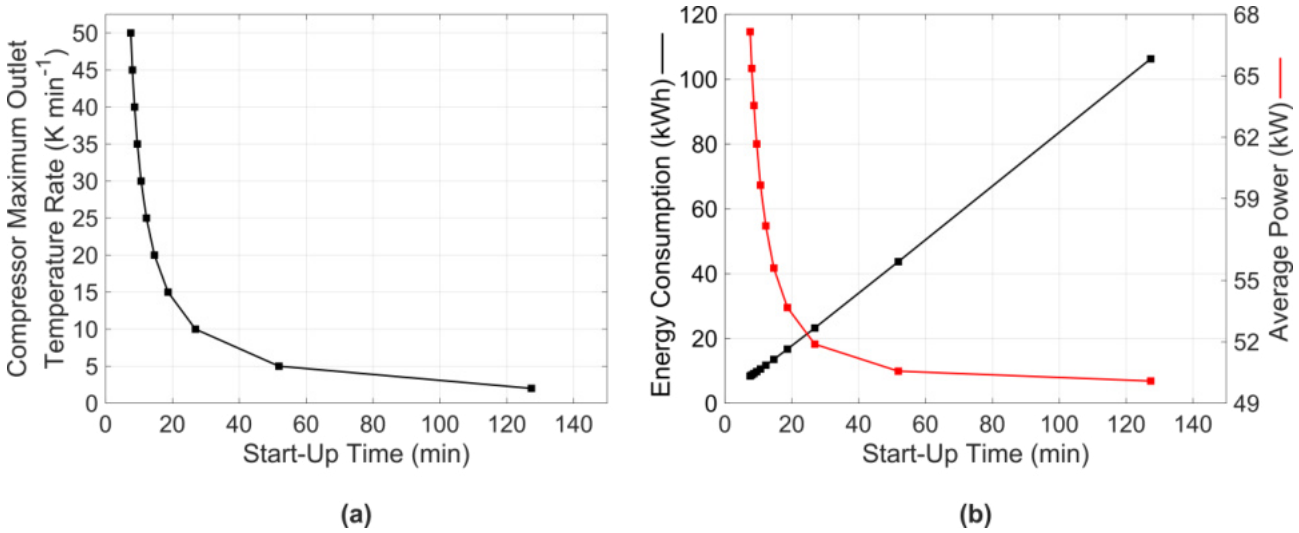

Figure. 7. Sensitivity to the maximum compressor outlet temperature rate: (a) start-up time; (b) energy consumption and average absorbed power during the start-up.

It can be observed that start-up time significantly reduces as the slope constraint is relaxed (Figure 7a). For instance, allowing for a temperature slope of 5 K/min leads to a start-up time of around 52 min (e.g., 60 % reduction), whilst in case of a slope of 10 K/min, the start-up time drops to 27 min (e.g., 80 % reduction), providing more flexibility of use in real applications. From there on, minor advantages are shown for higher temperature slopes. However, it is worth noting that such temperature slopes would require suitably designed heat exchangers, potentially increasing the capital cost of the plant and thus making it less appealing from an economic perspective. It can also be noticed that the system's energy consumption decreases almost linearly with the start-up time reduction (Figure 7b). Therefore, higher temperature slopes lead to lower energy consumption. On the other hand, less conservative slopes cause higher average power absorbed by the system increases, with a trend similar to the one reported in Figure 7a.

Apart from the considerations discussed above, shortening the start-up may lead to new technical challenges to be addressed. For instance, Figure 8 reports the cycle temperatures trend for a maximum temperature slope of 2, 10, and 15 K/min while performing the start-up.

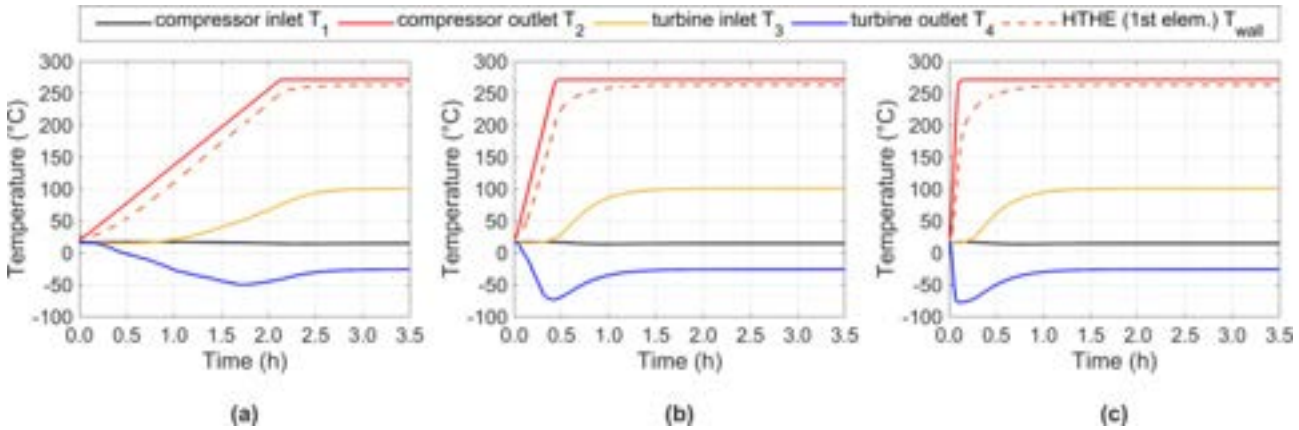

Figure. 8. Cycle and HTHE tube inlet temperatures for different values of temperature rate constraint at the compressor outlet: (a) $\dot{T}_2 = 2$ K min^{-1}; (b) $\dot{T}_2 = 10$ K min^{-1}; (c) $\dot{T}_2 = 50$ K min^{-1}.

It can be observed that higher allowable slopes lead to faster accelerations of the compressor, causing a quicker increase in both mass flow rate and pressure ratio. During rapid acceleration manoeuvres, the target pressure ratio and the bypass valve closing are reached before the metal temperatures in the high-temperature heat exchanger have settled. This leads to low turbine inlet temperatures and, consequently, turbine outlet temperatures of below −50 °C. As these low temperatures may lead to icing at the turbine outlet, further solutions are needed to handle these problems. A possible workaround may involve regulating the turbine shaft speed to operate with lower isentropic efficiencies, thereby mitigating the low outlet temperatures. However, at this stage of the work, it is not yet clear whether their adoption may affect the final start-up time of the plant. Therefore, further investigations must be conducted in this regard.

5. Conclusions

This paper investigates the transient behaviour of the DLR's CoBra heat pump during a cold start-up, assessing the time needed to reach design conditions and studying potential criticalities while performing such a manoeuvre. To this extent, a thermodynamic model of the system, comprehensive of mechanical, thermal and volume dynamics, was developed based on actual data characterizing the prototype. In addition, a control strategy was designed to automatically drive the compressor whilst ensuring the safe operation of the plant.

Results show the time needed to perform a cold start-up is around 2 hours when a maximum temperature slope is limited to 2 K/min to prevent thermal stresses at the heat exchangers. As expected, mechanical and pressure transient effects showed to be negligible when compared to the thermal dynamics characterizing the heat exchangers and piping. In particular, the heat exchangers showed delays of around 40 min.

Further analysis showed faster start-ups are possible in the case of less conservative temperature slopes. For instance, by increasing the maximum allowable slope to 5 or 10 K/min through adopting more advanced heat exchangers, the start-up time decreases to 52 and 27 min (e.g., start-ups shorter by more than 50 % and 80 % compared to a slope limit of 2 K/min). However, it was observed that quicker start-ups might lead to undesired effects at the turbine, as the outlet temperatures go below −70 °C during the transient, potentially causing icing. Further work is then required to assess the magnitude of these issues and to investigate whether possible solutions may negatively affect the start-up time of the plant, therefore nullifying the economic effort of using more sophisticated heat exchangers.

Finally, it is worth mentioning that the considered Brayton heat pump showed a start-up time consistent with the ones reported for a similar cycle specifically designed for energy-storage purposes [17], where start-up times in the 1.38−2 h range have been reported depending on the opening the compressor recycle valve opening. Here, differences in the results may be due to the different designs of the components, operating modes, temperature levels, and heat exchangers' size or technology, as the system are meant for different purposes. Although the comparison may suggest the validity of the proposed analysis, the proposed results should be confirmed through experimental data. Therefore, future work must be conducted in this direction in order to validate and further improve the developed transient model of the Brayton heat pump.

Investigation of a Heat Pump using Two-phase Refrigerant Compression

Abstract:

Two-phase compression in volumetric machines shows several advantages: sealing effects brought by the liquid blocking the gap between two working chambers and it allows to get closer to an isothermal process, reducing the thermal stress on moving parts and minimizing compressor work. However, such compression also comes with some disadvantages: the mechanical reliability of the machine is questioned due to the presence of liquid during the compression, moreover, literature has shown that compressing in the two-phase region usually tends to decrease the isentropic efficiency of the machine.

The irreversibility creation in cycles such as ORC's or vapor compression cycles comes from two sources: the deviation of compression/expansion processes from internally reversible processes and the temperature difference between the hot/cold sources/sinks and the working fluid along heat exchanges (external irreversibility). Therefore, two-phase refrigerant compression/expansion can be integrated to pursue a beneficial trade-off between internal and external irreversibility, searching to increase the performance of the cycle by allowing to match as close as possible the temperature profile of the hot/cold sources/sinks. This paper presents an investigation on vapor compression heat pump cycles where the pressure increase is performed by a two-phase compressor. To this aim, a validated semi-empirical model of a scroll compressor tested with two-phase refrigerant is integrated into the cycle model. Moreover, a moving boundary model is used to model the cycle heat exchangers. The overall model is used to investigate the performance of the heat pump cycle and to quantify both internal and external irreversibility. The results show that the exergy destruction rate of the compressor at low vapor qualities are too high to be counterbalanced by the optimal heat exchange in the condenser. Therefore, the maximum coeffient of performance (COP) is located at saturated vapor compressor inlet condition. Nevertheless, the analysis is strongly dependent on the compressor used and a more optimized compressor for the application could enhance the heat pump COP at low qualities.

Two-phase compression, Heat Pump, Performance analysis, Exergetic analysis

1. Introduction

1.1. Two phase compression/expansion: state of the art

Two-phase compressions and expansions can be categorized in two parts: on one hand, two different fluids can be used (e.g., air and water mixture or refrigerant oil mixture), on the other hand, the state of one single fluid can be located under the saturation bell resulting in the presence of a liquid phase and a vapor phase. In the former case, experimental studies have started in the nineteen fifties, where the use of oil to lubricate air screw compressors and expanders was necessary to expand machines lifetime. In the latter case, the first studies can be found in the nineteen seventies where the expansion of flashing liquid and expansion of refrigerant started to gain interest for better machine performance and reliability purposes.

Two-phase expansion/compression have many advantages, in addition to the sealing effects brought by the liquid blocking the gap between two working chambers, it also allows to get closer to an isothermal process, reducing the thermal stress on the moving parts [1]. Nevertheless, some disadvantages can also be found: the increase of the pressure losses in suction/discharge ports due to either the reduction of the speed of sound or the increase of the density but also the loss of mechanical efficiency resulting from the higher viscosity of the liquid phase in contact with the moving parts [8].

Nevertheless, the use of two-phase compression/expansion could bring some innovations to conventional thermal systems. For instance, the Trilateral Flash Cycle shows better power outputs than classical Organic Rankine Cycles or flash steam systems resulting in a reduced system cost (in $/kW) [9]. Despite the potential of two-phase expansion for power generation, it has not been applied on an industrial scale yet, with only a few experimental studies published in the literature. The innovative cycle currently being developed in the REGEN-BY-2 European project (Horizon 2020) is also making use of two-phase refrigerant to operate [3]. In [10], the

investigation of a two-phase compression in a heat pump is conducted numerically using wet fluids and non-azeotropic mixtures with high vapor qualities, and the results show a better COP when no superheat occurs in the cycle.

1.2. Objectives of the paper

In most of the studies where two-phase compression/expansion is used, the performances of the cycles are better than in classical cycles where a superheated state is reached before the compression or the expansion. However, the numerical results obtained strongly rely on the performance of the compression/expansion machine used in the cycle. Using internally reversible processes or not taking into account the increase of irreversibilities in the two-phase region is not always a valid assumption. For these reasons, the present study will numerically assess the performance of a heat pump using an experimentally investigated two-phase compressor. To this aim, experimental data from a commercial compressor tested with two-phase refrigerant flows are used to validate a compressor semi-empirical model. This model is embedded in a heat pump model, making use of a moving boundary model to simulate the heat exchangers. The irreversibility creation in the heat pump comes from two sources: the deviation of compression process from internally reversible processes and the temperature difference between the heat source/sink and the working fluid along heat exchanges (external irreversibility). Therefore, the integration of two-phase refrigerant compression in the heat pump allows to follow a trade-off between internal and external irreversibility and can, in some cases, increase the performance of the cycles by allowing to better match the temperature profile of the heat source/sink.

The investigated heat pump is a theoretical water-water heat pump providing hot water (50°C) with a heat sink power of 5 kW. It uses a high temperature lift (from 15°C to 50°C) from a 15 °C heat source. It uses the refrigerant R1233zd(E) as the working fluid. A diagram of the heat pump can be found in Fig. 1. The evolution of the Coefficient of Performance (COP) of the heat pump will be investigated with a varying vapor quality up to superheated states. An example of Temperature-Entropy and Pressure-Enthalpy diagrams can be found in Figs. 2 and 3. The conventional cycle using a superheat (10 K) at the compressor inlet is the cycle 1-2-3-4 while the cycle 1′-2′-3-4 makes use of a low inlet quality compression and cycle 1″-2″-3-4 a medium inlet quality compression.

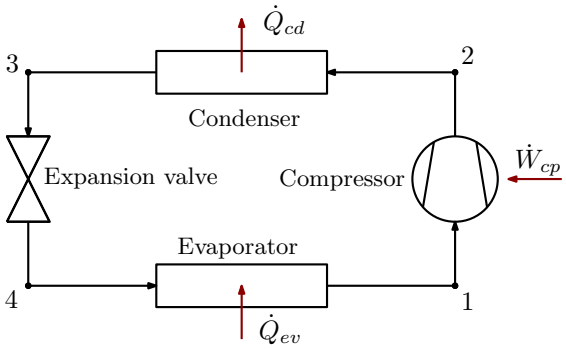

Figure 1: Heat pump cycle.

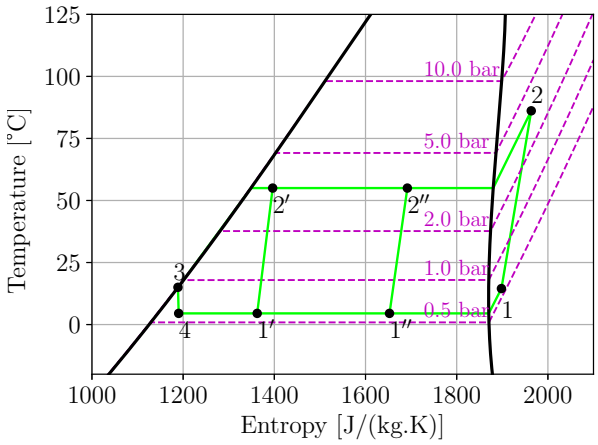

Figure 2: Temperature-entropy diagram of the heat pump cycle with different inlet qualities.

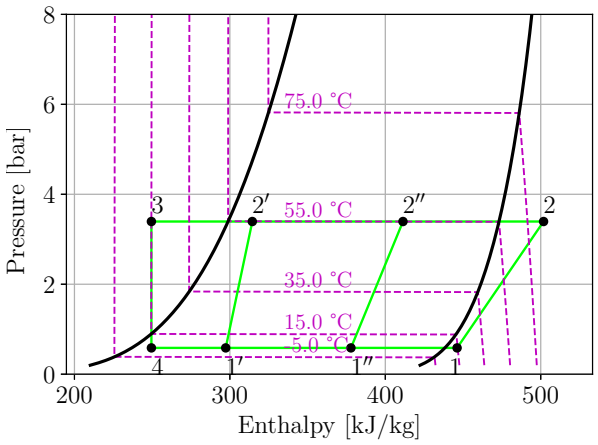

Figure 3: Pressure-enthalpy diagram of the heat pump cycle with different inlet qualities.

2. Modeling of the heat pump cycle

As previously said, the heat pump is modeled using a semi-empirical model for the compressor and a moving boundary heat exchanger model for the condenser and the evaporator. As presented in Fig. 4, the inputs of the model are the condenser inlet/outlet water temperature ($T_{w,su,cd}$, $T_{w,ex,cd}$) as well as its heat transfer rate ($\dot{Q}_{cd}$), the inlet vapor quality or superheating of the compressor ($Q_{su,cp}$ or SH) and the evaporator water inlet temperature ($T_{w,su,ev}$) and mass flow rate ($\dot{m}_{w,ev}$).

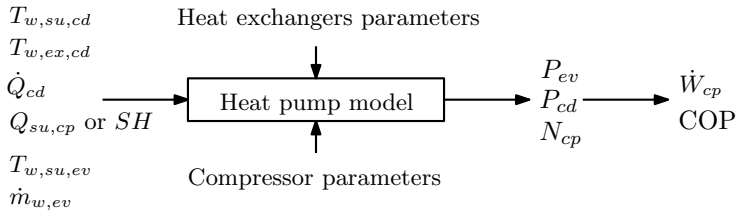

Figure 4: Model of the heat pump.

The model is then applying energy balances on the condenser and the cycle to find the evaporation pressure and the speed of the compressor giving the right working fluid mass flow rate. The condensation pressure could physically be fixed by the charge of refrigerant of the cycle, however, due to convergence problems, it has been decided to fix the condensation pressure with the condenser outlet temperature considering a pinch point of 5 K as can be seen in Fig. 15. Eventually, after fixing both level of pressure and the compressor speed, the compressor power consumption is determined and the COP can be calculated using 1. Obviously, the aforementioned procedure is an iterative process.

$$COP = \frac{\dot{Q}_{cd}}{\dot{W}_{cp}} \tag{1}$$

2.1. Compressor modeling

2.1.1. Experimental results

The compressor performance can be characterized using its volumetric and isentropic efficiencies. They can respectively be defined using the two following equations:

$$\varepsilon_v = \frac{\dot{m}_{tot}}{N_{cp} V_{disp} \rho_{su,cp}} \tag{2}$$

$$\varepsilon_s = \frac{\dot{m}_{tot}(h_{ex,cp,is} - h_{su,cp})}{\dot{W}_{shaft,cp}} \tag{3}$$

where $h_{ex,cp,is}$ is the isentropic compression exhaust enthalpy of the compressor. In particular, the isentropic efficiency (3) is used to characterize the irreversility creation of the compressor. In the case of an adiabatic and reversible evolution, the isentropic efficiency would be equal to one.

The variation of volumetric and isentropic efficiencies of the compressor with a varying pressure ratio and inlet vapor quality can respectively be found in Figs. 5 and 6, for a fixed inlet pressure, Oil Circulation Ratio (OCR) and speed. Those maps direclty comes from the experimental data used to calibrate the semi-emprical compressor model. The decrease of isentropic efficieny (thereby corresponding to an increase of irreversibilies) can clearly be observed, especially for high pressure ratios where the inlet-outlet volume ratio is getting furthest from the built-in volume ratio of the compressor. More information about the isentropic efficiency interpretation can be found in [6]. A similar behavior can be observed for the volumetric efficiency, although a sealing effect can be observed at low qualities and low pressure ratios.

2.1.2. Semi-empirical model

The scroll compressor model is a semi-empirical model inspired by [7]. The behavior of the compressor model relies on a set of physically-meaningful semi-empirical parameters to fit the experimentally tested compressor performances. The diagram of the semi-empirical model can be found in Fig. 7

This model considers a fictious isothermal envelope interacting with the fluid for supply and discharge heat transfer, taking the power losses of the compression process and rejecting ambient heat losses. It decomposes the fluid transformation inside the compressor in the following steps:

- $su \rightarrow su, 1$: isobaric heat transfer from the hot isothermal envelope to the working fluid.

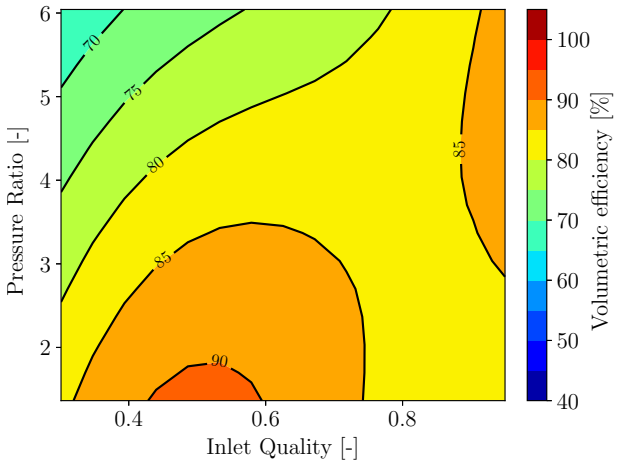

Figure 5: Evolution of the volumetric efficiency with the inlet quality and the pressure ratio for an inlet pressure of 1.5 bar, an OCR of 5% and a compressor speed of 4000 RPM.

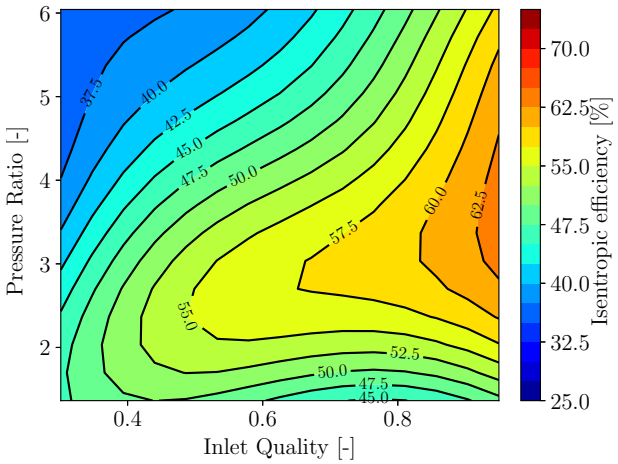

Figure 6: Evolution of the isentropic efficiency with the inlet quality and the pressure ratio for an inlet pressure of 1.5 bar, an OCR of 5% and a compressor speed of 4000 RPM.

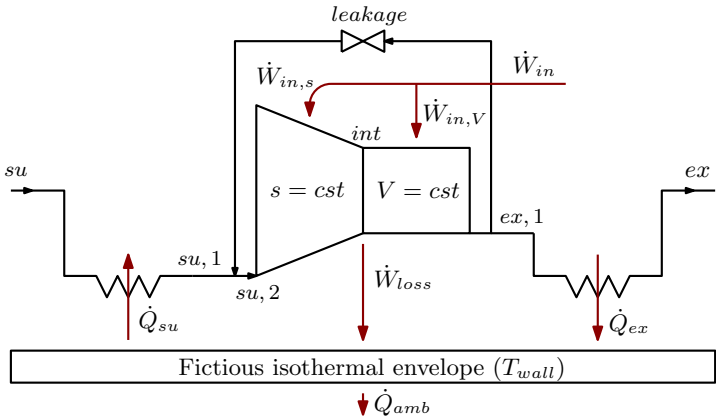

Figure 7: Model of the heat pump.

- $su, 1 \rightarrow su, 2$: energy balance due to the leakage flow adding to the compressor upstream flow
- $su, 2 \rightarrow int$: adiabatic and reversible (isentropic) compression. First part of the compression imposed by the built-in volume ratio of the compressor r_v and consuming a power $\dot{W}_{in,s}$.
- $int \rightarrow ex, 1$: constant volume compression to account for under/over compression losses. Second part of the compression consuming/producing a power $\dot{W}_{in,V}$.
- $ex, 1 \rightarrow su, 1$: leakage flow defined with an adiabatic pressure drop through a convergent nozzle.
- $ex, 1 \rightarrow ex$: isobaric heat transfer from the hot working fluid to the isothermal envelope.

The model uses 6 semi-empirical parameters. Among them, 3 are used for the supply, exhaust and ambient heat transfers, respectively, $AU_{su,ref}$, $AU_{ex,ref}$, AU_{amb}. Two other parameters are used for the friction losses characterization $\dot{W}_{loss,ref}$ and α_{loss}. The last parameter A_{leak} is used for the characterization of the leakage flow. The subscript *ref* stands for the reference, On the heat and mechanical power transfer side, the following definitions are set:

- $\dot{Q}_{su} = \varepsilon(AU_{su,ref}, \dot{C}_{wf})\dot{C}_{wf}\left(\frac{\dot{m}}{\dot{m}_{ref}}\right)^{0.8}(T_{wall} - T_{su})$: heat transfer from the hot isothermal envelope to the working fluid. ε is the heat exchanger efficiency computed using the Number of Transfer Units (NTU) method and $\dot{C}_{mix}$ is the heat capacity rate of the mixture flow.
- $\dot{Q}_{ex} = \varepsilon(AU_{ex,ref}, \dot{C}_{wf})\dot{C}_{wf}\left(\frac{\dot{m}}{\dot{m}_{ref}}\right)^{0.8}(T_{ex,1} - T_{wall})$: heat transfer from the working fluid to the isothermal envelope.

- $\dot{Q}_{amb} = AU_{amb}(T_{amb} - T_{wall})$: ambient heat transfer from the isothermal envelope.
- $\dot{W}_{in,s} = \dot{m}(h_{int} - h_{su,2})$: isentropic compression power.
- $\dot{W}_{in,V} = \dot{V}_{int}(P_{ex,1} - P_{int})$: constant volume compression power consumption.
- $\dot{W}_{loss} = \dot{W}_{loss,ref}\left(\frac{N}{N_{ref}}\right)^2 + \alpha_{loss}\dot{W}_{in}$: friction power loss of the compressor.

The calculation of properties considers the oil fraction in the whole working fluid path. Thereby, every enthalpy, entropy, density calculated takes into account the oil fraction similarly to what is used in [11]. Let X be a property of a pure fluid, the mixture property calculated would use the following equation:

$$X_{mix} = QX_{r,vap}(P,T) + z_o X_o(T) + (1 - Q - z_o)X^{\sigma}_{r,liq}(T) \tag{4}$$

where the subscripts r refers to pure refrigerant properties, *vap* and *liq* respectively refer to the vapor and the liquid phases, o stands for the oil and σ refers to a saturated property. The vapor quality Q, defined as vapor mass divided by the total mass, is linked with the oil fraction z_o using the Raoult law solubility equation. As can be noticed, 4 assumes that the oil only stands in the liquid phase.

The model takes five inputs: the compressor speed (N), the oil circulation ratio (OCR, z_o), the inlet pressure (P_{su}), pressure ratio (r_p) and the inlet quality (Q). It gives as outputs the mass flow rate and the power consumption at the shaft.

2.1.3. Model validation

As already mentioned, the compressor semi-empirical model is validated against experimental data. The experimental data comes from a commercial compressor with a displacement volume of 86 cm^3 and a built-in volume ratio of 2.3, tested with two-phase conditions on 110 operating points. The model validation is performed with the shaft power consumption and the mass flow rate, as those are the two relevant variables used in the heat pump model. The validations with regards to the shaft power and the mass flow rate can be found in Figs. 8 and 9.

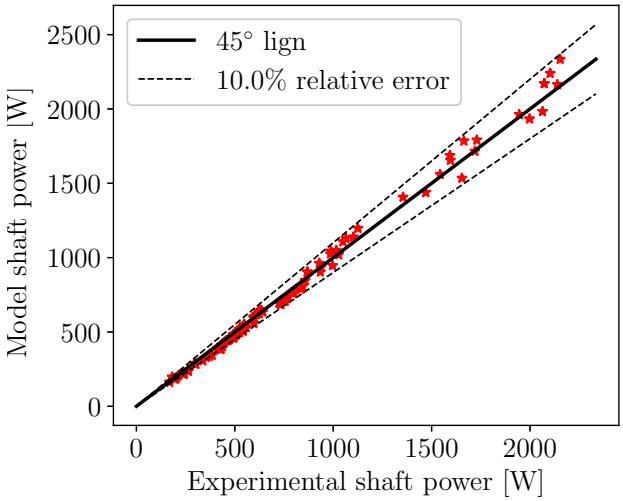

Figure 8: Shaft power prediction of the compressor model versus experimental data.

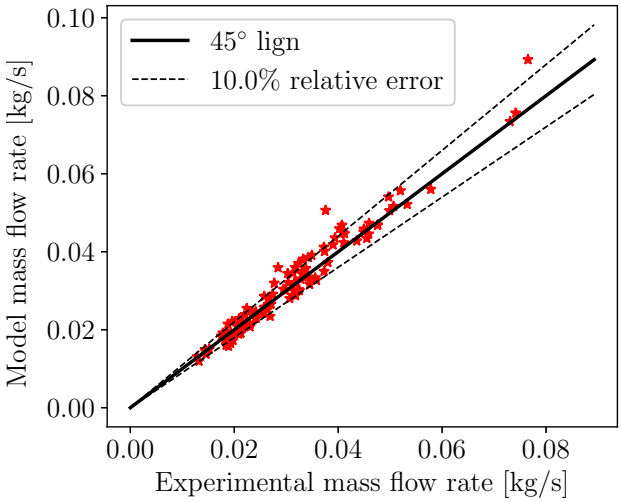

Figure 9: Mass flow rate prediction of the compressor model versus experimental data.

As can be observed in Figs. 8 and 9, the power predictions remain within the range of 10% of relative error with regards to the experimental power while the mass flow rate prediction is less precise, in particular, three points are going way outside the 10% relative error range. Nevertheless, the mean relative errors of the whole set of data are equal to 4.46% for the power and 6.47% for the mass flow rates.

Finally, the tuned parameters as well as the characteristics of the tested compressor can be found in Table 1. It can be noticed that the inlet and outlet heat transfer coefficients are abnormally high compared to what can be found in the litterature (between 1 and 10 W/K). On one hand, it can be explained by the two-phase conditions that increases the heat transfer coefficient. On the other hand, it could be explained by the lack of a suction pressure loss model. In particular, the model increases the inlet heat transfer to the fluid to increase its vapor quality to get lower mass flow rate, and adding an inlet pressure loss would have the same effect. However, the

inlet pressure losses were not added because of a convergence problem. Therefore, even though the semi-empirical parameters seems to predict with a relatively good accuracy the performance of the compressor, their physical meaning can not be trusted in every aspect.

Table 1: Parameters of the compressor semi-empircal model.

Parameter	Value	Unit
$AU_{su,ref}$	72.73	W/K
$AU_{ex,ref}$	46.47	W/K
AU_{amb}	2	W/K
$\dot{W}_{loss,ref}$	75.19	W
α_{loss}	0.0848	-
A_{leak}	$3.84 \cdot 10^{-7}$	m^2
V_{disp}	86	cm^3
r_v	2.3	-

2.2. Heat exchanger modeling

The heat exchanger model used for both the condenser and the evaporator is a moving boundary model inspired from [2], it has been selected for its ability to get the temperature evolutions of both fluids inside the heat exchangers. It calculates the maximum heat rate that can be transferred based on an internal and an external pinching analysis. Then, the heat exchanger is divided into a given number of cells having a fixed power transferred and two boundaries representing the saturated liquid and vapor points are are moving to define cells with subcooled liquid, two-phase fluid and superheated vapor. The log mean temperature difference is then solved on every cell to get the outlet and inlet temperatures on both primary and secondary fluid sides (refrigerant and water). The calculation of the heat transfer coefficients in each cell is different in two-phase regime and single-phase regime. For the two-phase regime, the evaporative and condensation heat transfer coefficients are respectively calculated using the Han boiling and condensing correlations in plate heat exchangers, while for single-phase regimes, the Gnielinski pipe heat transfer correlation is used. More information about these correlations can be found in [5].

The heat exchanger used for the present analysis is a plate heat exchanger and the same heat exchanger is used for both evaporator and condenser. The plate heat exchanger characteristics used can be found in Table 2, they are based on a real heat exchanger, oversized with regards to the application.

Table 2: Parameters of the plate heat exchanger used.

Parameter	Value	Unit
Surface exchange area	5.04	m^2
Number of plates	88	-
Cross section area	$2.1 \cdot 10^4$	m^2
Dimensions (H×L×l)	524×117×232	mm

2.3. Model limitations

The results of the heat pump model presented obviously have some limitations, although the main component, i.e., the compressor, is modeled based on experimental data. These limitations can be listed as follows:

- The compressor model is taking the OCR (z_{oil}) into account, it has therefore been tested with oil and the compressor performances shown in the subsequent section depend on this OCR. However, the heat exchanger model does not take the oil into account in the heat transfer coefficient correlations. Therefore, the oil will not be considered in the heat pump model. To make the conversion between the mixture vapor quality and the pure refrigerant vapor quality and vice versa, the following equation is used for the enthalpy conversion:

$$h_{r,pure}(P) = \frac{h_{mix}(T,P) - z_{oil} h_{oil}(T)}{1 - z_{oil}} \tag{5}$$

  A slight temperature change is therefore observed when doing the conversion. Moreover, only the refrigerant mass flow rate coming from the compressor model has been taken into account, this refrigerant mass flow rate is expressed as follows:

$$\dot{m}_r = \dot{m}_{mix}(1 - z_{oil}) \tag{6}$$

This theoretical separation is not feasible in reality, as the mechanical separation of the oil and liquid refrigerant is impossible to carry out. Nevertheless, this assumption should have a negative impact on the heat pump performance, as the oil compression work is taken into account in the compressor power. However, lower heat exchange coefficients could counterbalance this effect if the oil was circulated inside the cycle. In every simulation run, a OCR of 5% has been considered.

- The second model limitation comes from the compressor model simulated range that goes out of its testing range. In particular, the inlet pressure testing range lies in [0.8 - 2.3] bar, and the model inlet pressure goes down to 0.7 bar. This low pressure is necessary as the refrigerant used has a boiling point of 17 °C and the water of the heat source has a temperature of 15 °C. Thus, it is impossible to know if the compressor performance is well predicted or not. Nevertheless, the inlet pressure usually does not have a strong influence on the compressor isentropic and volumetric efficiencies.

  The two aforementionned reasons justify the need for a model instead of interpolations of experimental data for the compressor mass flow rate and power predictions.

- The last limitation is the fact that the model is using fixed-design components. For performance comparison, it is not always accurate to compare different conditions with the same designs, as, sometimes, the results are design-dependent. This is why the heat exchanger have been oversized, as the techno-economic aspect is not investigated in this paper. Moreover, the data to fit the compressor model comes from the testing of a commercial compressor, which has not been specifically designed for two-phase flows.

3. Heat pump performance analysis

3.1. Exergetic analysis

As stated by the second law of thermodynamics, the performance of a heat pump are limited by the efficiency of the reverse Carnot cycle. The performance gap between the ideal heat pump cycle and the real cycle can be evaluated using an exergy analysis, where the heat pump irreversibility creation can be assessed analytically. Exergy can be defined as the maximum work recoverable from a process with regards to a reference temperature and pressure. For reversible processes, the exergy is conserved, while when irreversibilites occur, a part of the exergy is destroyed. The exergy analysis allows to evaluate irreversibility losses in each component in the heat pump, the best performance of the heat pump will therefore correspond to the minimal total exergy destruction. The exergy of a point in the cycle can be seen as a thermodynamic property, defined as:

$$e = (h - h_0) - T_0(s - s_0) \tag{7}$$

where h_0, T_0 and s_0 are respectively the reference values of enthalpy, temperature and entropy. Similarly to the heat pump exergetic analysis performed in [4], the exergy destruction rate in each component of the cycle can be evaluated using the following equations:

$$\dot{E}_{D,cp} = \dot{W}_{cp} - \dot{m}\left[(h_{ex,cp} - h_{su,cp}) - T_0(s_{ex,cp} - s_{su,cp})\right] \tag{8}$$

$$\dot{E}_{D,cd} = \dot{m}\left[(h_{su,cd} - h_{ex,cd}) - T_0(s_{su,cd} - s_{ex,cd})\right] - \dot{Q}_{cd}\left(1 - \frac{T_0}{\overline{T}_{w,cd}}\right) \tag{9}$$

$$\dot{E}_{D,valve} = \dot{m}\left[-T_0(s_{su,valve} - s_{ex,valve})\right] \tag{10}$$

$$\dot{E}_{D,ev} = \dot{Q}_{ev}\left(1 - \frac{T_0}{\overline{T}_{w,ev}}\right) - \dot{m}[(h_{ex,ev} - h_{su,ev}) - T_0(s_{ex,ev} - s_{su,ev})] \tag{11}$$

where the temperatures of the heat sink $\overline{T}_{w,cd}$ and the heat source $\overline{T}_{w,ev}$ are calculated using a logarithmic mean (isentropic mean), with:

$$\overline{T}_{source} = \frac{T_{w,su} - T_{w,ex}}{\ln\left(\frac{T_{w,su}}{T_{w,ex}}\right)} \tag{12}$$

As already stated in the previous section, the irreversibility creation in the compressor mainly comes from the heat transfer and the pressure losses. Moreover, the mechanisms in contact, such as the scroll and the bearings, creates friction which is also a source of irreversibility. The tendency observed is a drop in isentropic efficiency, i.e. an increase of irreversibility creation when decreasing the inlet quality.

Regarding the heat exchangers, the irreversibility creation primarily comes from the temperature difference standing between the working fluid and the secondary fluid. Pressure losses can also create irreversibilities

in the heat exchangers, however, they have not been taken into account in the present analysis. By going from a superheated state to a two-phase state down to a low vapor quality at the compressor inlet, the outlet quality of the compressor is also going to decrease, allowing to better match the temperature profile of the heat sink, which reduces exergy destruction. The objective of the analysis is therefore to optimize the system with regards to the inlet quality of the compressor to minimize the total exergy destruction.

3.2. Results

As already stated, the studied model is a water-water heat pump model. To match the profile of the subcooling at the end of the condenser, the condenser supply water temperature is the same as the heat source temperature, i.e., 15 °C, and the exhaust available water temperature is 50 °C, resulting in a temperature lift of 35 K. The condenser thermal capacity, input of the model, is varied in order to investigate the influence of the design (compressor, heat exchanger) on the heat pump performance. Varying the nominal point by keeping the same design is actually equivalent to a variation of design for a constant nominal point. As a reminder, the inlet quality of the compressor is varying and the model adapts the evaporation pressure and the compressor speed, directly impacting the working fluid flow rate, to keep a constant water exhaust temperature and condenser capacity. The evaporator water mass flow rate has been fixed to 0.3 kg/s to avoid evaporator exergy destruction and to focus the analysis on the compressor-condenser exergy destruction trade-off.

The evolution of the COP with the compressor inlet condition can be found in Fig. 10. The corresponding compressor speeds and pressure ratios (the evaporation pressure being an output of the model) can be found in Fig. 11. The COP evolution tendency is clear, the maximum of the COP stands near the saturated vapor point. Furthermore, for a high condenser capacity, the performance seems to follow a plateau between an inlet quality of 0.6 and 1, on the contrary to a low condenser heat transfer rate where the COP sees a consequent drop at low qualities. For a high condenser capacity, the speed of the compressor is higher, which increases its isentropic efficiency at low qualites. Regarding the evolution of the pressure ratio, it seems that higher pressure ratios are needed when having a superheated inlet state, simply because the water supply temperature is fixed and must be higher than the compressor inlet temperature.

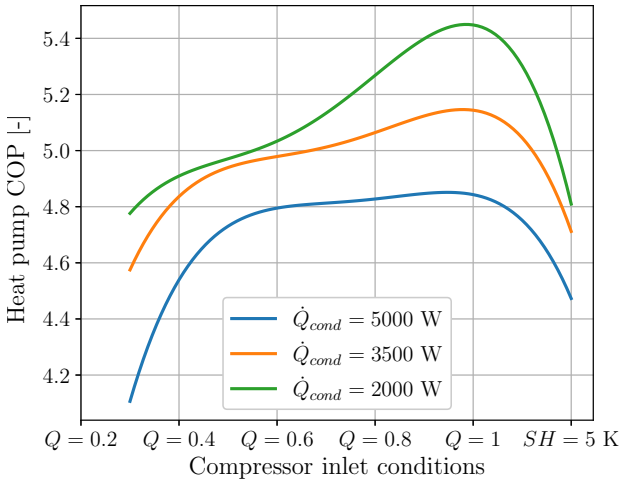

Figure 10: Heat pump COP for a varying compressor inlet condition for three different condenser powers.

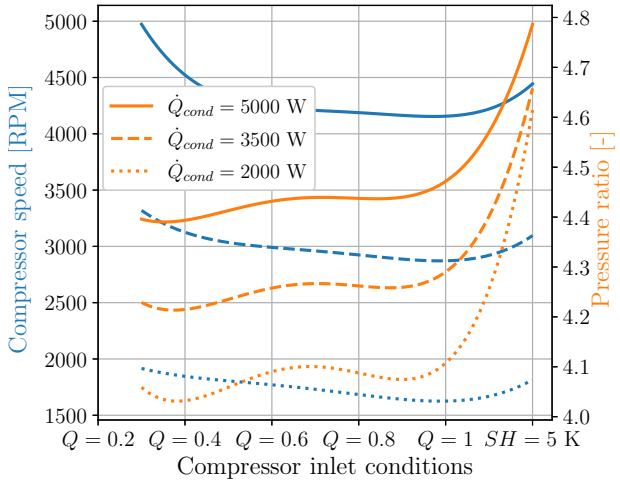

Figure 11: Compressor speed and pressure ratio for a varying compressor inlet condition.

The exergy destruction rate of each component for a 5000 W and a 2000 W condenser capacity can respectively be found in Fig. 12 and 13. In both cases, the exergy destruction of the evaporator and the valve are negligible, and the trade-off is well focused on the compressor and the condenser. When starting from a low vapor quality, the compressor exergy destruction rate is the highest, and it reaches a maximum at a vapor quality of 1 to eventually re-increase due to the increase of pressure ratios for superheated inlet states. Regarding the condenser curve, it is clearly lower for low vapor qualities, due to the better match with the condenser water curve, and increases when increasing the vapor qualities. The total exergy destruction is perfectly matching the tendency of the COP in Fig. 10, the COP maximum corresponds to the total exergy destruction minimum. Furthermore, Figs. 14 and 15 show the evolutions of the water temperature inside the condenser and the evaporator, respectively for a 0.3 quality and a 5K superheated inlet point. The temperature difference inside the evaporator can clearly justify the low exergy destruction rate in this heat exchanger. The same conclusion can be drawn on the condenser, where the exergy destruction rate is lower for the low quality compressor inlet condition due to the proximity between the temperature curves.

Finally, it seems that for both condenser capacities, the compressor exergy destruction rate variations with the

inlet conditions will always remain higher than the condenser exergy destruction rate variations. Therefore, the total exergy destruction rate tendancy is following the shape of the compressor exergy destruction rate. The present analysis is therefore very sensitive to the compressor performance. Hence, the compressor design has a strong influence on the results, and the current commercial compressor may not be the best candidate to be used with two-phase refrigerant flow. A compressor with a higher built-in volume ratio could better fit for the presented model as its performance would be better for higher pressure ratios. It should also be noted that reducing the water condenser outlet temperature could reduce the pressure ratio and enhance the heat pump performance.

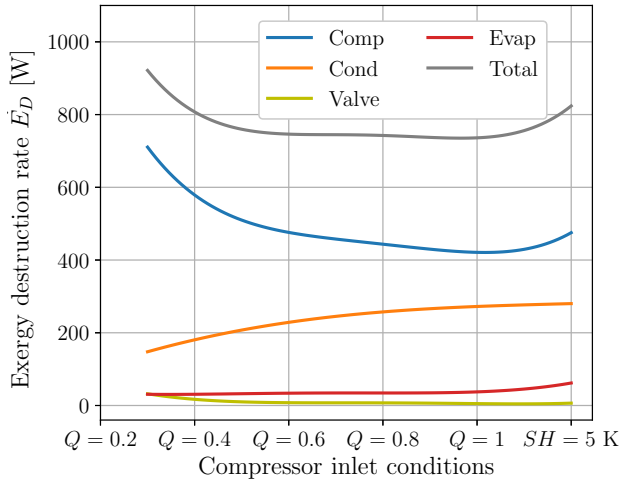

Figure 12: Exergy destruction rate of each heat pump component for a condenser power of 5000 W.

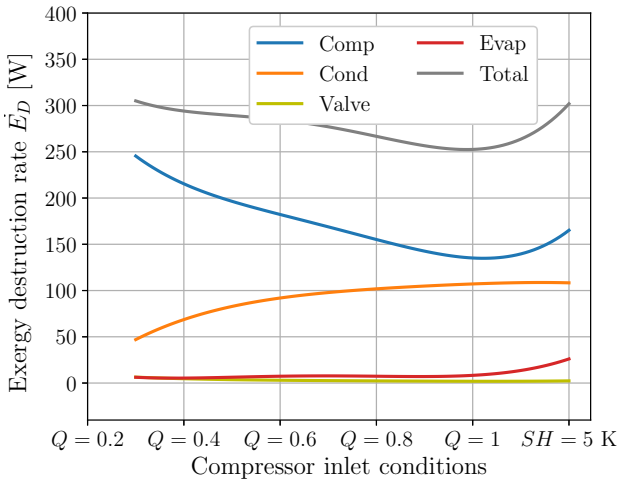

Figure 13: Exergy destruction rate of each heat pump component for a condenser power of 2000 W.

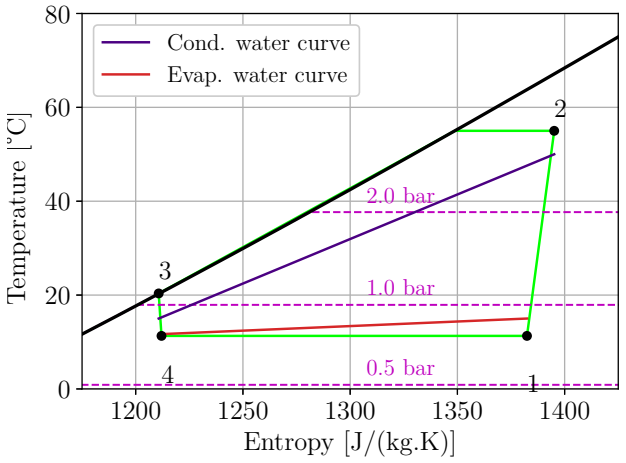

Figure 14: Temperature-entropy diagram of the heat pump with a condenser power of 5000 W and a compressor inlet quality of 0.3.

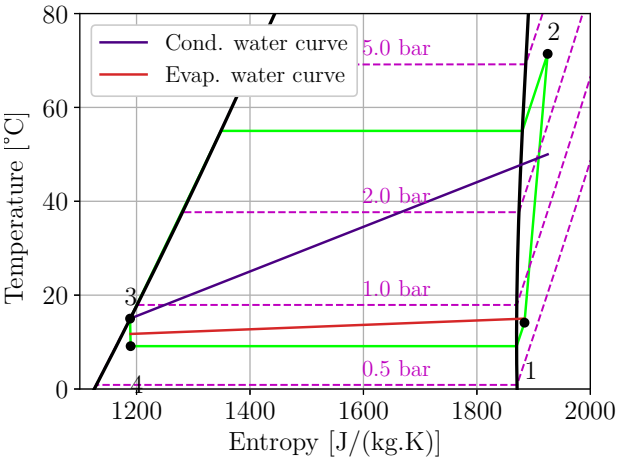

Figure 15: Temperature-entropy diagram of the heat pump with a condenser power of 5000 W and a compressor inlet superheat of 5 K.

4. Conclusions

The current study presents an investigation on a fixed-design water-water high temperature lift heat pump making use of two-phase compression. The objectives of the investigation is the heat pump performance assessment under varying compressor inlet conditions with two-phase refrigerant vapor qualitites as low as 0.3, up vapor with 5 K of superheat. To that end, the heat pump system has been described by coupling a validated scroll compressor semi-empirical model with moving boundaries heat exchanger models.

The model predicts good system efficiency. The performances of the heat pump at different operating conditions are governed by a trade-off between heat exchange and compressor irreversibilities. On one hand, when a low inlet vapor quality is used, the condenser temperature profiles of both fluid (refrigerant R1233zd(E) and water) are getting closer, reducing the irreversibilities. On the other hand, the compressor irreversibility

creation is increased when decreasing the inlet quality.

The heat pump model has been tested with a temperature lift of 35 K, from a water condenser inlet temperature of 15 °C to 50 °C and condenser capacities from 2 kW to 5 kW. The results have shown a maximum in the COP curve around a compressor inlet quality of 1. The compressor being the most important source of exergy desctruction, the trade-off could not find better performance at low inlet qualities because the exergy destruction rate of the compressor is too high. Finally, it is important to highlight that the results are very design-sensitive, and the use of a more optimized compressor for two-phase refrigerant flows could enhance the performance of the heat pump and the trade-off could find a lower optimal inlet quality. This potential scenario is the object of future research, as another compressor, specifically designed for two-phase flows with a higher built-in volume ratio is going to be experimentally tested. The integration of the new two-phase compressor performance will allow to see if the trade-off conclusion can be changed.

Aknowledgement

The project source of the results presented in this paper has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement N° 851541.

Abstract:

In residential buildings, the efficiency of heat pump systems (HPS) significantly depends on the HPS design and operation. In particular, HPS controllers often use ambient temperature-dependent heating curves for operation. The resulting supply temperature serves as the reference variable for the internal controller, which is used to manipulate the compressor speed. Typically, the internal controller has constant parameters for the PI controller, hysteresis, and operational time. While buildings have a highly dynamic, time-variant demand, these dynamics are rarely considered in controller development.

This work investigates internal control parameters' sensitivity to the overall HPS efficiency in annual, dynamic simulations and experiments. To consider different supply temperatures, two buildings with underfloor heating and radiators serve as case studies. Based on a validated simulation model, the one-factor-at-a-time sensitivity analysis method determines the controller's influence on the seasonal coefficient of performance (SCOP). Hardware-in-the-loop experiments are conducted for representative periods extracted from annual simulation results for experimental verification.

The results for the building with underfloor heating and radiators prove that the control parameter influences the SCOP up to 18.5 % and 4.2 %, respectively. In particular, different control parameters for the optimal operation were determined for both case studies, challenging the constant settings used in the state-of-the-art. In addition, we observe a significant increase of 300 % in the avoidable compressor starts in experiments due to poor parameter settings. To ensure maximum efficiency of HPS and significantly reduce the number of compressor starts in any residential building, we recommend integrating adaptive setting of control parameters into the HPS controller.

1. Introduction

Electrically-driven heat pump systems (HPS) are the most efficient solution for the defossilation of the building sector. Since emissions are mainly related to electricity consumption [1], HPS efficiency greatly impacts consumption reduction and thus on emissions.

Besides the refrigerant cycle design which is tailored to operate under dedicated temperature levels (design condition), the HPS controller influences the efficiency in off-design conditions. The controller aims to set the HPS thermal output to the building's heat demand by adjusting the compressor speed. Typically, the control loop begins with a weather compensation heating curve calculating the required supply temperature to reach the heating demand (part I). While On-Off HPS uses a hysteresis controller, inverter-driven HPS also uses a PID controller to realize the link between the set supply temperature and the compressor speed (part II).

Thermodynamic Carnot efficiency strongly depends on the source and supply temperature spread. Aiming for an efficient part I control loop means decreasing the supply temperature as low as possible with a well-designed heating curve or higher control strategies, e.g., model predictive control (MPC). The literature provides different solutions for the part I control loop [2]–[4]. This work focuses on part II of the control loop and uses a heating curve that fits the building load for each case study.

Part II of the control loop translates the set supply temperature value into a compressor speed. This part of the control loop is an internal variable to avoid compressor damage. To the best of the author's knowledge, the literature only provides a few studies about the influence of the part II control loop on the heat pump's efficiency. Uhlmann et al. [5] show in experimental and simulative studies that the loss of efficiency caused by the startup and shutdown processes is less than 2% if a continuous minimum running time of 15 minutes can be ensured. A related study [2] suggests that a compressor running time of at least 20 minutes is required to avoid degradation effects or startup losses. The study shows that the unit control and the system's thermal inertia strongly influence the heat pump's energy losses. Thus, the configuration of the hysteresis control strongly

influences the cycling behavior. Dongellini et al. [6] simulate the dynamic performance of three types of heat pumps (single-stage, multi-stage, and inverter-controlled). The results indicate that the efficiency losses during the heat pump startup process significantly impact the overall system efficiency, especially for single-stage units. In this case, the reduction in SCOP is up to 12%. Xu et al. [7] study focuses on inverter-controlled heat pumps, in particular, the hysteresis parameter of the control. In order to improve the dynamic performance under frequent partial load conditions, a control concept with variable hysteresis of the supply temperature was proposed, in which the lower threshold value increases piecewise with increasing outside air temperature. All the studies mentioned use the manufacturer's inverter control settings, i.e., the PID controller parameters remain unchanged. However, to the best of the author's knowledge, the sensitivity of PID parameters on the efficiency of inverter-controlled heat pumps is not discussed in the literature. Furthermore, the influence of the heat pump's operational behavior is only discussed in the context of efficiency but not on the degradation.

This paper closes the identified research gaps in a simulative and experimental case study:

- To access all parameters of the heat pump's control loop, we conduct measurement campaigns with a fully-controllable heat pump test bench [8].
- To integrate degradation into the evaluation process, we use the number of startups per hour as a key performance indicator (KPI).
- To prove the sensitivity of PID controller parameters, we develop a heat pump controller, which we use in a simulative and experimental case study.
- To verify our simulative results, we use the hardware-in-the-loop approach by coupling a heat pump test bench to a developed heat pump controller and a virtual building.

The paper is divided into five sections:

- Section 2 shows the simulative and experimental setup.
- Section 3 describes the results of the case studies.
- Section 4 discusses the results by underlining the influence of the control loop part II on the efficiency
- Section 5 concludes all findings and gives recommendations for future work.

2. Method

To investigate the sensitivity of the PID controller's parameters and the hysteresis bandwidth to the heat pump process, we develop a simulation model that comprehensively analyzes and evaluates the part II control concept. Subsequently, we use sections of the recorded measurement data in an experimental setup to verify the obtained results on a real heat pump. This section starts with an overview of the simulation models, followed by the experimental setup description, and ends with the introduction of the simulative and experimental case study.

2.1 Building Energy System Simulation

For the adequate execution of a parameter study, we develop a simulation model that computes the conditions of the system in a meaningful way and outputs system variables in a comprehensible and plausible manner. For this purpose, the simulation model of the building energy system (BES), which forms the basis for the parameter study, is presented in Figure 1, including the associated submodels. We develop the BES in Modelica using the Dymola [9] environment. The individual models are generally based on the *BESMod* library [10]. The library draws on *AixLib* [11], *BuildingSystems* [12] and *IBPSA* (basic library of the previous archives) [13].

Figure 1 shows the BES model, which consists of the submodels weather, user, transfer, building, control, generation, and distribution. The latter three together form the sub-model of hydraulics. The weather submodel is based on meteorological data recorded and published by the German Weather Service (DWD) at hourly intervals for a specific region within Germany during a representative year [14]. Concerning an appropriate computational time compared to the effort, we use a reduced building model as a heat sink. We reparametrize the basic model using the TeaserTool [15]. It allows building construction based on information about the net area, number, and height of floors, year of construction, and intended use of the building. The heating load calculated according to EN 12831 is 6596.21 W, and the volume of the heating zone is 325.0 m^3 with a net area of 130.0 m^2.

On the user side, we assume constant behavior to avoid the superposition of effects. For the same reason, we also neglect any internal gains. Therefore, the room's setpoint temperature is constant at 20 °C for each room, regardless of the time of year or day. We consider two systems for the hydraulic heating network within the scope of the analysis. Thermal energy distribution and transfer are accomplished by underfloor heating (UFH) or a radiator. We adopt the models from the *BESMod* library for this purpose. Both models have a throttle and a bypass valve, the latter to decouple the hydraulic cycle and thus protect the system from a sharp rise in the heating water pressure.

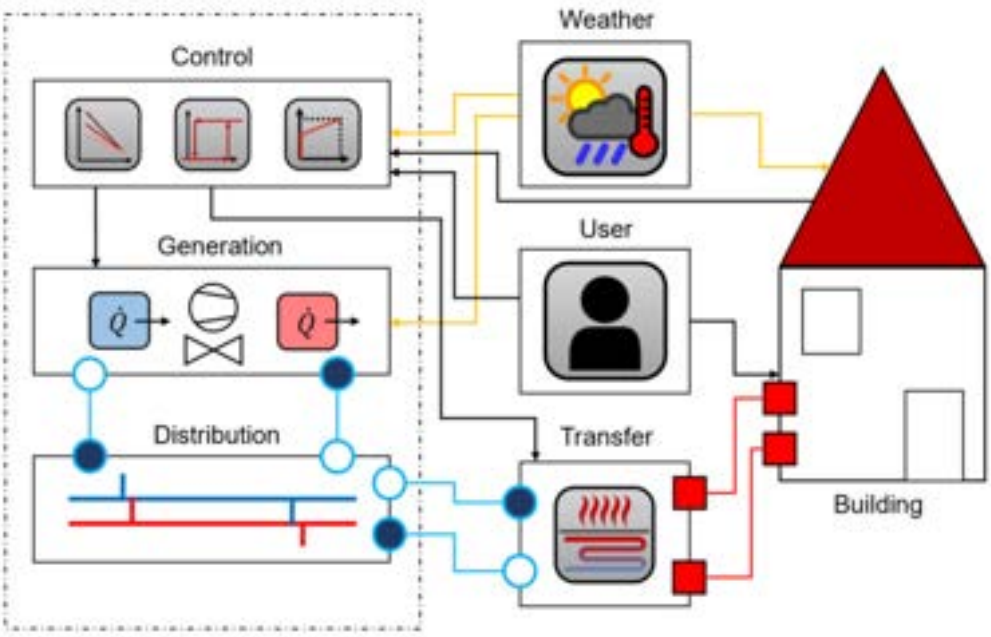

Figure 1: Simulation structure of the building energy system - With fluid flows in blue, heat flows in red, weather data in yellow and data transfer in black as connecting elements [10].

We have mapped the adapted control of the system in the *MonovalentOptihorst* model. In addition to the hysteresis-based heating curve controller, it also contains the integration of safety functions. With the help of the room temperature set by the user $T_{set,Room}$, and the current outdoor temperature T_{amb}, the heating curve specifies the required supply temperature T_{set}. The downstream hysteresis controller uses the difference between T_{set} and T_{sup} and determines whether the heat pump sets its operating mode to On or Off. If the supply temperature exceeds the set temperature by half of the set bandwidth of the hysteresis, the heat pump is switched off until it reaches the lower limit (T_{set} - $Hys/2$). This on/off-signal and T_{set} are then used via the PI controller to set the compressor speed n_{set} is output. The *SecurityControl* [16] model of *AixLib* then checks compliance with the safety functions and operating limits. In addition to the minimum runtime and resting time, these also include the maximum number of start operations per hour. Triggering the safety functions causes the heat pump to shut down or to continue running, depending on which safety function takes effect. For example, compliance with the minimum running time requires the machine to continue running to prevent damage, even though a signal from the PI control wants to switch it off.

The simulation model of the heat pump corresponds to the *HeatPumpAndHeatingRod* model of *BESMod.* We use a black-box model, which specifies the required electrical power P_{el} and the resulting heating power $\dot{Q}_{\mathrm{Con}}$ as a function of the supply temperature, the inlet temperature of the evaporator, and the compressor speed. When the compressor is switched on, it immediately requires electrical power. The problem of the missing dynamics of the model in relation to the provision of the heat is mitigated by the interposition of a PT3 element. Through the PT3 element, we can implement an artificial inertia, resulting in a delay of the effective heat flow analogously to the real system. The duration of the delay can be determined by the setting of a constant parameter, which corresponds to a cut-off frequency. [16]

To integrate the established model's dynamic processes within the heat exchangers and the mentioned cut-off frequency, we conduct experimental tests on a real heat pump to calibrate the model with the measured data. We calibrate the adjusted heat pump model using the fully-controllable heat pump test bench, which is also used in the experimental case study. Basically, calibration refers to the variation of model parameters so that the difference between simulated and measured values is as small as possible. Therefore, we use parameters of the condenser, such as the heat transfer coefficients or the condenser volume, and the cut-off frequency to match simulated and measured values. The program AixCaliBuHA [17] is used to calibrate the system. It allows the automatic calibration of dynamic buildings and heating systems using the Python-Dymola interface.

The different operating conditions associated with the inverter technology, as a result of the variably adjustable compressor speed, necessitate the inclusion of dynamic factors in the calibration. For example, several different temperatures are set for the source and sink in succession during the temperatures are set for the source and sink to compensate for the resulting transient and departure processes. For the calibration process, we record the temperatures T_{amb}, T_{sup} and T_{ret}, the mass flow in the condenser, the electrical power of the compressor P_{el} as well as the speed of the compressor. Here, P_{el} and T_{sup} correspond to the target variables of the calibration. The four remaining quantities are used as real input for the simulation. The temporal

resolution of the data intervals is one second, and the period of consideration is 8800 s. As a basis for evaluation, we use a normalized weighted error measure (NRMSE), which gives equal and scale-independent weight to both target variables.

The corresponding curves of the simulated and measured quantities for the minimum NRMSE are visualized in Figure 2. It can be seen that especially the supply temperature is sufficiently modeled. Quantitatively, this can also be confirmed with an NRMSE of less than one percent. The higher NRMSE for the electrical power of 2.37% is due to inaccuracies between 8000 - 8800 s. The noticeably broader curve section of the magnitude in this interval can be derived from perceived speed oscillations while recording the experimental measurement data. Overall, we achieve a final NRMSE of 1.658%. This can be considered a positive result; other works obtained results in a comparable range [16], [18].

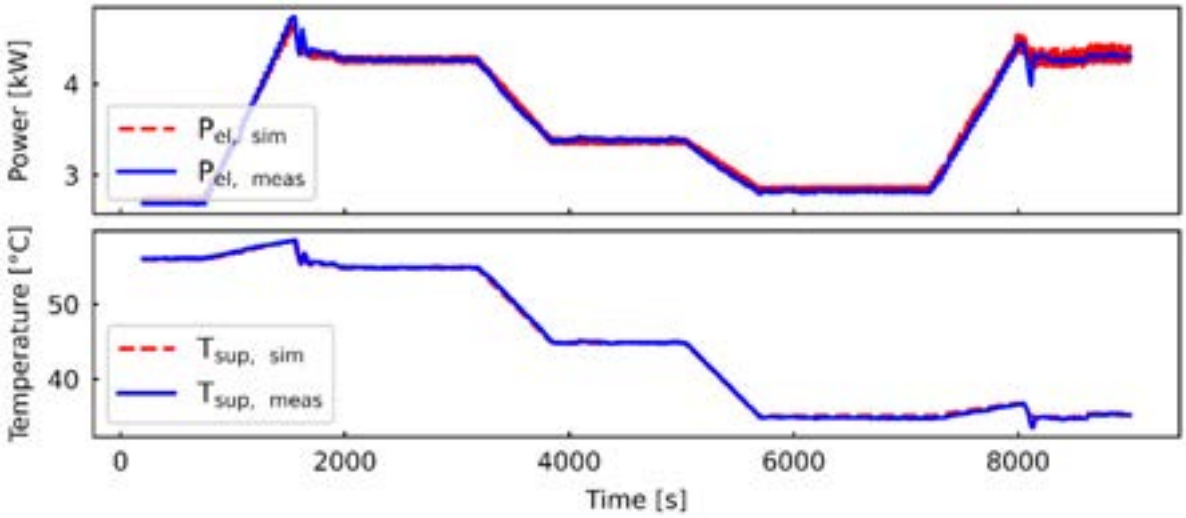

Figure 2: Visualization of the measured target variables $P_{el,meas}$, $T_{sup,meas}$ and the corresponding simulation variables $P_{el,sim}$, $T_{sup,sim}$.

2.2 Experimental setup

We validate all our findings in this work with experiments using the hardware-in-the-loop (HiL) approach and a fully-controllable heat pump test bench. The HiL approach connects virtual buildings to the heat pump by emulating the weather conditions and the thermal heat flows. Figure 3 shows the schematic overview of the experimental setup. The system consists of an air-to-water heat pump test bench in split design, which is fully controllable, test benches emulating the boundary conditions (climatic chamber and hydraulic test bench), simulation models for the building and the heat pump controller, and the cloud-based data infrastructure (MQTT-Broker and InfluxDB tick-stack). The used HiL approach and the corresponding test benches are well described in the literature [19], [20]. In this study, we use a self-developed heat pump test bench where we can freely control the compressor speed. The heat pump test bench has its own PLC, which gets the current set compressor speed via MQTT. Only necessary safety controllers (e.g., superheat) are part of the heat pump test bench. Further details about the test bench and its internal control can be found in the literature [8].

With the help of our method, it is possible to change between a pure simulation model and a HiL experiment without significant effort. Only the submodels of heat generation and distribution are swapped to communication models. Measured values (e.g., supply temperature) are subscribed from the test bench, and relevant values for the heat pump (e.g., return temperature) are published to the test bench.

We develop and calibrate our building energy system simulation models with the experimental setup to perform verified annual simulations and experimental results.

2.3 Annual and daily simulative case study

We use the one-factor-at-a-time (OFAT) method [21] for the annual and daily horizons parameter study. Here a single parameter is varied while the remaining ones assume constant reference values. The advantage of the OFAT method is that overlaps and synergies can be excluded by varying a single parameter. Thus we can relate system changes to modifying the input variable.

In the preliminary state of the parameter study, the framework conditions of the analysis must be defined. Table 1 shows the value ranges of the control parameters, the reference values, the safety functions' values, and the other models' relevant values. The control parameters consist of the proportionality factor K_P, the integral time T_N and the hysteresis bandwidth *Hys*. In the annual simulation studies, the proportionality factor K_P and the integral time T_N varies from 0.00001 to 20 and from 10 s to 50000 s, respectively, on a logarithmic

scale. We set the corresponding reference values to 0.5 and to 1000 s. Performing the OFAT method with the chosen parameter variation results in 42 simulations for each system. Thus, we perform a total of 82 annual simulations.

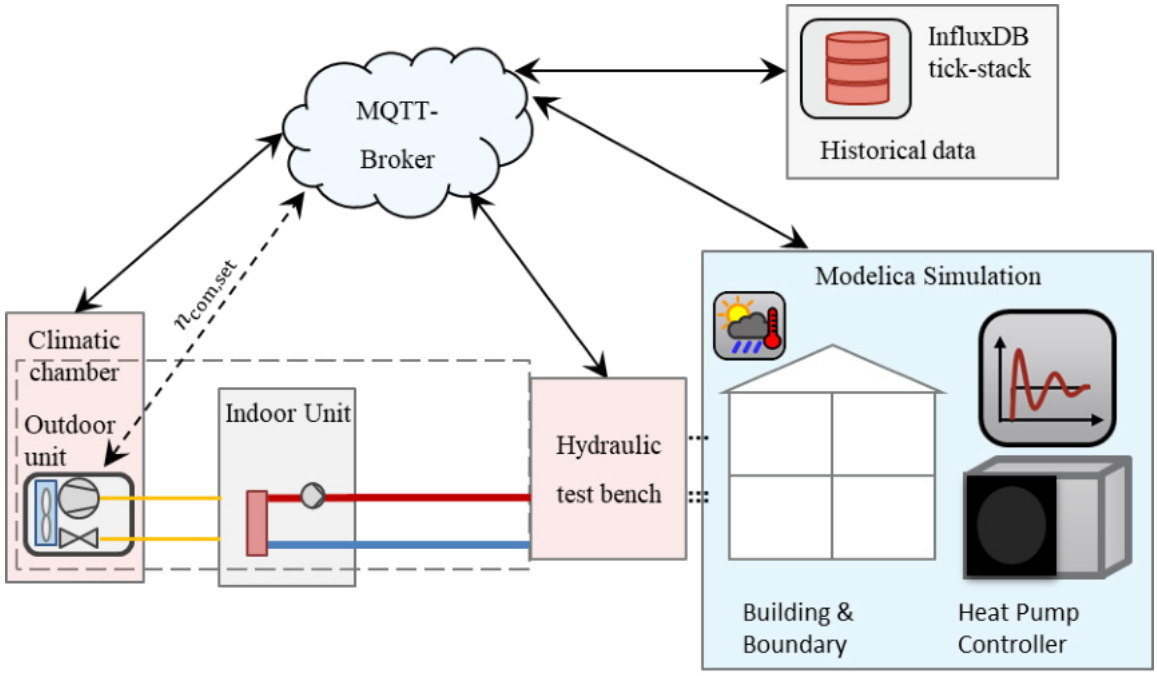

Figure 3: Schematic overview of HiL setup: heat pump test bench (indoor unit and outdoor unit), climatic chamber, hydraulic test bench, simulation model, InfluxDB tick-stack, and MQTT Broker

The safety parameters allow the heat pump to run a maximum of 10 times per hour for a minimum running time of 180 s. The resting time after shutdown has to be a minimum of 180 s. In addition, the maximum supply temperature is set to 70 °C. The presented simulation model with the underfloor system has a nominal supply temperature of 40 °C and a nominal mass flow of 0.315 kg/s. The system with radiators uses a nominal supply temperature of 55 °C with a nominal mass flow of 0.197 kg/s.

A detailed look into the operation behavior is realized with representative days. Thus, the interaction of the outdoor temperature and the solar irradiation with the variation of the control parameters can be considered in a bundled way. The outdoor temperatures of the three used representative days can be seen in Figure 4. The days correspond to representative periods calculated using the k-medoids clustering [22] and cover three different temperature levels.

Table 1: Value ranges, step sizes, and reference values of the controlled variables, the safety functions, and operating variables of both transfer systems.

Control parameter	Min. value	Max. value	Step size	Reference value
Proportionality factor K_p	0.00001	20	Log	0.5
Integral time T_N	10 s	50000 s	Log	1000 s
Hysteresis bandwidth	1 K	12 K	1 K	8 K
Safety parameter	Value	Transfer parameter	Value	
Max. runs per hour	10	UFH - nominal supply temperature	40 °C	
Min. run time	180 s	UFH – mass flow	0.315 kg/s	
Min. rest time	180 s	Rad. - nominal supply temperature	55 °C	
Max. supply temperature	70 °C	Rad. – mass flow	0.197 kg/s	

2.4 Experimental case study

Test runs under real conditions are necessary to validate the results obtained. Since field tests in real buildings are costly and time-consuming, we perform HiL experiments to emulate almost field behavior.

We conduct three experiments for the underfloor and radiator system. We vary the hysteresis bandwidth for each system from a low level over the reference level to a high level. The goal of the experiments is to validate the method and underline that the developed controller leads to the same operation behavior for the simulation model and the heat pump test bench.

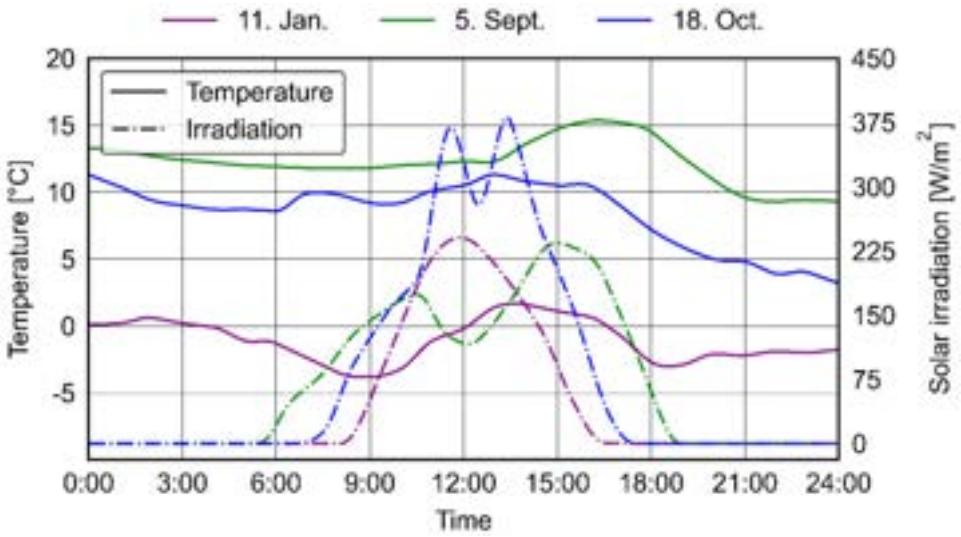

Figure 4: Outdoor temperature and solar irradiation for the reference days in Potsdam in 2015.

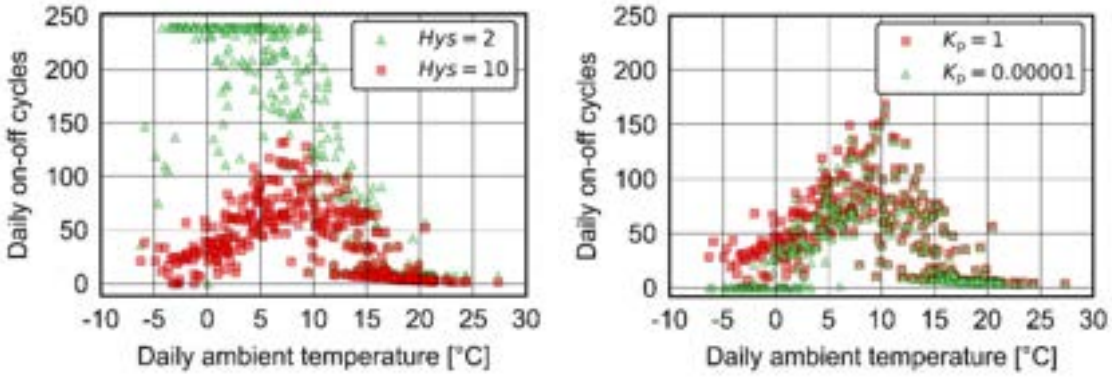
3. Results

This section starts with the sensitivity analysis results, which are mainly simulative performed and ends with the validation with the help of experimental results.

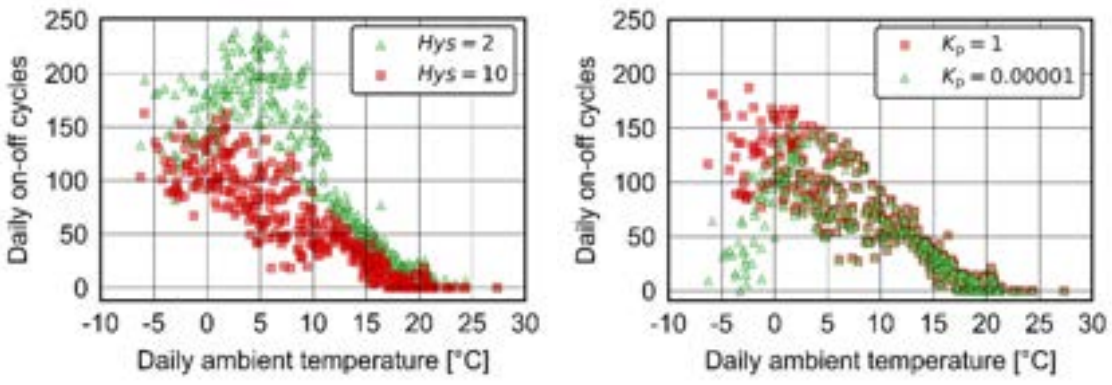
3.1 Simulative case study: sensitivity analysis

In order to visualize the effect of control parameters, it can be seen from Figure 5 to what extent different parameter values influence the number of daily on/off cycles. As shown in Figure 5 (a) for using a UFH, the number of cycles for a hysteresis bandwidth of 2 K below a temperature of 10 °C is increased in contrast to the use of a bandwidth of 10 K. Thereby, the number of cycles for a bandwidth of 2 K often reaches its maximum of 240 cycles per day. Notably, for a bandwidth of 10 K, the number of cycles initially increases at -5 °C before decreasing again from a temperature of 10 °C. A similar picture is also provided using K_p= 0.00001, shown in Figure 5 (b). Again, the daily cycles decrease for temperatures above 10 °C. Analogous to UFH, the radiator increases cycles for a decreased bandwidth. According to Figure 5 (c), we can identify a trend for the use of a bandwidth of 2 K and 10 K, according to which the number of cycles decreases with a rising outdoor temperature and the number of cycles increases with smaller hysteresis. Only using low proportionality factors ensures that the cycles decrease for outdoor temperatures below 5 °C, so the scatter plots of UFH and radiator show comparable results.



(a) UFH – Hysteresis

(b) UFH – Proportionality factor



(c) Radiator – Hysteresis (d) Radiator – Proportionality factor

Figure 5: Representation of the annual simulation's daily on/off cycles when using UFH (a,b) or radiator (c,d) as a function of the ambient temperature.

Figure 6 (a,c) shows that the Kp and TN boundary values represent the SCOP's respective minima and maxima. The variation's optimum reset time is at T_N = 50,000, with a value of 3.2. Whereas an increase of K_p continuously decreases the system efficiency, we observe an efficiency drop for T_N = 50 - 150. The SCOP decreases to a value of up to 2.70, corresponding to a relative change concerning the maximum efficiency of 15.6 %. We detect that the efficiency initially increases with a rising hysteresis bandwidth before continuously decreasing from a value of three Kelvin (Figure 6 (e)). Here, a SCOP maximum of 3.25 (3 K) contrasts with a minimum of 3.14 (12 K). The relative change is 3.6 %.

For the radiator as a heat sink, analogous to using UFH, we notice that the boundary values for K_p and T_N represent the maxima and minima. Again, K_p = 0.00001 and T_N = 50,000 s correspond to the highest SCOP parameters (cf. Figure 6 (b,d)). Their use implies a SCOP of 2.60 and 2.58, with the resulting relative efficiency differences of 3% and 3.9%, respectively. For the integral time variation, a noticeable reduction of the SCOP to 2.48 is shown only for T_N = 10.

For the proportionality factor, we observe that its increase means an increase in the cycles by up to 25 %. The hysteresis bandwidth's variation yields a maximum SCOP of 2.58 for a bandwidth of 12 K. Despite an increasing number of cycles with decreasing bandwidth, we cannot detect a significant change in efficiency (cf. Figure 6 (f)). The number of cycles increases by almost 250 %, while the SCOP varies only within a range of 2 %.

An overview of the obtained results of the most efficient parameter values for the considered periods is given in Table 2. It contains the SCOP, the relative change of the SCOP from the minimum to the maximum value (ΔSCOP), and the number of cycles per control variable and period. The associated results for the variation of the proportionality factor for both transfer systems show that the maximum values are different not only for the representative days but also for the same day for different transfer systems. Except for a proportionality factor of 0.00001 for the annual simulation, none of the best values for a given reference day are the same. For example, a value of 0.0001 for the UFH is compared to 0.1 for the radiator on 10/18. We recognize that the number of cycles increases with the average day temperature for the UFH system. At the same time, the SCOP rises with an increasing temperature for both transfer systems to a maximum of 3.77 and 3.02, respectively.

It is noticeable that proportionality between the number of cycles and the efficiency can only be determined to a limited extent. For the variation of K_p and T_N when using a radiator, the increasing number of cycles from reference day 01/11 to 10/18 inevitably increases efficiency due to the higher temperature level. However, comparing the various results of the control variables for a given day shows that more cycles do not necessarily result in lower efficiency. For example, we observe that for the under-floor heating on 10/18, the SCOP maximum of the hysteresis with a value of 3.51 at 156 cycles is higher than the respective maximums of the other two control variables, although their cycle numbers are lower (107).

Considering the ΔSCOP according to Table 2, we notice that the variation of T_N causes a high deviation, equivalent to a high sensitivity. Thus, we observe a deviation of 46.3 % for reference day 01/11 when UFH is used. The hysteresis variation also shows a high value of 27.3 % compared to the deviation of the remaining variables.

The collected consideration of the results finally show that the integral time T_N has the most significant sensitivity overall. As a variation result, it causes a deviation of 18.5 % (UFH) and 4.2 % (Radiator) from the lowest to the highest SCOP within the annual simulation and also shows the largest percentage on average for the reference days. Only when the radiator is used the hysteresis causes a significantly higher sensitivity

of 18.2 % and 11.0 %, respectively, for reference days 10/18 and 05/09. The various proportionality factors result in a deviation for the UFH and the radiator of 7.4 % and 3.2 %, respectively. Hysteresis has the lowest influence in annual simulation, with a difference of 3.2 % and 1.7 %, respectively.

Table 2: SCOP, relative change of SCOP from minimum to maximum value (ΔSCOP) and absolute number of cycles for a parameter variation of Kp ,TN and the hysteresis bandwidth for reference days and an annual simulation (AS). Listed are the highest values determined based on SCOP.

Reference days/ Annual simulation	Underfloor heating				Radiator			
	11.01	18.10	05.09	AS	11.01	18.10	05.09	AS
K_p - Value	**0.00001**	**0.0001**	**0.05**	**0.00001**	**0.01**	**0.1**	**0.75**	**0.00001**

3.2 Experimental case study: validation experiments

The conducted experiments underline the essential findings and trends. First, the developed controller results in equal operation behavior. Figure 7 compares the heat pump's supply and return temperature between the simulation (red) and the experiment (blue). The one-hour experiment begins with the start of the heat pump. After approximately 20 minutes, the experiment and the simulation resulted in similar behavior. The negligible error of under 0.2 K between simulation and experiments underlines the accurate simulation model and validates its application.

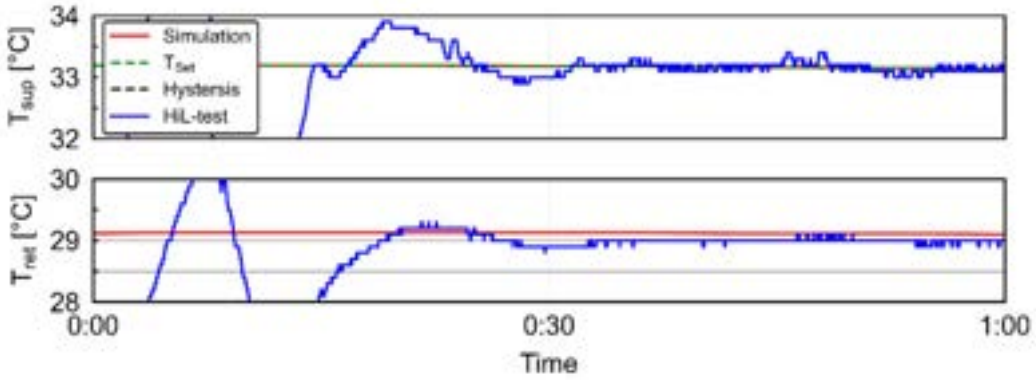

Figure 7: Comparison of supply temperature T_{sup}, and return temperature T_{ret} of the UFH system between simulation (red) and experiment (blue) for $Hys = 8\ \mathrm{K}$ on reference day 01/11.

Nevertheless, we also observe differences between simulation and experiment. Figure 8 compares supply and return temperatures between the simulation (red) and the experiment for the same day but with a lower hysteresis bandwidth of 2 K. The experiment the general operation behavior with many startups within one hour but at different temperature levels. The differences arise from an inaccurate mapping of the model's startup process and additional inertias on the test stand, such as leads, that were not part of the calibration process. In general, the successfully performed experiments show the applicability of the method and the possibility of fast model validation.

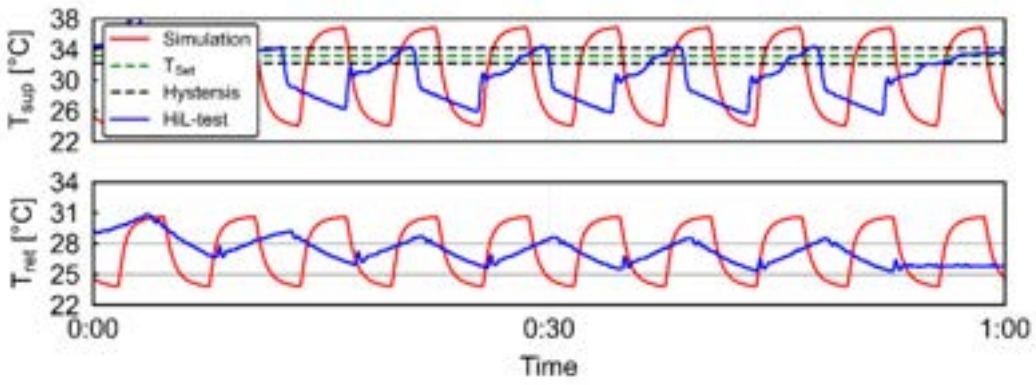

Figure 8: Comparison of supply temperature T_{sup}, and return temperature T_{ret} of the UFH system between simulation (red) and experiment (blue) for $Hys = 2$ K on reference day 01/11

4. Discussion

The following section discusses the obtained results in the context of the literature and is divided into four sections. While many studies discuss the heat pump's operation behavior only in the context of efficiency, we suggest considering the influence on the heat pump's service life (1). Furthermore, we observed discrete operating changes during periods with high solar irradiation (2) and due to bad hysteresis parametrization (3). Control parameters are also sensitive to the transfer system and boundary condition (4).

Typically, in the literature, system operation is only discussed concerning efficiency. Nevertheless, in this context, attention must be paid to assessing the system's service life due to the increased compressor starts. The service life is influenced by the number of operating hours and the frequency of the starting processes. For example, Perrin [22] found that a 12% increase in cycles can reduce compressor life by up to 15%. Therefore, overall consideration of the cycles is imperative for a comprehensive analysis.

The interplay between transfer mass flow and solar irradiation significantly influences the cyclic behavior of the system. From the analysis of the daily simulations, we found that for both transfer systems, there are significant amplitudes of the supply temperature in the midday hours compared to the morning and evening hours. The reason for this is the lack of a buffer tank, which significantly changes the inertia of the sink and solar irradiation. Lower heat output is required when solar irradiation heats the building midday. However, the heating curve only depends on the outdoor temperature, and the solar irradiance is not considered to determine the reference variable T_{set}. The result is that the overflow valve trips as a result of the rising pressure, thus reducing the transfer mass flow to a minimum. This causes high amplitudes of the supply temperature due to that low mass flow. Such cycles result in the system overshooting continuously due to the high control deviation. Because the cooling process is delayed due to the high amplitudes, fewer cycles can be observed overall if this operating state continues for longer. A cycles comparison of the radiator with the aid of Table 2 shows that this issue explains that the number of cycles is almost halved from reference day 10/18 to day 09/05. Accordingly, solar irradiation can result in a tipping point from which the heat pump operating switches from continuous to cycling behavior.

The interaction of the control variables, particularly the hysteresis, with the starting process, can also be regarded as a tipping point which we observe in the validation experiments using the real heat pump. For example, a hysteresis bandwidth of 6 K results in cyclic behavior, while a hysteresis bandwidth of 8 K results in continuous operation. Here, the startup process leads to a supply temperature that slightly exceeds the hysteresis's upper limit and thus maintains the cyclic state. Accordingly, there are threshold values which, as a result of the compressor starting process, mean different characteristics of the operation if they are under or exceeded. However, these threshold values differ between simulation and experiment since the starting process is not accurately modeled.

From the findings of Section 3 and Table 2, we can conclude that both the parameters by themselves in their variation influence the efficiency, and also, the transfer systems show different deviations concerning a SCOP maximum for the same day. Therefore, it is possible to adjust the controller to the building to increase efficiency. Furthermore, since differences in the SCOP-maximum parameter values for the different representative days can be found, the control should be adapted to the ambient conditions. One option for this is the adaptation of the control variables depending on the season or, ideally, based on weather forecasts for the following days.

Conclusion

This work contributes to the defossilation of the building sector by indicating the sensitivity of HPS controller settings on the efficiency and the service life of heat pump systems. In this paper, we develop a simulation model for Building Energy Systems applicable to purely simulation studies and hardware-in-the-loop experiments. The performed sensitivity analysis is based on 82 annual simulations considering various parameters for the proportional factor, the integral time, and the hysteresis bandwidth. We validate the trend of the annual results in further measurement campaigns with a fully-controllable heat pump test bench. The results show the impact of the controller settings on the heat pump's efficiency and operating behavior. Therefore, we analyze the daily heat pump's startups besides the SCOP. We show that the controller parameters influence the SCOP up to 18.5 %, and bad settings can increase the number of compressor starts up to 300 %. Furthermore, the results show discrete steps and nonlinear efficiency values over various parameters, which results from tipping points from which the heat pump operating switches from continuous to cycling behavior.

We will integrate the heat pump's starting process into the simulation model to increase the model's accuracy in future work. Further controller comparisons with the help of the experimental setup will support the efficient development of future systems. Dedicated studies should analyze the influence of the transfer system in more detail by focusing on the system's inertia.

Nomenclature

Acronym

BES	building energy system
HIL	Hardware-in-the-loop
HPS	heat pump system
KPI	key performance indicator
MPC	model predictive control
OFAT	one-factor-at-a-time
UFH	underfloor heating

Variables:

Hys	hysteresis bandwidth, K
K_p	proportionality factor
$\dot{m}$	mass flow rate, kg/s
n	rotational speed, 1/s
P	power, W
$SCOP$	seasonal coefficient of performance
T	temperature, °C/K
T_n	integral time

Greek symbols

η	efficiency
φ	maintenance factor

Subscripts and superscripts

amb	ambient
el	electric
ret	return
sup	supply

Abstract:

A general exergy based-design method for optimization of heat pump/refrigeration systems is proposed. It is based on a concept of overall temperature level of a flow-energy, to propose a general expression of overall exergy efficiency and losses of any heat pump/refrigeration cycle. Explicit and general relations of exergy efficiency and coefficient of performances are given to evaluate de performance of such cycles regarding the selection of working fluids, the characteristic of equipment (pinches on evaporators and condensers, performance characteristics of compressors and expansion valve) and the design methods for optimization.

Rigorously we introduce the overall and complete exergy efficiency for the most general cases where two energy services are provided, like producing simultaneously refrigeration and heating services or when the cycle is located in a temperature domain far from the atmospheric temperature. This complete exergy efficiency is determined by considering losses in the various components of the cycle and permits to analyse the various cases of heat pump systems including frigopump and thermopump with or without cogeneration systems. Such a method will facilitate the use of exergy theory in a way to highlight the existing link and relationship between energy and exergy losses of heat pump systems. Results of using such a method will be shown for simple and advanced cycles. Results show that the coefficient of performance of a heat pump/refrigeration installation does not necessarily depend on the reference atmospheric temperature but only on the intrinsic parameters relating to the choice of cycle, the operating conditions and the components of the machine. These parameters are obviously chosen according to the temperature levels of the available sources.

1. Introduction

"Pumping" heat from a lower temperature to an upper temperature can be done by using a vapor compression heat pump/refrigeration cycle most commonly used in heating and cooling applications. It consists of a process for which refrigerant vapor is compressed in the compressor and then used to the condenser where it is first cooled or desuperheated and then condensed and finally slightly subcooled. The saturated or slightly subcooled refrigerant is then expanded in a valve then evaporated in an evaporator and the cycle begins again. Whether operating in frigopump mode (providing cooling services while dissipating energy to the environment), in thermopump mode (providing heating service to customers while capturing energy from environment) or in cogeneration mode (providing heating and cooling simultaneously) the process is accompanied with different losses, resulting from various irreversibilities that occurred on their components. Generally, different approaches to assess exergy performances of such heating/cooling systems can be distinguished and applied at different levels [1, 2]:

- The method of calculating the exergy efficiency by quantitatively evaluating the global exergy losses $\dot{L}$ on the basis of internal/external losses [3, 4] (exergy losses $\dot{L}_D$ called also exergy destruction inside the strictly defined system and external exergy losses $\dot{L}_E$ or exergy destroyed between the system and the atmosphere) or on the basis of an exergy balance carried out on the boundary of the system extended to the atmosphere in order to internalize and attribute all losses to the system [1, 5]. Such a method is useful to compare different options or configurations of systems providing the same service (of heating and cooling);
- The assessment made on the basis of an exergy balance carried out on each of the components in the whole system in order to identify and locate the major losses. Borel & Favrat [5] subdivide $\dot{L}$ into:

$$\dot{L} = \dot{L}_r + \dot{L}_t$$

Where $\dot{L}_r$ includes the dissipation exergy losses (pressure losses and friction) inside the system and $\dot{L}_t$ includes the heat transfer exergy losses. The performance of a system is then characterised by calculating exergy losses of various components and/or subsystems.

In this article, we use the approach of components/subsystems level analysis to propose a **general exergy based-design method for optimization** of heat pump/refrigeration systems. Such method makes it possible to identify and locate the major losses in the whole system in order to take optimization measures and to determine the exergy efficiency characteristics of any heat pump system. New method [6] using explicit and general relations of exergy efficiency and coefficient of performances will be given to evaluate de performance of such cycles regarding the selection of working fluids and the characteristic of equipment (pinches on evaporators and condensers, performance characteristics of compressors and expansion valve).

Simplified effectiveness (or COP-coefficient of performance) models of heat-pumps/refrigeration cycles using perfect gases on the compressor and/or equation-fit models have been proposed in many studies. [7] performed models to calculate the COP by using a theoretical Lorentz efficiency multiplied by a constant exergy efficiency (of around 40% for boosters HP and 50% for the centralized HP). [8] gives a review of recent development in variable refrigerant flow (VRF) systems with models ranging from detailed physics-based models to equation-fit models. [9] proposed a modular simplified model using perfect gas in compression for a fast multi-year simulation. [10] performed a detailed simulation model based-exergy performance characteristics of heat-pumps and applied by in [11] to simulate different configurations of network integration where the performances in term of exergy efficiency on the substation are determined in function of the temperature of the network and the differential temperature on the primary network.

This detailed process exergy-based design model uses real working fluids with the possibility of evaluating the exergy efficiency in function of all key parameters that influence the system. This method allows to give precise recommendations on the optimization of a real process in operation or on the decision support for the conception or the design of a heating or cooling system.

2. The general exergy model of heat pump cycles

2.1. The concept of overall temperature for the calculation of flow-exergy

A fluid stream carrying a flow-energy ($\dot{Y} = \dot{M}\,\Delta h$) at constant pressure ($P$) between two states (1 and 2) can be characterized by its overall temperature level ($\bar{T}$) or logarithmic mean temperature. This temperature value is calculated on the basis of Gibbs equation of enthalpy variation ($dh = Tds + vdP$), for which we can thus write $vdP = 0$ and the integration will give a perfect relationship between enthalpy/entropy variations:

$$\frac{h_2 - h_1}{\bar{T}} = s_2 - s_1 \tag{1}$$

$$\bar{T} = (T_2 - T_1) \,/\, ln\left(\frac{T_2}{T_1}\right) \tag{2}$$

The logarithmic mean value of two different quantities is well known in Physics as well as in Thermodynamics, especially the calculation of a heat exchanger area with the method of mean temperature differences (heat transfer between fluids at constant pressure and without phase change. Considering Eq. (1) and the definition of co-enthalpy variation ($\Delta k = \Delta h - T_a \Delta s$) of the stream, the corresponding flow-exergy ($\dot{E}_y$) could then be given by the following equation:

$$\dot{E}_y = \dot{M}\,\Delta k = \left(1 - \frac{T_a}{\bar{T}}\right) \cdot \dot{Y} \qquad with \quad P = cste \tag{3}$$

This concept of logarithmic mean temperature (called here overall temperature) has been used and applied by various authors [12, 13] for the modelling of a stream flow-exergy. Indeed, a fluid stream can be seen as a succession of matter carrying exergy (co-enthalpy) at a temperature level $\bar{T}$. The latter is simply given by the variation of enthalpy of the fluid to the entropy variation (($\bar{T} = \Delta h / \Delta s$). The exergy losses associated to the flow-energy is given as:

$$\dot{L} = \dot{M}\, T_a\, (s_2 - s_1) = \dot{M}\, \frac{T_a}{\bar{T}} (h_2 - h_1) \tag{4}$$

In the case of a phase change fluid in evolution at constant pressure, Eq. (3) is still valid and the process is subdivided in different phases e.g. superheating, bi-phasic and subcooling phases. The expression given in Eq. (1) becomes:

$$\frac{h_2 - h_1}{\bar{T}} = (s_2 - s_l) + \left(s_l - s_g\right) + \left(s_g - s_1\right) \tag{5}$$

Where s_l and s_g represent respectively the liquid and gas saturated entropy.

2.2. Energy/exergy balances of a standard cycle

The vapor compression heat pump or refrigeration cycle that we considered (Figure 1-a) is so far an open system comprising a compressor, a condenser, an expansion valve and an evaporator, with various streams and with the following hypotheses: kinetic and potential energies neglected, heat devaluation in the condenser and in the evaporator but no dissipation in the heat exchangers (heat transfer processes occurring at constant pressures) and adiabatic compression and expansion with dissipation in the compressor and in the valve. Figure 1-b shows a T-s diagram of the refrigerant working fluid.

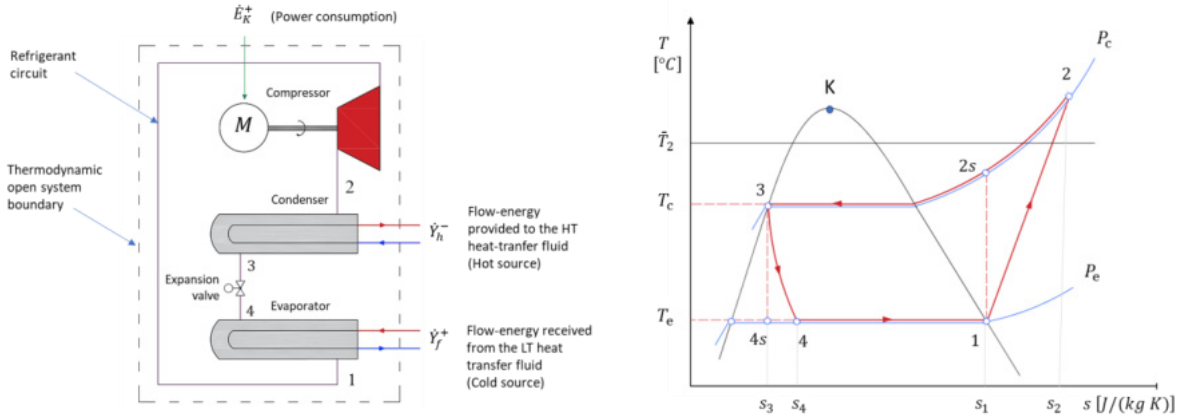

Figure. 1. Heating/cooling processes through a heat pump/refrigeration cycle
a) Schematic diagram, b) T-s diagram

The hot source is constituted by the HT heat transfer circuit in the condenser and the cold source is constituted by the LT heating circuit in the evaporator. The transformation (or flow) energy ($\dot{Y}_f^+$) received by the system from the cold source at a given temperature level ($\bar{T}_f$) is transferred through the heat pump/refrigeration system to the hot source ($\dot{Y}_h^-$) at a higher temperature level ($\bar{T}_h$). This is possible by consuming mechanical or electrical energy ($\dot{E}_K^+$) in the compressor. Note that the terms **hot** and **cold** here used to qualify the sources refer only to the temperature level of these sources. Not then to be confused with the **hot** and **cold streams** defined for heat exchangers where the cold stream is that of the flow to be heated by increasing its enthalpy level and the hot stream is that of the flow to be cooled by decreasing its enthalpy level. Thus,

- For the condenser, the hot stream is represented by the condensing refrigerant circuit at constant pressure (P_c) from state 2 to state 3. The overall temperature level of the stream is here noted ($\bar{T}_c$). The cold stream is represented by the HT heat transfer circuit heated in the condenser and supplying energy ($\dot{Y}_h^-$) to the hot source;
- For the evaporator, the hot stream is represented by the LT heat transfer circuit cooled in the evaporator and receiving energy ($\dot{Y}_f^+$) from the cold source. The cold stream is represented by the evaporating refrigerant circuit at constant pressure (P_c) from state 4 to state 1 ($\dot{Y}_e^-$).

These condensing or evaporating streams at constant pressure can be represented in the diagram T-s by their corresponding overall temperature values (or logarithmic mean temperature values at constant pressure), like $\bar{T}_c$ for the condenser and $\bar{T}_e$ for the evaporator. Figure 2 illustrates an example of this type of diagram with the advantage of showing the average pinches on heat exchangers characterizing the heat devaluation and the variations of entropies characterizing the dissipations in the compressor and the valve.

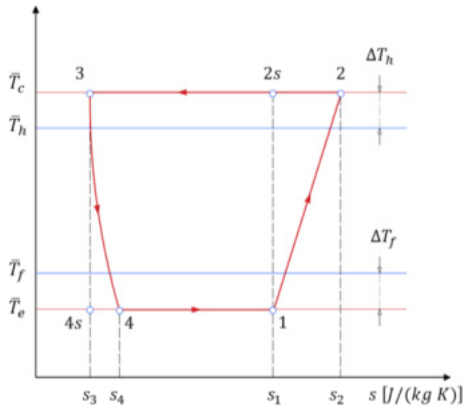

Figure. 2.: T-s diagram of a standard heat pump/refrigeration cycle

For adiabatic components with steady state open operation and based on the energy balance equation (Eq. xx), we can give the following relations:

$$\dot{Y}_h^- = \dot{Y}_c^+ = \dot{M}\,(h_2 - h_3) \qquad \dot{Y}_f^+ = \dot{Y}_e^- = \dot{M}\,(h_1 - h_4) \tag{5}$$

$$\dot{E}_K^+ = \dot{Y}_h^- - \dot{Y}_f^+ = \dot{M}\,(h_2 - h_1) \tag{6}$$

2.3. Overall exergy efficiency and losses of the cycle

From the general expressions given in [6], the overall exergy efficiency of a vapor compression heat pump/refrigeration system can be given as a function of the temperature levels of the hot ($\bar{T}_h$) and cold ($\bar{T}$) sources:

$$\eta = 1 - T_a \left(\frac{\varepsilon_h}{\bar{T}_h} - \frac{\varepsilon_f}{\bar{T}_f}\right) \qquad with \qquad \varepsilon_h = \varepsilon_f + 1 \tag{7}$$

Where $\varepsilon_h = \dot{Y}_h^- / \dot{E}_K^+$ and $\varepsilon_f = \dot{Y}_f^+ / \dot{E}_K^+$ respectively represent the effectiveness (or coefficient of performance) for heating and cooling. Considering that the mass flow rate of refrigerant ($\dot{M}$) is the same throughout the different component of the standard cycle, we can here work with energy/exergy quantities per unit of mass of refrigerant. Effectiveness for heating and cooling can then be done by using the specific energies of cooling ($y_h^- = h_1 - h_4$), of heating ($y_f^+ = h_2 - h_3$) and of power consumption ($e_K^+ = h_2 - h_3$):

$$\varepsilon_h = \frac{h_2 - h_3}{e_K^+} \qquad \varepsilon_f = \frac{h_1 - h_4}{e_K^+} \tag{8}$$

From Eq. (7), we found the well-known and particular relationships between the overall exergy efficiency of a heat pump cycle, the coefficient of performance (effectiveness) and the ideal effectiveness based on the Carnot factor :

For a thermopump ($\bar{T}_f = T_a$):

$$\eta_h = \varepsilon_h \left(1 - \frac{T_a}{\bar{T}_h}\right) \qquad COP_h = \eta_h \cdot \frac{\bar{T}_h}{\bar{T}_h - T_a} \tag{9}$$

For a frigopump ($\bar{T}_h = T_a$):

$$\eta_f = \varepsilon_f \left(\frac{T_a}{\bar{T}_f} - 1\right) \qquad COP_f = \eta_f \cdot \frac{\bar{T}_f}{T_a - \bar{T}_f} \tag{10}$$

Considering that the mass flow rate of refrigerant ($\dot{M}$) is the same throughout the different component of the standard cycle, we can here work with energy/exergy quantities per unit of mass of refrigerant. Equations Eq. 5.12 can then be done by using the specific energies of cooling ($h_1 - h_4$), of heating ($h_2 - h_3$) and/or of power consumption ($e_K^+ = h_2 - h_3$). These values can directly be read in the P-h diagram of the cycle.

$$\varepsilon_h = \frac{h_2 - h_3}{e_K^+} \qquad \varepsilon_f = \frac{h_1 - h_4}{e_K^+} \tag{11}$$

Based on Eq. (7) and Eq. (8), Exergy losses per unit of mass (l_G) of the **complete heat pump or refrigeration system** are then:

$$l_G = (1 - \eta) \cdot e_K^+ = \frac{T_a}{\bar{T}_h}\,(h_2 - h_3) - \frac{T_a}{\bar{T}_f}\,(h_1 - h_4) \tag{12}$$

Two components of exergy losses can be distinguished: exergy losses that are rather related to both the temperature level of the hot source ($\bar{T}_h$) and the specific energy of heating ($h_2 - h_3$) and exergy losses that are related to the temperature level of the cold source ($\bar{T}_f$) and the specific energy of cooling ($h_1 - h_4$). The temperature levels of the sources therefore play an important role in the assessment of the overall exergy losses or irreversibilities in heat pumps. The exergy losses do decrease with the temperature level of the hot source while they increase with the temperature level of the cold source.

Such global exergy efficiency and losses given by Eq. (7) and Eq. (12) are very useful for comparing the performance of different options or configurations of heat pump systems but are not explicit enough to provide more specific recommendations on the optimization of the cycle and more particularly on the design and operation of the components but also on the choice and characteristics of the refrigerant.

2.4. Detailed exergy assessment of the heat pump cycle

Not that, the exergy losses by dissipation in the compressor and in the valve enter into the expression of the global exergy loss (Eq. 12) through the enthalpy values of h_2 and h_4. If the isentropic efficiency of the compressor (η_{Ks}) decreases, h_2 increases and so does the compressor dissipation loss. If the pressure at the condenser (P_c) increases, h_4 increases and so does the loss in the valve. In general, the temperature level of a source is initially a known parameter based on the need of heating ($\overline{T}_h$) or of cooling ($\overline{T}_f$). Thus, improving the performance of a heatpump/refrigeration cycle (COP) shall involve improving its overall exergy efficiency by minimizing exergy dissipation ($\dot{L}_r$) and devaluation ($\dot{L}_t$) losses in the system.

Let us now determine the expression of exergy efficiency and losses by carrying out a detailed exergy assessment of losses in various components of the system (compressor, condenser, evaporator, valve). The global exergy losses ($\dot{L}_G$) here can be calculated by separating the dissipation exergy losses in the compressor and in the expansion valve ($\dot{L}_r = \dot{L}_K + \dot{L}_V$) and the devaluation (or heat transfer) exergy losses in the condenser and in the evaporator ($\dot{L}_t = \dot{L}_C + \dot{L}_E$). Then, the exergy efficiency of the cycle can be developed in function of these losses (dissipation and devaluation) per unit of power:

$$\eta = \ 1 - \left(\frac{\dot{L}_r}{\dot{E}_K^+}\right) - \left(\frac{\dot{L}_t}{\dot{E}_K^+}\right) \tag{13}$$

Let us then quantify these specific losses per unit of power.

Modelling dissipation exergy losses (compressor and valve)

Exergy losses in the compressor ($\dot{L}_K$):

For a compressor, adiabatic compression is aimed at, i.e. with perfect thermal insulation from the external environment to obtain the best exergy efficiency. In order to determine the compressor dissipation exergy losses $\dot{L}_K = \dot{M}\, T_a(s_2 - s_1)$ we first need to determine the variation of entropy in compression. According to Eq. (1) and to the fact that $s_1 = s_{2s}$ (Figure 2), the difference in entropy of the compression ($s_2 - s_1$) can also be determined in function of the overall discharge temperature ($\overline{T}_d$), when considering the refrigerant stream at constant pressure P_c from state 2 to state 2s (i.e., $vdP = 0$). The following equations can thus be defined:

$$s_2 - s_1 = \frac{h_2 - h_{2s}}{\overline{T}_d} = \frac{1 - \eta_{Ks}}{\overline{T}_d}\,(h_2 - h_1) \tag{14}$$

$$\overline{T}_d = (T_2 - T_{2s}) \,/\, ln\left(\frac{T_2}{T_{2s}}\right) \tag{15}$$

Where η_{Ks} represents the isentropic efficiency of the compression and $1 - \eta_{Ks} = (h_2 - h_{2s})/(h_2 - h_1)$ represents the part of dissipation losses in the compression. The variations in the kinetic and potential energies of the fluid are neglected in relation to the work energy consumed by the compressor. We can finally express the dissipation exergy losses in the compressor by the following simple relation:

$$\dot{L}_K = \dot{M}\,\frac{T_a}{\overline{T}_d}\,(1 - \eta_{Ks})(h_2 - h_1) \tag{16}$$

The power consumption is:

$$\dot{E}_K^+ = \dot{M}\left(\frac{\Delta h_{Ks}}{\eta_{Ks}}\right) \qquad with \quad \Delta h_{Ks} = h_{2s} - h_1 \tag{17}$$

Exergy losses in the expansion valve ($\dot{L}_V$):

In the case of the **adiabatic expansion** in a valve, i.e., with perfect thermal insulation thus avoiding external heat losses, the enthalpy variation of the fluid is equal to zero (isenthalpic expansion, $h_3 = h_4$). According to Eq. (4) and to the fact that $s_3 = s_{4s}$ (Figure 2), the difference in entropy of the compression ($s_4 - s_3$) can also be determined in function of the evaporation temperature ($\overline{T}_e$), when considering the evaporating pressure P_e from state 4s to state 4 (i.e., $vdP = 0$). The following equation can thus be defined:

$$\dot{L}_V = \dot{M}\, T_a(s_4 - s_3) = -\dot{M}\,\frac{T_a}{T_e}\,\Delta h_{Ks} \qquad with \quad \Delta h_{Vs} = h_{4s} - h_3 \tag{18}$$

From these Eq. (16), Eq. (17) and Eq. (18), we can deduce the specific dissipation losses as a function of the isentropic efficiency, a ratio of isentropic enthalpy variations between the valve and the compressor (here called isentropic expansion/compression ratio) and the overall discharge temperature level of the fluid at the outlet of the compressor:

$$\frac{\dot{L}_r}{\dot{E}_K^+} = \frac{T_a}{\overline{T}_d}(1-\eta_{Ks}) + \frac{T_a}{T_e}\left(\frac{-\Delta h_{Vs}}{\Delta h_{Ks}}\right)\cdot\eta_{Ks} \tag{19}$$

Such expression of dissipation exergy losses per unit of power can be given by the following simple equation:

$$\frac{\dot{L}_r}{\dot{E}_K^+} = \frac{T_a}{\overline{T}_d}(1-\eta_{Gs}) \tag{20}$$

Where we introduce a cycle global isentropic efficiency (η_{Gs}) which takes into account the total dissipation losses or irreversibilities in the compressor and in the expansion valve and therefore is intrinsic to the heatpump cycle:

$$\eta_{Gs} = \eta_{Ks}\left[1-\left(\frac{-\Delta h_{Vs}/T_e}{\Delta h_{Ks}/\overline{T}_d}\right)\right] \tag{21}$$

This relationship Eq. (20) clearly expresses the link between the exergy losses, the fluid temperature level (via the overall discharge temperature ($\overline{T}_d$) at the outlet of the compressor) and the dissipation losses in the whole cycle ($1-\eta_{Gs}$). For the same percentage of dissipation losses in the cycle ($1-\eta_{Gs}$), the dissipation exergy losses are lower the higher the discharge temperature level of the compressor ($\overline{T}_d$). The fluid temperature level plays an important role in the exergy assessment.

Modelling heat transfer exergy losses (condenser and evaporator)

From the general expressions given in [Kane, ecos 2023], the devaluation exergy losses on heat exchangers can be given as a function of the temperature levels of the streams.

Exergy losses in a condenser:

$$\dot{L}_C = \dot{M}\left[T_a\left(\frac{1}{\overline{T}_h}-\frac{1}{\overline{T}_c}\right)\right](h_2-h_3) \tag{22}$$

Exergy losses in an evaporator:

$$\dot{L}_E = \dot{M}\left[T_a\left(\frac{1}{\overline{T}_e}-\frac{1}{\overline{T}_f}\right)\right](h_1-h_4) \tag{23}$$

By combining equations Eq. (22), Eq. (23) and Eq. (8), we can determine the specific devaluation losses as a function of the effectiveness for heating and cooling and the overall temperature levels of the streams:

$$\frac{\dot{L}_t}{\dot{E}_K^+} = T_a\left[\left(\frac{1}{\overline{T}_h}-\frac{1}{\overline{T}_c}\right)\cdot\varepsilon_h + \left(\frac{1}{\overline{T}_e}-\frac{1}{\overline{T}_f}\right)\cdot\varepsilon_f\right] \tag{24}$$

Or then:

$$\frac{\dot{L}_t}{\dot{E}_K^+} = T_a\left[\frac{\varepsilon_h}{\overline{T}_h}\frac{\Delta T_h}{\overline{T}_c} + \frac{\varepsilon_f}{\overline{T}_f}\frac{\Delta T_f}{\overline{T}_e}\right] \tag{25}$$

The exergy losses by internal heat devaluation on the heat exchangers (condenser and evaporator) increase not only with the pinch differential temperatures of the hot (ΔT_h) and cold (ΔT_f) sources but are lower the higher the source temperature levels. The temperature therefore plays an important role in the assessment of the overall exergy losses or irreversibilities.

Let us know express the exergy efficiencies and effectiveness of a heatpump/refrigeration system explicitly in terms of all key parameters influencing the performance of the cycle: the overall discharge temperature level ($\overline{T}_d$) characterizes the type of the working fluid, the global isentropic efficiency (η_{Gs}) characterizes the losses by dissipation in the cycle and the pinch differential temperatures in the hot (ΔT_h) and cold (ΔT_f) sources characterize devaluation losses by heat transfer in the condenser and the evaporator.

2.5. Explicit relations between exergy efficiency and effectiveness

By developing the expression given in Eq. (24), the exergy loss by devaluation in a heat pump/refrigeration cycle can also be determined by the following relation:

$$\frac{\dot{L}_t}{\dot{E}_K^+} = T_a \left[\left(\frac{\varepsilon_h}{\bar{T}_h} - \frac{\varepsilon_f}{\bar{T}_f} \right) - \left(\frac{\varepsilon_h}{\bar{T}_c} - \frac{\varepsilon_f}{e_f} \right) \varepsilon_f \right] \tag{26}$$

Considering the general expression of exergy efficiency given by Eq. (7), we can deduct from Eq. (24) the expression of the system's devaluation exergy losses:

$$\frac{\dot{L}_t}{\dot{E}_K^+} = 1 - \eta - T_a \left(\frac{\varepsilon_h}{\bar{T}_c} - \frac{\varepsilon_f}{\bar{T}_f} \right) \tag{27}$$

By replacing equations Eq. (20) and Eq. (27) in Eq. (13) and by considering the general equation of overall exergy efficiency (Eq. 7), we found a simple expression between the effectiveness for heating ε_h) and cooling (ε_f), the overall temperature levels of the fluid in the evaporator (T_e), the condenser ($\bar{T}_c$) and the compressor ($\bar{T}_d$) and the global isentropic efficiency (η_{Gs}) defined above:

$$\frac{\varepsilon_h}{\bar{T}_c} - \frac{\varepsilon_f}{\bar{T}_e} = \frac{1 - \eta_{Gs}}{\bar{T}_d} \tag{28}$$

Such an expression Eq. (28) shows that the quantity or ratio $(1 - \eta_{Gs})/\bar{T}_d$ is in fact a decisive parameter for calculating the effectiveness (or coefficient of performance) of the cycle as a function of the evaporation and condensation temperature levels of the fluid. Considering the egality $\varepsilon_h = \varepsilon_f + 1$, we can finally deduce the following explicit expressions of effectiveness:

$$\varepsilon_h = \eta_{0h} \cdot \frac{\bar{T}_c}{\bar{T}_c - \bar{T}_e} \qquad with \qquad \eta_{0h} = 1 - \frac{\bar{T}_e}{\bar{T}_d}(1 - \eta_{Gs}) \tag{29}$$

$$\varepsilon_f = \eta_{0f} \cdot \frac{\bar{T}_e}{\bar{T}_c - \bar{T}_e} \qquad with \qquad \eta_{0f} = 1 - \frac{\bar{T}_c}{\bar{T}_d}(1 - \eta_{Gs}) \tag{30}$$

Where η_{0h} and η_{0f} correspond respectively to the exergy dissipation efficiency for the heating and the cooling application.

These expressions are similar to Eq. (9) and Eq. (10) for the coefficient of heating (COP_h) and for cooling (COP_f) given in function of the exergy efficiency for heating (η_h) and cooling (η_f) and the Carnot factors related to the temperature levels of the sources. The performances of a heat pump/refrigeration cycle are better than if it operates at higher temperatures. Dissipation exergy efficiency equal to unit ($\eta_{0h} = \eta_{0f} = 1$) corresponds to losses that are represented only by the internal heat transfer devaluation on heat exchangers. The final expressions for the exergy efficiency of a heat pump/refrigeration cycle are then determined by combining the equations of effectiveness for heating Eq. (9) and Eq. (29) and for cooling Eq. (10) and Eq. (30) and then become:

$$\eta_h = \eta_{0h} \cdot \frac{1 - \bar{T}_f/\bar{T}_h}{1 - \bar{T}_e/\bar{T}_c} \tag{31}$$

$$\eta_f = \eta_{0f} \cdot \frac{\bar{T}_h/\bar{T}_f - 1}{\bar{T}_c/\bar{T}_e - 1} \tag{32}$$

Where: $\bar{T}_c = \bar{T}_h + \Delta\bar{T}_h$ and $\bar{T}_e = \bar{T}_f - \Delta\bar{T}_f$ according to the diagram given in Figure 2.

These expressions Eq. (31) and Eq. (32) of exergy efficiency are explicit as a function of the various parameters that define the qualities that a heat pump/refrigeration cycle must have, namely: the temperature levels of the hot ($\bar{T}_h$) and cold ($\bar{T}_f$) sources, the pinch temperature difference characterizing the condenser (ΔT_h) and the evaporator (ΔT_f), the overall discharge temperature level of the compressor here expressing the type of the working fluid ($\bar{T}_d$) and the global isentropic efficiency (η_{Gs}) that expresses the dissipations in the compressor and the expansion valve.

3. Results and discussion

3.1. The exergy-based design method for optimization

As already shown for the detailed exergy model above, the coefficient of performance of a standard heating (ε_h) or cooling (ε_f) heat pump cycle is determined by the explicit relations of the equations Eq. (29) and Eq. (30). The terms η_{0h} and η_{0f} are exergy efficiencies defined with respect to ideal Carnot efficiency expressed here as a function of the difference ($\Delta\bar{T} = \bar{T}_c - \bar{T}_e$) of condensation ($\bar{T}_c$) and evaporation temperature levels ($\bar{T}_e$). Indeed, it can be shown that there is a simple relationship between these two exergy efficiency values by considering their expressions given in Eq. (29) and Eq. (30):

$$\eta_{0h} - \eta_{0f} = \frac{\Delta\bar{T}}{\bar{T}_d} \cdot (1 - \eta_{Gs}) \tag{33}$$

Based on this formulation of Eq. (33), we express what we already knew in practice or from the theory of exergy, that the best heat pump or refrigeration cycles are those which will:

- Reduce the difference in temperature levels of the refrigerant cycle ($\Delta\bar{T}$);
- Minimize the dissipations at the level of the expansion valve and the compressor ($1 - \eta_{Gs}$)
- Use a fluid with a higher discharge temperature at the compressor ($\bar{T}_d$) from the point of view of exergy analysis

For known evaporation and condensation temperature levels, these exergy dissipation efficiencies are fully determined if one knows the **overall isentropic efficiency** (η_{Gs}) and the compressor outlet **discharge temperature** ($\bar{T}_d$). The advantage is that they only depend on the parameters intrinsic to the refrigerant circuit. Knowing their values makes it possible to determine the cycle coefficient of performance in function of the evaporation and condensation temperature levels. Figure 3 shows an example of a refrigerant-ammonia ($R717$) with different temperature conditions (evaporation and condensation), the corresponding overall isentropic efficiencies and discharge temperatures. Knowing the temperature of evaporation ($T_e = -10°C$) and condensation ($T_c = 40°C$) streams for the heat pump, the overall isentropic efficiency can be determined, in the order of $\eta_{Gs} \cong 65\%$. The corresponding coefficient of performances based on Eq. (29) and Eq. (30) are in the order of $\varepsilon_h \cong 4.3$ for heating and $\varepsilon_f \cong 3.3$ for cooling.

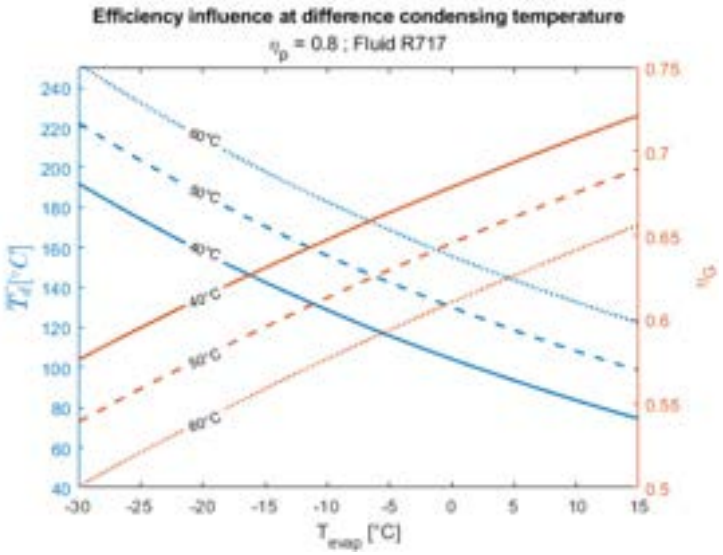

Figure. 3.: The effect of the evaporation temperature on the global dissipation efficiency of a heat pump cycle with parametric curves corresponding to the condensing temperature

Note that these quantities are a function of other parameters and are also dependent on each other:

- The difference in temperature levels of the cycle ($\Delta\bar{T}$) depends on the temperatures of the sources and the pinches at the evaporator and condenser and it is also influenced by the discharge temperature of the compressor;
- The overall isentropic efficiency of the cycle (η_{Gs}) defined above is also a function of the various characteristic parameters of the valve ($-\Delta h_{Vs}/\Delta h_{Ks}$), of the compressor ($\eta_{Ks}$) and of the refrigerant

fluid ($\bar{T}_d$). Figure 31 allows to highlight a dimensionless parameter enabling a fluid to be chosen if the operating conditions of evaporation and condensation and the isentropic efficiency of the compressor are known;

- Since the isentropic efficiency of the compressor is also not constant, it can be a function of various parameters including, for example, the built-in volume ratio (VR_i) and the compression ratio ($\pi_K = PR$) for volumetric compressors.

The thermodynamic optimization of the cycle based on the exergy criterion given by the Eq. (33) therefore makes it possible to obtain a better compromise between these different parameters. Different actions are mentioned theoretically in the literature or actually carried out in practice to improve the coefficient of performance of heat pump or refrigeration cycles and whose results find their explanation based on this analysis of the Eq. (33).

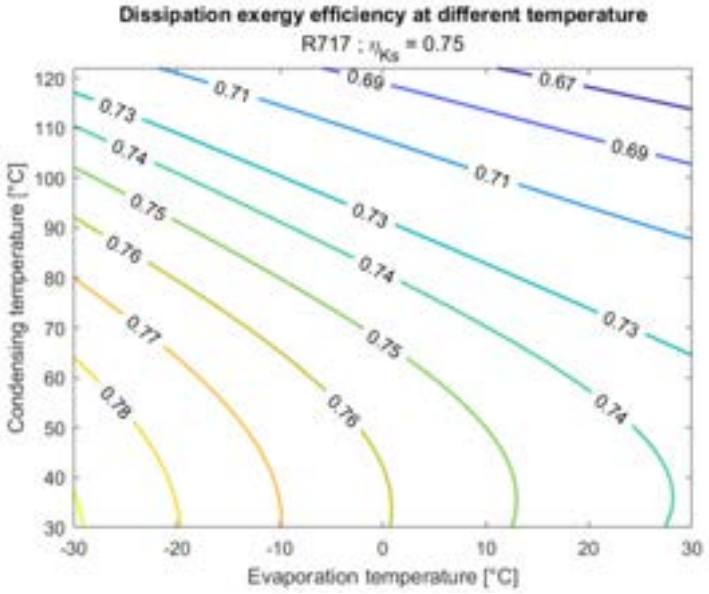

Figure. 4.: Dissipation exergy efficiency for heating in function of the condensing and evaporation temperatures

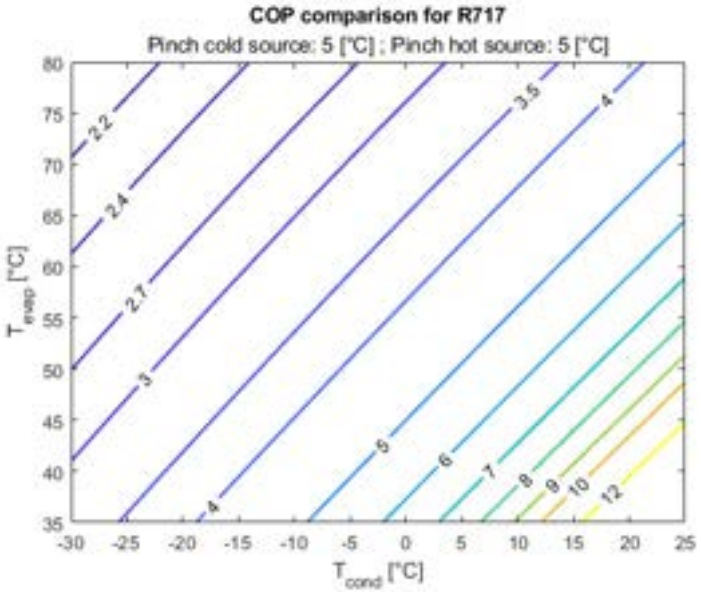

Figure. 5.: Coefficient of performance of heating, R717

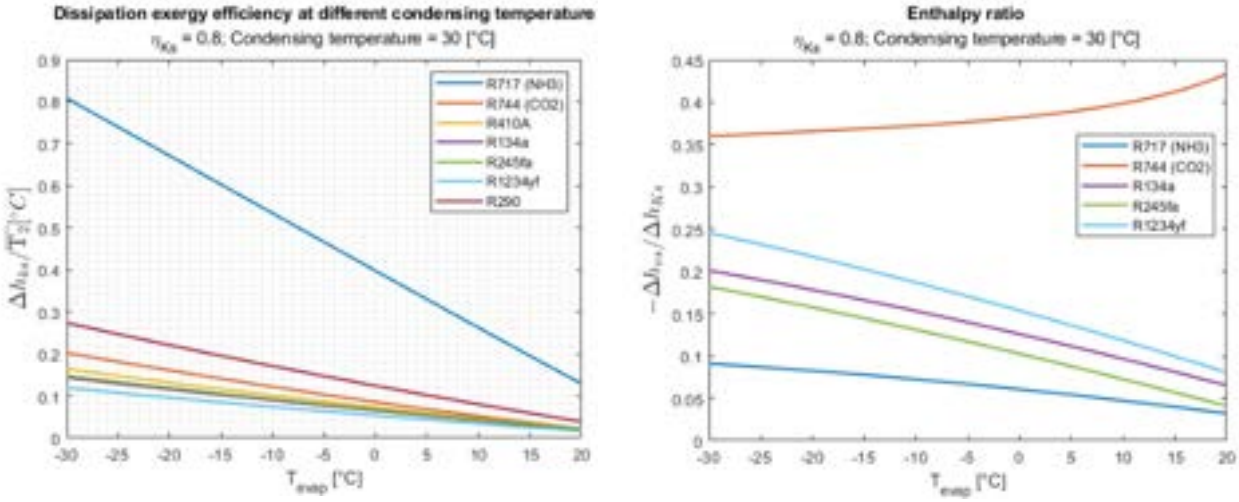
These expressions and curves clearly show that the coefficient of performance of a heat pump/refrigeration installation does not necessarily depend on the reference atmospheric temperature but only on the intrinsic

parameters relating to the choice of cycle, the operating conditions and the components of the machine. These parameters are obviously chosen according to the temperature levels of the available sources.

3.2. A dimensionless parameter to select the right working fluid

For the same evaporation and condensation temperatures, the specific power per unit of temperature of discharge compression ($\Delta h_{Ks}/\bar{T}_d$) is a decisive parameter for the selection of the working fluid for the compressor. On the other hand, for the valve, it is the isentropic expansion/compression ratio ($-\Delta h_{Vs}/\Delta h_{Ks}$) which is the determining parameter for the choice of fluid. Figure 6a and 6b show the variation of those parameters for various working fluids.



a) Specific power per unit of temperature b) Isentropic expansion/compression ratio

Figure. 6. Heat pump/refrigeration cycle with various working fluids

Refrigerants with the highest discharge temperature at the compressor e.g. with low molar mass refrigerants like ammonia also have the highest specific compression power per unit of discharge temperature ($\Delta h_{Ks}/\bar{T}_d$). The isentropic expansion/compression ratio ($-\Delta h_{Vs}/\Delta h_{Ks}$) is higher for CO2 than for other refrigerants.

An isentropic efficiency of $\eta_{Ks} = 80\%$ is considered for comparison. If this isentropic efficiency of the compressor decreases, the overall discharge temperature ($\bar{T}_d$) increases and so does the global dissipation loss (η_{Gs}). If the temperature at the evaporator (T_e) decreases, the loss in the valve increases too and so does the global dissipation loss (η_{Gs}). We identify an explicit dimensionless dissipation factor as a new criterion for estimating the exergy performance of the heatpump/refrigeration system:

$$a_s = \frac{-\Delta h_{Vs}/T_e}{\Delta h_{Ks}/\bar{T}_d} = \frac{1}{\eta_{Ks}} \cdot \left(\frac{\Delta s_V}{\Delta s_K}\right) \tag{34}$$

For same operating conditions of the cycle (evaporation and condensation temperatures), this dimensionless dissipation factor could be used as a good characteristic parameter to select the right working fluid. To illustrate this, we can visualize the effect of such a factor on the global isentropic efficiency (η_{Gs}) and for various refrigerants (Figure 7) and for different temperature levels (Figures 8).

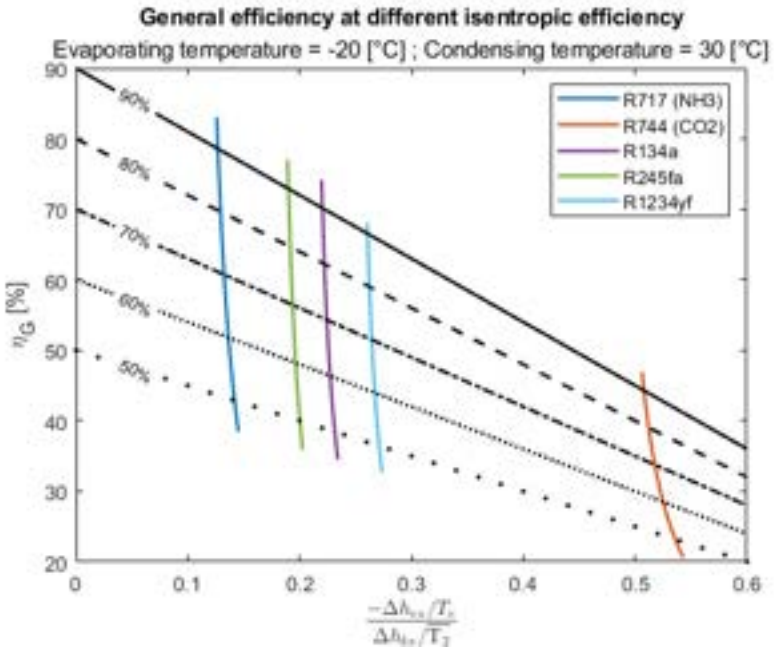


Figure. 7. Global isentropic efficiency in function of the dimensionless dissipation factor of a heatpump cycle and for various refrigerants (single stage cycle)

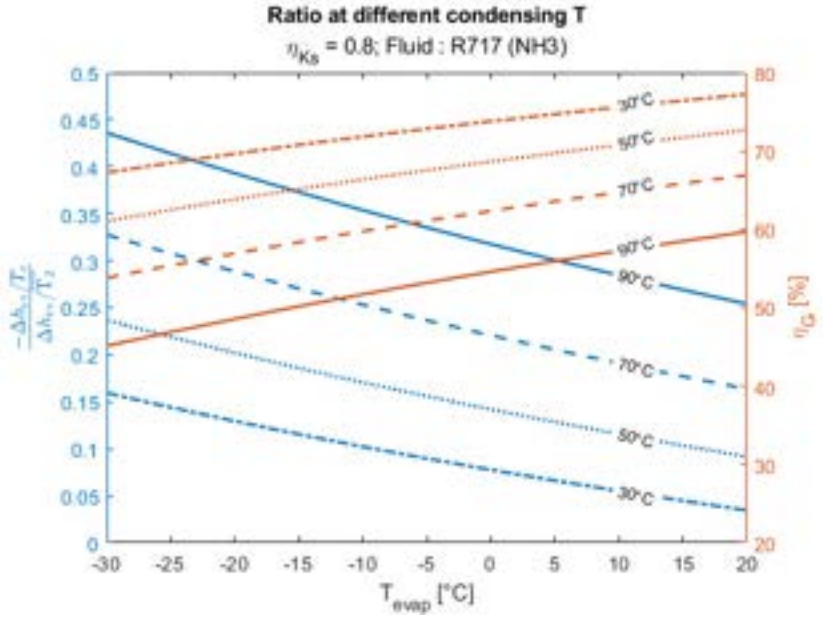

Figure. 8. Global isentropic efficiency in function of the dimensionless dissipation factor of a standard cycle working with R717-ammonia for different temperature levels

4. Conclusion

A **general exergy based-design method for optimization** of heat pump/refrigeration systems is proposed. It is based on a concept of overall temperature level of a flow-energy, to first propose a general expression of overall exergy efficiency and losses of any heat pump/refrigeration cycle.

Rigorously we introduced an overall and complete exergy efficiency for the most general cases where two energy services are provided, like producing simultaneously refrigeration and heating services or when the cycle is located in a temperature domain far from the atmospheric temperature. This complete exergy efficiency is determined by considering losses in the various components of the cycle and allows to analyse the various cases of heat pump systems including frigopump and thermopump with or without cogeneration systems. Main results of such a study are:

- Developing explicit and general relations of exergy efficiency and coefficient of performances of vapor compression heat pump/refrigeration systems. This allows to evaluate de performance of such cycles

regarding the selection of working fluids and the characteristic of equipment (pinches on evaporators and condensers, performance characteristics of compressors and expansion valve);

- Providing an explicit dimensionless dissipation factor as a new criterion for estimating the exergy performance of a heatpump/refrigeration system. For same operating conditions of the cycle (evaporation and condensation temperatures), this dimensionless dissipation factor could be used as a good characteristic parameter to select the right working fluid with the definition of a global isentropic efficiency given in a function of the various characteristic parameters of the valve, the compressor and the heat exchangers;
- Developing a new exergy-based method for the design and optimization of heat pump/refrigeration systems. Such a method has the advantage of facilitating the use of exergy theory in a way to highlight the existing link and relationship between energy and exergy losses of heat pump systems.

Nomenclature

Roman symbols

E work energy, exergy, J
k co-enthalpy, J
L global exergy losses, J
$\dot{M}$ mass flow rate, kg/s
Q heat energy, J
Y flow or transformation energy, J
T temperature, K
U utility, energy service, J

Greek symbols

η exergy efficiency
ε effectiveness, coefficient of performance

Subscripts and superscripts

a ambient, atmosphere
C condenser
E evaporator
f cooling service
h heating service
K compressor
V Expansion valve

Multi-objective optimization of a solar-assisted ground-source CO_2 heat pump system for space and water heating using the Taguchi method and utility concept

Thor Alexis Sazon[a], Qian Zhang[a], and Homam Nikpey[a]

[a] University of Stavanger, Stavanger, Norway, thor.a.sazon@uis.no

Abstract:

This work deals with the optimization of a solar-assisted ground-source CO_2 heat pump system using the Taguchi method and the utility concept. Nine control factors were investigated, including the Borehole Heat Exchanger (BHE) length, BHE spacing, BHE number, solar collector (SC) area, tank thermal energy storage volume, BHE-SC mass flow rate, space heating return temperature, heat pump high-side pressure, and heat pump's output temperature. The seasonal performance factor (SPF), levelized cost of heating (LCOH), and the estimated maximum annual ground temperature change (GTC) were chosen as the response factors to evaluate system performance. The system model was developed using Modelica and 27 simulation runs were implemented according to the L_{27} (9^3) Taguchi orthogonal array. Single objective optimizations were first performed using the Taguchi method to determine the parameter combinations that would optimize the SPF, LCOH, and GTC, separately. After that, multi-objective optimization was performed using the combined Taguchi method-utility concept to determine the control factor combination that would give the optimal overall performance when all response factors are considered simultaneously and given equal importance. Single objective optimizations show that the SPF, LCOH, and GTC are individually most sensitive to the target output temperature of the heat pump, the BHE length, and the SC area, respectively. Optimizing the response factors individually resulted in an SPF of 4.2, an LCOH of 0.122 USD/kWh, and a GTC of 100.24%. Multi-objective optimization resulted in a control factor combination that gave an SPF of 3.58, LCOH of 0.165 USD/kWh, and GTC of 100.03%. When optimized, this system exhibited a performance that is almost comparable to that of conventional systems.

1. Introduction

Recent occurrences that have impacted energy security and affordability have provided significant momentum for a transition away from fossil-fuel-based heating. However, much is still to be done since fossil fuels still meet over 60% of the heating energy demand [1].

Heat pumps (HPs) are recognized by the European Union as a key technology for replacing existing gas boilers and reducing the reliance on Russian natural gas [2]. They can facilitate the utilization of low-grade energy to replace the traditional building energy supply with renewable sources and reduce the consumption of high-grade energy, such as electricity and fuels. However, most HPs currently operate using Hydrofluorocarbons (HFCs) as the working fluid [3]. HFCs replaced the once widely-used ozone-depleting Hydrochlorofluorocarbons (HCFCs) and Chlorofluorocarbons (CFCs) because they exhibited similarly good performance, efficiency, low toxicity, and non-flammability. Unfortunately, they are very strong greenhouse gases, some of which are around a thousand times more potent that CO_2 [4]. Recent initiatives, like the EU's F-gases regulation (EC517/2014) and the Kigali amendment to the Montreal Protocol, suggest that HFC production and utilization will be phased down in the coming years [5,6].

The use of natural working fluids has gained more attention recently because they offer a long-term solution to the problems posed by conventional working fluids. Much interest has been given to CO_2 (R744) due to its zero ozone depletion potential, low GWP, non-toxicity, non-flammability, superior thermodynamic properties, and affordability [7]. Lorentzen first proposed the modern use of CO_2 in a trans-critical HP cycle [8]. So far, it has been commercially applied in different sectors, like combined cooling, heating, ventilation, and air conditioning in supermarkets [9], water heating [10], and automotive air conditioning [11].

Air source heat pumps (ASHPs) account for the majority of global sales (60% in 2021) [2]. However, they have the problem of poor low-temperature heating performance and frosting of the heat exchanger [12].

Ground source heat pumps (GSHPs) are considered more efficient for indoor climate control applications since they use the heat from the ground, which remains at a nearly constant temperature. There are already some studies that have investigated the performance of CO_2 GSHPs [13–16].

Some of the challenges of using a GSHP are: (1) its higher installation cost relative to ASHPs due to the need to drill boreholes and install Borehole Heat Exchangers (BHEs) and (2) the difficulty of operating a single-source HP system continuously and efficiently [12]. One way to overcome these is to add another heat source, such as solar collectors (SCs), to allow for shorter BHEs and more operational options.

There are only very few studies that tackled SAGSHPs that use CO_2 as the working fluid. Kim et al. [17] performed simulations that showed how the various operating parameters could affect the performance of a residential solar-assisted ground-source CO_2 heat pump (CO_2 SAGSHP). They showed that the performance of a CO_2 HP can be improved by using solar and geothermal heat sources and it could supply sufficient heat to the space during winter. Choi et al. [18] performed simulations to compare an R22 and a CO_2 SAGSHP. They found that the R22 SAGSHP had a more stable performance and exhibited a higher heating capacity. Both studies considered relatively low temperatures since their systems were only designed for space heating (SH).

Optimizing the design and operation of SAGSHP systems is necessary to maximize its benefits, considering its high initial cost. However, these are quite complex systems, and optimizing them concerning multiple performance indicators would require a heavy simulation workload.

The Taguchi method [19] is an approach that could be employed to reduce the simulation runs needed to optimize systems. It makes use of an orthogonal array (OA) experimental design with a single analysis of variance and utilizes the signal-to-noise (S/N) ratio to assess parameter settings that minimize the sensitivity of system performance to sources of variations. However, the Taguchi method focuses on the optimization of one performance indicator at a time. To optimize systems while simultaneously considering multiple performance indicators, some studies combined the Taguchi method with the utility concept [20]. Some studies on manufacturing and quality engineering have integrated it with the Taguchi method to handle muti-response optimization problems [21,22]. Some studies have applied the Taguchi method with the utility concept on GSHP systems [23–27].

Verma and Murugesan [28] applied the Taguchi method and the utility concept on a conventional SAGSHP system to optimize the BHE length and the SC area for optimum performance. This paper employs the same concept but with a trans-critical CO_2 heat pump instead of a typical sub-critical vapor compression HFC heat pump. The optimization of a CO_2 SAGSHP for simultaneous space and water heating was performed. Different design and operating parameters were optimized using the Taguchi method and the utility concept, considering the seasonal performance factor (SPF), levelized cost of heating (LCOH), and the estimated maximum ground temperature change (GTC) in a year as response factors.

2. System description

The thermal energy system model in this study was developed using Modelica [29] through the Dymola v2021x [30] environment. It includes a CO_2 HP, SCs, BHEs, and tank thermal energy storage (TTES). The CO_2 HP was modeled using the Thermal Systems library v1.6.1 [31] and then calibrated with experimental data; the BHEs were modeled using a modified version of the MoBTES library v2.0 [32]; the SCs and TTES were both modeled with the Buildings library v9.0.0 [33]. Modelica Standard Library (MSL) v4.0.0 was used here.

2.1. The CO_2 solar-assisted ground source heat pump system model

Figure. 1 shows the schematic of the Modelica model of the whole thermal system in this work while the models of the different system components are given in Figure. 2. Verification of the validity of a system model is best done by calibrating it against data from a real-world installation of the exact system. However, since neither the facility nor data is available to the researchers, the system model was built using component models that have been validated or calibrated individually.

The SCs and the BHEs, connected in series, provide the heat input to the CO_2 HP. This configuration was chosen to allow the storage of excess solar energy in the ground. Different studies [34,35] have shown that this configuration results in better performance. When solar irradiation is available, the SC heats the cold water-side fluid coming from the evaporator of the heat pump. The solar-heated fluid is then directed to the BHEs, where it either extracts or injects energy, depending on its temperature relative to the ground. After passing through the BHEs, the fluid then goes to the evaporator of the CO_2 HP.

A controller that varies the rotational speed of the HP's compressor is used to set the temperature of the hot fluid coming from the CO_2 HP. Another controller sets the flow from the bottom of the TTES to ensure that the temperature there does not go below 50°C. This ensures that the temperature in the DHW distribution system is kept higher than the proliferation temperature of Legionella (20 - 45°C) [36]. The used colder fluid

coming from SH, water heating, and from the bottom of the TTES gets recirculated, mixed, and then reheated in the system. The temperature of the fluid after being used for DHW production was set at 10°C since the city water was assumed to be at 7°C. Although not explicitly modeled here, this assumes that the heat exchange process to supply the heat needed for DHW production occurred at a 3°C pinch temperature. The SH return temperature is varied as one of the control factors. The weather of Bergen, Norway, obtained from the EnergyPlus database [37], was used in this work and the demand side was represented by one year of measured hourly thermal demand data.

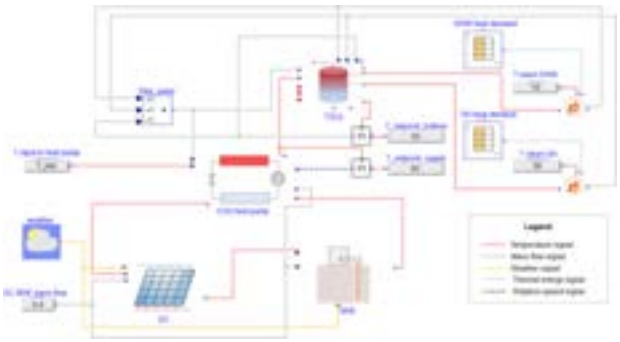

Figure. 1. The CO_2 SAGSHP system model.

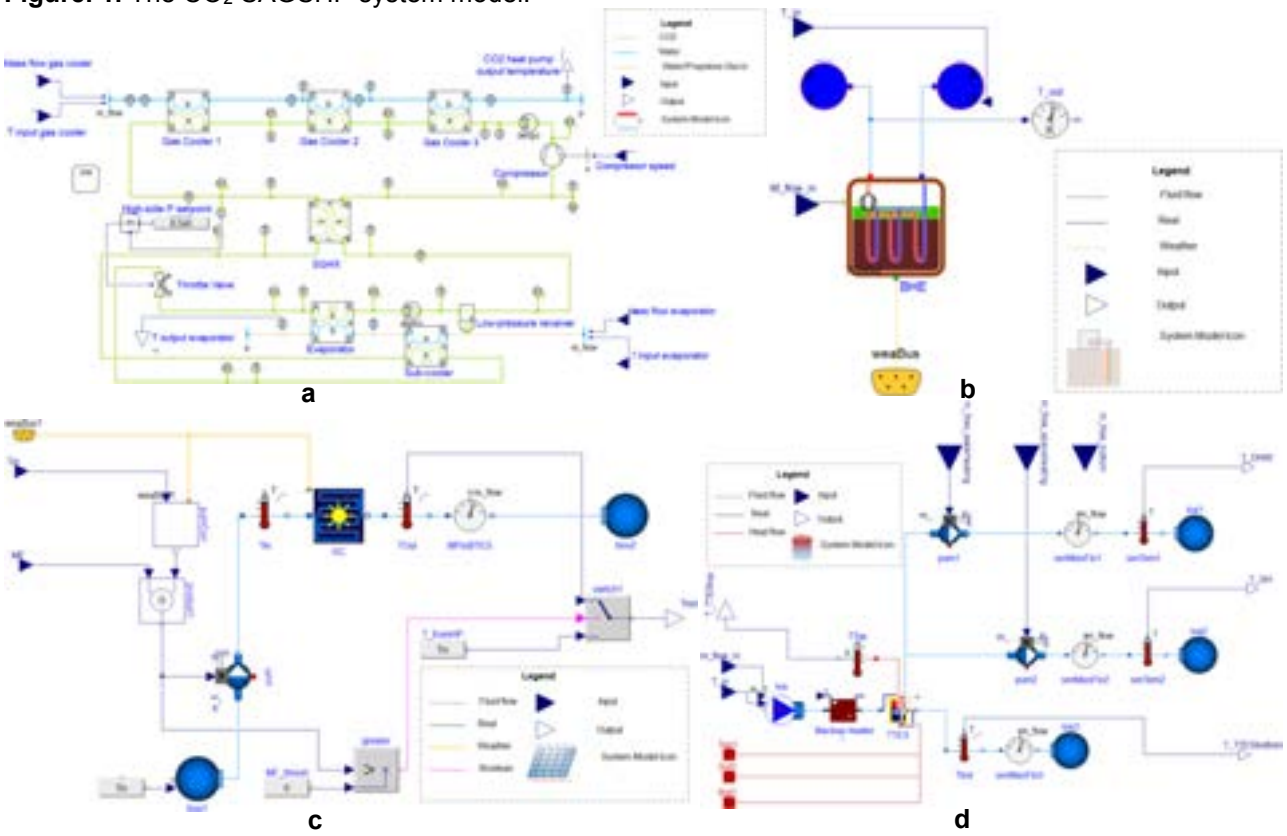

Figure. 2. Component models: (a) CO_2 HP, (b) BHE, (c) SC, (d) TTES.

2.2.1. The CO_2 heat pump model

The CO_2 HP (Figure. 2a), modeled after a 6.5-kW prototype unit [38,39], consists of counter-flow tripartite gas coolers, an evaporator, a compressor, a throttle valve, a suction gas heat exchanger (SGHX), a sub-cooler, and a low-pressure receiver. The throttle valve and the low-pressure receiver function together to control the high-side pressure of the HP [38]. The CO_2 HP model was developed using basic components, such as heat exchangers, valves, and compressors. Thus, it required calibration.

Measured data at the design condition at 85 bars were used to calibrate the model. Available information [38] was used to set the values of some parameters, including the tube diameters of all the tube-in-tube heat exchangers, as well as their weights, material of construction, and length; the size of the low-pressure receiver; and the compressor displacement and operating range. During the calibration, the values of the heat transfer coefficients of every heat exchanger and the efficiencies of the compressor were adjusted until

the model could simulate measured test data (Table 1). The model was calibrated against the data for the high-side pressure P_{GC} = 85 bars, while the other measured data were used to test the calibrated model. Calibration and test errors were obtained by comparing the measured and simulated COPs. The error generated by the calibrated model increases when it is used to simulate the off-design lower high-side pressure. This can be partly attributed to the choice of using a simplified compressor model that assumes constant efficiencies.

Table 1. Calibration of the CO_2 HP unit at ~60°C GC3 output temperature, ~35/30°C GC2 input/output temperature (GC refers the gas coolers; T_E is the evaporator temperature in the CO_2 loop).

Data type	P_{GC} (MPa)	T_E (°C)	Q_{GC1} (W)	Q_{GC2} (W)	Q_{GC3} (W)	Power (W)	Tin/out_{CO2_GC} (°C)	M_{CO2} (kg/s)	COP	Error

2.2.2. The borehole heat exchanger model

The BHE model (Figure. 2b) was developed using the MoBTES library [32]. MoBTES was originally developed under MSL v3.4, but in this work, it was revised to function with MSL v4.0. The parameters assumed for the BHE are given in Table 2. The ground was assumed to have the characteristics of Slate, one of the common rock types in some parts of Norway [40] while the thermal gradient was assumed to be 0.0125 K/m, similar to that of some wells drilled in Bergen, Norway [41].

Table 2. Summary of BHE parameters.

BHE parameter	Value
Geothermal gradient (K/m)	0.0125
Ground density (kg/m^3)	2760
Ground specific heat (J/kg-K)	920
Ground thermal conductivity (W/m-K)	2.1
BHE type	Single U
Borehole diameter (m)	0.15
Tube inner diameter (m)	0.034
Tube thickness (m)	0.003
Tube thermal conductivity (W/m-K)	0.4
Shank spacing (m)	0.08
Grout density (kg/m^3)	1900
Grout thermal capacity (J/kg-K)	1300
Grout thermal conductivity (W/m-K)	1.5

2.2.3. The solar thermal model

The solar thermal component model (Figure. 2c) was developed using the Buildings library v9.0.0 [33]. The main components used here are the solar pump controller and the SCs. The solar pump controller dictates whether the pump to the SCs is active or inactive depending on the value of the incident solar radiation. The pump is activated when the incident solar radiation is higher than the critical radiation, as defined by [42]:

$$G_{TC} = (F_R U_L (T_{in} - T_{ENV}))/(F_R(\tau\alpha)), \quad (1)$$

where G_{TC} is the critical solar radiation, $F_R U_L$ is the heat loss coefficient, T_{in} is the inlet temperature, T_{ENV} is the ambient temperature, and $F_R(\tau\alpha)$ is the maximum efficiency. When the incident solar radiation is lower than G_{TC}, the fluid bypasses the SCs. The solar collector was modeled according to the EN12975 [43] test data for a glazed flat-plate solar collector WTS-F1-K1/K2 from Max Weishaupt GmbH [44] (Table 3).

Table 3. Summary of SC parameters following the EN 12975 test standard

SC parameter	Value
Area/collector (m^2)	2.32
Dry weight (kg)	42
Fluid volume (m^3)	0.0023
Pressure drop during test conditions (Pa)	100
Mass flow per unit collector area (kg/s-m^2)	0.02
Maximum efficiency	0.802
Heat loss coefficient	3.601
Temperature dependence of heat loss	0.014
Incidence angle modifier	0.97

Nominal solar irradiance in ratings data (W/m^2)	1000
Nominal temperature difference in ratings data (K)	20

2.2.4. The tank thermal energy storage model

The TTES component (Figure. 2d) was also developed using the Buildings library. It uses the stratified storage tank model, which implements several volumes that exchange heat between themselves and with the ambient via conduction. Each volume contains a fluid port that may be used to inject or withdraw water to or from the tank. After passing through a backup heater, hot fluid from the heat pump is injected into the top layer. Relatively cold fluid is drawn from the bottom to manage the temperature inside the tank. Hot water from the top layer and the middle layer are withdrawn to provide the energy required for water heating and SH, respectively.

2.2.5. The thermal demand

Hourly demand data for SH and DHW production from a school in Stavanger, Norway was utilized as the reference of the demand input to this model. The choice of using heat demand and weather data from two different cities was due to data availability. Nonetheless, Stavanger and Bergen are two cities close to one another that have relatively similar climate conditions. The capacity of the system model in this study is limited to ~6.5 - 7 kW since the data used to calibrate the CO_2 heat pump is from a 6.5 - 7kW prototype unit. The demand data from the school is much higher than this so it was normalized, by dividing all data by the measured maximum demand, and then multiplied to 3 kW and 3.5 kW for SH and water heating, respectively (Figure. 3). Peak demands, which comprise less than 1% of the total demand data, were also filtered out for simplicity.

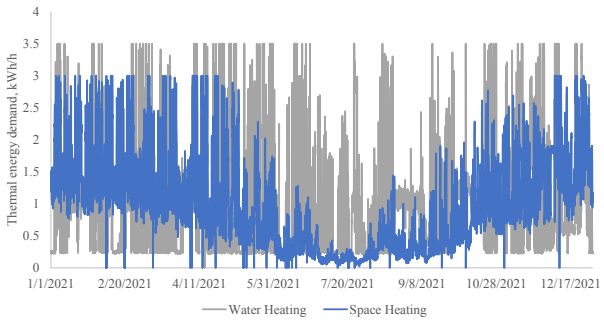

Figure. 3. The thermal energy demand.

3. Methods

The Taguchi method was implemented to determine the runs needed to be simulated, determine the parameters that significantly affect system performance, and determine how to optimize the system concerning individual performance indicators. Multi-objective optimization was then performed by combining the utility concept with the Taguchi method.

3.1. Taguchi method

The Taguchi method is a technique that applies the standard OA to determine the optimal number and set-up of the necessary trial runs for optimization. This allows the determination of the best level of each parameter (control factor) to optimize a given response factor. The first step in this method is the determination of the response factors, the objective functions, the parameters to be considered, and their corresponding levels. In this work, the response factors include the SPF, LCOH, and estimated maximum GTC. The objective is to keep the SPF and GTC high while keeping the LCOH low. Based on the number of control parameters and levels, the OA would be selected. The OA specifies the optimum number of trial runs needed to get maximum information about the system. The minimum number of trial runs to be conducted can be determined by:

$$N_{Taguchi} = 1 + NV(J-1). \quad (2)$$

Where $N_{Taguchi}$ is the minimum number of trial runs, NV is the number of variables, and J is the number of levels. Analysis of the results entails the calculation of the S/N ratio for each run and the analysis of variance (ANOVA). The S/N ratio is a measure of robustness, which is used to identify parameters that reduce process or product variability by minimizing the effects of uncontrollable factors. The S/N ratio of the SPF and GTC were calculated using the higher the better concept (Eq. 3), while the S/N ratio of the LCOH was calculated using the lower the better concept (Eq. 4).

$$Higher\ the\ better\ \frac{S}{N} = -10\ log_{10}\frac{1}{n}\sum_{i=1}^{n}\frac{1}{y_i^2} \quad (3)$$

$$Lower\ the\ better\ \frac{S}{N} = -10\ log_{10}\frac{1}{n}\sum_{i=1}^{n}y_i^2 \quad (4)$$

Where y_i is the raw response factor. ANOVA was used to determine the relative importance of the control factors by computing the percentage contribution of each parameter to the overall response. The degree of freedom (df), the sum of squares (SS), mean squares (MS), significance, and percentage of contribution were all calculated in the analysis.

3.2. The response and control factors

There are 9 control parameters considered, each having 3 levels (Table 4). Given this, an OA with 27 trial runs L_{27} was utilized. A full factorial combination will require 19683 experiments (3^9), which would be too time-consuming and complex. Applying the OA will give the same quality of information with just 27 runs. The BHE length, BHE number, SC area, and TTES volume were chosen since they are known to have a direct relationship with the cost of the system. The BHE spacing was included since it is a way to diffuse the thermal imbalance induced by the system to the ground [25]. The SC-BHE mass flow, CO_2 HP high-side pressure, and HP output temperature were chosen since they are parameters that could easily be controlled. The SH return temperature was included to represent the effects of the efficiency of the distribution system.

Table 4. Control factors investigated and their levels.

Parameter	Label	Level		
		1	2	3
BHE length (m)	A	50	100	150
BHE spacing (m)	B	3	5	7
BHE number	C	4	5	6
SC area (m^2) (number of collectors)	D	6.96 (3)	13.92 (6)	20.88 (9)

*the flow rate of the fluid circulating through the SC, BHE, and the evaporator's waterside
**the temperature of the water as it comes out of the water side of the gas cooler

The values of the different levels of the parameters were determined by running trial simulation runs, some initial sizing calculations, and some operational considerations to ensure that the system would be able to provide the thermal energy demand while keeping the performance at reasonable levels.

The response factors considered in this work are the SPF, LCOH, and GTC. The SPF was calculated by dividing the total energy delivered by the system to the demand for a year by the total energy utilized to run it. The system spends energy to run the compressors and the circulation pumps. The LCOH was calculated by dividing the total cost of the system by its total energy production throughout its lifetime. Note that the electricity cost from 1 year of simulating the operation of the system was assumed to be the cost of the yearly operation. The assumptions used for cost calculations are summarized in Table 5. The GTC was obtained from the BHE model, which gives out the average ground temperature as it is utilized as a heat source or heat sink. The GTC is calculated by dividing the ground temperature after one year of simulation by the initial ground temperature (GTC > 100%: temperature in the ground went up; GTC < 100%: the ground temperature went down). Changes to the GTC were kept minimal, but a higher-the-better concept was applied since the system was designed for heating purposes. SPF, LCOH, and GTC values that are more representative of the long-term performance of the system could be obtained if the model was run for more years. However, because of the relatively big computational load, the simulations were limited to one year only. Trial runs show that the SPF and LCOH do not vary so much. However, the GTC was seen as highest for the first year and substantially declines in the succeeding years, assuming the yearly weather and demand remain similar. Hence, the GTC calculated in this study was assumed to represent the maximum expected temperature decline throughout the lifetime of the system.

Table 5. Summary of parameters used for cost calculations.

Parameter	Value	Reference/Notes
Cost of flat plate SC (EUR/m^2)	632.5	Average of SC costs in [45]
Cost of BHE (EUR/m)	65	[46]
Cost of TTES (EUR/m^3)	1150	Average cost of 0.8 – 2 m^3 TTES [47]
CO_2 Heat pump compressor cost (RMB)	$17547W^{0.4488}$	W is the rated compressor power [48]
CO_2 Heat pump gas cooler cost (RMB)	$1874.4A^{0.9835}$	A is heat exchanger area [48]
CO_2 Heat pump evaporator cost (RMB)	$331.7A^{0.9390}$	A is heat exchanger area [48]
Lifetime of the system (years)	25	[46]
Weighted Average Cost of Capital (WACC)	2%	Weighted Average Cost of Capital (WACC) HP [49]
Exchange rate (USD/EUR)	1/1.01	Exchange rate in Sept. 2022
Exchange rate (USD/RMB)	0.14/1	Exchange rate in Sept. 2022
Exchange rate (NOK/USD)	1/0.0975	Exchange rate in Sept. 2022
Electricity cost (NOK/kWh)	2.4415	Average electricity price in Norway in 2022 [50]

3.3. The utility concept

The utility concept was used to perform multi-response optimization by combining the individual values of the response factors (SPF, LCOH, and GTC) into one unified index called utility [20]. The overall utility function can be expressed as the utility of every performance indicator. Assuming that the performance indicators are independent of one another, the overall utility can be calculated as the sum of individual utilities. Prioritization of the effect of a response factor on the overall utility can be done by introducing a weighting coefficient w_j (Equation 5).

$$U(y_1, y_2, \dots, y_n) = \sum_{j=1}^{n} w_j U_j(y_j) \quad (5)$$

In the utility concept, a preference scale must be set up to represent the lowest and the highest performance. As in previous studies that used the utility concept in thermal energy systems [24–26,28], this study employs a minimum preference number of 0 and a maximum of 9. In a logarithmic scale, the preference number is represented by the formula below so that it has a value of 9 at the optimal level of a performance indicator.

$$U_j(y_j) = P_j = A_j \log \frac{y_j}{y'_j} \;\; with \;\; A_j = \frac{9}{\log \frac{y*}{y'_j}} \quad (6)$$

Where y'_j is the minimum acceptable value of a performance indicator and y* is the optimal value of the performance indicator. The overall utility is then calculated by:

$$U = \sum_{j=1}^{n} w_j P_j. \quad (7)$$

4. Results and discussions

The main objective of the study is to optimize a CO_2 SAGSHP system considering 3 performance indicators: SPF, LCOH, and GTC. Taguchi method was performed first to optimize the systems with regard to each performance indicator individually. Afterward, a combination of the Taguchi method and the utility concept was implemented to perform multi-objective optimization, assuming that all response factors are equally important.

4.1. Taguchi method – the orthogonal array and the S/N ratios

Following the Taguchi design concept, an L_{27} orthogonal array was chosen. Each trial run was performed according to the combination of parameters determined by this array to get the values of the response factors and the S/N ratios (Table 6). The S/N ratio values for the SPF and GTC were calculated using the higher-the-better concept while those for LCOH were calculated with the lower-the-better concept. The S/N ratios were then averaged in consideration of the different levels of each control factor (Figure. 4).

Table 6. The Taguchi L_{27} (3^9) standard orthogonal array and the experimental plan.

Trial No.	A	B	C	D	E	F	G	H	I	Response Factors			S/N ratios

The combination of the levels that give the highest average S/N represents the optimal setup. Thus, the combination of control factors that gave the optimum SPF is A1B3C1D1E1F1G1H3I1. The effect of a certain control factor on the response factor could be inferred from the difference between the highest and the

lowest value of the S/N ratio. It could be seen that the SPF is most responsive to HP output temperature (I) and least sensitive to the TTES volume (E). Higher SPFs are expected when the target output temperature of the HP (I) is set low because less energy is needed by the compressor to reach a lower output temperature for a given high-side pressure. However, this is limited by the minimum temperature requirements of the DHW and SH distribution systems. Applying the determined control factor combination in simulation resulted in an optimal SPF of 4.2.

The combination of control factors that would give the optimum LCOH is A1B2C1D1E1F1G1H3I1. This resulted in an optimal LCOH of 0.122 USD/kWh, which is comparable to the LCOH of some conventional solar thermal combi HP systems [51]. As expected, optimizing the LCOH requires the reduction of capital and operation expenses, like using shorter and fewer BHEs (C), a smaller SC area (D), a smaller tank (E), a smaller pumping requirement (F), and a lower HP output temperature (I).

For GTC, the optimum parameter combination is A3B3C3D3E1F1G3H1I3. This resulted in an optimal GTC of 100.24%. The GTC is most responsive to the BHE spacing (B) and SC area (D). This means that the reduction of the temperature in the ground could be reduced by increasing the spacing between the BHEs or increasing the solar input to the system. Large solar input could even increase ground temperature, which could be beneficial to the system to some extent. Drilling deeper and more boreholes could also help, albeit would entail higher costs.

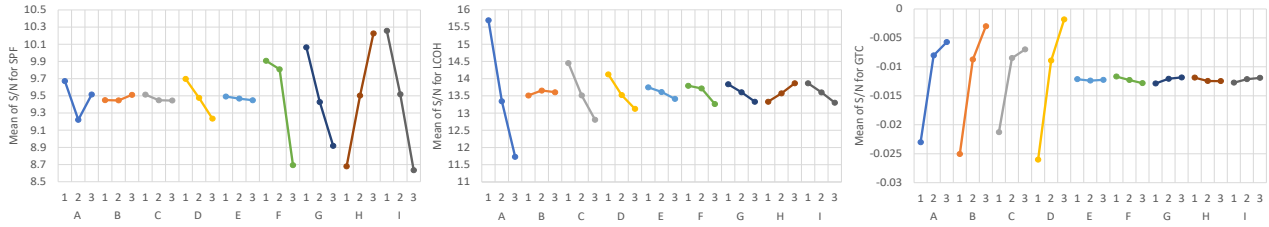

Figure. 4. The Taguchi average S/N ratio for each control parameter for every response factor.

4.2. Taguchi method – ANOVA analysis

ANOVA was used to estimate the relative significance of each parameter in terms of percentage contribution to the overall response (Table 7). The significance denotes which control factors could induce statistically significant effects on the response factor at different confidence levels. As shown, the SPF was most sensitive to the target output temperature of the HP. It is also noticeably more responsive to the operating parameters (F-I) than the design parameters (A-E). The LCOH is most sensitive to the BHE length (A) and number (C) since the BHE is the most expensive component of the system. This shows the influence of capital expenses. Almost all control parameters considered induced statistically significant changes to the LCOH. In contrast to the SPF, the GTC is mostly affected by the design parameters (A-D). The SC area (D) and BHE spacing (B) are shown to be the main contributors to the GTC.

Table 7. The results of the ANOVA for each response factor.

4.3. Utility-Taguchi – S/N ratios

The utility index for each trial run for every response factor was calculated assuming that all response factors have equal weights (Table 8). The utility index is a number between 0 to 9 that represents the performance of the system (closer to 9 = better performance). The corresponding S/N ratios of the global utility indices were next calculated using the higher-the-better concept. The average S/N ratios are plotted in Figure. 5.

Taking note of the highest S/N ratio for each control parameter gives an optimal parameter combination of A1B3C2D3E2F1G1H3I1. This combination gives the best overall performance of the system. This results in

a global utility index of 6.77 (SPF of 3.58, an LCOH of 0.165 USD/kWh, and a GTC of 100.03%). Compared to a SAGSHP system that uses a conventional working fluid, this optimized system exhibited a slightly lower SPF ($SPF_{conventional}$ = 3.89) [52] and comparable LCOH ($LCOH_{conventional}$ = 0.043 – 0.206 USD/kWh) [51], and GTC (<1°C increase) [52]. Although relatively good performance has been observed, other system or component changes can be explored to further improve its overall performance.

Table 8. The utility indices and their S/N ratios

Trial	SPF utility	LCOH utility	GTC utility	Global utility	S/N ratio global utility
1	6.76	8.41	0.15	5.11	14.16

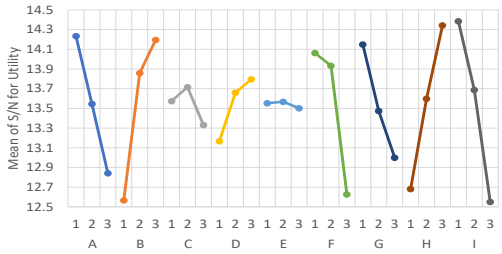

Figure. 5. The Taguchi average S/N ratio for each control parameter for every response factor.

4.4. Utility-Taguchi – ANOVA

As shown in Table 9, the utility index of a CO_2 SAGSHP is most sensitive to the BHE length (A) and least sensitive to the TTES size (E). Relatively significant contributions can also be seen from the output temperature of the HP (I), BHE spacing (B), high-side pressure of the HP (H), and mass flow rate of the fluid circulating through the BHE and SC (F).

Table 9. The results of the ANOVA for the utility index

	df	SS	MS	F	Pr(>F)	Significance	Contribution
			Utility Index				
A	2	25.138	12.569	22.415	0.001	***	22.64%

5. Conclusion

A SAGSHP system that utilizes CO_2 as a working fluid was modelled and then optimized in this study using the Taguchi method and the utility concept. The system was first optimized with regards to the SPF, LCOH, and GTC individually using the Taguchi method. Then a combination of the Taguchi method and the utility concept was then applied to perform multi-response optimization, considering the overall performance of the system if the SPF, LCOH, and GTC were deemed of equal importance.

