Special session. The future of thermoeconomics

ECOS2023

The Exergy Footprint and the resource cost of Externalities

Enrico Sciubba
Niccolò Cusano University, Roma
enrico.sciubba@unicusano.it

This paper provides a review of the concept of the Exergy Footprint, a novel Environmental Indicator formulated in a Thermo-Economic perspective. Every effort is made to present it as the latest -even if probably not the final- development of the brilliant intuition by Rant (formulated in 1955, almost 70 years ago) to use Thermodynamic principles to obtain a more rational cost allocation in multi-products lines. The ExF maintains that the real cost of a material or immaterial commodity is measured by the primary resource cumulatively consumed in its production, operation and disposal, i.e. in a life-cycle sense. Its novelty: it explicitly includes the externalities.

Starting from simple but rigorous examples, it is shown that if sufficient econometric data are available, a primary resource cost can be calculated for the Labour and Capital Externalities. It is then argued that the calculation of the Environmental Cost can be formulated in terms of an "extended exergy balance" in which the streams entering and leaving the system are either physical (material, energy) and "equivalent" (Labour, Capital). Once this step is completed, all three externalities are expressed by their equivalent primary exergy consumption.

For any technological chain it is then possible to calculate the actual amount of primary resource exergy "embodied" (in an extended sense) into a commodity. This amount is clearly a cost proper, and is called "Extended Exergy Cost" or, to better signify its importance, "Exergy Footprint", ExF.

For any human agglomerate it becomes then possible to derive an effective measure of its environmental impact, given by the weighted sum of the ExF of all of its "products". The Exergy Footprint can thus be also viewed as an Environmental Indicator and can be applied to every scale of a society, from the single production line to an entire city or region or nation.

Keywords: Environmental indicators; Non-equilibrium systems; Second Law; Sustainability; Exergy Footprint

1 – A NECESSARY HISTORICAL PRELUDE

Exergy definition by Bosniakovic [1961] & Rant [1955]: *The exergy of a system is the maximum useful work that can be extracted from a system by a process that brings it into equilibrium with a heat reservoir*.
And a more rigorous definition may add: "… (heat reservoir) *of infinite capacity, while the system interacts only with this heat reservoir* ".
I like also Szargut' definition: "*Exergy is the amount of work obtainable when some matter is brought to a state of thermodynamic equilibrium with the common components of the natural surroundings by means of reversible processes*" [Szargut 1988]

But important: *Exergy of a system in a state **x** is also the minimum reversible work that must be done on it to bring it from its equilibrium with the heat reservoir to state **x***.

Gibbs Available Energy "*The greatest amount of mechanical work that ideally can be obtained merely by proceeding from the given condition of the body to one on the surface of dissipated energy that has the same S and V*." [gaggioli 2002]. If we accept this definition, Exergy is NOT equal to Available Energy (but, see also [Keenan 1941])

(The word ‘‘availability’’ was introduced by Tait in 1868 and ‘‘available energy’’ by Maxwell ~1871. For over three decades, 1970-2008, “Availability” and “Exergy” were used to define the same thermodynamic function)

First mention of *economic value of exergy*, [Rant 1955]: “*Exergy is the part of energy having value. Energy without exergy is valueless*”
Exergists were criticized in Europe & Germany in the ’60-‘70s [Tuma 2016] (but they did not give up: in Germany Elsner [1965-1972], Fratzscher [1965-1977, Beyer [1972-1980] and many others; in Russia, Kalinina [1973-1978], Brodianskyi [1965], Nikul’shin [1980]; in Poland, Szargut [1957-1973]…
1962-1971: Tribus, Sama, Evans proposed a monetary cost balance based on exergy content of streams (=> there is a cost in destroyed exergy!) [1962-1981]
Exergists were criticized in Europe & US, 1980-1990, but Gaggioli founded the Second Law Group (1984) whose members did an impressive amount of scientific works and engineering applications that last until today.
Tsatsaronis (& Knoche) 1984/85 and Valero 1986 laid the basis for a) the exergy flowchart of a process; b) the TE assessment and optimization of a process.
Frangopoulos & von Spakovski: Environomics, ~1997: an attempt to explicitly include externalities in a TE formulation. Szargut had already proposed the inclusion of environmental effects in 1973, but his work did not obtain the due recognition until much later.
In fact, Gaggioli (& Petit, Reistad, Wepfer) had already presented an initial structuring of Exergy Economics between 1970-80:
Valero (& Valero-Delgado, Stanek) improved, completed and formalized Szargut’s idea of Exergo-ecological cost [1995-2014]
Jørgenssen proposed a niche application under the name of Eco-exergy, ~2005.
Many other contributions, most of which are included in the Reference list, were published between 1990 and 2021. TE-based Diagnostics paradigms were formulated [Lazzaretto, Serra, Valero, Verda, 1994-2004], the loss structure was more accurately identified [Lazzaretto, Tsatsaronis, Valero, Verda, 1996-2002], applications to more complex systems and the links to the emerging “sustainability” concept was proposed [Wall, Whiting, Dai et al., Nowak, Sciubba, Stanek, Valero, Morosukk, Petrakopoulos, 1977-2014]
The first explicit inclusion of the Labour, Capital and Environmental costs into a non-monetary framework, called Extended Exergy, was proposed by Sciubba [1998]
One possible description (NOT a definition!): Thermoeconomics, TE, is a versatile concept that provides a general, systematic and integrated approach for the analysis of design systems. Being an exergy-aided costing method, TE offers additional insight on the cost formation of primary and secondary streams in energy conversion plants, as well as on the interactions among thermodynamics and economics and among the various plant components, all of which are important for improvement of energy system design.

2 – MONETARY THERMO-ECONOMICS

Every process admits of a **cost balance** equation:

$$C_P = C_F + Z_K \qquad \text{(in €/yr, neglecting profit)} \qquad (1)$$

Z_K [€/s] is the capital repayment cost flow (it may include scheduled maintenance, insurance & Labour).
Consider as a simple example the heating of a room: the Product is Q_{room}, the Fuel Q_{source}

$$c_{source} * Q_{source} + Z_K = c_{room} * Q_{room} \qquad (2)$$

Since we are interested in the cost of space heating, we can run an **energy cost balance** (“how many kWh it takes to generate the desired product?”):

$$c_{source} * Q_{source} + Z_K = c_{room} * Q_{room} \qquad (3)$$

…c in €/kWh, Q may be expressed as Δh, in kWh

$$c_{room} = \frac{c_{source} Q_{source} + Z_K}{Q_{room}} \qquad \text{in €/kWh} \qquad (4)$$

Rant [1955] argued that the real “value” of a commodity is its exergy content. The cost equation can be rephrased in terms of exergy:

$$c_{source} * E_{Qsource} + Z_K = c_{room} * E_{Qroom} \quad (5)$$

…*c* in €/kWh, *E* in kWh

E_{Qroom} is rather low because the room is almost at its dead state (p_0, T_0), $E_{Qsource}$ is much higher because there is indeed some work-generating capacity in the hot source … so:

$$c_{room} = \frac{c_{source} E_{Qsource} + Z_K}{E_{Qroom}} \quad \text{in €/kWh} \quad (6)$$

The same formula, very different meanings! In fact, $E_Q = Q - T_0 \Delta s$ is always lower than the enthalpy of an amount equal to the Gouy-Stodola irreversibly "lost work". As a consequence, the c_{room} given by eqtn. (6) is higher than its energy equivalent given by eqtn. (4).

It is interesting to quote [Rant 1955]: "*A system, let us say a heated room, requires a given quantity of heat (Q_{room}) at temperature T_{room} (Sl. 2). This heat is represented in the s-T diagram by the area of rectangle 1-2-3-4. The heat is available at temperature T_{source} (e.g. the average temperature of flue gases in a furnace) and the environment temperature is T_0. The simplest method of heating involves direct removal of heat from the heat source and its transfer to the user. In this way, the amount of thermal energy Q_{source} removed from the source at temperature T_{source} equals the amount of heat supplied to the heated system:*

$$Q_{source} = Q_{room} \quad (7)$$

In Sl.2, Q_{source} is represented by the area 7-8-9-10, which is obviously equal to the area 1-2-3-4. There are no losses as far as energy is concerned.

What about the exergies? The exergy of heat Q_{room} is $E_{room} = Q_{room}\ (T_{room} - T_0)/T_{room}$, equal to area 1-2-5-6; the exergy of the thermal energy Q_{source} used for heating is $E_{source} = Q_{source}(T_{source} - T_0)/T_{source}$,; E_{source}=7-8 -11-12; considering $Q_{room} = Q_{source}$ and $T_{room} < T_{source}$, we can also establish that $E_{room} < E_{source}$. The exergy has been reduced in this process. The cause for the loss of exergy is the irreversible transfer of heat from the source to the system at a limited and, usually, quite large temperature differences $T_{source} - T_{room}$. Wherever irreversibilities are present, things are not in order energetically, even if it seems otherwise. The method of heating can be improved significantly as follows (Sl. 3):

Only as much heat Q'_s is removed from the source at temperature T_{source}, so that its exergy E'_s equals the exergy E_{room} of thermal energy Q_{room} used for heating. We get:

$$Q'_s = Q_{source} \frac{T_{room} - T_0}{T_{room}} \frac{T_{source}}{T_{source} - T_0} \quad (8)$$

The exergy E'_s coming from the source of removed heat Q'_s is converted to work using a power cycle, and this work is then used to drive a reversed Carnot cycle 1-6-5-2. Valueless heat 6-5-3-4 is removed from the environment in this process (this heat has zero exergy). The heated system is provided with heat Q_{room} =1-2-3-4 having the necessary exergy E_{room} = 1-2-5-6. This method of heating removes less energy from the heat source than that required for heating; but the exergy removed from the heat source equals the spent exergy. This is the operating principle of a Heat Pump." And in the conclusions: … "*The existing method for energy pricing (accounting) in combined plants on the basis of used enthalpies is fundamentally wrong. It has to be replaced with pricing (accounting) on the basis of used exergies, which is the only proper way.*"

(text slightly adapted by this author)

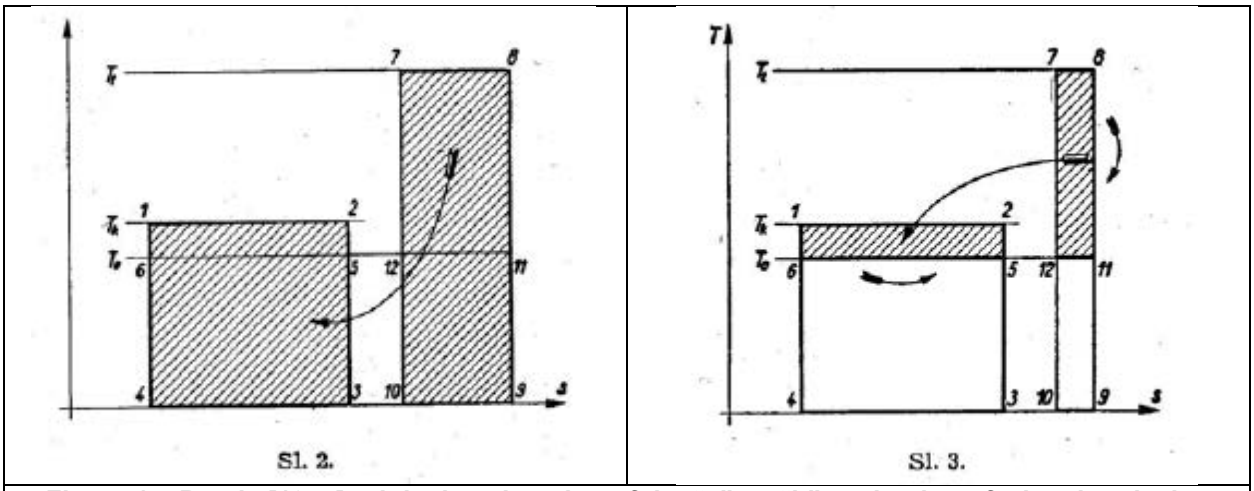

Figure 1 – Rant's [1955] original explanation of the "e" vs "h" evaluation of a heating device

Since realistic processes are much more complex, some "cost rules" must be introduced to maintain rigor and abide to common engineering sense. This was done by Gaggioli & coworkers, Lazzaretto, Tsatsaronis-Cziesla, Morozyuk, Reini [2021-2023],Valero.

In real processes, there are inevitably some material or immaterial discharges. The corresponding term C_D must be included in the cost balance, eqtn. (1), as well.

$$C_P=C_F+Z_K+Z_{ENV}+C_D \qquad (9)$$

There are additional prescriptions on how to handle the C_D term, but they are not essential to our scope here.

Let us provide a simplified outline of the procedure proposed by Tsatsaronis & Valero: (the following treatment is simplified for conciseness & clarity and is not completely rigorous!).

Let us write the cost equations for each individual component in figure 2:

$$\begin{aligned} c_1\dot{E}_1 - c_2\dot{E}_2 + c_7\dot{E}_7 + Z_A &= 0 \\ c_3\dot{E}_3 + c_4\dot{E}_4 - c_5\dot{E}_5 + Z_B &= 0 \\ c_5\dot{E}_5 - c_6\dot{E}_6 - c_7\dot{E}_7 - c_8\dot{E}_8 + Z_C &= 0 \\ c_2\dot{E}_2 - c_3\dot{E}_3 + c_8\dot{E}_8 - c_9\dot{E}_9 + Z_D &= 0 \end{aligned} \qquad (10)$$

Where $C_j = c_j\dot{E}_j = c_j\dot{m}_j e_j$ for material streams and $C_j = c_j P_j$ for immaterial ones (P being the power). Assuming the Z_j are known, system (10) has 4 eqtns. (the cost balances, 1 for each component) and 9 unknowns (the c_i). A possible set of 5 auxiliary equations needed to make its coefficient matrix square is:

$$\begin{aligned} c_1 &= \xi \\ c_4 &= \psi \\ c_6 - c_7 &= 0 \\ c_6 - c_8 &= 0 \\ c_9 &= \varphi \end{aligned} \qquad (11)$$

If the system (10+11) has a $Det(M_{coeff})\neq 0$, the system admits of a solution.
The auxiliary equations are derived on the basis of a proper set of general rules on the *function* of a stream in the component's operation.

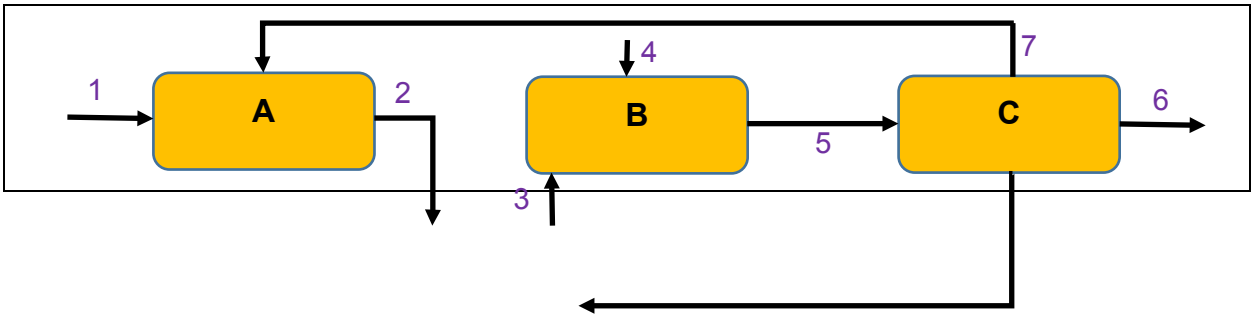

Figure 2 – Generic process scheme

3 – THE PROBLEM OF THE EXTERNALITIES

In Economics, *an **externality*** is *"a fact or an event that impacts a system or a procedure and that is not directly involved in the 'state of the universe' that causes that event"*.

In Engineering Economics it is customary to separate ***internal*** production costs, directly related to the machinery used, the physical parameters of the process and of the participating streams, from ***external*** costs, grouping under this denomination all cost items not depending directly from the installed process. Examples of external costs are land preparation, transportation, electrical connection to the grid, wages and salaries, start-up costs, financial flows, disposal of discharges, etc.

Engineers have borrowed the term "externality" from Economics, making it more precise and itemized. In a cost/benefit evaluation, there are thus three types of "externalities":

a) *Labour*, i.e., the cost of wages and salaries, usually expressed in €/yr or €/unit;
b) *Capital*, i.e. the financial costs necessary to operate the process: repayment of loans, amortization, differed cash flows, etc.
c) *Environmental costs*, neglected until the '70s and still lacking a universally accepted definition: in general, these are the monetary costs caused by actual or potential environmental harm caused by the process operation (most commonly, "emissions" and "discharges").

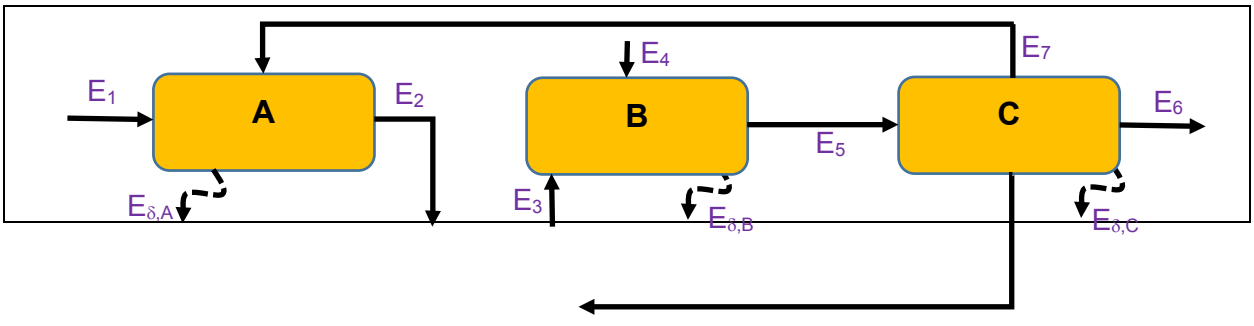
TE needs special additional procedures to handle these costs:

a) Capital costs are calculated as repayment rates on the TIC (Total Installed Costs) and accounted for in Z_K;
b) Scheduled maintenance, insurance, taxes, start-up, etc. costs can be added to Z_K and possibly adjusted to annual rates;
c) Labour costs can be included -with some caution- in Z_K as well;
d) Environmental costs can be accounted for in three different ways:
   - Z_{ENV} is set equal to the foreseen "pollution fees" set by national or international regulations;
   - Z_{ENV} is set equal to the calculated "remediation" costs directly and indirectly related to the process effluents;
   - Z_{ENV} is set equal to the avoidance costs, i.e. to the remedial actions to be taken within the process boundaries.

Depending on the mode of calculation, Z_{ENV} may vary of orders of magnitude; it is generally accepted that there are non-trivial problems in its calculation [Innes 2013]

4 – EXERGY COST, EXERGO-ECOLOGICAL COST, EXERGY FOOTPRINT

The following example is a simplified rendering mainly based on the works of Valero & coworkers [reff]. Notice though that already Rant [1955], Szargut [1965] and Gaggioli [1980] proposed the same -or a very similar- approach.



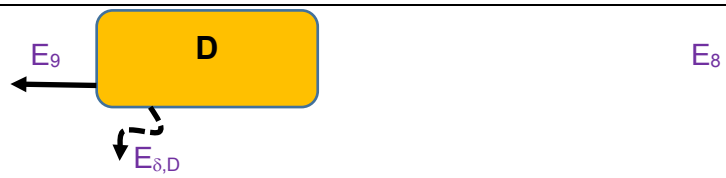


Figure 3 – Exergy flow diagram for the process of figure 3

Table 1 – Flow type identification ("production structure")				
	A	**B**	**C**	**D**
Fuel	**E_1+ E_7**	**E_3+ E_4**	**E_5**	**E_8- E_9**
Product	**E_2**	**E_5- E_3**	**E_6+ E_7+ E_8**	**E_3- E_2**

For the system of figure 3, a purely thermodynamic representation may be chosen: from the exergy flowchart an exergy budget can be derived ($\dot{E}_{in} = \dot{E}_{out} + \dot{E}_{\delta}$). In canonical form (see fig. 4), all terms in [W]:

$$\begin{aligned} \dot{E}_1 - \dot{E}_2 + \dot{E}_7 - \dot{E}_{\delta,A} &= 0 \\ \dot{E}_3 + \dot{E}_4 - \dot{E}_5 - \dot{E}_{\delta,B} &= 0 \\ \dot{E}_5 - \dot{E}_6 - \dot{E}_7 - \dot{E}_8 + \dot{E}_{\delta,C} &= 0 \\ \dot{E}_2 - \dot{E}_3 + \dot{E}_8 - \dot{E}_9 + \dot{E}_{\delta,D} &= 0 \end{aligned} \qquad (12)$$

(mass- and energy balances are assumed to have been successfully closed)

Now, what is the primary exergy required for the formation of the streams $\dot{E}_1, \dot{E}_2 \ldots$ etc.? Solution:

Call k_j the *exergy cost, defined as the amount of primary exergy required to generate the unit exergy* e_j: it is clear that while the *k* of streams 1 and 4 must be assigned somehow because they are entering the process boundary from the "outside" (the environment in this case), the k_j of all other streams depend on the cost balance of each component and on the process structure.

Identify the so-called "productive structure" of each component (Table 1), and consider that an exergy cost conservation rule applies:

$$\sum_j F_j = \sum_i P_i \qquad (13)$$

Applying (132) to the single component/process **B** of figure 3:

i- Case 1, design goal is to increase E_3 to E_5: $F_1=k_4E_4$; $P_1=k_5E_5-k_3E_3$
ii- Case 2, design goal is to mix E_3 & E_4 to produce E_5: $F_1= k_3E_3$; $F_2= k_4E_4$; $P_1= k_5E_5$

Cost balance: $$k_3\dot{E}_3 + k_4\dot{E}_4 - k_5\dot{E}_5 = 0 \qquad (14)$$

1 eqtn., 3 unknowns, need 2 auxiliary eqtns.:
Case 1: $k_4=CExC_4$; $k_3=k_5$
Case 2: $k_4=CExC_4$; $k_3=f(k_5,k_8,k_9)$

The procedure only makes sense if extended to the entire process:

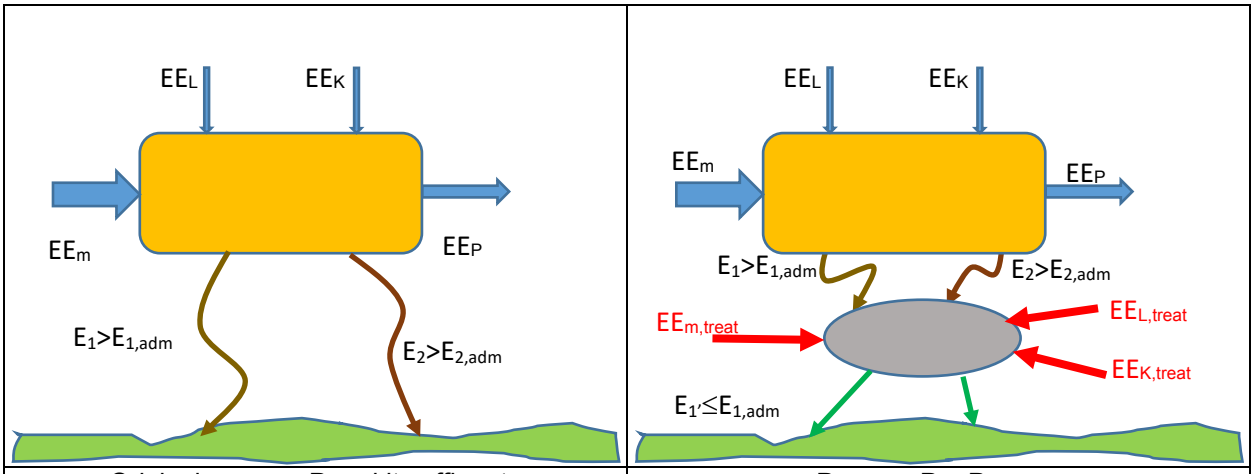
$$\begin{aligned} k_1\dot{E}_1 - k_2\dot{E}_2 + k_7\dot{E}_7 &= 0 \\ k_3\dot{E}_3 + k_4\dot{E}_4 - k_5\dot{E}_5 &= 0 \\ k_5\dot{E}_5 - k_6\dot{E}_6 - k_7\dot{E}_7 - -k_8\dot{E}_8 &= 0 \\ k_3\dot{E}_2 - k_3\dot{E}_3 + k_8\dot{E}_8 - k_9\dot{E}_9 &= 0 \end{aligned} \qquad (15)$$

Number of equations: 4 (1 for each component); number of unknowns: 9 (1 for each stream) $\Rightarrow$ Need 5 auxiliary eqtns: "exergy costing rules" that take into account the origin of the stream and its "function" in the economy of the production process.

Case 1: $k_1=0$; $k_4=CExC_4$; $k_3=k_5$; $k_2=k_3$; $k_8=k_9$
Case 2, $k_1=0$; $k_4=CExC_4$; $k_3=k_4$; $k_2=k_3$; $k_8=k_9$

The exergy cost method does not solve the problem of the externalities. Internalization procedures have been proposed by Szargut [1973], Frangopoulos [1997], Valero & Stanek [1998-2010]. The basic idea is mutuated from Szargut' work: link the mass flow rate of the emissions to a specific "cost of the pollution" using local or national monetary databases. As of today, the environmental externality problem has not found a universally accepted solution [Innes 2013].