The different combinations of control parameters that optimize the SPF, LCOH, and GTC individually, are A1B3C1D1E1F1G1H3I1, A1B2C1D1E1F1G1H3I1, and A3B3C3D3E1F1G3H1I3, respectively. Applying these set-ups to the model results in an optimal SPF of 4.2, LCOH of 0.122 USD/kWh, and GTC of 100.24%. According to the ANOVA results, the most influential control factors are the HP's target output temperature, the BHE length, and the SC area for the SPF, LCOH, and GTC, respectively.

Combining the Taguchi method with the utility concept allows multi-objective optimization to determine the parameter set-up that will give the optimal overall performance, considering all response factors are weighed equally. By this, the parameter combination that gave the optimal utility index is A1B3C2D3E2F1G1H3I1. This resulted in a 3.58 SPF, a 0.165 USD/kWh LCOH, and a 100.03% GTC. Compared to a SAGSHP system that uses a conventional working fluid, this optimized system exhibited a slightly lower SPF but comparable LCOH. Although relatively good performance has been observed, other system or component changes can be explored to further improve its overall performance. For instance, other system configurations could be examined.

Nomenclature

$\mathrm{F_R U_L}$	heat loss coefficient, W/(m² K)	NV	number of variables
$\mathrm{F_R}(\tau\alpha)$	maximum efficiency of the solar collector	T_{ENV}	ambient temperature, K
G_{TC}	critical solar irradiation, W/m²	T_{in}	inlet temperature, K
J	number of levels	U	overall utility index
$N_{Taguchi}$	minimum number of Taguchi trial run		

Subscripts and superscripts

C	compressor	DHW	domestic hot water
$CO2$	CO_2 working fluid	E	evaporator
$CO2\_GC$	CO_2 through the gas coolers	GC	gas cooler

Abstract:

This works aims at evaluating the impact of different ratios of heating design loads to cooling ones on the thermodynamic efficiency of a R290 air-to-water reversible heat pump with the aid of an exergy analysis. The potential improvements of the investigated solution were also assessed. The heat pump was sized for a two-pipe fan-coil system designed with supply/return water temperatures of 45/40 °C in winter and 7/12 °C in summer. The outdoor air was cooled from -7 ℃ to -12 ℃ in heating mode and heated from 30 ℃ up to 35 ℃ in cooling mode, respectively. The heating loads were varied in a range from 8 kW to 13 kW, whereas the cooling loads were ranged between 6 kW and 15 kW, respectively.

The results obtained showed that heat exchanger sizing plays a significant impact on the distribution of exergy destruction within the system components. As the system was sized based on the cooling load, the air-based heat exchanger was found to be oversized and the water-based heat exchanger was observed to be undersized for covering the heating loads and vice versa. It was also found that for the ratios of heating design loads and cooling ones less than 1.2 the system should be sized based on the cooling design loads. In this case lower system exergy destruction could be obtained. Furthermore, in this case the thermodynamic improvement of the air-based heat exchanger, the water-based heat exchanger and the compressor had approximately the same potential of increasing the efficiency of the system. As the ratios of heating design loads and cooling ones were higher than 1.2, the heating load should have been used for sizing the system components due to higher thermodynamic efficiency of the system compared to the previous case and technical possibilities to be operated. Removing the avoidable irreversibilities within the air-based heat exchanger offered the biggest decrease of the exergy destruction within the system.

Keywords:

Exergetic analysis; Exergy destruction; Heat pump; Propane; Thermodynamic enhancement.

1. Introduction

Today a large offer of reversible heat pumps with investment costs comparable to those of non-reversible units is available. These solutions are one of the most widely used heating, ventilation and air conditioning (HVAC) technologies in Europe. About 70 % of air-conditioned office buildings are cooled down by reversible heat pumps [1]. Such units have the ability to provide low carbon heating and cooling and great thermal comfort levels through one distribution system (assuming the emitter is capable of providing both modes).

During the last decades the research has demonstrated the impact of refrigerants on ozone depletion and global warming. So, the implementation of highly thermodynamically efficient heat pumps relying on very low global warming potential (GWP) refrigerants is compulsory.

The authors of [2] dealt with a numerical analysis of a reversible air-source heat pump incorporated into the HVAC system of a typical office building. The results obtained showed that energy performance of the system strongly depended on the of the unbalance indicator, estimated as the ratio of cooling loads to heating ones of the building, and of the overall index of heat pump oversizing/downsizing with respect to the design loads of the building.

In [3] the simulation model of an air-to-water R410A based reversible heat pump was developed to simulate its performance at off design conditions. The annual efficiency of the system was found to be able to be maximized by changing temperature, flow rate of air and water and refrigerant mass flow rate.

The relationship between air-to-water heat pump performance using R410A and the Italian building heating and cooling loads was numerically investigated by Madonna et al. [4]. The authors observed that the reversible heat pump oversizing can cause an excessive on/off cycling and an efficiency reduction (up to 25 %).

Most of current heat pumps use hydrofluorocarbons (HFCs), which have a massive GWP. Therefore, in the last decade several studies have been devoted to investigate environmentally friendlier alternatives, e.g. hydrofluoroolefins (HFOs) [5] and hydrocarbons (HFC) [6]. However, the recent environmental concerns on HFOs are promoting the adoption of natural refrigerants. In addition, [6] observed that R290 is a better substitute for R134a than R600a for residential heat pump water heaters.

From the review made above, it is possible to conclude that the reversible heat pump sizing strongly affects energy efficiency of such systems. Most of the investigations has been based on analyses focusing on conventional objective variables and conventional energy assessments. However, application of exergy analysis would provide better insight into possibilities to reveal the location, the magnitude and the sources of thermodynamic inefficiencies within the system. Advanced exergy analysis additionally considers thermodynamic interactions among components and the real potential for the system improving. Investigations of reversible heat pumps with ultra-low GWP refrigerants are also of high interest. Thus, the goal of this work is to bridge this knowledge gap by applying the exergy methodology for sizing an air-to-water reversible heat pump with propane and evaluating the real potential for its thermodynamic improvement.

2. Materials and Methods

2.1. Conventional Exergy Analysis

In the conventional exergetic evaluation of the k-th component of the investigated system, the following equations were used [7]:

- Gouy–Stodola theorem

$$\dot{E}_{D,k} = T_0 \dot{S}_{gen,k}, \qquad (1)$$

where $\dot{E}_{D,k}$ is exergy destruction rate within the k-th component, T_0 is temperature of the reference environment and $\dot{S}_{gen,k}$ is the entropy generation owing to internal irreversibilities;

- the exergy balance for the k-th component

$$\dot{E}_{F,k} = \dot{E}_{P,k} + \dot{E}_{D,k}, \qquad (2)$$

where $\dot{E}_{F,k}$ and $\dot{E}_{P,k}$ are exergy rates associated with fuel and product of the component, respectively.

2.2. Evaluation of Removable Exergy Destruction

Since evaluating removable parts of exergy destruction occurring in each system component was within the scope of the work the method presented in [8] was applied. According to this method, the avoidable exergy destruction rate ($\dot{E}_{D,k}^{AV,INT}$), which is internally caused, can be computed as the difference between the total exergy destruction of the investigated component ($\dot{E}_{D,k}$), i.e., calculated under real operation conditions, and its exergy destruction ($\dot{E}_{D,k}^{MIN,k}$) evaluated under conditions at which its irreversibilities are reduced by improving its efficiency while accounting for the fact that the remaining components are operating under real conditions:

$$\dot{E}_{D,k}^{AV,INT} = \dot{E}_{D,k} - \dot{E}_{D,k}^{MIN,k}. \qquad (3)$$

The avoidable exergy destruction within the k-th component, which is caused by the avoidable irreversibilities occurring within the r-th component (i.e., externally caused) ($\dot{E}_{D,k}^{AV,EXT,r}$), can be computed by subtracting the exergy destruction rate ($\dot{E}_{D,k}^{MIN,r}$) within the k-th component under the conditions at which the r-th component operates with reduced irreversibilities and the remaining components are operated under their real conditions from the exergy destruction rate ($\dot{E}_{D,k}$) occurring within the k-th component under its real operation conditions:

$$\dot{E}_{D,k}^{AV,EXT,r} = \dot{E}_{D,k} - \dot{E}_{D,k}^{MIN,r}. \qquad (4)$$

The importance of the components from the thermodynamic viewpoint and priorities for improving the k-th components were identified on the basis of the sum of the internally caused avoidable exergy destruction ($\dot{E}_{D,k}^{AV,INT}$) and the externally caused avoidable exergy destruction within the remaining components ($\dot{E}_{D,r}^{AV,EXT,k}$)

$$\dot{E}_{D,k}^{AV,\Sigma,INT,EXT} = \dot{E}_{D,k}^{AV,INT} + \sum_{\substack{r=1 \\ r\neq k}}^{n-1} \dot{E}_{D,r}^{AV,EXT,k} . \qquad (5)$$

2.2. Case Study

The investigated heat pump system was considered to be able to be reversed by means of a refrigerant change-over, which reverses the flow passage into the two exchangers (Figure 1). In cooling mode, the air-based heat exchanger (outside heat exchanger) worked as condenser, rejecting heat into the outdoor air, while the water-based heat exchanger (inside heat exchanger) worked as an evaporator, absorbing heat from the two-pipe water distribution system. In heating mode, the air exchanger worked as an evaporator, absorbing heat from outdoor air, while the water exchanger worked as a condenser, transferring heat into the same distribution system. It was assumed that the cold-emission terminal units were adapted for hot emission at low temperatures.

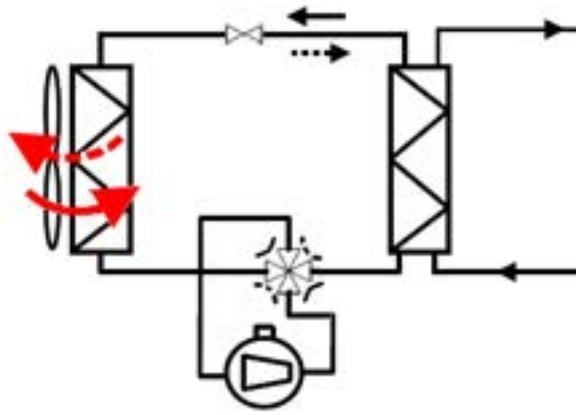

Figure. 1. Investigated reversible air-to-water unit connected to a two-pipe distribution system.

In heating mode the outside air was assumed to be cooled in the air-based heat exchanger from −7 °C down to −12 °C and the water was assumed to be heated in the condenser (water-based heat exchanger) from 40 °C up to 45 °C. In cooling mode the outside air was assumed to be heated in the outside heat exchanger (condenser) from 30 °C up to 35 °C and the chilled water was assumed to be cooled in the inside heat exchanger (evaporator) from 12 °C down to 7 °C. The pinch-point temperature in the outside and inside heat exchangers were taken as 12 K and 5 K, respectively. The pressure drop of the working fluids in the pipes and components was neglected.

In the design mode, which was used for sizing system, the following assumption were made:

- the evaporation temperature of R290 was calculated as the difference between the temperature of the secondary working fluid (air for heating mode and chilled water for cooling mode, respectively) at the evaporator outlet and the pinch point temperature difference in the evaporator (12 K or 5 K, respectively);
- the temperature of R290 at the compressor inlet was increased by 5 K due to superheating within the evaporator;
- the condensation temperature of R290 was calculated by adding the value of the pinch point temperature of the condenser (5 K or 12 K, respectively) to the temperature of the secondary working fluid (heated water or outside air, respectively) at the condenser outlet.

The specific power required by compressor was estimated from the following equation [3], [9]

$$l_{CM} = \frac{\left(h_{CM,in} - h_{CM,out}\right)}{\eta_{is}}, \qquad (6)$$

where η_{is} is the compressor's isentropic efficiency, and $h_{CM,in}$ and $h_{CM,out}$ are the specific enthalpies at the inlet and outlet of the compressor, respectively.

Specific enthalpy at the compressor outlet after real compression was calculated as

$$h_{CM,out} = h_{CM,in} + \frac{h_{CM,out,is} - h_{CM,in}}{\eta_{is}}, \qquad (7)$$

where $h_{CM,out,is}$ is the specific enthalpy at the compressor outlet after isentropic compression.

The volumetric (η_{vol}) and isentropic (η_{is}) efficiencies of the compressor were calculated using Pierre's correlations for "good" reciprocating compressors [10] following the methodology used in [11], [12]:

$$\eta_{vol} = k_1 \cdot \left(1 + k_s \cdot \frac{t_{CM,in} - 18}{100}\right) \cdot exp\left(k_2 \cdot \frac{p_{CM,in}}{p_{CM,out}}\right); \qquad (8)$$

$$\frac{\eta_{vol}}{\eta_{is}} = \left(1 + k_e \cdot \frac{t_{CM,in} - 18}{100}\right) \cdot exp\left(a \cdot \frac{T_1}{T_2} + b\right), \qquad (9)$$

where $t_{CM,in}$ is the refrigerant temperature at the compressor inlet, $p_{CM,in}/p_{CM,out}$ is the pressure ratio, T_1/T_2 is the ratio of the condensation and evaporation absolute temperatures (in Kelvin) corresponding to the discharge and the suction compressor pressures. The remaining symbols - k_1, k_s, k_2, k_e, a and b - are constants equal to 1.04, 0.15, −0.07, −0.1, −2.40, and 2.88, respectively.

The expansion valve was modelled as an isenthalpic component

$$h_{EXV,in} = h_{EXV,out}, \qquad (10)$$

where $h_{EXV,in}$, $h_{EXV,out}$ are the specific enthalpies at the inlet and outlet of the expansion valve, respectively.

Mass flow rate of R290 under design conditions in heating mode was calculated as

$$\dot{m}_{wf} = \frac{\dot{Q}_{Heat}^{Design}}{h_{CD,in} - h_{CD,out}}, \qquad (11)$$

where $\dot{Q}_{Heat}^{Design}$ is the heating load of the system at the design conditions, $h_{CD,in}$ is the specific enthalpy of the refrigerant at the condenser inlet (i.e. at the compressor outlet) and $h_{CD,out}$ is the specific enthalpy of the refrigerant at the condenser outlet.

And consequently, the heat transfer rate in the evaporator was calculated as

$$\dot{Q}_{EV} = \dot{m}_{wf}\left(h_{EV,out} - h_{EV,in}\right), \qquad (12)$$

where $h_{EV,out}$ and $h_{EV,in}$ are the specific enthalpies of R290 at the evaporator's outlet and inlet, respectively.

In cooling mode the mass flow rate of R290 was calculated by the following equation

$$\dot{m}_{wf} = \frac{\dot{Q}_{Cool}^{Design}}{h_{EV,out} - h_{EV,in}}, \qquad (13)$$

where $\dot{Q}_{Cool}^{Design}$ is the cooling load of the system at the design conditions, $h_{EV,out}$ is the specific enthalpy of the refrigerant at the evaporator outlet (at the compressor inlet) and $h_{EV,in}$ is the specific enthalpy of the refrigerant at the evaporator inlet (at the expansion valve outlet).

Hence, the heat transfer rate of the condenser was found as

$$\dot{Q}_{CD} = \dot{m}_{wf}\left(h_{CD,in} - h_{CD,out}\right). \qquad (14)$$

The power required by compressor was evaluated as

$$\dot{W}_{CM} = \dot{m}_{wf}\left(h_{CM,out} - h_{CM,in}\right). \qquad (15)$$

The compressor swept volume ($\dot{V}_s$) was estimated using the following equation

$$\dot{V}_s = \frac{\dot{m}_{wf}\upsilon_{CM,in}}{N\eta_{vol}}. \qquad (16)$$

where N is the compressor rotational speed, η_{vol} is the compressor's volumetric efficiency and $\upsilon_{CM,in}$ is the specific volume of R290 at the suction line of the compressor.

Mass flow rates of the secondary fluids through the heat exchangers were governed by the energy rate balance equations

$$\dot{m}_{air(water)} = \frac{\dot{Q}_{EV}}{\left(h_{air(water),in} - h_{air(water),out}\right)}; \qquad (17)$$

$$\dot{m}_{water(air)} = \frac{\dot{Q}_{CD}}{\left(h_{water(air),out} - h_{water(air),in}\right)}; \qquad (18)$$

where h_{air} and h_{water} are the specific enthalpies of the air and water at inlet (in) and outlet (out), respectively.

The condenser was divided into two main sections: the de-superheating region and the phase change region. The subcooled zone was neglected. The evaporator consisted of an evaporation region and a superheating one. The heat transfer rate within these sections was evaluated using the logarithmic mean temperature difference approach [3], [9]

$$\dot{Q} = U \cdot A \cdot LMTD, \qquad (19)$$

where $\dot{Q}$ is the heat transfer rate, U is the overall heat transfer coefficient, A is the heat transfer area of the considered section and $LMTD$ is the logarithmic mean temperature difference defined by the following equation

$$LMTD = \frac{\Delta T_2 - \Delta T_1}{ln\left(\frac{\Delta T_2}{\Delta T_1}\right)}, \qquad (20)$$

where ΔT_1 and ΔT_2 are temperature differences between the working fluids on the hot and cold sides at each end of the considered section.

For the air-based heat exchanger (finned-tube heat exchanger), the following expression for the overall heat transfer coefficient referring to secondary fluid heat transfer surface was applied

$$U = \left(\frac{1}{\alpha_{air}} + \frac{1}{\alpha_{wf}} \cdot \frac{A_{air}}{A_{wf}}\right)^{-1}, \qquad (21)$$

where A_{air} and A_{wf} are the heat transfer areas on the air and the refrigerant side, respectively, and α_{air} and α_{wf} are the corresponding heat transfer coefficients, respectively.

The plate heat exchanger was designed as the inside unit.

The data presented in [13], [14], [15] were generalized and used for calculation of the overall heat transfer coefficients within the specified condenser and evaporator regions.

The temperature and absolute pressure of the outside air were used to ascertain the thermodynamic properties at the evaporator inlet for heating mode and at the condenser inlet for cooling mode, respectively.

The thermo-physical properties of all the working fluids were evaluated via CoolProp [16]. The simulations were performed through MATLAB software package.

The same procedure was applied for the design of the system and estimation of internally and externally caused exergy destruction with pinch point temperatures in the air-based heat exchanger and the water-based heat exchanger equal to 6 K and 2 K, respectively and increased efficiency of the compressor by 10 % compared to real designed conditions.

After finding geometric parameters of the system, the operating characteristics were calculated for off-design conditions. During the off-design operations in heating mode, the water temperatures at the inlet and outlet of the water-based heat exchanger were equal to 40 °C and 45 °C, respectively. During cooling mode at the off-

design conditions, the water temperatures at the water-based heat exchanger's outlet and inlet were equal to 7 °C and 12 °C, respectively. Then, the mathematical approach suggested in [17] was adopted to assess the thermodynamic parameters of the investigated heat pumps under off-design conditions in both cooling and heating modes. During these calculations the mass flow rate of the working fluid was governed by the Eq. (16). Eq. (19) was used for the evaluation of either the heat transfer rates or the temperatures within considered heat transfer section.

As the main focus of this work is on the implementation of an exergetic evaluation, the overall heat transfer coefficients were considered as constant under off-design modes and equal to the ones estimated for the design mode.

The off-designed modes were estimated under real operation conditions and under conditions conducive to the evaluation of the removable exergy destruction.

Exergetic analysis was performed based on the selection of the ambient (outdoor) air parameters as the reference ones [18].

3. Results and Discussion

Heat transfer areas of the air- and water-based heat exchangers, which were required for covering heating or cooling loads by the inside heat exchanger, are presented in Figure 1. It could be observed that in general for covering cooling loads the air-based heat exchanger was found to be larger and the water-based heat exchanger was found to be smaller compared to the required heat transfer areas for covering the same heating loads with the same pinch point temperature. Also, the value of oversizing or undersizing depended on the ratios between heating and cooling loads ($\dot{Q}_{Heat}/\dot{Q}_{Cool}$), which then was found to affect the irreversibilities within the components.

For example, if the system had been sized with the specified pinch point temperature within heat exchangers on the base of heating design loads equal to 12 kW the area of the outside heat exchanger should have been 7.7 m^2 and the area of the inside heat exchanger should have been 2.2 m^2. However, for providing the same cooling load with the same pinch point temperature the heat transfer area of the outside and inside heat exchangers should have been 18.4 m^2 and 1.3 m^2, respectively. Thus, the system designed in this way would have had undersized area of the air-based heat exchanger for operation with 12 kW cooling load, which should have been compensated with larger temperature difference, leading to increased irreversibilities within the outside heat exchanger, expansion valve and compressor. On the other hand, the water-based heat exchanger of the system would have had oversized area for covering 12 kW cooling demand, which would have provided lower temperature difference within the heat exchanger and thus decreased irreversibilities within this component, expansion valve and compressor. The higher the ratios of heating demand to cooling one ($\dot{Q}_{Heat}/\dot{Q}_{Cool}$) for the system designed on the base of heating loads, the better agreement between the designed and required areas of the air-based heat exchanger and larger oversizing of the designed areas of water-based heat exchanger for covering cooling loads.

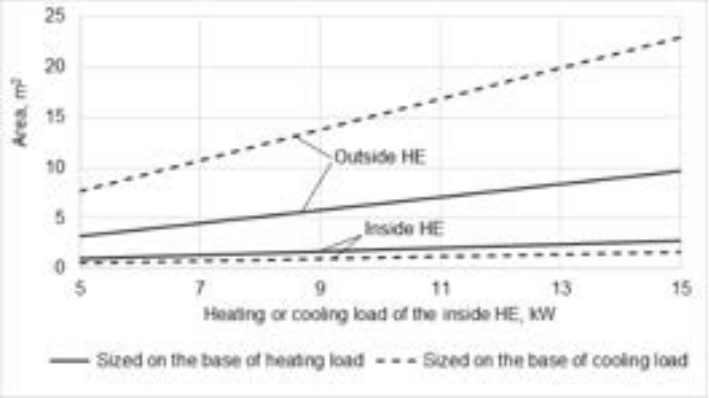

Figure. 2. Needed heat transfer areas for the air- and water-based heat exchangers required for covering the heating or cooling loads of the water-based heat exchanger.

If the system had been sized using a cooling design load of 10 kW, the areas of the outside and inside heat exchangers would have been equal to 15.3 m^2 and 1.1 m^2, respectively, and appropriate exergy destruction would have been obtained. In case of providing 10kW of heating load, due to oversized area of the air-based heat exchanger and undersized area of the water-based heat exchanger, this system would demonstrate other values of exergy destruction. For higher ratios $\dot{Q}_{Heat}/\dot{Q}_{Cool}$ of the system designed on the base of the cooling loads the degree of difference between the designed areas of the air-based heat exchanger and the needed

ones for covering heating loads would have been smaller. However, undersizing the water-based heat exchanger for covering heating loads would have been bigger.

The distribution of the exergy destruction rates in the components of the investigated system sized on the base of the heating design load with different ratios between heating and cooling loads ($\dot{Q}_{Heat}/\dot{Q}_{Cool}$) is shown in Figure 3. It could be seen that when the designed system was operated for covering cooling loads (empty circles in Figure 3a) at the ratios of heating loads to cooling ones ranging from 0.65 to 1.4 the air-based heat exchanger had much larger exergy destruction rates compared to the mode operated for covering heating loads (filled circles in Figure 3,a). This could be obtained due to undersized area of the outside heat exchanger, which was explained with the above suggestions (see Figure 2).

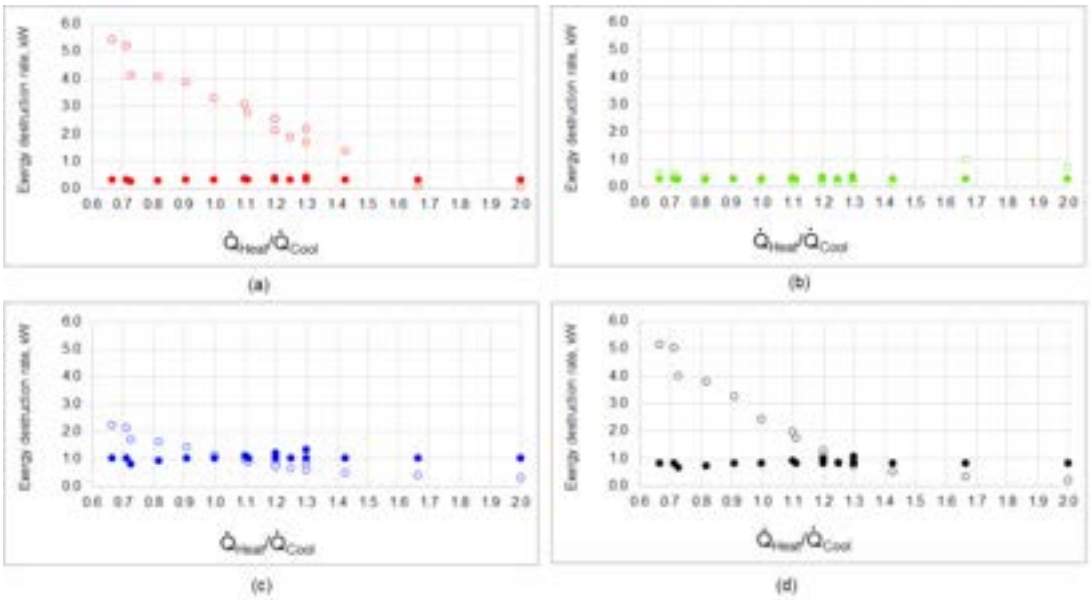

Figure. 3. Exergy destruction rates in the components of the system sized on the base of heating design loads with different ratios to heating loads and cooling ones: a) outside heat exchanger, b) inside heat exchanger, c) compressor, d) expansion valve, filled circles – operated for covering heating load, empty circles - operated for covering cooling load.

Oversized areas of the water-based heat exchanger did not change substantially exergy destruction rates within the inside heat exchanger operated for covering cooling loads (see Figure 3b).

At the ratios of heating loads and cooling ones ranging from 0.65 to 1.4 temperature differences in the air-based heat exchanger was increased. As a result, it provided higher pressure ratios in the compressor and the expansion valve. The exergy destruction within these components was incresed (empty circles in Figure 3c and Figure 3d) in comparison to heating modes (filled circles in Figure 3c and Figure 3d).

If the system had been sized on the base of the cooling design loads (Figure 4) it could not have been operated for the values of $\dot{Q}_{Heat}/\dot{Q}_{Cool}$ higher than 1.3 due to technological limitations. Similarly to the previous scenario, in case of sizing system based on cooling design loads the outside heat exchanger would have been oversized for covering heating loads, resulting in decreased exergy destruction rates (filled circles in Figure 4a) within this component compared to the cooling modes (empty circles in Figure 4a). For $\dot{Q}_{Heat}/\dot{Q}_{Cool}$ values higher than 0.8, in case of the use of an undersized water-based heat exchanger during heating modes, the exergy destruction rates would have been higher (filled circles in Figure 4b) than during cooling modes (empty circles in Figure 4b). As it was said above, oversized and undersized areas led to a decrease and an increase of temperature driving force for heat transfer (temperature differences) and pressure ratios, respectively. As a result, exergy destruction rates within compressor and expansion valve in heating mode (filled circles in Figure 4c and Figure 4d) were found to be larger than during cooling modes (empty circles in Figure 4c and Figure 4d).

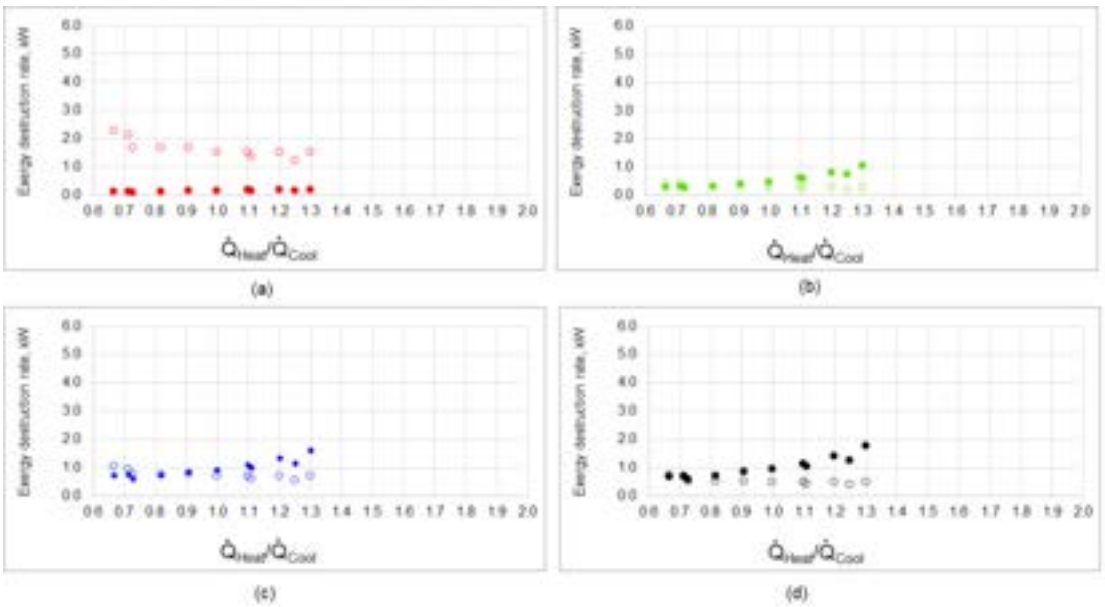

Figure. 4. Exergy destruction rates in the components of the system sized on the base of cooling design loads with different ratios of heating loads and cooling ones: a) outside heat exchanger, b) inside heat exchanger, c) compressor, d) expansion valve, filled circles – operated for covering heating load, empty circles - operated for covering cooling load.

The values of the total exergy destruction rates in the system with different ratios of heating loads and cooling ones are shown in Figure 5.

It was found that for the ratios of heating loads and cooling ones within the range 0.65 to 1.2 the system should have been sized based on the cooling loads. For such design lower total exergy destruction within the system could have been obtained (from 4.5 kW to 6.5 kW) compared to the system sized on the base of heating loads, which demonstrated higher total exergy destruction (from 12.0 kW to 6.5 kW).

As the ratios of heating design loads and cooling ones were higher than 1.2, the heating design load should have been used for sizing the system components. Under such design conditions thermodynamic efficiency of the system was substantially decreased.

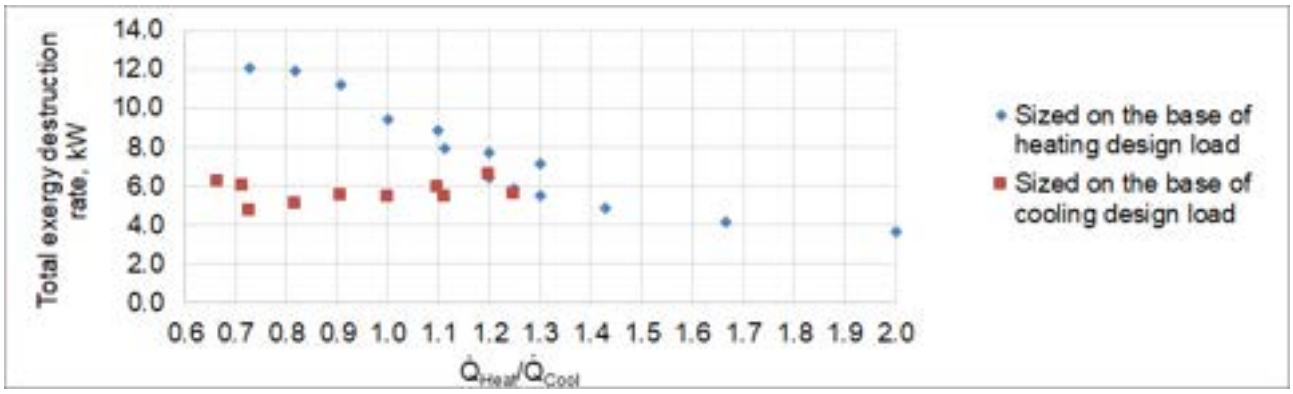

Figure. 5. Total exergy destruction rates in the system with different ratios between heating and cooling loads.

The values of the removable and internally caused exergy destruction rate within the k-th component ($\dot{E}_{D,k}^{AV,INT}$) and that of the removable and externally caused exergy destruction rate within the remaining components caused by the k-th component ($\dot{E}_{D,r}^{AV,EXT,k}$) for the system designed on the base of heating load are presented in Figure 6. The system was operated for covering 10 kW and 7 kW of heating and cooling loads, respectively.

It was observed from Figure 7 that 0.44 kW of removable exergy destruction rate in the compressor could be reduced by improving this component. Another smaller part of removable exergy destruction rate in the compressor was caused by the irreversibilities that occurred in the remaining components: inside heat exchanger (i.e. 0.07 kW) and outside heat exchanger (0.29 kW). Also, 0.11 kW of removable exergy destruction rate within the inside heat exchanger could be reduced by decreasing the irreversibilities within this component. Another part of removable exergy destruction rate within the water-based heat exchanger

(0.06 kW) could be eliminated by improving the remaining components (i.e. compressor and air-based heat exchanger). The results obtained from the proposed methodology indicated that the internally caused and removable exergy destruction rate in the expansion valve was zero. This means that the exergy destruction rate within this component could be reduced through the enhancement in the remaining components. The inside heat exchanger was found to be responsible for 0.12 kW of exergy destruction rate, which could be removed within the expansion valve. In addition, 0.38 kW of removable exergy destruction rate within the expansion valve were caused by irreversibilities within outside heat exchanger. Furthermore, 0.04 kW of removable exergy destruction rate within the expansion valve depended on irreversibilities taking place in the compressor. According to the results presented in Figure 6 the largest value of exergy destruction rate, which could be removed in the air-based heat exchanger, was internally caused (0.62 kW). Furthermore, 0.12 kW and 0.05 kW of avoidable exergy destruction within the outside heat exchanger depended on irreversibilities taking place in the compressor and the inside unit, respectively.

Therefore, according to the results obtained the highest priority for improvement of the considered system had to be given to the air-based heat exchanger. This was due to the fact that the sum of the internally caused and the externally caused exergy destruction rates, which could be avoided within the investigated heat pump with the help of improving this component, was the highest one and equal to 1.32 kW (i.e. 58 %) (Figure 6). Secondly, the investigator needed to focus on the compressor, being accountable for 0.63 kW (i.e. 27 %) of avoidable exergy destruction within the evaluated system. Thirdly, the water-based heat exchanger enhancement was found to lead to a potential decrease of 0.35 kW (i.e. 15 %) of exergy destruction.

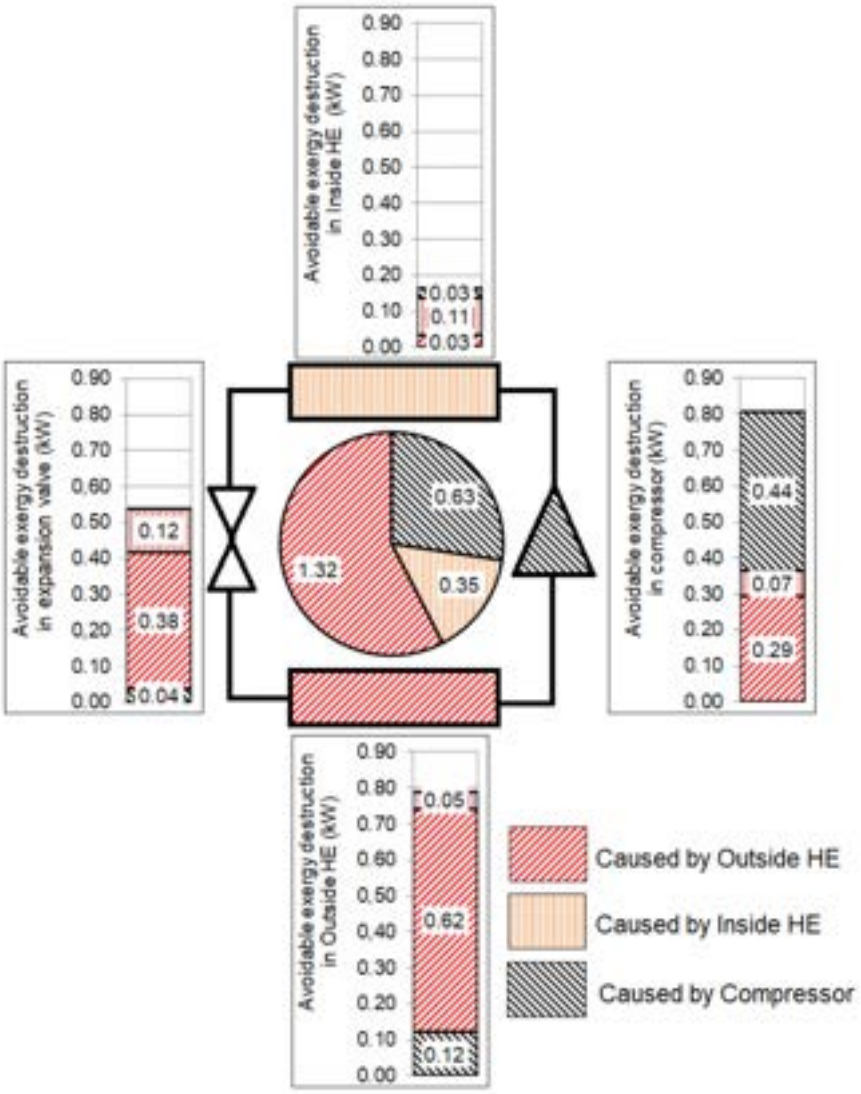

Figure. 6. Values of the internally caused and externally caused avoidable exergy destruction rates (kW) in the components of the R290 air-to-water reversible heat pump designed on the base of heating load and operated for covering 10kW and 7kW of heating and cooling loads, respectively.

Compared to the results obtained from the previous case, slightly different values of the avoidable exergy destruction were evaluated within the studied system designed on the base of cooling load (see Figure 7). The

system was operated for covering 8kW and 11kW of heating and cooling loads. The major differences were found to be associated with the avoidable parts of exergy destruction caused by the outside heat exchanger.

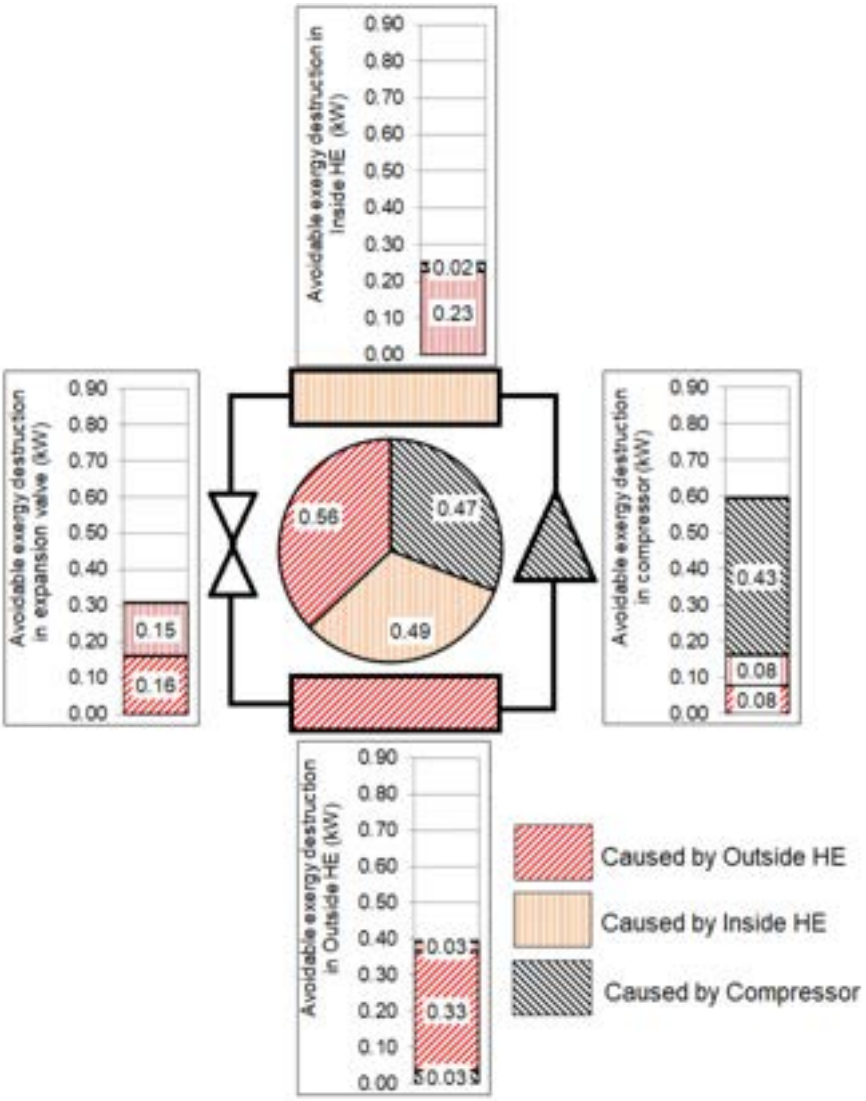

Figure. 7 Values of the internally caused and externally caused avoidable exergy destruction rates (kW) in the components of the R290 air-to-water reversible heat pump designed on the base of cooling load and operated for covering 8 kW and 11 kW of heating and cooling loads, respectively.

The impact of irreversibilities within the outside heat exchanger was decreased. As a result, the outcomes obtained showed that the outside, inside heat exchanger and the compressor had almost the same priority for improvement. The air-based heat exchanger revealed 0.56 kW avoidable exergy destruction within the system. Also, the water-based heat exchanger offered the potential to reduce 0.49 kW of exergy destruction rate. Also, the compressor enhancement was found to lead to a potential decrease of 0.47 kW of exergy destruction within the investigated system.

Conclusions

An exergy-based analysis has been carried out to evaluate the impact of different ratios between heating and cooling loads on the thermodynamic efficiency of a reversible air-to-water system with propane for providing heating and cooling needs. The following major findings have been found:

- For the system sized using heating design loads undersizing and oversizing areas of the air-based and water-based heat exchangers were obtained, respectively, for covering the same cooling loads with the same pinch-point temperature differences and vice versa;
- Such disagreement of designed and required heat transfer areas affect the distribution of irreversibilities within the components of the system significantly, mainly depending on the ratios between heating and cooling loads and the way of system design (based on heating or cooling load);
- It has been found that for the ratios of heating loads and cooling ones within the range from 0.65 to 1.2 the system should be sized based on the cooling loads. For such design approach lower total

exergy destruction within the system could be obtained compared to the system sized on the base of heating loads. As the ratios of heating loads and cooling ones are higher than 1.2, the heating design load should be used for sizing system components. This is because the system designed on the base of cooling load could not be operated for covering heating needs due to technological limitations.

- For the system sized on the base of heating loads removing the avoidable irreversibilities within the air-based heat exchanger offer the biggest decrease of the exergy destruction within the system;
- thermodynamic improvement of the air-based, water-based heat exchanger and the compressor have approximately the same potential for increasing efficiency of the system designed on the base of cooling loads.

A high-fidelity simulation model for the precise characterization of a solar air-cooled ammonia-water absorption chiller at part load operation

María Esther Palacios-Lorenzo[a], José Daniel Marcos[a]

[a]*Dept. of Energy Engineering, UNED, Madrid, Spain, epalacios@ind.uned.es*

Abstract:

A differential mathematical model has been developed for the simulation of the ammonia-water absorption refrigeration system ROBUR®, model ACF60-00 LB. The model, with modular structure, contains the governing equations based on mass, species, and energy, implemented for the main system components. The model captures both thermal and mass resistance in the mass and transfer processes that simultaneously occur in the system. A calculation procedure is presented to evaluate the performance of the cooling system under off-design conditions, when driven by hot water temperature ranging between 160 and 210 ºC. Performance of the system when the ambient temperature is up to 40ºC has been analysed, assumed that the pumped solution flow rate kept constant, and the high-pressure level may be used as a control strategy. Results show that, at ambient temperature of 40ºC, the cooling capacity of the is restricted by the size of the air-coolant absorber if the feed hot water temperature is 210ºC. However, difficulties in condenser operation reduce the cooling capacity of the system when the temperature of the feed water drops to 160ºC. In addition, at ambient temperature of 40ºC and feed water temperature of 210ºC, geometry restriction due to the rectifier and the solution-cooled absorber results in COP increase. In such working conditions, the refrigeration system operates at its maximum high-pressure level.

1. Introduction

The world's population is expected to reach 9,7 billion people in 2050 [1]. Population growth beside economic development and changing consumption pattern will be followed of a notable increase in energy and water consumption. Therefore, there is a greater concern to reduce the environmental impact of energy and to optimize the efficient use of water. Currently, there is a great deal of interest in absorption systems because of their environmentally friendly technology. Absorption systems can help to reduce CO_2 emissions, slowing global warming and biodiversity loss. One of the main advantages of absorption systems is the possibility of using both waste heat from industrial processes and solar energy as a power source. In addition, absorption systems when air-cooled have no water consumption.

In this framework, the European ASTEP project has, among other main goals, to demonstrate the feasibility of the application of solar thermal energy to partially cover the cooling demands at an industrial site. Specifically, one of the tasks is partially satisfy the MANDREKAS dairy company cooling demand, at 5ºC, at different operating conditions, such as feed hot water temperature and outdoor temperature. Feed hot water temperature is supplied by a patented solar concentrator (sun dial).

The ammonia-water mixture is particularly suitable for generating chilled water at sub-zero temperatures in air-cooled systems. The most relevant drawback of the ammonia-water mixture, which determines the operation of the absorption systems, is that the vapor pressure of the water is not negligible as compared to the vapor pressure of the ammonia. As a result, the refrigerant always contains a small amount of water. The presence of water in the evaporator significantly deteriorates the performance and the efficiency of the system. The water content in the refrigerant can be reduced by using a distillation column [2]-[3], a condensation rectifier [5]. The efficiency of the system may be improved when the absorption system operates according to a GAX cycle. The key problem in the GAX cycle is the heat transfer between the absorber and the generator [6].

In the present analysis, a differential mathematical model with modular structure has been developed. The model implemented is based on the equations developed by Colburn and Drew for the condensation of a binary vapor mixture with a miscible condensate, [7]. The model includes the mass transfer resistance in both the liquid and vapor phases, which is dominant in the mass transfer processes occurring in an absorber system

[8]. The discretized and modular character of the model together with the consideration of mass transfer resistances gives it a high reliability. The model studies the performance and efficiency of the ammonia-water absorption refrigeration system ROBUR®, model ACF60-00 LB, at part load operation, focusing on the operating condition in hot climate when driven with hot water at high and low temperature. Limitations in the operation of the chiller to ambient temperature beyond 40ºC are analysed.

2. Methodology

2.1 System description

To study the performance of the single effect air-cooled ammonia/water absorption chiller, a mathematical model has been implemented in Engineering Equation Solver Software, on the bases of mass, species and energy conservation balances. The material thermal properties have been evaluated from [9]. Figure 1 shows a schematic diagram of the chiller. The geometry of the different devices of which the chiller consists, are detailed in Table 1. The distillation column includes a rectifying section and a stripping section, located respectively, above and below of the column feed entry point. A rectifier completes the purification system to achieve vapor refrigerant with a high grade of purity. The lack of appreciable benefits that the rectifying section entails, beside the decrease of COP associated with the use of coupled fluid-cooled rectifier [2]-[3] justifies considering the purifying system to consist of a distillation column fed from above (only with striping section) helped by a concentrated solution-cooled rectifier to obtain refrigerant vapor of the required purity. This assumption is corroborated by the schematic diagram of the ROBUR [10]-[11]. An solution-cooled absorber operates as regenerative generator absorption heat chiller, GAX [12]. The chiller includes three restrictors. Restrictors 2 and 3 allow to reestablish the low-pressure level at the inlet of the solution pump. In this study, it is assumed that restrictor 1 allows regulate both high- and low-pressure levels to optimize the chiller performance.

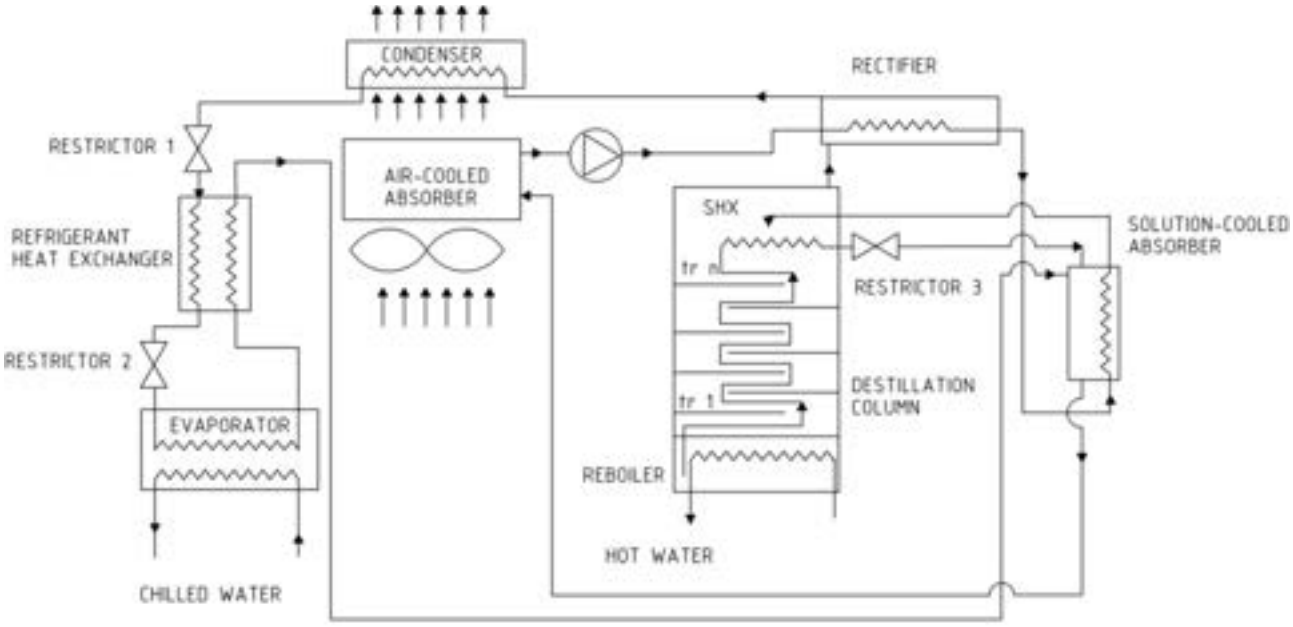

Figure. 1: Schematic diagram of the ammonia-water absorption chiller ROBUR model ACF60-00 LB

The coupling between the absorption and desorption processes is achieved in the solution-cooled absorber (CABS), which operates, on the one hand, thanks to the temperature reduction that occurs in the lean solution flow that leaves the desorber as it passes through the distillation tower (DC), the solution heat exchanger (SHX) and the solution valve (SV), to finally enter the CABS. On the other hand, the rich solution leaving the absorber increases significantly in temperature as it passes through the solution cooled rectifier (CR), until it reaches values close to the dew point temperature of the steam leaving the distillation tower to the rectifier. Therefore, the performance of the absorption system according to a GAX cycle depends on the heat recovery efficiency in DC, SHX and CR.

Condenser, air-cooled absorber, and evaporator tubes are described by its inner diameter, D_i, and thickness, e. The number of tubes is fixed for condenser and absorber, while the tubes length for these devices are obtained in the design process. Conversely, the evaporator tubes length, L, is fixed, while the number of baffles

for the chilled water passage is obtained in the design process. In addition, the refrigerant quality at the exit of evaporator is fixed at 0,96 to limit the temperature glide. It is assumed that both solution-cooled absorber and the solution-cooled rectifier consist of a helical tube. Vapor mass fraction at the rectifier outlet, efficiency of the solution-cooled absorber and the number of turns for both the rectifier and the air-cooled absorber are determined by an iterative process. Nevertheless, while the number of turns remain invariable once are determined, both vapor mass fraction at the rectifier outlet and efficiency of the solution-cooled absorber is determined according to the operational conditions of the chiller. Refrigeration heat exchanger is modeled assuming that its efficiency is 0,9.

The distillation column geometry is defined by its inner diameter D_i, hole diameter, d_h=0,00381 m, tray thickness, e_{tray}, tray spacing, S_t, weir length, l_w, hole pitch, s_h=3 d_h, weir height, h_w. and two relationships, f_1 and f_2 [13], being A_t=π/4 D_i^2, A_d, and A_a=A_t-2A_d, the column area, the downcomer area and the active area, respectively. e_w refers to the weight of the liquid entrainment per unit weight of vapor flowing in the distillation column. The reboiler is assumed to be a cylinder equipped externally with annular fins, with the hot water in cross flow over the cylinder, through the resulting fined annuli passage. The geometry of the finned external surface for condenser, absorber and reboiler annuli, determined by its thickness, t_m, and pitch, s, of their fins are shown in table 1.

Table 1. Chiller geometry.

Condenser/air-cooled absorber		Rectifier/solution cooled absorber		Evaporator

2.2. Mathematical models

Mathematical models have been developed for each of the key devices that make up the absorption machine [11]. Such models provide the flow, temperature, concentration of liquid and vapor phases throughout the length of these devices. The following assumptions have been considered:

- Processes are in steady-state
- Heat losses to the ambient are neglected
- Flow is one-dimensional
- Heat and mass transfer is in radial direction of the tube

- Pressure in distillation column, rectifier, solution-cooled absorber, air-cooled absorber, evaporator and condenser is constant

2.2.1 Distillation column

It is assumed that the rectifying section of the distillation column is avoided in the model, due to is low efficiency [3]. Vapor generated in a lower tray interacts with the liquid solution from the upper tray increasing its ammonia content. Simultaneously, the liquid solution coming from the reboiler dissimilates its temperature on its way to the heat exchanger, located at the top of the tower, by interacting with the liquid coming down from the successive trays. For simplicity, the interaction between the liquid coming from the reboiler and the steam generated in each of the trays is disregarded. The ammonia molar fraction of the vapor leaving the i-tray, $\bar{x}_{v,i}$, is obtained calculating the Murphree vapor plate efficiency, e_M. In that way,

$$\bar{x}_{v,i} = \bar{x}_{v,i-1}(1 - e_M) + e_M \bar{x}_{v\,e,i}, \tag{1}$$

where $\bar{x}_{v\,e,i}$, refer to the molar fraction of the vapor leaving the i-tray at thermodynamic equilibrium. The Murphree vapor plate efficiency is obtained as

$$e_M = 6.8 \left(N_{R_e} N_{S_c}\right)^{0.1} \left(N_{D_g} N_{S_c}\right)^{0.115}, \tag{2}$$

here N_{R_e}, N_{S_c}, N_{D_g} are dimensionless groups depending on some thermodynamic properties of the liquid (σ_L, μ_L, ρ_L, D_{kl}, evaluated with the Wilke-Chang expression [13], vapor velocity and geometrical characteristics of the column (fractional free area, A_h/A_t, and weir height, h_w). The effect of the liquid entrainment in the Murphree vapor plate efficiency has also been considered by using the Fair method [13]. The reboiler Murphree efficiency is assumed to be 1. The vapor purification process is eventually completed by partial condensation in the liquid-cooled rectifier. Reboiler is considered as an additional tray. Conservation equations for mass, species and energy in a generic tray are expressed as

$$\dot{m}_{L,F} + \dot{m}_{L,i+1} + \dot{m}_{V,i-1} = \dot{m}_{L,i-1} + \dot{m}_{V,i+1}, \tag{3}$$

$$x_F \dot{m}_{L,F} + x_{L,i+1}\dot{m}_{L,i+1} + x_{V,i-1}\dot{m}_{V,i-1} = x_{L,i-1}\dot{m}_{L,i-1} + x_{V,i+1}\dot{m}_{V,i+1}, \tag{4}$$

$$h_{L,F}\dot{m}_{L,F} + \tilde{h}_{L,i+1}\dot{m}_{L,i+1} + h_{V,i-1}\dot{m}_{V,i-1} + \dot{Q}_{reb} = \tilde{h}_{L,i-1}\dot{m}_{L,i-1} + h_{V,i+1}\dot{m}_{V,i+1}, \tag{5}$$

$$h_{L,i+1}\dot{m}_{L,i+1} + h_{dP,i}\,\dot{m}_{dP} = \tilde{h}_{L,i+1}\dot{m}_{L,i+1} + h_{dP,i+1}\dot{m}_{dP}, \tag{6}$$

$$\left(h_{dP,i} - h_{dP,i+1}\right)\dot{m}_{dP} = \pi D_{wo} e_{tray} h_{t,dP} \frac{(T_{dP\,i} - T_{w0}) - (T_{dP\,i+1} - T_{w0})}{ln\left(\frac{T_{dP\,i} - T_{w0}}{T_{dP\,i+1} - T_{w0}}\right)} \tag{7}$$

where *F* refers to the feed flow, applicable in the feed tray. $\dot{Q}_{reb}$ refers to heat flux supplied by the hot water supply, applicable in the bottom tray. Eq (7) models the heat transfer process that takes place between the dilute solution and the concentrated solution in the gap between consecutive trays. $h_{t,dP}$ refers to the heat transfer coefficient between the dilute solution and the tube wall.

2.2.2 Air-cooled absorber, solution cooled absorber and rectifier

Bulk temperature of the liquid phase, T_{bL}, is obtained by means of mass, species and energy balance at the vapor and liquid interface. Namely, mass balance at interface, which states than the mass transfer between the vapor and the liquid phases must be equal, can be expressed as Eq. (8), where a film model is used. Eq. (9) is obtained stating a balance energy at the liquid vapor interface [7]

$$f_1(T_i, z) = 0, \tag{8}$$

$$f_2(T_i, z) = 0, \tag{9}$$

In these equations, *z* refers to the ratio of ammonia to total molar flux through the interface and T_i is the temperature interface. An iterative process leaves to calculate total and partial mass fluxes transferred through the interface, $\dot{m}$, $\dot{m}_{NH3}$ and $\dot{m}_{H2O}$. New vapor condition is calculated from mass and energy balance in the bulk vapor phase based on the differential control volume, which stablish that

$$d\dot{m}_v = -\dot{m}, \tag{10}$$

$$d(x_{vb}\dot{m}_v) = -\dot{m}_{NH3}, \quad (11)$$

$$d(h_{vb}\dot{m}_v) = -\left(\dot{m}_{NH3} \cdot h_{v,NH3} + \dot{m}_{H2O} \cdot h_{v,H2O} + \dot{q}_{v,i}\right), \quad (12)$$

Similarly, flow rate, temperature and composition of the liquid phase at the exit of the control volume may be obtained with mass balance in the bulk liquid, which states that

$$d\dot{m}_l = \dot{m}, \quad (13)$$

$$d(x_{lb}\dot{m}_l) = \dot{m}_{NH3}, \quad (14)$$

$$d(h_{lb}\dot{m}_l) = -d(h_{vb}\dot{m}_v) - \dot{q}_{cf,i}, \quad (15)$$

The pumped mass flow rate is assumed to be constant, equal to 0,045 kg/s.

2.2.3 Evaporator and condenser

Bulk temperature of the biphasic phase is obtained by means of energy balance

$$h_i\dot{m}_i + h_{cf,i}\dot{m}_{cf} = h_{i+1}\dot{m}_{i+1} + h_{cf,i+1}\dot{m}_{cf}, \quad (16)$$

2.2.4 Reboiler

The energy balance is expressed as

$$h_{L\,2}\dot{m}_{L\,2} + h_{cf,reb\ in}\dot{m}_{cf,reb\ in} = h_{L,1}\dot{m}_{L,1} + h_{cf,reb\ out}\dot{m}_{cf,reb\ out}, \quad (17)$$

where subscripts *L1* and *L2* refers, respectively, to the liquid coming out to the tray 1 and 2 of the distillation column

2.2.5 Heat flux in condenser, air-cooled absorber and reboiler

These devices are externally finned. The heat flux transferred between the coolant and the bulk solution of the discrete element *i*, $\dot{q}_{cf,i}$, is evaluated as

$$\dot{q}_{cf,i} = UA_{cf,i} \cdot DTLM_i, \quad (18)$$

where $UA_{cf,i}$ is the thermal conductance referred to the element outer finned surface, $A_{cf,i}$, defined as

$$\frac{1}{UA_{cf,i}} = \frac{1}{h_{Lw}A_{L,i}} + \frac{1}{\eta \cdot h_{cf}A_{cf,i}} + \frac{D_i}{2\,k_w A_{L,i}} ln\left(\frac{D_{w0}}{D_{wi}}\right), \quad (19)$$

$DTLM_i$ is the logarithm mean temperature difference, calculated as

$$DTLM_i = \frac{(T_L - T_{cf\,i}) - (T_L - T_{cf\,i+1})}{ln\left(\frac{T_L - T_{cf\,i}}{T_L - T_{cf\,i+1}}\right)}, \quad (20)$$

η is the overall outer surface efficiency, evaluated as $\eta = 1 - A_{f,i}/A_{cf,i}\left(1 - \eta_f\right)$, where $\eta_f$is the fin efficiency and $A_{f,i}$ is the element fin area. In case of the reboiler, only one discrete volume has been considered. The cooling air-facing velocity is fixed at 1,25 m/s

2.2.6 Heat flux in rectifier, solution-cooled absorber and evaporator

The heat flux transferred between the coolant and the bulk solution of the discrete element *i* is evaluated as

$$\dot{q}_{cf,i} = \frac{A_{cf,i}(T_{w0} - T_{cf,i})}{\frac{1}{h_{cf}} + \frac{ln(D_{wo}/D_{wi})}{2k_{w/D_{wi}}}}, \quad (21)$$

where T_{w0} is the temperature of the outer wall of the tube

2.3. Heat and mass transfer coefficients

In the reboiler, the heat transport coefficient between the finned tube wall and the coolant is obtained from [15] and the heat transfer coefficient in the solution side is calculated from Táboas et al. [16], to consider the mass

transfer resistance though the liquid-vapor interface at solution side. The correlation proposed by Klimenko [17] is used between the biphasic refrigerant and the tube surface. In the evaporator, the heat transport coefficient between the tube wall and the coolant is obtained following the procedure described in [18] for the shell-side heat transfer in baffled shell-and-tube heat exchangers. In the condenser and in the absorber, the heat transfer coefficient between the liquid and the tube surface is calculated from the film wise condensation theory in a horizontal tube. In laminar regime, the heat transfer coefficient is obtained from the Nusselt equation for a smooth film [18] ignoring the vapor shear stress effect. The increase in heat transfer due to the waviness of the film flow is considered with the Kutateladze and Gogonin equation [18]. In turbulent regime, the Yüksel and Müller equation [18] has been used to calculate the heat transfer coefficient. Corrections proposed by Numrich equations [18] have been applied to consider the effect of the shear stress at the condensate film surface, both in laminar and turbulent regime. The heat transport coefficient between the solid surface and the coolant for absorber and condenser has been evaluated by [18]. In the absorber, the heat transfer coefficient between the liquid and the liquid vapor interface is assumed to be equal to the heat transfer coefficient between the liquid and the tube wall. The heat transfer coefficient in the refrigerant vapor phase is obtained from Gnielinski [18]. The mass transfer coefficient is calculated by means of the Chilton and Colburn analogy [18] from the heat transfer coefficient.

2.4. Solution method

An iterative process has been implemented to integrate each device that make up the absorption chiller and, thus, to determine the performance of the chiller. It is assumed that the following parameters have fixed values: geometry of the refrigeration system, detailed in Table 1, mass fraction of the solution filled, x_0, quality of the refrigerant at the evaporator outlet, $Q_{evap\ out}$, mass flow rate of the pumped solution, $\dot{m}_{dR}$, air-facing velocity, v_a, and mass flow rate of feed hot water,. Both $N_{turns,\ rect}$ and $N_{turns,\ cabs}$ are fixed values, which must be determined to satisfy all operating conditions. In addition, the mass flow rate of the chilled water, $\dot{m}_{cf,evap}$, may be altered, according to the manufacturer data.

For every operating condition of the absorption system, determined by the ambient temperature and the temperature of the hot water supply, the magnitudes that must be calculated are: the loss of pressure in the valve 1, that participates in determining P_H, and P_L, and thus, the minimum interface area of the condenser and of the air-cooled absorber, x_{ref}, which allows the coupling of the rectifier, eff_{cabs}, which allows the coupling of the solution-cooled absorber, and $\dot{m}_{cf,evap}$, which allows the coupling of the evaporator. The calculation procedure is summarized below.

1. Guess the number of the turns of the rectifier, $N_{turns,\ rect}$
2. Guess the number of the turns of the solution-cooled absorber, $N_{turns,\ cabs}$
3. Guess the los of pressure in valve 1, ΔP_{valv1}
4. Calculate the high-pressure level, P_H, given by ΔP_{valv1} added to the condensation pressure of the saturated refrigerant at ambient temperature
5. Guess the refrigerant mass fraction, x_{ref},
6. Guess the low-pressure level, P_L
7. Guess the refrigerant mass flow rate $\dot{m}_{ref}$
8. Calculate the circulation ratio f given by $\dot{m}_{ref}/\dot{m}_{dR}$
9. Calculate the mass fraction of the dilute solution, x_{dP}, given by $\left(f \cdot x_0 - x_{ref}\right)/(f-1)$
10. Calculate the mass fraction of the concentrate solution, x_{dR}, given by $(1-1/f)x_{dP} + x_{ref}/f$
11. Calculate the dilute solution flow rate, $\dot{m}_{dP}$, given by $\dot{m}_{dR} - \dot{m}_{ref}$
12. Calculate the reboil heat flux, $\dot{Q}_{reb}$, the mass fraction, mass flow rate and specific enthalpy of the vapor flow coming out of the upper tray of the distillation column and the temperature of the liquid flow from the reboiler, given by Eqs (1)-(7)
13. Guess the temperature of the solution at the pump outlet, $T_{pump\ out}$
14. Guess the efficience of the solution-cooled absorber, eff_{cabs}
15. Guess the reflux ratio and the mass fraction and temperature of the condensate at the rectifier outlet, T_R and x_R, respectively
16. Check $\dot{Q}_{reb}$ using Eqs (18)-(20). If verified, go to step 17. Otherwise, guess a new value of $\dot{m}_{ref}$ and go to step 8
17. Check the interface area of the evaporator using Eqs (16) and (21). If verified, go to step 17. Otherwise:
    - guess a new value of $\dot{m}_{cf,evap}$, and go to step 17, or
    - guess a new value of P_L and go to step 12

18. Check the reflux ratio and the temperature and mass fraction of the condensate at the rectifier outlet using Eqs (8)-(15). If verified, go to step 19. Otherwise, guess new values of reflux ratio, T_R and x_R and go to step 16
19. Check the number of turns of the rectifier, $N_{turns,\ rect}$ using Eqs (8)-(15) and Eq. (21). If verify, go to step 20. Otherwise, guess a new value of x_{ref} and go to step 9
20. Calculate the refrigerant mass flow rate absorbed in the solution-cooled absorber, $\Delta\dot{m}_{ref,cabs}$, using Eqs (8)-(15) and Eq. (21).
21. Check the number of the solution-cooled absorber, $N_{turns,\ cabs}$, using Eqs (8)-(15) and Eq. (21). Check eff_{cabs}. If verified, go to step 22. Otherwise, guess a new of eff_{cabs} and go to step 15
22. Calculate the interface area of the air-cooled absorber, A_{abs}, using Eqs. (8)-(15) and Eqs. (18)-(20). If the resulting frontal area is greater that of the comercial chiller, guess a new value for ΔP_{valv1} and go to steep 4
23. Check $T_{pump\ out}$. If verified, go to step 24. Otherwise, guess a new value of $T_{pump\ out}$ and go to step 16
24. Calculate the interface area of the condenser using Eqs. (8)-(16) and (18)-(20). If the interface area is greater that a certain máximum value, guess a new value for ΔP_{valv1} and go to steep 4

Table 2 shows input and output parameters of each device to carry out the described iterative process.

2.4.1. Mathematical model validation

Model has been validated with the data supplied by the manufacturer. Figure 2 compares measured (manufacturer data) and predicted (model), provided that the loss of pressure in valve 1 to be the suitable.

The agreement is fair in the whole range of ambient temperature and of hot feed water analysed. Nevertheless, the validity range of the implemented model cannot be extended to ambient temperatures above 40ºC, as explained below.

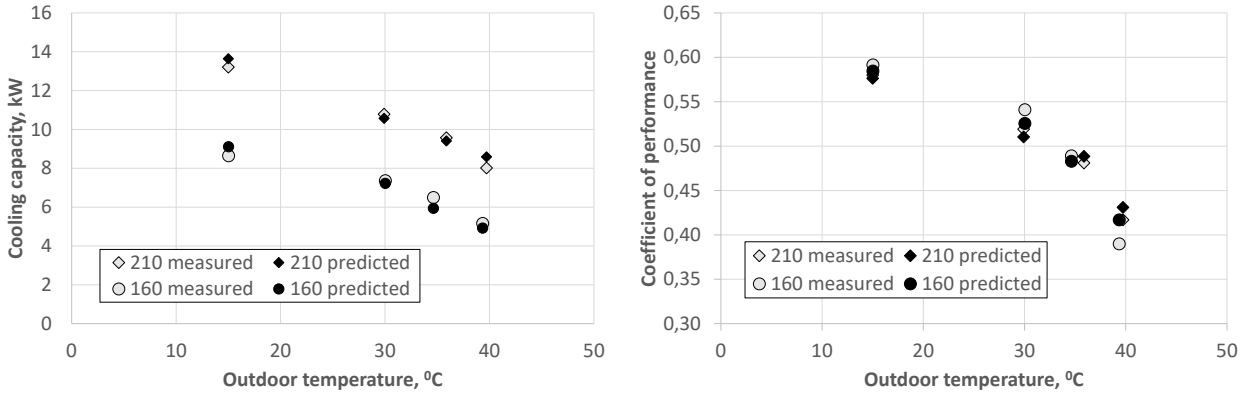

Figure. 2. Measured and predicted values for the performance of the ammonia-water chiller: a) cooling capacity, b) coefficient of performance.

3. Results

Figure 3 depicts shows the effect of the loss of pressure in valve 1 on the high-pressure levels at each operating condition, determined by the feed water temperature and the ambient temperature, ºC. It is observed that, for a certain value of ΔP_{valv1}, P_H increases with ambient temperature as the refrigerant condensing pressure increases. P_H also increases with hot water supply temperature as the mass fraction of the dilute solution decreases.

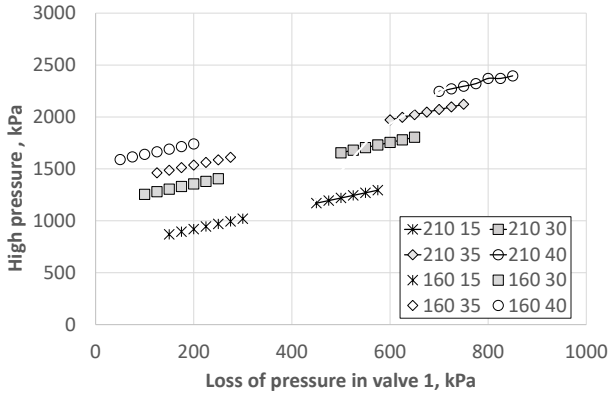

Figure. 3. High-pressure level in the ammonia-water absorption system. Box: feed hot water temperature and ambient temperature, ºC

Figure 4 shows the evolution of the logarithmic mean temperature difference in the condenser, $LMDT_{cond}$, when varying ΔP_{valv1}. The results shows that $LMDT_{cond}$ increases notably when ΔP_{valv1} increases, due to P_H rise. The ambient temperature has also influence on the $LMDT_{cond}$. This is because the condensing pressure of the refrigerant decreases.

It is concluded that the operational limit of an absorption system operating at high ambient temperature and low feed water temperature is established by the size of the air-cooled condenser.

Figure 5 left illustrates the evolution of the low-pressure level, P_L. Results shows that, in all operating conditions, P_L decreases as the ambient temperature drops. This is because P_L is eventually determined by thermal resistance between the refrigerant vapor being absorbed and the coolant-air at the outlet of the air-cooled absorber. Results also show that P_L increases as the temperature of the feed hot water decreases. This is attributable to the influence exerted by the refrigerant mass flow rate, $\dot{m}_{ref}$, as it is explained below.

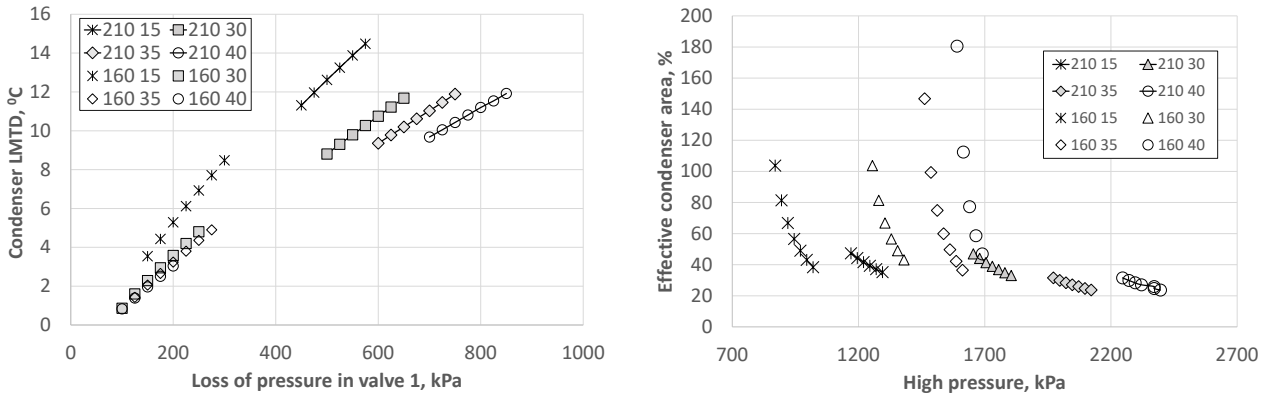

Figure. 4. Condenser: a) logarithmic mean temperature difference, b) Minimum required transfer area, expressed as a percentage of its geometric area. Box: feed hot water temperature and ambient temperature, ºC

Figure 6 left shows the evolution of the cooling capacity, that is, of the refrigerant mass flow rate, with the operating conditions. Figure 6 right illustrates the influence of the temperature of the feed hot water on the logarithmic mean temperature difference of the evaporator, $LMTD_{evap}$. When comparing results in Figure 5 and Figure 6, it can be observed that evaporator coupling results in P_L reduction and $LMTD_{evap}$ increase when $\dot{m}_{ref}$ increases. However, when the temperature of the hot water is 210º C, $LMTD_{evap}$ experiences a slight increase instead when $\dot{m}_{ref}$ is incremented. This is due to, at 210ºC, the rectifier coupling entails refrigerant mass fraction increases as the ambient temperature does, as will see later, what favours $LMTD_{evap}$ increase.

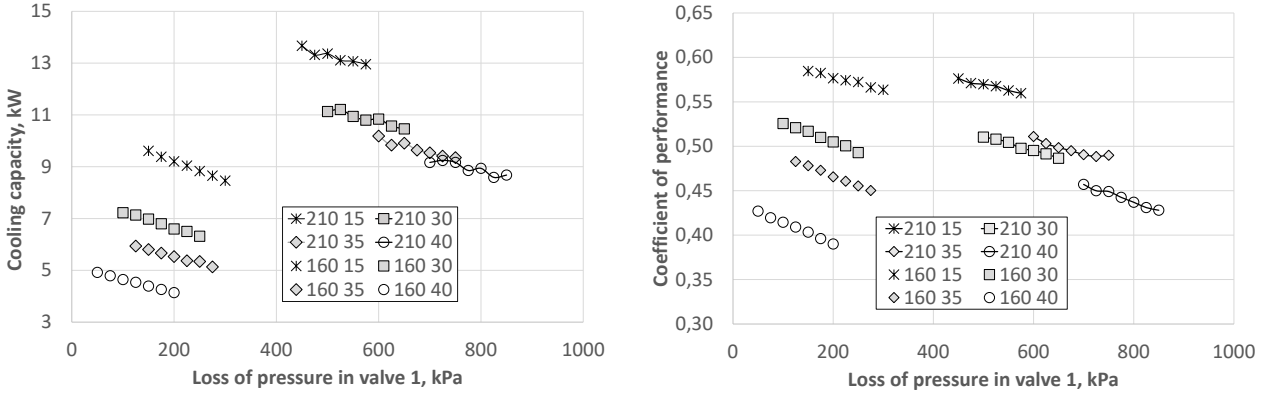

Figure. 5. a) Cooling capacity of the ammonia-water absorption system. b) Coefficient of performance. Box: feed hot water temperature and ambient temperature, ºC.

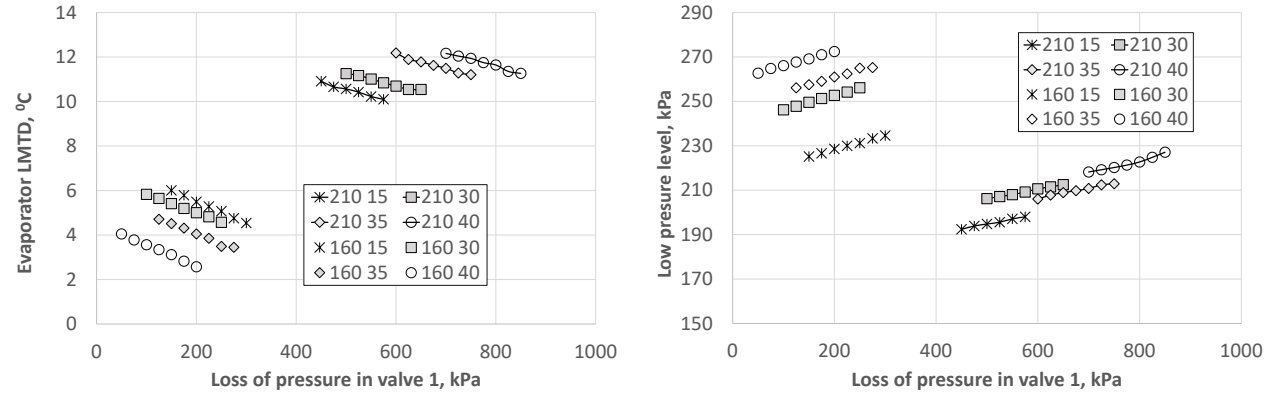

Figure. 6. a) Logarithmic mean temperature difference of the evaporator. b) Low-pressure level. Box: feed hot water temperature and ambient temperature, ºC.

Figure 7 left illustrates the evolution of the effectiveness of the solution-cooled absorber, eff_{cabs}, and the refrigerant mass fraction that allows the coupling of the rectifier and of the solution-cooled absorber. Results

show that eff_{cabs} decreases as the ambient temperature increase when the temperature of the feed hot water is 210ºC. Hence, the temperature of the concentrated solution flow at the CABS outlet reduces, what favours the absorption system to operate as a GAX cycle, even when the ambient temperature is high. In addition, results shows that x_{ref} increases as the ambient temperature increases when the temperature of the feed hot water is 210ºC. This behaviour, particularly noteworthy when the ambient temperature approach to 40ºC, favours COP when the ambient temperature is high.

Figure 7 right shows the influence of the feed water temperature on the minimum area required by the air-cooled absorber, A_{abs}, normalized with the geometric area of the air-cooled absorber. Results show that A_{abs} increases when the temperature of the feed hot water increases. In fact, set the feed water temperature, P_L must be larger than a certain value, which increases as the ambient temperature increases, to assure that A_{abs} remains below the geometric area of the air-cooled absorber. Results show that A_{abs} quickly dismisses when P_L increases. In this sense, since P_L increase as ΔP_{valv1} does, high values of ΔP_{valv1} are preferred when the ambient temperature is high to assure a high cooling capacity. However, reached the maximum value of P_H, a higher ambient temperature entails a reduction of $\dot{m}_{ref}$. Otherwise, $\dot{m}_{ref}$ cannot be absorbed in its entirety.

It is remarkable that, despite the feed water temperature is 210ºC, A_{abs} keeps far from its geometric value when the ambient temperature is 15ºC as compared with that obtained at 30ºC. This behaviour is due to PL is quite similar for both ambient temperatures.

It is concluded that the operational limit of an absorption system operating at high ambient temperature and high feed water temperature is established by the size of the air-cooled absorber.

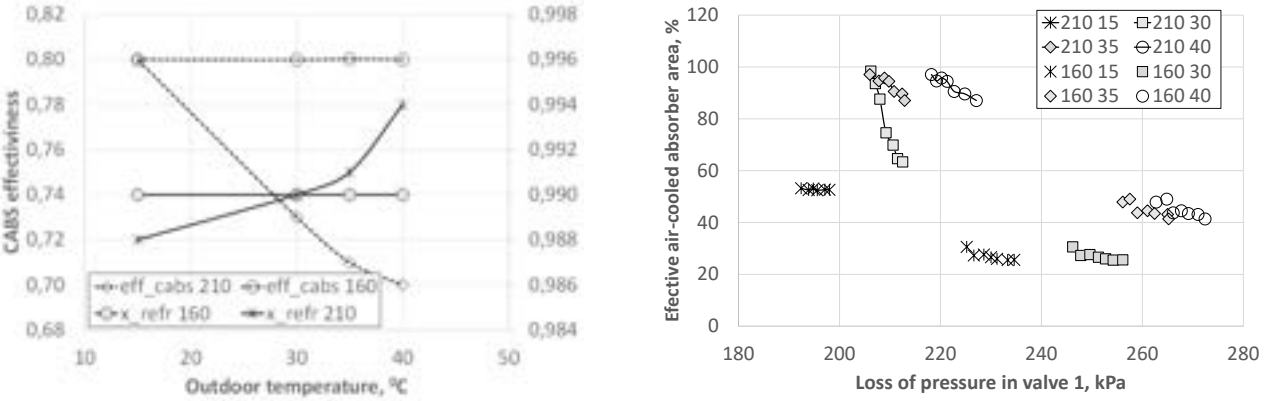

Figure. 7. a) Effectiveness of the solution-cooled absorber. Refrigerant mass fraction. Box: Feed hot water temperature, ºC, b) Minimum required transfer area of the air-cooled absorber, expressed as a percentage of the geometry area

4. Conclusions

In this studio, a detailed analysis of the heat and mass transfer processes that take place in an air-cooled ammonia-water system that operates according to a GAX cycle. The goal is to achieve a detailed inside of the refrigeration system when operates at part load, particularly in hot climates. With that objective, a mathematical model has been developed. The model captures both thermal and mass resistance in the mass and transfer processes that simultaneously occur in the system. The discretized character of the model, with modular structure, together with the consideration of mass transfer resistances gives it a high reliability. The model has been validated with the data of the absorption system manufactured by ROBUR®, model ACF60-00 LB, provided by the manufacturer.

A calculation procedure is presented to evaluate the performance of the cooling system under off-design conditions, when driven by hot water temperature in the range from 160 and 210 ºC and operating in ambient temperature from 15 to 40ºC. It has been assumed that the pumped solution flow rate keeps constant, and the high-pressure level may be used as a control strategy.

Limitations in the operation of the chiller to ambient temperature beyond 40ºC are analysed. Results show that, at high ambient temperature, the cooling capacity of the system when the hot water temperature is 210 ºC is restricted by the size of the air-coolant absorber. On the other hand, difficulties in condenser operation reduce the cooling capacity of the system at high ambient temperature when the feed hot water temperature is 160ºC. At high ambient temperature and high feed hot water temperature, geometry restrictions due to rectifier and to solution-cooled absorber results in high COP, what favours the system operation. However, at such operating condition, the refrigeration system demand for the maximum high-pressure level. Such COP improvement is due to the refrigerant mass fraction increase and efficiency solution-cooled absorber decrease.

Abbreviations

Symbols:

A	area transfer
A_a	active area of the tray, m
A_d	downcomer area
A_h	hole area of the tray, m
A_h/A_t	fractional free area
A_n	net open liquid area of one tray
A_t	tower cross-section area, m^2
CABS	solution-cooled absorber
D_w	wall diameter, m
DLK	diffusivity of the liquid light key
d_h	hole diameter of the tray in the distillation column
e	wall thickness, m
e_{tray}	tray spacing in the distillation column, m
e_M	Murphree vapor plate efficiency
e_w	weight of the liquid entrainment per unit weight of vapor flowing in the distillation column
f	circulation ratio, $\dot{m}_{dR}/\dot{m}_{ref}$
FA	fractional free area
G	superficial mass vapor velocity based on the cross-sectional area of the column
h	reboiler length, m
h	specific enthalpy, kJ/kg
h	heat transfer coefficient
h_f	fin length, m
h_m	mass transfer coefficient
h_w	weir length in the distillation column
l_w	hole pitch of the tray in the distillation column
$\dot{m}$	mass flux
N_{D_g}	dimensionless group, $\sigma_L/\rho_L U_v$
N_{S_c}	dimensionless group, $\mu_L/\rho_L D_{LK}$
N_{R_e}	dimensionless group, $h_w G/\mu_L FA$
P	pressure, kPa
$\dot{Q}$	heat flux
RECT	solution-cooled rectifier
RHX	refrigerant heat exchanger
s	fin pitch, m
S_t	weir length, m
SHX	solution heat exchanger
T	temperature, ºC
t_m	fin thickness, m
V	velocity
x	mass fraction
z	ammonia to molar flux ratio across the vapor-liquid interface

Greek symbols

μ	viscosity, kg/m-s
ρ	density, kg/m^3
σ	surface tension, N/m

Subscripts and superscripts

abs	air-cooled absorber
air	coolant air
cabs	solution-cooled absorber
cond	air-cooled condenser

cf	coupling fluid
dP	dilute solution in ammonia
dR	concentrate solution in ammonia
e	at thermodynamic equilibrium
evap	evaporator
H_2O	water content
H	high level
i	inner
i	interface
L	liquid
L	low level
F	feed of the column distillation
NH_3	ammonia content
o	outer
reb	reboiler
rect	solution-cooled rectifier
ref	refrigerant
V	vapor
¯	molar basis

Abstract:
The present study presents the thermodynamic design of a vessel waste heat recovery prototype based on a cascade Organic Rankine Cycle (ORC) and an ejector cooling-vapor compression cycle (EVCC) in the context of the ZHENIT project. The system can be driven by high-temperature (>120 °C) and a low-temperature (<80 °C) waste heat and features 3 main operating modes: 1) electricity-only, 2) combined heat and power (CHP) via heat recovery from the ORC condenser and 3) combined cooling and power (CCP) from the simultaneous operation of the ORC and EVCC. Waste heat is supplied to the ORC (topping cycle), while heat recovered during the desuperheating is used for driving the EVCC (bottoming cycle). A series of parametric analyses were carried out to investigate the influence of key design parameters (working fluids and maximum ORC and EVCC temperatures, recuperator temperature rise, condensation temperature, compressor pressure ratio) on the performance of the prototype and select its design point. R1233zd(E) and R1234ze were found to be the best-performing fluids in the ORC and EVCC, respectively. Furthermore, the selected design ORC evaporation temperature is 120 °C, the condensation temperature (CHP mode) is 50 °C, while the EVCC generator evaporation temperature and compressor pressure ratio (CCP mode) are equal to 52 °C and 0.84, respectively. Under the above conditions, the prototype ORC electric efficiency is up to 12.62% (electricity-only mode), while the overall electrical and CCP efficiency (CCP) are 10.29% and 14.96%, respectively. Finally, the electrical COP of the EVCC is 7.62.

Keywords: Thermodynamics; ORC; ejector cooling; waste heat; CHP; CCHP; trigeneration.

1. Introduction

The Organic Rankine Cycle (ORC) is a widely considered technology for electricity production from low-temperature heat sources such as solar, biomass, geothermal and waste heat from industrial processes as well as exhaust gases and hot jacket cooling water of internal combustion engines of stationary and mobile applications, such as maritime vessels [1, 2]. Especially in the maritime industry, large amounts of fossil fuels are annually consumed for ship propulsion, cargo operations and electricity production. Therefore, there is an abundance in waste heat that could be exploited by ORC systems [3] in the form of engine and genset exhaust gases, compressed air intercoolers and jacket water cooler with typical temperatures from 60°C to 250°C [4].

Vessel energy demand is not limited to electrical energy but also includes heating and cooling. The combination of ORCs with thermally activated cooling systems can also contribute to covering these demands. In the literature, cascade configurations of ORCs and sorption cooling technologies have been considered to this end, especially, absorption [5] and adsorption [6] chillers. In such configurations, low-temperature heat is recovered from the ORC desuperheater or condenser and is used for driving the chiller. An alternative thermally activated cooling technology is based on the ejector cooling cycle (ECC), which is typically considered for use in solar thermal applications (solar cooling) [7]. The operating principle of ECCs is similar to that of conventional vapor compression cycles (VCCs), however, it involves the substitution of the mechanical compressor with an ejector device that thermally compresses the low-pressure vapor exiting the cooling evaporator utilizing a high-pressure stream generated through the exploitation of waste heat.

Notably, ejectors of ECCs can be easily integrated with conventional electricity-driven vapor compression cycles (VCCs) to improve their performance and improve their reliability and flexibility. The aforementioned concept is the basis of the prototype to be developed in the ZHENIT project, which is based on an innovative ejector-vapor compression cooling cycle (EVCC). In particular, the prototype will be based on a cascade layout, with an ORC as a topping cycle and an EVCC as a bottoming cycle. The ORC will be driven by waste heat, while the EVCC will be driven by heat recovered from the ORC desuperheater.

The present work presents the preliminary thermodynamic design process and results of the prototype based on three operating modes: 1) electricity-only, 2) CHP and 3) CCP. For the design, a series of parametric investigations were carried out to select the most appropriate working fluids and investigate the impact of different key design parameters on its performance.

2. Methodology

2.1. System description

The ZHENIT ORC-EVCC prototype is designed for vessel engine waste heat recovery at temperature levels ranging from 60°C (jacket engine cooling water) to 150°C (engine exhaust gases) for electricity, heating and cooling production. Within the project, a micro-scale (10 kW_e) prototype will be developed and demonstrated at lab-scale, along with the alternative vessel waste heat recovery solutions that are part of the ZHENIT solutions.

In the present study, a high-T waste heat source consisting of Therminol VP1 oil [8] at a mass flow rate of 2.5 kg/s with inlet/outlet temperatures of 150 °C /130°C, is considered. Meanwhile, a low-T waste heat source is additionally considered, consisting of hot water at inlet/outlet temperatures of 60°C /52°C with a mass flow rate of 0.4 kg/s.

The layout of the prototype is pictured in ***Figure. 1***. The ORC is the topping cycle and is driven by the high-T and (provisionally) low-T waste heat sources. Heat may be recovered during the desuperheating of the ORC working fluid in a heat exchanger (Generator) and used for driving the EVCC, which is the bottoming cycle. The EVCC is based on integrating an ejector into a conventional VCC. Compared to a VCC, the compression process of the low-pressure working fluid exiting the cooling evaporator is accomplished not only by a mechanical compressor but also by an ejector. More specifically, in the ejector, the working fluid leaving the compressor is further compressed as it is entrained by and mixed with high-pressure vapor produced in the Generator. As a result, the electricity consumption compared to a conventional VCC can be potentially reduced.

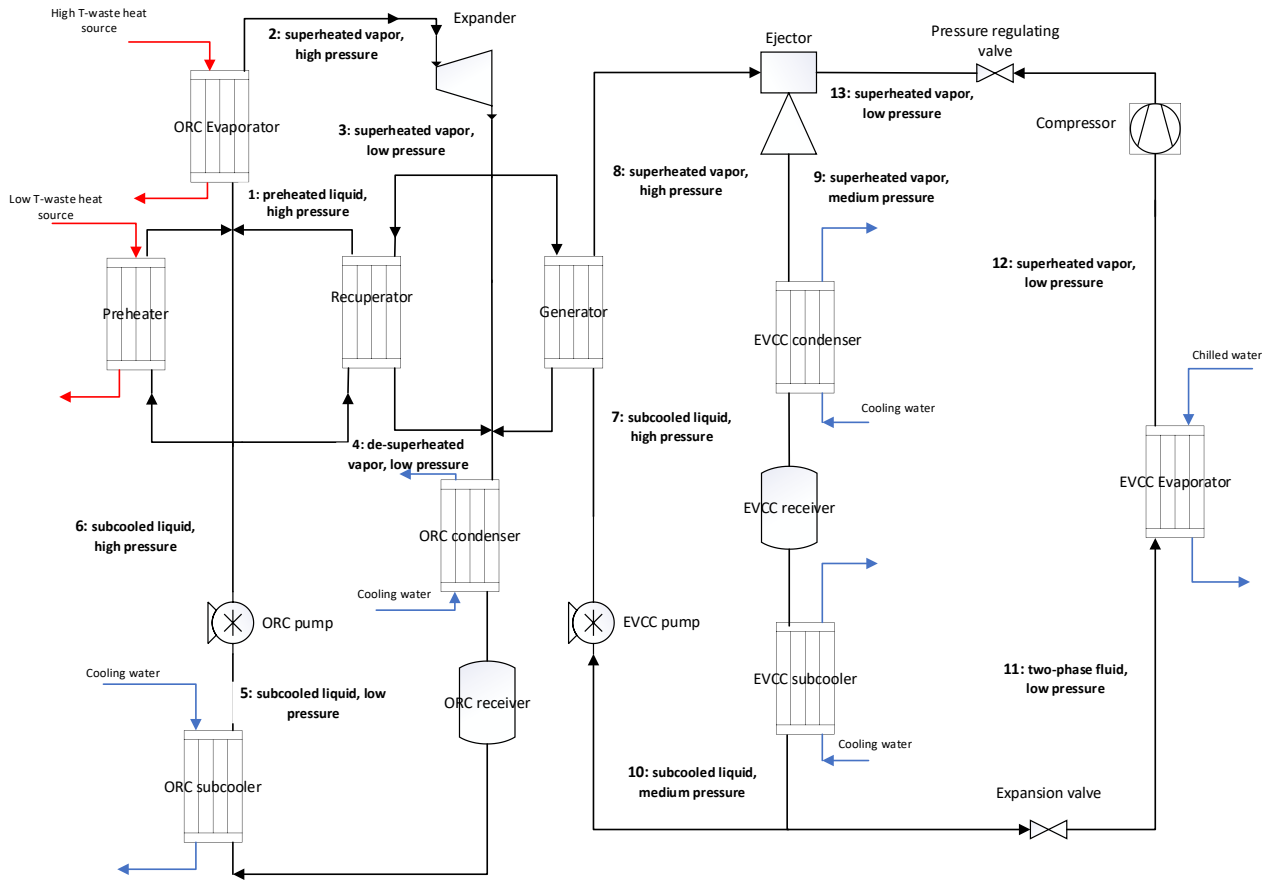

Figure. 1. Waste heat recovery ORC-EVCC layout

2.2. Operating modes

The prototype can operate in three different modes:

Mode 1 – Electricity-only: In this Mode, the EVCC is not operational and no cooling is produced. The ORC is driven exclusively by high-T waste heat. Furthermore, a recuperator is used to increase its efficiency.

Mode 2 – Combined heat and power (CHP): As in the previous case, the EVCC is not operational and the ORC is driven only by high-T waste heat. However, in this mode, the recuperator is bypassed and the condensation pressure of the ORC is increased to produce hot water at 45 °C.

Mode 3 – Electricity and cooling (CCP): In this Mode, both the ORC and EVCC are operational. The ORC may be driven by both a high-T and a low-T waste heat source. After exiting the expander, the ORC working fluid is desuperheated in the Generator, in which the EVCC working fluid evaporates on the cold side of the heat exchanger. Cooling (chilled water at 10 °C) is produced in the EVCC evaporator. The low-pressure working fluid exiting the cooling EVCC evaporator is compressed in the compressor and enters the low-pressure port of the ejector. Meanwhile, the high-pressure vapor exiting Generator enters the high-pressure port of the ejector. In the ejector, the two flows are mixed. The resulting mixed flow exits the ejector at an intermediate pressure and is driven to the EVCC condenser, where it is condensed by cooling water.

2.3. Working fluids

The investigated ORC and EVCC working fluids and their properties are summarized in **Table *1***. A set of hydrofluoroolefins (HFOs), namely R1233zd(E), R1234ze and R1234yf, were considered because of their low environmental impact (low global warming and ozone depletion potential (ODP), being compliant with the regulations imposed by the Montreal [9] and Kyoto Protocols [10], as well as the F-gases regulations [11]. Furthermore, these fluids have either no (R1233zd(E)) or low flammability according to the ASHRAE safety classification. For the ORC, R1233zd(E) and R1234ze were considered, owing to their relatively higher critical temperatures, resulting in improved cycle efficiencies. For the EVCC, R1233zd(E) was not considered because of its significantly lower evaporation pressure, which is below the atmospheric and may cause issues because of air leakage into the refrigerant circuit.

Table 1. Investigated working fluids and their properties

Working fluid	T_{crit} (°C)	p_{crit} (bar)	ODP	GWP	ASHRAE safety group
R1233zd(E) (ORC)	165.5	35.7	0	1	A1
R1234ze (ORC& EVCC)	109.4	33.4	0	6	A2L
R1234yf (EVCC)	94.7	33.8	0	4	A2L

2.4. Design

The modeling of ORC and ECC/VCC systems has been extensively investigated in the relevant literature [7]. Therefore, in the present work, only the most significant modeling aspects which are relevant to the particular investigated prototype are presented.

All modeling assumptions are summarized in ***Table 2***. The thermophysical properties of the heat source stream, working fluids and cooling water are calculated with REFPROP [12]. Two ORC evaporation temperatures are investigated, equal to 90 and 120 °C. Although higher ORC evaporation temperatures would potentially result in improved efficiencies, a maximum upper bound of 120 °C was considered because of technological limitations (material limitations and limitations of built-in volume ratios) of volumetric expansion machines (scroll and screw expanders) at the targeted scale of the prototype (around 10 kW_e) and technical challenges of testing higher temperature heat sources (above 140 °C) at lab scale. A condensation temperature (T_{cond}) of 30÷65 °C is assumed for the ORC (depending on whether only electricity or heating is also produced) and 30 °C for the EVCC. The subcooling degree in both condensers is 5 K to prevent pump cavitation problems, while the superheating degree at the ORC evaporator and EVCC generator is 10 K. Finally, the evaporation temperature in the EVCC evaporator is 5 °C while the working fluid leaves it superheated by 5 K. Additional modeling assumptions are included in the table. For some parameters, ranges are provided instead of particular values. This is because, for these parameters, parametric investigations are carried out (presented in Section 3).

Table 2 General modeling assumptions

Parameter	Value
High-T waste heat source	
HT source mass flow rate	2.5 kg/s
HT source inlet temperature	150°C
HT source outlet temperature	130°C
Low-T waste heat source	
LT source mass flow rate	0.4 kg/s
LT source inlet temperature	60°C
LT source outlet temperature	52°C
ORC	
Expander isentropic efficiency	0.70
ORC pump isentropic efficiency	0.65

Expander-generator electromechanical efficiency	0.92
ORC pump motor efficiency	0.95
Pinch point in Generator (ORC desuperheater)	5 K
Superheating degree at expander inlet	10 K
Condensation temperature	30 °C (Mode 1), 50÷65 °C (Mode 2)
Subcooling degree at condenser outlet	5 K
Recuperator cold stream temperature rise	10÷20 °C (Mode 1), 0 K (Mode 2 and Mode 3)
Evaporation temperature	70÷120 °C
EVCC	
EVCC pump isentropic efficiency	0.65
EVCC pump motor efficiency	0.95
EVCC compressor isentropic efficiency	0.65
Compressor-motor electromechanical efficiency	0.95
Superheating degree at ejector inlet	10 K
Evaporation temperature (EVCC cooling evaporator)	5 °C
Superheating degree at EVCC cooling evaporator outlet	5 K
Condensation temperature	30 °C
Subcooling degree at condenser outlet	5 K
Compressor pressure ratio (Eq. 9)	0.70÷0.98
Generator evaporation temperature	46÷60 °C
EVCC working fluid mass flow rate in generator	calculated to satisfy pinch point in Generator
Primary flow isentropic efficiency	0.95
Secondary flow isentropic efficiency	0.65
Ejector throat and constant area section cross-flow areas	calculated from ejector model
entrainment ratio	calculated from ejector model

The mass flow of the ORC working fluid ($\dot{m}_{ORC}$) is calculated from the energy balance equation in the ORC evaporator, based on the mass flow rate ($\dot{m}_{wh,HT}$) and enthalpy of the high-T waste heat stream at its inlet ($h_{wh,in}$) and outlet ($h_{wh,out}$):

$$\dot{Q}_{evap,ORC} = \dot{m}_{ORC}(h_2 - h_1) = \dot{m}_{wh,HT}(h_{wh,in} - h_{wh,out}) \quad (1)$$

In Mode 3, the enthalpy of the ORC working fluid at the preheater outlet is determined from the energy balance equation of this heat exchanger based on the mass flow rate ($\dot{m}_{wh,LT}$) and inlet ($h_{wh,in}$) and outlet ($h_{wh,out}$) enthalpy of the low-T waste heat stream in the heat exchanger:

$$\dot{Q}_{pre,ORC} = \dot{m}_{wh,LT}\left(h_{wh,in} - h_{wh,out}\right) = \dot{m}_{ORC}(h_1 - h_6) \quad (2)$$

The net electric power output of the ORC ($P_{e,ORC}$) is equal to the gross electrical power of the expander ($P_{e,exp}$) minus the electrical power consumed by the ORC pump ($P_{e,pump,ORC}$):

$$P_{e,ORC} = P_{e,exp} - P_{e,pump,ORC} = \dot{m}_{ORC}\left(\eta_{em,exp-G}(h_2 - h_3) - \frac{(h_6 - h_5)}{\eta_{M,pump}}\right) \quad (3)$$

These are calculated also considering the ORC expander-generator electromechanical efficiency ($\eta_{em,exp-G}$) and ORC pump motor efficiency ($\eta_{M,pump,ORC}$).

In Mode 2, useful heat is recovered from the ORC condenser ($\dot{Q}_{heat}$), calculated according to the following equation:

$$\dot{Q}_{heat} = \dot{m}_{ORC}(h_4 - h_5) \quad (4)$$

The EVCC is designed considering the thermal input provided to the cycle from the desuperheating of the ORC working fluid in Generator 1 in Mode 3. More specifically, for each EVCC generator evaporation temperature, the mass flow rate of the EVCC primary flow at the ejector inlet ($\dot{m}_p$), along with the state of the ORC working fluid at the Generator outlet are iteratively calculated to achieve the desired 5 K pinch point in this heat exchanger (Table 2), according to the energy balance equation:

$$\dot{Q}_{gen} = \dot{m}_{ORC}(h_3 - h_4) = \dot{m}_p(h_2 - h_1) \quad (5)$$

A critical operational parameter of the EVCC is the mass flow rate of the secondary flow entrained in the ejector ($\dot{m}_s$), which affects the cooling output of the system. For its calculation, a modified ejector design model based on the 1-D model by Huang [13] is applied. The details of the aforementioned model can be found in the

original publication by Huang [13]. The inputs to this model are: 1) the primary flow thermodynamic state (pressure and temperature), 2) the primary flow mass flow rate, 3) the secondary flow state (pressure and temperature) and 4) the backpressure of the ejector (imposed and equal to the EVCC condensation pressure).

The outputs of the model are the main ejector dimensions, namely the converging-diverging nozzle throat and outlet cross-sectional areas, the mixing section cross-sectional area as well as the diffuser outlet cross-sectional area, as well as the secondary flow mass flow rate of the ejector. The ratio of the secondary and primary mass flow rate of the ejector is defined as the ejector entrainment ratio (ω):

$$\omega = \frac{\dot{m}_s}{\dot{m}_p} \tag{6}$$

Higher entrainment ratios indicate that the ejector operates more efficiently, since more low-pressure vapor is entrained for the same amount of high-pressure vapor supplied to the ejector.

An important design parameter of the EVCC is the compressor pressure ratio (not to be confused with the common compressor pressure ratio definition), which is defined according to the following equation:

$$p_{r,comp} = \frac{p_{13} - p_{12}}{p_9 - p_{12}} \tag{7}$$

The compressor pressure ratio as it is defined in the present study is the ratio of the pressure increase of the secondary flow achieved by the compressor divided by the pressure difference of the EVCC working fluid in the condenser and cooling evaporator. It can theoretically vary from a minimum of 0 (the whole compression is achieved by the ejector and no compressor is used) to a maximum of 1 (the whole compression is achieved by the compressor and no ejector is used).

In addition to the mass flow rate of the secondary flow, an additional output of the ejector model is the state of the mixed flow at the ejector outlet.

The cooling produced in the EVCC evaporator ($\dot{Q}_{cool}$) is calculated from the equation:

$$\dot{Q}_{cool} = \dot{m}_s(h_6 - h_5) \tag{8}$$

The power consumption of the EVCC ($P_{e,EVCC}$) is equal to the power consumption of the compressor ($P_{e,comp}$) plus the power consumed by the EVCC pump ($P_{e,pump,EVCC}$):

$$P_{e,EVCC} = P_{e,comp} + P_{e,pump,EVCC} = \frac{\dot{m}_s(h_{13} - h_{12})}{\eta_{em,comp-M}} + \frac{\dot{m}_p(h_7 - h_{10})}{\eta_{M,pump,EVCC}} \tag{9}$$

For their calculation, the compressor electromechanical efficiency ($\eta_{em,comp-M}$) and the EVCC pump motor efficiency ($\eta_{M,pump,EVCC}$) are considered.

The total net power produced by the whole ORC-EVCC system ($P_{e,tot}$) in Mode 3 is equal to the net power produced by the ORC electrical generator minus the power consumption of the EVCC:

$$P_{e,tot} = P_{e,ORC} - P_{e,EVCC} \tag{10}$$

2.5. Performance assessment indexes

The electrical efficiency of the ORC is defined as follows:

$$\eta_{e,ORC} = \frac{P_{e,net,ORC}}{\dot{Q}_{evap,ORC} + \dot{Q}_{pre,ORC}} \tag{11}$$

The electrical COP of the EVCC is defined according to the following equation:

$$COP_e = \frac{\dot{Q}_{cool}}{P_{e,EVCC}} \tag{12}$$

The overall electrical efficiency of the ORC-EVCC in Mode 3 is defined as follows:

$$\eta_{e,tot} = \frac{P_{e,tot}}{\dot{Q}_{evap,ORC} + \dot{Q}_{pre,ORC}} \tag{13}$$

The combined cooling and power overall efficiency in Mode 3 is defined as follows:

$$\eta_{CCP} = \frac{P_{e,tot} + \dot{Q}_{cool}}{\dot{Q}_{evap,ORC} + \dot{Q}_{pre,ORC}} \quad (14)$$

3. Results and discussion

3.1. Parametric investigations

The design of the prototype is based on the selection of several parameters, some of the most significant being the following: 1) working fluid in ORC, 2) working fluid in EVCC, 3) ORC evaporation temperature, 4) EVCC generator evaporation temperature, 5) compressor pressure ratio (as defined in Eq. 7). The selection of these parameters is subject to thermodynamic (waste heat temperature, efficiencies) and technical constraints (equipment components). As a first step in the design process, a series of parametric investigations are carried out to examine their influence on the performance of the prototype. In the following investigations, while these parameters are varied, all other design parameters are kept constant, equal to the values summarized in ***Table 2***.

The ORC electrical efficiency variation as a function of the recuperator cold stream temperature rise for different ORC evaporation temperatures for Mode 1 (electricity-only) is presented in ***Figure. 2***. As expected, the highest evaporation temperature of 120 °C results in the highest efficiency. Because low evaporation temperatures are considered in the ORC, the possible cold stream temperature rise in the recuperator is relatively low, thus the efficiency improvement potential is very small. A maximum efficiency of 12% is achieved with R1233zd(E) for an evaporation temperature of 120 °C when the temperature rise is 20 K. For R1234ze(E), the maximum electrical efficiency is 8.86% when the evaporation temperature is 120 °C and the temperature rise in the recuperator is 14 K. Note that because of the significantly lower critical temperature of R1234ze(E) compared to R1233zd(E), the cycle's maximum operation temperature is lower, thus less heat can be recovered in the recuperator, and the cold stream temperature rise is limited .

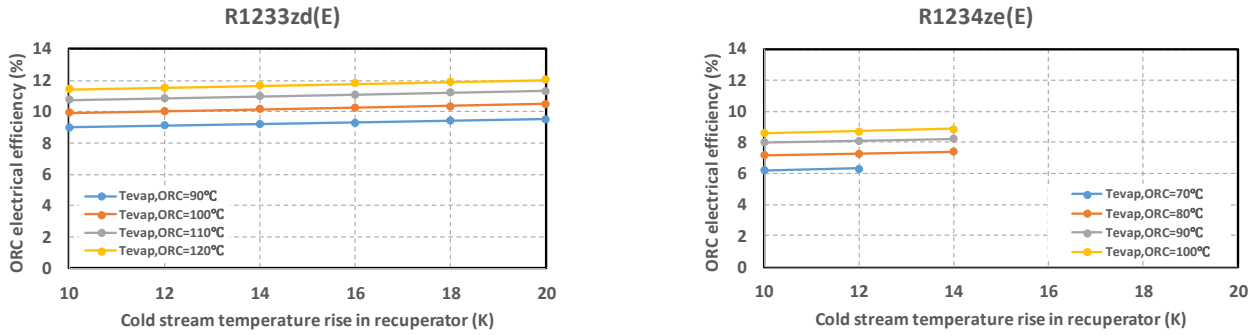

Figure. 2. ORC electrical efficiency as a function of the cold stream temperature rise in the recuperator for different ORC evaporation temperatures in Mode 1 (Electricity-only, T_{cond}=30 °C)

The ORC electrical efficiency as a function of the ORC condensation temperature for different evaporation temperatures in Mode 2 (CHP) is depicted in ***Figure. 3***. As expected, increasing the condensation temperature results in a significant, linear decline in electrical efficiency, since useful heat is produced to the detriment of electrical power. Therefore, the ORC condensation temperature must be selected to have an intermediate value in order to produce hot water at a sufficiently hight temperature as well as securing the highest possible ORC electric efficiency .

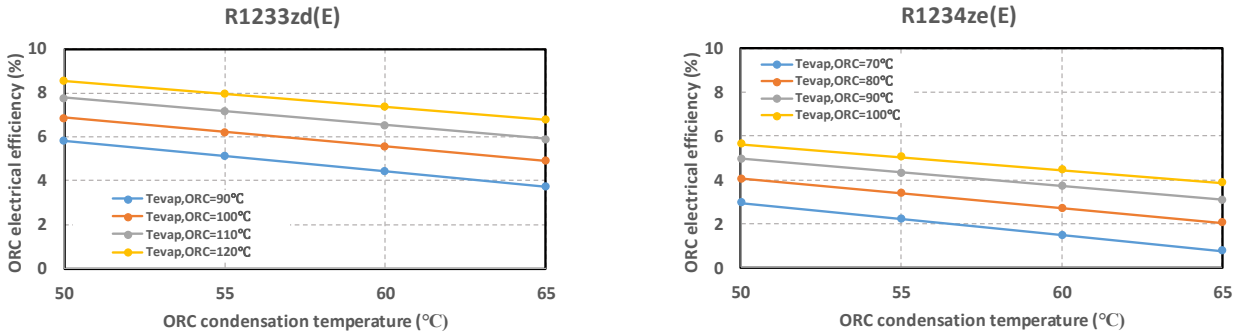

Figure. 3. ORC electrical efficiency as a function of the ORC condensation temperature for different ORC evaporation temperatures in Mode 2 (CHP)

The ejector entrainment ratio as a function of the compressor pressure ratio for different EVCC generator evaporation temperatures is illustrated in ***Figure. 4***.

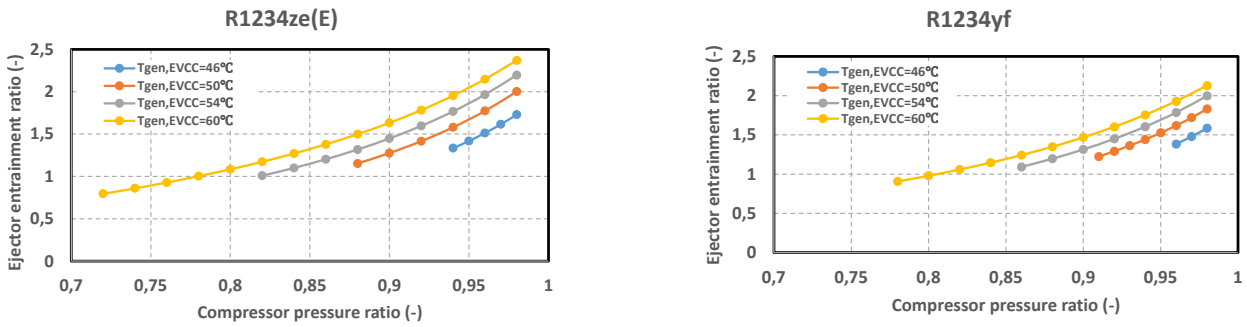

Figure. 4. Ejector entrainment ratio as a function of the compressor ratio for different EVCC generator evaporation temperatures

Higher compressor pressure ratios result in higher ejector entrainment ratios since the secondary flow enters the low-pressure port at a higher pressure and is more easily entrained by the primary flow. Furthermore, higher EVCC generator evaporation temperatures also result in increased entrainment ratios. This is because as the pressure of the primary flow is increased, it can more easily entrain low-pressure vapor. It can be observed that for each EVCC generator evaporation temperature, there is a minimum compressor pressure ratio which is necessary for the ejector to be able to operate. This is because, for lower pressure ratios, the primary flow can't entrain any low-pressure vapor exiting the cooling evaporator. The minimum required pressure ratio is positively correlated with the primary flow pressure (and hence the EVCC generator pressure). Notably, for an EVCC generator evaporation temperature of 46 °C, the compressor pressure ratio must be at least equal to approximately 0.94 (R1234ze) and 0.96 (R1234yf) for the ejector to be able to operate. On the other hand, if the EVCC generator evaporation temperature is increased to 60 °C, the compressor pressure ratio may be reduced to as low as 0.72 (R1234ze) and 0.76 (R1234yf).

If the compressor pressure ratio is higher than 0.9, essentially the whole compression is carried out by the compressor, which greatly assists the primary flow in entraining low-pressure vapor, reading to entrainment ratios above 1.5. Note that the ejector entrainment ratio is independent of the ORC evaporation temperature.

The EVCC electrical COP as a function of the compressor pressure ratio for different EVCC generator evaporation temperatures is illustrated in ***Figure. 5***. On the same diagrams, the electrical COP of a conventional VCC operating within the same cooling evaporation and condensation temperatures (see ***Table 2***) is illustrated (straight line).

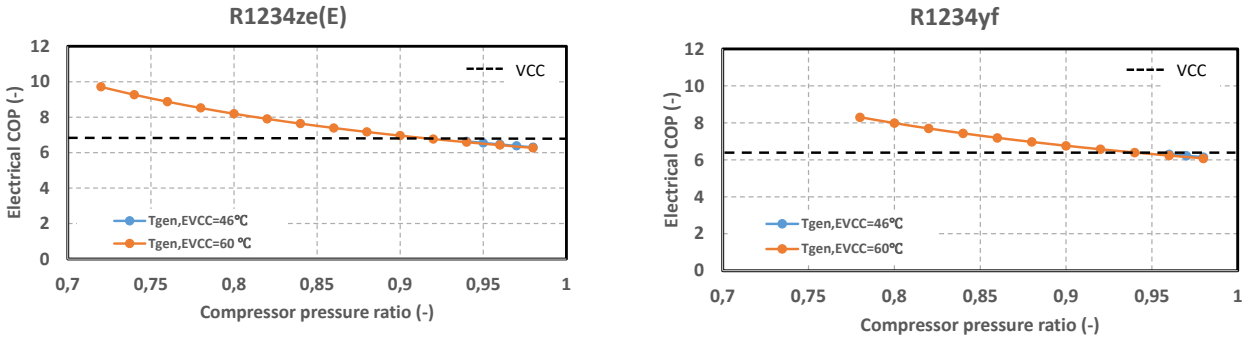

Figure. 5. Electrical COP of EVCC as a function of the compressor pressure ratio for different EVCC generator evaporation temperatures in Mode 3 (CCP)

As the pressure ratio increases, both the cooling output and the electrical consumption of the compressor increase. However, the increase in the compressor electricity consumption is more significant, and thus the electrical COP ultimately declines. Notably, for pressure ratios above approximately 0.95, the electrical COP of the EVCC is lower than that of a conventional VCC. In this case, the secondary's stream pressure rise through the ejector is significantly low, thus the whole cycle is operating practically as a VCC. However, due to the existence of EVCC pump the electrical power required is slightly higher compared to VCC, thus the electrical COP takes lower values. Although lower compressor pressure ratios result in higher electrical COP values, they are also associated with lower ejector entrainment ratios and cooling output. Therefore, the compressor ratio should be selected to ensure 1) a higher electrical COP than that of a conventional VCC and 2) a sufficiently high cooling production for a particular application, and 3) it should be sufficiently high to enable the ejector operation.

Note that the EVCC generator evaporation temperature does not affect the electrical COP. As the generator evaporation temperature is increased, the primary flow mass flow rate in the generator is decreased because the heat recovered from the ORC is reduced (this happens because the pinch point in the EVCC generator is located at the end of preheating and the start of boiling for the EVCC working fluid, thus increasing the EVCC generator saturation temperature results in less heat being recovered from the ORC working fluid), while the enthalpy difference of the EVCC working fluid in the heat exchanger is increased (Eq. 5). Although the entrainment ratio of the ejector is increased, the secondary flow mass flow rate is reduced, because the reduction of the primary flow mass flow rate is more significant. Consequently, increasing the EVCC generator evaporation temperature only leads to lower secondary flow mass flow rates, equally resulting in both lower compressor power consumption and cooling output for a given thermal input to the EVCC, affecting in the same way both the numerator and denominator of the electrical COP (Eq. 12). Considering the above, the EVCC generator evaporation temperature should be kept as low as possible so that more heat is recovered from the ORC, but at the same time the ejector is capable of operating at low compressor pressure ratios (that also lead to better electrical COP).

The overall electrical efficiency of the ORC-EVCC as a function of the compressor pressure ratio for different EVCC generator evaporation temperatures and ORC evaporation temperatures in Mode 3 is illustrated in ***Figure. 6***. For the results presented in both of these diagrams, the ORC working fluid is assumed to be R1233zd(E).

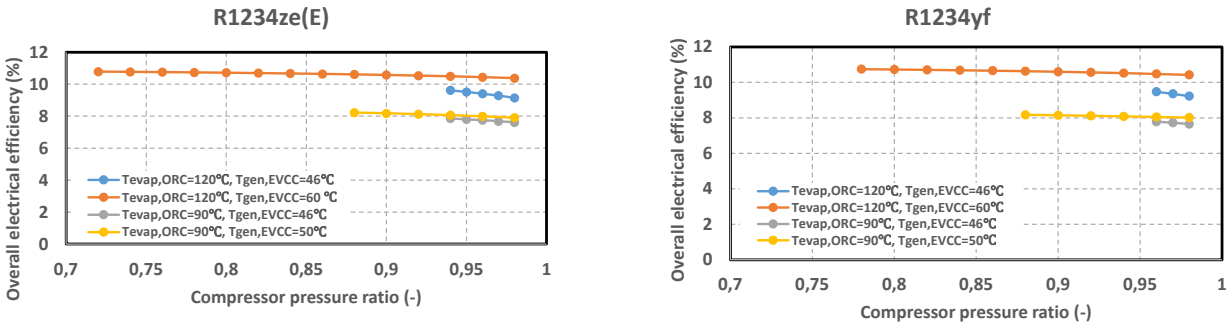

Figure. 6. Overall electrical efficiency of ORC-EVCC as a function of the compressor pressure ratio for different EVCC generator evaporation temperatures and ORC evaporation temperatures in Mode 3 (CCP)

Higher overall efficiencies are observed for the highest ORC evaporation temperature of 120 °C because of the significantly higher power output of the ORC. Furthermore, the overall electrical efficiency is increased for higher EVCC generator evaporation temperatures, since these lead to lower compressor power consumption (as described previously). Finally, for higher compressor ratios, more electric power is required to drive the compressor, thus the net electric power output (and overall electrical efficiency) is decreased. Regardless, the impact of the compressor pressure ratio on the overall electric efficiency is not significant. Therefore, to maximize the overall electric efficiency, both the ORC evaporation and EVCC generator evaporation temperatures must be as high as necessary.

The overall combined electrical and cooling efficiency of the ORC-EVCC as a function of the compressor pressure ratio for different EVCC generator evaporation temperatures and ORC evaporation temperatures is illustrated in ***Figure. 7***.

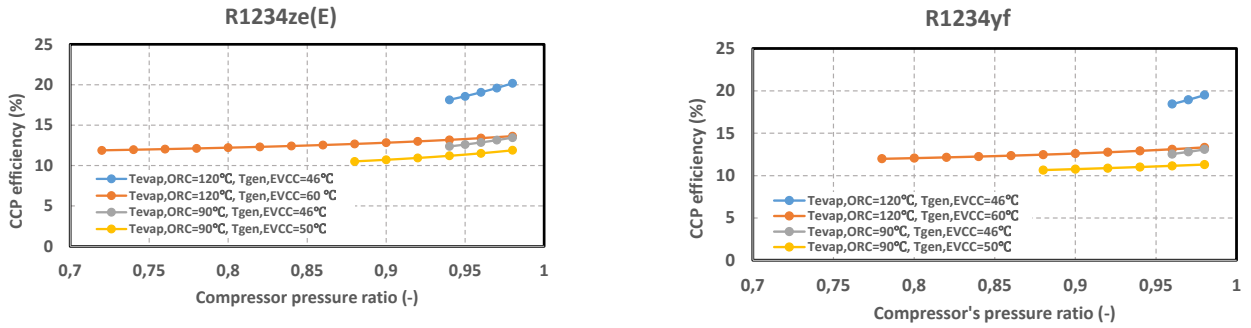

Figure. 7. Combined cooling and power efficiency of ORC-EVCC as a function of the compressor pressure ratio for different EVCC generator evaporation temperatures and ORC evaporation temperatures in Mode 3 (CCP)

The variation of the CCP efficiency depends on the combined variation of the net power output and the cooling output of the system. The highest CCP efficiency is observed for the ORC evaporation temperature of 120 °C,

for which the net power output is significantly high. The influence of the EVCC generator evaporation temperature on the CCP efficiency is not completely straightforward, since, as was mentioned previously, increasing the EVCC generator evaporation temperature results in both lower cooling output and also compressor power consumption. However, because the cooling output reduction is more significant, the CCP efficiency is reduced.

3.2. Design point selection

Based on the results presented in the previous section, R1233zd(E) and R1234ze show the best performance in the ORC and EVCC, respectively, as they result in higher power and cooling output. Therefore, these working fluids were selected to be used in the prototype. Moreover, higher ORC evaporation temperatures are favorable as they result in higher ORC electrical efficiencies and allow for more heat to be recovered by the EVCC, thus also leading to higher electrical COP values. Therefore, the highest possible ORC evaporation temperature (120 °C) is selected for the design of the prototype. Regarding the cold stream temperature rise in the recuperator, the maximum possible value of 20 K is selected, owing to its positive influence on the ORC electric efficiency in Mode 1. Regarding Mode 2, a condensation temperature of 50 °C is selected for the ORC, since it is sufficient for the production of hot water without severely penalizing the electrical efficiency. The final set of variables to be selected include the EVCC generator evaporation temperature and compressor pressure ratio. Based on the parametric investigations that were presented in the previous section, an ECC generator evaporation temperature of 52 °C and compressor pressure ratio of 0.84 represent a good compromise between a sufficiently high electrical COP and cooling output for the EVCC in Mode 3. The system design variables along with the system operating parameters in the three operating modes are summarized in **Table 3**.

Table 3 Design point operating parameters

	Mode 1 (Electricity-only)	**Mode 2 (CHP)**	**Mode 3 (CCP)**
ORC working fluid		R1233zd(E)	
ECC working fluid		R1234ze	
ORC evaporation temperature (°C)		120	
ORC condensation temperature (°C)	30	50	30
Cold stream temp. rise in recuperator (°C)	20	0	0
ECC generator evaporation temperature (°C)	-	-	52
Compressor pressure ratio (-)	-	-	0.84
Electric power output (kW_e)	11.35	8.06	10.57
Cooling output (kW_c)	-	-	4.80
Heating output (kW_{th})	-	85.5	-
ORC electrical efficiency (%)	12.84	10.01	12.62
CHP efficiency (%)	-	-	14.96
Electrical COP (-)	-	-	7.69
Overall electrical efficiency (%)	12.04	8.55	10.29
CCP efficiency (%)	-	-	14.96

4. Conclusions

The present study presented the thermodynamic design of a vessel engine waste heat recovery prototype based on a cascade Organic Rankine Cycle (ORC) and an ejector cooling-vapor compression cycle (EVCC) considering three operating modes: 1) electricity-only, 2) combined heat and power (CHP) via heat recovery from the ORC condenser and 3) combined power and cooling (CCP) from the simultaneous operation of the ORC and EVCC. To determine the preliminary design point, a series of parametric analyses were carried out to investigate the influence of key design parameters on the performance of the prototype and select its design point. R1233zd(E) and R1234ze were selected as the working fluids in the ORC and EVCC, respectively, as they led to the highest electrical efficiency and electrical COP in the two cycles. Furthermore, the selected design ORC evaporation temperature is 120 °C, which can lead to high ORC electrical efficiencies of up to 12.62% in electricity-only mode. The most suitable condensation temperature of the ORC in CHP mode was found to be 50 °C since it can allow the production of hot water at a sufficiently high temperature without penalizing the power output of the ORC. Regarding the design of the EVCC, higher EVCC generator evaporation temperatures do not influence the electrical COP but result in lower cooling outputs. Meanwhile, increasing the compressor pressure ratio has a negative impact on the electrical COP but leads to higher

cooling output. Therefore, an EVCC generator evaporation temperature of 52 °C was selected, as it allows the operation of the ejector at a compressor pressure ratio of 0.84, which results in good electrical COP and substantial cooling output. Under the above conditions, the prototype ORC electric efficiency is up to 12.62% (electricity-only mode), while the overall electrical and CCP efficiency (CCP) are 10.29% and 14.96%, respectively. Finally, the electrical COP of the EVCC is 7.62, being superior to that of a conventional vapor compression cycle.

Efficient Integration of advanced absorption heat pumps and chillers in District Heating and Cooling networks

Joan Carles Bruno, Addarda Irsyad Usman

Universitat Rovira i Virgili, Dept. of Mechanical Engineering, CREVER-Research Group on applied Thermal Engineering, Tarragona, Spain, juancarlos.bruno@urv.cat, CA

Abstract:

The design and analysis of District Heating and Cooling (DHC) networks using local renewable energy sources such as thermal energy from solar collectors is one of the most interesting tools to fight against greenhouse gas emissions. The development and viability of these networks will be facilitated by the parallel development of new highly efficient absorption systems to efficiently produce not only chilled water but also heating and/or cooling and working as booster absorption heat pumps for the fifth generation of DHC networks using very low temperatures. These new absorption units are already commercialized and ready to be integrated as central units or distributed as substations with other energy conversion technologies. The new absorption systems considered include the following: a) double-lift chillers to improve the recovery of waste heat by producing a very high temperature glide in the driving heat, b) double-lift absorption units, or very low-temperature driven systems. This paper examines the technical assessment of solar thermal based cooling networks using advanced absorption chillers and taking as a reference conventional DHC networks. The indicators used include the saving in energy and greenhouse gas emissions and a prospect of the economic benefit. The results show the role that the new advanced absorption chillers could play for the development of future net zero-emissions DHC networks.

Absorption chillers and Heat pumps; Thermal solar energy; District networks; Energy integration.

1. Introduction and objectives

There is a great interest to fulfil the increasing energy demand for refrigeration and air conditioning using renewable energies. Encouraged by the Renewable Energy Directive (EU) 2018/2001 [1], it is projected that by 2030, 40% of heating and cooling sector in Europe will come from renewable energy sources. If we compared this goal with the current situation, there is still a long way for renewable heating and cooling to fulfil the projected vision of the directive. One of the technological options could be the development of large-scale solar cooling plants to benefit from the scale economic factor in conjunction with the use of advanced absorption chillers.

In the project Task 55 of the International Energy Agency [2] (IEA SHC, 2016-20) was conducted a comprehensive study on the modelling, analysis, and real case study survey for the integration of large solar heating and cooling systems into District Heating and Cooling (DHC) Networks. The main conclusion was that in the selected case studies mainly in Denmark and Austria the main solar technologies used Flat Plate collectors and hot water as working fluid, and only a few of them used parabolic collectors. Using renewable energies for air conditioning applications, the preferred working fluid for absorption chillers is Water/LiBr instead of Ammonia/water because of its higher efficiency, although direct fired units using ammonia/water of could be considered for certain small capacity applications such as when air heat rejection is needed.

The objective of this paper is to provide a brief review of novel features incorporated in the current absorption chillers and their integration into DHC networks. It is presented a preliminary assessment of technologies using low-temperature flat plate solar collectors and the current state-of-the-art hot water driven absorption chillers in comparison with alternative and much more extended compression chillers using electricity grid. The idea is to compare different thermal solar cooling technologies by measuring its performance using key parameters with respect to an equivalent electric compression chiller but not to design cooling alternatives for a certain specific case study.

This paper is organized as follows. After the introduction to justify the research interest and to set the objectives in the second section are presented the current trends in the technology of absorption heat pumps and chillers followed in section 3 with a short review of how these units could be integrated in District networks. Finally, in

section 4 and 5 is presented a modelling and analysis to compare the performance of selected hot water driven absorption chillers being the conclusions summarized in section 6.

2. High efficiency absorption heat pumps and chillers

Some of the main new features related with the current high-efficiency absorption chillers could be classified as:

1. Improvement on the system components and internal arrangements such as:

    1.1. Double section components. This two-step evaporator and absorber technology has two pressure levels but the overall pressure is reduced. The absorption process is also divided in two steps reducing the solution concentration values but increasing the overall concentration different between the rich and poor solution [3]. This arrangement enhances absorption of the refrigerant into the concentrated solution, making the unit more efficient and reliable than conventional absorption chillers. The result is that quite simple cycles such as single effect units can reach COP values higher than 0.8 or up to 1.48 for double-effect steam driven configuration, the highest of its class. Moreover, the cost of the chiller benefits of lower solution concentrations due to the cost of the LiBr.

    1.2. Falling-film generator design provides superior heat transfer compared to a conventional flooded generator. This design also reduces the required amount of solution to be circulated, decreasing start-up time from a cold start [3].

    1.3. Internal heat recovery of the absorption heat. In this case one of the two absorber steps uses part of the absorption heat to reduce the demand for cooling water. This feature is really not new in the absorption field and was proposed in the past but only for ammonia/water systems [4].

    1.4. Some manufacturers produce water/LiBr absorption chillers that use refrigerant mixed with water and lithium bromide solution, so that they can decrease the evaporative temperature of refrigerant to 0℃ or less [5]. Delivering brine at temperatures down to -7℃, which is applicable not only to comfort cooling but also to phase change cold storage with its corresponding volume savings and provide below zero process cooling. Other chiller versions are prepared for onboard ship operation recovering hot water and waste steam from engines to produce cooling using sea water as heat rejection fluid.

2. Improvement of the thermal cooling cycles by the incorporation of additional components in multiple stages arrangements. The result is the development of new chiller types beyond the traditional single and double effect cycles:

    2.1. Single-effect double-lift absorption chillers. This configuration concept was proposed in the literature [6] and now implemented commercially and consist of a three-level pressure cycle (fig. 1) with a high temperature glide of the heat source that enables a higher heat input and consequently a higher cooling capacity for a given heat source. This thermally driven cycle uses the source heat in three generators (high-temperature generator, low-temperature generator and auxiliary generator) to lower temperature more efficiently than a conventional single-effect cycle. Several manufacturers offer this cycle configuration very suitable for district cooling systems that could benefit from its low return temperatures.

    2.2. Half effect absorption chillers use two water/LiBr solution circuits with the aim to recover very low temperature heat sources of about 70ºC to produce cooling. The COP is much lower than single effect cycles but could be an ideal solution for some specific cases such as geothermal energy sources or for the use of waste heat from low temperature fuel cells or electrolyzers.

    2.3. Triple effect absorption chillers are high-temperature chillers that claim a COP as high as 1.8 [7]. The high temperatures to drive double or triple effect chillers using fuel-fired units, steam, pressurized hot water or exhaust gas and certain specific manufacturing limitations, reduce the range of application of these type of chillers to medium or large size applications (starting at a few hundreds of kilowatts). Due to the materials used (stainless steel) and flow circulation, the rate of corrosion is negligible even for triple effect cycles that include also online concentration measurement [7]. Moreover, the variable frequency drives on solution pumps helps to improve the COP during part loads. The stainless-steel plate type solution heat exchangers also helps to increase the COP by offering maximum internal heat recovery.

3. New cycle arrangements to cover applications not fully available commercially until the last years:

3.1. Heat pumps of Type I driven by high-temperature heat to work as amplifiers from low temperature sources close to ambient temperature to medium temperature. The heat source can be steam, hot water, exhaust gas, fuel, geothermal energy, or any combination of these heat sources.

3.2. Heat pumps of Type II known also as heat transformers driven by medium-temperature than in part is degraded to ambient temperature and the other part upgraded to produce high-temperature hot water or steam.

3.3. Simultaneous production of heating and cooling using high-temperature driven systems such as waste steam or direct-fired units. In some case also multi-energy systems recovering hot water and exhaust gases simultaneously to produce cooling and hot water.

3.4. Reversible operation systems to provide cooling in summer and heating in winter or domestic hot water along the year. One of the weaknesses of absorption systems is the lack of reversibility so they operate only during certain periods of the year. However, using certain flow configurations [8] is possible to use the evaporator to increase the temperature glide of the heat-driving source and increase the temperature of the heat rejected at the condenser/absorber for useful heat applications.

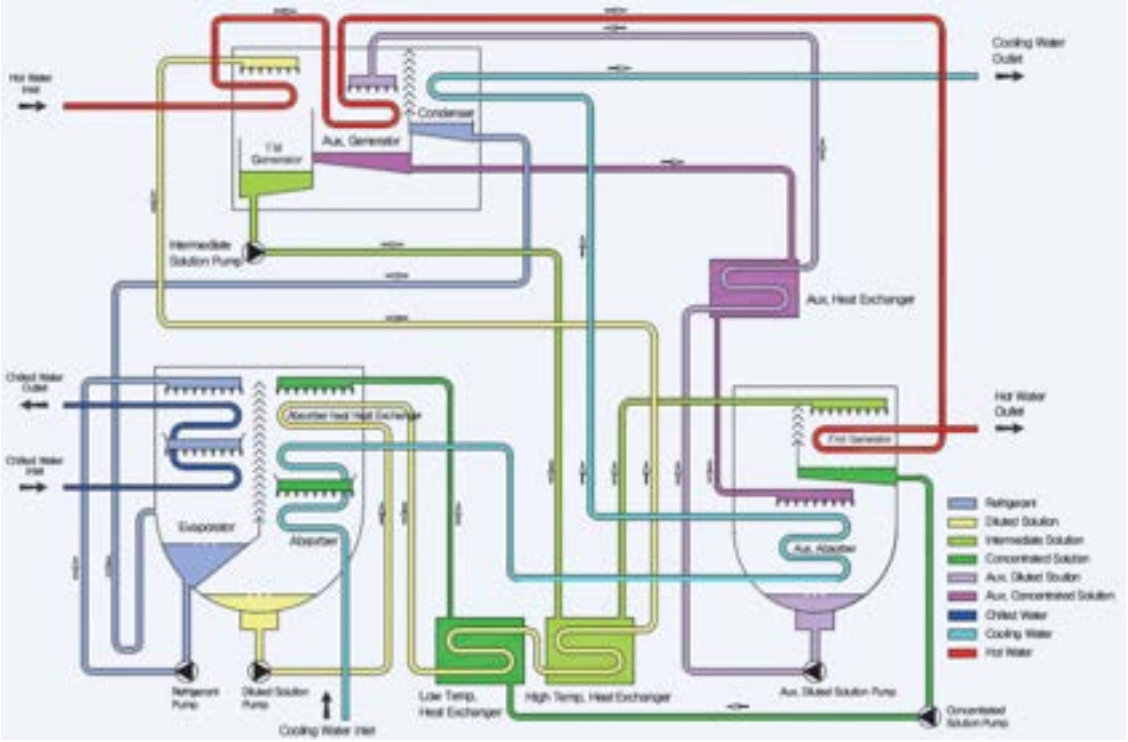

Figure 1. Single-effect Double Lift hot water driven absorption chiller (World Energy 2ABH). Source: [5].

3. Integration of absorption systems in DHC networks

District energy systems have been successfully implemented in many countries around the world and will play an important role in future sustainable cities. The current heating network technology, usually classified as 3rd generation district heating uses hot water between 70-100ºC. But other lower temperature networks are in development in order to reduce heat losses because of its lower operation temperature, the 4th generation working at around 55ºC and even a 5th generation using temperatures around the ambient temperature. The integration of compression heat pumps for their integration in this kind of networks has been started to be studied in the literature [9, 10] but not yet using absorption heat pumps. Nevertheless, the use of absorption systems in District heating networks has been used quite extensively to produce cooling using heat from a heating network [11]. One almost unexplored application is the use of absorption heat pumps and chillers as substations close to each user using smaller capacity units [8]. In that case, the absorption unit could also be configurated to provide heating and cooling in a reversible way (fig. 2) as shown in Ayou et al. [8].

The integration of some of the new advanced low-temperature absorption chillers mentioned in section 2 will be studied here for its integration in District cooling networks. The modelling for a preliminary assessment of these chillers for that kind of applications is given in the next section.

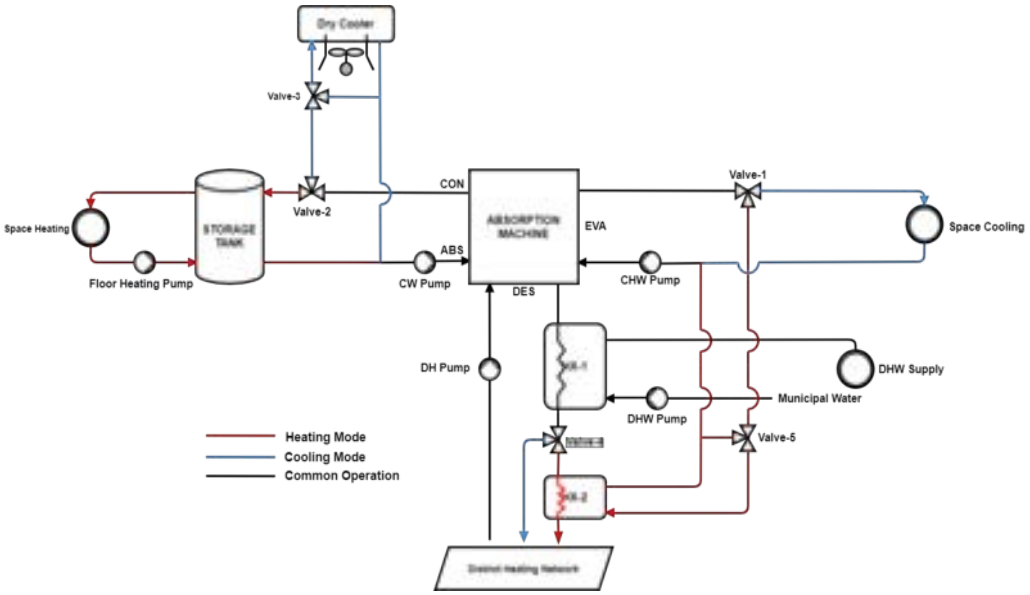

Figure 2. Connection as substation of district heating driven absorption heat pump for space heating and cooling. Source: [8].

4. Modelling of absorption chillers for District Solar Cooling

The electric efficiency factor for the rejection of heat at the condenser for compression chillers and condenser and absorber for absorption chillers is defined as:

$$f_{rej} = \frac{E_{rej}}{Q_{rej}} \tag{1}$$

The solar thermal collector efficiency is modelled using equation (2). The solar collector's area can be also calculated using this same equation.

$$\eta = \frac{Q_D}{I\,A_c} = c_0 - c_1 x - c_2\, I\, x^2 \tag{2}$$

Where x is given by:

$$x = \frac{(T_{av} - T_a)}{I} \tag{3}$$

The rejection of heat is higher for absorption chillers than in compression chillers. The additional heat that has to be rejected with respect to an electric chiller can be computed as:

$$\Delta Q_{rej} = Q_{rej,TDC} - Q_{rej,EC} = Q_D \cdot (1 + COP_{TDC}) - \dot{W}_e \cdot (1 + COP_{EC}) \tag{4}$$

The pump work required to provide the specified hot water flow rate to drive the absorption chiller has been estimated as:

$$\dot{E}_{sol} = \frac{\dot{V} \cdot \Delta P}{\mu_{pump}} \tag{5}$$

The internal electrical efficiency factor for the absorption chiller is defined as the ratio between the electricity consumed internally by the absorption chiller per unit of cooling capacity:

$$f_{el,int} = \frac{E_{TDC}}{Q_c} \tag{6}$$

Similarly, the electrical efficiency factor for the solar plant can be defined as:

$$f_{el,int} = \frac{E_{sol}}{Q_D} \tag{7}$$

Absorption systems are usually known by being bulky and heavy. To compare these characteristics among the considered chillers, it is defined the cooling density per unit of volume and weight as follows:

$$C_v = \frac{Q_c}{V_{chiller}} \quad (8)$$

$$C_w = \frac{Q_c}{W_{chiller}} \quad (9)$$

Thus, the total electricity consumption to run the absorption chiller will be mainly given by the electricity to run the absorption chiller itself, the electricity to be used for the additional heat rejected with respect to the electric chiller and the electricity used in the solar plant to pump the hot water from the solar collectors to the absorption chiller:

$$E_{tot} = E_{TDC} + E_{rej} + E_{sol} \quad (10)$$

The electricity to drive the compression chiller of reference can be easily estimated from its COP and used to compute the electricity savings provided by the absorption chiller:

$$\Delta E = \frac{E_{EC} - E_{tot}}{E_{EC}} \cdot 100\ \% \quad (11)$$

The saving in emissions is deduced from the considered emissions associated with the electricity mix. With respect to the economics comparison, the Levelized Cost of Cooling (LCOC) is selected to compare the three selected low-temperature absorption chillers. This LCOC is calculated using the following definitions and equations.

$$LCOC = \frac{I \cdot CRF + I \cdot f_{O\&M} \cdot n \cdot CRF}{Q_c \cdot N} \quad (12)$$

Where:

$$CRF = \frac{i}{1-(1+i)^{-n}} \quad (13)$$

5. Preliminary analysis of high-efficiency low-temperature absorption chillers

The most common Solar District Cooling networks consist of Flat plate collectors and hot water driven chillers. Even that parabolic solar collectors producing directly steam could be an option to produce high COP cooling using double-effect chillers, it would be difficult to justify its selection unless process steam could be required in the case studying specific small industrial applications.

The main objective of the present analysis is to compare the performance of three different types of absorption chillers using as a reference an electric compression chiller and the simple model described in the previous section 4. The selected chillers are: High-efficiency Single-effect (SE chiller), Single-effect Double-Lift (SE DL chiller) and Half-effect (HE chiller). The main technical data for these chillers is given in Tables 1, 2 and 3. These data is taken from the public catalogue data provided by the Korean company World Energy Co. Ltd [5]. The selected thermal solar collector is a large size double glazed flat plate collector used for District Heating applications manufactured by GreenOneTec. Table 4 shows technical data of these solar collectors and additional information used for the energy, environmental and economic assessment.

The results of the economic and environmental analysis are summarized in Table 5. At a first glance, the low driving temperature as the main advantage of the HE Chiller is not enough to produce an improvement in the solar collector efficiency that could compensate its lower COP. Therefore, it would not be a good idea to use an HE chiller in large scale solar cooling plants. Instead, the HE chiller is clearly a good candidate to be used as bottoming cycle of another cycle such as other higher driving temperature absorption chiller or Organic Rankine Cycle or any other cycle producing an outlet stream of at least 70ºC or used in smaller scale thermal solar plants working at those temperatures.

The main benefit provided by the SE DL chiller is the high temperature difference of the driving hot water. As a result, the hot water flowrate is reduced for a given cooling capacity. Two advantages are derived from this feature: the power required to pump the hot water is considerably reduced and the average temperature of the solar collector is also lower increasing the collector efficiency both with respect to the high efficiency SE chiller. The results show that even with a lower COP than the SE chiller the energy and emissions savings with respect to the compression chiller are similar (Table 5). However, the increased temperature glide is not enough to compensate for the lower COP and the economic indicators are favourable to the SE chiller (Table 6).

The SE chiller is simpler, thus it is not surprising that for the same capacity the other units are larger and more heavy as it is shown using the cooling density parameter (Table 5) and exhibits also the lowest internal electricity consumption. The increase of rejected heat in comparison with a compression chiller of similar size is also the lowest for the case of the SE chiller. Even that the solar collector efficiency is the worst, the required

size of the solar plant is the smallest. It is also true that for the case of an specific application, the heat at the outlet would not return to the solar collector plant but integrated into other applications such as the production of heating of domestic hot water because of its still high temperature, 80ºC. From the economics, the SE chiller is the one that exhibits the lowest Capex and best LCOC. Considering a CAPEX for the compression chiller of 250 €/kW and an average electricity cost of 30 c€/kWh, the payback for a solar thermal plant driven high-efficiency single-effect chiller would be slightly below 5 years.

6. Conclusions

The integration of the most efficient low-temperature absorption chillers is essential for the deployment of District heating and cooling renewable networks and particularly using thermal solar cooling to contribute to the abatement of greenhouse emissions. Many new features have been added to absorption systems beyond the typical single or double effect configurations. The result are higher efficiencies and a broader field of applications not only restricted to cooling but also different types of heat pumps and combined cooling and heating applications.

To compete with traditional compression electric chillers characterized for a continuous decrease in cost, the simple flat plate collectors driving low-temperature absorption chillers could be an interesting alternative. Due to the low driving temperature required by half effect absorption cycles, they provide the best collectors efficiency, but this is not enough to compensate its lower efficiency. Single effect double lift chillers have a very interesting low electricity consumption because of its characteristic high temperature glide of the driving heat. Nevertheless, the highly efficient single effect cycle incorporating the latest advance cycle improvements provide a good energy efficiency and the lowest levelized cost for the produced cooling. It is true also that despite this preliminary comparison among available low-temperature hot water alternatives, the real selection should be made for specific applications.

Abstract:

The paper presents design considerations for experimental investigation of the Ranque-Hilsch vortex tube effect (VT). The research aims to find physical mechanisms governing the thermal and mass separation of non-homogenous gases entering the VT. Also, an approach to study phase-change phenomena inside the VT will be undertaken to evaluate the applicability of the VT in refrigeration systems. For this purpose, it is essential to have a mutually validated experimental setup and numerical model.

The 1st generation test rig was based on a VT of 36 mm inner diameter and up to 1.62 m length. With inlet air supply at 3 bar abs, it was possible to achieve outlet temperature values from 0.1 C at the cold side to 42.3 C at the hot side, and the maximum air flow was 123 kg/h.

The 2nd generation should be reduced in size for two reasons. First, lighter and heavier gases (helium, carbon dioxide) will be supplied from pressurized cylinders and mixed with air or nitrogen. The flow rate should be minimized to enable a continuous operation from the pressurized cylinders. Second, to apply higher inlet pressure, it is required to reduce the flow channels to maintain the gas flow below the technical limit of about 60...100 kg/h.

The proposed test rig configuration is based on two supply options. In the first option, pure gases can be supplied from batteries (bundles) of pressurized cylinders, and then mixed to achieve the desired composition. The second option can be obtained by connecting the test installation to an air compressor, which is more suitable for test operation or for multiple-parameter measurements required to obtain boundary conditions for numerical modelling. Moreover, the test rig will be extended to include a multi-phase flow unit with a liquid dosing and separation equipment.

Ranque-Hilsch effect; Vortex Tube; Measurements; Gas flow; Mass separation.

1. Introduction

Ranque-Hilsch vortex tubes (RHVTs) is a device that allows separation of a pressurized and highly turbulent inlet stream into two distinct outlet streams of lower pressure and varying temperatures. Temperature and mass separation effects are unique and potentially useful phenomena occurring in RHVTs. The effect was discovered by Ranque [1] and then investigated by Hilsch [2], which is commemorated by the scientific community by the use of these surnames to denote both the effect and the device.

The effect of the inlet pressure on the temperature difference was observed and studied by Martynovskii and Alekseev. They observed that the temperature difference increases with the inlet flow pressure [3]. According to Crocker et al. [4], temperature increase at the hot side can be as high as 120 K. On the other hand, the temperature drop on the cold side is said to be up to 50 K with respect to the inlet temperature [5].

Significant number of papers has been published on temperature separation in RHTVs, contributing to our understanding of temperature separation phenomena occurring in vortex tubes (VTs). The current state of knowledge aimed to explain the phenomena occurring in VTs was presented by Xue et al. [6]. It was confirmed that when studying temperature separation in a RHTV, various factors such as pressure gradient, viscosity, secondary flow structure in the tube [7], and acoustic flow [8] should be considered. Furthermore, none of the above factors proved to be the real reason for the energy separation in his RHVT due to the complexity of the

flow structure in the pipe. The various and sometimes conflicting conclusions of the investigation suggested the need for deeper and more thorough experimental and theoretical research work to better understand the complex processes inside the tube.

Regarding the mass separation phenomena in RHTVs, the reduced number of publications, with respect to the temperature separation can be found in literature. Most of studies focused on the VT application using compressed air. However, hydrocarbon processing (such as natural gas) is an example where knowledge of gas species distribution is important to keep dew point and hydrate formation conditions under control [9–11]. Practical applications for LPG processing have recently been reported by Majidi et al. [12]. Several experimental studies have been carried out by various investigators to investigate the potential for gas species separation in Ranque-Hilsch counter-flow vortex tubes. As one example, Yun et al. [13] performed an industry-oriented experimental study for CO2 separation from its mixture with air, observing the importance of the inlet pressure and the cold mass fraction. However, no qualitative conclusions leading to the explanation of the physical mechanisms were given.

The availability of such decoupling mechanisms presents a valid opportunity to integrate RHVT into various design systems to improve overall system efficiency. The potential areas of application are very wide and include, for example, improving the performance of refrigeration circuits [14, 15] or separating gas network zones with different hydrogen contents. Although a wide range of applications for RHVT can be presented [16-18], the mechanism of temperature and mass separation still lacks a fundamental scientific explanation [19, 20] as well as proper design of RHVT as a functional part of the system.

The current paper presents the initial part of a new research project, dedicated to the understanding and to possible applications of the highly interesting and still not fully explained Ranque-Hilsch phenomenon.

1.1. The ATHLETE project

The aim of the project is to carry out fundamental experimental and numerical research to improve the understanding of the Ranque-Hilsch phenomenon in a vortex tube (VT), comprising the thermal, mass and phase separation, and to demonstrate the potential of applicability in the most promising engineering areas of refrigeration and gas separation.

The project contains experimental and numerical research, and investigation on gas mixtures will be preceded by a fundamental research on pure compounds. The project will be concluded by a thermodynamic study of RHVT-based systems.

The main questions to be answered are:

1. does the difference in gas density cause a systematic mass stratification?

2. can the stratification mechanisms be confirmed by numerical modelling and flow visualization?

3. can the stratification mechanisms contribute to the performance of selected energy/process systems?

The specific project objectives comprise: O1: to build a functional CFD model of RHVT validated by experiments, O2: to elaborate a 0D (functional) representation of RHVT, O3: to demonstrate the benefits of integrating an optimized RHVT into energy systems using two specific case studies. Accordingly, five work packages (WPs) are proposed. Work packages WP1 and WP3 are related with experimental research for pure fluids and gas mixtures, respectively. Similarly, packages 2 and 4 aim to mirror the experimental results using a numerical model, which is supposed to provide a more detailed information on the flow structure. WP5 is aimed at a demonstration of benefits of the RHVT in two selected technical systems:

1.R744 (CO2)-based refrigeration cycle with an integrated RHVT;

2. Pressure let-down station for hydrogen rich natural gas, equipped with RHVT for separation of network zones of different hydrogen content.

1.2. Aim and novelty of work

The aim of this paper is to present the project development starting from the previous work of two team members, and then to explain the design of the experimental test rig which will be used to carry out the WP1 and WP3. Moreover, some technical issues influencing the experimental set-up and some modifications in the assumed plan of experiments are presented.

The novelty of work is related to the investigation of mass separation in the vortex tube, carried out within the ongoing ATHLETE project. Moreover, a detailed presentation of the test rig design, along with scale evaluation based on gas dynamics equation and preliminary measurements represents an original contribution as well.

2. First generation test installation

2.1. Installation layout and measurement methodology

The first generation test rig was built in the Laboratory of High Temperature Processes at the Silesian University of Technology. It was partially adapted from the previous test installation for the natural gas industry,

therefore, one flow measurement unit was composed of a distribution-type turbine flow meter Elster G65 with an integrated RTD Pt100 temperature sensor and an electronic volume corrector with built-in pressure transducer (0...600 kPa). A scheme and a photograph of the installation is presented in Fig. 1.

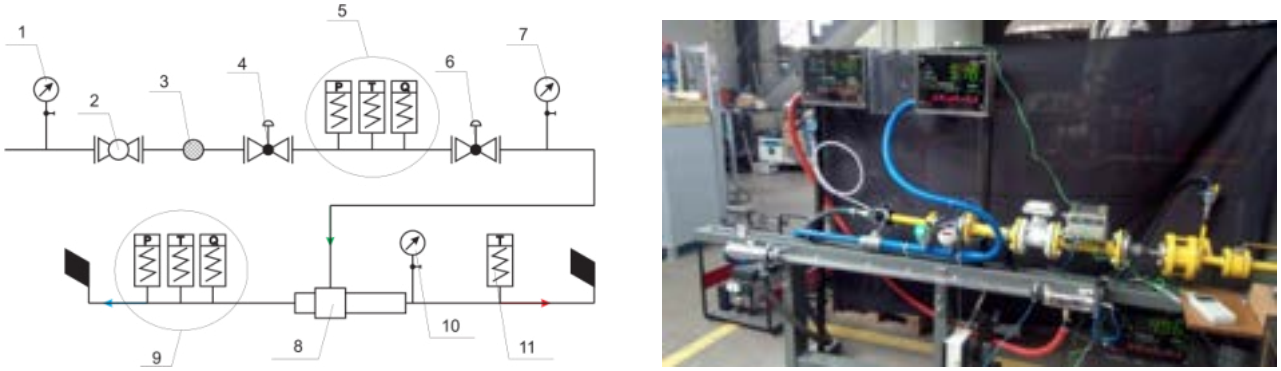

***Figure 1**. Experimental setup of the 1st generation installation. 1, 7, 10: Manometers, 2. Inlet valve, 3. Filter, 4. Pressure regulator, 5, 9 Pressure, temperature and volumetric flow measurement, 6. Fine pressure regulator, 8. Vortex tube, 11: Temperature measurement.*

The vortex tube was designed by the team member Paweł Bargiel and manufactured by an external company. The main purpose of the designed experimental rig was to use it for the validation of the numerical approach, based on which the original analytical description of the VT was proposed.

The inner VT diameter was 36.0 mm. The construction was based on a set of 2 identical nozzles tangentially located to the core part of the tube. Each nozzle had a dimension of 4.4 × 7.2 (channel height × channel width) and they were positioned in parallel. The set of nozzles was integrated with an orifice of a constant diameter equal to 13 mm.

The main set of measurements was performed for the maximum inlet pressure possible to maintain at the vortex tube inlet, i.e. about 360 kPa abs. It was found that lower values of inlet pressure decreased the thermal effect. For the maximum pressure, two key variables were modified:

a) The Length/Diameter ratio L/D, ranging from 15 to 45. This parameter was modified by replacing the core part of the tube.
b) The cold mass fraction (CMF), ranging approx. from 0 to 0.9. This value, representing the ratio of the mass flow rate at the cold outlet to the total inlet flow, was modified by adjusting the conical valve located at the ‘hot’ outlet of the VT.

2.2. Selected results

Fig. 2 Presents the total (inlet) mass flow rate of air flowing into the vortex tube in terms of the length/diameter ratio and in terms of the cold mass fraction.

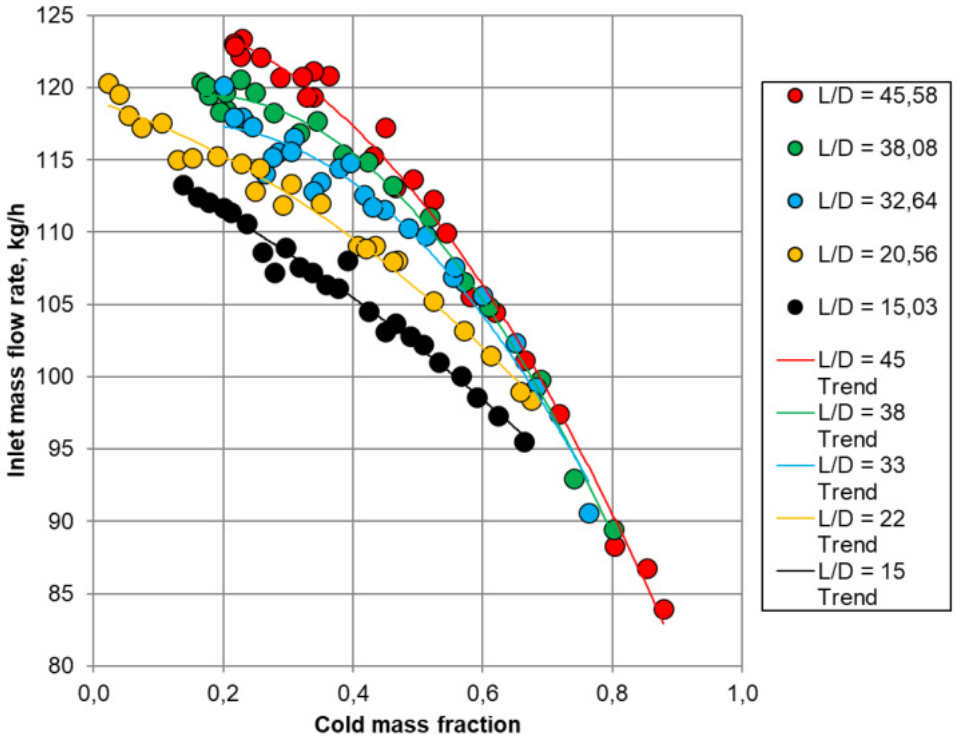

***Figure 2**. Total (inlet) mass flow rate of air through the vortex tube, inner diameter 36.0 mm; average inlet parameters: 363.5 kPa, 24.0°C.*

It can be seen that for the investigated design of the vortex tube, the total mass flow rate decreases with the cold mass fraction. However, from the point of view of the ATHLETE project, to properly design the new test installation it is essential to register the scale of the mass flow rate. In this case, inlet pressure of approx. 3.6 bar abs generates a flow exceeding 100 kg/h.

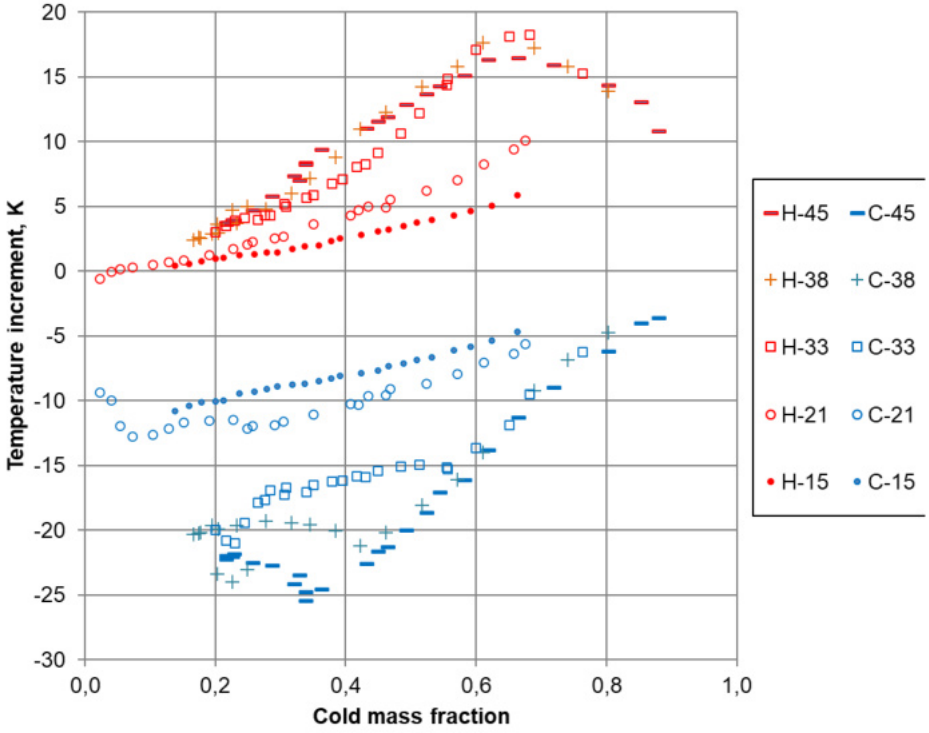

***Figure 3**. Thermal separation obtained in the 1st generation test rig with compressed air in terms of the Length/Diameter L/D ratio. Exact L/D values are given in Fig. 2. Pipe diameter (inner): 36 mm.*

Figure 3 presents the thermal performance of the studied vortex tube in terms of the length/diameter ratio. It can be observed that the increased L/D ratio improves the Ranque-Hilsch effect, however, there is no strict regularity for L/D > 33. Also, one cannot define a specific cold mass fraction corresponding to the maximum R-H effect. Maximum temperature drop at the cold outlet occurs for CMF = 0.3...0.4, while the maximum increment at the hot outlet corresponds to CMF = 0.6...0.7. For shorter vortex tubes (L/D = 15 and 21) no function maxima can be identified. Compared to similar reported studies [21], the function dependency for the hot outlet temperature in terms of the CMF is similar; different results are obtained for the cold outlet temperature. Here, a minimum value is obtained for most L/D ratios at CMF below 0.4, while Behera et al. [21] failed to obtain a minimum value as they only considered CMF ranging from 0.4 to 1.

Some more results of this work, including the numerical modelling, are shown by Bargiel et al. [22].

3. Second generation test installation

The first generation installation (related with a PhD programme) was designed to study the vortex tube operation using compressed air. To develop the idea according to the ATHLETE project assumptions, it is required to increase the scope of measurements which can be carried out at the experimental test rig. The most important modification is the adaptation to operation with compressed gases from gas cylinders, which in turn entails the reduction of the vortex tube size.

3.1. Preliminary assumptions

The initial concept of the ATHLETE research installation was based on the research questions formulated in the project application. The proposed scheme of the test rig is presented in Fig. 4.

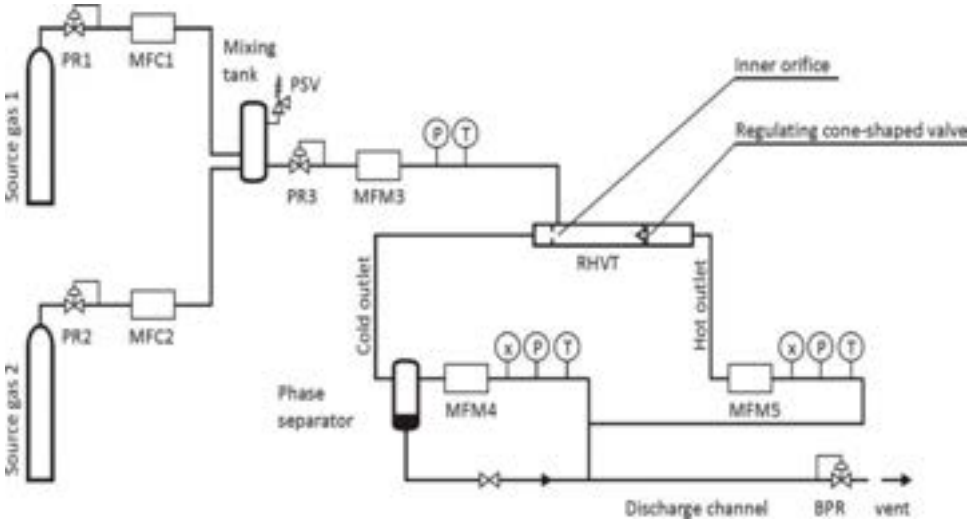

***Figure 4**. The initial concept of the ATHLETE project experimental set-up. {B]PR – [back] pressure regulators, MFC/MFM - mass flow controller/meter, p, T, x – measurement of pressure, temperature, concentration, PSV – pressure safety valve.*

In this configuration, it is possible to mix two source gases by means of two mass flow controllers supplying a specific quantity of gas to a mixing tank. Next, pressurized medium is supplied to the vortex tube, and its pressure is precisely adjusted in the regulator PR3. The discharge side of the VT is pressurized, its pressure is controlled by a back pressure regulator. This enables operation with carbon dioxide decompressed from supercritical conditions of approx. 140 bar to a back pressure of approx. 40 bar. Liquid phase of CO2 is collected in a phase separator. The objective of this set-up is to investigate the mechanism of phase separation in the vortex tube.

3.2. Simplified flow model and preparatory measurements

To evaluate the mass flow rate of a compressed gas flowing through a vortex tube of given dimensions, it was proposed to combine a simple analytical approach with some preparatory measurements.

Within the analytical approach, the flow through a vortex tube was approximated by a flow through a set of two consecutive nozzles (Fig. 5):

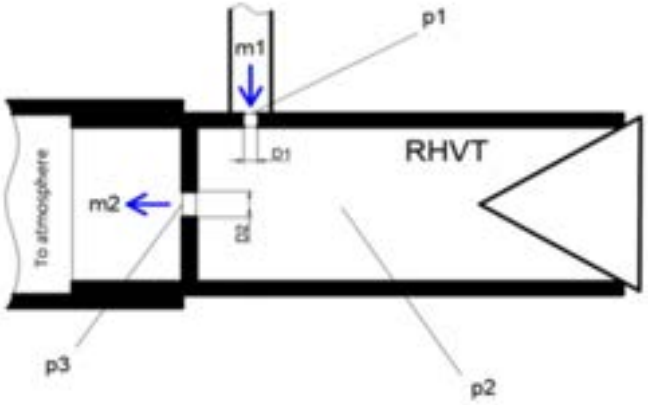

***Figure 5**. Simplified flow model for the estimation of the RHVT mass flow rate*

For the purpose of scale determination, it can be assumed that the hot outlet is completely closed. Results from the 1st generation installation show that, despite the increment in the total outlet cross section, opening the cone-shaped outlet valve does not cause any increment of the total inlet flow[1]. Accordingly, in the simplified model, mass flow rate through the inlet nozzles equals the flow rate through the orifice, provided that steady state is achieved.

For each nozzle, the outet-to-inlet pressure ratio $p_{\mathrm{out}}/p_{\mathrm{in}}$, henceforth denoted by β, generates a mass flow rate $\dot{m}$, which can be calculated as:

$$\dot{m} = C_D A \psi_s \sqrt{\frac{p_{\mathrm{in}}}{R T_{\mathrm{in}}}} \tag{1}$$

where C_D is the discharge coefficient (ideal nozzle = 1), A is the cross section area, R is the gas constant, and p_{in} , T_{in} are total (stagnation) inlet parameters. The flow coefficient ψ_s depends on the pressure ratio β, and it also determines the flow condition at the nozzle exit section (subsonic/sonic):

$$\psi_s = \begin{cases} \sqrt{\dfrac{2\kappa}{\kappa-1}\left(\beta^{\frac{2}{\kappa}} - \beta^{\frac{\kappa+1}{\kappa}}\right)}, & \text{if } \beta > \beta_{\mathrm{crit}} \\ \sqrt{\kappa\left(\dfrac{2}{\kappa+1}\right)^{\frac{\kappa+1}{\kappa-1}}}, & \text{if } \beta \le \beta_{\mathrm{crit}} \end{cases} \tag{2}$$

The critical value of the pressure ratio for the ideal gas model is:

$$\beta_{\mathrm{crit}} = \left(\frac{2}{\kappa+1}\right)^{\frac{\kappa}{\kappa-1}} \tag{3}$$

This value ranges 0.48 to 0.54 depending on the isentropic exponent κ. Accordingly, if the nozzle inlet pressure is approx. 2 times higher than the outlet pressure, sonic flow is achieved. The derivation of ideal and real gas nozzle equations was presented i.a. by Rist [23].

In the studied case, two nozzles are connected in series. The first nozzle has p_1 as inlet, and the unknown value of p_2 as outlet pressure. The second nozzle has p_2 as inlet, $p_3 \cong p_{\mathrm{atmosphere}}$ as outlet pressure. The model has a set of simplifications:

- Ideal gas model is used (acceptable for p < 4 bar);
- Stagnation parameters are approximated by static parameters;
- Outlet pressure is approximated by atmospheric pressure;
- The impact of the orifice geometry on the critical pressure value is neglected.

All these simplifications are attributed to the discharge coefficient C_D (which now includes flow contraction, the velocity coefficient and the above listed assumptions).

[1] This is an interesting paradox still to be investigated.

By setting the requirement of flow continuity $\dot{m}_{1-2} = \dot{m}_{2-3}$, the unknown internal pressure p_2 and the equalized flow rate $\dot{m}$ can be found within a simple numerical procedure.

The theoretically obtained value of the flow rate has been compared with the measured values for a commercially available small-scale vortex tube (Fig. 6). This VT is equipped with a suction chamber and a set of 6 identical nozzles. Each nozzle has a dimension of 0.9 × 3.1 mm (channel width × channel depth along the main VT axis). The set of nozzles is integrated with a divergent orifice with the smallest diameter of 4.7 mm.

a) b)

Figure 6*. a) A commercially available small-scale vortex tube used for system downscaling b) Set of nozzles in the commercially available vortex tube*

The commercially available small-scale vortex tube has been installed in the 1st generation test rig, however, due to the different scale of the object, only the inlet mass flow rate was measured. The objective of measurements was to define the range of mass flow rate which is critical for the selection of all process equipment, in particular the most expensive elements (flow meters, mass flow controllers and pressure regulators).

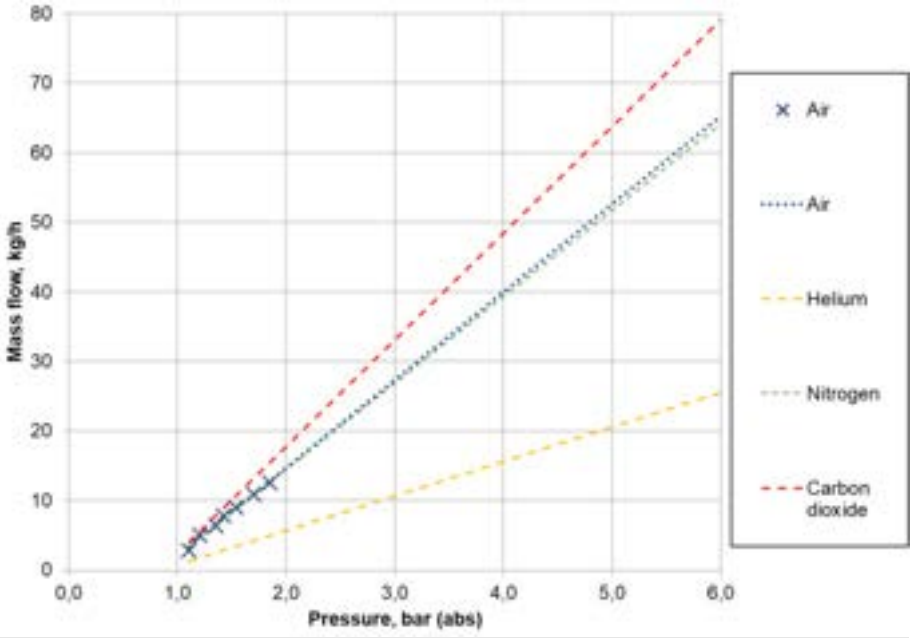

Figure 7*. System scale evaluation based on air flow under variable inlet pressure. Points represent the measured values. Dashed lines represent an extrapolation to higher pressure values and a flow estimation for other gases using the calibrated analytical model.*

The measured values have been compared with the simple analytical model (Eq. (1)-(3)). Assuming that the discharge coefficient for the inlet nozzles is 0.98, the discharge coefficient for the orifice 0.854 provides the

equality of the measured value and the calculated value. Accordingly, the simplified model is calibrated enough to be useful for the prediction of the flow range and the selection of process equipment. Values for other gases and for higher pressure have been calculated from the model, and the results are depicted in Fig. 7.

It can be concluded that if the designed vortex tube is kept at a similar scale, the range of flow 0...100 kg/s should be sufficient to analyze the flow of all technical gases foreseen in the project. Moreover, it was decided that heavier and lighter gases will be supplied at a maximum mass fraction of 10%, which should be sufficient to observe their possible stratification in the vortex tube.

3.3. Technical questions for the 2nd generation test installation

The conceptual design of the installation, depicted in Fig. 4, does not reveal technical details related to flow parameters. The selection of equipment and the estimation of the project budget was based on a single round of commercial requests which were sent to manufacturers of metering equipment, pressure regulators and tanks and to the suppliers of pressurized gases.

Within the first part of the project, a detailed, second round of commercial request was launched, followed by a series of meetings. In this way, the general idea was subject to verification with market reality, additionally suffering from consecutive global events, but most importantly, it was confronted with technical details. Several major conclusions could be drawn from this work are:

1. It is currently not possible to supply supercritical carbon dioxide from gas cylinders. Theoretically, the pressure of any gas in a cylinder can reach 300 bar or more, however, major suppliers of technical gases limit their offer here to a 2-phase fluid, with the saturation pressure resulting from ambient temperature (e.g. 57.3 bar @20°C);
2. Creating a closed-loop CO_2 system is technically possible, but it exceeds the budget of the current project. Also, there is no sufficient knowledge on how the vortex tube would operate and which part of the agent would condense. Accordingly, this idea represents an interesting field of future research.
3. It is essential to keep the topic of phase change inside the vortex tube within the scope of the project. To investigate a two-phase flow, an alternative strategy is required.
4. It was proposed to investigate the two-phase flow by dosing some liquid (e.g. water or ethyl alcohol) to the saturation level at the VT inlet, and then by measuring the liquefied quantity at VT outlet(s). A corresponding experimental installation is currently under design.
5. Using carbon dioxide as a heavy gas component is still possible and it enables to evaluate species separation (e.g. CO_2 from N_2). However, the CO_2 flow rate is technically limited by the evaporation rate in a gas cylinder, which is about 1 Nm^3/h. To ensure higher flow of CO2, a bundle of cylinders is needed.

The design of the experimental installation is presented in the subsequent section. The section of humidification and liquid separation is not included at this stage.

3.4. Current design of the installation

The key elements of the proposed installation are shown in Fig. 8.

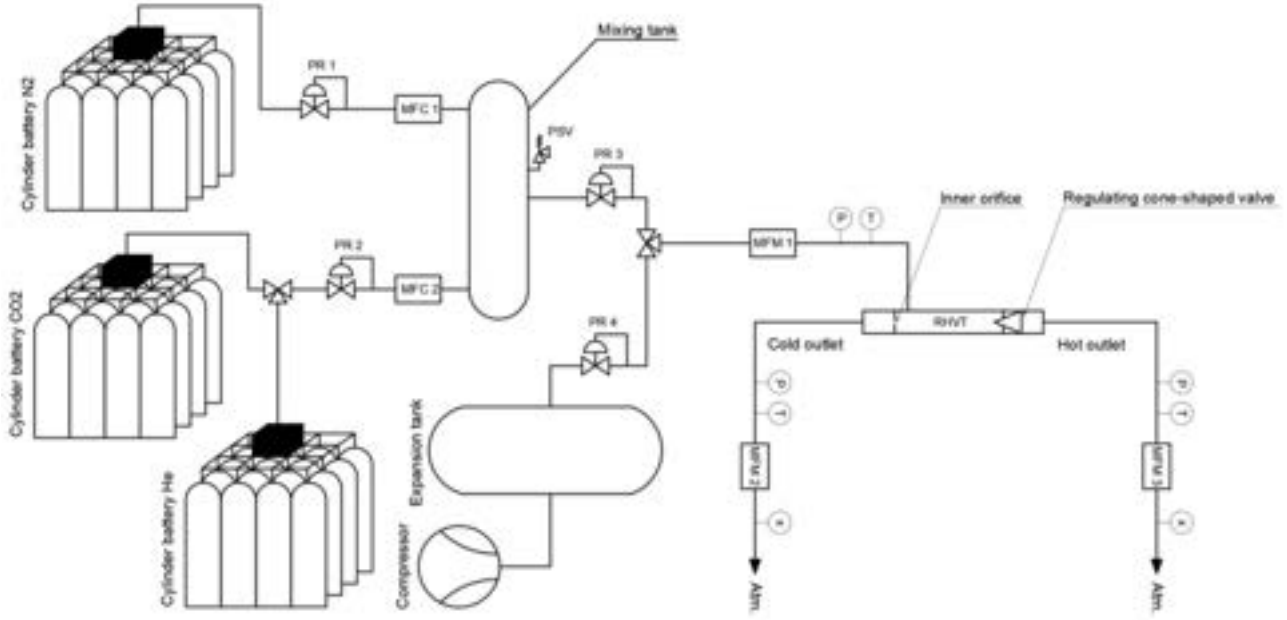

Figure 8. *The proposed test rig configuration for WP1 and WP3 measurements. Symbols are the same as in Fig. 4.*

The research installation is adapted to the supply of various gases. The first supply path leads from cylinder batteries (bundles), whereas the basic gas is nitrogen, obtain from a battery of 16 cylinders. Nitrogen can be mixed either with carbon dioxide CO_2 (a heavier gas CO2), or helium He (a lighter gas). Pressure of gases leaving the tank batteries is regulated by regulators PR1 and PR2. Next, a precisely determined mass of each gas is supplied to a mixing tank via mass flow controllers MFC1 and MFC2. The tank is protected by a pressure safety valve PSV. Currently, tank pressure of 16 bar is considered.

Next, the mixed gas leaves the tank and its pressure is adjusted again by a regulator PR3. The gas mixture passes through the mass flow meter MFM1. Here, a thermal flow meter with adjustable gas composition was selected. Once the gas pressure and temperature are measured, it enters the vortex tube and then leaves it through the hot and the cold outlet. Then, thermal parameters and mass flow rates are measured again by the same type of equipment. Finally, gas composition is measured at both ends. A dedicated gas composition measurement system will be developed based on commercially available calibrated gas sensors.

Another path for supplying the pressurised gas is obtained if an air compressor is used. In this case, compressed air passes through a tank and a local installation (this part of equipment was used in the 1st generation research). A newly adapted regulator PR4 will be installed for the reduced flow rate and increased pressure, compared with the 1st generation set-up.

The compressed air supply line is essential for multiple-parameter testing, where the use of pure gases is too expensive. Experimental results obtained with compressed air will be supplied as boundary conditions to multi-scenario numerical modelling. Only a reduced set of parameters obtained from the numerical modelling will be used for experimental work with pure gases.

4. Conclusions and further work

Results obtained from the 1st generation experimental set-up have been used to evaluate the scale of the system for the 2nd generation. In general, it is possible to maintain the previous maximum range of the mass flow rate at 100 kg/h maximum, however, the reduction of the vortex tube size enables the project team to work with higher supply pressures, reaching 6-10 bar depending on the final scale of the vortex tube.

The first stage of the project related with the detailed technical design of the experimental test installation revealed a series of problems, mostly related with the availability of pressurized carbon dioxide. To keep the desired flow capacity, it was decided to use bundles (batteries) of cylinders with pressurized gases instead of a single container, and to apply pressure regulators of higher capacity than that of standard cylinder regulators.

The current work within the project is performed in parallel in three areas:

1. Construction of an own vortex tube and its numerical model (twin); the construction is kept as simple as possible to enable an exact representation within the numerical model;
2. Completion of the experimental test rig, some elements (flow meters, temperature and pressure sensors, regulator PR4) have been purchased, other elements (mass flow controllers, pressure regulators PR1-PR3, tank) are at the selection stage and will be purchased in the upcoming weeks;
3. Design of the liquid phase dosing and separation system: this part of project is being carried out with a wider engagement of students within a dedicated Project-Based-Learning scheme, within a small grant obtained from the University.

Future work comprises advanced multi-scenario numerical modelling and optimization of the vortex tube, as well as elaboration of the gas composition measurement system and at attempt to flow visualisation.

The project team expects to obtain interesting and novel results, in particular in the topic of mass and phase separation, which is scarcely reported in subject literature.

Abstract:
High-temperature heat pump (HTHP) is a promising technology for decarbonization of process heating through electrification and energy efficiency. Exploiting the potentials requires a simultaneous optimization of the cycle layout and the working fluid. This paper proposes an efficient cascade HTHP and optimizes its thermodynamic performance. Using steam for high-temperature loop and use of alternative hydrocarbons for low-temperature loop are examined. On the application level, district heating is considered as a heat source and evaluated for different supply temperatures, including 80 °C, 70 °C and 40 °C.
The results reveal that pentane with highest critical temperature among the suggested hydrocarbons, shows the best energy performance to be paired with steam in the proposed cascade HTHP system. However, concerning the hydrocarbon compressor volumetric heating capacity (VHC) and safety issues, butane is an excellent candidate. In addition, when the heat available in the main transmission lines of district heating unit is considered as the source cooled from 80 °C down 70 °C, the highest value of coefficient of performance (COP) is achieved as 2.74 for the sink condensation temperature of 160 °C.

Keywords:
High-temperature heat pump, Low GWP working fluids, Steam, Hydrocarbons, District heating.

1. Introduction

High-temperature heat pump (HTHP) technology using renewable electricity is a promising solution to decarbonize the industrial process heat supply; which is mainly based on fossil fuels and contributes with 36.8 % to the CO_2 emissions in industry [1]. In this regard, optimizing the performance of the HTHP systems concerning various configurations and working fluids is a vital issue.

Chen et al. [2] investigated performance of an improved vapor injected cascade heat pump system for high-temperature applications, from the viewpoints of thermodynamics and exergoeconomics. Considering zero Ozone Depletion Potential (OPD) and low Global Warming Potential (GWP) as the main environmental criteria, they examined the use of R1233zd(E), R1336mzz(Z) and R245fa in the high-temperature loop and R1234yf, R290 and R134a through the low-temperature loop, meeting the required target temperatures. The highest coefficient of performance (COP) value of 2.3, when the evaporation and condensation temperatures are 10 °C and 100 °C, respectively, was achieved.

Performance of simple vapor compression HTHP system with condensation temperature up to 125 °C using low GWP working fluids of R1234ze(E) and R1234ze(Z) was compared by Fukuda et al. [3]. It was discussed when the condensation temperature is about 20 °C below the corresponding working fluid critical point, the COP is maximized, which is higher also for R1234ze(Z). In another study by Kondou et al. [4], again R1234ze(Z) showed promising performance among other low GWP refrigerants such as R1234ze(E), R717 and R365mfc for high-temperature applications of heat pumps up to 160 °C. In addition, performance of dual pressure condensation HTHP using 10 different working fluids including R600a, R1234ze(Z), R1224yd(Z), R245fa, R1233zd(E), R245ca, R601a, R1336mzz(Z), R365mfc and Isohexane was carried out and compared to the single-stage, two-stage and cascade systems, by Dai et al. [5]. It was revealed that the system using R1234ze(Z) shows the highest COP of 4.16, which is about 9 % higher than that of the conventional HTHP configurations.

In a semi-empirical work by Mateu-Royo et al. [6], they demonstrated that in a HTHP system covering the wide range of sink temperatures of 110- 140 °C, using HCFO-R1224yd(Z) shows promising performance from the energy efficiency and environmental perspectives and could be replaced with R245fa.

R1233zd(E) also was introduced as promising working fluid in heat pumps with high-temperature applications by Arpagaus et al. [7] and Frate et al. [8]. Mateu-Royo et al. [9] focused on the effects on the heat pump performance of superheating degree in an internal heat exchanger. They concluded that using HCFO-R1233zd(E), HFO-R1336mzz(Z) and HCFO-R1224yd(Z) instead of R245fa leads to an improvement of 27%, 21% and 17% in COP, respectively. In similar study, Mateu-Royo et al. [10] conducted experimental study of HTHP system to upgrade the heat from 60 °C to 80 °C to the temperature of 90 °C to 140 °C. Performance of the system was compared using different refrigerants such as R245fa, R1224yd(Z), R1233zd(E), and R1336mzz(Z). They reported that under the same operating condition, using R1336mzz(Z) leads to higher COP values and reduction in CO_2 emissions up to 57 %, compared to a natural gas boiler.

However, through another work, Mateu-Royo et al. [11] showed that using pentane as a hydrocarbon working fluid in heat pumps with condensation temperature up to 150 °C leads to higher COPs than for using R1233zd(E), R1336mzz(Z) and R245fa. Following the promising performance of using hydrocarbon refrigerants, a comprehensive study on the performance prediction of water source HTHP system screening various working fluids were performed by Yan et al. [12]. The results revealed that butane as hydrocarbon working fluid with a low GWP value, also shows a better performance than HFCs and HFOs. In addition, Mota-Babiloni et al. [13] reported that in a cascade HTHP system, butane and pentane are the best choices for the low-temperature and high-temperature loops, respectively. A 20 kW capacity cascade heat pump using such hydrocarbons as propane and butane in the low and high-temperature cycles, respectively, was investigated by Bamigbetan et al. [14]. It was revealed that recovering waste heat at 30 °C, the heating COP could reach 3.1 for the temperature lift of above 70 °C. Bai et al. [15] also reported that R600 (butane), R1224yd(Z), R1234ze(Z) and R1233zd(E) show high COPs and smaller compressor sizes in high-temperature applications of heat pumps.

However, despite the promising performance of heat pumps for high-temperature applications using hydrocarbons such as butane and pentane and also hydrofluoroolefins in particular R1234ze(Z), R1233zd(E) and R1336mzz(Z), steam as zero GWP working fluid showed a better performance with higher COP through the study conducted by Wu et al. [16]. Steam also was successfully used and recommended by Zühlsdorf et al. [17] in a cascade multi-stage HTHP system for steam generation and process heat supply up to 280 °C.

On the other, based on the recent reports, more than 6000 district heating networks operate in Europe and supply 11 % to 12 % of the total domestic heat demand [18]. District heating systems can be categorized in five generations, as summarized in Table 1 [18,19].

Table 1. Different district heating networks and their characteristics [18].

DH Network	Operating temperature	Main drawback
1G	120 °C to 200 °C	High implementation and maintenance costs and huge amount of thermal losses up to 30 %.
2G	120 °C to 160 °C	
3G	70 °C to 100 °C	
4G	35 °C to 70 °C	Emergent technologies and high electricity and HP costs.
5G	10 °C to 35 °C	

As briefly discussed in Table 1, due to the inefficient distribution processes for 1G and 2G DH networks, 4G and 5G DH systems are the most considered and dominant DH generations. They do not suffer from large thermal losses and as results sharp thermal stresses as well as high pressure drops in the pipelines [18]. In addition, comparing the traditional heating systems based on natural gas boiler, the CO_2 emissions could decrease up to 45%, which allies with the decarbonization of the heating sector, as well [18]. Regarding the promising environmental performance of new generation DH networks and their temperature range of operation, heat pumps (HP) can be effectively integrated with them to decarbonize the district heat sector.

Using R245fa and R134fa, thermodynamic and economic analyses of booster heat pump in low-temperature district heating was carried out by Roh et al. [20]. It was concluded that the economic feasibility of using heat pumps in the DH networks strongly is affected by the electricity and district heat prices. The optimum combination of booster heat pumps in a very low-temperature district heating was performed and compared with low-temperature district heating by Ommen et al. [21]. They reported that using central heat pump, the performance of the system is improved up to 12 %. Combining a ground source central heat pump and local boosters, Yang et al. [22] proposed and analyzed a system for domestic hot water production. According to the exergy analysis results, the low-temperature district heating operating at 55 °C showed higher efficiency

than high-temperature DH at 70 °C. Use of modern heat pumps in the existing district heating networks was investigated by Kontu et al. [23]. Possibility of utilization of various heat sources in the HP-boosted DH networks was introduced as one of the main advantages. However, it was outlined that using heat pumps in DH networks is very sensitive to the heat source and electricity prices.

Various scenarios on the integration of heat pumps with district heating concerning heat pumps location, connection and operations mode was studied by Sayegh et al. [24]. They reported that, higher share of heat pumps in district heating networks yields less emissions, and environmental impacts. Pieper et al. [25] evaluated integrating three different heat sources of groundwater, seawater and air with heat pumps to supply district heating. They reported that the most appropriate heat source to be integrated by heat pump is changed seasonally and using multi-source heat leads to the maximum COP. In addition, Arabkoohsar et al. [26] proposed a new generation of district heating system using booster heat pumps and triple pipes. They reported that the new system shows a better energy efficiency, especially during winter days.

In all aforementioned studies, the district heating was considered as the sink and the heat pump was supposed to supply or boost the required heat for the DH network. However, referring to Table 1, 4G DH networks, which provide heat up to 70 °C, can be considered as heat source for heat pumps, to supply heat for medium or high-temperature process applications. The main benefit of this integration is that the district heat is always available as a source. In this regard, the present study aims to evaluate the performance of a cascade heat pump system integrated with district heat. In addition, on the HTHP system configuration level, reviewing the literature outlines those hydrocarbons such as butane and pentane as natural working fluids shows competitive performance with synthetic hydrofluoroolefins. However, using steam could lead to higher COPs in the high-temperature applications. Since, considering the special environmental characteristics of steam (zero ODP and zero GWP), it turns into a very interesting choice, as the working fluid in HTHP systems. However, for industrial applications with high-temperature lifts, using single-stage steam heat pump brings about some serious challenges, in particular high superheating degrees at the compressor discharge. Therefore, this work also aims to address these challenges and then find solutions through proposing efficient system design and choosing appropriate natural low GWP working fluids.

2. System description and modelling

Selecting the optimal cycle layout and working fluid for a given application must consider a variety of thermodynamic and technical parameters, such as temperatures, pressures, and main operating parameters for the equipment. Steam is found to be an optimal working fluid for applications above around 100 °C, due to the high required volume flow rates, high pressure ratios and high superheating during compression for lower temperatures, as depicted in Figure 1. Therefore, a cascade system is suggested, consisting of a single-stage bottom cycle using a hydrocarbon and a steam compression as top-cycle.

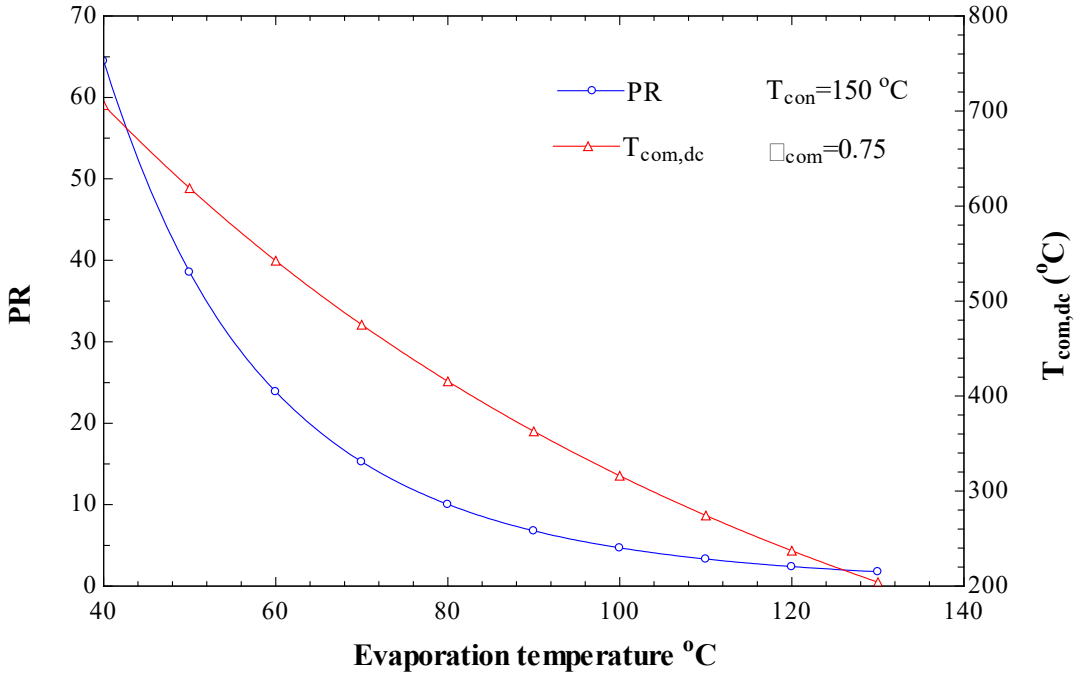

Figure 1. Steam compressor pressure ratio (PR) and discharge temperature ($T_{com,dc}$) of varying evaporation temperatures and a fixed condensation temperature

A schematic of the proposed cascade heat pump system is presented in Figure 2. In the proposed HP system, the high-temperature loop is not closed and steam as non-flammable and non-toxic fluid could be directly delivered to the sink after discharging from the compressor. The steam is generated through the steam generator, which receives thermal energy from the bottoming cycle. In the bottoming cycle, the working fluid absorbs heat in the evaporator and then is superheated through the internal heat exchanger. Then passing through the compressor, the pressurized hot stream cools down through the condenser and is throttled in the expansion valve.

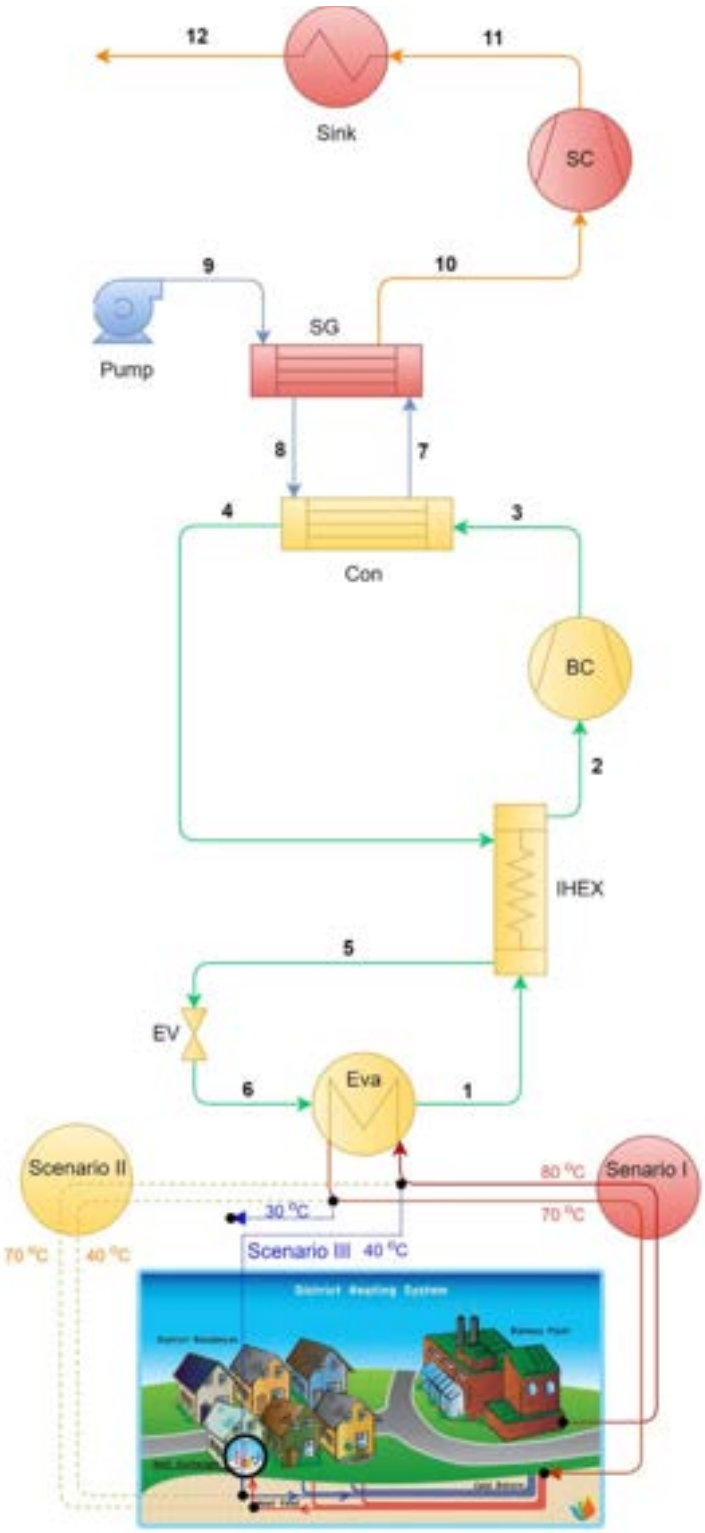

Figure 2. Proposed cascade high-temperature heat pump system (red and yellow lines: heat source, blue lines: water, green lines: alternative hydrocarbons, orange lines: steam)

For the low-temperature cycle, hydrocarbons with high enough critical temperatures above 130 °C are considered as the low GWP natural working fluids. The selected working fluids and their properties are listed in Table 2.

Table 2. Properties of the selected working fluids for the cascade HTHP system [1].

Working fluid	Safety group	ODP	GWP	P_{cri} (bar)	T_{cri} (°C)	Auto-ignition temperature (°C)
Steam (R718)	A1	0	0	220.6	374	-
Pentane (R601)	A3	0	5	33.64	196.6	260
Isopentane (R601a)	A3	0	5	33.7	187.2	420
Butane (R600)	A3	0	4	37.96	152	405
Isobutane (R600a)	A3	0	4	36.4	134.7	460

In addition, as illustrated in Figure 2, the HTHP system uses the heat available from district heating as the source through three different scenarios, which is explained in detail in Table 3.

Table 3. Three different scenarios for integrating the heat pump system with district heating.

Scenario	$T_{source,in}$ (°C)	$T_{source,out}$ (°C)	T_{eva} (°C)	Description	Connection
I	80	70	65	High-quality and expensive heat source	Main transmission line from biomass plant
II	70	40	35	Moderate heat source	DH Distribution lines
II	40	30	25	Cheapest heat source but low-quality	DH Return lines

Using Engineering Equation Solver (EES) and based on the input data given in Table 4, thermodynamic steady state model has been implemented using a control volume approach with energy and mass balances for each control volume. The heat exchangers are modelled with a defined minimum pinch point temperature difference and the compressor is based on an isentropic efficiency.

Table 4. The input data for modelling the HTHP system

Parameter	Value
Sink condensation temperature, T_{12}	160 °C
Superheating degree in IHEX, T_2-T_1	10 K
Pinch point temperature difference in HEXs except IHEX	5 K
Intermediate water circuit temperature difference, T_7-T_8	5 K
Feed water temperature, T_9	105 °C
Cascade temperature, T_{10}	105 °C (1.21 bar)
Compressors isentropic efficiency, η_{is}	75 %

Considering that high-temperature superheated steam is completely condensed through the sink, and is subcooled up to the feedwater temperature (105 °C), the COP and VHC of the compressors are defined, as follows:

$$COP = \dot{Q}_{sink}/(\dot{W}_{BC} + \dot{W}_{SC}) \quad (1)$$

$$VHC_{SC} = \dot{Q}_{sink}/\dot{V}_{10} \quad (2)$$

$$VHC_{BC} = \dot{Q}_{con}/\dot{V}_{2} \quad (3)$$

Here, $\dot{Q}_{sink}, \dot{W}_{BC}$ *and* $\dot{W}_{SC}$ are the heat transfer rate delivered to the sink and power consumption of the hydrocarbon and steam compressors, respectively.

3. Results and discussion

The HTHP system has been simulated for the three scenarios with 4 different refrigerants in the bottom cycle. The COP of the HTHP system is depicted in Figure 3. Referring to this figure, the HTHP system gets higher COPs, when is integrated with district heating based on scenario I. This is because; considering the 5 K pinch point temperature difference in the evaporator, it could operate at 65 °C under scenario I, which is much higher than 35 °C and 25 °C in scenarios II and III, respectively. Therefore, the temperature lift of the cascade HTHP system in scenario I is lower than that of the other scenarios, which leads to a significant reduction in the pressure ratio and power consumption of the compressors as shown in Figures 4 and 5, respectively.

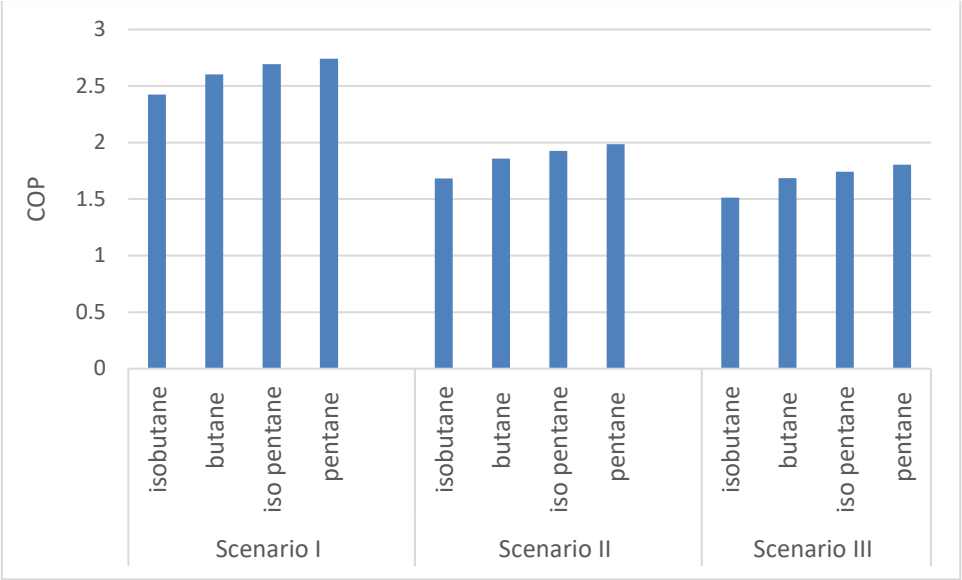

Figure 3. COP of the HTHP system using various hydrocarbons in the low-temperature loop based on the three different scenarios

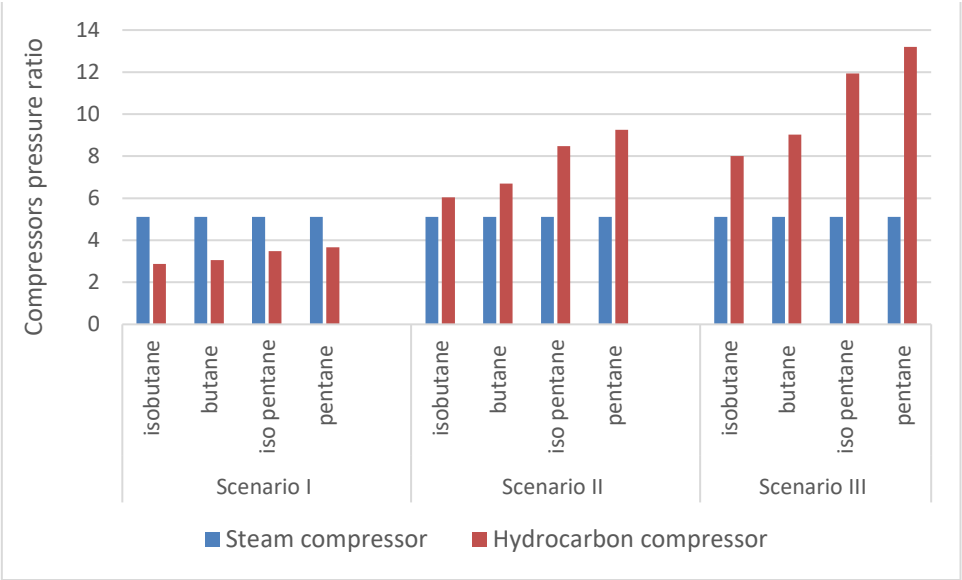

Figure 4. Pressure ratio of the compressors using various hydrocarbons in the low-temperature loop based on the three different scenarios

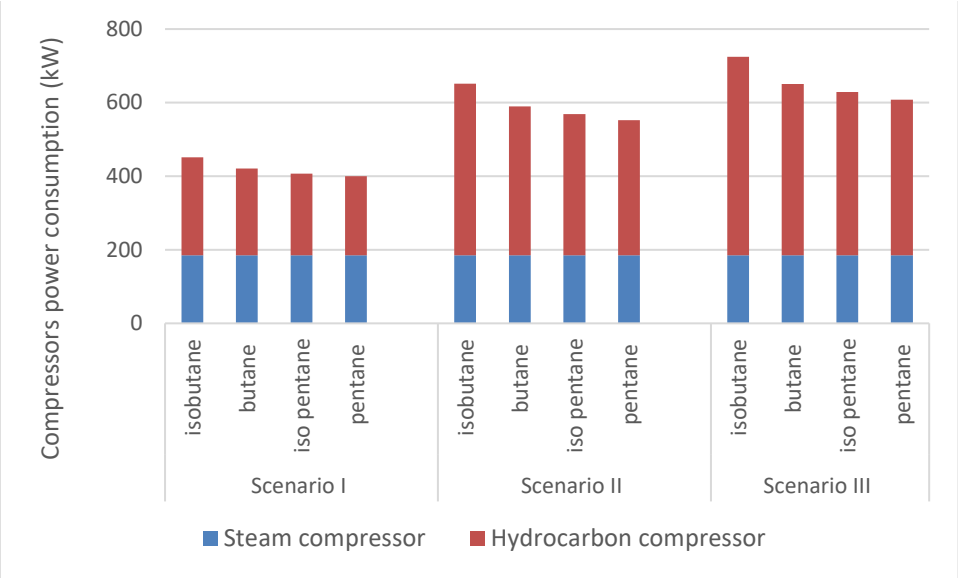

Figure 5. Power consumption of the compressors using various hydrocarbons in the low-temperature loop based on the three different scenarios

Referring to Figures 4 and 5, the pressure ratio and power consumption of the steam compressor in all the cases does not change (5.1 and 185 kW, respectively). This is due to the constant evaporation pressure of the steam generator.

However, referring to Figure 4, in all the scenarios, pentane compressor shows higher pressure ratios, which is mainly due to the higher critical temperature of pentane compared to the other hydrocarbons. Though, thanks to the relatively smaller mass flow rate of pentane through the compressor, the hydrocarbon compressor consumes less power in the case of using pentane, as depicted in Figure 5.

In conclusion, the HTHP system achieves the highest COP of 2.74, when is integrated with district heating based on scenario I and uses pentane as the working fluid in the low-temperature loop, as shown in Figure 3. Therefore, from the energy point of view, pentane is the best candidate to be used as the working fluid in the bottoming loop.

However, Figure 6 shows that pentane has a higher specific volume compared to the other hydrocarbons, meaning that the volumetric flow rate of pentane in the compressor suction is larger, requiring a bigger hydrocarbon compressor. Thus, from the viewpoint of sizing, butane is introduced as a good candidate with almost twice VHC compared to pentane, just in the expense of about 5 % reduction in the HTHP COP. In addition, using butane could be safer, as well, due to its higher auto-ignition temperature compared to pentane (405 °C Vs 260 °C).

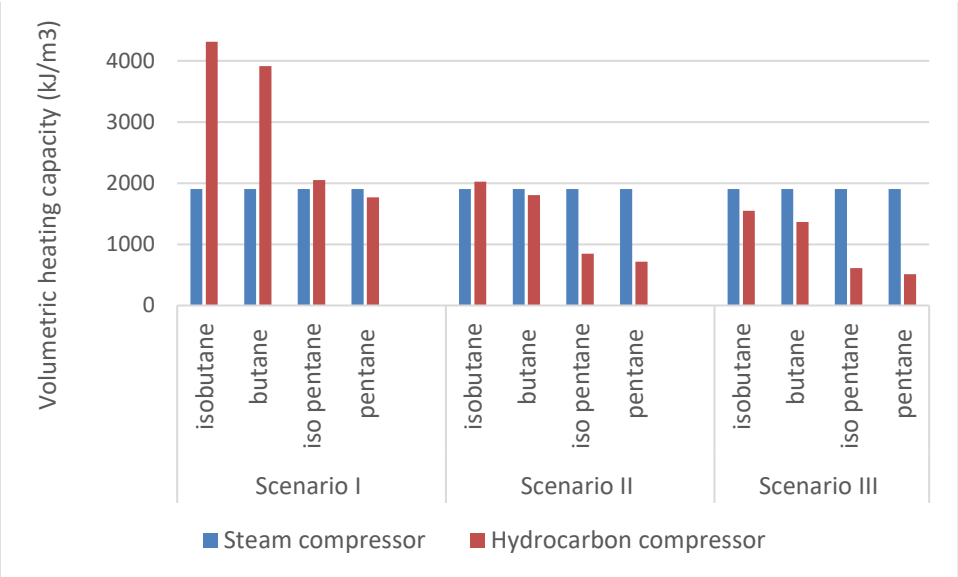

Figure 6. VHC of the compressors using various hydrocarbons in the low-temperature loop based on the three different scenarios

Moreover, as shown, in Figure 6, the steam compressor VHC is a constant value in all the cases, due to the unchanged operating condition of that.

All in all, depending on the objective function, either maximizing the COP or minimizing the sizing and auto-ignition risk, pentane and butane are recommended, respectively, as the low-temperature loop working fluids to reach out a promising HTHP system performance.

However, in all the twelve case studies, the steam compressor discharge temperature is a high value. In this regard, some technology improvements e.g. water injection and re-designing the system could enhance the COP, as well.

4. Conclusions

Thermodynamic analysis of a cascade high-temperature heat pump using steam in the high-temperature loop and low GWP hydrocarbons including isobutane, butane, isopentane and pentane in the low-temperature loop, was carried out. The importance and advantages of using steam as well as the necessity of using cascade layout was discussed. On the application level, there different scenarios for integrating the proposed HTHP system with a district heating unit were studied and compared, in terms of the COP, pressure ratio, power consumption and VHC of the compressors. The most significant results of the present study are summarized, as follows:

- Integrating the HTHP system with district heating based on scenario I- which suggests the use of district heat available in the main transmission line at 80 °C cooled down 70 °C - leads to the higher COP values compared to the other scenarios.
- Among the suggested hydrocarbons, pentane shows the most promising performance from the energy perspective, leading to high COP values.
- The highest COP value of 2.74 is achieved for the case based on scenario I and using pentane as the low-temperature loop working fluid.
- Concerning the hydrocarbon compressor sizing criterion, butane is introduced as a good candidate; with VHC value of about two times more than that of pentane, in the expense of just about 5 % reduction in the HTHP COP.
- Considering the high auto-ignition temperature of butane, it is also suggested for the high-risk applications.
- Regarding the high discharge temperature of the steam compressor, technology improvements e.g. water injection or proposing more effective layouts are recommended for the future works.

Abstract:

Electrifying the heat supply of buildings is key to mitigate climate change. Inhere, photovoltaic and heat pump systems are promising technologies. Studies indicate that an increase in self-consumption is economically beneficial. Coupling photovoltaic with heat pump systems enables the aspired increase of self-consumption, especially in combination with thermal energy storages. The coupling of the systems is influenced by the control strategies, for which rule-based and model predictive-based approaches exist. Research finds that optimal control methods heavily depend on the system design and vice versa. Contrary to these interdependencies, current design guidelines neglect a possible influence of photovoltaics on the design of the heat pump system.

To analyze a possible influence on the optimal heat pump system design, we apply nonlinear, dynamic simulation-based optimization to find the optimal design of the heat pump system for three different cases: no photovoltaic, no supervisory control, and a state-of-the-art supervisory control. The model consists of the whole building energy system, including the building envelope, radiators, a heat pump, a photovoltaic, and a grid connection. The dynamic simulation covers a whole year. To obtain generalizable results, we conduct optimizations for varying boundary conditions, including changes in weather and photovoltaic roof area.

Consistent over all boundary conditions, results indicate that cost optimal heat pump system design does not change for current price assumptions. However, maximizing the thermal energy storage is vital to obtain maximal costs savings compared to the case with no photovoltaic system. Thus, for different price assumptions, the optimal design will change.

Simulation-based Optimization, Rule-based Control, Dynamic Simulation, Modelica, Design of Experiments

1. Introduction

The residential building sector accounts for 25 % of Germany's CO_2 emissions [1]. To reduce these CO_2 emissions, electrification of the residential building heating sector is vital. Inhere, heat pumps (HPs) and photovoltaic systems (PVs) are essential technologies [2–5].
Heat pumps are able to provide space heating (SH) and domestic hot water (DHW) using electrical energy. Besides refrigerant leakage, operational emissions depend on the emission factor of the used electrical energy [5].
PVs generate generate emission-free electricity during operation. Typically, a higher self-consumption leads to faster pay-off rates. Combining heat pumps and PV, synergies arise. While the heat pump can utilize the emission-free electricity, the self-consumption and, thus, viability of PV increases as well [2, 3]. However, this effect is impeded by asynchronous supply and demand of residential buildings on a daily and seasonal timescale. At daytime, the PV generates more electricity due to solar radiation; simultaneously, the heat pump requires less, as the heat demand decreases. In summer, the PV generates overall more electricity; but the heat pump, if only used for heating, requires electricity only for DHW applications.

Several storage technologies are suitable to overcome this issue. Battery storages enable a shift of emissions-free PV-generated electricity to more useful times, while thermal energy storages shift the heat pump operation to more useful times. As a storage medium, water or the building's mass may be used. In residential heat pump systems, water-based thermal energy storages are already used for several reasons: Storing DHW [6], buffering defrost cycles [5], limiting on/off cycling at part load [6], or acting as a hydraulic separator to enable different mass flow rates [7]. Hence, using the existing water-based storages is a viable option compared to the capital-cost-intensive invest into a battery [2, 3, 8].

Minimizing costs and emissions requires optimizing the design and control of the heat pump, the PV, and the thermal energy storage. Researchers use advanced design and control methods to achieve optimality, such

as supervisory model predictive control (MPC) [9] or simulation-based optimization of heat pump systems [5]. However, these advanced methods are not state-of-the-art [10, 11]. In practice, rule-based design and control methods are applied [4,6,12]. With an expected service-life of around 20 years [12], each suboptimal design of a building energy system today impedes the climate goals of Germany for 2045 [13]. Additionally, the market share of heat pumps in the German building stock is only 5 % [14]. To enable a fast ramp-up of heat pump systems in the building stock, practitioners require simple rules for design. For control, manufacturers will presumably not open up the internal control interfaces to external energy management systems. In Germany, a heat pump is considered Smart-Grid-Ready (SG-Ready), if it allows four modes: (1) block the heat pump, (2) normal operation, (3) turn-on request, and (4) turn-on command [15]. The latter two may increase setpoints in the local control of the heat pump and, hence, indirectly the compressor frequency [16]. Hence, current state-of-the-art heat pumps only support mode-based supervisory controls. Resulting, this contribution focuses on ready-to-use, rule-based design and control methods for heat pump systems with photovoltaic.

In the following, we review contributions regarding (1) rule-based design approaches and (2) rule-based control approaches. In this review, we focus on heat pump systems with PV using thermal energy storages.

1.1. Rule-based design approaches

Research contributions highlight the importance of a correct heat pump and thermal energy storage size [2, 5, 10, 17]. As central guideline in the European Union, the EN 15450 provides rules for sizing heat pump systems based on the bivalence temperature T_{Biv}, the heat demand at nominal outdoor air temperature, and further assumptions for space heating as well as DHW usage [6]. German guidelines follow similar approaches relying on the bivalence temperature for design [12]. The bivalence temperature affects the sizing of the heat pump and, thus, invest and operational costs. Furthermore, the space heating storage is sized with a factor depending on the heat demand $V_{\dot{Q}_{\mathrm{Bui}}}$ between 12 and 35 l kW^{-1}. Despite the influence of T_{Biv} and $V_{\dot{Q}_{\mathrm{Bui}}}$ on the design, current guidelines require both T_{Biv} and $V_{\dot{Q}_{\mathrm{Bui}}}$ as an input [6, 12]. Recommendations depending on the boundary conditions, like weather or building envelope, are not given. Additionally, a potential influence of PV on the rule-based design is neglected.

In research, several contributions aim at an optimized design of heat pump systems. They highlight that the operational phase determines the optimal design. Consequently, they perform annual simulations and integrated design and control optimizations. While heat pump and storage sizes are varied, the influence of PV is not assessed. [5, 10, 17]
Designing heat pump systems with PV, Kemmler and Thomas [2] vary heat pump and storage sizes for different buildings and technologies, always considering PV and an MPC. However, MPC is not yet state-of-the-art. Huang el al. [18] perform a design optimization for a system containing PV, heat pump, thermal energy storage, and electric vehicles using simulation-based generated load profiles as an input. This impedes the control analysis and a possible influence on the optimal design. For PV-thermal systems, Miglioli et al. [19] state optimal design heavily depends on the boundary conditions. They advise to size the heat pump independent from the PV-thermal sizing, as summer operation is dominant for the optimal sizing of solar-based technologies.

Overall, contributions either do or do not consider PV for the optimal design of the heat pump system. A direct comparison between using PV and using no PV in optimal design is only given by Fischer et al. [20]. They analyse the impact of PV on the optimal heat pump system design using mixed-integer linear programming. Varying boundary conditions, they find that the heat pump size does not change with PV. Moreover, the thermal energy storage size changes only slightly. Therefore, they follow that current guidelines are sufficient. However, they assumed optimal control and simplified component models, highlighting the need for detailed simulations in their outlook.

1.2. Rule-based control approaches

Fischer et al. [4] compare control approaches for heat pump systems with PV. Both predictive and non-predictive controls are considered. While predictive controls are more efficient, current state-of-the-art heat pump rely on non-predictive, rule-based approaches. However, the non-predictive, rule-based controls applied in [4] or [21] use the compressor frequency as an actuator, which is not state-of-the-art.

Rule-based supervisory controls using setpoint changes follow the same principle: If enough PV surplus is present, thermal storage setpoints are increased - either by a fixed temperature difference, or to a maximal value [3, 4, 8, 21]. Both Haller et al. [8] and Pinamonti et al. [3] first increase DHW setpoints and later space heating setpoints. Pinamonti et al. [3] go further and activate the building inertia as well.

In general, the optimal values for these controls depend on the design of the system [4, 22]. For instance, different contributions find that increasing the storage volume is not necessary to achieve an increase self-consumption with good control values [8,21]. However, these results depend on price assumptions and storage

insulation levels.

1.3. Research questions

The review on rule-based design and control approaches shows their mutual dependence. However, it is not apparent to what extent PV and the use of a state-of-the-art supervisory control may influence the optimal design of the heat pump system [2–5, 8, 10, 18, 19, 21].

Therefore, we conduct an analysis by means of detailed annual simulation-based optimization aiming to answer two questions:

1. *Does the existence of PV affect the optimal design of residential, retrofit heat pump systems?*
2. *Does the usage of a state-of-the-art, rule-based control for PV surplus affect the optimal design of residential, retrofit heat pump systems?*

To answer these questions, the remainder of the contribution is structured as follows: Section 2 presents the simulation model, rule-based control approach, and the study design to analyse the influence of PV on the design. In Section 3, we analyse the results. Section 4 presents limitations and implications of this contribution. In Section 5, we summarize the findings and highlight future research prospectives.

2. Methods

2.1. System model

As motivated in Section 1, we focus on retrofit residential buildings in the German building stock. Following current guidelines [6], a typical building energy system consists of: A heat pump and heating rod (HR) connected in series; a space heating storage connected in parallel; a separate DHW storage with an internal heat exchanger connected in parallel; radiators to transfer heat to the rooms; analogue thermostatic valves which control the volume flow through each radiator to ensure thermal comfort; and rule-based controllers.

We model this system using the open-source Modelica library BESMod [23]. In here, components, control, and building envelope are modelled in a dynamic, nonlinear fashion:

- **Heat Pump**: Air-to-water heat pump with Propane as refrigerant [24, 25].
- **Heating Rod**: Ideal heater with a constant efficiency of 97 % [5, 25].
- **PV**: Model from [26] based on manufacturer data [27] with 133 $\mathrm{Wp/m^2}$ maximum power peak (MPP) per area.
- **DHW storage**: Indirect heat exchanger and a constant volume of 125 l [6, 25].
- **Space heating storage**: Directly charged storage with a volume depending on $V_{\dot{Q}_{\mathrm{Bui}}}$ [6].
- **Radiators**: Model according to EN 442 [25, 28] with a nominal supply temperature of 55 °C.
- **Building envelope**: The reduced order approach from the AixLib [25] is used, which is coupled to TEASER [29].

In the following, we highlight the control approach of the building energy system. As in literature, we separate the control into two layers: supervisory and local control.

2.1.1. Supervisory control

Rule-based, non-predictive supervisory control approaches in literature follow the basic principle of [3, 30]. As we analyse a retrofit building with low mass and radiator transfer system, only overheating of the DHW and space heating storage are considered.
Figure 1 depicts the implemented control logic. The electrical surplus power, $P_{\mathrm{el,Sur}}$, acts as an input. The electrical subsystem calculates the surplus based on current PV generation and all electrical power demands of the heat pump system.
Then, a hysteresis checks if the current surplus exceeds the upper hysteresis limit $P_{\mathrm{el,Hys}}$. The lower hysteresis limit is 0 W. Current research uses the minimal electrical power of the heat pump, $P_{\mathrm{el,HP,Min}}$ as a value for $P_{\mathrm{el,Hys}}$ [21]. At the same time, [4] highlights that the control strategy and component sizing is strongly interconnected. As $P_{\mathrm{el,Hys}}$ essentially defines the number of times the supervisory control overrides the local control, we vary the value as a fraction $f_{\mathrm{HP,PV}}$ based on the heat pumps nominal electrical power $P_{\mathrm{el,HP,Nom}}$, which is given in datasheets at rated conditions A2W35:

$$P_{\mathrm{el,Hys}} = f_{\mathrm{HP,PV}} \cdot P_{\mathrm{el,HP,Nom}} \tag{1}$$

If surplus exceeds the threshold, the control increases the DHW storage setpoint to $T_{\text{set,DHW,PV}}$. If the measured DHW storage temperature from the uppermost layer $T_{\text{mea,DHW}}$ exceeds this setpoint, the control increases the space heating storage setpoint by $\Delta T_{\text{SH,PV}}$. Using a winter mode from September until April, space heating is never affected during summer period.

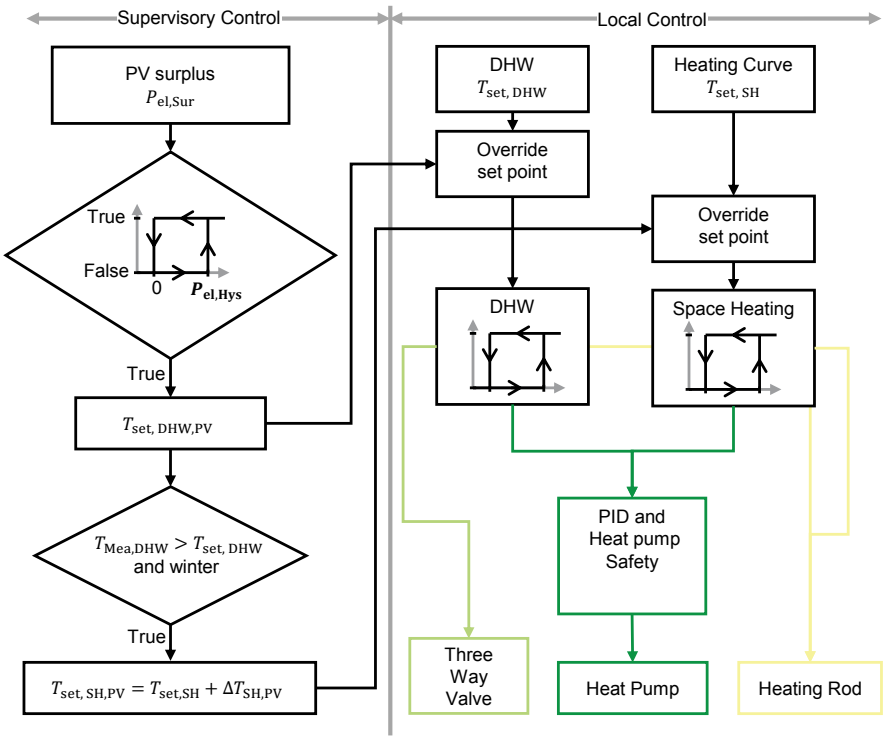

Figure 1: Rule-based supervisory and local control logic following the approaches in [3,30,31]. Colors indicate the flow of the lines.

The supervisory control only changes the setpoints of the local control. Three parameters may be changed: $f_{\text{HP,PV}}$, $T_{\text{Set,DHW,PV}}$, and $\Delta T_{\text{SH,PV}}$. We performed a separate control optimization for a single guideline-based design using the same model. Here, the values $T_{\text{Set,DHW,PV}}$ =60 °C and $\Delta T_{\text{SH,PV}}$ =15 K are pareto-optimal for relevant objectives (cf. Section 2.2.3.). The detailed analysis of this control optimization exceeds the scope of this contribution. It is noteworthy that 60 °C is also the maximal value used by [21].
As the parameter $f_{\text{HP,PV}}$ dictates to what extent surplus may be used, we include this parameter in a design and control optimization (cf. Section 2.2.2.).

2.1.2. Local control

A local controller actuates the different components based on these setpoints.
The local control follows the approach in [31] and is depicted in the right part of Figure 1. Two hystereses decide whether the heat pump and heating rod turn on or off for space heating and DHW. DHW has priority over space heating. For the heating rod control, the time-based approach from [5] is used. If the lower hysteresis limit is violated for more than 30 minutes, the control activates the heating rod. A PI controller actuates the heat pumps compressor frequency based on the set and measured values in the system. Moreover, a safety controller ensures minimal runtime, off-time, and limits the maximal number of starts per hour to three [24].

2.2. Study design

The research question's answers depend on uncertain economic parameters (i.e., electricity tariffs) and involves multiple relevant objectives, for instance, costs, emissions, efficiency or self-consumption. To evaluate multiple scenarios and objectives, we use a full-factorial design of experiments to evaluate every possible combination of discrete optimization variables [32]. Factors of the full-factorial design are different boundary conditions (cf. Section 2.2.1.) and optimization variables (cf. Section 2.2.2.). Section 2.2.3. highlights relevant objectives for our analysis.

Using discrete variables leaves untapped potential. For instance, a 9.48 kW heat pump could be the global optimum; whereas the discrete choice for a 10 kW heat pump is only near-optimal. However, manufacturers only offer discrete component sizes anyway. Thus, insights on whether these discrete choices change is

sufficient to answer the question if the optimal design changes. If the continuous optimum is of interest, a surrogate-based optimization approach can be applied to efficiently search for it [33].

2.2.1. Boundary conditions

The boundary conditions may influence the findings in this contribution. To limit the complexity of the study, we only vary certain boundary conditions. In the following, we motivate our choices.

Weather

The system design according to guidlines [6, 34] depends on the nominal outdoor air temperature $T_{\mathrm{Oda,Nom}}$, which is defined by the buildings's location [35]. Additionally, the solar radiation at different locations may influence the design of a heat pump system with PV. Thus, we define three weather cases: cold, average, and warm. We extract these cases from the German guideline DIN 4710 [36], which seperates Germany into 15 climatic regions. For weather data, the test reference year *average* is selected for each location provided by Germany's Meteorological Services [37].
Using this data, we calculate $T_{\mathrm{Oda,Nom}}$, the minimal temperature $T_{\mathrm{Oda,Min}}$, the mean temperature $T_{\mathrm{Oda,Mean}}$, and the sum of direct and diffuse radiation on a horizontal plane H_{Glo}. Based on the values, we select the coldest (Fichtelberg), warmest (Bremerhaven), and average (Bad Marienberg) region based on $T_{\mathrm{Oda,Nom}}$. Table 1 lists all four relevant characteristics for the three regions. With cumulative global radiation between 931.59 kW h m^{-2} in Hamburg and 1123.95 kW h m^{-2} in Weihenstephan, the selected locations represent a typical range of global radiation in Germany.

Table 1: Values for relevant characteristics of climatic regions in Germany.

Region	$T_{\mathrm{Oda,Mean}}$ in °C	$T_{\mathrm{Oda,Nom}}$ in °C	$T_{\mathrm{Oda,Min}}$ in °C	H_{Glo} in kWh/m^{2}a
Bremerhaven	9.8	-7.8	-10.2	1023.8
Bad Marienberg	7.8	-11.0	-17.6	955.8
Fichtelberg	3.4	-16.1	-18.4	984.2

Building Envelope

For the building envelope, we select a non-renovated building from the construction period 1983 with a net-floor-area of 156.25 m^2 from the German TABULA standard [38]. Using TEASER, the envelope model is generated [29].

The roof has a total area of 72.9 m^2 and two sides, each with a tilt of 35°. One half is south-facing, the other half north-facing. As south-facing installations are a common recommendation, we focus on this orientation [39]. Using 100 % of the south-facing roof, the MPP equals 4.8 kW.

User

Besides weather and building envelope, user profiles may influence the optimal design of the system. At the same time, user profiles are inherently uncertain and stochastic. To neglect a possible influence of stochastic profiles, we assume deterministic profiles based on guidelines.
For DHW, Profile M according to European Union Regulation 811/2013 [40] is used.
For internal gains, standard profiles from TEASER are used [29]. However, we neglect the influence of internal gains on the electricity demand. All available PV electricity may be used for the heat pump system. This either represents a tenant-landlord scenario or a best-case scenario, where homeowners adjust their appliances usage in favour of the heat pump. While the latter is not realistic, it maximizes the possible influence of PV on the heat pump system, and, thus, its optimal design.

2.2.2. Design and control optimization

Table 2 lists the factors and levels of the integrated design and control optimization. Following findings in recent literature, we use 1 K levels for the bivalence temperature, as this parameter has the highest influence on efficiency, cost, and emissions [5, 17].
Aside from the aforementioned factors, we enable and disable the supervisory control. Combined with the roof area usage factors, this leads to three cases which we use to analyse the influence of PV and the control strategy on the optimal design of the heat pump system:

1. *No PV*: Reference case with no PV and no supervisory control
2. *No Control*: PV but no supervisory control
3. *Control*: PV and a rule-based supervisory control

Case 2 applies when components of different manufacturers are used which are not able to communicate with a supervisory control.

Overall, 2640 annual simulations are run, with an average computation time of 15 min[1].

Table 2: Full-factorial design for the design and control optimization

Factor	Values	Number of levels
Weather	Fichtelberg, Bad Marienberg, Bremerhaven	3
Roof area usage	0 %, 50 %, 100 %	3
Supervisory Control	Disabled, Enabled	2
$f_{\mathrm{HP,PV}}$	10 % to 100 %	4
T_{Biv}	$-16\,^{\circ}\mathrm{C}$ to $5\,^{\circ}\mathrm{C}$	20
$v_{\dot{Q}_{\mathrm{Bui}}}$	$5\,\mathrm{l\,kW^{-1}}$ to $100\,\mathrm{l\,kW^{-1}}$	4

2.2.3. Objectives

As the invest decision of a homeowner may depend on more than one objective, we analyse the optimal design with regard to multiple objectives.

Besides costs and efficiency, the self-consumption rate and the self-sufficiency degree are often used as characteristic values for the evaluation of systems with PV [30].
Emissions are not analysed in detail within this contribution. However, the full-factorial design enables a post-analysis of further objectives.

Economics

The cost functions for annuity of the heat pump system follow [10, 41]. Inhere, invest, operation, and maintenance costs are considered.
As we want to analyse a possible change in the heat pump system design if PV is used, we explicitly neglect the investment in PV. In reality, the economic viability of PV depends on the self-consumption rate, which is influenced by household appliances. As we neglect those, assessing economic viability of PV is not within the scope of this contribution.

Further, we assume current electricity tariffs from Germany, with 36.06 $\mathrm{ct_{EUR}/kWh}$ for electricity consumption and 8.2 $\mathrm{ct_{EUR}/kWh}$ for feed-in.

Efficiency

The seasonal coefficient of performance $SCOP_{\mathrm{Sys}}$ indicates the annual efficiency of the heat pump system. To incorporate the whole system, we define the $SCOP_{\mathrm{Sys}}$ according to an energy balance around the building energy system:

$$SCOP_{\mathrm{Sys}} = \frac{\int_{0a}^{1a} (\dot{Q}_{\mathrm{SH}}(\tau) + \dot{Q}_{\mathrm{DHW}}(\tau)) d\tau}{\int_{0a}^{1a} (P_{\mathrm{el,HP}}(\tau) + P_{\mathrm{el,HR}}(\tau)) d\tau} \tag{2}$$

Inhere, $\dot{Q}_{\mathrm{SH}}$ is the building's space heating demand, $\dot{Q}_{\mathrm{DHW}}$ is the DHW's demand, as well as $P_{\mathrm{el,HP}}$ and $P_{\mathrm{el,HR}}$ the heat pump's and heating rod's electrical power consumption, respectively.

Self consumption rate

The ratio of directly used PV electricity $W_{\mathrm{el,PV,use}}$ and the generated PV electricity $W_{\mathrm{el,PV}}$ defines the self consumption rate SCR [39]:

$$SCR = \frac{W_{\mathrm{el,PV,use}}}{W_{\mathrm{el,PV}}} \tag{3}$$

In literature, the SCR is commonly used to evaluate design and control approaches for PV systems [3, 4, 8].

Self-sufficiency degree

The ratio of directly used PV electricity $W_{\mathrm{el,PV,use}}$ to the total electricity demand defines the self-sufficiency degree SSD [39]:

$$SSD = \frac{W_{\mathrm{el,PV,use}}}{W_{\mathrm{el,tot}}} = \frac{W_{\mathrm{el,PV,use}}}{W_{\mathrm{el,PV,use}} + W_{\mathrm{el,Grid}}} \tag{4}$$

[1] Intel(R) Xeon(R) CPU E5-1650 v3 @3.50GHz, 32 GB DDR3 RAM, 64 bit, SSD hard drive

3. Results

We separate the results of the design and control optimization into two cases. First, we analyse if the existence of PV changes the optimal design. Second, we highlight the influence of the design on the optimal control parameters.

3.1. Influence of PV on the heat pump system design

Figure 2 illustrates three cases for the medium weather case and a south-facing PV installation with 100 % roof area usage. For all other cases, the absolute values change, but the relative deviations are comparable. Thus, we focus on this case for our analysis.

First, the optimal design does not change; neither when using no supervisory control, nor when using a supervisory control. Second, the relative objective space, i.e. the gradients, does not change between the cases. This observation holds for all simulated boundary conditions. Thus, for the current price assumptions (cf. Section 2.2.3.), PV does not influence the optimal design of the heat pump system.

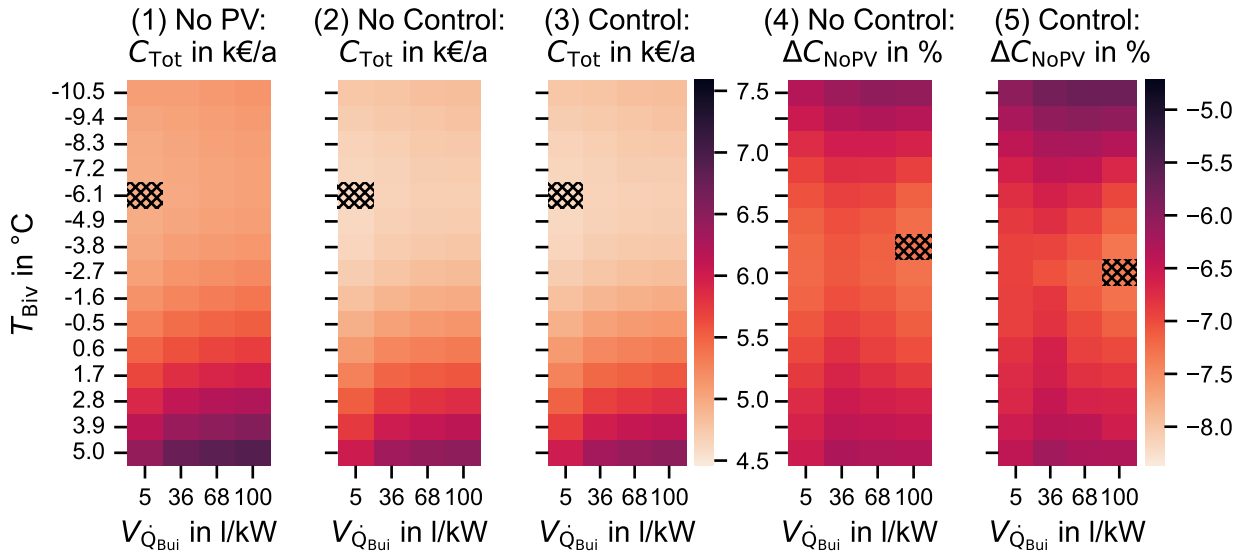

Figure 2: Optimal total costs over T_{Biv} and $V_{\dot{Q}_{Bui}}$ for the three cases (1) *No PV*, (2) *No Control*, and (3) *Control*. Furthermore, the percentage change in total costs compared to case *No Pv* ΔC_{NoPV} for the cases (4) *No Control*, and (5) *Control* is depicted. Results are for location Bad Marienberg and a south-facing PV installation with 100 % roof area usage. The hatched cell indicates the optimal design.

Looking at further differences in the objective space, Figure 2 also depicts the change in total costs compared to the case *No PV*. For these boundary conditions, the case *No Control* yields cost reductions between 5.8 % and 7 %, while the case *Control* obtains cost reductions between 5.7 % and 7.3 %. Over all boundary conditions, the case *No Control* obtains cost reductions between 5.3 % and 7.7 %, while the case *Control* obtains cost reductions between 2.6 % and 7.9 %. With 0.3 % additional cost reduction, case *Control* is only slightly better than case *No Control* for the highest cost reduction. At the same time, case *Control* achieves lower cost reductions in some cases compared to case *No Control*.

Consistent over boundary conditions, the highest cost reductions are achieved with smaller heat pumps and larger thermal energy storages compared to the economic optimum.

Figure 3 illustrates four important metrics to explain why the optimal design changes. Inhere, the self-sufficiency degree *SSD* closely resembles the cost reductions. Essentially, the *SSD* is a superposition of the self-consumption rate *SCR* and the system efficiency $SCOP_{Sys}$.

First, the *SCR* increases with bigger thermal energy storages and smaller heat pumps. Bigger thermal energy storages enable a better exploitation of surplus electricity. Smaller heat pumps lead to higher times of heating rod usage t_{HR} and, thus, an increased electricity demand. This increased electricity demand increases the chance of PV electricity being used and, therefore, the *SCR*.

Second, the $SCOP_{Sys}$ decreases with smaller heat pumps and increases slightly for bigger storages, as the local control requires the heating rod less frequently. For small storages and monovalent heat pumps, the $SCOP_{Sys}$ decreases slightly. Suboptimal PID-values lead to this decrease.

The results in this section hold for the optimal control value $f_{PV,HP}$. The following section analyses how the optimal values of $f_{PV,HP}$ change with the design.

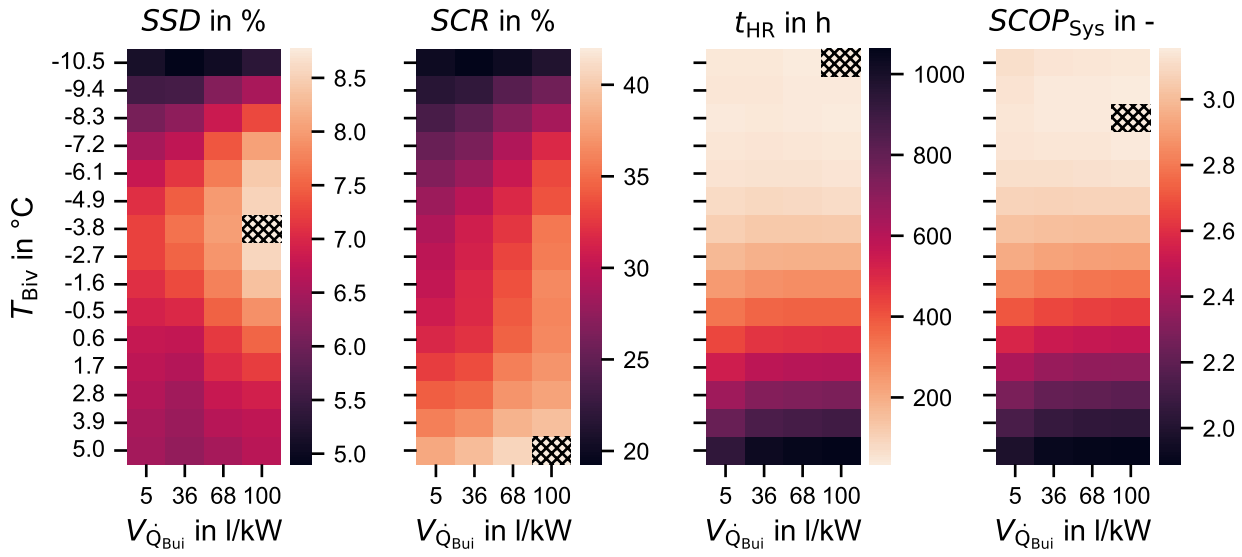

Figure 3: Optimal values for the *SSD*, *SCR*, heating rod on-time t_{HR}, and $SCOP_{Sys}$ over T_{Biv} and $V_{\dot{Q}_{Bui}}$ in case *Control*. The results hold for location Bad Marienberg and a south-facing PV installation with 100 % roof area usage. The hatched cell indicates the optimal design.

3.2. Influence of the design on the optimal control

The control parameter $f_{HP,PV}$ defines the threshold to increase setpoints and, thus, use surplus electricity. Figure 4 illustrates the optimal settings for $f_{HP,PV}$ depending on different designs of heat pump and storage, as well as relevant objectives. For cases with multiple optima, especially for monovalent designs (minimal T_{Biv}), the maximal value of $f_{HP,PV}$ is used.
Looking at total costs, settings equal or greater than 40 % are optimal. For bivalence temperatures around $-6\,°C$, the lowest values of 40 % are optimal for larger storages. This design is concurrent with the highest cost reduction through the control. Thus, to achieve the highest cost reduction, the supervisory control needs to be included into the optimization problem.
Focusing on the efficiency, maximal values of $f_{HP,PV}$ maximize the $SCOP_{Sys}$. Only for the smallest heat pump, where the efficiency is already low, smaller values of $f_{HP,PV}$ are advisable. Looking further at *SSD* and *SCR*, minimizing $f_{HP,PV}$ is advisable. These findings hold for different boundary conditions considered in this study.

4. Discussion

Before discussing the implication of our results, we highlight limitations in the methods applied.

4.1. Limitations

The results show that the applied rule-based control is better or worse for different designs compared to using no control. Overall, not more than 0.3 % of costs are additionally saved due to the supervisory control. We optimized the set-temperatures in a separate study and the threshold in our design and control optimization. Including the set-temperatures may yield further saving potential. However, as the separate operational optimization is conducted for designs close to the optimal design, we do not expect the optimal design to change. In contrast to [3], we do not consider space cooling. Further, we study colder climates and buildings with a DHW share of only 5 % to 8 %. As Fischer et al. [21] point out, DHW is the dominating factor for PV. Our study confirms these results. Fischer et al. study a DHW share of 16 % [21], Pinamonti et al. of 23 % up to 48 % [3]. While investigating higher DHW shares might benefit the supervisory control, it does not affect the optimal rule-based design according to current guidelines [6]. In here, the DHW storage volume is fixed by demand. However, future studies should check if an optional over-sizing factor could be introduced to guidelines to increase self-sufficiency for heat pump systems with PV.
Furthermore, the rule-based control in current research are either based on digital thermostats or the ability to control the compressor frequency. Especially the latter is not given for the current SG-Ready label. Thus, we follow that the rule-based control is plausible for current state-of-the-art retrofit systems in Germany.

A further limitation in the methodology is the assumption that PV is only used for the electricity demand of the heat pump system. In reality, household appliances decrease the PV surplus. This further minimizes the chance of the heat pump system to use cheap PV electricity. While not relevant to our research questions

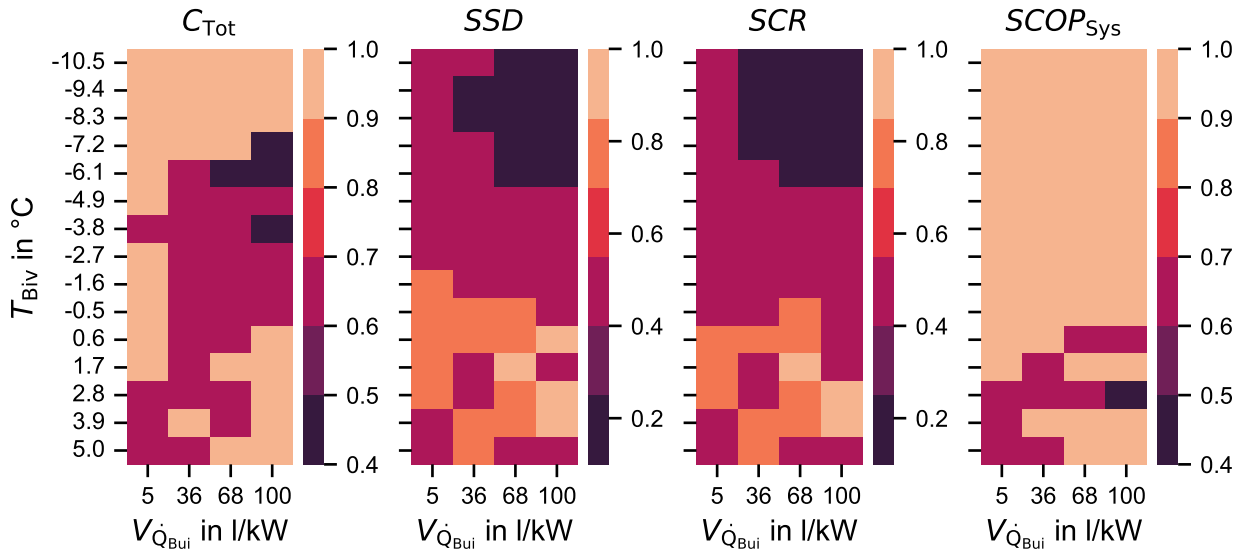

Figure 4: Optimal control values for $f_{HP,PV}$ with regard to the optimal objective values given in Figure 2 and Figure 3. Values are given over T_{Biv} and $V_{\dot{Q}_{Bui}}$ and hold for location Bad Marienberg with a south-facing PV installation and 100 % roof area usage.

regarding the change in optimal design, realistic internal gain profiles should be used if an optimal design for a specific case is required.

Our results are consistent for varying weather data and PV areas. However, other boundary conditions such as the ratio of roof area to heating demand may influence the results. For our cases, PV surplus is mostly available during spring, summer, and autumn. For better-insulated buildings with a larger roof, the surplus usage and, thus, the optimal design may change. The same holds true for the orientation of PV. West- or east-facing installations with different tilts could benefit PV surplus during heating season. Last, the usage of a battery or dynamic energy tariffs could impact the heat pump and thermal energy storage design.

Aside from control and boundary conditions, only some components of the dynamic simulation model are empirically validated [24]. The others follow white-box model approaches or are verified using comparative validation [25]. As the thermal energy storage enables the efficient exploitation of PV surplus, experimental validation should be carried out.

4.2. Implications

Keeping the limitations of this study in mind, three implications for current practice arise.

First, optimal design of the heat pump does not change when using PV with no or ineffective supervisory controls. While minor changes in T_{Biv} occur depending on the price assumptions, heat pumps are only available in discrete steps anyway.

Second, for current price assumptions, the optimal design of the storage does not change. However, to maximize PV usage, the thermal energy storage should be maximized. This contradicts the optimal design without PV, where the economic optimum is always at minimal storage volumes. However, other factors, such as defrost or utility blocking times may require the need of a larger thermal energy storage for space heating. Thus, simply minimizing the storage volume is not advisable when combining PV with heat pumps. Third, the four discrete options of the SG-Ready-Label do not enable a substantial increase of self-sufficiency. Hence, different interfaces for supervisory controls, such as the compressor speed, should be opened for external access.

5. Conclusion

This contribution analyses the influence of PV on the optimal design of heat pump systems for retrofit buildings using state-of-the-art rule-based controls. Applying annual simulation-based optimization of design and control using detailed Modelica models, we highlight findings and implications for practice and research:

1. At least in retrofit, PV does not influence the optimal heat pump size for the used rule-based controls. For current practice, neglecting PV is a valid assumption in current guidelines [6]. However, advanced control strategies could change the optimal design in future systems.

2. PV does not affect the cost-optimal thermal energy storage size. However, optimal storage sizes change

when changing price scenarios or objective functions. Thus, PV should be considered when sizing the thermal energy storage. The same could apply for the DHW storage, as DHW enables an efficient PV usage during summer.

3. Future studies should incorporate additional boundary conditions and technologies. Different DHW profiles, internal gains, or PV installations may impact the influence of PV on the optimal design.

4. Future research should develop simplified design rules - both for rule-based controls and system design. First, assessing advanced approaches as in [4] for different designs is advisable. Afterwards, design-independent rules should be extracted to enable a fast and optimal planning of building energy systems.

Abstract:

Steam generating heat pumps show great potential for reducing carbon emissions in the industrial sector. However, predicting their performance is challenging as the exergy destruction of e.g., compressors and expansion valves increases with the temperature lift and condenser temperature. With over seventy design improvements mentioned in the literature, selecting the most effective design improvements is crucial. In this study, energy and exergy-based methods were compared in their ability to identify design improvements for a single stage subcritical heat pump to produce steam from hot condensate. The energy-based method suggested the addition of a sequential compressor with an intermediate cooler; however, this design did not improve the heat pump's techno-economic performance. The suggestion of adding either an internal heat exchanger or a flash vessel by exergy-based methods did lead in both cases to improved techno-economic performance. The internal heat exchanger performed best and increased the coefficient of performance from 2.3 to 2.8 and reduced operational costs by 0.8 M€ after 5 years of operation. Additionally, the initial investment decreased by 135 k€, and the total costs of operation decreased from 10.3 M€ to 8.7 M€. These findings show that exergy-based methods are the way forward in identifying effective design improvements for steam generating heat pumps.

1. Introduction

1.1. Steam generating heat pumps

Heat pumps are being widely considered as a crucial technology for reducing carbon emissions in the industrial sector by 2030, and steam generation heat pumps (SGHPs) are a notable example. By converting renewable electricity into heat, SGHPs can effectively contribute to the sector's CO_2-reduction goals. These heat pumps have the potential to decrease energy consumption in the European industrial sector by almost 30%, as they can supply heat at a temperature of up to 300 °C [1]. SGHPs have three major advantages over other high temperature heat pumps: 1. they have a low installation costs factor because they can be connected to existing steam networks, 2. they have a good heat transfer coefficient compared to other working media (organic vapours), and 3. they are easier to control compared to hot water systems [2].

A large temperature lift is required to produce steam from waste heat. The typically used subcritical single stage heat pump, also known as simple cycle heat pump, becomes uneconomical at temperature lifts exceeding 50°C [3] due to increased inefficiencies in the compressor and expansion valve [4]. Advanced heat pump configurations, on the other hand, are an economically viable alternative at these large temperature lifts [3]. The coefficient of performance (COP), which is the key technical performance indicator of heat pumps, reflects this increase in techno-economic viability. By advancing the simple cycle through intermediate cooling in the compressor, for example, the heat pump's COP can be increased. Advanced configurations can have a COP up to three times that of the simple cycle at the same temperature difference [5]. Many researchers have explored the performance and techno-economic potential of advanced heat pump configurations, including Arpagaus [6, 7], Schlosser [5], and Adamson [8]. These studies have identified over seventy different configurations that can help improve upon the simple cycle's performance.

However, it is important to note that selecting an advanced heat pump configuration based solely on its listed performance in a different technical context can be ill-advised, as a heat pump's performance is highly sensitive to its technical surroundings. An example of the sensitivity of a heat pump's performance to its technical surroundings is demonstrated by Bless et al. [2], who found that the COP of high-temperature heat pump configurations for steam generation appeared comparable at first, but differed by almost two times when applied to the same case. This highlights the need for caution when selecting advanced heat pump configurations based solely on listed performance in a different technical context.

While there are over seventy possibilities for optimizing the simple heat pump configuration, currently, there is no systematic method for determining the optimal improvements. In other words, there is no established approach for selecting the most effective configuration for a specific application. This presents a challenge for researchers and engineers who seek to develop more efficient heat pump systems, as trial-and-error is currently the only means of determining which advanced heat pump configurations will perform optimally in a given context. It is, therefore, needed to develop a systematic method for selecting the most efficient and effective heat pump configurations for specific applications.

1.2. Economics and exergy analysis of high temperature heat pumps

Arpagaus [6, 7], Schlosser [5], and Adamson [8] have identified various advanced heat pump configurations that aim to minimize irreversibilities resulting from non-ideal pressure changes and heat exchange. These modifications involve adding expanders, compressors, flash vessels, open connections, heat exchangers, or switching the working fluid. The reduction of irreversibilities results in less work being required by the compressor and therefore a higher COP. Simple cycle heat pumps typically operate at about 50% of their ideal COP, due to these irreversibilities. Hence, they require twice the amount of shaft work to drive the compressor compared to the ideal operation [9]. Exergy analysis is a technique that helps to identify where irreversibilities occur. Opposite to energy, exergy is not a conserved measure. Hence, an exergy balance needs to account for exergy loss to the environment or loss to irreversibilities. The latter is known as exergy destruction.

Bergamini et al. [10] used exergy analysis to study the exergy destruction in a high temperature single-stage ammonia heat pump that produced heat at 140°C from an isothermal 30°C source. They found that the exergy destruction of the heat pump’s components increased at different rates and that exergy destruction in the expansion valves was the most sensitive to the temperature lift, whereas its initial contribution to the total exergy destruction was limited. Hence, the dominant source of exergy destruction in the heat pump varied among components as the temperature lift was increased. Hu et al. [11] found similar results when assessing a heat pump that produced pressurized water at 120 °C from a heat source ranging from 50 to 90 °C. They concluded that there is a strong correlation between exergy loss in the heat pump and the temperature lift, while exergy destruction in the evaporator and the condenser remained relatively constant.

Moran et al. [12] combined exergy with economic analysis to help decision makers in identifying how much an additional component would increase both the technical and economic performance. Wang et al. [13], for instance, applied the exergoeconomic principle of exergy loss per total capital investment to compare the performance of mechanically and thermally driven heat pumps. Their analysis shows that exergy loss per capital investment as a function of temperature lift differs between mechanically and thermally driven heat pumps. Based on this distinction, they formulated a guide map to aid in the selection of the technologies. In a follow-up study, Wang et al. [14] used the same principles when evaluating the performance of a transcritical heat pump cycle for hot water production and increased the heat pump’s cost rate by 17%.

Hence, exergy-based economic analysis has emerged as a valuable tool for enhancing the techno-economic performance of heat pumps. However, its application to high temperature heat pumps has been limited. Moreso, to the author’s knowledge, no known cases exist where exergy-based economic analysis has been applied to a SGHP despite the challenges in selecting design changes and their significant potential for improvements.

1.3. Objective

Assessing the performance of advanced heat pump configurations is challenging due to their substantial dependence on the temperature of the heat source and sink. This is especially true for steam generating heat pumps, where the exergy destruction of pressure equipment increases with the temperature lift and condenser temperature. To address this issue, this paper employs exergy-based economic analysis to identify techno-economic improvements to a steam generating heat pump and compares the results with an energy-based method. The objective of this paper is to illustrate how exergy-based economic analysis can be used to identify techno-economic improvements to a steam generating heat pump and show how the results differ from an energy-based method.

2. Method

The method section is built up out of three sections. The first section goes into the general description of the followed approach. The underlying thermodynamic analysis is explained in section 2.2 and the costs calculations in 2.3.

2.1. Identification of techno-economic improvements

Advancements to a simple cycle heat pump configuration to produce steam were explored by using a four-step method: 1. setting costs targets, 2. performing energy, economic, and exergy analysis (3E-analysis), 3. assigning costs to exergy losses, and 4. assessment of design changes.

Step No. 1: To set cost targets, the performance of an ideal (i.e., lossless) heat pump was compared to an electric boiler. This comparison is common in industry because both are a way to industrial electrification. The heat pump was defined to be economically viable when the total costs of ownership (TCO) after five years of full-time operation (8000 h) were lower than that of an e-boiler. The cost of electricity was taken to be 0.041 €/kWh [15] based on the expected average electricity costs between 2022 and 2030 in the Netherlands for large consumers. The required capital investment for an e-boiler of the required size was based on a capital costs price of 165 €/kW [15]. For both the e-boiler and the heat pump an installation costs factor of 3 was used to convert bare unit costs to installed costs. Based on the TCO of an e-boiler and the operational costs of an ideal heat pump, the maximal capital investment for a heat pump was calculated.

The next step was initiated when the capital costs price of the heat pump was at the high end of typical heat pump cost price ranges (100-1000 €/kW) [16].

Step No. 2: An energy, economic, and exergy (3-E) analysis was applied to a heat pump. The thermodynamic states of the heat pump were fixed by the outlet conditions of both the evaporator and the condenser. For both heat exchangers the pinch point temperature difference was set to 5 K with respect to the heat source and sink and conditions are assumed to be saturated [17]. When subcooling and super heating are considered using an internal heat exchanger, the amount of heat transferred was limited by the temperature at the outlet of the compressor to below 175 °C to limit the degradation of compressor lubricants and seals [3]. In the assessment, the exergy value of heat was omitted when assessing heat exchangers, as an exergy balance was made over both sides. The compressor's isentropic efficiency was stated to be 70% and its mechanical efficiency was 85%. The costs of the bare units, e.g., the heat exchangers, were based on their duty and cost functions. The bare unit costs were indexed to December 2022 with the Chemical Engineering Price Index (CEPI) [18] and converted into total costs of installation (TCI) using an installation factor to account for the cost of integrating the unit, contingencies, and other fees.

Step No. 3: Exergy-aided cost minimization was applied and the exergy losses were translated into additional operational costs [19]. Since the operational costs of a heat pump consist mainly of electricity consumption by the compressor, the amount of work required to compensate for the exergy destruction of a component can be translated to additional operational costs with the help of electricity costs and the number of operational hours.

Step No. 4: advancements to the evaluated heat pump cycles were made. The component whose performance caused the largest increase in operational costs was selected to be changed. This change was realized by adding one of the standard cycle's components; i.e., a compressor, an expansion valve, an internal heat exchanger, an ejector, a closed economiser, a flash tank, a desuperheater, a cascade condenser, or an expander. The selection among these components was based on the origin of the exergy destruction and the estimated costs of the design change. This was also done based on an energy analysis to benchmark the results of the exergy analysis. Once selected, a 3-E evaluation was done on the advanced configuration. The resulting component, together with the changes in exergy destruction, were used to evaluate the techno-economic validity of the change in the design. The performance of the advanced heat pump should have exceeded that of the e-boiler and the previously evaluated heat pump configurations. This performance is defined based on four performance indicators: 1. the total costs of ownership, 2. the initial investment, 3. the coefficient of performance, and 4. the total exergy destruction. Of these, the first two indicate the economic viability, whereas the third and fourth give insight into the technical and environmental performance of the proposed configuration, respectively.

To illustrate the application of the method, it was applied to a case study where 10 tonnes per hour (t/h) of 2 bar(a) pressure steam is produced from a water condensate steam of 50 kg/s and an initial temperature of 80 °C. This case study was selected for its common appearance in different industries like chemical, paper, and food production. All configurations were modelled using refrigerant R-1234ze(Z) due to its high critical point, low GDP and ODP [11].

2.2. Thermodynamic analysis

2.2.1. Energy balance

The basis of the energy balance was a consistent mass balance. For the simple cycle, the mass flow rate of the refrigerant (m_r) was defined by the heat transferred required in the condenser (Q_{cd}), the enthalpy after compression, and after condensation, as shown in Eq. (1):

$$Q_{cd} = m_r(h_{cd,in} - h_{cd,out}) \quad (1)$$

The refrigerant exited the condenser as a saturated liquid. All open systems were assumed to operate in a steady state and did not accumulate mass. This also holds in the case of a (flash) vessel, where an enthalpy balance defined the quality of the vapour and hence the mass ratio of its outgoing streams, and thereby the mass ratio between the top and bottom cycle.

Work added to the system (W_c) by the compressor based on the isentropic enthalpy difference (Δh_{is}) between the pressure stages and an isentropic efficiency (η_{is}) of 70%, as indicated in Eq. (2):

$$W_c = \frac{m_r \Delta h_{is}}{\eta_{is}} \quad (2)$$

The required amount of work by the compressor's drive (W_D) was based on a correction for electrical, volumetric, and mechanical losses based on overall motor efficiency (η_m) of 85%, as shown in Eq. (3):

$$W_D = \frac{W_c}{\eta_m} \quad (3)$$

The intermediate pressure (p_i) is corrected by 0.35 bar when multiple pressure stages are considered based on the work by Mateu-Royo et al. (2018), see Eq. (4):

$$p_i = \sqrt{p_1 p_2} + 0.35 \quad (4)$$

where p_1 and p_2 are the pressures before and after the compressor, respectively. Pressure relief in expansion valves is considered isenthalpic. Other forms of pressure loss are neglected, as well as heat losses. The coefficient of performance (COP) of the heat pump was based on the heat delivered at the condenser and the work required by the compressor's drive, as shown in Eq. (5):

$$COP_{hp} = Q_{cd}/W_D \quad (5)$$

The energy balance of the heat pump was closed by defining the required thermal duty of the evaporator as the difference between the duties of the condenser and the compressor.

2.2.2. Exergy balance

The influx of exergy (Ex_{in}) equals the outflux of exergy (Ex_{out}) plus exergy losses. The loss of exergy is the sum of internal exergy destruction (Ex_{des}) and transfer of exergy to external sources [20]. Since heat loss to the environment was neglected and all heat transferred from the heat pump to the environment is valuable, the exergy balance simplifies to Eq. (6):

$$Ex_{des} = \Sigma Ex_{in} - \Sigma Ex_{out} \quad (6)$$

Exergy destruction will be zero in the case of an ideal operation. In that case, the exergy flowing into the system in the form of heat at the evaporator and work by the compressor is equivalent to the exergy of the outflow of heat at the condenser. The exergy value of the streams is defined by the enthalpy (H) and entropy (S) of the stream shown in Eq. (7) [21]:

$$Ex = H - H_0 - T_0(S - S_0) \quad (7)$$

Where subscript "0" denoted the reference state at T_0 = 298,15 K and p_0 = 101325 Pa. Substituting Eq. (7) in Eq. (6) and accounting for the exergy value of heat: $Q(1 - T_0/T)$ at a thermodynamic mean temperature and that of work: W, results in Eq. (8):

$$Ex_{des} = \left(1 - \frac{T_0}{T}\right) Q + W - [H_2 - H_1 - T_0(S_2 - S_1)] \quad (8)$$

Exergy destruction due to mechanical losses in the drive was taken as equivalent to the loss of work during transfer.

2.3. Costs equations

The total cost of ownership and the total capital investment are taken as the key performance indicators for the economic evaluations. These costs are based on the indexed bare unit costs of the components, the cost

of installation, and operation. The bare unit costs ($C_{0,p}$) required for the heat pump's components were based on the costs function provided by Zuhlsdorf et al. (2019), which is presented in Eq (9):

$$\log(C_{0,p}) = k_1 + k_2 \log x + k_3 (\log x)^2 \quad (9)$$

where "x" is the scaling parameter of a certain technology and "k_i" is a calibrated value. Table 1. shows the used values adapted from Zuhlsdorf et al., [17].

Table 1. Parameters for estimation of component capital costs according to Zuhlsdorf et al., [17]

Component	Scaling Parameter X	Range	k_1	k_2	k_3	f_{cepi}	f_{bm}
Centrifugal compressor	Fluid power	450 - 3000 kW	2.2897	1.13604	-0.1027	2.3749	2.8
Drive	Shaft power	75 - 2600 kW	1.9560	1.7142	-0.2282	2.3749	1.5
Plain vessel	Volume	1 – 800 m^3	3.5970	0.2163	0.0934	2.0793	3.0
Shell & tube heat exch.	Area	10 – 900 m^2	3.2476	0.2264	0.0953	2.0793	3.2
Radial turbine	Fluid power	100 – 1500 kW	2.2476	1.4965	-0.1618	2.3749	3.5

These values were homogenized into the equivalent costs of the components for December 2022 with f_{cepi} based on the Chemical Engineering Price Index (CEPI) [18]. Bare module costs were converted into total capital investment (TCI) using the installation costs factor (f_{IF}), as shown in Eq. (10):

$$TCI_p = C_{0,p} f_{cepi} f_{IF} \quad (10)$$

For the centrifugal compressor and its drive, Eq. (4) was used as input for the scaling parameter by either including or excluding η_m, respectively. The resulting costs were benchmarked to the costs data provided in the DACE-booklet [22] and found to be plausible. In case multiple compressors were used, their scaling parameters were combined to account for the economics of scale. Their respective costs were based on the ratio between the scaling factor of the individual component and the scaling factor of the combined components. The volume of a vessel was based on being able to supply the outlet streams for 10 minutes without an influx of new refrigerant. The heat exchanging area (A) of the heat exchangers was calculated using Eq. (11):

$$Q_{hx} = U \cdot A \cdot \Delta T_{lm} \quad (11)$$

where "U" is the heat transfer coefficient and ΔT_{lm} is the logarithmic mean temperature difference between the hot and cold streams. A heat transfer coefficient of 1000 W/m^{2}K is used for heat transfer between a liquid and an evaporating liquid and 1250 W/m^{2}K was used when both sides were changing phases [17]. The total costs of the installation were equal to the sum of all the TCI of the components. This value is expressed as a factor of the condenser duty for benchmarking purposes.

The operational costs of the heat pump were defined to be equivalent to the electricity consumption by the compressor. Hence, the amount of work required to compensate for the exergy destruction of a component was translated to costs (c_i) by using electricity costs (c_{el}), and the number of operational hours in a certain period (t), as indicated in Eq. (12):

$$C_i = Ex_{des,i} \cdot c_{el} \cdot t \quad (12)$$

herein, the payback time of the process change should be less than five years of full-time operation or 40,000 hours. The costs resulting from non-ideal operation of the components were listed in descending order.

3. Results

Exergy-based cost minimization is used to advance the design of the heat pump. The performance of an ideal heat pump is compared to that of an e-boiler to indicate whether a heat pump would be an economically viable alternative. Thereafter, the performance of a single stage subcritical heat pump, a simple cycle, is assessed. Alterations to this base design are suggested based on its energetic and exergetic performance. The techno-economic performance of these advanced designs is thereafter compared.

3.1. Costs targets for a steam generating heat pump

To identify the techno-economic best heat pump configuration, an exploration of its technical surroundings and technical competitor, of the e-boiler was carried out. Producing 10 t/h of 2.0 bar(a) steam with an e-boiler required 6.5 MW of electricity. Based on the assumed bare unit costs of 165 €/kW and an installation factor of 3 this resulted in the costs as listed in Table 2. The total costs of ownership of the heat pump must be below that of the e-boiler to be competitive. In an ideal operation, this heat pump required 1.0 MW to operate, or 1.7 M€. Hence, the total installed costs must be below 12.3 M€, or 625 €/kW$_{th}$, which seemed

plausible based on the benchmarked 100-1000 €/kW_{th} [22]. The heat pump would then operate with a COP of 6.38 and reduce electricity consumption by 85%.

Table 2. Costs comparison of an ideal e-boiler with an ideal heat pump based on 5 years of operation, 8000 h/year, and an electricity price of 0.041 €/kWh – iterated values in italic

Unit	Supplied power [MW_{th}]	Required power [MW_e]	Specific costs [€/kW_x]	Bare unit costs [M€]	Total installed costs [M€]	Operational costs [M€]	Total costs of ownership [M€]
e-boiler	6.5	6.5	165	1.1	3.2	10.8	14.1
Heat pump	6.5	1.0	<625	<4.1	<12.3	<1.7	<14.1

3.2. Energy, Exergy, and Economic (3-E) performance assessment of a simple heat pump

The layout of a simple, single stage subcritical, heat pump thermodynamically consists of an evaporator, compressor, condenser, and expansion valve. The results of the 3E analysis of this cycle are presented in Table 3. These results show that the compressor's drive is the largest energy consumer. The electric drive of the compressor required 2.9 MW, and the COP was therefore 2.3. Hence, 1.9 MW is required to compensate for exergy destruction compared to the ideal heat pump. No costs were assigned to the expansion valve as the required capital investment was two orders of magnitude less than the other components. The compressor and its electric drive cost 3.2 M€ and made up for more than 70% of the total installed costs. Total costs of ownership (TCO) of 9.2 M€ were based on the electricity consumption of the drive and the total installed costs. The economic performance of the simple heat pump is a cost competitive option to the e-boiler, with a bare module cost of 234 €/kW.

The energy analysis presented in Table 3 highlights that work is solely required by the compressor and its driver. Consequently, enhancing the compressor's efficiency emerges as a viable solution based on the energy analysis. However, when subjected to exergy analysis, it is revealed that the expansion valve is responsible for the majority of exergy destruction, accounting for 689 kW (or 37% of total exergy destroyed) and incurring operational losses of over 1.1 M€. In addition, both the compressor and its drive account for 53% of the total 1848 kW destroyed. As a result, modifying the process to utilize the work potential before the expansion valve, and thereby reduce work requirement, is viewed as a promising avenue for improving the cycle based on the exergy analysis.

Table 3. 3E-evaluation of a simple cycle heat pump based on 5 years of operation, 8000 h/year, and an electricity price of 0.041 €/kWh.

Component	Heat transfer [MW]	Required power [MW]	Exergy destruction [kW]	Operational losses [k€]	Scaling factor [X]	Indexed bare unit costs [k€]	TCI [k€]	TCO [M€]
Evaporator	4.1	0.0	95	156	278	161	514	
Compressor	0.0	2.4	545	894	2,448	724	2,028	
Drive	0.0	2.9	432	708	2,880	412	1,153	
Condenser	6.6	0.0	87	142	1,054	248	792	
Exp. Valve	0.0	0.0	689	1,131				
Total			1,848	3,031		1,544	4,488	9,2

3.3. Improving the heat pump configuration

Increasing the efficiency of the compressor, as suggested by the energy-analysis, was pursued in advanced configuration No. 1 (Figure 1.A.), which depicts the common [4, 8] configuration of sequential compression with intermediate cooling to improve upon the compressor's efficiency. Utilization of the exergy before the expansion valve, as suggested by the exergy analysis, was pursued with advanced configurations No. 2 (Figure 1.B.) and No. 3 (Figure 1.C.). The aim of advanced configuration No. 2 is to use the exergy available before the expansion valve to reduce work requirements by the compressor with the help of an internal heat exchanger (IHX), also known as a closed economizer. Various authors cite this option as an interesting configuration due to its low equipment costs [23]. Advanced configuration No. 3 was designed to utilize the exergy before the expansion valve and to increase the compressor's efficiency by reducing the temperature of the pressure gas after the first compressor and utilizing the exergy available after the condenser [24]. All three configurations are well-established in current practices and have a relatively high performance [8].

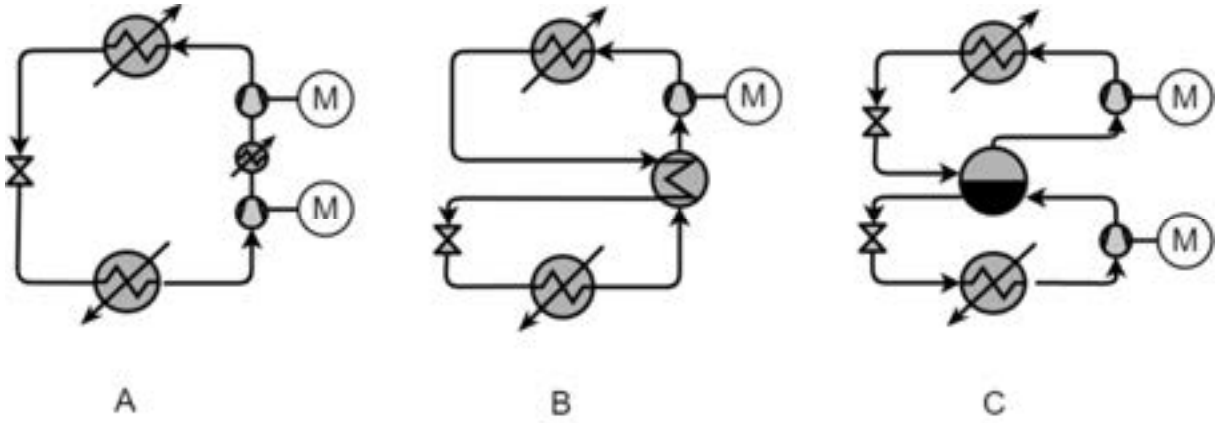

Figure. 1. Overview of advanced configurations. A) Advanced configuration No. 1: the reference simple cycle updated with an additional compressor and intermediate intercooler, B) Advanced configuration No. 2: the reference simple cycle updated with an internal heat exchanger (IHX), and C) Advanced configuration No. 3: the reference simple cycle updated with an open economizer.

3.3.1. Advanced configuration No. 1: Two stage compression with intermediate intercooling

The introduction of a second compression stage with an intermediate cooling step reduced the COP from 2.3 to 2.2, as work requirements by the driver increased to a total of 2.6 MW (Table 4.). Exergy losses are dominated by the expansion valve at 641 kW, or 32%. However, combined losses in both compressors and drives account for 1,042 of the total 2,016 kW exergy destroyed, or 53%. Though the specific work requirements by the compressor were slightly reduced by the intermediate cooling step, these gains are negated by the required increase in refrigerant mass flow to meet the energy demand in the condenser. This is partially a result of not being able to utilize the apparent heat in the intercooler due to its relatively low temperature of 92 – 89 °C and an initial sink temperature of 80 °C with an advised minimal temperature difference of at least 5 K [17]. Due to the higher work requirements and the additional investment, the total cost of ownership of this configuration is higher than that of the simple cycle. The total installed costs of the configuration are 5.3 M€, with a TCO of 10.3 M€, or 255 €/kW as a bare module.

Table 4. 3E-evaluation of advanced heat pump configuration No. 1 with two compression stages and intermediate cooling based on 5 years of operation, 8000 h/year, and an electricity price of 0.041 €/kWh.

Component	Heat transfer [MW]	Required power [MW]	Exergy destruction [kW]	Operational losses [k€]	Scaling factor [X]	Indexed bare unit costs [k€]	TCI [k€]	TCO [M€]
Evaporator	4.3	0.0	174	286	282	161	516	
Compressor 1	0.0	1.4	343	563	1,392	397	1,112	
Drive 1	0.0	1.6	246	403	1,637	223	625	
intercooler	0.3	0.0	55	90	102	121	388	
Compressor 2	0.0	1.2	264	433	1,183	338	946	
Drive 2	0.0	1.4	209	342	1,392	190	946	
Condenser	6.6	0.0	84	138	1,054	248	792	
Exp. Valve	0.0	0.0	641	1,052				
Total			2,016	3,307		1,678	5,325	10.3

3.3.2. Advanced configuration No. 2: Internal heat exchanger

The addition of an internal heat exchanger (IHX) is a viable option to significantly increase the overall performance of the heat pump, leading to a reduction in the total costs of ownership (TCO) by 0.5 M€ in comparison to the simple cycle. Although the installation of the IHX increases the initial installed costs by 0.5 M€, the reduction in the size of the compressor and electric drive results in savings of 135 k€ in installed costs and a reduction of 0.8 M€ in operational costs after 5 years (Table 4.). The total cost of ownership for the heat pump with the IHX is 8.7 M€ or 249 €/kW as a bare module.

The lower operational cost is primarily attributed to the increase in the COP to 2.8 from 2.3, resulting from the addition of the IHX. This decrease in the work required by the drive from 0.6 MW to 2.3 MW is the main reason behind the increase in the COP. The total exergy destruction was reduced by 490 kW to 1,358 kW, with the compressor contributing the most to the total exergy destruction at 379 kW (28%), followed by its

driver at 351 kW (25%), and the condenser at 476 kW (22%). The exergy destruction became evenly distributed among the components with the introduction of the IHX. The increase in exergy in the evaporator is due to the higher COP, requiring more energy from the sink and a temperature drop from 55 to 54 °C of the source. The exergy destruction in the condenser significantly increases due to its high inlet temperature, which is increased by superheating the suction gas before the compressor with the IHX. The introduction of the IHX led to an exergy destruction of 64 kW.

Table 5. 3E-evaluation of advanced heat pump configuration No. 2 with an internal heat exchanger based on 5 years of operation, 8000 h/year, and an electricity price of 0.041 €/kWh.

Component	Heat transfer [MW]	Required power [MW]	Exergy destruction [kW]	Operational losses [k€]	Scaling factor [X]	Indexed bare unit costs [k€]	TCI [k€]	TCO [M€]
Evaporator	4.6	0.0	195	319	288	162	520	
Compressor	0.0	2.0	379	621	1,991	682	1,909	
Drive	0.0	2.3	351	576	2,342	406	1,137	
IHX	2.3	0.0	64	105	185	143	456	
Condenser	6.6	0.0	290	476	1,054	248	792	
Exp. Valve	0.0	0.0	79	130				
Total			1,358	2,227		1,640	4,814	8.7

3.3.3. Advanced configuration No. 3: Two stage heat pump with open economizer

The addition of an open economizer splits work requirements over two compressors with a combined duty of 2 MW, or 2.4 MW at the electric drive. Hence, the required 6.6 MW at the condenser can be delivered with a COP of 2.8. Exergy destruction is evenly distributed among the components. The second stage compressor was the main source of exergy destruction at 269 kW (19% of total exergy destroyed), followed by its drive at 212 kW (15%) and the expansion valve directly after the condenser at 207 kW (15%). Together with the first stage and their drives, the compressors accounted for 60% of total exergy destruction, compared to 21% of both expansion valves, with a total of 1,4 MW destroyed. The exergy destruction in the evaporated increased by 100 kW as more heat is transferred. The intermediate cooling in the vessel slightly reduced exergy destruction in the condenser compared to the simple cycle. The vessel itself also has a negligible amount of exergy destruction, when considering heat transfer between the top and bottom cycle. Exergy destruction in the expansion valves went from 689 kW in the simple cycle to 294 kW for both valves. As a result, total exergy destruction was reduced by 445 kW. The reduced size of the compressors and electric drive reduced investment costs by 43 k€. However, the installation of the vessel requires an additional 0.55 M€. The TCO is 8.8 M€, or 255 €/kW as a bare module. Hence, the initial investment increases compared to the simple cycle, but the increased efficiency mitigates the impact of operational costs and reduced the TCO by 0.4 M€ during the five years.

Table 6. 3E-evaluation of advanced heat pump configuration No. 3 with an open economizer and two stage compression based on 5 years of operation, 8000 h/year, and an electricity price of 0.041 €/kWh.

Component	Heat transfer [MW]	Work transfer [MW]	Exergy destruction [kW]	Operational losses [k€]	Scaling factor [X]	Indexed bare unit costs [k€]	TCI [k€]	TCO [M€]

4. Discussion

The central question of this study was whether an exergy-based economic analysis provides a solid basis for identifying improvements to a heat pump's configuration. This question is answered by first evaluating the quality of the output and thereafter discussing the usability of the method.

4.1. Quality of output

The approach described in this paper yields outputs in two phases. Firstly, the feasibility of an ideal heat pump is compared to an e-boiler based on the findings of section 3.1. The second phase involves modifying the heat pump's configuration to improve its techno-economic performance, based on the results of sections 3.2 and 3.3. It is worth noting that advanced configuration No. 1 is not included in this evaluation, as it was the outcome of design changes stemming from an energy analysis.

The first phase provides a broad indication of the feasibility of a heat pump compared to an e-boiler. The simplicity of this approach makes it inherently vulnerable to the quality of the data input. For example, changes in the installation costs factor or the costs of electricity are likely to move the solution in a certain direction. A “plug-and-play” e-boiler design is likely to reduce the installation costs factor, which will result in the capital costs being a smaller percentage of the TCO, and a lower TCO overall. Changes in the electricity price can have a similar impact on the decision between an e-boiler and a heat pump, as an e-boiler uses more electricity. The easiness of the approach makes it a valuable tool for a first assessment and conducting a sensitivity analysis will aid in exploring tipping points in the decision-making process. Moreover, additional considerations like the size of the grid connection and the dynamic behavior of both systems should be considered when comparing these techniques.

The second phase explored the advancement of the simple cycle heat pump configuration. This option is already an economically interesting alternative based on its COP of 2.3 and a bare unit cost of 234 €/kW compared to a COP >1 and a bare unit cost of 165 €/kW for the e-boiler. The TCO of the simple cycle is 9.2 M€ after 5 years of full-time operation, which is significantly less than the 14.1 M€ of the e-boiler. The expansion valve is the largest single source of exergy destruction in the simple cycle, as it accounts for 37% of the total exergy destruction. This is in line with the findings of Bergamini [10] and Hu [11]. Moreso the COP of 2.3 compared to the listed COP of 1.7 to 2.3 when transferring heat at 60 to 100 °C to a heat sink of 140 °C by Adamson et al. [8]. However, when considering the compressor (29%) and its drive (23%) as a single operational unit, they become the dominant source of exergy destruction at a combined 53%, on a total exergy destruction of 1,85 MW. Exergy destruction by the compressor’s drive is quite significant, despite its efficiency of 85%. This impact can be explained by the high exergy-value of the drive’s energy, work. The drive’s losses are entirely dependent on its duty and electric, volumetric, and mechanical efficiency. Hence, after the duty is reduced by advancing the cycle, this destruction could be reduced by more advanced mechanical equipment.

The addition of the internal heat exchanger reduced the amount of work that must be delivered to the compressor compared to the simple heat pump and increased the COP from 2.3 to 2.8. This is 22% larger than the 2.3 reported by Adamson et al. [8] at the same temperature lift with the same working media. This difference is the result of the 20 °C higher condenser temperature in the case of Adamson’s findings. This highlights the sensitivity of a heat pump's techno-economic performance to the temperature of the heat source and sink.

Advancing the simple cycle heat pump with an internal heat exchanger seems to be the preferred route compared to the open economizer, as it has similar operational (and emission) savings at a lower cost. This is in part due to the high efficiency with which the IHX can utilize the work potential compared to the vessel and the lower unit costs. This outcome is the opposite of what is expected based on the commonly found link between higher exergy efficiency and capital costs, as mentioned by Rosen and Dincer [25]. One possible explanation for this discrepancy is that the use of a constant compressor efficiency in the analysis does not account for the volumetric efficiency gains offered by the open economizer. Overall, the analysis highlights the importance of considering a detailed unit operation when evaluating the performance and economic feasibility of heat pump configurations.

4.2. Usability of exergy-based costs minimization

The starting point of this study was that a framework is needed that aids in identifying advanced configurations that improve the techno-economic performance of a considered heat pump and help decision-makers in their quest to identify techno-economically feasible options. The proposed approach helps visualize where losses manifest together with their accompanying costs. This is different from an energy analysis, which will only be able to account for the costs of the operation of the drives and the profits from supplying heat to the condenser. Advanced configuration No. 1., where an additional compression stage and intermediate cooling are added to the simple cycle design, is a logical result of energy analysis, as it uses a common strategy to improve upon the efficiency of the compressor. However, the changes did not increase techno-economic performance in this case study. Moreso, it reduced the COP by 0.1, increased exergy destruction by 168 kW, increased the total capital investment by 837 k€, and increased the total cost of operation by 1.1 M€. Hence, reducing the overall performance of the simple cycle heat pump. Another route based on the outcomes of an energy analysis would be to buy a more efficient compressor and drive. For these upgrades to be economically competitive with the second advanced configuration with the internal heat exchanger, the overall motor efficiency must increase from 85% to 95% and the isentropic efficiency from 70% to 85%, whilst the cost increase of the compressor increases is limited to 13%.

In contrast, both design changes based on exergy analysis improved the techno-economic performance of the simple cycle heat pump. However, both advanced options still had an exergy destruction of 1.4 MW. The degree to which this can be reduced is currently unknown.

5. Conclusions and recommendations

Exergy based economic analysis can be used to identify techno-economic improvements to a steam generating heat pump. Not only was the method able to quickly assess the boundaries to its economic performance compared to other technologies (e.g., an e-boiler), but also improved on the technical performance of a single stage subcritical heat pump layout, whereas suggestions by an energy analysis were not.

The exergy-based costs minimization method identified the expansion valve as the source of most operational costs, as it accounts 37% of the total exergy destruction. However, the compressor and its drive combined contributed 53%. The work potential available before the expansion valve can be used to improve on the compressor efficiency by either a closed or an open economizer. The closed economizer, or internal heat exchanger, increased the heat pump's COP from 2.3 to 2.8 at the cost of an additional investment of 0.5 M€. This additional investment reduces the total costs of ownership by 0.6 M€ after five years of operation. The open economizer also increased the COP from 2.3 to 2.8 and required an additional investment of 0.5 M€. The total costs of ownership are reduced by 0.4 M€ after five years of operation. The approach thus succeeded in identifying techno-economically beneficial process changes and helped to produce two options that both increased the technical and economic performance of the heat pump, whereas the energy-based approach did not.

However, the exergy-based approach only pinpoints the exergy destruction that could be utilized. It is not able to identify how much the exergy destruction could be reduced. A variation of exergy analysis link *Advanced exergy analysis* as proposed by Tsatsaronis [20] may aid in this process. Moreover, the method does not suggest the technology that should be selected. Hence an extension of the framework is needed in which a strong link is made between the techno-economic performance gains of an additional component and the operational context of the heat pump. The same holds for a link to other working media, where a link between the gradient of the isentropic curves and exergy destruction is a likely candidate based on the presented results (i.e., the two stage compressor with intermediate cooling requiring more work). Lastly, it is recommended to use a more detailed thermodynamic analysis of the operational units to provide a fair basis for the comparison of added components. The assumption of a constant isentropic efficiency is likely to skew the presented results.

Abstract:

With uncertainty in energy markets, and the effects of climate change looming, reducing energy use and operational cost of existing building systems is more important than ever. To this end, this paper presents a grey-box modelling approach to characterise the behaviour of chilled and frozen and coldrooms using basic system specifications and measured data. An overall energy balance is used to devise a discrete state space model for each cabinet, characterised by unknown empirical parameters relating to heat capacity and heat transfer properties. Historical system data from a UK supermarket are used in combination with a genetic algorithm optimisation to determine the optimal empirical parameters for 10 display cases and 10 coldrooms. The resulting cabinet temperature predictions have a good level of accuracy, achieving a root-mean squared error (RMSE) of 0.37℃ to 0.98℃. Overall this data-driven approach is effective and efficient in modelling refrigeration systems, and can be easily generalised to any system where historical data is available. Finally, the use of the proposed approach in cost minimisation or demand response application is presented.

Keywords:

Supermarket, Refrigeration, Genetic Algorithm, Model Predictive Control, Demand Response

1. Introduction

Commercial refrigeration systems are highly energy intensive and can be responsible for up to 40-60% of a supermarket's overall electricity use [1]. As such, there is clear motivation to reduce energy use and operating costs of such systems through smart control applications. At a high level these control schemes aim to utilise the thermal capacity of refrigerated foodstuffs to shift cooling requirements to low-price or low overall grid demand periods based typically on real-time energy prices to minimise operating costs [2], [3] or demand-side response scenarios [4], [5] to alleviate periods of high grid demand. Such control methods often require simulation models in order to test and calibrate the proposed approach ahead of real-world deployment, which motivates a better understanding of the data requirements and best practices for developing such a model.

A popular refrigeration modelling approach is discussed in [6], which presents 3 separate sub-models to characterise the performance of the chilled cabinets, suction manifold and condenser. A grey-box approach is used to devise the fundamental mass and energy balances across the sub-systems, for which empirical constants are then fit using historical data via an iterative prediction-error minimization (PEM) method. Optimal empirical parameters and temperature fitting results are presented for 7 chilled cabinets, but deliberately excludes behaviour during defrost periods and doesn't consider frozen cabinets. This limits the application of the method to control of real-world systems. An alternative grey-box modelling approach is presented in [7], which uses a state-space model derived from thermodynamic heat and mass balances of individual cabinets and evaporators. Model parameters were estimated using a maximum likelihood estimation approach, based on 2.5 years of minutely telemetry from 6 chilled and 4 frozen units. The approaches lumps the cabinet air and food temperatures together, preventing individual tracking of food temperature which is a key variable to monitor in control applications.

This paper demonstrates a grey-box modelling approach to model temperature dynamics in commercial chilled and frozen cabinets. This is achieved using a genetic algorithm to fit unknown physical parameters for individual cabinets, demonstrated using a UK supermarket as a case study. The method improves over existing literature by modelling temperature dynamics during defrost cycles, as well as explicitly accounting for electric defrost elements present in frozen units.

2. Case Study

2.1. System Description

This paper uses two identical R744 CO_2 booster refrigeration systems installed in a UK food retail store as a case study, shown in Figure 1. Each refrigeration loop services roughly 50% of the cabinets and coldrooms in the store, as detailed in Table 1. They are designed to operate in both the subcritical and transcritical regions depending on the ambient temperatures, but typically they operate subcritically [8]. The flash tank feeds saturated liquid refrigerant to the medium temperature (MT) evaporators in the refrigeration cabinets and coldrooms, as well as feeding the low temperature (LT) evaporators in the frozen cabinets and coldrooms. ”Cabinets” refer to display cases which hold the chilled or frozen food on the shop floor, while ”coldrooms” refer to large rooms in the back of house area which hold additional chilled or frozen stock. Expansion valves are present in each individual cabinet or coldroom, which are locally controlled to maintain the specific cabinet temperature setpoint. A superheat control also operates on the cabinet valves to ensure the refrigerant leaving the evaporators and entering the compressors is only in the gas phase. The LT evaporator outlet feeds directly into the low pressure (LP) compressor bank, and then the MT evaporator outlet mixes with this LP compressor outlet before entering the high pressure (HP) compressor bank. The LP compressor bank is comprised of three 2ESL-4k Bitzer compressors and the HP bank uses six 4FTC-20k Bitzer compressors, one of which has a variable speed drive. The HP compressor outlet then passes through a series of plate heat exchangers which facilitates heat recovery from the refrigeration system into the primary side of the ground-source heat pump (GSHP) which provides heating and hot water services for the building. Refrigerant then enters the gas cooler to remove the remaining heat, the outlet of which feeds the refrigerant flash tank.

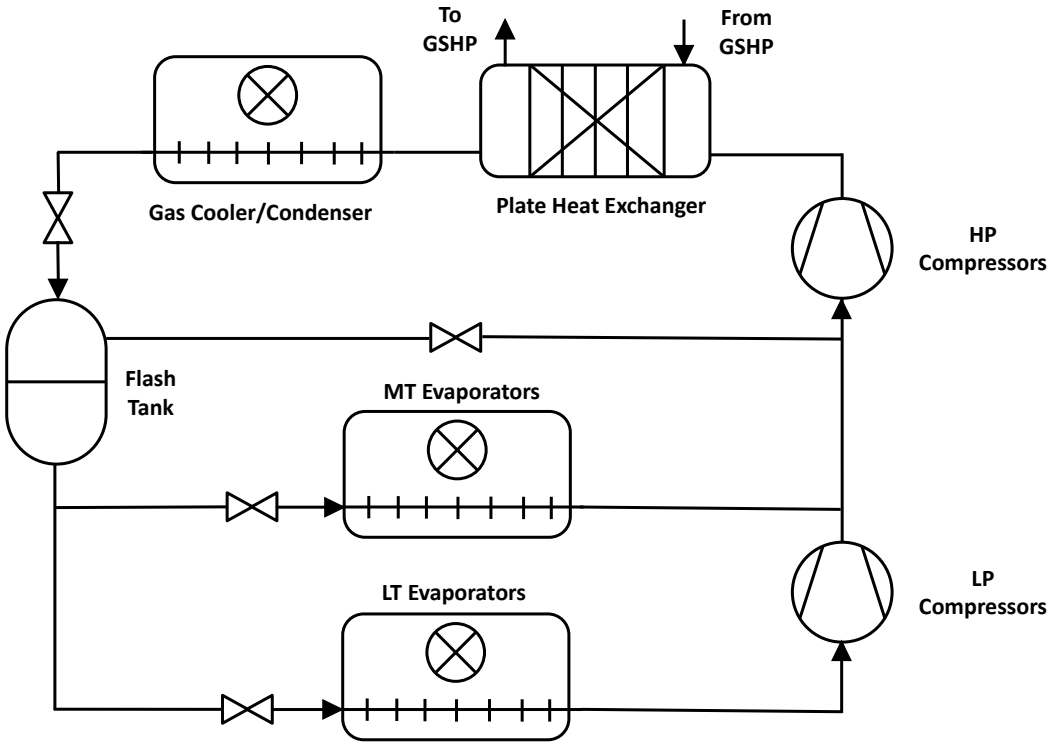

Figure 1: Schematic of typical CO_2 booster refrigeration system.

Due to the subzero refrigerant temperatures required to absorb sufficient heat from the cabinet air, moisture in the air will condense and then freeze over the evaporator. Over time this ice layer can build up and prevent sufficient circulation of the cabinet air which dramatically reduces the available cooling capacity. To prevent this, regular defrost cycles are run in both the LT and MT evaporators. For MT evaporators, an off-cycle defrost is used meaning the refrigerant valve is fully shut for 15-30 minutes, which warms the cabinet and melts the ice, and in LT evaporators an additional heating element is used to actively melt the ice. The operating power of the heating element can be found in the system specification documents for each cabinet. This study is based on data from 10 cabinets (5 chilled, 5 frozen) and 10 coldrooms (5 chilled, 5 frozen) chosen across the two refrigeration systems present in this store.

Fixture	Setpoint [℃]	Refrigeration Load* [kW]	Defrost Power [kW]	System 1 Count	System 2 Count
Fridge Cabinet	1 - 4	2.1 - 7.7	-	36	39
Frozen Cabinet	-20	1.0 - 2.6	5.0 - 21.0	11	12
Fridge Coldroom	1	6.2 - 6.7	-	5	4
Frozen Coldroom	-21	2.6	5.0 - 8.0	3	3

Table 1: Cabinet specifications for each refrigeration system. *Under 25℃ and 60% RH.

2.2. Operating Behaviour

To showcase the operating behaviour of the chilled and frozen cabinets, 12 hours of telemetry data are presented for each cabinet type in Figure 2. All system data are collected using a cloud-based monitoring platform, presented in more detail in [9]. As seen in this plot, the cabinet air temperature is maintained at the setpoint using a local PI controller which manipulates the opening degree (OD) of the expansion valve to provide the required cooling duty. During the off-cycle defrost periods (highlighted in blue) expansion valves fully shut which raises the cabinet air temperature and melts any ice build up. Immediately following the end of the defrost, the valve opens to pull the cabinet temperature back down to setpoint. Frozen cabinet telemetry looks similar but has some notable differences. Firstly, they operate using hysteresis control on the expansion valve, which opens and closes the valve as the cabinet air temperature breaches upper or lower temperature bounds. This control approach is more suitable for frozen cabinets as they use case doors which maintain air temperature much more steadily compared to doorless chilled cabinets. The lack of doors also causes chilled cabinets to need more frequent defrosts compared to frozen units, due to increased ingress of warm, humid air from the shop floor.

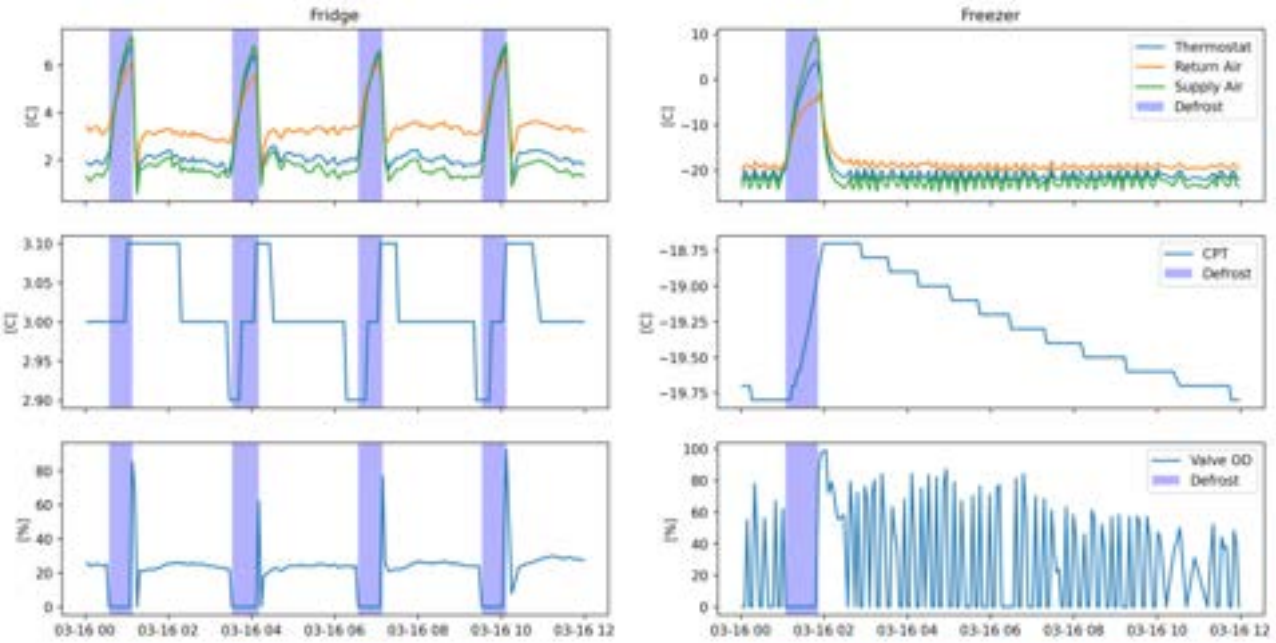

Figure 2: Cabinet telemetry for a chilled cabinet (left) and frozen cabinet (right).

In addition to cabinet air temperature and valve OD sensors, the calculated product temperature (CPT), also referred to as food temperature, in each cabinet is estimated using a proprietary algorithm provided by a resource data management (RDM) panel which monitors and collects data from the local cabinet controllers. As seen in Figure 2, the CPT in chilled cabinets only changes by 0.2℃ during an off-cycle defrost, but can change by up 1℃ during a frozen cabinet defrost due to the additional electric heating element in the evaporator.

3. Modelling

3.1. Cabinet Temperature

The proposed cabinet temperature model is adapted from a popular approach seen in [6], based on an energy balance over an individual cabinet. In cabinets, heat is transferred from the food items to the cabinet air,

$\dot{Q}_{foods/c}$, as well as from the internal building to the cabinet air, $\dot{Q}_{load}$. Heat is then exchanged between the cabinet air and the evaporator, $\dot{Q}_e$. This paper improves upon previous approaches by including the additional term, $\dot{Q}_D$, to account for the heat added by the electrical defrost element present in the evaporators of most frozen units. For all chilled and frozen cabinets, the cabinet air temperature, T_c, and internal building temperature, T_{indoor}, are directly measured using temperature sensors and the calculated product temperature (CPT), T_{food}, is estimated using the previously discussed approach. Assuming purely conductive heat transfer, the energy balance on this system can be written as

$$MCp_{food}\frac{dT_{food}}{dt} = -\dot{Q}_{food/c} \tag{1}$$

$$MCp_c\frac{dT_c}{dt} = \dot{Q}_{load} + \dot{Q}_{food/c} + \dot{Q}_D - \dot{Q}_e \tag{2}$$

$$\dot{Q}_{food/c} = UA_{food}\,(T_{food} - T_c) \tag{3}$$

$$\dot{Q}_{load} = UA_{load}\,(T_{indoor} - T_c) \tag{4}$$

where MCp_{food} and MCp_c are the product of mass and specific heat capacity for the food and cabinet air respectively, and UA_{food} and UA_{load} are the heat transfer coefficients between the cabinet air and the food and store air respectively. The cooling duty of the evaporator can then be written as

$$\dot{Q}_e = \beta\, OD \tag{5}$$

$$\beta = K_v\,(h_{oe} - h_{ie})\,\sqrt{\rho_{suc}\,(P_{rec} - P_{suc})} \tag{6}$$

where OD is the opening degree of the expansion valve, K_v is a valve specific constant, ρ_{suc} is the density of the refrigerant on the suction side, P_{suc} and P_{rec} are the suction and receiver pressures, and h_{oe} and h_{ie} are the specific refrigerant enthalpies at the inlet and outlet of the evaporator respectively. Under normal operation, compressor controllers aim to keep the operating pressures and temperatures of the refrigerant constant at specific points in the cycle, allowing the combination of these parameters into one constant β.

From this point, the above system (1)-(6) can be rearranged and expressed as an LTI state space model.

$$\begin{cases} \dot{\boldsymbol{x}} = A\boldsymbol{x} + B\boldsymbol{u} \\ \boldsymbol{y} = C\boldsymbol{x} \end{cases} \tag{7}$$

with the state values, $\boldsymbol{x} = [T_{food},\, T_c]^T$, controls and disturbances, $\boldsymbol{u} = \left[OD,\, \dot{Q}_D,\, T_{indoor}\right]^T$, and model parameters

$$A = \begin{bmatrix} \frac{-UA_{f/c}}{MCp_f} & \frac{UA_{f/c}}{MCp_f} \\ \frac{UA_{f/c}}{MCp_f} & \frac{-UA_{load}-UA_{f/c}}{MCp_c} \end{bmatrix}, \qquad B = \begin{bmatrix} 0 & 0 & 0 \\ \frac{-\beta}{MCp_c} & \frac{1}{MCp_c} & \frac{UA_{load}}{MCp_c} \end{bmatrix}, \qquad C = \begin{bmatrix} 1 & 1 \end{bmatrix} \tag{8}$$

In order to fit model parameters from historical data, the continuous state space model (7), should be discretised using the sampling time of the sensors.

$$\begin{cases} \dot{\boldsymbol{x}}\,[k+1] = A_d\boldsymbol{x}\,[k] + B_d\boldsymbol{u}\,[k] \\ \boldsymbol{y}\,[k] = C_d\boldsymbol{x}\,[k] \end{cases} \tag{9}$$

3.2. Parameter Estimation

The required input data, namely T_{food}, T_c, T_{indoor} and OD are collected for a range of chilled and frozen cabinets from the case study system. An additional binary variable is collected from the cabinet controllers which shows when the cabinet is in defrost mode to allow calculation of $\dot{Q}_D$ using the rated defrost power discussed previously. Raw telemetry is collected at irregular 2-3 minute intervals and resampled to 1 minute intervals using linear interpolation to better capture the dynamics of the system. One day of data from 10/03/2023 is used for each cabinet to show the flexibility of the method using even just a small sample of N total data points. The system (7) - (9) is expressed using the *StateSpace* function within the *scipy*.*signal* package in Python [10]. This system is then wrapped within a genetic algorithm (GA) optimisation which finds the optimal empirical parameters MCp_{food}, MCp_c, UA_{food}, UA_{load} and β, by using measured system states, $\boldsymbol{x}$ and measured control and disturbances $\boldsymbol{u}$ to estimate the system states in the next timestep $\hat{\boldsymbol{x}}[k+1]$ and compare these to the measured system states $\boldsymbol{x}[k+1]$. This multi-objective optimisation is formulated as

$$\min_{\boldsymbol{Z}} \left(RMSE_c, RMSE_{food}\right) \tag{10}$$

$$RMSE_i = \sqrt{\frac{1}{N}\sum^{N}\left(\hat{T}_i - T_i\right)^2} \tag{11}$$

subject to constraints

$$\begin{cases} \boldsymbol{Z} = [MCp_{food}, MCp_c, UA_{food}, UA_{load}, \beta] \\ \boldsymbol{Z} \geq [0, 0, 0, 0, 10^3] \\ \boldsymbol{Z} \leq [10^9, 10^6, 10^4, 10^4, 10^4] \end{cases} \tag{12}$$

In this paper we utlilise the Python optimisation package *Pymoo* [11] and their implementation of a Non-dominated Sorting Genetic Algorithm (NSGA-II) [12]. Each generation has a population of 100, and the optimisation terminates after 100 generations, and all other GA parameters are left at their default values.

4. Results

The optimal empirical parameters for the chilled and frozen cabinets are shown in Table 1, with *MCp* values given in [J/K], *UA* values in [W/K], β in [W/OD%] and *RMSE* in [K]. For each cabinet, the GA fitting process took at most 2 minutes to complete on a desktop PC with a Ryzen 5 3600 6-core CPU. On average the chilled cabinets have a satisfactory fit, with an RMSE of 0.56℃ and 0.13℃ for cabinet air and food temperature predictions respectively, while frozen cabinets are slightly higher at 0.89℃ and 0.17 ℃ respectively. Chilled cabinets also have higher UA_{load} values, ranging from 42-82 W/K compared to only 1-4 W/K for the frozen cabinets, and higher β values, 3,769 - 6,450 W/OD% compared to 1,000 - 1,576 W/OD% for frozen cabinets. Both of these differences are due to chilled cabinets not having doors, causing a larger heat transfer from the building air to the cabinet air, and consequently requiring a larger evaporator cooling duty to keep the food at setpoint.

	Chilled Cabinets					Frozen Cabinets				
Cabinet ID	1	2	3	4	5	6	7	8	9	10
MCp_{food} ($\times 10^6$)	942.5	222.5	865.8	138.0	951.0	10.7	13.2	577.4	6.3	36.0
MCp_c ($\times 10^5$)	3.2	1.6	2.5	2.2	1.7	2.0	2.1	1.9	1.5	1.8
UA_{load}	82	64	42	60	63	4	3	2	3	1
UA_{food}	391	254	301	222	100	174	189	191	134	194
β ($\times 10^3$)	5738	3796	6450	6308	4673	1576	1050	1000	1050	1032
$RMSE_c$	0.46	0.37	0.68	0.56	0.72	0.98	0.87	0.84	0.89	0.87
$RMSE_{food}$	0.13	0.11	0.15	0.09	0.17	0.18	0.19	0.11	0.18	0.18

Table 2: Empirical parameters and RMSE values for the chilled and frozen cabinets.

Figure 3 shows 24 hours of cabinet air and food temperature predictions from the training sample compared with measured values for the two best chilled and frozen cabinets. Air temperature predictions are generally

good, fitting well the temperature spikes due to defrost, but struggling sometimes to predict the smaller, higher frequency temperature variations when the cabinet is at setpoint. This is particularly noticeable in the frozen cabinet which use hysteresis control to maintain the air temperature within a bound around the setpoint.

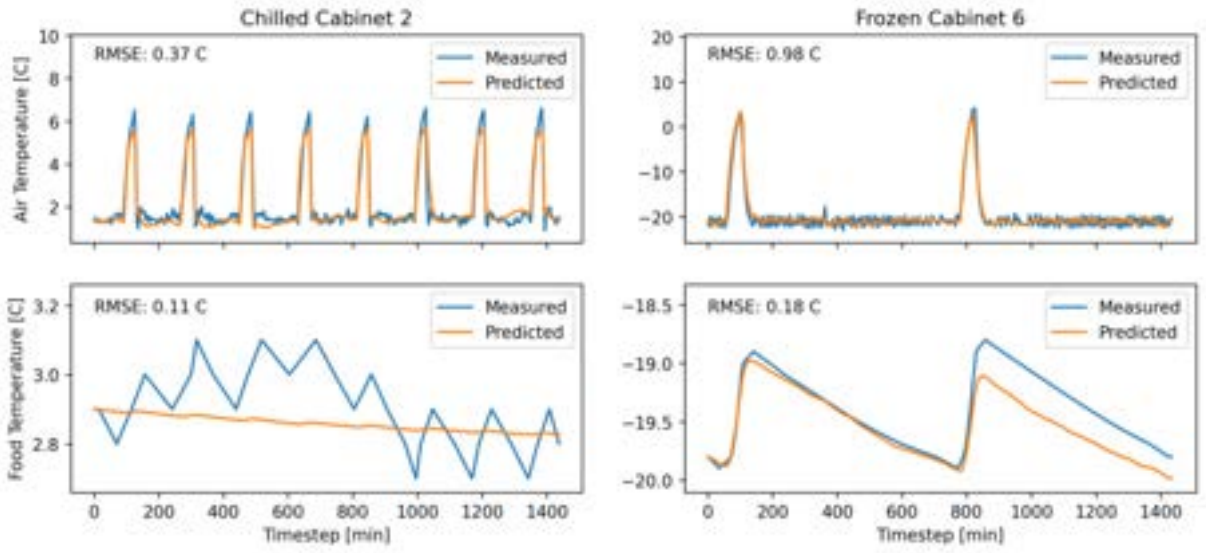

Figure 3: Cabinet temperature predictions based on optimal GA fitting.

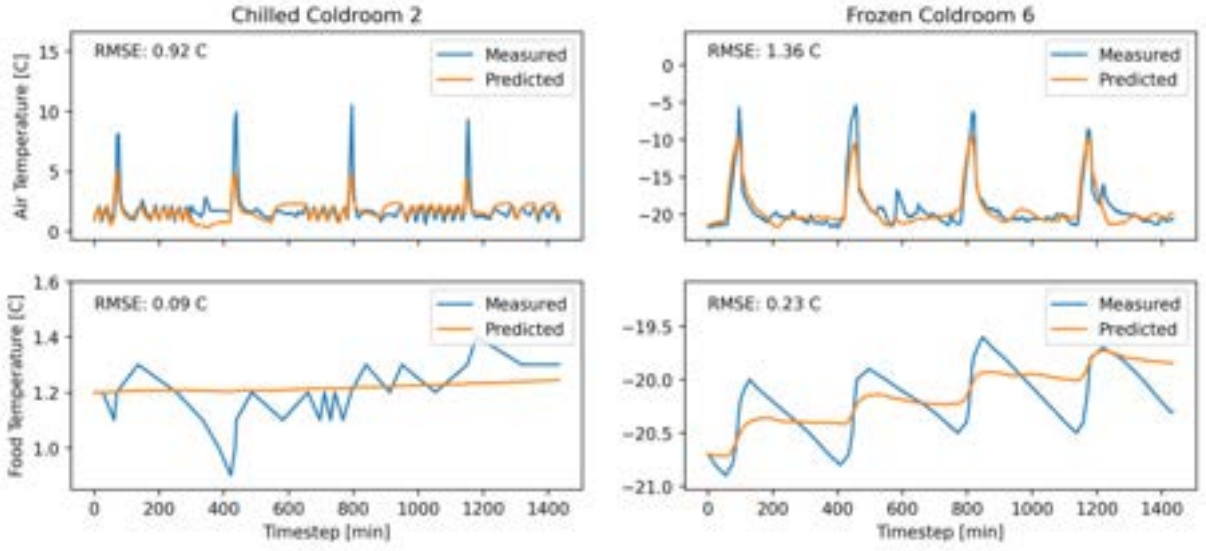

Figure 4: Coldroom temperature predictions based on optimal GA fitting.

Food temperature predictions are less reliable, particularly for the chilled cabinets. Over most of these cabinets the food temperature predictions fail to pick up any of the observed changes in food temperature due to defrost, instead just predicting a constant value which is on average correct. In addition, the food temperature in the chilled cabinets only changes by a maximum of 0.3℃ during a defrost, which is small temperature change for this model to account for, especially compared to the air temperature which varies by around 5℃. Empirical parameters for the 5 chilled and 5 frozen coldrooms analysed can be found in Table 3, and temperature predictions compared to measured values are shown in Figure 4. The air temperature predictions are not as accurate compared to the chilled and frozen cabinets, especially during the defrost periods, achieving an average RMSE of 0.61℃ and 0.16℃ for cabinet air and food temperature predictions respectively for chilled coldrooms, which increases to 2.74℃ and 0.37℃ for frozen coldrooms. This could be due to uneven temperature distribution in coldrooms, which are much larger than cabinets, and so this effect is not by the individual air temperature sensors.

	Chilled Coldrooms					Frozen Coldrooms				
Coldroom ID	1	2	3	4	5	6	7	8	9	10
MCp_{food} ($\times 10^6$)	22.0	799.7	318.6	998.9	997.9	413.0	5.5	15.1	5.2	9.4

$RMSE_{food}$	0.08	0.09	0.14	0.18	0.30	0.26	0.23	0.56	0.31	0.50

Table 3: Empirical parameters and RMSE values for chilled and frozen coldrooms.

5. Application Example

In advanced control applications, simulation models are often required to test and refine the chosen approach prior to real-world implementation. A schematic demonstrating an example framework for a supervisory model predictive control (MPC) approach applied to a refrigeration system can be seen in Figure 5. The MPC scheme will have a user-defined objective function, which is typically minimising operational cost subject to variable electricity prices, or tracking a reference power consumption sent from the grid for demand-response applications. In either case, the key control variable is the optimal temperature setpoint, T^*_{sp}, which can be forwarded to the local cabinet controllers to enact the required expansion valve position OD. The devised cabinet models can then be used to simulate the resulting cabinet and food temperature changes. An equivalent modelling and control approach has been demonstrated for a commercial HVAC system in the UK and simulations show the ability to reduce operational costs while adhering to user specified constraints [9].

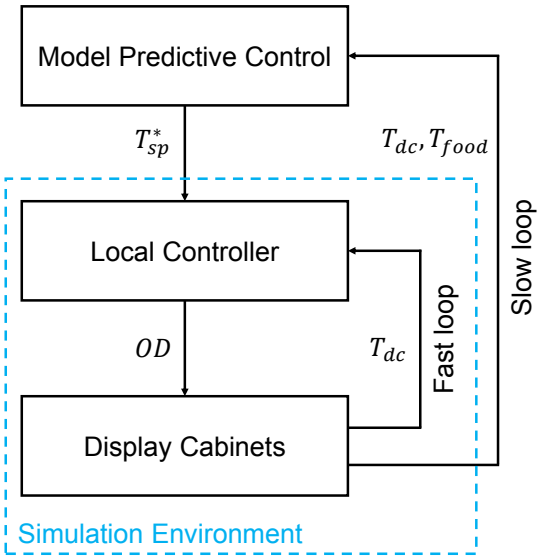

Figure 5: Example supervisory MPC application using refrigeration cabinet model.

The proposed cabinet modelling approach is well suited to these control applications for a number of reasons. Firstly, a large number individual cabinet models can be fit offline with low computational overhead, allowing a user to easily simulate a entire supermarket refrigeration system. Additionally, the modelling approach shows satisfactory modelling accuracy when trained on only a small snapshot of 24 hours of data. Finally, once the optimal empirical parameters are known, the cabinet models are a simple system of linear equations providing a fast, efficient method to test any proposed control approach.

6. Conclusion

This paper presents a data-driven modelling approach to simulate the behaviour of chilled and frozen cabinets and coldrooms, using a UK supermarket as a case study. Individual units are modelled using a discrete LTI state space model, based on an overall system energy balance, for which empirical parameters are determined using a genetic algorithm fitting approach. The proposed approach is demonstrated using 24 hours

of historical data from 10 display cabinets and 10 coldrooms, and shows satisfactory performance across the range of cabinets tested. Finally, a high-level example application of the proposed modelling approach to a supervisory, model predictive control scheme was discussed. Future work should look to better understand the food temperature dynamics, perhaps using temperature probes instead of an estimated CPT value, as this is the most important variable to track in control applications.

Abstract:

The heat pump market is experiencing remarkable growth and rapidly expanding in various sectors. Industrial heat pumps are an emerging technology for electrifying and decarbonizing the heat supply, such as hot water, hot air, and steam. However, integrating industrial heat pumps into business models is not yet common. As a result, little research has been conducted linking business model frameworks to the rapidly evolving heat pump sector. Besides, there are challenges in the transition from fossil fuel heating to electrical-driven heat pumps, including unfavorable electricity-to-gas price ratios, regulatory issues, alternative heating technologies, low maturity of services, the requirement for tailor-made designs, more complex integration principles, simultaneous need for excess heat, and higher CAPEX (compared to fossil or electric boilers). This study reviews business models for industrial heat pumps based on scientific literature and interview results with manufacturers as part of the EU Horizon project PUSH2HEAT. The goal is to explore innovative business models that could emerge from industrial heat pumps based on the changing framework conditions. First, the status of business models is reviewed to identify gaps in the academic literature. Next, ideation inputs are considered from case studies on high-temperature heat pumps, analogies to other markets such as domestic heat pumps, large-scale heat pumps for district heating networks, waste heat recovery, combined heat and power generation, as well as lessons from other innovative business models in the energy sector (e.g., energy contracting, heat as a service). Then, various players in the value chain (e.g., planners, manufacturers, integrators, installers, service providers, etc.), their capabilities, and the added value will be analyzed. Finally, a short list of business models will serve as a basis for decision-making for existing players, such as utilities and new companies considering entering the heat market.

Keywords:

Heat pumps; industry; innovative business models; value-chain.

1. Introduction to industrial heat pumps

Industrial heat pumps (HP) will play an important role in decarbonizing process heat and improving the energy efficiency of industrial processes in the future while driving the shift from fossil fuels to renewable electricity as an energy source [1], [2]. There are more and more suppliers of industrial heat pumps, as summarized in the IEA Annex 58 project [3], [4]. Four types of heat pump technologies are most relevant for industrial applications:

- standard heat pumps with supply temperature < 80 °C,
- high-temperature heat pumps (HTHP) with supply temperature > 100 °C,
- steam-generating HP with mechanical vapor compression (MVR) and supply temperature < 200 °C,
- heat transformers with supply temperature < 300 °C [5].

These heat pump technologies cover heat capacities ranging from about 100 kW to 10 MW [4]. In most cases, the heat source is excess heat from the processes with a typical temperature level of 30 °C to 80 °C, while some are also used to provide cooling simultaneously.

Examples of existing and potential industries using industrial HPs include the food, paper, chemical, and refinery industries, where processes such as drying, pasteurization, sterilization, evaporation, and distillation can be made more energy-efficient [2].

An estimate of the European industrial HP market potential showed that the cumulative heating capacity of industrial HPs in EU28 is about 23 GW, consisting of 4’174 heat pump units that could cover 178 TWh/a of process heat demand up to 200 °C [6]. Standard HPs could meet 50% of the cumulative heating capacity of the total market with heating capacities up to 10 MW; for above 10 MW, tailormade HP solutions are required.

In general, the ongoing energy transformation and the growth of renewable energies are changing the structure and value creation of the energy industry, enabling new business models that can be classified according to customer proximity [7]. In particular, there is a need for new business models for industrial heat pump market players (e.g., heat pump manufacturers, energy service companies ESCOs [8]) to strengthen market acceptance and faster market uptake.

This study aims to identify innovative business models to drive the market introduction of industrial heat pumps. Because there are limited sources of business models for industrial heat pumps so far, the current state of business models for large-scale heat pumps for district heating networks and domestic use is first analyzed to identify gaps in the scientific literature. Then, business models from empirical interviews from the perspective of manufacturers of high-temperature heat pumps are evaluated based on the value chain. Next, a short list of business models is summarized to serve as a basis for decision-making when entering the industrial heat pump market. Finally, the study should help motivate existing companies in the value chain and start-ups to develop new business models for commercializing industrial heat pumps.

2. Business model development

2.1. The “magic triangle”

At its core, a business model describes the rationale of how an organization creates, delivers, and captures value [9]. Value creation describes what benefits are created by the company, and value capture explains how the company can generate revenue from the offered benefits. To assist companies in designing business models, researchers and practitioners have developed tools and procedures to facilitate development. A simple way to describe business models is the "magic triangle," which consists of four essential dimensions – WHO, WHAT, HOW, and VALUE (see Figure 2).

The "magic triangle" was developed at the University of St. Gallen (HSG) by Prof. Gassmann and team [10]–[12]. Briefly, the triangle aims to clarify the logic behind a business model by answering 4 questions (i.e., dimensions) about a business model:

1. WHO is your target customer? (Customer segment)
2. WHAT do you offer to the customer? (Value proposition)
3. HOW is the value proposition created? (Value chain)
4. How is VALUE achieved? (Revenue or profit mechanism)

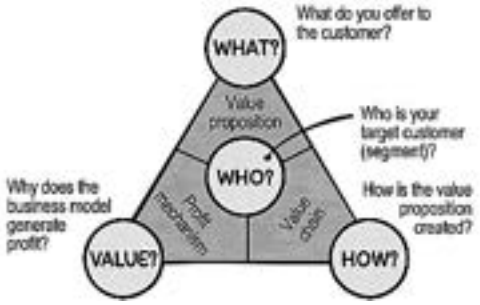

Figure. 1. Business model definition – the “magic triangle” (Adapted from [10]–[12])

The “magic triangle” is a qualitative representation to support companies in (re)designing their business model. The different dimensions can be further elaborated. By answering the 4 interrelated questions, a company's business model becomes more tangible.

- **WHO** - Each business model serves a specific group of customers. Defining the target customer is the first dimension in designing a new business model. Therefore, it should answer the question, "Who is the target customer?"
- **WHAT** - The second dimension describes what is offered to the target customer or the customer’s value. This term is commonly referred to as the value proposition. It can be defined as a holistic view of a company's bundle of products and services that are of value to the customer.
- **HOW** - The third dimension describes how to build and disseminate the value proposition. To do this, a company masters multiple processes and activities, along with the resources and capabilities involved and the value chain behind creating that value.
- **VALUE** - The fourth dimension explains why the business model is financially sustainable and thus refers to the revenue model. Essentially, it combines aspects such as the cost structure and the profit mechanism applied and refers to the elementary question of any business, namely, how to make money from the business.

For a given technology, e.g., an industrial heat pump, the question is how to use it profitably. Depending on the business model, different actors can play the central role. It is, therefore, worth considering from whose perspective the business model is viewed. This study focuses on industrial heat pump manufacturers.

2.2. The "business model canvas" framework

This study also uses the "business model canvas" framework to describe innovative business models [9], [13], [14]. Business model canvas provides a common language for representing, evaluating, and changing key aspects of complex business models.

As shown in Table 1, the business model canvas contains nine elements arranged in a structured format. The nine interdependent building blocks are (1) customer segments, (2) value proposition, (3) customer relationships, (4) customer channel, (5) revenue streams, (6) key activities, (7) key resources, (8) key partners, and (9) cost structure. Applying the business canvas methodology involves answering a series of key questions in a particular sequence (see numbering (1) to (9) in Table 1). In this study, a business model canvas is developed from the perspective of industrial heat pump manufacturers.

Table 1. The Business Model Canvas framework, the mapping phases in development (numbering from 1 to 9), and the key questions (Adapted from [9], [13], [14])

(8) Key partners	**(7) Key resources**	**(2) Value proposition**	**(1) Customer segments**
Who can help you? • Who are our key partners? • Who are our key suppliers? • Which key resources are we acquiring from partners? • Which key activities do partners perform?	What do you need? • What key resources do these business activities require?	What do you do? • What value do we deliver to the customer? • Which customer's problems are we helping to solve? • Which customer needs are we satisfying?	Whom do you help? • For whom are we creating value? • Who are our most important customers
(9) Cost structure	**(6) Key activities**	**(4) Customer channel**	**(3) Customer relationships**
What will it cost? • What are the most important costs inherent in our business model? • Which key resources are the most expensive? • Which key activities are the most expensive?	How do you do it? • What key activities do our value propositions, distribution channels, customer relationships, and revenue streams require?	How do you reach them? • Through which channels do our customer segments want to be reached?	How do you interact? • What type of relationship does each of our customer segments expect us to establish and maintain with them?
		(5) Revenue streams	
		What will it generate? • For what value are our customers willing to pay?	

3. Business models of heat pumps for district heating and domestic use

Before focusing on industrial heat pumps, this section briefly overviews published work on business models with heat pumps for district heating and domestic use. Table 2 summarizes the studies.

Various studies exist on the utilization of heat pumps for district heating networks in different European countries (e.g., Denmark [15], Austria [16], and Sweden [14]). A quick starting point for business model theory and contract theory concerning district heating can be found in the ReUseHeat report [17]. Their conclusions on urban waste heat recovery investments with a payoff of 15 years and more could apply to their respective regions. However, general conclusions should be made with caution.

Østergaard et al. (2019) [15] conducted a business analysis of heat pumps for small district heating systems combined with heat storage on Samsø island in Denmark. Simulations showed that heat pumps and heat storage are useful for fluctuating renewable energy in part-load operation but are not economically competitive with straw-fired boilers. However, this conclusion may not be entirely applicable outside of Denmark.

Terreros et al. (2020) [16] explored different potentials of heat pumps in rural district heating networks in Austria. Through simulations, it was found that the optimal bidding strategy for the heat pump is to buy 50% of the electricity on the day-ahead spot market and to offer 50% of the capacity for negative balancing energy for the automatic frequency restoration reserve, as this allows a significant reduction of the heat generation costs. The optimal operating strategy reduced heat generation costs by up to 17.7% for use cases with flue gas as a heat source for the heat pump and up to 27.5% for cases with sewage water. In addition, the results showed that variations in biomass price and call probabilities could significantly affect heat pump profitability.

In Sweden, Lygnerud et al. (2021) [14] applied the business model canvas concept to map the required change in the district heating networks to generate cost and emission savings by integrating small-scale heat pumps in buildings. The authors showed that by combining efficient small heat pumps in district heating networks with optimal control, maximum cost savings of 33% and CO_2 emission savings of 75% could be achieved. However, challenges exist due to the tendency of Swedish district heating companies to view heat pumps as competition.

Vivian et al. (2018) [18] studied the economic performance of a low-temperature district heating system below 45 °C. They used booster heat pumps in customers' substations to provide the temperature required for space heating and domestic hot water. Two types of business models were considered a district heating utility responsible only for heat recovery and distribution and a utility that also invests in heat pumps and electricity. At the same time, the user pays for the delivered heat. The economic analysis showed that the system with booster heat pumps is already competitive with single gas boilers for multi-family buildings, provided a local low-temperature heat source with minor marginal costs can be used.

Heat pump flexibility can play a major role in enabling a transition towards a renewable heat and electricity sector. In this context, Fischer et al. (2017) [19] analyzed different business models that could arise from using the flexibility of domestic heat pumps in a smart grid context. Results showed that due to high-end customer prices, grid fees and complicated market requirements, less integrated business models were more attractive than the direct use of heat pump flexibility on the reserve or spot market or the provision of balancing energy. However, additional revenues could be generated by using heat pump flexibility, such as providing a secondary reserve or balancing energy.

Lyon et al. (2021) [20] considered the challenge of retrofitting existing residential buildings in Europe, where heat pumps struggle to compete against traditional heating systems. The alternative business model “heat as service” (HaaS) proposition was investigated, which involves a residential building occupier signing a contract for heating provision and heating equipment for a fixed monthly fee rather than purchasing the heat pump equipment. It was concluded that the HaaS business model could be a critical step for overcoming the end-user barriers for heat pumps, i.e., high upfront costs, risk of high running costs and lack of trust in the technology. The potential of HaaS has also been explored as a route to decarbonize the domestic heat supply in Scotland [21] to increase the uptake of low-carbon heat, improve the energy efficiency of people’s homes, and reduce fuel poverty.

Table 2. Studies on business models with heat pumps for district heating applications and domestic use

Paper	Description	Business model
Østergaard et al. (2019) [15]	• Heat pumps and heat storage combination for small district heating system in Denmark covering fluctuating renewables	• Simulations of optimal business economic design • No business model was discussed
Terreros et al. (2020) [16]	• Heat pumps in rural district heating networks in Austria • Flue gas and sewage water as heat sources	• Electricity market options • Costs savings by optimal bidding strategy (day-ahead & balancing market)
Lygnerud et al. (2021) [14]	• Combination of small-scale heat pumps in district heating networks in Sweden	• Efficiency gains impacting cost and CO_2 emissions (business model canvas method used for business model mapping)
Vivian et al. (2018) [18]	• Booster heat pumps with low-temperature district heating network (15 to 45 °C) • System is economically competitive to gas boilers • Utility investing in heat pumps and electricity	• District heating utility responsible only for heat recovery and distribution • Customer pays for heat delivered
Fischer et al. (2017) [19]	• Flexibility of residential heat pumps in a smart grid context	• Provision of the secondary reserve or balancing energy (business model canvas established for various business cases)
Lyon et al. (2021)[20]	• Retrofit existing residential buildings with heat pumps • Increasing trust in heat pump technology • Reduction of risk of high running costs	• Heat as a Service • Contract for the heating provision • No high upfront costs
Fleck et al. (2021) [21]	• Decarbonization of domestic heat in Scotland • Increase the uptake of low-carbon heat, improve the energy efficiency of homes, and reduce fuel poverty	• Heat as a Service
Britton et al. (2021) [22]	• Heat pumps for cooling or keeping temperatures in the UK domestic market	• Heat as a Service • Consumer pays for produced heat, annual service fee, initial installation

HaaS business models have also been reviewed in the UK domestic market by Britton et al. (2021) [22]. Recommendations for policy and research were made based on insights from facilitated group discussions with key stakeholders and experiences from HaaS trials in the UK. Based on the findings, policy and research recommendations were proposed to better understand the role of HaaS business models in decarbonization.

Skovshoved & Sandqvist (2017) [23] discussed HaaS from a more academic perspective and aimed to identify value propositions for heat pumps in Sweden. The same study also described a business model in Denmark by Best Green, where end users pay an annual service fee and initial installation costs for the heat generated by the heat pump. However, the heat pump is purchased and owned by the service provider.

Further studies published on business models in the heat and energy sector with heat pumps include:

- solar heat pump water heaters [24],
- solar thermal air conditioners [25],
- district energy providers [13],
- perspective of the electrical grid operator [26],
- urban waste heat recovery [17],
- combining district heating and heat pumps in buildings [27],
- heat pump retrofits in metro Vancouver [28],
- small-scale heat energy production in Finland [29], and
- heat purchase agreements [30].

4. Business models specific to industrial heat pumps

To the best of the authors' knowledge, no free literature is available on business models specifically for industrial heat pumps. Therefore, interviews with manufacturers of industrial high-temperature heat pumps (i.e., SPH, Enertime, BSNOVA, and QPinch) with reciprocating and turbo compressors, absorption and thermochemical technology were conducted as part of the EU Horizon project PUSH2HEAT [31].

The following section summarizes the empirical findings from initial interviews with the heat pump manufacturers and ongoing studies. The interviews were conducted in a structured manner using a questionnaire. The aim was to gain a deeper understanding of the topic, identify innovative business models, and draw parallels between the general answers of the manufacturers. The "magic triangle" and the "business model canvas" framework were used to describe and visualize the business models.

4.1. Business models and value chain of industrial heat pumps

Figure 2 illustrates the main activities in the value chain of the industrial heat pump market ranging from research and development (R&D), manufacturing, consulting, design, distribution, installation, and commissioning to after-sales (maintenance, service), energy data management (EDM) and trading of heat (e.g., with heat storage and back-up systems) or CO_2 certificates on the energy markets. Innovative approaches to business models can be mapped along the value chain. As customer integration increases, so does the degree of collaboration with the customer and involvement in the value chain.

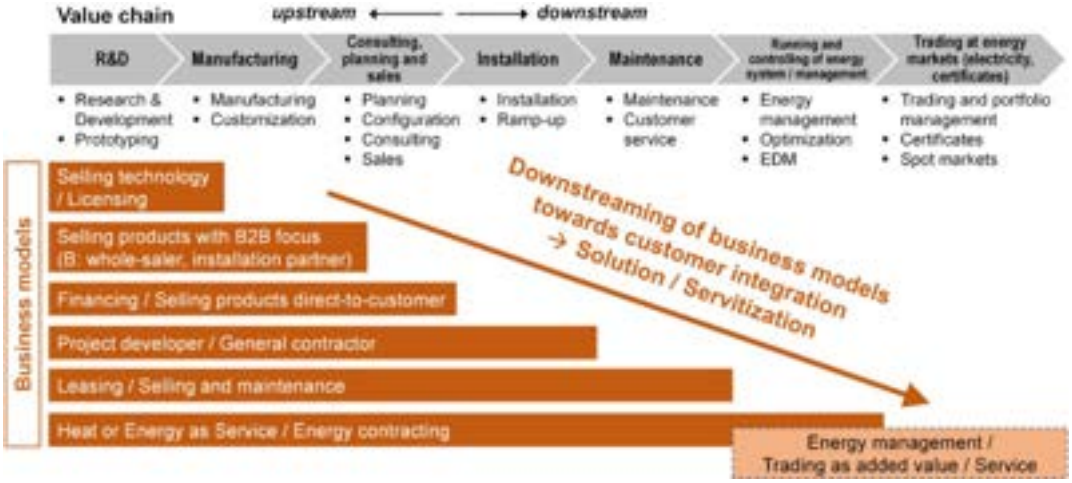

Figure. 2. Business models and value chain of industrial heat pumps (Source: PUSH2HEAT project)

Figure 3 shows three basic types of companies within the value chain, which differentiate by a targeted selection of core activities (indicated by arrows in different colors). A distinction is made between integrator, specialist, and solution provider. The integrator offers everything from a single source and masters the entire value chain in depth. The specialist supplies specific parts of the value chain and benefits from economies of scale, achieving quality advantages and flexibility. Finally, the solution provider (or orchestrator) can select the best from all specialists and thus offer the customer the most suitable solution.

Figure. 3. Basic types of companies within the value chain (integrator, specialist, and solution provider)

Table 3. List of likely business models from the perspective of a manufacturer of industrial heat pumps

Business model	Value proposition (WHAT)	Revenues (VALUE)	Key activities (HOW)
Licensing of heat pump technology	• Subcontractor using HP technology for own production • Users: Local partner	• Licensing fees from subcontractor (recurring), e.g., depending on units	• Licensing agreement • Trustworthy subcontractor
Selling heat pump technology (IP)	• Buyer receives state-of-the-art technology without any R&D risks	• One-time sales	• Technology readiness • IP purchase contract
Selling heat pump products with a B2B focus (B: wholesaler, project developer, installation/sales partners)	• Local partner (distributor) as a one-stop shop for user customer	• Income and profits from sales	• Trustworthy sales partner/dealer network
Selling heat pump products Direct2Customer	• Customization One-Stop shop: installed pump (Financing as added service)	• Earnings from sales and installation • Customer loyalty/customer data • Provisions from a financing partner	• Sales • Installation resources
Project developer / General contractor	• "One-stop-shop" solution from idea to operating system	• Fixed income for the successful project (in-time, in-budget)	• Coordination of entities/partners • Sales resources • Resources for installation and planning
Leasing / Selling and maintenance	• Low capital spending • All services included • Service level agreed	• Fixed earnings over the project duration • Provisions from financing/leasing partner or earnings in case of self-financing	• Service level and leasing agreements • Resources for installation, planning, maintenance
Energy contracting	• Guaranteed efficiency performance (energy, costs, CO_2, white certificates, etc.) • Monetization of efficiency increase (achieve financial benefit)	• Fixed, recurring earnings • Further revenues arising from efficiency surpluses	• Risk management and assessment of projects and contracts
Heat as a Service (HaaS)	• Heat for a fixed price over the contract duration	• Fixed, recurring earnings	• Financial resources
Energy as a Service (EaaS) (Running the whole energy infrastructure of a customer)	• Energy for a fixed price over the contract duration	• Fixed, recurring earnings	• Construction and provider of a heat pump in own response
Trading and profiting on arbitrage: • Energy markets (e.g., spot markets EPEX/EEX), • Selling Carbon certificates (CO_2-ETS, CO_2-voluntary like VCS, Gold • Electricity (renewables) - Efficiency (White like ESC, EEC)	• Earnings from certificates	• Service fees, provisions from sales of certificates • Energy management fees	• Trading capabilities • Energy management capabilities
Energy consulting and management	• Energy management competence	• Consulting fees • Energy management service fees	• Energy management and consulting capabilities

Table 3 summarizes the list of likely business models from the perspective of an industrial heat pump manufacturer and describes the business models based on value propositions, revenue streams and key activities (according to the “magic triangle”). The list of business models is intended to serve as a common basis for further discussion and is, therefore, neither very detailed nor conclusive or complete. The target customers are industrial companies (i.e., end users of the pulp, paper, food, and oil industry) that need to decarbonize their heat supply in the wake of climate targets. A brief description of each likely business model for industrial heat pump manufacturers follows.