The Extended Exergy formulation is an attempt to solve this problem by calculating the Labour and Capital costs in terms of the primary exergy budget of a society (a city, a region, a Country). Once these parameters (ee_L, primary exergy equivalent of 1 workhour) and ee_K (primary exergy equivalent of 1 unit of monetary circulation) are known, the environmental cost can be assessed by using a remediation approach: how much primary exergy (EE'_{fuels}, EE'_L, EE'_K) would be necessary to reduce the effluents' exergy to the limits prescribed by the locally applicable regulations. This solves the Externality problem, but the calculations depend on the availability and accuracy of an additional, very disaggregated, data set. The resulting cost of a commodity is in kJ_p/unit, kJ_p/kg or kJ_p/kJ, "kJ_p" being the primary exergy needed to generate that commodity.



Original process P and its effluents | Process P + $P_{treatment}$

Figure 4 – Treatment of the Environmental externality in EEA

This EEA cost has been called "Exergy Footprint", ExF, because it represents the burden on the Environment caused by the production. Here "burden" is literally meant to signify "the amount of primary resources subtracted from the overall Earth's budget".

5 – WHAT NEXT?

Exergy analysis generally accepted today as best analysis tool;

TE still not practiced by industry and Energy Agencies;

TE diagnostics still considered a niche topic;

Exergy cost and ExF can be valid "sustainability" indicators: ECOS community ought to push for this recognition;

Need to work with media, institutions, schools to clarify correlation between exergy consumption & degree of unsustainability;

Need to aggressively address water-nexus and material replacement & substitution issues.

6 – REFERENCES

The reference list comprises almost 300 items. Not all of them are quoted in the paper, but they represent a useful compendium of the exergy literature over the years. I will make available on a digital support upon request.

Abstract:

Thermoeconomics was born as a combination of the Second Law of Thermodynamics and Economics in search of the process of cost formation. Linking the physical origin of cost with irreversibility is the central paradigm of Thermoeconomics. Irreversibility is best identified in energy systems, so Thermoeconomics has concentrated on them without extending its scope to other industrial systems, such as chemical or metallurgical processes. As well as to cost accounting for the irreversibilities of all commodities from the cradle to the grave. The concept of cost is universal, so there is no reason not to extend applications to geological, biological, or purely economic systems. The accumulation of irreversibilities can quantify (in kWh) the destruction of the (natural) resources used to produce a commodity, from the cradle to the market and beyond its degradation as waste and its return to the cradle. It is the natural cost of any human activity - subject to its calculation assumptions. This requires an extension of thermodynamics, which we could reasonably call thermoeconomics. At the University of Zaragoza, we have developed the concepts of Thanatia and thermodynamic rarity to identify the loss of the Mineral Capital of the Planet. We also have identified the idea of waste as external irreversibility, the basis of Circular Thermoeconomics. We have also proposed the idea of a new and more precise function that could be used for the diagnosis of processes that we call Relative Free Energy. All these new concepts need further development, which we invite future researchers to develop. Today's economy is disconnected from physics; prices do not internalise the destruction of natural resources. Our vision is that thermoeconomics provides a bridge between the two, valuing nature in such a way as to replace what has been destroyed and regenerate what has been degraded. In effect, thermoeconomics becomes the economics of physics.

Keywords:

Exergy, Dead State, Thanatia, Pristinia, Circular Thermoeconomics, Relative Free Exergy

1. Preamble

Cost, in its physical expression, accounts for the loss of natural resources. In other words, cost accounts for the irreversibilities accumulated in the formation of any product or service. This is the central paradigm of thermoeconomics, which will be analysed in section 4..

The economy sees nature as a supplier of raw materials or solace. It is designed to value the exchange of services between humans. We do not pay nature for its resources, we only pay the extractor, not what is extracted. Nor do we pay for its regeneration or even its depreciation. To overcome this shortcoming, the economy includes as externalities those unavoidable repairs of the natural environment. Money has been created to measure exchanges between individuals or organisations, it is a human construct that nature does not understand, as it only follows the principle of action and reaction.

The second law of thermodynamics is conclusive: degradation is a physical and unavoidable process in any real activity, and this degradation can be measured with entropy generation. So why not use thermodynamics to account for the loss of the planet's natural resources?

As not all energy is usable, exergy is a better alternative analysis when dealing with natural systems. Exergy is not a conservative property and is partly destroyed in every real process. We call the destroyed exergy irreversibility, which, in turn, is related to the entropy generated in the process and thus its degradation (Gouy-Stodola Law): $I = T_0 S_g$.

While the cost accounts for the loss of natural resources, this loss could be identified with the accumulated irreversibility from cradle to commodity. To do this, we need only extend the concept of dead state to assess exergies. In other words, we have opened up thermodynamics to evaluate the planet's resources. The expectations are immense.

From the intersection of thermodynamics and economics comes thermoeconomics, which we consider the concept of cost to be central. Thermoeconomics, in our opinion, is not only about valuing the physical cost in

monetary units but the more objective cost can and should be measured in physical units, kWh. In this way, costs are left out of the vagaries and fluctuations of money. Strange as it may seem, it is linking economics with nature again, as the early physiocrats did, who considered nature as the source of all wealth because they believed that it regenerated itself. Interestingly, when the value of a currency is in doubt, the gold carat is used as a safe haven.

Thermoeconomics should draw on and recognise many concepts of economics, but it can also complement and illuminate others that conventional economics calls shadow costs, i.e. those that are not accountable or are subjectively valued as externalities.

On the other hand, many authors have built bridges between thermodynamics and economics, among them Nicholas Georgescu-Roegen with his book "The Law of Entropy and the Economic Process" [1] marked the foundation of ecological economics, although he called it bioeconomics. However, this term has been used more recently to relate biology to economics for better utilisation of biological resources and by extension natural resources. Another important author and father of biophysical economics is Charles Hall who developed the concept of energy return on energy investment (EROI) and described its Implications in the book "Energy and the Wealth of Nations: An Introduction to Biophysical Economics". [2]. Incidentally, he previously called it Thermoeconomics. Nor should we forget the contributions of Howard Odum [3] and collaborators on the concept of emergy, to say the least.

In this paper, we do not seek to make an extensive review of the use of the name Thermoeconomics and the work of numerous authors who linked thermodynamics, biology, ecology, physics, etc., with economics. We simply focus on a view of thermoeconomics from the concept of exergy and the immense room for future development by integrating the extraction of geological resources with economics. This new view of thermoeconomics allows us to assess the planet's mineral resources and can be a guide to evaluate the damage our civilisation is inflicting on it. It helps to clarify its costs and to act accordingly.

The purpose of this article is twofold: on the one hand, we describe, from the Zaragoza school of thermoeconomics, its conceptual advances and the needs for future development based on them. We have divided it into four parts: The first deals with Thanatia, exergy costs and rarity. The second is Pristinia, a planetary model for assessing the degradation of fertile soils. The third is the principles of a new Circular Thermoeconomics based on the thermodynamic concept of waste. And finally, an introduction to Relative Free Energy as a new thermodynamic function that depends on both the fluid and the machine at work. It opens a new perspective on the diagnosis of thermal systems.

2. Thanatia, a planetary reference state for exergy calculation

One of humanity's biggest problems in the coming decades, if not centuries, is the fast destruction of the planet's natural resources, especially non-renewable minerals. In fact, they are extracted, processed, used and, in the last stage, we disperse them into the earth's crust, the oceans or pollute the atmosphere and fresh waters. Therefore, it would be an immense contribution of thermoeconomics to planetary sustainability to construct a physical theory to evaluate the periodic cost of this destruction to at least minimise and manage it.

Ecological economists have resorted to the law of entropy as an uncountable and even immeasurable metaphor. On the contrary, we believe that thermoeconomics can expand its explanatory capacity and appraise this destruction based on the concepts of cost and irreversibility.

We note that the entropic generation, and with it, the irreversibility of the processes, depends on the reference state we choose. In conventional process exergy analysis, the choice of a reference state is linked to the type of problem we want to solve, i.e. we explicitly or implicitly delimit the relevant costs/irreversibilities. Consequently, if we want to evaluate the destruction of the planet's resources, we need to define a reference environment, also called *dead state*, that allows us to evaluate the costs of both resource depletion and waste generation at the planetary level.

The most important property of a reference environment, RE, is that it actually acts as an attractor of our system's intensive properties. Spontaneous evolution is found in the difference in temperatures, or pressures, or concentration, or composition, of a system with its environment. Therefore, it is necessary to define the temperature, pressure, composition and concentration of all chemical substances composing the reference state that can interact with the system. Their exergy loss in both quantity and quality will make it possible to assess the degradation of the planet's mineral resources.

Thanatia would represent a hypothetical end state of the current exponential trajectory of human-induced degradation: The Earth's crust, hydrosphere and atmosphere would have reached the maximum dissipation of all spent materials [4]. Although this scenario is hypothetical and indicates a final depletion, it is purely instrumental and devoid of social or economic connotations, which would obviously take place long before it is reached. This model was developed by Alicia Valero in her PhD thesis in 2008 [5], with the current geochemical

and geological information on the atmosphere, hydrosphere and crust described below.

The crepuscular or twilight atmosphere would be produced after all conventional fossil fuel reserves have been depleted, with an atmospheric injection of about 2,000 Gigatonnes of carbon. According to previously published simulations, the crepuscular atmosphere would have a carbon dioxide content of 683 ppm, an average surface temperature of 17℃ (maximum carbon dioxide-induced warming of 3.7℃ above pre-industrial temperatures), a pressure of 1.021 bar and a composition, by volume, of 78.8% N2, 20.92% O2, 0.93% Ar and 0.0015% trace gases. (Note that, even if the atmosphere were filled with anthropogenic CO_2, it would be "only" 0.07% [6]).

Saline water accounts for about 97.5% of the entire hydrosphere; the other 2.5% is kept as freshwater, almost all of it in the form of ice, mainly in Antarctica and Greenland. The rest is marginal, although it may seem immense to us, found in groundwater, lakes, rivers, soil and moisture in the atmosphere and biosphere. Only 0.3% of the total amount of freshwater is concentrated in lakes, reservoirs and river systems, yet this is the part of the hydrosphere that we all need to live and is most at risk of being polluted. In addition, due to climate change, a significant part of the glaciers and other ice in the cryosphere is melting. Therefore, we assume that the crepuscular hydrosphere would have the current chemical composition of the oceans at an average temperature of about 17℃. That is, it is implicitly assumed that all ice sheets will have molten and dissolved into saline waters.

According to the US Geological Survey [7] the mass of non-fuel industrial mineral resources worldwide is of the order of 10^{15} kg. Furthermore, the World Energy Council [8] estimates the amount of available conventional and unconventional fossil fuels to be about 10^{16} kg. This means that all concentrated mineral resources of fuel and non-fuel origin represent only 0.001% of the total mass of the Earth's upper continental crust (about 10^{22} kg, according to [9]. Therefore, without any significant error, we can state that the crepuscular continental crust can approximate the average mineralogical composition of the present-day Earth's upper crust [10].

The problem we faced was to identify what type and how many significant and distinct (in a thermodynamic sense) minerals are present in the upper continental crust. To do so, we proposed a model based on the mineralogical composition studied by Grigoriev [11], which would ensure consistency between species and chemical elements. The resulting crustal model comprises at least the 292 most common minerals.

In short, the current state of the biosphere is incredibly close to Thanatia. In our hypothetical reference state, the atmosphere would have reached the state predicted by long-term climate change models. Even if the amount of CO_2 doubled, there would be less carbon dioxide than argon, and this noble gas is considered a trace element. Even if all mineral deposits were increased tenfold in the Earth's crust, the crust would contain no more than 0.01% of them (less than the crustal mass estimation error). Thus, whereas if all commercially exploitable mineral deposits disappeared, the composition of the crust would be virtually the same. Accordingly, the dispersion and degradation of all already used materials mean nothing compared to the amount of common rocks (mostly silicates) that are mostly found in the crust.

As for the hydrosphere, the pollution of all freshwaters and the melting of the Arctic, Greenland and Antarctic ice would have a quantitatively more significant effect, but not more than 2.5% of the total waters of the blue planet. The hydrological cycle driven by solar radiation would still exist, but it must be accountable that water in the atmosphere is only 0.00093% of the total water while rivers account for 0.00015% of all the water on the planet [5]. Therefore, we hold that the hydrosphere of Thanatia would be composed almost entirely of standard salt water.

The present Earth is not in the equilibrium state, whose continental masses evolve slowly in geological times, but more rapidly and spontaneously in chemical terms towards Thanatia. This is by the logic of the second law and there is no catastrophism in it. How fast we get to Thanatia does depend on human beings. But before we get there, one can imagine, without too much difficulty, that economic and perhaps civilisational collapse will be reached sooner as a possible end of the Anthropocene period [12].

2.1. The exponential behaviour of mining demand and the exergetic "U".

Our society does not comprehend exponential behaviour. The extraction of minerals on the planet is growing at such a rate that by 2050 more than twice (or perhaps three times) as much will be consumed as is extracted today, and by 2050 more minerals will have been extracted than in the entire history of human civilisation. Agriculture is heavily dependent on phosphate mines. A mobile phone requires more than 35 chemical elements; a conventional or electric vehicle requires more than 50; and renewable energies, electrochemical storage, and green hydrogen production require huge quantities of rare metals. Therefore, it is necessary to review the message of entropy: its exponential character will help us to understand and assess those behaviours.

It is relevant to analyse the phenomenon of mixtures thermodynamically. As is well known, the irreversibility of a mixing process takes the form:

$$I = -R\,T_0 \sum_{i=1}^{n} x_i \ln x_i = -R\,T_0\,\ln 10 \sum_{i=1}^{n} x_i \log_{10} x_i,$$

where x_i are the mole fractions of the n substances to be mixed. And for the case of a mixture between two substances A and B

$$I = -R\,T_0\,[x_A \ln x_A + (1 - x_A)\ln(1 - x_A)] \quad \text{(kWh)} \qquad \text{and} \qquad \frac{dI}{dx_A} = -R\,T_0\left[\ln \frac{x_A}{1 - x_A}\right]$$

This equation is symmetric around x = 0.5, where it has a minimum, and is asymptotic with x_i = 0. This means that the irreversibility increases exponentially when wanting to decontaminate A from B, or B from A. The separation of the last contaminating particles requires an exponentially increasing exergy. We call this behaviour the exergetic “U”.

This exergetic ”U” is incredibly important from a practical point of view. Oregrades of many mineral deposits are usually at very low concentrations of the 10^{-1}, 10^{-2},...,10^{-n} type. These low ranges imply that when depleting a mine with an initial concentration of 10^{-1} and reducing it to one of 10^{-2}, the exergy required for the same amount of extraction is multiplied by 10, and so on by 100, 1000,..., whereas what remains are declining residual traces. For example, this trend is historically proven with gold, where its ore grades have been reduced by several orders of magnitude over the last 120 years [13]. In addition, as the actual processes are far from reversible, extraction and beneficiation of minerals require an amount of energy several orders of magnitude higher than the thermodynamic minimum.

It is not our technological ignorance that imposes such behaviour, but thermodynamics, which describes the ideal case of separation. In other words, even if today’s mining operations operate gigantic equipment, the physical decline of global oregrades will require more and more energy per tonne of ore extracted.

Unfortunately, metallurgical processes are also subject to the law of entropy. The energy costs for the reduction, purification and refining of metals are even much higher and always far from their thermodynamic minimum the more we want to purify them.

In other words, the law of entropy is evident in the earth’s crust. It is not an orderly reservoir of minerals, like in a ”department store”. This phenomenon had to be added to the Thanatia theory. Many techno-optimistic messages say that there are enough minerals to sustain global development based on new technologies because abundant minerals are in the earth’s crust. Apart from the fact that there are unexplored areas with some constraints, they forget that mineral concentrations are not homogeneous, but declining. The best oregrades are first exploited -”low-hanging fruits”- then decline until they become unviable. So energy, water, tailings movement, environmental, social and economic impacts will grow exponentially, perhaps in decades or centuries.

2.2. Exergy, extraction and replacement costs and thermodynamic rarity

The chemical reactivity of non-fossil minerals is very weak and undistinguishable among them. Therefore, their chemical exergy cannot be used to create a theory to value them. Their demand is linked to the physicochemical properties of the chemical elements or compounds obtained from them. To become useful, they are extracted, beneficiated, processed and refined. And all these operations require energy from chemical or electrical sources. So instead of valuing minerals by their exergy content, through, for instance, the well-known Reference Environment by Szargut [14], we have to value them by the amount of exergy needed to process them from cradle to market, i.e. by their exergy cost of extraction, which can be measured in kWh.

The value of a mine is linked to its mineral concentration or oregrade. This value decreases as the mine is exploited. So, the variation of their costs is also important because it is an indicator of mine depletion and, by extrapolation, of the loss of the planet’s mineral capital.

However, extracting cobalt is not the same as extracting aluminun. The latter is abundant in the earth’s crust, and the former is very scarce. So scarcity is also an indication of value. Whereas we relate the value of scarcity to the physical cost of forming it, we have a problem because the exergy cost depends on the limits of analysis we choose. The resources used to measure it have a cost that expresses the amount of resources used to produce them, and so on, down to the cradle. This accounting has to start from the earth’s crust, which can only be measured in exergetic terms once a reference state describing the dead state of the crust itself has been defined.

Note the linkage of the search for natural costs with the need to identify the terrestrial biosphere as the cradle or reservoir and the origin of all chemical elements. To value these costs, a theory is needed to define the ”physical effort” in extracting the minerals. Exergy is the key, but quantifying it requires a reference environment, which we call *Thanatia*, as previously explained. An economic theory of costing mineral scarcity without defining a physical reference environment would be highly controversial.

In addition, mineral deposits often contain a variety of metallic compounds that are extracted together (metal companions). In the beneficiation or downstream processes, allocating costs between products and waste is necessary. This brings us back to the exergy analysis.

Let us clarify concepts. We call *exergetic cost of extracting and processing a mineral* the amount of exergetic

resources needed to extract a mineral and process it until the market of a given commodity. Therefore, all commodities should have their cost measured in kWh, for example. Whereas, if standardised energy consumption data were available for all mines, it would be possible to classify and catalogue these costs. The lack of standardised data from mines around the world is disappointing.

However, these costs do not consider the scarcity of metals in the upper crust. Indeed, whereas a metal is very scarce, its composition in Thanatia will be of the 10^{-n} type, with a very high n. For example, n is 9 for cobalt, while aluminium is 3. In other words, aluminum is a million times more abundant in the crust than cobalt. Extracting 1 kg of cobalt from Thanatia with the same technology would require a million times more waste rock removal than 1 kg of aluminum. However, the price of cobalt is not a million times higher than that of aluminum, which shows that the market may be more or less sensitive to extraction costs but not at all to geological scarcity. Therefore, the loss of mineral capital from the earth must be sensitive to genuine geological scarcity to know the limits of depletion.

To properly assess geological scarcity, it is necessary to resort to the exergetic "U", which formulates an exponential behaviour for the consumption of exergy in the systematic replenishment from Thanatia to the mine. Continuing with the example of cobalt, its concentration in present-day mines is of the order of 10^{-3}, so the cost of replenishing that mine from Thanatia would require one million times the energy of current cobalt extraction. No current or future economy could bear such costs, which makes cobalt management a global problem.

Consequently, we define "replacement cost of an ore (at zero level)" as the exergy that would be necessary to replace, with current technology, the concentration of an ore found in its mine from its concentration in Thanatia [15]. In essence, this cost is an avoided cost or bonus that nature offers us for free (see Figure 1). An imaginary cost can be assessed by measuring the energy it would take to concentrate a chemical from a common rock to a concentration equal to that of the mine. Examples of these avoided costs are presented in Thanatia's books [4, 16].

When the replacement costs of metals that are not as scarce as cobalt or gold are assessed, the replacement cost of some metals is close to their extraction cost. This is the case for rare earths, which are more common than copper but very expensive to extract and separate. To solve this paradox, we proposed the concept of thermodynamic rarity [17], which is defined as the sum of the replacement cost plus the extraction cost. Indeed, some metals are scarce but feasible to obtain, such as cobalt, and others are abundant but difficult to separate, such as rare earths. And all the others are in the middle of this range.

However, the idea of replacement from Thanatia is extremely radical because long before reaching Thanatia, extraction would be stopped as technically unfeasible. Therefore, we scale the concept of rarity to an R_1, R_2, R_3 that would correspond to a replacement cost from a concentration 10, 100 or 1000 times higher than that of the metal in Thanatia. Logically, the rarity calculated from the concentration in Thanatia would be R_0.

Skinner [18] and others consider that there is a mineralogical barrier whereby the extraction of a metal does not make sense because of the immense impacts it would cause. Although this barrier can be variable, we consider it one-for-all-metals with a concentration ten times lower than the current minimum for gold extraction. That is, 0.2 gr/tn rock. This would imply removing and treating 500 tn of waste rock per kg of metal.

Moreover, some authors, [19,20] and notably UNEP [21] have focused their concerns based on "mass" scarcity. We believe it is better to approach the concept of energy scarcity, which we call thermodynamic rarity. This concept considers the actual ore grades and is based on physical phenomena. On the contrary, geological mass scarcity becomes meaningless when we look at the magnitude of the earth's crust. Whereas the crust contains 10^{22} tn of rocks and, for example, cobalt has a concentration of 10^{-9} /ton crust, what is several thousand tons of annual extraction versus 10^{11} tn total cobalt, most of it dispersed in the crust that can never be mined?. i.e. cobalt is not massively scarce, but exergetically scarce. It is rare.

The accompanying figure explains the exergetic path of a metal from Thanatia to the mine and then to the market. X represents the concentration of the metal. X=1 would be the pure metal. X_B is the concentration after the beneficiation process. X_m is the metal concentration in current mines; X_L is the concentration in landfills, while X_C is the concentration in the crust (in Thanatia). The mineralogical barrier is somewhere in the red zone for each metal.

Unfortunately, the lack of statistics on mining and metallurgical energy consumption means that many concepts described here have yet to be developed. We leave it to young researchers to assess the mineral capital losses of the planet, as well as to outline and evaluate the mining capital losses of countries or mines over time, as well as market failures, and why not, a different way to hold nature's value. The theory outlined here does not ignore the databases of Life Cycle Analyses but complements them. Their data are fundamental to assessing all the physical impacts of mining. Indeed, water consumption, waste rock movement, reagent use, greenhouse gas emissions, ecosystem destruction and other pollution and consumption are necessary to fully assess the current degradation of mineral resources and the need to conserve them for future generations.

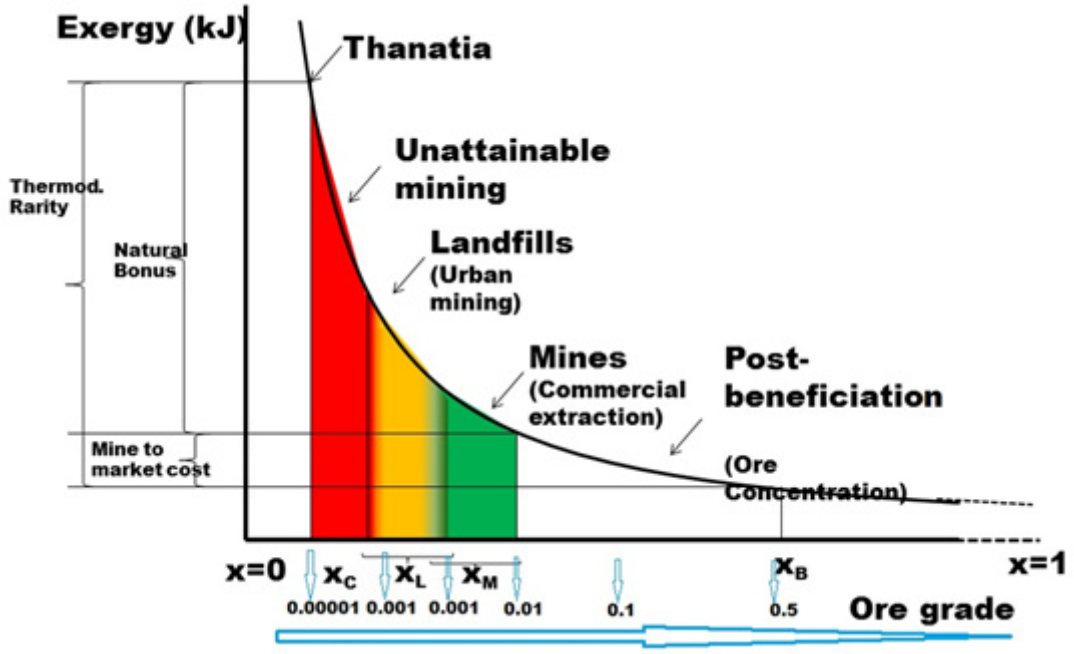

Figure 1: The concept of Thermodynamic Rarity

A final thought in this section: What has been described could perfectly well be called a Thermodynamics of Sustainability. According to the ecological economist J.M.Naredo [22] "Thermodynamics is the Economics of Physics". However, by introducing the concept of cost with all its meanings, in our opinion, the name Thermoeconomics fits better. Not only does it live up to the name it was given in the sixties, but thermodynamics extends its applications to the field of economics, not with metaphors but by quantifying the value of nature that our society ignores, perhaps due to a lack of method, or an excessive interest in forgetting it. It must also be said that by incorporating the word economy in the name, we are honouring all economic mathematics and all the concepts that have been developed until today, for example, input-output analysis, or Lagrange multipliers, to say the least.

3. Pristinia, is exergy appropriate for assessing soil fertility?

When we studied the use of exergy to assess the loss of the planet's mineral capital, we found that fertile soils were left out of our analysis. The problem of soil degradation is even faster than that of mineral depletion, Fertile soils are neither abiotic nor biotic but an amazing mixture. Could soil fertility be assessed through exergy? We have done so, but there is a lack of researchers in soil science and thermodynamicists who want to go into this area.

The sustainability of agroecosystems is an important issue considering that food demand will continue growing as the global population increases. A 49 per cent increase in agricultural production is expected to be required by 2050 [17]. In the last decades, crop production yield has been raised by means of employing intensive agriculture based on high inputs of inorganic fertilizers and pesticides, resulting in severe environmental impacts, erosion, and soil quality loss. In fact, the agricultural sector causes approximately 25 per cent of the global greenhouse gases [23]. Besides, degradation caused in soils threatens around 40 per cent of the land area. In Europe, it is estimated that there are 12 million hectares affected by erosion [24].

Compared with the 15 km de upper crust, fertile soils only occupy, on average 15 cm, of topsoil. They are a complex system composed of three main structures: physical, chemical and biological structures. First, their physical texture comprises a variable clay, sand and silt composition. Second, its chemical composition with an inorganic part of at least 19 nutrients and a rich and varied organic part is essential to improve the physical characteristics and as food for the soil biota. The 19 inorganic nutrients are divided into macronutrients like N, P, K, Mg, Ca and S, then micronutrients like Fe, Mn, Cu, Ni, Mo, B, Zn and Cl, and then, other beneficial elements essential for certain species or under specific conditions like Na, Si, Co, Se and Al. Third, their biological content consists of macro and microbiota with bacteria, fungi and viruses. Besides that, water, air and a specific range of temperatures are vital needs.

It is clear that the Thanatia model is not suitable for assessing soil fertility. Moreover, each area of the globe has different local textures and fertility also depends on climate. Therefore, it is necessary to establish a suitable

methodology to serve as a starting point for assessing soil degradation. We adopt a new strategy, proposing an optimum soil that allows us to analyse all real soils as deviations from an optimum towards Thanatia, Figure 2. Accordingly, we introduce a perfect fertile planetary crust, OPTSOIL [25], composed of nutrients, OPTNUT, and organic matter, OPTSOM, that is invariant and independent of different local textures, but not independent of its water content and aeration. We call this imaginary, copiously fertile crust Pristinia as opposed to Thanatia, a dead state referring to abiotic resources. Thus, any real agricultural soil will be in an intermediate state between Pristinia and Thanatia.

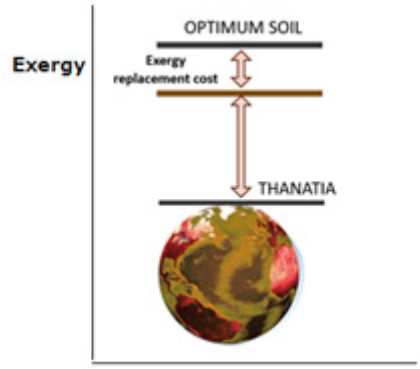

Figure 2: Degraded soils are between Thanatia and an optimal soil in nutrients, organic matter and biota.

The departure of each agricultural soil from the optimum soil can be associated with a sum of physical, chemical and biological causes that can be assessed exergetically. The idea is to evaluate a spectrum of actual degradations of agroecosystems, including those occurring in the soil, and to see the physical cost of their regeneration. For this purpose, the concept of exergy replacement cost is used. As shown in Figure 3, the exergy costs of mechanical processes, fertilisers, pesticides and plant protection products, water and diffuse emissions generated in the agricultural process are quantified. In addition, the substitution processes necessary to return the soil from the final state to the initial state (or optimum state) have been defined and evaluated. In this sense, losses due to erosion, nutrient amendments, organic matter, salinity and acidification are quantified through their exergy costs.

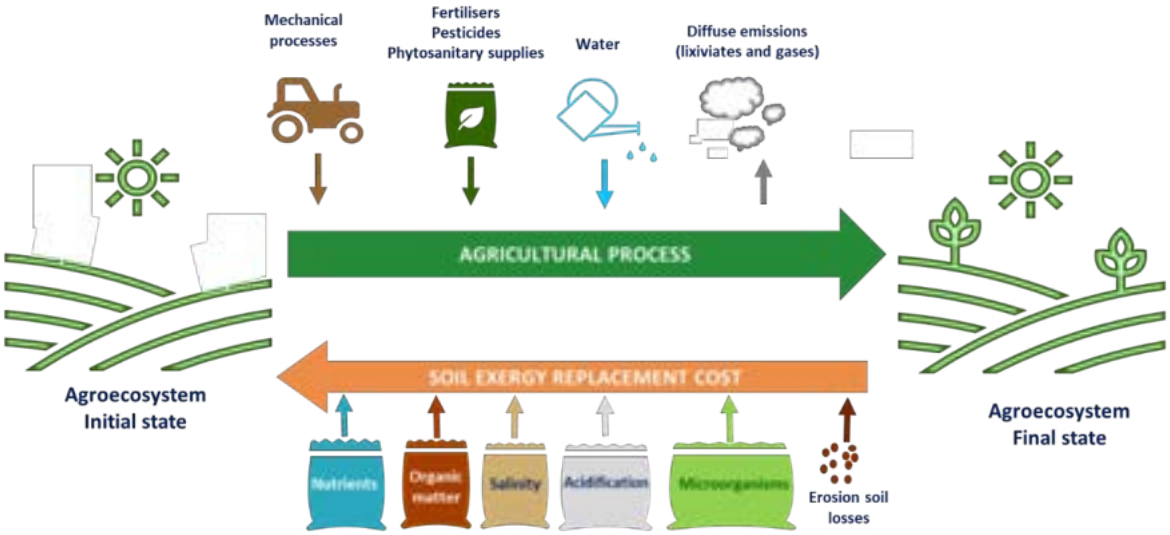

Figure 3: Graphical summary of the exergy-based methodology for the evaluation of agroecosystems.

These are the foundations of an incipient line of work. The next steps should focus on the importance of soil microbiota, OPTMIC, using Jorgensen's concept of eco-energy [26], also in evaluating organic matter in terms

of CO_2 sequestration achieved, which is controversial because of the difficulty of demonstrating its long-term stabilisation. Further development will aim to assess soil considering not only its agricultural production and carbon sequestration functions but all the different ecosystem services it provides, such as habitat provision, biodiversity, water regulation and purification, and environmental quality, among others.

Even with these drawbacks, our methodology has been awarded with a recognition of a reference document from the European Committee for Standardization (CEN).with the title: “Methodology to quantify the global agricultural crop footprint including soil impacts” [27].

This European CWA specifies a methodology for identifying, characterising, and implementing a single indicator to assess the quality and degradation of agricultural soils and the overall impact of the agriculture processes. The agriculture impacts are assessed through the associated mechanical, fertilisation and irrigation activities. Furthermore, soil impacts are evaluated accounting for soil erosion and parameters such as nutrients, texture, and organic matter. The developed methodology allows a simple but robust assessment of soil biogeochemical processes and the loss of fertility and degradation

4. Waste and Circular Thermoeconomics

The concept of waste has not been sufficiently analysed in thermoeconomics. By waste, we mean any unwanted material or energy flow, solid, liquid or gaseous, or a heat, noise or any radiative flow. From a thermodynamic point of view, it is simply the external irreversibility that generates entropy outside the system under analysis. Waste is harmful because it still has exergy and we have to consume it to get rid of it.

Every time we produce, we generate waste. And every product, sooner or later, also becomes waste. This consideration is important because it allows us to distinguish between waste from production processes and the end-of-use waste of material goods. The former corresponds to the remains of the resources used in the processes; let us call them primary waste because they are produced simultaneously as the products are obtained. The latter corresponds to the degradation or elimination of material goods of an inorganic nature or to the discarding of parts of organic substances. Municipalities usually collect this type of waste, and we call it here secondary waste. Their treatment, reduction and disposal require more energy, water and raw materials, which constitute the input for their processing, while new products and tertiary waste are produced, which constitute their output. Thermoeconomic analysis can therefore be applied to them.

Thermoeconomics enables to obtain a coherent and significant set of costs in a given energy structure [28]. Costing allocation essentially looks for the amount of resources needed to produce both intermediate and final products. The irreversibility cost formula [29] allows to calculate the (direct) exergy cost as the exergy content of a flow plus the sum of the irreversibilities generated to produce that flow.

$$B_i^* = B_i + \sum_j^n \phi_{ij}\, I_j \tag{1}$$

The coefficients ϕ_{ij} represent the part of the irreversibility of the equipment -j- that has been generated to produce one unit of the flow -i-. These coefficients depend exclusively on the definition of the production structure of the plant and the definition of the efficiency of each of its components. Therefore, this formula is the connection between thermodynamics and the second law (exergy and irreversibility) and economics (costs) derived from the definition of the productive purpose of the plant components.

As waste is an integral part of the production, just as one assesses the process of product cost formation, the process of waste cost formation must also be evaluated. Considering that waste has exergy, it is rational to think it could still be used for production. But there is a lack of technology and a surplus of ignorance of nature. Externalisation’ is the endorsement of the harms we cause outside the production system. At best, we pay money, in the form of taxes or fines, for society to mitigate them, or we send them to those countries that accept them in return for payment, thus creating an increasingly unequal world. Otherwise, society must adapt to environmental degradation, leaving the burden on future generations.

A responsible society must ”internalise” waste and its costs. For this, it is necessary to develop techniques that rigorously assess, for example, both the CO_2 emitted and the CO_2 avoided in each waste treatment process.

Many thermoeconomic analysts have focused on proposing costing assessment procedures for polygeneration plants [30, 31]. Some of these analyses assess the costs of waste remediation or abatement [32], which must then be added to the cost of the products. The result is clear: the cost of the products increases. And the more complex the waste, the higher the costs added to production and, thus the higher the prices of all goods. This is something that today’s society does not easily accept.

However, whereas waste has exergy, it can be used to improve the plant’s or plants’ efficiency in a cyclical production chain and thus reduce production costs, creating the positive effect of reducing resource consumption and waste emissions.

In many cases, this use of waste energy requires new industrial processes and/or new companies that make up the links in the industrial chains. It is clear that innovation can come from the thermoeconomic analysts themselves, leaving behind more or less irrelevant procedural discussions on achieving a better cost allocation.

The process of waste cost formation must be a priority objective in this new Circular Thermoeconomics. Waste costs must be rigorously assessed because they are the compass for decisions to improve production processes, both within production plants and/or in increasingly complex industrial chains. Whereas we internalise waste costs, eq. (1) will also be accountable for these wastes as (external) irreversibilities. The coefficients ϕ_{ij} also contain information on the internalisation of waste. Therefore, if external irreversibilities (wastes) are recovered, the production costs are reduced. The keyword recycling must be intrinsically related to efficiency and cost. It can be used interchangeably by thermoeconomics, circular economy and industrial symbiosis.

Although it may seem to direct ideas to one's advantage, using exergy makes it possible to quantify any material or energy waste in kWh. This makes it possible to create a general theory based on exergy. Furthermore, exergy can be evaluated with any other energy indicator, e.g. in kg or natural gas equivalent. This allows us to convert it into CO_2 equivalent emitted in the production or, alternatively, to evaluate the CO_2 equivalent savings between two production structures. This is important because it gives rigour to the huge simplifications of GHG emission calculations that are made today in increasingly complex systems.

When applying thermoeconomics to the exergy recovery process of waste, a pinch point of recoverability always appears where total recycling is unattainable because a further increase in recycling does not correspond to the same efficiency increase. The "pinch points" of waste must be identified and systematically diminished. Reality imposes the fact that it is not possible to recycle everything. Hence we should not speak of Circular Economy but of Spiral Economy [33]. The latter makes it possible to assess the degree of spiralling of a material cycle, understood as the percentage of exergy loss with respect to the exergy brought into play in the whole cycle. In this way, spirality can be related to the concept of pinch point, as the economically viable exergy percentage of recovery of a residual flow, measured in the potential for narrowing of its intensive properties of the type ΔT, ΔP, etc.

It is remarkable to see that the search for better energy efficiency is often linked to reduced material efficiency. Nonetheless, this fact has been systematically forgotten. For example, cars, which are nothing more than mobility production plants, consume less and less fuel per kilometre, but we forget that the material complexity of their digitisation has radically reduced their material efficiency. A vehicle from 50 years ago contained only steel, aluminium, copper, rubber, glass, wood and some plastic. Today's vehicles contain more than 55 chemical elements, with a myriad of plastics, alloys and micro-components full of critical raw materials. Their non-recyclability is notorious, and they are not designed to recover their spare parts. Circular thermoeconomics can provide striking answers to this problem because whereas the exergy costs of extraction and replacement of the materials are involved in the analysis, it is possible to assess the relationship between exergy savings and the exergy invested in obtaining them, ExROI. The results obtained yield important conclusions on how our society is squandering the earth's mineral capital in favour of a pseudo-energy efficiency of all processes. This is a strong reason to recycle materials, especially the most critical ones.

The message we can give is that goods are cheap because we internalise the price of products, neither the cost of the scarcity of natural resources nor the impact our waste has on planetary habitability.

Nature closes its material cycles, because the waste generated by one living becomes the resources of others, making the biosphere-geosphere complex a sustainable system driven by solar energy and the planet's internal heat. Nature has its rhythms and the closing of these cycles can even take geological time, as is the case with fossil resources. On the contrary, our society is in a hurry and lets its waste go underground (landfills), turn into gases (incineration) or be diluted in the atmosphere and the hydrosphere.

This is no small task, the production of waste and the depredation of natural resources are closely related to the nine planetary boundaries that Rockstrom et al, [34] point out: climate change, ocean acidification, stratospheric ozone, nitrogen and phosphorous cycle, global freshwater use, deforestation and topsoil degradation, biodiversity loss, chemical pollution, and atmospheric aerosol loading. To these must be added, among others, the more recently reported phenomena such as oceanic pollution by microplastics or the massive extraction of critical raw materials to sustain new digital and renewable technologies.

Against this scenario, thermoeconomicists cannot close their eyes to the most efficient use of waste. Beyond the processes of remediation or abatement of waste, it is necessary to think about the use and reuse of industrial and individual waste. This is the origin of Circular Thermoeconomics. We must learn from nature. The waste of one production plant should be the resource of another. We must design to make the use of waste materially and energetically viable. Cyclical industrial chains must be created to give new life to waste. The concepts of industrial symbiosis and urban-industrial symbiosis must be extended to the whole productive system, which will affect a social change of attitudes.

An introduction to Circular Thermoeconomics can be found in [35]. We invite new researchers to develop both

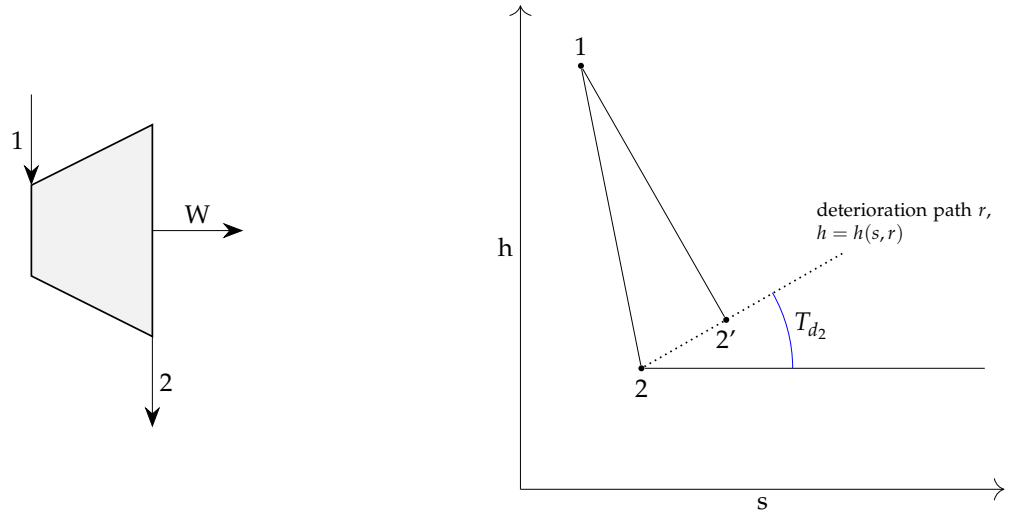

Figure 4: The deterioration path of a turbine.

this theory and its multiple applications that have been proposed with these reflections.

5. Exergy or Relative Free Energy?

There is a consensus among practitioners that exergy is the thermodynamic property that best distributes production costs among various streams, which then helps to establish the economic costs of the streams that interact in any energy system. However, the exergy calculation has the shortcoming that it depends on the reference environment applied, which in turn is an arbitrary selection of the user and not a physical behaviour of the system under analysis. If this is the case, the concept of exergy efficiency, although more precise than the first law efficiency, still depends on the chosen reference environment.

This problem is even worst in thermoeconomic diagnoses of very complex plants using exergy costs, since the chains of causation may induce wrong malfunctions and dysfunctions. There might be a consensus regarding which is the most suitable. However, convergent opinions are not mathematical proofs. Is it possible to find a better function to get rid of this problem? The answer will need future research, perhaps the “relative free energy function” has the ”way” of solving this problem. This section explains why is it.

Any machine that uses a working fluid is designed to change its intensive properties, such as its pressure, temperature, chemical potential or electromagnetic potential, making its energy transfer to another part of the machine.

Suppose now that the working fluid malfunctions due to intrinsic reasons of the machine. If the fuel quality, f, does not change, it will be necessary to increase the amount of fuel to get the same product, P. Then, this excess fuel becomes dissipated in the form of heat.

The enthalpy and entropy balances of the working fluid process, under the conditions (h_1, s_1) and P constant, will be:

$$(h_1 - h_2)\, dm = m\, dh_2$$
$$(s_2 - s_1)\, dm + m\, ds_2 = dS_g$$

As the deterioration process of the machine is compensated by higher fuel consumption, both dm and the entropy generated are positive. So is the heat dissipated, $m\, dh_2$, and the entropy increase of the fluid, $m\, ds_2$. If one defines the deterioration temperature of flow in state #2 as the quotient:

$$T_{d_2} \equiv dh_2 / ds_2$$

the result of the combined balances is as follows:

$$\left(\frac{dm}{dS_g}\right)_r = \frac{T_{d_2}}{(h_1 - h_2) - T_{d_2}\,(s_1 - s_2)}\,, \tag{2}$$

where r is the deterioration path in the (h, s) plane of the outflow, as show in Figure 4 for the case of a turbine.

Equation (2) states that any deterioration process in an energy component has an associated T_d in the exit stream of supplying fuel. This parameter possesses temperature dimensions even if it is not a gauging temperature; it can be calculated by measuring the quotient dh_2/ds_2 experienced by the output stream of the component’s fuel.

This equation is the mathematical expression of the relationship between the additional consumption of the resource needed to compensate for an internal degradation of the machine when the output of the machine is kept constant.

Equation (2) and the function ℓ, whose variation is defined as:

$$\ell_1 - \ell_2 \equiv h_1 - h_2 - T_d(s_1 - s_2)$$

where presented in [36], and was called the *relative free energy*, RFE. It is surprisingly similar to the exergy variation of the working fluid, which may explain the attachment and intuition of process analysts to exergy. However, RFE is mathematics while exergy comes from consensus.

However, the deterioration temperature no longer depends on the chosen reference temperature for exergy calculations. Although T_d has temperature dimensions, is not a gauging temperature; it can be calculated by measuring the ratio dh_2/ds_2 experienced by the machine´s fuel at its output.

For a given deterioration cause r of a machine, a geometric path in the (h, s) plane of the possible exit flow states can be identified. Let $h_2 = h_2(s_2, r)$ be the function describing this outflow deterioration path, and it can be considered as the mathematical description of the effects on the exiting flow caused by such deterioration.

As it is shown in Figure 5 the intersection of the tangent line of the deterioration path r with the h- axis is and its slope is T_d:

$$\ell = h - T_d\, s \tag{3}$$

It means ℓ is a function of T_d, with the caveat that both l, h and s refer to the same zero state.

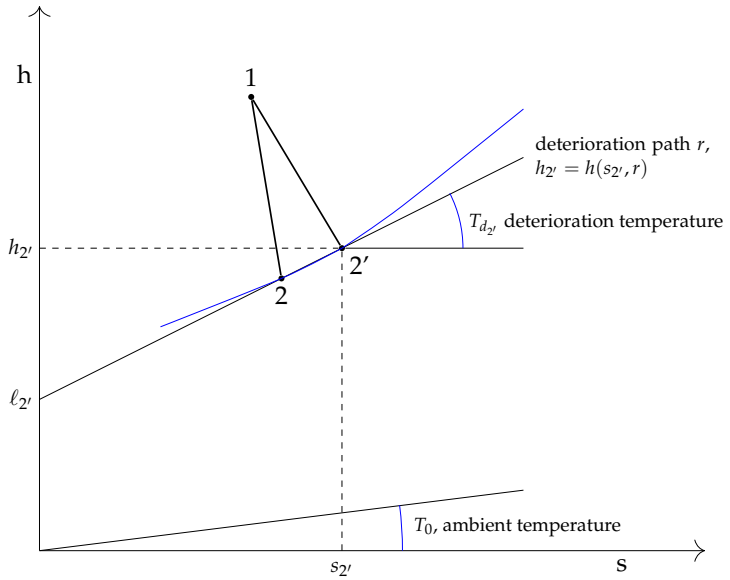

Figure 5: Geometric representation of relative free energy and deterioration temperature.

In reference [37] is shown that (3) is the Legendre transform of the deterioration r.

According to the definition of relative free energy (3), the expression (2) could be written as:

$$\left(\frac{dm}{dS_g}\right)_r = \frac{T_d}{\ell_1 - \ell_2} \tag{4}$$

Note that this equation is always positive, under the specified conditions. Moreover, since $T_d > 0$, then $\ell_1 > \ell_2$, i.e., the working flow has lost part of its relative free energy. In fact, for the same deterioration, $dS_g = const$, the higher the T_d, the greater the amount of resource required to yield the same product. This trade-off is not linear because whereas the numerator increases, the denominator also decreases. On the contrary, when T_d tends to T_0, the impact of this compensation will decrease. Only in the case where $T_d = T_0$, the decrease of relative free energy will coincide with the exergy decrease.

As the environment is an attractor, the T_d of the components of an installation will decrease until it reaches T_0, just as the relative free energy will tend to exergy.

In order to evaluate T_d, it is necessary to know the cause(s) of machine deterioration and its behaviour, which is additional information to be incorporated into the plant diagnosis. In other words, the cost of a malfunction is directly related to the physical behaviour of the machine.

The relative free energy function, ℓ, is the amount of specific energy of the exiting stream of a fuel, which is not affected by the deterioration of the machine. In fact, when the exit flow changes its state owing to the deterioration, h and s, vary by following the path $h_r = h_r(s_r)$. Consequently, the following expression is obtained:

$$d\ell_2 = dh_r - \left(\frac{dh}{ds}\right)_r ds_r = 0 \qquad \text{or} \qquad \ell_2 = \text{const.} \tag{5}$$

Besides that, a new definition of efficiency (or its inverse specific consumption), For example, in a turbine it is:

$$k_L = \frac{F_L}{P_L} = \frac{\mathcal{L}_1 - \mathcal{L}_2}{W} = \frac{H_1 - H_2 - T_d\,(S_1 - S_2)}{W} \tag{6}$$

Where $\mathcal{L}$ is the corresponding extensive property of ℓ, i.e. $\mathcal{L} = m\ell$. This "relative" efficiency, k_L, has an astounding property that exergy lacks.

When a malfunction in the turbine follows a trajectory r at W constant, it follows:

$$\ell_1\, dm = \ell_2\, dm + W\, dk_L \tag{7}$$

because $\ell_1 - \ell_2$ is constant along trajectory r. Therefore:

$$\frac{dk_L}{k_L} = \frac{dm}{m} \tag{8}$$

in other words, any additional percentage of malfunction following a trajectory r at W constant result in an additional percentage of the mass of fuel entering the turbine. This property is very promising for simplifying the mathematical apparatus of plant diagnosis. Note instead that exergy does not fulfil this property since:

$$ex_1\, dm = ex_2\, dm + m\, dex_2 + W\, dk \qquad dex_2 \neq 0$$

which may induce false dysfunctions. Furthermore, the definition of k_L incorporates the information of the physical behaviour of the machine through T_d, whereas the unit exergy consumption is a black box to what happens inside the machine.

A noteworthy observation is that companies usually account for the resource consumption per unit of output of their installation. This accounting at the facility level is the one we propose in this section at the component machine level. Therefore, whereas we have for each cause of deterioration, r, the derivative $(\partial m_{local}/\partial S_g)$ and whereas we could evaluate how the amount of local equipment resources is related to the facility resources (of the same quality), i.e., $(\partial m_{plant}/\partial m_{local})$, we could obtain a new theory of energy system diagnostics. In theory our proposal would obtain the derivative: $(\partial m_{plant}/\partial S_g)$,that is $(\partial F_T/\partial S_g)$, where F_T are the plant resources. Note that what says "plant" here could also mean any disaggregated part of the overall plant structure, without needing to resort to the reference environment. This is what companies need for good energy consumption management, i.e. the genuine costs of the deterioration of each and every component of their installation.