4.2. Licensing of heat pump technology

When licensing a heat pump technology or parts of the technology, a subcontractor uses the technology to produce heat pumps. The heat pump manufacturer receives recurring license fees from the subcontractor, e.g., depending on the number of sold units. The business model requires a license agreement and a trustworthy subcontractor. For example, licensing can be interesting for a European heat pump manufacturer to reach certain markets (e.g., USA, China).

4.3. Selling heat pump technology (IP)

When selling a heat pump technology's intellectual property (IP), the buyer receives the most advanced technology without R&D risks. For the technology provider, it is a one-time sale based on an IP purchase agreement and the provision of the technology according to a defined technology readiness level (TRL).

4.4. Selling heat pump products with Business2Business (B2B) focus

When selling heat pump products over B2B (B: wholesaler, project developer, installation partners), the local partner is a one-stop shop for customers. Revenues are generated from the sale of heat pump products. Important is a trustworthy distribution partner and distributor network.

4.5. Selling heat pump products Direct2Customer

The heat pump products are sold directly to end customers by salesforce, and technicians or subcontractors carry out the installation. This is today's traditional and most common business model for industrial heat pump manufacturers. It leaves the customer with most of the risks (i.e., financial and technical). For a "new" technology like HTHP, this generates extra risk for the customer. In comparison, this risk is quite low for refrigeration systems due to long market experience. In most cases, key aspects are maintenance and service by third-party companies. Certain heat pump manufacturers are developing modular heat pumps to offer customized solutions. Here, the aim is to offer a package (i.e., package supplier). Some compressor manufacturers sell their products directly to heat pump manufacturers as subcontractors.

4.6. Project developer / General contractor

A project developer/general contractor acts as a one-stop shop and offers the heat pump solution from concept to commissioning. This provides a fixed income for the successful project (in-time, in-budget). The business model requires coordination of units/partners, sales resources, and resources for installation and planning.

4.7. Leasing / Selling and maintenance

Leasing (including maintenance) promises low investment costs, and all services are included depending on the agreed service level. Service level and leasing agreements and installation, planning, and maintenance resources are required. This generates fixed income over the project duration. Heat pump manufacturers might find this business model interesting but require a financial partner with know-how.

4.8. Energy contracting

Energy contracting is a comprehensive energy service normally provided by an energy service company (ESCO) [22]. The flexible operation of utility processes holds great potential and creates opportunities for third-party involvement. Examples include outsourcing activities by industry towards ESCOs, especially for technologies used in utility processes. Energy contracting guarantees performance in terms of efficiency (e.g., energy, cost, CO_2, white certificates, etc.). Efficiency improvements allow for fixed, recurring revenues. Additional revenues result from efficiency surpluses. Risk management and evaluation of projects and contracts are required.

4.9. Trading and arbitrage profits

As a complementary revenue stream, an industrial company may install a heat pump for its processes and use unused capacity for trading/arbitrage. Participation in trading on the energy markets (e.g., spot markets on the European Power Exchange (EPEX), European Energy Exchange (EEX)) and sales of carbon certificates in the emissions trading scheme (CO2-ETS, CO_2-voluntary such as Verified Carbon Standard (VCS, Gold) enable revenue from certificates using heat flexibility [32]. Revenue arises from service fees,

provisions from certificate sales, and energy management fees. Key activities include trading capabilities and energy management capabilities.

4.10. Heat as a Service (HaaS)

An increasingly popular business model for industrial heat pumps is heat as a service (HaaS) [20]–[23], [33]. Instead of a company investing directly in a new heat pump, HaaS allows a third party (e.g., service provider, ESCO) to bear the capital costs and guarantee the availability and performance of the heat pump system during the contract period. The ESCO designs, builds, owns, operates, maintains, and finances the heat pump system [33]. In addition, the ESCO can achieve better economies of scale and potentially receive volume discounts by buying several heat pumps. Delta-EE Ltd. estimated that the number of customers currently using a HaaS-type business model is in the low 1,000s across Europe in the domestic sector [20].

Among others, the Danish Energy Agency introduced a subsidy program to encourage direct heat pump uptake in oil-heated homes in areas where district heating is not available [20]. Under this business model, the company that buys HaaS essentially pays an upfront cost for the installation of the heat pump, a fixed price per kWh of heat delivered and a fixed annual fee to the service provider to pay for the cost of the heat pump, installation, and any maintenance costs. Depending on their business model, energy service providers are free to adjust each of these three factors. The minimum contract period is typically 10 years [20]. In another example, Fleck et al. (2021) [21] described the potential of HaaS as a way to decarbonize residential heat supply in Scotland.

4.11. Energy as a Service (EaaS)

Beyond HaaS, there are also further developments possible, such as Comfort as a Service, Cooling as a Service [34], Temperature as a Service, or more general Energy as a Service (EaaS) [35]. The EaaS market is flourishing and is expected to be worth over 140 billion by 2027 [36].

Figure 4 shows an example of an EaaS concept from ANEO Industry AS (Norway) [37] for high-temperature heat pumps to generate steam between 100 °C and 150 °C (1 to 5 bar(a)). With its sustainable EaaS platform, ANEO reduces fossil emissions and energy consumption in the process industry and increases energy efficiency. ANEO's services include engineering, installation, operation, and maintenance of industrial heat pumps from the initial case study to the system’s life cycle.

Figure. 4. Example of an Energy as a Service (EaaS) concept from ANEO Industry AS (Norway) [37] for high-temperature steam-producing heat pumps. Currently, ANEO’s EaaS is more a HaaS, but the intention is to supply electricity within the same framework.

Like HaaS, the basic idea of EaaS is to take financial and technical risks (i.e., investment, operation, and maintenance) of the heat pump system out of the scope and liability of the end customer, meaning that the investment risk, financial risk, and operational risk are placed in the scope and liability of a service provider. The EaaS provider purchases the heat pump system under a contractual agreement with a technology partner and certain performance guarantees, such as operability, availability, capacity, etc., with penalties for non-performance.

Energy is guaranteed at a fixed price during the contract period (e.g., service agreement). This results in fixed, recurring revenue while profit for the EaaS provider is generated over the life cycle of the heat pump system (typically 10 years) and covers management, administration, risk mitigation, etc., in addition to profit margin. Depending on the project's location, investors in EaaS agreements can benefit from predictable cash flow, CO2 tax credits, and renewable energy certificate revenue. The EaaS business model allows the customer to focus its capital and resources on its core business.

5. Business model building blocks of a heat pump manufacturer

Finally, Table 4 attempts to compile various business model building blocks from an industrial heat pump manufacturer's perspective based on the interview responses. This overview represents a snapshot and needs to be refined in further studies to identify the relevant building blocks for each business case.

Table 4. Business model building blocks from the perspective of an industrial heat pump manufacturer

(8) Key partners	(7) Key resources	(2) Value proposition	(1) Customer segments
• Heat pump producer • Suppliers of key components (e.g., compressor, heat exchanger, valves, control system, etc.) • Distribution partners like OEM integrators to expand the network • Demo customers for on-site visits • Regional, national, and European public institutions for the promotion • Private and public investment funds and banks for financing projects • Technical consultants and process integration experts • Universities and research partners	• Know-how about heat pump design and compressor integration • Intellectual property • Supply chain management for key components • Proof-of-concept and demonstration projects • Sales with a large industry network • Dedicated sales force • Technical resources for after-sales service and maintenance	• Sustainable process heat supply • Reductions in energy consumption, energy costs, and CO_2 emissions (i.e., carbon-free on-site heat source) as a contribution to carbon neutral/net zero strategies • Saving fossil fuels • Integration into existing industrial processes • Training the customer regarding heat pump technology (how it works and what benefits it can bring)	• Various energy-intensive industries (e.g., food & beverage, paper, chemical, oil) • Sugar mills, distilleries, petrochemical plants, paper mills, gypsum, ceramics, etc. • Steam and drying processes • Energy service suppliers (ESCOs) and providers of district heating networks; infrastructure providers for large industry parks • B2B resellers, wholesalers, project developers, and utilities
(9) Cost structure	**(6) Key activities**	**(4) Customer channel**	**(3) Customer relationships**
• Investment costs for equipment and technical works (i.e., construction, mechanics, electrification, electricity grid, etc.) • Operating costs (i.e., electricity consumption during lifetime) • Maintenance costs (i.e., annual inspections, spare parts) • Subsidy programs	• Development of high-quality heat pump technology (TRL9) • Demo units • Standardization and modularization • Sales and marketing activities • Hiring and training new competent employees	• Direct sales • Sales through distribution partners • Reference customers (i.e., pilot projects)	• Direct sales of equipment to end users or integrators • Direct sales of turnkey projects (100% one-stop-shop) • Sale of heat pump products through partners • Special leveraged tenders (e.g., waste heat recovery, virtual power plants)
		(5) Revenue streams	
		• Direct sales of heat pump equipment (hardware) • Installation and commissioning • Maintenance and service contracts (EaaS) • Subsidies and incentives • Licensing/IP fees	

5.1. Customer segments

As heat pump technology is a cross-sectional technology, the end users of industrial heat pumps can be found in various process industries. Most requests come from the food and beverage industry, followed by the paper and chemical industries. End users own energy-intensive industrial plants such as sugar mills, distilleries, petrochemical plants, paper mills, gypsum, ceramics, etc. The focus is on processing heat supply through steam and drying processes. Process integration is often performed confidentially within an industrial company. Developing specific industry solutions to take advantage of the multiplication potential is possible. Customers can also be B2B resellers, wholesalers, project developers, utilities, and energy service companies (ESCOs) focused on plant operations (facility management).

5.2. Value proposition

The main added value to customers by industrial heat pumps is the conversion of several industrial sectors to a sustainable process heat supply and significant reductions in energy consumption and CO_2 emissions (i.e., carbon-free on-site heat source). This enables:

- Reduction of energy consumption and energy costs (i.e., operating costs)
- Increasing the share of renewable energies
- Reduction of greenhouse gas emissions (CO_2, carbon emissions, carbon neutrality)
- Saving of fossil fuels (e.g., independence from gas imports)
- Reducing dependency on energy markets and their volatility (level of energy autarky)
- Increasing the use of energy from excess heat sources
- Profits from trading on the spot market

Training the customer about how a heat pump works and what benefits it can bring is also a value proposition. The heat pump manufacturers assist potential customers in the selection, purchase and integration process and provide customers with a lower-cost alternative (life cycle costs) compared to competing or existing heating technologies such as gas boilers or biomass. At the same time, technical innovation will stimulate the creation of numerous jobs and significantly contribute to the economy's growth.

5.3. Customer relationships

Building trust, good sales and customer support, and a good network in the industry are crucial for establishing successful customer relationships. In service concepts, a distinction is made between long-term and short-term customer relationships. In the eyes of the customers, individual and customized solutions are important.

5.4. Customer channels

The customer relationship can take place through various channels:

- Direct sales of heat pumps to end users
- Direct sales of heat pumps to integrators
- Direct sales of turnkey projects (100% one-stop-store) to end users
- Sales of heat pump products through partners
- Special tenders with leverage effect (e.g., waste heat recovery)

As a confidence-building measure, demo sites of industrial heat pumps for on-site visits are important.

5.5. Revenue streams

The current revenue streams come mainly from direct heat pump equipment (hardware) sales to customers or integrators and a little from installation and commissioning. This means turnkey projects will be sold directly to end customers (100% one-stop-shop). In the future, revenue will also be generated from the sale of maintenance and service contracts. Energy as a Service is a very interesting business model (e.g., lease-like contracts with fixed lease rates and residual purchase value at the end of the contract). Important sources of revenue are also local, national, and European subsidies and incentives.

5.6. Key activities

Because industrial high-temperature heat pumps are a relatively new technology, the development (R&D) of a stable, high-quality product is a top priority. Some heat pump manufacturers need more operational experience (i.e., operating hours) to increase the technology readiness level from TRL7 to TRL9. A goal is also to build standardization and modularization into the product line. In sales, high growth and demand for heat pump products are expected in the coming years. At the moment, sales activities are reactive rather than active. Nevertheless, numerous discussions are being held with customers in various countries, particularly Europe, to sell the technology throughout Europe. Depending on the order situation, project planning is a key activity for which additional employees must be hired. Project execution also expects a strong increase in personnel for the delivery, installation, and commissioning of the heat pump products. The biggest challenge will probably be finding enough competent employees and training them quickly and properly.

5.7. Key resources

The most important resources are internal know-how about heat pump design and the integration of compressors into a heat pump circuit, which may be based on intellectual property. Supply chain management for key components is important for delivery capability (i.e., enabling short delivery times). Proof-of-concept and demonstration projects are important to customers. Internally, marketing and sales with a large industry network are advantageous. A balance is needed between new human resources for marketing (e.g., dedicated sales force) and technical resources for after-sales service and maintenance.

5.8. Key partners

Important partners for a heat pump manufacturer are subcontractors and equipment suppliers for the core components such as compressors, heat exchangers, valves, control systems, etc. For commercialization, some heat pump manufacturers act as original equipment manufacturers (OEM). They actively work with distribution partners in selected countries to expand their sales network by integrating heat pump products into their portfolio. It is also crucial to have companies as demo customers that operate the first units to gain operational experience (i.e., running hours). For example, demo units are returned to the heat pump manufacturer after 6 to 12 months to check for wear.

Furthermore, there is the possibility of inviting end customers for an on-site visit to see the demonstration units in operation to build trust in the market (i.e., seeing is believing). Finally, important partners are also:

- Regional, national, and European public institutions for promotion,
- Private and public investment funds and banks for financing projects,
- Technical consultants and experts for knowledge transfer, and
- Universities and research partners for further development of the heat pump technology (e.g., cooperations with other technology providers).

5.9. Cost structure

The costs arising from the sale of industrial heat pumps and services are mainly investment costs for equipment and technical work (i.e., construction, mechanics, electrification, electricity grid, etc.), but also operating costs (i.e., electricity consumption during lifetime) and maintenance costs (i.e., annual inspections, spare parts). In some cases, subsidy programs are used to pre-finance project development.

6. Conclusions

Industrial heat pumps are on the rise for the electrification of process heat in industry and are an important cross-cutting technology for the transition to renewable energies. Accordingly, the market will experience increased competition in the coming years, pushing industrial heat pump manufacturers to develop new business models. This review has shown that business models for industrial heat pumps are overall insufficiently described and that a scientific research gap exists. Initial findings could be summarized based on empirical responses from interviews with manufacturers and literature research analyses.

The most widespread business model appears to be the Direct2Customer, which primarily involves project development and directly selling heat pumps to end customers. Revenues from installation and commissioning and future services from maintenance and servicing supplement this. However, each heat pump technology (e.g., vapor compression, MVR, absorption, thermochemical heat pump) requires its own business model evaluation using the proposed model building blocks. The highly customer-integrated business models such as Energy-as-a-Service (EaaS) and especially Heat-as-a-Service (HaaS) are opening new market opportunities for industrial heat pumps. However, none of the heat pump manufacturers interviewed has yet implemented HaaS in connection with industrial heat pumps. So far, only individual energy service companies (ESCO) now offer EaaS business models for industrial heat pumps.

As an outlook, an attempt could be made to quantify the effectiveness and impact of the different business models, e.g., on marginal prices, consumer behavior or societal acceptance. Further interviews with industry partners in the industrial heat pump value chain need to be conducted for a more detailed investigation of customer needs and business models. A PESTEL analysis with political, economic, social, technological, environmental, and legal influencing factors will be realized within the PUSH2HEAT project.

Further research could examine the structure of business relationships between the organizations involved in manufacturing, distributing, and using industrial heat pumps. Such an ecosystem-level analysis can identify ways to better align the respective business models to accelerate the adoption of heat pumps by industrial customers and ensure high-quality installations.

Acknowledgments

This study is part of the EU-funded Horizon Europe project PUSH2HEAT (Pushing forward the market potential and business models of waste heat valorization by full-scale demonstration of next-gen heat upgrade technologies in various industrial contexts, Grant Agreement No. 101069689) (www.push2heat.eu). Abstract:

Power trains based on fuel cells hybridized with any secondary power sources provide similar effectiveness levels than current powertrains based on internal combustion engines but achieve better efficiency values and have the potential to be free of harmful emissions. However, the development of these powertrains is still in its childhood and research efforts must be reinforced, especially in marine and aeronautical applications. One part of the project GreenH2CM will provide a valuate tool that will support the research in this area. In the frame of the GreenH2CM Activity Line "Uses of hydrogen in heavy transport, aviation and maritime sectors", the research group PiCoHiMA from the Universidad Politécnica de Madrid (Spain) is developing a Laboratory for testing fuel cell integrations for marine and aeronautical applications. The resulting installation will allow to test fuel cell stacks with powers up to 300 kW and the simulation of hybridized secondary power sources as batteries or capacitors. The laboratory will not only allow to monitor and control the critical parameters of the stack under study to simulate adequate environmental conditions, besides, a 6-freedom degrees hexapod will allow to simulate the movements of the platform to study its impact.

1. Introduction

Although green hydrogen is a versatile energy carrier that will play a key role in meeting the decarbonisation targets to which Spain has committed, a major R&D&I effort is still needed for it to be considered as an economically viable alternative.

The project that is presented here, "Strategic Positioning of the Community of Madrid in Green Hydrogen and Fuel Cell R&D&I GreenH2CM", is being developed by several national and regional research institutions and is funded by the Ministerio de Ciencia e Innovación de España (Spanish Ministry of Science and Innovation) MCIN/AEI/10.13039/501100011033, by "NextGeneration EU/PRTR", and by the Regional Government of Madrid, in the frame of the Complementary Plans. GreenH2CM project pursues three general objectives in the field of Hydrogen and Fuel Cells:

- To structure and coordinate the R&D&I capacities of the Madrid Region, among themselves and with other Spanish Regions with common interests, around the green hydrogen value chain and its application by means of: (i) optimisation of the connection between renewable electricity generators and electrolysers, (ii) innovative high temperature hydrogen production techniques with reversible operation capability, (iii) optimisation of fuel cell integration and (iv) safe combustion techniques of hydrogen and its mixtures for use in the industrial, residential and transport sectors. These innovative concepts will allow the necessary progress in reducing the production costs of green hydrogen so that it can reach the market.
- To collaborate in defining the Madrid Region strategic lines of work on new concepts of green hydrogen production and fuel cell applications that generate industrial and economic value and act as an instrument to position the Madrid Region at national and European level in the development of these technologies. It also aims to establish alliances and cooperation agreements on renewable energies,

green hydrogen and fuel cells and to promote technological surveillance and competitive intelligence to identify new work niches in this area.

- To educate and train researchers, through the recruitment of research personnel at different stages of their training, and to generate human capacities for the development of a national industry covering the entire value chain around green hydrogen and fuel cells.

Therefore, this R&D will complement and help support national industry in the development of innovative electrolyser concepts with higher efficiency, longer life and lower cost, as well as other hydrogen generating systems from concentrated solar energy; integration of fuel cells in transport (air, maritime, rail and road), industry and building applications and the development of new combustion devices and/or the adaptation of existing ones to move towards decarbonisation and climate neutrality.

The GreenH2CM Project addresses the development of five main lines of action (LIA), out of the 13 lines included in the Green Energy and Hydrogen programme of Complementary Plans:

- LIA1: Low temperature green hydrogen generation from renewable energy.
- LIA3: High-temperature hydrogen generation from renewable energy and waste heat utilisation.
- LIA7: Uses of hydrogen in heavy transport, aviation and maritime sectors.
- LIA8: Uses of hydrogen in the industrial combustion sector.
- LIA11: Techno-economic studies and market launch of utility models. Dissemination, education and training activities for new researchers.

2. Uses of hydrogen in heavy transport, aviation and maritime sectors (LIA7) in GreenH2CM

Since the beginning, mankind has need for mobility. Means of transport have evolved looking for higher speed, safety, and more power and efficiency. This evolution has been always supported by scientific and technical developments allowing the transition from human or animal power to steam, from steam to oil and, more recently, from oil to electrochemical energy stored in batteries and alternative fuels to look for more environmentally friendly solutions. In this sense, hydrogen and fuel cells are a promising technology for the mobility of the future that should make it possible to decarbonise those transport segments in which electrification does not provide a competitive solution compared to conventional combustion technologies. The aim of LIA7 is to investigate and develop advanced technological solutions for the integration and optimal operation of hydrogen-based systems for heavy, air and maritime transport applications.

The overall objective of Line of Action 7 (LIA7), *Uses of hydrogen in heavy transport, aviation and maritime sectors*, of the GreenH2CM project is to:

- Design, build and operate a facility for the testing of fuel cell integrated power trains in the maritime and aviation sectors.

In general terms, this line of action includes: a) Development of technology to improve the reliability of the energy and degradation models of fuel cells to optimise their subsequent sizing and operation in hydrogen-based vehicles. b) Development of advanced methodologies to optimise the sizing of hybrid traction solutions (fuel cells with batteries) and their configuration and thermal management. c) Generation of innovative solutions for the intelligent management of hydrogen-based vehicles, ships and aircraft to optimise their operation throughout their useful life.

The *expected results* are summarized as follows:

- Training to develop detailed dynamic models of the tested power generation system and its components for real-time simulation and/or digital twin applications;
- Implementation of a power distribution system that will connect the primary and secondary sources (fuel cell, battery and supercapacitor) to the load, which will reproduce the power operating profile under test;
- Development and qualification of the heat exchangers necessary to perform proper thermal management of a fuel cell-based power generation system on board a commercial aircraft;
- Prototype demonstrator of a hydrogen fuel cell hybrid vehicle, operational and functional in the field of heavy road, port and/or airport transport;
- Fuel cell testing capability with impurity measurements in the gas streams under various operating conditions.

The main work involved in this LIA7 of GreenH2CM is the development of a laboratory for the testing of powertrains in the maritime and aviation sectors. It is described in Section 3.

3. Laboratory for testing fuel cell integrations for marine and aeronautical applications

In order to be able to carry out research, training and provide services to private companies, it is necessary to develop the design, construction and commissioning of a facility to test fuel cell integration in power trains for marine and aeronautical applications. Figure 1 shows the preliminary design of the facility.

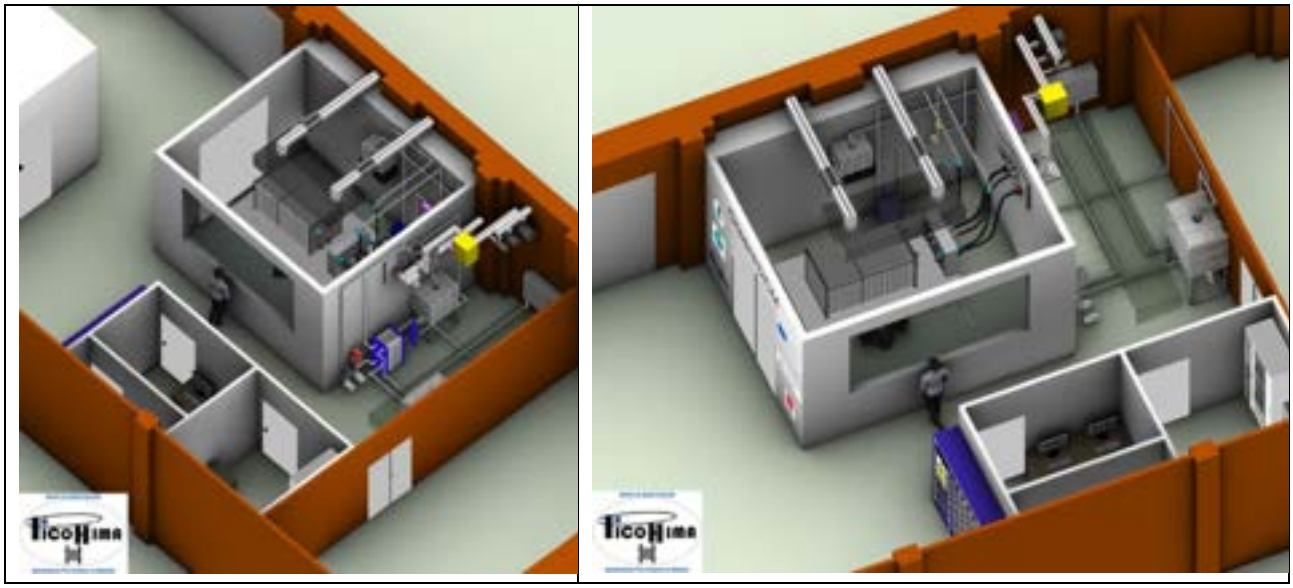

Figure 1. Two views of the preliminary design of the Laboratory for testing fuel cell integrations for marine and aeronautical applications in the frame of the GreenH2CM project.

The tasks planned to achieve this facility are as follows:

- Detailed design of the test facility.
- Selection of components and services for the test facility.
- Procurement of components and services for the test facility.
- Construction of the test facility.
- Configuration, testing and commissioning of test facility systems.
- Operational tests with real operating profiles of a fuel cell and battery integration, with and without movements.

In addition to this, it is planned to develop: a Doctoral thesis on the subject, dissemination activities and establish company-university agreements.

The resulting installation will allow to test fuel cell stacks with powers up to 300 kW and the simulation of hybridized secondary power sources as batteries or capacitors. The laboratory will not only allow to monitor and control the critical parameters of the stack under study to simulate adequate environmental conditions, but a 6-freedom degrees hexapod will allow to simulate the movements of the platform to study its impact.

This facility will be located at the Escuela Técnica Superior de Ingenieros Navales (Technical School of Naval Architects and Marine Engineers) of the Universidad Politécnica de Madrid (Spain) and will be under the management of the PiCoHiMA Research Group [1]. This Laboratory is an important asset that will offer valuable services to both the academy and the private sector. This facility can be integrated into large projects, allowing fuel cell solutions to be tested not only at a laboratory scale but also at a near-market scale, ensuring the quality of the final product at a critical stage of its development where such tools are scarce. This is an advantage for companies and research institutions in ensuring the reliability of their developments.

4. Conclusions

GreenH2CM is an important project that poses the basis for the development of critical knowledge and facilities around hydrogen technologies in the Madrid Region also structuring and coordinating the R&D&I capabilities in this Region.

Among the five Lines of Action covered by this project, the Line of Action 7 “Uses of hydrogen in heavy transport, aviation and maritime sectors” stands out.

The purpose of this Action Line to research and develop advanced technological solutions for the integration of hydrogen-based systems for heavy transport, aviation and maritime applications is reflected in its main objective, i.e. the design, construction and operation of a facility for the testing of fuel cell integrated power trains in the maritime and aeronautical sectors.

The resulting installation will allow to test fuel cell stacks with powers up to 300 kW and the simulation of hybridized secondary power sources such as batteries or capacitors, including the impact on the fuel cell stack of the movements induced by a 6-freedom degrees hexapod that simulates the movements of the platform where the stack is embarked.

This laboratory is an important asset that will provide valuable services to both academia and the private sector, facilitating the testing of fuel cell systems not only at laboratory scale but also at near market scale, ensuring the quality of the final product at a critical stage.

Acknowledgments

This work has been carried out thanks to the Project GreenH2CM funded by MCIN/AEI/10.13039/501100011033, by “NextGenerationEU/PRTR” and the Regional Government of Madrid and to the Grant PID2021-124263OB-I00 funded by MCIN/AEI/10.13039/501100011033 and by “ERDF a way of making Europe”.

Abstract:

Direct methanol fuel cells, DMFCs, have a great interest due to their applications in the development of devices for portable energy applications due to their ability to produce electricity using methanol as fuel. These systems are environmentally friendly. Nevertheless, the methanol crossover from the anode to the cathode through the electrolytic membrane, the poisoning of the catalyst and the cost of these systems are some of the problems. One of the responsible of the high cost of these systems is the use of platinum, Pt, for the development of the electrodes.

The objective of this work is to develop catalysts Pt-free. Materials based on FeCo solid solutions are synthesized by the combustion method and characterized for their further application as anode catalysts in DMFC. In addition, a post-treatment in reactive environments has been carried out the aim of improving the metal solution. The prepared materials have been morphological, structural and electrochemically characterized to test their activity towards methanol oxidation. Further, the catalytic layer composition has been designed to prepare electrodes by spray, in such a way that the slurry can be homogeneously sprayable on the surface of the carbon paper gas diffusion layer. The catalyst and electrodes have been studied to know if they are good candidates as anode of DMFCs, and to modify the synthesis and/or the different processes to improve their activity.

DMFC; electrocatalyst; Pt free; catalytic layer; combustion synthesis.

1. Introduction

The development of the society has increased the consumption of energy. The high cost of energy, the lack of resources and the pollution among others, make urgently to seek and develop new and renewable energies [1,2]. Fuel cells, which convert chemical energy into electrical energy via electrochemical reactions on the electrode surface are a promising alternative and clean energy resource [3-5]**.**

Direct methanol fuel cells, DMFCs, have a great interest due to their high energy density, high conversion efficiency, low operating temperatures, low emissions of toxic substances [4] and also to their applications in the development of devices for portable energy applications [6-8]. Moreover, these systems are environmentally friendly, have easy operation and simple construction [4,9]. However, the crossover of methanol from the anode to the cathode through the electrolytic membrane, sluggish oxidation kinetics and the durability and deteriorating catalyst performance are some factors which have restricted the commercialization of DMFC tools [1]. Another problem is the high cost of the catalysts due to the use of Nobel metals like platinum. Consequently, it is necessary to reduce the cost of fuel cell catalyst and enhance their lifespan.

As catalysts in DMFC are commonly supported on conductive and porous membranes being this another important fact. It is well known that supported metal catalysts show improved stability and higher activity compared to unsupported bulk metal catalysts. Surface area, porosity, electrical conductivity, electrochemical stability, and surface functional groups characterise a support [5,10]. In this sense, carbon materials have been used as catalyst support due to remarkable properties, such as good electronic conductivity, better stability and environment friendliness. There are several materials such as mesoporous carbon, carbon black, carbon quantum dots, carbon nanotubes, carbon nanofibre, graphene and other carbon forms such as carbon nanosheet, nanohorns, nanosphere as electrocatalyst support have been reported [11].

In order to diminish or avoid the use of platinum in fuel cells several low-platinum catalyst, Pt-C or free Pt catalyst have been developed including Pt-based alloying, Pt-based nanostructure design and supports-enhanced methods [10,12-17]. Alloying Pt with more abundant and cheaper 3d-transition metals (such as Fe, Co, Cu, Ni) is considered as a facile strategy for heightening the electrochemical properties of [18-20].

Combustion synthesis is an effective, low-cost method for production catalysts and nanocarries by solid state and solution combustion [21,22]. The exothermicity of the redox chemical reaction is used to produce the material. Depending on the nature of reactants different methods has been developed [22].

The objective of this work is to develop catalysts Pt-free. Materials based on FeCo solid solutions are synthesized by the combustion method and characterized for their further application as anode catalysts in DMFC. Further, the catalytic layer composition has been designed to prepare electrodes by spray, in such a way that the slurry can be homogeneously sprayable on the surface of the carbon paper gas diffusion layer. The prepared materials have been morphological, structural and electrochemically characterized to teste their activity towards methanol oxidation.

2. Experimental

2.1. Sample preparation by combustion method

To prepare the catalysts have been used are used iron (II) nitrate and cobalt and cobalt (II) nitrate as precursors. Urea has been chosen as fuel to maintain or modify the balance of valences. To obtain different local conditions during combustion different amounts of fuel have been employed. The nominal compositions formulated for the catalysts are Fe_xCo_{1-x} (x=0, 0.25, 0.5, 0.75, 1).

2.2. Structural and morphological characterization

The structural identification was performed by XRD with a Bruker to D8 Advance (CuKα radiation, 30 mA, 50kV). For composition determination was used EVA Application V6.0 program with PDF-2 Database sets 1-46.

2.3. Electrochemical measurements

Catalytic activity of the prepared powders towards methanol oxidation reaction was analysed by CV in a three-electrode cell (CE: Pt sheet, RE: Ag/AgCl and the material ink onto a glassy carbon tip as WE), at 25ºC. Using $HClO_4$ 0.1M + CH_3OH 0.5M as electrolyte. All data are collected in a I-V curve by AUTOLAB PGSTAT302N, firstly the samples have been activated, and measurements have been recorded at 50 mV/s from -0.1 to 1.3 V vs Ag/AgCl.

3. Results and discussion

Combustion synthesis exhibit four more or less rapid stages depending on raw materials (Fig. 1). The ignition temperature achieved allows obtaining, in a short time, the crystalline phases of the nanopowder material with porous structure. That phenomenon accelerates the kinetic reaction that is why this is the stage that controls the global process.

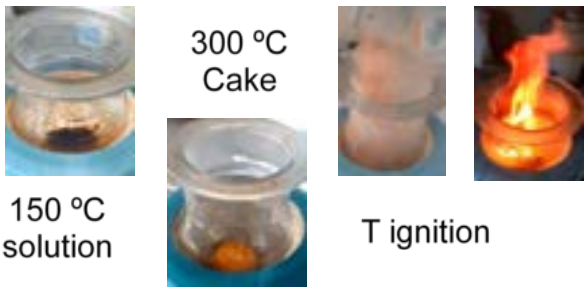

Figure 1. Scheme of urea synthesis processes.

Figure 2 shows that a mixture of oxides is obtained directly from the combustion with stoichiometric urea, observing small amounts of mixed oxides of iron and cobalt when different proportions of them are used to prepare the distinct nominal compositions.

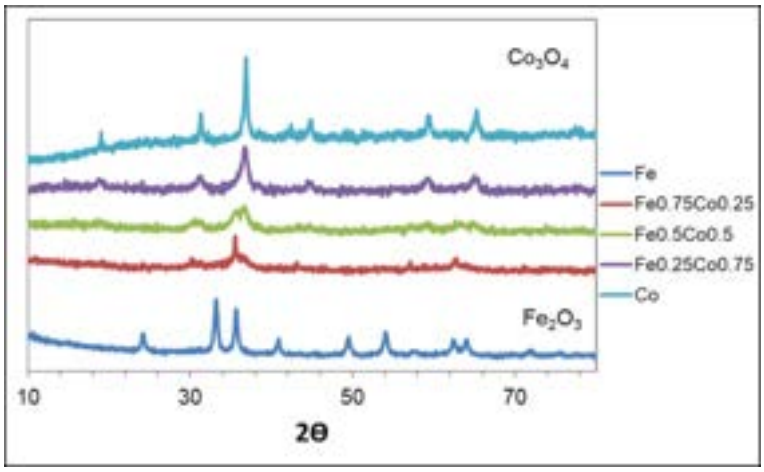

Figure 2. XRD of FexCo1-x (x=0, 0.25, 0.5, 0.75, 1) prepared by combustion synthesis with stoichiometric urea.

While in Fig. 3 it can be seen how the variation in the proportion of fuel makes it go from having Co_3O_4 to obtaining CoO.

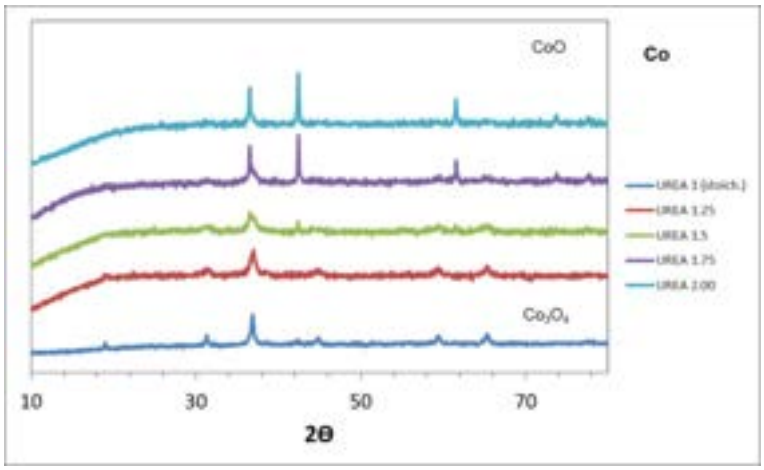

Figure 3. XRD of FexCo1-x (x=0) prepared by combustion synthesis with different ratios of urea.

By varying the stoichiometry of urea, in the case of x=0.25, 0.5, 0.75, the concentration of the mixed oxides of iron and cobalt increases.

Regarding the preliminary electrochemical measurements carried out, it has been observed that when iron or cobalt oxide is found alone there is no activity against methanol oxidation. But this activity begins to appear, although slightly, as the iron-cobalt mixture appears in the catalyst formulation.

4. Conclusions

The ignition stage of the combustion synthesis determines the final crystallographic and morphological properties of the powders due to the number of gases released in that condition and both the atmosphere and the local synthesis temperature. The combustion method has been studied tailoring the properties of the final product based on the raw mixture used. It has been proven that final features and electrochemical behaviour is different, mainly due to the different crystalline phases achieved in the synthesis.

The higher electrochemical activity is related to the crystal structure, the microstructure and morphology of the material. And these differences are directly related with time of reaction, local temperature and oxygen partial pressure reached.

Abstract:
The current energy crisis has accelerated the interest in sustainable energy sources and cryogenic propellants, liquid hydrogen (LH_2) or liquefied natural gas (LNG). The thermal management of these systems requires advanced control strategies to minimize the boil-off losses produced by heat leakages and sloshing-enhanced heat and mass transfer. This work presents a data-assimilation approach to calibrate a 0D thermodynamic model for cryogenic fuel tanks from data collected in real time from multiple tanks. The proposed approach combines ideas from traditional data assimilation with multi-environment reinforcement learning, where an agent's training (i.e., model assimilation) is carried out simultaneously on multiple systems (environments). The real-time assimilation uses a mini-batch version of the well-known Limited-memory Broyden–Fletcher–Goldfarb–Shanno with bounds (L-BFGS-B) and adjoint-based gradient computation for solving the underlying optimization problem. The approach is tested on synthetic datasets simulating multiple tanks undergoing different operation phases (pressurization, hold, long-term storage and sloshing). We present the general closure problem for the tank's thermodynamics and the multi-environment assimilation framework. The results show that the simultaneous sampling from multiple environments and loading scenarios significantly accelerates the assimilation. Moreover, it is shown that the time scale for the training process is shorter than the relevant time scales of the tank's thermodynamics. This opens the path towards model predictive control based on data-driven engineering models.

Keywords:
Thermodynamics; Cryogenics; Sloshing; Modeling; Machine learning; Data assimilation.

1. Introduction

Cryogenic fuels such as liquid hydrogen (LH_2) or liquefied natural gas (LNG) are managed and stored at extremely low temperatures (typically $\approx$-170 °C for LNG and $\approx$-250 °C LH_2). LH_2 has been mainly used in rocket engines [1] but is now actively explored as alternatives to fossil fuels in many applications, including naval [2] and aeronautical [3] industries. The need for cryogenic temperatures stems from the need to maximize the fuel density without resorting to extreme operating pressures ($>$ 300 bars for gaseous H_2) [4]. In addition, the higher thrust-to-weight ratio compared to classical propulsive solutions [4] and the absence of pollutant emission make LH_2 a promising energy carrier for a carbon-neutral future [3, 5]. LNG is not entirely emission-free but can still bridge the gap between traditional fossil fuels and a fully renewable energy system [3].

Nevertheless, storage at cryogenic temperatures requires a complex thermal management system, which poses significant challenges to any application requiring long holding times, from marine to aeronautical, from ground transportation to deep space exploration. No insulating system can entirely prevent heat exchanges with the surroundings. Thus some of the fuel unavoidably evaporates over time and increases the tank pressure [6]. Additional challenges are faced in tanks installed on vehicles, as the external accelerations induce sloshing. Sloshing, defined as the movement of the free liquid surface, can (suddenly) increase heat and mass transfer rates between the liquid and ullage gasses and thus produce significant variations of the tank's pressure [7, 8].

This work proposes a data assimilation framework for identifying closure laws in a 0D thermodynamic model from real-time measurements of pressure, temperature, and liquid level in cryogenic tanks. The underlying optimization problem is efficiently solved via gradient-based optimization using the L-BFGS-B (Limited-memory Broyden–Fletcher–Goldfarb–Shanno with bounds) algorithm [9] coupled with the adjoint method [10] for evaluating the cost function gradient. The main novelty in our approach lies in the simultaneous assimilation of observations from multiple fuel tanks (i.e., multiple environments) undergoing distinct thermodynamic evolution in potentially widely different operating conditions.

The proposed approach takes inspiration from multi-agent reinforcement learning (MARL) [11]. MARL is a subfield of reinforcement learning where multiple agents learn to interact with each other and with the environment

to maximize a global reward. This is an active area of research with many open questions and challenges [12] on handling communication and coordination between agents and learning effective policies in large-scale multi-agent systems. Nevertheless, we believe that the potential impact of this concept in data assimilation is enormous and worth investigating. This work moves the first steps towards its application to the problem of data-driven calibration of thermodynamic models for cryogenic tanks. Leveraging synthetic data, we aim to quantify the performance of the model's calibration as the number of *environments* increases, using a single *agent* to learn the closure terms. As a complementary investigation, the single-environment scenario is also investigated to assess the impact of noise on the training data and the uniqueness of the solution.

This article is structured as follows. Section 2. outlines the physical modeling of the cryogenic fuel tank implemented in this work. The real-time data assimilation and inverse method strategies are outlined in Section 3.. Furthermore, this section also describes how the synthetic test cases were generated. Lastly, Section 4. overviews the results of the model calibration in single-environment and multi-environment conditions. Concluding remarks and future outlook are discussed in Section 5..

2. Thermodynamic modeling

The cryogenic propellant tank considered in this work is a single-species system composed of a liquid and its vapor enclosed in an insulated tank Fig. 1 provides a schematic of the problem with the relevant parameters involved. Subscripts l, v, and w are used to distinguish variables related to the liquid, the vapor, and the wall, respectively. The gas-liquid interface separating vapor and liquid is treated as an infinitesimally thin region where heat and mass transfer occurs. The system exchanges heat and mass, both on the liquid and the vapor side, during various operations (e.g., pressurization, venting, filling). The reader is referred to the list of symbols at the end of the article for the nomenclature.

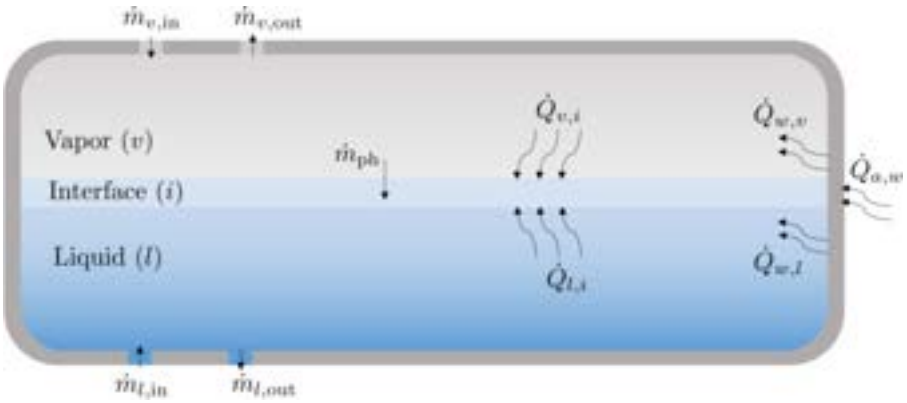

Figure 1: Schematic of the cryogenic fuel tank and its subsystems: vapor (v), liquid (l), and insulating walls (w). The heat and mass exchanges between these control volumes are expressed through the $\dot{m}$ and $\dot{Q}$ fluxes.

The 0D thermodynamic model used in the assimilation expresses the conservation of mass and energy applied to three control volumes: the liquid, the vapor, and the solid. Considering mass-averaged thermodynamic properties, these balances result in a system of ordinary differential equations (ODEs), which must be closed with empirical relations for the heat and mass transfer rates. Finding closure from sampled data is the objective of the assimilation.

The mass conservation between the liquid and the vapor is given by

$$\frac{dm_v}{dt} = \sum \dot{m}_{v,\text{in}} - \sum \dot{m}_{v,\text{out}} - \dot{m}_{\text{ph}} \quad ; \quad \frac{dm_l}{dt} = \sum \dot{m}_{l,\text{in}} - \sum \dot{m}_{l,\text{out}} + \dot{m}_{\text{ph}} \,, \tag{1}$$

where $\dot{m}_{\text{ph}} = \dot{m}_{\text{cond}} - \dot{m}_{\text{evap}}$ is the net mass flux through the interface, accounting for the balance of condensation and evaporation. The mass conservation in the vapor and liquid phases give

$$\frac{dU_v}{dt} = \sum \dot{m}_{v,\text{in}} \hbar_{v,\text{in}} - \sum \dot{m}_{v,\text{out}} \hbar_{v,\text{out}} - \dot{m}_{\text{ph}} \hbar_{v,\text{sat}} - \dot{Q}_{v,i} + \dot{Q}_{w,v} + \dot{W}_v \tag{2}$$

$$\frac{dU_l}{dt} = \sum \dot{m}_{l,\text{in}} \hbar_{l,\text{in}} - \sum \dot{m}_{l,\text{out}} \hbar_{l,\text{out}} + \dot{m}_{\text{ph}} \hbar_{v,\text{sat}} - \dot{Q}_{l,i} + \dot{Q}_{w,l} + \dot{W}_l, \tag{3}$$

where U_v and U_l are the internal energies of the vapor and liquid phases, $\dot{Q}$ denotes the general heat flux, $\hbar$ is the specific enthalpy, and $\dot{W} = -pdV/dt$ is the expansion/compression work due to changes in filling level.

The model closure is required to link the heat transfer rates at the interface. Assuming that the heat transfer occurs at much larger time scales than the interface dynamics, we consider quasi-steady formulation and use Newton's cooling law for the closure relation:

$$\dot{Q}_{v,i} = A_i h_{v,i}(T_v - T_i) \;\; ; \;\; \dot{Q}_{w,v} = A_{w,v} h_{w,v}(T_w - T_v) \;\; ; \;\; \dot{Q}_{l,i} = A_i h_{l,i}(T_l - T_i) \;\; ; \;\; \dot{Q}_{w,l} = A_{w,l} h_{w,l}(T_w - T_l), \tag{4}$$

where $h_{v,i}$, $h_{l,i}$, $h_{w,v}$, $h_{w,l}$ are the heat transfer coefficients, A_i is the gas-liquid interface area, $A_{w,v}$ and $A_{w,l}$ are the surface exchange areas between the walls-vapor and walls-liquid phases. The heat transfer coefficients are unknown and must be identified from the data. The interface temperature in (4) is assumed to be the saturation temperature evaluated at vapor pressure p_v; hence the energy balance at the interface provides the mass flux due to phase change as $\dot{m}_{\text{ph}} = (\dot{Q}_{l,i} - \dot{Q}_{v,i})/\mathcal{L}_v$, with $\mathcal{L}_v$ the latent heat of vaporization.

Concerning the exchange areas in (4), we do not account for the time variation of A_i (due to, e.g., sloshing), and take it as the tank's cross-section when the tank is half-filled. On the other hand, given the tank's geometry, the areas $A_{w,v}$ and $A_{w,l}$ are updated at each time step depending on the liquid level. This can be computed from the liquid and vapor masses and their properties. In particular, treating the liquid phase as incompressible (as in [13]), its density is solely a function of temperature $\rho_l(p, T) \approx \rho(T)$, hence

$$\frac{dV_l}{dt} = -\frac{dV_v}{dt}. \approx \frac{1}{\rho_l}\frac{dm_l}{dt} - \frac{m_l}{c_{p,l}\rho_l^2}\left(\frac{d\rho_l}{dT}\right)_p \frac{du_l}{dt}, \tag{5}$$

where c_p is the specific heat at constant pressure, ρ is the density, and $u = U/m$ is the specific internal energy. Finally, in the 0D formulation, the insulating walls are treated as a single control volume which can exchange heat with the vapor and liquid phases, as well as with the external environment at ambient conditions. For a single control volume with mass-averaged properties, the internal energy of the walls is described through

$$\frac{dU_w}{dt} = \dot{Q}_{a,w} - \dot{Q}_{w,v} - \dot{Q}_{w,l} \tag{6}$$

where $\dot{Q}_{a,w}$ is the heat entering the tank from the environment. This term could be computed from existing literature correlations [14], but in this work, this is taken as a user-defined function that depends on the specific scenario experienced by the tank (described in the following section). It is worth noticing that (6) can be written as a function of the mass-averaged solid temperature by introducing $dU_w = m_w c_w dT_w$.

Finally, all thermodynamic properties (c_p, ρ), as well as the link between internal energies, temperatures and pressures, were evaluated using the CoolProp package [15] in Python. This library implements pure fluid equations of state and transport properties using the Helmholtz energy formulations.

To conclude this section, we note that the thermodynamic model is constituted of equations (1)-(6) and can be cast in the form of a parametric initial value problem:

$$\begin{cases} \dfrac{d\mathbf{x}}{dt} = \mathbf{f}(\mathbf{x}, t; \boldsymbol{\theta}) \\ \mathbf{x}(0) = \mathbf{x}_0 \end{cases} \tag{7}$$

where $\mathbf{x} = [m_v, m_l, u_v, u_l, T_w, V_v, V_l] \in \mathbb{R}^7$ is the state vector (composed by the masses, volumes and internal energies of each control volume), describing the thermodynamic condition of the system at time-instant t, $\mathbf{x}_0 \in \mathbb{R}^7$ is the (known) initial condition and $\boldsymbol{\theta} \in \mathbb{R}^p$ is the vector of unknown parameters. These identify a function mapping the state vector to the heat transfer coefficients in (4) as further detailed in Section 3.1..

3. Real-time data assimilation framework

We describe the generation of the synthetic database in section 3.1. and the multi-environment real-time assimilation approach in section 3.2..

3.1. Synthetic database generation

Borrowing from the reinforcement learning terminology, the assimilation is carried out by an *agent* interacting with an *environment* to achieve a goal. In our context, the *agent* is a function that must predict the closure parameters (heat transfer coefficients) with the goal of having the model prediction as close as possible to the available data. In our context, the *environment* definition requires defining (1) the geometry of the fuel tanks, (2) the working fluid, (3) the initial conditions of the system, (4) the temporal evolution of the heat transfer coefficients (unknown to the agent), and (5) the sequence of operations applied to the tank. These are summarised in Fig. 2.

The proposed multi-environment formulation involves learning the *same* closure law from multiple environments. In this work, we consider multiple cryogenic fuel tanks, partly filled with LH_2. The environment parameters in terms of dimensions and initial conditions are presented in Table 4 in Appendix A. Tank 1 is the

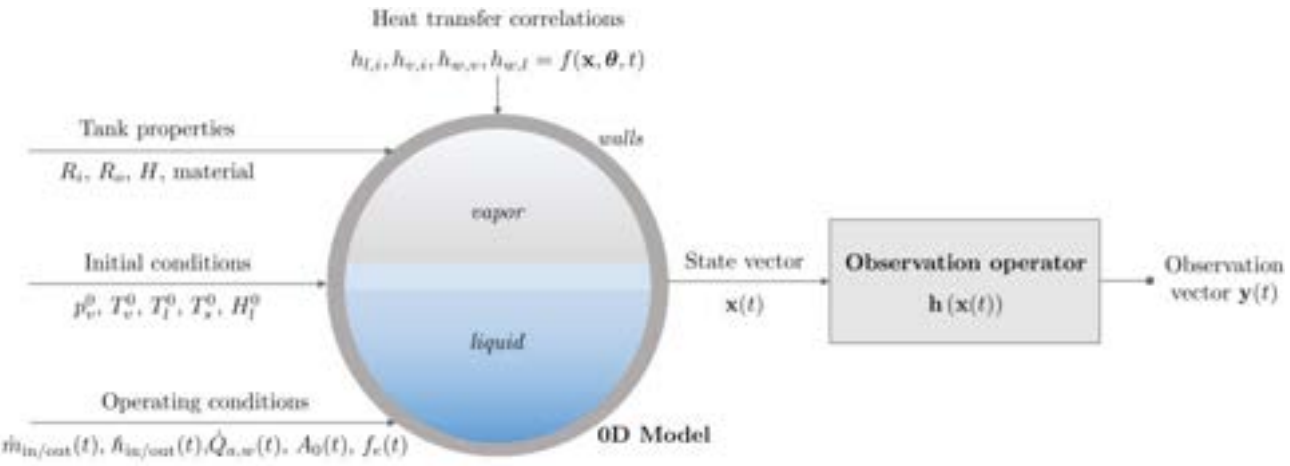

Figure 2: Schematic of the parameters required to define an environment for the data assimilation of the 0D thermodynamic model of the cryogenic tank. Interaction with the environment produces the observation vector $\mathbf{y}(t)$ simulating measurements from the tank.

reference case used to assess the single-environment performance of the assimilation framework (Section 4.1.). The remaining tanks are added to the analysis of the multi-environment scenario (Section 4.2.).

In all environments, the heat transfer coefficients in (4) were modeled as

$$h_{v,i} = \frac{k_v}{R}\left(\theta_0 \mathrm{Re}_{s,v}^{0.69}\mathrm{Pr}_v^{1/3} + \theta_1 \mathrm{Ra}_v^{0.15}\right) \;;\; h_{l,i} = \frac{k_l}{R}\left(\theta_2 \mathrm{Re}_{s,l}^{0.69}\mathrm{Pr}_v^{1/3} + \theta_3 \mathrm{Ra}_l^{0.15}\right) \;;\; h_{w,v} = \theta_4 h_{v,i} \;;\; h_{w,l} = \theta_5 h_{l,i} \tag{8}$$

where Re_s is the Reynolds number due to sloshing, $\mathrm{Pr} = \nu/\alpha$ is the Prandtl number, Ra is the Rayleigh number, and $\theta_0 - \theta_5$ are the set of parameters governing the heat and mass transfer evolution in the tank.

The dimensionless numbers in (8) are defined as

$$\mathrm{Re}_s = \frac{f_e}{f_{11}}\left(\frac{b}{R}\right)^2 \frac{\left(gR^3\right)^{1/2}}{\nu}\sqrt{1.841} \quad ; \quad \mathrm{Ra} = \frac{g\beta\Delta T R^3}{\nu\alpha} \tag{9}$$

where f_e is the frequency of the forcing motion acting on the tank, f_{11} is the natural frequency of the tank [1], b is the maximum expected wave-height during sloshing, which is a function of the forcing amplitude A_0 [8], R is the tank's radius, ν is the kinematic viscosity, g is the gravitational acceleration, β is the volumetric thermal expansion coefficient, and α is thermal diffusivity.

The $h_{l,i}$ and $h_{v,i}$ coefficients simultaneously account for forced convection through the Reynolds and Prandtl numbers, as well as buoyancy-driven fluxes through the Rayleigh number. All synthetic test cases were generated using the set of parameters $\boldsymbol{\theta} = [\theta_0, \theta_1 \ldots]$ presented in Table 3 in Appendix A. These were tuned to roughly portray the experimental pressure and temperature reported in [7, 16].

Assuming that the functional relations in (8) are prescribed beforehand, the scope of data assimilation consists in identifying the parameters $\boldsymbol{\theta}$ from multiple environments. A general formulation of the problem could be based on general parametric models (e.g. using radial basis functions expansions or artificial neural networks) to learn the closure laws. These are currently being explored and will be presented in future work.

The interaction between the agent and the environment is carried out by monitoring some observations of the system, here denoted as $\mathbf{y}(t) = \mathbf{h}(\mathbf{x}(t))$, with $\mathbf{h}(\cdot)$ the observation function simulating a measurement process. The observations considered in this work are the vapor pressure $p_v(t)$, the mass-averaged vapor $T_v(t)$, liquid $T_l(t)$, and wall $T_w(t)$ temperatures, and the fill-level $H_l(t)$. These quantities were retrieved from the state vector. Hence the observation function is $\mathbf{h}(\cdot) : \mathbb{R}^7 \to \mathbb{R}^5$.

3.2. Real-time inverse method for multiple environments

Identifying the parameters $\boldsymbol{\theta}$ requires solving an optimization problem. The optimal parameters are those that minimize a cost function $\mathcal{J}(\boldsymbol{\theta})$ measuring the discrepancy between model prediction and data across all the available environments. Denoting as $\mathbf{x}_{\{j\}}(t)$ the time evolution of the thermodynamic state in the j^{th} environment and as $\mathbf{y}_{\{j\}}(t)$ the evolution of the corresponding observations, the cost function considered in this work is

$$\mathcal{J}(\boldsymbol{\theta}) = \frac{1}{N}\sum_{j=1}^{N}\int_{t_i}^{t_i+T} g(\mathbf{y}_{\{j\}}, \mathbf{x}_{\{j\}}, t; \boldsymbol{\theta})dt = \frac{1}{2N}\sum_{j=1}^{N}\int_{t_i}^{t_i+T}\left(\mathbf{y}_{\{j\}}(t) - \mathbf{h}(\mathbf{x}_{\{j\}}(t))\right)^T \mathbf{R}_{\{j\}}^{-1}\left(\mathbf{y}_{\{j\}}(t) - \mathbf{h}(\mathbf{x}_{\{j\}}(t))\right) dt \tag{10}$$

where N is the number of environments, T is the observation time and $\mathbf{R}_{\{j\}}$ is the covariance matrix accounting for measurement noise. Since the assimilation seeks to learn the full set of parameters from all environments, the proposed formulation is a multiple-environment but single-agent framework, as opposed to a multi-agent formulation in which different agents could be assigned to learn different coefficients in the same environment.

In this work, the function $\mathcal{J}(\boldsymbol{\theta})$ is minimized through gradient-based optimization using the L-BFGS-B optimizer [9] coupled with the adjoint method [10] to compute the gradient $\nabla_{\boldsymbol{\theta}}\mathcal{J}$. The adjoint method allows computing this gradient without computing the sensitivity of the state with respect to the closure parameters, i.e. $d\boldsymbol{x}/d\boldsymbol{\theta}$.

The gradient is computed by relying on the augmented Lagrangian function $\mathcal{L}(\boldsymbol{\theta})$

$$\mathcal{L}(\boldsymbol{\theta}) = \mathcal{J}(\boldsymbol{\theta}) + \sum_{j=1}^{N} \left(\int_{t_i}^{t_i+T} \left(\mathbf{f}(\mathbf{x}_{\{j\}}, t; \boldsymbol{\theta}) - \frac{d\mathbf{x}_{\{j\}}}{dt} \right) \boldsymbol{\lambda}_{\{j\}}(t)^T dt \right) \tag{11}$$

where the (row) vector $\boldsymbol{\lambda}_{\{j\}}(t) \in \mathbb{R}^7$ is the vector of adjoint variables for each environment. The cost function (10) and the augmented cost function (11) are equivalent because the additional term is identically null for any finite choice of the variable $\boldsymbol{\lambda}_{\{j\}}$ (by definition of the underlying dynamics in (7)). Therefore, it is possible to make the gradient computation of both cost functions independent of the sensitivities if the adjoint variables are taken as the solution of the following terminal value problem [17]:

$$\begin{cases} \dfrac{d\boldsymbol{\lambda}_{\{j\}}}{dt} = -\left(\dfrac{\partial g}{\partial \mathbf{x}}\right)_{\{j\}} - \boldsymbol{\lambda}_{\{j\}}(t) \left(\dfrac{\partial \mathbf{f}}{\partial \mathbf{x}}\right)_{\{j\}} \\ \boldsymbol{\lambda}_{\{j\}}(T) = 0 \end{cases} \tag{12}$$

This is a linear system of equations that must be integrated backward in time to solve for $\boldsymbol{\lambda}_{\{j\}}$. The gradient can then be computed as

$$\nabla_{\boldsymbol{\theta}}\mathcal{J}(\boldsymbol{\theta}) = \sum_{j=1}^{N} \left(\int_{t_j}^{t_j+T} \left(\frac{\partial g}{\partial \boldsymbol{\theta}}\right)_{\{j\}} + \boldsymbol{\lambda}_{\{j\}}(t) \left(\frac{\partial \mathbf{f}}{\partial \boldsymbol{\theta}}\right)_{\{j\}} dt + \boldsymbol{\lambda}_{\{j\}}(0) \frac{d\mathbf{x}_{\{j\}}}{d\boldsymbol{\theta}}(0) \right) \tag{13}$$

where $d\mathbf{x}_{\{j\}}/d\boldsymbol{\theta}(0)$ is known from the initial conditions of each environment (tank). Thus, in the adjoint-based approach, the gradient of the loss function is evaluated by solving two systems of equations for each environment in the ensemble (i.e., one forward pass to obtain $\mathbf{x}_{\{j\}}(t)$, and one backward pass to obtain $\boldsymbol{\lambda}_{\{j\}}(t)$).

The vector of parameters is iteratively updated throughout the optimization loop as

$$\boldsymbol{\theta}^{(k+1)} = \boldsymbol{\theta}^{(k)} - \mathbf{B}^{(k)} \nabla_{\boldsymbol{\theta}}\mathcal{J}(\boldsymbol{\theta}^{(k)}) \text{ for } k \in [0, 1 \dots n_k] \tag{14}$$

where the superscript $^{(k)}$ indicates the iteration counter, and $\mathbf{B}$ is the approximation of the Hessian matrix inverse according to [9]. The gradient computation in (13) and the updates in (14) define two-time scales of the assimilation problem. The first scale is the observation time T, linked to the rate at which new information is collected. The second is the learning time scale implicitly defined by the number of optimization iterations n_k carried out before an update on the gradient is requested (or is available). The first time scale defines the rate at which the cost function changes because of the dynamics of the system and the potential occurrence of unseen scenarios. The second time scale defines the rate at which the optimizer travels along the parameter space before the cost function changes.

The optimal setting of these scales poses a fundamental question on the impact of the observation time T in relation to the observed scenarios and the quality of the gradient computation: one might ask, for example, whether the observation time should be long enough to observe at least two or three pressurizations or sloshing events. This work investigates the impact of this parameter by making it vary from T = 10 min until T = 60 min, with the five environments observing different scenarios and different combinations of events.

4. Results and discussion

We split the presentation of results and the discussion into a section dedicated to the performance of a single environment (Section 4.1.) and a section dedicated to multiple environments (Section 4.2.).

4.1. Single-environment performance

We first describe the investigated scenario in 4.1.1.. Section 4.1.2. studies the impact of measurement noise in the collected data for different observation times T. Finally, section 4.1.3. reports on the impact of mini-batching the assimilation using only a portion of the data.

4.1.1. Test case description

We consider the environment denoted as 'case 1' in Table 4. Figure 3 illustrates the loading and operation scenario of the tank in an observation of 1 hour. The first row of plots illustrates the time evolution of the ullage gas pressure (on the left), and the mass averaged temperatures of the vapor, the liquid and the solid volumes (on the right). The second row plots the time amplitude (left) and the frequency (right) of sinusoidal sloshing events. The third row plots the mass inflow/outflow of vapor (left) and liquid (right) as a function of time. Finally, the last row shows the heat flux exchanged through the walls (left) and the liquid level (right).

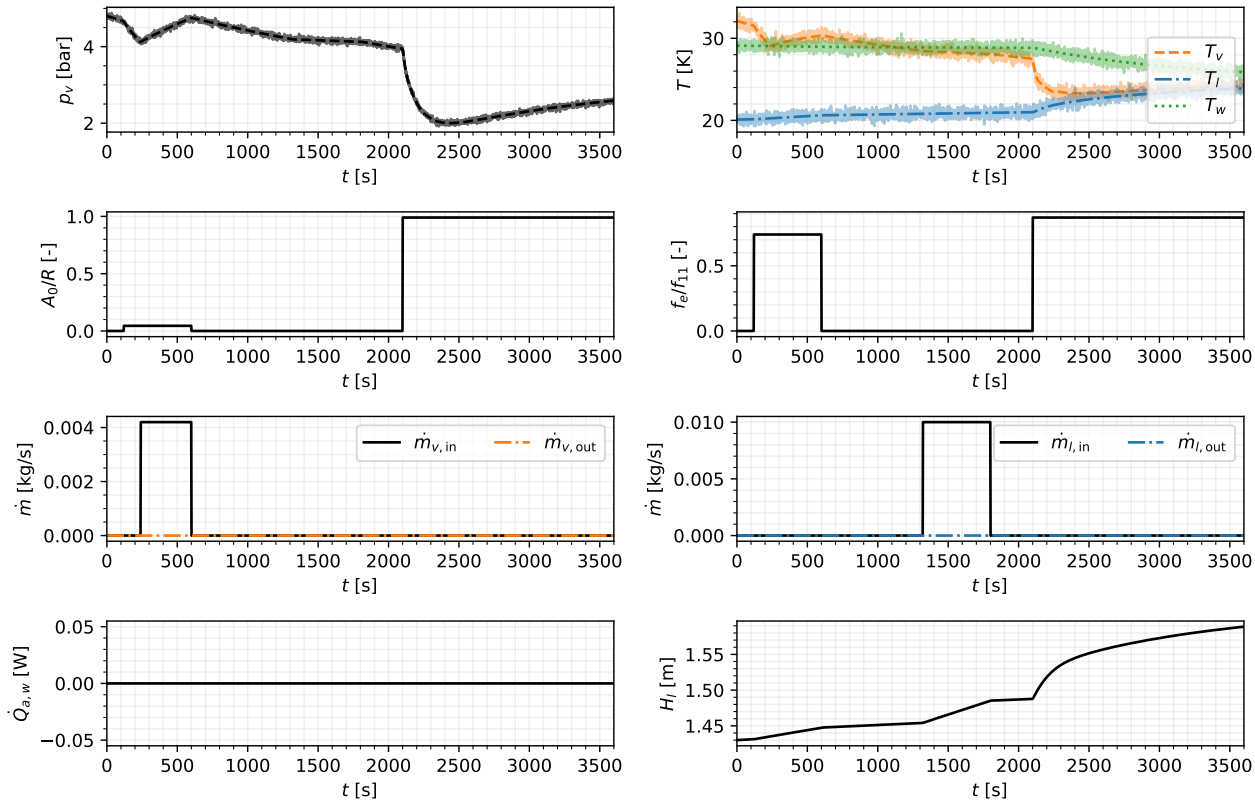

Figure 3: Synthetic data generated for Tank 1 (see Table 4) used to evaluate the single-environment performance. The components of the observation vector are displayed alongside the injected/removed mass fluxes, the non-dimensional excitation conditions, and the external heat flux.

A detailed overview of these graphs helps understand the complexity of the system control problem. In the presented scenario, the tank is undisturbed in the first 2 minutes. Then, a moderate sloshing event occurs with a dimensionless amplitude of $A_0/R = 0.045$ and dimensionless frequency $f_e/f_{11} = 0.8$ (see definitions of sloshing conditions in (9)). This triggers a visible pressure drop. To counter-balance this, at time $t = 4$ minutes, hydrogen vapor at 40 K and 2 bar is injected in the ullage at a rate of 4.2 g/s for 6 minutes. This allows the tank to recover 4.8 bar pressure at 10 minutes when the sloshing event ends. From $t = 10$ to $t = 22$ minutes, the tank is again undisturbed but the temperature difference between the wall, the gas, and the liquid results in the warming of the liquid and the cooling of the vapor. This slightly reduces the pressure in the ullage. Finally, between $t = 22$ and $t = 30$ minutes, liquid at 22 K is injected into the system at a rate of 0.01 kg/s. This reduces the ullage volume, resulting in a moderate compression that arrests the decreasing trend. Finally, at $t = 35$ minutes, a violent sloshing event occurs and continues until the end of the observation. This results in a violent pressure drop due to the significant condensation (see liquid level evolution), followed by a moderate pressure rise due to heat exchanges with the (now) warmer walls. Throughout this test, no heat exchange is assumed to occur from the environment.

4.1.2. Impact of noise in the observation data

We here consider three scenarios in terms of measurement noise in the collected observations; these are termed (1) 'clean' (2) 'low-noise', and (3) 'high-noise'. No noise is present in the first, while Gaussian noise (with zero average) is added in the other two. In (2), the noise's standard deviation is 2 kPa on the pressure, 0.2 K on the temperature, and 0.5 mm on the fill level. In (3), these values are doubled.

We considered various observation windows T of the environment described in the previous section for the

three scenarios. Figure 4 shows the results of the real-time data assimilation applied to the 'clean' data for T = 10, 20, and 30 minutes. The thick solid lines indicate observations from the virtual experiment, whereas the thin dashed lines indicate the predictions given by data assimilation. The columns of the figure show the tank pressure, vapor temperature, and liquid temperature as the observation time increases.

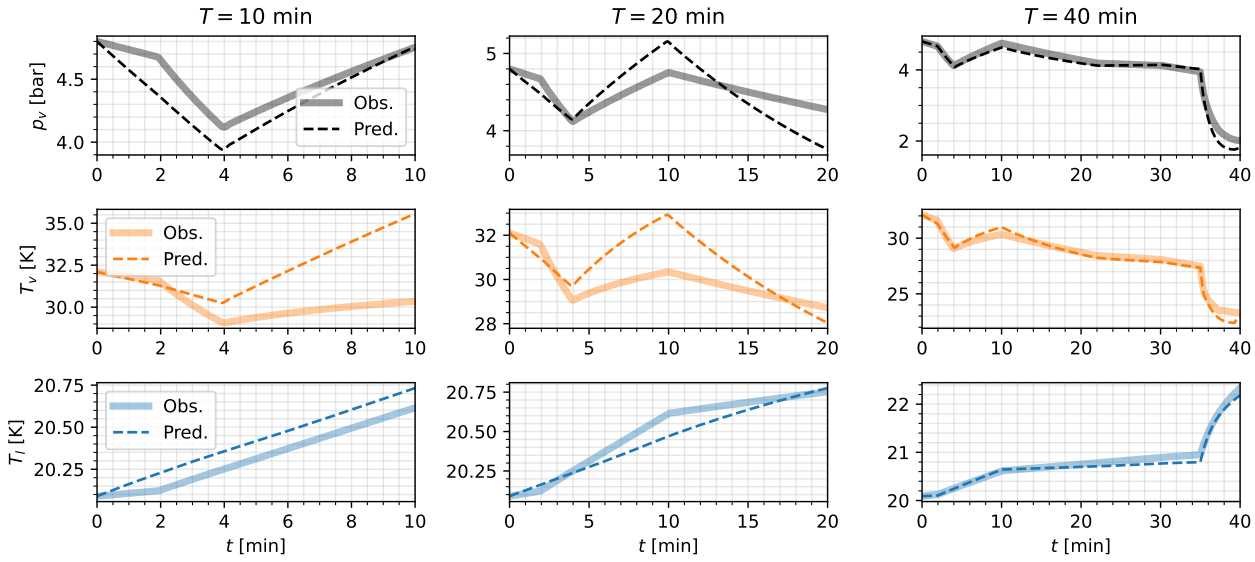

Figure 4: Model predictions and observation data extracted from the test described in Section 4.1.1. for 10, 20 and 40 minutes of observation.

Interestingly, the assimilation produces excellent matching between the model and observation if the observation time is sufficiently long. In the virtual experiment analyzed, this is of the order of T = 40 min, i.e., enough to see all the events in the environment (sloshing, filling on the vapor and the liquid side).

The analysis of the noise impact is thus completed in Fig. 5, which presents the minimum of $\mathcal{J}$ (on the left) and the l_2 relative error norm of $\boldsymbol{\theta}$ (on the right) as a function of the observation time, for the three tested scenarios as a function of the observation time. When noise is added, the minimal cost function is expected to be larger in the presence of noise since the underlying model filters it out from the data. Nevertheless, these results show that the noisy cases consistently produced smaller values of $\mathcal{J}$ when the full observation is used. Surprisingly, the measurement noise helps the optimization avoid local minima, and the parameters identified in the assimilation are more accurate (right plot in Fig. 5) and learned with shorter observation times. Interestingly, in all cases, the learning of the parameters saturates for $T > 40$ min.

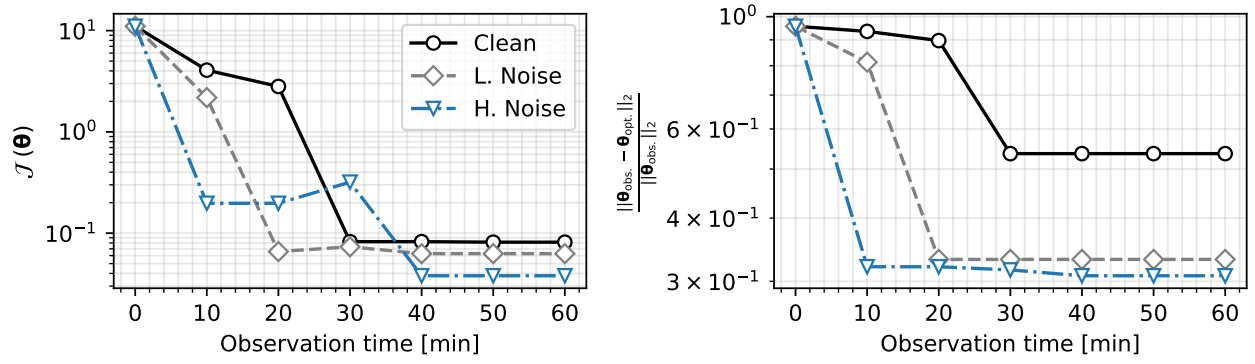

Figure 5: Performance of the data assimilation framework applied to one environment for different noise levels in the data. Left: minimum of the cost function as a function of the observation time. Right: l_2 relative error norm associated with $\boldsymbol{\theta}$.

We close this analysis by comparing the retrieved parameters from the assimilation and those used to generate the data; these are reported in the next section and presented alongside the impact of data batching for the gradient computation.

4.1.3. Impact of approximating the gradient of the cost function via mini-batches

The mini-batch sampling [18] is a classic approach to escape local minima and limit memory requirements in the gradient descent method. The idea consists in computing the cost function gradient using a randomly chosen subset of the observation data; this produces an approximation of the gradient $\nabla_\theta \mathcal{J}$ that might point away from local minima.

The use of mini-batch strategies on quasi-Newton methods, such as the L-BFGS-B technique used in this work, is the subject of active research (see [19]). Nevertheless, in this work, we explored its impact on the 'high-noise' configuration from the previous subsection. We test the assimilation using 80%, 50%, 20% and 5% of the observed data to evaluate $\nabla_\theta \mathcal{J}$. To account for the stochasticity of the process, the assimilation is repeated one hundred times in each case and the results are averaged. The average behavior of the cost function evolution and the convergence of the parameters are shown in Fig. 6. Remarkably, the additional stochasticity of the minibatch selection further improves the result of the assimilation in both aspects. Interestingly, the relative error is nearly identical when sampling 80%, 50%, and 5% of the training data, whereas for the 20% bath size the error is reduced by roughly 6%. The cost function, on the other hand, is slightly higher.

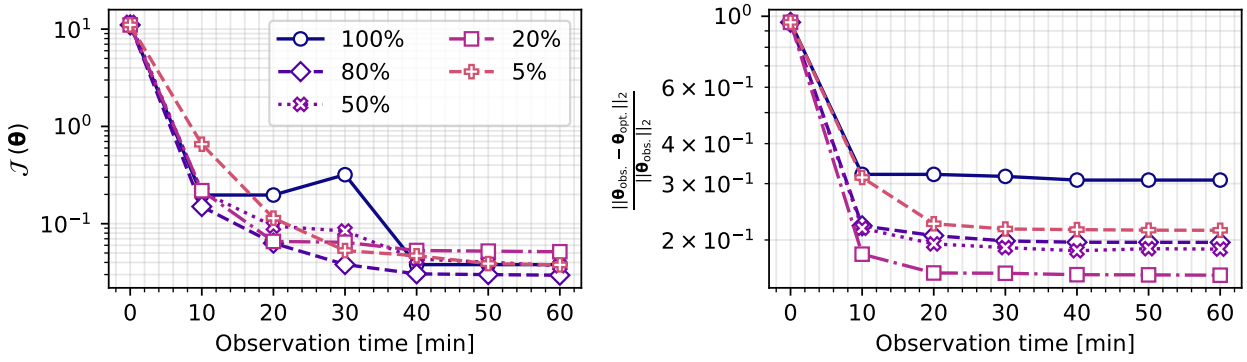

Figure 6: Performance of the data assimilation framework applied to one environment. Left: minimum of the cost function as a function of the observation time. Right: l_2 relative error norm associated with θ.

Finally, we compare the parameters obtained in the assimilation for different mini-batch sizes in table 1. For each coefficient, the table collects the average and the standard deviation (over 100 repetitions of assimilation). The reference coefficients used to generate the synthetic data are shown in the last row of the table. These results confirm that the best match of θ was achieved when 20% of the training data was sampled at each gradient computation, even though this case reported the highest cost function evaluation on average.

Table 1: Mean coefficients obtained during the model training, alongside their respective standard deviation. The cases in which $\nabla_\theta \mathcal{J}$ was approximated via mini-batches were repeated 100 times.

Data sampled	min $\mathcal{J}$	θ_0	θ_1	θ_2	θ_3	θ_4	θ_5
100%	3.8e-2	98.3	17.2	65.2	1.21	8.91	11.6
80%	2.7e-2	134.1 ± 14.6	10.7 ± 2.4	51.6 ± 4.7	1.9 ± 0.2	34.9 ± 37.5	10.1 ± 0.4
50%	2.8e-2	128.3 ± 16.4	11.1 ± 2.9	50.9 ± 3.8	1.9 ± 0.3	28.8 ± 32.0	10.2 ± 0.7
20%	3.4e-2	134.5 ± 16.3	10.0 ± 3.6	49.6 ± 5.5	2.0 ± 0.3	18.1 ± 19.2	10.0 ± 0.6
5%	3.0e-2	120.0 ± 23.8	12.8 ± 4.2	53.3 ± 7.2	1.8 ± 0.4	18.7 ± 16.6	10.0 ± 0.6
Reference	-	140.0	10.0	50.0	2.00	20.0	10.0

The table shows that the standard deviation for each component of θ increases as the batch size decreases. This is attributed to less accurate gradient evaluation during the parameter updates. The only outlier to this trend is θ_4, which shows the opposite behavior. However, this is characterized by a significantly larger standard deviation. This parameter is associated with the heat transfer coefficient $h_{w,v}$, governing the heat exchanges between the vapor and the insulating walls, which appears to have a minor impact on the system's dynamics. Thus, given the insensitivity of the model to this parameter, the assimilation cannot determine its true value from the observed data.

In summary, these results showcased that sampling portions of the training data during the optimization can improve the assimilation results. Furthermore, this sampling provides an approximation of $\nabla_\theta \mathcal{J}$, which allows for a broader exploration of the parameter space, yielding better predictions for θ, even if the value of the cost

function is not significantly affected (on average). For the current training data set, the best compromise was obtained by sampling 20% of the input data.

4.2. Multi-environment performance

We here extend the previous analysis to the case of multiple environments characterised by vastly different geometries, sloshing profiles, thermal loading and inflow/outflow control actions.

The first environment is the tank described in Section 4.1.1. while the geometrical parameters, and initial conditions for the others are summarised in Table 4 in Appendix A. All environments are observed for the same T = 60min, but their thermodynamic evolutions differ by imposing different sequences of filling, pressurization, venting, sloshing, and external heating.

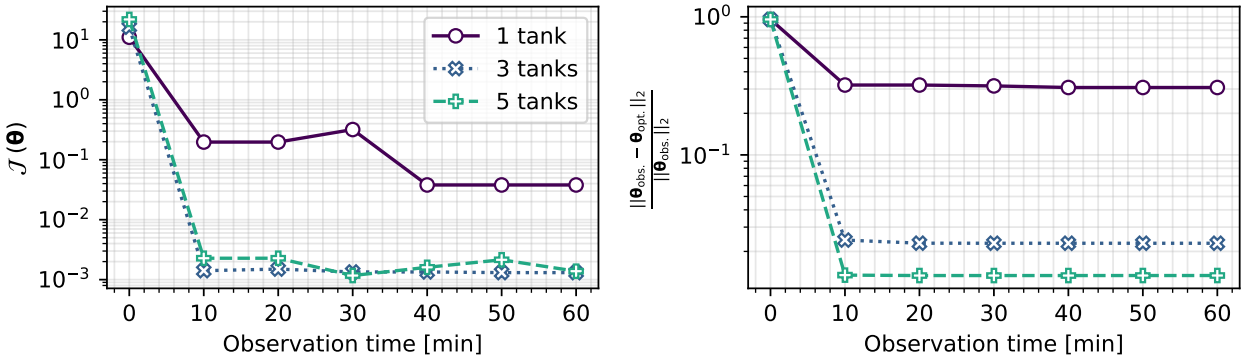

Figure 7: Performance of the data assimilation framework applied to multiple environments. Left: minimum of the cost function as a function of the observation time. Right: l_2 relative error norm associated with $\boldsymbol{\theta}$.

The multi-environment framework requires solving for N forward and backward passes for every parameter update. However, these evaluations could be performed in parallel to improve runtimes and could be batched also across multiple environments. We repeat the same analysis as in the previous section, applying high noise to the observed data and using a batch of 20% of the observation points to update $\boldsymbol{\theta}$ during the optimization loop. The results for $N = 1, 3, 5$ environments are shown in Fig. 7.

The increase in the learning convergence as the number of environments increases is evident, as the cost function drops by one order of magnitude compared to the single-environment scenario for an observation time of T =10 min. The increase in performance between 3 to 5 environments is much less significant, hinting that saturation with respect to the number of environments is to be expected.

Table 2: Mean coefficients obtained during the model training, alongside their respective standard deviation for the multi-environment network. The assimilation of each case was repeated 10 times.

No. of tanks	min $\mathcal{J}$	θ_0	θ_1	θ_2	θ_3	θ_4	θ_5
1	3.8e-2	134.5 ± 16.3	10.0 ± 3.6	49.6 ± 5.5	2.0 ± 0.3	18.1 ± 19.2	10.0 ± 0.6
3	3.9e-3	137.3 ± 19.9	10.6 ± 4.0	49.8 ± 0.7	2.0 ± 0.1	21.3 ± 22.8	10.0 ± 0.1
5	6.9e-3	138.7 ± 32.8	10.2 ± 3.4	50.0 ± 4.8	2.0 ± 1.3	19.3 ± 2.2	10.0 ± 10.7
Reference	-	140.0	10.0	50.0	2.00	20.0	10.0

Like in the previous section, Table 7 collects the average and standard deviation of the identified parameters over 100 realizations in the case of multiple environments. The accuracy in the detection is comparable, although the standard deviation grows for some coefficients (e.g. θ_4 and θ_5). This might be due to the relative importance of these terms with respect to the various scenarios considered: θ_0 strongly influences the model performance in the presence of sloshing, but the relative importance of sloshing events over the five scenarios is reduced with respect to the first environment as other physical mechanisms are more present.

5. Conclusions

We presented a multi-environment real-time data assimilation framework for the data-driven thermodynamic modeling of cryogenic fuel tanks.

The implemented approach sets up an optimization problem in which the error between system observations and model predictions must be minimized by acting on closure parameters. The model is based on a lumped

formulation of mass and energy balances for each of the system's control volumes (i.e., the vapor, liquid, and solid walls), and the optimization is carried out by combining a quasi-Newton approach with the adjoint-based evaluation of the cost function gradients.

The training data is collected by multiple environments, i.e. different tanks undergoing various operating conditions (e.g., sloshing, filling, etc.). To provide the first proof of concept of the proposed framework, synthetic data generated through the model was used as a reference for the learning algorithm. The heat transfer closure relations in this model depend on six closure coefficients. The assimilation algorithm aimed to identify these from noisy pressure and temperature observations, which simulate measurements sampled from multiple fuel tanks.

Various tests were performed for the data assimilation applied to a single environment: we assessed the impact of measurement noise on the training data and the effect of 'mini-batches' in the gradient computation alongside the duration of an observation within which the assimilation is carried out. Remarkably, it was found that measurement noise improves the data assimilation, allowing for better identifying the underlying coefficients in shorter observation times. Similarly, an optimal batch size of 20% of the available data produced systematic improvements in the assimilation convergence. Finally, further improvements in the assimilation were achieved in a multi-environment scenario considering three or five tanks undergoing widely different loads and control scenarios.

To conclude, this work provides a solid proof of concept for applying a multi-environment data assimilation framework for the data-driven calibration of thermodynamic models of cryogenic tanks, potentially enabling model predictive control in thermal management systems. In the era of the fourth industrial revolution, where intelligent sensors are becoming widely available, the perspective of deploying the proposed multi-environment assimilation to a large fleet of heavily instrumented tanks appears particularly promising.

Abstract:

The implementation of new low-carbon technologies for electricity generation and storage will involve the use of new resources such as hydrogen. In this sense, the use of hydrogen fuel cells will make it possible to store and transport energy for subsequent use by industry or other consumption. However, these devices generate large amounts of heat, which reduces their electrical efficiency. For this reason, recent studies have focused on the use of carbon allotropes, such as graphene, as heat sinks. This work presents a reduced model of a hydrogen fuel cell with graphene sheets, which has been subjected to several experimental tests, varying its heating and cooling conditions. Thus, the main objective of the experiment was to find out how the graphene sheets behave under different heat gradients and to assess their suitability as a heat sink. Specifically, temperature values, gradients and heat maps have been obtained in the different cells that make up the experimental prototype. In this way, the high performance of graphene as a heat sink in hydrogen fuel cells has been confirmed.

Keywords:

Heat dissipation; graphene; hydrogen fuel cells; experimental test rig.

1. Introduction

Hydrogen, the most abundant chemical element in nature, is a low-carbon resource whose only emission when burned is water vapour. This inert gas has been used in industry since the beginning of the 20th century and today, thanks to the stabilisation of its volatility, it has begun to be used in the automotive and aerospace industries [1]. The main advantage of this fuel is that it does not emit polluting gases to atmosphere. It is this last characteristic that has recently attracted increasing interest. In fact, the World Hydrogen Council (WHC) estimates that by 2030 the energy generated by the use of this green fuel will reach 3000 TWh/year [2].

Hydrogen energy is stored using electrochemical devices called fuel cells, where chemical energy is converted directly into electricity. The fuel (hydrogen) and comburent (oxygen) undergo a chemical exchange to produce water and electricity in the form of direct current and heat [3]. There are several types of hydrogen fuel cells, depending on the type of electrolyte used, which determines the type of chemical reactions that take place in the cell (see Table 1).

Table 1. Classification of hydrogen cells according to electrolyte type [3].

Fuel cell	Proton Exchange Membrane Fuel Cell (PEMFC)	Phosphoric Acid Fuel Cell (PAFC)	Molten Carbonate Fuel Cell (MCFC)	Solid Oxide Fuel Cell (SOFC)
Electrolyte	Solid polymer	Phosphoric acid	Molten carbonates	Solid polymer
Operating temperature (ºC)	60 – 80	200 – 250	600 – 700	50 – 120
Power range (kW)	5 – 250	5 – 150	100 – 2000	5
Advantages	Low temperature	Accept impure H_2	Cogeneration	No fuel reforming required
Applications	Transport	Electricity generation	Electricity generation	Electricity generation
Efficiency	34%	38%	48%	47%

These devices have among their characteristics the need to operate in an optimum temperature range to achieve high performance and minimise their degradation [4]. Specifically, the most common ways of removing excess heat inside hydrogen cells are free convection, condensers, heat sinks and cooling plates [5]. Heat dissipation by convection is therefore the simplest system, since all that is done is to add fins to the cell interfaces and leave them in contact with air, so it is only feasible at low temperatures [6]. Dissipation by condensers or cooling plates involves much more complex designs and the incorporation of devices that force the movement of a fluid (water or air) to force this dissipation, so they are used in batteries with high temperature ranges [7]. Finally, the use of heatsinks is based on the concept of thermal conductivity to transport heat to a cold source (passive or active). This implies the use of different materials that have adequate thermal conductivity behaviour (K in W/mK) [8].

In the specific case of heatsinks, the material from which they are made is particularly important, as it will transfer heat more or less efficiently depending on its thermal conductivity. In addition, other properties such as anisotropy, size, aspect ratio or the orientation of its atomic structure are key to ensuring proper heat exchange [9]. Up to now, the main materials used to dissipate heat in hydrogen fuel cells have been steel, aluminium and copper, the latter being the most suitable but also the most expensive [10]. However, the use of new polymers and carbon-derived materials (allotropes) is taking over much of the research into heat dissipation in hydrogen fuel cells.

The most important compound of carbon allotropes is graphene, since it is the basic element from which other materials such as graphite, fullerenes or carbon nanotubes (CNTs) are obtained. On the one hand, the main properties of these compounds are a well-defined atomic structure [11], high thermal conductivity (≈ 2000 W/mK), low coefficient of thermal expansion, strong mechanical and chemical resistance and anisotropy [12]. On the other hand, they have the disadvantage of being technically difficult to produce, and their high price undermines their competitiveness compared to other common materials. In fact, these materials have only been studied using advanced numerical models and, after sintering in the laboratory, they have been thermally characterised [13].

For example, in the research by Bahru et al…, a study is carried out using different techniques to characterise graphene, determining some thermal parameters according to the manufacturing method used (thickness, K or thermal resistance) for its subsequent use as a heat dissipating material in fuel cells [14]. In addition, the paper by Sun et al. carried out a numerical simulation of the heat transfer phenomena that occur in high-power LED light emitters, complementing the study with experimental tests based on thermography [11]. Finally, the article by Suzsko et al. presents a numerical analysis of the anisotropy of graphene for its use as a dissipator in high-efficiency microprocessors and its comparison with other materials [15].

In this sense, the present paper carries out an experimental study on the use of graphene sheets for heat dissipation inside a hydrogen fuel cell. For this purpose, a reduced scale model of a hydrogen fuel cell has been designed and fabricated, which has been subjected to a series of experimental tests simulating the heat exchange processes that occur during the operation of the cell. In each of the tests, temperature, gradient and heat map values were obtained to study the behaviour of graphene as a heat spreader.

2. Materials and methods

2.1. Experimental model

To study the thermal conductivity of graphene as a heat spreader, a reduced model of a hydrogen cell was designed, manufactured and studied in different experimental tests. In addition, to know its behaviour under different operating conditions, three different cases were simulated: Case 1, 2 and 3 (see Figure 1). In cases 1 and 2, passive cooling is used since the fins (case 1) and the graphene solid (case 2) are in exclusive contact with air. In case 3, however, both the fins and the graphene solid are in direct contact with a liquid cooling unit (active cooling).

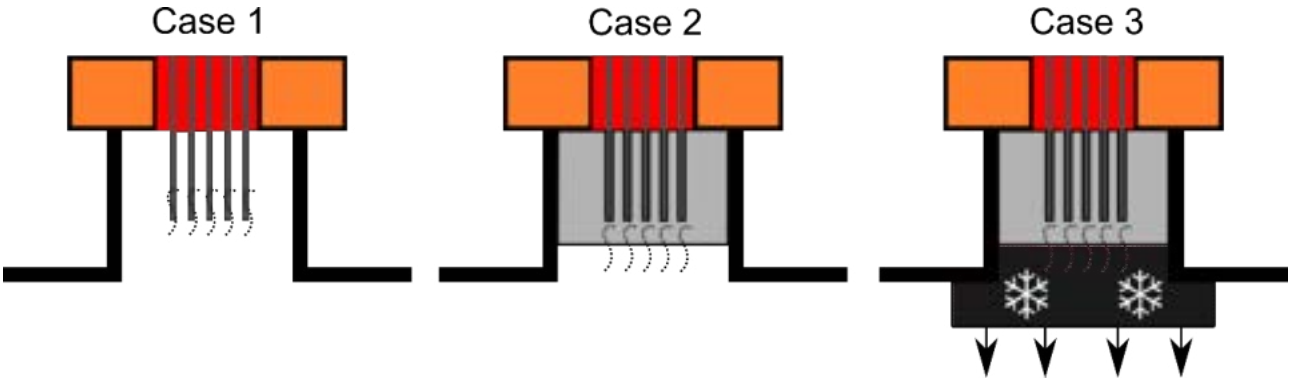

Figure 1. Geometry of the different cases implemented.

In all three cases, the functional scheme of the experimental model was the same. Specifically, the battery is made up of 5 identical cells placed one after the other. Each cell contains a heating pad with a maximum power of 5 W and a size of 100x50 mm, powered by a DC power supply. This makes it possible to control the operating temperature range of the system. This pad is flanked on both sides by a thermal interface with a conductivity of 3 W/mK to ensure heat transfer between cells. In turn, between two successive cells, a 0.5 mm thick graphene sheet measuring 120x50 mm has been placed to channel the heat flow towards some external fins where the cooling (passive or active) will take place. Finally, the whole system is supported by a 20 mm thick wooden case and a clamping system that ensures suitable contact between all the layers. Figure 2 shows a photograph of the implemented scale model and the location of the temperature sensors in each layer.

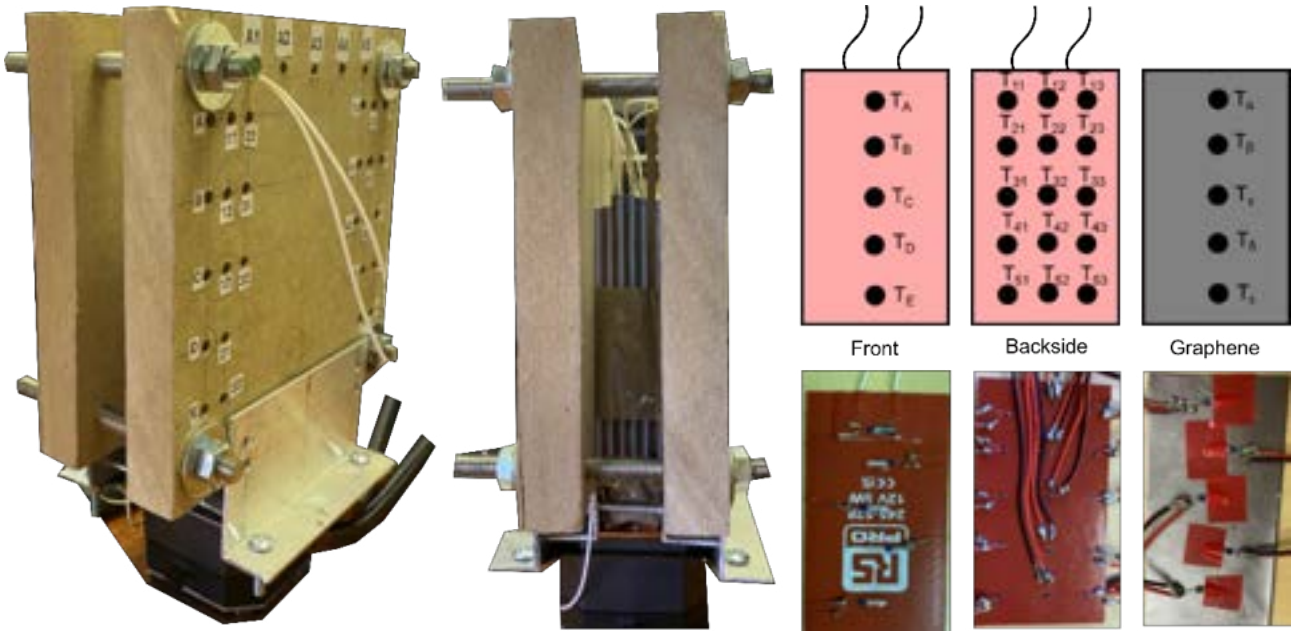

Figure 2. Photograph of the reduced experimental model and location of temperature sensors on each sheet of the fuel cell.

The parameter used for the study was temperature, using resistance thermometers according to the required accuracy of measurement. These sensors were only placed in the central cell of the reduced model because it was considered that this is the section where the greatest amount of heat is generated and therefore the study will be more interesting. Thus, as shown in Figure 3, fifteen temperature sensors were placed in an array on the back (T_{ij} ... $T_{(i+4,j+2)}$) and five temperature sensors on the front (T_A ... T_E) of the heating pad. In this way, the first ones make it possible to obtain a map of the heat distribution over the entire surface where the heat is generated, while the second ones were placed along the centre line to obtain the temperature gradient in the heating pad. In addition, five temperature sensors were placed along the axis of the graphene sheet (T_α ... T_ϵ) and one additional temperature sensor in the lamellar area (T_{flap}). In this way it was possible to obtain the temperature gradients in the carbon allotrope. Finally, it should be noted that several temperature sensors resistors were also used to obtain the temperature in other parts of the model: the contact zone between the graphene and the cooling unit (T_{con}), and two to obtain the ambient temperature on the surface of the case (T_m) and in the room (T_{amb}).

The temperature data are recorded using a data acquisition unit (model DAQ970A) for subsequent analysis. In addition, the cooling unit used (model iCUE H150i ProXT) can be controlled by computer, allowing the heat dissipation of the experimental model to be varied. All the tests were carried out in the maximum heat extraction mode. The experimental test rig used is shown in the following photograph (see Figure 3).

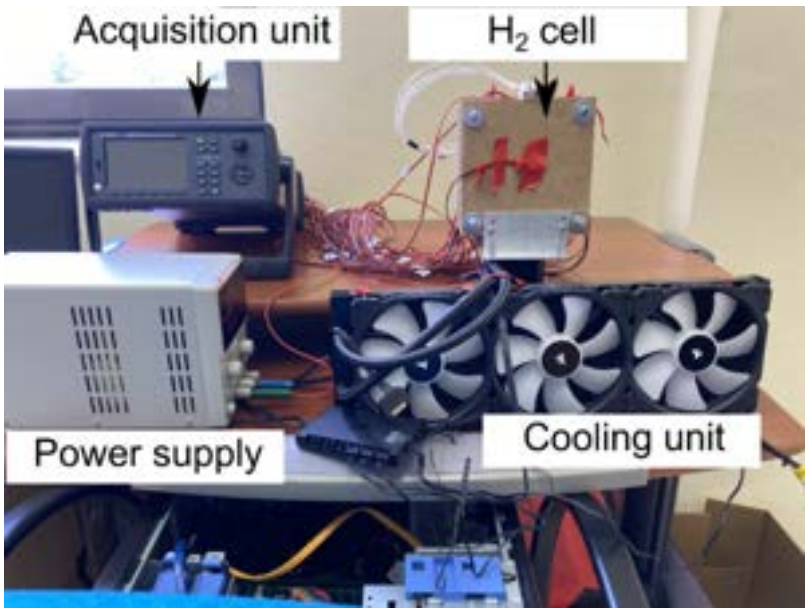

Figure 3. Experimental test rig designed and used for experimental tests.

To minimise the influence of external effects on the experiment, a constant temperature of 23°C was maintained in the room through the use of an air-conditioning unit. In addition, the prototype has been protected from solar radiation due to the use of opaque curtains that prevent the penetration of the sun's rays into the interior of the room. Finally, it should be noted that the effect of artificial convection was not considered relevant during the tests, since the air-conditioning unit kept the temperature values constant.

3. Results and analysis

For each of the cases implemented, tests were carried out focusing on the behaviour of the graphene sheet, while at the same time confirming the correct functioning of the heating pad. In this way, it was possible to obtain the temperature variation over time, the temperature gradient along the central part of the graphene sheet and the thermal maps in both materials.

The test consisted of switching on each of the heating pads with a power of 1 W, producing a heating phase of the stack for 40 minutes. This simulates the heat that would be generated inside the battery during operation. After this time, the power supply is switched off and the cooling phase begins. In cases 1 and 2 the cooling was passive (natural convection), while in case 3 the cooling unit remained on throughout the test (heating-cooling phases). The tests were repeated twice, obtaining consistent and reproducible results.

In case 1, the curves of the temperature variation with time during the whole duration of the test and the variation of the temperature gradient along the length of the sheet at the moment t = 40 min were obtained (see Figure 4).

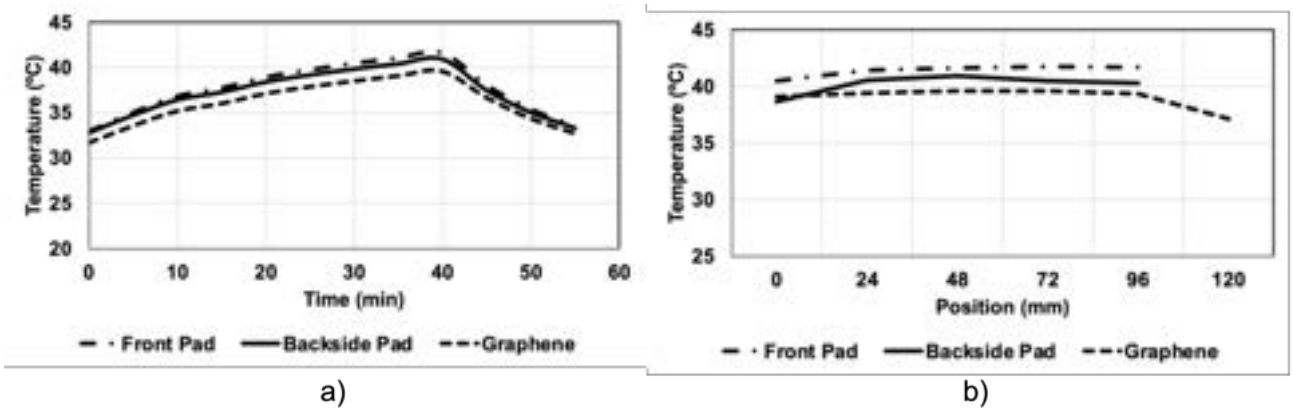

Figure 4. a) Temperature variation throughout the test and b) temperature gradient along the central section of the pad and graphene at t=40 min. Case 1.

For case 2, the same curves have also been obtained (see Figure 5).

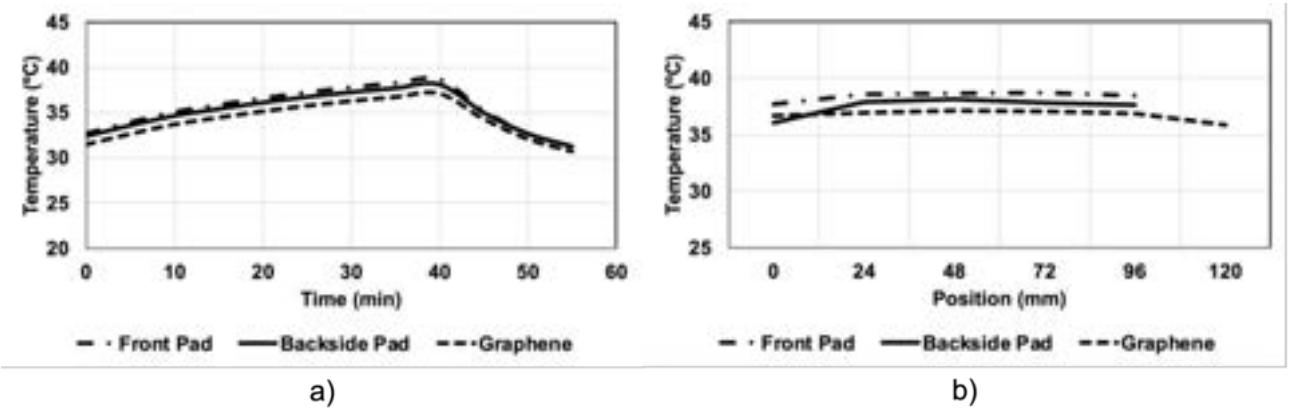

Figure 5. a) Temperature variation along the whole test and b) temperature gradient along the central part of the pad and graphene at t=40 min. Case 2.

Finally, Figure 6 shows the same graphs as above but for case 3.

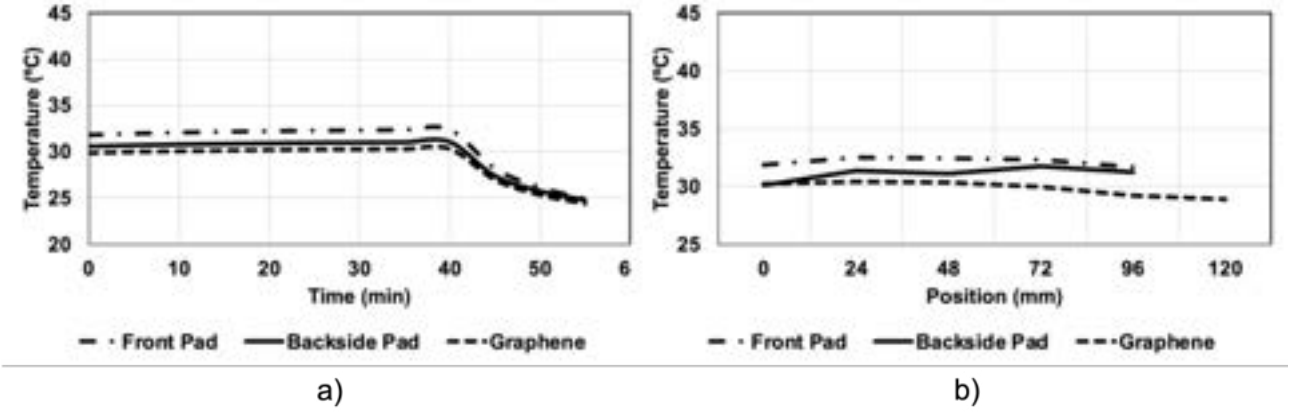

Figure 6. a) Temperature variation during the test and b) temperature gradient along the middle part of the pad and graphene at t=40 min. Case 3.

Note that in all cases both the back and the inside of the pad reach a higher temperature than the graphene sheet, which corresponds to reality as it is the heat source. Furthermore, looking at the temperature gradients, the pad still reaches a higher temperature than the graphene. It should be noted that the line representing the graphene sheet reaches up to 120 mm, since this position corresponds to the fins or the contact with the cooling unit, depending on the case considered. These results confirm that the equipment worked correctly in the three experimental cases considered. In addition, Figure 7 shows the heat maps obtained in the back of the heating pad in cases 1, 2 and 3.

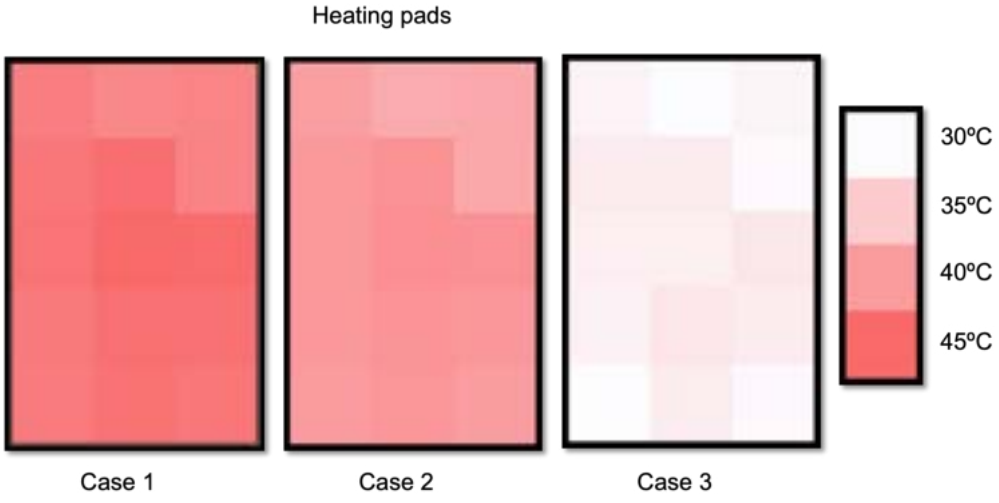

Figure 7. Heat maps for all three cases on the backside of the heating pad.

It can be seen that, in all cases, the temperature differences are less than 275,15 ºK, so it can be considered that the entire surface of the heating pad has a homogeneous behavior, confirming its correct functioning. Focusing on the graphene sheet, Figure 8 shows a comparison of the three experimentally studied cases.

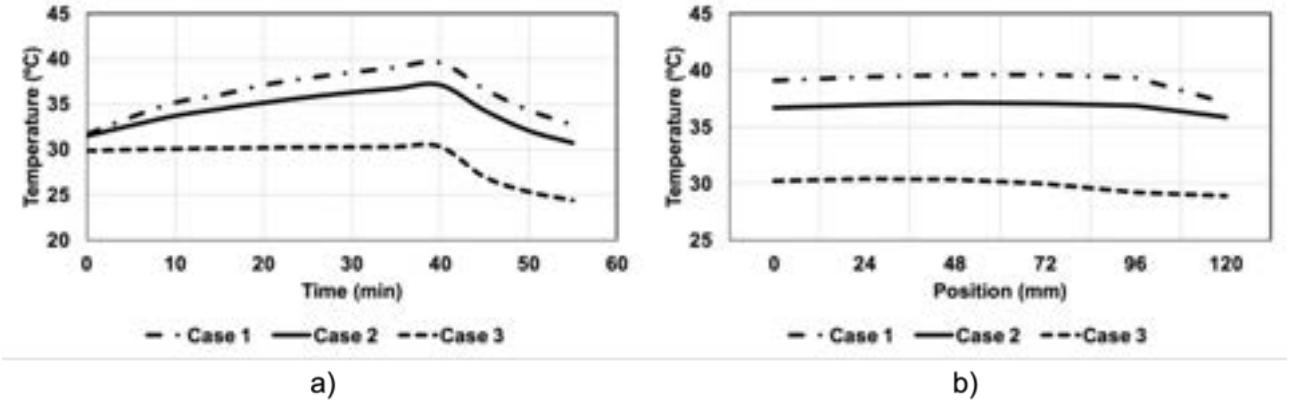

Figure 8. Comparison between the three cases considered: a) temperature variation in the graphene during the test and b) temperature gradient along the graphene sheet at t=40 min.

On the one hand, looking at Figure 8a, we can see that in the passive cooling cases, the graphene gradually increases its temperature until, at t=40 min, it abruptly starts its cooling phase. However, in case 3, since the cooling unit is on throughout the test, we can see how the graphene maintains a constant temperature during the heating phase, thanks to its thermal homogeneity properties. Then, from t=40 min, its temperature drops abruptly as the cooling unit actively removes the heat.

On the other hand, in Figure 8b, the temperature gradients in the central part of the graphene sheet show a negative slope to the left, i.e. the heat extraction is at the 120 mm position. Moreover, this slope is weak due to the latent isotropy in the graphene, which acts as a suitable heat sink.

4. Conclusions

The development of new low-carbon technologies for electricity generation and the construction of devices that allow more effective energy storage will be key to addressing future energy scenarios. In this sense, hydrogen-based technology will play a fundamental role through the development and implementation of batteries that allow safe and effective energy storage. However, these devices generate large amounts of heat, which significantly reduces their efficiency. To improve the efficiency of these devices, carbon allotropes such as graphene have recently been used. One of the many properties of these materials is their high thermal conductivity, which makes them ideal for use as heat sinks. Recent research has been based on the in-depth characterisation of this new material from a technical point of view, achieving in some cases conductivity values close to 6000 W/mK.

This publication shows an investigation through the construction of a reduced hydrogen cell model to study how graphene works as a heat sink in these devices. Specifically, three different cases were carried out in which the cooling conditions (passive and active) were varied. In this way, the aim is to verify that graphene can be used as a thermal conductor, allowing optimal heat extraction inside hydrogen cells. To this end, the temperature variation at different points of a graphene sheet under heating and cooling conditions was studied. In addition, the temperature gradients and their variation with the position in the material sheet itself have been calculated by studying the thermal slopes. In both cases, it has been confirmed that the heat dissipation takes place towards the location of the fins and the cooling unit, thus presenting a suitable thermal homogeneity.

In particular, graphene performs very well as a heat spreader, with temperature differences of less than 2ºC achieved along the entire length of the sheet. Moreover, when the same graphene surfaces are used to dissipate heat to the outside (cases 1 and 2), the temperature does not increase by more than 15ºC with respect to the ambient temperature. Finally, if a sufficiently powerful active cooling unit is used, the temperatures inside the cell are only 3ºC higher than the ambient temperature.

From the results obtained, it was found that the high thermal conductivity of the graphene allows efficient heat extraction to the cooling points. In addition, the graphene sheet has a very homogeneous behaviour, so that its entire surface reaches practically the same temperature, which translates into efficient heat transport.

Future work will validate a numerical model based on CFD, which will allow the simulation of passive and active cooling conditions, so that it will be possible to vary the heat extraction scenarios. It will also be possible to test other materials used as heat sinks, such as aluminium or copper. It is also planned to repeat the experimental tests but with different materials and compare the results with those presented in this article.

Acknowledgments

This work was carried out in the framework of Next Generation Heat Sink Design Project (Reference AYUD/2021/57485), funded by Principality of Asturias through FICYT and co-funded by ERDF. Also, the authors would like to thank the company The Next Pangea for their participation and collaboration.

Abstract:

This work applies techno-economic optimisation modelling to investigate how electrification of the basic material industry (ammonia, cement, plastics, and steel) impacts hydrogen production costs when considering flexibility options for the electrified industry. The context of the work is a zero-carbon emissions energy system of the EU, including future electricity demands from transport, heat, and industry.

The modelling results show that in the future electricity system, the lowest hydrogen production cost is the outcome of the production with full flexibility, i.e., the flexibility of time and location, and flexibility of CO_2 utilisation. Among the flexibility options, flexibility in time, i.e., the ability to follow electricity price variations, gives the largest reduction in hydrogen production costs in comparison to the scenarios without industrial flexibility options. With flexibility in location, it is possible to utilise solar power sites and remote areas for wind sites to satisfy electricity demand from industry. The difference in hydrogen production cost between scenarios with different combinations of flexibility options decreases with the size of the hydrogen demand. The decreased value of industrial flexibility when electricity demand from industry grows is due to the reduced access to sites with good conditions for VRE and some regions invest in nuclear power which benefits less from the industrial flexibility options. Still, even with the electrification of all ammonia, cement, steel and plastics production in the EU, there remains a value in industrial flexibility options.

1. Introduction

In the coming decades, as efforts to meet climate targets intensify, the demand for hydrogen within Europe is expected to significantly increase [1]. Hydrogen has the potential to play a crucial role in eliminating carbon dioxide emissions in the industry and transport sectors [2].

The production of basic materials (ammonia, cement, steel, and plastics) accounts for 70% of European industrial CO_2 emissions (2020), including energy and process-related emissions [3]. The basic materials industry faces two main challenges in achieving carbon neutrality: providing high-temperature heat without carbon emissions, and mitigating process emissions. The decreasing costs and low-carbon environmental impacts of wind and solar power, along with the potential to utilize low-cost electricity for flexible consumers, have made direct and indirect (through hydrogen) electrification a key pathway towards electrification of the basic materials industry [4]. Consequently, there are several ongoing projects related to hydrogen deployment in the basic material industries [5,6].

To implement and utilize hydrogen effectively for emissions reduction, it is crucial to study and analyse the cost of hydrogen. Calculating the cost of hydrogen produced through electrolysis commonly involves using the levelized cost of electricity (LCOE) from wind or solar power, combined with an assumed cost and capacity factor for the electrolyser [7]. In the method of calculating the cost of hydrogen using LCOE is assumed that hydrogen is always available at a certain cost, independently of when and how much hydrogen is required. In addition, the possibility of hydrogen production which follows the electricity price variations using hydrogen storage is not considered. An average annual cost for hydrogen can be a useful benchmark when comparing different energy systems in terms of the role that hydrogen can play and at what cost. However, consideration of the operational flexibility of hydrogen production (including both investments in over-capacity and storage) is an important factor when designing new industries that plan to use hydrogen in their processes.

Walter et al. [8] have shown the impacts of the hydrogen demand (varying it from 0 TWh_{H2} to 2,500 TWh_{H2} in steps of 500 TWh_{H2}) on the future European zero-emission electricity system, taking into consideration

flexibility in time (hydrogen storage and investments in overcapacity of hydrogen-consuming industries) and location. They find that the scenarios implementing flexibility options (flexibility in time (by means of both overcapacity and storage), and in location) for the electrolyser have the lowest production costs. However, the location of future industrial plants (including commodities trade) was not analysed in the above works.

By implementing a techno-economic optimisation model of the European electricity system, Öberg et al. [9] have shown that flexible operation of the electrolyser, i.e., the ability to follow electricity price variation due to overcapacity of the electrolyser and hydrogen storage capacities, have significant impacts on the cost of hydrogen. Unlike Walter et al., Öberg et al. considered hydrogen demand connected to its usage, i.e., they consider additional hydrogen demand from transport and industries (ammonia, cement, and plastics). They conclude that the characteristics of the hydrogen demand also impact hydrogen production costs. Flexible operation of industry (i.e., overcapacity is available) can reduce the cost of hydrogen production by up to 35% compared to constant operation of the industrial units. However, the model developed by Öberg et al. does not account for the additional cost for overcapacity of industrial units and storage of the products or intermediate products.

The studies from [8,9] have also shown that flexibility in the time of the electrolyser can have a major influence on the hydrogen production cost. The impacts of industrial electrification on process design (investments in industrial overcapacity and available commodities storage options) are not studied in the previous works.

Therefore, the aim of this work is to further improve the understanding of the electrification of industries (ammonia, cement, plastics, and steel) impacts on the hydrogen production cost in systems with high shares of VRE taking into consideration industrial flexibility options (flexibility in relation to time, location and CO_2 utilisation). We address the following research questions:

- How the potential future electricity demands from industries that have different types and levels of flexibility influence the cost of hydrogen?
- How does electrification of industry influence a cost-efficient spatial distribution of new locations of electrified industrial plants?

1.1. Electrification of industry

Table 1 lists the assumptions made on electrification options for the basic materials industry, including annual direct electricity and hydrogen demands. Direct electrification refers to the direct use of electricity as an input (plasma rotary kiln, EAF, electrified heat of steam cracker). Indirect electrification is the production of hydrogen and hydrogen-rich fuels and feedstocks from electrolysis.

Table 1. Annual assumed electricity demand for the basic materials industries.

Industry	Electrification option	Basic materials production in the EU[a], Mt	Annual direct electricity demand, TWh	Annual hydrogen demand, TWh_{el}	References
Ammonia	Power-to-ammonia	21	20	185	[10,11]
Cement	Plasma	133	174	-	[12,13]
Steel	H-DR	115	95	279	[14–16]
Plastics	Thermochemical recycling	38	349	436[b]	[17,18]

[a] The geographical scope corresponds to the area of the EU (excluding Cyprus and Malta), UK, Norway and Switzerland subdivided into 22 regions corresponding to major bottlenecks in the transmission grid. These investigated regions are: Northern Sweden (SE_N), Southern Sweden (SE_S), Northern Germany (DE_N), Southern Germany (DE_S), Estonia, Latvia and Lithuania (BAL), Northern Poland (PO_N), Southern Poland (PO_S), Ireland (IE_T), Norway (NO_T), Portugal and Western Spain (IB_W), Eastern Spain (IB_E), Northern France (FR_N), Southern France (FR_S), Switzerland and Northern Italy (ALP_W), Southern Italy (IT_S), Austria, Czech Republic and Slovakia (ATCZSK), Croatia, Slovakia (Slovak Republic) and Hungary (CRSIHU), Romania, Bulgaria and Greece (ROBGGR), Belgium, Netherlands and Luxembourg (BENELUX), Finland (FI_T), Scotland (UK_N) and Southern UK (UK_S).

[b] Depends on CO_2 utilization, i.e., the CO_2 emissions that arise from the process can be captured and converted to olefins through a synthesis process, or they can be captured and stored.

1.2. Process description – electrified ammonia production

The electrified ammonia production is the most hydrogen intensive commodity produced by basic materials industries investigated in this study, with an average hydrogen intensity of 8.6 MWh_{el} per 1 t of ammonia (cf. Table 1).

Figure 1 shows that the electrified ammonia production process includes electrolysis for H_2 production, an air separation unit (ASU) for nitrogen production and the ammonia synthesis via the Haber-Bosch (HB) process.

An ASU uses a cryogenic distillation process to separate ambient air into nitrogen, oxygen, and argon. All products can be stored in storage tanks [19]. The inlet air compressor is the main electricity consumer of an ASU [20]. The Haber-Bosch process combines hydrogen and nitrogen under high pressure and temperature. The HB process is normally optimized for continuous mass production, however, reconfiguration for dynamic production is possible [11]. The total electricity consumption of the ammonia production process, including electricity for hydrogen is 9.6 MWh/tNH_3.

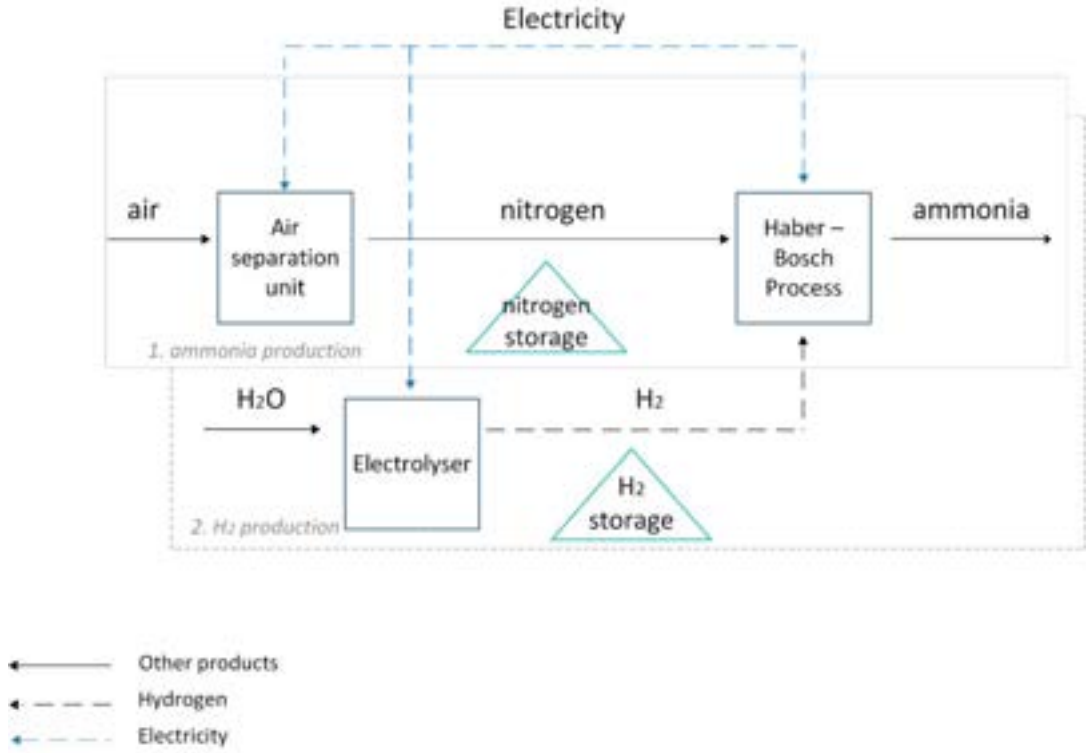

Figure. 1. Schematic representation of the electrified ammonia production process.

A detailed description of the electrification options (cf. Table. 1.) assumed for the basic materials industry investigated in this work is given in [21].

1.3. Industrial flexibility options

Three types of flexibility for the electrified industry were considered in this work: flexibility in relation to time, location, and CO_2 utilisation.

The ability of the industrial unit to vary the output within the load ranges, i.e., operational flexibility, is defined as flexibility in time. The lack of flexibility in time gives the capacity utilisation rate of 100%, i.e., there is no investment in overcapacity and storage. With flexibility in time, storage of commodities (e.g., hydrogen, hot-briquetted iron, nitrogen, and methanol) allows for rescheduling electricity consumption to periods with lower cost when available.

The electrification of the basic materials industry can significantly change cost structures of industrial production and with them the most cost-effective geographic location for production. The optimal location for production may shift from being close to demand and/or raw material supply centres to places where zero-emissions electricity is readily available at low cost, or where there are favourable conditions for CCS [22]. Flexibility in location is defined by the ability to export commodities. With flexibility in location, it is possible to locate new industrial units into regions without existing basic materials industries, increase capacity and/or production in the regions with existing industry, and separate parts of the existing supply chain. Distance-dependent transport costs for commodities are assumed, i.e., we consider the transport distance between regions and the amount of transported commodity. To represent some of the material and immaterial values in the current industrial sites, i.e., regions with existing industries, we apply an investment penalty for investments in new production sites for regions without existing industries: a 50% increase in investment cost—compared to investments in existing sites—for units producing commodities in regions without existing production of that basic material.

For some basic materials, such as plastics, electrification is not enough to eliminate production CO_2 emissions. Here, we assume that for plastics the process-related CO_2 can be captured and converted to olefins through

a synthesis process (CCU mode) and/or captured and stored (CCS mode). The term flexibility in CO_2 utilisation refers to the ability of production units to vary between CCU and CCS.

2. Method

To investigate how the potential future electricity demands from industries that have different types and levels of flexibility influence the cost of hydrogen in EU we deploy the cost-minimising electricity system investment model ENODE (Figure 2). The wide range of the electricity generation technologies considered in the model, including storage and transmission technologies. The model accounts for the economic and technical properties of the technologies, including start-up cost, start-up time and minimum load level of thermal generation. In terms of energy storage technologies, investments in lithium-ion batteries and H_2 storage are possible.

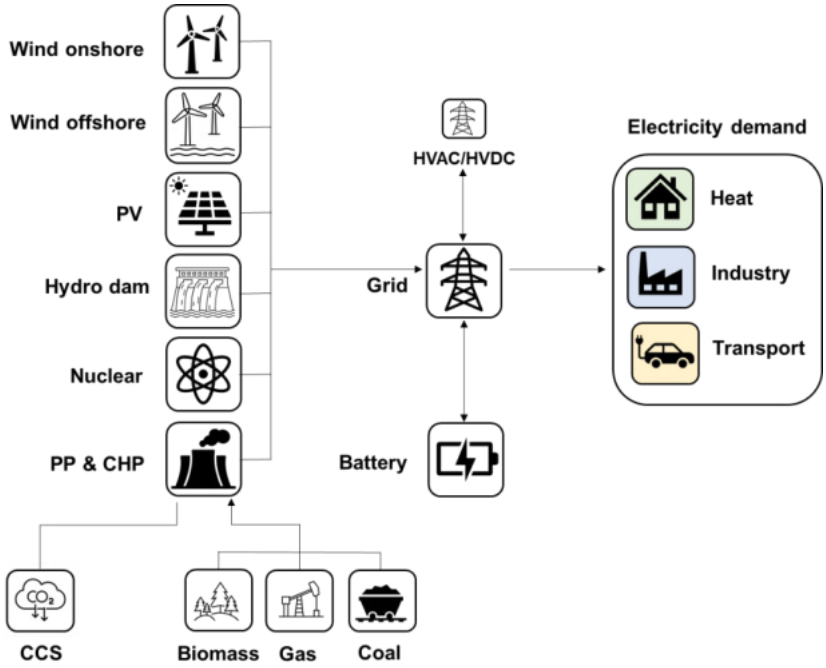

Figure. 2. Schematic representation of ENODE model.

ENODE was designed by Göransson et al. [23] to investigate the interactions between VRE and thermal generation technologies. Our version minimises the cost for investments in and operation of the electricity system and electrified industry, while meeting the demands for electricity and commodities. The objective function is expressed as:

$$min: C^{tot} = \sum_{r\in R} \sum_{p\in P\setminus P^{transm}} i_{p,r}(C_p^{inv} + C_p^{O\&M,fix}) + \sum_{t\in T} C_{p,t}^{run} g_{p,t,r} + \sum_{r_2\in R\setminus r} \sum_{p\in P^{transm}} C_{p,r,r_2}^{inv} i_{p,r,r_2} + \sum_{p\in P^{ind}\cup P^{transm}} \sum_{t\in T} C_{r,r_2}^{transp} e_{p,t,r,r_2}^{pos} + \sum_{p\in P^{plastic}} \sum_{t\in T} C^{st} b_{p,t}^{CCS} \quad (1)$$

where P is the set of all technologies, T is the set of time-steps, and R is the set of the regions. The annualized investment costs, the fixed operational and maintenance costs and the running costs per technology p at time-step t are denoted C_p^{inv}, $C_p^{O\&M,fix}$, and $C_{p,t}^{run}$, respectively. The variable $i_{p,r}$ is the capacity investment per technology p installed in region r, and $g_{p,t,r}$ is the generation of electricity and production of commodities per time-step t and region r, respectively. For the product trade that is transmitted/produced by technologies P^{transm} (the subset of P for transmission lines) and P^{ind} (the subset of P for commodity production units) between regions r and r_2 at per time-step t, the costs C_{r,r_2}^{transp} are considered. The CO_2 emissions $b_{p,t}$ from technology $P^{plastic}$ at time-step t are captured and stored at cost C^{st}.

Equation (2) represents the H_2 balance. Hydrogen is produced in the electrolyser and used to satisfy demand from basic materials industries. Hydrogen can be traded via a pipeline network.

$$g_{P^{Electrolyser},t,r}\eta_p + \sum_{p\in P^{H_2}} z_{p,t,r}^{dis} \geq \sum_{p\in P^{ind}} g_{p,t,r}\, a_p + \sum_{p\in P^{H_2}} z_{p,t,r}^{ch}$$

$$\forall t \in T, \forall r \in R \quad (2)$$

where a_p is the coefficient applied to relate commodities (ammonia, cement, steel, and plastics) production to H_2 demand for technology $p \in P^{ind}$. The efficiency of electrolyser is written as η_p.

The cost of electricity and hydrogen for the basic material industries is calculated according to Eq. (3),

$$C_i = \frac{\sum_t C_{t,i}^{maginal} g_t}{\sum_t g_t} \quad (3)$$

where the marginal cost $(C_{t,i}^{maginal})$ of electricity or hydrogen (i) per time-step (t) is weighted by the amount of electricity or hydrogen demanded by commodities production units (g_t) in each time-step. The marginal cost of electricity is taken as a proxy for the electricity price and is a result of the modelling, i.e., the marginal value from Eq. (1). The marginal cost of hydrogen is the marginal value of Eq. (2). The marginal value reflects the cost to supply one additional unit of electricity or hydrogen to the energy system.

The ENODE model is a green-field model, in which a new system is designed from scratch. A full mathematical description of the original eNODE model is given in [8].

2.1. Electricity demand

In the ENODE model, the electricity demand is classified into four categories: present demand used as a base level for the hourly demand profile and new electricity demand from transport, heat, and industry. The present electricity demand is determined on annual electricity consumption levels of the European countries obtained from Eurostat [24] and is subject to an hourly demand profile obtained from ENTSO-E [25]. The electricity demands from transport and heat are exogenously added to the present electricity demand. The electricity demand from heat is the electricity required to replace individual natural gas-based heating for decentralised heat pumps in Germany and the UK [26]. The electricity demand from the transport sector is modelled based on [27]. Full electrification of the passenger car fleet and partial (60 %) electrification of the heavy-duty vehicle fleet is considered in this model. The annual demand for commodities production (cf. Table 1) is given exogenously while the hourly electricity demand from basic materials industry is endogenous, thus investments in units producing commodities as well as the dispatch of these units are a result of the optimisation. The current production of commodities in the investigated regions is used as the regional demand for commodities in all scenarios to reflect the connection of the basic materials industry to the location of other industries.

2.2. Scenarios description

Figure 3 shows that the scenarios in this work vary in the type of industry that is electrified (ammonia, cement, steel, plastics) and the flexibility options that can be applied (flexibility in time and location and flexibility in CO_2 utilisation, the square under the parameter name indicates "yes" if included). The electrified ammonia industry is used as the reference industry to investigate how the electrification of industries impacts hydrogen production costs, since ammonia production is the most-hydrogen-intensive industry and has the highest operational flexibility among all the industries investigated in this study. The names of the scenarios with all flexibility options start with *Flex*; with limited flexibility in time - *Inflex_time*; with limited flexibility in location - *Inflex_location*; and with both limited flexibility in time and location – *Inflex_time_location*.

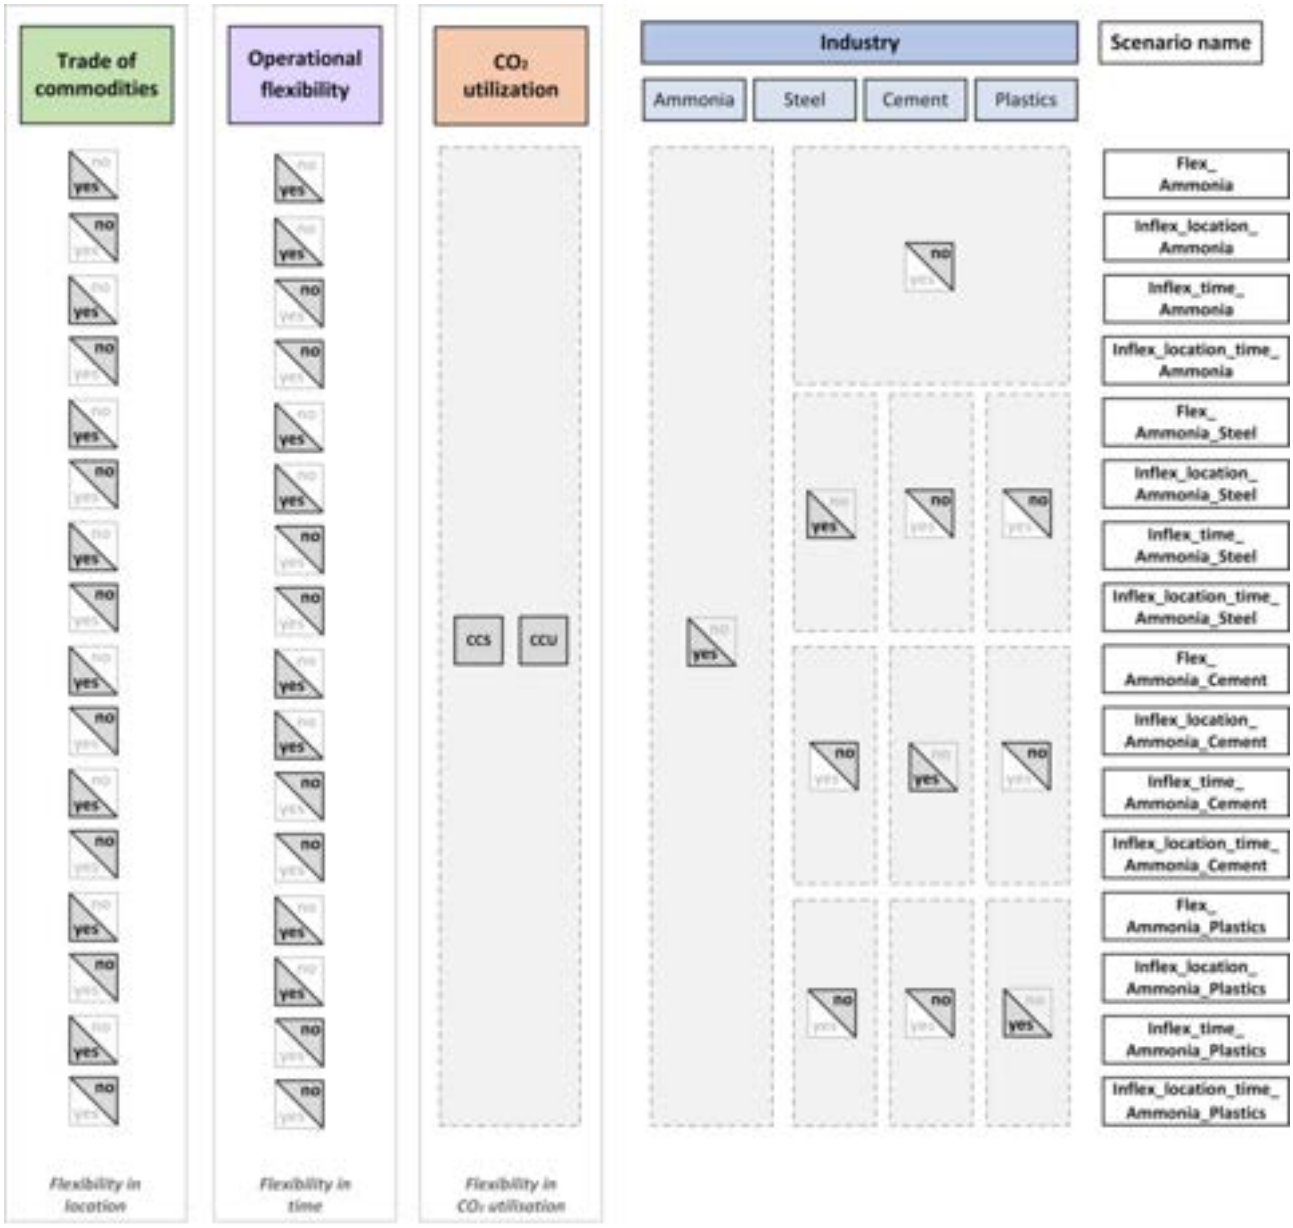

Figure. 3. Schematic overview of the parameters that define the investigated scenarios.

3. Results

The result presentation is divided into the following two parts: how electrified basic materials industries influence the production cost of hydrogen for the investigated scenarios (Section 3.1) and the location and production levels of the electrified industrial unit (for the example of direct reduction shaft furnace (DR shaft)) for the investigated scenarios (Section 3.2).

3.1. Hydrogen production cost

Figure 4 shows the break-down of the hydrogen production cost per MWh for the scenarios in which: only the ammonia industry is electrified; the ammonia and steel industries are electrified; and all the investigated industries (i.e., ammonia, cement, steel, and plastics) are electrified. The model results for the scenarios with electrified ammonia and cement industries, as well as with electrified ammonia and plastics industries are given in Figure A.1, Appendix A. Hydrogen production cost includes the annualized investment cost, the fixed O&M costs, the electricity cost, and hydrogen transportation costs for the investigated scenarios.

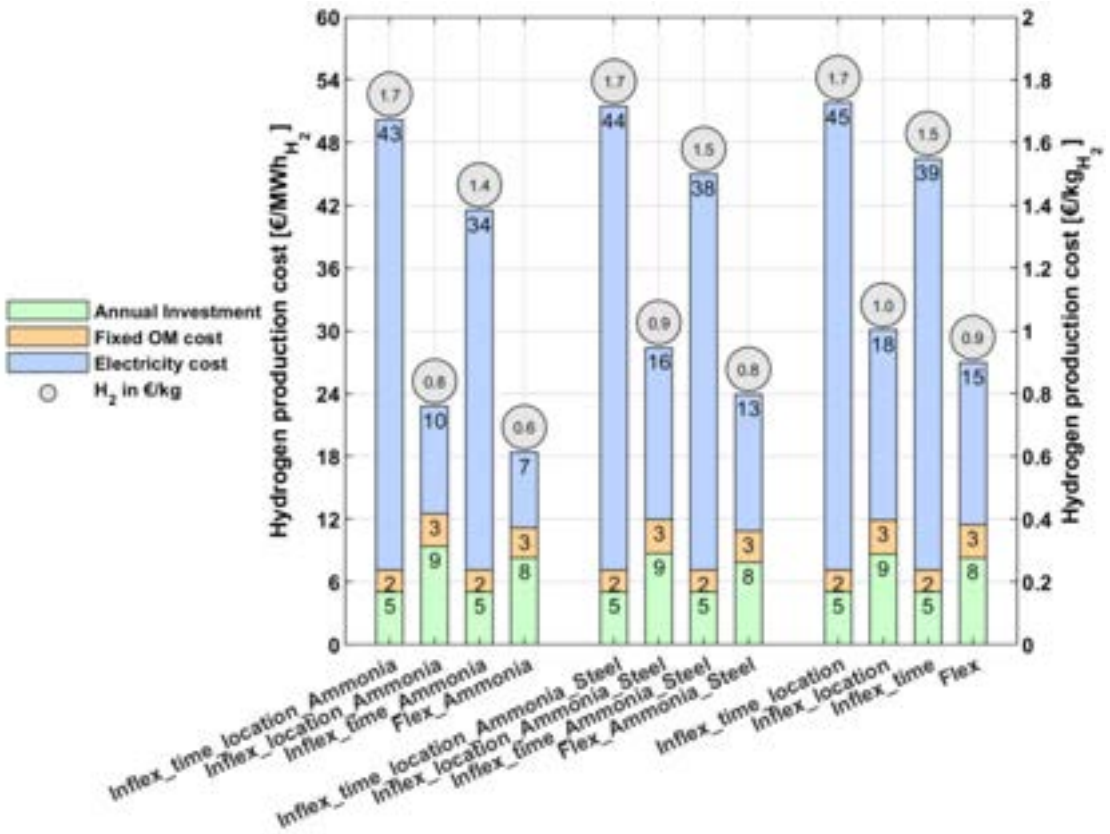

Figure. 4. The hydrogen production cost obtained from the modelling for the scenarios in which only the ammonia industry is electrified, scenarios in which the ammonia and steel industries are electrified, and scenarios in which all industries are electrified (i.e., ammonia, cement, steel, and plastics) are electrified. The scenarios with all flexibility options begin with *Flex*. Scenarios with limited flexibility in time or location are denoted by *Inflex_time* or *Inflex_location*, respectively. Scenarios with limited flexibility in both time and location are titled with *Inflex_time_location*.

The modelled costs given in Figure 4 yield a hydrogen production cost that ranges from 18 to 44 €/MWh$_{h2}$ (corresponding to 0.6–1.7 €/kg of hydrogen) for the investigated scenarios. The relatively low hydrogen cost obtained in this work is due to the ability of the electrolyser to follow electricity price variations. The range of hydrogen costs projected by the IEA is 1.1–4.0 €/kg of hydrogen. The electricity cost constitutes 55% of the total hydrogen production cost obtained from the IEA, if in regions with good access to renewable energy, the cost of electricity (mainly from solar power) for hydrogen production is 14 €/MWh and that the electrolyser operates for 2,600 full-load hours. According to the IEA projections, by Year 2030 the electrolyser investments cost will have decreased to 300–500 €/kW compared to the current levels (1,400–1,770 €/kW), due to the scaling up of electrolyser capacity [28]. Because of the falling costs for electrolysers, BloombergNEF [29]projects that renewable hydrogen could be produced for 0.6–1.4 €/kg in most parts of the world before Year 2050. The current work and other projections [8,9]suggest that two important factors are crucial to decreasing the cost of producing hydrogen: the flexible consumption by the electrolysers of the electricity supplied from VRE; and the scaling up of the electrolyser capacity.

The modelling results show that in the future European electricity system, the lowest cost for hydrogen production arises from production with full flexibility, i.e., flexibility in both time and location, and flexibility of CO_2 utilisation. The limitation of the flexibility in time for the industrial units has a stronger impact on the hydrogen production cost compared with the scenarios in which the flexibility in location is limited. For scenarios with limited flexibility in time, the hydrogen cost increases by 100%, and for scenarios with limited flexibility in location the hydrogen cost increases by 20%, as compared with the scenarios in which all flexibility options are available.

The hydrogen production cost is affected by not only industrial flexibility options but also by commodity demands. The low-medium operational flexibility of plasma kilns makes it challenging to follow electricity price variations. Nonetheless, the electrification of both the ammonia and cement industries, when at least one flexibility option is available, leads to a 1%–4% increase in the hydrogen cost compared to electrifying only the ammonia industry. In contrast, electrification of the ammonia and steel industries results in an 8%–23% increase in the hydrogen cost, and electrification of ammonia and plastics production processes leads to a 2%–17% increase in the hydrogen cost. The lower increase in hydrogen cost when the ammonia and cement

industries are electrified, as compared to the scenario where the ammonia industry is electrified along with steel and plastics production, is attributed to the low total electricity demand from cement production driven by the demand for cement. In other words, the lower hydrogen cost increase can be attributed to the fact that the cement industry requires less electricity in total (under the given assumptions regarding the cement demand) than the steel and plastics industries.

Among the scenarios in which only two industries are electrified, the highest cost for hydrogen production arises when the ammonia and steel industries are electrified. The high electricity demand driven by the steel demand reduces access to sites with good conditions for VRE. Thus, the number of high electricity price events increases, and this diminishes the value of the operational flexibility of the steel production units.

When electrifying the plastics and ammonia industries, flexibility in CO_2 utilisation compensates for the limited flexibility in time. Thus, the ability to switch between CO_2 utilisation modes (i.e., between CCU and CCS) allows the industrial units to avoid the consumption of electricity during high-cost events, which also implies increased costs for feedstock and CCS.

3.2. Locations and sizes of industrial units

Figure 5 presents the location and size of the DR shaft furnace capacity (in ktonnes) for two scenarios (*Flex* and *Flex_Ammonia_Steel*) in which the industrial units have full flexibility. In the *Flex* scenario, all the investigated industries are electrified, while in the *Flex_Ammonia_Steel* scenario, only the ammonia and steel industries are electrified.

Figure 5 shows that electrification of only the ammonia and steel industries, as applied in the *Flex_Ammonia_Steel* scenario, leads to the clustering of the DR shaft furnace capacity around countries that have good conditions for VRE and low-cost access to iron ore, such as FR_N. The electrification of the ammonia, cement, steel, and plastics industries (*Flex* scenario) results in investments, and investments in DR shaft furnace capacity increase in the regions that have existing steel production in UK_S, SE_N and FI_T, as compared with the *Flex_Ammonia_Steel* scenario.

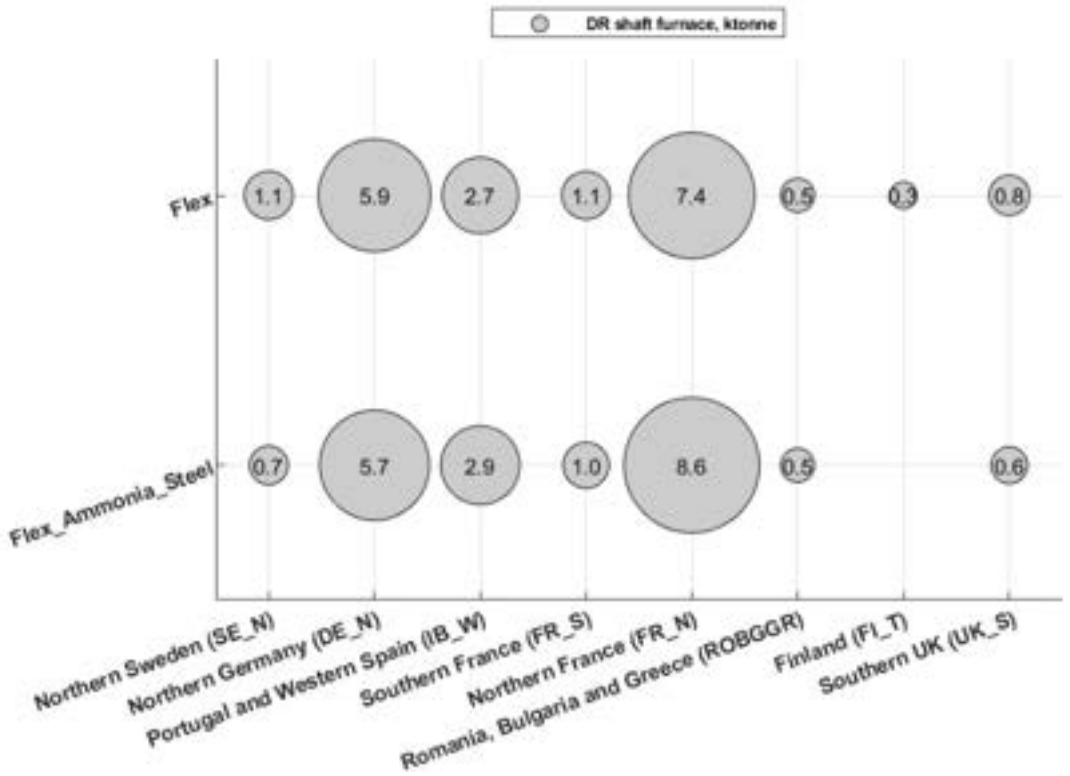

Figure. 5. The modelling results for the regional allocations of the steel production capacities in terms of the DR shaft furnace (in ktonnes) for the *Flex_Ammonia_Steel* and *Flex* scenarios.

The effects of electrification, such as the cost of hydrogen production for the industry, may vary depending on whether one or multiple sectors are electrified simultaneously. Investment decisions regarding industrial units, such as those in over-capacity and storage to take advantage of electricity price variations, which are made by the "first" industry that electrifies its production could impact the investment decisions of subsequent industries. Furthermore, the benefits of the industrial flexibility options provided by electrification might lessen as more industries electrify their production processes. Thus, further analysis is needed to understand the different stages of the industrial transition toward electrification.

4. Conclusions

This work applied a techno-economic optimisation model to analyse and discuss how electrification of energy-intensive basic materials industry impact hydrogen production cost, considering industrial flexibility options. The model is developed for a zero-carbon emissions electricity system of the EU that considers the current electricity demand as well as future demands from the transport, heat, and industrial sectors

The modelled costs yield a hydrogen production cost that ranges from 18 to 44 €/MWh$_{h2}$ (corresponding to 0.6 – 1.7 €/kg of hydrogen) for the investigated scenarios. Full flexibility (flexibility with regards to time and location, and flexibility of CO_2 utilisation) of the energy-intensive basic materials industry yields in the lowest hydrogen production cost.

The results indicate that in a future electricity system with more fluctuating electricity prices (in comparison to today's price fluctuations), the production of the basic materials which follows electricity variations gives lower hydrogen production cost, as compared to the scenarios with the optimised geographical location of industries. The electricity price following production would require investment in over-capacity of industrial units (i.e., electrolyser) and commodities storages (i.e., hydrogen).

In the scenarios with flexibility in location which are defined by the ability to export commodities, the basic materials industry capacity and/or production increase in the regions with existing industry and access to low-cost electricity. As a result, it is possible to utilise solar power sites and remote areas for wind power generation sites to satisfy the hydrogen demand from industry.

Finally, the modelling results indicate that as the demand for hydrogen increases, the difference in hydrogen production cost between scenarios with different combinations of flexibility options decreases. The decreased value of industrial flexibility when the electricity demand from industry grows is due to the reduced access to sites with good conditions for VRE and the fact that some regions invest in nuclear power, which benefits less from the industrial flexibility options.

Abstract

Over the past few decades, data centers have made significant strides in enhancing their sustainability practices. These efforts range from minimizing power usage effectiveness (PUE) and carbon usage effectiveness (CUE) to enhancing water usage effectiveness (WUE). However, it's time for the data center industry to take a groundbreaking step forward. By effectively managing waste heat, data centers can become energy providers, boosting their profitability, and improving their energy reuse effectiveness (ERE) metrics. In this paper, we explore the crucial role of efficient heat management in optimizing the performance of an electrolyzer and maximizing the production of green hydrogen. Specifically, we focus on the importance of maintaining the stack temperature of the electrolyzer within a specific range to ensure maximum efficiency. We then propose a novel and integrated design concept for data centers that combines hydrogen production with district heating. An electrolyzer can be connected to both the data center and district heating systems, enabling the heat management system of the data center (e.g., heat pump) for powering the electrolyzer. Additionally, district heating can be utilized for thermal management of the electrolyzer, further improving the overall efficiency of the system. Additionally, the waste heat produced during the electrolysis process can be harnessed and employed to supplement the district heating system. This symbiotic relationship between the two systems results in a reduction in carbon emissions and improved energy efficiency. Our paper examines the technical feasibility of this proposed system and highlights the potential benefits for data centers and district heating systems.

1. Introduction

Data centers are essential for the modern digital economy, enabling the storage, processing, and transmission of vast amounts of data [1]. However, data centers have become a significant contributor to global energy consumption and carbon emissions, which has led to a growing focus on sustainability in the industry [2]. In recent years, data centers have made significant strides in improving their energy and water usage effectiveness, but there is still untapped potential for waste heat recovery to generate energy and improve their environmental metrics [3]. The energy consumption of data centers (DCs) has significantly expanded in response to the expansion of the information technology industry, which in 2019 used around 3% of the world's electricity supply [4]. The consumption is growing at a pace of 15-20% annually [5]. The electricity needed to run cooling systems accounts for around 40% of the power utilized by DCs [6]. On the one hand, the usage of high-grade electrical energy to fulfill the low-grade cooling DC requirements results in a considerable energy loss of energy flow in DCs [7]. On the other hand, the electric refrigeration systems in DCs often discharge a significant quantity of waste heat to the external environment, which results in urban heat islands [8]. Therefore, it is necessary to enhance the DC energy systems' structure and thermodynamic energy efficiency. If significant quantities of low- and medium-grade waste heat could be efficiently recovered and used for things like building heating, water heating, and refrigeration, DCs may be regarded as energy producers [9]. As a result, data centers (DCs) could fully embrace the concept of prosumers, who simultaneously act as producers and consumers, and surpass the current energy efficiency optimization model, which only considers the consumer perspective. Apart from utilizing waste heat across the system, a DC energy system can be tailored

to the overall energy system, an integrated energy system, or a systematic approach to the energy network. With the expected growth in demand for data-based services and the accompanying power consumption, data centers are seeking cost-effective, sustainable, and dependable ways to power their operations. Hydrogen and fuel cells are viable options that could fulfill these requirements and integrate with a variety of potential benefits.

What is the need for a new design in data centers? There are multiple factors that could drive a departure from the conventional data center design. Data centers have significant power and space requirements, which necessitate considering regional factors such as land and labor costs, access to affordable power, and business-friendly governmental policies when selecting their locations. Stricter air permitting regulations for diesel backup generators in certain regions could reinforce the case for integrating hydrogen and fuel cells. Furthermore, some companies have established corporate strategies to increase their reliance on non-carbon or green fuels, with a few already transitioning to 100% renewables and other co-locators following suit. This provides further rationale for using green hydrogen or locating data centers near wind or other renewable power sources [10].

The literature on sustainable data centers has focused on reducing energy and water consumption, improving energy efficiency, and exploring renewable energy sources. Grange et al. [11] developed an algorithm for scheduling the data center by renewable energy. Their results showed a reduction of brown energy consumption up to 49%. According to Khosravi et al. [12], an ejector heat pump was designed to recover waste heat from a data center for use in a low temperature district heating network in Finland. The study revealed that the use of a water-water heat pump is a viable method for recovering waste heat from data centers. Iverson et al. [13] focused on the design of hybrid renewable energy systems (HRES) for data center applications, leveraging hydrogen storage technology. The aim of their research was to develop an optimal design for HRES that would effectively meet the energy demands of data centers, while minimizing energy costs and reducing the environmental impact of the system.

While these studies provide valuable insights into the potential for waste heat recovery in data centers, there is a need for more research on the specific technical and economic aspects of integrating hydrogen generation into data center infrastructure. This paper aims to contribute to this literature by proposing a novel and integrated data center concept design based on hydrogen production and conducting an analysis to determine its feasibility and potential. This paper proposes a novel approach to data center sustainability, in which waste heat is captured and reused to generate hydrogen fuel. By integrating an electrolyzer into the data center infrastructure, waste heat can be converted into a valuable energy source that can be used for district heating or as an ancillary service. This approach not only increases the overall profitability of data centers but also improves their environmental metrics by enhancing their energy reuse effectiveness. The proposed approach has the potential to transform the data center industry by making waste heat recovery a viable and profitable solution to energy generation. The approach not only improves the sustainability of data centers but also positions them as energy suppliers, which could have far-reaching implications for the broader energy industry. Overall, this paper contributes to the ongoing conversation on data center sustainability by proposing a novel and integrated design that has the potential to enhance both the environmental and economic performance of data centers.

2. Case study

Data centers are characterized by their use of air cooling, the most widely used technique in the sector, to provide low temperature, high capacity, and reliable heat. About 40% of the power utilized by DCs goes to power cooling systems. However, the electric refrigeration systems in DCs often release a significant amount of waste heat into the environment. The current Danfoss design for the data center at Nordborg is depicted in Figure 1. This system uses air cooled system to cool the data center. Danfoss is seeking for an alternate system because the current system is no longer providing economic benefits.

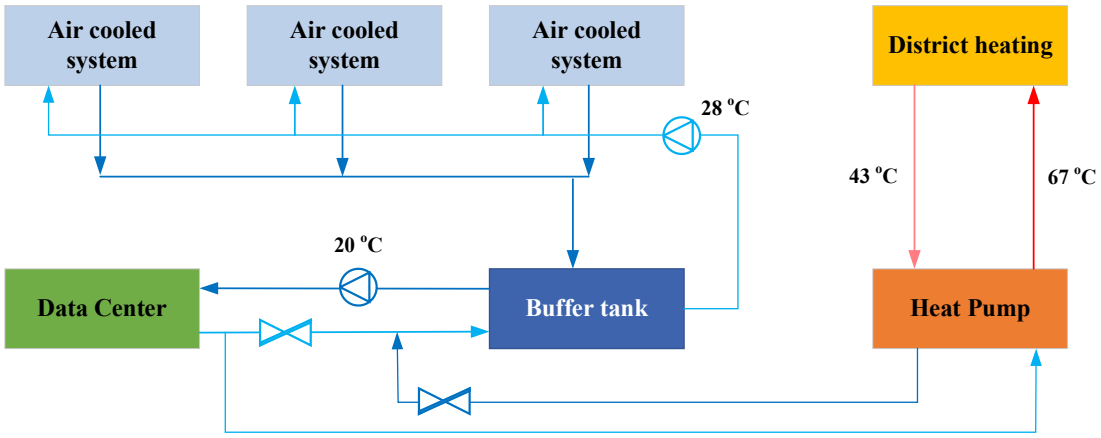

Figure 1. *Danfoss Nordborg data center, the current design.*

3. Material and methods

3.1 The proposed system

The system proposed in this paper incorporates an alkaline electrolyzer into a district heating system, heat pump layout, and data center, with the goal of optimizing the efficiency and sustainability of energy production. As shown in Figure 2, temperature control is a crucial factor in achieving optimal performance of the electrolyzer. To achieve this, the fourth generation of district heating networks is proposed for use with this technology, with the possibility of using the district heating for heat management of the electrolyzer. The heat pump is also an essential component for providing cooling for the data center and can be utilized for heat management of the electrolyzer. The heat pump has an electricity input of 174 kW and is capable of generating 824 kW of heat output and 650 kW of cooling output. The alkaline electrolyzer has a capacity of 2 MWe and produces 16.3 kg/h of hydrogen.

The system is powered by electricity from the NordPool electricity spot market, which is used to meet the electricity demand of the data center, which is 10,932,821 kWh as well as electricity demand for heat pump and electrolyzer. Additionally, the cooling demand of the data center is 3,000,000 kWh. To manage the thermal energy generated by the system, heat storage with a capacity of 6952 kWh and cooling storage with a capacity of 1158 kWh are included in the system design.

Furthermore, the electrolyzer is connected to the district heating network, allowing for the waste heat produced during the electrolysis process to be harnessed and employed to supplement the district heating system. The district heating system can be utilized as a free source for heat management of the electrolyzer. The system model proposed in this paper consists of an electrochemical model, a thermal model, and a model of the cooling system. The electrochemical model simulates the relationship between current and voltage for various operating temperatures and pressures, describing the kinetics of the reactions that take place and providing details required for precisely modeling the creation of heat inside the alkaline electrolyzer. The system proposed in this paper provides valuable insights into the potential for integrated energy systems to improve the sustainability and efficiency of energy production. Further research and development in this area may lead to the widespread implementation of similar systems, resulting in significant improvements in sustainability and energy efficiency.

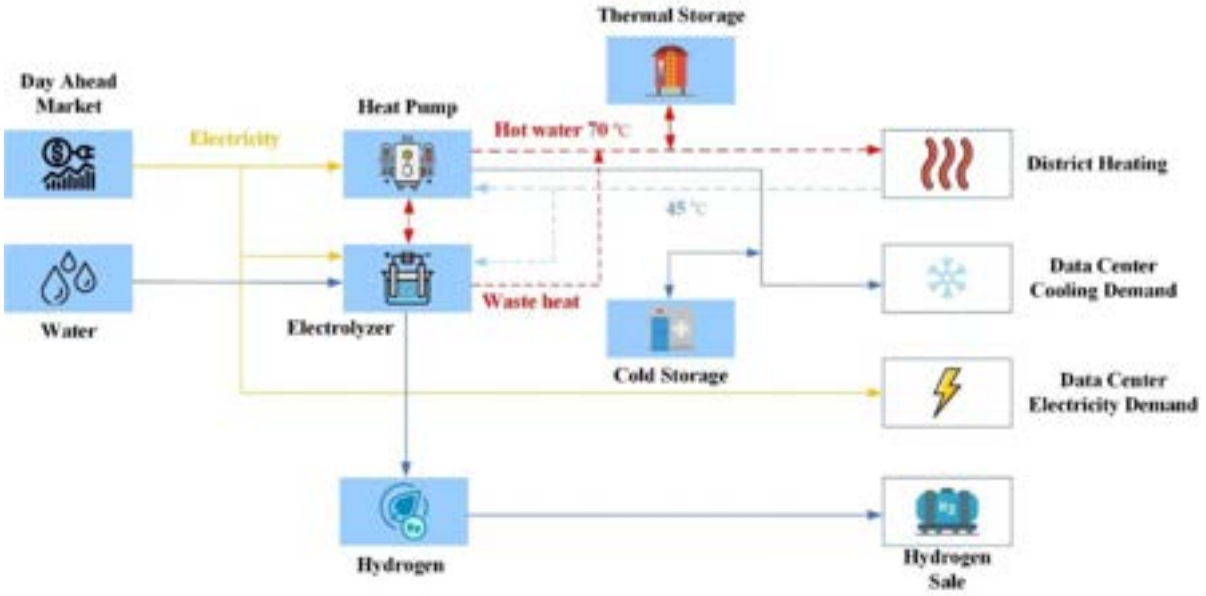

Figure 2. *Data center incorporated with alkaline electrolyzer.*

3.2 Electrolyzer Model

The following is a description of a mathematical model designed for a high-pressure alkaline water electrolyzer. The model is constructed by integrating fundamental principles of thermodynamics, heat transfer theory, and empirical electrochemical relationships. Additionally, the model includes a dynamic thermal component. The electrochemical model is based on a temperature dependent current-voltage curve at a specific pressure, as well as a Faraday efficiency relation that is not influenced by temperature or pressure.

The process of breaking down water into hydrogen and oxygen can be accomplished through the use of direct current (DC) passed between two electrodes that are separated by an aqueous electrolyte with strong ionic conductivity. The overall reaction for the separation of water can be expressed as:

$$H_2O(l) + \text{electrical energy} \rightarrow H_2(g) + \frac{1}{2}O_2(g) \quad (1)$$

For the reaction to take place, a minimum electric voltage must be applied to the two electrodes. This minimum voltage, also known as the reversible voltage, can be calculated using the Gibbs energy for water splitting. Alkaline electrolyzers typically use aqueous potassium hydroxide (KOH) as the electrolyte, with the potassium ion (K^+) and hydroxide ion (OH^-) facilitating ionic transport. The anodic and cathodic reactions that occur in this system can be described as follows:

$$\text{Anode: } 2OH^-(aq) \rightarrow \frac{1}{2}O_2(g) + H_2O(l) + 2e^- \quad (2)$$

$$\text{Cathode: } 2H_2O(l) + 2e^- \rightarrow H_2(g) + 2OH^-(aq) \quad (3)$$

In an alkaline solution, the electrodes must possess properties such as resistance to corrosion, good electrical conductivity, and catalytic activity, as well as structural integrity, while the diaphragm should have low electrical resistance. This can be achieved by using anodes made of materials such as nickel, cobalt, and iron (Ni, Co, Fe), cathodes with a platinum-activated carbon catalyst on a nickel base (Ni, C-Pt), and diaphragms made of nickel oxide (NiO).

3.2.1 Thermodynamic Model

Thermodynamics serves as a framework to describe reaction equilibrium and thermal effects in electrochemical reactors and provides a basis for defining driving forces for transport phenomena in electrolytes. Additionally, it aids in describing the properties of electrolyte solutions. The thermodynamics of the low-temperature hydrogen-oxygen electrochemical reactions utilized in the electrolyzer model are described below.

Assumptions can be made about the water splitting reaction: (a) hydrogen and oxygen are ideal gases, (b) water is an incompressible fluid, and (c) the gas and liquid phases are separate. Based on these assumptions, changes in enthalpy (ΔH), entropy (ΔS), and Gibbs energy (ΔG) of the water splitting reaction can be calculated with respect to pure hydrogen (H_2), oxygen (O_2), and water (H_2O) at standard temperature and pressure (25°C

and 1 bar). The total change in enthalpy for water splitting is the enthalpy difference between the products (H_2 and O_2) and the reactants (H_2O), and the same applies for the total change in entropy. The expression for the change in Gibbs energy is as follows [14]:

$$\Delta G = \Delta H - T\Delta S \tag{4}$$

In electrochemical processes, the splitting of water requires a significant amount of energy due to its positive change in Gibbs energy. At standard conditions (25°C and 1 bar), the standard Gibbs energy for water splitting is 237 kJ/mol, indicating that the reaction is non-spontaneous. However, Faraday's law states that the electrical energy required to split water is directly proportional to the chemical conversion rate in molar quantities. Therefore, the reversible cell voltage or *emf* for a reversible electrochemical process can be calculated using the change in Gibbs energy. This information is crucial when designing and optimizing electrochemical processes for the production of hydrogen and oxygen from water. The reversible cell voltage, also known as the electromotive force (*emf*) of a reversible electrochemical process, can be expressed as:

$$U_{rev} = \frac{\Delta G}{zF} \tag{5}$$

The expression relating the thermoneutral cell voltage to the total energy demand (ΔH) is:

$$U_{tn} = \frac{\Delta H}{zF} \tag{6}$$

3.2.2 Electrochemical model

Empirical current-voltage (I-U) relationships can be utilized to model the electrode kinetics of an electrolyzer cell. There are multiple suggested empirical I-U models for electrolyzers. In this study, the I-U curve utilized has a fundamental form that is dependent on the temperature, and can be expressed as:

$$U = U_{rev} + \frac{r}{A}I + s\,log\left(\frac{t}{A}I + 1\right) \tag{7}$$

The Faraday efficiency, also known as the current efficiency, is the ratio between the actual and theoretical maximum amount of hydrogen produced in an electrolyzer. The efficiency is affected by parasitic current losses along the gas ducts, which increase with decreasing current densities due to an increasing share of electrolyte and lower electrical resistance. The parasitic current is linearly proportional to the cell potential, which means that the fraction of parasitic currents to total current increases with decreasing current densities. An increase in temperature results in lower resistance, higher parasitic current losses, and lower Faraday efficiencies. Understanding the Faraday efficiency is essential for optimizing the performance and efficiency of an electrolyzer.

$$\eta_F = \frac{(I/A)^2}{f_1 + (I/A)^2} f_2 \tag{8}$$

Faraday's law states that the production rate of hydrogen in an electrolyzer cell is directly proportional to the transfer rate of electrons at the electrodes, which is equivalent to the electrical current flowing through the external circuit. Therefore, the total rate of hydrogen production in an electrolyzer, which comprises multiple cells connected in series, can be mathematically represented as:

$$\dot{n}_{H_2} = \eta_F \frac{n_c I}{zF} \tag{9}$$

The rate of oxygen production can be determined straightforwardly using stoichiometry, as shown in Eq. 11, which is expressed on a molar basis as:

$$\dot{n}_{H_2O} = \dot{n}_{H_2} = 2\dot{n}_{O_2} \tag{10}$$

The primary source of heat generation in an electrolyzer is attributed to electrical inefficiencies. The efficiency of energy conversion can be determined by utilizing the thermoneutral voltage (Equation 3) and the cell voltage (Equation 4), and is expressed mathematically as:

$$\eta_e = \frac{U_{tn}}{U} \tag{11}$$

3.2.3 Thermal Model

To determine the temperature of the electrolyte in an electrolyzer, a simple or complex thermal model can be employed depending on the required level of accuracy. If a lumped thermal capacitance model is assumed, the overall thermal energy balance can be expressed as a linear, non-homogeneous, first-order differential equation. This model enables the calculation of the stack temperature and analytically solves for the temperature distribution [14]:

$$C_t \frac{dT}{dt} = \dot{Q}_{gen} - \dot{Q}_{loss} - \dot{Q}_{cool} \tag{12}$$

$$\dot{Q}_{gen} = \eta_c (U - U_{tn}) I = n_c U I (1 - \eta_e) \tag{13}$$

$$\dot{Q}_{cool} = C_{cw}\left(T_{cw,i} - T_{cw,o}\right) = U A_{HX} LMTD \tag{14}$$

4. Results and Discussion

The figure presented in this section, Figure 3, depicts the behavior of the cell voltage (V) of an alkaline electrolyzer as a function of current density (mA/cm^2). The results demonstrate that as the current density is increased, the cell voltage also increases, starting from 0 and reaching 1.88 V. Interestingly, after a current density of 300 (mA/cm^2), the cell voltage becomes nearly constant and remains horizontal. This suggests that the performance of the electrolyzer plateaus at higher current densities and that further increases in current density may not result in a significant improvement in performance. This finding is significant because it indicates the importance of careful selection of current density to achieve optimal performance of the electrolyzer for hydrogen production. By identifying the point of plateau in cell voltage, it is possible to determine the maximum current density that can be used for efficient and sustainable hydrogen production. Overall, the results presented in Figure 2 provide valuable insights into the behavior of the cell voltage of an alkaline electrolyzer as a function of current density. These insights are important for optimizing the performance of the electrolyzer and achieving maximum efficiency in hydrogen production.

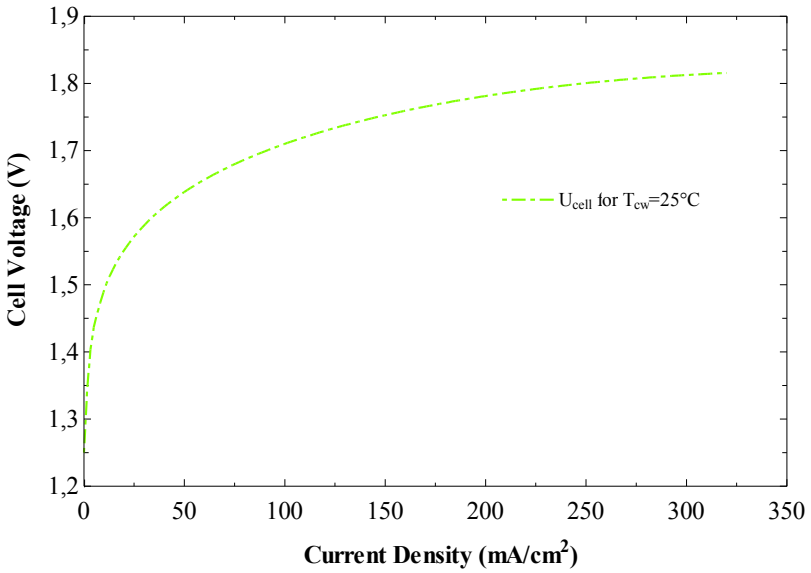

Figure 3. *Relationship between Cell Voltage and Current Density at 25℃ Cooling Water Temperature.*

Figure 4 presents the results of an investigation into the effects of current density and cooling water temperature on the temperature of an electrolyzer. The figure clearly shows that as the current density increases, the temperature of the electrolyzer also increases. Similarly, an increase in cooling water temperature results in a corresponding increase in the electrolyzer temperature. These findings highlight the importance of careful temperature management in optimizing the performance of the electrolyzer. If the electrolyzer temperature becomes too high, it can lead to reduced efficiency and potentially cause damage to the system. The results presented in Figure 4 have significant implications for the design and operation of electrolyzers. Specifically, they suggest that careful consideration must be given to the impact of both current density and cooling water temperature on the temperature of the electrolyzer. The analysis also shows that the use of district heating return water, which typically has a temperature of 43-45 ℃, could potentially be used

to manage the temperature of the electrolyzer and maintain it at the desired value. Overall, the results presented in Figure 4 provide valuable insights into the factors that influence the performance of electrolyzers and offer guidance for their design and operation.

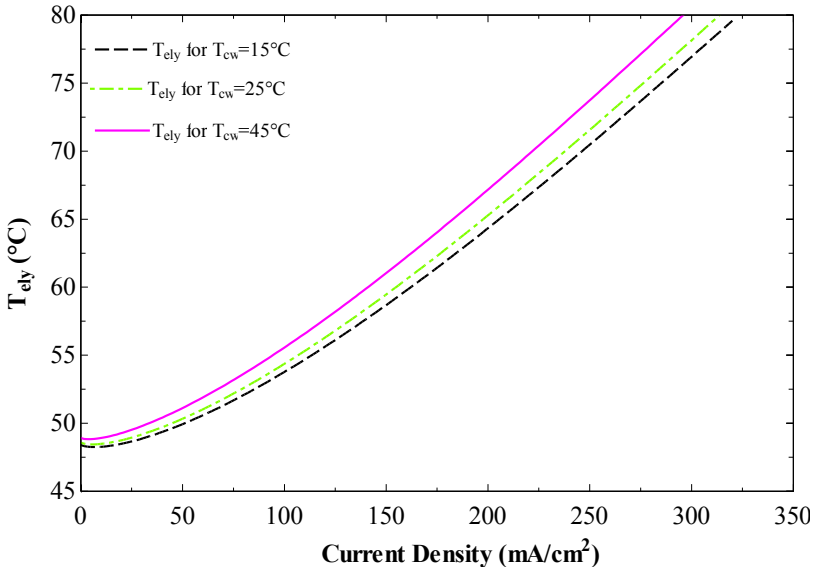

Figure 4. *Relationship between Current Density and Electrolyzer Temperature for Different Cooling Water Temperatures.*

Figure 5 illustrates the relationship between current density and the efficiency of hydrogen production in an alkaline electrolyzer. The figure indicates that as the current density increases from 0 to approximately 50 (mA/cm^2), the efficiency of hydrogen production increases from 0 to 80%. This finding highlights the potential for significant improvements in the efficiency of hydrogen production by increasing the current density. However, the results also show that beyond a current density of 50 (mA/cm^2), the efficiency of hydrogen production becomes almost constant, suggesting that further increases in current density may not result in a significant improvement in efficiency. These findings are significant for the optimization of electrolyzer performance in hydrogen production, as they emphasize the importance of carefully selecting the appropriate current density to achieve maximum efficiency. The results presented in Figure 5 offer valuable insights into the relationship between current density and the efficiency of hydrogen production in an alkaline electrolyzer and can inform the design and operation of electrolyzers for sustainable and efficient hydrogen production. Overall, Figure 5 provides important information for researchers and engineers working in the field of hydrogen production and underscores the potential for further advances in this critical area.

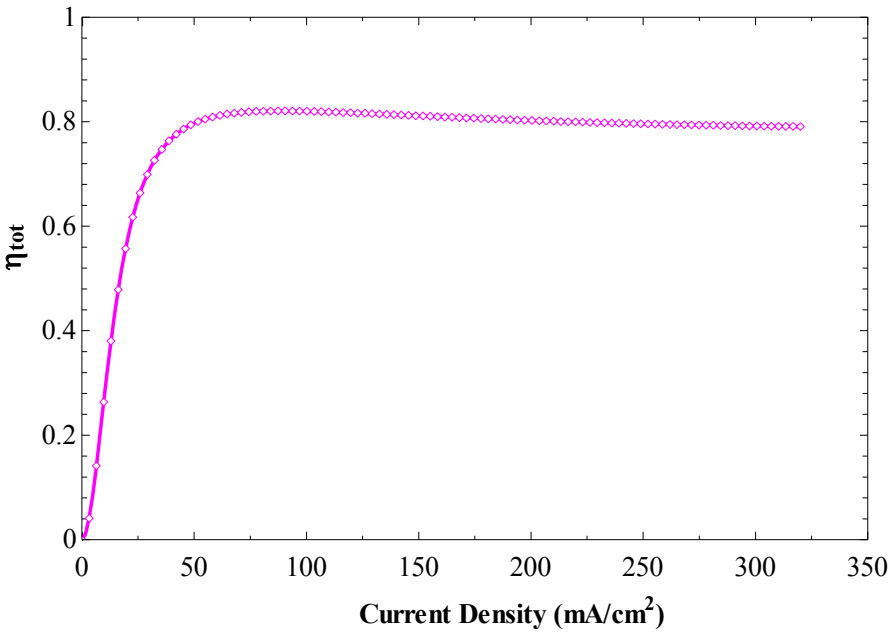

Figure 5. *Impact of Current Density on the Efficiency of Hydrogen Production.*

Figure 6 presents the results of an investigation into the impact of cooling temperature on the efficiency of hydrogen production in an electrolyzer (A), as well as its effect on electrolyzer temperature (B). The figure demonstrates that increasing the cooling temperature results in an increase in the efficiency of the electrolyzer, which in turn leads to an increase in the efficiency of hydrogen production. This finding is significant because it highlights the importance of careful temperature control for optimizing the performance of electrolyzers for hydrogen production. By maintaining an appropriate cooling temperature, it may be possible to improve the efficiency of the electrolyzer and increase the overall efficiency of hydrogen production. The results presented in Figure 6 provide valuable insights into the factors that influence the efficiency of hydrogen production in an electrolyzer and suggest that the use of district heating could potentially be used to manage the temperature of the electrolyzer and maintain it at an optimal value. In summary, the findings presented in Figure 6 demonstrate the importance of temperature control in the optimization of electrolyzer performance for hydrogen production.

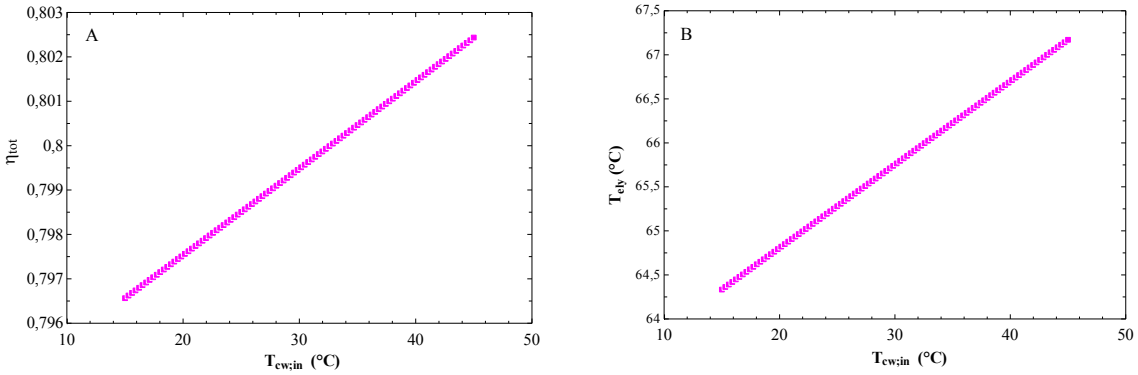

Figure 6. *(A) The effect of cooling water temperature over the efficiency of hydrogen production, (B) the effect of cooling water temperature over the electrolyzer temperature.*

Figure 7 presents an overview of the heat generation by a heat pump and electrolyzer, as well as the heat demand of a district heating system. The figure highlights that the demand for district heating in the summer months is significantly lower than in the winter months. This finding is important because it underscores the need to carefully consider the demand for waste heat when connecting an electrolyzer to a district heating network. In particular, it is crucial to ensure that there is sufficient demand for the waste heat generated by the electrolyzer in order to avoid potential inefficiencies or even system failures. The results presented in Figure 7 suggest that the design of the heat management system for an electrolyzer should consider the seasonal variation in district heating demand. If there is always sufficient district heating demand, then there may be no concerns about delivering the waste heat generated by the electrolyzer. However, if there is a significant

imbalance between the heat generation and demand, then it may be necessary to explore other strategies for managing the waste heat, such as storage or alternative uses. Overall, Figure 7 provides important insights into the relationship between heat generation, demand, and waste heat management in the context of an electrolyzer connected to a district heating network. The results offer guidance for the design and operation of electrolyzers and can inform decision-making related to the integration of these systems with district heating networks. In this case the operation of electrolyzer is 73% and heat pump 90%.

Figure 8 illustrates the operation of thermal energy storage (TES) in the context of a district heating system. During periods of excess heat production, such as in the summer months when demand for district heating is low, the excess heat can be stored in the hot water tank. The TES system can then release the stored heat during periods of high demand.

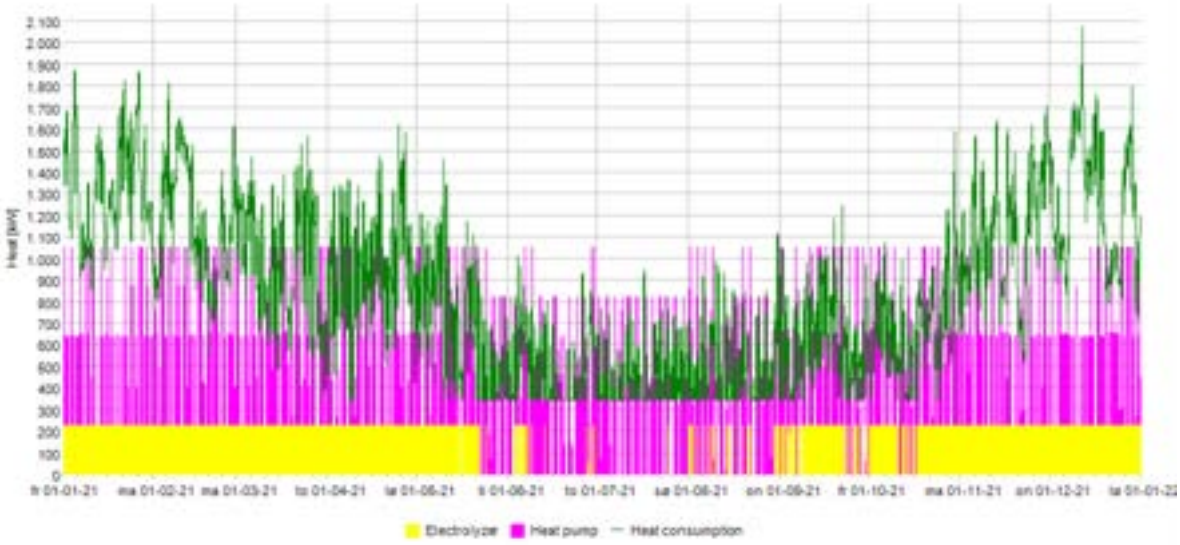

Figure 7. *Heat generation by heat pump and electrolyzer and heat demand of district heating.*

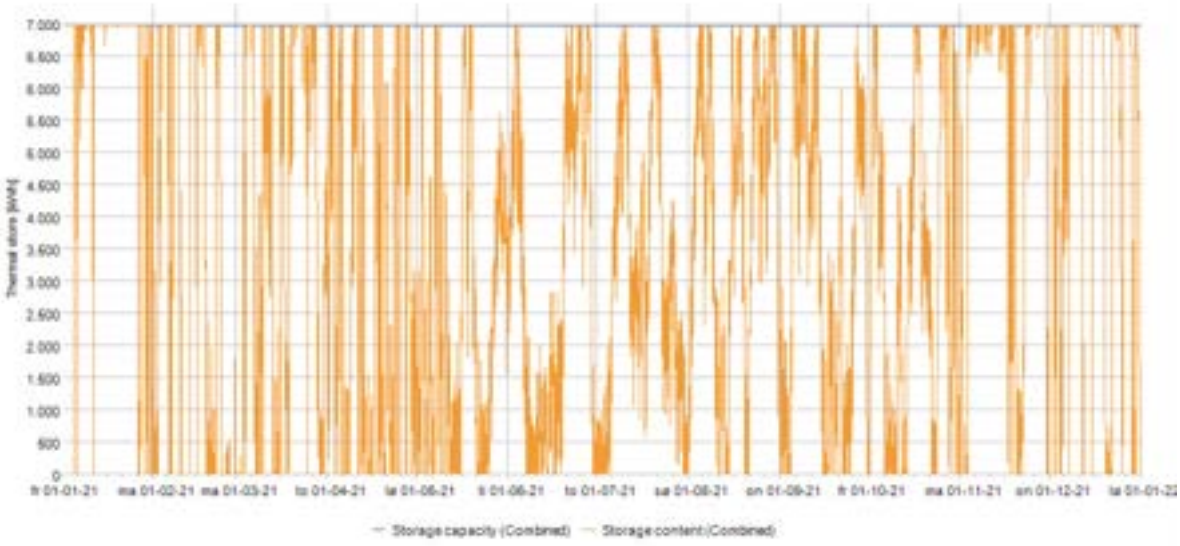

Figure 8. *The operation of thermal energy storage.*

Figure 9 presents the pattern of electricity consumption for a data center, heat pump, and electrolyzer over the course of one year. The figure provides valuable insights into the electricity consumption patterns of these systems and highlights the potential for optimization and efficiency improvements.

***Figure 9**. Electricity consumption of heat pump, electrolyzer and data center.*

5. Conclusion

In conclusion, this paper has explored the crucial role of efficient heat management in optimizing the performance of alkaline electrolyzer and maximizing the production of green hydrogen. Specifically, the importance of current density and cooling temperature on the efficiency of the electrolyzer for hydrogen production has been demonstrated. The paper also proposed a novel and integrated design concept for data centers that combines hydrogen production with district heating, enabling waste heat to be harnessed and employed to supplement the district heating system. The results of this study showed that increasing the current density and cooling temperature can lead to significant improvements in the efficiency of hydrogen production, while careful temperature control is important for optimizing the performance of electrolyzers. Furthermore, by integrating hydrogen production with district heating, the waste heat produced during the electrolysis process can be harnessed and employed to supplement the district heating system, resulting in a reduction in carbon emissions and improved energy efficiency.

The technical and economic feasibility of the proposed system was examined, highlighting the potential benefits for data centers and district heating systems. The results suggest that the proposed system has the potential to improve the sustainability and efficiency of energy systems, contributing to the development of more environmentally friendly and economically viable solutions for energy production. Overall, this paper provides valuable insights into the future of sustainable energy systems and the potential for data centers to play a crucial role in this transition. Further research and development in this area may lead to the widespread implementation of integrated energy systems, resulting in significant improvements in sustainability and energy efficiency.

Abstract:

Energy transition currently brings focus on fuel cell micro-combined heat and power (mCHP) systems for residential uses. The two main technologies already commercialized are the Proton Exchange Membrane Fuel Cells (PEMFCs) and Solid Oxide Fuel Cells (SOFCs). The pollutant emissions of one system of each technology have been tested with portable probes both in laboratory and field-test configurations. In this paper, the nitrogen oxides (NOx), sulphur dioxide (SO_2) and carbon monoxide (CO) emission levels are compared to other combustion technologies such as a recent Euro 6 diesel automotive vehicle and a classical gas condensing boiler. At last, a method of converting the concentration of pollutants (in ppm) measured by the sensors into pollutant intensity per unit of energy (in g/kWh) is documented and reported. This allows for comparing the pollutant emissions levels with relevant literature, especially other studies conducted with other measuring sensors.
Both tested residential fuel cell technologies fed by natural gas can be considered clean in terms of SO_2 and NOx emissions. The CO emissions can be considered quite low for the tested SOFC and even nil for the tested PEMFC. The biggest issue of natural gas fuel cell technologies still lies in the carbon dioxide (CO_2) emissions associated with the fossil fuel they consume.

Keywords:

SO_2; Fuel cell; mCHP, NOx, pollutant emissions; CO.

1. Introduction

In its latest Sixth Assessment Report in April 2022, the Intergovernmental Panel on Climate Change has reported a maximum carbon budget of 890 $GtCO_2$ that humanity can emit from January 1st 2020 in order for global warming to likely remain under the +2 °C widely acknowledged limit compared to preindustrial temperature levels [1]. Even at residential scales, this much-needed GreenHouse Gases (GHG) mitigation brings focus on cleaner power sources and on combined heat and power (CHP) systems, such as fuel cells [2]. The two primary technologies that have already been commercialized are the Proton Exchange Membrane Fuel Cells (PEMFCs) and the Solid Oxide Fuel Cells (SOFCs), which are compared in Table 1. GHG emissions (in terms of CO_2 or CO_{2eq}) of such systems have already been addressed [3, 4] but another key element in assessing the environmental impacts of those technologies lies in the other common air pollutants : the emissions of nitrogen oxides (NOx), sulphur dioxide (SO_2), and carbon monoxide (CO).

The novelty of this study lies within the evaluation of SO_2, NOx and CO emissions of fuel cell technologies commercialized for residential applications in both laboratory and field-test configurations (in real dwellings in Belgium). This has been performed on several machines of different ages, for one PEMFC-based and one SOFC-based technology, thanks to a combustion analyser portable meter. This study compares the emission levels of those pollutants measured for the studied fuel cell systems with other combustion technologies, such as a recent Euro 6 diesel automotive vehicle and classical gas condensing boilers. To facilitate comparison with relevant literature, a method of converting the concentration of pollutants (measured in ppm) detected by the sensors into pollutant intensity per unit of energy (in g/kWh) has been documented and reported, which has never been the case in an academic paper to the knowledge of the authors. This approach enables the assessment of pollutant

emissions levels across different studies, including those conducted using alternative measuring sensors.

Table 1. Comparison between PEMFCs and SOFCs. Reproduced and adapted from reference [9].

Fuel cell type & Charge carrier	Typical electrolyte	Major contaminants	Stack operating temperature (°C)	Specific advantages	Specific disadvantages	LHV Electrical efficiency (%)
PEMFC & H^+	Solid Nafion®, a polymer	Carbon monoxide (CO) [a] Hydrogen sulfide (H_2S) [a]	60–80 (only low-temperature PEMFC are currently commercialized [5])	Highly modular for most applications High power density Compact structure Rapid start-up due to low temperature operation Excellent dynamic response	Complex water and thermal management [a] Low-grade heat High sensitivity to contaminants [d] Expensive catalyst Expensive Nafion® membrane [6]	40-60 (with H_2) (Max 38.5 with CH_4 as some fuel needs to be burned to provide heat to a methane reformer [7])
SOFC & O^{2-}	Solid yttria-stabilized zirconia, i.e. YSZ, a ceramic	Sulfides	800-1000	High electrical efficiencies High-grade heat High tolerance to contaminants Possibility of internal reforming Fuel flexibility Inexpensive catalyst Simpler water management (SOFC can work at a perfect drying state [8])	Slow start-up Low power density Strict material requirements High thermal stresses Sealing issues Durability issues High manufacturing costs	55-65 (with H_2) (Max 60% with CH_4 [5], i.e. still high thanks to the SOFC fuel flexibility)

[a] Contaminants, thermal and water management of PEMFC stacks have been discussed more deeply in a previous work [10].

2. Material and methods

2.1 Tested systems

2.1.1 PEMFC hybridized to a gas condensing boiler

The PEMFC is not a standalone unit. It is hybridized to a gas condensing boiler and to a Domestic Hot Water (DHW) tank. It is fed by natural gas and is designed to cover all the heat demands, including DHW, of residential houses and to participate locally in the electrical production. This particular system exists in several versions all based upon the same PEMFC module of nominal constant power of 0.75kW$_{el}$ (and 1.1kW$_{th}$) and the same 220L DHW tank. The only module that may vary is the gas boiler that is supposed to ensure peak heat demands. Indeed, it exists in four rated power versions from 11.4 to 30.8kW$_{th}$, depending on thermal needs [11]. The heat rate output of the field-test system considered in this study is rated to 24.5 kW$_{th}$ and is located in Huy, in Belgium. System's architecture is presented in Figure 1 (which does not show the double walled chimney used for both the air inlet and flue gases exhaust [12]) and main datasheet characteristics are presented in Table 2.

Table 2. PEMFC gas boiler hybrid expected targets (data published by manufacturer) [11].

Datasheet figures	Values
Maximum electrical production a year	6200kWh$_{el}$
Fuel cell rated electrical and thermal power as defined by EN 50465 [2]	0.75kW$_{el}$ & 1.1kW$_{th}$
Electrical fuel cell efficiency	37% (LHV)
Max global Fuel cell efficiency	92% (LHV)
Max boiler efficiency (at rated power) [a]	108.6% (LHV)
NOx, class 6 [13]	7.2 mg/kWh
Size without chimney (Hight x Width x Depth)	1800 mm x 595 mm x 600 mm

[a] Considering High Heating Value (HHV) to Low Heating Value (LHV) ratio of 1.1085 [14]

The complete system behaviour is heat driven. Its PEMFC has not been designed to be driven by the electrical demand and it is preferable that it runs as long as possible. It includes a methane reforming apparatus to feed the fuel cell stack with clean hydrogen and requires an automated fuel cell shutdown recovery procedure of 2.5 hours at least every two days to handle some reversible ageing processes

[10]. For further information, this system has been quite exhaustively studied in other publications [2, 4, 10, 15, 16, 17].

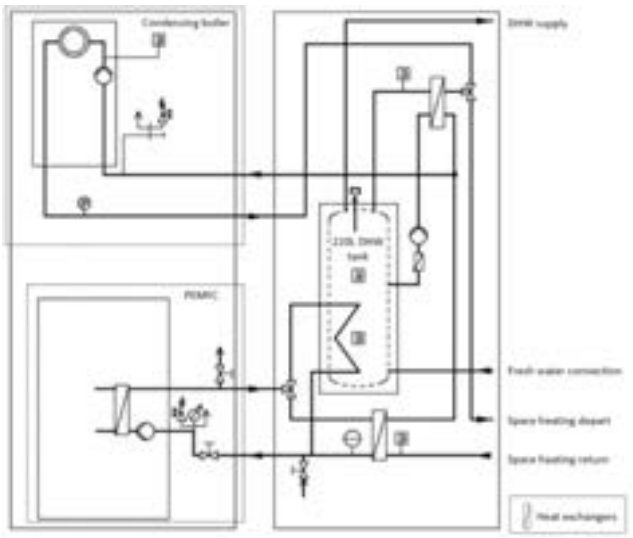

Figure 1. PEMFC system's architecture, including two heat exchangers, several 3-way valves, several circulators, the gas condensing boiler and the DHW tank.

2.1.2 SOFC

The studied SOFC is also fed by natural gas. It is designed to provide 1.5 kW_{el} of nominal output power with a high announced LHV electrical efficiency of 60%, along with a heat recovery of 0.6 kW_{th} representing a LHV thermal efficiency up to 25%. The output power can be modulated down remotely (by the manufacturer, upon the owner's request) as wanted in the 0.5 - 1.5 W_{el} range, affecting those announced efficiencies. It is not advised to completely shut it down because thermal cycles affect its durability and because start-up operations are long and have been reported in the user manual to last up to 30 hours [18] .

Discarding its chimney, the system has approximately the same size as a dishwasher, as it can be seen in Figure 2. Its internal schematics has not been disclosed but has been discussed in a previous publication [3], based on observations of the system and cogeneration SOFC literature. Amongst other particularities, the reforming process of the inlet natural gas (into hydrogen) is not only internal, i.e. directly onto the stack, at the anode (allowed with high operating temperatures occurring with that fuel cell technology [19]), but it also uses an external steam reformer upstream of the stack (called 'pre-former' [3]). The system is reported by the manufacturer as belonging to class 6 in terms of NOx [13] but the exact emission levels have not been quantified in the datasheet.

Figure 2. Tested mCHP SOFC in the laboratory facilities of the University of Liege

2.1.3 Gas condensing boiler

The tested mural gas condensing boiler dates from 2005 and is quite classical. Its identification name is 'Buderus Logamax plus GB142-45' and it can provide up to 45 kW_{th} (that can be modulated down to 30%). It is able to provide heat to an optional DHW tank but cannot provide instantaneous DHW directly

as it has only one hydraulic inlet/outlet (for close circuit water). The emissions of CO and NOx are reported by the manufacturer respectively to 15 mg/kWh and 20 mg/kWh.

2.1.4 Euro 6 diesel vehicle

The tested vehicle is a 4-year BMW X1 sDrive18d that is proper maintenance and had 111210 kilometers on the odometer at the moment of the test. Its four-stroke engine has four cylinders and represents a displacement of 1995cm³. Net power is 100 kW at 4000 rpm. The certificate of conformity presents average emissions on the New European Driving Cycle (NEDC) for CO and NOx respectively of 86.8 mg/km and 19.2 mg/km. Maximum Real Driving Emissions (RDE) NOx emissions are reported to be equal to 168 mg/km. Considering an effective consumption of 6L per 100 km (according to the dashboard of the vehicle), considering a diesel LHV of 43.51 MJ/kg and a density of 827 kg/m³ [20], those emissions correspond respectively to 145 mg/kWh (average CO emissions on the NEDC), 32 mg/kWh (average NOx emissions on the NEDC) and 280 mg/kWh (maximum Real Driving Emissions NOx). They are relative to the diesel LHV input to the engine.

2.2 Measurement device

To perform the pollutants emissions analyses of the tested systems, the same portable combustion analyser meter has been used. It is called 'Multizyzer STx' and is shown in Figure 3 whereas its specifications are shown in Table 3.

It measures CO, NO, NO_2 and SO_2 in ppm, whereas O_2 and CO_2 concentration levels are expressed in percentage (by volume). Carbon monoxide sensors have generally a significant cross-sensitivity to hydrogen, meaning that the real carbon monoxide concentration can be overestimated if hydrogen is present as well in the tested gas sample [21]. Therefore, as presented in Table 3, the 'Multizyzer STx' combustion analyser portable meter has implemented a hydrogen compensation for its carbon monoxide measurements.

Figure 3. 'Multizyzer STx' combustion analyser portable meter

Table 3. Specifications of the 'Multizyzer STx' combustion analyser portable meter

Sensor	Range	Accuracy	Resolution
NO	0 - 5000 ppm	± 5 ppm (< 50 ppm) ± 5% reading (> 50 ppm)	1 ppm
NO_2	0 - 500 ppm	± 10 ppm (< 50 ppm) ± 10% reading (> 50 ppm)	1 ppm
SO_2	0 - 5000 ppm	± 10 ppm (< 200 ppm) ± 5% reading (> 200 ppm)	1 ppm
CO (hydrogen compensated)	0 - 10000 ppm	± 5 ppm (< 50 ppm) ± 5% reading (> 50 ppm)	1 ppm
O_2	0 - 21 % vol.	± 0,2% vol.	0,1% vol.
CO_2 (calculated from O_2 level)	0 % vol. up to $(CO_2)_N$ which depends on fuel type, see Equation (1)	± 0,2% vol.	0,1% vol.
Gas temperature	0 - 1150 °C	± 1 °C (0 - 300°C) ± 1% reading (> 300°C)	0,1 °C

2.3 Conversion ppm to mg/kWh

Literature on space heating appliances pollution levels is quite rare and pollutant emissions are regularly reported in terms of concentration (in ppm [22]) or in terms of intensity (in mg/kWh [23]). However, it is quite rare for both information to be provided. In this case, the pollutant emissions measurements are provided by the metering device in ppm (see Table *3*) whereas, for comparison purposes, it would be more meaningful to express them in terms of mg/kWh, as reproduced in Table 4, which reports from literature the NOx emission levels of several space heating appliances. In addition, as it has been seen in *Section 2.1 - Tested systems*, the datasheets of the tested space heating appliances only express the emissions in terms of mg/kWh. Therefore, to use those figures as references for this study, measured emissions must be converted from ppm to mg/kWh.

For natural gas appliances, this can be performed for carbon monoxide emissions thanks to Equation (*1*) [13]:

$$CO_{(mg/kWh)} = 1.074 \times CO_{(ppm)} \times \frac{(CO_2)_N}{(CO_2)_M} \quad (1)$$

Where $CO_{(mg/kWh)}$ is the carbon monoxide emissions level per unit of energy (kWh) that must be established for the studied combustion test, $CO_{(ppm)}$ is the measured carbon monoxide concentration at the exhaust of the system during the combustion test (in ppm), $(CO_2)_M$ is the measured carbon dioxide concentration at the exhaust of the system during the combustion test (in %) and $(CO_2)_N$ is the maximum carbon dioxide concentration of the dry, air-free combustion products (in %), which depends only on the natural gas type that is fed to the studied system during the combustion. $(CO_2)_N$ is equal to 11.7% for G20 natural gas and 11.5% for G25 natural gas [13].

Indeed, in Belgium [24] (as in France or Germany [25]), natural gas comes from different sources, which implies different gas compositions and different HHV, which leads to the appellations 'lean' and 'rich' gas, respectively for the natural gas source providing the lower and the higher HHV [26]. Lean gas is also called 'L-gas' [27], 'type L' gas [24] or G25 [25] whereas rich gas is also called 'H-gas' [27], 'type H' gas [24] or G20 [25]. The type of gas provided on the grid only depends on the localization of the delivery point but lean gas deliveries are supposed to be progressively replaced (in Belgium) by 2030 by rich gas deliveries [27].

As reported in the previous section, $(CO_2)_M$ and $CO_{(ppm)}$ are provided by the meter used in this study. Also, in Equation (*1*), the 1.074 constant is the unit conversion coefficient related to CO emissions from natural gas appliances [28].

Table 4. Combustion only and Life Cycle Assessment (LCA) NOx emission level reported from Energie+ [23] (website developed by the University of Louvain-la-Neuve and the Energy department of the Walloon Region, in Belgium)

Space-heating appliance	NOx range (source from 1998 : Electrabel-SPE – combustion only) mg/kWh$_{LHV}$	NOx (source from 2007 : Fondation Rurale de Wallonie - combustion only) mg/kWh$_{th}$	NOx (source accessed in 2007: Gemis 4.5 - complete LCA cycle) mg/kWh$_{th}$
Old oil-fired boiler	up to 200	Unavailable	Unavailable
Non-Low NOx oil-fired boiler	150 – 180	144	244
Low NOx oil-fired boiler	90 – 120	Unavailable	Unavailable
Old gas boiler	150 – 200	Unavailable	Unavailable
Atmospheric gas boiler	100 – 180	Unavailable	Unavailable
Modulating gas condensing boiler	20 – 90	144	140
Old log wood boiler	Unavailable	180	Unavailable
Modern log wood boiler	Unavailable	151	235
Wood chip boiler (wood chips)	Unavailable	162	Unavailable
Condensing wood boiler (pellets)	Unavailable	Unavailable	344

Similarly, ppm to mg/kWh conversion for NOx emissions of natural gas appliances is obtained thanks to Equation (*2*) :

$$NOx_{(mg/kWh)} = \frac{\left(C_g \times NOx_{(ppm)} \times \frac{(CO_2)_N}{(CO_2)_M}\right) - 0.85(20 - T_m) + \frac{0.34(h_{m-10})}{1-0.02(h_{m-10})}}{\left(1 + \frac{0.02(h_{m-10})}{1-0.02(h_{m-10})}\right)} \quad (2)$$

Where $NOx_{(mg/kWh)}$ is the nitrogen oxide emissions level per unit of energy (kWh) that must be established for the studied combustion test; C_g is the unit conversion coefficient related to NOx emissions from natural gas appliances [29] and is equal to 1.764 for G20 (rich gas) or 1.767 for G25 (lean gas) [13]; $NOx_{(ppm)}$ is the sum of the measured nitrogen dioxide and nitric oxide concentrations at the exhaust of the system during the combustion test (in ppm); $(CO_2)_N$ and $(CO_2)_M$ have already been described for Equation (*1*); T_m is the temperature of the outdoor air used for the combustion (in °C); h_m is the absolute humidity of the outdoor air used for the combustion (in g of water per kg of dry air). h_m is the only variable of Equation (2) that is not provided by the combustion analyser meter (see Table 3). By assimilating inlet air to humid air of relative humidity between 40 and 80%, at atmospheric pressure and at the T_m temperature, h_m can be approximated with the Engineering Equation Solver (EES) software. It is worth mentioning for Equation (*2*) that the allowable ranges for T_m, h_m $NOx_{(mg/kWh)}$ and are respectively 15 - 25 °C and 5 - 15 g of water per kg of dry air, and 50-300 mg/kWh. However, industrial partners in this project advise to use Equation (*2*) anyway even if some parameters are out of those ranges.

The European standard from which Equation (*1*) and Equation (*2*) are deduced [13] unfortunately does not provide any information about SO_2 emissions conversion. Fortunately, another reference [30] provided Equation (3), which has been reported to be relevant not only for SO_2 but also for CO and NOx emissions, giving similar conversion results respectively to Equation (*1*) and Equation (*2*) (in its allowable range).

$$PEI_{(mg/kWh)} = F \times PEC_{(ppm)} \times \frac{20.9}{20.9-(O_2)_M} \quad (3)$$

Where $PEI_{(mg/kWh)}$ is the pollutant emissions intensity, i.e. the emission level per unit of energy (kWh) that must be established for the studied combustion test, F is an emission rate conversion factor that depends on the pollutant (and the type of fuel) and that is given in Table 5, $PEC_{(ppm)}$ is the measured pollutant emissions concentration at the exhaust of the system during the combustion test (in ppm) and $(O_2)_M$ is the measured oxygen concentration at the exhaust of the system during the combustion test (in %). Equation (3) has the particularity to consider O_2 concentration (in %) in the exhaust whereas Equation (*1*) and Equation (*2*) lies on CO_2 concentration (in %).

Similar conversion equations for diesel engine have not been reported in this paper but can also be found in literature [31].

Table 5. Natural gas F coefficients for Equation (3) depending on the pollutant type [30]

Pollutant	F mg/(kWh-ppm)
CO	0.974313
NOx	1.608389
SO_2	2.242466

3. Testing procedure and results

The end of the probe of the 'Multizyzer STx' must be placed at the centre of the exhaust gas chimney (or tailpipe) and the probe axis can either be oriented in the perpendicular plane of this chimney (or tailpipe) or parallel to it (if the measurements are conducted at the exit of the chimney/tailpipe). The probe disposes of a conical adjustable mechanical stop to ensure the correct probe depth to the centre of the chimney (see Figure 3).

The studied PEMFC system, which is composed of a PEMFC stack hybridized to a gas condensing boiler (see *Section 2.1 - Tested systems*), has the advantage of being equipped by design with a small, sealable access hole fitted with a cap directly at the exhaust of the system (in the first 5 cm of the chimney). There is thus no need with the PEMFC system to place the combustion analyser meter at the exit of the chimney, which access is very often difficult and potentially risky if it figures on the roof of the building. However, some measurements have still been taken at the exit of the chimney for comparison purposes (with the probe fully inserted in the chimney). Indeed, temperature (which varies all along the double walled chimney that cools down the flue gases and heats up the inlet air from outdoors) is not only known to influence the NO_x formation but also the NO-NO_2 equilibrium. This is especially the case in the near-post-flame zone [32] (close to the outlet of the system), but also in the atmosphere in the presence of Volatile Organic Compounds (close to the exit of the chimney) [33], which can be co-emitted in hydrocarbons combustion [32]. The PEMFC hybrid system was tested in two separate modes : with only the PEMFC turned on and with only the gas condensing boiler turned

on. This system, installed in 2019, was tested in a field-test application (in a real house) in Huy (in Belgium). At the moment of the tests, the whole machine has been functioning for about 15000 hours but its integrated fuel cell has only been producing electricity for about 5500 hours. It is worth mentioning that another machine of this system, which was perfectly new, was tested in a laboratory environment (see Figure 4).

The studied SOFC system does not involve any hole in its chimney by design. However, since one machine of this system was tested in laboratory facilities, a hole was manufactured at a chimney height of 50 cm (above the system flue gases outlet). For one pollutant test campaign (at full rated electrical power output, i.e. 1500 W_{el}), the combustion analyser meter was also placed at the exit of the chimney (and fully inserted in it) since this campaign was performed on another machine (with the same reference) in a field-test application in Riemst (Belgium). At the moment of the pollutant measurements, this machine, installed in 2017, has already been functioning for about 45000 hours. For the other two pollutant test campaign (conducted at minimum and intermediate electrical power output, i.e. 500 W_{el} and 1000 W_{el}), this SOFC mCHP system was tested in laboratory facilities and the return temperature of the heat recovery circuit could be controlled [18] (which affects the exhaust gas temperature). At the moment of the pollutant measurements, this other machine, installed in 2021, has already been functioning for about 6000 hours.

As mentioned in *Section 2.1 - Tested systems*, another classical gas condensing boiler has been tested (only at the exit of its chimney, with the probe fully inserted in it). This system was tested in a field-test application in Riemst (Belgium).

At last, the Euro 6 diesel vehicle was tested at the exit of both of its tailpipes. The probe of the sensor could be oriented parallel to the tailpipe so it has either been fully inserted in the tailpipe (about 35 cm before its exit) or only inserted over about 15 cm. The purpose was to see the changes in the exhaust gas temperature and their impact on the pollutant measurements. It is worth mentioning that the car engine was tested at idle (±850 rpm) and at 1500 rpm but the clutche was always disengaged.

All the tests include a purge with clean air before starting the test. It is indeed a mandatory step requested by the 'Multizyzer STx' combustion analyser meter. At last, the sample time was always one second.

All the tests have other specificities in the way they have been conducted and those are reported accordingly in Table 6 along with the pollutant emissions results.

In addition, a graphical example of the type of the PEMFC only startup phase is given in Figure 4. In that test, no NOx nor SO_2 could be measured. Startup phase (duration between the machine startup with a thermal demand and the moment when the fuel cell starts producing electricity) takes about 7 min whereas the total duration to reach steady-state is about 15-20 min (gradually from 0 W_{el} to its nominal output power of 750 W_{el}). A CO peak of about 2 minutes, with a maximum at 55 ppm, can be noticed at the beginning of the power and heat generation phase, probably due to transient behaviours of the internal reformer required for this PEMFC fed by natural gas [10]. The stepped behaviour of the CO_2 percentage measurement is explained by the resolution of the sensor and the fact that it is not directly measured but established by the combustion analyser from O_2 measurements (Table 3). The CO_2 peak is probably an outlier as it could not be explained.

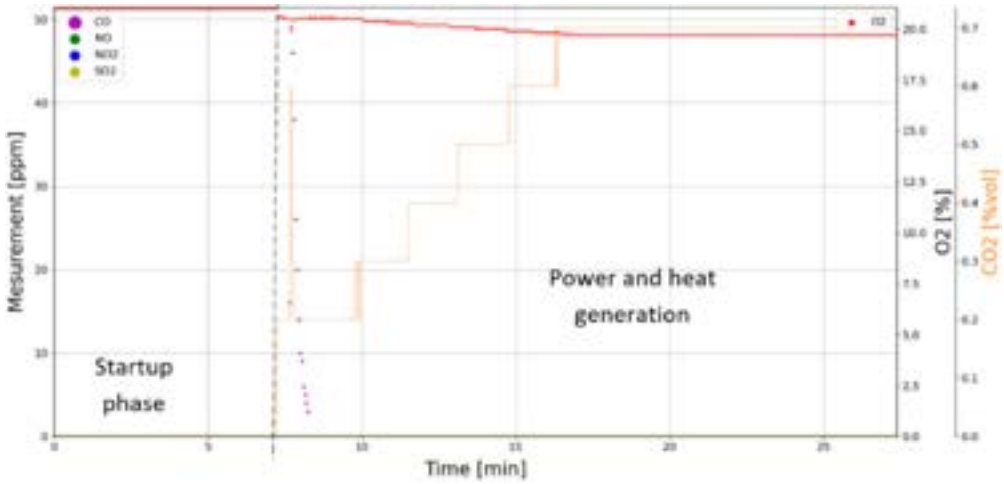

Figure 4. Pollutant measurements of the fuel cell (only) startup phase of the PEMFC-gas condensing boiler hybrid system (performed in a laboratory environment).

Table 6. Pollutant emissions measurements results (in all tests, the sensor indicated 0 ppm of SO_2 emissions).

Test and conditions	NO [a]	NO_2 [a]	CO [a]	Remarks
PEMFC hybrid system (**PEMFC only mode**) Measured on the field-test site in Huy without control on the return temperature (or on the exhaust gas temperature)	0	0	- Startup : short peak up to 55 ppm for 2 min (in total). Also measured in the laboratory (Figure 4). - Steady state : 0 but an unexplainable short peak similar to FC startup has been measured while the PEMFC was running	- Boiler turned down by closing the radiator valves in the house - No difference in the pollutant measurement between the exit of the chimney (on the roof) and the exit of the system
PEMFC hybrid system (**condensing gas boiler only mode**) Measured on the field-test site in Huy without control on the return temperature (or on the exhaust gas temperature)	- Startup : peak up to 7 ppm for 5 min (in total) - Steady state : 0	- Startup : 3 ppm - Steady state : 3 ppm, i.e. 6.7 mg/kWh	- Startup : short peak up to 80 ppm for 30 sec (in total) - Steady state : 30 ppm, i.e. 40.7 mg/kWh	- Boiler turned on by opening the radiator valves in the house and setting a high temperature setpoint on the thermostat (the PEMFC happened to be turned off, probably conducting a regeneration procedure [10])
SOFC – 500 and 1000 W_{el} output Tested in laboratory with different heat recovery temperatures, i.e. different exhaust gases temperature (from 45°C to 25°C)	0	0	5 ppm (at 500 W_{el}), i.e. 28.3 mg/kWh 11 ppm (at 1000 W_{el}), i.e. 41.5 mg/kWh	- Return temperature of the heat recovery circuit has no influence on the pollutant measurements - Only steady state data (the system in supposed to be turned on continuously and the startup test was not conducted)
SOFC - 1500 W_{el} output Measured on the field-test site in Riemst with only one heat recovery temperature corresponding to 60°C of exhaust gases temperature	0	0	8 ppm, i.e. 17.0 mg/kWh	- Same reference but a different system as the previous row) - Only steady state data (the system in supposed to be turned on continuously and the startup test was not conducted)
Classical gas condensing boiler - high DHW load (exhaust gases temperature of about 65°C at the exit of the chimney) Measured on the field-test site in Riemst	- Startup : peak up to 8 ppm for 2 min (in total) - Steady state : 5 ppm, i.e. 10.1 mg/kWh	- Startup : peak up to 4 ppm for 2,5 min (in total) - Steady state : 2 ppm, i.e. 4.1 mg/kWh	- Startup : peak up to 50 ppm for 2 min (in total) - Steady state : 10 ppm, i.e. 12.3 mg/kWh	- No remark
Classical gas condensing boiler - low temperature space heating load (exhaust gases temperature of about 30°C at the exit of the chimney) Measured on the field-test site in Riemst	- Startup : Untested - Steady state : 0 ppm	- Startup : Untested - Steady state : 0 ppm	- Startup : Untested - Steady state : 8 ppm, i.e. 10.7 mg/kWh	- No remark
Euro 6 Diesel Engine at idle, i.e. ±850 rpm (car in neutral)	- Startup : continuous increase for about 20 min up to 60 ppm - Steady state : 55 ppm, i.e. 238 mg/kWh [31]	0	- Startup : rapid increase for about 3 min to the 200-300 ppm range - Steady state : 200-300 ppm, i.e. 800-1200 mg/kWh [31]	- The probe must be fully inserted in the tailpipe to record pollutant emissions - There is no difference between the left and right tailpipes
Euro 6 Diesel Engine at 1500 rpm	- Startup : unavailable (engine already warmed up) Steady state : 40 ppm, i.e. 173 mg/kWh [31]	0	- Startup : unavailable (engine already warmed up) Steady state : 850 ppm, i.e. 3430 mg/kWh [31]	- The probe must be fully inserted in the tailpipe to record pollutant emissions - There is no difference between the left and right tailpipes

[a] Equation (3) has been used to convert ppm measurement into mg/kWh for steady-state measurements only (of natural gas appliances). The similar conversion law for diesel engines comes from literature [31]. Peaks and start-ups have highly transient dynamic behaviours both on the pollutant concentration and the O_2 percentage signal, making the ppm to mg/kWh conversion hazardous.

4. Discussion and conclusion

None of the tested systems (PEMFC, SOFC, gas condensing boilers and Euro 6 diesel engine) showed any SO_2 emissions. This is either an indication of an issue with the SO_2 sensor or it proves the efficiency of the desulphurization treatment implemented in the natural gas process before it enters the grid [10]. Regarding the diesel vehicle, the lack of SO_2 emissions could be explained by the oxidation of SO_2 into SO_3 in the selective catalytic converter used in the exhaust of the engine to reduce NOx emissions [34].

Both fuel cell systems (PEMFC and SOFC) do not show any NOx emissions even if they involve reforming processes [3, 10]. Oppositely NOx emissions of gas boilers (in steady state) were measured between 3 and 7 ppm, which is rather low. Using Equation (3) and thus considering the O_2 percentage measurement (not shown in Table 6), those figures can be converted in the 6.7-14.2 mg/kWh range, which is slightly better than literature provided (see Table 4). The lower part of that range, i.e. 6.7 mg/kWh, corresponds to the gas boiler of the PEMFC hybrid system, and it is indeed under the 7.2 mg/kWh figure announced by the manufacturer. For the other classical gas condensing boiler, it is also under the announced value of 20 mg/kWh (see *Section 2.1 - Tested systems*). In comparison, the diesel Euro 6 engine showed NOx concentration of 55 ppm in neutral and 40 ppm at 1500 rpm (without any load since the clutch was not engaged). Considering another conversion equation from ppm to mg/kWh provided by literature relevant for diesel engines [31] (Equation (3) and the coefficients of Table 5 being only relevant with natural gas appliances) and a molar mass of NO of 30, these NOx emission concentrations corresponds to the 173-238 mg/kWh range, i.e. under but close to the maximum NOx Real Driving Emissions announced at about 280 mg/kWh, assuming an average consumption of 6L per 100 km (see *Section 2.1 - Tested systems*). It also approximately corresponds to the emissions of an old oil-fired boiler (Table 4).

For all tested systems, the NO_2 emissions are either nil or quite low compared to NO emissions, which was expected as NO has been reported to be the predominant nitrogen oxide emitted by combustion devices [32].

There were no CO emissions regarding the steady state operating conditions of the PEMFC (other than an explicable peak that is similar to the transient CO peak that occurs at the PEMFC startup). This was expected since CO is a major pollutant of PEMFC stacks and since it has been reported that the system is equipped with a CO removing apparatus in the fuel (natural gas) processing system (prior to the stack) [10]. Transient CO peaks are surely not caused by the fuel cell stack but by the fuel processor of the PEMFC system (when the reforming processes start and is not yet at its steady state temperature levels, impeding the CO remover to operate efficiently). During these transients for which CO can occur, the PEMFC stack must surely be bypassed [10]. Also, it has been reported that the PEMFC system involves an afterburner for reforming purposes (because methane reforming requires temperatures much higher than the one occurring in the PEMFC stack) [10]. In addition to burning the stack exhaust gases when the PEMFC is running (the anode exhaust still contains used hydrogen and the cathode contains air at a higher temperature that the ambient air), this afterburner also requires a direct feed from the natural gas supply to ensure enough heat for the reforming processes [10]. The inexplicable CO peak while the PEMFC was running is likely to be related to this afterburner (after the stack) and it can be assumed that no CO has gone through the PEMFC stack. Oppositely, the SOFC system (two machines tested) showed slight CO emissions (5 ppm, 11 ppm and 8 ppm respectively at 500 W_{el}, 1000 W_{el} and 1500 W_{el} of power output) with no dependence on the thermal output or on the exhaust gases temperature (driven by the return temperature of the heat recovery system). Through Equation (*3*), these CO concentrations respectively correspond to 28.3 mg/kWh, 41.5 mg/kWh and 17.0 mg/kWh. It is worth mentioning that the PEMFC system was only tested in field-test real applications so the return temperature (and the exhaust gas temperature) could not be controlled, although it is not believed to affect the pollutant emissions in steady state (which were nil).

CO emissions peak (between 50 and 60 ppm) at gas condensing boilers startup is probably due to the momentary incomplete combustion in this highly transient starting process. In steady-state, the tested machines showed 8 to 30 ppm of CO emissions, corresponding to 10.7 mg/kWh to 40.7 mg/kWh using Equation (*3*) (very similar to the SOFC CO emissions range). The gas condensing boilers were tested in field-test applications so the return temperature (and therefore the exhaust gases temperature) could not be controlled. Regarding the diesel engine, the steady state CO emissions were much higher, between 200 and 300 ppm at idle and up to 850 ppm at 1500 rpm. Equation (*3*) and the coefficients of Table 5 can only be used with natural gas. Therefore, another conversion law has been found in literature [31], leading to the 800-1200 mg/kWh range at idle and to about 3430 mg/kWh for the 1500 rpm test. Those levels of CO emissions are far greater than the one announced on the certificate of

conformity for the average NEDC (calculated in this work to about 145 mg/kWh, as seen in *Section 2.1 - Tested systems*). This is another proof of the inadequacy of the NEDC to account for pollutant emissions [35] but it also should be reminded that maintaining the engine at 1500 rpm while keeping the vehicle stationary is also not a representative test of real driving conditions (although it provides interesting results for comparisons).

As a final conclusion, both tested residential fuel cell technologies fed by natural gas can be considered clean in terms of SO_2 and NOx emissions. The CO emissions can be considered quite low for the tested SOFC and even nil for the tested PEMFC. Those statements apply even with machines that have already been running for up to 45000 hours. Therefore, the biggest issue of natural gas fuel cell technologies still lies in the CO_2 emissions associated with the fossil fuel they consume.

Abstract:
Within the last years, there has been an increasing interest in the use of alternative fuels, among others, methanol. This fuel is liquid at ambient temperature and pressure and can be obtained through a synthesis process from hydrogen and captured CO_2, becoming e-methanol. Direct methanol fuel cells (DMFC) are devices that use this fuel in liquid form, without a reforming step, to produce electricity. These fuel cells have few moving parts and are used in portable electronic devices and electric vehicles. However, DMFC have efficiencies around 32 % and its commercial application is limited at present. Besides, advances need to be made to solve problems such as methanol crossover, sluggish methanol oxidation reaction and demand of noble metal for fabrication of these fuel cells. In this work, the effect of the depth of an anode serpentine flow field design on the performance of a direct methanol fuel cell is investigated experimentally. Stainless steel plates (SS316L) with single serpentine flow fields of different depths are designed, fabricated and tested. The study is conducted with these plates forming a single cell of 16 cm^2 of active membrane area. The aim of this work is to study the effect of the anode channel depth on the performance of a DMFC, analysing the influence of this parameter on the power density of this device and the methanol crossover that takes place during its operation. When the channel depth decrease from 1.5 mm to 0.5 mm, can be observed a power density increment of 18.86 %. However, the decrease of the channel depth resulted in an increase of the limiting methanol crossover current density by 28.75 %.

Keywords:
Methanol; fuel cell; anode flow field design; single serpentine flow field.

1. Introduction

Fuel cells are electrochemical devices that convert the chemical energy from a fuel and oxidant directly into electrical energy and heat. Theoretically, this way of obtaining electrical energy has higher efficiency as compared to internal combustion engines [1]. Fuel cells have the capability of supplying energy meanwhile the corresponding reactants are fed, and they are very versatile and scalable. Therefore they are a good alternative to traditional energy devices such as Li-ion batteries, having an enormous growth potential [1]–[3]. Considering the type of electrolyte used, there is a wide variety of fuel cell types. One of the most popular choices for renewable and sustainable energy conversion devices is the Proton Exchange Membrane Fuel Cell (PEMFC) [2]. This type of fuel cell is popular due to its high-power output, high efficiency, high specific energy, cleanliness, low operating temperature (below 100ºC), quick start-up times, longer life span and quiet operation [4],[5]. The main feature of the PEMFC is the electrolyte used, a proton conductive polymer membrane whose main function is the transport of protons from the anode to the cathode. Meanwhile, this membrane avoids the transport of electrons or reactants [5],[6]. PEMFC can use different fuels, being hydrogen the most studied, but its properties imply some drawbacks that make difficult their commercialization at this moment [3],[7]. Hydrogen has high flammability and a low volumetric energy density (hydrogen volumetric energy density in liquid state is 10.1 MJ/L, and compressed at 70 MPa is 5.6 MJ/L, while the volumetric energy density of natural gas is 22.2 MJ/L) [8]–[10]. This leads to the use of high-pressure technologies (like bulky pressure tanks or compressors) or/and very low temperature technologies for its handling, storage and

distribution [8]. These particularities represent a technological challenge at this moment. Nevertheless, the use of liquid fuels at room temperature, like methanol or ethanol, requires a notably easier storage and refuelling systems, because liquid fuels can be operated at standard temperatures and pressure [3],[9].

Direct methanol fuel cells (DMFC) use methanol as fuel, which offers advantages compared to hydrogen fuel cells, as a cheaper refuelling system, as methanol is easy to handle at standard temperatures and pressures derived from its liquid state [3],[11]–[13]. DMFCs are especially effective at delivering electricity for portable electronic devices and other mobile applications. [9],[13],[14].

DMFCs are fuel cells of PEMFC type and essentially consist of a membrane-electrode assembly (MEA), composed by two electrodes (anode and cathode) separated by an electrolyte (usually a polymeric membrane) [13]. The MEA is sandwiched between two bipolar plates (BPs) which have channels to distribute the fuel and oxidant through the gas diffusion layer [12],[13].

In DMFCs, methanol is oxidized at the anode yielding protons, electrons and CO_2. The protons are transported to the cathode, through the membrane, while the electrons are transported via an external circuit to the cathode. On the cathode the electrons and protons react with oxygen to produce water. By-products from both reactions, methanol oxidation and oxygen reduction, CO_2 and water are formed on anode and cathode respectively, and they are evacuated by BPs [3],[12],[13],[15]. The reactions are:

Anode: $\mathrm{CH_3OH} + \mathrm{H_2O} \rightarrow \mathrm{CO_2} + 6\mathrm{H^+} + 6\mathrm{e^-}$ (R1)

Cathode: $\frac{3}{2}\mathrm{O_2} + 6\mathrm{e^-} + 6\mathrm{H^+} \rightarrow 3\mathrm{H_2O}$ (R2)

Overall: $\mathrm{CH_3OH} + \frac{3}{2}\mathrm{O_2} \rightarrow \mathrm{CO_2} + 3\mathrm{H_2O}$ (R3)

The efficiency of fuel cells is determined by many variables, including operational parameters, such as cell operating temperature, mass transport, flow rates and other physical components of the cell like the membrane electrode assembly (MEA) as well as the BPs [4], [16].

BPs have fundamental roles that affect the performance of the fuel cell. Their design determines water management for the DMFC, preventing the flooding of the cathode. Also, BPs provides structural support for the thin and mechanical weak MEAs, facilitating heat and electrical conductivity, and mass transport (reactants and by-products). In fact, the geometry of BP channels helps the entry and distribution of the reactants onto the active surface of the cell, the gas diffusion layer, and the evacuation of the by-products. In addition, the geometry of BP channels influences the crossover process. Experimental results show that single serpentine flow fields present low pressure drops between the inlet and the outlet of the channel, which effectively removes products and prevents blockages of the flow field [11],[17].

The objective of this work is to determine the influence of channel depth on the electrochemical performance of a DMFC and crossover produced during the operation of this device. For that purpose, three different anode channel depths (0.5, 1.0 and 1.5 mm) have been studied. Channels depth affects the mass transport, fluid velocity and the fraction of the two phases (gas and liquid phase) thus affecting the cell performance [14]. In this work, a series of experiments was designed to obtain the polarization curves and measure the limiting methanol crossover current density for each depth.

2. Methodology

This section outlines the methodology used to determine the impact of the anode channel depth on the performance of a DMFC. The parameters of the anode channel configuration, as well as the material of the single cell plates, are set except for the depth.

As previously stated, BPs have fundamental roles on cell performance, as supply reactants, remove reaction products, act as current collectors and facilitate thermal management and structural support [4]. Having those fundamental roles in mind, the material used in this work for bipolar plates is stainless steel 316L (SS316L). As metallic material, SS316L has good mechanical resistance, high electrical conductivity, it is easily machinable [19] and it has good characteristics over a prolonged period of time [20]. Stainless steel is also capable of self-passivating, which allows a significant reduction of corrosive rate, however, it results in a notable increase in interfacial contact resistance with other elements such as gas diffusion layer in the case of fuel cells [21].

The DMFC single cell used this work (Figure 1A) is composed by two plates of stainless steel 316L (anode and cathode plates), two gaskets which prevent the electrical contact between the plates and avoid fluid leaks, and a MEA. The MEA is composed by a Nafion membrane, sandwiched between two layers of commercial electrodes.

Figure 1B shows the front view of the flow field plate used in this work, depicting stainless steel plates for the anode flow field. These plates feature single-channel serpentines measuring 1 mm of channel width. The channel depths studied include 0.5, 1.0 and 1.5 mm. As introduced before, according to literature the single-channel serpentine configuration prevents the blockage of the channel, allows the effective removal of products, suitable two-phase mass transport and appropriate flow behind the ribs [22], and facilitates a uniform reactant distribution [23]. For all these reasons single-serpentine flow field is the flow pattern more commonly used at present. However, this flow pattern presents significant concentration gradient between the inlet and the outlet [23].

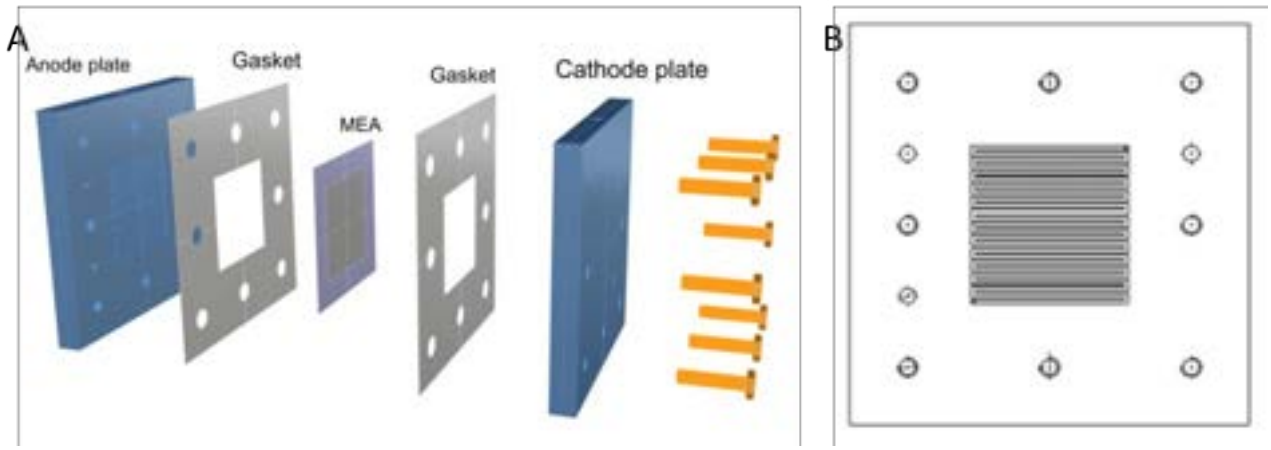

Figure 1. A- Exploded view of the designed and fabricated in-house DMFC single cell used in this work. B- Front-view projection of the flow field design of the anode plate studied.

The performance of the DMFC is also affected by the direction of the supply of the reactant, as this direction is related to the uniformity of the reactant distribution and temperature over the cell [24]. The methanol solution inside the anode is supplied bottom-up, against gravity. In this way, the formed gaseous CO_2 would be swept by the methanol solution, following the natural pressure gradient for easier evacuation [25]. Analogously, the oxidant, oxygen, is supplied from the top inlet of the cell to ease the evacuation of the liquid water produced in the cathode, to prevent the cathode channels from flooding [24].

The design parameters of the anode and cathode plates, used with the aim of determining the effect of the depth channel on the cell performance, are summarized in Table 1.

Table 1. Parameters of the anode channels studied in this work.

Parameter	BP1	BP2	BP3
Depth of anode channels, mm	0.5	1.0	1.5
Depth of cathode channels, mm	0.5	0.5	0.5
Material of the bipolar plates	SS316L	SS316L	SS316L
Number of channels	25	25	25
Width of the channel, mm	1.0	1.0	1.0
Open Ratio	0.624	0.624	0.624
Contact surface treatment	N3	N3	N3

The fuel and oxidant flow rates are set to obtain excess supply of the reactants avoiding possible mass transfer losses. The parameters used in this work are summarized in Table 2.

Table 2. Parameters used during the experimental tests developed in this work.

Parameter	Value
Temperature, °C	60
Methanol concentration, mol/l	1
Methanol flow rate, ml/min	3
Methanol supplier	Panreac AppliedChem (99.9%)
Oxygen flow rate, ml/min	110
Oxygen pressure, MPa	0.1
Anode catalyst	Pt/Ru
Anode catalyst charge, mg/cm^2	3
Anode commercial reference	BC-H225-10F
Anode supplier	Quintech
Cathode catalyst	Pt
Cathode catalyst charge, mg/cm^2	1
Cathode commercial reference	BC-M100-30F
Cathode supplier	Quintech

3. Results and discussion

Figure 2 shows the polarisation and power density curves obtained for each of the anode channel depths studied.

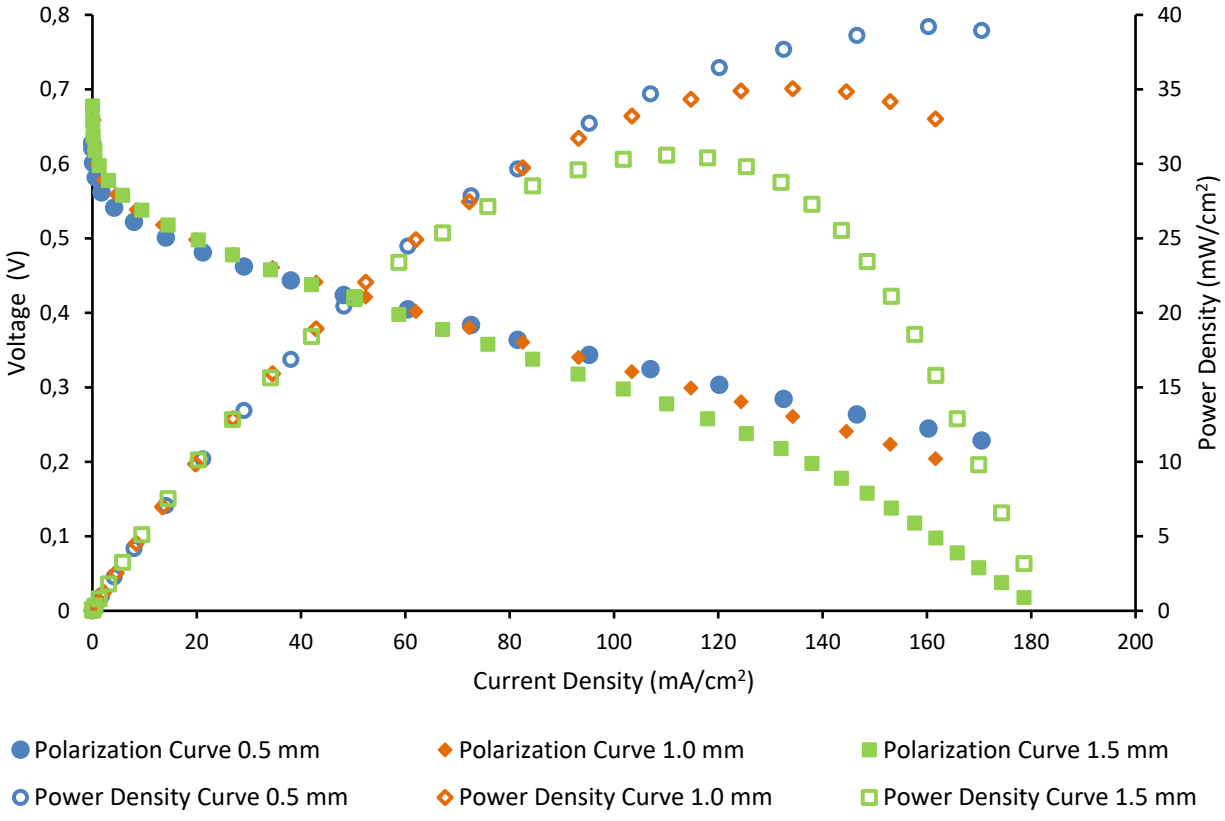

Figure 2. Polarization and power density curves of the DMFC single cell with anode channel depths of 0.5 mm, 1.0 mm and 1.5 mm, results obtained at a temperature of 60 ºC, cathode pressure 1 bar, oxygen flow rate of 110 ml/min, a methanol concentration of 1 M and methanol flow rate of 3 ml/min.

The results suggest that, for a given operating condition, a decrease in the anode channel depth leads to an improvement in the DMFC performance, contrary to the conclusions of the work of Chen et al. for a DMFC stack [14], as a reduction in the depth of the anode channels of the stack does not cause significant changes in the analysed stack performance. This may mean that the performance of the channel configuration in a single cell and a stack could not have a directly proportional relationship, so smaller improvements can be observed when working with a stack.

Furthermore, during the tests for obtaining polarization curves using the anode channel depth of 1.5 mm it was observed an accumulation of CO_2 in the anode channel. Results suggest that difficulties on CO_2 removal can affect the DMFC performance producing a decrease in peak power density.

In Figure 2 it can be observed that the peak power density increases from 32.76 mW/cm^2 with 1.5 mm of depth to 38.94 mW/cm^2 with 0.5 mm of depth. However, it should be noted that reducing the depth of the flow channel results in increased pressure drops along the channel [27]. This, in turn, increases the power required for pumping the methanol solution. Consequently, the overall efficiency of a DMFC system may decline. Furthermore, a higher pressure drop could cause a portion of the methanol solution to bypass the flow channel and instead flow directly through the diffusion layer. Also, a lower channel depth than the 0.5 mm tested could produce a worst performance due to factors including methanol crossover and the void fraction of CO_2 [27]. For these reasons, future research should examine the trade-off between the advantages and disadvantages arising from the alteration in channel depth for a DMFC stack and its auxiliary systems.

Figure 3 shows the impact of channel depth on limiting crossover current density. Methanol crossover causes electrode depolarization, mixed potential, resulting in an open-circuit voltage below 0.8V. Besides it consumes some reactant at the cathode, so it produces intermediates of the reaction, like carbon monoxide, that poisons the cathode catalyst and generates water accumulation on the cathode. Consequently, the crossover current density cause the reduction of fuel cell performance [26],[15].

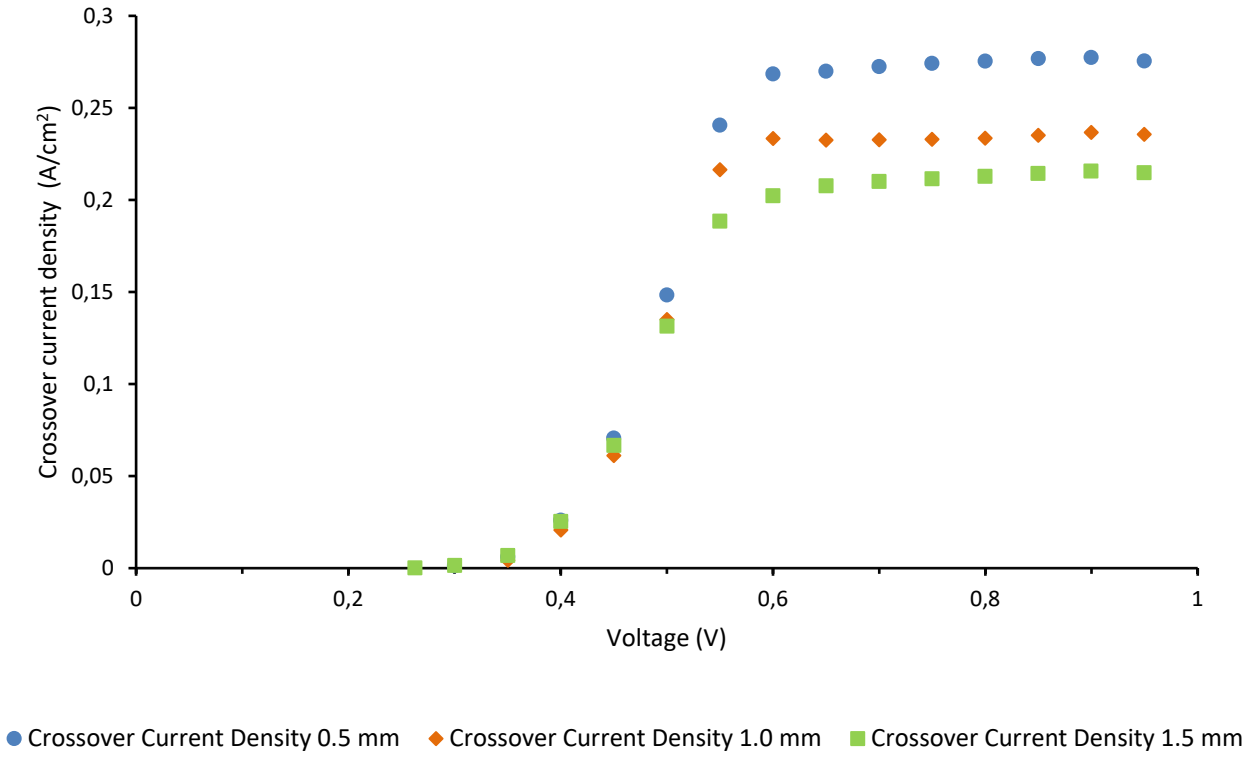

Figure 3. Crossover current density of the DMFC with bipolar plate with 0.5 mm, 1.0 mm and 1.5 mm of channel depth, results obtained at a temperature of 60 ºC, cathode pressure 1 bar, nitrogen flow rate of 110 ml/min, a methanol concentration of 1 M and methanol flow rate of 3 ml/min.

The graph presented in Figure 3 illustrates the relationship between the applied potential and the current density generated by the oxidation of methanol as it passes through the assembly. The maximum current density observed for each MEA represents its respective limiting crossover current density. Minimizing methanol crossover through the membrane is crucial for enhancing both fuel utilization and the potential at the cathode in DMFC operations [28]. Regarding this matter, Figure 3 demonstrates that deeper channels feature superior properties in preventing methanol crossover compared to shallower channels. This is evident from its slightly lower limiting methanol current density. As a result, the DMFC with the 1.5 mm channel displays the lowest limiting crossover current density value (215 mA/cm^2), which is significantly lower than that of 1 mm (236 mA/cm^2) and 0.5 mm (277 mA/cm^2).

Comparing the results shown in Figures 2 and 3, it can be concluded that despite producing a higher crossover, a shallower channel depth seems to give better results when analysing the power density of the studied single cell.

4. Conclusions

The effect of the anode channel depth on the DMFC performance has been investigated experimentally. The results show that an anode channel depth of 0.5 mm provides a higher peak power density than 1.0 mm and 1.5 mm channels depths, obtaining an increase of 18.86 % in peak power density with respect to the deepest channel. It has also been found that gas bubbles, formed during the reaction on the anode, can generate a decrease in the cell performance when the channel depth increases. These results suggest that shallower channels improve CO_2 removal and consequently cell performance. However, changes in the anode channel depth also have an influence on the limiting crossover current density obtained, as measurements of this parameter with 0.5 mm channel depth show an increase of 28.75% over those obtained with 1.5 mm channel depth.

Future studies should be carried out to analyse the effect of anode channel depth in combination with other parameters, like temperature, methanol concentration and oxygen flow rate, to improve the performance of DMFC.

Abstract:

Despite the impact of global warming on the living conditions of the Earth, fossil fuels still dominate the global energy scenario. The precariousness of our energy system requires the use of more reliable and less polluting energy sources, but a greater penetration of intermittent renewables implies the need for large-scale flexible energy storage. This need, combined with the growing interest in the use of hydrogen in mobility and industry, makes the prospect of including this energy vector in our daily lives tangible. However, the problems related to the development of dedicated infrastructures make its positioning on the market complex. In a transition phase, power-to-gas systems constitute an emerging solution that allows the use of existing structures for natural gas and, at the same time, solves the problem of hydrogen storage. In this study, a power-to-gas system producing synthetic methane from wind energy was modelled. Management strategies for both the electrolysis system and the hydrogen storage tank were tested to assess the flexibility and versatility of the system. Particular attention was dedicated to the analysis of the impact of the storage on the mitigation of the operating condition fluctuation of the methanation unit. Results of the simulations showed similar performances of the four electrolyzers and a limited number of methanation unit shutdowns. Nevertheless, the annual utilization factor of the subsystems was low, and this suggests a further investigation of the subsystems' sizing. Overall, the effectiveness of the management strategies developed for the power-to-methane system makes the proposed model a good instrument to be used for further analysis and evaluations.

1. Introduction

Decarbonizing the world's energy system requires the use of green and renewable energy sources (RES). However, a high penetration of renewable sources in the global energy mix creates additional challenges related to the more complex management of energy flows and the difficulty of synchronizing energy demand and production. This problem can be solved using energy storage systems. In this context, hydrogen has been identified as a sustainable energy vector for electricity and heat generation; nevertheless, today 96% of the produced hydrogen is obtained from fossil fuels and only 3.9% comes from electrolysis [1] due to the elevated costs associated with its entire supply chain.

Although some hydrogen production technologies (e.g.: alkaline electrolysis) alternative to fossil fuel-based ones are already mature, the lack of dedicated infrastructures makes the introduction of hydrogen in the market difficult [2]. Using hydrogen for the synthesis of various hydrocarbons, including methane [3,4], could be considered a promising solution to foster hydrogen economy while using the existing infrastructure. Lewandowska-Bernat & Desideri [4] identify various opportunities for the power-to-methane systems (both in off-grid and on-grid systems) that are considered promising for the development of more efficient and flexible energy systems, the reduction of polluting emissions, and the increase of sustainability in sectors such as industry and mobility. After a comparison among short-term storage systems, Belderbos et al. [5] conclude that power-to-fuel systems can play a significant role in scenarios with a high share of renewable energy. In particular, they analyze four case studies each of which characterized by a different type of RES (onshore wind, offshore wind or solar). Their study illustrates the different trends of methane production and how power-to-gas systems play a more important role when the renewable energy production profile has a seasonal trend. Furthermore, Walker et al. [6] identify power-to-fuel as an attractive solution to implement, especially for seasonal storage.

Some issues arise and should be considered when electrolysis systems are directly coupled with variable RES. In particular, alkaline electrolyzers have some limitations on the lower operating load because of safety reasons, and they can generally operate in a range of 20-100% of the nominal power [7].The variability of these sources might affect the system operation by causing frequent shutdowns, part-load and dynamic operation. However, frequent shutdowns can speed up the stack degradation and should be limited. In addition, the intermittent RES availability causes a low number of annual equivalent operating hours that negatively affects the specific production cost of hydrogen. Several studies investigated techno-economic aspects of electrolysis systems coupled with RES. Liponi et al. [8] investigate the effect of the electrolyzer size on the levelized cost of hydrogen in the case of PV-electrolyzer coupling. The choice of the electrolyzer size should be a trade-off between the maximization of hydrogen production and the needs of limiting shutdowns and having sufficiently high electrolyzer utilization factors to minimize the specific production costs. The possibility of adopting an electric storage [9] and/or grid-electricity support [10] to mitigate wind variability has also been investigated. On one side, by allowing grid support, the electrolyzer operation can be more continuous and annual operating hours are increased, resulting in a reduction of specific production costs. However, on the other side, if the electricity grid is not completely decarbonized, CO_2 emissions are associated with hydrogen production. In another study [11] Liponi et al. perform a techno-economic comparison of different configurations of an electrolysis system consisting of multiple electrolysis units that can operate separately for hydrogen production from wind sources.

In this study, an electrolysis system composed by several separated units is adopted and a management strategy is implemented to limit the number of electrolyzers shutdowns.

Several models for power-to-gas systems were proposed in the literature. In particular, Baccioli et al. [12] analyze the costs associated with the production and sale of liquefied methane and oxygen from a power-to-gas plant associated with a CO_2 source from a geothermal plant. This study reveals that using hydrogen storage does not increase the cost-effectiveness of the plant, while "only small storage systems will be needed for managing the different dynamic behavior of the components" [12]. Gorre et al. also published two studies in this subject [13,14]. In the first study, they observe that the production costs of methane in a power-to-gas system can be reduced by releasing the operation of electrolyzer and methanation unit by using an intermediate storage system. They also assert the importance of optimizing the size of the methanation unit. In the second study, they underline the importance of using an intermediate storage to decouple the electrolysis system and the methanation unit, but also the need to optimize its size to reduce production costs, depending on the operation strategy and the case study.

In a 2009 study [15] Frate et al. investigate the use of electric storage systems to counter the problem of wind power fluctuations in small-sized wind farms. In particular, they study the effectiveness of Li-Ion batteries and flywheels in managing the rates of power output from a wind turbine. Nevertheless, the impact of the management strategy of hydrogen and electricity surplus on the mitigation of the operating condition fluctuation of the methanation unit have not been deeply investigated.

In the present work, a mathematical model to simulate the operation of a power-to-gas system with wind-energy source is proposed. The problems related to the variability of the energy source will be addressed by developing a management strategy for both the electrolysis system and the hydrogen storage tank, in order to limit the number of shutdowns (and consequently the equipment degradation) and, at the same time, to exploit to the maximum the electricity produced by the wind farm.

2. Modeling

A schematic representation of the power-to-gas system modelled in this study is given in Figure 1. The first step is the production of hydrogen (and oxygen) through an electrolysis system (composed of four alkaline electrolyzers of equal nominal power) powered by a dedicated wind farm. The produced hydrogen is partly sent to the methanation unit and partly injected in a storage system before the methanation unit. The conversion of hydrogen and CO_2 to methane takes place in a catalytic methanation reactor. The main components of the system are modelled (wind farm, electrolyzers, and methanation unit) as described below.

2.1. Alkaline electrolyzer

Several models for the simulation of the operation of an alkaline electrolyzer are provided in literature. The foundations of “semi-empirical” alkaline electrolyzers models are built by Ulleberg [16], whose model is based on a combination of fundamental thermodynamics, heat transfer theory and empirical electrochemical relationships. An extension of this model is proposed in the study of Amores et al. [17] in which the effect of electrolyte concentration and cell architecture is also studied. Sánchez et al. published two other relevant studies on this subject [18,19] in which a semi-empirical mathematical model based on the polarization curve and the Faraday efficiency in dependence of pressure, temperature and current density is proposed. Dièguez et al [20] develop a thermal modeling of the electrolyzer focusing on coupling the stack with a renewable energy source.

Whereas the above-mentioned studies use a simplified lumped parameter configuration for the description of the electrolyzer, in which stack, gas-liquid separators and heat exchangers are treated as a single component,

in this study a more detailed modelling is performed, paying greater attention to individual elements and control systems. The baseline study used is from Sakas et al. [21], in which a model based on energy and mass balances with adjustable parameters with a zero-dimensional approach is proposed.

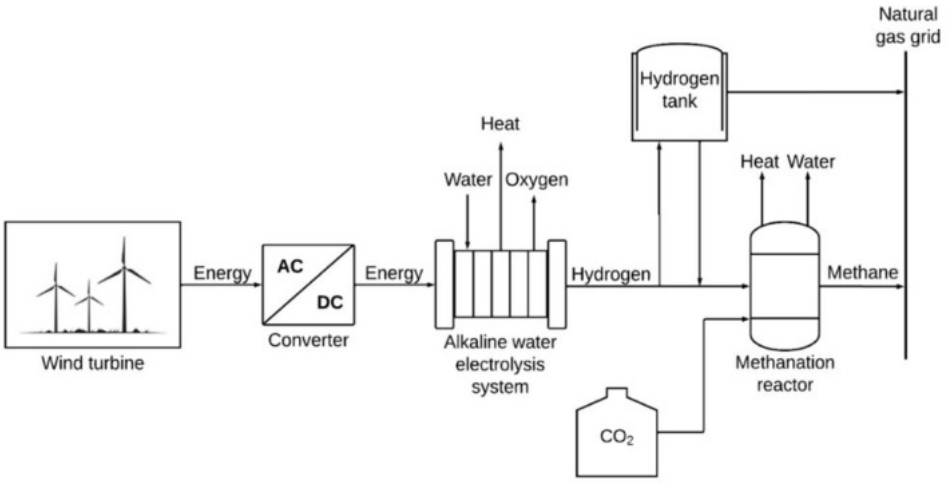

Figure 1. Schematic representation of the power-to-gas system.

Electric current powers the stack for the production of gaseous hydrogen and oxygen. At the stack outlet, a mixture of electrolyte (25wt% KOH) and hydrogen on one side, and oxygen on the other side, are sent to the horizontal gas-liquid separators. Hydrogen and oxygen are removed from the separator, while the electrolyte mixture is sent to the mixer where it is mixed with the make-up water. The oxygen leaving the separator is just flushed from the process, while the produced hydrogen is sent to the methanation unit (see Figure 2).

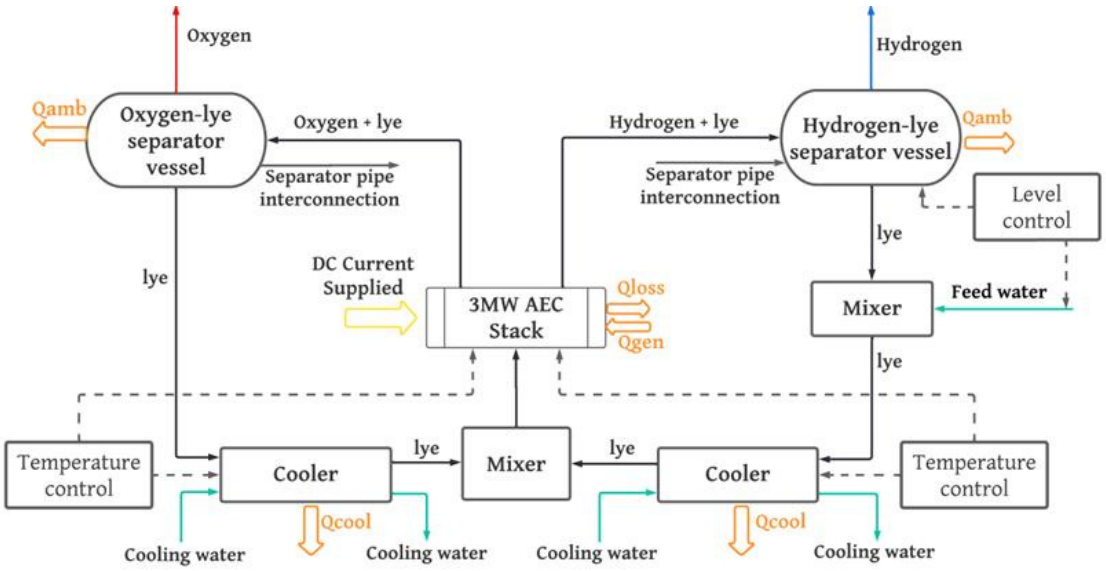

Figure 2. Alkaline water electrolyzer plant process diagram.

The stack is modeled in Matlab assuming the parameters listed in Table 1.

Table 1. Stack model parameters [21]

Parameter	Unit	Value
Number of cells	-	326
Cell lateral area	m^2	2.66
Cell block diameter	m	1.84
Free cell volume	m^3	0.027
Distance between bipolar plates	m	0.01
Stack length	m	5.85

A thermal model and an electrochemical model are used to calculate the production of hydrogen, the trend of flow rates, temperatures, energy losses, cell voltage and cell current.

2.1.1. Electrochemical model

The cell voltage is calculated as the sum of the reversible potential and overvoltage terms:

$$E_{cell} = E_{rev} + E_{act} + E_{ohm} + E_{conc} \quad (1)$$

The reversible potential is the minimum voltage necessary for the water splitting reaction to take place and depends on the temperature and pressure according to Nerst equation. Overvoltage are expressed through semi-empirical expressions as a function of temperature and current density [21].

The polarization curve is defined as a function of the cell current, which is calculated through Newton's iterative method using the parameters adopted by Sakas et al. [21] for a 3 MW alkaline electrolyzer.

2.1.2. Thermal model

The stack temperature of an alkaline electrolyzer is one of the parameters that most affects its performance. In this paper, internal temperature gradients in the stack are assumed spatially uniform, according to Sakas et al.'s lumped thermal capacitance model [21].

The overall thermal energy balance is expressed by:

$$C_{stack} \cdot \frac{dT_{stack}}{dt} = Q_{gen} - Q_{loss} + \dot{m}_{lye,stackin} \cdot \bar{c}_{p,lye} \cdot T_{stackin,cooled} - \left(\dot{m}_{lye} + \dot{m}_{cons,wat}\right) \cdot \bar{c}_{p,lye} \cdot T_{stack} \quad (2)$$

The term on the left in Equation (2) represents the rate of change of the electrolyzer temperature over time, while Q_{gen} is the heat generated inside the stack, Q_{loss} is the total heat loss to the ambient and the other two terms are the enthalpy flows of the incoming and outgoing electrolyte mixture from the stack.

Since the flow rates of hydrogen and oxygen are very low compared to the flow rate of the electrolytic mixture circulating in the system (0.0138 kg/s, 0.12 kg/s and 19.68 kg/s respectively at nominal conditions), they can be neglected in the energy balances.

The hydrogen and oxygen produced by the electrolysis process exit from the stack in the form of a mixture of gas and electrolytic solution, therefore it is necessary to separate them from liquid phase through two horizontal gas-liquid separator vessels. In the present study, for simplicity, the separation efficiency is considered unitary.

To prevent gas-liquid separators from excessively emptying or filling, an on/off control of their liquid level is applied to the water make-up pump to keep the separators' level within a certain range (0.4 m – 0.6 m) for the entire duration of the simulation.

After gas separation, the electrolytic mixture enters the mixer where the consumed water is refilled. Although mixing with low temperature water (15°C) results in a lowering of the temperature of the electrolyte mixture, this is not enough to reach the target temperature of the stack. Therefore, a cooling system with a temperature control is required. The regulation has the aim to keep the stack temperature always near the target value (70°C).

The efficiency of the electrolyzer was defined as:

$$\eta_{ele} = \frac{\dot{m}_{H_2} \cdot LHV_{H_2}}{P_{stack}} \quad (3)$$

2.1.3. Operation at nominal conditions

The simulation is performed using a 5-minute time discretization. By simulating the operation of a single electrolyzer fed with nominal power, the results obtained were very close to those obtained in the reference study [21], whose model was validated. In Table 2, the main operating parameters of the electrolyzer are given.

2.2. Hydrogen storage tank

The storage system was considered an ideal component, and it was modeled as a variable volume at constant pressure (16 bar). Its storage capacity is 4,434 Nm^3 of hydrogen, corresponding to the amount of hydrogen required by the methanation unit to operate continuously for two-and-a-half hours at nominal conditions. The State of Charge (SOC) of the tank is defined as:

$$SOC(t) = \frac{V_{H_2,tank}(t-1)}{V_{H_2,tank,cap}} \quad (4)$$

Where $V_{H2,tank}(t-1)$ is the hydrogen volume content inside the tank at the timestep "t-1" and $V_{H2,tank,cap}$ is the storage capacity of the tank.

2.3. Methanation unit

The methanation unit is modelled in Matlab without going into the thermodynamic details of its operation. The model provides the methane flow rate on the basis of the produced hydrogen according to stoichiometry.

The methanation unit is assumed to operate in a range of 40-100% of the nominal flow rate, without major changes in the quality of the produced gas, with a maximum load change rate of ±10%/min [13]. Since the electricity input might fluctuate strongly and electrolyzers and the methanation unit work at different loads, it is necessary to decouple the two components. For this purpose, a hydrogen storage tank is installed between the electrolyzer and the methanation unit, and it is modeled as an ideal component. In this study, the methanation unit, the electrolysis system and the storage system are considered at the same pressure (16 bar), but compressing the hydrogen after the electrolysis system could significantly decrease storage volume. The methane flow rate is retrieved from the methanation efficiency according to the Eq. (5).

$$\eta_{\mathrm{met}} = \frac{\mathrm{LHV}_{\mathrm{CH_4}} \cdot \dot{m}_{\mathrm{CH_4}}}{\mathrm{LHV}_{\mathrm{H_2},} \cdot \dot{m}_{\mathrm{H_2,in}}} \cdot 100 \quad (5)$$

Table 2. Alkaline electrolyzer operating parameters at nominal conditions.

Parameter	Unit	Value
Stack target temperature	°C	70
Ambient temperature	°C	25

Nominal hydrogen molar flow	Nm^3/h	1,773

3. Management algorithms

3.1. Electrolysis system

The power generated by the wind farm is sent to an electrolysis system composed of four alkaline electrolyzers, each of which has a nominal power of 3 MW. During the simulations, due to the variability of the renewable source, the wind farm rarely produces its nominal power. For this reason, a management algorithm is developed to ensure that the four electrolyzers have similar operating conditions and, at the same time, a limited number of shutdowns.

Three operating states are defined: on, off and standby. The management algorithm ensures the electrolysis system to work always within its operative range (20-100% of its nominal power). Based on the input power, which is fairly divided among the operating machines, the electrolyzers state is established at each timestep according to the following parameters:

- the state of the electrolyzer at the previous timestep.
- the equivalent operating hours.
- the duration of the off and the standby states.

The aim of the management algorithm is to ensure that the four electrolyzers have averagely similar performances in terms of number of shutdowns, equivalent operating hours and hydrogen production.

3.2. Methanation unit and hydrogen storage system

The hydrogen flow rate feeding the methanation unit is often different than the nominal flow rate depending on the power supplied by the wind farm. In particular, if the inlet hydrogen flow rate from the electrolysis system

exceeds the value of methanation unit nominal feed flow rate, the methanation unit works at maximum load, and the storage tank provides the missing amount of hydrogen (Figure 3, timesteps "i+1"). On the other hand, if the produced hydrogen is lower than the minimum flow rate of methanation, the methanation unit is set to its minimum load, and the storage tank stores the surplus hydrogen (Figure 3, timesteps "i-1"). When the electrolysis system has greater load change rates than those tolerable by the methanation unit, the storage system acts as a "ramps mitigator" (Figure 3, timestep "i+2"). When the methanation unit operates within the load range, it does not only convert into methane the produced hydrogen flow from the electrolysis system, but the hydrogen feed flow rate could be increased or decreased (if SOC > SOC_{target} or SOC < SOC_{target} respectively). The SOC_{target} is set to 50%.

Then, when the methanation unit operates within the load range, the inlet flow rate is calculated as:

$$\dot{m}_{met}(t) = \dot{m}_{ele}(t) + \dot{m}_{SOC}(t) \quad (6)$$

Where $\dot{m}_{SOC}(t)$ depends on the SOC at the timestep "t-1".

The storage system, therefore, has the function of absorbing the off-range hydrogen production peaks, keeping the ramps within the constraints imposed to the load change rate of methanation, and methane production support.

Depending on the size of the methanation unit, during the simulations the electrolysis system could produce a certain amount hydrogen which cannot be converted into methane. However, the storage tank can store hydrogen until it reaches the full status, after which the surplus hydrogen can no longer be stored. In this case, we could have hydrogen losses.

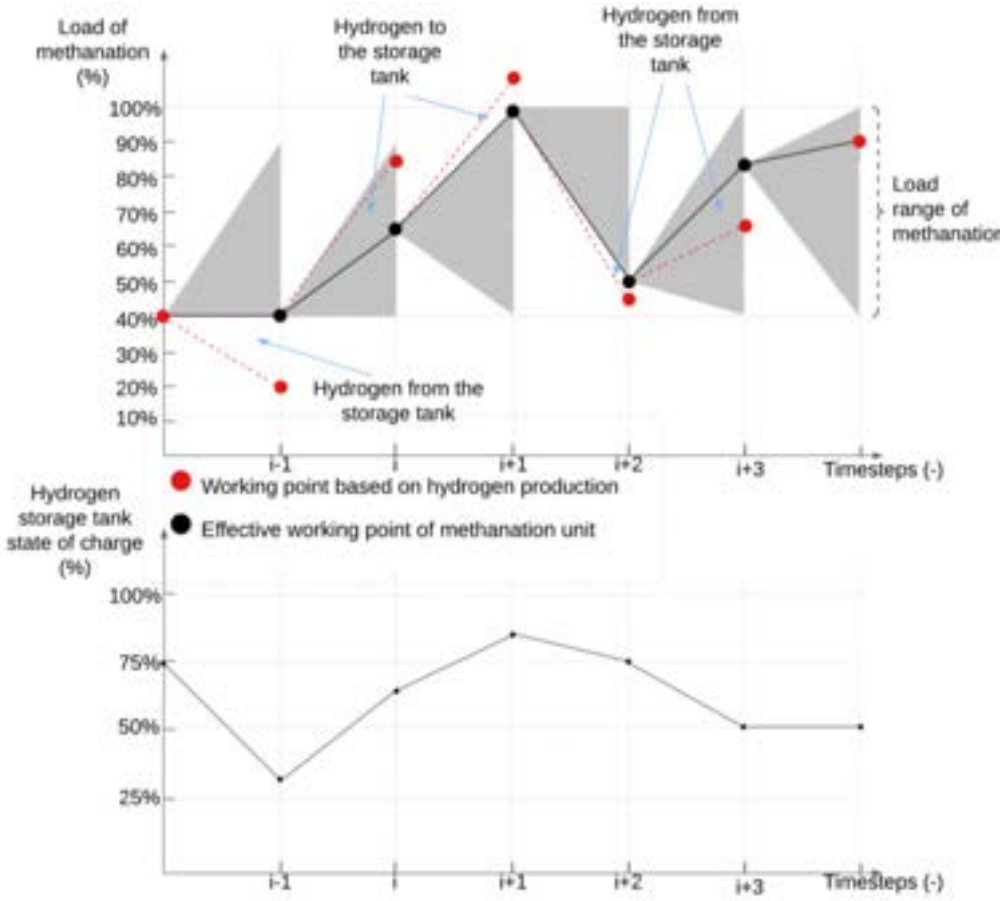

Figure 3. Example of operating of the methanation unit management strategy. The grey area represents the permissible operating points of the methanation unit at each timestep [15].

In order to avoid excessive shutdowns, a minimum SOC is imposed to allow the methanation unit to extract the required hydrogen from the storage tank to ensure operation at the minimum load. This constraint is needed only if the methanation unit was in the "off" state at the previous timestep. In fact, especially during less windy seasons, the hydrogen production is not enough to ensure the operation at minimum load. Therefore, allowing an uncontrolled adsorption of hydrogen from the tank would cause excessive on/off cycles of the methanation unit, since the low hydrogen production and the low SOC of the tank are not able to support continuous operation. Setting a minimum SOC (SOC_{min} = 50%) to be achieved to withdraw from the hydrogen storage tank

allows it to reach the conditions for supporting the methanation unit for a certain period, limiting its shutdowns and, consequently, its degradation.

4. Results and discussion

In a first phase, simulations of the single electrolyzer operation powered by a 3 MW wind farm were carried out on four typical days characterizing the seasonal trend of the wind: December 21, September 25, March 22, June 21 (solstices and equinoxes, or, when the wind data for those specific days seemed to have an untypical trend, days close to solstices and equinoxes). Figure 4 and Figure 5 show the performance of the cooling system and the separators level control system, respectively. During windy days (December 21 and September 25) the cooling system was in the “on” state for almost all the day. This happens because a greater windiness results in a most intensive use of the electrolyzer and then in a greater heat generation.

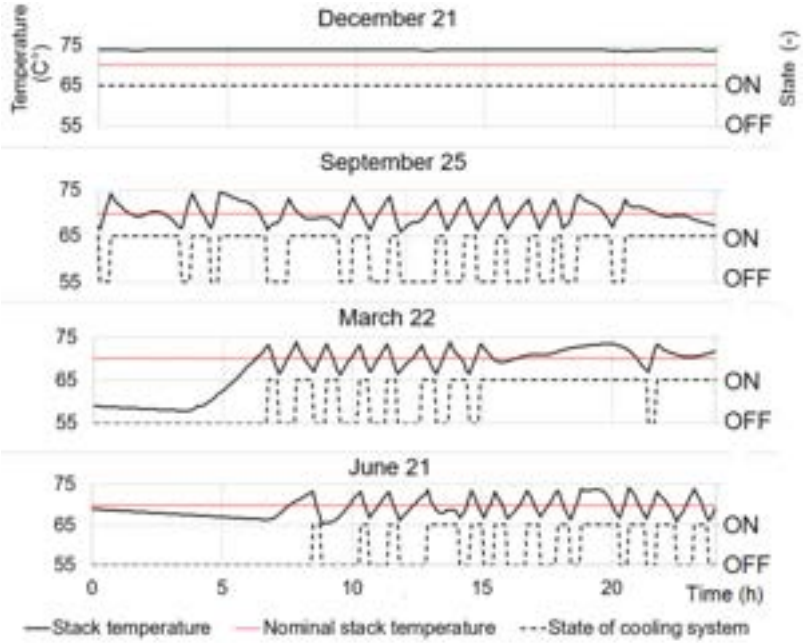

Figure 4. Performance of the cooling system during four seasonal characteristic days.

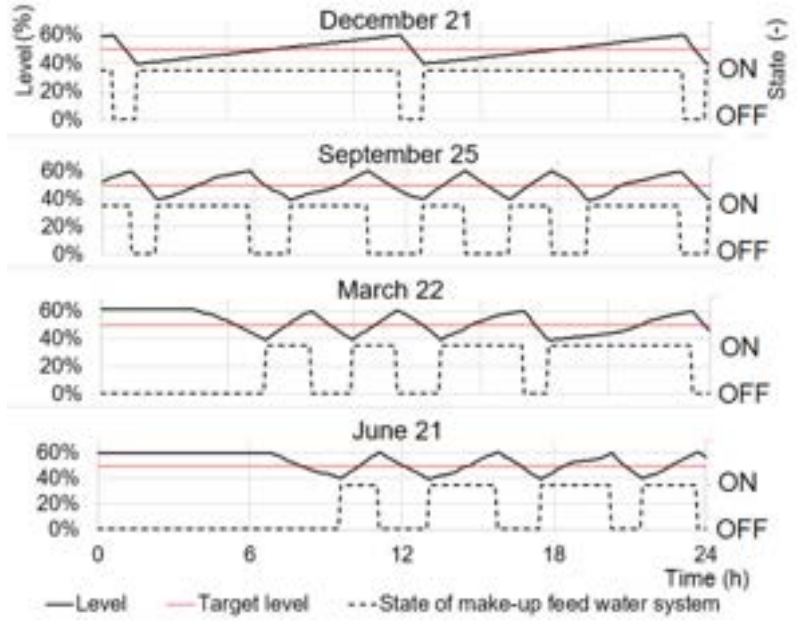

Figure 5. Performances of the separators level control system during four seasonal characteristic days.

Similarly, the separators level control system showed a longer working time of the make-up feed water system in winter and autumn (Figure 5). However, both the stack temperature and the separators level were always within the required range (70 ± 5°C and 50 ± 10% of the separator height, respectively), which is a sign that the applied control systems ensure the desired management of the alkaline electrolyzer.

Figure 6 shows the power distribution between the four electrolyzers of the electrolysis system during a daily simulation (September 25). The sizing of the electrolyzers was such as to ensure the utilization of all the renewable power and, on the other hand, the respect of the constraints imposed to the electrolyzers.

The four electrolyzers exhibited different performances in terms of hydrogen production, number of shutdowns and utilization factor (Table 5). However, the duration of a daily simulation is not enough to observe the efficacy of the proposed management algorithm.

Regarding to the whole power-to-gas system, Figure 7 shows the operation of the management algorithm for the methanation unit and hydrogen storage during a two-days simulation. Until 4 pm of the first day the the SOC of the hydrogen storage tank was under 50%; then, a certain share of the produced hydrogen incoming from the electrolysis system was used to fill the storage tank, while the remaining flow rate was sent to the methanation unit to be converted in methane.

Table 4. Performances of the alkaline electrolyzer for four seasonal typical days.

Day	Feed water system at the "on" state (%)	Stack average temperature (°C)	Average efficiency (%)	Cooling system at the "on" state (%)	Hydrogen production (Nm^3)	Utilization factor (%)
21-Dec	100	73.9	60	89	13,316	100
25-Sep	64	70.0	62	63	9,380	69
22-Mar	52	68.0	62	52	7,964	59
21-Jun	33	69.2	63	38	5,569	42

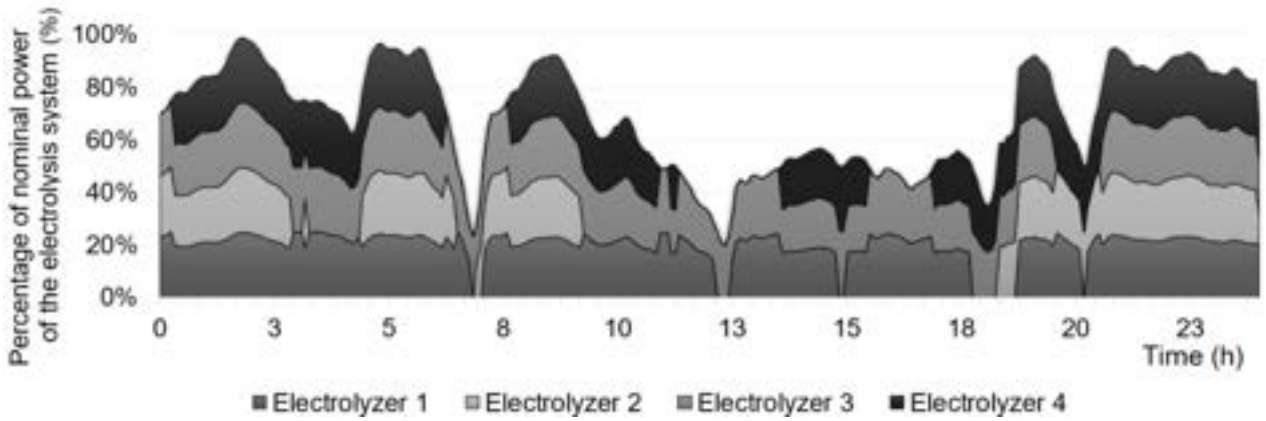

Figure 6. Power distribution between the four electrolyzers during a daily simulation.

From 4 pm of the first day the SOC of the hydrogen storage tank was over 50%; in particular, approximately from 8:30 pm to 10 pm of the first day and 2:30 am to 5 am of the second day the produced hydrogen and a certain share from the storage tank are sent to the methanation unit. During the remaining period, the produced hydrogen was out of the constraints of the methanation unit; in fact, the methanation unit was set to the maximum load or switched off, and the surplus hydrogen was stored up to the filling limit of the storage tank.

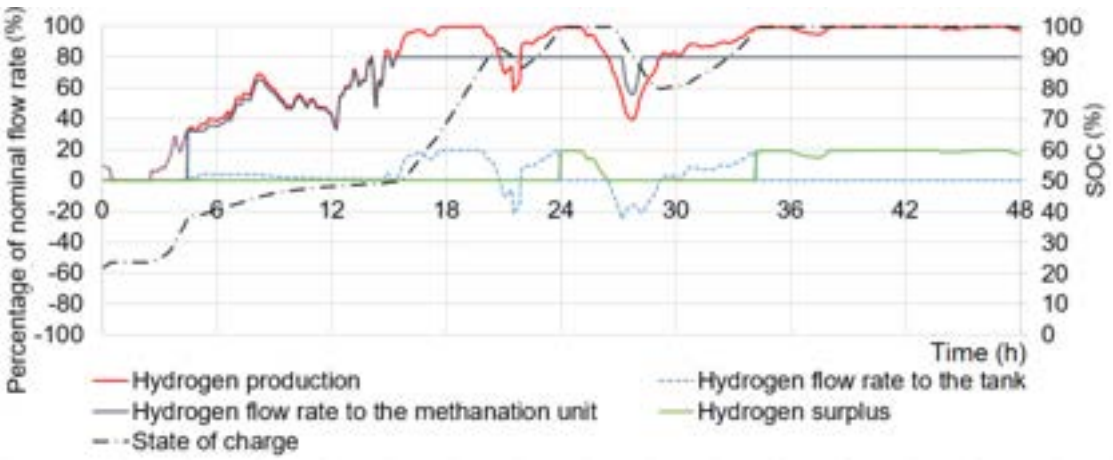

Figure 7. Performance of the management strategy for the methanation unit and hydrogen storage during a two-days simulation.

Table 5. Performances of the four electrolyzers in a daily simulation.

Electrolyzer	Efficiency (%)	Hydrogen production (Nm^3)	Utilization factor (%)	Number of shutdowns (-)	Oxygen production (Nm^3)	Water consumption (kg)	Average tack temperature (°C)	Maximum duration of the off period (h)
1	60	10,619	80	1	5,283	8,532	70.5	0.5
2	60	6,388	48	2	3,171	5,133	67.9	8.6
3	60	10,993	82	1	5,470	8,833	70.1	0.5
4	60	8,716	65	3	4,333	7,003	69.6	1.8
Electrolysis system	-	36,716	-	-	18,258	29,500	-	-

In Figure 8 the characteristic variable trends of the power-to-gas system during four seasonal characteristic days are shown. The hydrogen flow rates and the methane production were expressed as percentages of the nominal hydrogen production of the electrolysis system ($\dot{V}_{H_2,nom,ES} = 2{,}216\,Nm^3/h$) and the nominal production of the methanation unit ($\dot{V}_{CH_4,nom} = 439\,Nm^3/h$), respectively.
The methane production and the utilization factors for the methanation unit and the storage tank for four seasonal typical days are given in Table 6.

Table 6. Methane production and utilization factors for the methanation unit and the hydrogen storage system for four seasonal typical days.

Day	Methane production (Nm^3)	Storage utilization factor (%)	Methanation unit utilization factor (%)	Surplus hydrogen (Nm^3)	Number of shutdowns (-)	Average load (%)
21-Dec	10,538	80	100	10,539	0	100
25-Sep	8,831	45	84	0	0	84
22-mar	6,952	43	66	76	1	66
21-Jun	5,014	26	48	0	1	47

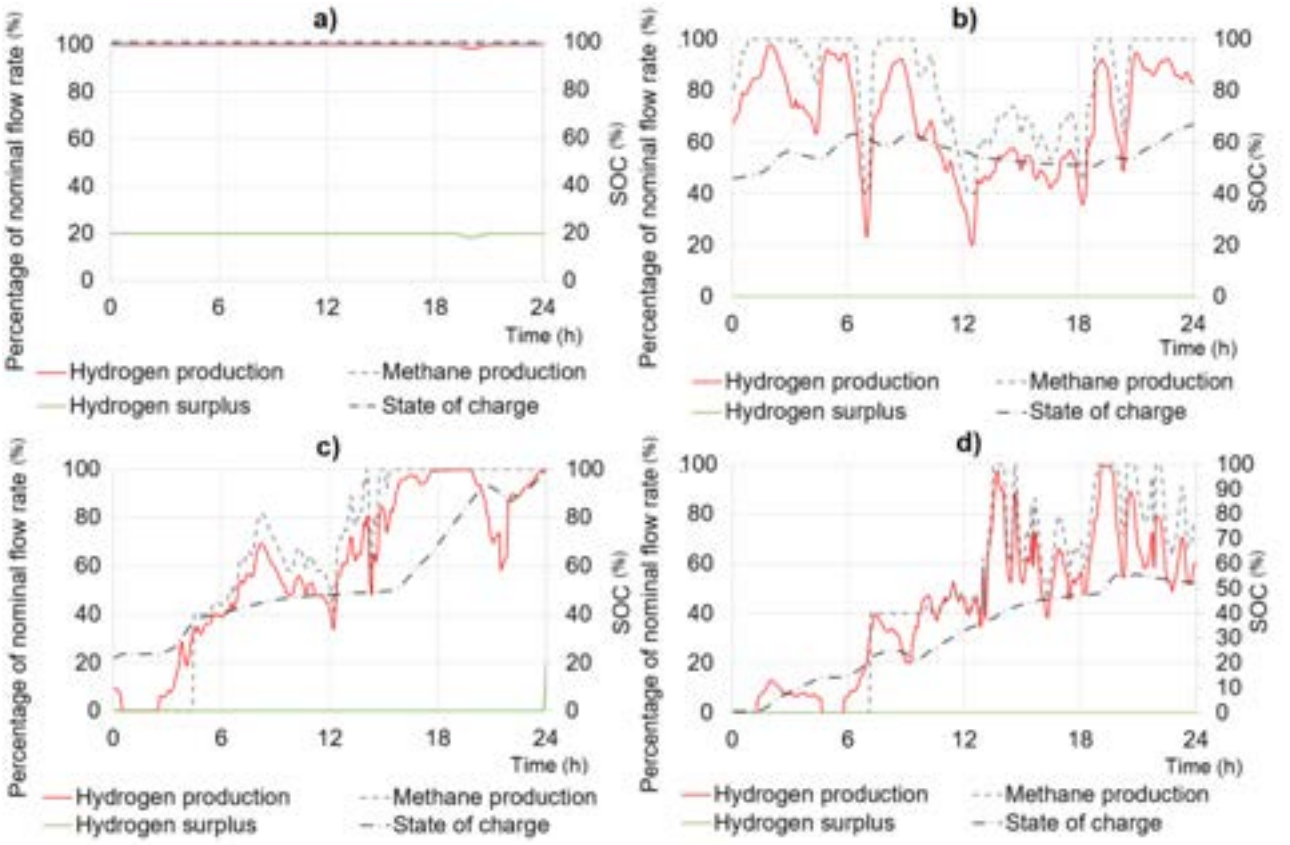

Figure 8. Performances of the power-to-gas system during four seasonal characteristic days: a) December 21; b) September 25; c) March 22; d) June 21.

Similarly to the electrolysis system, the results for the daily performances of the power-to-gas system showed a seasonal trend with a higher methane production in the windiest season, from which derives a most intensive use of the methanation unit.

During the summer, the SOC of the hydrogen storage tank was very low. This is due to the poorer wind conditions typical of this season, which makes the methanation unit work at relatively low load, even below the minimum limit value. In this condition, the methanation unit needs the support of the storage tank to be able to continue to work at his minimum load. When the storage tank is empty, it can no longer support the methanation unit. This could result in frequent shutdowns and a non-continuous operation ot the methanation unit.

On the other hand, on windy days the methanation unit worked at higher average loads, and, in some period, also exceeding the upper limit value. When the methanation unit is set to the nominal working point, and the storage tank SOC is 100%, a certain share of the produced hydrogen can't be converted in methane or stored. This condition mainly occurred during the winter, when the highest share of surplus hydrogen can be detected.

Table 7. Performances of the four electrolyzers at the end of a one-year simulation.

Electrolyzer	Efficiency (%)	Hydrogen production (Nm^3)	Utilization factor (%)	Number of shutdowns (-)	Water consumption (kg)	Stack temperature (°C)	Maximum duration of the off period (h)
1	61	1,597,493	33	537	1,283,546	66.5	62
2	61	1,598,248	33	548	1,284,152	66.3	62
3	61	1,595,090	33	541	1,281,615	66.2	64
4	61	1,597,295	33	546	1,283,387	66.6	56
Electrolysis system	-	6,388,126	-	-	5,132,700	-	-

In a second phase of this study an annual simulation on the power-to-gas system was carried on. Contrary to what results of the daily simulations suggested, the electrolyzers exhibited similar behavior and comparable performances in terms of all the observed variables on a yearly basis.In Table 8 and Table 9 the performance of the methanation unit and the hydrogen storage tank at the end of the one-year simulation are shown. Only the 2.4% of the produced hydrogen was in surplus. In addition, the management strategy effectively minimized the number of shutdowns.The use of an hydrogen storage, in fact, decreased the annual number of methanation-unit shutdowns from 1,006 within a year to only 301. Also, the imposed value of the SOC_{min} was essential to achieve this purpose. Indeed, without this constraint the annual number of methanation-unit shutdowns have been 5,950.

Nevertheless, the utilization factor of the subsystems at the end of the simulation was low, and this suggests that the sizing may not be optimal.

Table 8. Performances of the methanation unit at the end of a one-year simulation.

Methane production (Nm^3)	Surplus hydrogen (Nm^3)	Utilization factor (%)	Number of shutdowns (-)	Maximum duration of the OFF period (h)	Percentage of time in the ON state (%)	Percentage of time at the minimum load (%)	Percentage of time at the maximum load (%)
1,542,389	154,949	40	301	114	63	37	23

Overall, the management strategies performed both for the electrolysis system and for the methanation unit adequately managed to operate the power-to-fuel system minimizing the yearly surplus of hydrogen while ensuring a limited number of shutdowns that would otherwise increase the system degradation.

Table 9. Performances of the storage tank in a one-year simulation.

Percentage of time that SOC < SOC_{target} (%)	Utilization factor (%)
77	34

5. Summary and conclusions

In this study, a mathematical model of a power-to-methane system has been developed. An electrolysis system composed of four alkaline electrolyzers, each of which has a nominal power of 3 MW, is powered by a wind

farm with a nominal power of 12 MW. A hydrogen storage tank was designed for two-and-a-half hours of independent operation of the methanation unit, which nominal production of the methane is 438 Nm^3/h.

A management strategy of the electrolysis system, hydrogen storage and methanation unit to limit fluctuating and discontinuous operation of both the electrolysis system and the methanation unit was adopted. The management strategy of the electrolysis system was conceived to averagely ensure similar operating conditions of the four electrolyzers. The management strategy proposed for the methanation unit and the hydrogen storage tank effectively kept the operation of the methanation unit within the imposed constraints, and, at the same time, ensured a limited number of shutdowns while minimizing the surplus of hydrogen.

The simulated results over four seasonal typical days revealed a more intensive use of the electrolyzers, the methanation unit and the storage tank in windy seasons; however, the on/off control systems developed for the stack temperature and the separators level kept both the variables within the established range.

In addition only the 2.4% of the hydrogen producing during the year was in surplus and the number of shutdowns of the methanation unit turned out to be drastically reduced then without any storage tank (from 1,006 to 301). Nevertheless, the utilization factor of the subsystems at the end of the simulation was low (40% for the methanation unit and 34% for the storage system), and this suggests to explore different sizes of the subsystems. A sensitivity analysis should be carried out to determine the optimal value of the parameters (SOC_{min} and SOC_{target}) impacting the management strategy and the optimal size of the subsystems.

In addition, the influence of different management strategies on the operation of the power-to-methane system could be investigated in future studies.

Abstract:
Solid oxide fuel cells (SOFCs) are being recognized as one of the promising energy conversion technologies. To study SOFCs systems operation, numerical modeling is a helpful tool, which allows one to understand and improve their operation. Moreover, a crucial feature of numerical modeling is the opportunity to reduce economical and time cost in prototyping methodology. In this work, a banded SOFC stack, which includes six 12 mm x 12 mm cells, connected in series, applied on a single electrolyte support, is studied numerically, using the finite-volume method. A mathematical model, which includes the heat, mass and electron/ion transport phenomena, was provided. To validate the model, a comparison of electrical characteristics obtained from the numerical and experimental study was performed. To inspect the possibilities of applying geometrical improvements to the existing prototype design, different versions of fuel and air channels were numerically modeled and inspected, including the option of extending the system into two or more stacks, connected by a shared fuel channel of two adjacent stacks. Moreover, the influence of the electrolyte thickness was tested. The proposed design modifications enhance the system by reducing the volume of the stack and improving the electric performance compared to the existing prototype design. The numerical model can be used to test further design modifications to the stack, including performance analysis by changing the operating parameters of the system and applying new materials.

Keywords:
Banded SOFC stack, Hydrogen Use in Energy Systems, Numerical Analysis, Solid Oxide Fuel Cell, Transport Phenomena.

1. Introduction

The use of hydrogen in energy systems is one of the promising and ecologically friendly ways to develop the energy and transport industry. To efficiently convert the chemical energy of hydrogen directly into electrical energy, fuel cells are often utilized. Solid Oxide Fuel Cells (SOFCs) are one of the most efficient fuel cells, with a low manufacturing price compared to other types of fuel cells and a wide range of systems power scale, recognized as the most advanced power generation systems, characterized by the highest thermal efficiency [1]. The prototyping of SOFCs is a highly complex process that involves many costs and time consumption. To reduce these factors, numerical modeling is often used.

Numerical modeling of Solid Oxide Fuel Cells is being recognized as a highly complex but helpful tool in order to better understand the operation and phenomena occurring inside the stack. Many different tools are used for the numerical modeling of SOFCs, while ANSYS Fluent forms one of the most popular and widely used [2]. Three-dimensional numerical modeling of SOFCs is often applied to simulate single-cell operation [3–6], as well as entire stacks [7–9]. 3D SOFC stack simulation was performed successfully by Wei et al. [7], using numerical modeling to study a novel stack arrangement and verify the new shape of the flow channel. The model allowed to observe the thermal stresses in the stack, as well as conduct a transport phenomena verification. To verify the results of the study, a comparison with the results found in the literature was presented. Wei et al. [7] has presented the geometry of the anode-supported planar SOFC stack, which consists of square cells connected electronically using metal interconnectors with ribs, which contribute fuel and air channels. The analyzed geometry of cells is conventional in SOFC systems, also in commercial usage. A proposed multistacking method introduces the original shape of interconnectors. Another interesting approach to the numerical modeling of the SOFC stack was demonstrated by Dong et al. [8]. An anode-supported, five planar, rounded cells stack was modeled. The cells were connected into a stack using nickel and crofer meshes, closed between the outer plates and separators, sealed with mica and the separators. Again, the alignment of cells is one on another. Dong et al. [8] presented the study of the flow uniformity and transport processes inside the stack. The research was also focused on the temperature distribution and electron transport. The

results were compared to the experimental study to demonstrate the correctness of the numerical model. The influence of system size and stack design in terms of flow arrangement was also examined by Pirasaci [9]. Research included the verification of the model by comparing with the results found in the literature. The commercial CFD package, ANSYS Fluent was used in order to simulate the behavior of different design options and study the influence of implemented modifications on the performance of the stack. The analyzed stack geometry is conventional and widely used in commercial systems with rectangular cells closed between metal interconnectors.

Solid Oxide Fuel Cells could also operate using alternative fuels, such as hydrocarbons, ammonia, and carbon monoxide. Due to the high temperature operation, the resistance to impurities in the fuel is elevated [13]. To better understand the processes during operation with alternative fuels, the numerical simulation of single cell SOFCs is also widely used [5, 6].

As shown in the literature review, most research focus on conventional stack designs with one on another single cells arrangement, connected using metal interconnectors in different shapes. When comparing our stack design with common SOFC stacks, the originality is clearly visible. Separate electrodes banded on a single electrolyte contribute the novel and original stack arrangement in SOFC systems subject. Moreover, the presented stack banded on the single electrolyte could significantly increase the output voltage, even in small-size systems. The studied design, introduced in [10], also consists of unusual flow channels and electrical connections. Because this paper discusses the impact of channel geometry on the transport phenomena within the recently proposed banded solid oxide fuel cell stack, the electrical connections were simplified. This study focuses on possible improvements in geometry and stack arrangement options. The developed computational fluid dynamic simulation considers momentum, heat, mass, electron and ion transport phenomena.

2. Geometry description

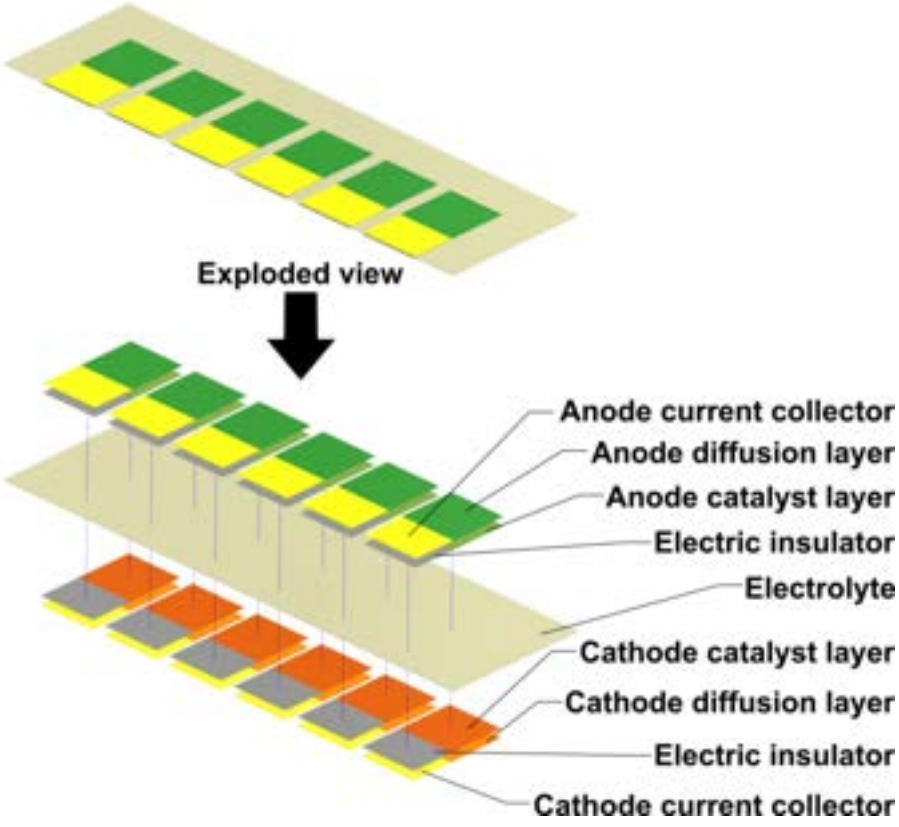

Figure 1: Investigated SOFC stack design with exploded view.

The studied SOFC stack is a novel, patented design [10], which prototype was successfully built and tested [11]. For further development of the stack, a numerical modeling method is used. To prepare a 3-dimensional (3D) numerical model, a computational domain has to be created. Using Autodesk Inventor software, a stack CAD model was created. The stack model, shown in Fig. 1, is composed of six pairs of 12 mm x 12 mm x 0.1 mm electrodes, banded on a single 105 mm x 30 mm x 0.3 mm electrolyte support. Electrolyte support provides high strength and durability of the stack, while maintaining a low production cost [12]. In this paper, the electrolyte of 0.1 mm of thickness is also investigated. The electrodes are divided into two bodies, contributing

catalyst and diffusion layers, as needed for numerical simulation. To simplify the geometry, current collectors are modeled as non-porous solid bodies with side contact to electrodes. Between the electrolyte and the current collectors, electric insulators were applied. Fig. 1 presents the stack assembly, and also to better visualize the model, an exploded view with descriptions was provided.

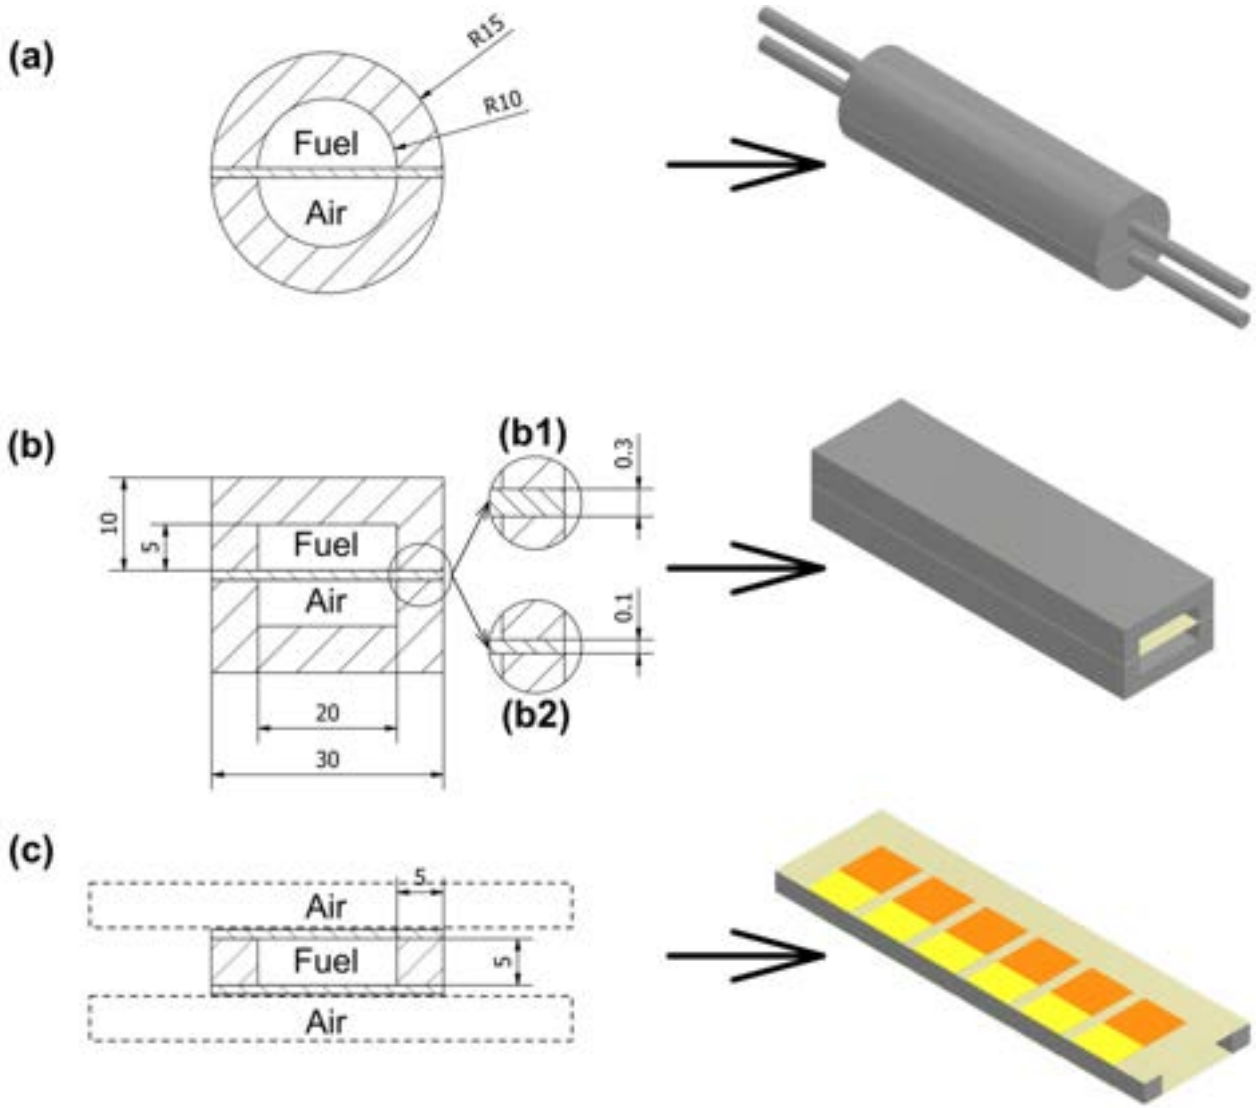

Figure 2: Stack configuration options with schematic cross-sections. Stack supported on 0.3 mm of electrolyte thickness, closed in half-tubular covers, marked (a). The stack with rectangular covers marked (b) comes in two versions: 0.3 mm of electrolyte thickness, marked as (b1), and 0.1 mm of electrolyte thickness, marked (b2). Multi-stack composition with 0.1 mm of electrolyte thickness, marked as (c).

The initial prototype design of the stack includes two ceramic covers, which contribute gases supply elements. During the investigation, a different covers shape and stack arrangement was provided, as shown in Fig. 2, which is divided into three sections. In the (a) section of Fig. 2, the electrolyte support of 0.3 mm of thickness, with deposited cells and the applied current collectors, is enclosed by two half-tubular covers, which state the fuel and air channels, as in the initial design. The (b) section of Fig. 2 presents a rectangular shape of the covers, which was modeled to reduce the stack volume and simultaneously increase the volumetric power density. Moreover, the (b) section was divided into two options. The section marked (b1) is the (b) design supported on 0.3 mm electrolyte, while (b2) is the (b) design supported on 0.1 mm electrolyte. In Fig. 2, the (c) section provides a new idea of extending the system into two or more stacks. By combining two stacks, of which anodes are targeted face to face, a fuel channel is created, while cathodes facing the outer sides could be supplied in the air without an air channel, using a fan. This case consists of two stacks supported on 0.1 mm of electrolyte thickness. This design allows to reduce the volume of the stack even more, and theoretically double the power. To better illustrate each design, schematic cross sections and 3D models were included, respectively. The cross sections demonstrate the arrangement of the stack(s) and covers that

determine the gases paths. This paper also includes a numerical verification of the influence of electrolyte thickness on stack performance, by comparing designs (b1) and (b2).

3. Mathematical model

The mathematical model contains a description of transport phenomena, using a set of partial differential equations. To simplify the model and focus on the demanded areas of physics, a few assumptions were contributed. The model assumes steady state behavior of the operation, the incompressible characteristics of fluids. The energy dissipation and gravitation were ignored. Flow in fluid and porous areas is described as laminar, and all fluids are treated as Newtonian ones.

Steady-state mass conservation equation is used to describe the mass transport in fluid and porous areas, written as follows [8]:

$$\vec{\nabla} \cdot \left(\rho\varepsilon\vec{v}\right) = S_{\mathrm{p}}, \tag{1}$$

where S_{p} (kg m^{-3} s^{-1}) represents the source term of mass, as a result of reactants consumed and produced in electrodes through the electrochemical reactions in SOFC. In areas other than porous anodes and cathodes $S_{\mathrm{p}} = 0$ and $\varepsilon = 1$ (-), which is the porosity rate. In the fluid areas, an equation that describes the conservation of momentum is solved as follows [8]:

$$\vec{\nabla} \cdot \left(\rho\vec{v}\vec{v}\right) = -\vec{\nabla}p + \vec{\nabla}\bar{\bar{\tau}} + \vec{S}, \tag{2}$$

where $\vec{S}$ (kg m^{-2} s^{-2}) is the source term, that describes the viscous and inertial pressure drop.

In porous and fluid areas, the species conservation equation describes the components of the gas mixture, given as follows [8]:

$$\vec{\nabla} \cdot \left(\rho\varepsilon\vec{v}Y_i\right) = -\vec{\nabla} \cdot \vec{J}_{i,\mathrm{eff}} + S_i, \tag{3}$$

where S_i (kg m^{-3} s^{-1}) represents the source and sink terms of species rates, written as follows [8]:

$$S_{\mathrm{O_2}} = -\frac{j}{4F}M_{\mathrm{O_2}}, \tag{4a}$$

$$S_{\mathrm{H_2}} = -\frac{j}{2F}M_{\mathrm{H_2}}, \tag{4b}$$

$$S_{\mathrm{H_2O}} = \frac{j}{2F}M_{\mathrm{H_2O}}. \tag{4c}$$

The electrons and ions transport potential equations, are given as [3]:

$$\vec{\nabla} \cdot \left(\sigma_{\mathrm{el}}\vec{\nabla}\phi_{\mathrm{el}}\right) + j = 0, \tag{5a}$$

$$\vec{\nabla} \cdot \left(\sigma_{\mathrm{ion}}\vec{\nabla}\phi_{\mathrm{ion}}\right) + j = 0, \tag{5b}$$

where j (A m^{-3}), the volumetric transfer current density, for the electrons transport on the anode side $j = -j_{\mathrm{an}}$ and on the cathode side $j = +j_{\mathrm{cat}}$, and for the ions transport $j = +j_{\mathrm{an}}$ and $j = -j_{\mathrm{cat}}$. The volumetric transfer current density j is described by the Butler-Volmer equation, written for the anode and the cathode side as follows [3]:

$$j_{\mathrm{an}} = \left(\zeta_{\mathrm{TPB}}i_{\mathrm{an}}^{\mathrm{eq}}\right)\left(\frac{X_{\mathrm{H_2}}}{X_{\mathrm{H_2,ref}}}\right)^{\gamma_{\mathrm{an}}}\left(e^{\alpha_{\mathrm{an}}^{\mathrm{a}}F\eta_{\mathrm{an}}/(RT)} - e^{-\alpha_{\mathrm{an}}^{\mathrm{c}}F\eta_{\mathrm{an}}/(RT)}\right), \tag{6a}$$

$$j_{\mathrm{cat}} = \left(\zeta_{\mathrm{DPB}}i_{\mathrm{cat}}^{\mathrm{eq}}\right)\left(\frac{X_{\mathrm{O_2}}}{X_{\mathrm{O_2,ref}}}\right)^{\gamma_{\mathrm{cat}}}\left(e^{-\alpha_{\mathrm{cat}}^{\mathrm{c}}F\eta_{\mathrm{cat}}/(RT)} - e^{\alpha_{\mathrm{cat}}^{\mathrm{a}}F\eta_{\mathrm{cat}}/(RT)}\right). \tag{6b}$$

The local surface overpotential η (V), for the anode and cathode side is given in the following form [3]:

$$\eta_{\mathrm{an}} = \phi_{\mathrm{el}} - \phi_{\mathrm{ion}}, \tag{7a}$$

$$\eta_{\mathrm{cat}} = \phi_{\mathrm{el}} - \phi_{\mathrm{ion}} - \phi_{\mathrm{OCV}}, \tag{7b}$$

where ϕ_{OCV} (V) represents the open-circuit voltage.

The heat transport in solid zones is described as the steady-state energy equation, written in the following form [8]:

$$\vec{\nabla} \cdot \left(\varepsilon\vec{v}\rho h\right) = \vec{\nabla} \cdot \left(\left(\varepsilon k_{\mathrm{eff}} + (1-\varepsilon)\,k_{\mathrm{s}}\right)\vec{\nabla}T - \sum_i h_i\vec{J}_i\right) + S_{\mathrm{h}}, \tag{8}$$

where S_h ($W\,m^{-3}$) is the total heat source. The heat source in the catalyst layers of electrodes and the electrolyte and is calculated as follows [8]:

$$S_h = -\frac{jh_{react}}{2F} + j\eta + \frac{i^2}{\sigma}. \tag{9}$$

In fluid zones, the steady-state energy equation is given in the following form [8]:

$$\vec{\nabla} \cdot \left(\vec{v}\rho h\right) = \vec{\nabla} \cdot \left(k_{eff}\vec{\nabla}T - \sum_i h_i \vec{J}_i\right). \tag{10}$$

4. Numerical analysis

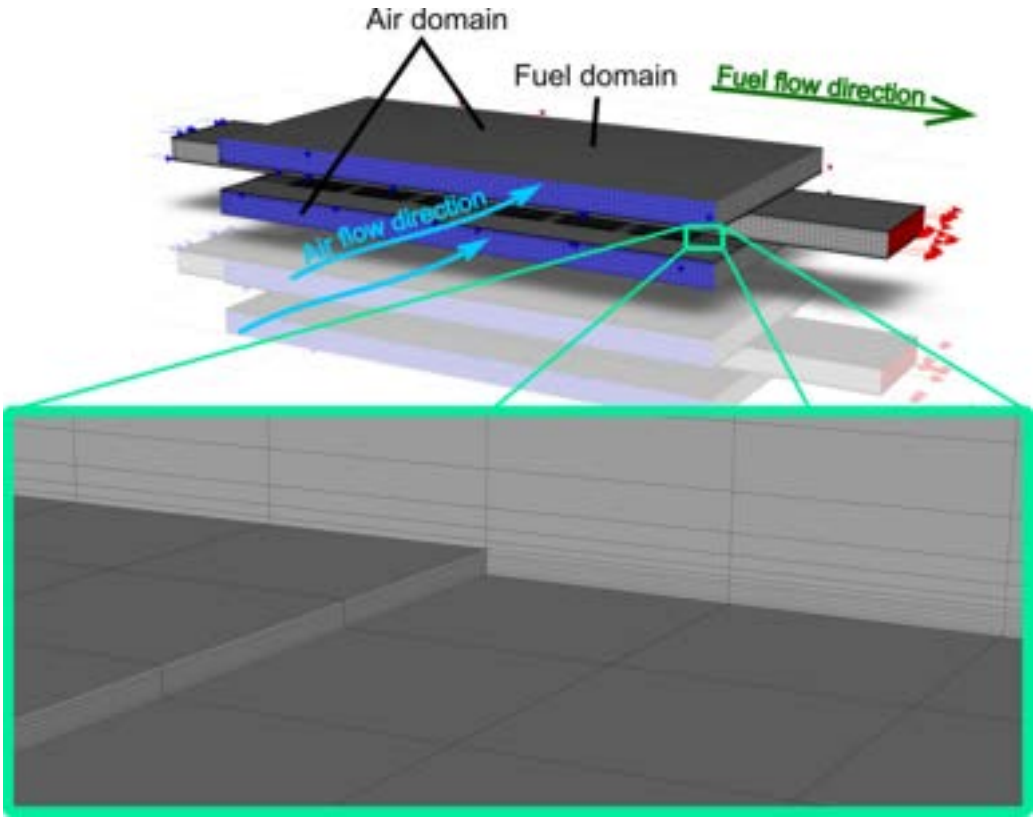

Figure 3: Visualization of computational mesh of multi-stack design with detailed view.

After the described mathematical model was determined, a series of 3D numerical simulations was performed using the finite-volume method. For the finite-volume method, a computational mesh must be made. To build the mesh of each design described in Section 2., the 3D models were modified to include bodies that represent the paths of the gases. To reduce the number of mesh elements, ceramic covers were removed from the geometries and replaced by the boundary conditions, which represent the behavior of the furnace maintaining constant temperature. Each mesh was created as a compromise between quality and the number of elements, which determined resolution, accuracy, and computational time. The mesh sensitivity study was performed for four different mesh sizes for the initial design marked as (a) in Fig. 2, starting from the number of elements of $1.6 \cdot 10^5$, through $6 \cdot 10^5$, $1.1 \cdot 10^6$ on $4 \cdot 10^6$ of the mesh elements ending. The measured time per iteration was: 1.05 s, 2.14 s; 3.68 s; 17.45 s, respectively. Since the mass conservation for each case remained values under 10^{-8} $kg\,s^{-1}$, and the electric characteristics did not change, the chosen mesh was the $1.1 \cdot 10^6$ of the elements one. As a result of the large difference in scale between the thin layers of the stack area and the gases domains, a smooth transition of element sizing was applied. Each mesh was built using hexahedral elements. The main mesh element was determined as a 1 mm x 1 mm x 1 mm cube. In the stack area, elements are flattened up to 0.01 mm to retain a minimum of three layers per body in the thickness direction, to then inflate smoothly in the gases areas to main dimensions. In Fig. 3, a computational mesh of multi-stack design, shown in Fig. 2(c), is illustrated, including the detailed view in the zoom box, which shows the inflation of elements thickness in the area of the solid and fluid zones contact. Other designs computational meshes are consistent with the illustrated one.

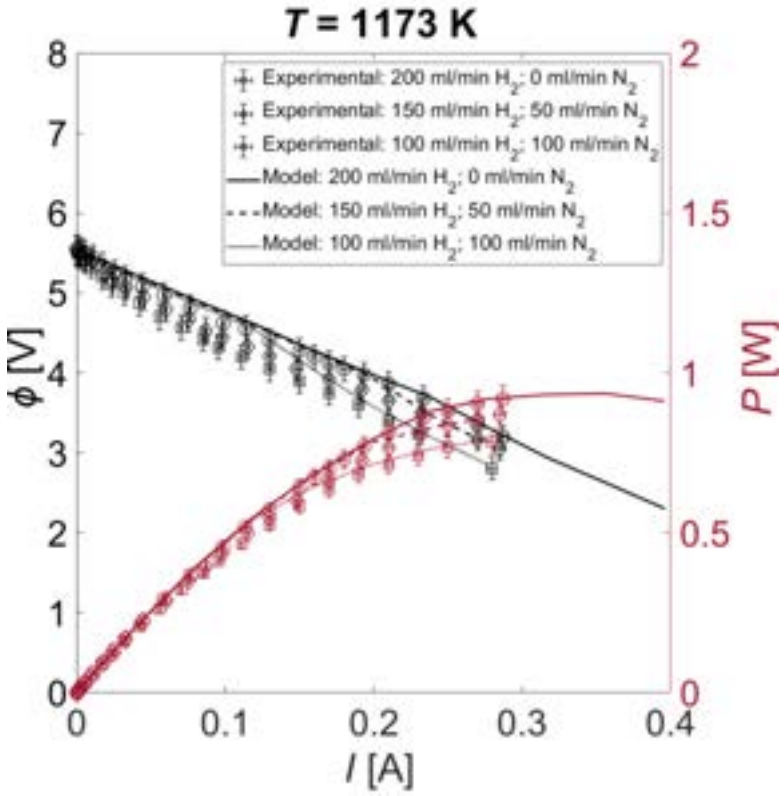

Figure 4: Comparison of current-voltage and current-power characteristics of initial design ((a) in Fig. 2), obtained from numerical analysis and experimental study [11]. Flow rates fitted to tested ones.

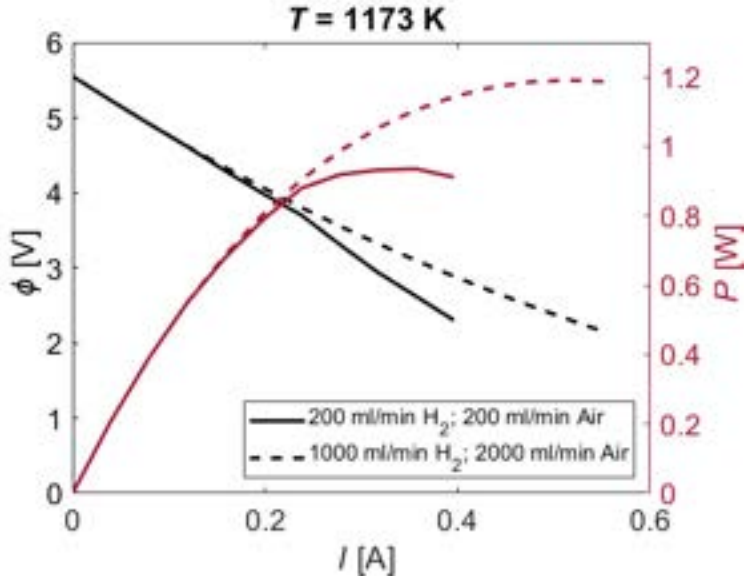

Figure 5: Comparison of current-voltage and current-power characteristics of initial design ((a) in Fig. 2) for different flow rates.

To make an accurate comparison of each investigated design, boundary conditions were retained in all simulations, as well as electrochemical, material, and operating parameters determined for the initial design. To simulate the behavior of the furnace interior and substitute the ceramic covers, constant temperature and zero species flux boundary conditions at the outer walls of the fluid domains were established. On the outer walls of the solids, no current leakage was allowed, except current collectors taps. At the current collectors tap walls, on the anodes side, a zero potential is forced, on the cathode side, a current flux was established. The constant current load simulates the in-series connection of the stack to build up the potential value. Constant velocity, temperature, and gas composition boundary conditions were formed at the inlets of flow channels. A

Table 1: Operating parameters applied for all stack configuration options comparison.

Parameter	Value (Unit)
Inlets/furnace temperature	1173 (K)
Air flow rate	2 (L/min)
Hydrogen flow rate	1 (L/min)

constant atmospheric pressure and furnace temperature were applied to the channels outlets.

The numerical modeling was conducted using the SIMPLE scheme with the Richie-Chow distance-based flux type. Different spatial discretization methods were used to compute each parameter. Green-Gauss Node-Based method was used to calculate gradient, pressure was computed using Second Order spatial discretization method. Density, momentum, energy, species, and potential equations were computed using First-Order Upwind spatial discretization.

In order to conduct a comparison of each design shown in Fig. 2, a series of simulations were performed. To obtain current-voltage and current-power characteristics, an electric load in the form of a constant current was applied to the cathodes current collectors in the value from zero until the power drop. To validate the model, a comparison of electrical characteristics, obtained from the numerical simulation and the experimental study [11], was presented in Fig. 4. The operating parameters of the simulations were fitted to the parameters used during the experimental study. The experimental points with error bars included are presented in the form of circles, triangles and deltiods. The numerical analysis results are presented as solid, dashed, and dotted lines. The numerical model introduced in this paper allows to simulate highly predictable characteristics, which is confirmed in the comparison contained in Fig. 4. During the analysis, the lack of fuel and air was clearly visible, so the decision to increase the flow rates was made. The hydrogen flow rate was increased ten times and the air flow rate twenty times. The comparison of electrical characteristics obtained during numerical analysis, for flow rates tested during the experimental study and increased as mentioned above, is presented in Fig. 5. The solid lines represent the characteristics for flow rates as experimentally tested, and the dashed lines represent the characteristics for increased flow rates. It clearly revealed the gain in power in the value of 27.4 percent, from $P = 0.935$ W at a current of $I = 0.356$ A up to $P = 1.191$ W at $I = 0.515$ A. In order to conduct a reasonable comparison of each presented in Fig. 2 design, including the multistack design that consists of twelve cells, the increased flow rates remained constant for the whole further study. The operating parameters for the study of different designs, applied for all cases, are presented in Table 1.

To clarify the comparison of the performance of each design, four different graphs were shown in Fig. 6. For reference, the marks (a), (b1), (b2), and (c) are consistent with the geometries shown in Fig. 2. The first graph of Fig. 6 illustrates the current-voltage and current-power characteristics of case (a) and (b1), so the comparison of half-tubular and rectangular covers, with the electrolyte of 0.3 mm of thickness. The second graph presents the comparison of the characteristics of the initial case (a) and the design with rectangular shape of covers with reduced electrolyte thickness up to 0.1 mm (b2). The third plot presents a comparison of the performance of the initial case (a) and the multi-stack design (b), which consists of 12 cells. To better illustrate the performance comparison of four cases (a), (b1), (b2) and (c), a bar plot of the peak power density, located at the bottom of Fig. 6, was presented. Between the (a) and (b1) cases, the difference is almost unrecognizable, flattening the channels by changing the shape to rectangular resulted in the power drop from 1.19 W (a) to 1.16 W (b1). Reducing the electrolyte thickness resulted in an increase in the performance, as expected, due to an enhancement of electrolyte ionic conductivity. The power of case (b2) reaches 1.46 W. Multistack design (c) is clearly the most powerful arrangement option, power reaches the value of 2.87 W, but the power density is slightly lower than the case (b2). Furthermore, in the (c) case, a concentration loss at the characteristics is clearly visible, which could mean insufficient hydrogen supply, due to doubling of the number of cells, which could be a reason for the drop in power density. Moreover, at this it is worth to underline that the multi-stack design (c) volume is still reduced compared to the initial design (a), so the volumetric power density, which considers whole system volume, would increase.

Comparison of the temperature distribution, shown in Fig. 7, was presented to compare the inspected geometries in terms of heat transfer. The (a), (b1), (b2) and (c) design marks are consistent with geometries shown in Fig. 2. The temperature scale for each case was set as a global range to visualize the differences between cases. The initial design (a), as well as designs (b1) and (b2), are co-flow arranged, flow direction from left to right. The multistack design cross-flow is shown in Fig. 3 (fuel flow according to x-axis, air flow opposite to the z-axis). The distributions illustrated in Fig. 7, are shown in the form of semi-transparent shadow, where the minimum value is fully transparent and the maximum value is opaque. Each distribution was presented for the peak power point, determined during the study of electric characteristics. The temperature distribution does not change meaningfully between (a) and (b1), for both cases, peak power retains the same value of

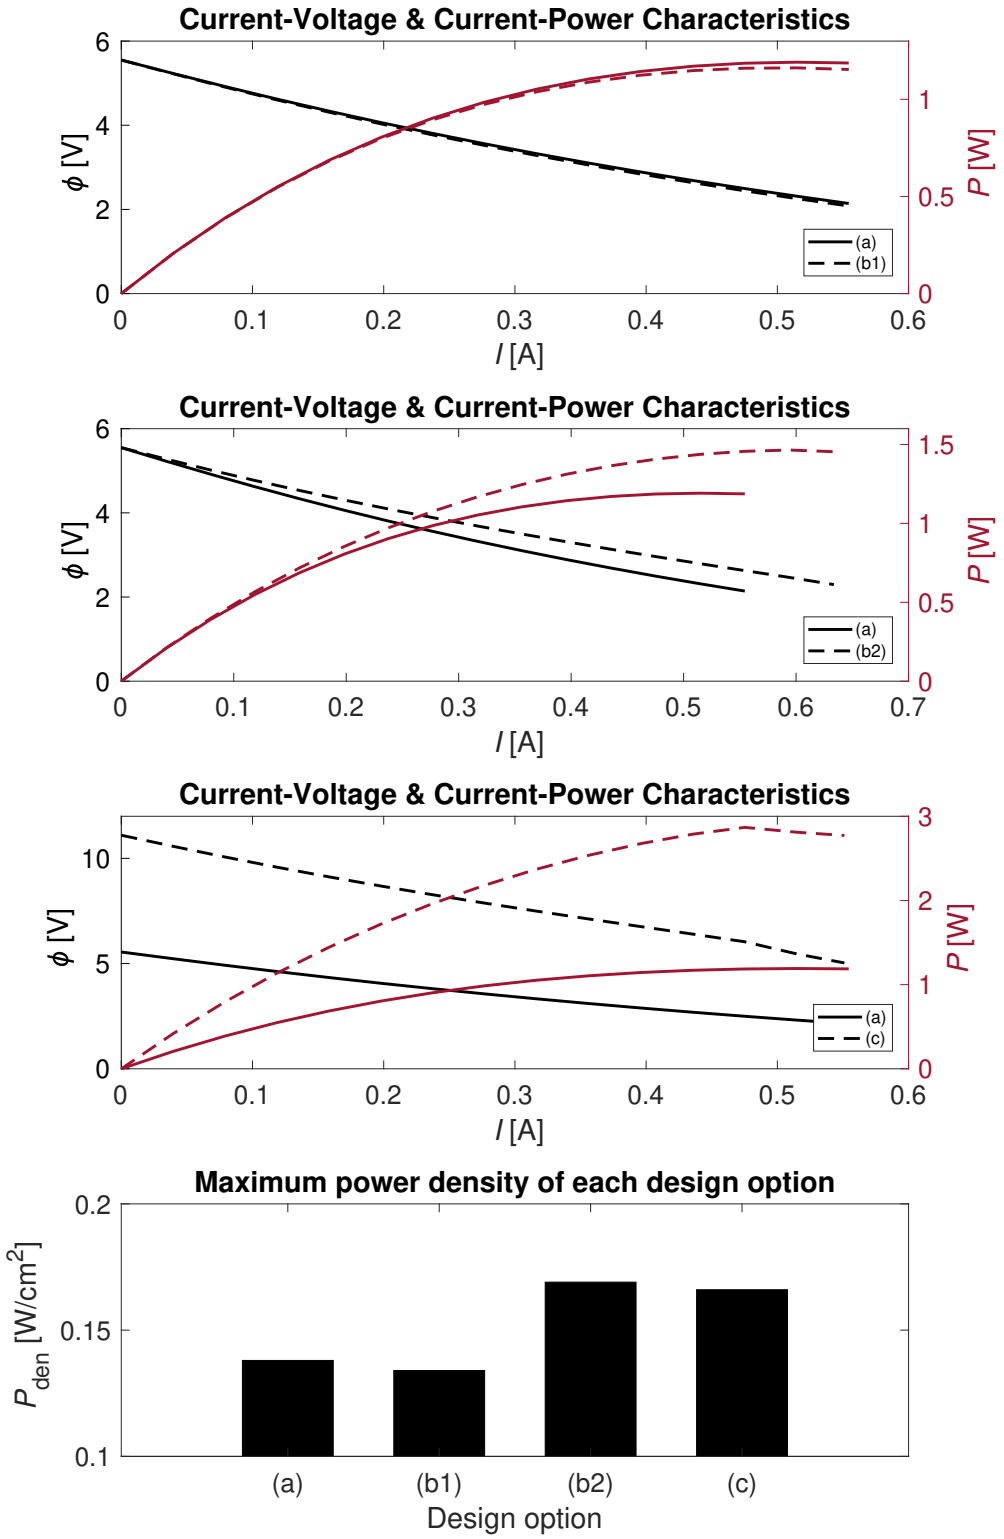

Figure 6: Comparison of current-voltage and current-power characteristics of four different designs, with a bar plot illustrating power density peak of each. Design marks (a), (b1), (b2) and (c) are consistent with geometries shown in Fig. 2.

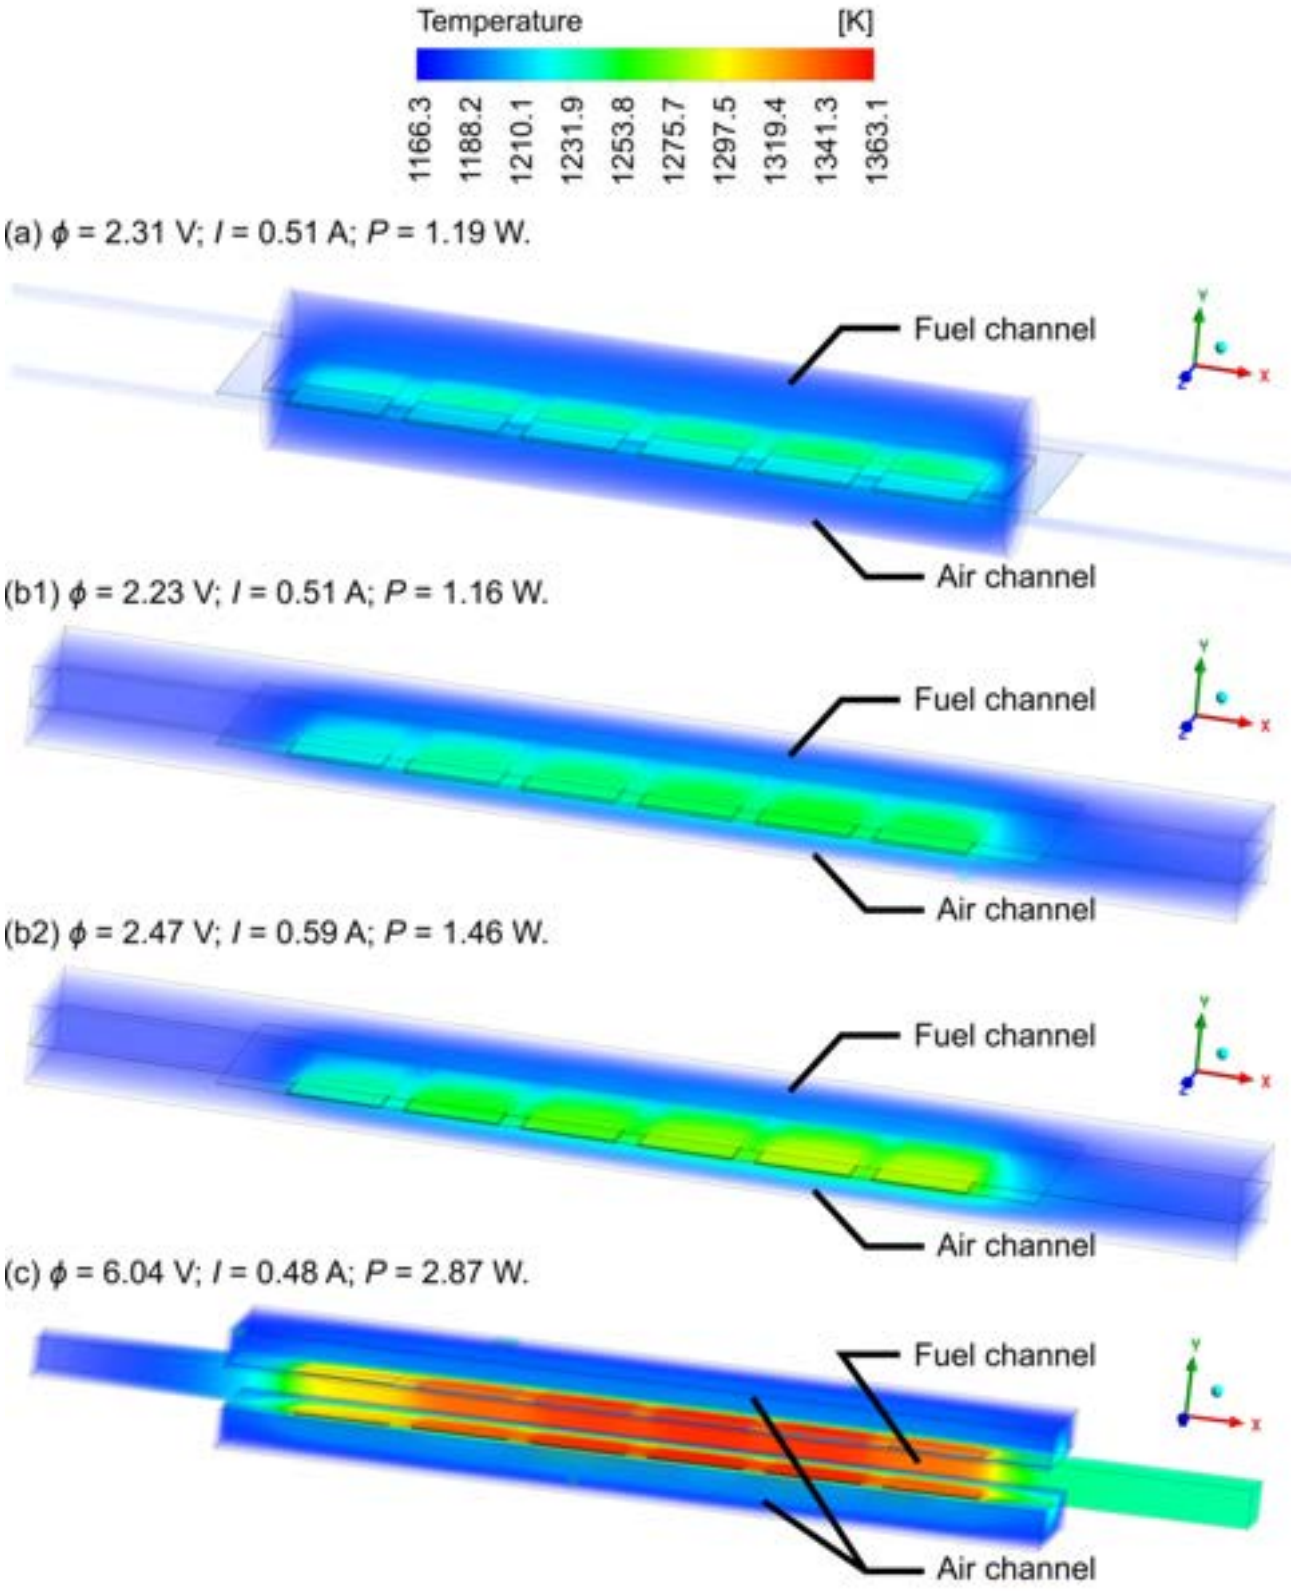

Figure 7: The temperature distribution comparison of peak power point of each inspected geometry. Design marks (a), (b1), (b2) and (c) are consistent with geometries shown in Fig. 2. The cases (a), (b1) and (b2) are co-flow formed, flow direction determines the x-axis. The (c) case cross-flow was shown in Fig. 3. current. After implementing a thinner electrolyte (b2), the increase in current allowed the power peak to rise. Due to a higher load, a significant temperature increase occurs. The analysis of the multi-stack design reveals a major temperature increase in the fuel channel, between two sets of anodes. The interaction between both

The cases (a), (b1) and (b2) are co-flow formed, flow direction determines the *x*-axis. The (c) case cross-flow was shown in Fig. 3. Distribution in the form of semi-transparent shadow (min. value - transparent, max. value - opaque).

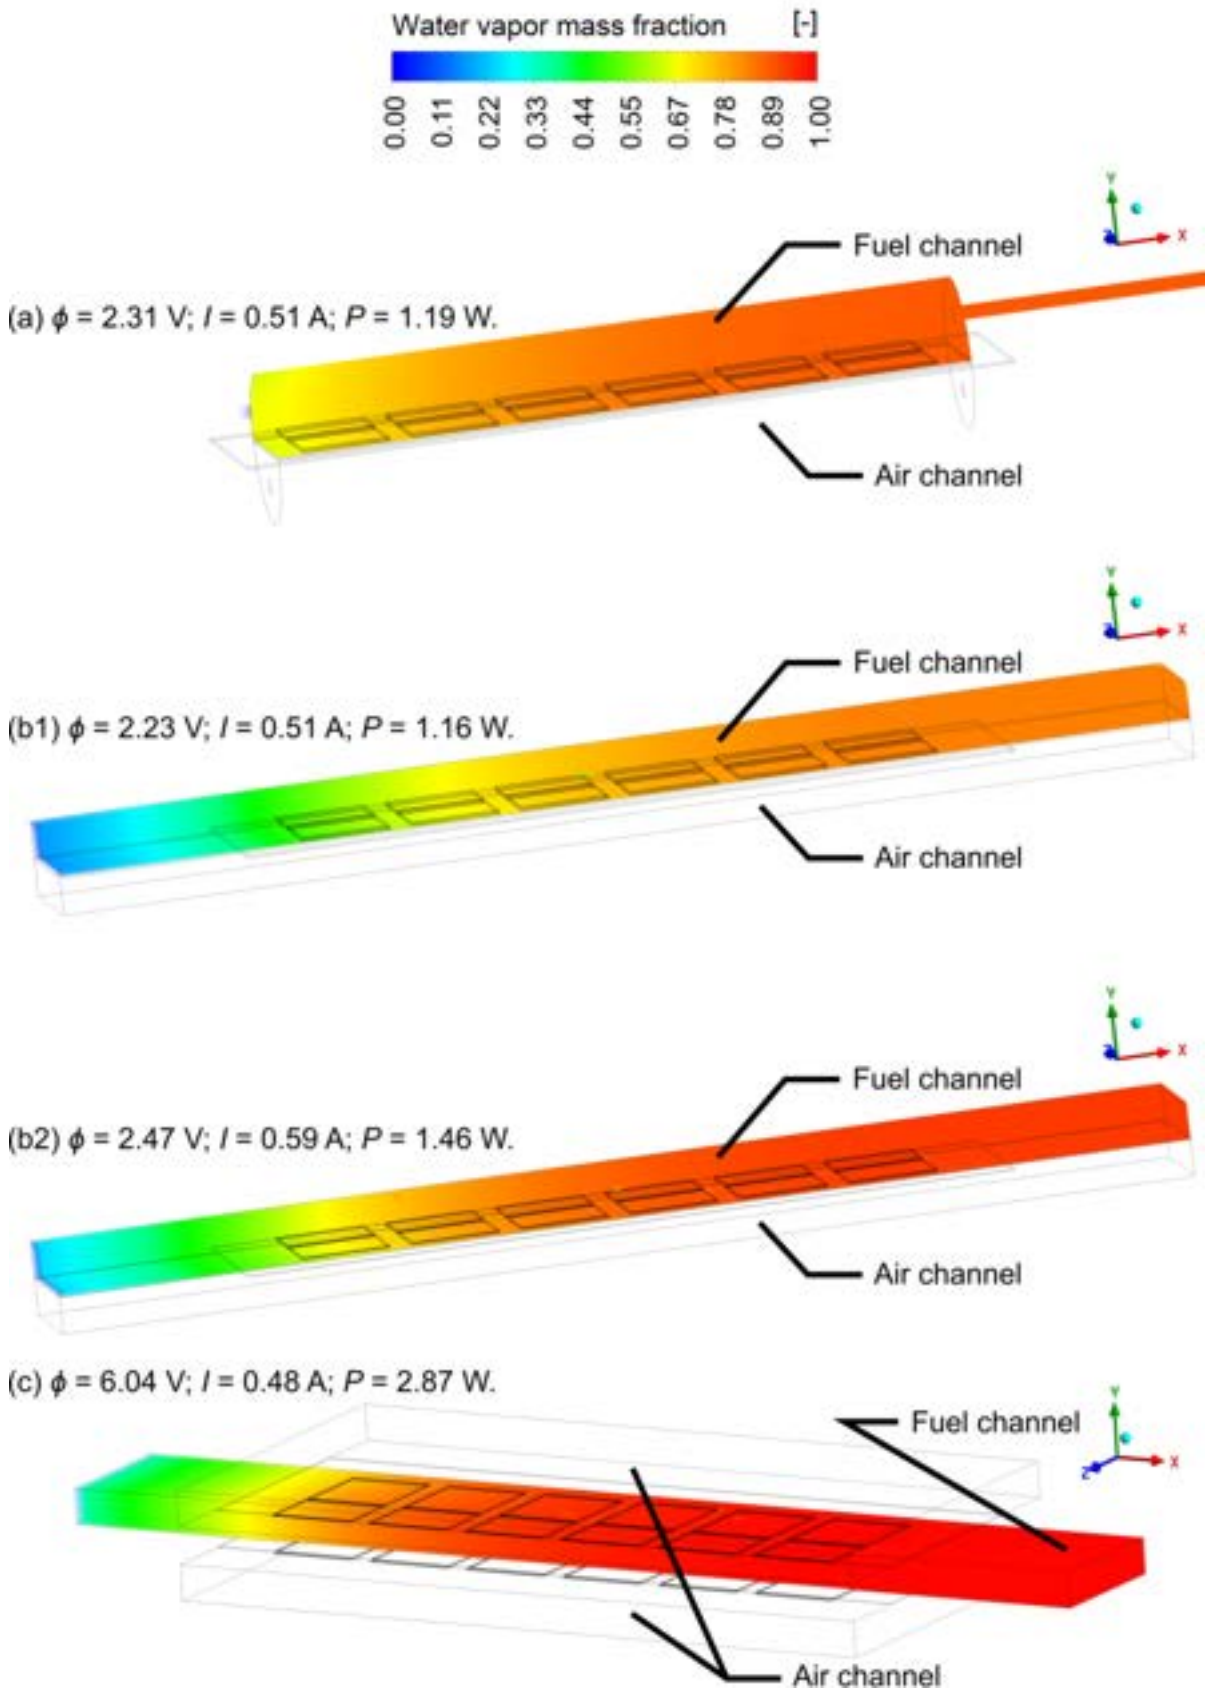

Figure 12: The water vapor mass fraction distribution comparison of peak power point of each inspected geometry. Design marks (a), (b1), (b2) and (c) are consistent with geometries shown in Fig. 2. The cases (a), (b1) and (b2) are co-flow formed, flow direction determines the x-axis. The (c) case cross-flow was shown in Fig. 3. Distribution in the form of semi-transparent shadow (min. value - transparent, max. value - opaque).

erating temperature with low input of furnace heating. The heat sources distributions are presented in Fig. 8 and Fig. 9, for ohmic and reaction heat sources, respectively. The distributions are illustrated in the form of semi-transparent shadow, similar to a temperature distribution. The case chosen to illustrate the heat sources is the (c) design (as shown in Fig. 2), due to the highest power density, as shown in Fig. 6. The flow direction is in accordance with the x-axis. The range of values is global, so the maximum visible value is the highest observed. As illustrated, the greatest impact on temperature rise has the reaction heat source, shown in Fig. 8, where the values remain an order of magnitude higher compared to the ohmic heat source, shown in Fig. 9.