Perhaps, the described procedure is much simpler than assessing the diagnosis using exergy costs:

$$\left(\frac{\partial Ex_{plant}}{\partial Ex_{local}}\right)_r$$

Regrettably, actual installations may have several simultaneous causes of degradation and their impact on overall efficiency would not necessarily be the sum of each cause separately.

Thanks to the Legendre transform we have shown that the RFE and the deterioration temperature are as real as the actual path of degradation of the working fluid in a machine. They have a physical basis and are not merely theoretical inventions. Unlike other thermodynamic functions that only depend on the equilibrium states of the system, the pair (RFE, T_d) only exists whereas the machine exists. It is like transferring the deterioration message from the machine to thermodynamics,

Incredibly, it was first presented in 1992 at the ECOS conference [36], with the earliest work by Alefeld at the University of Munich [38] that went almost unnoticed, perhaps because of the excessive cult of exergy. In spite of this, the use of this function in diagnostic applications and cost assessment of malfunctions in industrial energy systems is still to be developed. We leave it to future thermoeconomics practitioners to develop such ideas.

6. Conclusions

Science to be positive must be quantifiable and predictive. In general, the use of the messages of the second law of thermodynamics in the social sciences and in economics is more philosophical than operational. In

contrast, by redefining cost as a sum of irreversibilities and setting it up from the cradle to the market, we are connecting Thanatia with economics. That is Physics with Economics in a quantifiable and predictive way.

The first ideas of thermoeconomics and its very name are due to Myron Tribus, Robert Evans and Yehia El-Sayed in the sixties of the last century [39, 40]. It was created before Georgescu-Roegen published his book *The law of entropy and the economic process* [1] which claimed that economics had forgotten the concept of irreversibility. Unfortunately, thermoeconomics focused mainly on analysing industrial thermal systems, forgetting the message of its own name.

We believe that beyond converting irreversibility into money and weighing it against investments in production equipment, it is necessary to measure economic activities in terms of irreversibility in order to give value to the services provided by the planet.

The concept of a planetary dead state, Thanatia, allows the loss of mineral capital to be assessed in terms of quality and quantity. What is rare is valuable and must be conserved. We can move from the yes/no dichotomy to the physical quantification of nature's losses. And thus weigh the nature we lose against what we gain by engaging in any activity. And in doing so we will give value to the regeneration, repair, replacement and restoration of materials that are key to sustaining humanity for many generations to come. The supply of planetary wealth is not of an economic origin of the demand/supply equilibrium type, but of planetary limits. And in the face of this phenomenon, agreements between people or between countries are not valid, but rather in the assumption of the irreversibility that will condition the future of humanity itself.

Available mineral phosphates are limited to sustain the supply of a few generations. Electric mobility is limited by the enormous amount of chemical elements, more than 50, needed for high-tech vehicles. The digital economy is based on the profusion of non-recyclable microchips and printed circuit boards, extremely short-lived and full of rare metals. The same is true for renewable energy. The energy transition must be accountable for its material impact.

Similarly, current agricultural practices are degrading fertile soils which are the scarcest natural resource of all. Again, it is the second law that allows us to objectively evaluate all deviations from a model copiously fertile crust, called Pristina, as opposed to Thanatia. With the exergy methodology, we have a single indicator to value all the factors that intervene and form the soil. The recognition of this methodology awarded as a reference document from the European Committee for Standardization opens the door to refining and developing its applications.

Another major global problem is the production of waste, not only solid but also liquid, gaseous, noise, heat and radiation of all kinds. They are produced at the same time as we manufacture goods and consume them. They disturb and above all affect the planet in the form of climate change, pollution and the degradation of ecosystems. Whereas they do this damage, it is because they still have exergy. Harnessing them minimises remediation and abatement costs. Society must learn to internalise waste in order to give it new life and avoid its effects. To this end, industrial symbiosis must be generalised, in which the waste or by-product of one company is the resource of another, trying to close cycles (spirals) of all materials. This activity implies the promotion of a new industrial sector that will need to assess (and optimise) all the losses and savings that occur. The circular thermoeconomics outlined here will be an important branch of the future of second law analysis.

Last but not least, the relative free energy and its conjugate, the deterioration temperature, can take a step beyond the use of exergy in the diagnosis of energy systems, and above all to explain why the diagnosis should not depend on the analyst's choice of reference state. Throughout history, the emergence of new basic functions has been a far-reaching scientific event that has opened up new avenues and applications of thermodynamics. As such, it deserves to be welcomed by the thermoeconomic community.

In short, we at the Zaragoza School of Thermoeconomics believe that the "second law analysis" should be expanded to apply it to important problems facing our civilisation, such as the conservation of the planet's energy, water and material resources; the diagnosis and intelligent management of fertile soils to feed current and future living beings; and the minimisation of waste by closing material supply chains, promoting new industrial sectors for waste recovery, still in its infancy. The Thermodynamics of Sustainability of the future must include Thermoeconomics and all theoretical developments that help with these problems are welcome.

From thermoeconomics to environomics and beyond

Daniel Favrat[a]

[a] EPFL, Ecole Polytechnique Fédérale de Lausanne,(Energy center) Lausanne, Switzerland, daniel.favrat@epfl.ch

Abstract:
Modern energy systems are more and more based on integrated technologies in a world evolving towards increasing concerns not only for economics but also for environmental issues with a growing focus on resources and emissions. In parallel, information technologies including advanced simulation and optimization algorithms develop at a rapid pace. Thermoeconomics based on either the First Law or exergy, together with cost factors distributed through its equipment, also evolved during the last 30 years. However modern muti-objective evolutionary optimization techniques, extending the capacity to tackle optimization considering a growing number of parameters including the internalization of the costs of emissions of whole systems has also emerged. The latter is called environomics. So far, the supply of energy services was essentially dominated by fossil-based resources with a high focus on operational costs. The new trends towards renewable energies requires a growing need to consider the embedded exergies since renewable energy, like solar energy, is economically free and operational costs are inherently low. While economic factors can vary over a broad spectrum throughout the years of operation, the embedded exergies are more stable values, particularly because the systems are built in a known economic and energetic environment. A new class of methods is only emerging to deal with more complete exergy approaches to formulate more holistic exergy life cycle analyses. Those should provide a lower bound of the expected exergy payback over the lifetime of the systems to be compared with thermoeconomic or environomic optima. It is still a huge challenge ahead to provide practical tools to do it.

Keywords:
Thermodynamics; Exergy; Environomics; Thermoeconomics; Second Law.

1. Introduction

The world is facing major challenges regarding environmental threats and resource constraints at a time where geopolitics tends to have a growing influence and globalization is questioned. In this context there is a growing need for efficient integrated systems. Apart from technical progress, engineering methods have to constantly evolve to account for energy efficiency, economic viability and environmental constraints, taking in particular advantage of progress made in optimisation schemes and data processing.

During the early days of thermoeconomics, with pioneers like Tribus and El-Sayed referred to in Frangopoulos [1], as well as Tstsaronis [2], Valero [3], and von Spakovsky [4], a strong emphasis was put on thermodynamic formulations that would favour the decentralisation of the optimisation of each component due to the lack of available adequate algorithms. In terms of Second Law of thermodynamics each component of a system has to “pay” for its inefficiencies, that is for the entropy it created, and the cost associated with its dumping to the environment. The earlier energy systems considered were primarily fossil based and for systems in steady-state conditions.

The broad name of thermoeconomics includes both energy analyses and optimisation based on the First Law with costs minimisations, while a narrower approach considers only exergy consideration with cost minimization.

Quickly the need for developing methods accounting for the increasing complexity of investment and operation of real energy systems arose to deal in particular with:

- Environmental emissions both local and global (environomics).
- Time dependent operating conditions.
- Reliability constraints implying both active and passive redundancy for example.
- Global resource considerations including considerations of the embedded exergy of components.

2. Competing methods

While the Second Law fundamentals with the exergy theory were rarely questioned two different methodology paths were pursued.

- The mathematical approach with the continuous development of Second Law based thermoeconomics [5] in parallel to First Law thermoeconomics, and
- The graphical approach using a simplified second Law approach, called pinch technology, with an emphasis on minimizing the costs linked to the heat transfer exergy losses. The latter is a clever graphical application of the Second Law to optimize the energy integration of industrial processes [6-10].

Ultimately all benefitted from the considerable progress made by the optimisation algorithms with, in particular, evolutionary algorithms able to reliably tackle problems with non-linear and even discontinuous solution spaces. With such computational capabilities the need for decomposition of the problems to allow easier optimisation faded somewhat. Methods based on non-linear mono- and later multi-objective optimisation emerged allowing to deal with both design and operation factors, even for expected changes in operation over the lifetime of the energy systems [11,13].

2.1 Second Law and environmental aspects

One problem in trying to include environmental pollutants with the Second Law approaches of exergy-based thermoeconomics is that the detrimental effects of local pollution are generally not linked to the entropy of the substances in the environment. Therefore, the need to express the cost of emissions with complementary factors was identified and Frangopoulos coined the term environomics [1] for methods dealing with the internalization of the specific individual costs of pollutants. This allowed to do sensitive analyses on specific pollutants and the economic penalties when having to reduce the emissions. Individual pollutant costs could even be modelled with functions accounting for the distance between the pollutant source and the density of the population directly affected [14] as illustrated in [15-16]. The impact of pollutant could also be accounted for when dealing with downstream pollutant capture as shown for the optimisation of combined cycle plants with or without considering pollutant costs by Pelster et al. [17]. The internalisation of pollutant costs is important in the context of the introduction of taxes like the CO_2 tax. It can also be of great help in assessing new measures for decision makers or in studying the potential financial risk differences between competing designs. Pareto frontier representations of the solutions developed with environomic bi-objective optimisation is a powerful tool as shown in Figure 1. This illustrates the trade-offs related to the design of District heat system [11] and their effects, among others on the temperature of heat distribution. These results nicely complement the mono-objective optimisation initially made by Curti [15-16].

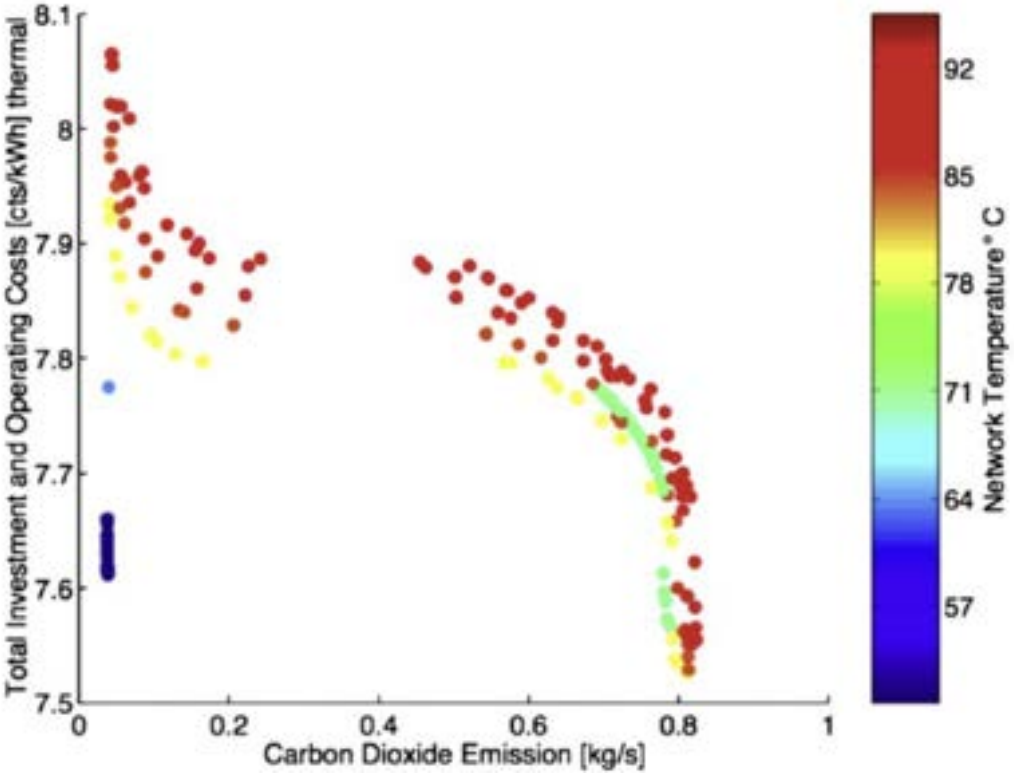

Figure 1. Solutions for a District Heating network with both centralized and decentralized heat pumps. Each dot represents a configuration of components both centralized and decentralized in individual buildings [11].

It particularly highlights the switch that can be observed in District heating networks from central plant with relatively high distribution temperatures to networks operated at “ground temperature levels” with decentralized heat pumps in each building (blue dots on the left). These low temperature networks, sometimes called District Energy Networks of fifth generation or anergy networks, not only increase the synergy between providers and users of energy services but also allow direct air-conditioning services with simple heat exchangers. Operating networks at low temperatures limits the need for thermal insulation and opens the opportunity to capture all kind of waste heat. It further favours some seasonal storage with, for example, fields of shallow geothermal wells. District heating and cooling networks (DHC) are expected to grow fast in the light of the enhanced decarbonization policies.

In Figure 1 the most cost-effective solutions but with the highest emissions are shown on the right and correspond to a central plant with a heat pump for 50%, a cogeneration gas turbine for 20% and ancillary gas boilers for 30% of the heat demand. In this particular case, the peak heating power considered was 63 MW, the specific electricity price was 0.13 $/kWh for a natural gas cost of 0.05 $/kWh. A NOx pollution cost of 13$/kg and a CO_2 cost of 0.03 $/kg [11] was also considered. It is easy to see on the graph that the recent increase of energy prices, that is likely to be maintained in the search for regional independence in energy supply, will further improve the importance of the electric heat pump only solutions.

2.2 Thermoeconomic analysis of time-dependent processes

Obviously, energy systems must be designed for a proper adjustment over time between the needs of the users and the constraints of the suppliers. Hence the need for multi-period/multi time optimization as described in [12,18]. This can be approached with sequential optimization inside the more global optimization. Employing typical operating time periods, like typical days throughout the season, is often the way to reduce the computational efforts. The introduction of energy storage components often generates alternatives to the strategies based on the power modulation of oversized supplying technologies that need to be compared with. Seasonal storage needs often to consider synthetic fuels easy to store over long periods of time. This is part of the actual discussion occurring around energy and cost intensive synthetic fuels compared to the investments in an overcapacity of power production like was favored previously by France with nuclear or Germany with coal plants.

In process engineering a hybrid approach between pinch technology and evolutionary algorithm optimization was proposed by [19] for batch processes including graphical representation of the solutions with multi-storage tanks.

Needless to say that these brief comments are by no means exhaustive and further methodological improvements of these broader thermoeconomic approaches accounting for time variations are needed.

2.3 Thermoeconomic optimisation accounting for reliability

It is imperative for many energy systems to provide reliability guaranties and liabilities could be quite costly during operation. Therefore, including elements like active or passive redundancies of components might significantly modify the thermoeconomic or environomic optimisation of designs. Examples applied to waste incineration plants are shown in [12,13], where increasing the number of furnaces that is less economic at first sight can finally be among the most adapted options.

For all the above requirements a first phase based on exergy considerations is required to build the super-structures (or super-configuration) on which the optimisation problems are based.

3. Influence of the current energy system trends on the thermoeconomic methods

With increasing concerns about greenhouse gases and following the Paris international agreement, the trends are going for an increasing pressure to improve the efficiency of systems and rely more and more on renewables. While the present thermoeconomic or environomic methods based on exergy are already adequate for efficiency, new considerations regarding resources and the increasing ratio between investment versus operational cost with renewables modify the relative importance of the different factors.

If, as mentioned above, the polluting emissions are not directly linked to entropy, the material resources are linked to the concentration of the elements in the Earth crust and therefore to entropy. So, at a time where humans increase the use of most parts of the Mendeleev chart of elements, all the present efforts to account for this in exergy approaches should be pursued. The Second Law approaches for processes, from the early work of [20] to the deeper considerations of materials in [21] represent valuable background approaches that are well initiated. The recent update of [22] adequately complement the methodological aspects on how to deal with resources with the Second Law in mind. Those approaches provide a methodological answer to the crucial problem of the scarcity of materials, like the Rare Earth Elements, in the development of renewable energies and the efficiency improvements links to the growing electrification of our societies. This cannot be

dissociated from the recycling processes or even the material substitutions that follow the fast growth of specific storage components like those used in the electric batteries, often with a significant time delay.

When it comes to graphical approaches the earlier work on extended composites in [8] provides some examples on how embedded exergies of components could be accounted for. Figure 2 illustrates the extended composites related to the implementation of an industrial heat pump in a drying process together with a gas engine (410 kW) to provide the power (265 kW) needed for the compressor of the heat pump as well as the power (145kW) requested by the various fans of the dryer tunnel. It relies on two related diagrams, the main one related to pinch technology approach completed by a second one (electric power versus a pseudo-Carnot factor to illustrate the exergy losses including embedded exergy linked to the compressor of the heat pump. It has also the advantage of visualizing the electricity balance in each process. The exergy losses in the evaporator and condenser of the heat pump are directly shown in the main pinch composite diagram while the exergy losses linked to the engine are shown in the top diagram with a pseudo-Carnot factor superior to one.

A similar diagram was made in [9] for the dryer equipped only with gas furnaces and the exergy losses with the retrofit solution given in Figure 2 were reduced from 1725 kW to 1040 kW.

Note that the notion of embedded exergy losses is strongly inspired by the earlier of work of Bejan [23] when discussing the optima in heat exchangers accounting for heat transfer, friction losses and embedded energy losses.

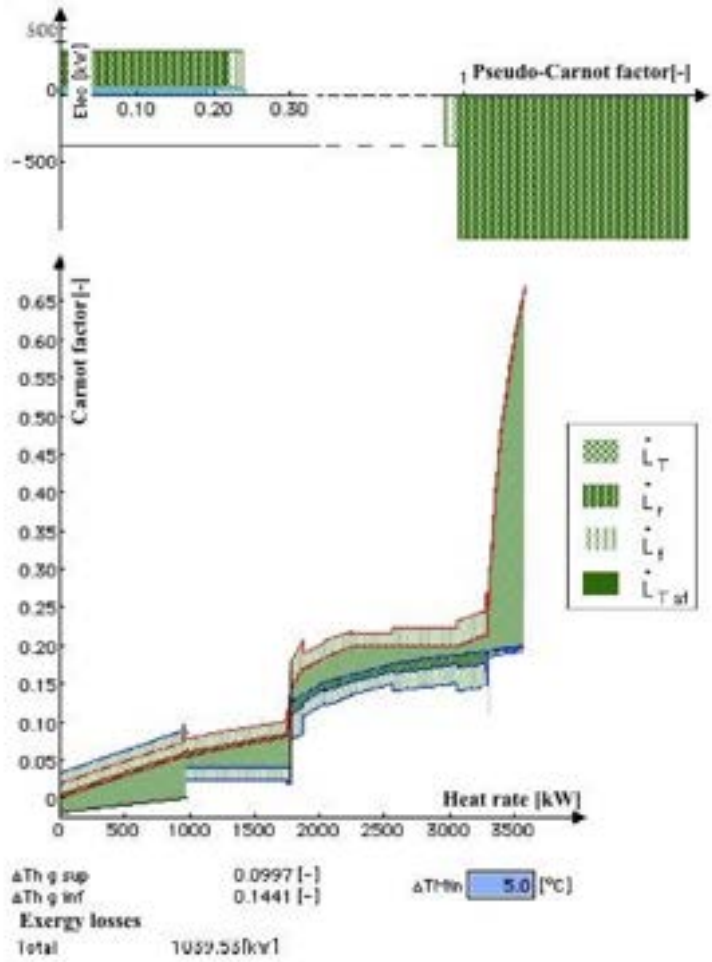

Figure 2. Extended composites proposed in with a visualisation of the exergy losses of heat transfer $\dot{L}_T$, friction $\dot{L}_F$ and embedded exergy losses $\dot{L}_f$ for a plaster drying case with gas engine and heat pump [9]

Contrary to fuel-based approaches, for many renewable technologies like solar or wind the actual resource is free and the embedded exergies together with the implementation, the maintenance and disposal costs are to be accounted for. One earlier paper [24] advocates that the best way to deal with such renewable is to include the rate of embedded exergy divided by the expected lifetime of the equipment among the exergy losses to be taken into consideration. This is particularly valid for solar and wind where the resource does not cost anything. The situation is more complex for biomass for which the resource has a cost and a hybrid approach needs to be taken.

The major hindrance when it comes to embedded exergies is the large inventories of data on materials and processes that are often to be considered. There is a place for advanced methods of data mining in this context.

The extension of exergy-based methods including exergy LCA aspects is particularly interesting in the present context of the implementation of Carbon Capture and Storage or utilisation technologies [25]. The exergy of diffusion of CO_2 in the atmosphere as expressed in [26,27] is providing an absolute minimum of exergy (work) required to extract CO_2 from the atmosphere as is promoted by some companies. It allows an immediate comparison with the extraction from flue-gas pipes in advanced concepts like published in [28]. In the latter CO_2 extraction can be made at negligeable exergy requirements. However, introducing the embedded exergy in the components would allow a much better estimates when comparing these technologies, since the amount of heat exchanger surfaces is high. Synergies with the recent efforts in so-called exergoenvironmental methods [25,29] should be exploited. Nevertheless, optimization based on exergy life cycle analyses can only provide a minimum value that always needs to be compared with economically based optima. They are however much more robust knowing that monetary costs are subject to significant variations linked to geopolitical influences and potential speculation on resources among others.

4. Conclusions on the future of thermoeconomics or environomics

In spite of the interest of “narrow” thermoeconomic approaches, that also include exergoeconomics, from an academic thermodynamic standpoint, the future lies in extended environomic approaches ideally including embedded exergy considerations in connection with broader use of exergy LCA analysis. Furthermore, researchers should be encouraged to further develop graphical tools for easier interpretation of the optimized results. Researchers should also question the results of their methodological approaches when the optimized solution only vary in the range of uncertainties of the major variables. There is also a major effort to be made to try to simplify the approaches and tools, for engineers in practice to be able to concentrate on innovation with new integrated concepts, rather than on the development of sophisticated computer formulations.

Abstract:

'Thermoeconomics' was introduced and its foundations were laid down by Tribus, Evans and El-Sayed in the late 1950's – early 1960's as a method that combines Thermodynamics (in particular Second-Law quantities) and Economics for the analysis, evaluation and optimization of thermal systems. Since that time, many researchers throughout the world taking various roads helped in developing Thermoeconomics from theoretical point of view and applying it in a variety of systems, thus establishing it as a particular field.

Today, questions such as the following may be posed:

- Is there room for further theoretical development of Thermoeconomics?
- Are there areas where Thermoeconomics has not been applied yet, however its application would be beneficial?
- What additional features should Thermoeconomics have, in order to be applied to these areas?
- Is it possible to introduce other considerations, in addition to thermodynamic and economic, in a more holistic approach? If yes, which are they?

In this paper, the authors present in brief their own approach to Thermoeconomics and then they attempt to give answers to the questions, without any claim of completeness.

Keywords:

Thermodynamics; Economics; Thermoeconomics; Second-Law analysis; Optimization.

1. Introduction

'Thermoeconomics' has been coined by M. Tribus as a name for the technique that combines thermodynamic with economic considerations for the analysis and optimization of thermal systems. As it is written by El-Sayed [1], the first landmark of work on thermoeconomics was by Tribus and Evans [2,3] and dealt with seawater desalination processes. The seeds of this work, however, are found in an earlier report by Tribus and co-workers [4], while Evans and El-Sayed developed it further [5-7] and extended the application to thermal systems in general. Significant contributions along these lines in the US were made also by R. Gaggioli and W. Wepfer [8,9].

As it is written by R. Gaggioli [10], the idea of using exergy (availability in the US) for costing energy products appeared in the US in the 1930's:

'… Keenan, who refers to the costing idea in the appendix to his 1932 paper [11]*. (As others have informed us, while teaching at Stevens Institute, Keenan had informed a perplexed cost accountant from a local cogeneration utility, how to charge fuel costs to its steam and electricity products).'*

The idea of combining second law (and exergy, in particular) with economics appeared also in Europe in the same period with thermoeconomics. It is interesting to quote a statement written in a paper by Z. Rant published in Slovenian [12] and translated in English:

'The existing method for energy pricing (accounting) in combined plants on the basis of used enthalpies is fundamentally wrong. It has to replace with pricing (accounting) on the basis of used exergies, which is the only proper way.'

It is worth noting that the word 'exergy' ('eksergij' in Slovenian) appears already in this article, one year before Rant's landmark article [13], where he explains how he coined the word 'exergy'.

Important contributions in these early years in Europe were made also by Szargut [14,15], Beyer [16], Borel [17] and Fratzscher [18].

As written by El-Sayed [1], thermoeconomics rises on three main pillars:

1. Improved thermodynamic analysis (includes second law of thermodynamics quantitatively rather than qualitatively).
2. Improved costing analysis (a closer look at the interaction between fuel and equipment).
3. Enhanced optimization (interdisciplinary approach: thermodynamics, design, manufacture, economics).

In the decades following the early years, the interest in thermoeconomics has increased internationally, a variety of methods have been developed and many applications have demonstrated the usefulness and importance of thermoeconomics.

Today, questions such as the following may be posed:

- Is there room for further theoretical development of Thermoeconomics?
- Are there areas where Thermoeconomics has not been applied yet, however its application would be beneficial?
- What additional features should Thermoeconomics have, in order to be applied to these areas?
- Is it possible to introduce other considerations, in addition to thermodynamic and economic, in a more holistic approach? If yes, which are they?

In the following, the authors present in brief their own approach to Thermoeconomics and then they attempt to give answers to the questions, without any claim of completeness.

The structure of the paper is as follows. The main methodologies are mentioned in Section 2 with emphasis on the functional approach developed by the authors. Section 3 presents thermoeconomics with additional aspects at an early stage and the needs of further development. In Section 4, further considerations and application areas of thermoeconomics are presented together with needs for proper methodological development. The paper closes with remarks regarding the aforementioned four questions and a more or less comprehensive list of references.

2. Progress to date

2.1. Thermodynamic and economic considerations

Several schools of thought have been evolved in the last four decades [1,19], each one characterized by the particular approach it follows, such as the exergoeconomic analysis [20], thermoeconomic functional analysis [21-25], structural theory [26], specific exergy costing (SPECO) [27,28].

2.2. Environmental considerations in addition to thermodynamic and economic

The concern for the depletion of energy / exergy resources led to the development of the aforementioned methods, in an attempt to save energy / exergy by proper analysis and optimization of energy systems.

Soon became evident that energy-related activities cause depletion of other scarce natural resources, in addition to energy, as well degradation of the environment. In order to take these effects into consideration, thermoeconomics had to broaden its basis and methods such as the following appeared in the literature: Cumulative Exergy Consumption [29-31], Thermo-ecological Analysis [31-34], Extended Exergy Accounting [35-37], Environomics [38-41], Exergo-environmental Analysis [42].

Since other contributors to the development of thermoeconomics participate in the discussion about its future, the presentation in this section is not intended to be a general review of thermoeconomics and, therefore, only certain characteristic publications are cited, while more emphasis is given to the functional approach developed by the authors.

2.3. Thermoeconomic functional analysis and optimization

2.3.1. The basic formulation

The basic formulation of thermoeconomic functional analysis (TFA) appears in [21-22]. In TFA, it is considered that the system consists of a set of inter-related units, with each unit having one particular function (purpose or product). Functional analysis is the formal, documented determination of the function of each unit and of the function of the system as a whole.

The functional diagram is a picture of the system consisting of geometrical figures representing the units and a network of lines representing the distribution of the unit functions (Figure 1). Junctions connecting the functions of two or more units and branching points distributing the function of a unit to two or more units are additional features of the functional diagram. The functions of units are quantified by means of second-law properties such as exergy and negentropy.

Since the beginning, TFA is formulated so that it can be applied for analysis, evaluation, product costing [44] and optimization of energy systems. If needed, decomposition of the system into subsystems facilitates the

solution of the optimization problem [23]. Even though the formulation is such that physical economics can be used (every cost is measured in physical units such as exergy), the method has been applied with monetary economics.

It is interesting to note that the productive structure introduced later on by Valero and his co-workers is based on the functional diagram, as written in Ref. [45].

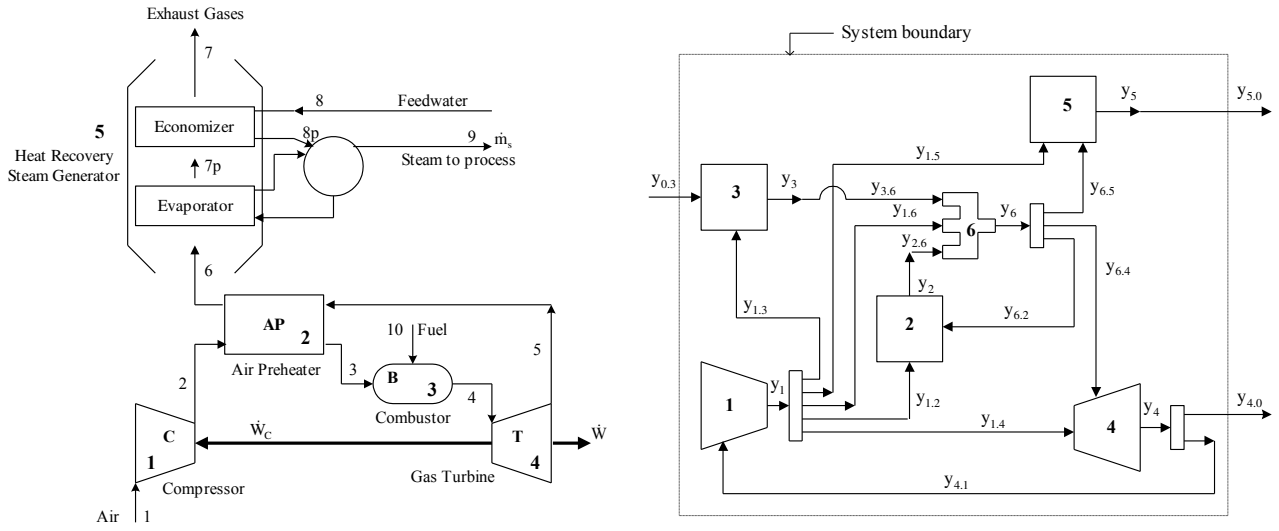

Figure 1. Example of a functional diagram: a) flow diagram of a gas-turbine cogeneration system, b) the functional diagram of the system [43].

2.3.2. The intelligent functional approach (IFA)

Optimization can be considered at three levels (Figure 2): synthesis (components and their interconnections), design (nominal technical characteristics of each component and of the whole system) and operation (operating state at each instant of time): SDO optimization. If complete optimization is the goal, each level cannot be considered in isolation from the others. Thus, the optimization problem can be stated by the following question:

> *What is the synthesis of the system, the design specifications of the components as well as of the whole system and the operating state at each instant of time that lead to the overall optimum?*

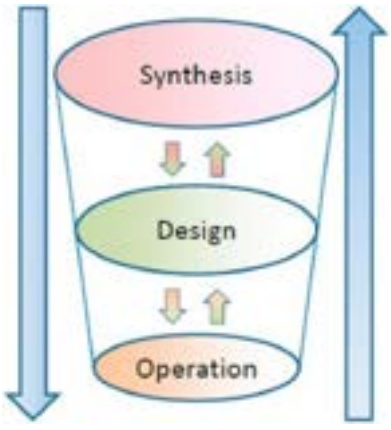

Figure 2. The three interrelated levels of optimization.

Thus, TFA was further developed, in order to address this complex optimization problem [46,47]. The name ‘intelligent’ is due to (i) the information (‘intelligence’) obtained by the analysis and during the optimization procedure in the form of proper indexes (e.g. Lagrange multipliers) and (ii) the intelligent (guided by intellect,

rational) use of this information for the solution of the optimization problem. The superstructure approach is followed for the synthesis optimization.

Of course, if the synthesis of the system is given, the optimization determines the optimal design and operation. If both the synthesis and design are fixed, operation optimization is performed. IFA can be applied for any of these problems.

2.3.3. Environomic functional analysis and optimization

IFA was further developed, in order to take into consideration environmental aspects quantitatively, in addition to the thermodynamic and economic considerations [38-41].

Pollution indexes and degrees of abatement of the various pollutants are defined, and pollution abatement equipment is included in the system. Thus the total cost consists of the (i) installed cost of components including pollution abatement equipment, (ii) cost of resources, (iii) environmental and social cost due to pollution. Complete optimization (synthesis, design, operation) can be performed. The degrees of abatement are among the independent variables of the optimization problem, which determine the design and operation characteristics of the pollution abatement equipment.

The costs to the environment and the society due to damages caused by pollutants emitted from energy conversion systems are called 'external costs' (external to the system) or 'externalities'. It is noted that damages are caused not only in the vicinity of the system, but also in distant areas, even in other countries, that are in the trajectory of pollutants dispersion. Methods for estimation of these costs and publications with first results are mentioned in [48], while joint systematic research at the European Union level led to the development of a method for environmental impact analysis [49] and estimation of externalities [50] supported by related software. More information and an application are presented in [51]. It has to be recognized, however, that this is an effort that has to be continued for improving the methods and decreasing the uncertainty of the results.

Numerical examples including sensitivity analysis demonstrated that, in spite of the uncertainty, it is prudent to take environmental and social costs into consideration in the analysis and optimization of energy systems, than to ignore those.

2.4. Other approaches to the thermoeconomic optimization of synthesis, design and operation of energy systems

The SDO optimization of energy systems requires the derivation of the system configuration either through the automated synthesis during the optimization process or by the definition of a generic super-configuration – consisting of all possible alternatives examined – with the optimal one determined as the output of the optimization procedure. The former approach has been followed in [52,53], while the latter was used in [54-57]. Further, the complex optimization problem of three levels (SDO) can be reformulated in two levels: (A) synthesis and design, and (B) operation. The solution is obtained by iteration between the levels A and B [54-56]. This improves significantly the computational cost of thermoeconomic optimization allowing for complex models of systems and cost functions to be used.

The works presented in [54-56] introduced thermoeconomic optimization in marine energy systems for cruise ships and LNG carriers. In further works, thermoeconomic optimization was applied to Organic Rankine Cycles for low temperature waste heat recovery from ship energy systems [57] and to a marine combined cycle system [58]. In [59] the complete SDO optimization problem is tackled at a single step, with no need of reformulating it in the aforementioned levels A and B. Of course, higher computer capabilities are required for such an approach.

Further developments appear in [60-61] with the introduction of dynamic and intertemporal optimization in the SDO optimization. Dynamic and intertemporal optimization describes situations where subsequent decisions are affected by decisions taken earlier in the time horizon of the optimization problem. Coupling this class of problems to thermoeconomics allows for a wider and more realistic range of energy systems applications to be addressed.

The application of thermoeconomic SDO optimization to ship energy systems is an important contribution to the extension of thermoeconomic approaches due to the complexity of the marine environment. Ship energy systems are isolated (sailing at sea), resource constrained, and highly interconnected with many space, weight and safety constraints. Further, they have many operational modes and wide mission profiles. Therefore, the thermoeconomic methodologies and optimization algorithms often need special adaptation to be successful in marine applications, as the referenced works suggest.

2.5. Achievements not possible without thermoeconomics

The use of thermoeconomics in the analysis and optimization of energy conversion systems acts as a "common denominator" in identifying the sources of losses and their impact on efficiency and costs throughout the system. The major achievement of thermoeconomics lies in to having a methodology that can attribute both costs and energy / exergy efficiency to components and products of a system in a rational and

uniformly applicable manner. This increases the objectivity, trust and transparency of the engineering decision making process when assessing, comparing and optimizing various design and technology alternatives.

Thermoeconomics also uses correlations, i.e. cost functions, of the capital expenditure for the various components of an energy conversion system with their respective design characteristics and performance figures. This is a unique way to assess the impact of technology both in the performance and energy efficiency as well as the cost of the products per unit of energy or exergy. More simple technoeconomic analyses often fail to reveal the dependency of technology with performance and cost of useful products. Therefore, thermoeconomics offers the means for a more robust and informed decision-making process when considering the synthesis, design and operation of energy conversion systems.

3. Thermoeconomics with additional aspects at an early stage of development

Formulations and applications of thermoeconomics with reliability analysis, risk analysis and control of energy systems are presented in brief here. These are interesting subjects but they are at an early stage of development with very few publications. Further development of methodologies combined with more applications would be more than welcome.

3.1. Thermoeconomics with reliability analysis and optimization

In optimization of energy systems it is usually considered that the equipment is not subject to failure and, consequently, it is available for operation at any instant of time, except of predetermined periods of maintenance. Redundancy is provided empirically and as a consequence the configuration of the system may be non-optimal. Let it be mentioned that the reliability and availability of energy systems is a critical economic and efficiency factor.

In [62], reliability and availability are introduced in the thermoeconomic model (IFA formulation) of the system and optimization of synthesis, design and operation under time-varying conditions is performed. The IFA facilitates the solution. A numerical example with a cogeneration system shows that the introduction of reliability leads to an entirely different optimal solution for each one of the three levels (synthesis, design, operation), while profits from selling the products of the system (electrical and thermal energy) are overestimated, if reliability aspects are ignored. More recently in [63], thermoeconomic optimization is coupled with availability considerations for the assessment of a compressed air storage system. Though no optimization is attempted, the differences in expected cost of electricity and profits are assessed with and without reliability considerations highlighting important differences.

Incorporation of reliability into thermoeconomics requires methodological advances on the reliability modelling of energy systems. The most suitable approach, the state-space-method appearing in [62], exhibits an exponential computational burden when the number of system components is increased. There is need of developing reliability assessment methodologies that have significantly lower computational cost and, at the same time, are capable of describing the multiple states of partial failures and reduced output that the whole system may encounter.

In addition, reliability considerations need to be also coupled with the individual component cost functions allowing for increased time between failures or reduced time to maintain a system component, factors that affect the capital cost per unit of time. A revision is also needed on how the maintenance operational expenses are considered up to now, incorporating the mean time to repair as a component of the maintenance costs.

3.2. Thermoeconomics with risk analysis – Thermorisk

Combined quantitative risk and exergy analysis is proposed in [64-65], in order to assess impacts from major accidents in energy systems. Impacts on human health are considered. The method is used to minimize damages of major accidents by proper energy system design. An application example is presented in [64] that minimizes the specific risk (risk per unit exergy of the plant product) of a geothermal drilling plant connected to an organic Rankine cycle system.

In [66], a power and fresh water cogeneration system is studied, consisting of a Rankine cycle, an organic Rankine cycle and a reverse osmosis module. Exergy, economic and risk analyses are performed, followed by multi-objective optimization of the system with the total cost rate and the total specific risk as objective functions.

The work initiated in [64-66] introduces an important dimension in thermoeconomic analysis. In real-world applications the decisions affecting the selection, design and operation of a system also address the total cost of ownership (TCO). The present forms of thermoeconomics account for many of the TCO dimensions such as capital expenditure, operational, maintenance and environmental costs. However, the implicit costs due to safety, major accidents, regulatory compliance and loss of production due to spares availability are

not addressed in a thermoeconomic context up to now. These dimensions are typically assessed via risk assessments methodologies either qualitatively or quantitatively.

The expansion of thermoeconomics towards incorporating risk assessment elements and results will allow for a more holistic framework of analysis, insight and optimization of energy conversion systems. The main extensions required are in the areas of correlating the probability (likelihood) and severity with cost incurred to the system and its components. Then the well-established thermoeconomic methodologies can incorporate and correlate these costs with exergy flows and technical characteristics of the components of the system. Such an extension of thermoeconomics with risk assessment elements will further increase the applicability of the methodology to realistic decision making processes.

3.3. Thermoeconomics with control of a system

Only few publications are mentioned here, but they are adequate for understanding the current state of development.

In [67,68] the thermoeconomic approach is used to evaluate compare and improve the performance of alternative control strategies. An exergetic cost and a monetary cost are associated with the control system. Application to a gas turbine unit driving a generator shows that, with proper control, fuel consumption and operational cost at part load can be significantly reduced in comparison with typical control strategies.

In [67] the effects of the control system on the thermoeconomic diagnosis of a power plant are studied. The role played by the control system on the propagation of malfunctions is analyzed. The control system sometimes forces the plant to operate in a less efficient mode, inducing inefficiencies and malfunctions in the components. In order to avoid these effects, thermoeconomic diagnosis is applied that takes the control system behavior into consideration in the analysis directly. The procedure is applied to a gas turbine cogeneration system.

A review of applications of the second law of thermodynamics to control of energy systems is given in [69], primarily in the building sector. Out of 58 papers reviewed, only three papers apply thermoeconomics / exergoeconomics. In [70] an economic analysis of the exergy-efficiency control strategy of a geothermal district heating system is performed and it is estimated that the new controller (PID) has a payback period of 3.8 years. In [71] the structural theory of thermoeconomics is applied in order to determine the optimal load allocation strategy of the HVAC system of an airport terminal. In [72] energy-based, exergy-based and exergoeconomic-based control strategies of an HVAC system in the built environment is performed and it is shown that the last one could reduce the annual operation costs by up to 23%.

It is noted that in the literature, the words ‘control’ and ‘dynamic’ are used with two different meanings: (a) control of multi-stage operation with steady state in each stage; it sets the operating point of a system at each stage as the conditions (load, environmental temperature, etc.) change from stage to stage, without taking into consideration the transients; (b) control of transients; it specifies the trajectory that a system will follow, in order to go from a steady state to another one. References [67,71-73] belong to the first category, while Refs. [68,70] belong to the second category. In the following, the word will be used with the meaning ‘control of transients’, while setting the operating point of a system in each stage of a multi-stage process is covered by the intertemporal SDO optimization. Needs of further development are presented in brief.

Thermoeconomic control optimization can be considered either in isolation, i.e. optimization of the transient(s) only, or integrated with the intertemporal SDO optimization of the system. In both cases the control unit itself is subject to SDO optimization. There are several configurations of controllers depending on the required control action such as on-off, proportional (P), integral (I), derivative (D) and combinations of those (e.g. PID). The optimal configuration of the control unit is requested (synthesis). For each configuration, the optimal specifications of the components have to be determined (design), followed by optimal adjustment of characteristics (e.g. time constant, gain, damping ratio) in particular periods (operation).

Of course in order for the optimal control to be thermoeconomic, a proper objective function has to be defined. An example of such a function is formulated as follows. During a transient operation along a trajectory specified by the control unit, exergy is used by the whole system including the control unit. Minimization of this exergy is desirable, but such a control action may overstress certain components of the system, thus increasing the frequency and cost of maintenance and/or decreasing their lifetime; the last one causes an increase of the capital cost per unit of time. The total cost (exergy+maintenance+capital) is a very proper thermoeconomic objective function. With appropriate selection of the additive terms, such a function can be defined for the optimization of a single transient operation or for the optimization of the whole period of operation, including transients, as written in Subsection 4.2.

4. Further considerations and application areas of thermoeconomics with proper development of methodology

4.1. Social aspects in thermoeconomics

Currently, thermoeconomics includes thermodynamic, economic and environmental considerations. In the last one, the cost to the society due to emission of pollutants and depletion of natural resources is included either in physical units (exergo-environmental analysis, extended exergy accounting) or in monetary units (environomics). However, the construction and operation of energy systems has not only adverse effects but also benefits to the society. Therefore, an interesting and important extension of thermoeconomics is to include both cost and benefit to society.

Evaluation of projects for their effect on the society with criteria such as job creation, general welfare, standard of living, etc., is widely performed, but the quantitative inclusion of these aspects in thermoeconomic analysis and optimization needs to be developed. Hints of how this can be performed are given by the following publications (indicative only).

In [74] a system of forest-based biorefineries and biofuel supply chain is studied and a multi-objective optimization is performed with three objective functions: (i) maximization of newly created jobs, (ii) maximization of the net present value, and (iii) maximization of the GHG emission savings compared to the current supply chain.

Closer to the energy systems studied by thermoeconomics is the work presented in [75]. Optimization of a thermal-solar-wind combined power system is performed with two objectives: (i) Minimization of economic cost (construction, operation and maintenance, CO_2 cost) and (ii) maximization of social benefits that consist of consumer surplus, government revenue and environmental benefits brought by CO_2 reduction.

The effort is still at its infancy and there is need of significant methodological development for inclusion of social aspects in thermoeconomic analysis and optimization of energy systems.

4.2. Thermoeconomic dynamic optimization of synthesis, design and operation including transients

Even though very few, there are publications on thermoeconomic SDO optimization with multi-stage operation or on optimization of transients, but the complete problem of thermoeconomic SDO optimization addresses the whole life of an energy system taking the complete operating profile into consideration that consists of interrelated periods (stages) of practically stead-state operation as well as transients.

The only publications known to the authors with such an approach are two papers [76,77], where optimization of the energy system of an aircraft that includes the phases of take-off, flight and landing is presented. Each phase is described by a different system of differential and algebraic (DAE) equations and the optimization must be performed for the whole trip. The method is open to further improvement and adaptation to other applications.

The required simulation model of an energy system may contain hundreds even thousands of differential and algebraic equations, making it computationally heavy and very time consuming. Therefore for practical applications there may be need of developing reduced models that are fast, yet with satisfactory accuracy. Examples of methods for developing reduced models are given in [70,78].

4.3. Thermoeconomic SDO optimization of energy systems including synthesis of the working fluids

In the preceding, the optimization of energy systems refers to the components, their interconnections, the technical specifications and the operating state at any instant of time, while the working fluids are selected in advance. If there are several fluids appropriate for the particular system, optimization is performed for each fluid in separate and the one with the best performance is selected.

In [79] computer-aided molecular design (CAMD) of the working fluid in an ORC system is applied that makes it possible to optimize the fluid and the thermodynamic system simultaneously in a single CAMD-ORC framework. The fluid is synthesized during the optimization procedure using several molecular groups (e.g. –CH3, –CH2–, =CH2, =CH–, etc.). The thermodynamic properties of the fluid are calculated by the group-contribution equation of state, SAFT-γ Mie, while critical and transport properties such as thermal conductivity, dynamic viscosity and surface tension are estimated using empirical group-contribution methods. The aim of the optimization is to determine the optimal combination of the molecular groups and thermodynamic variables that maximize the power output generated by the ORC for specified heat source and heat sink.

In a subsequent paper [80], the same system is studied, and two optimization problems are solved: (a) single-objective, minimization of the specific investment cost, and (b) double-objective, minimization of the specific investment cost and maximization of the power output generated by the ORC.

In these works, the synthesis of the system is fixed and operation is considered at the nominal power. It would be very interesting to extend the method by applying thermoeconomic analysis and optimization of synthesis, design and operation under time varying conditions.

It should be mentioned that the term 'thermoeconomic optimization' is used in [80], but neither exergy is used, nor the second law is mentioned explicitly. This fact raises the question as to whether the use of the word 'thermoeconomic' is justified.

4.4. Thermoeconomic SDO optimization with variable synthesis through time

The recent decarbonization concerns for land-based and marine energy systems introduce new fuels, technologies and energy improvement measures to be considered. International and regional decarbonization regulations are introduced in gradual manner, becoming stricter and stricter over time. This entails that the environmental performance of a system has to gradually improve, usually staying below a regulatory trajectory over time. Therefore, a system that is compliant and cost effective now, may not be any more at some point during its economic lifetime. The question that arises is when to invest or re-invest in energy efficiency measures and environmental technologies in order to optimize the system throughout its lifetime.

This question becomes even more important under the new requirements for environmental performance goals with stricter limits (trajectories) over time. Thermoeconomic optimization methodologies should be adapted to identify the optimal point in the economic life of the system, in which a suitable technology is introduced. This needs to be extended also to the selection of the right type of technology or measure from a set of available and feasible technologies. Examples of technologies and measures that affect the environmental performance of energy systems are carbon capture systems, alternative fuels like hydrogen or ammonia (and their auxiliary systems), fuel cells, advanced waste heat recovery.

A further cause of complexity, especially in marine systems, is that some technologies cannot be introduced (retrofitted) later in the lifecycle of the system, unless the system is suitably prepared (becomes "ready") during construction to accept this technology afterwards. For example, introducing a carbon capture system in a ship is significantly less costly if there is an initial provision of space, strengthening of structures and sizing of the energy conversion system to deliver more thermal and electric energy when needed by the carbon capture system.

The above considerations indicate that the standard formulations of thermoeconomic optimization problems need to be revised to account for variable investment points in the time horizon. In addition, the synthesis part of the optimization becomes more important with larger sets of available technology alternatives.

4.5. Low and zero carbon fuels and cryogenic systems

In close relationship with the Subsection 4.4, decarbonization concerns have introduced new fuels, technologies and systems that require analysis, assessment and optimization. Although thermoeconomics has proven its general applicability, there is need for a refinement of methodologies in conjunction with decarbonization considerations.

The decarbonization of land-based, offshore and ship energy conversion systems introduces a multitude of new fuels with low or zero carbon footprint such as hydrogen, ammonia, methanol and synthetic gas or liquid fuels. The actual emissions footprint of these fuels depend on their production, storage, transportation and energy conversion processes. Each of these stages consumes energy and has an inherent efficiency that affects the carbon footprint, the efficiency and cost of the fuel. Introducing exergy analysis and thermoeconomics to the assessment of the value chain of the production, delivery and use of the fuels will significantly enhance the rational and uniform evaluation of their value chain impact on greenhouse gas emissions and overall costs – including the effect of capital expenditure of production and storage infrastructure. Further, the introduction of novel fuels with novel production methods like hydrogen and ammonia poses some challenges with respect to their exergetic analysis and reference state selection that need to be revised and updated accordingly.

Furthermore, most of these new fuels require cryogenic transportation, permanent or temporary storage and fuel gas handling systems. This is also true for liquified natural gas with its global transportation and use intensified due to the recent geopolitical developments. The thermoeconomic analysis of cryogenic and refrigeration systems, although it is well established, poses some challenges related to states below the reference [81,82]. One additional complexity is also related to the muti-component mixtures, with real gas behavior that need to be assessed in vapor-liquid equilibrium conditions, often appearing when assessing the cryogenic storage and handling of the new fuels.