The distributions of the mass fractions of hydrogen in the fuel channel, oxygen in the air channel, and water vapor in the fuel channel are illustrated in Fig. 10, Fig. 11 and Fig. 12, respectively. The distributions are presented in the form of semi-transparent shadow, where minimum values are fully transparent, and maximum values are opaque. The (a), (b1), (b2) and (c) design marks are consistent with geometries shown in Fig. 2. The scales for each case were set as global ranges to visualize the differences between cases. The initial design (a), and the designs (b1) and (b2) are co-flow arranged, flow direction in accordance with the x-axis. The multi-stack design cross-flow is illustrated in Fig. 3, where fuel flows according to x-axis and air in the opposite way to the z-axis. The distribution of the hydrogen mass fraction reveals the proper reaction of the model, while the comparison of (a) design and (b1) design does not give clear changes, between (b1) and (b2), the influence of changing the electrolyte thickness and simultaneously increasing the power, presents a visible difference. The case (b2) compared to (b1) utilizes much more fuel compared to the case (b1). In the (c) case, the fuel supply is utilized in full measure, so it is expected that the power density was lower than in (b2) due to the lack of fuel, especially counting the higher operating temperature in (c), which should result in higher performance. The high level of concentration loss in the (c) case is also visible in Fig. 6. The current load value in (c) case is also lower at the power peak point than in (b2), so the increase in fuel supply should yield in performance increase, and allow to apply load similar to (b2). The oxygen mass fraction illustrates the assumed surplus of air flow rate in all studied cases. The difference between the (a), (b1), and (b2) cases is subtle, the main difference is visible in the (c) case, due to doubling of cells amount, but still remaining some margin of oxygen. The water vapor mass fraction distribution also presents the proper operation of the model. After the oxygen and hydrogen are consumed, steam is produced and gradually fulfills the fuel channels. The steam mass fraction in cases (a) and (b1) remains at a similar level. After the increase in load and power gain, due to the decrease in the thickness of the electrolyte in case (b2), hydrogen and oxygen are consumed in greater amounts and the increase in steam generation is clearly visible. In the (c) case, the multistack generates the steam the most heavily and the value of steam mass fraction remains high since the first cells, while in the last cells area the water vapor fulfills the channel entirely.

5. Conclusions

This paper has provided an important analysis, in terms of further prototyping, of the novel banded SOFC stack. Four different geometries were designed as CAD models to include the influence of the configuration of the stack system on the performance. Also, different electrolyte thickness values were modeled. The computational mesh of each design was established to provide a domain for the finite-volume computation method. The mesh size was a result of the mesh sensitivity study to complete the requirements of high precision of the solution, high resolution, and reasonable computational time. As presented, the meshes were formed to fulfill the mentioned requirements, by forcing the elements dimensions changes in crucial areas. To understand the conducted research, a mathematical model was described, including implementing the model into the numerical analysis.

The main goal of this research was to inspect the performance changes. To validate the model for different gas flow rates, a comparison of electrical characteristics obtained from numerical analysis with experimental study results was performed and revealed the high level of predictability of the model. In order to obtain a proper comparison of different designs, including changes in the air and fuel channels, the electrolyte thickness, and the method of multistacking, the flow rates were set to higher value to maintain a surplus. To illustrate the results of the comparison, current-voltage and current-power characteristics were studied. Each design presented a response to applied modifications. The whole process of modification, from initial single stack with half-tubular covers design, to the final multi-stack design resulted in the performance increase of 141.2 %, from 1.19 W up to 2.87 W, while maintaining a comparable volume of the system. The multi-stack design proved to be the right way of extending the stack design into a bigger system. An arrangement of joining two stacks to one fuel channel, established partially by the stacks themselves, in terms of extending the system size, can double the power of the system without increasing the volume. Moreover, realizing the air supply as the side fan could significantly simplify the initial design. Temperature distribution analysis revealed another advantage of multistacking method as proposed. The neighboring stacks heat up each other, which in the prototype scale, could allow to minimize furnace input, and in the commercial scale, could enforce cooling the system, by fitting the gases flow rates. The full analysis of transport phenomena was performed including heat, mass, and electron transport. The results of hydrogen distribution exposed the lack of fuel in the multistack design, so the

final gain in power could be even higher than presented. The influence of load on transport phenomena was illustrated and inspected. In comparison of the studied stack with conventional, commercial-like designs the power density is not impressive, the highest power density value obtained during this study was 0.17 $\mathrm{W\,cm^{-2}}$, while it is common to reach values over 0.5 $\mathrm{W\,cm^{-2}}$ [9], so there is much space for further improvements.

In the future, the developed simulation can be used to analyze electrolyte and electrodes geometry and current collectors arrangement, allowing the construction of new and improved stack versions. Moreover, after contributing a new method of extending the single-stack system into a multistack, an analysis of the extended-scale fuel supply system in terms of fluid mechanics can be conducted. The model can also be used to analyze the influence of materials improvements by conducting material and electrochemical parametric studies, such as the impact of the electrolyte conductivity on performance, since it is considered as one of the most important parameters for this kind of stack.

Abstract:
According to regulations from the EU Commission, investments in nuclear energy and fossil gas are considered sustainable. These new EU taxonomies, which are intended to provide financial markets with guidance on climate and environmentally friendly investments, actually exclude conventional fossil power- and heat plants. However, the reinterpretation of natural gas as a transitional energy until 2035 allows the construction of new gas-fired power plants. As a limiting factor, an increasing share of low-emission gases have to be used, primarily green hydrogen. In the future, fuel cell power plants could serve as an alternative to such new H_2-ready gas power plants. High-temperature solid oxide fuel cells can not only use fossil methane-containing natural gas and/or hydrogen efficiently, but can also be used reversibly for electrolysis and thus provides flexibility to the power grid. This study uses energy system optimization to analyse the behaviour of both technologies, H_2-ready gas turbines and fuel cell power plants. Across three scenarios, fuel cells are used to provide baseload and flexibility especially in periods of low wind and solar irradiation, whereas hydrogen gas turbines appear last in the order of operation. However, short-term flexibility is provided by battery storage, e.g. by using existing battery capacities from electric vehicles. As Germany has a lower potential for local hydrogen production in an international comparison, significant quantities of hydrogen will only be produced in Germany if import possibilities are strongly limited and technology costs decrease at the same time.

Energy system simulation, Hydrogen, rSOC, sector coupling.

1. Introduction

The decision to make the European energy system, or rather the entire European economic area, climate-neutral by 2050 at the latest is associated with high costs, especially in a short-term period. These costs can lead to a competitive disadvantage for the involved economies. In order to partially compensate for this, the European Commission has introduced regulations, e.g. the European Union (EU) taxonomy. The aim of the taxonomy is a clear definition or classification of sustainable (”green”) economic activities. In this context, the European Commission has agreed that the energy transition to a fully defossilised system can only succeed over a transition period in which fossil feedstocks continue to be used. These transitional technologies, in particular conventional natural gas (NG) and nuclear power plants, are initially intended to replace plants with higher specific emissions such as coal-fired power plants. Later on, these power plants are converted to be emission-free. [1]

Focusing on the German energy system, due to the nuclear phase-out, only NG power plants are affected. In recent system studies, it is usually assumed that centralised large-scale power plants will play an important role in energy supply both during the energy transition and in the long-term [2]. Thus, it is assumed that NG-fired power plants will initially replace coal and nuclear power plants in terms of supply security and flexibility. Subsequently, a fuel switch is expected beginning in 2040, whereby both hydrogen-fuelled gas turbines and synthetic natural gas (SNG) are mentioned. However, while these studies assume that the corresponding technology will be available at the respective time, hydrogen gas turbines are not yet state of the art. For this reason, the technical association of energy plant operators (vgbe energy e.V.) has published a position paper and a fact sheet [3] on the topic of *H_2-Readiness* of gas turbines. This includes the definition that *H_2-Readiness* only applies if a gas turbine can be used with 100 % hydrogen or can be upgraded to this in the future. Finally, it is stated that the necessary regulations are still missing at EU level. Thus, it can be concluded that the final boundary conditions for hydrogen utilisation have not yet been finalised. As policy makers often use energy system studies as part of the decision process, extensive research regarding hydrogen and other synthetic energy carrier utilisation is needed [4]. Reviewing existing literature, Yue et al. conclude the not cost-competitiveness is one of the major reasons for the slow increase in hydrogen utilisation worldwide [5].

They also note that a lack of system integration, e.g. as a planning model, could be a reason why policy makers hesitate to further promote the development of a hydrogen economy. Looking more detailed into existing literature, Ball et al., e.g., modelled the German energy system including a high spatial resolution to discuss the possibility of a German hydrogen economy, focusing on the infrastructure demand and impact on greenhouse gas emissions [6]. Here, hydrogen is not only seen as an alternative to fossil fuels, but also as a storage and flexibility option in fully renewable energy systems. However, the expected hydrogen demands and feedstock costs are outdated due to developments in the energy market in recent years. Robinius et al. discuss the possibilities of power-to-gas as a network expansion alternative [7]. It is shown that there are scenarios in which the use of electrolysers is more reasonable than the expansion of the power grid. Especially when considering both the possibility of selling hydrogen and the saved costs for laying new transmission lines. Li and Mulder evaluated the impact of hydrogen on the electricity and hydrogen market from an more economic point of view [8]. They show that especially in combination with the volatility of renewable power generation power-to-hydrogen brings huge economic advantages. However, they also state the importance of greenhouse gas emission reduction targets, as steam methane reforming still is the cheapest way to produce hydrogen. He et al. published a more detailed study of the complex interactions of sector-coupled systems considering hydrogen as a decarbonisation option on a northern american example [9]. In summary, the concept of sector coupling itself reduces total system costs. For example, since the round-trip efficiency of electricity-to-hydrogen-to-electricity is still low, using hydrogen in other sectors such as transportation reduces losses. They were also able to show that as the demand for hydrogen increases, the specific cost of flexibility decreases. However, the assessment lacks the inclusion of industrial and heating demand. In an extensive review on sector coupling Ramsebner et al. conclude, that there will always be the competition between the higher efficiency of direct electrification versus long-term storage capabilities of power-to-gas applications [10]. As there are many different system-wide effects, no specific predictions can be made. Especially since regional climate goals and policies can strongly influence the final technology deployment. Nevertheless, as some applications are not able to be electrified, there will be a non-neglectable share of hydrogen-based applications.

The use of hydrogen as a flexibility and storage option for the power sector has not been consensually agreed on. It strongly depends on the chosen scenario and assumptions regarding technological and economic parameters. The invention of innovative technologies, such as solid oxide cells (SOCs) with their ability to be operated reversibly for both hydrogen and electricity generation, adds further degrees of freedom to the decision-making process. In this study the utilisation of hydrogen as flexibility option in the electricity sector is evaluated. Therefore, both fuel cell and gas turbine based pathways are benchmarked alongside battery storage as main flexibility option (Figure 1). Due to the great influence of sector coupling on the use and the specific costs of hydrogen, a highly coupled energy system model is used. The German energy system embedded in an abstracted, interconnected European system serves as an example. The focus is on the application of the used technologies, as well as the interactions between different sectors. Therefore, different scenarios are considered and individual system parameters are evaluated. The assessment is related to the EU taxonomy rules, although the latest updates to the regulation regarding temporal and geographical correlation and additionality as defined in [11] are not considered.

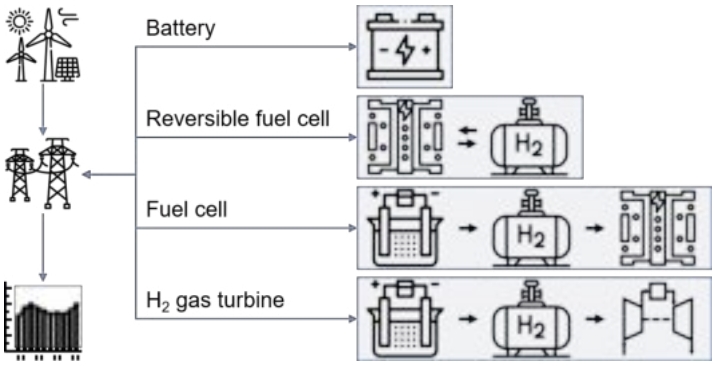

Figure 1: Overview of the considered hydrogen utilisation pathways, including separated hydrogen generation and consumption and the utilisation of reversible technologies.

2. State of the Art and Methods

2.1. Political Boundary Conditions and Current Situation

The use of hydrogen as a sustainable energy carrier is primarily based on the climate protection goals of the German government. The latest amendments to the climate protection law mandate that Germany should be

climate-neutral by 2045. This necessarily includes the replacement of fossil energy carriers with sustainable ones. This cost-intensive undertaking is also supported by the EU. Here, several regulations for the member states of the EU have been adopted, which are intended to provide security in financial planning. This includes, for example, the EU taxonomy, which defines whether an investment is beneficial for climate protection and in terms of sustainability. To qualify as a sustainable investment under the new rules, several technical screening criteria must be met [1]. In the case of power generation from fossil gases, a distinction is made between two groups. Plants with life cycle emissions of 100 $g_{CO2e}\,kWh^{-1}{}_{el}$ or less will be considered sustainable without any further conditions. In addition, there is the possibility to also fall under the label of sustainability for plants that receive their permit to operate by 2030. To do so, a set of criteria must be met, two of which are directly related to the use of hydrogen. For example, specific emissions must initially only comply with a limit of 270 $g_{CO2e}\,kWh^{-1}{}_{el}$. However, it must be ensured that by 2035 the plants are capable of running entirely on low-carbon fuels. In this context, the results of a UNECE[1] study can be used, in which the life cycle emissions of several power generating technologies are calculated [12]. Here, natural gas based combined cycle power plants without carbon capture and storage have emissions of 403-513 $g_{CO2e}\,kWh^{-1}{}_{el}$ and with carbon capture and storage 92-220 $g_{CO2e}\,kWh^{-1}{}_{el}$. Considering only the stoichiometric combustion of natural gas the emissions under assumption of a combined cycle plant efficiency of 63 % are already higher than 315 $g_{CO2}\,kWh^{-1}{}_{el}$ (see Figure 2). Using an Aspen Plus simulation, Figure 2 also shows the correlation of the specific direct CO_2 emissions with increasing hydrogen admixture. To comply with the limit value of 270 $g_{CO2e}\,kWh^{-1}{}_{el}$, at least 36.1 vol.-% hydrogen would be required, and for 100 $g_{CO2e}\,kWh^{-1}{}_{el}$ even more than 87.7 vol.-% hydrogen.

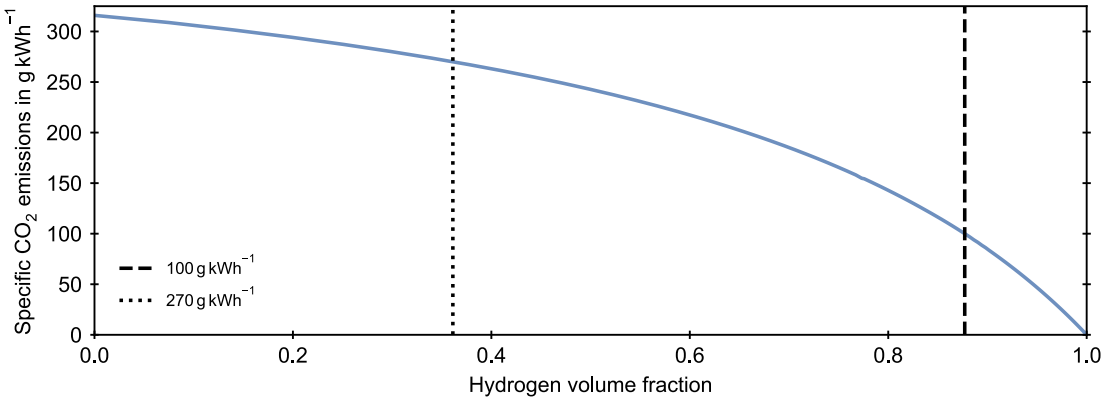

Figure 2: Specific CO_2 emissions of the stoichiometric combustion of a hydrogen-methane mixture with a varying hydrogen fraction.

2.2. Hydrogen Technologies

The aim of the study is to evaluate the flexibility supply via hydrogen in comparison to battery technologies. In the following, the technological and economic parameters of the hydrogen technologies are presented. On the side of battery technology, it is assumed that by 2045 the goals of the German government regarding the expansion of e-mobility and the large-scale application of bidirectional charging (vehicle to grid (V2G)) will have been implemented.

2.2.1. Hydrogen Supply

The supply of green hydrogen in context of this work is realised exclusively via water electrolysis. Both local production within the German energy system and import are allowed. The generation itself can take place via the three technologies alkaline electrolysis (AEL), polymer electrolyte membrane electrolysis (PEMEL) and solid oxide electrolysis (SOEL). The technological and economic parameters are based on literature values for all technologies. As several detailed studies and reviews on each of the technologies, as well as comparative work, are already available, a detailed description is not provided. For more detailed information, the authors refer to the existing literature such as [13, 14]. A summary of the parameters used and the corresponding references are given in Table 1. The import of hydrogen is again divided into two segments. First, the import via sea route is possible. Based on [15, 16], it is assumed that the import of hydrogen based on renewable power from Saudi Arabia will be possible for a cost of 2.4-3.1 $\$\,kg_{H2}{}^{-1}$ or 5.2 $€\,kg_{H2}{}^{-1}$ respectively. In addition, hydrogen pipelines can be used to import from sun-rich countries in the EU. For this purpose, the energy system model has the possibility to expand renewables in Italy or Spain in combination with electrolyser capacities to supply hydrogen to the German subsystem[2].

[1] United Nations Economic Commission for Europe

[2] For example the decision to extend the pipeline from the *H2Med* project to Germany.

2.2.2. Techno-Economic Parameters of Hydrogen Gas Turbines and rSOC

Hydrogen Gas Turbine

When assessing the hydrogen compatibility of gas turbines (GTs), it is necessary to distinguish between two types of combustion methods. Initially, gas turbines utilised a simple diffusion mechanic to burn fuel, which is a robust process. Indeed diffusion-style are already capable of burning pure hydrogen, but comes with the downside of higher NO_x emissions and lower efficiency. To reduce emissions, gas turbine manufacturers introduced a lean-premixed combustion process in the 1980s, for which fuel and air is mixed in a lean ratio before introduced into the combustion chamber. Since then, basically all heavy-duty gas turbines incorporate some form of premixing fuel and air. While the NO_x emissions can be significantly lowered using lean-premixed combustion, the stable operational range of these gas turbines is narrow, making them susceptible for any type of disturbances, like a fuel switch from natural gas to hydrogen, which has fundamentally different combustion characteristics, especially regarding flame temperature, flame speed, volumetric heating value and quenching distance. [17, 18]

The most challenging problem during the combustion of lean-premixed gas is the occurrence of flame flashbacks. Due to the combustibility of the fuel-air mixture, flames in premixed gas turbines can shift from the combustion chamber upstream to the fuel injection nozzles, damaging the turbine hardware. Fuelling hydrogen increases the risk of flame flashback as the higher flame speed of hydrogen more often fulfills the prerequisite of the local flame speed being higher than the local fuel-mixture flow velocity. Additionally, hydrogen has a shorter autoignition delay time. The autoignition delay time corresponds to the time interval for a reactive mixture to react without an ignition source. If this time interval is shorter than the fuel–air mixing residence time in the non-combustion zone, autoignition can occur and lead to local flame holding or further flashbacks. [19]

Another concern are thermoacoustic instabilities, which describe an unwanted feedback loop of combustion fluctuations leading to an unstable heat release and thus pressure oscillations which can excite natural acoustic modes of the combustor, intensify and cause more combustion fluctuations closing the loop. Consequences can reach from affected plant efficiency to damaged hardware. While not being an inherent consequence of fuelling hydrogen, thermoacoustic instabilities are a concern when switching to hydrogen in gas turbines former designed for fuelling natural gas and may prevent an easy retrofit. [20]

Lastly, the higher flame temperature of hydrogen and the increased heat input due to the larger water content in the hot gases have higher demands on materials used for turbine parts like heat shielding or turbine blades. The increased thermal stress will lead to a degradation of parts. Also, effects like hydrogen embrittlement and hot corrosion must be considered. [21]

While there will likely be technical solutions for all of the aforementioned issues, it becomes clear that hydrogen can not simple be burned in today's gas power plants. Yet there are no reports of successfully operating a premixed heavy-duty gas turbine with pure hydrogen. However, for state-of-the-art turbines like the Ansaldo GT36 up to 70 % hydrogen by volume are available for operation. [22]

SOFC and rSOC

SOCs are solid-state electrochemical devices which can either be configured as fuel cell (solid oxide fuel cell (SOFC)) producing electricity directly from oxidizing a fuel or, if configured as electrolyser cell (SOEL), produce hydrogen through water electrolysis. The reactions in a solid oxide cell are reversible, if a solid cell is configured to work alternating as a fuel cell and a electrolyser, it is called reversible solid oxide cell (rSOC) (see Figure 3). SOCs are made of four main components: the anode and cathode (defined in fuel cell-direction), named fuel and oxygen electrode to avoid confusion when the cell operation is reversed, the solid electrolyte layer and the interconnector. [23]

SOCs recently received increased attention due to advantages over other fuel cell/electrolyser technologies. First, the efficiency in both operation modes are the highest reported with over 65 % for SOFCs and over 80 % for SOELs [14]. Second, the aforementioned reversibility, which allow for a high utilization of rSOCs. Third, SOCs can utilize different fuels, like hydrogen, methane or ammonia, making them deployable for a wide range of applications. Fourth, due to their simple layer structure, the currently favoured design, they are predestinated for mass manufacturing and are scalable to any capacity. Additionally, no rare materials like iridium are used in SOCs. While research focuses on finding improved materials, currently mostly Ni-based alloys and yttria-stabilized zirconia (YSZ) are utilised. [24]

Drawbacks of SOCs are the current high investment costs which belong to the highest among all fuel cell/electrolyzer technologies and reported degradation issues. However, the high costs are predicted to decline from todays $>2000\,€\,kW_{el}{}^{-1}$ to less than $800\,€\,kW_{el}{}^{-1}$ in 2045 due to economics of scale (see Table 1). The lifetime is being constantly improved through better material choices and operating modes, like the reversible operation. An example for the improved durability is a long-term test of an SOFC in Jülich, which was shut down after 100,000 h of operation without major power degradation. [25]

Depending on the costs of imported hydrogen, rSOC are an attractive technology to provide flexible power gen-

eration to a future energy system as they have a natural investment advantage over an alternative combination of electrolysers and hydrogen gas turbines. They are considered a viable long-term energy storage technology and could improve the integration of renewable energy sources by utilising surplus electricity production for electrolysis.

Currently, SOCs are entering an early commercial phase with several manufacturers announcing investments to scale up their production in the gigawatt range. While this developments mainly relate to SOEC production, exemplary pilot-projects for dedicated rSOC are a 140 kW_{SOEC}/50 kW_{SOFC} installation in 2016 [26] and a 80 kW_{SOEC}/15 kW_{SOFC} in 2018. [27]

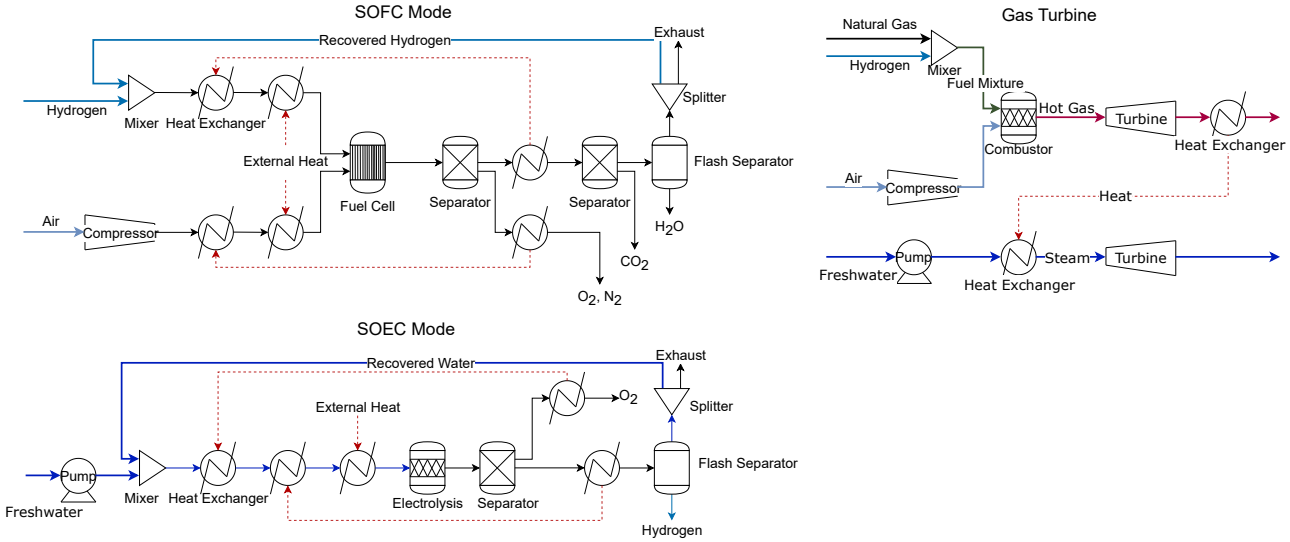

Figure 3: Process flow-sheets of SOC in fuel cell and electrolysis mode (left) and of a combined cycle gas turbine (right).

Cost estimations

Table 1 summarises the key parameters of the hydrogen technologies, where in case of H_2 gas turbines a CCGT is assumed. Included are the efficiency, expected lifetime, as well as the fixed and variable costs. Since the energy system model considers a whole year for each scenario, the costs must be scaled to the annual costs. For this purpose, the annuity method is used.

Table 1: Summary of the hydrogen technologies including technological and economic parameters.

Technology	TRL	Efficiency	Lifetime	CAPEX	OPEX	Reference
Hydrogen CCGT	6-8	0.630	45 a	920 € kW_{el}^{-1}	18 € kW_{el}^{-1} a^{-1}	o.a.[a]
SOFC	5-7	0.699	30 a	640 € kW_{el}^{-1}	51 € kW_{el}^{-1} a^{-1}	o.a.[a]

2.3. Energy System Model Framework

The energy system model used is based on the framework ”OpTUMus”, which is described in detail by the authors in [30]. The energy system model is a linear optimization problem, which is solved with IBM ILOG CPLEX 22.10.0 using a barrier optimization algorithm. The temporal resolution for each optimisation problem corresponds to one year in one-hour steps. The model itself is constructed as a *nodes and edges* model. *Nodes* represent different forms of energy or energy carriers such as electricity, hydrogen or natural gas. According to Equation 1 in each time-step t energy and material balances must be conserved for all nodes n.

$$P_{demand}[n][t] + P_{out}[n][t] = P_{in}[n][t] \quad (1)$$

Edges, on the other hand, describe all possible transformation paths and thus all technologies for energy conversion and transport. This includes the efficiency of energy transportation or transformation from node n to m in each time step t (Equation 2). A simplified example is shown in Figure 4a.

$$P_{in}[n][t] = a_{mn} \cdot P_{in}[m][t] + b_{mn} \tag{2}$$

The model contains an abstract digital twin of the German energy system. This includes the electricity and heating sector as well as the supply of mobility and the supply of energy and a selection of basic chemicals to industrial applications. The German energy system is divided into four regions (Figure 4b) in order to be able to map the local potentials of renewable energies, energy demands and transport limitations. Furthermore, the model includes Germany's direct neighbors as well as Norway, Sweden, the United Kingdom, Spain and Italy, each reduced to the electricity sector. A graphical summary of the regions considered is given in Figure 4c. In order to enable the import of synthetic energy carriers from the southern European regions, electrolysers and pipelines can be built.

On the demand side of the German energy system model, the four sectors

(1) electricity (2) heat (3) mobility (4) industry

are considered. Here, it is important to note that the electricity sector includes all power demands consisting of conventional demands as well as electricity for heating, transport and industry. Each of the demand segments is based on a separate model, which determines the hourly demand for electricity. The material demands for basic chemicals and fuels (methanol (MeOH), SNG, Fischer-Tropsch (FT)-fuels, ammonia (NH_3), hydrogen (H_2)) are also calculated specifically for the respective applications and transferred to the model as a summed demand time series. The same accounts for the heating demand both in domestic and industrial applications. The overall demands are divided into the four regions using statistical methods. Each region is optimised by itself, having the possibility to interact with all neighboring regions. Additionally, the northern and southern Germany regions are allowed to built direct connections for both power and hydrogen transportation. In the same manner, Spain and Italy are connected to the southern German region via the possibility of an hydrogen pipeline. Finally, northern Germany has the option to import hydrogen by ship. The demand side models are adopted from previously by the authors published works [31–33] and therefore are not further discussed. However, an overview of the included technologies and the respective demand side connections are summarised in the appendix in Table 5.

(c) Overview of the considered Subsystems of the European energy system model.

Figure 4: Overview of the energy system model basic structure (a), the spatial resolution of the German subsystem (b) and the considered countries of the European energy system model (c).

2.4. Scenario Definition

Various scenarios are important in energy system optimisation to assess the robustness and flexibility of energy systems under different conditions, to identify potential risks and opportunities, and to inform decision-makers for long-term planning and policy development. In context of this work, a variation of hydrogen connected parameters is performed, to identify the influences of the energy system behaviour. Therefore, the parameters hydrogen demand, hydrogen import costs and the technology cost developments are chosen. In a base case scenario, most parameters of the entire model are set to the mean expected values found in literature. Two additional scenarios are defined, one with a higher hydrogen demand (H2-high) and one with a lower

penetration of hydrogen and a restricted availability, e.g. reduced pipeline availability, (H2-restr.). At the same time it is assumed, that a higher hydrogen demand correlates with lower specific technology costs and vice versa. Additionally, the overall end-use energy demand stays constant over the different scenarios. Therefore, a higher hydrogen demand is connected to a lower direct electrification. A summary of the scenarios and the respective parameter variation is given in Table 2.

Table 2: Scenario definition with the respective parameter variation.

Scenario	H_2 demand[a]	H_2 import[b]	Tech. costs[c]	Comment
BC	113 TWh a^{-1}	2.4 € kg_{H2}^{-1}	-	-
H2-high	172 TWh a^{-1}	2.1 € kg_{H2}^{-1}	-15 %	Electrification ↓, H_2-tech. costs ↓
H2-restr.	113 TWh a^{-1}	5.2 € kg_{H2}^{-1}	-25 %	H_2 availability ↓, H_2-tech. costs ↓

[a] Only predefined hydrogen demand. Not included are demands for power generation and for further synthesis.

[b] Import via ship from MENA region.

[c] Own assumption; Relative cost reduction for PEMEL, AEL, SOEL, SOFC and rSOC

3. Results

The energy system is largely based on electrical energy. As expected, most of this is provided by wind turbines and photovoltaics, as summarised in Table 3. The contribution of biomass via biogas and combined heat and power is also not to be neglected, whereas plants with higher complexity as polygeneration plants are only used in the restricted scenario. In addition to battery storage or V2G, both conventional gas turbines and hydrogen-based technologies are used to cover the flexibility demand. A summary of the amount of energy provided per technology is given in Table 3. In all scenarios the biomass potential of Germany, which summarises to around 420 TWh a^{-1} for all regions, is fully utilised. Large shares are needed for the heat supply and as carbon source for synthesising chemicals and fuels. This indicates the rising demand for carbon sources in future energy systems. Since this model only allows biomass as a sustainable feedstock, potentials from the use of residues and waste materials - as required in a circular economy - are neglected. In particular, technologies such as polygeneration plants will also be used in the future to exploit residues such as plastic waste and municipal solid waste as input for the synthesis of high-value products or for the efficient supply of flexibility to the electricity and heat sectors. However, doubling the sustainable feedstock potential could reduce the total system costs by 10 %[3], by using the same boundary conditions as in the base case scenario.

Table 3: Summary of the power generation in Germany without storage technologies or grid as comparison between the scenarios BC, H2-high and H2-restr.

	Biomass[a]	GT	H2GT	Hydro	PV	WOFF	WON	SOFC	PolyGen
BC in TWh	86.7	16.0	22.0	12.5	326.8	137.0	224.0	70.5	0.0
H2-high in TWh	85.1	5.5	25.0	13.2	284.9	91.0	225.3	128.0	0.0
H2-restr. in TWh	84.8	35.2	8.2	13.1	415.9	136.6	224.9	7.0	0.9

[a] Sum of all biomass based power plants and CHPs.

As can be seen in Table 4, in the base case scenario hydrogen is exclusively imported. As electricity prices are most of the time (90 %) higher than the import costs of hydrogen, hydrogen production in Germany is not viable under the given boundary conditions. The electricity and hydrogen prices are calculated as shadow prices, which is not directly comparable to the pricing on the stock exchange. In this case, they can rather be interpreted as the hourly system costs for one additional unit of electricity or hydrogen. Summarised, the hydrogen demand is covered mainly by pipeline import from Spain (66 %) and import via ship (30 %). From a system perspective, the mean electricity supply costs 64.06 € MWh^{-1} and the mean hydrogen supply costs 44.95 € MWh^{-1} in the base case scenario. In a restricted overarching system, both electricity and hydrogen prices rise. In the H2restr. scenario, in more than 20 % of the time hydrogen production in Germany becomes more viable than import. While the average electricity costs increase only slightly, the average hydrogen supply costs increase by almost 25 %, with significantly higher extremes in times of low renewable availability. Here, in some hours of the year, even hydrogen production from biomass becomes economical.

Figure 5 gives an overview of the time-resolved utilisation of flexible power in the described energy system, aggregated for all four regions in the base case scenario. As no electrolysis is operated only battery storage

[3] The number is based on a separate optimization in which the identical system but with twice the sustainable feedstock input potential was calculated.

Table 4: Summary of the hydrogen supply in Germany as comparison between the scenarios BC, H2-high and H2-restr.

	AEL	PEMEL	SOEL	rSOC	ES	IT	Ship
BC in TWh	0.0	0.0	0.0	0.0	176.2	9.6	80.8
H2-high in TWh	0.0	0.0	0.0	0.0	173.5	32.6	202.9
H2-restr. in TWh	0.0	0.0	77.9	0.0	18.1	16.0	36.9

via V2G is used to cover peaks in renewable power generation. Battery storage systems are particularly useful for short-term electricity generation. The available capacity of battery electric vehicles ultimately leads to a factor of 10 greater utilised power of V2G compared to SOFC and H2GT. However, the total amount of energy provided, 94.4 TWh, is comparable to the sum the power generation by fuel cells and gas turbines.

Due to the higher efficiency of the SOFC, fuell cells are used preferably to gas turbines. The load curve in Figure 5 shows that the fuel cells are used to provide the base load in both summer and winter, with a higher share in winter. Particularly during periods of low wind in winter, the fuel cells are operated at full load for several days, as shown in Figure 5 (top left and top right). The fluctuation in the utilisation is greater in summer, which, as can be seen in Figure 5 (top center), falls on the daily rhythm of PV electricity generation and thus behaves comparably to the load peaks of battery storage. Hydrogen gas turbines, in contrast, are used as the last flexibility provider. Particularly in the winter months, some periods can be identified in which gas turbines are operated at full load. However, during the rest of the year, hydrogen gas turbines are only used to cover peak loads for a few hours. The infrastructure of the hydrogen supply via ship combined with the storability of synthesis products as well as the sector coupling effect of hydrogen lead to no further[4] demand of hydrogen storage facilities.

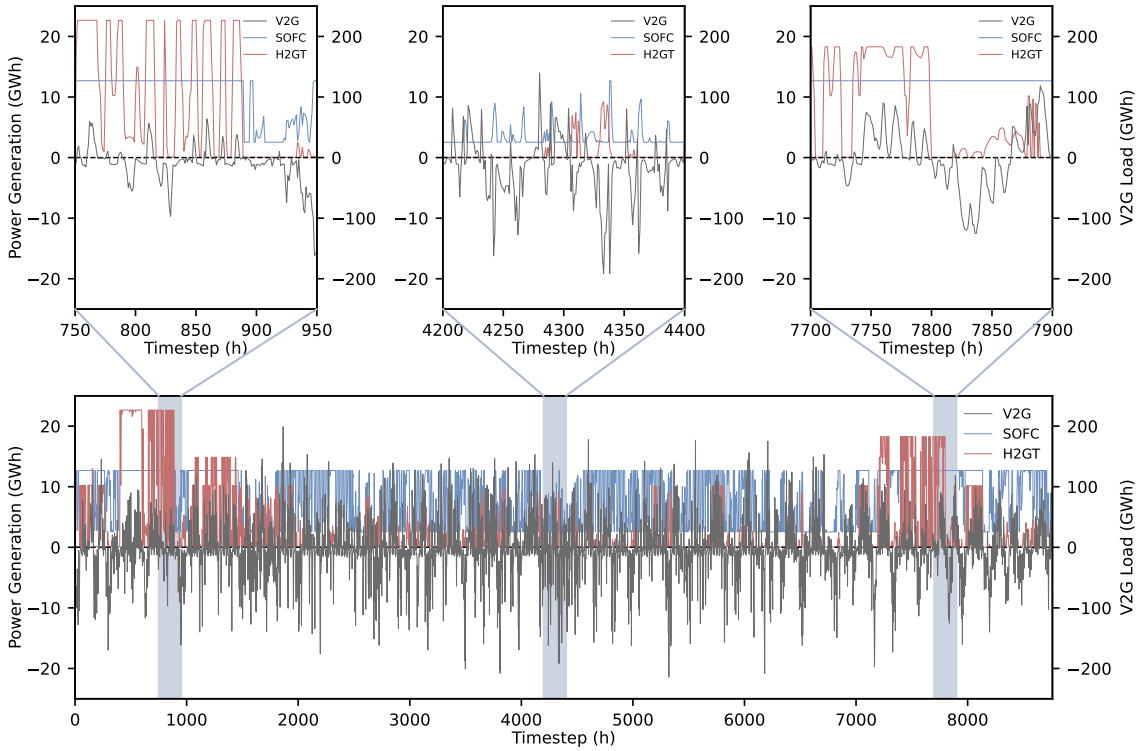

Figure 5: Timeline of the base case power generation via SOFC and hydrogen gas turbines and the utilisation of vehicle-to-grid (V2G) battery storage with additional cut outs for specific time periods.

A more detailed evaluation of the application of hydrogen as a feed-in fuel for electricity generation is shown in the residual load curves of the three scenarios in Figure 6. In the BC scenario and the case of significantly higher hydrogen penetration (Figure 6 left and centre), it can be seen that due to the significantly larger scaled hydrogen production worldwide, on-site generation in Germany is not economical. In contrast, in the restricted scenario (Figure 6 right), electrolysers are operated almost throughout the year. In the case of high residual

[4]Beyond the storage capacity of the ship discharge stations and the storage capacity of the grid.

load, hydrogen serves to provide base load in all cases, whereby a flexible behaviour with short load cycles can be observed except for a few hours. As the residual load decreases, the demand for electricity generation from hydrogen also decreases and fuel cells and hydrogen gas turbines are only required for flexible power. In case of negative residual load, hydrogen is continuously produced in the restricted scenario, whereby high fluctuation can also be seen here.

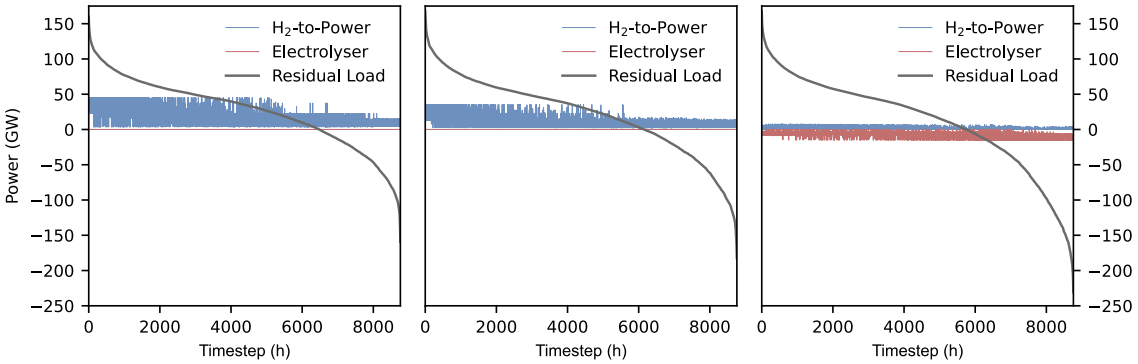

Figure 6: Residual load curve of the H2-high scenario (left), BC scenario (mid) and H2-restr. scenario (right) including the electrolysis and hydrogen based power generation.

4. Conclusion and Outlook

In this work the potential of hydrogen-fuelled gas turbines and solid oxide cells (SOCs) as solutions for providing flexibility in the future electricity grid is evaluated. The study reviews recent publications on both technologies, focusing on the engineering challenges that need to be overcome. Two simplified process simulations ware used to estimate future performance capabilities, and a cost estimation was conducted for both systems.

The analysis finds that both technologies are capable of providing flexible power output in future energy systems with high shares of renewable energy sources. While gas turbines benefit from higher technology maturity and availability, SOCs are more efficient and could act as energy storage due to their reversibility (rSOC), making them a potentially more economical option when considering the whole power-to-gas-to-power chain. However, both technologies still need to overcome significant engineering challenges, such as flashback avoidance in hydrogen gas turbines and better electrolyte and oxygen electrode materials in rSOCs. Cost-wise, gas turbines are currently favored over rSOCs, but rSOCs have the potential to decline in costs as mass manufacturing comes into play.

Energy system modeling shows that if SOCs become economically viable, they could make large scale usage of hydrogen turbines obsolete. Additionally, the results suggest that as long as the electricity supply costs stays to high, electrolysis is not cost-competitive compared to hydrogen import. However, if conservative estimates of future rSOC costs prove correct, the benefits of combining an efficient electrolyser and fuel cell in a single device could make up for the higher costs. Both gas turbines and fuel cells based on SOCs are viable options for providing flexible power output in future energy systems with high shares of renewable energy sources. The choice between these technologies will depend on their respective costs, efficiency, and performance capabilities, as well as the specific requirements of the energy system in question. Both technologies can reduce the overall system costs due to a lower demand of renewable power generation capacities.

However, further model development is needed for a broader discussion of the utilisation of hydrogen in energy systems. On the one hand, the carbon supply for the synthesis of fuels and chemicals could be identified as a limiting factor. Limiting the usability of biomass to what is currently assumed to be sustainable potential by using it to provide heat and electricity and as a carbon source leads to competitive behavior. The utilisation of residues should also be taken into account in order not to impose restrictive boundary conditions on the system. Furthermore, the largest influencing variables could not be clearly determined, which makes the use of a sensitivity analysis indispensable.

Acknowledgments

This study was carried out in the framework of the projects VERENA (project no.: 03EE5044B) sponsored by the Federal Ministry for Economic Affairs and Climate Action (Germany) and GOLD (grant no.: 101006873) as part of the European Union's Horizon 2020 Research and Innovation Program. The financial support is gratefully acknowledged.

Abstract:

Proton exchange membrane fuel cells have been identified as suitable for vehicle implementation. As for all fuel cell types, thermal management is a critical issue: the redox reactions taking place in the membrane electrode assembly generate water; a humid membrane is able to enhance transport phenomena, but too much water could flood the pathways of reactant gases. Recently, interest has grown with respect to the properties of the gas diffusion layer of membranes: its fibres pattern can critically affect water removal rates. Computation fluid dynamics represents a powerful tool that can be used for understanding the key design factors of fuel cell components to improve the overall performance. Specifically, in the case of the diffusion layer, 3D simulation can investigate droplet dynamics and define the optimized surface structure for water management. In this paper, optical data and numerical results were combined to characterize the behaviour (oscillation, detachment, etc) of a couple of droplets on the woven gas diffusion layer with a structure retrieved by using an approach typical of the textile industry. High-spatial resolution imaging allowed the evaluation of warp/weft size; these parameters were used for building the 3D mesh for simulations based on the Volume of fluid method. The dynamics of droplets, with diameters ranging from 200 to 600 µm, were investigated under the effect of a constant 10 m/s airflow for different gas diffusion layer geometries. In addition, the cases of the droplet pairs, deposited at different reciprocal distances, were studied by using the same methodological approach. Results demonstrated the impact of layer structure on the results obtained through simulations; moreover, an optimised design can contribute to control water removal and minimise flooding effects.

3D CFD, optical visualization, water dynamics, gas diffusion layer

1. Introduction

Among the numerous types of fuel cells, Proton Exchange Membrane (PEM) Fuel Cells (FCs) have gained a lot of interest in automotive industries due to the absence of pollutant emissions from the end gases pipeline and its low operative temperature. PEM FC is an established and reliable technology, but it still presents unresolved issues. Among them, water management is one of the most critical, given the need to humidify the membrane and the simultaneous risk of flooding the reactant pathways toward the catalyst layer.

In the last decade, research activities regarding water dynamics in PEM FCs were mainly focused on the design and characteristics of bipolar plates [1]: fabrication methods and innovative materials, suitable coatings and efficient channel design to simultaneously improve reactants diffusion and water removal rate. Those were the routes to further develop PEM FCs. Only recently, the design of properties of cloth Gas Diffusion Layer (GDL) have been considered more carefully [2], with the aim of improving water management by means of a potentially controlled droplet adhesion on the surface, while also studying flow through GDL. In this regard, efforts were mainly directed toward a deep comprehension on how the number and the pores dimension [3], fibers radius and distribution [4], porosity and permeability [5-6] and interface between GDL

and Catalyst Layer (CL) [7-8] can improve the FCs overall performances: optimization of the design of this layer is fundamental since GDL serves both as pathway for reactant gases and escape route for the forming water. However, as water emerge from GDL, is also important to boost its removal rate. Thus, starting from the well-known concept that the GDL wettability and surface roughness affect water dynamics [9-10], specific solutions such as GDL perforation [11] characteristics have been studied to enhance the drainage of the water from the electrode to the gas channel and to reduce the risk of flooding. As concern the numerical simulation of water detachment/rolling/sliding, both the lattice Boltzmann and the Volume Of Fluid (VOF) methods have been widely used to investigate droplet behaviour on the GDL with different channel geometry. A common assumption made in these models is to consider a smooth GDL surface [12-13], but recently authors started to investigate the role that microgeometry may play in membrane optimal design. Hou et. Al [14] used the lattice Boltzmann method to simulate droplet motion on a realistic GDL, confirming that a smooth surface led to faster water removal. Liu et al. [15] performed a 3D VOF assuming different patterns for the GDL: it was still an impermeable and hydrophobic surface, but they used a striped, dotted and waved surface to study the effects of GDL's microstructure and optimize the shape parameters of those "disturbances". Anyanwu et al. [16] compared the liquid water transport in wave-like channels for smooth and rough GDL. They substantially demonstrated that smaller fiber diameters and more ordered and uniform microstructure reduced the flooding of flow channels by favouring water removal. Wang et al. [10] performed molecular simulation of a droplet and proposed to improve water removal capacity by controlling superficial roughness of the GDL. Gao et. Al [4] focused their effort on reconstructing a realistic microgeometry for the outer layer of the Membrane Electrode Assembly (MEA) and evaluated the fluid flow through it. The nature of the woven structure allowed them to define a primitive cell: the interlaced GDL was represented by serial repetition of this primitive element.

Currently, few research efforts have combined experimental results and simulation analysis related to the droplet movement on a real GDL surface. In this paper, optical data and numerical results were combined to characterize the behaviour (oscillation, detachment, etc) of droplets on the woven GDL with a structure retrieved by using a typical approach of the textile industry. High-spatial resolution imaging allowed the evaluation of warp/weft size; these parameters were used for building the 3D mesh for CFD simulations based on the VOF method. The single droplets and pairs, with diameters ranging from 200 to 600 μm, were deposited at different reciprocal distances and their dynamics were studied under the effect of a constant 10 m/s airflow. Results obtained by simulations with different microstructure geometries were compared. In particular, a completely smooth surface and a hybrid one between the previous two were generated.

2. Experimental setup

Water dynamics were studied on the carbon cloth GDL of a Celtec®-P1000 membrane electrode assembly (MEA) with an active area of 45 cm^2 (6.72 by 6.72 cm). In order to support the CFD simulations, optical methodologies were applied to determine the structure of the GDL and the static contact angles of deposited water droplets. The GDL texture and profile were visualised by means of an 8-LED ring crown illuminator mounted on a 1280x720 digital microscope (Technaxx TX-158). This was equipped with a 1000x digital zoom system that permitted to range the spatial resolution up to 5.8 μm/pixel in full chip configuration. In Fig.1a-b, the texture with woven fibres is clearly distinguishable. Following an approach derived from the textile industry [17-18], a custom routine for image processing was developed by using NI Vision [19]; it allowed delineating the GDL geometrical cross-section (Fig.1c).

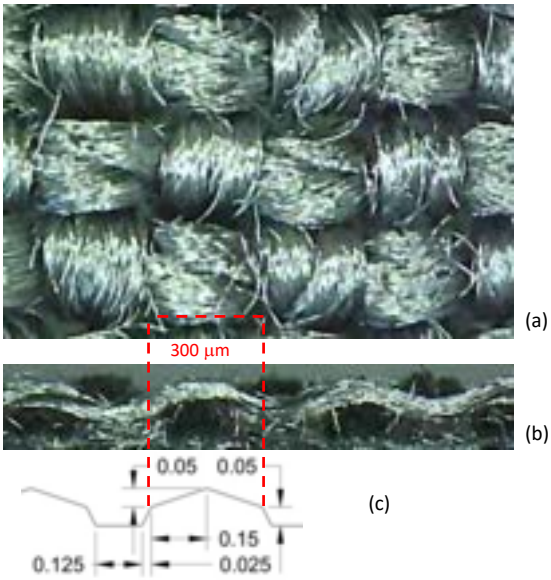

Figure. 1. GDL carbon cloth texture: (a) experimentally visualised surface and (b) profile; (c) geometrical profile used for CFD simulations (units are expressed in µm).

The GDL surface was mapped in 25 regions of interest 1x1 cm in size (Fig. 2a). On each region, a stainless-steel needle of a high-precision medical device (NIPRO) was used for depositing several droplets with a minimum diameter of 400 µm (due to the internal dimension of the capillary) [19-20]. With the digital visualization set-up described previously, droplet morphology was evaluated in terms of diameter and static contact angle. The occurrence distribution related to 115 droplets (Fig. 2b) demonstrated that the most probable contact angle (CA) for droplet in the 400-800 µm size range was 123±2 deg. This value agreed with those considered by other researchers for woven GDL surfaces [21]. The measured contact angles were practically constant, as shown in Fig. 3 that reports the average values measured for 9 classes of droplet diameters (from 400 µm to 800 µm step 50 µm). Consequently, 123 deg was used as boundary condition for the wettability parameter in the CFD simulations.

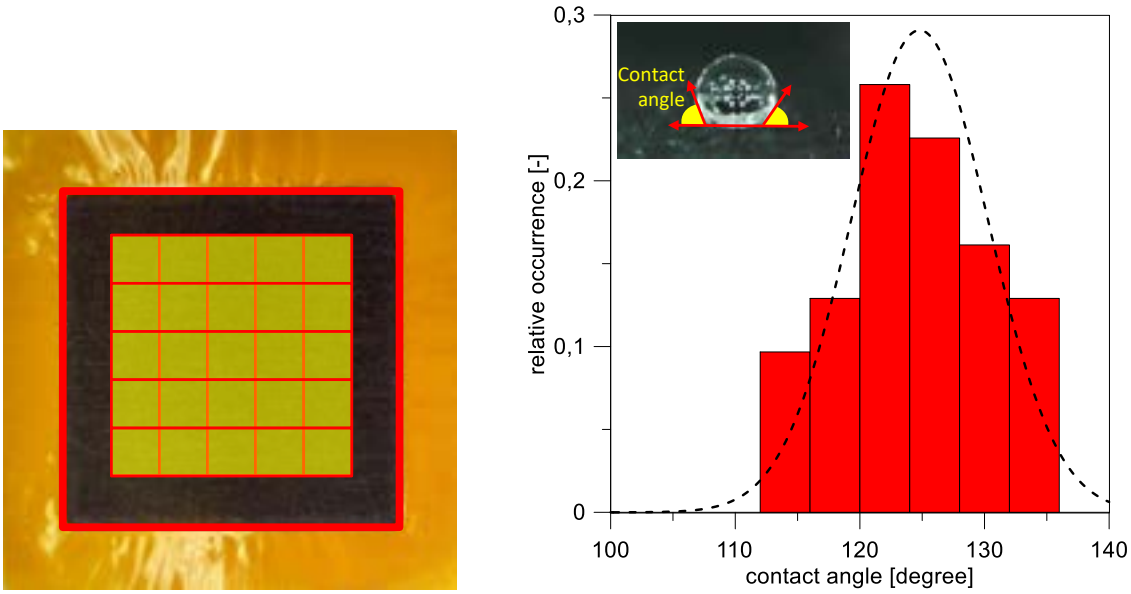

Figure. 2. (a) MEA with 25 regions of interest highlighted on GDL surface for optical investigations and (b) occurrence distribution of droplet contact angles.

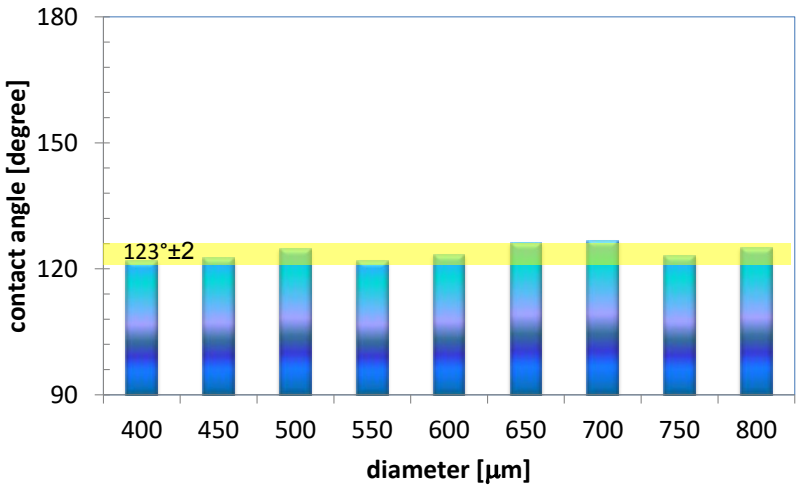

Figure. 3. Average contact angle of 9 classes of droplet diameter.

Droplet dynamics were investigated by using a 512x512 CMOS camera (5000fps in full chip configuration) coupled with a 25 mm objective. The setup allowed to achieve a spatial resolution of 55 µm/pixel. The exposure time was fixed in order to detect 1000 images per second; the setting represented a good compromise between luminosity and temporal resolution. Another image processing procedure developed

using NI Vision 2020 was applied for assessing the instantaneous contour and the centre of mass of the droplets. For dynamic conditions, 10m/s airflow was provided by a fan positioned at 50 mm from the region of droplet deposition; local air velocity was measured with an accuracy of 0.1 m/s by using a hot-film probe.

Optical investigations were performed in open-channel conditions. Since the air-flow rate and static wettability were fixed, the surface roughness was the only parameter that influenced the dynamic wettability and the adhesive force at the liquid-solid interface. In real-working configuration, humidity of the reactant gas should be considered when evaluating the removal efficacy of droplets from the GDL and flow channel. This is due to the fact that phase change phenomena and modifications in surface tension could occur. Nevertheless, this study mainly focused on the effects of airflow and GDL roughness on droplet removal; the effects of reactant gas humidity was out of the scope of the present work, but will be considered in future investigations.

3. Methodology

3.1. GDLs design

Taking into account the GDL's microstructural characteristics determined by optical methodologies, CREO Parametric 8.0 was used to design the 3D profile. The optical analysis was able to recover the two key parameters to reconstruct a realistic geometry: the height and length of the sinusoidal waves that interlaces on the surface. These dimensions, together with the width of the weft, were used to trace four sweep trajectories for a trapezoidal profile. The four surfaces were then merged and trimmed to obtain a squared elemental region. The latter could be used in the "Serial Repetition" CREO function to create a surface of the desired dimensions. Figure 4 shows the generation process and the obtained elemental region. Two more GDL surfaces were generated: a completely smooth and a hybrid solution one. The generation of the latter follow the same methodology showed in Figure 4, but amplitude and length were set equal to 0.075 mm and 0.4 mm respectively.

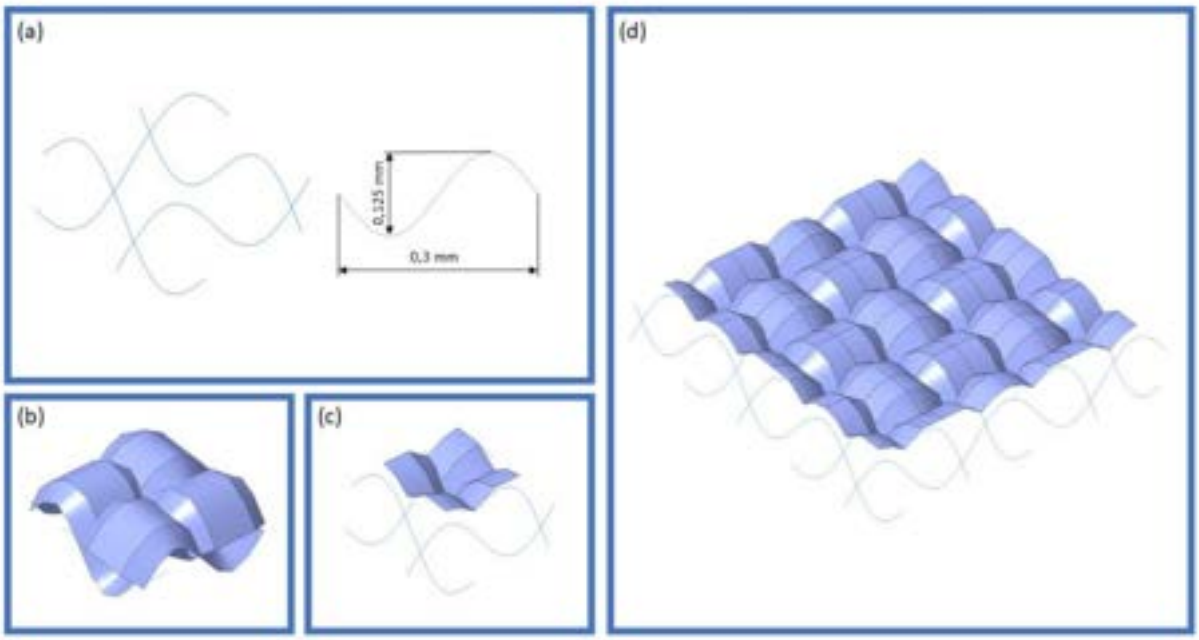

Figure. 4. Steps followed in generating the realistic GDL: (a) definition of 4 sinusoidal waves and their dimensions; (b) sweep of a trapezoidal profile on the defined trajectories; (c) surface trimming and identification of elemental regions; (d) serial repetition of elemental regions.

3.2. Governing equations

The VOF is one of the most used methods to simulate multiphase flow and it is the one adopted in this paper. The main characteristic of this method is that it assigns a numerical value to each cell. This index α_q represent the fraction of secondary phase presents in the cell; in particular:

- $\alpha_q = 0$, the cell contains pure primary phase,

- $\alpha_q = 1$, the cell contains pure secondary phase,
- $0 < \alpha_q < 1$, the cell contains a mixture of the two phases,

given that:

$$\sum_{q=1}^{n} \alpha_q = 1 \quad (1)$$

For every cell, with n equals to the number of phases in the flow. Considering two phases (air and liquid water), viscosity μ and density ρ are evaluated through a weighted mean as shown in Formula (2) and (3).

$$\rho = (1 - \alpha) \cdot \rho_1 + \alpha \cdot \rho_2 \quad (2)$$

$$\mu = (1 - \alpha) \cdot \mu_1 + \alpha \cdot \mu_2 \quad (3)$$

Mass conservation is expressed as:

$$\frac{\partial \rho}{\partial t} + \nabla(\rho \cdot \overline{v}) = 0 \quad (4)$$

A single momentum equation is solved through the domain:

$$\frac{\partial}{\partial t}(\rho \cdot \overline{v}) + \nabla(\rho \cdot \overline{v} \cdot \overline{v}) = -\nabla p + \nabla\left[\mu\left(\nabla\overline{v} + \nabla\overline{v}^T\right)\right] + \rho \cdot \overline{g} + \overline{F} \quad (5)$$

The Continuum Surface Force (CSF) model for a two-phase flow can be simplified as:

$$\overline{F} = \sigma \cdot \frac{\rho \cdot k \cdot \nabla\alpha}{\frac{1}{2} \cdot (\rho_1 + \rho_2)} \quad (6)$$

where σ and k are surface tension coefficient and surface curvature of the interface respectively.

3.3. Domain definition and simulation setup

The elemental square previously defined was used to model one of the surfaces of a 1x1x4.8 mm box and to obtain the simulation domain. The modified surface would represent the hydrophobic and impermeable GDL, whilst the others would represent the velocity inlet, pressure outlet and channel walls. The base dimension of the cell was set to 0.02 mm. A three layers inflation was added on the GDL.

Simulations were performed with Ansys Fluent 2022 R1. The whole domain was initialized as still air, then a water droplet was deposited on the GDL surface at 1 mm distance from the velocity inlet. Droplets ranged from 200 to 600 μm. From 0 to 1 ms of simulation, the inlet would be set to 0 m/s to allow the droplet to properly set on the surface. Thereafter a constant airflow of 10 m/s started to push the droplet. The flow was assumed to be laminar. Surface tension coefficient between water and air was set to 0.072 N/m and wall adhesion model was enabled.

The pressure-based solver was used for transient 3D simulation. Pressure-Implicit with Splitting of Operators (PISO) algorithm was selected for pressure-velocity coupling. PREssure STaggering Option (PRESTO!), Second Order Upwind and Geo-Reconstruct schemes were used respectively for pressure, momentum and volume fraction. Adaptive multiphase specific time step was adopted to improve solution stability. Simulated time was set to 25 ms.

4. Results and discussions

The typical liquid drainage process inside a GDL flow channel includes droplets emerging, growing, detachment, and removal. After the detachment, the airflow drives the liquid droplet out of the channel and another droplet emerges from the GDL pore simultaneously [13]. Water removal is mainly realized according three modes of movement: rolling, lifting, and break-up [22]. Studies demonstrated that the occurrence of each mode was influenced by the airflow rate, while no definitive results on the effects of surface roughness were discussed [23]. The first case in which it is possible to immediately identify the importance of a realistic interlaced GDL surface is the one that features 300 μm droplet diameter. Figure 5 clearly shows how the droplets on the realistic and hybrid surface were able to reach the exit of the closed channel, but with a significant time difference with respect to the flat design.

Dimensions of pores between warp and weft yarns of GDL texture comparable with the droplet diameter led to a longer detachment phase and slower movement towards the outlet. Figure 6 shows that at increasing droplet size the GDL microstructure decreased its influence on the water removal process; 600 μm droplets moved out the channel domain almost simultaneously for the realistic and hybrid case. For a more detailed characterization of droplet dynamics, high-speed visualization was applied for diameters of 600±20 μm as

estimated in static conditions. Fig.7a reports several selected frames of a 50ms sequence recorded for a 605 μm droplet. In agreement with the literature [24], after liquid deposition (#1) switching-on the fan determined around 1 second of droplet contour oscillations (as shown in frames #2-#3) due the balance between detaching and retention forces [25-26]. This occurred until a critical local velocity was reached; then the droplet started to move in the direction of the air-flow (#4) and reached the limit of the optical region in about 6 ms. It should be noted that the droplet motion was characterised by rolling rather than sliding. Thus the assumption to fix the GDL wettability without differentiating between advancing and receding angles resulted reasonable.

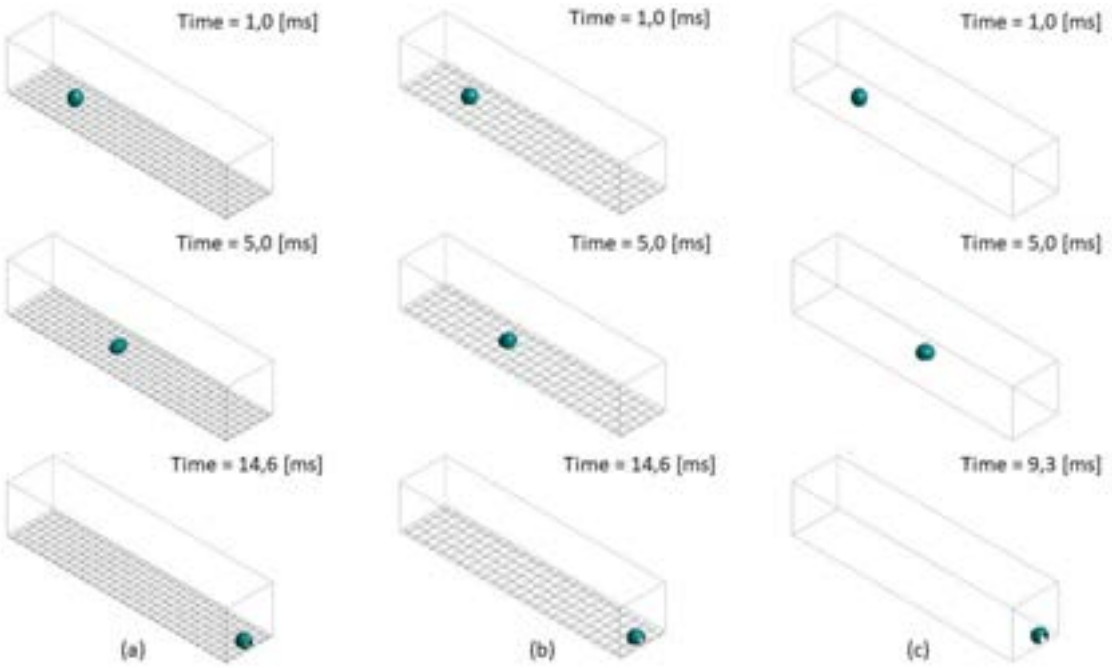

Figure. 5. Water fraction isosurface (equal to 0.8) for different GDLs for a 300 μm droplet. (a) Realistic GDL, (b) Hybrid GDL, (c) Flat channel surface.

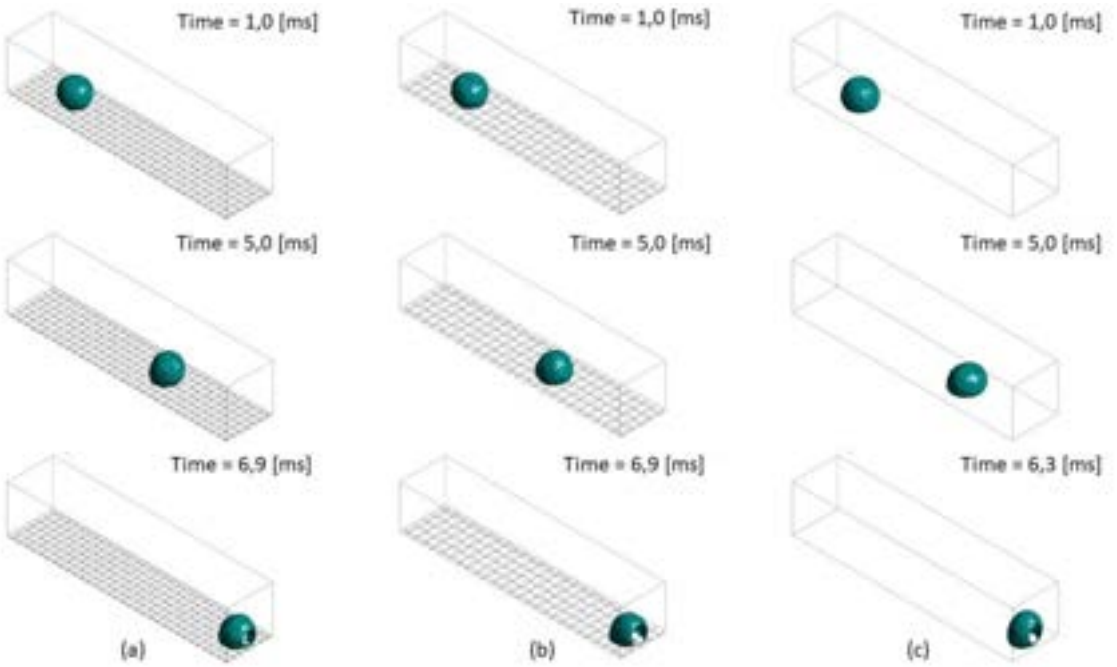

Figure. 6. Water fraction isosurface (equal to 0.8) for different GDLs for a 600 μm droplet. (a) Realistic GDL, (b) Hybrid GDL, (c) Flat channel surface.

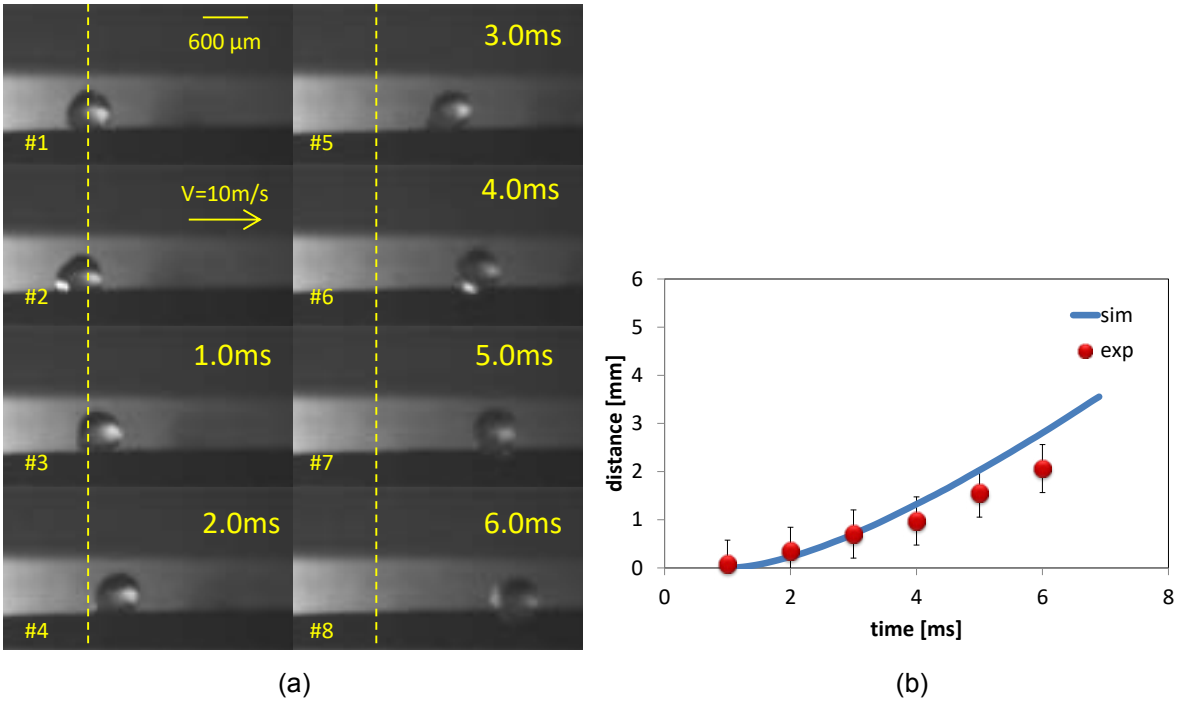
The optical data were used for validating the simulation results; Fig.7b shows the comparison between the temporal evolution of the distance from the deposition point along the air-flow direction of a 600 μm droplet. The experimental results show the average value of the luminous center of mass calculated based on 15 sequences. The error bars correspond to the standard deviation. The agreement between simulation and experiments is very good; the discrepancy observed after 5 ms was due to the open channel condition of the optical tests that determined lower pressure forces on the droplet and thus lower acceleration. Nonetheless, it can be stated that model validation is satisfactory.



(a) (b)

Figure. 7. Visualization of the droplet motion on the GDL (a) and comparison with simulation results (b).

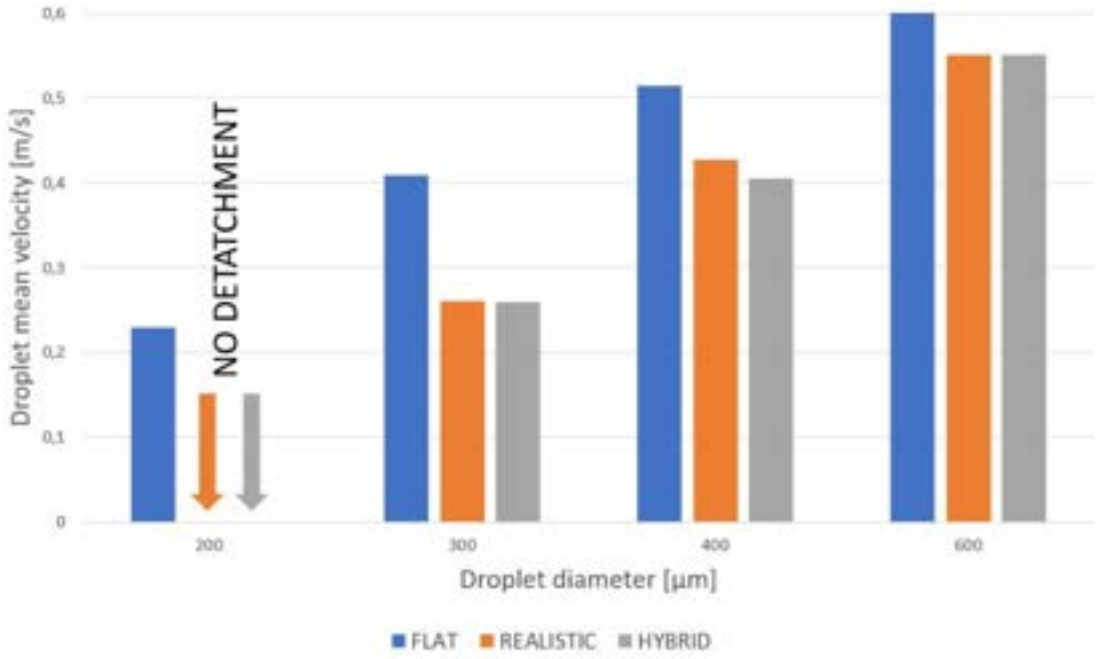


Figure. 8. Comparison of droplet mean velocity for all dimensions and cases analysed.

Fig.8 shows the mean droplet velocity for all the analyzed cases. Once again, the graph remarks that the importance of GDL microstructure is noticeably higher for smaller dimension, when droplet and pores have comparable sizes. However, even in the 600 µm case the droplet mean velocity is around 8% lower for the realistic and hybrid case, so still a significant amount.

Initial water removal time was defined as the instant in which the droplet as a whole surpassed a plane perpendicular to the airflow and passing through the middle of the drop when it is deposited. Figure 9 shows simulations results. For sure the flat surface is the one that led to faster removal since there are no obstacles in the way of the droplet. On the other hand, the pores of the realistic and hybrid surfaces offer a certain resistance to the initial rolling of the droplet. Moreover, even though the hybrid case has a lower sinusoidal amplitude and a higher wavelength and thus should be more similar to the flat one, it seems to offer more initial resistance. This outcome is linked to the fact that it also has a bigger wet area with respect to the realistic surface, increasing the adhesive force. These results agree with literature [14-15] that found that the GDL microstructure can slow down the droplet motion compared to the smooth surface simplification.

It worth noting that for both Fig. 8 and Fig. 9 the leftmost column reports a “no detachment” condition for the 200 µm case, since the droplet get stuck in membrane pores. This is a critical condition for the FC operation, since those droplets decrease overall efficiency by:

- blocking reactants flux towards the CL causing flooding and thus cell starvation.
- shielding the incoming airflow, thus reducing water removal rate for downstream drops; as distance increases, airflow reattach to GDL and this effect is reduced.

Water keeps on forming in the CL and the droplet will reach critical dimension and finally be removed. In this sense, the design of GDL superficial microgeometry determines critical detachment diameter.

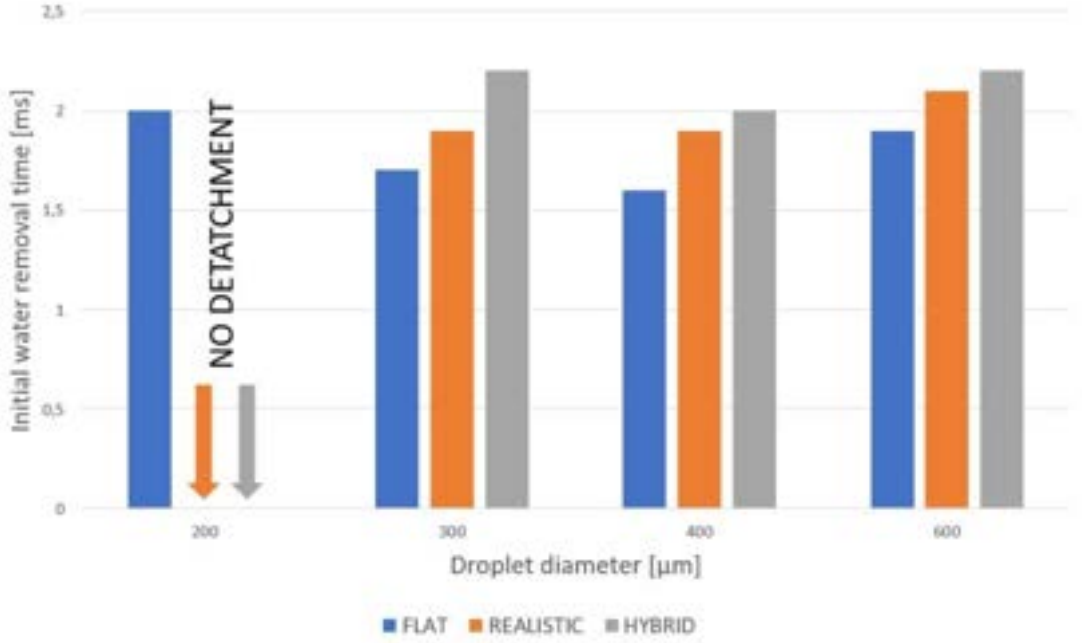

Figure. 9. Confront on droplet initial water removal time for all dimensions and cases analysed

The following step was to investigate how a second droplet could influence the behaviour of the first one. With this purpose, another set of simulation was prepared: a 300 µm droplet was deposited in the same position of the single case (1 mm from the inlet, middle of the channel), and a second one was initialized further in the channel, at a distance that depended on GDL microgeometry. For the real and the hybrid case, the second droplet was deposited in the fourth pore after the first droplet. Figure 10 graphically shows the used principle. For the flat case the used distance was the mean of the distances for the two other cases.

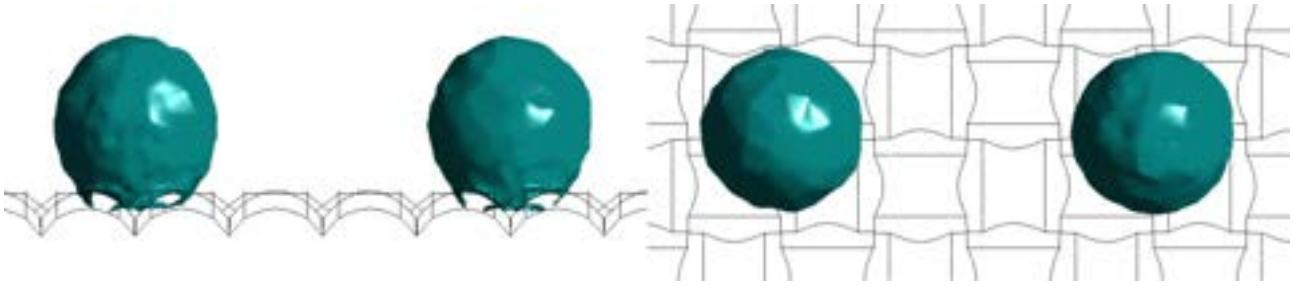

Figure. 10. Reciprocal positioning of the two droplets on the GDL

Simulated droplets at different time steps are shown in Figure 11. Once again, the effect of microgeometry design is highlighted by the difference in flat-realistic cases and realistic-hybrid one. As already seen for the single droplet case, the flat surface offers minimal resistance to the rolling of the pair, however the first droplet partially shield the second one from the incoming airflow, thus it moves at an higher speed. Moreover, the lower the distance between the two droplets, the higher seems to become the speed difference. A parametrization of droplet pair diameters and distances could be of interest for future study. As concern the realistic case, a similar behaviour was observed, but the mean velocities are lower and the initial detachment phase is longer. The comparison of realistic and hybrid case remarked the importance of GDL microstructure: in the hybrid case the second droplet was stuck in position due to the shielding of the first one and the higher wet area with respect to the realistic one. The hybrid GDL showed the highest exit time for this set of simulations.

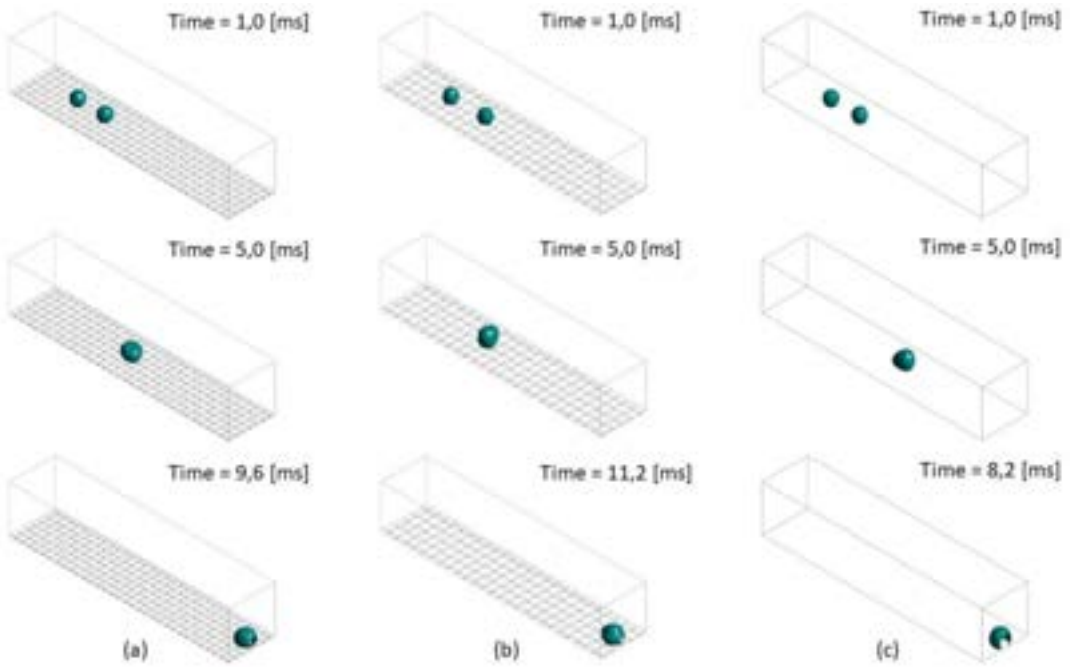

Figure. 11. Water fraction isosurface (equal to 0.8) for different GDLs for the 300-300 μm droplets pair. (a) Realistic GDL, (b) Hybrid GDL, (c) flat GDL

5. Conclusions

PEM FCs represent a decisive step in the direction of a cleaner mobility, but it is a device still far from optimal operation conditions. Experimental and simulation studies are fundamental to fully develop the technology, and in realizing models able to reproduce the actual behaviour of a cell it is important not to over-model a phenomenon. The surface microgeometry of a fuel cell is often deemed as negligible in channel flow simulations. The aim of this study has been to evaluate the importance of this microgeometry and to state if it should be taken into consideration when accounting for water removal rate of a cell.

The main results of this study can be summarized as follow:

- The importance of pores on the surfaces rises as smaller droplets are considered. Starting from the same initial and boundary conditions, the 200 μm droplet on the flat surface was able to reach the outlet, whilst for the others GDLs the drop was stuck in the pore. The influence of the surface is lower for bigger droplet, however even for the 600 μm droplet the mean velocity difference is around 8%.
- The microstructure also affects the initial water removal time of the droplet. The flat surface is the one that shows lower removal time, whilst the other two structures seem to slow down this phenomenon due to the presence of pores that work as obstacles for the droplet. In particular, the hybrid case is the slowest one, due to the fact that it has a bigger wet area with respect to the realistic surface, increasing the adhesive force.
- Simulations showed the influence of a second droplet deposition on different GDLs. Flat surface offers the highest water removal rate, while realistic and hybrid cases shows a behaviour linked to microgeometry design. In particular, due to the partial shielding effect and the higher wet area of the hybrid surface, the second droplet resulted stuck in the pore until it merged with the first one.

Next steps of the reported activity are planned for further improving the water dynamic modelling and evaluate the weight of commonly used approximations on predictive simulations. Specifically, the GDL intrusion in the gas channel and surface deformation near the channel ribs due to the clamping pressure of the cell will be estimated for a more realistic design. Moreover, the reactant gas humidity in closed channel configurations will be considered in the model. These parametric studies are on-going to further shed light on the possibility of a design for promoting controlled water removal mechanisms.

Acronyms

CA	Contact angle
CL	Catalyst Layer
CSF	Continuum Surface Force
FC	Fuel Cell

GDL	Gas Diffusion Layer
MEA	Membrane Electrode Assembly
PEM	Proton Exchange Membrane
VOF	Volume Of Fluid

Abstract:
Sustainable synthetic carbon-based fuels can play a crucial role in the sectors of transportation, heating, and power, which can be challenging to electrify. Many of these synthetic fuels are based on green hydrogen produced by electrolysis. Due to difficulties in the handling and storage of hydrogen, an interesting solution is to convert it into hydrocarbons such as methane, with the advantage of using a well-established infrastructure and having the drop-in capability to substitute fossil natural gas.
In the presented study, the partial load and the transient behavior of a sorption-enhanced catalytic reactor for methane synthesis is analyzed. This kind of reactor can achieve high conversion through adsorption of product water. Its performance is defined and compared to that of a simulated conventional fixed-bed catalytic reactor without sorption-enhancement. In particular, the focus is on investigating the response to partial loads and load transients. These operating conditions are typically met when the hydrogen production system is directly coupled with fluctuating renewable electricity production, and storage is minimized. The results show an excellent partial load behavior, and, unlike traditional reactors, sorption-enhanced catalysis did not show ignition problems.
This article points out the strength of sorption-enhanced catalysis applied to the process of carbon dioxide methanation in transient and partial load operations both from the point of view of synthesized fuel quality and operation stability.

Keywords:
CO_2 methanation; Sorption-enhanced reactor; Synthetic fuels; Transient operation.

1. Introduction

Nowadays, carbon-neutral fuels are considered as an interesting solution for the energy transition in hard-to-abate sectors. An example is the synthesis of methane from hydrogen and carbon dioxide as a substitute for natural gas.
Methane production is carried out through the Sabatier process, which is characterized by the following reaction [1]:

$$\mathrm{CO_2} + 4\mathrm{H_2} \leftrightharpoons \mathrm{CH_4} + 2\mathrm{H_2O}, \qquad \Delta H_r^0 = -165\ \mathrm{kJ\ mol^{-1}} \tag{R1}$$

This strongly exothermic reaction can take place using heterogeneous catalysis in fixed-bed reactors. The relevance of this system can be deduced since it has been investigated in many experimental studies [2].
If the hydrogen feeding the process is produced via electrolysis from a fluctuating renewable energy supply, its availability would be discontinuous, and this leads to the need for the storage of either electrical energy or hydrogen. In both cases, high storage costs [1] lead to the need to reduce the battery capacity or the volume and the number of hydrogen tanks as much as possible. For this purpose, the synthesis reactor must be able to withstand continuously changing operating conditions. Therefore, an analysis of the behavior of methane production systems with regard to transient and partial load conditions has been developed by the authors and is presented in this paper.
Investigations of the performance of catalytic reactors for methane synthesis at dynamic load conditions reported in the literature are mainly focused on the thermal stability of the system [3,4]. This is due to the fact that too high temperatures could lead to deactivation and degradation of the catalyst while too low

temperatures could lead to failures in igniting the reaction [5]. Moreover, a decrease in reaction yield at transient and high load conditions is usually highlighted [6].
Many efforts have been made in the scientific community to deal with these problems, and various methods have been used to this end. Fischer et al. [7] and Bremer et al. [8] chose to use an adaptive temperature of the coolant, the former at the design stage and the latter by adopting a steady state “multiplicity” control strategy.
Another option available for managing the temperature distribution is the use of a reactor with recirculation, as investigated in Refs. [9–11]. The recirculation ratio was identified as an additional degree of freedom for thermal control.
With specific reference to the reactor, different approaches, mainly concerning temperature control, were evaluated. Stiegler et al. [6] experimentally analyzed the behavior of a rack-type reactor with a high thermal conductivity metal structure. Sun and Simakov [12] simulated a reactor internally cooled by molten salts and Kreitz et al. [13] numerically studied a microstructured fixed-bed reactor with a periodically oscillating feed composition. Another proposed approach is to dilute the catalyst with an inert material, which was done by means of simulation by Fache et al. [14] and both experimentally and numerically by Herrmann et al. [15].
In order to address these challenges while preserving high product quality, there are grounds for deepening the sorption-enhanced catalysis [16].
Therefore, in this study, the behavior of a methanation reactor of the sorption-enhanced type at an unsteady operating condition is investigated and presented. In order to do so, the reactor was tested experimentally at partial load conditions (i.e. partial inlet flow rates) and during transients (i.e. with single-step or multiple-step changes in inlet flow rates). In addition, a model of a catalytic methanation reactor without sorption-enhancement was set up and its results were compared with the measured data.

1.1. Sorption-enhanced CO_2 methanation

In the literature, sorption-enhanced methane synthesis reactors have been reported to achieve very high conversion yields through the removal of water (which is one of the two reaction products) due to in-situ adsorption [16]. Generally, the catalyst bed is composed of a bi-functional material with catalytic and adsorption properties. An important difference with respect to systems without sorption-enhancement is the way in which the reaction takes place. As shown by Borgschulte et al. in [17], sorption-enhanced methanation reactors differ from conventional plug flow reactors in that there is a moving coupled reaction and adsorption front. The propagation velocity of the reaction front (which separates the water saturated section of the reactor from the unsaturated one) depends on the adsorption capacity of the bed and the amount of water that is produced and adsorbed. The greater the amount of water that will interact with a section of the bed, the sooner it will be saturated and the faster the reaction front will move on [18]. From an engineering point of view, this means that a reactor saturated with water must be regenerated. Consequently, at least two reactors operating alternately are needed for continuous methane production.
As regards chemical kinetics, it should be noted that the removal of water leads to a significant increase in the partial pressure of the reactants and especially a decrease in water partial pressure, which leads to improved reaction rates.
In the zone of the reaction front, additional heat is released due to the adsorption process [19] which further promotes the conversion. The water adsorption capacity is inversely proportional to the temperature and directly proportional to the pressure. This behavior leads to a self-stabilizing effect since the greater the amount of adsorbed water, the greater the heat released, but if the temperature rises the bed will be saturated faster and the front will proceed [18].

2. Materials and methods

2.1. Experimental setup

The experimental apparatus involved a fixed-bed oil-cooled catalytic reactor consisting of four reactors arranged in parallel (Fig. 1). The bed consisted of pellets of adsorbent material impregnated with catalyst. In more detail, it was constituted by zeolite 13X pellets with a diameter of 1.6 mm to 2.6 mm impregnated with 5 % nickel on a mass basis [18]. In the inlet sectors of the reactors, these pellets were mixed with aluminum beads to improve heat transfer in that zone and partially absorb the released heat. This approach was used to deal with the problem of the continuous heat release in the inlet sector as reported by Kiefer et al. [18].
Each of the four reactors contained a pellet bed with a height of 1 m and a diameter of 32 mm. The reactors were cooled by thermal oil flowing into an external jacket in each reactor tube. The temperature was adjusted and kept constant with a PID controller (Julabo HT60 thermostat).

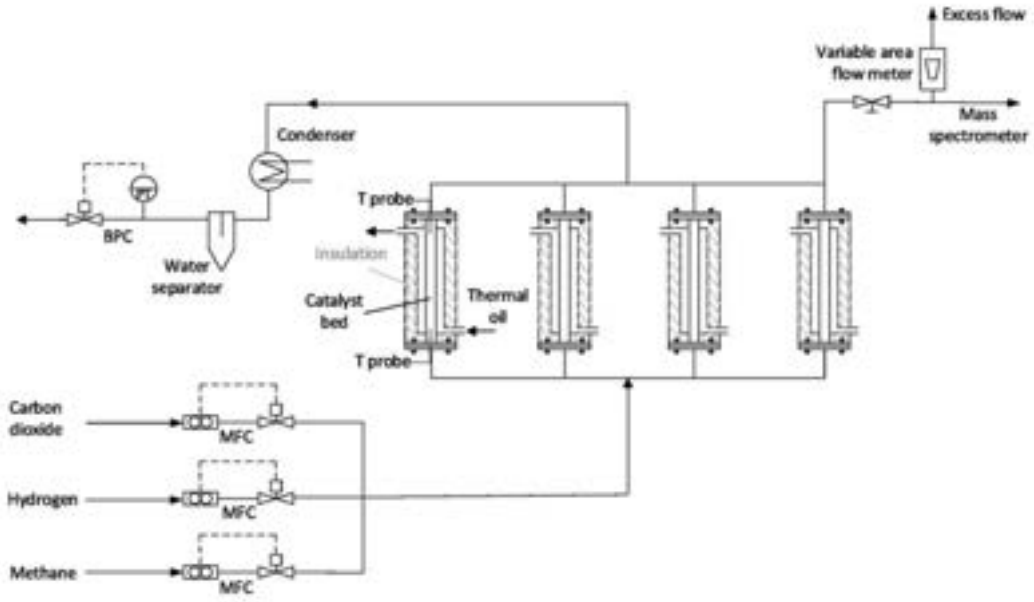

Figure 1. Schematic representation of the sorption-enhanced methanation test rig.

At the inlet and outlet sectors of each reactor duct the temperatures were measured by thermocouples (Type K class A, 1.5 mm jacket diameter) with a sampling period of 2 s. The inlet gas flow was controlled by means of mass flow controllers (MFC, Bronkhorst EL-FLOW Prestige) while the pressure was regulated through a back pressure controller (BPC, Bronkhorst EL-PRESS) located downstream of the reactor.
A sample of the produced syngas mixture was taken at the outlet of one of the four reactors and then directed to a mass spectrometer (Hiden Analytical RGA) to measure the mole fractions of the different gaseous species.

2.2. Testing procedure

Before each experiment, the reactors were heated to the operating temperature of 300 °C via the thermal oil and were purged with a stream of inert gas (i.e. nitrogen). After reaching the desired temperature, the reactors were purged with methane and the absolute pressure was increased to an operating point of 10 bar. Once stable conditions were reached, the reaction was started by flushing a defined mixture of the reactants. A carbon dioxide mole flux of 0.4 mol m^{-2} s^{-1} was set as the reference condition. The reactant ratio, for the full and the partial load tests, was then tuned to be close to stoichiometric conditions with a minimal excess of H_2 to overcome the inaccuracy of the control instrumentation. A small percentage of hydrogen was considered acceptable assuming that the produced syngas would be fed into the natural gas pipeline infrastructures.
The reaction phase of an experiment was terminated when the temperature values measured at the reactor outlet showed that the front had reached the end of the reactor. Afterwards, the reactor drying phase was initiated and the bed was purged with hydrogen to reach the initial state as regards the water content.
The partial load behavior of the system was investigated at loads of 25 %, 50 % and 75 % of the reference inlet mole flow of carbon dioxide.
The reaction time is inversely proportional to the load since the less the water is produced, the longer it takes to saturate the bed. In each case, the reaction time was not fixed a priori but it was determined through temperature and product gas measurements. On this basis, the step variations defined to characterize the considered transients were included in these time frames.

2.3. Mathematical model

A dynamic model based on Ref. [20] and implemented in Matlab®/Simulink® for catalytic methane synthesis reactors was used as a reference for reactors without sorption-enhancement.
The model was based on the equations of chemical kinetics of the process and on mass and energy balances. A one-dimensional approach has been used, discretizing the reactor bed with cylindrical sections in series assuming homogeneous properties of the gas mixture in each of them. While the gas flow is assumed as one-dimensional, the heat exchange with the coolant is estimated with reference to the cylindrical wall surface of each section. Changes in pressure, temperature and mole composition are calculated for each section using the aforementioned equations, written in differential form and solved using the stiff solver ode15s.
The kinetic model considered the Sabatier reaction (R1), methanation of carbon monoxide (R2), and reverse water gas shift (R3) [1]:

$$\mathrm{CO} + 3\mathrm{H_2} \leftrightharpoons \mathrm{CH_4} + \mathrm{H_2O}, \qquad \Delta H_r^0 = -206\ \mathrm{kJ\ mol^{-1}} \tag{R2}$$

$$\mathrm{CO_2} + \mathrm{H_2} \leftrightharpoons \mathrm{CO} + \mathrm{H_2O}, \qquad \Delta H_r^0 = +41\ \mathrm{kJ\ mol^{-1}} \tag{R3}$$

Reaction rates were modelled as proposed by Xu and Froment [21], using the following equations:

$$r_{R1} = \frac{k_{R1}}{p_{H_2}^{3.5}}\left(p_{CH_4}p_{H_2O}^2 - \frac{p_{H_2}^4 p_{CO_2}}{K_{R1}}\right)/(DEN)^2 \quad (1)$$

$$r_{R2} = \frac{k_{R2}}{p_{H_2}^{2.5}}\left(p_{CH_4}p_{H_2O} - \frac{p_{H_2}^3 p_{CO}}{K_{R2}}\right)/(DEN)^2 \quad (2)$$

$$r_{R3} = \frac{k_{R3}}{p_{H_2}}\left(p_{CO}p_{H_2O} - \frac{p_{H_2}p_{CO_2}}{K_{R3}}\right)/(DEN)^2 \quad (3)$$

$$DEN = 1 + A_{CO}p_{CO} + A_{H_2}p_{H_2} + A_{CH_4}p_{CH_4} + A_{H_2O}p_{H_2O}/p_{H_2}, \quad (4)$$

where k, K, and A are terms of the Arrhenius-type temperature functions.
The pressure drop in the reactor was calculated using the Ergun correlation [22].
Regarding heat exchange, the model of heat and mass transfer in packed beds with fluid flow, as described by Tsotsas in [23], was taken as the reference.
The radial heat flux has been estimated using the global heat transfer coefficient, evaluating the transfer coefficient at the reactor inner wall (α_w) as follows:

$$Nu_w = \alpha_w \frac{d}{\lambda_f} \quad (5)$$

$$Nu_w = \left(1.3 + \frac{5}{D/d}\right)\frac{\lambda_{bed}}{\lambda_f} + 0.19\, Re^{0.75} Pr^{1/3} \quad (6)$$

The characteristic length of the Reynolds number is, in this case, equal to the pellet diameter.
Fluid properties were calculated according to Ref. [24]. In particular, for the calculation of the thermal conductivity, the correlation of Mason and Saxena was used, while for the viscosity, the correlation of Wilke was applied.

3. Results and discussion

As a reference for partial load and transient experiments, a single experiment is analyzed to illustrate the operation of a sorption-enhanced catalytic reactor. To this extent, Fig. 2 shows plots of changes in the outlet mole fractions of the most relevant gases in the mixture and the temperatures measured respectively in the inlet and outlet sectors of the reactor. This experiment has been carried out with a CO_2 set flux of 0.3 mol m^{-2} s^{-1} and a CO_2/H_2 ratio as determined in the sorption-enhanced reaction experiments (see Table 1). The data reported ranges from the test initial condition (i.e. when no water is adsorbed in the bed) to the final condition (i.e. when the bed is completely saturated with water and the conversion process stops).
In Fig. 2 (a) the composition of the gas mixture at the reactor outlet is reported. The methane content at the beginning refers to the gas initially contained in the reactor after increasing the pressure of the system (see Section 2.2). The decline in CH_4 content corresponds to the point when the produced methane reached the reactor outlet.
It should be noted that when the first synthesized methane reached the reactor outlet, its mole fraction undergoes a slight downward peak. This is due to an overshooting of the hydrogen flow rate at the time when the reactant input was set through the flow controllers.
The decrease in methane mole fraction at the end of the test corresponds to the moment when the sorption front reached the outlet, which means that a mixture of reactants and products arrived at the outlet due to the lack of water removal capability (i.e. there is not sufficient sorption-enhancement taking place anymore). In the last part of the measuring period, the behavior of the reactor clearly shows that the synthesis phase has ended (usually in real operations the reaction is stopped, and the bed drying phase starts before reaching that point).
During the sorption-enhanced phase, the content of carbon dioxide was always below 1 %. Moreover, ethane and propane were measured below 0.5 % and water below 0.2 % as adjusted during the regeneration phase.
The temperatures shown in Fig. 2 (b) follow a trend determined by the displacement of the reaction front and the heat removal from the catalyst bed. Considering the temperature changes measured in the inlet sector of the reactor, it can be concluded that the peak is due to the front traveling through the temperature sensor at that point. Afterwards, in the inlet sector of the bed, the reaction takes place without sorption-enhancement because it is completely saturated with water. The heat released due to the exothermic reaction causes the temperature to stabilize at a value higher than that of the coolant.
The maximum temperature in the inlet sector is lower than that measured close to the outlet due to the mixing of the catalyst bed with aluminum beads.

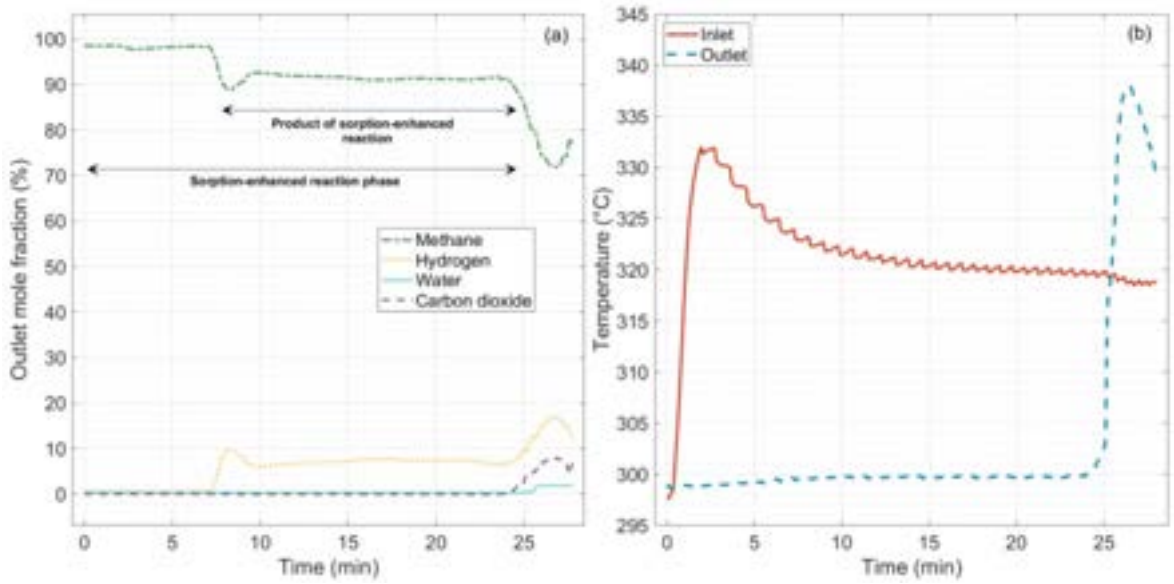

Figure 2. Outlet mole fractions measured by the mass spectrometer (a) and temperatures measured in the inlet and outlet sectors of the reactor (b) using a constant CO_2 set flux of 0.3 mol m^{-2} s^{-1}, and reaction absolute pressure of 10 bar.

Furthermore, a comparison of the behavior of the methanation reactors with and without sorption-enhancement that demonstrates the underlying differences of the two systems is shown.
For this purpose, Fig. 3. shows the simulated steady state temperature profile along the reactor axis of a conventional fixed-bed catalytic reactor considering the bed geometry and the operating conditions as introduced above for the sorption-enhanced case. More specifically, a CO_2 flux of 0.3 mol m^{-2} s^{-1}, a CO_2/H_2 ratio as determined in the sorption-enhanced reaction experiments (see Table 1), an initial reactor temperature and temperature control setpoint of 300 °C, and a reaction absolute pressure of 10 bar. Since a discretized lumped parameter approach was used, the profile is depicted by steps.
In the conventional reactor, the temperature profile reaches a steady state as shown in Fig. 3 (it should be considered that the section where maximum temperature is reached depends on the value of the inlet reactant flow rate). In contrast to this behavior, considering Fig. 2 (b), it can be noted that the temperature peak for sorption-enhanced systems is not static, but moves through the reactor together with the reaction front.
In the following, the partial load (Section 3.1) and transient operation of the system (Section 3.2) are presented, while in Section 3.3 the thermal behavior will be discussed.

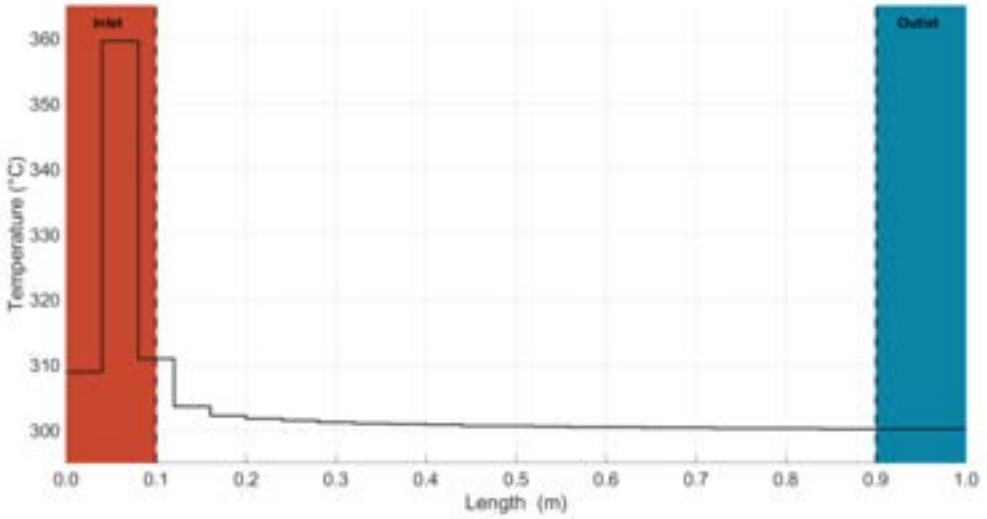

Figure 3. Temperature profile along the length of a simulated non-sorption-enhanced reactor with a constant CO_2 flux of 0.3 mol m^{-2} s^{-1}, an initial reactor temperature of 300 °C, and a reaction absolute pressure of 10 bar.

3.1. Partial load behavior

The reactor system was analyzed at partial load conditions by repeating the above-introduced experiment (i.e. 75 % of the reference load) at inlet flow rates of 25 %, 50 %, and 100 % of the reference load.
Table 1 presents the carbon dioxide conversion determined from the measured outlet gas composition. For the sake of comparison, the results are presented for a simulated conventional reactor, an equilibrium conversion calculation at a temperature of 300 °C and the measurements on the sorption-enhanced reactor.
The carbon dioxide conversion was calculated by means of the following equation:

$$Conv_{\mathrm{CO_2}} = 1 - x_{outlet\ \mathrm{CO_2}} / x_{inlet\ \mathrm{CO_2}} \quad (7)$$

The measured mole fraction was averaged over the timespan marked in Fig. 2 (a) as "product of sorption-enhanced reaction".
For the simulations and the calculation of equilibrium conversion, the actual flux determined from the experiments was used.
The simulation results for the conventional reactor show a decreasing conversion with increasing load, i.e. increasing inlet mole flux. This is due to a decreased residence time.
Compared to the equilibrium calculations, the gap between the equilibrium conversion and the simulated conversion in the reactor increases with the load. The changes in equilibrium conversion given in the table are due to the changes in the inlet stoichiometry determined for the different load conditions. In contrast to the conventional reactor, the CO_2 conversion determined for the sorption-enhanced reactor experiments does not show a dependency on the load. The conversion is significantly higher than the equilibrium conversion for all cases. This goes hand in hand with the above-introduced shift in the chemical equilibrium through water removal.
In addition to the CO_2 conversion given in Table 1, Table 2 shows the outlet CH_4 content for the simulation of the conventional reactor, the equilibrium value, and the average values measured for the sorption-enhanced reaction. This is the measurement relevant for the application of the product, e.g. feeding into a gas grid. The CH_4 mole fraction of the simulation and that of the calculation for the equilibrium were considered on a dry basis.
In addition, for further considerations on sorption-enhanced reactor measurements, the standard deviation of the averaged data is also presented.
The results for the simulated conventional reactor are in line with the trend observed for the CO_2 conversion. The theoretical maximum CH_4 content given by the equilibrium shows the strong influence of the non-stoichiometric reactant ratio, especially at low partial load. The CH_4 content in the product measured for the sorption-enhanced reactor shows a dependency on the stoichiometry. The quality of the product is limited by the accuracy of the initial mixing and not by the conversion. Furthermore, the low values of the standard deviation of the measured data imply that production is highly stable.
Another major characteristic of the sorption-enhanced reactor system is the duration of the production phase. With the aim of exploring this aspect, Fig. 4 shows the duration at the partial load conditions measured from the start of the feed supply until detecting an increase in CO_2 mole fraction at the reactor outlet above 1 %.

Table 1. Partial load CO_2 conversion with the corresponding inlet mole fluxes.

Inlet mole flux (mol m^{-2} s^{-1})	Reactant ratio (-)	$Conv_{\mathrm{CO_2}}$ (-)		
CO_2	H_2/CO_2	Conventional reactor simulation	Equilibrium* at 300 °C and 10 bar	Sorption-enhanced reactor measurements
0.1	4.18	0.9622	0.9985	0.9998
0.2	4.14	0.9187	0.9960	0.9998
0.3	4.09	0.8864	0.9902	0.9997
0.4	4.09	0.8657	0.9892	0.9999

** Calculations performed using Cantera [25].*

Table 2. Partial load CH_4 outlet content with the corresponding inlet mole fluxes.

Inlet mole flux (mol m^{-2} s^{-1})	Reactant ratio (-)	Outlet CH_4 mole fraction (%)		
CO_2	H_2/CO_2	Conventional reactor simulation	Equilibrium* at 300 °C and 10 bar	Sorption-enhanced reactor measurements
0.1	4.18	82.965	84.116	84.548 (std: 0.625)
0.2	4.14	73.682	87.053	88.063 (std: 0.454)
0.3	4.09	67.476	89.097	91.565 (std: 0.435)
0.4	4.09	63.852	89.269	92.364 (std: 0.460)

** Calculations performed using Cantera [25].*

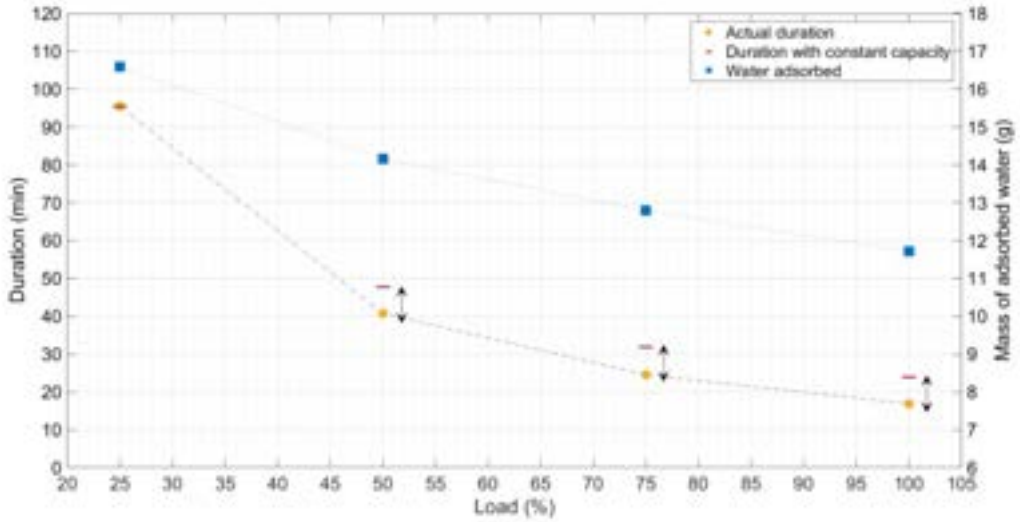

Figure 4. Actual durations of the production phase and calculated durations in the case of constant adsorption capacity at different partial loads with the mass of adsorbed water under the same conditions.

In addition, to the measured durations, those that would have been encountered if the adsorption capacity were constant and equal to that found at the lowest load are included in the figure. Furthermore, on the secondary vertical axis, the amount of water adsorbed at the corresponding conditions is presented. The water adsorbed (and consequently the adsorption capacity of the reactor) was estimated by multiplying the duration by the water production calculated from the conversion of the inlet CO_2 flow rate.
In an ideal system, the water adsorption capacity would be constant for the different load conditions. In Fig. 4, however, a decline in this capacity with increasing load can be seen. The measured durations of sorption-enhanced reactions are slightly shorter as the adsorption capacity decreases.
This behavior goes hand in hand with observations reported in Ref. [18], where it was contributed to increased bed temperatures and less distinct reaction fronts caused by kinetic limitations. This is an important aspect to consider when designing similar systems.

3.2. Transient response

The sorption-enhanced reactor system was assessed to load changes by investigating the system response to single and multiple subsequent steps in the feed flow rate. For the single step, the system was operated at 100 % of the load for 6 min, then the load was reduced to 25 % for 6 min and increased again to 100 % afterwards. Figure 5 (a) shows the outlet mole fraction of the species measured in the gas mixture at the outlet with reference to the single step case. As a multiple step case, the procedure was repeated with three steps lasting 3 min each as shown in Fig. 5 (b). Figures 5 (c) and 5 (d) show the respective feed flow rates as set by means of the mass flow controllers.
Figure 5 (a) presents the same characteristic features of methane synthesis that were evaluated in Fig. 2 with respect to the steady state case. In addition, it can be seen that the downward spike in methane fraction relates to the time when the step was imposed by decreasing the inlet flux. The same general behavior can be seen in Fig. 5 (b).
As the transition between one load to the other occurs, the methane content gradually changes to the levels obtained when the steady state is reached in the partial load tests. In fact, as presented in Table 2, the outlet methane mole fraction value changes for different tests at partial load.
The spikes in the hydrogen fraction are related to the change in the H_2/CO_2 ratio used in the corresponding partial load conditions. When considering the carbon dioxide outlet fraction, it can be argued that the steps have no impact on CO_2 conversion.

3.3. Effect on temperature

As a final analysis, the maximum temperature values measured during the different load and transient conditions are analyzed. These temperatures correspond to the peaks of the front measured in the reactor inlet and outlet sectors. In this regard, Table 3 shows that the variation of these peaks is limited for the different load conditions. The values measured at the inlet are lower than those at the outlet because, as mentioned earlier, in the first section of the reactor the catalyst was mixed with aluminum beads.

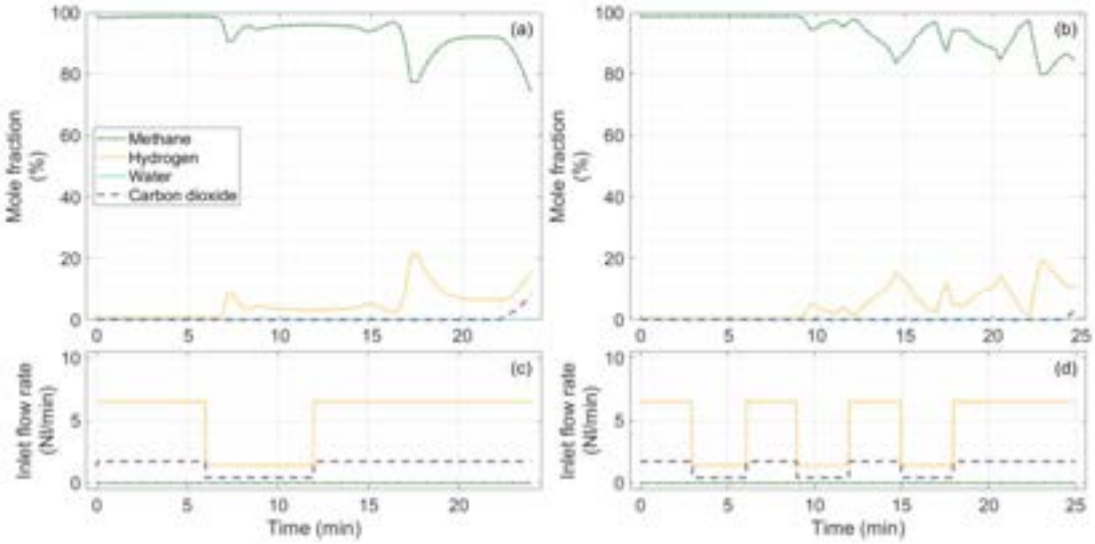

Figure 5. Outlet mole fraction as measured by the mass spectrometer in the case of single step input (a) and multiple step input (b); inlet flow rate of reactants in the case of single step input (c) and multiple step input (d).

Table 3. Maximum temperatures observed in the cases analyzed.

Partial load/step response	Maximum temperature measured at the inlet sector (°C)	Maximum temperature measured at the outlet sector (°C)
25 % load	323.5	333.8
50 % load	328.3	338.1
75 % load	332.0	338.0
100 % load	331.7	340.8
Single step	326.2	339.4
Multiple step	323.4	339.5

The location where the front is present at any given time experiences maximum conversion and concurrently maximum heat release due to both the exothermic nature of the reaction and that of the adsorption process. The local increase in temperature improves the chemical kinetics of the reaction and increases the conversion of the reactants to the products. The faster the water is produced, the more rapidly the bed will be saturated and consequently the front will move along the reactor axis. Since the temperature peak is not static, the system is able to handle the problem of hot-spot formation. This is not the case in conventional fixed-bed catalytic methanation reactors where, as explained when discussing Fig. 2, the temperature peak at a given flow remains steady.

4. Conclusion

In the perspective of sustainable fuel production from renewable sources, an investigation of methane production at transient and partial load conditions was presented. The potential of sorption-enhanced catalysis applied to the methanation of carbon dioxide has been analyzed for its potential of having high conversions at flexible operation conditions.

To this extent, the behavior of an oil-cooled fixed-bed methanation reactor with a bi-functional catalyst has been experimentally tested and compared to a dynamic model of a fixed-bed reactor without sorption-enhancement.

Partial load conditions were tested in terms of varying reactant flow rates. Furthermore, transient load changes were investigated by evaluating the response to abrupt changes from a partial load to another. These responses were evaluated considering conversion and thermal stability, which is the main issue discussed in the literature for conventional catalytic reactor systems.

The results show exceptional thermal stability of the system in response to transients, despite the exothermic nature of both the methanation reaction and the adsorption phenomenon. The system is able to autonomously manage the temperature so that deactivation of the catalyst by thermal degradation is avoided. Nonetheless, the sorption-enhanced catalyst allows for full conversion without ignition problems.

From the point of view of product quality, the sorption-enhanced reactor shows an excellent CO_2 conversion above 99.97 % independent of the load. In contrast, the simulation results for a conventional catalytic reactor of the same size show a CO_2 conversion ranging from 96.2 % to 86.7 %, which decreases as the feed flow rate increases. Sorption-enhanced reactors achieve higher CO_2 conversions than those calculated for an

equilibrium reactor, due to the continuous water removal. The conventional reactors simulated in this study approach the theoretical equilibrium conversion for low flow rates.
Another characteristic of the sorption-enhanced reaction is the existence of a coupled reaction and adsorption front moving through the reactor. The duration of a sorption-enhanced reaction phase is determined by the water adsorption capacity of the catalyst bed at the given conditions. Consequently, decreasing the load leads to slower movement of the front through the reactor. It was observed that the adsorption capacity of the reactor slightly decreases with the increasing load, which was attributed to transport limitations in the reactor bed. Nonetheless, this allowed the system to operate at low partial loads.
The investigations of step responses to analyze the transient behavior showed that there is no influence on the CO_2 conversion, which stays constantly high throughout the sorption-enhanced production phase, even for abrupt load changes. This is beneficial considering the direct coupling with the fluctuating supply of reactants. The characteristics identified help to design power-to-gas systems and to minimize electricity or gas storage as the system can be operated at very low partial loads during phases with a low wind speed or solar irradiation.
Based on these results, this paper shows the excellent performance of sorption-enhanced catalysis during transient operations or at partial load conditions in the perspective of coupling methane synthesis with renewable energy sources.

Abstract:

Hydrogen production through water electrolysis can play a role in the decarbonisation of energy systems when powered by electricity obtained from low carbon energy sources. The decision of deploying hydrogen technologies at a large scale in the future implies to get a comprehensive overview of the benefits and drawbacks on a variety of impacts compared to other alternative energy supply scenarios. The aim of this study was to perform a dynamic techno-economic and environmental impact assessment of renewable-based hydrogen supply chains relying on some of the characteristics of the GreenHysland EU deployment project in Mallorca (Spain). In this paper the optimization of the design and operation conditions of two hydrogen transport modes (trucks and pipeline) has been addressed for the supply of hydrogen to fuel cell buses and considering the possibility of injecting hydrogen into the natural gas grid. These hydrogen chains were assessed using PERSEE dynamic optimization tool developed at CEA relying on a Mixed Integer Linear Programming approach. A front of optimal solutions has been obtained considering both economic (Net Present Value) and environmental (cumulated equivalent carbon dioxide emissions) optimization criteria. Finally this study emphasizes the potential interest of such dynamic optimization approach to support impact assessment in pre-design phases of hydrogen projects complying with current and future greenhouse gases savings assessment methodologies defined at European level (e.g. RED II and related Delegated Acts) and corresponding green or low carbon hydrogen certification processes. This initial work opens the way to several perspectives for improvement in order to increase the robustness of these energy chain comparisons including sensitivity studies and the consideration of a broader set of environmental impact categories. These improvements are being reviewed by the research team and will help achieve a more complete analysis of the impacts of potential large-scale hydrogen deployment scenarios in the future energy mix of the Balearic Islands.

Keywords:

GreenHysland; Hydrogen; Supply chains; Optimization; Environmental impacts; Scenarios; PERSEE.

1. Introduction

1.1. Context: the GreenHysland EU project

The study presented in this paper has been performed in the frame of the GreenHysland EU project. This five years project (2021-2025) aims to deploy a fully functioning hydrogen (H_2) ecosystem on the island of Mallorca (Spain), turning the island into the first H_2 hub in Southern Europe [1]. The project comprises:

- The development of hydrogen production, transport and distribution infrastructure (green hydrogen production plant, hydrogen truck trailers, deployment of a hydrogen pipeline and hydrogen refuelling station)

- The demonstration of three types of end-use applications (hydrogen vans and buses, stationary fuel cells and hydrogen injection into the natural gas grid).

In addition to the technical aspects, the project also addresses the analysis of the economic, environmental and social impacts of the potential larger scale deployment of hydrogen as an energy carrier in the Balearic Islands. Part of these studies relies on dynamic simulation and optimization of current and future energy chains. Therefore, in the present paper, a methodology for a first analysis of hydrogen supply scenarios in the Balearic Islands is addressed considering economic and environmental evaluation criteria.

1.2. Topic of the paper

1.2.1. Disclaimer

The study presented in this article contributes to the development of appropriate methodologies for impact analysis activities planned within GreenHysland project. The authors do not pretend to provide here an evaluation of economic or environmental performance of the project in itself. The case study detailed in this paper consists in a theoretical evaluation of an energy system inspired by some of the technical characteristics of the project. This theoretical evaluation aims at illustrating a multi-criteria optimization methodology based on dynamic simulation. This study does not refer to potential hydrogen upscaling scenarios within the Balearic Islands

1.2.2. General objectives

The main goals of this study are:

- To illustrate how a multi-criteria optimization approach based on dynamic modelling can help assessing hydrogen supply chains from an economic and environmental impacts perspective;
- To provide insights about the most influencing components regarding cost and environmental emissions breakdown of these hydrogen chains.

We consider a theoretical case study relying on some of the characteristics of the GreenHysland project. This case study (described in Section 2) consists in a hydrogen energy chain comprising a 7.5 MW electrolyzer connected to a local PV plant and to the local electrical grid. The end-use applications consist in five hydrogen fuel cell buses and a flexible hydrogen injection into the natural gas grid. Two hydrogen transport modes are considered (truck trailers and pipeline) for connecting production and end-use applications separated by a distance of 30 km.

The main originality of the work relies in the simultaneous optimization of economic and environmental criteria considering all types of emissions (direct from fuel consumption, indirect from electricity consumption, and indirect from equipment manufacturing) within a dynamic optimization approach.

1.3. Background about optimization of hydrogen energy chains

1.3.1 Evaluating the carbon content of hydrogen

Hydrogen as an energy carrier is widely considered as one of the technologies that could help decarbonizing several energy demand sectors. However, this statement depends on the direct and indirect environmental impacts generated from the primary energy from which hydrogen is produced as well as life cycle impacts of the newly developed technologies over the whole hydrogen supply chains. As an example, water electrolysis is often considered as an environmental-friendly method for hydrogen production. However even though hydrogen produced by electrolysis tends to minimize environmental impact, the impact is not zero since electricity production involves environmental footprints as well as electrolysis and associated processes such as water treatment and desalination [2].

Hence several initiatives are being undertaken at National, European and International levels in order to support ramping-up of clean hydrogen market and related industry in the next years and decades by setting new rules and certification processes. The new version of the European Renewable Energy Directive commonly referred as RED II (2018) defines the global rules and targets for increasing deployment of renewable energies across European Union. Complementary to this directive, a specific Delegated Act recently published (February 2023) establishes a “Union methodology setting out detailed rules for the production of renewable liquid and gaseous transport fuels of non-biological origin” (RFNBO). These rules refer to consideration of additionally (new dedicated renewable power plants associated with hydrogen production plant), temporal correlation (from calendar month basis to hourly correlation basis) and geographical correlation (notion of bidding zone). Another Delegated Act establishes the minimum threshold for greenhouse gas emissions savings of RFNBO fuels at -70% compared to reference process. Complementary to the RED II directive and Delegated Acts, several initiatives (such as CertifHy, IPHE or GH2 standard) have been launched in order to define green or low-carbon hydrogen certification process). For instance, the so-called GH2 standard has been established by the Green Hydrogen Organization which refers to "near-zero greenhouse gas emissions". This standard requires green hydrogen projects to operate at a level of emissions less than or equal to 1 $kgCO_{2\text{-}eq}$ per kgH_2, taken as an average over a 12-month period [3]. However, GH2 considers emissions only during hydrogen production, without evaluating them in later stages of the process,

such as in hydrogen transportation, end-use applications, and so on. Therefore, if a study scope includes transportation, the expected emissions might be higher than 1 $kgCO_{2\text{-}eq}$ per kgH_2.

Hence, hydrogen stakeholders may be facing a new challenge regarding the appropriate and optimized size and operation of hydrogen equipment to fulfill the GHG requirements while maximizing the profitability of the production plants. Multi-criteria optimization techniques relying on dynamic simulation could help addressing this issue and then providing support to investment decision and daily operation of hydrogen plants. The next sections provide some background information about optimization approaches (section 1.3.2), multi-objective optimization (section 1.3.3) and environmental information in energy system optimization tools (section 1.3.4). Finally, section 1.3.5 presents the PERSEE optimization tool that has been used in the frame of this study.

1.3.2 Optimization approaches

Despite the various benefits resulting from renewable energy and hydrogen production, there are still new issues to overcome, such as system losses caused by inadequate operation, sizing or selection of location and sizing of systems [4]. By including optimization techniques, the design and operation of energy systems can be addressed, resulting in more efficient and cost-effective scenarios [5].

Numerous optimization techniques have been implemented in this area, and one of the most widely used is mixed integer linear programming (MILP) [6]. The main advantage of a MILP Solver method is the accuracy of the solution. If the problem is well defined, the solution found with the use of MILP Solver is the global optimal solution of the problem. The other advantage is that the optimal dispatch is found without the need to adjust the operating strategy of the units [7].

1.3.3 Multi-objective optimization methodology

Energy system optimization inherently involves multiple and conflicting objectives. As way of example, the most efficient energy processes are not necessarily the most economical ones, or a system with low $CO_{2\text{-}eq}$ emissions can suppose high investment costs. Therefore, energy system optimization is much more realistic and reliable if different evaluation aspects, such as cost, technical and environmental concerns, are explicitly taken into account. This can be accomplished by giving them an explicit role as objective functions, rather than aggregating them into a single economic indicator objective function [8]. Thus, the problem of optimizing energy systems can be addressed with a multi-objective approach, where the solution vector is not determined by a single technical solution, but by a set of optima. The optimal solution points form what is commonly referred to as a non-dominated set or Pareto optimum. For each of the Pareto arrangements, improving one objective without worsening another is not possible. For the calculation of the Pareto front, the epsilon-constraint method is widely used, especially for cases where there are two objectives. This is due to the fact that it provides high reliability of the results within brief computational time [9].

1.3.4 Environmental information in energy system optimization

Optimization techniques are used in various simulation software packages to plan energy systems. These pieces of software have been developed not only to evaluate the technical and economic potential of energy systems, but also to simplify the design and operation process of systems that include renewable sources maximizing, at the same time, their profitability [10]. Even though the use of software programs seeks to maximize the use of renewable energies and thus, minimize the environmental impact, most of them do not include environmental impact as a decision variable [11]. Moreover when environmental information is considered the impact related to equipment manufacturing is often excluded from the analysis perimeter.

In order to obtain and include environmental information in an optimization problem, a Life Cycle Analysis (LCA) of all components of the energy system must be performed. LCA is a standardized methodology developed to assess the environmental impacts of a product, a process or even a system [12]. Despite the fact that different LCA software have been developed over the past two decades, the research community has always developed its own software implementations that could be adapted and extended to build advanced, non-standard LCA models. As a way of example, Brightway version 2 has been developed since 2012 as an open source Python-based LCA framework, and has been widely used throughout the research community [13]. This software has been chosen for this study due to its flexibility for building parametrized environmental impact models (see Section 2.4.2).

1.3.5 PERSEE optimization tool

The technical and economic study presented in this paper is carried out with PERSEE software developed at CEA by members of LSET laboratory in Grenoble, France. PERSEE is a tool for optimizing the sizing and management of multivector energy systems, based on MILP formulation [14]. The software allows the modeling and multi-objective optimization of energy systems, such as industrial processes or energy production facilities. Two approaches can be implemented. If the size or production capacity of an existing facility is already known, optimization is performed to optimally extrapolate its performance over several years of operation. Conversely, if the facility size or production capacity is an unknown variable, it is optimized in order to determine the system optimal management. Whatever the case, from all the information entered by

the user, PERSEE creates a system of equations containing the objective function and all the constraints of the problem. Subsequently, this system of equations is solved using a commercial solver, such as Cplex.

As regards the multi-optimization criteria, PERSEE software works with the Net Present Value (NPV) and the cumulated greenhouse gases emissions over the entire industrial project lifetime. In order to build the front of optimal solutions, the epsilon-constraint method is currently implemented. Once the environmental, technical and economic constraints are set, the optimization is spread over a period of one year, with a specific time step, for example, one hour. Then PERSEE has to meet the imposed constraints maximizing the NPV and/or minimizing $CO_{2\text{-eq}}$ emissions.

2. Case study

2.1. System description

As it was mentioned before, the study presented in this paper is based on the GreenHysland hydrogen hub. Some of the characteristics of the GreenHysland project are used as a reference situation from where several scenarios are created. In this section, the overall flowsheet of the theoretical case study is described. Figure 1 shows a schematic representation of the case study general architecture.

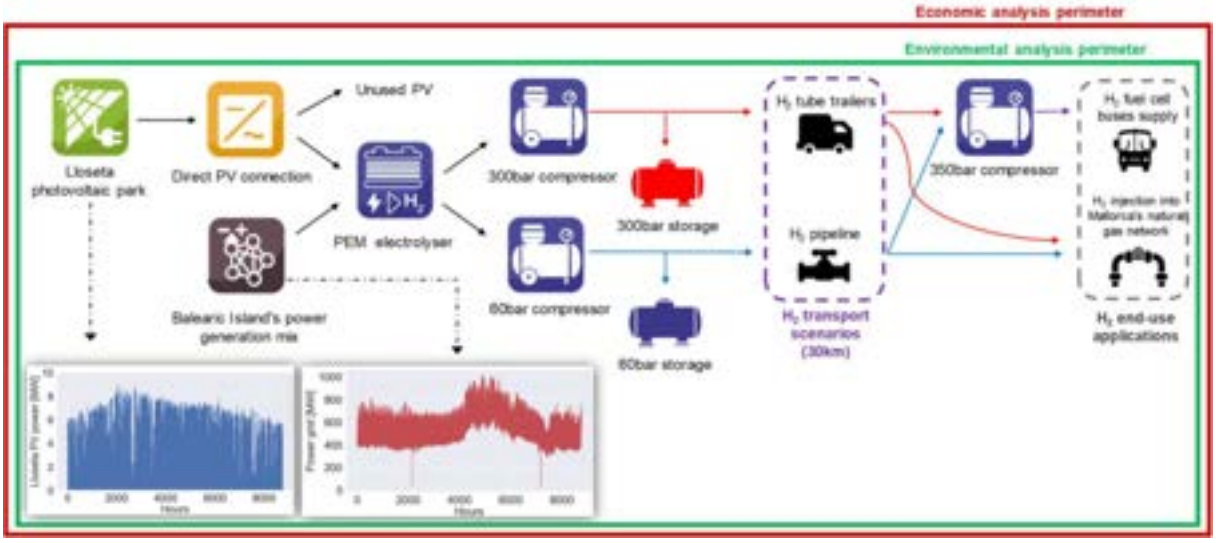

Figure. 1. Illustration of the considered hydrogen supply chains and applications.

As it can be seen in Figure 1, hydrogen is produced via water electrolysis. The green hydrogen production facility is placed in the municipality of Lloseta, at almost 30 km northeast from the capital city Palma de Mallorca. The electrolyzer plant mainly includes a 7.5 MW Proton Exchange Membrane (PEM) electrolyzer, compressors, and on-site hydrogen storages to allow desynchronizing hydrogen production and demand. Regarding energy sources, the electrolyzer is coupled to the electricity generation of a photovoltaic park located also in the municipality of Lloseta. This solar farm has a generation capacity of 8.56 MWp [1]. Additional power can be obtained from the Islands' electricity power grid.

Once produced, we assume that the hydrogen is compressed and subsequently transported to Palma de Mallorca to supply two applications: public transport mobility (hydrogen buses) and hydrogen injection into the Mallorca's gas grid.

- In the first end-use application, hydrogen is used as a fuel for a fleet of five fuel cell buses. As the buses refuelling station is placed in Palma de Mallorca, hydrogen must be transported 30 km from Lloseta municipality to the capital city. Each bus has five 350bar hydrogen tanks of 312 liters each, which makes 1,560 liters in total. We assume that this volume is equivalent to a usable capacity of 37.5 kg of hydrogen. It is supposed that all buses are refuelled once a day, hence ~70 tons of hydrogen are needed in a complete year corresponding to an average flowrate demand of 8 kg/h.
- For the second end-use application, green hydrogen is injected into the Mallorca's natural gas network. The injection point is supposed to be also in the capital city, therefore, 30 km hydrogen transport has to be considered. In this case, we consider a maximal allowable hydrogen injection flow rate of 4% of the natural gas volumetric flow.

For both applications, two hydrogen transport modes are considered: truck trailers and hydrogen pipeline.

2.2. Perimeter of economic and environmental evaluations

The environmental impact considered in this study is limited to greenhouse gases (GHG) emissions. As shown in Figure 1 the environmental analysis perimeter comprises the whole direct and indirect emissions of the

hydrogen supply chains. The cumulated emissions E_{GHG} ($kgCO_{2\text{-eq}}$) are calculated considering direct emissions $DE_{t,i}$ during each hour t over year i (e.g. from diesel combustion in truck trailers), indirect emissions $IEG_{t,i}$ related to grid electricity consumption, indirect product emissions IPE_{el} related to manufacturing of element el of the energy system (also referred as "capex-related emissions") and avoided emissions $AE_{t,i}$ related to substitution of diesel in buses by hydrogen and substitution of natural gas in the grid by hydrogen (this study only compares the avoided emissions in terms of fuel substitution and not the technological equipment involved in the fuel substitution; it is beyond the scope of the study to compare impacts of manufacturing of diesel buses and hydrogen buses). Equation (1) presents the calculation of the cumulated emissions considering a project lifetime of Y years, an annual operating time H of 8760 hours, a number of N elements and annual hydrogen production $M_{H2,i}$ (kgH_2). Then the specific emissions e_{GHG} ($kgCO_{2\text{-eq}}/kgH_2$) are obtained by dividing the cumulated emissions E_{GHG} by the cumulated hydrogen production M_{H2} (kgH_2) over the a Y years.

$$E_{GHG} = \sum_{i=1}^{\mathrm{Y}} \left[\sum_{t=1}^{H} DE_{t,i} + \sum_{t=1}^{H} IEG_{t,i} + \sum_{el=1}^{N} IPE_{el} - \sum_{t=1}^{H} AE_{t,i} \right] \quad (1)$$

As shown in Figure 1 the same perimeter has been considered for the economic analysis. PERSEE minimizes the total cost function $f(x)$ presented in Eq. (2) which is the opposite of the Net Present Value. This equation shows that the cost of each element el of the energy system is computed considering specific capital expenditures CA (€ per unit size) and size S (in the present study, only the sizes of 60bar and 300bar stationary hydrogen storage systems are optimized) as well as yearly operational expenses comprising direct operation and maintenance costs OP (€/year), energy buying costs BC (computed from hourly grid electricity price data in our case) and selling price SP (hydrogen prices for mobility application and gas grid injection application). These operational expenses are computed considering hourly dynamic flux over each year of operation.

$$f(x) = \sum_{el=1}^{N} \left[CA * S + \sum_{i=1}^{\mathrm{Y}} \frac{OP + BC * Flux * Dt - SP * Flux * Dt}{(1+k)^i} \right] \quad (2)$$

2.3. Optimization approach

2.3.1 Scenarios

In the present study a multi-criteria optimization of three hydrogen supply scenarios is addressed:

- [Truck scenario]: We assume that tube trailers are used to transport hydrogen from Lloseta photovoltaic plant to Palma de Mallorca, where the applications of mobility and injection into the natural gas grid are placed. In this case, it is assumed that all hydrogen produced by the PEM electrolyzer is transported by trucks. Here, 2 trucks are used to supply hydrogen to the refuelling station, whereas other 4 are involved in potential hydrogen injection into the natural gas grid. These numbers of trucks have been pre-determined based on electrolyzer maximal flowrate, hydrogen demand and unitary truck capacity ensuring, therefore, permanent availability of transport capacity at production site.
- [Pipeline scenario 1]: A pipeline is used for the transport of hydrogen from Lloseta to Palma.
- [Pipeline scenario 2]: In this scenario, the pipeline capacity is supposed to be oversized by a factor of 10 in order to cover an increase in the hydrogen production capacity of the production plant, compared to the initial value (135 kg/h). Therefore, the capital cost and embedded Greenhouse Gases (GHG) emissions of the pipeline are adjusted, being divided by 10.

2.3.2 Optimization variables

Table 1 provides an overview of the optimization variables considered in this study.

Table 1. Optimization variables

Type of optimization variables	Variables	Units
Size of components	300bar stationary storage capacity (Truck scenario)	kg
	60bar stationary storage capacity (Pipeline scenarios)	kg
Power or mass flow management (dynamic optimization of operation)	PV electricity consumption	MW
	PV electricity injection to electrical grid	MW
	Grid electricity consumption	MW
	PEM electrolyzer production	kg/h
	H_2 injection in NG grid at 4%vol max	kg/h

2.3.3 Multi-criteria optimization method

The optimization of the energy system is performed by using the economic objective function and restrictions on total $CO_{2\text{-eq}}$ emissions. In order to build the Pareto front, two mono-objective optimizations are performed. In the first one, NPV is maximized without applying any $CO_{2\text{-eq}}$ emissions restrictions. In the second one, $CO_{2\text{-eq}}$ emissions are minimized. This allows to obtain the extreme points of the Pareto front. Afterwards, the internal points in the front are determined by selecting 10 equidistant $CO_{2\text{-eq}}$ emissions values between the two extreme points (highest and lowest $CO_{2\text{-eq}}$ emissions cases). Each of them is fixed as a $CO_{2\text{-eq}}$ emissions constraint in subsequent mono-objective optimization problems, where the NPV is maximized. This means that 10 NPV optimization runs are generated for each hydrogen transport scenario, in which a restriction value of maximum $CO_{2\text{-eq}}$ emissions is set.

2.3.4 Project lifetime and discount rate

We assume a project lifetime of 20 years. However, as it is explained in the following section, data series are based only on information of the year 2019. For this reason, each time series is replicated over the years in order to guarantee the optimization over the 20-years period. The Net Present Value optimization is performed considering a discount rate of 7%.

2.4. Data sources and assumptions

A summary of all numerical assumptions is given in Appendix of this paper. In the following paragraphs, we provide more details about the sources and construction of input temporal data and environmental data.

2.4.1 Temporal data

The Table 2 provides the list of temporal data used in the present study.

Table 2. Input temporal data considered in the study

Type of temporal data	Units	Sources and characteristics
PV production	MW	PVGIS platform (Lloseta location)
Grid electricity price and emissions	€/MWh & $CO_{2\text{-eq}}$/MWh	UIB personal communication and additional calculations related to emissions from HVDC mainland connexion
Maximal allowable hydrogen injection	kg/h	4%vol of natural gas (NG) consumption NG consumption approximated from electrical production
Hydrogen demand for fuel cell buses	kg/h	Considered constant 8kg/h

Data of the hourly power generation mix and its $CO_{2\text{-eq}}$ emissions in 2019, as well as the hourly electricity spot price in 2019 in the Balearic Islands were provided by the Industrial Engineering Department of the University of the Balearic Islands. Even though data series from 2020 and 2021 were also available, they were not considered in the present study given that both 2020 and 2021 were atypical years due to the COVID-19 pandemic. As it was mentioned before, hydrogen demand for the mobility application is fixed at 8 kg/h. This constant value might not be representative of the real hourly hydrogen demand profile due to the fact that demand can vary, for instance, from summer to winter when the amount of tourists visiting the Islands is considerably lower. However this value represents a fixed constraint which forces the system to produce hydrogen to supply the demand. Thanks to this constraint, in the optimization problem there is at least one constant hydrogen demand to fulfil. In the case of hydrogen demand for injection into the natural gas network, a maximum constraint of 4% in volume of the existing natural gas flow is considered. As no information regarding real consumption of natural gas could be found, a roughly estimation is performed. It is supposed that all the natural gas sent to the Island is used exclusively for power generation. Figure 2 represents the maximum hydrogen mass flow that can be injected in to the natural gas grid.

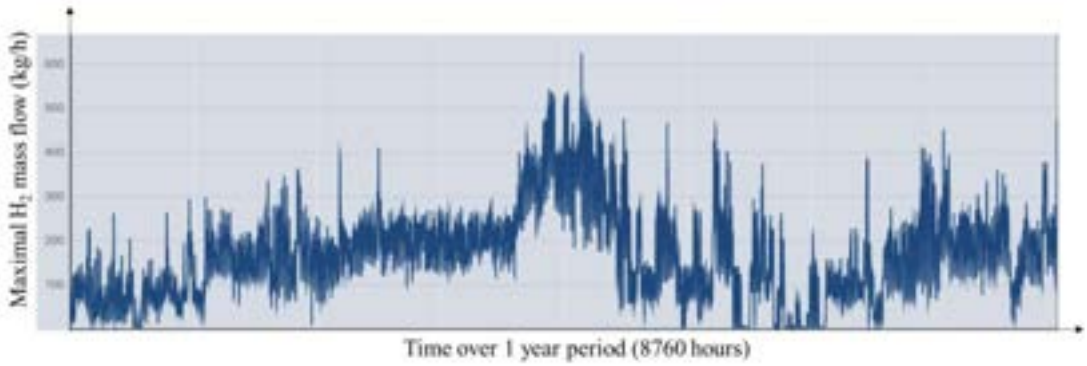

Figure. 2. Illustration of the yearly maximal hydrogen mass flowrate injection considering a limit of 4%vol of hydrogen in natural gas.

2.4.2 Environmental data

In order to obtain the results of the direct and indirect emissions of the different components of the system, it is necessary to define the boundaries and the impact categories. In this case, only the end-of-life stage of the components is not considered. In addition, the environmental impact category selected for the Life Cycle Impact Assessment (LCIA) is the Global warming potential of the EV3.0 method. Ecoinvent 3.8 database [15,16] is used for the selection of the activities for the diverse components. It is important to highlight that when selecting the Ecoinvent activities, a geographic prioritization is established. For this study, priority is given to Spain data in the database. If there is no Spain reference, European data (RER) is selected and, if the latter is not available, "global" (GLO) and "rest of the world" (RoW) data is chosen. In the next paragraphs a description of the environmental aspects of some elements of the system is presented (all other input data are available in the Appendix).

2.4.2.1 Compressor

In the case of the compressor, in order to obtain the $CO_{2\text{-eq}}$ emissions values, the study published by Ghandehariun and Kumar [17] is used. Since the assumptions between the literature and the studied system are different, particularly the system capacity, the exponential rule in Eq. (3) is applied for the calculation of energy and material inputs. In this way, the mass of the components and the energy required for compressor manufacturing are adapted to the system size, based on the study reported by Lee et al. [18].

$$\mathrm{m}_{1,\mathrm{BOP}} = \mathrm{m}_{2,\mathrm{BOP}} \times \left(\frac{\mathrm{P}_1}{\mathrm{P}_2}\right)^{\mathrm{f}} \quad (3)$$

Where m is the mass (or energy input), P the system capacity and f the scale factor.

This equation is used for the different components of the Balance of Plant (BOP) for electrolyzers. However, information must be adjusted in such a way that it can be added to the MILP optimization problem. Therefore, the value of the environmental impact, expressed in $kgCO_{2\text{-eq}}$, has been calculated for different compressor capacities and a linear regression was made resulting in the linear function expressed in Eq. (4) where $IPE_{compressor}$ refers to indirect production emissions ($kgCO_{2\text{-eq}}$) of compressor manufacturing and $P_{compressor}$ refers to compressor electrical power (MW).

$$IPE_{compressor} = 258027 * P_{compressor} + 24217 \quad (4)$$

2.4.2.2 Hydrogen Storages and Pipeline transportation

Equations 5, 6 and 7 provide the considered linear functions for calculating indirect product emissions $IPE_{product}$ ($kgCO_{2\text{-eq}}$) related to the manufacturing of type I tank for 60bar storage, type II tank for 300bar storage and hydrogen pipeline respectively. Variables $C_{storage60bar}$ and $C_{storage300bar}$ refer to storage capacity (kgH_2) and variable $L_{pipeline}$ refers to the length of the pipeline (km). Numerical coefficients are based on data from Ecoinvent [15,16] and [19] from which a dedicated environmental model has been built.

$$IPE_{storage60bar} = 310 * C_{storage60bar} \quad (5)$$

$$IPE_{storage300bar} = 350 * C_{storage300bar} \quad (6)$$

$$IPE_{pipeline} = 80000 * L_{pipeline} \quad (7)$$

2.4.2.3 PEM Electrolyzer

The PEM electrolyzer inventories used in this study are updated from the study published by Sharma et al. [20]. $CO_{2\text{-eq}}$ emissions for the production phase of the PEM system have been calculated for 10 system capacities, since some components of the PEM do not increase in a linear way. The information obtained must be adjusted so that it can be added to the MILP optimization problem. Therefore, a linear adjustment is made for the system, giving as a result the linear function shown in Eq. (8) where $IPE_{electrolyzer}$ refers to indirect production emissions ($kgCO_{2\text{-eq}}$) of electrolyzer manufacturing and $P_{electrolyzer}$ refers to electrolyzer electrical power (MW).

$$IPE_{electrolyzer} = 261351 * P_{electrolyzer} + 45156 \quad (8)$$

2.4.2.4 Mallorca Grid Data

Since the objective of the study is to optimize the hydrogen production, including the environmental impact, $CO_{2\text{-eq}}$ emissions of the Balearic Islands' electricity grid is required. Different sources such as Ecoinvent [15, 16] provide an average value of $CO_{2\text{-eq}}$ emissions resulting from the overall Spain electricity grid. Other

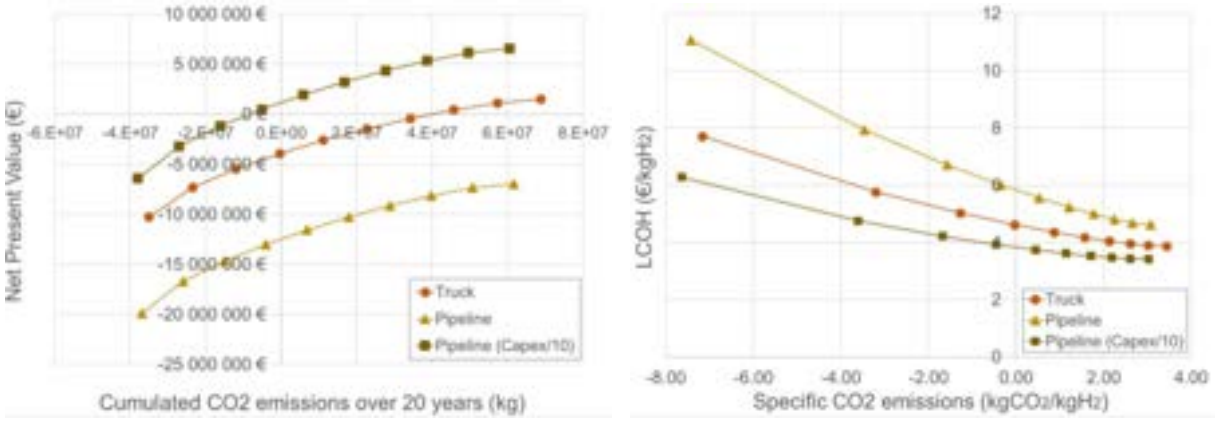
sources, such as ENTSOE [21] and REE [22] give hourly, monthly and yearly average values of $CO_{2\text{-eq}}$ emissions. However, this data correspond to the $CO_{2\text{-eq}}$ emissions of the energy generation mix in the Balearic Islands, without taking into account the energy import from Spain Mainland. Therefore, in order to know the $CO_{2\text{-eq}}$ emissions of the electricity consumed in the Balearic Islands, emissions from energy imports need to be taken into account.

For this purpose, ENTSOE and REE emission data of power generation in Spain Mainland were weighted, averaged and added to the $CO_{2\text{-eq}}$ emissions database provided by the Industrial Engineering Department of the University of the Balearic Islands. An emission factor of 590 $kgCO_{2\text{-eq}}$/MWh was obtained for our reference year 2019. In addition, we considered a reduction of carbon intensity of the electrical grid based on the scenario proposed by the Ministry for Ecological Transition and the Demographic Challenge of the Balearic Islands [23] and assuming an emission factor below 160 $kgCO_{2\text{-eq}}$/MWh for year 2039. This hypothesis implies a Balearic generation mix composed of 65% renewables and 35% of energy imports from the Peninsula. Thus, a reduction coefficient was implemented in PERSEE in order to take into account this decrease in grid $CO_{2\text{-eq}}$ emissions over the supposed 20 years of the project.

3. Optimization results & Discussion

3.1. Pareto Front

As it was explained in the section 2.2, a Pareto front is generated for each hydrogen transport scenario. Figure 3a shows the NPV and cumulated emissions over the 20 years project time. It can be noted that, as avoided $CO_{2\text{-eq}}$ emissions are being considered, the three scenarios present negative values of $CO_{2\text{-eq}}$, when the emissions are being exclusively optimized. We observe that all scenarios adopt negative values of NPV, meaning that the system is not economically profitable when environmental aspects are being exclusively optimized given our set of assumptions (see Appendix). Besides, in terms of emissions, tube trailer (truck) scenario and pipeline scenario do not considerably differ. In other words, for this study case, these two means of H_2 transportation produce similar amount of $CO_{2\text{-eq}}$ emissions. However, in economic terms, they present great differences, being the scenario of pipeline with reduced CAPEX the most profitable.



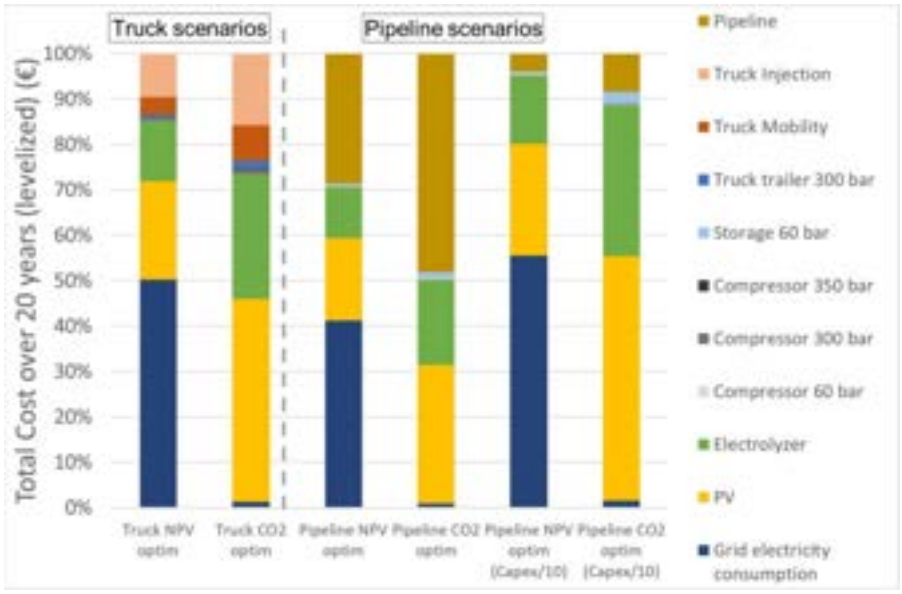
(a) *(b)*

Figure. 3. a) Pareto Front obtained for each of the three scenarios, b) Levelized Cost of Hydrogen compared with Specific $CO_{2\text{-eq}}$ emissions.

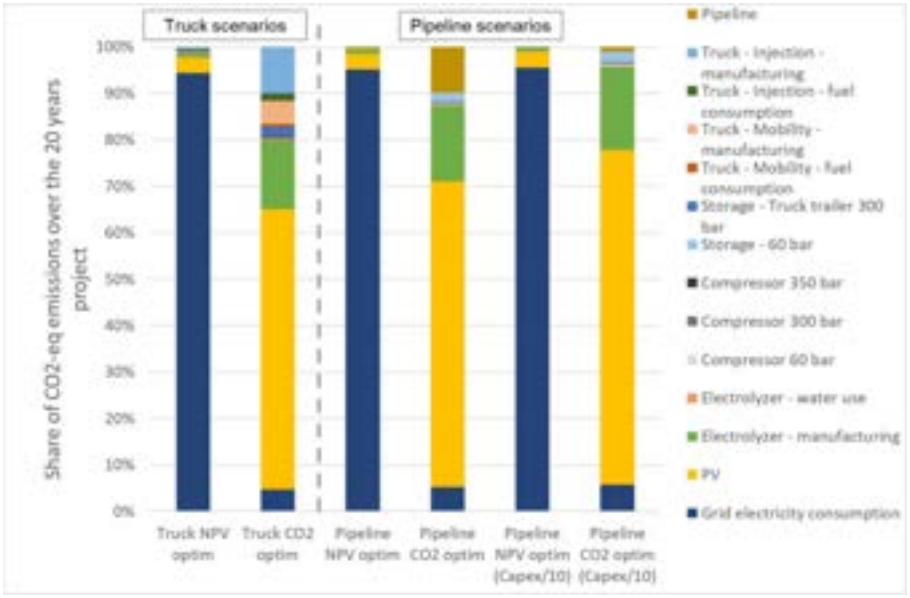
Figure 3b illustrates the Levelized Cost of Hydrogen and the specific emissions, expressed in kilograms of $CO_{2\text{-eq}}$ per kilogram of hydrogen. It can be seen from the Figure that, when the NPV is being exclusively optimized, the pipeline with reduced CAPEX scenario presents the lowest LCOH value, accounting for ~3.4€/kgH_2. It is then followed by the tube trailer scenario (~3.9€/kgH_2) and the original pipeline scenario (~4.6€/kgH_2). For each scenario, the reported LCOH values determine the minimum H_2 averaged sell price from which the system is profitable. In addition, the specific emissions give hint of which group of solutions generates a reduction in current emissions. This implies that the solutions with positive specific emission values lead to higher overall emissions. Therefore, the solutions considered as more sustainable would be the ones that present negative values of specific emissions despite higher cost.

3.2. Cost and emissions structure

In the present section, the cost and emissions breakdown analysis of the projects is performed. Figure 4a depicts the components relative contribution to the cost, while Figure 4b shows their relative contribution to the emissions.



(a)



(b)

Figure. 4. Structure of each scenario considering: a) relative cost, b) relative emissions

For the NPV optimization cases, it can be observed that the electrical grid is responsible for the highest percentage of costs and $CO_{2\text{-eq}}$ emissions. This proves that, in this case, energy extraction from the grid takes the highest shares. For the $CO_{2\text{-eq}}$ optimization cases it can be seen that the photovoltaic farm is responsible for most of the costs and emissions. In this optimization case, the use of the grid is minimized in order to reduce overall $CO_{2\text{-eq}}$ emissions. Even though an emission reduction factor is assigned to the energy extracted from the grid, it seems that, environmentally speaking, it is better to reduce energy grid extraction anyway.

Finally, considering that the size of the components such as the photovoltaic farm, the electrolyzer, the compressors and the gas transport medium are fixed, the variations of the cost breakdown between the solutions are mainly due to the use of the electrical grid. In the set of solutions where emissions are exclusively optimized, the generation behavior of the electrolyzer follows the trend of the PV production, as it avoids the use of the grid. However, the hours of use of the electrolyzer are considerably reduced, generating an economically oversized system.

4. Conclusions and perspectives

In this paper a multi-criteria optimization approach based on dynamic modelling has been implemented for evaluating the economic performance and greenhouse gases emissions of a PV based hydrogen energy chain.

We considered a theoretical case study relying on some of the characteristics of the GreenHysland EU project deployed in Mallorca, Spain. This case study consisted in a hydrogen energy chain comprising a 7.5 MW electrolyzer connected to a local PV plant and to the local electrical grid. The end-use applications consisted in mandatory refuelling of five hydrogen fuel cell buses and a flexible hydrogen injection into the natural gas grid up to 4%$_{vol}$. Hydrogen truck trailers and hydrogen pipeline were both considered for connecting production and end-use applications. The optimization was conducted over 20 years plant lifetime and considering one year of data at a timestep of one hour. The two optimization criteria were the Net Present Value and the cumulated greenhouse gases emissions including direct (fuel combustion), indirect (capex-related and from grid electricity) and avoided emissions (substitution of diesel buses and natural gas).

Several fronts of non-dominated solutions were obtained using the epsilon-constraint method. These fronts show that the cumulated greenhouse gases emissions could become negative mainly due to the greenhouse gas emission savings from substitution of natural gas by hydrogen in the natural gas grid. The structure of costs and emissions was also analysed. It was shown that when maximizing the Net Present Value, the grid electricity consumption takes the greatest share of cost breakdown and $CO_{2\text{-eq}}$ emissions for all scenarios, as the optimizer tends to maximize the utilization rate of the electrolyzer for minimizing the costs.

On the contrary, when the cumulated $CO_{2\text{-eq}}$ emissions are being minimized, the optimizer prefers using direct production from the local PV plant, which in turns reduces the utilization rate of the electrolyzer and increases the costs. Hence, in this case the cost associated with photovoltaic power production represents the highest proportion in the cost structure (except in high capex pipeline scenario were pipeline becomes the highest cost factor). In terms of emissions, the photovoltaic production involves the biggest contribution for all scenarios. However, the optimal solution shows that share of embedded emissions from “other than Solar” elements (electrolyzer, pipeline, compressors, storages, truck trailers) is not negligible, representing between 25% and 35% of the emissions breakdown.

Hence, this study emphasizes the potential interest of such dynamic multi-criteria optimization approach to support impact assessment in pre-design phases of hydrogen projects complying with current and future GHG savings assessment methodologies defined at European level (RED II and related Delegated Acts) as well as green or low carbon hydrogen certification processes. By year 2030 the evolution of EU regulation towards mandatory hourly temporal correlation between renewable production and hydrogen production may increase the need of relevant dynamic multi-criteria optimization approaches.

Several perspectives can be envisaged for increasing the robustness of these approaches. In terms of environmental inventory information, a comprehensive study of the waste management of the system should be carried out, i.e. the end-of-life analysis of all components. Besides, in the LCA section, several other impact categories, such as water consumption and land use, could be added to the optimization problem. Future studies should focus on how to perform a complete environmental optimization study, considering several environmental indicators as objective functions. Finding the optimal solution in an optimization problem involving more than two objectives constitutes a challenge in terms of resolution time and appropriate algorithms should be investigated to reach this objective. Uncertainties regarding all types of inputs should also be included and handled in energy system optimization problems. Including them would ensure the derivation of more robust conclusions useful for investment decision-making process and daily optimal operation. However, such methods and tools do not substitute to stakeholders investment decisions which may depend on additional local and global considerations such as regulation, market readiness, business model, social acceptance or political support.

Acknowledgments

The authors acknowledge specially the University of Balearic Islands, in particular Dr. Vincent Canals for his highly valuable inputs. The authors thank the GreenHysland EU project. This project has received funding from the Fuel Cells and Hydrogen 2 Joint Undertaking (now Clean Hydrogen Partnership) under Grant Agreement No 101007201. This Joint Undertaking receives support from the European Union’s Horizon 2020 Research and Innovation programme, Hydrogen Europe and Hydrogen Europe Research. The content of this publication reflects only the authors' view and the JU is not responsible for any use that may be made of the information it contains.

[b] Aston University, Birmingham, UK, j.sodre@aston.ac.uk

Abstract:

This paper presents an exergoeconomic model of a proton-exchange membrane (PEM) fuel cell stack. The model was calibrated using data from experiments performed in a 1.2 kW PEM fuel cell with varying load, operated at steady state. The exergy analysis was performed with fuel cell operation in the air stoichiometry range between 2 to 4. The results showed the system exergy efficiency varied from 26% to 39%, while the energy efficiency ranged between 37% and 56%. This range is slightly above the fuel cell data sheet from the manufacturer, which declares a rated energy efficiency of 48%. High pressure, temperature and cell voltage give better exergy efficiency. Variation of system temperature showed no significant impact on the exergy cost, as the PEM fuel cell operates at relatively low temperature in its load range not exceeding 174°C. The exergy cost of the system can be improved by adopting any combination of higher operating pressure, inlet air stoichiometry or cell voltage, which demonstrates a significant improvement in the exergy cost. By reducing the hydrogen cost from 6.7 $/kg to 1.9 $/kg, a 15 $/GJ decrease in exergy cost can be achieved.

1. Introduction

The importance of using clean fuels is acknowledged by the need to reduce emissions caused by fossil fuels. The current geopolitics in Europe and the energy crisis related to it made the demand for renewable energy even more appealing. In this respect, hydrogen-fed energy systems such as proton-exchange membrane (PEM) fuel cells can positively affect the future energy sector [1]. PEM fuel cells is a promising renewable power generation system that solves some of the existing and future energy shortages [2]. Low or zero emissions is the main advantage of PEM fuel cells as they convert chemical energy directly into electricity by combining hydrogen with oxygen from the air without combustion thus providing higher thermodynamic efficiency than heat engines and turbines.

After decades of research and development, practical PEM fuel cell systems became available and are expected to attract a growing share of automotive and electricity markets as costs decrease to competitive levels. Low-temperature PEM fuel cells can be used for aeroplanes, trains and passenger vehicles. PEM fuel cells use an electrolyte to conduct hydrogen ions from the anode to the cathode. The electrolyte is, in most cases, composed of a solid polymer film consisted of a form of acidified Nafion membrane. The membrane is treated on both sides with highly dispersed metal alloy particles, mainly platinum or platinum alloys, that are effective catalysts. Hydrogen is supplied to the anode side of the fuel cell where, due to the impact of the catalyst, hydrogen atoms discharge electrons and turn into hydrogen ions (protons). The electrons move in the form of an electric current that can be utilised before it returns to the cathode, where oxygen is fed from the ambient air. The protons disperse across the membrane to the cathode, where the hydrogen atom is re-joined and reacted with oxygen to produce water, thus completing the overall process [3].

Two primary performance analyses are usually applied: energy-based analysis and exergy-based analysis. Several authors [4-6] emphasise that the energy-based analysis can be misleading because it does not identify deviations from ideal situations. In contrast, the exergy of an energy form or substance is a measure of its usefulness, quality, or potential to cause change. However, a better understanding of exergy and the insights it can provide into the efficiency, environmental impact and sustainability of energy systems are required for researchers working in energy systems and the environment. Further, as energy policies play an increasingly important role in addressing sustainability issues and a broad range of local, regional and global environmental concerns, policymakers must also appreciate the exergy concept and its ties to these concerns.

During the past decade, the need to understand the connections between exergy and energy, sustainable development and environmental impact has become increasingly significant. Indeed, the universe's energy content is constant, just as its mass content is. On the other hand, exergy is not conserved; once the exergy is wasted, it can never be recovered. When energy is used for heating homes or public places, it is not destroyed but merely converted to a less proper form, a form of less exergy. The exergy of a system can be

defined as its work potential compared to an exergy reference environment. The work potential is intimately related to the maximum work obtainable when the analysed system interacts with the reference environment and simultaneously reaches equilibrium. The term exergy is also related to the thermodynamical availability of a system [7]. The exergy analysis complements the energy analysis and allows including the effect of the temperature level at which the analysis is being carried out [8].

The concept of exergy has also been explored in the area of fuel cells [9]. A thermodynamic and exergoeconomic assessment of the PEM Fuel Cell system was conducted at steady-state operation conditions [10]. The study found that, by increasing the current density, power density, exergy destruction rate, hydrogen consumption and the cost rate of power generation increases. An exergy analysis was carried out on a hybrid system consisting of 64 photovoltaic modules, a 5.5 kW fuel cell and an electrolyser [11]. The study concluded that the average annual exergy efficiency of the fuel cell is 32.8%.