Finally, in terms of component cost functions, there is a significant gap in research and literature. Namely, cryogenic heat exchangers and equipment, natural gas and hydrogen compressors, and many of the associated auxiliary equipment cannot be described or extrapolate their cost functions from conventional power generation ones, used in most of the literature. Efforts should be made to develop representative cost functions describing new equipment and technologies associated with these decarbonization options.

Closure

In a discussion on the future of thermoeconomics, the fundamental question that can be posed is: “does thermoeconomics have a future?” After the fundamental question, other questions such as the four questions written in the Introduction can be posed.

In order to help in answering the four questions, the preceding sections give arguments regarding the necessity of applying thermoeconomics and a few suggestions regarding the introduction of considerations in addition to thermodynamic and economic, areas where the application of thermoeconomics can be extended, and needs of further development of thermoeconomics. Of course, the whole subject is open to additional ideas and suggestions.

After the aforementioned, the answer to the fundamental question is clear: “Yes, thermoeconomics has a future”.

Acknowledgments

The authors are thankful to Prof. Enrico Sciubba for making them aware of early works in European countries combining exergy with economics.

The future of Thermoeconomics: from industrial cost minimization toward cumulative resources accounting and sustainability assessment

Mauro Reini[a] and Melchiorre Casisi[b]

Abstract:
Thermoeconomics has been developed with the main object of first identifying, and then reducing the costs of the energy produced by industrial power plants. More recently, the same approach formalized in the Exergy Cost Theory has been recognized as a useful tool also in a wider field, like industrial symbiosis and sustainability assesment. To do this, exergy supply chains have been tracked backward and backward, to include in the primary resource consumption a more and more complete inventory of the indirect consumption. In Authors' opinion, the future of Thermoeconomics is to go on in this directions. If a very complete inventory of all indirect consumption were obtained, the sustainability assessment of a production process could be performed (at least in principle) by applying the idea that the lower its consumption (direct and indirect) of scarce primary resources, the more sustainable a production process is.
In this paper, the idea of the Thermoeconomic Environment (TEE) is summarized, to highlight as it is a consistent ultimate boundary of the exergy cost accounting, where the origin of the exergy supply chains can be properly placed. Then, the frame of the TEE is used to discuss some possible options for obtaining a more complete inventory of all indirect consumption, and to outline possible perspective connections with some relevant environmental models, coming from Biology, Dynamic of Populations, or Climatology.

Keywords:
Thermoeconomics; Exergy Replacement Cost; Exergy equivalent of capital and labour; Exergy costs of bioproducts; Sustainability.

1. Introduction

Thermoeconomics has been developed with the main object of first identifying, and then reducing the costs of the energy produced by industrial power plants (see, for instance [1-3]). From the beginning, the very fundamental ideas of this approach were:

- All *Fuels* (local resource consumed by a process, or by a component) have to be evaluated in term of the exergy of the streams entering (or leaving) the considered control volume, and the same for the *Products* (goods or commodities locally obtained for the usage in a different part of the system, or for the outside).
- For a process, or a component, the exergy cost of the Products have to be calculated taking all Fuels into account, with their specific exergy costs, disregarding if some Fuels come from the upstream, or the downstream part of the production chain.
- The total cost of the Fuels is allocated on the Products. If a process, or a component, obtains more than one Product at the same time, the total cost is allocated in proportion to the exergy content of each Product.

As a consequence of the previous assumptions, the exergy cost is a conservative magnitude, and the exergy costs obtained by aggregating contiguous control volumes, are consistent with the exergy costs obtained by the previous, smaller, control volumes. These are similar to the properties of the monetary cost, in a closed economy without profit. This analogy is at the basis of the name *Thermoeconomics*.

From the very beginning of Thermoeconomics, the problem arose of including in the exergy cost balance also the resources consumed for owning, operating and maintaining the hardware of the system, i.e. the capital costs of all its parts. The first solution found was consistent with the objective of limiting the Thermoeconomic Analysis to the control volume of a power plant, converting all input flows of resource in terms of monetary costs, using the known values of the unit costs of the energy carriers at the control volume frontier.

In the 80s, a lot of previous ideas about Thermoeconomics have been clarified and organized in an algebraic formulation, named the Exergy Cost Theory (ECT) [4-6].

More recently, the same approach formalized in the ECT has been recognized as a useful tool also in a wider field, like the Industrial Symbiosis [7] and the analysis of eco-industrial parks [8].

In the ECT formulation (as well as in other accounting methodologies, based on the input/output approach [9]) the space boundaries of the analysis are not defined in advance, but they can be adapted case-by-case. In this way, it should be possible, at least in principle, to extend the space boundaries of the analysis, so that the exergy supply chains can be tracked backward and backward, to reach the real primary resources, directly and indirectly consumed, like the raw minerals, the solar radiation, or the biomass in the living ecosystems. If a very complete inventory of all direct and indirect consumption were obtained, the sustainability assessment of a production process could be performed by applying the idea that the lower its consumption (direct and indirect) of scarce primary resources, the more sustainable a production process is. Notice that the idea of *scarcity* plays an important role for assessing sustainability, because the consumption of a certain amount of a very abundant, not renewable resource has to be regarded as more sustainable than the consumption of the same amount of a scarce not renewable one. If this concept is disregarded, we go towards a poor on/off evaluation of sustainability: Goods and process completely based on renewable resources (very few) are identified as sustainable, while all the others, completely, or partially, based on non-renewable resources, are identified as unsustainable!

In view of using the Thermoeconomic approach for cumulative resources accounting and assessing sustainability, a common boundary for the analysis of different goods and processes should be defined. Very recently, the idea of Thermoeconomic Environment (TEE) has been presented [10], highlighting that it may be regarded as a consistent ultimate boundary of the exergy cost accounting, where the origin of the exergy supply chains can be placed, consistently with different exergy accounting methodologies.

In the following, the idea of the Thermoeconomic Environment (TEE) is summarized and then it is used to outline some possible answers to the questions still under discussion in the scientific ambit of exergy accounting. In particular:

- the exergy cost embodied into money capital and human work,
- the proper specific exergy cost to be used for of non-fuel mineral resources,
- the proper approach to be used for the exergy cost accounting of externalities like polluting emissions,
- the proper specific exergy cost to be used for the products of biological systems, which cannot be regarded as supplied “for free” by the ecosystems, neglecting the consumptions and the environmental effects for the production of living stocks, or biomass, inside the ecosystem.

Finally, some possible perspective connections with some relevant environmental models, coming from Biology, Dynamic of Populations, or Climatology are also outlined.

2. The Thermoeconomic Environment

Ones the cost allocation rules have been defined, consistently with the conservative cost balances of all control volumes, the ultimate boundaries of the exergy cost accounting have to be defined, consistently with the purpose of assessing the impact in primary exergy resources of a good, or a service [11].

In the perspective of exergy cost accounting for assessing sustainability, it is evident that the Reference Environment, used in the basic exergy analysis [12], is not well suited for representing the ultimate boundary of the exergy cost accounting analysis. In fact, (i) it is perfectly homogeneous, (ii) its temperature and pressure cannot be modified and (iii) by hypothesis, it cannot be affected in any way by the interaction with the considered system, neither technological nor biological.

Although these characteristics are often considered mandatory for a precise definition of the exergy magnitude, it must also be recognized that they mean that:

- the Reference Environment does not contain any resource; in fact, it is perfectly homogeneous while a resource is generally a concentrated reservoir of some useful substance, or a localized energy flow, which is able to produce useful work while its thermodynamic state is transformed approaching the equilibrium with the defined reference conditions;
- the global warming cannot be accounted for, even in theory, because the temperature of the Reference Environment cannot be modified, in contrast with the evidence of a global temperature change that is happening as a consequence of the interaction of the real environment with the industrial system made by man [13];
- any polluting emissions from the considered production systems have no effect at all on the Reference Environment.

The last point in particular may be regarded as inconsistent, in Authors’ opinion, with the target of an appropriate exergy evaluation of the environmental impact of the industrial processes, at global scale.

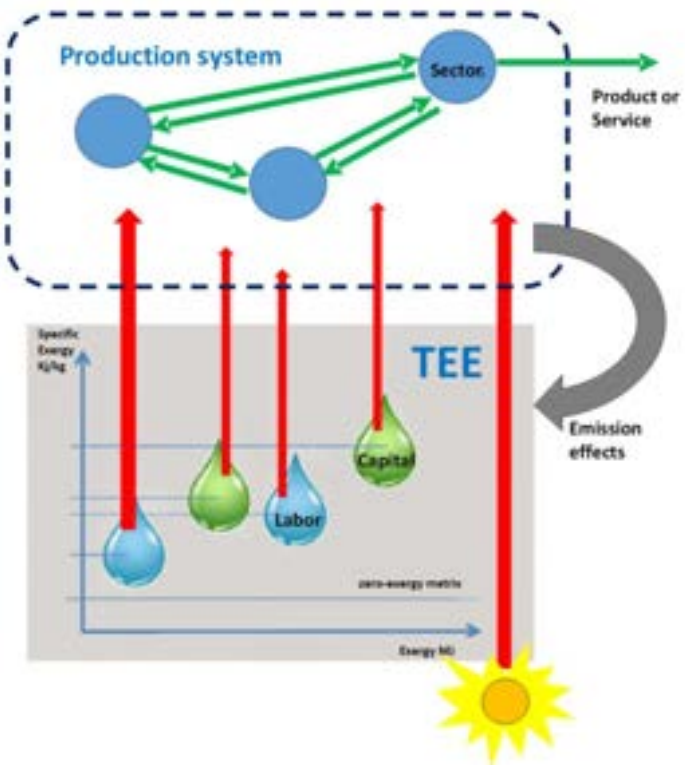

Fig. 1. A qualitative description of some reservoirs in the TEE [10].

To overcome the drawbacks highlighted previously, the TEE has been recently proposed. It is a model of environment, defined as a set of reservoirs, where different kind of natural resources are confined, consistently with the physical nature of the real-world energy systems, which do not operate in a homogeneous environment, but they are fully immersed in the biosphere. All reservoirs are surrounded by the zero-exergy matrix, which plays the role of the dead state for calculating the exergy of all flows inside the energy systems, as well as of all reservoirs (Fig.1). Notice that a specific exergy content greater than zero has to be assigned to each available resource.

From the previous definition, it can be easily inferred that the TEE is not too big to be modified by the interactions with the production processes, because the amount of exergy in each reservoir is limited and because the confined conditions of the reservoirs can be compromised, directly or indirectly, by the production processes. In addition, it must be recognized that even the zero-exergy matrix may change its temperature T° and composition in consequence of some real-world phenomena, like the periodic oscillations of the availability of solar energy or the global warming, which is nowadays increasing as consequence of GHG emissions.

3. Extending the boundary of Thermoeconomic Analysis

If the history of Thermoeconomics and of all exergy-based cost allocation techniques is revised (see, for instance [14]), it clearly appears that this historical development may be regarded as a continuous effort to extend backward the exergy supply chains, toward the primary resources available in the environment (i.e. the reservoirs included inside the TEE).

Very few years after the first application of the Thermoeconomic thinking (1973), the effort of extending the control volume from the gates of the industrial plants, toward the primary resources was formalized by Szargut [15]. He proposed an accounting method based solely on exergy, and properly named it Cumulative Exergy Consumption (CExC): its objective is to compute the cumulative consumption of natural resources, quantify this consumption in units of exergy, and attribute the total resource cost to the products. In its original formulation, CExC focused mainly on mineral resources, assuming an exergy cost equal to one for the chemical exergy of those resources, and it did not include any externalities. A list of CExC values for a large number of finished materials and energy vectors are available in literature [16].

At that point, it appeared as evident that the industrial plants do not consume only the conventional productive factors passing the gates of the plants. Also the polluting emissions, generated during the production process do consume natural resources, to be dispersed and neutralized in the biosphere. To consider this additional resource consumption, the Thermo-Ecological Cost (TEC) [17] was introduced by Szargut. In this last approach, a fictitious extension of the plant is considered, where the polluting emissions are treated in order of obtaining a completely neutralized effluent (or at least an effluent respecting the more restrictive prescriptions actually operating) which can be released in the environment without any damage. The resources

expected to be consumed for the fictitious extension of the plant constitute the ecological cost for polluting emissions, which is used to complement the CExC and to obtain the TEC.

Notice that other Authors, too, use the same procedure for an exergy evaluation of polluting emissions, in particular Sciubba [11] in the Extended Exergy Accounting (EEA), where special emphasis is put in taking into account the entire life cycle of a good, or a service.

After including in the total consumption the effect of polluting emissions and all the main direct and indirect exergy resources supplied to the plant (being the exergy content of some non-fuel minerals quantitatively negligible) the picture could seem complete. Nevertheless, it is not. In fact, even if the hypothesis of a specific exergy cost equal to one for all reservoirs inside the TEE is accepted (as implicitly assumed by TEC and EEA), the operation of tracking back all supply chains towards the indirect primary exergy consumptions may be a very difficult task. In particular, when money capital and human work are considered among the production factors involved in those chains. Money links all sectors of an industrial economy to each other and is used at different stages in the construction and operation of manufacturing facilities. The availability of human work requires food, clothes, instruction, houses, transports, healthcare, etc. All of them are complex products in an industrial economy. To untie all these tangled links, the EEA introduces the exergy equivalent of work and the exergy equivalent of capital, which can be computed based on the Human Development Index (HDI) and the total quantity of circulating money and financial activities that can perform the same functions as money (M2) [18]. Notice that, in the frame of the TEE, this approach means that the TEE contains a reservoir of capital and another of human work and that the specific exergy costs of both resources is known.

4. The proper exergy cost of primary resources

Not only the specific exergy costs of capital and human work have to be known, but also those of all available resource inside the TEE have to be identified, in order of obtaining a meaningful set of product costs by applying the exergy accounting. A straightforward option is considering equal to one by hypothesis (see, for instance, [5]) the specific exergy costs of all exergy reservoirs present in the TEE. This approach expresses the idea that a certain exergy stock of non-renewable resources is available in the TEE at the present moment, jointly with a set of exergy flows of renewable resources (including the renewable part of all partially renewable reservoirs). It is consistent with the CExC and the derived approaches, and with the EEA, too. Then, the exergy cost of a good, or service, is the part of the exergy available in the TEE that is consumed directly or indirectly for obtaining it. This may be correct if the dynamic processes allowing the exergy accumulation inside the reservoirs can be neglected. This is possible, for instance, when the accumulation process is very slow, compared with the production process considered in the analysis, like for natural fossil fuel, or other mineral reservoir. Otherwise, if a dynamic exists inside the TEE and it provides an exergy accumulation inside the reservoirs at a time scale comparable with that of the considered good, or service, it should be taken into account. In fact, the exergy extraction from a certain reservoir may produce an exergy destruction in some other reservoirs of the TEE, in addition to the extraction up from the former reservoir. In this second case, two options can be immediately identified: (i) to extend the supply chain describing the indirect consumption of resources, or (ii) to define a set of specific exergy costs, not equal to one, which takes into account the effect of the mechanism of additional exergy resource consumption. As previously noted, this second option has been used for introducing the externalities of capital and human work consumptions into the EEA.

The meaning of the first option is that the TEE has its own internal production processes. In this case, the specific exergy costs of the exergy reservoirs should be determined by applying the same exergy accounting techniques considered for the manufacturing systems.

Various Authors, in particular Valero A. C. and Valero A. D. [19], have highlighted that, if the specific exergy costs of all exergy reservoirs present in the TEE were fixed at a value equal to one, a sort of inconsistency would arise: all non-fuel mineral resources would have a very low exergy cost, because of their poor chemical exergy content. This happens although some of them are quite rare and someone even valuable. Consequently, some industrial products appear to have an exergy cost that is extremely little dependent on the presence of rare materials and this is in strong contrast with the technological effort undertaken to reduce the presence of such materials, or to replace them with non-rare ones. This effort implies actions in parallel, or in competition with those for increasing the exergy efficiency of the modern production of goods and services, so that, it cannot be simply disregarded.

Paying attention to the rare or valuable characteristic of some minerals may seem irrelevant to the issue of accounting for exergy costs, and only meaningful in relation to the market economy. However, consider the conceptual example of an industrial economy fed by a TEE with only two non-renewable reservoirs, let's say coal and iron ore. That economy could obtain many technological products, but certainly not all the modern industrial goods. This example allows us to infer easily that the availability inside the TEE of many abundant reservoirs of *different* chemical nature is an asset for the industrial system, just like the availability of fossil fuels. In few words, the *Chemiodiversity* (that can be defined analogously to the most popular *Biodiversity*) of the TEE is a resource and has to be accounted for in the calculation of the exergy costs. In addition, consuming

a scarce resources is different (less sustainable) that consuming an abundant one, even if they both were, for instance, not renewable.

The proper specific exergy cost to be used for non-fuel mineral resources has been proposed by Valero A. C. and Valero A. D. [19], by introducing the exergy replacement cost (ERC) of mineral resources. The ERC has to be regarded as the exergy cost required for producing a reservoir of a certain mineral resource, from the conditions defined for the Thanatia planet, where the confining constraints of all reservoirs have been destroyed and all mineral resources are mixed together. In other words, the reconstruction of the mineral deposits (i.e. the cradle of the resources consumed by the production process) requires an exergy expenditure, because real-world, irreversible technologies are used. An exergy cost greater than the mere content of chemical exergy can be identified in this way for all mineral reservoirs in the TEE. In its original formulation, the ERC calculation implicitly assumes that the input exergy is available for the ideal process of reconstruction of a mineral resource as it is in the real-world industrial system, being the process constrained only by the concentration of each chemical substance in the Thanatia environment. Notice that this makes sense (at least for an ideal experiment) if the replacement of a small sample of a certain mineral resource is considered. On the contrary, the replacement of *all the mineral resources consumed* by the global industrial system is not possible, neither in principle, because of the exergy losses in both cradle-to-grave and grave-to-cradle conversion processes. To make it possible (at least for an ideal experiment) an exergy source external to the bio-geosphere of the planet Earth should be considered.

4. The future of Thermoeconomics

In Authors' opinion, the future of Thermoeconomics must continue in the directions outlined above, in particular:

a) integrate the ERC concept into exergy cost accounting methodologies and sustainability assessment,
b) identify an appropriate specific exergy cost to be used for products of biological systems,
c) develop the exergy assessment of the environmental impact of industrial processes, on a global scale,
d) explore alternatives to evaluate the exergy cost embedded in money capital and human labour.

4.1. ERC integration

A first progress in the direction indicated in point a) has been recently obtained by integrating the ERC with the CExC approach, obtaining the new thermoecological-cost methodology [20].

When the object of the analysis is assessing the sustainability of a technology, or of an industrial sector, it is important to pay attention to the replacement of all the mineral resources consumed by the industrial sectors, directly or indirectly connected inside the global system.

As just mentioned, this is possible only if an exergy source external to the bio-geosphere of the planet Earth is considered. The only exergy input external to the geo-biosphere is solar energy (and possibly tidal and geothermal energy). Thus, the ERC may be understood as the exergy cost that should be payed to re-obtain a certain non-renewable resource by using additional renewable external exergy input [10], i.e. to allow its usage as it were renewable, excluding its exhaustion, on a human time scale. This interpretation does not require any conceptual modification of the ERC definition and is consistent with the idea that unit exergy costs greater than one can be considered for the reservoirs in the TEE. The numerical values of the ERCs of the different mineral resources may result amplified by a factor equal to the inverse of the exergy efficiency of the conversion process that produces the form of exergy required by the replacement process starting from solar radiation. Notice that this occurrence is implicit in the idea of using real-word technologies, so that, when the technologies change, also the values of the ERCs may change.

4.2. Products of biological systems

For what concern the direction indicated in point b), it has to be recognized as a difficult task, with few suggestions available in Literature. In fact, the products of the biological systems are resources of the kind having their own dynamic connecting many different reservoirs each other inside the TEE, for which a natural exergy accumulation may be present, at a time scale comparable with that of goods production by the industrial economy. Bakshi and co-workers [21] have proposed one of the few historical contribution in this direction. They have defined the approach named Ecological Cumulative Exergy Consumption (ECEC), that is identical to the CExC for what concern the contribution of mineral resources, whilst the exergy cost of the products of the biological systems are assumed to be equal to the emergy of the same products, calculated in the ambit of the EMergy Analysis (EMA) [22].

The EMA allows overcoming the difficulties related to a detailed knowledge of the exergy flow network that is required to apply The CExC, or the ECT. In fact, only the inputs to the whole ecosystem have to be known in detail. Unfortunately, in the EMA approach, the ultimate boundary of the accounting analysis is placed in the solar energy that fed the whole geo-biosphere from the distant past to now, not in the TEE as it is at present time. In addition, special allocation rules (the Emergy Algebra), are used, which are only in part analogue to a conservative cost balance. In summary, the EMA has some characteristics that make energy engineers often

sceptical about the option of incorporating the results of this approach inside the exergy cost accounting of goods and services [23].

The frame of the TEE offers an alternative for the calculation of the exergy costs of the products of biological systems, similar to the ERC of the mineral resources and consistent with the EEA approach. In this case, too, some information is required about the ecosystem dynamic, but it mainly consists of the parameters of natural growth rate and of extraction rate, which are not difficult to obtain (see, for instance [24]).

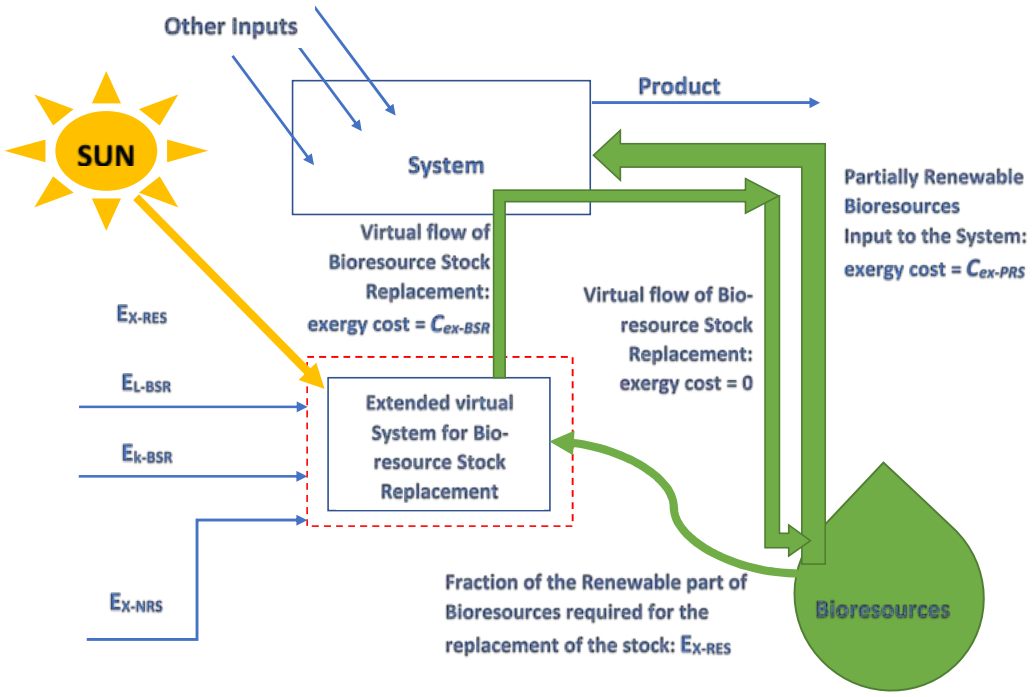

Fig. 2 The concept of Bioresources Stock Replacement Cost [10].

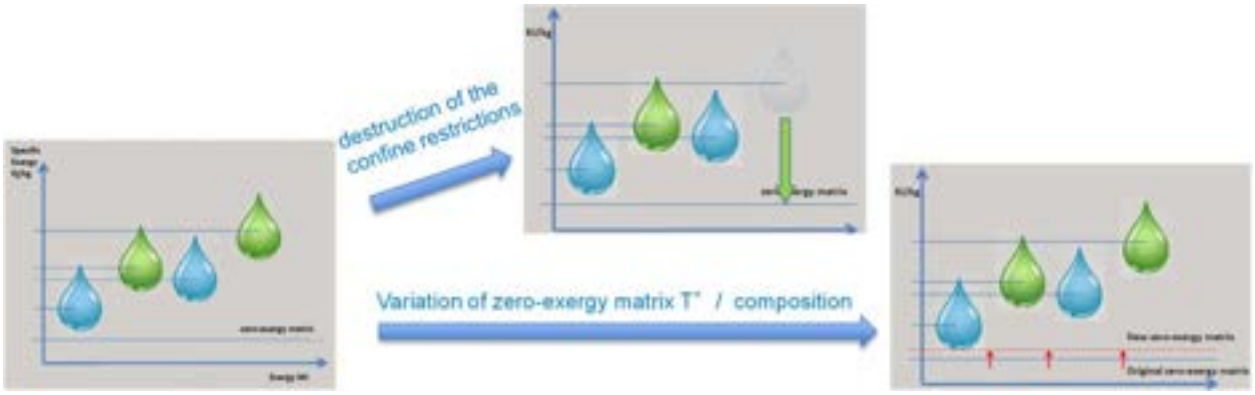

Fig. 3 A qualitative description of possible depletion of the exergy stock inside the TEE.

An extension of the system is considered (see Fig. 2), the function of which is to replace the stock of the bioresource reservoir in the TEE, if the stock has been affected by the operation of the system. In fact, if the bioresource is consumed at an extraction rate lower than (or equal to) its growth rate, the stock is not affected and the input to the production system can be regarded as completely renewable, like solar radiation, and its exergy cost can be equal to one as that of the solar radiation. On the contrary, if the extraction rate is greater than the growth rate, the exergy stock of the TEE is consumed and the extended system has to cultivate the ecosystem, to produce the biomass required to replace the original stock. The bioresource stock replacement cost (BSR) can be calculated because the exergy costs of the inputs of the extended system can be known [10, 25].

4.3. Environmental impact

To develop the exergy assessment of the environmental impact of industrial processes (point c), it is worth noting that the remediation cost for neutralizing the chemical and physical exergy of waste (the cost considered by both the CExC and the EEA, among others) may be the same whether or not waste treatment strategies

are actually applied. In fact, part of the costs are actually incurred within the real plant, while the other part (so as, to have virtually neutralized emissions) is incurred in the fictitious extension of the plant. In other words, the cost charged on the plant products because of polluting emissions may independent by the degree of emission cleaning actually operated. Moreover, the cost for the actual treatment may be even higher, because real processes are generally less efficient than virtual ones. The result is that a highly polluting plant may appear to be less resource-consuming (more sustainable) than a plant that obtains the same product cleanly. To avoid this inconsistency, an alternative approach has been suggested in the frame of the TEE [10, 25], where the actual exergy cost of polluting emissions has to be defined as the real exergy stock depletion produced by the polluting emissions. Bearing in mind the definition of TEE, it is easy to deduce that a certain depletion of the exergy stock can be caused, besides consumption, also by:

- destruction of the confine restrictions of reservoirs (see Fig. 3),
- variation in the zero-exergy matrix temperature or composition(see Fig. 3),
- dilution of substances inside the reservoirs, reducing their concentration,
- indirect destruction of the (living) biomass stock inside the reservoirs.

In this way, virtuous plants, which effectively include emission neutralization systems, may have a specific exergy cost of their products lower than polluting plants, highlighting that the former requires less consumption of resources (i.e., they are more sustainable).

It is worth noting that the suggested alternative approach requires an inventory of the effects of the identified polluting emissions and then the translation of those effects in terms of depletion of the exergy content of the reservoirs inside the TEE. The effort of the first step is similar to that required by the LCA [26] of a process, whilst the second step requires an appropriate evaluation of the specific exergy cost attributed to each reservoir, in order of obtaining the total exergy cost of the polluting emissions [27]. Moreover, the evaluation of the exergy stock depletion produced by some pollutant may vary, because new effects may be discovered. This may be regarded as a negative point, because the evaluation is, to some extent, dependent on the historic moment. Or as a positive point, because new discoveries can be integrated in the evaluation, allowing well supported decision for improving the sustainability of the production processes. It is worth noting that this alternative approach define a connection among Thermoeconomics and the ecological models developed in different scientific fields, in particular with the climatic models, that have assumed increasing importance in the recent years [13] because of the arising of the global warming.

4.4. Money capital and human labour

The final topic (d) of the future development of Thermoeconomics will be, in Authors opinion, the development of alternatives to evaluate the exergy cost embedded in money capital and human labour. The exergy equivalent of money capital and of human work following the methodology of the EEA have been presented in the previous sections. Rocco and Colombo [28] have proposed an alternative approach, which can be regarded as an exergy extension of the input/output analysis, originally formulated by Leontief [9]. In this approach, the interactions among the sectors of the whole production system are described by the monetary magnitudes, usually adopted in the economic analysis. Then, the exergy cost accounting of each flow in the model is obtained considering the exergy of all inputs coming from the environment and feeding the sectors (the nodes) of the production network. The exergy equivalent of capital has not to be evaluated explicitly in this procedure and (if it is evaluated *a posteriori*) it may result different for the different production sectors considered.

As far as the exergy cost accounting of human work is concerned, the suggestion by Rocco and Colombo [28] is again a direct extension of their exergy input/output analysis. Human labour is embedded as an additional sector, without the need of any arbitrary assumption. Obviously, additional information is required, in particular the quantitative evaluation of the inputs required by the human working activities from each one of the other sectors and, likewise, the human working hours required by each of them.

It has been previously highlighted that the development of the exergy assessment for the environmental impact of polluting emissions will imply a more strict connection with the ecological models developed in different scientific fields. In conclusion, it is worth noting that, in the same way, the identification of a detailed information about the exergy cost embedded in money capital and human labour will imply a strict integration with the input/output models coming from the economic analysis.

5. Is Thermoeconomics a science?

This question has been always present, even not explicitly asked, from the very beginning of the exergy based cost accounting methodologies:

Is Thermoeconomics a science?

The question may appears as inappropriate, out of place, and even insulting. Thermoeconomics comes from the exergy analysis that means from the Second Law of Thermodynamics. It has to be close to the holy hart of Physics.

Unfortunately, the exergy cost cannot be measured like mass, or energy. In fact, these magnitudes can be measured independently from the thesis to be demonstrated. By using the measured values of two masses, it can be demonstrated that the gravitational attraction between them is proportional to the product of the two masses. By using the measured value of the potential energy of a body, the Joule experiment can be performed, demonstrating the energy equivalent of heat. On the contrary, the exergy cost cannot be measured independently by the cost allocation rules, the inventory of the flows regarded as relevant (whilst a lot of others are disregarded), the hypotheses about the exergy equivalent of money capital and of human labour, and so on. Ones the cost allocation rules are defined, together with all other required information, the calculated exergy costs cannot be wrong, *they are right by hypothesis*. They may be more or less useful from an engineering point of view (this is true), but this is far from a clear scientific result.

To claim Thermoeconomics as a science, it should be shown that the exergy costs (or the specific exergy costs) are involved in some physical phenomena different from their calculation procedure. Perhaps, this could be investigated referring to a process without any requirement of money capital or human labour, and with a clearly identified environment, where all resources come from. Such a process could be a network of chemical reactions, where reactants and products could be identified for each reaction, or better, the metabolic network of a simple bacterium in a Petri dish.

This investigation line is nowadays under development [29, 30]. The object is to show that, under well-identified conditions, the minimization of the specific exergy costs of the products plays a role [31, 32] analogous to the Constructal Principle, formulated by Bejan [33] and often considered to be a physical principle of the same rank of the First and Second Law of thermodynamics [34]. If this hypothesis were confirmed, it would be definitely demonstrated that Thermoeconomics is more than a useful engineering tool, but a real scientific field.

6. Conclusions

In the paper the history of Thermoeconomics is quickly summarized, highlighting how its development may be regarded as a continuous effort to extend backward the exergy supply chains, toward the primary resources available in the environment. In fact, this allows including in the economic and sustainability assessment a more and more complete inventory of direct and indirect consumption. If a very complete inventory of all direct and indirect consumption were obtained, the sustainability assessment of a production process could be performed by applying the idea that the lower its consumption (direct and indirect) of scarce primary resources, the more sustainable a production process is. In spite of being apparently a simple idea, this effort is still not completed.

In Authors' opinion, the future of Thermoeconomics will be going on in the direction of improving the inventory of all direct and indirect consumption related to a production process, in order to supply a more complete information to the decision-makers in the field of industrial sustainability. In the paper, some specific directions have been identified, like:

a) The integration of the Exergy Replacement Cost of rare mineral resources into the exergy cost accounting methodologies and sustainability assessment.
b) The identification of an appropriate specific exergy cost to be used for the products of the biological systems. In this direction, the exergy Bioresources Stock Replacement Cost has been presented as an alternative to other approaches, keeping the consistency with the exergy cost accounting and the Exergy Replacement Cost formulations.
c) The continuous improving of the exergy assessment for the environmental impact of industrial processes, on a global scale. In this direction, the frame of the Thermoeconomic Environment may help overcoming a drawback of the exergy assessment of pollution, in which a highly polluting plant may appear to be less resource-consuming (more sustainable) than a plant that obtains the same product cleanly.
d) The exploration of alternatives to evaluate the exergy cost embedded in money capital and human labour.

Is worth noting that the development of the exergy assessment for the environmental impact of the production processes will imply a more strict connection with the ecological models developed in different scientific fields. In the same way, the identification of a detailed information about the exergy cost embedded in money capital and human labour will imply a strict integration with the input/output models coming from the economic analysis. In addition, all these improvements of the inventory of direct and indirect consumption have to be integrated into a unique frame. For instance, the exergy cost embedded in human labour should be accounted for in the Exergy Replacement Cost of rare mineral resources, and Bioresources Stock Replacement Cost should be accounted for in the assessment for the environmental impact of industrial processes, if even distant ecosystems are affected by their emissions.

In conclusion, the question if Thermoeconomics has to be regarded as a science, or not, is briefly discussed and a possible path to demonstrate that Thermoeconomics is more than a useful engineering tool, but a real scientific field, is outlined.

Abstract:

Exergoeconomics has played an important role in the analysis and optimization of energy systems in the last decades. The idea of using exergy as a “carrier of value” allowed defining an unambiguous criterion to allocate costs among the products of energy systems and paved the way to a deeper analysis of the losses of potential work within the systems. With the development of efficient optimization algorithms, the exergoecomic procedures of analytic optimization and the design improvement procedures based on heuristic exergoeconomic criteria have been gradually replaced by more efficient optimization procedures aimed at minimizing a “cost” objective function, leaving the calculation of exergoecomic costs in the optimum as final step. The increasing attention to the mitigation of the effects of human activities on climate change, together with increasingly higher disparity in the availability and use of energy, enlarged the perspective to a wider set of goals of the energy system designer, which has to consider the energy systems as a part of the whole society. This asks the energy systems designer to move the attention also towards energy users, integrating the design and operation optimization of energy conversion systems with smarter methodologies to reduce energy consumption. Therefore, we propose the Exergoeconomic methodologies to evolve towards Thermo-X Optimization methodologies involving a wider set (X) of goals and constraints than the economic ones, to solve the “energy problems” of our society with a wider perspective. The paper briefly summarizes the history of Exergoeconomic analysis and optimization methodologies and outlines the path for developing a general methodology including all the aspects mentioned above.

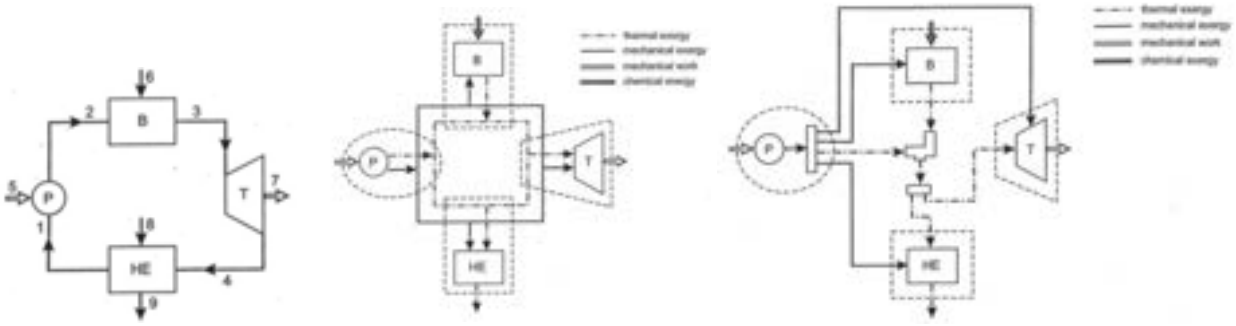
Keywords:

Exergoeconomics, design optimization, UN goals

1. Introduction: exergoeconomic methods

Exergoeconomics aims to evaluate the exergetic and monetary costs associated with mass and energy flows in the energy system. Building on the pioneering work of [1–4], the idea is to allocate the input costs of the total system between the internal mass and energy flows of the system, up to the final products, in proportion to the associated exergy flows. The principle that exergy is the most appropriate variable for cost allocation actually needs to be supplemented with the definition of the desired exergetic "Product" and the exergetic resources needed to obtain it ("Fuel"). Thus, all exergoeconomic methodologies proposed in the literature suggest allocating the costs of the input streams based on the exergy carried by the Fuel and the Product of the system components. However, this introduces an inherent degree of subjectivity, as the definitions of Product and Fuel that satisfy the energy balance of each component are not unique. The various exergoeconomic methodologies in the literature ultimately differ each other only in the ways of defining or representing the Fuel and the Product of the components. The "algebraic" approach initially suggested in [4] and [5,6] as well as the "algebraic theory" proposed by [7,8] leaves a fairly large degree of freedom on these definitions and their representation, i.e., on the so-called production structure, specifying some rules only to avoid other arbitrariness at the system level (e.g., to handle energy losses - "residuals" - of the total system). The SPECO method, proposed by Lazzaretto and Tsatsaronis [9–13], avoids any ambiguity in the definitions of Fuel and Product by providing specific rules for obtaining them, simply based on the principle that any addition of energy by the considered component belongs to the Product, while any removal belongs to the Fuel. The resulting representation of the production structure is also unique and keeps every interaction

between Fuel and Product and the flows of exergy into and out of each component within the boundaries of the component itself.



(a) (b) (c)

Figure 1. Simplified physical structure of a steam power plant with “hot” heat exchanger (a) and corresponding productive structures according to the SPECO (b) and Functional (c) approaches [14].

A substantially different approach has been proposed by the "functional" approaches [3,15–19], where functions (i.e., product) are defined according to a “purpose” of the component in the system in which it operates, i.e. considering how the single component “serves”, and therefore interacts, with the rest of the system structure. In this way, the same component does not have the same "function" independently of the system in which it operates, as the SPECO approach states, but it may have different functions depending on the system in which it is embedded. In this way, a "functional diagram" is constructed that has the same logical meaning as the productive structure of the SPECO criterion or other thermoeconomic approaches, but is generally different from it, thus involving a different cost allocation criterion [14,20–23]. For any functional or production structure, costing requires formulating a conservative balance of the cost streams entering and leaving the component under consideration and formulating auxiliary equations equal in number to the number of exergetic streams leaving the component minus one (since the balance equation is always available). For example, for the k_{th} component receiving a heat transfer ($\dot{E}_{q,k}$) and generating power ($\dot{W}_k$), the cost balance is [24].

$$\sum_e \left(c_e \dot{E}_e\right)_k + c_{w,k}\dot{W}_k = c_{q,k}\dot{E}_{q,k} + \sum_i \left(c_i \dot{E}_i\right)_k + \dot{Z}_k$$

where $\dot{E}_i$, $\dot{E}_e$ and c_i, c_e denote exergy flow rates (*kJ/s*) and costs per monetary unit (*$/kJ*), respectively, at the inlet (*i*) and exit (*e*) of the k-*th* component, $\dot{Z}_k$ is the amortization cost for the investment and maintenance and $c_{w,k}$ and $c_{q,k}$ are costs per monetary unit of the work and heat, respectively.

Auxiliary equations are formulated according to the *F* and *P* rules [7,10–12]. Referring to the SPECO approach, the *F* rule states that the exergy removal in a component occurs at the average unit cost at which the exergy removed was supplied in the upstream components, whereas the *P* rule states that every exergy unit belonging to the product has the same unit cost (Fig. 2).

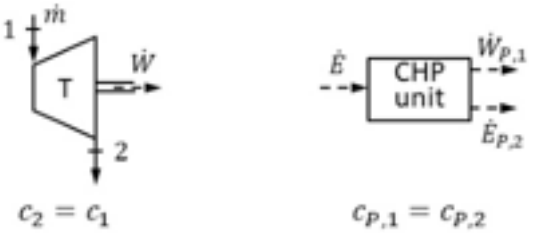


Figure 2. F rule applied to a turbine (left) and P rule applied to a CHP engine (right).

The result is an overall picture of the exergetic or monetary cost flows associated with the different mass and energy flows in the system. In particular, this makes it possible to estimate product costs, showing that products of components further downstream in the energy conversion system are loaded with higher costs as they are affected by all the irreversibilities generated by upstream components. Regardless of the differences between the different methods, which are generally quite small, they have had the merit of calculating the least ambiguous possible cost of the different energy products of a system, and thus of being able to make comparisons about the ability of different systems to generate products at higher or lower costs.

The method of design improvement proposed in [6] and subsequently included in [24] is based on finding the best efficiency-cost trade-off at the component level, so as to create an overall picture of the main sources of irreversibility and costs in the various components of the energy system, and intervene mainly on those

components with the highest values of the sum of depreciation costs and energy destruction costs. This method may require some iteration steps to improve the system design, driven by the designer's ability to choose the appropriate performance modification of the components responsible for the highest destruction of exergy and cost.

On the other hand, starting from the 70ies several researchers proposed to optimize the system design with a Lagrangian analytical approach [3,15–19] that searches for the minimum unit cost of the total system product as objective function. Compared with the design improvement criterion proposed by Tsatsaronis and co-workers [6,24], this approach has the advantage of finding the optimal values of the system design variables (pressures, temperatures, flow rates) without the need for iterations, but at the expense of a quite difficult search for the analytical solution. Langrange multipliers in this case take the meaning of marginal costs at the point of optimality found. However, setting up and solving an optimization problem with an analytical method limits the use of this approach to relatively simple system configurations, or requires strong simplifying assumptions.

An evolution of this approach was the development of “Environomics”, which, in addition to the exergetic and monetary costs of mass and energy streams in the system, considers the costs associated with the consumption of other resources and the emission of pollutants [25]. The thermo-economic objective function is still used with the addition of one or more terms, which depend on: the environmental and social costs of undesired emissions [26]; on the pollution costs associated with system manufacturing and dismantling system equipment; the costs associated with resource preparation and transport [27]. Since all these terms are costs, the objective function is still economic (in this sense, the unabbreviated term thermo-enviroeconomics would be more appropriate, as recognized by Frangopoulos [25]), with penalties applied according to the pollution generated. A variant of the environomic approach is used in [28], where the objective function considers a carbon tax on CO2 production as a penalty term and includes the costs of pollutant abatement devices and CO2 sequestration in the cost of equipment. A different penalty term linked to operational inefficiencies is considered in [29].

Going back to the design improvement methods, from the beginning of 2000s onward, Tsatsaronis and co-workers introduced the concepts of "avoidable" and "not avoidable" exergy destruction to understand the actual margins of improvement achievable in the iterative design based on the calculation of exergoeconomic variables [30]. Moreover, they suggested overcoming the problem associated with the mutual interdependence of the components behavior by splitting the total exergy destruction within a component into its endogenous and exogenous parts [31]. The former refers to the exergy destruction occurring within the component when all other components operate in an ideal way, whereas the latter is the difference between total and endogenous exergy destruction in the same component. In spite of the interesting conceptual approach, the practical applicability of this exergy splitting is not trivial. Several papers were written in the last years on these advanced exergy-based methods for developing, evaluating, understanding, and improving energy conversion systems by Tsatsaronis and Morosuk. A good review of these approaches is supplied in [32].

Other important developments have also been made to use exergoeconomics in the diagnosis of energy systems malfunctions. The paper by [6] first evaluated the effects of variations in exergy destruction in a component of a complex system on the total system fuel in the system design. This concept was later applied by Valero and co-workers [33] to evaluate the system-level effects of malfunctions, understood as changes in efficiency or product in a component relative to the design condition. Reini in 1994 [34] fully formalized how to calculate the "impact" on total system fuel due to changes in the efficiency or product of its components for any system configuration. Torres at al. [35] introduced the concepts of malfunction and dysfunction to distinguish between variation of the component behavior that depend on the component in hand or originate in other components. In [36] a criterion was proposed to identify and localize malfunctions using exergoeconomic performance variables.

However, as already in the iterative design improvement procedures mentioned earlier [6] the main drawback in the application of exergoeconomics to the search of malfunctions lies in the dependency relationship between the exergetic performance variables (exergetic efficiency and exergetic product) of different components. This implies that a variation in one of these variables due to changes in one of more design variables (pressure, temperature, mass flow rate..) generally results in induced changes in the exergetic variables of other components as well, thus “hiding” the “real” malfunctions and making their identification difficult. To overcome this intrinsic drawback, Toffolo and Lazzaretto suggested a fundamentally different approach to detect malfunctions, based simply on identifying components that vary their characteristic curve through an exergetic indicator that accounts for the changes in the derivatives of irreversibilities at the design point of this curve with respect to the independent variables of the component under consideration [36].They also reviewed all exergoeconomic diagnostic methodologies to highlight their strength and limitations [37]. A good synthesis of different points of view on the use of exergoeconomics in the detection of malfunctions and evaluations of their effects is presented in [38,39].

Most of the mentioned drawbacks either of the exergoeconomic method for the design improvement or of the Langrangian optimization approaches were subsequently overcome by the introduction of new optimization

algorithms that allowed researchers to develop new and often more efficient methods for the design optimization of energy conversion systems, as shown in this paper.

In this context, the goals of the paper are:

- To demonstrate that exergoeconomics has paved the way for the recent design optimization methods and can still be used to obtain more in-depth information for a comprehensive understanding of the optimal design of single energy conversion systems;

- To understand the direction in which newer optimization methods have developed;

- To foresee how these optimization methods may develop in the future to include not only energy and economic performance aspects of individual systems but also all the other aspects that must necessarily be considered when designing groups of energy conversion systems that fulfil the time-varying demands of multiple users, in larger or smaller geographic areas, through different energy distribution networks.

- To emphasize the need to focus on reducing energy demand, avoiding energy waste in wealthier countries, and instead help increase consumption in poor countries while maintaining a good balance with the environment.

The paper identifies themes and asks questions about these problems without claiming to give exhaustive answers, which are impossible given the complexity and enormity of the problems, which involve virtually all human activities. Rather, it aims to retrace the evolution of research in order to identify lines of development that are respectful of the developmental needs of individual states, but at the same time narrow their limits in order to give every human being the same opportunities, not only now but also in the future.

2. Critical aspects and limitations of the exergoeconomic methods

Exergoeconomics is based on concepts and assumptions that have a certain degree of subjectivity, which is reflected in the results obtained and in their utilization for improving the design and operation of energy conversion systems. The critical issues associated with this subjectivity are discussed in the following, separating those associated with simple cost accounting from those involved in the use of exergoeconomics for the design improvement according to the criteria proposed by Tsatsaronis and co-workers [6,24].

2.1. Cost accounting

As shown in the Introduction, the cost balance and the auxiliary equations obtained by the *F* and *P* rules allows calculating the exergetic and monetary costs associated with mass and energy streams. Given that the *F* and *P* rules require the definition of Fuel and Product of each component, these definitions become crucial for an effective and unambiguous cost allocation criterion [9–12].

The criteria for defining Fuel and Product, and consequently the exergetic efficiency (ratio of Product to Fuel), have been extensively discussed in the literature and converge toward the general idea that the Fuel and Product of a component consist of the decreases and increases, respectively, in each form of exergy between the input and output of that component. This general criterion and the very few exceptions to it are discussed in detail in [11,12,40]. On the other hand, the *F* and *P* rules used to define the auxiliary equations are essentially based on the principle that every unit of exergy removed or added by the component has the same cost. Although consistent with the idea that exergy is the “carrier of value”, this principle is arbitrary and does not take into account the fact that exergy is the maximum work "ideally obtainable" from a mass or energy stream, which differs from the maximum work actually obtainable from such streams. In particular, the exergy destruction to Product ratio associated with real world processes, decreases as the temperature of the process decreases, more than what expected by theoretical thermodynamics. Accordingly, a unit of thermal exergy does not have the same "value" in reality as a unit of mechanical energy, so that units of thermal exergy at lower temperatures have less "value" than those at higher temperatures or, even more, units of mechanical work (Fig. 3).

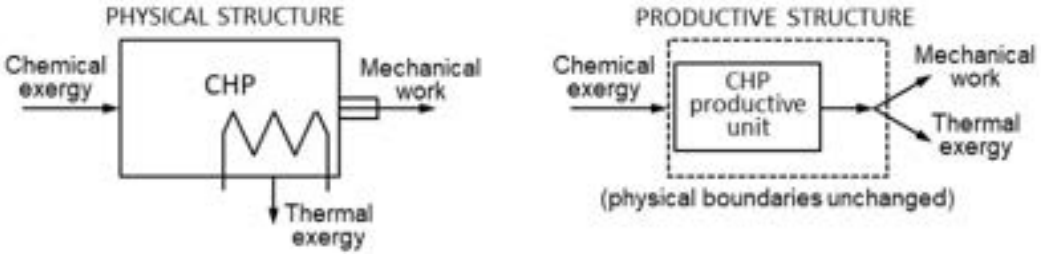

Figure 3. According to exergoeconomic accounting methodologies, a unit of thermal exergy at the outlet of a CHP engine has the same exergetic cost of a unit of mechanical work.

Moreover, this allocation criterion is normally applied at design conditions, whereas more reliable results could be obtained considering the hour by hour operation, throughout the year, as only few papers in the literature

highlighted [41,42]. On the other hand, other equally meaningful allocation criteria than the exergoeconomic one could be used for multi-product systems, as shown in [43,44].

2.2. Design improvement

As reported in the Introduction, the picture of the costs associated with the individual components employed in the procedure of design improvement [6,24] provides information for design improvement that does not allow to obtain the best design in a single iterative process. This is because the improvement in either the exergetic or exergoeconomic performance of one component does not necessarily result in a corresponding improvement for the overall system, since it may have a worsening influence on the exergoeconomic performance of the other components. In fact, there is a dependency link between the exergetic variables of the different components, and thus between the costs associated with them, since exergy values depend, to a greater or lesser extent, on the set of values of the independent design variable set (including temperatures, pressures, flow rates) on which the designer has the ability to act.