Energy and exergy analyses were performed for a 1.2 kW Nexa PEM Fuel Cell unit in a solar-based hydrogen production system [12]. The study used a model and experimental setup of the system with different operating conditions and found that the increase in current density reduces the energy and exergy efficiencies by 14%. Varying pressure, temperature and anode stoichiometry, the research concluded that the energy and exergy efficiencies respectively increased by 23% and 15% when the pressure was increased, and by 17% and 14% while increasing the anode stoichiometry. Unlike pressure and anode stoichiometry, increasing the temperature has not affected the efficiency level. Exergy analyses were conducted on 10 kW [13] and 1.2 kW [14] PEM fuel cells, respectively, to observe the effect of the operating temperature, cell voltage, air stoichiometry and pressure on the efficiency. The studies concluded that the air stoichiometry should be less than 4, otherwise the membrane will dry out at a high temperature and the relative humidity level in the product air will not be maintained.

The economics of producing electricity from a PEM fuel cell was examined under various conditions [15], investigating the possibility of using a fuel cell vehicle to generate power while parking outside houses or offices. The study found that, for California, USA, net savings could be reached if the fuel cell costs are about $6000 for a 5 kW home system ($1200/kW) with favourable natural gas costs of $6/GJ at residences.

Cogeneration using PEM and other potential fuel cell types was investigated, using both exergy and energy analyses [16]. The research found that exergy analysis is more rational and meaningful as it considers the equivalent work potentials of the thermal and electrical energy products. The study added that energy analyses often present misleadingly optimistic views of performance. The feasibility of fuel cells in cogeneration applications was studied concentrating on both engineering and economic viewpoints [17], using an optimisation approach through a numerical study. The investigation concluded that, in terms of plant capacity, economics, and energy savings, fuel cell cogeneration is better than conventional gas engine cogeneration.

In this work, a MATLAB model was developed to provide an exergoeconomic analysis of a 1.2 kW Nexa™ PEM fuel cell module at variable operating mass flow rates, pressure, temperature, cell voltage and air stoichiometry. The model calculates the fuel and product exergy and the cost rates associated with these energies. Further details are given in the following sections.

2. Exergy and exergoeconomic analysis of the PEM fuel cell

The exergy efficiency of the PEM fuel cell, defined as the ratio between the fuel cell power output and maximum possible work output [18], is carried out by applying the second law of thermodynamics to the control volume shown by Fig. 1. By adding the cost, capital investment, operations, and maintenance cost, the exergoeconomic analysis is also performed. The exergoeconomic analysis is defined by the ratio of the difference between the exegetic cost rate (cost per unit time) of the streams entering and exiting the PEM fuel cell plus the capital investment, operation and maintenance cost of the PEM fuel cell to the electrical power output. The analyses consider all inlet hydrogen is consumed in the reaction, therefore the excess H_2 is zero.

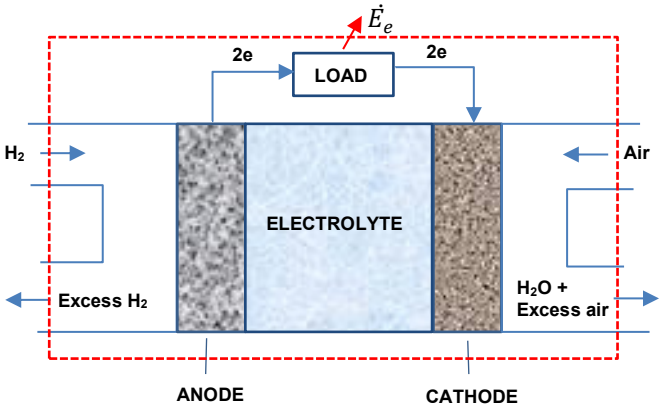

Figure 1. PEM fuel cell schematics.

2.1. Exergy analysis

The fuel cell efficiency (η) is calculated by the ratio of the electrical power output ($\dot{E}_e$) and the differences between the reactant and the product exergies [13]:

$$\eta = \frac{Electrical\ output}{(Total\ exergy)_R - (Total\ exergy)_P} = \frac{\dot{E}_e}{\left(\dot{E}x_{air,R} + \dot{E}x_{H_2,R}\right) - \left(\dot{E}x_{air,P} + \dot{E}x_{H_2O,P}\right)} \quad (1)$$

Where *R*, *P* and $\dot{E}x$ are reactants, products, and the total exergy, respectively. Kinetic and potential energy effects are neglected in the cell reactions.

The electrical power output is the sum of the auxiliary load ($\dot{E}_{aux}$) and the external load from reactant consumption ($\dot{E}_{ext}$), calculated by:

$$\dot{E}_e = \dot{E}_{aux} + \dot{E}_{ext} = I_{fc} \cdot V_{fc} \quad (2)$$

where I_{fc} and V_{fc} are the fuel cell stack current and voltage, respectively.

The external load ($\dot{E}_{ext}$) is the product of the measured current (I_m) and voltage (V_m):

$$\dot{E}_{ext} = I_m \cdot V_m \quad (3)$$

The auxiliary load is determined by the difference between the electrical power output and the external load.

The fuel cell current is calculated by:

$$I_{fc} = \frac{\mathrm{n}_{H_2} \cdot F \cdot \dot{m}_{H_2}}{N} \quad (4)$$

where n_{H_2} is the number of moles of hydrogen consumed per mol of oxidant in the reaction, taken as 2, F is Faraday's constant (96,485 C/mol), $\dot{m}_{H_2}$ is hydrogen mass flow rate, and N is the number of cells in the stack. The total exergy transfer per unit mass (ex) of products and reactants includes both chemical (ex_{CH}) and physical exergies (ex_{PH}) [13]:

$$ex = ex_{CH} + ex_{PH} \quad (5)$$

The physical exergy combines the pressure and temperature of both reactants and products. It can be distinguished as the maximum beneficial work attained by passing the unit of mass of an element from the generic state (T, P) to the environmental state (T_0, P_0). The general expression of the physical exergy is [13]:

$$ex_{PH} = (h - h_0) - T_0(s - S_0) \quad (6)$$

Where h and s are the specific enthalpy and entropy at the actual temperature and pressure condition (T, p), and h_o and s_o are the specific enthalpy and entropy at the standard condition of T_o = 298 K and p_o = 1 atm. The physical exergy of an ideal gas with constant specific heat c_p and specific heat ratio k is written as [13]:

$$ex_{PH} = c_p T_0 \left[\frac{T}{T_0} - 1 - ln\left(\frac{T}{T_0}\right) + ln\left(\frac{p}{p_0}\right)^{\frac{k-1}{k}}\right] \quad (7)$$

The chemical exergy is the attainment of a maximum quantity of valuable work by assigning a system in equilibrium with the environment using T_0 and P_0, calculated by [13]:

$$ex_{CH} = \sum x_n ex_{CH,n} + RT_0 \sum x_n ln x_n \quad (8)$$

where x_n, ex_{CH}^n are the respective mole fraction and chemical exergy of each component (n).

The total exergy $\dot{E}x$ of products (*P*) and reactants (*R*) are calculated by the following equations [13]:

$$\dot{E}x_{H_2,R} = \dot{m}_{H_2,R} ex_{H_2,R} = \dot{m}_{H_2,R}(ex_{CH} + ex_{PH})_{H_2,R} \quad (9)$$

$$\dot{E}x_{air,R} = \dot{m}_{air,R} ex_{airR} = \dot{m}_{air,R}(ex_{CH} + ex_{PH})_{air,R} \quad (10)$$

$$\dot{E}x_{H_2O,P} = \dot{m}_{H_2O,P} ex_{H_2O,P} = \dot{m}_{H_2O,P}\ (ex_{CH} + ex_{PH})_{H_2O,P} \quad (11)$$

$$\dot{E}x_{air,P} = \dot{m}_{air,P} ex_{airP} = \dot{m}_{air,P}(ex_{CH} + ex_{PH})_{air,P} \quad (12)$$

The chemical and physical exergies, efficiency and mass flow rates are calculated at temperature (T/T_0) and pressure (p/p_0) ratios from 0.94 to 1.2 and 7.40 to 4.88, respectively, which are performing temperature and pressure varieties distinctive for PEM fuel cells [13]. The voltage used in the calculations varies are 0.001 V and 0.79 V at air stoichiometry (λ) between 12.0 and 2.0 to examine its effect on efficiency.

2.2. Exergoeconomic analysis

The exergoeconomic analysis considers the exergy cost (c) of all reactants and products of the electrochemical process at several operating conditions, such as cell voltage, inlet air stoichiometry, temperature and pressure. The cost balance of the PEM fuel cell is given by [18]:

$$c_{H_2O}\dot{X}_{H_2O,P} + c_{air}\dot{X}_{air,P} + c_E\dot{E}_e = c_{air}\dot{X}_{air,R} + c_{H_2}\dot{X}_{H_2,R} + c_{FC,I} \quad (13)$$

Rearranging Eq. (13) for the exergetic power cost (c_E) to find the exergy cost [18]:

$$c_E = \frac{c_{air}\dot{X}_{air,R} + c_{H_2}\dot{X}_{H_2,R} - c_{H_2O}\dot{X}_{H_2O,P} - c_{air}\dot{X}_{air,P} + c_{FC,I}}{\dot{E}_e} \quad (14)$$

The total fuel cell investment cost ($c_{FC,I}$) is given by summation of the fuel cell stack capital cost ($c_{FC,C}$) and the cost rate of operation and maintenance (c_{OM}) [18]:

$$c_{FC,I} = c_{FC,C} + c_{OM} \quad (15)$$

The fuel cell investment cost can be calculated in terms of the power output ($\dot{E}_e$), capacity factor (CF) , i.e., the projected functioning rate, and the annual capital cost (ACC) [18]:

$$c_{FC,I} = \frac{ACC \cdot \dot{E}_e}{CF \cdot 8760(h/year) \cdot 3600(s/h)} \quad (16)$$

Taking the projected functioning rate CF as 90%, the annual capital cost, ACC, can be calculated in terms of the fuel cell stack capital cost and the capital recovery factor (CRF), which can be considered based on the equivalent annual cost over the number of years (n_y) of a specified venture at an annual interest rate (i_r) [18]:

$$ACC = c_{FC,C} \cdot CRF \quad (17)$$

The capital recovery factor can be calculated through the following equation [18]:

$$CRF = \frac{i_r(1+i_r)^{n_y}}{(1+i_r)^{n_y} - 1} \quad (18)$$

Where (i_r) has been chosen to be 10% and (n_y) is five years [18]. CRF is calculated as 0.264/year. The fuel cell capital cost, $c_{FC,C}$, is calculated based on the annual average cost for mass production as 2500 $/kW of power output [19]. The PEM fuel cell parameters and the related costs are shown by Table 1 [15,18,20-22]. Considering the annual operation and maintenance cost (C_{OM}) of 300 $/kW [15], the cost rate of operation and maintenance, c_{OM}, can be calculated as follow [18]:

$$c_{OM} = \frac{C_{OM} \cdot \dot{E}_e}{8760(h/year) \cdot 3600(s/h)} \quad (19)$$

Table 1. Baseline properties of PEM fuel cell for exergoeconomic evaluation.

PARAMETER	VALUE
Standard conditions	298 K, 1 atm
Electrical energy output	1.2 kW
Air stoichiometry	3
Hydrogen cost	10 $/kg
Water cost	1 $/m^3
Air cost (O_2)	0.011 $/kg
Fuel cell cost (capital cost)	2500 $/kW
The capacity factor of the fuel cell	0.9
Fuel cell lifetime	5 years
Average annual interest rate	10%
Annual operation and maintenance cost	300 $/kW yr

3. Experimental setup

Both the exergy and exergoeconomic analyses use data from experiments performed in a Ballard Nexa model fuel cell stack system consisting of 47 cells capable of generating 1.2 kW DC power output with 48% efficiency at 65°C. Each cell produces 1.0 V and 0.6 V at open-circuit and maximum current output, respectively. The stack voltage is 43 V and 26 V at no load and full load, respectively. The fuel is 99.99% hydrogen, maintained by the control system at 0.3 bar. The reactant oxygen comes from the ambient air, which pressure is maintained at 0.1 bar and humidified by a built-in humidifier. The area of the cells is 120 cm^2. The fuel cell stack specifications are shown by Tab. 2.

Table 2. Fuel cell stack specifications.

DOMAIN	PARAMETER	VALUE
Performance	Rated power	1.2kW
	Dissipated heat at rated power	1.6kW
	Idle/full voltage at rated power	43 V / 26 V DC
	Operating voltage rate	22 V to 50 V
	Input voltage allowable	18 V to 30 V
	Current at rated power	46 A DC
	Number of cells	47
	Lifetime	1,500 hours
Reactant	Hydrogen (dry)	99.99%,
	Pressure range of hydrogen	0.7 to 17 bar
	Hydrogen consumption	<18.5 L/min
	Process Air	≤ 90 L/min
	Air pressure	atm
Operating environment	Ambient temperature	(3°C to 40°C)
	Maximum stack temperature	65°C
	Humidity	5% to 95%
Product	Pure water (vapour and liquid)	0.870 L/h
Physical	L x W x H	56 x 25 x 33 cm
	System mass	13 kg

4. Results and discussion

The results presented in this section were obtained considering fuel cell operation along 5 years (Tab. 1) without the need of replacement, corresponding to 39,420 h of operation according to Eq. (16). This is based on a previous report that the polymer membrane of a PEM fuel cell can exceed 40,000 h of operation at harsh conditions [22]. Thus, the manufacturer's declaration of 1,500 h lifetime (Tab. 2) and the need of capital reinvestment each time this limit was reached along the evaluation period have not been part of the calculation.

4.1. Exergy analysis

Figure 2 illustrates the energy and exergy efficiencies of the system. While the exergy efficiency was calculated using Eq. (1), the energy efficiency was determined by the ratio of the fuel cell electrical power output and the inlet hydrogen energy content given by the product of hydrogen high heating value and its mass flow rate. It can be observed that both the energy and exergy of the fuel cell system decrease as the current density increases. The energy efficiency varies between 37 to 56% and the exergy efficiency ranges from 26 to 39% as the current density is changed from 0.02 to 0.37 A/cm^2. This behaviour is due to the increase of reactant air and decrease of hydrogen pressure with increasing current density (Fig. 3). The maximum energy efficiency here found is 9% lower compared with the fuel cell manufacturer datasheet, while the exergy efficiency is 3% lower compared to values reported by other authors [23]. The ambient air conditions may have been determinant to the discrepancies.

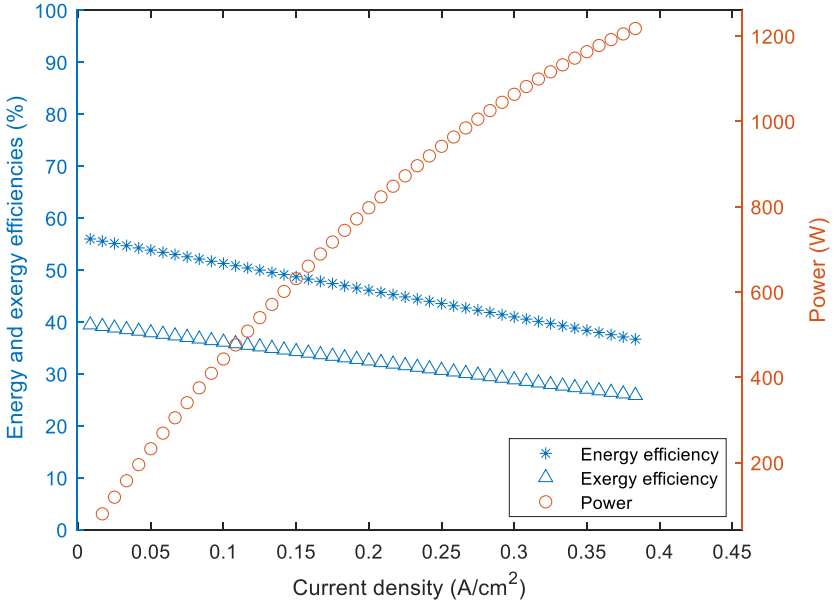

Figure 2. Variation of fuel cell output power, energy and exergy efficiencies with current density.

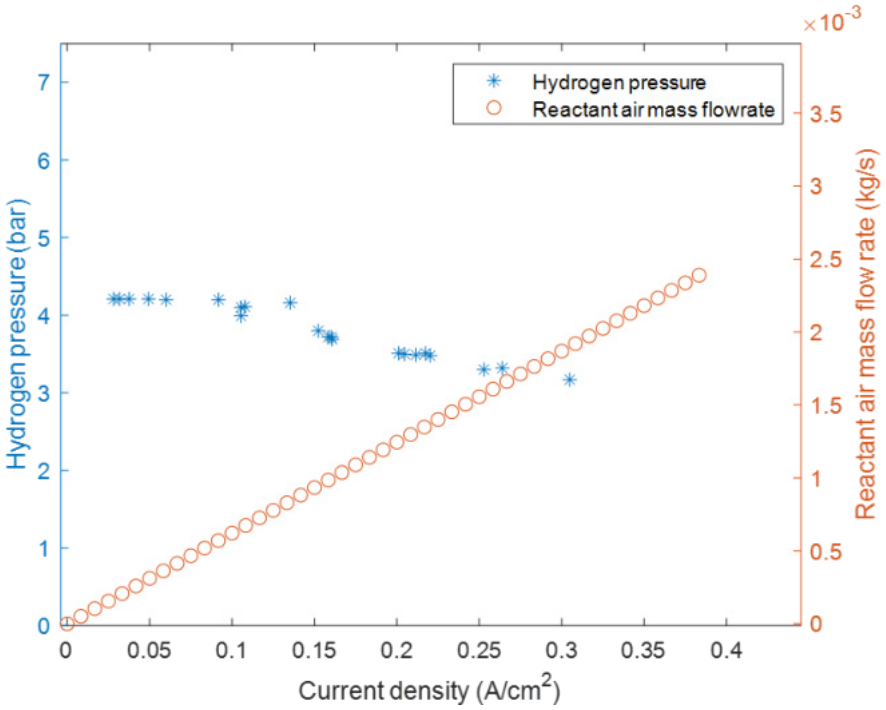

Figure 3. Variation of fuel cell hydrogen pressure and inlet air mass flow rate with current density.

Figures 4 and 5 show that the physical exergy of the flow stream through the fuel cell increase with both temperature and pressure ratios, though with different patterns. Higher temperature ratios intensify the growth of the physical exergy (Fig. 4), while, with increasing pressure ratio, the growth of physical exergy tends to be less intense (Fig. 5). Higher temperatures increase the diffusivity of the reactants and improve ionic conduction of the membrane, but they also lead to greater evaporation of water and, therefore, drying of the membrane and reduced conductivity [24]. The fuel cell system here considered has a humidity exchanger, therefore water vapour in the reactant gases balances the drying effect of temperature. On the other hand, increasing pressure benefits performance as this increases the diffusivity of the reactant gases, facilitating mass transport to the electrodes. The fuel cell humidity exchanger minimises the diffusion of product water into the membrane by the pressure gradient towards the anode, as the product water is used to humidify the inlet air.

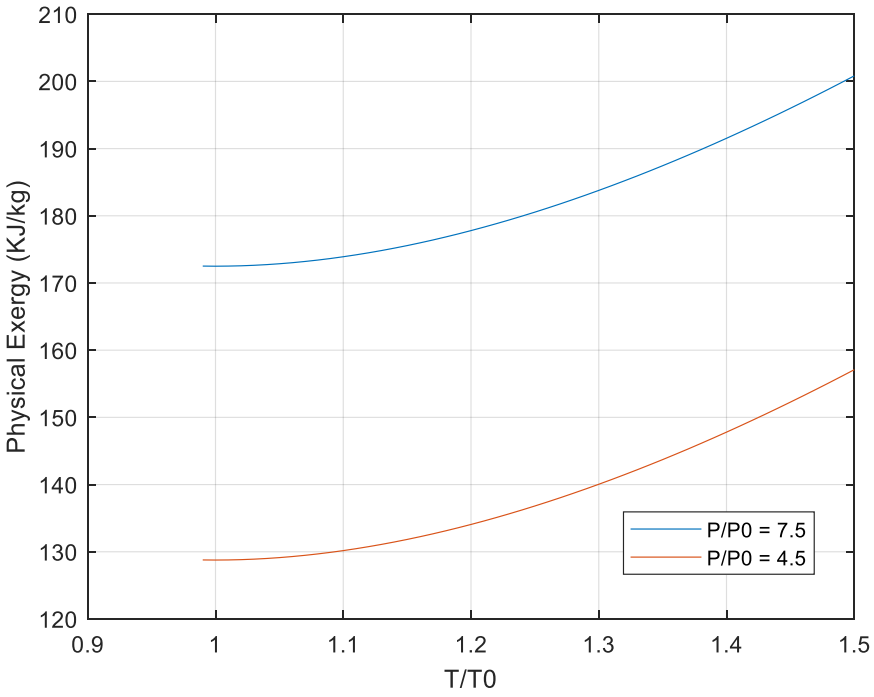

Figure 4. Variation of fuel cell physical exergy with temperature ratio.

The physical exergy of product water is shown by Figs. 6 and 7, as it varies with temperature ratio and pressure ratio, respectively. The increase of product water helps the reactant air to attain an ideal temperature without the need to operate at low pressure as it is heated when flowing through the compressor, thus evaporating the water to be used by the humidifier. The absence of an internal humidifier could lead to nonattractive options such as lowering the temperature, which increases losses, lowering air flowrate and hence the air stoichiometry, which would reduce the cathode performance, or increasing pressure, which would increase the auxiliary power to run the compressor [25]. Furthermore, the humidification of reactants favours the conduction of hydrogen ions in the membrane. Water content dramatically influences the membrane conductivity, and it is vital to transport the reactants and the reaction kinetics in the electrode. If water diffusion between the cathode and membrane is insufficient to keep the membrane hydrated, the ohmic losses in the membrane at high current density can cause a significant fraction of the cell voltage loss. Consequently, to minimise ohmic losses, the hydrogen flow must also be humidified [26].

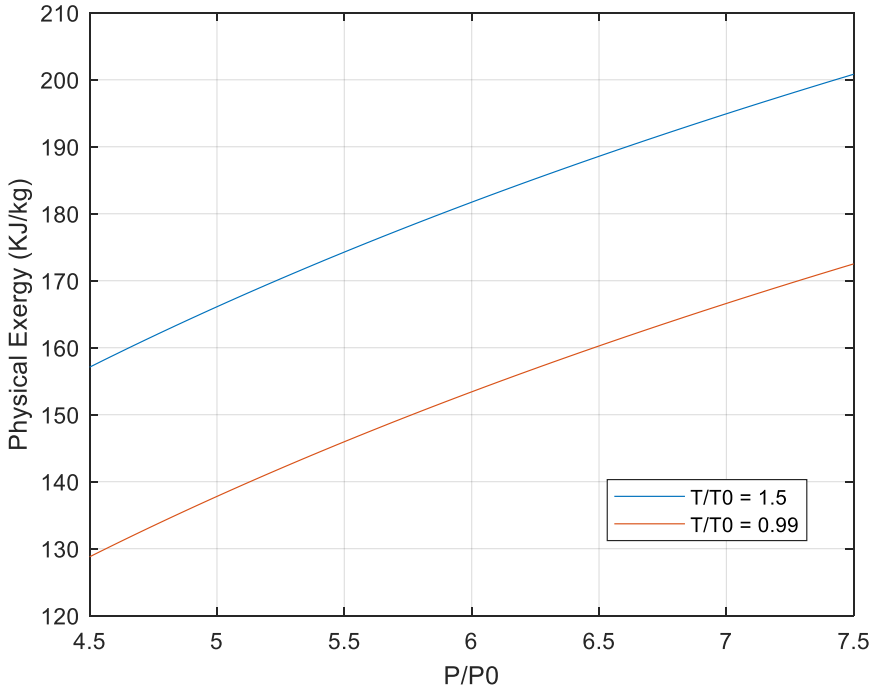

Figure 5. Variation of fuel cell physical exergy with pressure ratio.

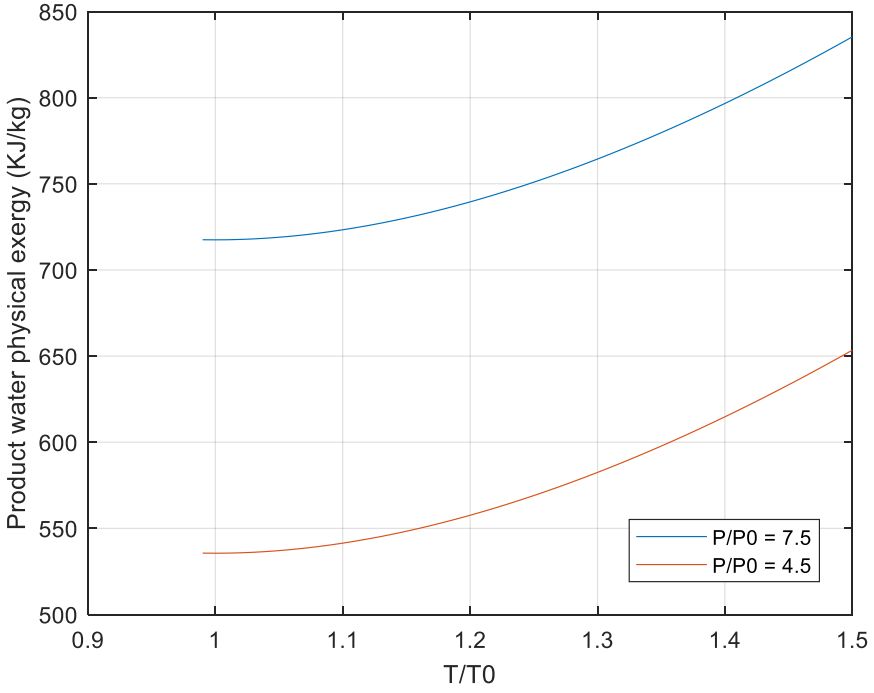

Figure 6. Variation of product water physical exergy with temperature ratio.

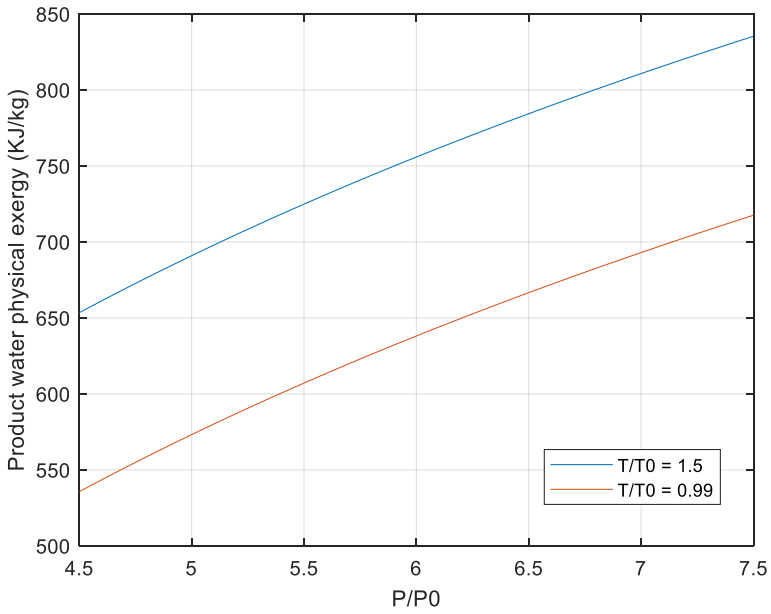

Figure 7. Variation of product water physical exergy with pressure ratio.

4.2. Exergoeconomic analysis

The exergoeconomic analysis considers the exergy cost of all reactants and products for the electrochemical process in the system at various operating conditions, such as temperature, pressure, cell voltage and inlet air stoichiometry (λ). The analysis was performed for cell operation from 0.55 V to 0.85 V, air stoichiometry ranging between 2 and 4, pressure ratio from 4.5 to 7.5, and temperature ratio ranging from 0.99 and 1.5. The capital recovery factor CRF was calculated by Eq. (18) as 0.244 per year. The fuel cell cost could range from as high as 9000 \$/kW to as low as 300 \$/kW for mass production, from which an average value of 2500 \$/kW of power output was used in this analysis. The exergy cost of the fuel cell system is not significantly affected by temperature and pressure variation, as shown by Fig. 8, staying in the range of 115.46 ± 0.01 \$/GJ.

Since hydrogen costs are expected to decrease dramatically over the next decade due to production, distribution, equipment and component manufacturing scale up, the estimated hydrogen price in 2030 was assumed to be 1.9 \$/kg to build the results of Fig. 9, representing a drop of 71.6% to the current hydrogen price of 6.7 \$/kg used in the exergy cost analysis of Fig. 8 [27]. The predicted hydrogen price will reduce the exergy cost by about 14.3 \$/GJ, corresponding to a relative decrease of 12.4% compared with today's price. These results reveal a long way to go to decrease hydrogen price in order to obtain a significant improvement on the fuel cell exergy cost. Anticipated lowering of capital cost due to production of electrodes, membranes and catalyst layers at a mass scale may further reduce the fuel cell exergy cost [28,29].

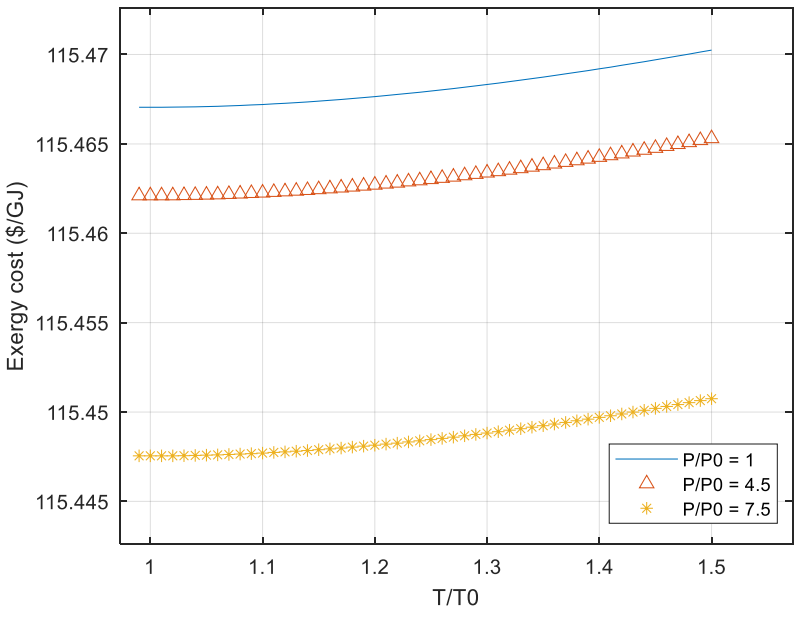

Figure 8. Variation of fuel cell exergy cost with temperature and pressure ratios, at current hydrogen cost.

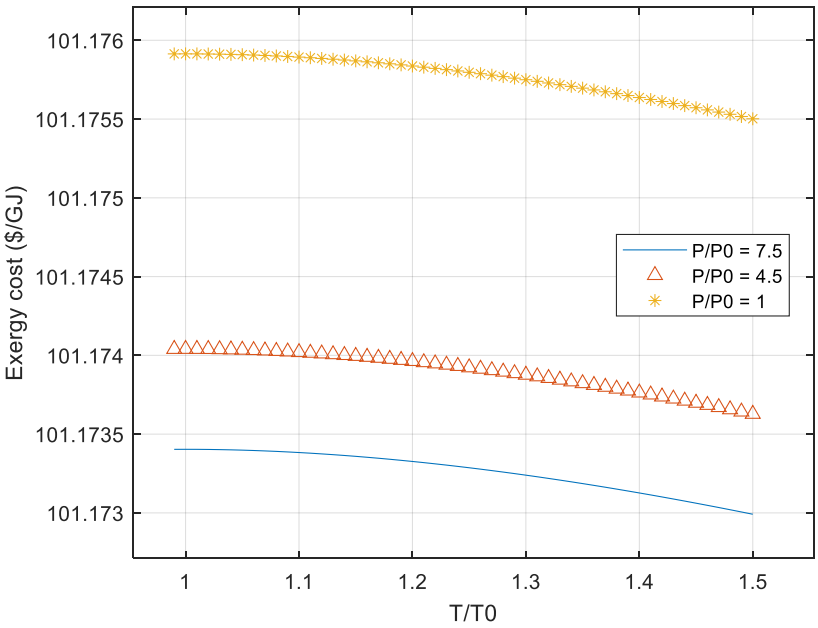

Figure 9. Variation of fuel cell exergy cost with temperature and pressure ratios, at estimated 2030 hydrogen cost.

An improvement of 35 $/GJ can be achieved by operating at a higher stoichiometric ratio (λ = 4) rather than using the recommended ratio of λ = 3, as shown by Fig. 10. In opposition, a similar increase of exergy cost will occur if operating at the lower stoichiometric ratio of λ = 2. However, one should be extremely careful in setting up the air stoichiometry higher than the recommended range because, at high fuel cell operating temperature and air stoichiometry, the relative humidity of the product air will be lowered. Hence, a higher risk of the cells dehydrating could occur, causing a sharp decrease in the system's efficiency [25,30].

The fuel cell system voltage can also play a key role in its exergy cost, as Fig. 11 shows. The cost can be lowered from 115.5 $/GJ to 108.40 $/GJ if the cell voltage is increased from 0.56 V to 0.6 V. The lower the cell voltage, the higher will be the mass flow rates required for reactants and the products to operate the system to produce the desired power output thus leading to lower exergetic efficiency and higher exergy cost. Changes in the exergy cost of the fuel cell system from various operating temperatures are negligible (see Fig. 8), as opposed to the effect of various cell voltages. However, it should be noted that PEM fuel cells are regarded as a low-temperature systems (up to 65°C) in comparison with other fuel cell types such as solid oxide fuel cells or molten carbonate fuel cells. For these fuel cells, the operating temperatures should play a more significant role to exergy efficiency and costs [25].

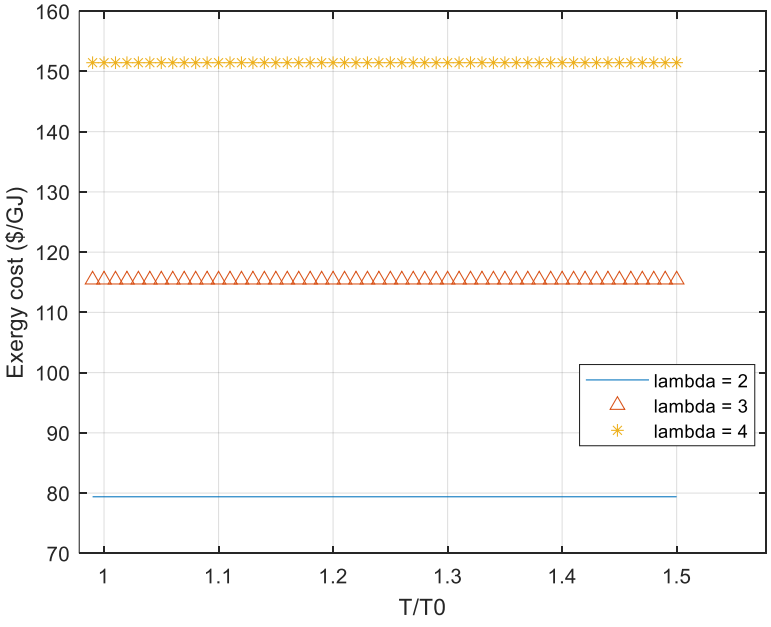

Figure 10. Variation of exergy cost with temperature and air/fuel stoichiometric ratios (V= 0.56 V, P/P_0 = 1).

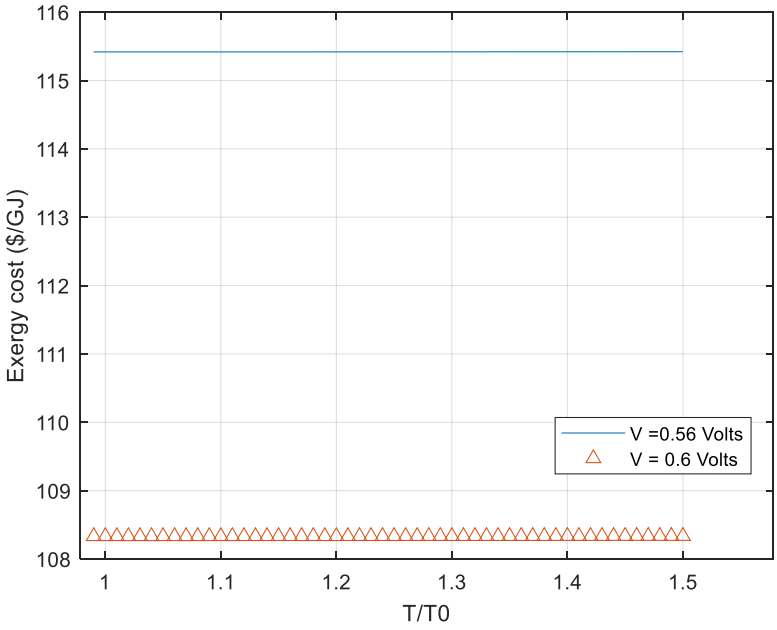

Figure 11. Variation of exergy cost with temperature ratio and voltage (λ = 3, and P/P_0 = 1).

5. Conclusion

This work revealed that the PEM fuel cell and product water physical exergies can be improved with increased operating temperature and pressure. However, operation at high temperatures is limited by excessive water evaporation with consequent drying of the membrane and, thus, reduced conductivity, while operation at increased pressure will require higher power demand by the compressor. High product water exergy benefits membrane conductivity and cathode performance as water evaporated during the air compression process can be used to humidify the membrane and enhance its conductivity. The operating temperature and pressure had negligible effect on the exergy cost, but it can significantly be affected by hydrogen price, air/fuel stoichiometry and operating voltage. An estimated reduction of just over 70% on the hydrogen price by 2030 will produce a decrease of the exergy cost by about 12%. Increasing the air stoichiometry by a third of its recommended value can reduce the exergy cost by 30%, but there are imposed limitations on this strategy by the risk of cell dehydration causing loss of efficiency. Operating voltage increase by 7% can produce a reduction of exergy cost by a similar rate. As overall recommendation, the fuel cell exergy cost can noticeably be improved by adopting a combination of higher inlet air stoichiometry and cell voltage, while more emphatic enhancement will be achieved by lowering the capital cost, annual operation and maintenance cost and hydrogen price.

Nomenclature

ACC	annual capital cost, US$
c	cost, US$
CF	capacity factor, dimensionless
CRF	capital recovery factor, dimensionless
$\dot{E}_{aux}$	auxiliary load, kW
$\dot{E}_e$	electrical power output, kW
$\dot{E}_{ext}$	external load from reactant consumption, kW
ex	total exergy transfer per unit mass, kW/kg
ex_{CH}	chemical exergy per unit mass, kW/kg
ex_{PH}	physical exergy per unit mass, kW/kg
$\dot{E}x$	exergy, kW
F	Faraday's constant (96,485 C/mol)
h	specific enthalpy, kJ/kg
i_r	annual interest rate, dimensionless
I_{fc}	fuel cell stack current, A
I_m	measured current, A
$\dot{m}_{H_2}$	hydrogen mass flow rate, kg/s
n_{H_2}	number of moles of hydrogen consumed per mol of oxidant in the reaction, mol
n_y	number of years, dimensionless
N	number of cells in the stack, dimensionless

P pressure, kPa
s specific entropy, kJ/kg.K
T temperature, K
V_{fc} fuel cell stack voltage, V
V_m measured voltage, V
x_n mole fraction of component n, dimensionless

Greek symbols

η fuel cell efficiency, %

Subscripts and superscripts

Abstract:

To mitigate climate change, a stronger reliance on renewable energy sources is foreseen, and Power-to-Hydrogen systems can be adopted to minimize curtailment losses derived from the intermittent nature of wind and solar power. Among different alternatives, alkaline water electrolysis is the most mature process for hydrogen production using sustainable electricity as its main energy source. The mathematical modelling of the alkaline electrolysis process is a crucial tool to improve green hydrogen production, energy conversion efficiency, sizing (model-based design) and thermal energy management. Although several studies have investigated alkaline electrolysis modelling, these analyses often neglect property variations along the stack area and its economic implications. In this work, the need for increasing the modelling complexity in system models by introducing a one-dimensional model of the alkaline electrolyzer cell/stack is investigated. With this, several operation parameter variations can be modelled, and among these, the internal temperature variation plays a crucial role in both technical and economic aspects. Results show that efficiency could vary between 58-70% while the Levelized cost of hydrogen is within the range of 1.3-1.6 €/kg, when various inlet-outlet temperature differences are considered. Furthermore, from both technical and economic aspects, the optimal temperature control of alkaline electrolysis is to maintain a very low-temperature difference (~1°C), from inlet to outlet, controllable with the alteration of the electrolyte flow rate.

Keywords:

Power-to-Hydrogen, Alkaline electrolysis, Temperature control, Levelized cost of hydrogen, Hydrogen production.

1. Introduction

The mitigation of the effects of climate change can be achieved through the integration of renewable energy sources into the electricity grid. However, the intermittent nature of these sources necessitates the use of storage and management mechanisms. One solution is the implementation of Power-to-X technologies, which involve the conversion of excess renewable electricity into other forms of energy that can be stored and utilized when needed. This facilitates the integration of intermittent renewable energy sources into the grid and supports the transition to a low-carbon energy system.

Water electrolysis can be divided into categories based on operating temperature: low-temperature electrolysis, working below 120°C, and high-temperature electrolysis. Among these technologies, alkaline water electrolysis, which utilizes a liquid electrolyte and Nickel-based catalysts, is the most mature and economically viable solution. However, it has lower efficiency and a limited current density range, as well as a constrained dynamic operating range [1].

Experimental investigation and modeling are essential tools for understanding the water electrolysis process. Based on the assumptions adopted, models can be classified as either data-driven or physical ones. Data-driven models rely on the mathematical treatment of experimental data and their parameters do not have a physical meaning, while pure physical models are based on the underlying physics of the electrolysis process

and all parameters have physical meanings. These models can be used to expand understanding of hydrogen production, energy conversion efficiency, sizing, thermal energy management and optimization.

The most known data-driven alkaline water electrolysis model is developed by Ulleberg [2], where the polarization curve, i.e., variation of voltage due to the current density through the alkaline cell, is modelled through six parameters. Several other researchers carried on this pathway, indeed Busquet et al. [3] carried on with the same approach using four parameters, while Ursua et al. [4] developed a sixteen parameters-based model. Since parameters are evaluated through experimental data, they can vary significantly even due to a slight variation of input data. Furthermore, more are parameters to be assessed, and more experimental variations are needed to generate unique data points. Indeed, with Ulleberg's model [2], the curve fitting requires following a seven-step procedure. Not to mention that these parameters do not have a physical meaning, thus is arduous to have a range estimation of these numbers.

As regards physical models, Hammoudi et al. [5] employed a multi-physical approach using Matlab Simulink® to carry out the physical model, considering both geometry and operating condition influence. They subsequently expanded this approach by coupling MATLAB-Simulink-SimPowerSystems®, validated using a Hydrogen Research Institute electrolyzer [6]. Such models can consider many aspects of the electrolysis process, however, but a high number of unknown physical parameters are needed, which are not easily achievable.

Both approaches have their opportunities and limitations, indeed, are applied to different cases of applications. Where at the system level. Fast and repeatable iterations, for a different set of operating conditions, are required, hence the data-driven models, once characterized are the most suitable ones; conversely, as for stack-level design, physical models are most suitable.

The temperature highly influences the operating conditions of the alkaline electrolyzers. To maintain it within the opportune range, several techniques can be used to control it. One approach is to use the water flow rate within the liquid electrolyte to maintain the desired temperature, such that the heat generated by the cell is efficiently dissipated or absorbed. When considering the techno-economic performance of an alkaline electrolysis system, it is crucial to carefully analyze the impact of temperature on the overall efficiency and cost of the system. For instance, Jang et al. [7] have built a model assessing electrolyte flow rate, needed as a temperature control measure, using a polynomial correlation, proposed by the same authors, based on temperature and current density, analyzing effects at various temperature differences, between inlet and outlet, of 1-3-5-10°C.

This work aims to cover the research knowledge gap by understanding the temperature dependencies of the alkaline electrolyzer system, solving the temperature evolution along the cells, and hence within the electrolyzer, based on a validated zero-dimensional/lumped model, extended to a one-dimensional model solving for mass and energy conservation, obtaining the electrolyte flow rate information by the physical meaning of the water electrolysis process, allowing to unlock the assessment of system performance at any temperature difference.

The main contributions of this work are the following:

- Propose and validate, with literature data, a semi-empirical alkaline water electrolysis model with four parameters, which can be applied to different types of electrolyzers.
- Formulation of a one-dimensional water electrolysis model, based on the physical process, solving ordinary differential equations. Which can assess the evolution of all operating parameters, such as temperature and pressure, illustrating its comparison with other dimensions models.
- Techno-economic assessment of the temperature control, by the sense of heating mass (electrolyte flow rate) variation, at a continuous range of gap temperatures.

The paper is structured as follows: Section 2 describes the methodology adopted in this work, highlighting the proposed semi-empirical model, validated and extended to a one-dimensional model, while Section 3 describes the results obtained and finally the conclusion of the work is reported in Section 4.

2. Methods

In this section, firstly a novel data-driven model, for Potassium Hydroxide (KOH) electrolyte-based alkaline electrolysis modelling, is proposed. Secondly, the model has been fitted with empirical data provided by literature, where four distinct datasets have been tested; Furthermore, the extension into the one-dimensional model, solving ordinary differential equations of mass, and energy balancing, has been discussed, concluding finally the indicators adopted for the technical and economic comparison of the work.

2.1. Alkaline electrolyzer modelling

Despite different assumptions and refinements present in alkaline electrolyzer modelling, they share the same goal, which is to describe accurately the polarization curve, indeed it is the curve which underlines the voltage (V_{cell}) variation due to the fluctuations of the current density (j), and it can be described with the following equation:

$$V_{cell} = V_{rev} + \eta_{act} + \eta_{ohm} + \eta_{bubble} \quad (1)$$

Where the V_{cell} is the voltage of a single electrolysis cell, V_{rev} is the reversible voltage i.e. the minimum electrical potential to have the electrolysis process going, η_{ohm} the ohmic overvoltage comprising both electrolyte and electrodes overpotential, η_{act} the activation overpotential of both electrodes and finally η_{bubble} is the overpotential, caused by bubble formation from liquid electrolyte.

Each term of the equation (1). can be modelled in different ways, based on the approach and researchers' decisions. It was found that almost all commercial alkaline electrolyzers adopt bipolar electrical configuration, meaning the cells are electrically connected in series since it allows to have higher utilization of the cell area, as reported in [8], therefore the whole electrolyzer has the same current of the cell level, while the overall voltage of the stack is the sum of all the cell's voltages. Furthermore, the polarization curve provides insights into hydrogen production as well as conversion efficiency.

The proposed model describes the polarization curve as follows:

$$V = V_{rev} + \left(\frac{1}{\alpha}\right)\frac{RT}{2F} ln\left(\frac{j}{j_0}\right) + j \cdot \left(\frac{\delta_{el}}{\sigma_{el}}\right) \quad (2)$$

$$j_0 = B \cdot \exp\left(-\frac{E_a}{RT}\right); \ln(j_0) = \ln(B) + \left(-\frac{E_a}{R}\right) \cdot \frac{1}{T} \quad (3)$$

Where V_{rev} can be assessed using the Nernst equation, which changes based on electrolyzer operating conditions, as reported in [9]. While for σ_{el}, using KOH electrolyte, is assessed through the empirical equation investigated by experiments performed by Gilliam et al.[10], and finally j_0, exchange current densities for both electrodes can be described through the Arrhenius equation.

Thus, four parameters remain to be estimated through the alkaline electrolyzer operating data. They are respectively: α, $\ln(B)$, $\left(\frac{E_a}{R}\right)$ and δ_{el}. Furthermore, several simplifications have been made to obtain a simple and versatile for different types of electrolyzers. Indeed, (i) both electrodes' activation overpotentials are grouped with a single Tafel equation, (ii) both diaphragm and electrolyte ohmic overpotential are grouped, due to the lack of information on the diaphragm material composition and experimental correlation, and finally (iii) the bubble formation overpotential, since its effects on activation overpotential are reduced the activation area and changes in electrolyte ionic conductivity, both effects are implicitly taken into account thanks to the parameter-estimation, through the electrolyzer operating data.

2.1.1. Model validation

The proposed model is further tested and validated, using the experiments presented in the literature by different researchers, to represent different types of alkaline electrolyzers with different set-ups of operating conditions. Such operating conditions are namely i) temperature, ii) KOH concentration, and iii) pressure. Additionally, the model's robustness, i.e. its ability to have reasonable accuracy, dealing with the minimum quantity of the data available, has been also tested.

The procedure of calibration of the model, based on the type of the electrolyzer with its results, is illustrated in Figure 1, which can be divided into 3 phases:

- Experimental data processing, ensuring at least 6 data points are present, ensuring a good accuracy of the model. If more data is available, they can be also included, however, not all available data should be used, to prevent the over-fitting problem.
- The pre-processed data is then inserted into a curve-fitting framework, commonly used ones are Matlab and Python adopting the proposed model, assessing 4 calibrating parameters ($\delta_{el}, \alpha, \ln(B), -E_a/R$),
- As a consequence of the previous step, the model is now defined, and as such, polarization curves at temperatures, different from the ones used to calibrate the parameters can be obtained and used as validation data.

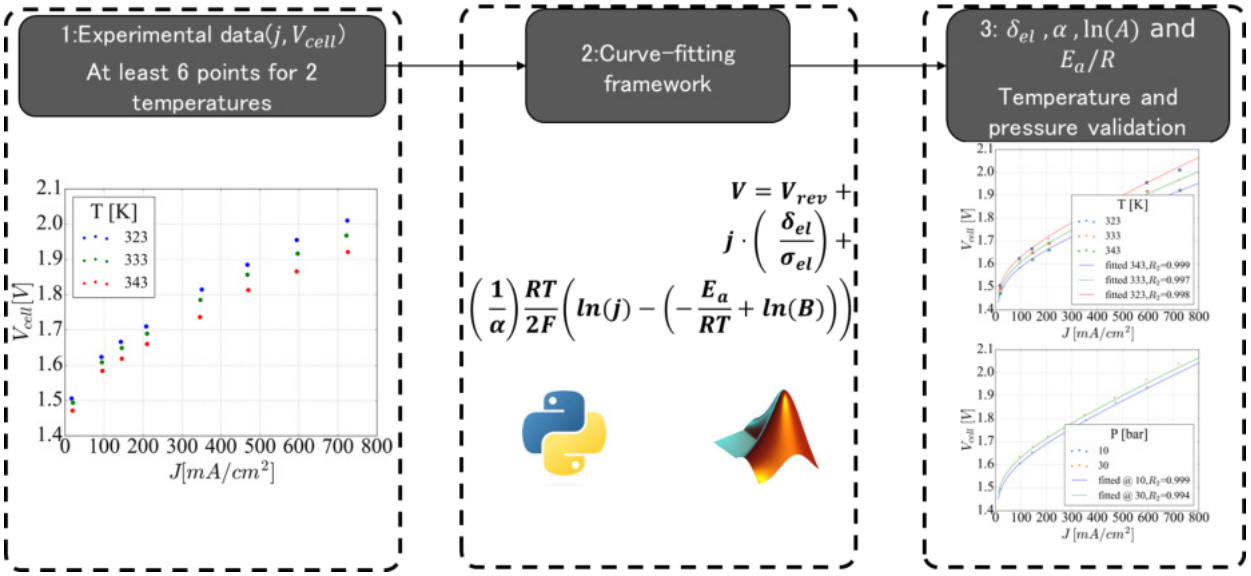

Figure 1. Parameters estimation procedure. Divided into three phases: 1) collection of experimental data at different temperatures, 2) parameter estimation and 3) temperature and pressure influence validation.

2.1.2. Extension of lumped model: one-dimensional model

The proposed model, describing the water electrolysis at the single cell level, can be called a zero-dimensional model/lumped model, in the sense that it assesses the performance of the cell with only a single set of operating conditions, meaning no variation of i) temperature ii) pressure and iii) KOH concentration along e.g. the flow direction and the temperature is considered.

It is possible to extend the lumped model to a half-dimensional model, where two sets of operating conditions are considered, namely inlet and outlet ones. However, this approach has an evident drawback, which is the need for information in advance about the outlet conditions, which is not always available, but can be assumed through e.g. a linear variation of parameters along the stack e.g. current density.

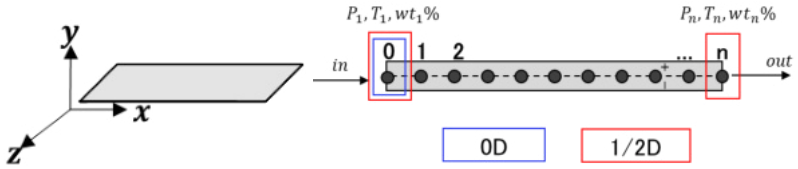

Figure 2. Alkaline electrolysis cell models. With the x-axis as the flow direction.

Therefore, in this study, such a model is further extended into a one-dimensional model, obtaining a complete cell performance evaluation (Figure 2), as an extension of zero-dimensional and half-dimensional ones, which can be applied also to stack-level once defined the electrolyzers cells interconnection, that for this study, bipolar configuration, i.e. cells electrically connected in series, is adopted, as illustrated by Figure 3.

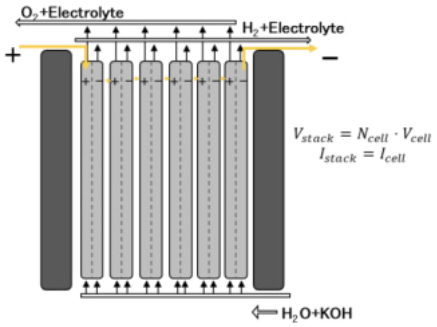

Figure 3. Alkaline electrolyzer bipolar configuration 1D model.

As a modeling assumption, it is considered that all properties vary only along the flow direction, which is the x axis, ignoring their contribution in other axes, in other meaning:

$$\frac{d\Gamma}{dy} = 0; \frac{d\Gamma}{dz} = 0 \tag{4}$$

Where Γ represents a generic physical property. The one-dimensional model proposed uses discrete element modeling, solving differential equations, wherein each element (i), molar flow rate ($\dot{n}_{H2}$), and temperature (T) are solved:

$$\frac{d\dot{n}_{H2}}{dx} = \frac{J_i}{2F} \cdot \Delta \tag{5}$$

$$\frac{dT}{dx} = \frac{(V - V_{th}) \cdot J_i}{\dot{n}_e \cdot Cp_e + \dot{n}_{H2} \cdot Cp_{H2} + \dot{n}_{O2} \cdot Cp_{O2}} \cdot \Delta \tag{6}$$

$$i = 0,1,2,3 \dots n; \Delta = \text{const} \tag{7}$$

While different parameters are defined in the nomenclature at the end of the paper, such equations represent the molar mass, and energy balance along the x-axis, where Δ represents the cell width (cell dimension in z-axis), which is constant. While for the standard chemical species, their thermodynamical properties, like specific heat (Cp) can be consulted or calculated using the well-known empirical equations from the database of NASA [11]. The electrolyte, composed of water and a certain mass fraction of KOH, its thermal properties can be assessed using empirical formulas reported in the [12], obtained as results of experiments, where for this study, Zaytsev empirical relationship has been used [13]:

$$Cp_{el} = k_1 + k_2 \ln\left(\frac{T_{\circ C}}{100}\right) + (k_3 + k_4 \cdot wt + 8 \cdot T_{\circ C}) \cdot wt \tag{8}$$

With the obtained Cp_e is expressed in [J/kg K], to converted into [J/mol K] using the following equation:

$$Cp_{e,mol} = Cp_e \cdot M_e \tag{9}$$

$$\sum \frac{wt_i}{M_i} = \frac{1}{M_{tot}} \sum \frac{n_i}{n_{tot}} \cdot \frac{M_i}{M_i}; M_{tot} = \frac{1}{\sum \frac{wt_i}{M_i}}; \; M_e = \frac{1}{\frac{wt}{M_{KOH}} + \frac{(1-wt)}{M_{H2O}}} \tag{10}$$

$$wt = \frac{m_{KOH}}{m_{KOH} + m_{H2O}} \tag{11}$$

The flowchart of the proposed 0D model, extension to the 1D cell model, and finally into the 1D stack model, is illustrated in Figure 4.

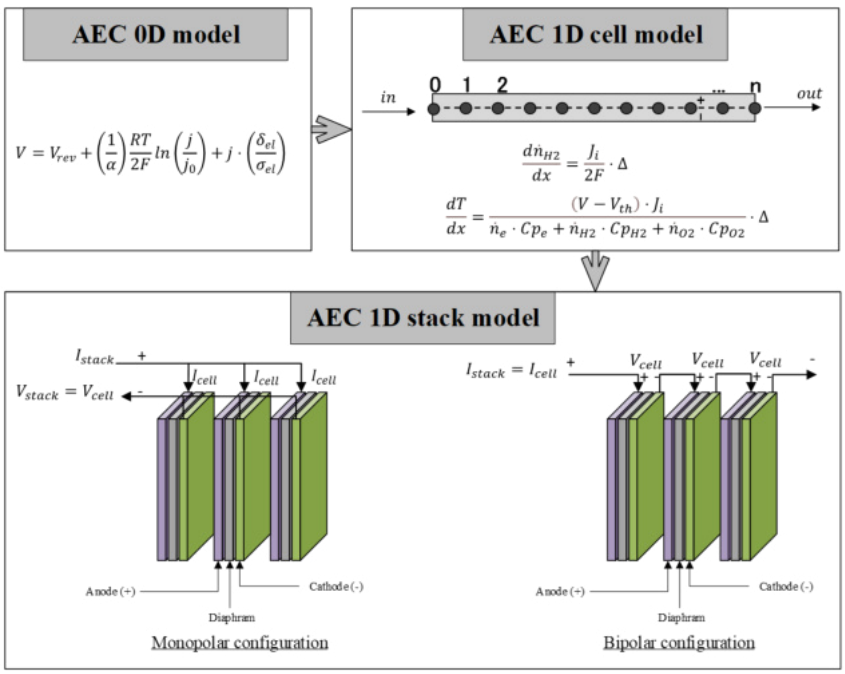

Figure 4. Alkaline 1D stack model flowchart. Starting with the single cell 0D model, extended to 1D cell model, solving mass and thermal balance, and finally 1D stack model, based on the electrical configuration among cells.

2.2. Technical and economic comparison

To have an overview of different models' comparison, in terms of both technical and economic perspectives, the assumption of having inlet and outlet temperature is the same for all models, whereas the 0D model considers only the inlet temperature.

$$\text{0D: } T_{inlet}; J = J_{inlet} = f(T_{inlet}, V, wt, p) \tag{12}$$

$$\text{1/2D: } T_{\text{inlet}}, T_{outlet}; J = J_{avg} = \frac{J_{inlet} + J_{outlet}}{2} \tag{13}$$

$$\text{1D: } T_i; i = 0, \dots n; J = J_{avg} = \frac{\int J_{i} \cdot dx}{n \cdot \Delta X} \tag{14}$$

$$Area = x \cdot width; x = 0, 1 \cdot \Delta x \dots, n \cdot \Delta x \tag{15}$$

Furthermore, for the technical comparison among different models, since the temperature-controlling components are included in this analysis, namely heat exchangers and pumps, the interconnection of these parts with the electrolyzer is described in Figure 5. Where heat exchangers, have the objective to cool the outlet electrolyte, warmed up by the inefficiencies, down to the inlet setting temperature. While temperature control can be done by controlling the flow rate of the inlet water, as described in equation (6) and equation (8) the increase of the water flow rate can lower the temperature gap, hence increasing the cell's overall working efficiency, however, with an expense of a higher required power for the electrolyte circulation. The pressure gap is assumed to be equal to 1 bar for the sake of simplicity.

The system integration between alkaline electrolyzer and other components of the plant is illustrated through the flow diagram reported in Figure 5, despite having multiple components present in the plant, not all of them have been modelled in the present study, as they are out of the scope of the objective.

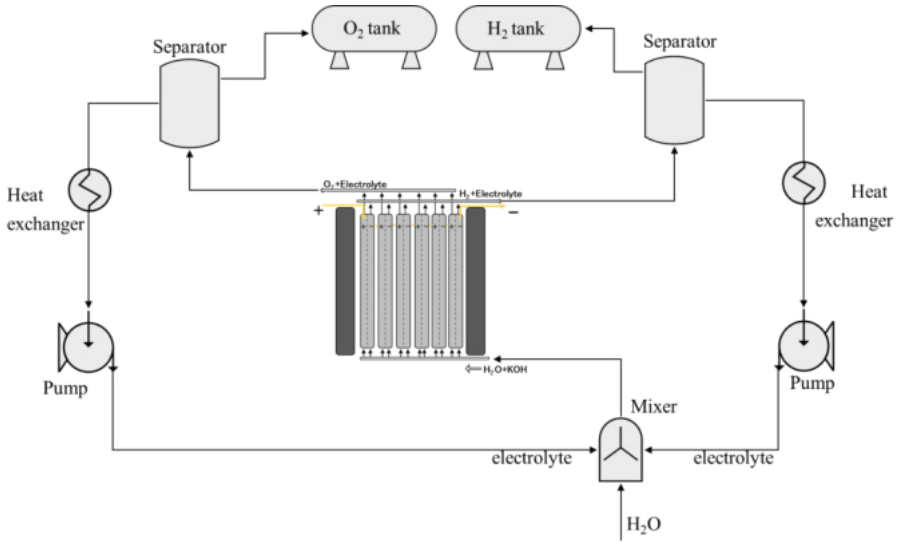

Figure 5. Systems connections. Illustrating auxiliary systems to be coupled with electrolyzer stack.

Indeed, the components that accounted for the evaluation of the temperature control, besides the electrolyzer stack itself, are water pumps and heat exchangers, where their characteristics, used for this work, are reported in Table 1.

Table 1. Model parameters.

Pheobus electrolyzer		Reference
Cell area (m2)	0.25	[2]
#n cells	21	[2]
Operating pressure (bar)	7	[2]
Nominal power (kW)	26	[2]
Unitary cost (€/kW)	830	[14]
Stack lifetime (years)	10	[14]
Water pump		
Efficiency	0.7	[14]
Input power	$P = \eta_{pump} \cdot \Delta P \cdot Q_e$	[-]

Pressure Gap	1 bar	[-]
Cost	60 €/(kg/s)	[14]
Heat exchanger		
Cost (€)	$C = C_1 \left(\frac{A_{HEX}}{0.093}\right)^{0.78}$	[14]
C_1	110 €/m^2	[14]
U (W/m2 K)	700	[14]
ΔT_{HEX} (K)	5	[-]
A_{HEX} (m2)	$A_{HEX} = \frac{\dot{n}_{H2O} \cdot M_{H2O} \cdot Cp_{H2O} \cdot \Delta T_{H2O}}{U \cdot \Delta T_{HEX}}$	[-]
Lifetime (years)	15	[14]
Levelized Cost of Electricity		
€/MWh	20-60	[14]

As evaluation indicators, exploiting the temperature effects, system-level efficiency, and levelized cost of the produced hydrogen are adopted to assess the temperature influence. And these indicators assessment criteria are reported in the following equations:

$$\eta_{tot} = \frac{N_{cell} \cdot \dot{n}_{H2_{cell}} \cdot LHV_{H2}}{P_{el} + P_{pump}} \quad (16)$$

$$LCOH = \frac{CAPEX_{el,a} + CAPEX_{HEX,a} + CAPEX_{WP,a} \cdot + LCOE \cdot E_{elc}}{m_{H2}} \quad (17)$$

Where all investment costs ($CAPEX$), that depend on the nominal size of the technology, are actualized while E_{el} is the electrical energy consumed to produce the m_{H2}.

3. Results & discussions

Different types of results are reported in this section, firstly the results regarding the validation of the novel are illustrated, to be followed with the comparison of different dimensionality of the model, and finally the technical andeconomic analysis of the temperature control effects, are discussed.

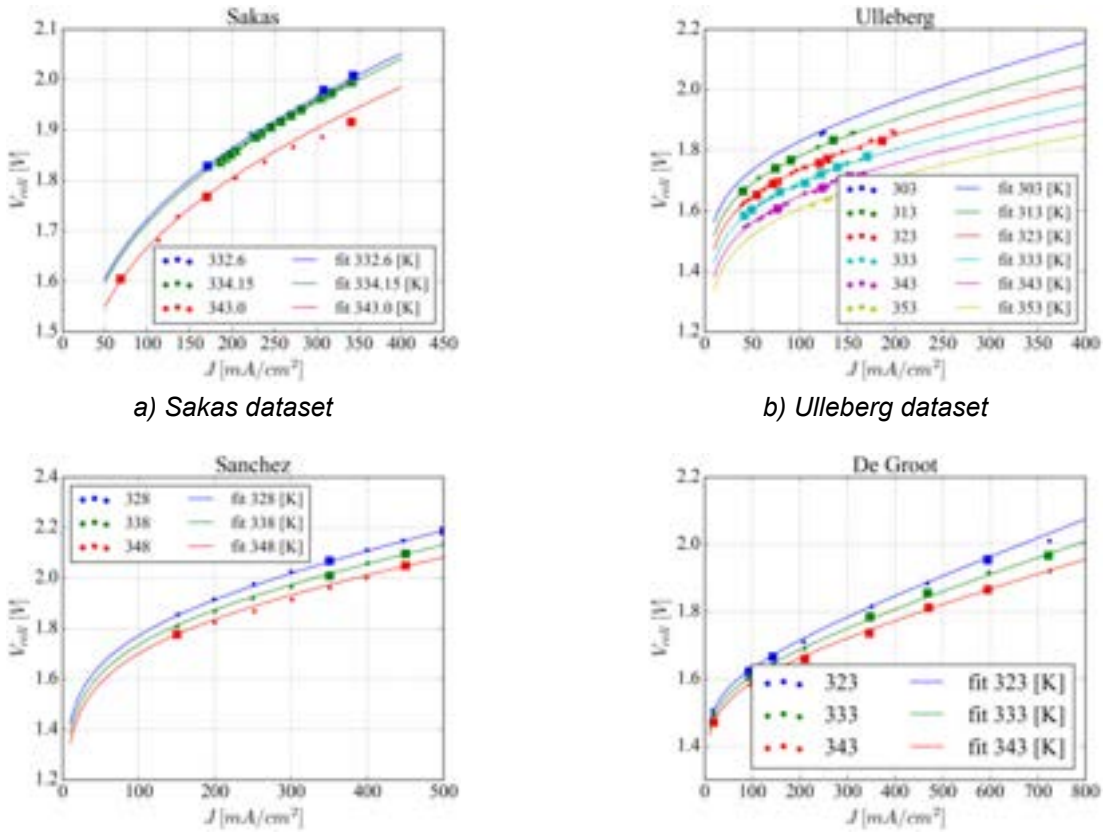
3.1. Ability for the model to fit data

The proposed model proved its validity and robustness; indeed, the results show that only six data points, three data points for each, and two temperatures are needed, to capture the temperature and the current density dependency. Of course, the parameters are strictly dependent on the data points used to estimate them, however, the difference is not significant, and they are listed in Table 2.

Table 2. Parameters for the datasets analyzed.

	Experiments conditions		**Calibrated parameters**				
	p	T	wt	δ_{el}	α	$-E_a/R$	ln(B)
Units	$[bar]$	$[°C]$	$[-]$	$[cm]$	$[-]$	$[K]$	$\left[\ln\left(\frac{mA}{cm^2}\right)\right]$
Sakas [15]	16	59.6-61.15-70	0.25	0.3914	0.1253	-6330	13.11
Ulleberg [2]	7	30-40-50-60-70-80	0.30	0.6637	0.1726	-5331	9.184
Sanchez [16]	7	55-65-75	0.35	0.5711	0.1181	-3592	4.768
Groot [17]	30	50-60-70	0.28	0.2716	0.2764	-3906	3.864

During the parameter estimation process, the dataset is split into two separate datasets. Namely train and test datasets, to prove the model's robustness. Indeed, the training dataset, i.e. the data used to find parameters, is randomly selected, with the only constraint that they need to be at least six data points, from at least two different operating temperatures. The results of the estimation, illustrating the model's wide applicability, are reported in Figure 6.



a) Sakas dataset

b) Ulleberg dataset

c) Sanchez dataset

d)De *Groot* dataset

Figure 6. Parameter estimation and validation with temperature variation. Where squared-dotted data are from the training dataset while the circle ones are from the test dataset.

Whereas the temperature dependence is explicitly highlighted, in activation overpotential, other operating conditions influence, namely KOH weight concentration and pressure are implicitly considered, through the ohmic overpotential and reversible voltage, respectively.

3.1. Accuracy of model dimensionality

The one-dimensional model is controlled by voltage; hence the voltage is an input parameter of the model. Whereas the current density, thus also the hydrogen production is an output data from the model.

The benefit of having a one-dimensional model resides in the possibility to perform analysis at different temperatures, between the inlet and outlet of the cell. Indeed, Figure 7 is reported the results of the 1D model for a 0.30x0.30 m cell, working at 1.8V, with an outlet temperature fixed at 80 °C with different gap temperatures, namely 1-2-10 °C.

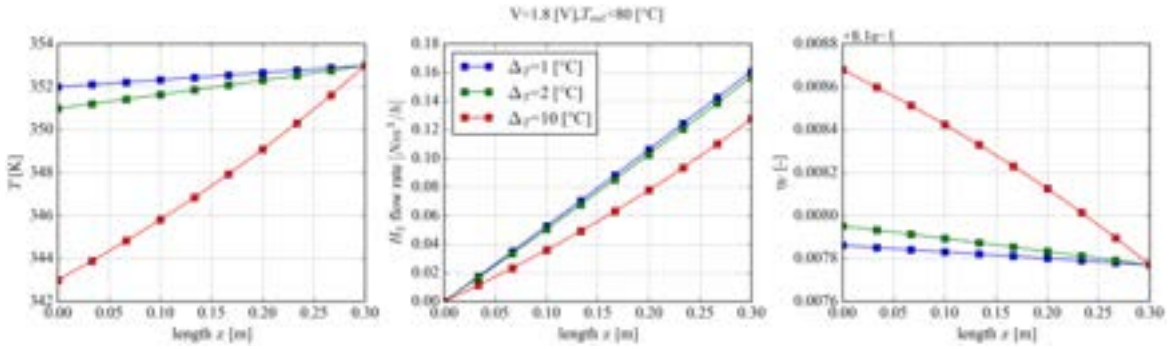


Figure 7. 1D model at 1-2-10 °C temperature difference. Illustrating namely i) temperature, ii) hydrogen production and iii) voltage efficiency along the cell. Where the outlet temperature is kept constant. Despite having a higher temperature difference achieves a higher efficiency, the produced hydrogen flow is lower.

A comparison of the different dimensionality of the model is illustrated in Figure 8. The 1D model is used as a reference, as this is considered the most accurate. The current density at a fixed potential of 1.8 V is compared. This is done at different flow rates of the electrolyte through the stack for cooling, resulting in different temperature increases over the stack.
The comparison shows that the 0D model is always underestimating the current density and thus the hydrogen production rate. The 1/2D model, in contrast, is overestimating the two. Furthermore, with an operating temperature of 80°C (353 K) and voltage of 1.8 V, considering the one-dimensional model as the benchmark, with a gap temperature of 5°C between the inlet and outlet, while the half-dimensional model's deviation is almost neglectable (0.75%), the zero-dimensional model has a significant deviation, underrating about 11% the hydrogen production.

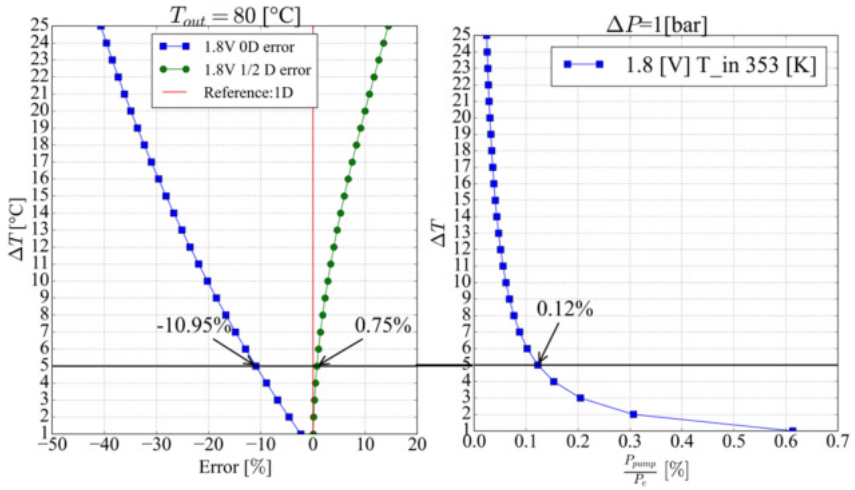

Figure 8. Models' comparison at different temperature increase over the stack. Where error is the difference between the models' average current density, compared with the 1D model's average current density, in percentage.

Regarding temperature effects, with a temperature increase, between the inlet and outlet of the electrolyzer stack, larger than 1°C, the overall efficiency (defined in equation (16)) remains almost constant at a value of 0.69 (Figure 9); and since the model is fixing voltage as input, results are implying that, after such threshold, the influence of the water pump energy consumption, which depends on the water flow rate, required to control the operating temperature, is almost neglectable, compared to the energy absorbed by the electrolyzer.

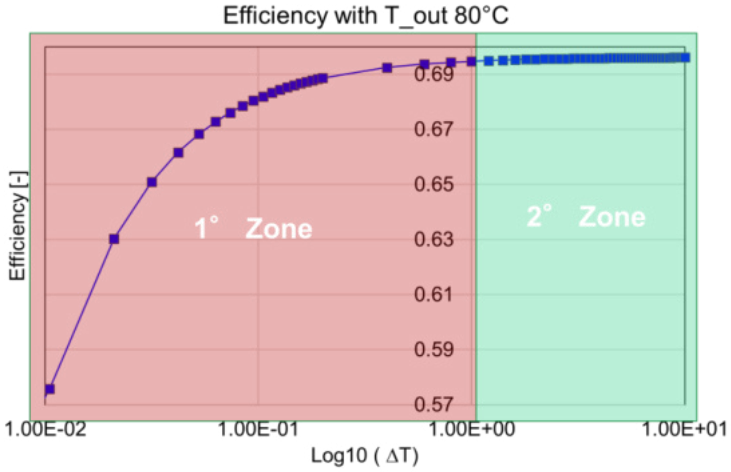

Figure 9. Influence of temperature difference (inlet to outlet) in system efficiency. Where the outlet temperature is set as 80°C.

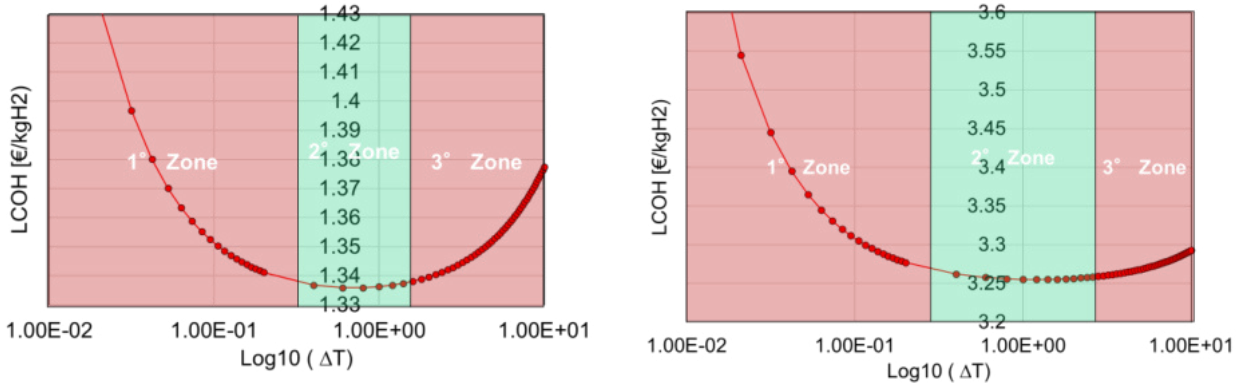
As for the economic aspect, as illustrated in Figure 10, there's a clear zone (2° zone), where the LCOH stays at its minimum level, indeed, such range is around the gap temperature of 1°C, independently from the LCOE adopted, however, with a slope of LCOH (defined in equation (17)) decrease/increase different in two cases. However, the LCOH are higher in the other two zones (1° zone and 3° zone), due to different reasons, while for the 1° zone, the cause is the high operational cost due to the water pump energy absorption, for the 3°

zone instead, is due to a drop in current density, indeed with a higher gap temperature, the overall hydrogen production, results to be lower and lower.



a) LCOH with minimum LCOE *b) LCOH with maximum LCOE*

Figure 10. Influence of temperature difference (inlet to outlet) in the levelized cost of hydrogen. Where the outlet temperature is set as 80°C

There are several limitations of the proposed model. It does not consider the faraday efficiency, because of the lack of an aligned approach to it in literature, furthermore, the water vapor formation has not been properly addressed. Nevertheless, since the objective of the work is to assess the temperature influence and its control, such limitations would not change the discussed results, yet they can certainly be subject to further investigation.

4. Conclusion

In this study, the assessment of the alkaline operating temperature effects and its control, from both technical and economic aspects, has been carried out.

To seize these quantities of the electrolysis process, a novel alkaline cell model is proposed. The model was fitted to various data from the literature and shown to provide good fits for all the considered measurements. The model included only four parameters, which are a combination of the physical parameters as well as empirical parameters describing certain physical phenomena.

Furthermore, after validating the proposed cell model, it has been extended to one-dimensional modelling, based on the finite element approach, including the mass and energy balance, which provides the evolution of different operating parameters along the cell, such as temperature. To understand the impact of model accuracy on system models, a comparison of different model refinements was conducted, i.e. a 0D, 1/2D and a 1D model. The 0D model is significantly underestimating the hydrogen production (-11%), while the 1/2D model has a slight overestimation (+0.75%), as compared to the more accurate 1D model.

Furthermore, the effect of electrolyte rate on the overall efficiency was investigated - both technically and economically. There are clear benefits of increasing the flow rate of the electrolyte to keep temperature increase over the stack close to 1°C.

The efficiency with increasing flow rates will go down, however, remains constant if the temperature increase is kept above 1°C. Economically there is an optimum flow rate, where losses from the pumping of electrolytes and losses in the stack due to higher resistance at lower temperatures are balanced.

Although the global trend of the LCOH does not change, with different values of LCOE (20-60 €/MWh), its value is quite different, where for 20 €/MWh, it can be 1.33-1.43 €/$kg_{H2,}$ alternately, 3.25-3.6 €/kg_{H2} for 60 €/MWh.

Nomenclature

$\dot{n}$	Molar flow rate, mol/s
LHV	Low heating value, J/mol
A	Area, m^2
B	Arrenhius constant, mA/cm^2
$CAPEX$	Capital Expenditure, €
E	Energy, kWh
F	Faraday constant, 96500 C/mol
H	Enthalpy, J/mol

I	Current, A
$LCOE$	Levelized Cost of Energy, €/kWh
$LCOH$	Levelized Cost of Hydrogen, €/kg
M	Molarity of the solution, mol/l
N	Number,-
P	Power, W
R	Universal gas constant, 8.314462618 J/mol K
T	Temperature, K
U	Heat transfer coefficient, W/m^2 K
V	Voltage, V
a	Water activity, -
j	Current density, A/m^2
m	mass, kg
n	Number of elements,-
p	Pressure, bar
v	Velocity, m/s
wt	Weight concentration, [0.0 - 1.0]

Greek symbols

α	Charge transfer coefficient, -
δ	Reaction distance, cm
η	Overpotential, V
σ	Ionic conductivity, S/cm
Δ	Cell width, m
Γ	Generic property, -

Subscripts and superscripts

$\%$	Percentage
H_2O	Water
$°C$	Celsius
$H2$	Hydrogen
HEX	Heat exchanger
KOH	Potassium Hydroxide
$O2$	Oxygen
X,a	Actualized cost of X technology
act	Activation
$bubble$	Bubbles
$cell$	Single cell
d	Diaphragm
el	Electrolyte/Electrolyzer
elc	Electricity
$inlet$	Cell inlet
ohm	Ohmic
$outlet$	Cell outlet
$pump$	Water pump
rev	Reversible
th	Thermo-neutral
v	Vapor

Abstract:

The combination of emerging technologies such as fuel cells with well-known internal combustion engines, gas turbines and/or batteries is expected to enhance the efficiency of the resulting hybridized power plants compared to conventional ones installed onboard ships. Besides, the use of alternative fuels such as hydrogen, methanol or ammonia to power ships will allow to reduce the carbon footprint of vessels. However, hybridization and the use of alternative fuels imply that several variables such as efficiency, reliability, flexibility, space requirements, mass, investment costs or maintenance costs need to be taken into account simultaneously. To approach these designs Genetic Algorithms can be helpful. Genetic Algorithms are a powerful tool for solving a wide range of optimization problems in which several variables play a key role on the performance of the solution demanding a trade-off solution that also considers conflictive phenomena between these variables. In this work, the application of Genetic Algorithms to the design of hybridized marine power plants aiming to find compromised solutions is described. The outcome of these applications will help in the decision-making process to select the different components within the power plant, as well as the dimensioning of their capacities to get the most suitable design in accordance with a defined set of requirements that must be met.

Keywords:

Multi-objective optimization; Genetic algorithm; Hybrid power plant; Alternative fuels; Maritime.

1 Introduction

Multi-objective optimization problems (MOPs) arise frequently in engineering applications where several objectives need to be optimized simultaneously. In such cases, optimization algorithms are commonly used to solve that MOPs due to their ability to handle multiple criteria and objectives and search for the solution space efficiently. In the present work, the methodology for the application of an optimization algorithm on the design of a marine hybrid power plant is presented. This methodology will allow to create a tool to help in the decision-making process of the different power generation components of a marine hybrid power plant.

In Section 2, a brief review about the state-of-the-art of multi-objective optimization algorithms applied to power plant generation problems is presented. Non-Dominated Genetic Algorithm II (NSGA-II), Particle Swarm Optimization (PSO) and Strength Pareto Evolutionary Algorithm II (SPEA II) are found among the most used algorithms used for power plant generation problems. Economics, emissions and efficiency are found as the main objective functions defined.

The combination of emerging technologies such as fuel cells with well-known internal combustion engines, gas turbines and/or batteries is expected to enhance the efficiency of the resulting hybridized power plants compared to conventional ones installed onboard ships. Besides, the use of alternative fuels such as hydrogen, methanol or ammonia to power ships will allow to reduce the carbon footprint of vessels. However, hybridization and the use of alternative fuels imply that several variables such as efficiency, reliability, flexibility, space requirements, mass, investment costs or maintenance costs need to be taken into account simultaneously. All this results in a problem with multiple inputs, multiple variables well as multiple goals to fulfil simultaneously. Multi-objective algorithms are a powerful tool to cope with this problem. Nevertheless, a case-specific methodology adapted to the problematic of a modern marine hybrid power plant from needs to be developed to allow the use of multi-objective algorithms. In Section 3, this methodology is explained. Key aspects and future works to the methodology are discussed in Section 4.

2 Multi-objective optimization algorithms

Multi-objective optimization problems arise frequently in engineering applications where several objectives need to be optimized simultaneously. Applied to power generation plant problems, Non-Dominated Genetic Algorithm II (NSGA-II), Particle Swarm Optimization (PSO) and Strength Pareto Evolutionary Algorithm II (SPEA II) have been found to be widely used in the literature. This Section presents a brief review of these algorithms for such applications. Table 1, compares briefly the main features of these algorithms.

NSGA-II

Non-dominated Sorting Genetic Algorithm II (NSGA-II) is a powerful multi-objective optimization algorithm that is widely used in engineering and scientific applications. It is a variation of the NSGA algorithm, which is based on the concept of non-dominated sorting, where solutions in the population are classified into different "fronts" based on their dominance relationship with other solutions. NSGA-II builds on this concept by introducing several improvements that allow it to search for optimal solutions more efficiently and effectively. One of the key enhancements is the use of a crowding distance metric to maintain diversity in the population. This metric is used to encourage the selection of solutions that are spread out in the objective space, rather than focusing on a single region.

Another important improvement of NSGA-II is the use of an elitist selection mechanism. This ensures that the best solutions in the population are preserved from one generation to the next, which helps to prevent the loss of good solutions during the search process. NSGA-II also employs tournament selection, which involves selecting individuals for reproduction based on their dominance and crowding distance values. The algorithm uses binary tournament selection in the early generations to encourage diversity, and switches to crowding tournament selection in later generations to promote convergence towards the Pareto-optimal front.

Mayer et al. use NSGA-II in a multi-objective optimization problem of a household with renewable energy supply in which the net present cost and environmental footprint are the objective functions chosen to search for the Pareto-front solutions [1]. The results prove multi-objective optimization to be satisfactory to investigate trade-offs solution between two conflicting objective functions.

Similarly, Oyekale et al. develop a thermo-economic optimization of a solar organic Rankine cycle power plant with the NSGA-II. The Pareto-front is obtained with the objective functions of biomass mass flow rate and investment cost rate [2].

NSGA-II is also the algorithm chosen by Bolbot et al. for the optimization of a cruise ship power plant considering as objective functions the Life Cycle Cost and lifetime CO2 emissions [3]. The optimization has taken into account existing and future SOx and NOx IMO regulations, which were used as constraints in the optimization process. The algorithm has proved to succeed in finding an optimal solution that meets with these regulations.

Villalba-Herreros et al. make use of the NSGA-II in a multi-objective optimization of a power plant based on Direct Methanol Fuel Cells (DMFCs) with a CO2 capture system to power an Autonomous Underwater Vehicle (AUV) [4].

PSO

Particle Swarm Optimization (PSO) is a nature-inspired metaheuristic optimization algorithm that is widely used to solve complex optimization problems. The algorithm is based on the movement of particles in a multidimensional search space, which is designed to explore the space and find the best solution. In PSO, a population of particles represents candidate solutions, and the movement of the particles is influenced by their own best position (i.e., personal best) and the best position found by the swarm (i.e., global best). Each particle adjusts its position and velocity based on its own experience and the experience of the swarm, using a set of mathematical equations that determine the direction and speed of movement. This process is repeated over multiple iterations until a stopping criterion is met or the best solution is found.

One of the advantages of PSO is its simplicity and ease of implementation. The algorithm has a small number of parameters, which makes it easy to use and adjust for different optimization problems. PSO is also computationally efficient and can handle large and complex optimization problems, as it can quickly converge to a good solution with a small number of function evaluations. Additionally, PSO can handle both continuous and discrete optimization problems, and can be easily extended to handle multi-objective optimization problems. Despite its advantages, PSO can suffer from premature convergence and a lack of diversity in the population, which can result in suboptimal solutions. To mitigate these issues, various variants of PSO have been proposed, such as adaptive PSO, hybrid PSO, and cooperative PSO.

Vijayakumar et al. propose the use of a modified PSO algorithm in [5], in a load distribution optimization to find the lowest electric power generation cost. The results were compared with genetic algorithms and conventional PSO algorithms, offering the modified PSO the lowest electric power generation cost among them.

Azaza et al. use the PSO in a Multi-objective optimization of a hybrid micro-grid system composed of photovoltaic panels, wind turbines, diesel generators and battery storage [6]. The objective functions set were reliability, Cost of electricity (COE) and the renewable factor to minimise the use of the diesel generator.

SPEA II

Strength Pareto Evolutionary Algorithm II (SPEA II) is a multi-objective optimization genetic algorithm that uses a fitness function to evaluate the quality of solutions in the population. The fitness function considers both the solution's objective values and its distance to other solutions in the population. Solutions with high fitness are selected for the next generation, and the process is repeated to obtain a set of non-dominated solutions. SPEA II has been applied to various engineering problems, including transportation planning, manufacturing, and structural optimization. However, SPEA II can be computationally expensive for problems with a large population size.

This algorithm is used by Mehrdad et al. in [7] for the optimization of organic Rankine cycle used in a power plant. The objective functions used in the Pareto-front are the Levelized Energy Cost (LEC) and the exergy efficiency.

Dufo-López et al. make use of SPEA II in [8], where this algorithm is applied for the optimization of stand-alone photovoltaic, wind and diesel systems with battery storage. The objective functions are

the Levelized Cost of Energy and the equivalent CO2 life cycle emissions. The results of the optimization allowed to dimension and select the power generation devices for the plant, as well as discard others.

Table 1. Comparison features between NSGA-II, PSO and SPEA II.

Features	NSGA-II	PSO	SPEA II
Type of algorithm	Genetic	Stochastic	Genetic
Multi-objective	Yes	Not by default	Yes
Search space technique	Non-dominated sorting / crowding distance	Swarm of particles	Strength metric
Optimization criteria	Pareto dominance	Fitness function	Strength and distribution
Convergence criteria	Quality measure convergence	Fitness function convergence	Limit of space distance
Robustness	High	Lower	Higher
Computational demand	High	Light	Medium
Discontinuous functions	Yes	Struggle	Yes
Weakness	Computationally demanding	Discontinuous functions	Requires large population to maintain diversity
References	[1-4]	[5-6]	[7-8]

In summary, three different types of optimization techniques have been shown in the present Section and references of all of them related to power generation/distribution problems have been briefly explained. As can be observed, regardless of the method used, in all cases the economics are one of the objective functions of the Pareto-front. The second objective function is related either to the efficiency of the system or the emissions produced.

3 Methodology

The main focus of the investigation outlined in this work is shown in Figure 1. The figure shows the main overview of the algorithm methodology. In the following Sections 3.1 to 3.5 the steps of this workflow are explained.

3.1 Input data - Operational profile and fuels

The initial conditions that are the basis of the optimization process are given by the operational profile of the vessel and the fuels used.

The operational profile is broken down into endurance of the vessel, electrical demand and heat demand.

The electrical demand considered is defined as the sum of the propulsion power in a vessel with electric propulsion, and the auxiliary power demand of the vessel. This auxiliary power initially does not consider the electrical demand needed to make the power plant operational, that is, the power of the balance of the plant (BoP) as it depends on the size of the power plant itself. The BoP is sized in an iterative process further explained in Section 3.2.

The selection of one, two, three, four or all the fuels to be considered during the optimization process will depend on the specific case to which the methodology presented in this work is applied.

Regarding the fuels used onboard, five alternative fuels are considered: liquid hydrogen (LH2), methanol (MeOH), ammonia (NH3), liquid natural gas (LNG) and biofuels.

The different power plant components will be dimensioned according to the required demands as explained in Section 3.2.

Lastly, the endurance input is fed directly to the mathematical modelling of the algorithm as explained in Section 3.2.

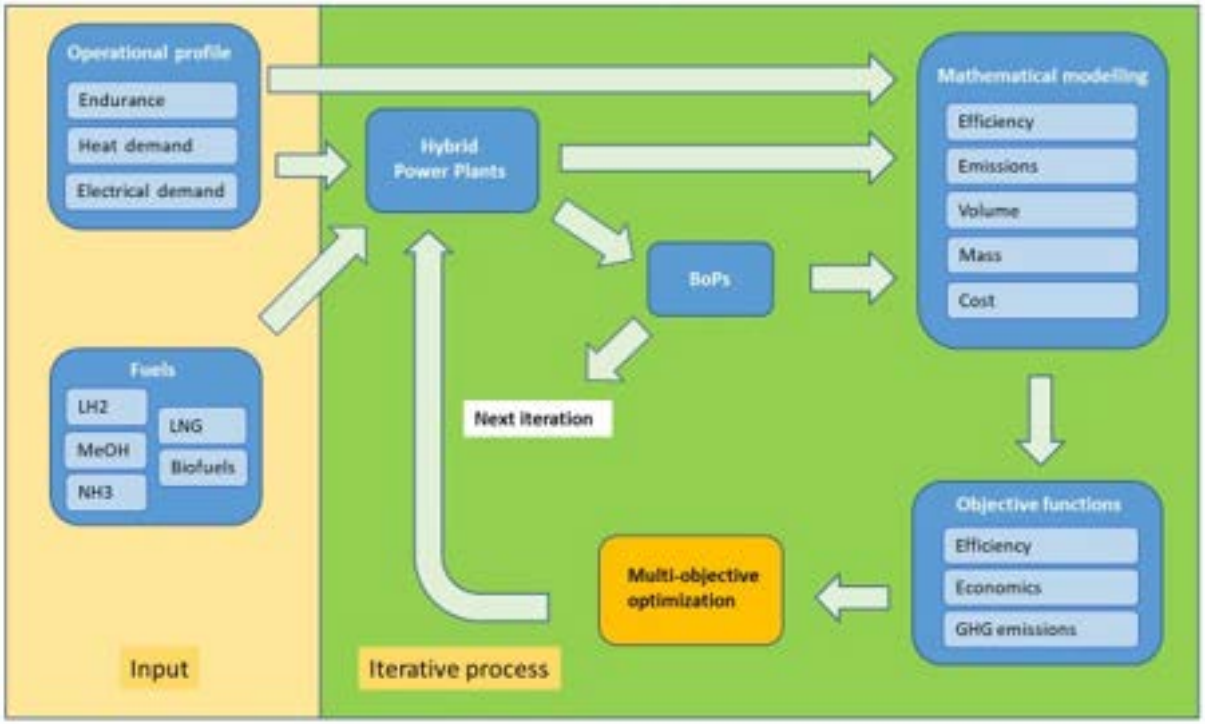

Figure 1. Methodology diagram of the multi-objective algorithm.

3.2 Hybrid Power Plants

The input parameters defined in Section 3.1 are introduced into the iterative process shown in Figure 2.

Electrical and heat demands of the operational profile as well as the fuels selected are used to establish an initial dimensioning of the power generation devices of the hybrid power plants.

During the first iteration, the population of hybrid power plants is created randomly, varying the power capacity of the different power generation devices.

The power plant components of the marine hybrid power plants are:

- PEM Fuel Cells (electricity generation)
- Generator sets (electricity generation)
- Battery energy storage (electricity storage/generation)
- Boiler (heat generation)
- Heat recovery systems (heat generation)

The set of hybrid power plants obtained in this step form the population that is subjected to the optimization process in the algorithm. In this respect it will be assumed that each individual of the population will make use of only one of the fuels. This is an extended practice in the maritime industry (although the use of two different fuels onboard a ship is also common) in order to minimize the amount of equipment needed to make the power plant functional.

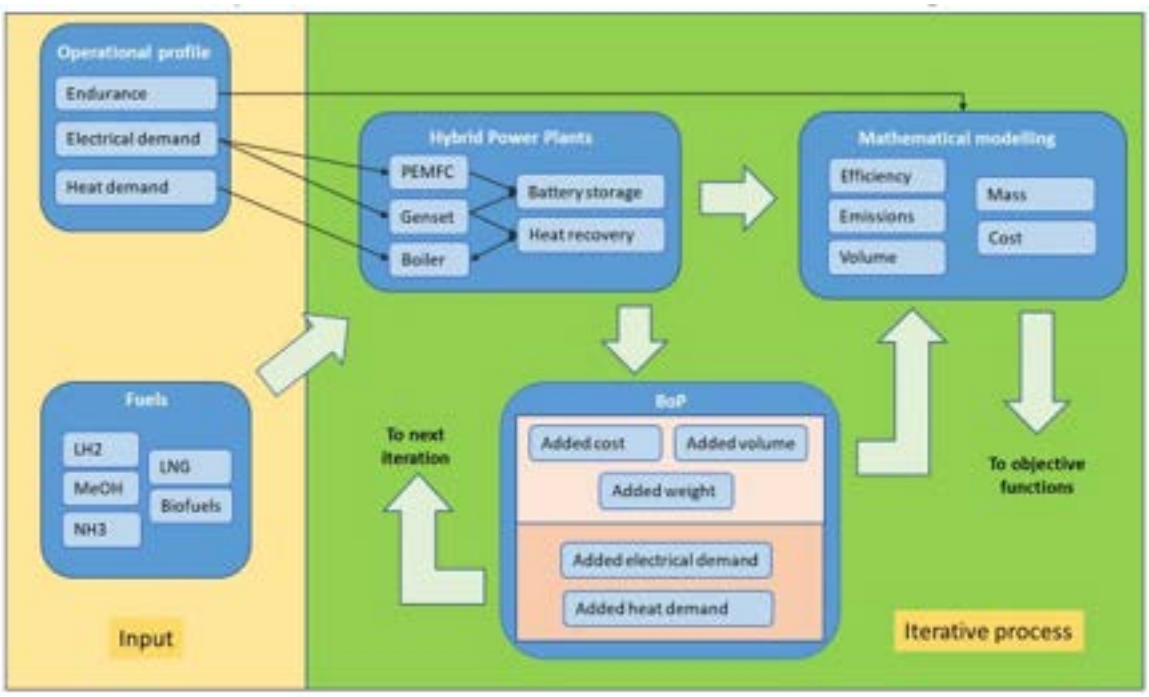

Figure 2. Workflow diagram of the mathematical modelling.

3.3 Mathematical modelling of hybrid power plants

Each individual of the hybrid power plants will have its own configuration of fuel, PEM Fuel Cells, generator sets, battery storage, boiler and heat recovery systems. For each individual, the mathematical model is the step in which the performance of the plant is assessed. Efficiency, emissions, volume required on board, mass and cost of the plant are calculated in this step.

The endurance of the vessel is also introduced at this step. Once the efficiency of the hybrid power plant is known, it will be possible to assess the volume of the fuel storage as well as its mass contributions.

3.3.1 Mathematical modelling of the balance of plants (BoPs)

Simultaneously to the mathematical modelling of the hybrid power plant individuals, the balance of plant (BoP) is also assessed. BoP is an important component of a marine power plant that refers to all of the auxiliary systems and equipment required to support the power generation process. It involves a wide range of systems and equipment, such as the electrical grid connection, transformers, control systems, fuel supply systems, reformers, exhaust systems, lube oil systems, compressed air or refrigeration systems.

Combining different power generation and power storage devices in a hybrid power plant needs to take into account that there will be interfaces and share of equipment between them, thus affecting the BoP. Such combination is taken into account in the BoP in order to create a model that considers the integration of different power plant devices.

The calculation of the BoP for each individual will allow to estimate the additional contributions of electrical demand, heat demand, cost, volume required onboard the vessel and mass.

As mentioned in Section 3.1, added electrical demand and heat demand will be used in the next iteration process to dimension the next generation of hybrid power plants. This will allow to estimate future individuals of hybrid power plants taking into account these contributions, so that after a few generations the additional electrical and heat demands will tend to zero.

Added cost, volume and mass parameters are combined with the contributions of these parameters calculated for the hybrid power plants in the mathematical model.

3.4 Objective functions

In Section 2, works found in the literature regarding multi-objective optimization cases applied to the dimensioning of hybrid power plants have been analysed. The analysis has shown that the objective functions selected to carry out the multi-objective optimizations are in most cases focused on costs combined with efficiency or greenhouse gas emissions. These objective functions entail the search of trade-off solutions in which a Pareto-Front is obtained in the multi-objective optimization process. This is one of the key elements that is seek in the present work, as the aim of the methodology proposed is to help during the decision-making of the optimum hybrid power plant. A range of hybrid power plants forming a Pareto-Front will give the end-user the possibility to take a decision based on a set of criteria that have opposite impacts.

In Figure 3 it is shown the workflow of how the parameters calculated in the mathematical model are distributed into the objective functions.

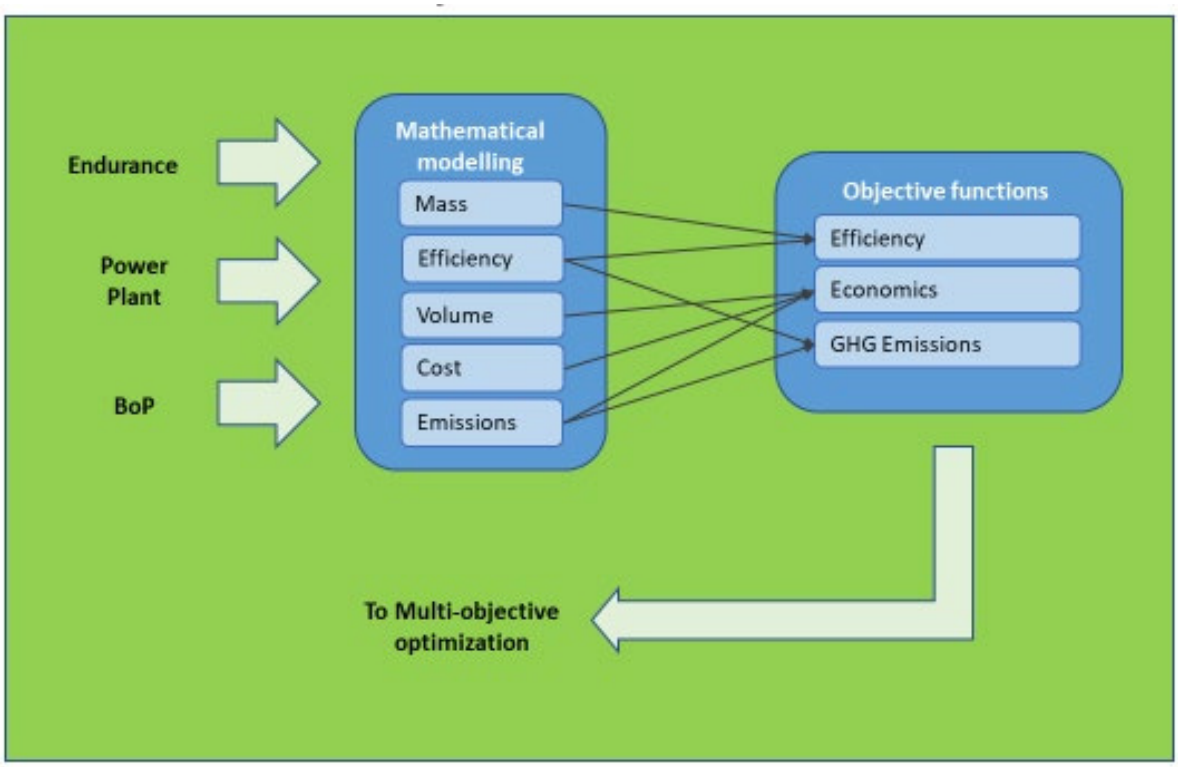

Figure 3. Workflow from mathematical modelling to objective functions.

3.4.1 Efficiency

The objective function of efficiency allows to give information of the performance of the hybrid power plant. Besides, it is a parameter that will not be subject to considerable changes in mid or long-term perspectives. Even though devices like the PEM Fuel Cells are emerging technologies in the maritime, efforts on their development are being focused on reducing their investment cost through the use of new materials. Therefore, this objective function will have the quality of a stability with high reliability.

3.4.2 Economics

The objective function of the economics has contributions from three different parameters of the mathematical model: costs, volume and emissions.

As it is reasonable, the costs of the hybrid power plant obtained in the mathematical model, which are calculated in capital expenses (CAPEX) and operational expenses (OPEX) of the plant, contribute greatly to this objective function.

The volume of the hybrid power plant, and the volume on the vessel required to store the fuel, can affect, depending on the type of vessel, to other spaces such as cargo, that would report a benefit otherwise. Therefore, the volume parameter calculated in the mathematical model can also influence the objective function of economics.

The emissions, which depending on the power generation device, can be composed of greenhouse gases and others such as NOx, SOx or PM, can be subject to penalties from the international regulatory organizations. Therefore, this is also taken into account in this objective function.

3.4.3 GHG Emissions

The purpose of objective function of greenhouse gas emissions is to be evaluate and compare the environmental impact of the hybrid power plants. Taking the operational profile of the vessel allows to calculate the mass of CO2 emitted to the atmosphere during in a specific amount of time. For each hybrid power plant analysed, this mass will be calculated and serve as basis of this objective function.

3.5 Multi-objective optimization and iteration

The multi-objective optimization is performed with the three objective functions defined in Section 3.4, economics, efficiency and GHG emissions. As a result of the optimization, a set of new hybrid power plants are obtained and introduced into the next iteration. The added electrical demand and added heat demand are introduced also in the next iteration, as explained in Section3.2, and their values will tend to stabilize as the number of iterations increase. The workflow of this step is shown in Figure 4.

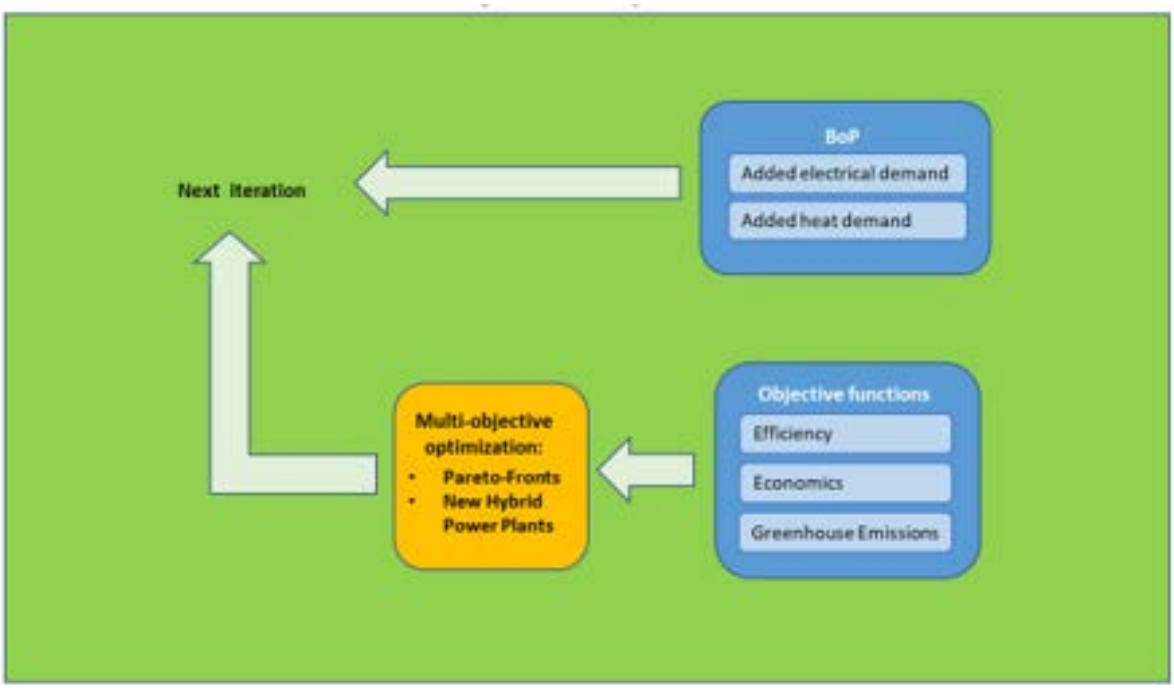

Figure 4. Workflow of multi-objective optimization.

The Pareto-Front generated in the optimization process will be based on the three objective functions defined. To take into account the three objective functions simultaneously, the Pareto-Front is represented in a 3-dimensional graph.

4 Discussion

In the present work a methodology to optimize maritime hybrid power plants fuelled with alternative fuels has been presented. In Section 2, the results of a search of optimization algorithms used in the literature applied to cases of dimensioning hybrid power plants are presented. Three optimization algorithms (NSGA-II, PSO and SPEA-II) have been found with positive results throughout the cases applied. Among the cases found in the literature, two objective functions are normally used in the

optimization process, from a group of three, efficiency, economics and GHG emissions. Pareto-Fronts of two objective functions are therefore the outcome of these works. The authors find that the three objective functions mentioned are of high relevance in the decision-making process of dimensioning a maritime hybrid power plant. For this reason, it has been decided that the methodology proposed in Section 3 makes use of the three objective functions simultaneously. Pareto-fronts are therefore represented in 3-dimensional graphs, with each x-y-z axis associated to each of the objective functions.

Hybrid power plants require to integrate different power generation devices working together in harmony. In order to achieve this integration, the auxiliary systems to make the hybrid power plant operational, known as the balance of plant (BoP), have a higher level of complexity compared to power plants with single power generation devices. For this reason, in the methodology proposed in Section 3, the BoP has been given significant relevance and importance within the algorithm. For each hybrid power plant, its BoP will have its specific needs, which results in specific mass of the equipment, volume required on board, costs, but also electrical power demand and heat demand. The workflow of the BoP is shown in Figure 2. As the BoP is based on the information of the hybrid power plant, the added electrical demand and heat demand are no longer considered in the current iteration step, otherwise this would affect the dimensioning of the hybrid power plant that has been already stablished. Therefore, added electrical demand and heat demand are introduced in the next iteration of the algorithm. As the number of iterations increase, the hybrid power plants tend to be dimensioned matching the needs of the BoP. Therefore, the added electrical demand and heat demand of the BoP will tend to zero as the iterations grow.

As explained in Section 3.1, one part of input data to be applied to the algorithm comes from the operational profile of a vessel with electric propulsion. Electrical power demand and heat demand are used to dimension initially the hybrid power plants. To do so, the reference points from which these demands are considered have to be common for all types of hybrid plants., e.g., the ship propeller, that has a mechanical demand to be moved, has a prime mover that is an electric motor, this electric motor has an electrical demand to move the propeller that can be common for any given hybrid power plant considered in this work. Future works that could include mechanical propulsion of the vessel would need to take this into account.

5 Conclusions

The emerging technologies that are being implemented in the maritime field regarding the use of alternative fuel devices such as PEM Fuel Cells have a direct impact on the power plants of vessels. The combination of different power generation devices entails a level of hybridization of power plants that requires a higher complexity to make the hybridized power plant to function in harmony. To solve this problem, a methodology for a multi-objective optimization process that will help during the decision-making process of the power plant has been proposed. The main conclusions obtained from are summarized below:

- The methodology proposed is able to integrate the different power generation devices through specific balance of plant oriented to each hybrid power plant considered.
- Three objective functions (efficiency, economics and GHG emissions) have been defined. The objective functions will allow to create a 3-dimensional Pareto-Front to assist the user on the decision-making process of the optimum hybrid power plant.
- The point of reference from the electrical demand and heat demand given by the operational profile of the vessel needs to be common for all hybrid power plants.

Abstract:
Interest in hydrogen as a transportation fuel is growing. Fuel cell electric vehicles fed by hydrogen are expected to play a key role in the decarbonization of the transportation sector. Its impact will depend upon the existence of reliable and cost-effective fuelling stations. Numerical simulation allows sizing hydrogen refuelling on-site stations in order to identify the most cost-effective solution for a specific utilization pattern. This study aims to define a numerical optimization model for a hydrogen refuelling station to supply both light and heavy vehicles. The objective function is to minimize the total storage volume, taking into account the number of vehicles to be refuelled. The pressure at each storage skid is considered a decision variable, as well as the hydrogen mass that is provided at each vehicle filling. The model considers the hydrogen properties and the physical constraints to size the station prior to its construction. Additionally, a cost analysis based on the capital expenditure concept was developed. The hydrogen refuelling station must be able to supply 300 kg/day of hydrogen. The station includes four main systems: the hydrogen production equipment, an electrolyzer, and a system that can store hydrogen to feed the compression cascade. The station should be able to fill 10 heavy vehicles at 350 bar (H35), considering 2 skid pressure levels and a supplied mass of 30 kg and 30 light vehicles at 700 bar (H70), considering 3 skid pressure levels, dispensing 4.2 kg of hydrogen each. At all vehicle fillings, a pressure differential of 50 bar between the high-pressure skid and the vehicle tank is mandatory so the refuelling can be validated. The results show that it is possible to refuel 10 heavy vehicles considering a total storage volume of 36.9 m^3, whereas, for light vehicles, it is possible to refuel 30 vehicles with a total volume of 22.9 m^3. Based on capital expenditure, the most representative capital costs are the production equipment (30%), high-pressure storage unit (20%) and the hydrogen compression system (18%).

1. Introduction

Hydrogen as an energy carrier is currently seen as one of the most favourable ways to accelerate the decarbonization of various industrial sectors and vehicular mobility [1]. According to Perna et al [2], currently, there are approximately 200 hydrogen refuelling stations, mostly located in Japan, Germany, and USA. Yet, more than 5000 new stations are planned to be constructed by 2030.
Hydrogen-based refuelling stations comprise mainly four main steps, namely, production, storage, safety and utilization [3]. The selection of hydrogen production via requires considerable resources and their use, technological availability, efficiency, costs, environmental impacts and system integration options [4]. After production, the hydrogen needs to be stored [5]. According to the literature [4–9], storage and transport are the most difficult phases of the hydrogen supply chain. In order to use hydrogen as fuel, its physical state has to be altered in order to improve its density. Being hydrogen an energy vector that can be produced in a clean and environmentally friendly way, this gas is generally stored for local consumption or for transportation to the point of final consumption [3]. Either way, each solution must be studied individually in order to meet the specific needs. According to Demir and Dincer [8], identifying cost-effective pathways for supplying hydrogen remains an appealing prospect.

Refuelling gaseous hydrogen is a process that comprises two main ways: either the hydrogen is directly compressed in a tank using a compressor or the hydrogen is moved from a tank with higher pressure to the target tank at lower pressure [10]. In the context of vehicle refuelling stations, the storage of hydrogen in a gaseous state remains the most viable option [11]. Compressed hydrogen is a highly efficient methodology for hydrogen storage, but it requires the use of high-pressure systems. This represents an important issue because the energy density of the gas varies with the pressure inside the container. The fatigue caused by the repetitive cycles of high to low pressure, as well as, the inherent risks in having a pressurized gas are a key aspect in sizing the storage system [6,9,12].

For vehicular applications, it is required to have high-density storage systems, low weight and low cost, that are suitable for the hydrogen delivery system. High-pressure hydrogen storage technology is usually applied at hydrogen refuelling stations and hydrogen vehicles. The majority of refuelling stations require most of the following components: (i) hydrogen production equipment with a purification unit to secure that hydrogen purity meets the standards for supplying fuel cells; (ii) hydrogen compression system for high-pressure storage inside the station's main tanks; (iii) hydrogen storage tanks for either compressed gas or liquid hydrogen; (iv) equipment able to regulate pressure to 350 bar or 700 bar during the refuelling procedure; (v) a cooling unit to reduce hydrogen gas temperature down to − 40 °C to guarantee that during fast refills the vehicle's hydrogen tank does not exceed 85 °C, mostly to ensure the station safety; (vi) dispensers used to fill the vehicles tanks from the station's compressed storage containers; (vii) electrical and mechanical equipment such as valves, piping, pressure relief valves and hydrogen sensors [13].

Refuelling stations are categorized into off-site hydrogen stations and on-site infrastructures. The first type includes all the stations where hydrogen is delivered from a central production plant, being transported through pipelines or by heavy-duty trucks where hydrogen is stored in tube trailers as compressed gas [14]. For on-site stations, the hydrogen used to refuel the vehicles is generated locally. This represents a technical limitation because the station efficiency depends on the output quantity of the hydrogen generators, which typically ranges from 100 kg/day to 1000 kg/day. From an economic perspective, on-site hydrogen refuelling stations have a significantly higher capital investment cost due to the hydrogen production components, especially, on-site water electrolysis production. According to Perna et al [2], the investment cost of on-site stations may represent a capital cost 1.5 times higher than similar off-site stations with the same capacity.

Several authors are focused on studying the technical aspects of refuelling station operation. Miguel et al [15] showed with their experimental studies that the maximum gas temperature reached at the end of the filling increases linearly with the increase of the initial temperature while the temperature increase and the state of charge decreases linearly with increasing initial temperature. Zhao et al. [16] have developed numerical simulations, to identify the temperature increase within the hydrogen vehicle tank during the refuelling process at 350 bar (i.e., the so called H35 refuelling at 35 MPa). A similar study was performed by Wang et al [17] for fast filling at 700 bar (i.e., the so called H70 refuelling at 70 MPa). Maus et al [18] investigated the filling procedure taking into account tank systems with different storage volumes, from 2 kg to 10 kg hydrogen.

Some studies have been presented in the literature regarding the modelling of hydrogen refuelling station. These are mostly focused on thermodynamic models based on on-site electrolysis looking for energy-efficient station configurations, off-site production systems and respective delivery supply chain, and the definition of refuelling network location with or without production method [1,19–21]. However, these studies do not apply optimization algorithms in the design of the station operating conditions. Moreover, the focus is on finding the most economical design and not purely on energy efficiency. Also, it is important to notice that the current network park of refuelling stations for hydrogen vehicles is in its early stages. Thus, the refuelling infrastructure must be cost-effective in order to achieve successful market growth. The present work aims to contribute to the appeal of new mobility solutions.

The main purpose of this paper is to define a numerical optimization model for a hydrogen refuelling station for light and heavy vehicles. The station should include a hydrogen production unit, an electrolyzer and a system able to store hydrogen at high-pressure to later feed the compression cascade. The model considers the hydrogen properties and the physical constrain to size a hydrogen refuelling station, prior to its construction. It was defined as the objective function the minimization of the total storage volume, taking into account the expected number of vehicles to be fuelled.

2. Vehicle hydrogen refuelling

The process of vehicle refuelling with compressed hydrogen is subjected to control requirements in order to ensure that the vehicle tank is within a specified operating condition defined by an upper limit on pressure, and an upper and lower limit on temperature [19]. Thus, refuelling protocols have been established to define specific conditions for sizing hydrogen refuelling stations. In this section, SAE supply protocols are presented and discussed in order to understand the main constraints in the design of hydrogen refuelling stations.

2.1. Refuelling protocols

The hydrogen filling of light and heavy vehicles has been studied, improved, simulated and standardized by the Society of Automotive Engineers (SAE) since 2010. The purpose of defining these refuelling protocols is to ensure that this process is safe and that it maximizes supply performance. The first refuelling protocol, TIR J2601, was published in 2010, defining the standard for light-duty gaseous hydrogen surface vehicles [22].

Afterwards, in 2014 after a period of development with simulations and field tests, new versions were published: “J2601-2 – Refuelling Protocol for Gaseous Hydrogen Powered Heavy Duty Vehicles” and “J2601-3 – Refuelling Protocol for Gaseous Hydrogen Powered Industrial Trucks”. More recently, in 2020, a new version of TIR J2601 allowed modifying the protocols to facilitate the supply of H70 (hydrogen at 70 MPa for light cars) in tanks with a capacity of over 10 kg of hydrogen. Figure 1 presents the evolution of SAE supply protocols over the years [23].

This protocol determines the conditions under which the vehicle storage tank and dispenser should operate. The dispenser is connected to a high-pressure storage unit that ensures the pressure range required for refuelling. The supply pressure depends on three factors, namely, the ambient temperature, the precooling temperature of the hydrogen in the dispenser, the vehicle's tank volume and the respective initial pressure. During the refuelling process, the initial tank pressure should be 5 bar and the vehicle's Nominal Working Pressure (NPW) is defined as 35 MPa for heavy vehicles and 70 MPa for light vehicles). The mass flow rate of hydrogen to be supplied cannot exceed 60 g/s. Also, the hydrogen temperature limits vary between - 40 ºC and 85 ºC [22,24].

As stated, the NPW for light and heavy vehicles is different. For light vehicles, it is necessary to increase the pressure at which the gas is stored in order to increase the mass available in the system. As compression increases the temperature, when refuelling light vehicles, it is necessary to include a chiller in the station so the maximum admissible temperature in the tank at a pressure of 700 bar is not exceeded. In contrast to light vehicles, heavy vehicles have tanks with higher storage capacity, allowing these vehicles to be refilled with 35 kg of hydrogen at 35 MPa [22].

Thus, the expected performance for the protocol aims to guarantee a refuelling with a duration in the range of 3 minutes at a station, capable of pre-cooling the hydrogen to - 40 ºC. These conditions allow reaching a state of supply between 90 and 100% of the vehicle's capacity for NPW conditions and considering an ambient temperature of 15 ºC [19].

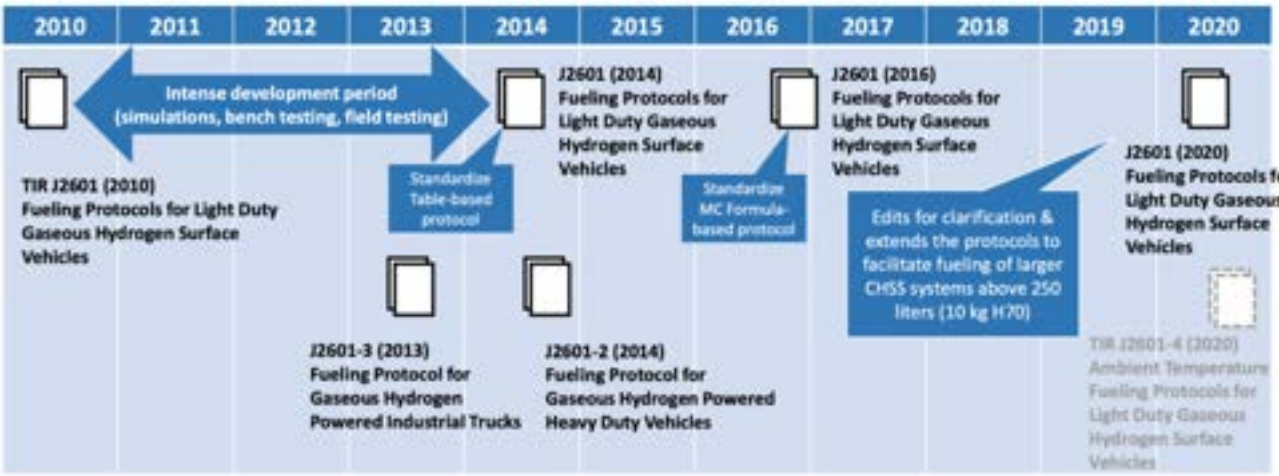

Figure. 1. Identification of SAE supply protocols between 2010 and 2020. The protocol J2601 determines the conditions under which the vehicle storage system and dispenser should operate. Adapted from [24].

The SAE J2601 protocol includes three main phases: (1) startup point; (2) refuelling phase; and (3) refuelling termination. In the first stage, it is ensured a secure connection between the dispenser nozzle and the vehicle. As soon as the connection is established, a signal is sent to verify that there is no error in the connection. Then, a pressure signal is sent to the tank to set the initial refuelling pressure and the second one to detect possible leaks and estimate the tank volume (estimated with an error of +/- 15%). During this phase, the hydrogen mass transfer limit to the tank is 200 g. Knowing the ambient temperature, the initial tank pressure, the refuelling temperature and the dispenser condition (hot or cold), the Average Pressure Ramp Rate (APRR) corresponding to the measured data is selected and the refuelling pressure condition is calculated. The initial phase is concluded when the mass of hydrogen begins to be transferred into the vehicle's tank. This is followed by the second phase, the main refuelling, in which the pre-cooling temperature is monitored during the refuelling and according to the calculated APRR. The temperature of the hydrogen when filling a tank needs to be monitored to ensure the safety of the process and to avoid overheating.

The validation of this process is based on the guarantee that the pre-cooling temperature is achieved. Otherwise, a process called Fallback Pressure Ramp Ratio (FPRR) is initiated and a new APRR is calculated. From the moment the refuelling process starts, the station controls the pressures at which the dispenser is delivering hydrogen. When the pressure in the dispenser reaches the limit established as the termination pressure, the refuelling process is complete [25].

Two main methods are used to implement SAE J2601 protocol: the LookUp Table method and the MC Formula. The LookUp Table method controls the evolution of the hydrogen pressure during the refuelling process based on the pressure and temperature in the vehicle's tank. It uses standardized table values, that specify pressure increases taking into account: vehicle tank capacity; type of refuelling system; hydrogen temperature when refuelling (T40, T30 and T20, i.e., the refuelling temperature of – 40 ºC, – 30 ºC, – 20 ºC, respectively); refuelling pressure (H35 or H70); type of vehicle-station interface and the hydrogen temperature at the dispenser outlet [22,26].

The method is based on the three identified phases of SAE J2601 protocol through the calculation of an APRR for a specific condition of ambient temperature and initial tank pressure.

The MC Formula is an alternative method based on a version of Honda's MC method that consists of analytical calculations. It uses thermodynamic properties to dynamically determine the APRR that controls the refuelling flow [10]. The MC formula can be illustrated in Figure 2, where all the parameters are presented. This method is defined for SAE J2601 boundary conditions and the APRR is adjusted according to the temperature measured at the dispenser outlet. It uses empirical equations whose coefficients are determined through the initial tank pressure, ambient temperature and tank capacity, constantly calculating the filling pressure throughout the filling.

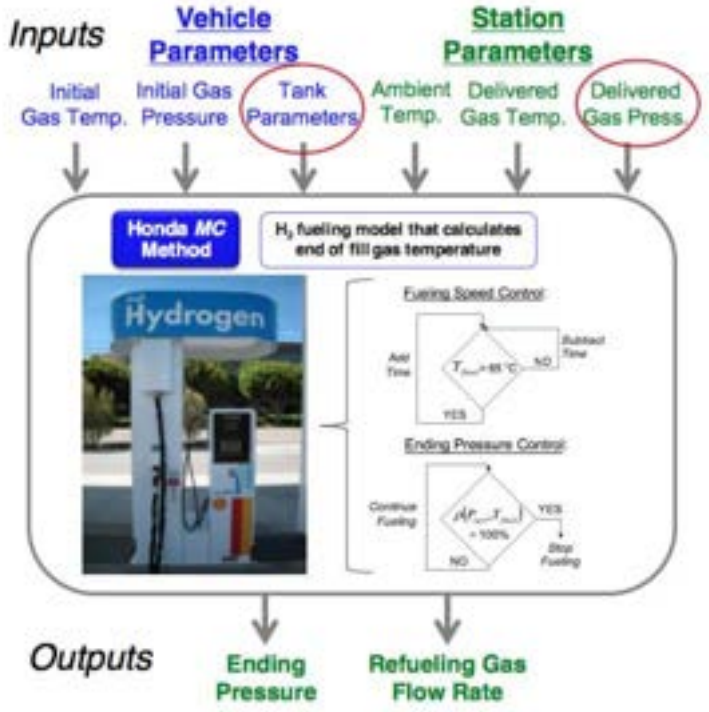

Figure. 2. Diagram control for MC formula method implementation considering the SAE J2601 protocol requirements. Adapted from [10,22].

Similarly to the LookUp Table method, the MC Formula is based in three phases. In the refuelling phase, the formula MC measures and actively uses the precooling temperature in the dispenser to calculate the hydrogen Mass Average Temperature (MAT) and the mass average enthalpy used to decide the APRR and termination pressure during the refuelling [27,28]. The refuelling process is controlled by both APRR and target pressure. The APRR is calculated based on the mass flow rate and pre-cooling temperature measured at the dispenser outlet. The actual pre-cooling temperature at the dispenser is calculated, as well as, the time defined as the total period needed to fill the vehicle tank, varying from a minimum to a maximum pressure [22]. The MC Formula method uses a MAT based on the pre-cooling temperature measured after thirty second (MAT30) to control the process until the transition pressure is reached. It is important to mention that both LookUp Table and MC formula methos apply the same boundary conditions and both collect information from the station to complete the refuelling safely.

2.2. Hydrogen Refuelling Constraints

As previously stated, the hydrogen refuelling station needs a hydrogen production equipment, a system able to store hydrogen to later feed the compression system, a chiller and a dispenser. Thus, the refuelling station operation is based on six main steps [20]:

- Step 1 – Hydrogen in gaseous state is produced through the water electrolysis in the electrolyzer which is stored at low pressure;
- Step 2 – A buffer is used to storage the hydrogen at low pressure to accumulate the required mass of hydrogen to start the compression;
- Step 3 – Hydrogen is admitted into the compression unit, able to pressurize the gas up to 10 times higher than the inlet condition;
- Step 4 – Hydrogen is stored at high pressure in containers after its compression in the gas cascade system;
- Step 5 (mandatory only for H70) – A chiller is used for hydrogen cooling till it reaches the required temperature;
- Step 6 – Hydrogen is filled through a dispenser connected to the vehicle's nozzle.

One of the main operational constraints of a refuelling stations is related with the hydrogen compression. Hydrogen rapid compression leads to the temperature increase inside the tank which, in case of an exaggerated increase, can compromise the complete refuelling station [9]. As previously mentioned, to prevent this event, the maximum temperature limit inside the tank was set at 85 ºC. In addition to safety considerations, this limitation is imposed because the density of the gas changes with the temperature, and, consequently, the existing mass inside the tank decreases with the temperature, affecting the State of Charge (SOC). A SOC close to 100% means that the refuelling allowed filling the tank with the highest mass capacity of hydrogen possible, maximizing the vehicle's autonomy. The technological solution to control this problem is cooling of hydrogen, incorporating a chiller in the refuelling system [10].

As the chiller represents an additional investment cost, the hydrogen refuelling mass flow rates must first be set, which should be lower than 60 grams of hydrogen per second for H70 and 120 grams of hydrogen per second for H35 (SAE J2601).

Regarding safety, ISO 19880 [29] defines some conditions that must be fulfilled so the refuelling station could operate. The refuelling stations must be designed to minimize gas leaks during station operation. Closing valves should be incorporated to minimize the risks in the event of a hydrogen leak. Regarding storage, containers must be equipped with valves activated by pressure or temperature. All materials must be compatible with hydrogen at the operating temperatures and pressures. Materials should be selected according to ISO 15916, ISO 11114 and ISO 16573.

3. Refuelling station modelling

The aim of this study is to define a mathematical model for the design of a hydrogen refuelling station for light and heavy vehicles. Thus, a case study was defined to model a real problem regarding the refuelling requirements for H35 and H70 and considering tangible operational parameters explained in this section.

3.1. Description of refuelling station

The refuelling station under modelling (Figure 3) must be able to supply 300 kg of hydrogen per day. The system needs to include the production equipment, an electrolyser, which feeds a low-pressure storage buffer tank at 35 bar. The compressors aim to raise the pressure to a maximum of 500 bar and store the hydrogen in high-pressure containers arranged in a cascade system, in order to minimize their energy consumption. The hydrogen is stored in skids with several containers connected to a certain pressure. Note that a pressure cascade storage system is considered in order to prevent multiple fatigue cycles that the skid containers are subjected from successive hydrogen filling processes. For cascade storage system, when the fuelling is initiated, the hydrogen pressure in the vehicle tank is compared with the tank pressure value, level by level till the final pressure and mass are reached. When the refuelling process is complete, the storage is refilled, starting by the lowest pressure level [12,19].

The mass of hydrogen is supplied through a dispenser from the high-pressure storage system, depending on the pressure level. A very important requirement that defines a large part of the problem is related to the need in guaranteeing a pressure differential of 50 bar between the vehicle tank and the stored hydrogen so the refuelling process can be validated.

In the case of refuelling heavy vehicles (buses), hydrogen is supplied directly from storage unit at 500 bar to the dispenser. In case of refuelling light vehicles, hydrogen stored at 500 bar is compressed to a second storing level, till reaching a pressure of 900 bar. Thus, to proper sizing the refuelling station, it is necessary to stablish the number of vehicles to fill, calculate the required mass of hydrogen, define the number of pressure levels and minimum hydrogen volumes to store at each pressure level. For this study it was assumed that the refuelling station should be able to:

1. Supply 10 heavy vehicles at 350 bar (H35), considering 2 skid pressure levels. This solution allows refuelling hydrogen at a maximum of 120 g/s, in order to comply with the maximum required refuelling time of 15 minutes. It is assumed that a mass of 30 kg is supplied by the dispenser. It is also assumed that the vehicle arrives at the station with the minimum hydrogen mass of 6 kg at 50 bar.
2. Supply 30 light vehicles at 700 bar (H70), considering 3 skid pressure levels. During the refuelling process is theoretically expected to dispense 4.2 kg.

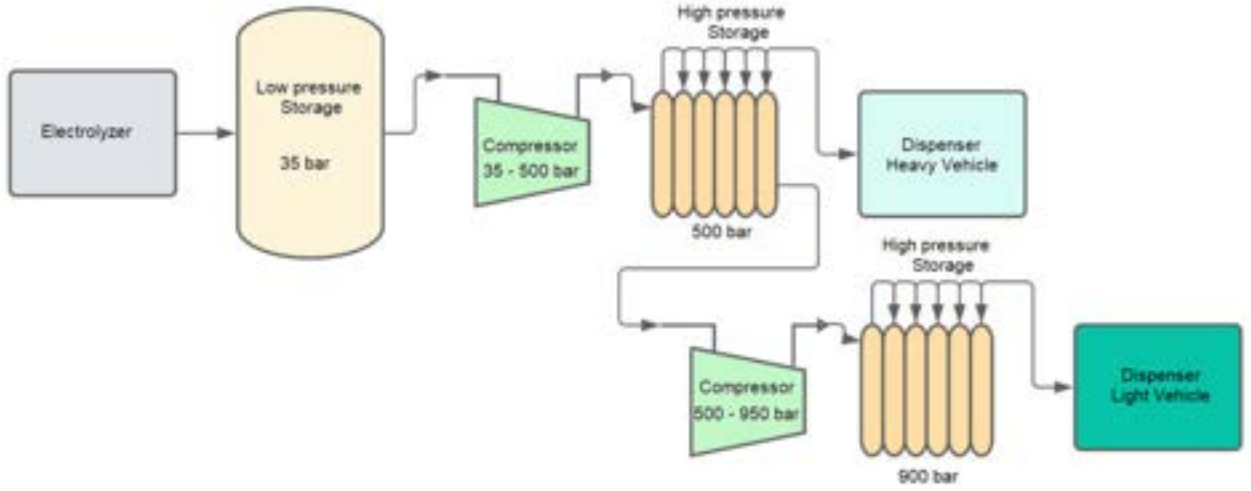

Figure. 3. Schematic representation of the hydrogen refuelling station considering the compression levels and the low and high-pressure storage.

3.2. Mathematical modelling

The model formulation includes the definition of the objective function, decision variables and physical constraints, for which an optimization algorithm is applied in order to disclose the best solution domain. Thus, at each complete simulation, the implemented model runs, iteratively, all the routines of the physical model [30].

3.2.1. Objective function

The mathematical model for storage sizing and refuelling is based on several physical variables, such as the storage volume (v), the pressure at which the hydrogen is stored (p) and the mass of hydrogen filled (m).

The objective function of the mathematical model is to minimize the total volume of high-pressure storage, whereas, the volume can be calculated through the hydrogen density. Thus, the objective function is defined by equation (1).

$$\begin{aligned} &min \quad v \\ &where \quad v = \frac{m}{Fp^2 + Gp + H} \end{aligned} \tag{1}$$

In equation (1), terms F, G and H correspond to the coefficients from the function of the density variation of hydrogen. The determination of these coefficients is based on the numerical approximation through *Polyfit* routine at Matlab®, considering reference discrete values that relates the density of hydrogen with the pressure for an operating temperature of 25ºC. The 2nd degree polynomial is presented in equation (2).

$$\frac{m}{v} = -2.55\times10^{-2}\,p^2 + 7.39\times10^{-2}\,p + 3.64\times10^{-1} \quad [\mathrm{kg/\,m^3}] \tag{2}$$

3.2.2. Decision variables and constraints

Defining the decision variables is in fact one of the hardest and/or most crucial steps in formulating an optimization problem. Three types of physical quantities were defined as explicit decision variables for the numerical model. For all of them upper and lower bounds were set in order to establish the operational relationships. The bounds in the variables guarantee that the optimum solution is within the technical operating capability. One of the main decision variables is the pressure at which the hydrogen is stored in the high-pressure system. The lower and upper pressure limits for each skid level are based on values that take into account the components to be used in the station and its operating requirements. Table 1 presents the pressures limits for both light and heavy refuelling models. For both H35 and H70 refuelling, it is defined a minimum pressure of 100 bar on skid 1. The lower pressure limit at each skid corresponds to the maximum value obtained by the optimization model at the previous skid pressure level. Thus, the hydrogen pressure at skid 1 ($p_{H35,1}$ and $p_{H70,1}$) varies between 100 and 375 bar.

The pressure in the skid 2 ($p_{H35,2}$ and $p_{H70,2}$) cannot exceed a maximum pressure of 500 bar. For H70 refuelling, a third skid level was considered ($p_{H70,3}$), establishing an upper limit of 900 bar.

Table 1. Lower and upper limits for skid pressure

Type of vehicle	Skid level	Variables and respective limits [bar]	
Heavy vehicles (H35)	Skid 1	$100 \leq p_{H35,1} < 375$	(3)
	Skid 2	$p_{H35,max,1} \leq p_{H35,2} \leq 500$	(4)
Light vehicles (H70)	Skid 1	$100 \leq p_{H70,1} < 375$	(5)
	Skid 2	$p_{H70,max,1} \leq p_{H70,2} < 500$	(6)
	Skid 3	$p_{H70,max,2} \leq p_{H70,3} \leq 900$	(7)

The second decision variable is the volume of hydrogen stored at each skid level, $v_{H35,1}, v_{H35,2}$ for H35 refuelling and $v_{H70,1}, v_{H70,2}, v_{H70,3}$ in the case of H70 refuelling. Due to operational considerations, it was set that the volume stored at high-ranked skids with pressure levels (see equation (8) and equation (9)).

$$v_{H35,1} \leq v_{H35,2} \quad [\mathrm{m}^3] \tag{8}$$

$$v_{H70,1} \leq v_{H70,2} \leq v_{H70,3} \quad [\mathrm{m}^3] \tag{9}$$

The third decision variable is the mass of hydrogen transferred from the skid to the vehicle during the refuelling ($m_{H_2 out,x}$). At each filling, there is a quantity of mass provided by the skid, depending on the final mass that is required to complete each refuelling. Yet, the mass that is supplied in the first H35 filling by the first pressure level must be lower or equal to 30 kg (equation (10)).

$$m_{H_2 out,1} \leq 30 \quad [\mathrm{kg}] \tag{10}$$

For all refuelling processes, the pressure drop of 50 bar between the station skid and the vehicle tank must be guaranteed (equation (11)).

$$p_{skid} - p_{\text{vehicle tank}} \geq 50 \quad [\mathrm{bar}] \tag{11}$$

3.2.3. Optimization method

In order to implement the optimization problem, the *MS Excel® Solver* was used, considering the Generalized Reduced Gradient (GRG) method. This popular optimization method is able to solve nonlinear optimization problems, only requiring that the objective function is differentiable. This method allows to solve the nonlinear problem dealing with active inequalities. The variables are separated into a set of basic (dependent) variables and non-basic (independent) variables. Then, the reduced gradient is computed in order to find the minimum in the search direction. This process is repeated until the convergence is obtained.
The used solver includes a multi start method that can improve the prospects of finding a globally optimal solution for an optimization problem [31,32].

4. Results and discussion

After defining the decision variables, their maximum and minimum limits, as well as the problem constraints, the mathematical model was programmed and the results obtained are presented in this section. The simulation results are depicted for heavy and light vehicles. The optimal values of pressure at each storage skid, the skid storage volumes and the hydrogen mass that is provided at each fuelling are presented considering the minimum storage capacity required.

4.1. Refuelling of heavy vehicles

The value of the objective function - minimize the total storage volume – corresponded to a storage volume of 36.90 m^3, being obtained a volume of 10.58 m^3 in the first skid and 26.32 m^3 in the second skid. The total stored volume can be considered high, since it represents a large volume to physically store, assuming normal conditions of pressure and temperature.

According to the results (Table 2), the pressures in the high-pressure storage system fulfil the functional requirements defined by equations (3) and (4). The pressure in the first skid does not exceed 375 bar and in the second level does not exceed 500 bar.

Table 2. Optimal solution for heavy vehicles refuelling (H35)

Parameter	Variable	Value
Volume [m^3]	Total volume, v	36.90
	Skid 1, $v_{H35,1}$	10.58
	Skid 2, $v_{H35,2}$	26.32
Pressure [bar]	Skid 1, $p_{H35,1}$	128.6
	Skid 2, $p_{H35,2}$	395.6

Figure 4 presents the mass of hydrogen dispensed at each skid ($m_{H_2\,out,x}$). As the number of fillings increase, the mass of hydrogen to be dispensed from the skid 1 decreases. This decrease is compensated by the raising mass provided skid 2. By the end of the 6th refuelling, it is observed that the mass provided by both skids is similar. This outcome is related to the fact that the initial pressure at which the hydrogen is stored in the skid 1 is very close to the supply pressure, which means that the useful mass in that first level is smaller than the useful mass available in the second. Also, it is shown that the first refuelling provides a mass lower than the required 30 kg.

Figure 5 shows the pressure drop between the heavy vehicle tank and the storage containers. It appears that the pressure decreases as fillings are accomplished, since the decrease in the usable available mass of hydrogen results in a decrease of the pressure in storage.

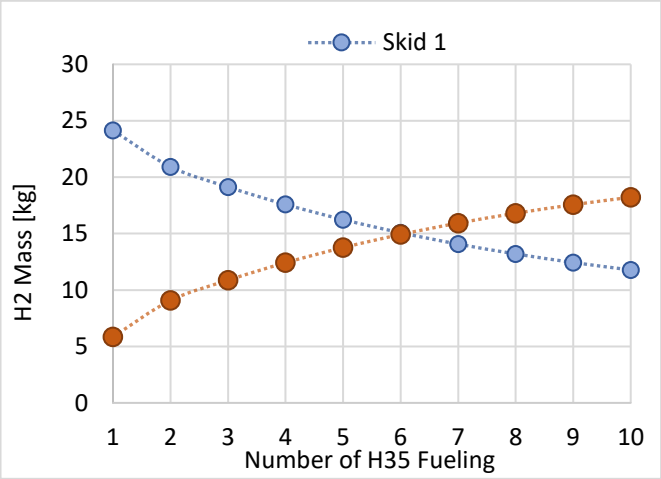

Figure. 4. Mass of hydrogen dispensed at each skid level for H35 refuelling.

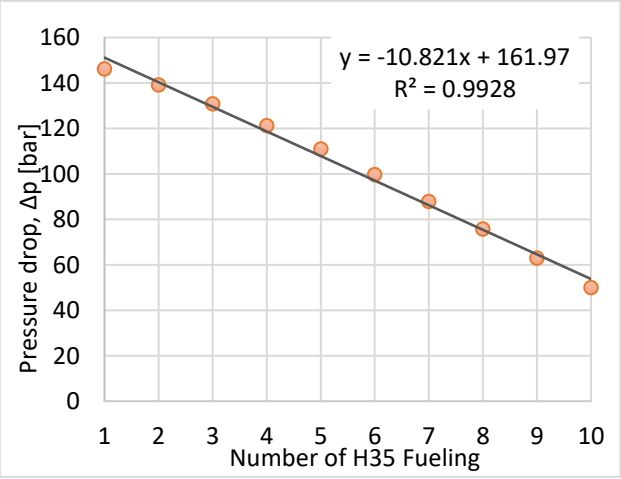

Figure. 5. Evolution of pressure drop between the station skid and the vehicle tank for H35 refuelling.

4.2. Refuelling of light vehicles

Regarding the light vehicles, the results for the total storage volume and the respective skid values are presented in Table 3. The total volume corresponded to 22.89 m^3, being obtained an equal volume of 7.63 m^3 for all 3 skids. Taking into account the number of vehicles to be fuelled and the pressure required by the system, these values are acceptable and allow all vehicles to be filled with the expected 4.70 kg of hydrogen. Thus, in order to respect all problem constraints, it is necessary a 5 hours period to fuel the 30 light vehicles.

The pressure in skid 1 and skid 2 corresponds to the lower limit established as the boundary condition, a value of 100 bar and 375 bar, respectively. In the skid 3, the pressure reaches the value of 750 bar. The value of the maximum pressure of the storage system is, in theory, the most limiting input parameter, but also the most important one in the sizing of the filling station. It is estimated that changing this input will cause sudden changes in the total volume required for hydrogen storage. Consequently, larger volumes of storage required imply a greater initial investment in the construction of the station.

Table 3. Optimal solution for light vehicles refuelling (H70)

Parameter	Variable	Value
Volume [m^3]	Total volume, v	22. 9
	Skid 1, $v_{H70,1}$	7.63
	Skid 2, $v_{H70,2}$	7.63
	Skid 3, $v_{H70,3}$	7.63
Pressure [bar]	Skid 1, $p_{H70,1}$	100
	Skid 2, $p_{H70,2}$	375
	Skid 3, $p_{H70,3}$	750

Figure 6 presents the mass of hydrogen dispensed at each skid ($m_{H_2\,out,x}$) considering the refuelling time. Equally to the results obtained for heavy vehicles, as the number of fillings increase, the mass of hydrogen to be dispensed from the skid 1 decreases. This decrease is compensated by the raising mass provided by both skid 2 and skid 3. In the skid 3, where the hydrogen storage pressure is higher than the final pressure in the vehicle tank ($p_{\text{vehicle tank}} = 671.4\ \text{bar}$), the results show that in the last hour of refuelling, almost 50% of the total mass of the vehicle's tank comes from the skid 3, taking into account that the two skids lose their ability to respond as fillings occur. Figure 7 shows the pressure drop between the light vehicle tank and the storage containers. As the refuelling is completed, the pressure differential decreases.

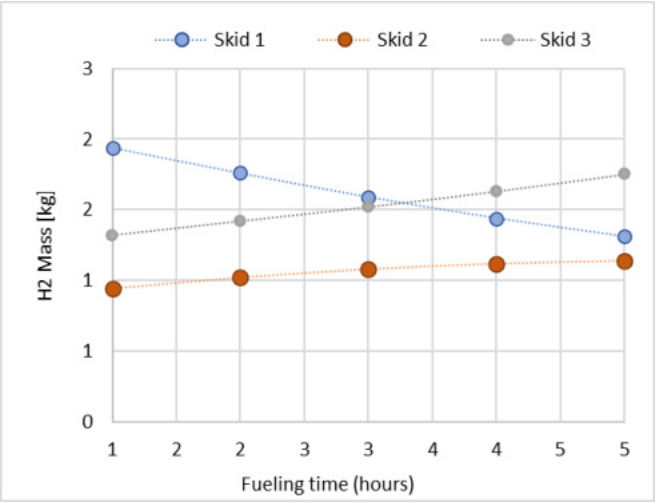

Figure. 6. Mass of hydrogen dispensed at each skid level for H70 refuelling.

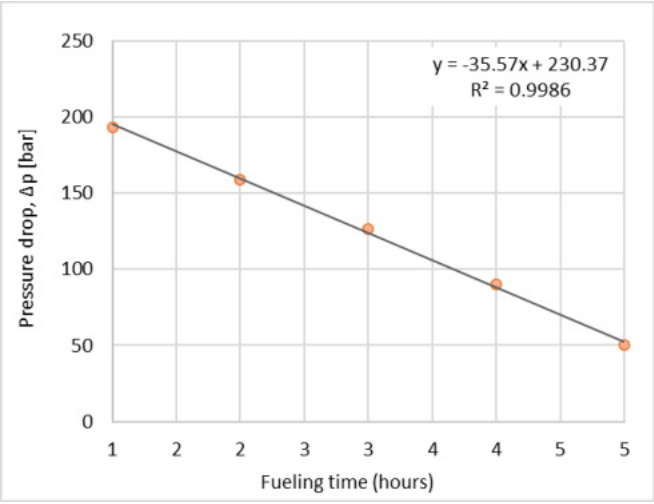

Figure. 7. Evolution of pressure drop between the station skid and the vehicle tank for H70 refuelling.

4.3. CAPEX determination

The costs of a hydrogen refuelling station depend on the characteristics of the equipment and components. Considering the components that the hydrogen refuelling station, the total investment cost can be determined by market sourcing of components with the characteristics closest to those obtained from the optimal solution. When determining the total capital costs, in addition to all the components already identified, it is necessary to calculate all accessories and labour costs.

The CAPital EXpenditure – CAPEX – is the total amount invested in the project [33]. Considering the data collected from the market, it was possible to estimate the relative weight of each component of the hydrogen refuelling station. Based in Figure 8, the highest percentages are represented by the cost of production equipment (30%), high-pressure storage unit (20%) and the hydrogen compression system (18%).

When sizing a hydrogen refuelling station, the electrolyzer and the compressors are components with more standardized working characteristics and their capital costs do not vary significantly with the increase in installed capacity. However, high-pressure storage unit cost depends on the capacity required for a given filling frequency, which in turn depends on the total volume and daily hydrogen requirements. The analysis also shows that the hydrogen dispenser only represents 7% of the total capital costs.

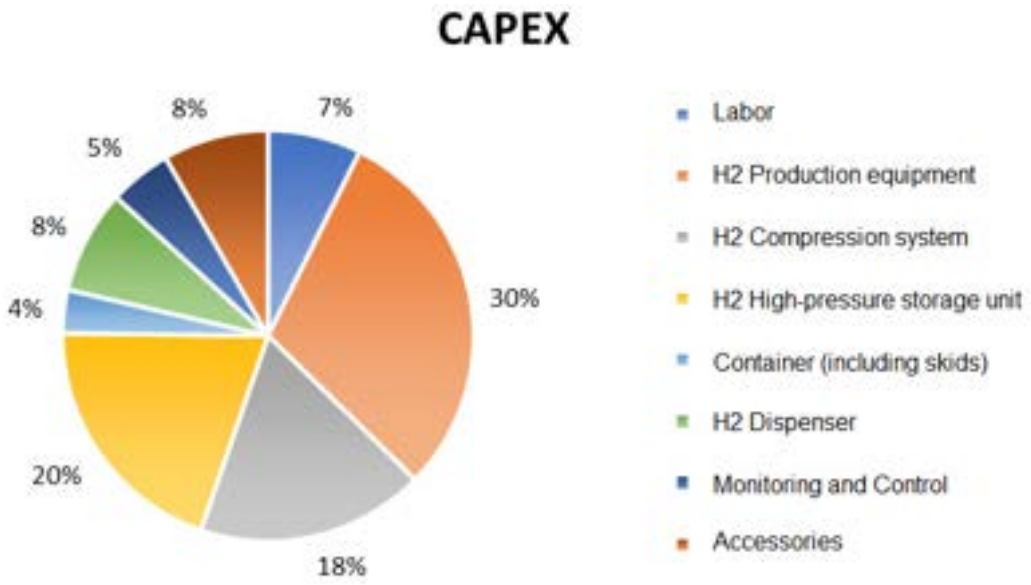

Figure. 8. CAPEX for the hydrogen refuelling station considering the commercial options for the optimal solution disclosed by the numerical model.

5. Conclusions

This paper aims to define a numerical optimization model for a hydrogen refuelling station to supply both light and heavy vehicles. The objective function is to minimize the total storage volume, taking into account the number of vehicles to be refuelled. The process of vehicle refuelling with compressed hydrogen was subjected to control requirements to ensure that the vehicle tank is within a specified operating condition defined by an upper limit on pressure, and an upper and lower limit on temperature. The

The refuelling station was defined considering the electrolyzer, a low-pressure storage buffer, the compressors aim to raise the pressure and the hydrogen high-pressure containers arranged in a cascade system in order to minimize their energy consumption. The hydrogen is stored in skids with several containers connected to a certain pressure. The station should be able to supply light and heavy (buses) vehicles. Thus, theoretically, the on-site infrastructure, 10 heavy vehicles at 350 bar and 30 light vehicles at 700 bar should be supplied. For H35 fuelling, 2 skid pressure levels were considered, allowing two fillings per hour. In this case, it is assumed that a mass of 30 kg is supplied by the dispenser. The compression cascade for light vehicles considers 3 skid pressure levels and is expected to dispense 4.2 kg. The objective function is to minimize the total storage volume required. As decision variables, the pressure at each storage skid is considered, as well as the hydrogen mass dispensed to the vehicle tank. One of the most important constraints is the pressure differential of 50 bar between the high-pressure skid and the vehicle tank that should be guaranteed at all vehicle fillings, so the refuelling can be validated. The requirements regarding the refuelling process in order to prevent over-heating and over-filling significantly influence hydrogen refuelling station design and have a strong impact on its performance.

Thus, the hydrogen filling of light and heavy vehicles has been studied and standardized by SAE through the implementation of fuelling protocols. According to the SAE J2601 protocol, the mass flow rate of hydrogen to be supplied cannot exceed 60 g/s. Also, the hydrogen temperature limits vary between - 40 ºC and 85 ºC.

Also, fast refuelling of hydrogen is constrained by the thermodynamic properties of hydrogen under compression. The optimization results show that is possible to refuel 10 heavy vehicles considering a total storage volume of 36.9 m^3, whereas, for light vehicles, it is possible to refuel 30 vehicles with a total volume of 22.9 m^3. Based on CAPEX, the most representative capital costs are: the production equipment (30%), high-pressure storage unit (20%) and the hydrogen compression system (18%).
In conclusion, the skid pressure, the useful mass of hydrogen and the storage volume are the most important parameters in the design of hydrogen refuelling station. Their variation can cause drastic changes in the capital investment cost to construct the station. As future work, it is proposed the development of a techno-economic model, considering the integration of costs in the process of optimizing the design of the on-site hydrogen refuelling station.

Abstract:

The transportation sector is one that has had more hurdle conversion to renewable energy sources. The purpose of this research is to determine whether a renewable source of energy like 100% biodiesel (B100) could be used in the vehicles and equipment of a fleet that supports an air force squadron instead of conventional diesel fuel. To accomplish this, a selection of vehicles and machinery was examined for three months while the working procedure remained as usual, and then introduce a change in the fuel type, using biodiesel considering the same monitoring process during a similar period. This made it possible to compare any modifications that might have been made to fuel consumption, performance, emissions, maintenance, and reliability. The findings demonstrated that, with an average increase of less than 5%, using biodiesel does not result in a noticeable rise in fuel consumption. Additionally, there is a slight decline in the power that is available from the engine, however at less severe levels than anticipated. Depending on the engine, and the operation mode, there are a variety of emission-related scenarios, but overall, NOx and CO_2 emissions were reduced. Additionally, it was confirmed that there were no important concerns with the operation of the machinery or vehicles; the only issue of notice was the requirement to anticipate the replacement of a few fuel filters.

Biodiesel; Internal Combustion Engines; Vehicles; Energy; Sustainability.

1. Introduction

Biofuels, such as biodiesel, contribute very little to the accumulation of greenhouse gas emissions. Biodiesel is a versatile fuel that may be combined with diesel in 7% (B7) mixes, like the mixture provided in 2022 in all fuel stations in Portugal, and potentially in 20% or even 100% blends, known as B20 and B100 respectively.

The conversion of biomass feedstocks into biofuels is a low-impact process. The usage of biofuels as transportation fuels can help to reduce atmospheric CO_2 by using this renewable fuel instead of diesel in different ways: it prevents the some of the emissions associated with diesel engines, it allows the CO_2 content of fossil fuels to remain stored and give a mechanism for absorbing CO_2 through the growth of fresh biomass for fuels.

Biofuels are the most advantageous solution for decreasing greenhouse gases from the transportation sector since they are compatible with the natural carbon cycle and can be used in vehicles actual technology. Increased use of biomass would hasten the deposition of fossil fuels and reduce greenhouse gas emissions in transport sector.

1.1. Research question

The use of biodiesel in actual vehicles is a possibility and some authors present that has a real path to reduce greenhouse gas emissions and the fossil fuel transport sector dependence.

The real-world exhaust emissions and fuel consumption of on-road diesel vehicles was an issue that deserves a particular attention. Two light-duty diesel trucks and two heavy-duty diesel trucks were fuelled by waste cooking oil biodiesel blends, considering four mixed fuels with blend ratios of 0% (neat diesel), 5% (B5), 20% (B20), and 100% (B100) (biodiesel in traditional fossil diesel). The results show that the total fuel consumption (biodiesel + traditional fossil diesel) did not clearly decrease, but blending biodiesel into traditional fossil diesel

could clearly decreased the consumption of traditional fossil diesel, reduce the countries' dependence on oil imports. The CO, HC, and PM emissions for all of the tested vehicles decreased with increasing biodiesel content in the blend, and the NO_X emissions also showed a decrease with increasing biodiesel content in the blend, not for all, but for most vehicles in this study [1].

Other research [2] examined several biofuels blends on a 2019 performance diesel EURO VI heavy-duty truck, with the objective of preparing a fuel consumption measurement and a performance analysis, an experimental procedure was developed based on the homologation cycles and processes of heavy-duty truck on a chassis bench roll, testing the following samples: B7, B15, B100 and a HVO15.

The powertrain performance results reveal that the fuel which presented higher power values was the HVO15, followed by B7, B15 and B100. With B100, the maximum power output decreases 4,5%, compared to B7. On fuel consumption, the smaller results were obtained for B7 and B15, without reasonable differences, followed by B100 and then HVO15. With B100, the fuel consumption increases 9%, compared to B7. To evaluate the fuel economy performance of neat biodiesel compared to fossil diesel on a real road use, three buses on their daily utilization were analysed. In this experiment, the biodiesel buses had an increase on fuel consumption about 4,5%.

1.2. Objective of the work

The use of biodiesel has been analyzed in different laboratory studies, with different levels of incorporation of biodiesel in commercial diesel, either using engine test bench or using chassis dynamometers. There are also some works that consider the use of biodiesel blends in vehicles in road use, analysing the effects that blending small amounts such as 15, 20, or 30% biodiesel have on the use of these vehicles.

This study attempted to employ a more severe change, such as switching from commercial diesel to a wholly renewable fuel, i.e., 100% biodiesel, in a wide range of vehicles and equipment in real-world use, over an extended length of time. This allows to understand what changes occur as a result of this fuel change in conditions as close to reality as possible, allowing to effectively evaluate the environmental impacts, energy, and performance of using this fuel in vehicles, as well as analyse the potential effects on the reliability and maintenance of these vehicles.

2. Experimental Methodology

As mentioned earlier, the study was divided into three types of tests: fuel consumption, emissions, and bench testing. Therefore, this chapter will be subdivided into each of the tests performed. However, firstly, we will discuss some important properties of diesel fuel for this study.

2.1. Fuel Properties

The fuels considered in this study are quite similar, however they have significant differences that could explain some discrepancies in engine and fuel injection system behaviour. A quick description of the engine's most influential characteristics is presented.

Density relates the mass of the fuel to the volume it occupies. Therefore, the higher the density, the greater the mass in the same volume, and consequently, the greater the energy. Thus, since fuel is quantified by volume, higher density results in greater fuel economy. Biodiesel has a density between 873 and 883 kg/m^3, while petroleum diesel has a density between 820-845 kg/m^3. These values are for a temperature of 15°C [3,4].

Viscosity is a measure of a fluid's resistance to flow. If the viscosity is high, the injection cone decreases and concentrates on a narrower and more concentrated jet, resulting in poor atomization. Poor atomization leads to poor engine performance. Additionally, the greater resistance to fluid movement creates greater difficulty in operating the fuel pump. According to the European standard EN14214:2008, diesel viscosity at 40°C must be between 3.5 and 5 mm^2/s. The viscosity of biodiesel is approximately 4 to 5 mm^2/s under the same conditions. In very cold temperatures, the increased viscosity can compromise proper fuel circulation, resulting in starting and initial engine operation problems [3].

Calorific Value is defined as the amount of energy available per unit mass, during the combustion process in which the reactants are at 25°C and the products cool to the same 25°C. Generally, two values are defined as "higher" and "lower", HHV and LHV, depending on the physical state of water in the products, liquid or vapor, respectively. In the context of internal combustion engines, LHV is usually used. The Lower Heating Value (LHV) of diesel has a range of values that varies between 42.9 and 43.3 MJ/kg. The calorific value of diesel is about 10 to 14% higher than that of biodiesel [5].

Cetane Number Indicates the ease with which the fuel enters in self-ignition. The higher this value, the easier and faster the fuel will ignite when injected. This characteristic is critical in compression ignition engines, as it is essential that the fuel quickly self-ignite after injection. In the previously mentioned standard (EN14214:2008), a minimum value of 51 is defined for the cetane number. The cetane number of biodiesel depends on the base raw material used to form the fuel, however, a large percentage of them remain above this mentioned limit [1].

The equivalent amount of oxygen content present in the fuel is one of the most altered characteristics of the mineral and renewable fuels. In petroleum-based fuel, this content is zero, whereas in biofuel, it can have a value between 10 and 12% oxygen [6].

Oxidative stability is closely related to the Iodine value, as it reflects the tendency of a fuel to react with other substances. Therefore, oxidation stability decreases with an increase in the Iodine value. The value of this parameter varies depending on the composition and storage of the fuel. Biodiesel, due to its chemical unsaturation, becomes more susceptible to deterioration, which can have various implications such as an increase in fuel viscosity and acidity, the development of contaminations, and the formation of insoluble products, which can damage the engine or compromise its performance [7].

The Cold Filter Plugging Point (CFPP) indicates the minimum temperature at which significant crystal formation does not occur, in other words, the minimum temperature at which the fuel is liquid enough to be filterable under certain conditions. As previously mentioned, this property complements the pour point and cloud point.

To determine the CFPP value, a certain volume of fuel is subjected to a rapid and constant cooling process and, by vacuum action, forced to pass through a filter. The value is fixed at the minimum temperature that allows this filtration within a stipulated time interval. Naturally, all these parameters and equipment are standardized to develop a universal test and enable comparison between fuels. The required CFPP values vary depending on the climatic conditions of the country or region where the fuel operates.

Biodiesel shows a significantly higher tendency than diesel to form crystals at low temperatures, acquiring higher CFPP values. This can be problematic in colder climates, as previously mentioned, since the presence of crystals in the fuel causes clogging of filters, the injection system, and consequently affects the performance of the engine. The solution may be to include additives in the fuel that counteract this tendency or reduce the percentage of biodiesel in the fuel blend [7].

In summary, Table 1 presents the characteristics of the two fuels considered in this work and it reveals a comparison between biodiesel and petroleum diesel for the previously mentioned parameters, indicating the typical changes introduced by B100 relative to B7.

Table 1. Indicative comparison of fuel B100 relative to B7.

Proprieties	**B7**	**B100**	Comparison with petroleum diesel (B7)
Density (kg/m^3, at 15ºC)	843,3	881,7	↑
Viscosity (mm^2/s, at 40ºC)	3*	4,6*	↓
Calorific Value (MJ/kg)	42,62*	37,21*	↓
Cetane Number	52,5*	56,2*	↑
Oxygen content (%)	0	10-12	↑
CFPP (ºC)	-15	-1	↓

2.2. Fuel consumption test

To carry out this type of test, initially, equipment and vehicles were selected for study, with the primary objective of avoiding any situation that could compromise the normal operation of the fleet.

Analysing the series of vehicles under study, it is visible that there is a great variety of typologies, from light to heavy-vehicles, both for goods and passengers, and even tanker trucks. The great variety previously mentioned is also noticeable in the engine displacement of the engines under study, where the smallest has a total displacement of 1868 cm^3, and the largest has a total displacement of 12760 cm^3. All are diesel cycle, and operate at 4 strokes, varying between 4, 6 and 8 cylinders. These characteristics can be seen as an advantage in carrying out this study. However, the vehicles do not have the most current injection and exhaust gas treatment systems, since the newest vehicle has 18 years old, and the oldest has 42 years old. In summary, the influence of ZeroDiesel was analysed in 14 vehicles.

Analysing the series of equipment used in the study, it is evident that there is a wide range of typologies with engines ranging in displacement from 916 cm^3 to 9050 cm^3. All of them are Diesel cycle, operate in 4-stroke, varying between 3, 4, and 6 cylinders, with both in-line and V configurations, except for one equipment that operates in 2-stroke. These characteristics can be seen as an asset in conducting this study. The influence of the use of ZeroDiesel was analysed in 8 pieces of equipment.

After the selection of vehicles and equipment, there was a period of monitoring the kilometres and litters of commercial diesel fuel (B7) consumed by the vehicles and monitoring the corresponding operating hours of the equipment with the litters of diesel fuel consumed. The monitoring was scheduled to start on January 31,

2022, and end on March 21, 2022, however, this period was extended until April 28. After this period, the same monitoring occurred but with ZeroDiesel (B100). It began after the end of B7 use and extended until August 8. The counting of hours or kilometres travelled, and fuel consumed was considered for both periods allowing to have the comparative information of

2.3. Emissions testing

The main objective of this type of test is to evaluate the influence of fuel types (B7 and B100) on pollutant and CO_2 emissions. For this purpose, two representative vehicles and two ground support equipment were selected from the analysed fleet. The operating regimes were also representative of the normal operation of each vehicle and equipment, with tests performed with the engine cold (immediately after starting) and at normal operating temperature. However, no load was imposed on the engine during the vehicle tests, deviating from normal operation.

The measurement of emitted gases was carried out with the TESTO brand equipment, model 350 XL. The analyser unit includes several gas sensors, allowing for the measurement of the concentration of CO, CO_2, NO, NO_2, SO_2, H_2S, or C_XH_Y, among others. The range extension allows measurements to be made without restrictions, even when there are high gas concentrations. To protect the sensor technology, the range extension (dilution) is automatically activated when unexpectedly high gas concentrations are detected. Of all the substances that can be measured, the acquisition of data on the concentration values of O_2, CO, NO_X, CO_2, C_XH_Y, and also the lambda factor and the temperature of the exhaust gases was considered most important. The last two parameters were only used to ensure that the regimes considered with B7 and B100 were identical. The lambda value and hydrocarbon emissions could not be considered for the study because the measuring equipment had an anomaly that prevented the presentation of these parameters. Two sets of data were collected: one when the vehicles and equipment had been operating for more than a month with B7 and another when they had been operating for more than a month with B100.

2.4. Power and Consumption Test – WLTP

The main objective of these tests is to accurately evaluate the fuel consumption and performance of a vehicle using B7 and B100. Both tests are carried out on a roller dynamometer. For the power test, three tests are performed to obtain data from both the dynamometer and the vehicle via OBD. Afterwards, an arithmetic mean is calculated for the acquired torque and power values, provided there are no incongruent values. The present study aims to perform a comparative analysis of the engine performance results when using B7 and B100 fuel.

The dynamometer used in this study is the MAHA LPS 3000, a brake-type roller test bench based on the principle of eddy currents. This equipment enables testing of various situations, such as instant maximum power, power at pre-defined rotation speeds, and simulation of loads (constant traction, constant speed, etc.). Furthermore, it is possible to measure vehicles with 2 or 4-wheel drive, with a maximum permissible power per axle of 257 kW and 522 kW respectively, for a maximum speed of 260 km/h.

To evaluate the power of the vehicle, it is accelerated to maximum rotation speed, covering the range of engine rotation speeds in a controlled manner by the dynamometer (roller bench). This control is continuously performed throughout the engine's rotation range (continuous test). Alternatively, it can be performed discretely at pre-defined rotation points, which are established to allow for a more effective comparison between different tests (discrete test).

To obtain the desired results (engine power and torque), the dynamometer measures the power at the wheel, to which the power losses in the transmission (resistive power) obtained in the deceleration process are added. After obtaining these two parameters, the value of the engine power is obtained, which is already corrected based on environmental conditions, assuming the designation of "Norm power". Through this power value, dividing by the corresponding rotation, the value of the engine torque is obtained. The correction selected is according to the standard also used by the manufacturer when announcing the engine characteristics. In this study, continuous and discrete performance tests were performed.

In the case of fuel consumption evaluation, the test performed follows the standardized WLTP cycle, considering its use on a roller bench. For this test, a series of sensors are added to monitor the vehicle's fuel consumption, such as a flow meter (to obtain volume flow) and a scale, to obtain mass flow. The cycle is divided into 4 phases, one called "low" with an average speed of 18.9 km/h, a medium with an average speed of 39.8 km/h, a high with an average speed of 56 km/h, and an extra-high with an average speed of 92.9 km/h, with a total cycle duration of approximately 30 minutes. Data acquisition was performed at a frequency of 5 Hz. To ensure data synchronization, data processing was based on the definition of the initial point of the test, for which the average fuel mass present on the scale was considered over a period of 2 seconds, 5 seconds before the vehicle's movement began. Similarly, the transition point between each stage was the average of the mass measured on the scale for a period of 2 seconds, 5 seconds after the cessation of the vehicle's wheel movement.

As previously mentioned for the power test, in each WLTP cycle, 3 tests are performed, and the arithmetic mean of the results obtained in these tests is then considered. Similarly, to the previous procedure, a comparative analysis was intended to be carried out regarding the use of the two fuels in the same vehicle, so

the entire procedure was repeated considering a first test in which the vehicle was fuelled with B7 fuel, and then a second test was performed fuelling the vehicle with B100 fuel. The vehicle chosen for the study was a passenger car of the Citroën Berlingo make/model equipped with a direct injection engine with a displacement of 1900 cm^3.

3. Results and Discussion

Similarly, to the presentation of the experimental procedure, this chapter of results discussion will be divided into 3 subheadings, one for each test previously mentioned.

3.1. Fuel consumption test

To obtain the average fuel consumption values, the averaging of consumption for each refuelling was considered, assuming that all kilometres travelled (or hours of operation) were performed with the corresponding fuel of that refuelling. This assumption is not entirely valid, however, the fluctuations in the obtained averages are compensated by the multiple refuelling's existing in each equipment or vehicle, since the final average was considered as the average of each refuelling. In a careful analysis of the averages of each refuelling, if they presented values that were very discrepant from expected, they would not be considered for analysis. Therefore, the average consumption was calculated for each fuel and the percentage difference between them. The results obtained are presented in Table 2 for equipment and in Table 3 for vehicles. The same results are also presented in the following Figure 1 and Figure 2 for fuel consumption and percentage difference for equipment and vehicles, respectively.

Table 2. Indicative comparison of fuel B100 relative to B7.

Equipment	B7 Fuel consumption (l/h)	B100 Fuel consumption (l/h)	Difference
EE01	4,62	4,28	-7,25%
EE03	1,18	0,98	-16,95%

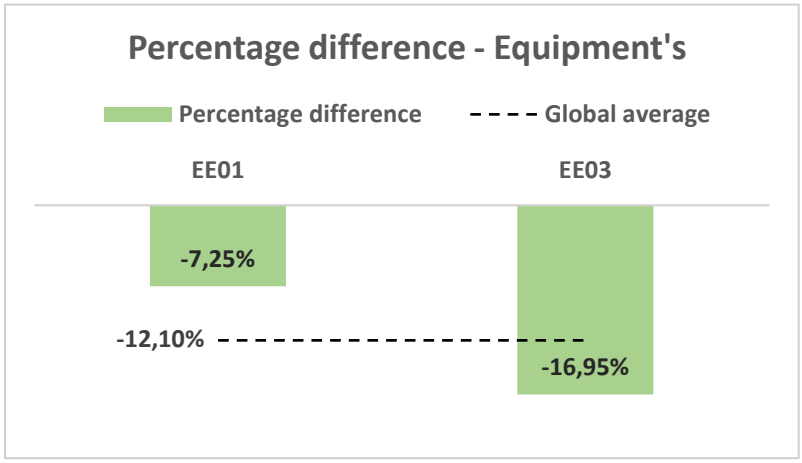

Figure. 1. Difference percentage in fuel consumption of the equipment.

Initially, it is noticeable that results for all vehicles and equipment under study are not presented. This is due to the lack of refuelling data for a particular type of fuel under study. It should be noted that for equipment EE01, there is no certainty in the results presented since only data from one refuelling for both fuels was available. Similarly, for vehicles AM05 and AMV12, the average consumption presented for fuel B7 is based on only one refuelling.

From the analysis of the results obtained, it is not possible to prove an increase or a decrease in fuel consumption when using biodiesel. For example, there is an increase in consumption of vehicle AMV03 in the order of 15% (corresponding to 1L/100km) and a decrease in consumption of vehicle AMV13 of about 13% (corresponding to 2L/100km). This difference in consumption can be justified, not due to differences in the chemical properties of the fuel but rather due to uncertainties in the obtained data, since there are several variables not controlled, such as different routes and drivers, which lead to different consumption rates, which is normal and corresponds to the operation of these vehicles even when fuelled with the same fuel. Additionally, since the consumption of vehicles is based on the distance travelled, it is not possible to determine whether they were stationary, consuming fuel without covering any distance. This aspect is particularly critical, for

example, in tanker trucks, where the pumps that transfer the fuel are operated by the vehicle's engine. Therefore, it is not possible to directly correlate an increase in fuel consumption when using B100, in the order of magnitude of the difference in calorific value between this and B7, as would be expected. Overall, in vehicles, the use of biodiesel increased consumption by 1.36%, while in equipment, there was an average decrease of 12.10%.

Table 3. Fuel consumption for each vehicle for both studied fuels and their respective percentage difference.

Vehicle	B7 Fuel consumption (l/h)	B100 Fuel consumption (l/h)	Difference
AM01	4,94	5,30	7,24%
AM02	7,37	8,04	9,10%
AM03	6,33	7,27	14,91%
AM04	8,31	7,84	-5,69%
AM05	10,89	10,64	-2,28%
AM06	10,27	10,94	6,54%
AM07	13,37	12,59	-5,78%
AM08	8,74	8,98	2,77%
AM09	75,62	80,48	6,42%
AM10	83,41	86,07	3,19%
AM11	17,65	17,64	-0,02%
AM12	10,90	10,24	-6,08%
AM13	17,41	15,20	-12,69%

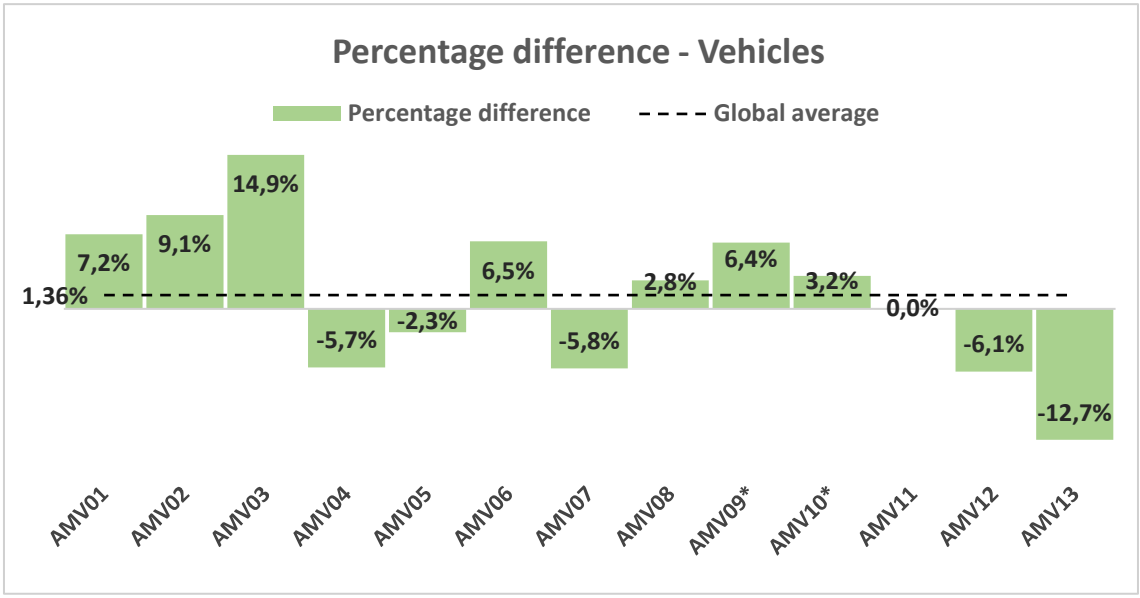

Figure. 2. Percentage difference in fuel consumption per vehicle.

3.2. Emissions testing

Analysing now the results obtained for emissions, Table 4 and Table 5 present respectively the vehicles and equipment results, with the representative operating conditions of their normal operation, the percentage differences in emissions between B100 and B7 with the overall average by chemical substance. It should be noted that, in the equipment, all tests were carried out considering their normal operating temperature.

The cases where the value presented is negative, for example, it indicates that after using B100 fuel, there was a decrease in the emission of the chemical substance being analysed, like it is clearer in the figure 3.

Table 4. Percentage difference in vehicle emissions.

Vehicle	Engine speed	O_2	CO	NO_x	CO_2
AM09	Hot Idle	0,24%	42,29%	-10,48%	-2,91%
AM09	1300 RPM (Hot)	0,79%	14,91%	-8,21%	-7,94%
AM09	1800 RPM (Hot)	0,79%	3,55%	-5,88%	-6,12%
AM11	Cold Idle	1,53%	59,81%	-63,32%	-7,28%
AM11	Hot Idle	-0,13%	201,02%	-49,03%	1,00%
AM11	2000 RPM (Hot)	-1,09%	12,70%	-28,33%	6,79%
AM11	3000 RPM (Hot)	-2,86%	1,36%	-16,16%	14,01%
Global Average		-0,06%	32,86%	-34,81%	0,37%

Table 5. Percentage difference in equipment's emissions.

Equipment	Engine speed	O_2	CO	NO_x	CO_2
EE03	Idle	-0,27%	51,68%	-4,06%	1,20%
EE03	Under Load	-1,12%	36,16%	0,67%	3,16%
EE04	Idle	-0,16%	-16,22%	7,49%	0,71%
EE04	1700 RPM	-0,88%	0,00%	12,03%	1,65%
EE04	2400 RPM	-3,77%	22,41%	1,27%	6,06%
Global Average		-1,12%	26,57%	5,78%	3,01%

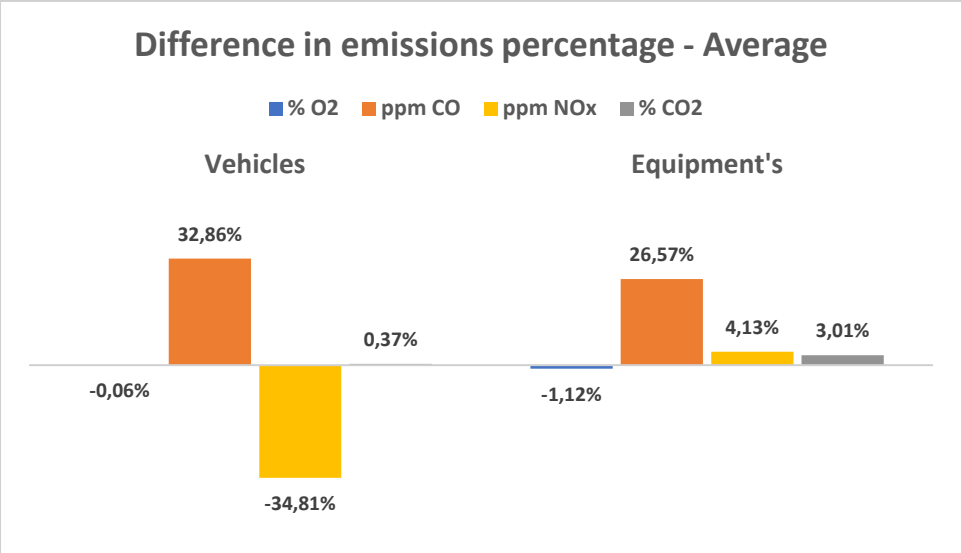

Figure. 3. Differences in global average, for both fuels, by chemical species.

3.2.1. Oxygen (O_2)

The changes obtained in oxygen (O_2) emissions were insignificant, demonstrated by the difference in the global average of -0.06% in vehicles and -1.12% in equipment, so it was considered an unchanged parameter when using biodiesel. The differences presented may be related to inaccuracies in the measurement device, meteorological differences, among others. When using B100, an increase in the emission of this compound derived from the higher percentage of O_2 present in the fuel would be expected, however, this was not observed.

3.2.2. Carbon monoxide (CO)

An increase in carbon monoxide (CO) emissions was observed in all regimes studied, except for one measurement at idle for the EE04 equipment, which is visible by analysing the difference in the global average, both for vehicles and equipment. The increase in the emission of this substance was more significant at idle with a warm engine, since it is mainly formed in rich mixing zones. Therefore, the increase in its concentration when using B100 can be explained by the higher viscosity of this fuel, which hinders atomization and subsequent combustion. This greater difficulty in atomization is more prevalent at idle due to the lower injection pressure associated with this regime. Although the values presented have a very significant percentage increase (on the order of 200%, for example), the emission of CO in diesel engines is not noticeable, as they always operate on lean mixtures, since the concentration values of this substance are quite low. Therefore, it is natural and expected that the percentage differences present more significant values.

3.2.3. Nitrogen oxides (NO_X)

Overall, there was a decrease in nitrogen oxides (NO_X) in all regimes, except for equipment EE04, where the emission of these substances increased. This is visible by analysing the difference in the global average in vehicles, which decreased by 34.81%, contrary to what happened in the equipment (which increased by 5.78%), solely provided by the aforementioned equipment. An explanation for the decrease in the emission of this substance, given that in the case of vehicles the tests were performed without load, is the lower temperature reached when the vehicle operates with biodiesel due to the lower calorific value of this fuel. Therefore, since temperature is the most important factor in NO_X emissions, a decrease in this chemical substance would be expected. In situations where the engine was tested under load, there may be greater emissions of this substance due to the greater amount of oxygen in the combustion, derived from the biodiesel itself. It should be noted that if the vehicles or equipment had gas treatment systems, the emission of this compound would be more controlled.

3.2.4. Carbon dioxide (CO_2)

It is not possible to correlate the presence of CO_2 emissions with the use of biodiesel in all equipment and vehicles. While there was a decrease in emissions for AMV09, the emission of this substance either slightly increased or stabilized in the other machines. CO_2 emissions are directly related to fuel consumption. As it was not unequivocally found that there was an increase in fuel consumption, only slight fluctuations in the emission of this compound would be expected for the various vehicles and equipment. Overall, there was a very slight increase in carbon dioxide emissions with the use of biodiesel, at 0.37% for vehicles and 3.01% for equipment.

3.3. Power and Consumption Test – WLTP

The power tests obtained are represented in the following Figure 4, where the power and torque developed as a function of rotation speed are visible for the two fuels under study.

The percentage difference between the values obtained for power is presented also in the same Figure 4. In this case, when the value presented is positive, it translates to a higher power obtained when the vehicle was operating with B100 compared to when it was operating with B7.

From the analysis of both graphs, it is visible that the differences obtained between the use of B7 and B100 are minimal. A decrease in power, in the order of magnitude of the difference in the calorific value of the fuel, i.e. 10%, could be expected, which could be attenuated by the greater volumetric mass of the fuel. However, this was not the case, and there was even an improvement in the delivered power at high speeds, after 4000 RPM. A slight decrease in the developed power occurred at low and medium speeds, which was less noticeable between 1500 and 2500 RPM. The increase in power at high rotation speeds would not be expected and may be related to some measurement problem, fundamentally in the final part of the test where the transition from measuring the power at the wheel to measuring the transmission losses occurs. The average numerical results for maximum power and torque are presented in the following Table 6. Therefore, the following percentage differences are obtained, visible in the same Table 6. If the presented value is negative, for example, it indicates that there was a decrease in this parameter after the use of B100 fuel.

Analysing the numerical results, it is visible that, contrary to expectations, an increase in the engine's delivered power occurs when using biodiesel. This may be related to some intervention that the vehicle has undergone or the alteration of any mechanical component that affects the maximum power delivered by the engine, mainly in high speed. A decrease of approximately 10%, corresponding to the difference in the calorific value of the fuels, would be expected when using biodiesel. On the other hand, the maximum torque obtained when using B100 decreased and was reached earlier.
Examining the results corresponding to the WLTP test, Table 7 presents the values of the average fuel mass flows obtained for each speed profile for each of the analysed fuels and also the results considering the percentage difference.

From the analysis of the results, it is possible to observe an increase in the average fuel mass flow for B100 in all speed profiles considered from 1% to 5%. This difference has a greater impact in the low-speed profile, decreasing with increasing speed, with a slight increase in the high-speed profile. The increase in fuel consumption can be explained by the lower calorific value present in biodiesel. However, since the result is shown on a mass basis, it makes sense to also analyse consumption on a volumetric basis, as is typically considered in vehicle usage. The average fuel consumption obtained, considering a typical volumetric mass for B7 of 839.8 kg/m^3 and for B100 of 881.7 kg/m^3, is visible in Table 8 and graphically in Figure 5.

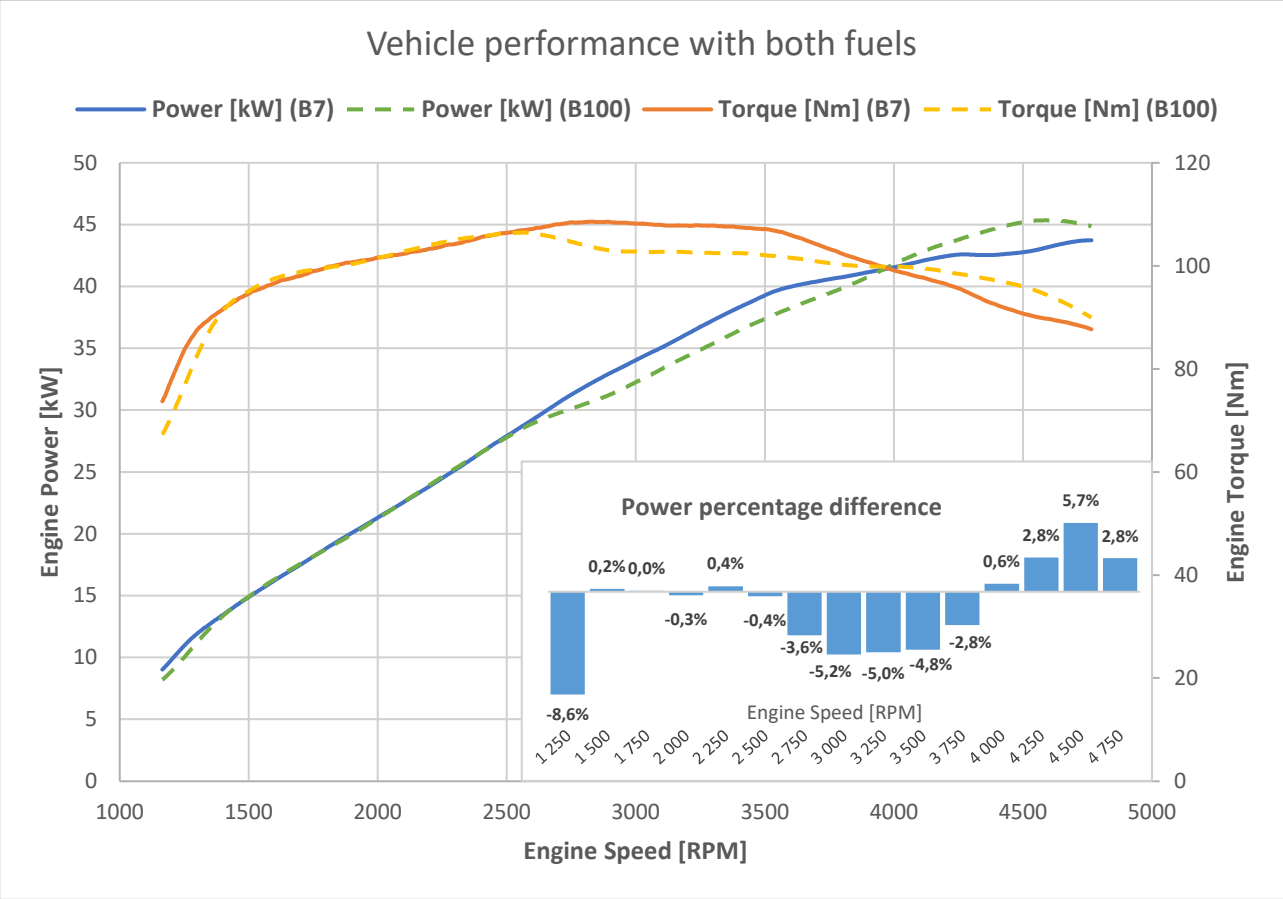

Figure. 4. Power and torque chart, and power percentual difference obtained between both fuels.

Table 6. Percentage difference and Maximum power and torque obtained.

Parameter	B7	B100	Unit	Percentage difference [%]
Standard power	43,8	45,4	kW	3,8
Engine power	44	45,2	kW	2,7
Wheel power	29,8	33,2	kW	12,6
Resistive power	14,1	11,6	kW	-18,2
@	4760	4590	rpm	-3,5
Standard torque	108,7	106,5	Nm	-2,0
@	2870	2600	rpm	-10,6

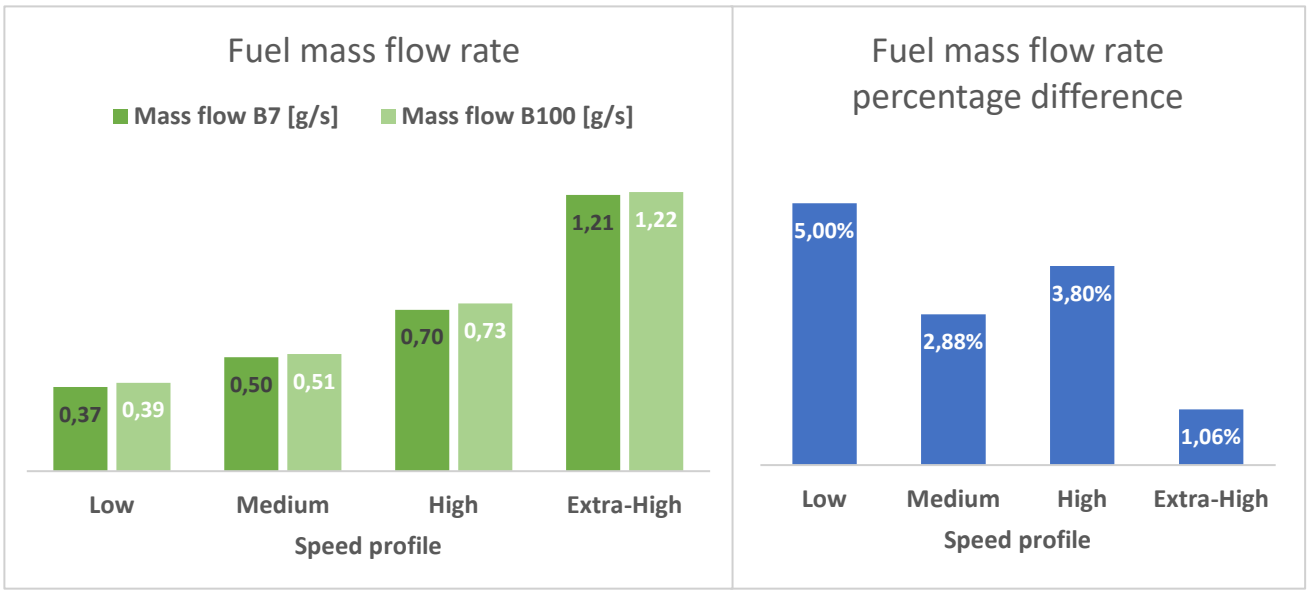

Figure. 5. Mass flow rates of fuel and percentual differences obtained in the WLTP test, for B7 and B100.

Table 7. Mass flows and percentage differences obtained in the WLTP test, for B7 and B100.

Speed profile	Mass flow B7 [g/s]	Mass flow B100 [g/s]	Percentage difference
Low	0,367	0,386	5,00%
Medium	0,497	0,511	2,88%
High	0,705	0,732	3,80%
Extra-High	1,206	1,219	1,06%

Table 8. Fuel consumptions and percentage differences obtained in the WLTP test, for B7 and B100.

Speed profile	Average consumption [l/100km] - B7	Average consumption [l/100km] - B100	Average consumption [l/100km]
Low	7,426	7,336	-1,21%
Medium	6,234	6,104	-2,08%
High	5,836	5,687	-2,54%
Extra-High	6,567	6,441	-1,93%

4. Conclusion

Just like the body of the work, the conclusions that can be drawn from this work can be grouped by the typology of the tests used:

4.1. Fuel consumption test

From the analysis of the results, it can be concluded that the use of biodiesel does not necessarily increase fuel consumption, as there were vehicles that showed increases and others that showed decreases. These fluctuations occur not only due to differences in fuel properties but also due to natural causes associated with the use of vehicles by different drivers on different routes, among other factors, which implies a fluctuation in vehicle consumption. Overall, there was a very slight increase of about 1% in the vehicles analysed. In the equipment, there was even a decrease in fuel consumption. This is not only due to differences in fuel properties but perhaps more to the different modes of operation to which they may have been subjected. Overall, in the equipment, there was a decrease in consumption of about 12% when B100 was used.

4.2. Emissions test

Analysing the exhaust gas emissions, it is evident that, in vehicles, the use of biodiesel causes an average increase in CO emissions (32.86%) and a decrease in NOx (34.81%), while there was virtually no change in O2 and CO_2. The increase in CO is not critical in diesel engines since they always operate in a lean mixture. The decrease in NOx is beneficial because it is one of the most critical pollutants associated with the use of diesel engines. For the equipment, globally, the same as in vehicles occurred, except for NOx emissions, which increased by about 6%, although this increase was only observed in one of the two pieces of equipment considered in this study. In both cases, there was no significant increase in CO_2 emissions, so it is possible to conclude that, by using biodiesel, there will be a decrease in emissions of this substance when considering the entire life cycle given the renewable nature of this fuel.

4.3. Power and Consumption Test – WLTP

Analysing the differences in power output by the vehicle under study when using biodiesel, there is no decrease in the vehicle's performance, with even a slight increase in the maximum power output by the engine. This may be related to some intervention that the vehicle has undergone or alteration of a critical component that affects the maximum power reached at higher engine rotation. Nevertheless, in a typical case, there would not be a significant decrease in the power output by the engine.

For the power bench consumption tests (WLTP), there is a visible increase in the mass fuel consumption in all speed profiles, between 1 and 5%. Even so, this value was lower than expected, which would be around 10%. Analysing the average volumetric consumption per distance travelled (l/100km), there is a slight decrease, around 2%. This is explained by the higher density of biodiesel.

Acknowledgments

The authors would like to acknowledge the major Rui Cotovio and his team that give an important and decisive contribution for this work. Authors also would like to express their acknowledgement to PRIO Energy who made this research possible.

Abstract:

Within the strategies for sustainable transition and decarbonization, biomass gasification represents an interesting solution to yield renewable fuels that can be used in internal combustion plants for power and combined heat and power (CHP) generation. The use of syngas instead of original biomasses allows industrial internal combustion engines to achieve higher conversion efficiencies and lower pollutant emissions. However, limited experience on real operative plants has led to a lower diffusion of the technology than expected.

To investigate the real behavior of a gasifier fed with lignocellulosic woodchips and coupled with a CHP engine, a commercial-grade system has been installed in the Science and Technologies Campus of the University of Parma. The aim of the research project Synbiose was to gain a better understanding of the processes to enhance the application of small-scale gasification and CHP plants in the tertiary sector. Operating parameters of the system – properly instrumented – have been monitored to analyze its performance and to improve its maintainability. In order to investigate the effects of woodchips from different tree species on system performance, a second smaller plant was built and has been used for a specific experimental activity.

An extended modelling study has been developed to enhance the comprehension of the gasification process and of the plant operation. A hybrid thermochemical model has been used for the simulation of the gasification process, while a lumped parameter dynamic model and multiphase CFD simulations have been applied and integrated to analyze the operation of the whole plant.

The aim of the paper is to summarize the results of these research activities highlighting the issues that arose during the project with specific reference to the implemented solutions.

Keywords:
Biomass; Cogeneration; Experimentation; Gasification; Simulation.

1. Introduction

Renewable energy sources play a key role in the sustainable transition and decarbonization of the power system. Together with solar and wind technologies (which are typically non-programmable), biomasses represent an interesting way to exploit the use of renewable energy without having relevant storage issues.

Currently, biomasses are used for direct combustion in combined heat and power (CHP) steam plants (i.e. wooden biomass direct combustion, giving rise to noteworthy issues of pollutant formation), or they are converted into so-called biogas through anaerobic fermentation that can be used as fuel for CHP plants based on internal combustion engines or micro-gas turbines. In both cases the size and flexibility of the comprehensive conversion and generation plants hinder their applications in the tertiary sector (e.g. hospitals, university campuses).

Within this context, the gasification process of wooden biomasses is an interesting alternative allowing for the production of a gaseous fuel (syngas) that can be properly cleaned and used for CHP generation. Moreover, the use of thermochemical conversion and of internal combustion engines allows for smaller and more flexible plants, which can use locally available solid biomasses more efficiently.

However, the lack of field testing knowledge on these plants (with particular reference to operation and maintenance issues and to syngas production and cleaning technologies) still seems to limit their use in real applications. In the current Italian context, almost no small-size syngas-fed operating CHP plants can be found on which adequate operating experience has been acquired to evaluate their performance and reliability.

To overcome this issue, the Synbiose project has been started with the aim of enhancing the theoretical and experimental comprehension of small-scale gasification-CHP plants to allow for their wider application in the tertiary sector. The project lasted from February 2017 to May 2021 and involved the installation, instrumentation, testing and modelling of a commercial-grade plant based on a gasifier fed with lignocellulosic woodchips. The project partners were Siram S.p.A., the Center for Energy and Environment-CIDEA of the University of Parma, and the Department of Engineering of the University of Ferrara. The plant is installed in the Campus of the University of Parma and is directly connected to the local electrical grid and to the district heating network (fed by natural gas boilers) which fulfil the demands of the Campus buildings (with a total peak heating power demand of 16 MW).

Many examples can be found in the literature regarding the optimization of the gasification process [1] and its modelling [2, 3] or regarding experimental tests [4]. There are very few examples related to applications in an operating environment [5, 6] and none with an experimental and numerical approach.

1.1. Aim of the paper

The aim of this paper is to give a concise presentation of the outcomes of the activities of the 51-month project and to present a summary of the main lessons that have been learned from the experience gained. The main goal of the project was to bring the gasification technology to a sufficient level of maturity to be able to represent a viable technical solution for its application in the tertiary sector. To achieve this goal, the partners were involved in experimental and computational research which are summarized in the following sections. In particular, Section 2 presents the two plants that have been installed at the Campus and their measurement and acquisition systems.

The first plant is characterized by an installed nominal electrical power of 125 kW and it was used for long run testing to evaluate the reliability of the technology. The second, with an installed electrical nominal power of 25 kW, was instead used to evaluate the fuel flexibility of the technology by testing its operation with different tree species. The results of these experimental activities are summarized in Section 3.

Beside the experimental activity, the project also dealt with the development of the mathematical models of the process, of the whole plant and of its components. Section 4 briefly shows the mathematical model of the gasification process and its validation, the dynamic model of the whole syngas cleaning line and the CFD analyses that have been performed on relevant components.

Finally, some conclusions have been made in Section 5, wrapping up the whole project, and providing useful hints for those who will try to replicate the experience.

2. The plants

The experimental equipment used in the project consists of two biomass-fueled syngas cogeneration plants (Figure 1). The sizes of these two plants, in terms of electrical power output, are 125 kW and 25 kW, respectively. Both plants are located at a dedicated facility in the Science and Technologies Campus of the University of Parma.

2.1. The 125-kW plant

The plant consists of biomass storage, i.e. wood chips, which is fed by means of an auger system into a storage chamber that can guarantee an operating autonomy of the plant of approximately 3 to 4 days at maximum power. Downstream of this biomass storage site is a vibrating screener, consisting of opposing grates that allow the wood chips to be sieved in order to remove the finest fractions. These fine fractions would cause occlusions inside the gasification reactor, affecting the empty/full ratio and limiting the passage of the syngas, which would therefore not be able to flow properly inside the reactor.

The feeding of biomass into the reactor is not continuous, but is regulated by a rotating blade sensor which, once the wood chip level decreases, activates an auger system that transfers the wood chips from a hopper downstream of the vibrating screener to the gasifier. The inlet to the gasifier is regulated by two valves that open alternatively, introducing a finite amount of wood chips, so as to minimize unwanted air inlets at the top of the reactor, since the reactor operates at lower barometric pressure conditions in the range of - (3÷8) mbar gauge pressure. The gasification reactor is of the fixed-bed downdraft type, with an hourglass shape. The biomass is fed into the upper part and, as it descends into the gasifier, undergoes the reactions of drying, pyrolysis, combustion, and gasification.

In the restriction zone (i.e. the throat), air is supplied through the nozzles located on the reactor circumference, driven by a fan. Locally, exothermic combustion reactions take place (although the reactor works with a lack of oxygen compared to the stoichiometric quantity), which sustain the other endothermic reactions taking place in the gasifier. All reactions take place because the system is kept under negative gauge pressure due to the suction of the internal combustion engine. By means of this pressure, the syngas, at a temperature of approximately 750 °C, is forced to pass through a grate in the lower part of the gasifier, which prevents the passage of the coarser pieces of char or wood chips, and then the syngas passes through an air-syngas countercurrent exchanger that preheats the reaction air.

Figure. 1. The two plants in the Synbiose area of the thermal power plant of the Campus in Parma.

The gas is then filtered through ceramic fiber filter elements (alumina silicate wool) at a temperature of approximately 600 °C. This filtration stage separates the carbon particles and char that the syngas has dragged along with it in its flow. Downstream of this filter, the gas passes through a so-called check filter, consisting of a very fine metal grid. Within this filter, a differential pressure sensor detects the fouling on the metal grid and, if a ceramic filter element has broken, it interrupts the engine operation by sending the gas to the flaring to preserve the integrity of the engine. Downstream of this element is a water-syngas heat exchanger, of the shell-and-tube type, which allows the syngas to cool down to approximately 110 °C, dropping below the dew temperature of certain classes of tar, which, as they condense, can thus be removed from the gas stream and removed from the exchanger via a double valve system.

Approximately 20 kW of heat output can be recovered from this heat exchanger. After this element, the syngas is fed into a metal filter that separates a final portion of tar (consisting of elements with a lower molecular weight than those removed previously) by coalescence and also a portion of the moisture present in the syngas. At this point, the syngas is fed into an aspirated internal combustion engine to produce electricity and heat. Under optimal conditions, up to 125 kW of electrical power and 200 kW of thermal power can be recovered from the cooling of the engine and combustion gasses. The combustion gasses then pass through a trivalent catalytic converter before being emitted into the atmosphere. A dedicated dry cooler is used to dispose of the heat output in the event of no demand from the user. Both electrical and thermal power are fed to the electricity and district heating networks that supply the University Campus, respectively.

The plant was entirely equipped with measuring instruments (Figure 2). The measured data was acquired on a quarter-hourly basis. Pressure and temperature sensors were placed upstream and downstream of each component. All temperature sensors are RTD PT100 type except for the K-type thermocouple installed for the syngas at the outlet of the gasifier (where temperatures at start-up can exceed 1100 °C). Type J thermocouples were installed up to the point downstream of the main filter, again due to the high temperatures. The pressure sensors, connected to the process via a steel capillary that protects the instrument from high syngas temperatures, are of the capacitive type with a ceramic membrane and have an operating range of (- 400 ÷ 400) mbar.

An air flow meter is placed upstream of the fan feeding air into the gasifier. Two flow meters and two temperature sensors are placed on the hot water circuits recovered on the water-syngas exchanger and on the internal combustion engine in order to measure the thermal energy exchanged.

There are also temperature sensors inside the reactor (at the top and in the central part near the nozzles) and a negative gauge pressure sensor placed at the top of the reactor. In addition, there is a differential pressure sensor located across the ceramic filter elements to assess their state of fouling and to provide periodic cleaning by means of compressed air supplied in the counterflow.

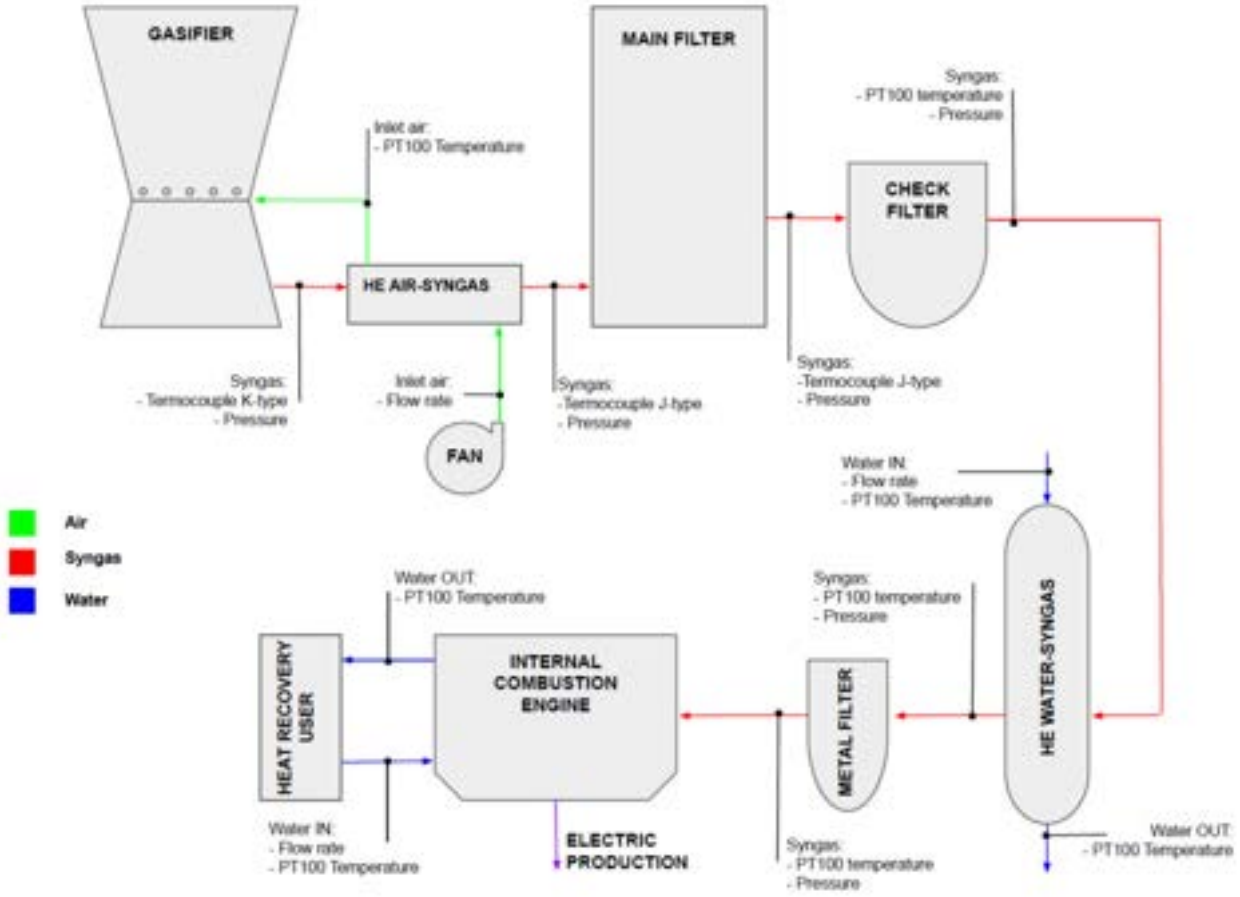

Figure. 2. A schematic representation of the measurement points on the 125-kW plant.

Since the syngas, rich in impurities, would have compromised any measuring instrument fitted to the line, the syngas flow rate was estimated by means of an energy balance on the syngas-air exchanger. Ambient temperature and pressure sensors were installed to characterize the ambient atmosphere.

2.2. The 25-kW plant

Due to its smaller size and easier maintenance, a smaller plant than the previous one was used for the experimental characterization of different wood species. This plant consists of a hopper in which approximately 0,33 m^3 of biomass is stored, which is then fed to a downdraft reactor. At the base of this reactor is a grate shaker system that removes the thicker flakes of char and favors the advancement of the biomass. The syngas thus produced is then further purified of carbon particles first through a cyclone, then cooled through a syngas-water tube bundle exchanger and subsequently, at lower temperatures, filtered in a fabric bag filter. Before being fed into the aspirated internal combustion engine, the air-syngas mixture is filtered through a paper filter.

For the sampling of the syngas required to perform characterization analyses, a suitable sampling valve is placed downstream of the bag filter.

3. The experimental campaign

The two plants presented in Section 2 were used for the experimental campaign. In particular, the 125-kW plant was operated in long run sessions with the aim to monitor the performances of each component and to improve its availability that was limited by its heavy maintenance needs. The 25-kW plant instead was used to test wood chips from different tree species in order to evaluate the quality of the syngas produced.

3.1. Long run sessions

The 125-kW plant was monitored during its operation while feeding the electrical and district heating networks of the Campus. The electrical power output was generally kept within the range (90÷100) kW. The measurements were collected every 15 minutes and stored for elaboration. In Fig. 3a, for example, the evolution of the absolute pressure at the filters is shown for one day. The oscillations are due to the deposit of dust cake on the ceramic candles of the main filter and their jet-pulse cleaning.

Since it was not possible to directly measure the mass flow rate of the syngas, this needed to be estimated indirectly. It was decided to use the energy balance at the air-syngas heat exchanger, since the air mass flow rate, the air inlet and outlet temperature, and the syngas inlet and outlet temperature are measured.

$$\dot{m}_{syn} = \frac{\dot{m}_{air} c_{p,air} (T_{air,out} - T_{air,in})}{c_{p,syn} (T_{syn,in} - T_{syn,out})} \quad (1)$$

The resulting mass flow rate ranged between (0.06÷0.10) kg/s and its evolution for one day is reported in Fig. 3b, confirming that the oscillations in pressure at the check filter were not due to a variation in mass flow rate.

The data gathered from the experiment have been used to train and validate the models presented in Paragraphs 4.2 and 4.3 and to evaluate health indices regarding the different components (e.g. pressure loss coefficient on filters and pipes, as shown in Fig. 4 for the ceramic candles).

3.2. Syngas characterization

The 25-kW plant was used to test 8 different tree species dried both naturally and artificially. The wood chips were sampled before the test. Then the elemental analysis and the evaluation of the ash content, of the moisture, and of the lower heating value on a dry basis were performed. The result of this characterization is reported in Table 1.

The test was then performed by feeding the 25-kW plant and keeping it at a constant electrical power output (i.e. 7.5 kW) until a steady state was reached. The syngas was then sampled with a Tedlar bag and analyzed through gas chromatography–mass spectrometry. Table 2 presents the results in terms of mass fraction of carbon monoxide, hydrogen, methane, carbon dioxide, hydrogen sulfide, oxygen, and nitrogen in the anhydrous syngas. Moreover, the water and tar content and the lower heating value is reported.

It can be noted that the data do not show any significative correlation between the characteristics of the biomass and those of the produced syngas.

4. The simulation campaign

4.1. Gasification process

A model for the simulation of the gasification process that takes place in a fixed-bed downdraft gasifier was developed and implemented in Scilab. The model combines a lumped parameter stoichiometric equilibrium model for the pyrolysis and oxidation zones with a one-dimensional kinetic model for the reduction zone.

In particular, the former takes into consideration two reactions, i.e. water gas shift (R1) and char methanation (R2), which are assumed to be at the equilibrium. The molar fraction of each species at the outlet of the pyrolysis and oxidation zones are constrained by the mass balances of each element (i.e. C, H, O) and by the ratio given by the equilibrium constants (Eq. 2):

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad \text{(R1)}$$

$$C + 2H_2 \leftrightarrow CH_4, \quad \text{(R2)}$$

$$K = \frac{\prod_{products} x_p^{sp}}{\prod_{reactants} x_r^{sr}} \quad (2)$$

The value of the equilibrium constant for each reaction is calculated through Eq. 3, where the temperature is determined by means of the energy balance in the pyrolysis and oxidation zones.

$$K = e^{-\frac{\Delta G^0}{RT}} \quad (3)$$

The kinetic model for the reduction zone, takes into consideration four reactions.

$$C + CO_2 \leftrightarrow 2CO \quad \text{(R3)}$$

$$C + H_2O \leftrightarrow CO + H_2 \quad \text{(R4)}$$

$$C + 2H_2 \leftrightarrow CH_4 \quad \text{(R5)}$$

$$CH_4 + H_2O \leftrightarrow CO + 3H_2 \quad \text{(R6)}$$

The rate of each reaction is evaluated through Eq. 4, where the equilibrium constant is calculated as seen before with Eq. 3 and the energy balance, for each control volume into which the reduction cone is divided. The net formation/destruction rate of each species is calculated considering all the reactions in which the species participates.

$$r = C_{\mathrm{RF}} A e^{-\frac{E}{RT}} \left(\prod_{reactants} x_r^{s_r} - \frac{\prod_{products} x_p^{s_p}}{K} \right) \quad (4)$$

The model is validated by applying it to a literature test case [7]. The main input data are reported in Table 3, and the output data in Table 4. It can be noticed that the results are satisfactory for the species (H_2 and CO) responsible for the lower heating value of the syngas.

4.2. System simulations

A comprehensive 0D lumped parameter dynamic model was developed for the simulation of the whole system (i.e. gasifier, syngas cleaning line and engine) and it was implemented in Matlab®/Simulink® by assembling component models. The model is based on the energy and mass balances for each component. Some of the components are considered as capacities (in green in Fig. 5a) and the balances are implemented with integral equations allowing for mass and energy storage. On the other hand, there are the resistances (in orange) with the balances implemented with algebraic equations. Particular care has been devoted to syngas conductivity, density, specific heat capacities and viscosity calculation. The model is able to simulate the behavior of the system both under stationary and transient conditions (e.g. the pressures before and after cleaning are shown in Fig. 5b). The most significant results are presented in [8, 9], showing that the model is a valuable tool for the diagnosis of the syngas cleaning line.

Table 3. Input of the gasification model for the validation [7].

Power	Fixed Carbon	Volatile Matter	Ash	C	H	O	S	N	Moisture	Biomass mass flow rate	Air to fuel ratio

4.3. Component CFD simulations

An integrated 0D-3D approach is a methodology which combines a simplified thermodynamic 0D lumped parameters model (such as the one presented in Paragraph 4.2) with 3D CFD simulations. The 0D model is then able to describe the entire process by integrating information obtained by a detailed 3D CFD simulation of the individual components (such as performance maps, pressure drops, etc.). This information may be unknown or can be known with high uncertainty (for instance, from empirical correlation) and, thus, this procedure consents to obtain the set-up coefficients of the 0D models. Moreover, by means of the CFD simulation, it is possible to study the behavior of the specific components in detail in order to debug design weakness and optimize their operation. In a more sophisticated approach, then, the 0D and 3D models can actively interact as follows: the 0D model calculates the thermodynamic quantities and flow rates in the characterizing sections; it supplies them to the 3D models as the boundary conditions on which to carry out the simulation and to return the performance of the components to the 0D model; then the 0D model recalculates the thermodynamic quantities and flow rates through the balance sheets. This methodology offers a series of advantages, combining the speed and robustness of the 0D simulation model of the system with the complexity and accuracy of the 3D numerical fluid dynamics simulation. The most relevant results related to three of the most relevant components of the 125-kW plant (see Fig. 2) were the following:

- the gasifier, where the focus was on the inside (consequent to gasification reactions) and outside (consequent to the coupling with the environment) fluid dynamics and heat exchange processes;
- the syngas feeding duct, where the focus was on the fouling phenomena and on the consequences of the residual tar carried by the syngas;
- the water-syngas heat exchanger, where the focus was on both of the above topics, i.e. the internal and external fluid dynamics and heat exchange processes, and the fouling issues due to the cooling of the syngas through the heat exchanger.

4.3.1. Gasifier

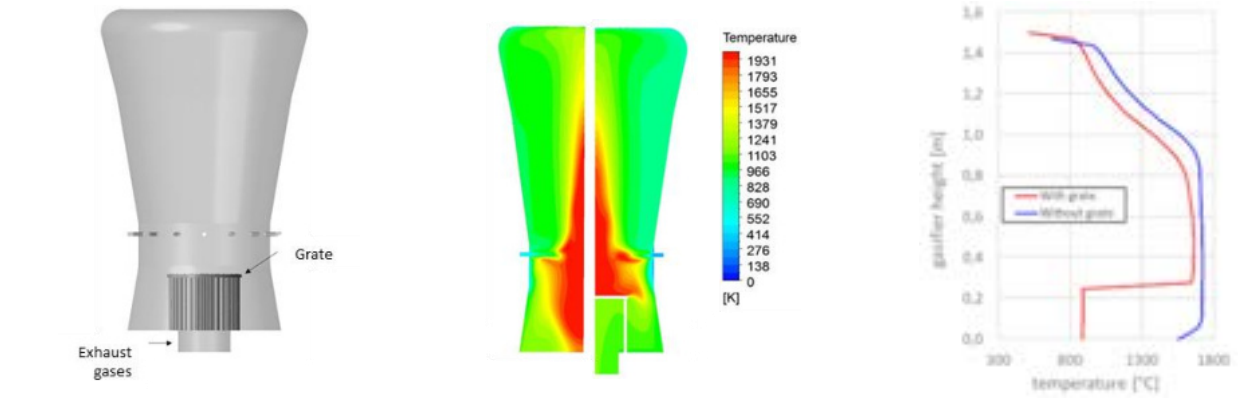
The downdraft gasifier was simulated by means of the two commercial finite volume CFD codes of the ANSYS platform. The preliminary results obtained with FLUENT are reported in [10]. Subsequently, by acquiring the real geometry with a reverse engineering CAD-based methodology which make use of a 7-axis laser scanner, it was possible to verify that the gasifier worked as a “quasi-throatless” downdraft principle, and it was also possible to simulate the actual geometry by means of CFX. An interesting result is reported in Fig. 6, in which it is possible to appraise the influence of the grate on the internal temperature from a distribution point of view. Even though there is a restriction, the grate shifts the operation of the gasifier from throated to throatless. This can be seen from the variation of the temperature profile near the restriction which shifts from a typical throated profile (blue line) to a typical throatless profile (red line), as seen in [11]. Moreover, the influence of the grate can also be seen from a quantitative point of view, i.e. the calculated average temperature of the exhaust gases passes from 1148 °C (without grate) to 839 °C (with grate). It is also interesting to notice that the CFD calculation is in agreement with the experimental results T_{syn} = 750 °C (about 10 %).

4.3.2. Syngas feeding duct

The syngas feeding duct was simulated by means of the open-source finite volume CFD code OpenFOAM. In [12], the numerical methodology developed based on a mesh-morphing algorithm is presented. The analysis made it possible to estimate the amount, rate, and area of tar deposition on the duct, which was simulated as a mixture of 5 tar classes characterized by different concentration and dew points. In Fig. 7a, by comparing a take-over on a section of the actual duct and the numerical result in terms of deposition (grey area) in the same section, it can be noticed how the numerical simulation was able to capture the shape and amount of deposition. Subsequently, the same methodology was used to estimate the increase in duct pressure drop caused by the growth of the deposit over time (Fig. 7b). In this manner, the pressure drop in the duct module of the 0D model can be updated during the life of the plant.

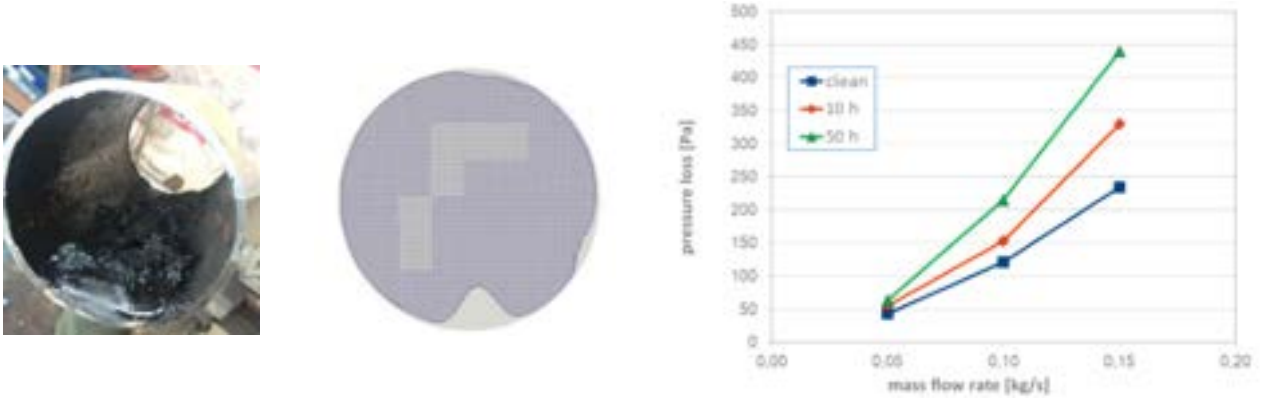
4.3.3. Water-Syngas heat exchanger

The Water-Syngas heat exchanger geometry was also acquired on the real plant by means of reverse engineering methodology. The geometry (which is a vertical shell-and-tube heat exchanger) was then simulated by means of ANSYS CFX in clean and degraded conditions, the latter obtained by generating a modified domain according to on-field inspection of the device after several operating hours. The implanted faults were fouling (50 % area reduction of 21 tubes) and clogging (38 % of tubes fully blocked by tar solidification) [13]. The analysis showed how fouled and clogged conditions caused a decrease in heat exchanger effectiveness, an increase in pressure drop and a decrease in the capability of the heat exchanger to condense tar and separate it from the gas stream (which is the second most important function of the heat exchanger). The outcome of the simulation was also to characterize the performance of the heat exchanger which was not provided by the manufacturer since the heat exchanger was designed ad hoc and built on site. This characterization was used to feed the 0D model, as described below.



(a) (b) (c)

Figure. 6. Gasifier geometry (a), temperature distribution without grate on the left and with grate on the right (b) and temperature profile (c).



(a) (b) (c)

Figure. 7. Actual tar deposit (a), numerical tar deposit (b) and pressure drop curves as a function of elapsed time (c).

4.4. 0D-3D model integration

As depicted in Fig 8., by taking advantage of the CFD characterization described above, the 0D model can be fed by the obtained numerical 3D results to make the plant simulation more realistic. In the Figure, the interaction between the syngas feeding duct numerical 3D simulation and the 0D model are outlined.

5. Discussion

The project promoted the penetration of a renewable source technology, which is efficient as it is cogenerative, into a portion of the market (the tertiary sector) which is currently almost exclusively the domain of photovoltaic technology. Another impact on the national power system is the reductions in both climate-altering emissions (reduction in carbon dioxide emissions as renewable and cogeneration source technology) and pollutant emissions (by using biomass-derived fuels in internal combustion engines there is a reduction in pollutant emissions compared to direct biomass combustion). By experimenting with the potential expansion of the use of virgin and residual biomass blend technology, the research program has enabled the expansion of the technology to the use of residual biomass resulting in the increased sustainability of the supply chain. Finally, it should be emphasized that the diffusion of a technology such as the one being tested allows for an increase in the share of electricity produced from renewable sources without affecting the stability of the electricity grid as the technology is programmable. These benefits for the grid are amplified by the fact that it is a distributed generation technology with simultaneous self-consumption. Therefore there is no significant power transmission and it consequently decongests the grid.

After more than five thousand hours' monitoring the 125-kW plant, it can be stated that this kind of plant, although functioning from a technical point of view, has not yet reached a technological maturity allowing it to be operated continuously without continuous close monitoring. It require costly and constant maintenance, with many variables that can affect the performance of the system, beginning with the quality of the wood chips.

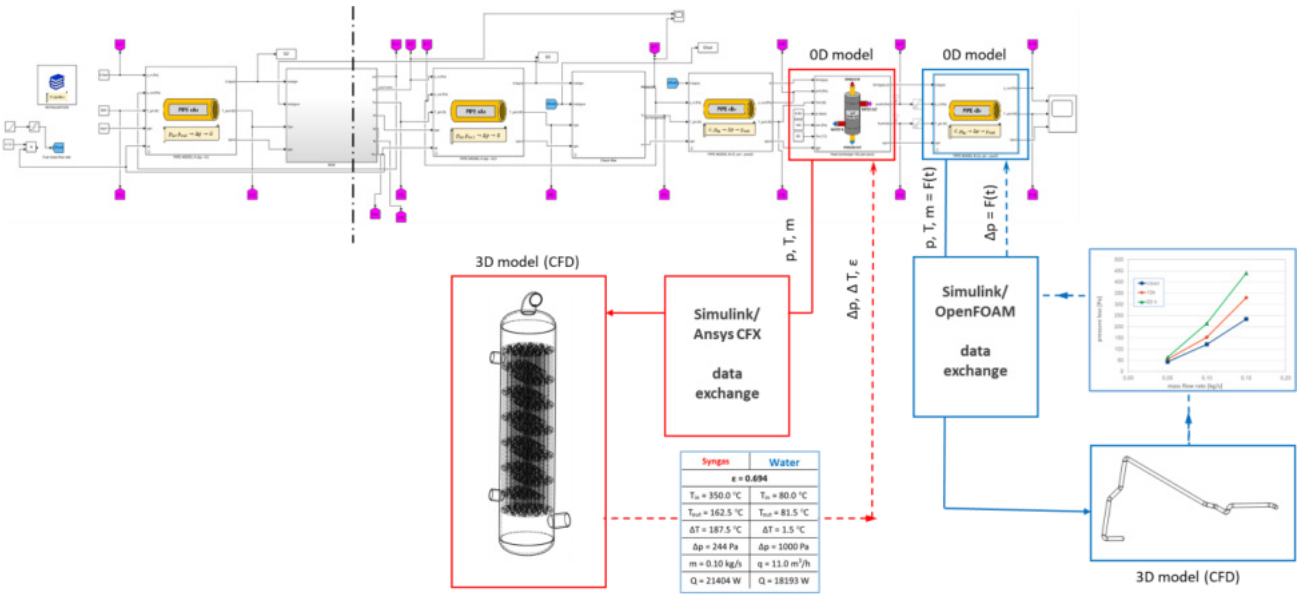


Figure. 8. 0D-3D methodology concept: interaction between the heat exchanger and syngas feeding duct 3D model results and the 0D lumped parameter model.

Since the raw material is inhomogeneous by nature, it is impossible to find standard operating conditions, as would be the case for a natural gas-fired plant. In addition, tar deposition creates major problems that require constant maintenance and cleaning. The cleanliness of the syngas, in terms of tar content, therefore, remains the point on which to focus research in order to make the plants more manageable.

It would be interesting to be able to feed the plants with residual biomass instead of virgin wood chips, e.g. those recovered from agricultural or forestry activities, to lower the cost of the feedstock. From an economic point of view, in fact, such plants can only be sustained in a context where there are incentives for the sale of energy.

5.1. Implemented plant improvements

Following an initial phase in which the plants were operated as delivered by the manufacturers, the following improvements were implemented:

- Substitution of the flaring torch with one more suitable for syngas, which has large passage sections, especially on the flame arrestor, to limit pressure drops because of tar condensation on this component. Moreover, to process syngas, a centrifugal fan with backward-curved blades and wide clearance between the case and rotor was adopted, so that any tar deposits would not compromise the functionality of the machine. Finally, the torch, compared to what was originally planned, was supplemented with support gas, to facilitate the ignition of the gas when it was still poor in the initial ignition phases, which also helped to limit the fouling of the torch itself;
- Insertion of a calm chamber upstream of the flare fan to limit the dust processed by the fan;
- Insertion of a metal filter upstream of the engine, to limit the presence of tar in the combustion chamber. Tar, if not burnt inside the engine cylinders, can condense as a result of low temperatures after mixing with air, creating a sticky layer that compromises engine functionality. A high molecular weight tar class condenses in the syngas-water exchanger; due to temperatures above around 105 °C, light-weight tar and water content do not condense in the heat exchanger. This metal filter, which operates at lower temperatures, allows the condensation of the moisture component and, by coalescence, the removal of a further proportion of the tar. This filter consists of a packed metal fiber. It preserves the life of the engine which, in the overall balance of the system, is a delicate and expensive component.

5.2. Designed improvements

Other solutions have been designed to further improve the plant, but they have not yet been implemented:

- Insertion of a cyclone between the gasifier and the main filter. By adopting this solution, it would be possible to eliminate an initial portion of carbon residues and thus relieve the ceramic filters of some of the fine dust. In this way, the frequency of pulsejet cleaning with compressed air would decrease, thus guaranteeing fewer interruptions to production and increasing the life of the filters. These filters tend to become fragile and break as a result of pulsejet cleaning; the cost of these components is not negligible and the intervention of stopping to replace them is rather onerous, so limiting the frequency of these occurrences would bring a significant benefit.

- Increasing the size of the filter case, by adding additional filter elements, would bring a benefit in terms of the quality of the syngas fed to the engine.
- It could be useful to include an ash/char removal system from the bottom of the gasifier, as is already present in the filter case, so that the frequency with which reactor cleaning is carried out can be reduced. In fact, this operation, carried out every 250 hours at the same time as the maintenance of the internal combustion engine, takes a long time (usually a couple of days) so that the system can cool down and be accessible by the operators. Doing so would also improve the general cleanliness, positively affecting the operational stability of the entire system.
- Following the CFD study, it was shown that the heat exchanger is not optimized and only condenses the tar in the last section of the tube bundle. Optimizing its fluid dynamics or simply adopting a longer heat exchanger could allow even more tar to be removed and feed a cleaner syngas to the engine.
- Increasing the cross-section of the piping, in addition to reducing pressure drops in general, could make it possible to reduce the frequency of any maintenance work, which entails disassembling the piping to remove any solidified tar that is obstructing the syngas passage.
- The flame arrestor serving the safety flare has very small gas passage sections and is extremely sensitive to the presence of tar. The deposition of tar on it leads to its complete obstruction with consequent problems for the functionality of the flare and safety problems in general, since the gas cannot find an outlet to the outside. The adoption of a hydraulic guard system, while bringing with it the burden of disposing of contaminated process water, would solve the problem of the fouling of the arrestor, which could be removed, itself representing an anti-backfire system. This would feed filtered syngas to the flare from the hydraulic stop, improving its performance.

Acknowledgments

The work was carried out within the framework of the research project ”SYNBIOSE - Gassificazione di biomasse lignocellulosiche in sistemi di cogenerazione di piccola taglia (<200 kW) per applicazioni nel settore terziario” (CUP G96G16000800003) funded by ”Cassa per i servizi energetici e ambientali” within the call ”Bando di gara per progetti di ricerca di cui all’art. 10, comma 2, lettera b) del decreto 26/1/2000, previsti dal Piano triennale 2012–2014 della ricerca di sistema elettrico nazionale e dal Piano operativo annuale 2013.”

Nomenclature

A	pre-exponential factor, s^{-1}
c	specific heat, J/(kg K)
C_{RF}	char reactivity factor [14]
G	Gibbs free energy, J/mol
K	equilibrium constant
LHV	lower heating value, kJ/kg or MJ/Sm^3
$\dot{m}$	mass flow rate, kg/s
R	gas constant, J/(mol K)
r	reaction rate, s^{-1}
s	stoichiometric coefficient
T	temperature, °C or K
x	molar fraction

Subscripts and superscripts

air	air
in	inlet
out	outlet
p	product
r	reactant
syn	syngas

Abstract:

To reduce greenhouse gas emissions in the aviation sector, the development of so-called sustainable aviation fuel (SAF) is indispensable. SAF can be produced via different synthesis routes and has identical properties to fossil-based conventional aviation fuel. Based on the results of previous research, a process pathway to produce SAF via a Biomass-to-Liquid (BtL) concept using entrained flow gasification and Fischer-Tropsch synthesis is simulatively investigated. To optimize overall process efficiency, high-temperature co-electrolysis can be integrated into the process chain resulting in a Power-and-Biomass-to-Liquid (PBtL) approach. Co-electrolysis makes it possible to split carbon dioxide as well as water electrochemically in a single apparatus and to produce synthesis gas with the required properties for Fischer-Tropsch synthesis. A detailed 0D Python model of a reversible solid oxide cell (rSOC) was developed at the Chair of Energy Systems to calculate the steady-state fuel cell and electrolysis operation based on a defined input parameter set. The validation using measured and literature data shows that the current density-cell voltage behaviour can be reproduced with an average relative error of less than 5%. Based on the existing BtL process, two concepts for the integration of co-electrolysis are identified and the 0D rSOC model is integrated into the Aspen Plus® flowsheet simulation. The newly developed process options are compared with alternative PBtL process variants showing that an identical product yield and carbon efficiency is achieved in different configurations and that electrical power demand can be significantly reduced by integrating co-electrolysis.

Keywords:

Power-and-Biomass-to Liquid; rSOC; Sustainable Aviation Fuels; co-electrolysis.

1. Introduction

To defossilize the aviation sector sustainable ‘‘drop-in’’ fuels are the only realistic strategy. These so-called sustainable aviation fuels (SAF) can be produced via the biomass-to-liquid (BtL) route. Using lignocellulosic biomass such as carbon-neutral biomass residues as feedstock, the thermochemical BtL route is based on combining high TRL gasification technology with Fischer–Tropsch synthesis (FTS). However, such processes typically result in low system performance because the carbon efficiency η_c of the overall process is limited [1]. The main reason for this is the low H/C ratio in the raw biomass resulting in the necessity of carbon removal from the syngas after gasification to reach a molar H_2/CO ratio of about 2 suitable for FTS.

Electrification of the BtL route can help to overcome the overall η_c limitation of the BtL pathway. Indirectly or directly electrifying the BtL process, results in a hybrid process which not only aims at increasing the processes product yield PY per input biomass, but also presents a way to defossilize the energy intensive sectors such as aviation or maritime transport. Such Hybrid Power-and-Biomass-to-Liquid (PBtL) systems thus enable higher η_c than BtL routes at lower electrolysis requirements than pure Power-to-Liquid (PtL) alternatives. Additionally, the energy efficiency of the such a process is greater than that of the pure biomass-based ones, while being less sensitive on the electricity price than PtL processes.

In indirect electrification, providing additional H_2 from water electrolysis powered by renewable electricity makes it possible to overcome the η_c limitation of conventional BtL processes. This concept not only allows overall η_c close to 100% but also enables complete utilization of the electrolysis products as O_2 produced in electrolysis can be used for gasification [2]. Several studies exist on this indirect PBtL approach [3–9] .

In direct electrification, electricity can be used within one of the BtL process steps itself for supplying energy to the process. One promising option for direct electrification of the BtL process is the use of high-temperature co-electrolysis in the form of solid oxide electrolysis (SOEL). In co-electrolysis H_2O and CO_2 are split into H_2, CO and O_2 in one single step. This enables the targeted production of synthesis gas, which is

why co-electrolysis is an alternative for the WGS reactor used in the existing BtL process or the separate production of green hydrogen in the indirect PBtL approach. The integration of a SOEL into the process is facilitated by the fact that reforming reactions are catalysed internally due to the electrode materials [10]. Consequently, the purity requirements for the fuel gas are low compared to other electrolysis processes and an in-cell conversion of low hydrocarbons is possible.

There are few published studies that consider integration between gasification and co-electrolysis and even fewer that include FTS as the fuel synthesis step. Integrating co-electrolysis into a BtL process the SOEL can be in parallel to the BtL process chain, using a CO_2 stream separated from the syngas for example during acid gas removal. Samavati et al. investigated a such a PBtL process option using entrained flow gasification (EFG) coupled with co-electrolysis with FTS [11] and Zhang et al. compared a different PBtL concepts using either SOEL in co-electrolysis mode or hydrogen addition from SOEL featuring an EFG and producing SNG, MeOH, DME or SAF via FTS [5]. Using a CO_2 streams separated from the main syngas stream results in an increased partial pressure of the reactants and the total volume flow through the electrolysis can be reduced resulting in economic savings. The resulting process variants allow for increased PY and energy efficiency compared to pure BtL processes. A similar approach is taken in Nielsen et al. [12]. Here, the SOEL is integrated into a BtL process with FTS, using the volatile products from the FTS reactor as the inlet stream [12]. When compared with process variants in which H_2 is added to the process by water electrolysis, the power requirement of the process can be reduced as a result of co-electrolysis and increased energy efficiency can be achieved [12].

The main objective of this work is to demonstrate to what extent the integration of co-electrolysis is a way to efficiently electrify the BtL pathway. To this end, the operating mode of a SOEL is first modelled in Python and then integrated into the BtL Aspen Plus® process simulation using suitable integration concepts. The process variants are then evaluated and compared to those of Dossow et al. 2021 [8]. Apart from the evaluation of the integration concepts developed within the scope of this work, further development possibilities for the individual SOEL integration options are also shown in the following.

2. Fundamentals

2.1. Reference (P)BtL Process Description

The PBtL model framework into which the 0D rSOC model is integrated is based on the work of Dossow et al. [8] with their PBtL pathway serving as a reference case and is shown in Figure 1. The pretreatment of the lignocellulosic feedstock consists of a dryer and the dried biomass stream is fed to a torrefaction reactor. The solid so-called torrcoal produced has a high energy density and is ground in a downstream mill to a defined particle size of less than 300 µm [8]. To produce synthesis gas with a low methane and tar content from the torrcoal, an oxygen-blown EFG is used in the PBtL process. In addition to the thermodynamic modelling approach for CO, CO_2, H_2O, H_2 and CH_4, the formation of N-, S- and Cl-containing compounds is also modelled, assuming a carbon conversion of 99% [8]. In addition to the solid torrcoal, the gaseous by-product streams from the torrefaction reactor and the light-ends from FTS are fed to the gasifier [8].

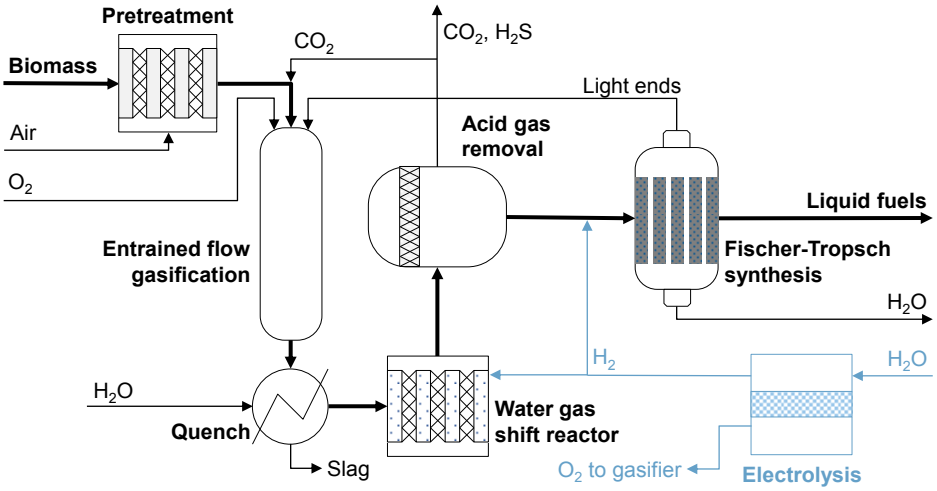

Figure 1. Schematic representation of the (P)BtL concept to produce SAF by Dossow et al. [8].

After EFG, slag and particles are removed, and the gas is abruptly cooled down by a water quench. Since halogen- and sulphur-containing impurities can lead to fouling in subsequent process steps or act as catalyst poisons, HCL is separated to a defined concentration by a chemically reactive filter system [8]. One of the key process parameters is the H_2/CO ratio of the synthesis gas. Typically, H_2/CO is below 1 directly after gasification and must be increased to a value of about 2 for the FTS. For this purpose, a sour WGS reactor

is used in the BtL process. It is assumed that the WGS reactor is operated isobarically and that the formation of H_2S and NH_3 is also catalysed in the reactor. The gas is then fed into an adsorption process that enables the separation of sulphur-containing components at high temperatures. The adsorbent used is ZnO, which is converted to zinc sulphide (ZnS) by a heterogeneous reaction. CO_2 is also removed from the synthesis gas in a downstream purification step. This is realised with the aid of a pressure swing adsorption (PSA) process, which is modelled in simplified form in the overall process. The products released in the process are removed from the process or, in the case of CO_2, partially used for pneumatic transport in the gasifier [8].

The synthesis gas prepared in the previous process steps is reacted in an FTS reactor at 230 °C and 20 bar using a cobalt-based catalyst. At the outlet of the reactor, the product stream is separated into a gaseous, an aqueous and an organic phase. The latter represents the crude fuel, which can be upgraded to SAF by a refinery process. The gas stream, which mainly contains unreacted synthesis gas and short-chain hydrocarbons, is fed into the FTS inlet stream or to the EFG via various recirculation routes. This can further increase overall η_c and PY [8]. The FTS reactor is modelled as a continuously operated stirred tank representing a slurry bed reactor. The reaction kinetics and product distribution are modelled using a macrokinetic model which is implemented as an object-oriented Python model using a FORTRAN subroutine that enables the exchange of calculation results between the two simulation environments [8].

In addition to the BtL process described above, Dossow et al. investigate different PBtL process variants. Here, an electrolyzer unit is integrated into the existing process and water is split into H_2 and O_2 which is then fed to the process. The electrolysers are assumed to be simplified stoichiometric reactors, with the product streams separated by a downstream separator [8]. An overview of the different PBtL process variants is provided in Table 1. Though the reference study contains both, PEMEL and SOEL, for comparison reasons in the following, only SOEL cases are considered.

Table 1. Indirect (P)BtL reference processes according to [8].

Process case	Description of the process modification
BtL case	Air separation is used to supply O_2 to the EFG. No electrolysis is used.
PBtL case 1	O_2 for the gasification is supplied from electrolysis instead of an air separation unit. The produced H_2 is fed partly to the WGS to adjust the H_2/CO ratio and partly to FTS.
PBtL case 2	No WGS to reduce complexity. H_2 is added to FTS to reach the desired H_2/CO ratio.
PBtL case 3	rWGS is used to convert CO_2 for maximum η_c H_2 is fed to FTS.

2.2. Solid oxide electrolysis (SOEL)

To substitute the WGS, a fuel electrode supported solid oxide electrolyser is chosen. A simplified model of the cell consists out of the supporting substrate layer, the electrolyte and the two electrode layers as shown in Figure 2.

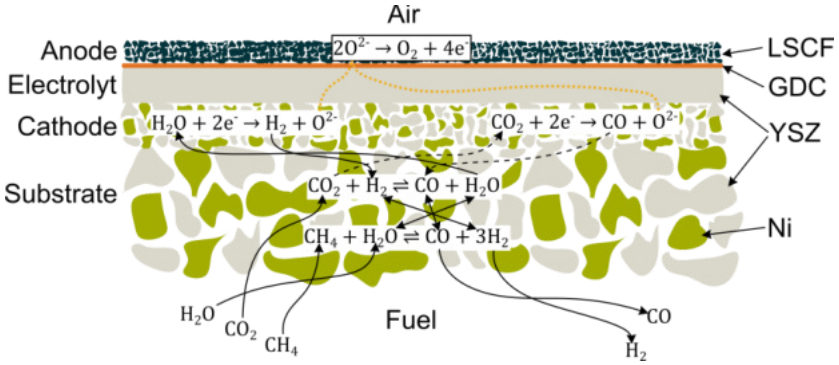

Figure 2. Schematic cross section of a solid oxide electrolysis with an internal reforming fuel.

The YSZ electrolyte is an O^{2-}-Ion conductor. The ions are created via the electrochemical reaction eq. 1 and eq. 2 under the consumption of electrons. These reactions are taking place at the triple phase boundaries where electrons from the electrically conducting nickel, Ions from the YSZ and gas from the porous layers meet.

$$H_2O + 2e^- \rightarrow H_2 + O^{2-} \quad (1)$$

$$CO_2 + 2e^- \rightarrow CO + O^{2-} \quad (2)$$

The simultaneous reduction of H_2O and CO_2 is referred to as co-electrolysis and, due to the catalysed side reactions, is based on a complex reaction network that has not yet been conclusively researched. Due to the high operating temperatures and the use of nickel, reforming and conversion reactions are catalysed on the surface of the fuel electrode in addition to the electrochemical reactions. The reaction equations for the steam reforming of methane eq. 3 and the reversed WGS reaction eq. 4 are given below, which take place when CH_4 or CO-containing fuel gas is fed to the fuel electrode. [13]

$$\mathrm{CH_4 + H_2O \rightleftharpoons CO + 3\,H_2} \qquad \Delta_R\overline{H}^0 = 206\,\frac{\mathrm{kJ}}{\mathrm{mol}} \tag{3}$$

$$\mathrm{CO_2 + H_2 \rightleftharpoons CO + H_2O} \qquad \Delta_R\overline{H}^0 = 41\,\frac{\mathrm{kJ}}{\mathrm{mol}} \tag{4}$$

These reactions take place in the substrate layer as well as in the fuel electrode layer. In addition to the already listed reaction equations, different pathways for the formation of CH_4 [14] or the separation of elemental carbon [15,16] are discussed in the literature. The extent to which the individual reactions are involved in the overall mechanism depends on the pressure and temperature as well as the process and material parameters due to the position of the reaction equilibrium [16–18]. To increase the efficiency of the SOEL, the O_2 generated on the anode side is discharged via a purge gas [16].

2.3. Electrochemical Model

The performance of the SOEL is calculated by subtracting the losses from the thermodynamically reversible cell voltage V_{Gibbs} calculated via eq. 6 by the global Gibbs Enthalpy difference of the reactions and the operational current J.

$$V_{Gibbs} = \frac{|\Delta G|}{J} \tag{5}$$

The global Gibbs enthalpy difference is calculated from the inlet and outlet streams via eq. 6.

$$\Delta\dot{G} = \dot{G}_{fuel,in} + \dot{G}_{oxy,in} - \dot{G}_{fuel,out} - \dot{G}_{oxy,out} \tag{6}$$

The operational voltage V_{op} of the electrolyser is calculated via eq. 7, by subtraction of the different loss mechanisms from the reversible cell voltage.

$$V_{op} = V_{gibbs} - \eta_{\mathrm{act}} - \eta_{ohm} - \eta_{diff} \tag{7}$$

The different loss mechanisms are included via over potentials: The activation over potential η_{act} is induced by the activation energy required for the electrochemical reaction. It is modelled with the Butler-Volmer formulation with a hyperbolic sine approach for fuel and oxygen electrode. The ohmic over potential η_{ohm} is induced by the temperature-dependent ohmic resistance of the electrolyte concerning the ion conduction and the constant contact resistance of the cell. The diffusion over potential η_{diff} models the loss mechanisms induced by the diffusion processes from the bulk phase to the electro-chemical reaction sites at the triple phase boundaries. These are modelled via Knudsen and binary diffusion for the fuel and the oxygen site. The bulk concentration is estimated via the mean over inlet and outlet concentrations with an inclusion of Methane and carbon monoxide for the hydrogen concentration. A complete description of the model used can be found in [19]. This recently updated model has been used in this work [20].

3. 0D rSOC Python Model

To meet the requirements of an open-source software solution with an simple syntax and object oriented paradigm, python coupled with Cantera is utilized for the thermodynamic equilibrium calculations. SOEL is still in the research and development phase (TRL<8), which is why the study results on co-electrolysis available in the literature are based on simulations or laboratory measurements on single cells or small stacks. In addition to the further development of the cell materials, the generation of synthesis gas is also the focus of research. The setting of the syngas parameters that is used to fuel the SOEL depends primarily on the composition of the inlet current and the location of the equilibrium of the WGS reaction. In addition, the current density has an influence on how much CO is formed.

3.1. SOEL Model

The calculation process of the SOEL model is shown in Figure 3: Both inlet gas streams are defined via their temperature, pressure, gas composition and flow rate. At the oxygen site, the temperature is increased to the operational temperature, the oxygen flow through the O^{2-}-Ions is added and in the last step the temperature is changed to the outlet temperature. At the fuel side after the temperature increase to operational temperature, an isothermal Gibbs reactor is positioned. Afterwards, the steam recycle stream is added and the electrochemical water splitting reaction takes place. The generated oxygen stream is removed and the chemical Gibbs equilibrium is formed. Afterwards, a portion of the stream is separated and recycled. In the last step, the temperature of the stream is changed to the outlet temperature. The steam recycle is required

to take the constantly ongoing water gas shift reactions in the cell into account. The positions of the Gibbs enthalpy for calculation of the global Gibbs enthalpy difference via eq. 5 are respectively marked.

To calculate the diffusion over potential, the partial pressures in the bulk phase are required. The inlet and outlet compositions x are used at the respective positions in the figure. For the over potential, the mean value between inlet and outlet is used. For the hydrogen diffusion, methane and CO are due to the water gas shift reaction and methane reforming considered as well.

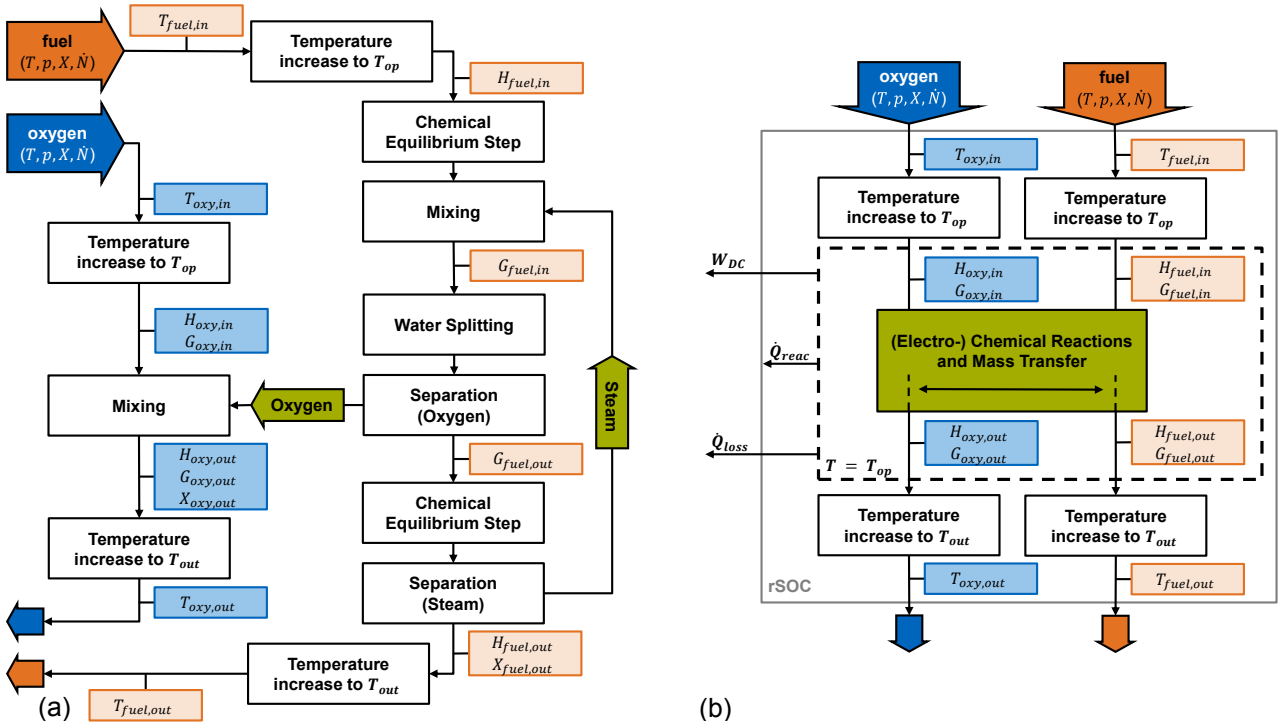

Figure 3. Calculation procedures of the SOEL model (a) and the energy balance (b).

All processes inside the SOEL model are isotherm at the operational temperature. Therefore, the energy balance is formulated via eq. 8.

$$\dot{Q}_R = \Delta\dot{H}_{oxy} + \Delta\dot{H}_{fuel} - W_{DC} - \dot{Q}_{loss} \tag{8}$$

The enthalpy difference of the inlet and outlet streams over the cell model, as well as the electrical power W_{DC}, heat losses $\dot{Q}_{loss}$ and the heat of reaction $\dot{Q}_R$ are considered. The positions for the enthalpy calculations of the streams are added into Figure 3.

3.2. Validation of the Python rSOC model

As described in [20], the parameters for the electrolyte activation energy and the electrolyte preexponential factor from [19] were optimized to fit experimental data. To validate the performance of the SOEL model for electrolysis and co-electrolysis operation experimental data is used [21]. The simulated data is compared to the experimental results for two different gas compositions in Figure 4.a). Gas composition A is a 50/50 H_2O/H_2, composition B is 25/25/25/25 $H_2/H_2O/CO/CO_2$. Both experiments were conducted at 770 °C.

The mean relative error of the SOEL mode is for the H_2/H_2O system 1.2 ± 1.2 % and for the co-Electrolysis operation with Gas B 0.5 ± 0.3 %. The accuracy of the model is reduced at higher current densities due to the increased influence of the diffusion losses. Due the usage of the mean concentrations over inlet and outlet for the bulk concentrations, nonlinear effects at low concentrations are not included. Besides the validated electrochemical performance of the cell, the fuel gas outlet composition of the electrolysis is crucial for a process integration. Hence, the outlet compositions for a relevant gas composition are validated as well, utilizing the experimental data from Schäfer et al. [15]. The model outlet concentrations are validated for an operation at 800 °C in a 10/60/30 $H_2/H_2O/CO_2$ gas composition. The comparison between the model and the experimental results by Schäfer are shown in Figure 4.b). For all gas species, an absolute error of the mole fraction of equal or below 0.02 is achieved. The accuracy of the model is high, expect for the methane concentration at high current densities. This relative high methane concentration at high current densities is discussed in Schäfer et al. [15], and is possible based on side reactions at the electrode. This phenomenon is still part of ongoing research.

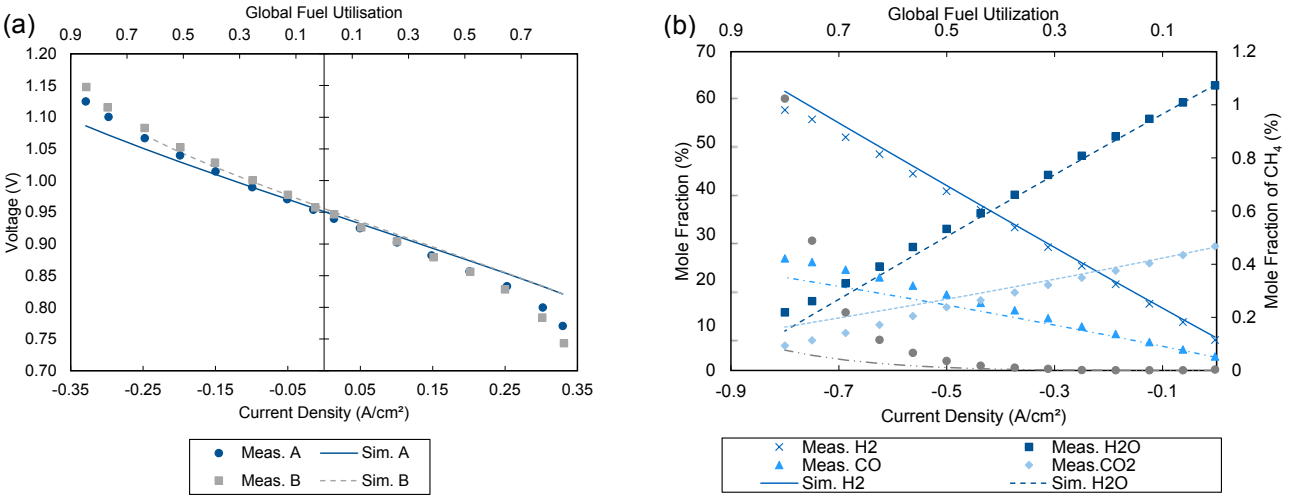

Figure 4. Validation of model performance with different fuels with experimental data [21] (a) and validation of the exhaust gas fractions in electrolysis mode with experimental data [15] (b).

4. PBtL Process Model using co-Electrolysis

The central objective of integrating co-electrolysis into the BtL process is to optimize and maximize the process in terms of PY, η_c, costs incurred and energy efficiency. For this purpose, the 0D rSOC model is integrated into the Aspen Plus® framework. Optimal points of integration of co-electrolysis into the BtL process are identified and suitable operational conditions are selected. To compare the different PBtL process options, a biomass inlet flow of 200 MW_{LHV} is assumed for all cases.

4.1. Integration of SOEL into PBtL Framework

The coupling between Python, FORTRAN and Aspen Plus® follows the procedure described in [8] as shown in Figure 5.a) For the integration of the rSOC into Aspen Plus®, a User2 model is used, as shown in Figure 5.b). This allows user-defined modelling of basic operations for any number of entry and exit streams. In addition to the material streams representing the entering and exiting fuel and O_2 streams, heat and work streams are also linked to the User2 block. Q-RSOC, Q-LOSS representing the heat of reaction and the heat losses that occur, and W-DC representing the required DC power, are calculated based on the energy balance solved within Aspen Plus®.

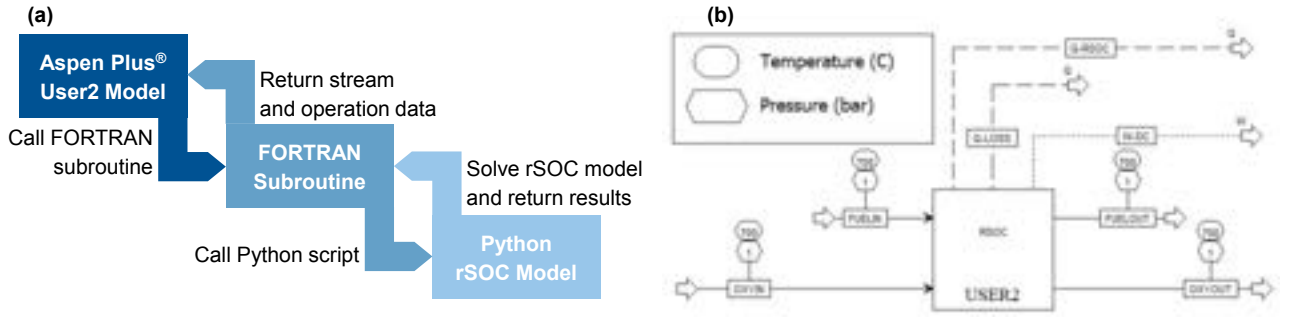

Figure 5. a) 0D rSOC Python model implementation in Aspen Plus® by using FORTRAN subroutine, b) Integration of subroutine into Aspen Plus® using USER2 model.

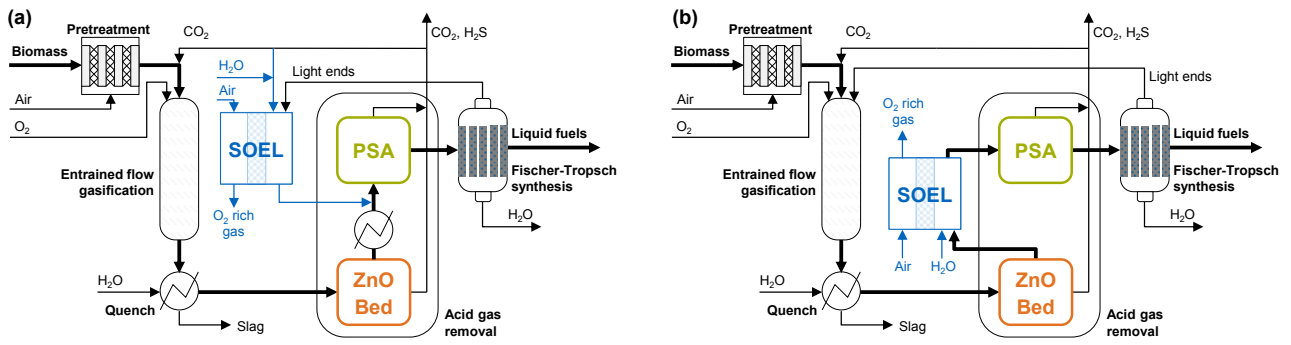

Figure 6. Process model for case I (a) and case II (b).

The SOEL makes it possible to produce H_2, O_2 and CO in one process step and to produce synthesis gas with defined properties. Thus, SOEL co-electrolysis offers an alternative to the WGS reactor as well as the additional feed of electrolytic H_2 as done in the reference PBtL process. For the PBtL concepts developed in this work, both, WGS and water electrolysis, can be dispensed. By removing the WGS reactor, the H_2/CO ratio of the synthesis gas required for the FTS must be adjusted with the help of co-electrolysis. The possible integration options are limited by catalyst poison and particle impurities in the raw syngas stream after gasification. If the SOEL is to be integrated into the main syngas stream, it must be located downstream of the ZnO bed and upstream of the CO_2 stream separation. At this point, the synthesis gas contains primarily H_2, CO, H_2O and CO_2 components. The catalyst poisons are removed down to very low concentrations <1 ppm. The corresponding process position is shown in Figure 6.a) and will be referred to as PBtL case I) in the following.

The SOEL makes it possible to produce H_2, O_2 and CO in one process step and to produce synthesis gas with defined properties. Thus, SOEL co-electrolysis offers an alternative to the WGS reactor as well as the additional feed of electrolytic H_2 as done in the reference PBtL process. For the PBtL concepts developed in this work, both, WGS and water electrolysis, can be dispensed. By removing the WGS reactor, the H_2/CO ratio of the synthesis gas required for the FTS must be adjusted with the help of co-electrolysis. The possible integration options are limited by catalyst poison and particle impurities in the raw syngas stream after gasification. If the SOEL is to be integrated into the main syngas stream, it must be located downstream of the ZnO bed and upstream of the CO_2 stream separation. At this point, the synthesis gas contains primarily H_2, CO, H_2O and CO_2 components. The catalyst poisons are removed down to very low concentrations <1 ppm. The corresponding process position is shown in Figure 6.a) and will be referred to as PBtL case I) in the following.

A second integration option is the insertion of a SOEL into the gaseous recycle stream of the FTS as shown in Figure 6.b). The FTS light ends primarily consist of unreacted H_2 and CO, as well as CH_4 and short-chain hydrocarbons, which can be converted to synthesis gas by the internally catalysed reforming reactions inside the SOEL. Since the corresponding material stream exits directly from the FTS reactor, the concentration limits for possible catalyst poisons are always met due to the upstream EFG. In this approach which locates the SOEL in parallel to the main syngas stream, the CO_2 contained in the main syngas stream after ZnO bed and SOEL is removed using a PSA. While part of the separated CO_2 is used as a carrier gas for the torrefied biomass at the gasifier section, the remaining CO_2 is recycled to the inlet fuel gas stream of the SOEL. This can increase η_c and PY. This PBtL case II) is similar to the approach of [12] for the integration of co-electrolysis into a BtL process with FTS. However, in the present work, as described at the beginning, the SOEL is used to adjust the H_2/CO ratio and, in contrast to [12], no additional WGS reactor is used.

4.2. Operational conditions of the SOEL

The SOEL are operated at atmospheric pressure and 800 °C. The active cell area and fuel utilisation are variable and defined in the simulation. The molar gas fractions are given in Table 2. The H_2S and HCl fractions are below ppm and thereby meet the quality requirements for the SOEL. Case II has non neglectable fraction of higher hydrocarbons in the range of C_2-C_4 from the FTS light end. Therefore, the risk of carbon formation for in case II is discussed in section 5.3.

Table 2. SOEL inlet gas fractions.

	H_2	H_2O	CO	CO_2	CH_4	C_{2-4}^{-}	$C_{2-4}^{=}$	HCl	H_2S
Case I	0.411	0.134	0.196	0.250	$8.69 \cdot 10^{-4}$	0.0	0.0	$8.30 \cdot 10^{-15}$	$8.08 \cdot 10^{-9}$
Case II	0.420	$1.72 \cdot 10^{-3}$	0.234	0.032	0.154	0.027	0.017	$1.90 \cdot 10^{-15}$	$9.25 \cdot 10^{-10}$

5. Results and Discussion

The PBtL cases I) and II) using co-electrolysis are evaluated in terms of operating parameters and possible heat integration. In addition, the occurrence of impurities and catalyst poisons as well as the formation of elemental carbon is considered.

The reference parameter used here is the syncrude produced in FTS, which is liquid at standard conditions (25 °C and 1 atm) and consists of a mixture of linear, saturated, and unsaturated hydrocarbons (mainly C5+). In addition to absolute parameters, such as the electrical power requirement or the raw syncrude or *fuel* mass flow produced, the focus of process development is on maximizing $PY = \dot{m}_{fuel} \cdot \dot{m}_{biomass,dry}^{-1}$, $\eta_c = \dot{m}_{C,fuel} \cdot \dot{m}_{C,biomass}^{-1}$, energy yield $EY = \dot{m}_{fuel} LHV_{fuel} \cdot \left(\dot{m}_{biomass} LHV_{biomass} + \dot{E}_{SOEL}\right)^{-1}$, and overall net energy efficiency $\eta_E = \dot{m}_{fuel} LHV_{fuel} \cdot \left(\dot{m}_{biomass} LHV_{biomass} + \dot{E}_{SOEL} + \dot{E}_{auxilaries}\right)^{-1}$.

5.1. Evaluation of the integration concepts

The operating behaviour of the SOEL can be influenced by the parameters FU and $\zeta_{CO_2,rcy}$. Suitable operating points for PBtL case I) are summarized for a fuel utilization between FU = 0.5 and 1.0 in Table 3. While U_Z increases only slightly between FU = 0.5 and 0.8, a very large increase is observed when comparing the cell stresses at FU = 0.9 and 1.0. This is due to mass transfer limitation because of high fuel utilization, which causes the over potentials to increase sharply. The ASR, whose value almost doubles for the two operating points starting from 0.25 to 0.47, confirms this assumption. $\dot{m}_{H_2O,SOEL}$ decreases with increasing FU, resulting in an overall lower total fuel flow entering the SOEL. As the inlet flow decreases, so does the area of the SOEL. Since the capital cost of a SOEL stack correlates with the area, this can be reduced because of operation at high fuel utilization. At this point, it should be noted that the conducted cell area determination is only a simple estimate for sizing the SOEL and shortening the computation time. For a comprehensive consideration of the integration concepts in the context of a techno-economic analysis, the choice of a constant active area is necessary.

Since the SOEL is directly integrated into the synthesis gas stream in PBtL case I), the product gas always exits with the same H_2/CO ratio of 2.10. This is not the case with integration at process position II). Here, the gaseous by-products of the FTS are reformed inside the SOEL and then recycled to the syngas stream. Since there is an H_2/CO ratio of about 1 at the outlet of the EFG, the H_2 content must be strongly increased in the used side recycle stream. Therefore, for the exemplary operating points investigated according to Table 3, a significantly higher H_2/CO ratio between 10.55 and 6.70 results, which decreases with increasing FU and $\zeta_{CO_2,rcy}$ and varies due to the composition of the FTS light ends stream.

At the operating points for PBtL case II), a larger additional water flow $\dot{m}_{H_2O,SOEL}$ enters the SOEL compared to case I). This is because the inlet fuel flow is coupled to the active area which decreases with increasing fuel utilization, whereas the supply of additional CO_2 leads to an increase. The ASR is determined to be a constant value of 0.20 for the simulated operating points regardless of the variable parameters FU and $\zeta_{CO_2,rcy}$. This indicates that no mass transfer limitations are simulated at a value of FU=0.9, which is confirmed by the slightly increasing values for cell voltage and DC power, respectively. The global fuel utilization is below the respective fuel utilization for the operating points investigated in the integration concepts. This serves as an input parameter in the simulation, and the difference between the two variables is due to the simplified modelling in co-electrolysis operation. To solve the energy balance around the SOEL, the inlet temperature of the oxygen stream is adjusted. This is limited by the maximum temperature level of the waste heat occurring in the process, which occurs at the exit of the EFG through a raw syngas cooler from 1400 °C to 1200 °C depending on the operating point. To ensure that the waste heat is also used efficiently in the integration concepts and that the temperature of the oxygen stream does not exceed the maximum limit, the mole flow at the oxygen electrode is increased as required for the simulated operating points. The ratio of oxygen and fuel mole flow is included in Table 3.

Table 3. SOEL parameters of selected operating points in PBtL cases.

Parameter	Unit	I.1	I.2	I.3	I.4	II.1	II.2	II.3	II.4

5.2. Evaluation of the heat integration in the integration concepts

The indirect PBtL process variants developed by Dossow et al. are fully integrated with respect to the integration of the heat flows occurring within the process sequence [8]. The simulation results show that by using EFG, process heat is available at high temperature levels of over 1200 °C. In addition, the gasification, the WGS reaction as well as the FTS are exothermic process steps, whereby large heat flows are released.

These cover the required heat demand of the biomass pretreatment as well as the flue gas cleaning section. Based on the previous investigations, detailed modelling of the heat integration is omitted in this work. The integration of the SOEL into the process heat utilization is estimated using a $\dot{Q}$-T diagram.

For the PBtL case I), the $\dot{Q}$-T diagram representative for the operating point I.3 from Table 3 is shown in Figure 7.a). The curves show that despite the integration of the SOEL, sufficient process heat is available to cover the heat demand of the endothermic process steps. Starting from the maximum temperature level at 1293 °C, the heat is transferred between the occurring hot and cold heat flows. As can be seen from the graph, an excess heat flow of 116 MW_{th} remains at the cold end of the $\dot{Q}$-T diagram. This cannot be used within the process chain and must therefore be dissipated via additional cooling power to be expended. Since part of the waste heat is generated at an almost constant temperature level of approx. 230 °C, it could be used to generate process steam. The remaining heat flow must be removed from the process.

The $\dot{Q}$-T diagram of operating point II.4, which is shown in Figure 7.b), differs significantly from PBtL case I). Although the maximum temperature level of the waste heat present in the process is not exceeded, the curve of the cold heat flows plotted in blue is not completely below the red curve of the hot heat flows. As a result, assuming a minimum pinch point temperature difference of 10 K, additional process heat is required in the form of a cooling capacity of 112 MW_{th} and a heating capacity of 18 MW_{th}. The latter occurs at a very high temperature level of over 1235 °C and, with regard to the use of renewable energies, must be supplied with the aid of electricity or through the combustion of synthetic gases.

One possible reason for the increased heat demand is due to the high internal recycle ratio $\zeta_{CO_2,rcy} = 0.9$. As a result, the rWGS reaction, which is also endothermic, occurs in the SOEL in addition to the endothermic water electrolysis. To maintain the specified temperature difference across the SOEL of 0 K, the heat demand must be balanced by the enthalpy of the incoming oxygen gas stream. A large portion of the high-temperature process heat is transferred to this stream and the SOEL is heated to the operating temperature specified in the assumptions. Aa lower CO_2 recycle flow as well as the adjustment of the SOEL operating temperature can lead to a reduction of the high-temperature heat demand.

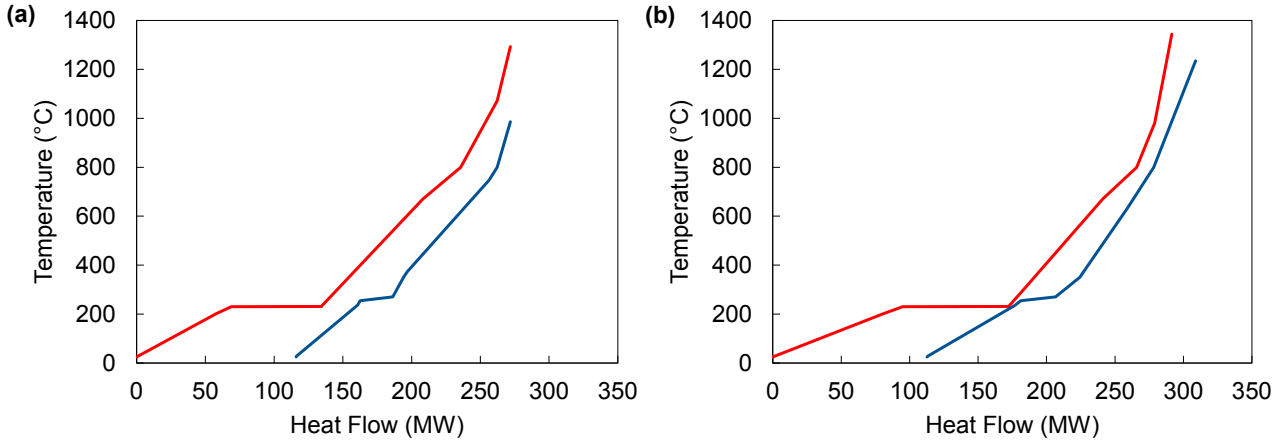

Figure 7. $\dot{Q}$-T diagrams of operating points I.3 (a) and II.4 (b) as a result of heat integration.

5.3. Discussion of the formation of carbon deposits

The SOEL is operated at 800 °C as part of the integration concepts. The risk of carbon deposition is investigated with a ternary diagram. On the fuel side, the recycle stream of the gaseous by-products of the synthesis FTS REC enters the SOEL hierarchy block. Its composition is within the carbon deposition region. With additional water and the CO_2 recycle stream defined by $\zeta_{CO_2,rcy}$ being introduced upstream of the electrolysis, the inlet composition at the SOEL is in a deposition free area. Despite FU = 0.9, the outlet composition is as well below the formation of carbon deposits. The integration into the FTS by-product stream requires a significantly higher H_2/CO ratio in the SOEL product gas to set the required syngas inlet parameters at the FTS reactor. At this point, it should be noted that in the FTS by-product stream, in addition to the unreacted syngas, the CH_4 and the short-chain hydrocarbons, long-chain, saturated and unsaturated hydrocarbons with more than four C atoms also occur in significant concentrations of several 100 ppm. These are not supported by the Cantera input file used in the simulation and are therefore considered inert in the rSOC Python model. In a real system, this is not the case. Here, the components are involved in the reactions taking place, and internal reforming of long-chain hydrocarbons is not possible. To prevent the rapid degeneration of SOEL, it is necessary to have an external pre-reforming step that converts the long-chain impurities.

5.4. Comparison with the Reference Processes

The influence of FU and $\zeta_{CO_2,rcy}$. on the overall process in terms of total electrical power demand, PY, and η_C for part of the operating points is shown in Figure 8. The electrical power requirement of the SOEL increases with fuel utilization. This determines the required electrical power in the overall process, with the additional auxiliary electrical power requirement ranging from 38.3 to 46.2 MW_{el}. With an increase in FU and $\zeta_{CO_2,rcy}$, PY increases and reaches a maximum value between 36.0% and 55.7% at operating point II.4. By incorporating co-electrolysis into the BtL process, the syngas composition can be influenced, and η_c can be more than doubles from 40.5% for the BtL process to 94.4% for the case II.4. Due to η_C and PY, operating points I.3 and II.4 are used for the comparison with the PBtL process variants according to [8].

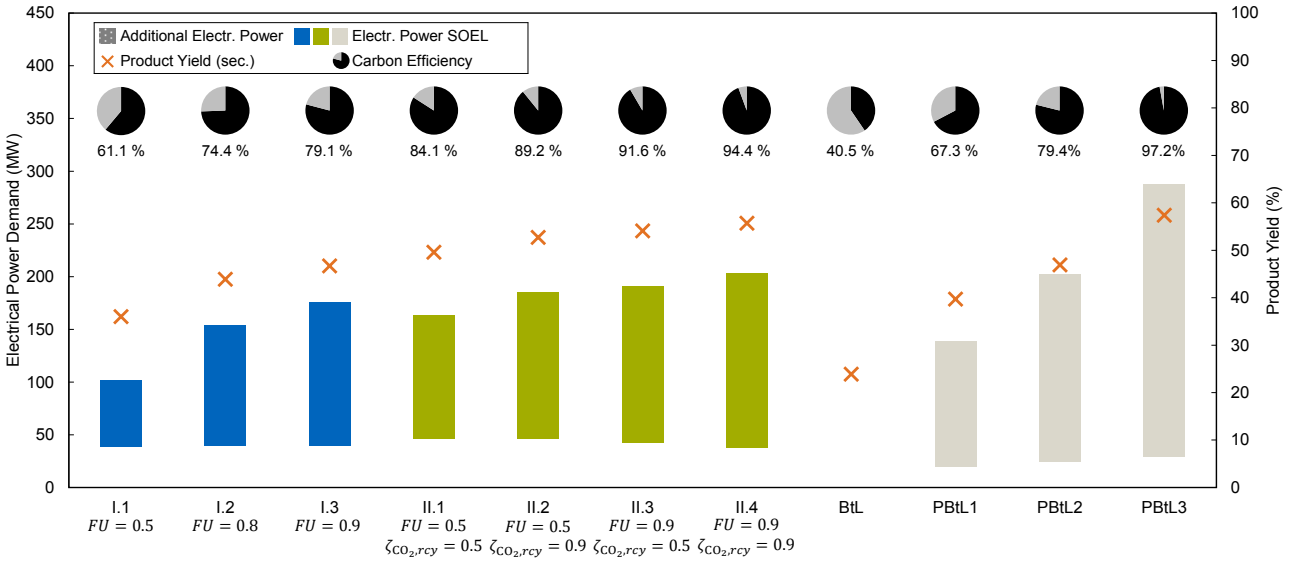

Figure 8. Overall process performance in terms of carbon efficiency, product yield and electrical power requirement for selected operating points of integration concepts I) and II) compared with the indircet (P)BtL process options according to Dossow et al. [8].

When comparing the different process options, it becomes clear how strongly the integration of electrolysis affects the electrical power requirement. While merely 18.7 MW_{el} is required for the BtL process, the value increases depending on the PBtL process variant up to a maximum of 287.4 MW_{el} for the indirect PBtL3 concept. The direct comparison of the integration concepts I.3 and II.4 with the PBtL process variants shows that almost identical product mass flows occur as for the indirect PBtL concepts 2 and 3. However, the power demand of the overall process can be significantly reduced by integrating co-electrolysis. The relative difference is 13.1% and 29.2% for the simulatively investigated cases I) and II), respectively.

Apart from the total electrical power P_{el} large deviations can also be observed in the inlet flows. The co-electrolysis concepts require more than three or four times the molar air flow than the indirect cases. The reason for this is the use of air as a purge gas for discharging the formed O_2 at the oxygen electrode of the SOEL. This is not considered in the PBtL process variants in Dossow et al. [8], so that only the air flow for the pretreatment of the biomass enters the process chain. It can be concluded that O_2 is produced in excess and cannot be further integrated into the process chain within the concepts presented here. When calculating the value, only the oxygen produced in the SOEL and consumed within the process chain is considered. The proportions in the purge gas used, if any, are not included. In addition to the air flow, the incoming hydrogen flow also increases in the integration concepts. This is due to an increased cooling demand in the quench section as well as the additional water flow to adjust the H_2/CO ratio. The latter is highly dependent on the SOEL operating point and can be reduced by adjusting the operating temperature and pressure.

It can be stated that by integrating co-electrolysis into the existing BtL process, large PY s as well as high η_c can be achieved, and the electrical power demand can be significantly reduced compared to the indirect PBtL process variants according to Dossow et al. [8]. A disadvantage is the high additional air and water flow required to operate the SOEL. To summarize to what extent EY and PY can be increased compared to the BtL concept, the relative deviations of both parameters with respect to the initial process are shown in Figure 9. While PY can be increased by up to 140% by incorporating electrolysis water or co-electrolysis, the increase in EY is lower at a maximum of 27%. However, this is strongly dependent on the respective process option, with values greater than 10% being achieved exclusively for the integration concepts developed in this work.

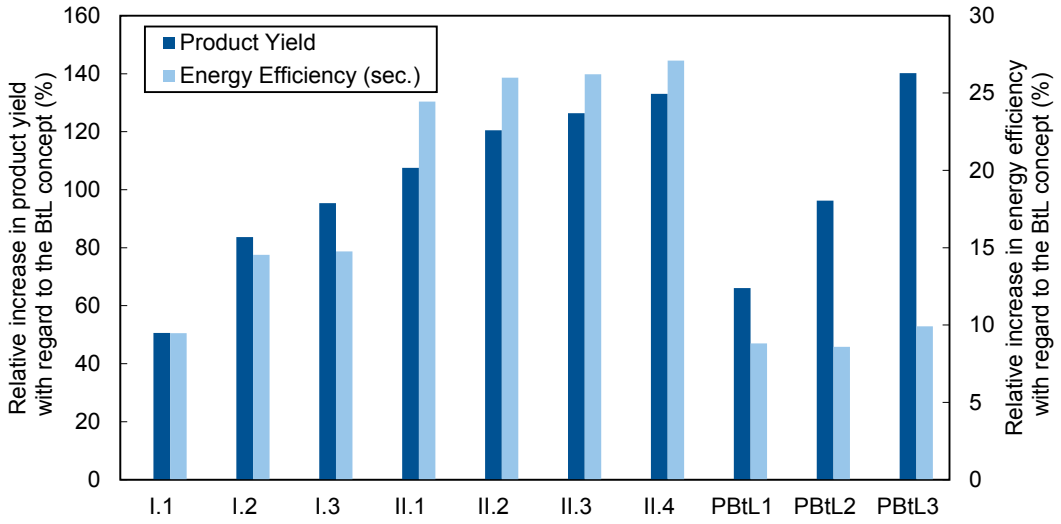

Figure 9. Relative increase in product yield and energy yield compared to the BtL process for the integration of co-electrolysis and the indirect PBtL process variants according to Dossow et al. [8].

6. Conclusion and outlook

To evaluate the suitability of the SOEL in co-electrolysis mode to enhance process efficiency of the BtL process, the newly developed 0D rSOC model is integrated into the existing simulation model. The SOEL replaces the WGS reactor and the additional feed of electrolysis hydrogen in the existing process chain. Two different process options are developed. In process option I, the SOEL is integrated into the syngas stream directly downstream of the ZnO bed, whereas in process option II the internally catalysed thermochemical reactions are used to reform the gaseous by-products of the FTS. In both cases, the SOEL is operated at 800 °C and 1 bar and optimized to set the necessary H_2/CO ratio for the synthesis. This is controlled by an additional water flow and the fuel utilization FU. In the integration concept II, the recirculation of the CO_2 stream separated in the EGR is also possible.

The simulation results of the developed process variants are compared with the PBtL reference processes from Dossow et al. [8]. In a first step, the influence of the fuel utilization FU assumed to be variable, and the CO_2 recycle ratio on the process parameters is investigated. The electrical power demand and PY increase with FU and CO_2 recycle ratio. A possible occurrence of carbon deposits is excluded with the help of the ternary diagram plot and the additional heating and cooling demand, if any, is estimated by a Q-T-diagram. The comparison with the PBtL process variants according to Dossow et al. [8] shows that an almost equal raw PY and η_c can be achieved in the integration concepts. The demand for electrical energy can be reduced by 27 MW_{el} and 84 MW_{el}, respectively, by integrating co-electrolysis for the simulative investigated operating points with an almost identical product flow. This corresponds to an increase in energy efficiency of up to eight percentage points, although the required air and water flow increases sharply. Nevertheless, the integration concepts developed in this work represent a promising alternative to the existing PBtL process variants due to the high product yields and the large potential savings in electrical power.

Numerous simplifying assumptions are made both in the creation of the Python rSOC model and in the integration of the SOEL into the BtL process. There is often the possibility to further develop the existing models and to increase their level of detail. For the Python rSOC model, the primarily concerns are the consideration of CO_2 electrolysis, which is neglected in the existing modelling approach, and the reduced accuracy at high fuel utilizations. Both issues can be addressed with an upgrade into a 1D model. Furthermore, the risk of carbon deposition for concept II is rather high, a more detailed investigation is required as well as the addition of a reformer prior to the SOEL. An investigation of the influence of the impurities at the SOEL to ensure a degradation free operation is required.

In simulative investigations of the integration concepts, constant SOEL operating parameters are assumed. Since these have a major influence on the position of the equilibrium of the internally catalysed reactions and therefore affect the product composition, the identification of an optimal operating range is conceivable. This could reduce the water and heating requirements as well as the associated costs. For a comprehensive comparison with the process variants according to Dossow et al. [8], a comprehensive heat integration as well as techno-economic analysis of the integration concepts is also required. In addition, it must be clarified how the O_2 rich purge gases can be further purified for use in the EFG.

7. Acknowledgments

The investigations have been supported by the Federal Ministry of Education and Research (BMBF) within the project REDEFINE H2E (01DD21005) which is gratefully acknowledged.

Abstract:

Recent policies which promote climate-neutral energy systems and rising energy prices overburden the planners of energy supply systems. This leads to an increasing need for cost-effective, yet environmental-friendly, solutions. One interest-arousing approach is utilizing hydrogen-based technologies within cross-sectoral, residential energy systems. However, the economic and environmental potentials of this approach have not yet been fully uncovered. Hence, the aim of this work is to investigate the impacts of considering hydrogen-based technologies on the total costs and CO_2 emissions when designing a residential energy system. For this purpose, we developed a design optimization model using mixed-integer linear programming, whose main objective function is the minimization of total costs. The minimization of total CO_2 emissions is implemented as an epsilon constraint, where a Pareto front is created to represent optimal solutions under both objectives and their trade-off. Consequently, the optimal sizing and operation plan of the considered technologies to fulfill the energy demands of the residents are determined. Besides hydrogen-based fuel cells, electrolyzers, compressors and storage systems, the model includes photovoltaics, batteries, gas-based combined heat and power units, heat pumps, gas boilers and heat storage. For a case study of an exemplary German residential district, we carried out the design optimization for three energy systems, where two involved typical sector-coupling generation units and one included hydrogen technologies. Through the resulting Pareto fronts, we found that the energy system with hydrogen had a comparable, yet limited performance in terms of emissions reduction. However, the hydrogen system showed a poor economic competitiveness.

Cost Minimization, Emission Minimization, Hydrogen Systems, MILP Optimization, Sector Coupling

1. Introduction

Nowadays, planning energy systems for residential districts is facing more challenges. Decision planners must satisfy the rising energy demands while fulfilling other goals. Those goals include maintaining cost efficiency with increasing energy prices, mitigating CO_2 emissions to follow policies promoting climate-neutral energy systems, and integrating renewable energy resources with fluctuating generation. Therefore, it is becoming necessary to consider sector coupling, which describes connecting different energy sectors, such as electricity, gas and heat, while they interact with each other. Solutions to unlock the potential of sector coupling have been discussed in the literature, including electrification of heating, co-generation and power-to-gas [1–3].

Utilizing hydrogen as an energy carrier and involving it in cross-sectoral energy systems has recently attracted researchers and energy systems planners. It has been viewed as an alternative to fossil fuels and a possible storage medium for varying renewable energies. To produce and store hydrogen, electrolyzers and pressurized tanks can be used. Additionally, hydrogen can be fed to a fuel cell, which exploits electrochemical and thermodynamic hydrogen-oxygen reactions to simultaneously generate electricity and heat [4]. Solid oxide fuel cells (SOFC) and proton exchange membrane fuel cells (PEMFC) are the most installed types in residential energy systems. Nonetheless, a major drawback of hydrogen systems is their high capital and operating costs. Compared to other energy generation technologies, investing in fuel cells and electrolyzers is currently not a cost-efficient solution [5]. Another disadvantage for own hydrogen production and utilization is the low round-trip efficiency when converting electricity to hydrogen and then back to electricity [6]

Models to optimally size hydrogen-based technologies along with renewable and decentralized energy equipment have been the focus of multiple publications. For example, the authors in [7] presented a multi-objective design optimization model, using-mixed integer programming (MILP), for a multi-energy system in a neighborhood. The model included PEMFC and SOFC. While the latter could only use natural gas, the PEMFC could additionally consume hydrogen produced by a PEM electrolyzer and stored in high-pressure tanks. It has been

found that gas-based fuel cells were not optimally selected. Another optimization model to design energy hubs was introduced in [8]. It involved a fuel cell, an electrolyzer, a compressor and a refueling station. For the conducted use cases, it was not economic to install fuel cells. Another study in [9] demonstrated a developed model to optimize the sizing of an off-grid energy system for a village. The system contained a hydrogen system besides photovoltaics and batteries. The design of a similar energy system was optimized in [10], where the evolutionary algorithm and MILP were both implemented for the design and operation optimization.

We have observed that those studies focused on sizing hydrogen-based technologies as part of energy systems which also include typical generation and storage units. In most case studies, the hydrogen system was not favorable to be installed. However, it is not clear how the hydrogen systems will perform in terms of cost efficiency and emission reduction when comparing their optimal sizing and operation to typical cross-sectoral energy systems. Therefore, we created three energy systems, where a PEMFC and a PEM electrolyzer are essential elements in one of them. Using a multi-objective design optimization model, we compare the optimal solutions of the three energy systems at different points of optimal costs and emissions.

In this paper, the methodology is described in Section 2., which starts with an overview of the optimization model. Then, the objective function is presented in Section 2.2., followed by an explanation of the epsilon-constraint method in Section 2.3. Next, the model constraints are demonstrated for energy generation and storage in Section 2.4. and specifically for the hydrogen system in Section 2.5. In Section 3., the case study is illustrated. The structure of the energy systems is first clarified in Section 3.1., followed by the description of the input data in Section 3.2.. After that, the results are demonstrated in Section 3.3. and discussed in Section 3.4. Finally, Section 4. summarizes the presented work and suggests future studies as a conclusion.

2. Methodology

2.1. Overview and Implementation

To design residential energy systems under economic and environmental criteria, a multi-objective optimization model, formulated as a MILP problem, has been developed. Its aim is to minimize the total annual costs and total annual CO_2-equivalent emissions. In order to minimize two contradictory objectives, the epsilon-constraint method is utilized [11]. Simply put, the cost-minimization function is implemented as an objective function, while the emission-minimization function is applied as a constraint.

The model has been implemented using the python-based optimization package pyomo and the energy modeling package oemof-solph [12]. It provides modules that enable the modeling of various elements of an energy system. In the presented model, grids of electricity (EG) and gas (GG) are modeled by the *source* module, while the *sink* module portrays the electricity or heat demands of residential buildings. To connect different elements and ensure an energy balance, the *bus* module is added accordingly. Nevertheless, additional modules have been developed to model energy generation and storage units. In other words, decision variables and constraints describing the operation and design limits of a unit are defined inside the respective module. Those units include photovoltaics (PV), gas-based combined heat and power (G-CHP) units, battery storage (BATT), heat pumps (HP), gas boilers (GB), heat storage (HS), hydrogen fuel cell combined heat and power (FC-CHP), electrolyzers (EZ), hydrogen compressor (H2C), and hydrogen storage (H2S). This modular nature is advantageous for flexibly designing energy systems. Figure 1 provides an overview of the optimization model. It also demonstrates the inputs necessary to run the optimization model and the expected outcome of each run.

In the following subsections, a decision variable is denoted by a bold symbol, e.g., $\mathbf{P^{unit}_{out,max}}$, while a model parameter is represented by an italic symbol, e.g., $c^{unit}_{inv,a}$.

2.2. Cost-minimization function

For an optimization run, the decision variables are optimized such that the total annual costs are minimized. The objective function in (1) shows the components of the minimized costs.

$$\min : \sum_{unit} \left(\mathbf{C^{unit}_{inv,a}} + \mathbf{C^{unit}_{op,a}} \right) + \sum_{sto} \left(\mathbf{C^{sto}_{inv,a}} + \mathbf{C^{sto}_{op,a}} \right) + \sum_{grid} \left(\mathbf{C^{grid}_{imp,a}} \right) - \mathbf{R_{tot,a}} \tag{1}$$

For each unit, except for the EZ and H2C units, the annual investment cost $\mathbf{C^{unit}_{inv,a}}$ (Eur/a) is linearly dependent on the maximum output power $\mathbf{P^{unit}_{out,max}}$ (kW) as per (2). The slope of the linear function is the specific variable investment cost $c^{unit}_{inv,var,a}$ (Eur/kW/a), while the intercept is the fixed investment cost $C^{unit}_{inv,fix,a}$ (Eur/a). The latter is multiplied by the binary variable $\mathbf{y^{unit}_{inst}}$, which value decides whether the unit is installed. Regarding the annual operating cost $\mathbf{C^{unit}_{op,a}}$ (Eur/a), equation (3) includes a power-capacity-related operating cost, $c^{unit}_{op,fix,a}$ (Eur), and a variable operating cost, $c^{unit}_{op,var,a}$ (Eur/kWh), which refers to the total output power $\mathbf{P^{unit}_{out,t}}$ (kW) over all time steps t. Regarding EZ and H2C units, the specific investment and operating costs refer to the input power

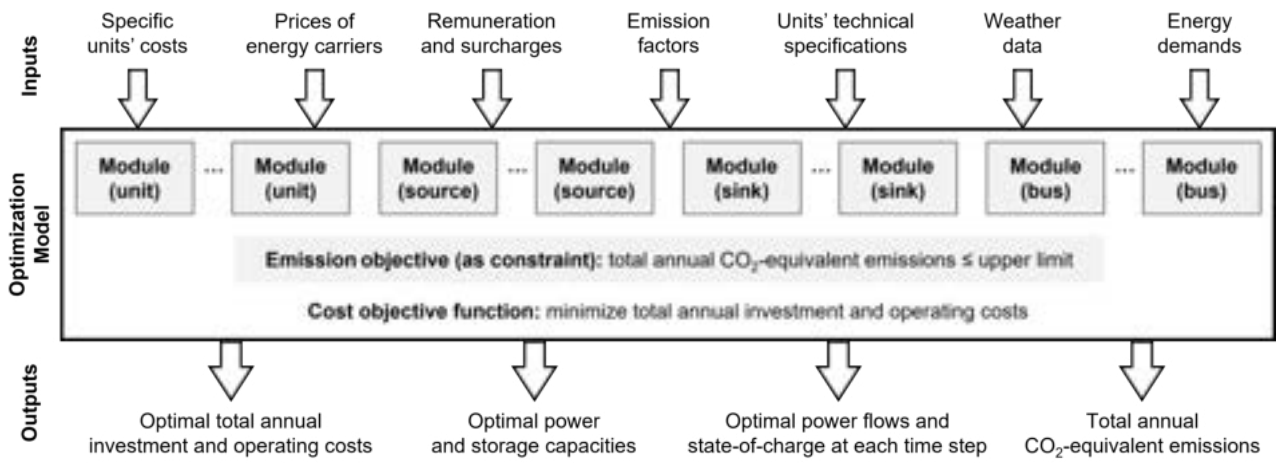

Figure 1: Overview of the developed optimization model including inputs and outputs. The optimization constraints and the decision variables are implemented accordingly in the modules.

of the unit $\mathbf{P^{unit}_{in,t}}$ (kW) or its maximum $\mathbf{P^{unit}_{in,max}}$ (kW) as demonstrated in (4) and (5). Similar to (2) and (3), the investment and operating costs for storage units (sto) are additionally considered in (6) and (7), respectively. In this case, $c^{sto}_{inv,var,a}$ (Eur/kWh/a) and $c^{sto}_{op,fix,a}$ (Eur/kWh/a) refer to the maximum usable energy capacity $\mathbf{E^{sto}_{max}}$ (kWh). Furthermore, the annual costs of importing electricity and gas from their respective grids are taken into account according to (8), where $c^{EG}_{imp,t}$ and $c^{GG}_{imp,t}$ (Eur/kWh) are the prices of electricity and gas, respectively, while $\mathbf{P^{EG}_{imp,t}}$ and $\mathbf{P^{GG}_{imp,t}}$ is the corresponding imported powers at a time step t.

$$\mathbf{C^{unit}_{inv,a}} = c^{unit}_{inv,var,a} \cdot \mathbf{P^{unit}_{out,max}} + C^{unit}_{inv,fix,a} \cdot \mathbf{y^{unit}_{inst}} \quad \text{for } unit \notin \{EZ, H2C\} \tag{2}$$

$$\mathbf{C^{unit}_{op,a}} = c^{unit}_{op,fix,a} \cdot \mathbf{P^{unit}_{out,max}} + c^{unit}_{op,var,a} \sum\nolimits_t \left(\mathbf{P^{unit}_{out,t}} \cdot \Delta t\right) \quad \text{for } unit \notin \{EZ, H2C\} \tag{3}$$

$$\mathbf{C^{unit}_{inv,a}} = c^{unit}_{inv,var,a} \cdot \mathbf{P^{unit}_{in,max}} + C^{unit}_{inv,fix,a} \cdot \mathbf{y^{unit}_{inst}} \quad \text{for } unit \in \{EZ, H2C\} \tag{4}$$

$$\mathbf{C^{unit}_{op,a}} = c^{unit}_{op,fix,a} \cdot \mathbf{P^{unit}_{in,max}} + c^{unit}_{op,var,a} \sum\nolimits_t \left(\mathbf{P^{unit}_{in,t}} \cdot \Delta t\right) \quad \text{for } unit \in \{EZ, H2C\} \tag{5}$$

$$\mathbf{C^{sto}_{inv,a}} = c^{sto}_{inv,var,a} \cdot \mathbf{E^{sto}_{max}} + C^{sto}_{inv,fix,a} \cdot \mathbf{y^{sto}_{inst}} \tag{6}$$

$$\mathbf{C^{sto}_{op,a}} = c^{sto}_{op,fix,a} \cdot \mathbf{E^{sto}_{max}} \tag{7}$$

$$\mathbf{C^{grid}_{imp,a}} = \sum\nolimits_t \left(\left(c^{EG}_{imp,t} \cdot \mathbf{P^{EG}_{imp,t}} + c^{GG}_{imp,t} \cdot \mathbf{P^{GG}_{imp,t}}\right) \cdot \Delta t\right) \tag{8}$$

Moreover, the energy system can generate annual revenues, R_a (Eur/a), by exporting excess electricity from PV and CHP units, denoted by $\mathbf{P^{PV}_{exp,t}}$ and $\mathbf{P^{CHP}_{exp,t}}$ (kW), respectively. For this case, the feed-in tariffs $r^{PV}_{exp,t}$ and $r^{CHP}_{exp,t}$ (Eur/kWh) are applied. Another source of revenues is the remuneration r^{CHP}_{rem} (Eur/kWh) for consuming a kWh of electricity from a CHP unit, symbolized by $\mathbf{P^{CHP}_{dem,t}}$ (kW), according to the CHP Act in Germany [13]. The total annual revenues are calculated as per (9).

$$\mathbf{R_{tot,a}} = \sum\nolimits_t \left(\left(r^{PV}_{exp} \cdot \mathbf{P^{PV}_{exp,t}} + r^{CHP}_{exp} \cdot \mathbf{P^{CHP}_{exp,t}} + r^{CHP}_{rem} \cdot \mathbf{P^{CHP}_{dem,t}}\right) \cdot \Delta t\right) \tag{9}$$

In this paper, the optimization horizon is one year. In order to consider investment costs of units of different lifetimes on an annual basis, they are discounted using the annuity factor as shown in (10). This factor depends on the average weighted cost of capital, *wacc*, and the lifetime of the unit, *LT* (years).

$$c^{unit}_{inv,a} = c^{unit}_{inv} \cdot \frac{wacc \cdot (1 + wacc)^{LT}}{(1 + wacc)^{LT} - 1} \tag{10}$$

2.3. Emission minimization using the epsilon-constraint method

In Fig. 2, the steps to implement the epsilon-constraint method for emission minimization are demonstrated. The aim is to create a Pareto front that shows the trade-off between costs and emissions. In the first step, the

optimization problem is created with the decision variables and the constraints of the energy system components and the cost-minimization objective function as shown in Fig. 1. Next, the constraint in (11) is added (Step 2), which implies that the total annual emissions at the first Pareto iteration, $\varepsilon_{tot,a,1}$ (kg CO_2-equivalent/a), has no limit since it is unknown before carrying out any optimization.

$$0 \leq \varepsilon_{tot,a,1} \leq \infty \tag{11}$$

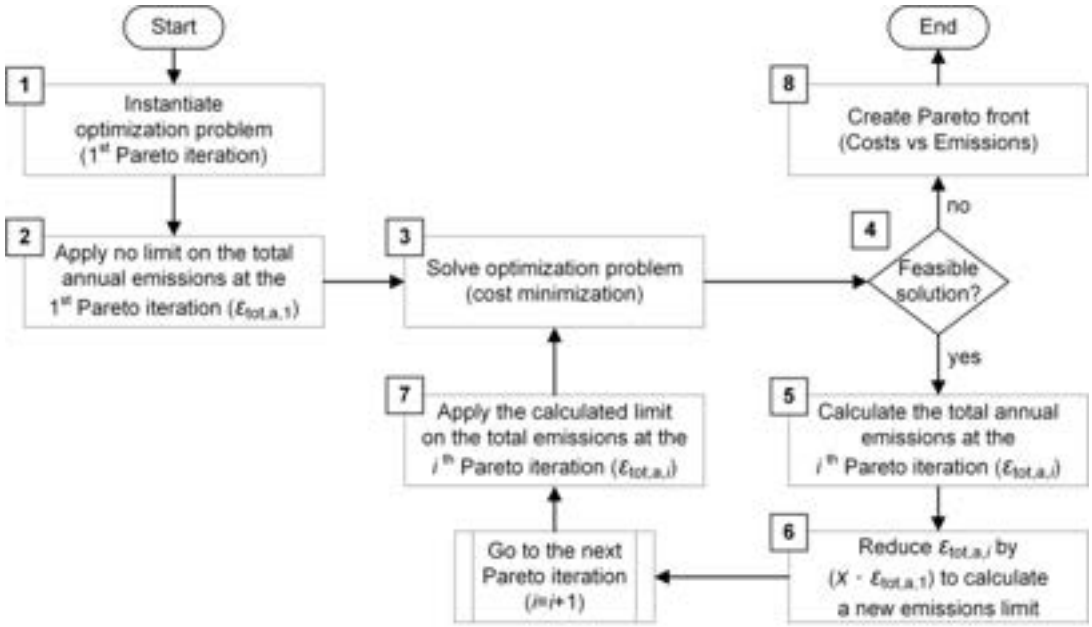

Figure 2: Process flow chart of the epsilon-constraint method.

After solving the optimization problem (Step 3), an if-statement checks whether a feasible solution has been found. If it is true, the total annual emissions at the i^{th} Pareto iteration, $\varepsilon_{tot,a,i}$ (kg CO_2-equivalent/a), is calculated as per (12) (Step 5). It involves the amount of CO_2-equivalent emissions of the district caused by importing electricity and gas, which is determined by the respective emission factors, ε^{EG}_{kWh} and ε^{GG}_{kWh} (kg CO_2-equivalent/kWh). However, the district can reduce these emissions by exporting PV and CHP electricity to the grid, which is represented by a negative emission factor in (12), and, hence, lower the emissions in the grid. For the following Pareto iteration, a new emission limit, $\varepsilon_{tot,max,a,i+1}$, is determined by deducting a percentage x of $\varepsilon_{tot,a,1}$ from $\varepsilon_{tot,a,i}$ as per (13) (Step 6). The new limit is then applied on the total annual emissions according to (14) (Step 7). The optimization is carried out again and the loop continues until the problem has no feasible solution; i.e., the emission-optimal solution has been found. Finally, the Pareto front is created to enable the analysis of the optimal design at different points of optimal costs and emissions (Step 8).

$$\varepsilon_{tot,a,i} = \sum_t \left(\left(\varepsilon^{EG}_{kWh} \cdot \mathbf{P^{EG}_{imp,i,t}} + \varepsilon^{GG}_{kWh} \cdot \mathbf{P^{GG}_{imp,i,t}} - \varepsilon^{EG}_{kWh} \cdot \left(\mathbf{P^{PV}_{exp,i,t}} + \mathbf{P^{grid}_{CHP,i,t}} \right) \right) \cdot \Delta t \right) \tag{12}$$

$$\varepsilon_{tot,max,a,i+1} = \varepsilon_{tot,a,i} - x \cdot \varepsilon_{tot,a,1} \tag{13}$$

$$0 \leq \varepsilon_{tot,a,i} \leq \varepsilon_{tot,max,a,i} \tag{14}$$

2.4. Constraints for energy generation and storage units

Based on a unit's input power, $\mathbf{P^{unit}_{in,t}}$ (kW), and its conversion factor, CF^{unit}, its output power $\mathbf{P^{unit}_{out,t}}$ (kW) is optimized as shown in (15). For instance, the conversion factors of a CHP unit are η^{CHP}_{el} and η^{CHP}_{th}, which describe the electrical and thermal efficiencies of converting the input fuel to electricity and heat, respectively, multiplied by the lower heating value of the input fuel. Another example of a conversion factor is a heat pump's coefficient of performance (COP). In this model, the COP is calculated for each time step based on the source and flow temperatures. Furthermore, the output power cannot surpass $\mathbf{P^{unit}_{out,max}}$ as per (16). In addition, the constraint in (17) implies that $\mathbf{P^{unit}_{out,max}}$ is limited between an upper bound, $P^{unit}_{max,upper}$, and a lower bound $P^{unit}_{max,lower}$, but only if the installation of that unit is optimal; i.e., $\mathbf{y^{unit}_{inst}}$ is selected to be 1.

$$\mathbf{P}^{\mathbf{unit}}_{\mathbf{out,t}} = CF^{unit} \cdot \mathbf{P}^{\mathbf{unit}}_{\mathbf{in,t}} \tag{15}$$

$$0 \leq \mathbf{P}^{\mathbf{unit}}_{\mathbf{out,t}} \leq \mathbf{P}^{\mathbf{unit}}_{\mathbf{out,max}} \tag{16}$$

$$\mathbf{y}^{\mathbf{unit}}_{\mathbf{inst}} \cdot P^{unit}_{out,max,lower} \leq \mathbf{P}^{\mathbf{unit}}_{\mathbf{out,max}} \leq \mathbf{y}^{\mathbf{unit}}_{\mathbf{inst}} \cdot P^{unit}_{out,max,upper} \tag{17}$$

For a PV unit, a time series of normalized output $P^{PV}_{out,norm,t}$ (kW/kWp) is obtained using the solar irradiation and weather data of the geographical location. Based on $P^{PV}_{out,norm,t}$ and the peak power $\mathbf{P}^{\mathbf{PV}}_{\mathbf{out,t}}$ (kWp), the PV output $\mathbf{P}^{\mathbf{PV}}_{\mathbf{out,t}}$ is determined in (18). Besides the constraint in (17), $\mathbf{P}^{\mathbf{PV}}_{\mathbf{out,t}}$ is limited in (19) by the total available area A^{PV}_{tot} (m^2), where A^{PV}_{kWp} (m^2/kWp) is the area of a kWp PV.

$$\mathbf{P}^{\mathbf{PV}}_{\mathbf{out,t}} = P^{PV}_{out,norm,t} \cdot \mathbf{P}^{\mathbf{PV}}_{\mathbf{out,max}} \tag{18}$$

$$A^{PV}_{kWp} \cdot \mathbf{P}^{\mathbf{PV}}_{\mathbf{max}} \leq A^{PV}_{tot} \tag{19}$$

Regarding a storage unit, equation (20) ensures the energy balance between the stored energy $\mathbf{E}^{\mathbf{sto}}_{\mathbf{t}}$ (kWh) at the current and previous time steps, along with the charging and discharging powers $\mathbf{P}^{\mathbf{sto}}_{\mathbf{ch,t}}$ and $\mathbf{P}^{\mathbf{sto}}_{\mathbf{dis,t}}$ (kW), and the respective charging efficiencies η^{sto}_{in} and η^{sto}_{out}. To represent self-discharging losses, the parameter σ^{sto}_{self} represents the percentage of energy lost per hour. The constraints in (21) to (23) represent the bounds for $\mathbf{E}^{\mathbf{sto}}_{\mathbf{t}}$, $\mathbf{P}^{\mathbf{sto}}_{\mathbf{ch,t}}$ and $\mathbf{P}^{\mathbf{sto}}_{\mathbf{dis,t}}$. In order to prevent simultaneous charging and discharging, the binary variable $\mathbf{y}^{\mathbf{sto}}_{\mathbf{ch,t}}$ is utilized in (24) and (25). If it is 1, then the storage unit is being charged. Similar to (17), optimizing $\mathbf{E}^{\mathbf{sto}}_{\mathbf{max}}$ is limited between $E^{sto}_{max,upper}$ and $E^{sto}_{max,lower}$ (kWh) with the association of $\mathbf{y}^{\mathbf{sto}}_{\mathbf{inst}}$.

$$\mathbf{E}^{\mathbf{sto}}_{\mathbf{t}} = \mathbf{E}^{\mathbf{sto}}_{\mathbf{t-1}} \cdot \left(1 - \sigma^{sto}_{self}\right) + \left(\mathbf{P}^{\mathbf{sto}}_{\mathbf{ch,t}} \cdot \eta^{sto}_{ch} - \mathbf{P}^{\mathbf{sto}}_{\mathbf{dis,t}} / \eta^{sto}_{dis}\right) \cdot \Delta t \tag{20}$$

$$0 \leq \mathbf{E}^{\mathbf{sto}}_{\mathbf{t}} \leq \mathbf{E}^{\mathbf{su}}_{\mathbf{max}} \tag{21}$$

$$0 \leq \mathbf{P}^{\mathbf{sto}}_{\mathbf{ch,t}} \leq \mathbf{P}^{\mathbf{sto}}_{\mathbf{max}} \tag{22}$$

$$0 \leq \mathbf{P}^{\mathbf{sto}}_{\mathbf{dis,t}} \leq \mathbf{P}^{\mathbf{sto}}_{\mathbf{max}} \tag{23}$$

$$0 \leq \mathbf{P}^{\mathbf{sto}}_{\mathbf{ch,t}} \leq \mathbf{y}^{\mathbf{sto}}_{\mathbf{ch,t}} \cdot P^{sto}_{max,upper} \tag{24}$$

$$0 \leq \mathbf{P}^{\mathbf{sto}}_{\mathbf{dis,t}} \leq \left(1 - \mathbf{y}^{\mathbf{sto}}_{\mathbf{ch,t}}\right) \cdot P^{sto}_{max,upper} \tag{25}$$

When connecting units, sources and sinks to each other, a bus component is included accordingly in the energy system. Its addition is equivalent to considering (26), which guarantees that the sum of all inflows equals the sum of all outflows at any time step. A special case of the bus component is the heat network (HN) module, where the inflows are multiplied by an efficiency parameter, η_{HN}, to describe distribution losses as per (27).

$$\sum\nolimits_{inflow} \mathbf{P}^{\mathbf{bus}}_{\mathbf{inflow,t}} = \sum\nolimits_{outflow} \mathbf{P}^{\mathbf{bus}}_{\mathbf{outflow,t}} \tag{26}$$

$$\sum\nolimits_{inflow} \mathbf{P}^{\mathbf{HN}}_{\mathbf{inflow,t}} \cdot \eta^{HN} = \sum\nolimits_{outflow} \mathbf{P}^{\mathbf{HN}}_{\mathbf{outflow,t}} \tag{27}$$

2.5. Constraints for hydrogen-based units

The presented constraints for hydrogen-based units are based on the work in [14], where an operation optimization model for energy systems with EZ, H2C, H2S and FC-CHP has been developed. The first component in a hydrogen system is the electrolyzer, which generates the hydrogen gas using electrical work. Equation (28) shows how the output mass flow $\dot{\mathbf{m}}^{\mathbf{EZ}}_{\mathbf{out,t}}$ (kg/h) is dependent on the input power $\mathbf{P}^{\mathbf{EZ}}_{\mathbf{in,t}}$ (kW), the standard density of hydrogen ρ_{h_2} (kg/Nm^3), and the specific energy consumption $e^{EZ}_{h_2}$ (kWh/Nm^3). Moreover, $\mathbf{P}^{\mathbf{EZ}}_{\mathbf{in,t}}$ is limited below $\mathbf{P}^{\mathbf{EZ}}_{\mathbf{max}}$ as formulated in (29). The latter is also confined in (30) by $P^{EZ}_{in,max,upper}$, $P^{EZ}_{in,max,lower}$ and $\mathbf{y}^{\mathbf{EZ}}_{\mathbf{inst}}$.

$$\dot{\mathbf{m}}^{\mathbf{EZ}}_{\mathbf{out,t}} = \mathbf{P}^{\mathbf{EZ}}_{\mathbf{in,t}} \cdot \rho_{h_2} / e^{EZ}_{h_2} \tag{28}$$

$$0 \leq \mathbf{P}^{\mathbf{EZ}}_{\mathbf{in,t}} \leq \mathbf{P}^{\mathbf{EZ}}_{\mathbf{in,max}} \tag{29}$$

$$\mathbf{y}^{\mathbf{EZ}}_{\mathbf{inst}} \cdot P^{EZ}_{in,max,lower} \leq \mathbf{P}^{\mathbf{EZ}}_{\mathbf{in,max}} \leq \mathbf{y}^{\mathbf{EZ}}_{\mathbf{inst}} \cdot P^{EZ}_{in,max,upper} \tag{30}$$

The output of the EZ unit is then fed to an H2C unit to compress the hydrogen and enable its storage in high-pressure tanks. A balance constraint, as shown in (31), is applied to the input and output mass flows. Based

on the hydrogen flow, the necessary power for compression, $\mathbf{P^{H2C}_{in,t}}$, is found in (32) using the electric efficiency η^{H2C}_{el} and the specific enthalpies at the compressor's inlet and outlet, h^{H2C}_{in} and h^{H2C}_{out} (J/kg), respectively. Both parameters depend on the pressure of the input, p^{H2C}_{in} (bar), and the output, p^{H2C}_{out} (bar), as well as the temperature at the inlet, T^{H2C}_{in} (K). The calculation is carried out using the python-based function *PropsSI* [15], which finds the value of a thermophysical property for a selected fluid by inputting the values of two other properties. Additionally, a factor of $3.6 \cdot 10^{-6}$ is used in (32) to obtain the result in kW. Constraints similar to (29) and (30) are applied to $\mathbf{P^{H2C}_{in,t}}$ and $\mathbf{P^{H2C}_{in,max}}$ with the corresponding parameters of the H2C unit.

$$\mathbf{\dot{m}^{H2C}_{in,t}} = \mathbf{\dot{m}^{H2C}_{out,t}} \tag{31}$$

$$\mathbf{P^{H2C}_{in,t}} = 3.6 \cdot 10^{-6} \cdot \mathbf{\dot{m}^{H2C}_{in,t}} \cdot \left(h^{H2C}_{out} - h^{H2C}_{in} \right) / \eta^{H2C}_{el} \tag{32}$$

To identify the charging and discharging powers of the H2S unit, the average storage enthalpy h^{H2S}_{avg} (J/kg) is found using *PropsSI* by inputting the maximum and minimum storage pressures, p^{H2S}_{max} and p^{H2S}_{min} (bar), respectively, and the storage temperature T^{H2S} (K). The operating powers are then determined by (33) and (34). Analogous to (20), the stored energy E^{H2S}_{t} (kWh) is tracked at each time step as per (35). Further, the storage constraints (21) to (25) are applied to the energy and power variables of the H2S unit. Finally, the operation and design constraints of an FC-CHP unit are identical to the generation units' constraints in (15) to (17).

$$\mathbf{P^{H2S}_{in,t}} = 3.6 \cdot 10^{-6} \cdot \mathbf{\dot{m}^{H2S}_{in,t}} \cdot h^{H2S}_{avg} \tag{33}$$

$$\mathbf{P^{H2S}_{out,t}} = 3.6 \cdot 10^{-6} \cdot \mathbf{\dot{m}^{H2S}_{out,t}} \cdot h^{H2S}_{avg} \tag{34}$$

$$\mathbf{E^{H2S}_{t}} = \mathbf{E^{H2S}_{t-1}} + \left(\mathbf{P^{H2S}_{ch,t}} - \mathbf{P^{H2S}_{dis,t}} \right) \cdot \Delta t \tag{35}$$

3. Case Study

3.1. Structure of energy systems under investigation

To examine the hydrogen system economically and environmentally, a case study of an exemplary German residential district is conducted, where three energy systems (ES) are created. Two systems, ES 1 and 2, represent typical sector-coupling approaches. Figure 3 demonstrates the complete energy system, how the units are interconnected and which units are included in each ES. In ES 1, the primary heat supplier is a gas-CHP unit. It can also feed the electricity demand and export excess generation. In ES 2, a heat pump is solely responsible for heat generation. Finally, an FC-CHP unit is taken into account in ES 3. In this energy system, the electrolyzer produces hydrogen at 35 bar, which is then compressed to 300 bar to be stored in the hydrogen storage. In ES 1 and 3, a gas boiler is additionally considered for peak heat demands. In all systems, PV units can be installed to cover the electricity demand, supply the heat pump (in ES 2) or the electrolyzer and the compressor (in ES 3), or export the surplus energy to the grid. Besides, all energy systems can include batteries and heat storage units. The bus component *heat network* connects the central heat generation node to the demand with 5% distribution losses.

3.2. Input data

The district under study includes 13 multi-family houses with electricity and heat demands. The demand profiles were generated based on the guideline VDI 4655 [16] for one year, assuming that the total annual demands amount to 244 MWh of electricity and 1030 MWh of heat. The peak loads of both demands are 48 kW_{el} and 670 kW_{th}. The majority of the input data used, including prices of energy carriers, remunerations, surcharges and weather data, is based on the year 2020. To import electricity from the grid, a time-varying price with a mean of 0.304 Eur/kWh is applied, which is based on day-ahead prices and additional network charges and taxes [17,18]. For importing gas, a constant price of 0.076 Eur/kWh is inputted [19]. In the case of exporting PV or CHP electricity, the energy system receives revenue of 0.065 Eur/kWh [20] and 0.087 Eur/kWh [13, 21], respectively. A remuneration of 0.0305 Eur/kWh is additionally awarded for the own consumption of CHP electricity [13]. Concerning the costs of technologies, linear investment functions and operating costs have been extracted from several studies and market data for PV [22], battery [9], gas CHP, gas boiler, heat pumps, heat storage [23], FC-CHP [24], electrolyzer [25], hydrogen compressor [26] and hydrogen storage [8] units. Furthermore, only emissions from importing electricity and gas from respective grids are taken into account in this study. Hence, emission factors of 0.438 [27] and 0.228 kg CO_2-equivalent [28] per kWh of imported electricity ang gas, respectively, are inputted.

A flat roof area of 4000 m^2 in total is available for the PV modules. These modules can be mounted with two different configurations: a south orientation or an east-west orientation. The available area corresponds to

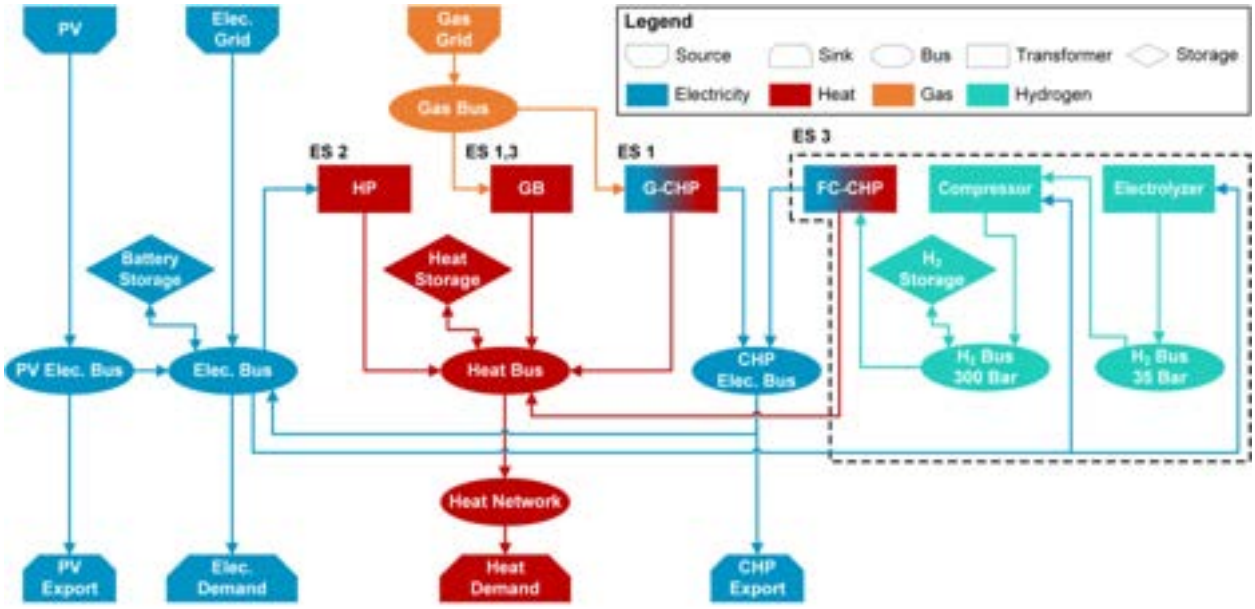

Figure 3: Complete structure of the optimized residential energy systems. Categorization of the elements follows the description in Section 2.1. The abbreviation ES implies in which energy system a unit is considered. ES 1 has a G-CHP and GB, ES 2 has only an HP, and ES 3 has a GB and hydrogen-based units.

331.5 kWp of south-oriented PV or 796 kWp of east-west-oriented PV. The PV output for each configuration, in addition to ambient temperature data, was obtained from PVGIS [29]. For the heat pump, the COP was calculated based on the given data in [30] for a flow temperature of 65 °C. The remaining technical specifications of the units are based on [4, 14, 23]. Since the gas boiler is installed to only support the main heat generator in ES 1 and 3, its sizing is limited to 400 kW.

3.3. Results

The following demonstrated results are obtained by solving the optimization problem with an hourly temporal resolution for each energy system, for multiple iterations, using the solver Gurobi [31]. Following the method presented in Section 2.3., the emission limit is reduced by x = 5% (Step 6 in Fig. 2) of the initial total annual emissions, calculated at the first Pareto iteration. Figure 4 illustrates the Pareto fronts of each energy system. Each point on the plotted curves corresponds to a solution with an optimal total annual cost for a set total annual emission. For each curve, the point on the far right portrays the cost-minimum solution (first Pareto iteration), while the far-left point represents the emission-minimum solution (last Pareto iteration). The curves also depict the best solutions in terms of costs and emissions; i.e., there are no feasible solutions with better cost-emission combinations below or to the left of the curve. For further investigation, the optimal unit sizing in terms of maximum power and maximum storage capacity is plotted for each ES in Fig. 5, while costs and emissions are demonstrated by respective categories in Fig. 6. In both figures, only selected Pareto iterations, including the first and the last, are shown for improved readability.

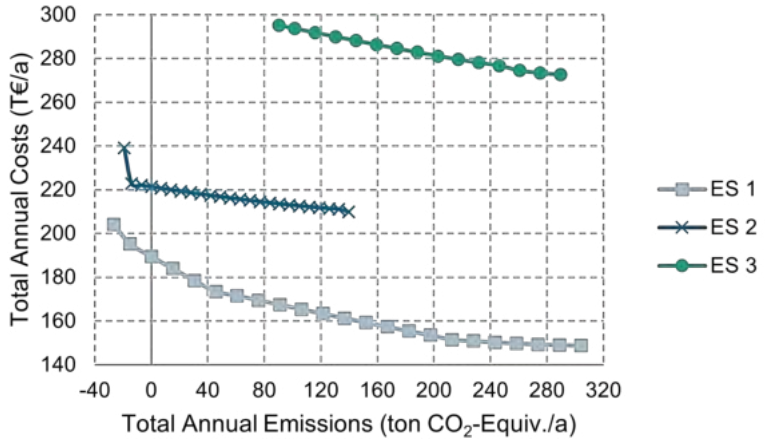

Figure 4: Pareto front (total annual costs vs. total annual emissions) of each energy system.

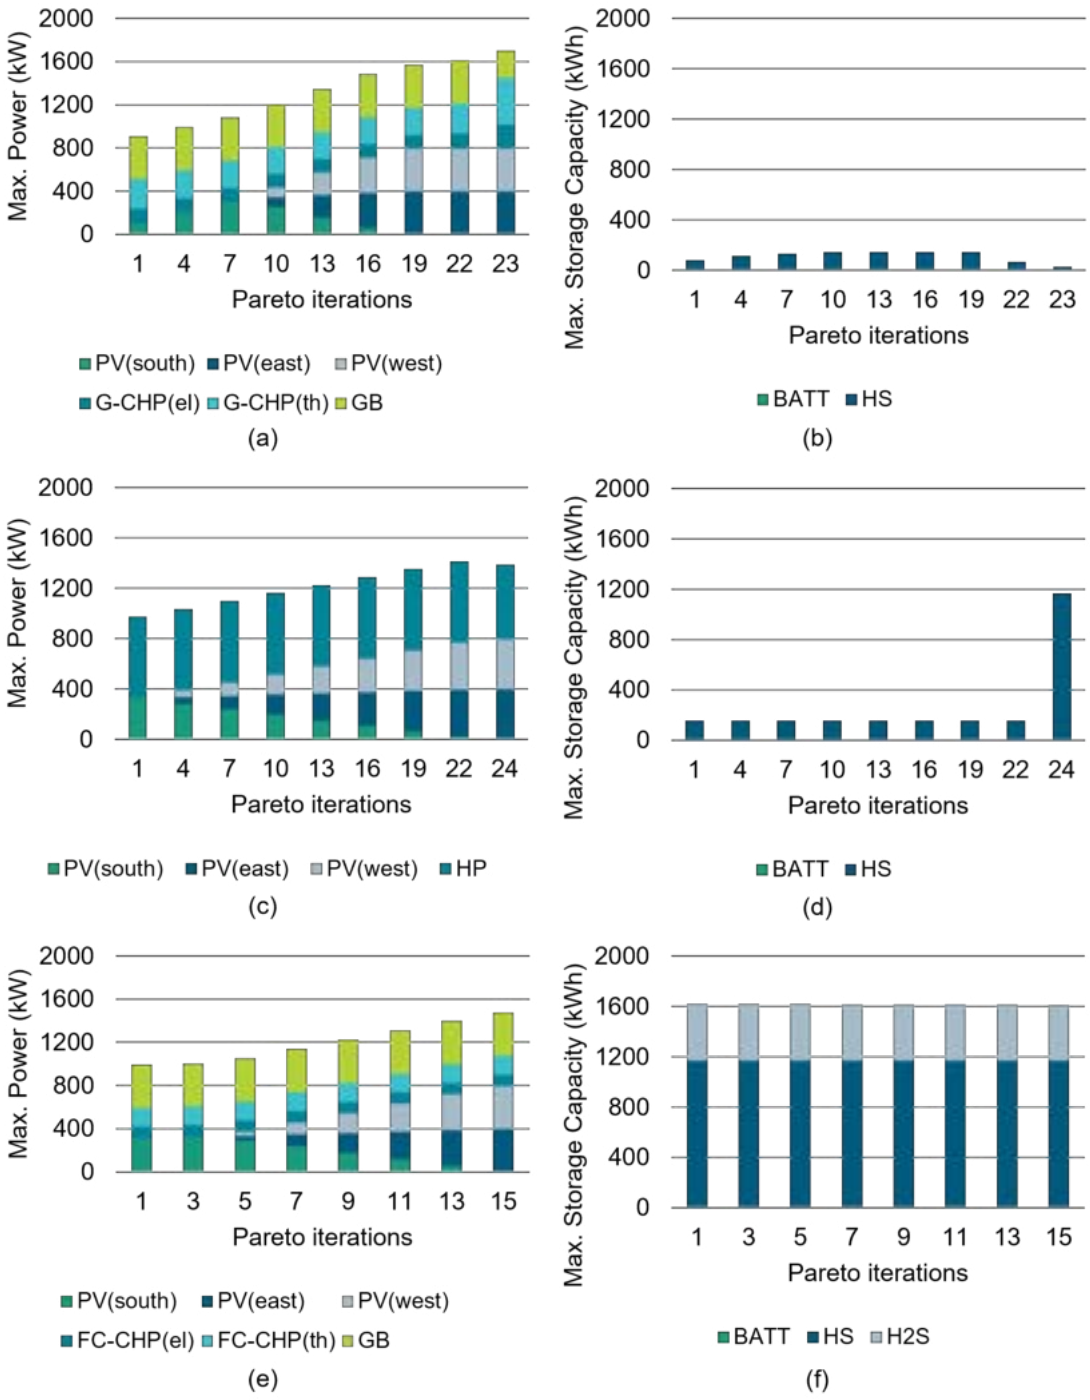

Figure 5: Optimal maximum power of generation units (a, c, e) and optimal storage capacity of storage units (b, d, f) for ES 1 (a, b), ES 2 (c, d) and ES 3 (e, f) among selected Pareto iterations. The first and last iteration corresponds to the cost optimum and the emission optimum, respectively.

3.4. Discussion

In Fig. 4, it is noticeable that the energy system with the hydrogen-based units is remarkably outperformed by the other two in terms of cost efficiency among all the Pareto iterations. In Fig. 6(e), it is evident that ES 3 has notably increased investment and operating costs in comparison to ES 1 and 2. Another observation is the comparable emission-saving performance of the hydrogen system with ES 1 and 2 for a limited number of iterations. Nevertheless, ES 1 and 2 can reduce emissions by 108% and 113%, respectively, in comparison to the first iteration. Exceeding 100% emission reduction implies that the district is producing negative emissions and, consequently, contributing to the emission mitigation in the electricity grid. On the other hand, the hydrogen system can only achieve 68%. Moreover, ES 1 economically surpasses ES 2. The main justification is that the installation of the heat pump leads to additional electricity consumption, which is more expensive than

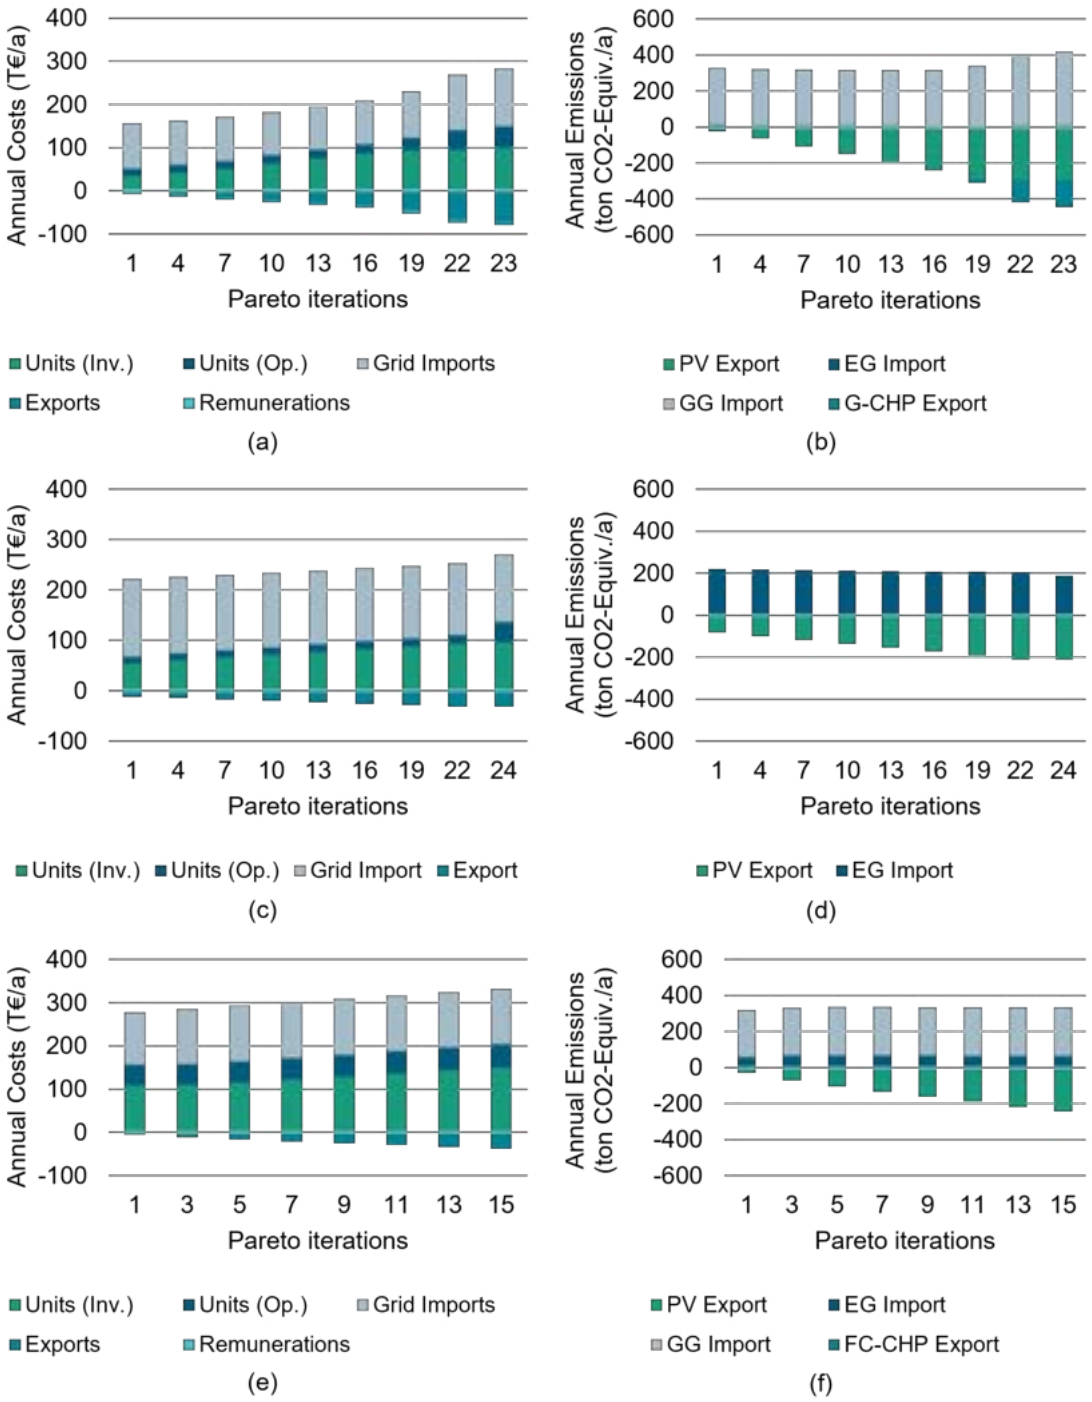

Figure 6: Optimal annual costs (a, c, e) and optimal annual emissions (b, d, f), categorized by source, for ES 1 (a, b), ES 2 (c, d) and ES 3 (e, f) among selected Pareto iterations. The first and last iteration corresponds to the cost optimum and the emission optimum, respectively.

gas, and, hence, results in higher grid import costs as shown in Fig. 6(c).

By observing the trend of reducing emissions in Fig. 4 and the resulting optimal design in Fig. 5, it can be inferred that installing additional PV peak power is the primary strategy for achieving low emission solutions for all energy systems. While lowering the emissions limit to find the emission-optimal solution, the solver attempts to first fully utilize the available area with south-oriented PV modules. After that, those modules are reduced while more east-west-oriented PV modules are recommended, since they require less area to produce the same amount of electricity as the south-oriented area, until the maximum possible peak power is reached. The primary reason is that increasing PV installation can lead to exporting more electricity to the grid and, consequently, increases the negative emissions.

Other strategies can be also noticed among the last Pareto iterations, especially after the first strategy is fully

implemented. For instance, in Fig. 5(a), the maximum power of the gas CHP unit is expanded while the sizing of the gas boiler and the heat storage is reduced in order to produce more electricity and export it to the grid. Another strategy occurs for ES 2, which is noticeable through the last iteration in Fig. 5(a) and (b). The solver recommends decreasing the heat pump's maximum power and increasing the heat storage capacity. This is accompanied by a decrease in emissions from electricity imports and fewer negative emissions from PV exports according to Fig. 6(d). This implies a rising PV supply to feed the heat pump and generate excess heat to be stored, which reduces the amount of imported electricity. However, this strategy causes comparably higher investment costs than the other iterations.

Another remark is the absence of batteries in all energy systems. A possible explanation is that in this district, exporting electricity is more economical than storing it in a battery, which requires an additional investment.

It is important to point out that the demonstrated results correspond exclusively to the input data presented in Section 3.2. Nevertheless, the drawn conclusions agree with recent literature, such as the remarks in [5] regarding the economic disadvantages of hydrogen technologies. In addition, the presented methodology with the multi-objective optimization model can be applied to other residential districts where input data are available as per described in Section 2. and illustrated in Fig. 1. Furthermore, other scenarios can lead to distinctive outcomes. For example, considering an electricity mix with a high share of renewable energy, i.e., a lower emission factor, can result in different Pareto fronts than in Fig. 4.

4. Conclusion

In this paper, we investigated the economic and environmental effects of considering hydrogen-based units on the design optimization of residential energy systems, where sector coupling could be implemented. First, a multi-objective optimization model has been developed to find the cost- and emission-optimal design and operation of different generation and storage technologies in a district, including technologies to produce and utilize hydrogen. The emission minimization has been accomplished by means of the epsilon-constraint method.

To assess the impacts of the hydrogen system, three energy systems for an exemplary district in Germany have been created. The first two involved sector coupling by gas-based co-generation and electrification through a heat pump, while the third included the hydrogen system. By comparing the respective Pareto front, it has been concluded that using hydrogen in a cross-sectoral energy system was unfavorable to obtaining competitive designs in terms of costs and emissions in comparison to typical sector-coupling approaches. It has been also determined that utilizing PV systems was a major factor in mitigating emissions.

Using the developed model, further examinations can be carried out for different energy systems structures. Another possible future work is to conduct sensitivity or scenario analysis to evaluate the performance of hydrogen systems while varying different model inputs. Moreover, further assessment criteria such as degree of self-sufficiency or self-consumption can be investigated for hydrogen systems.

Acknoweldgement

The presented work in this paper has been carried out within the project "ODH@Bochum-Weitmar", which has been funded by the Ministry of Economic Affairs, Industry, Climate Protection and Energy of North-Rhine Westphalia as part of "Program for Rational Energy Use, Renewable Energies and Energy Saving - progres.nrw - Program Area of Innovation (progres.nrw - Innovation)".

Nomenclature

Letter Symbols

C	cost, Eur
c	specific cost, Eur/kW or Eur/kWh