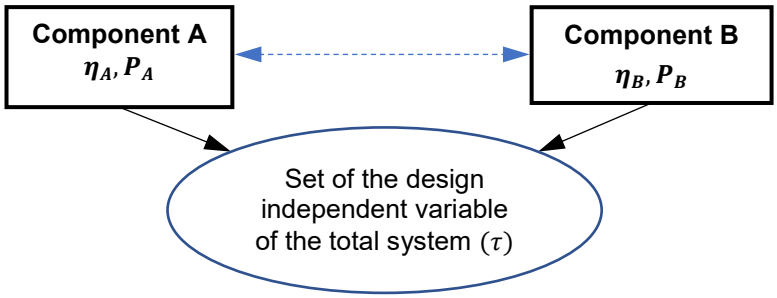

Figure 4. In general, the exergetic performance variables of different components (e.g., η_A, P_A and η_B, P_B) depend on the set of independent variables of the total system (τ), so that they depend on each other (dotted line).

Moreover, the need to guide the different iterations by the designer's "experience" limits the applicability to the more experienced designers in the exergoeconomic field. Furthermore, as already pointed out about cost accounting, the scope of these exergoeconomic procedures concerns the behavior of the plant under design point conditions only, because of the major complication that would result with an application under off-design operation.
However, these limitations do not negate the usefulness of exergoeconomic accounting and exergoeconomic design improvement procedures, but suggest a partially different use for them, as shown in Section 6 (Fig. 9).

3. Single or multi-objective design optimization of individual energy conversion systems

This section briefly describes why, starting in the late 1980s-early 1990s, the design of advanced energy conversion systems shifted from the iterative exergoeconomic design improvement described in Section 2 to the more efficient numerical optimization approach. At that time, the difficulty of setting up and executing design constrained optimization with the Lagrangian analytical method was overcome first with the development of efficient descent optimization algorithms and then with the new and more efficient genetic algorithms.

3.1. Single economic objective

The work of Lazzaretto and Macor [21] showed that, unlike the Lagrangian approach used up to that time for thermoeconomic design optimization, the search for the economic optimum can be separated from the cost calculation by first setting up and solving the following optimization problem, and then calculating the costs in the optimum.

$$\text{Find } \mathbf{x}^* \in \mathbb{R}^n \text{ that minimizes } f(\mathbf{x}) \tag{1}$$

$$\text{subject to } \begin{matrix} g_i(\mathbf{x})=0, & i=1,\ldots,p \\ k_j(\mathbf{x})\geq 0, & j=1,\ldots,q \end{matrix} \tag{2}$$

where $f(\mathbf{x})$ in Eq. (1) is the objective function, the equality and inequality constraints in Eqs (2) represent the energy system model including mass and energy balances of its components and the equations describing the properties of the working fluids, and $\mathbf{x}$ is the set of the design decision variables including pressures, temperature, mass flow rates and fluid properties.

The objective function $f(\mathbf{x})$ is the total cost flow rate ($\dot{C}_{total}(x)$) associated with the amortization of the investment and maintenance costs and of the costs for the fuel utilized by the system.

$$\dot{C}_{total} = \dot{C}_{fuel}(x) + \dot{C}_{inv+maint}(x) \quad (3)$$

3.2. Multi-objective optimization: energetic, economic, environmental

Multi-objective optimization techniques have been introduced into energy system design optimization since the end of 1990s-early 2000s, with the concomitant development of evolutionary algorithms. In particular, the paper [45] expands the perspective of traditional thermoeconomic optimization, by applying a multi-objective approach to evaluate the complete spectrum of solutions that satisfies both the economic and energetic objectives. In fact, a "pure" single-objective approach that considers only the economic objective or only the thermodynamic one is able to find one of the two extreme points on this spectrum of optimal solutions: the minimum of the cost objective function, or the maximum of the efficiency objective function. In [45] the Pareto approach is used to find the optimal set of design variables, since the concepts of Pareto dominance and optimality are straightforward tools for determining the best trade-off solutions between conflicting objectives. An evolutionary algorithm is then chosen to carry out the search for the Pareto optimal solution (Fig. 5) for the cogeneration gas turbine used in [46], since evolutionary optimization techniques were conceived to deal with a set of solutions (a "population") to pursue their task. Consequently, a multi-objective Pareto-based evolutionary algorithm is able to make the population converge to the entire set of optimal solutions in a single run.

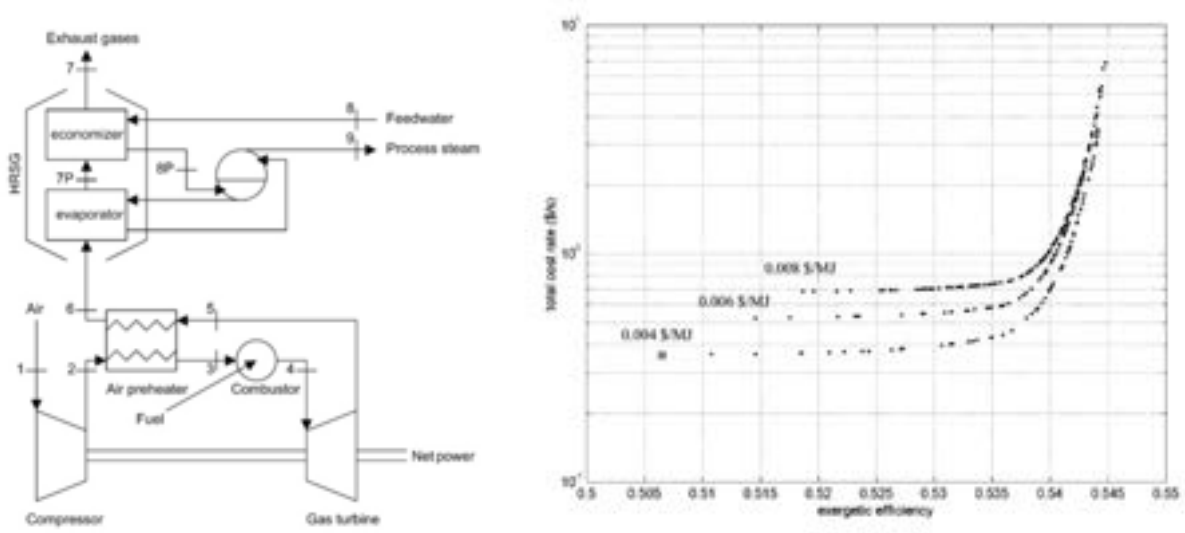

Figure 5. Pareto front (on the right) for different unit costs of fuel of a cogeneration gas turbine (on the left) [45] considering the total system cost rate ($/s) and the exergetic efficiency as objective functions.

The paper [47] shows how the design of the same cogeneration gas turbine in Fig. 5, as well as that of any thermal system, modifies if the optimization capabilities of the multi-objective approach are further exploited by adding an environmental objective function to the energetic and economic ones. The work compares and discusses the three-objective approach with a single-objective thermo-economic optimization and a two-objective energetic and economic optimization. In particular, the energetic, economic and environmental objective functions were defined as:

Energetic $$\varepsilon = \frac{\dot{W}_{NET} + \dot{m}_{steam}(e_9 - e_8)}{\dot{m}_{fuel} \cdot e_{9fuel}} \quad (4)$$

Economic $$\dot{C}_{total} = \dot{C}_{fuel} + \sum_i \dot{Z}_i \quad (5)$$

Environmental $$\dot{C}_{env} = c_{CO_2}\dot{m}_{CO_2} + c_{NO_x}\dot{m}_{NO_x} \quad (6)$$

The environmental one is expressed in terms of cost, weighting carbon dioxide and nitrogen oxide emissions according to their unit damage costs. Thus, a three dimensional spectrum of optimal solutions can be extracted from the space defined by the three objective functions by an evolutionary algorithm (Fig. 6).

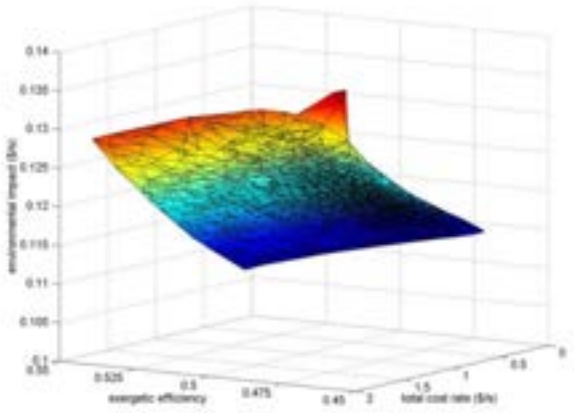

Figure 6. Optimal values of the three-objective functions (Pareto front) in Eqs (4), (5) and (6) [47].

The main novelty in that paper consists in considering the environmental impact no longer as a limitation to be met, according to legal regulations, but as an objective to be pursued. This paradigm shift, however, requires the correct formulation of the environmental objective function. Eq. (6) indicates that on the one hand it is necessary to consider local pollution related to toxic emissions, and on the other hand the impact on the atmosphere of elements that have a high global warming potential. In the design procedure this environmental goal is only partially independent from that of maximum efficiency, because achieving too high temperatures is environmentally pejorative. Of course, considering environmental impact as an objective instead of a constraint leads to a general rethinking of objective functions, as discussed below.

4. The need of proper objective functions for the whole society

The previous section showed how the design of energy conversion systems has naturally moved toward goals other than just maximum efficiency or maximum profit/cost. Indeed, the use of the design and operation of these systems have implications that go far beyond these goals. Thus, some questions naturally arise:

“Is efficiency the best energy goal? or is it instead absolute energy consumption? Are thermo-economic analyses sufficient, or should we better move toward thermo-X analysis? Which are the right environmental goals? Is decarbonization the best one? Is it sufficient to measure the environmental impact?”

As much as conversion technologies continually evolve over time, many of those involving the bulk of global consumption, and particularly those using fossil fuels, have reached levels close to the maximum achievable ones relative to unavoidable physical constraints (e.g., the Second Law of thermodynamics in case of thermal systems). Thus, it is reasonably not conceivable that further developments in technologies could contribute to efficiency gains for these systems that are relevant to the overall system. Moreover, the introduction of more efficient technologies often leads to the so-called “rebound effect” that, in turn, can offset, at least partially, the reduction in primary energy consumption associated with the efficiency gains [48]. On the other hand, it is certainly desirable that there be major increases in the efficiency of technologies based on renewable sources, but it is hardly conceivable that these can really become complete replacements for fossil fuels in a short period of time. Following the 2015 Paris Agreement on climate change mitigation actions adopted at the 21st Conference of the Parties [49], the legislations of the most technologically advanced states have evolved in the direction of promoting the development of renewable sources, and they have certainly been successful in terms of total installed capacity. However, the share of renewable energy consumption is struggling to grow significantly still remaining in the minority worldwide due to the concomitant increase in overall consumption together with the inherent low capacity factor of renewable sources (solar, wind, hydro in some cases). We can therefore state that,

"*From an energy perspective, the goal of efficiency should be considered concurrently with that of reducing overall consumption*."

Without this reduction, it will be difficult to achieve the increase in renewable share stated in the legislations, as, for instance, the European Green Deal [50], which aims at reaching carbon neutrality for European countries in 2050. Thus, the limitedness of the atmosphere and of every other natural element involved in energy generation (water, raw materials, ...) must necessarily direct us towards the search for new consumption patterns that reduce the overall energy consumption, which is the primary cause of changes in environmental balance.

The focus must then shift to the whole of society, no longer to the individual conversion plant, seeking the best interaction between different energy conversion and storage systems according to the objectives we want to pursue. Therefore, starting from the consideration that our society requires a complex multi-energy system and its associated energy distribution networks, we certainly cannot proceed only with a "plant-by-plant" optimization, and we must necessarily ask the following question:

"Which are the objectives of the society?"

Figure 7 shows a block scheme of the Italian energy system. The blocks included in the red-dotted box represent different types of energy conversion units, energy storage capacities and energy transport infrastructures. In the left side of the box, all categories of renewable and traditional energy sources are shown, while in the right side, all the energy demands. Each part of this very complex system can be modeled with the desired level of detail depending to the number and type (linear, bi-linear, non-linear) of the utilized equations. For example, it is possible to include many kinds of external constraints (e.g., the transportation limits imposed by the capacity of the energy networks). This flexibility allows build statewide models of design and operation that predict what the future system might look like, in relation to variations in boundary conditions that depend on human activities (demands, costs, legislation, ...) and more or less predictable changes in the availability of energy resources.

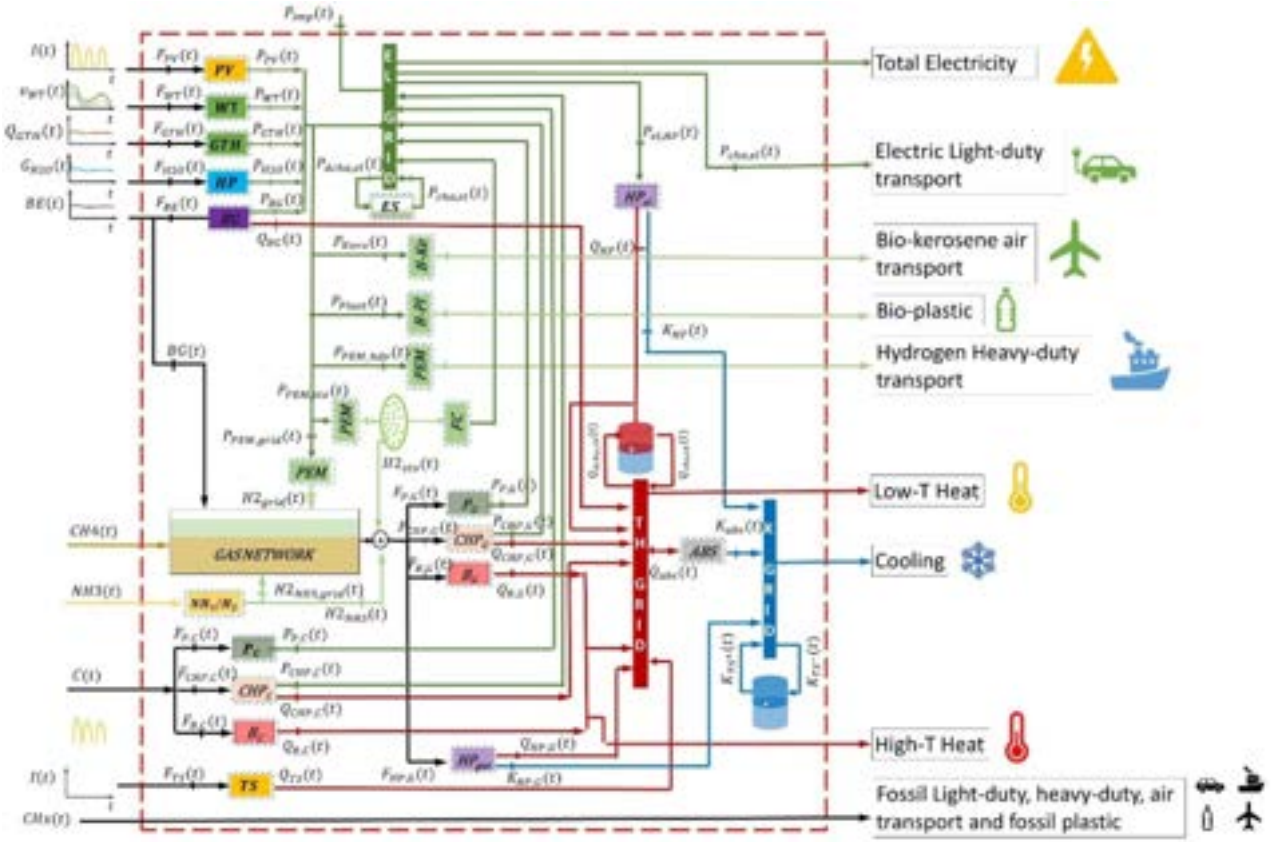

Figure 7. Superstructure of a multi-energy system representing the Italian energy system.

A representation like the one in Figure 7 could be made for any country, region, city, industrial or housing district in the world. However, certainly, this model would be very different from zone to zone. How might it look, for example, for a developing country? Again, some questions arise, which are not easy to answer:

"*What are the most sensible objective functions to consider for those systems that barely achieve survival conditions for the majority of the population?"*

"Are there universal goals toward which every state should converge?"

Certainly the goals must be enlarged, and thermo-economic or environomic analyses must also include other constraints than those strictly associated with the energy conversion (e.g., social and political ones) in addition

to the evolution of these constraints over time (dynamic optimization). Figure 8 shows shows the well-known seventeen goals of the United Nations [51] stated in 2015 as part of the 2030 Agenda for Sustainable Development. Those most directly related to energy conversion and consumption are the seventh (affordable and clean energy) and twelfth (responsible consumption and production). All the others are actually closely related to them because of any interaction with the environment and the socio-economic conditions of humanity. All 17 goals are well summarized, in the following three: **end poverty, protect the environment and ensure prosperity for all** [52]**.**

Figure 8. UN sustainable development goals [51].

The question is,

"*What can researchers, and particularly engineers, do to find realistic solutions to make the overall energy system as consistent as possible with these three general goals?*"

A certain and unambiguous answer is impossible, and would require investigating and establishing the meaning of "prosperity," and "poverty" in addition to knowing in a general sense what the best criteria are for truly defending the environment. What is certain is that some problems (poverty eradication) have a much higher priority than others, and this requires innovative models of intervention and development, which can also develop within market logic [53], and certainly a comprehensive global view of energy and environmental problems. On the other hand, it is equally certain that in every country, region, area of the World, there is the need to satisfy the current energy demands with an appropriate energy conversion system [54].

However, different countries have different "energy needs" and more or less urgent actions to undertake. We can measure prosperity with the Human Development Index [55], and increase this Index by increasing availability and consumption of energy of poor countries while keeping their already existing good equilibrium with environment. Conversely, to drastically reduce the environmental impact of "rich" (developed) countries, with high HDI but too high energy consumption, we must first rationalize the usage of energy to decrease the absolute value of primary energy consumption. This can be done by pushing low-consumption/low-environmental impact technologies. This necessity requires us to ask several questions, including:

"What does it mean to "waste" energy?" "How can the "minimum waste" goal (objective function) be defined?" Are there criteria for defining the minimum/proper energy needs of a human being regardless of location? What are the acceptable levels of consumption for the planet? "

Independently of the definition, the "waste objective function" must be minimized everywhere to meet the three general objectives mentioned above (end poverty, ensure prosperity for all, protect the environment).

Dealing with the *energy conversion process*, a *waste* can be defined as *the use of an excess of energy compared to the minimum required to fulfill a specified energy demand or to obtain a certain product*. All research in the field of energy conversion systems is, and has been, aimed at maximizing efficiency, which is equivalent to minimizing waste, defined in this way. However, this definition covers the energy conversion only, and does not consider the demand side, that is the way in which energy is consumed by the end users. Clearly, it has little effectiveness to seek waste reduction in energy conversion without seeking waste reduction in the use of energy itself. This issue obviously invokes the need to evaluate without conditioning or mistaken habits the ways in which energy is actually used, questioning the uses that are "not properly necessary" because they are overabundant compared to real needs. As such, they cannot be proposed to everybody, because

they would not be bearable by the ecosystem. Spreng [56] proposed a primary energy consumption target of 2000 W per capita ("*the 2000 W/capita society*") to be applied worldwide and that can be sustainable for both environment and society. However, this target is utopistic for the Author himself.

This article was written a few years ago, but this still open problem has subsequently been only much discussed but little addressed, thus greatly lengthening the energy transition towards a renewable system. The delay in becoming aware of the impossibility for the environment to bear an excessive consumption of energy (and consumer goods in general) now leads to the need to intervene "immediately" to avoid even catastrophic consequences [57]. However, this is not rationally possible due to the long installation times of the plants generating the huge renewable energy needed to replace all fossil energy, and requires first considering those interventions that have the best impact on the environment and society as a whole. Given the complexity of the problem, experts from the various disciplines involved propose different recipes, including the need to accept these catastrophic events, or to return to technologies already abandoned for safety and health reasons (nuclear) [58].

In the final analysis, it is a matter of considering the energy problem as a global problem involving all humanity, where the excessive consumption of some leads to energy shortages for others, and thus results, if nothing else, in a "lack of respect" toward them. Of course, these considerations cannot disregard the "models" of societies of individual countries. Many countries have acquired the so-called "western" model based on the search for GDP growth as the only criterion for increasing the individual's wealth, although often disregarding adequate wealth distribution criteria. Is this the way? Certainly, this approach has led to an enormous improvement in the well-being of many people, and of entire countries as a whole. However, at the same time, it can be certainly be improved to ensure a more equitable distribution of energy use and the benefits that come with it. Can "prosperity for all" be ensured by increasing GDP, regardless of appropriate distribution criteria and regardless of the fact that there are other cultural and developmental patterns of individual countries? Interesting ideas on this issue have been proposed and applied by a former president of Uruguay, Mujica (see for example his speech to the United Nations General Assembly on September 24, 2013 [59]). Moreover, some Authors proposed to integrate social science in energy research and energy policy (see, e.g., Sovacool et al. [60] and Spreng [61]). In any case, this issue must shift the attention of engineers to the "consumption" side, as highlighted in the following Section.

5. From engineering of "energy conversion" to engineering of "energy utilization"

Most of the discussion in Section 4 focused on the critical need to reduce overall energy consumption, while improving the efficiency of individual energy conversion systems, with an effort to achieve as much as possible the three general principles enunciated in that section: end poverty, ensure prosperity for all, and protect the environment."

Having established that the generation efficiency of individual energy conversion systems is generally very difficult to improve for most existing systems, attention must necessarily shift to what might be the most effective actions to reduce our society's total energy consumption. Below we try to list some of them:

- Actions aimed at better integrating individual conversion and storage units to take advantage of potential generation synergies between them, thereby optimizing the design and operation of multi-energy systems that supply energy to our society [62–64];
- Actions aimed at aggregating different local generation and demand loads of different energy users into "energy communities" to reduce demand peaks and thus the required power to be installed [65–67]. Consequently, also the efficiency of the plant and the environmental impact in the operation would be improved, as they it would work at more constant load.
- Actions aimed at more efficiently coupling the entire generation system with the entire "demand system" [54] to size and deploy each plant in the most efficient, least costly, and least impactful way for the entire generation-demand system.
- Actions and criteria aimed at reducing the absolute value of demand, such as through appropriate price- and incentive-based demand-response programs [68,69], or appropriate incentive policies, public awareness and education on proper energy use starting from elementary school training levels.

Actions to limit the maximum amounts of energy available for individual use should not be ruled out either, since it is quite inconceivable that a reduction in overall consumption (particularly, but not only, of fossil fuels) could take place without limitations on the consumption of individuals. However, it should be considered that these limitations on direct energy consumption (for individual use, as heating, cooling, etc.) would still not include all indirect energy consumption, associated with the purchase of goods (and even devices that use renewable energy but are not "strictly necessary," still involve energy consumption for construction and disposal of materials).

The list of actions listed can be summarized as the search for the best possible integration among the elements that make up a society's energy system, namely the energy conversion plants, the networks that distribute it, and the users who consume it. This integration requires a substantial paradigm shift in the overall design and

management of the energy system. The system based on individual production facilities for individual users must be replaced by a system designed to serve the whole society, and the whole society must constitute itself as a community of people who consume energy to improve (or maintain) a better living condition. The design of the system must therefore be unique and optimized for the common good. This vision, which is reasonably utopian, can nevertheless be a reference to be pursued. Actions concerning aggregations of users into energy communities certainly go in this direction.

We stress the importance of aggregation as a key element for a prosperous future of society. In this regard, actions should start from local communities with the support of politicians. Local governments should rank different utilities (i.e., energy users acting as consumers or prosumers) to identify those with the greatest synergies and coupling possibilities. The energy “demand system” could then consists of the aggregation of these local communities, rather than being composed of individual utilities, with the ultimate goal of achieving an overall energy demand curve that is more consistent with the total renewable availability curve, and at the same time, leading to a net reduction of the total consumption. This would have the added benefit of reducing the need for energy storage, resulting in lower costs for the system as a whole. The search for mechanisms ensuring a fair distribution of benefits from user aggregations, as well as a fair distribution of costs associated with the installation of new renewable plants among those who benefit from them, must therefore become a central theme of research in the field of energy conversion systems. Efforts in this direction have been already the subject of several research [66,67], and may also benefit from allocation criteria based also on exergoeconomics analysis [44]. It is natural to think that every place in the world is different in habits, religions, customs, but every place can benefit from aggregation and interaction, while respecting and recognizing individual specificities. Energy policies must therefore seek universal means of aggregation, such as the identification of the most suitable energy users that could participate into energy communities, fair criteria for the distribution of profits resulting from aggregation, and compensation mechanisms for those who may suffer damages as a result of aggregation itself, or for those who may not be able to fulfill their commitments due to force majeure (e.g., illness).

6. The dynamic optimization model of the society or of its portions

The need for an integrated design and management of the whole energy system, including generation and storage plants, energy distribution networks and users (with different habits and customs), requires the development of tools that allow modelling this complex system in its totality by considering in it all variables involved, and especially those on which actors from different disciplines (i.e., engineering, economics, sociology, philosophy, politics) can intervene. The models should take into account contextually, on one hand, all the laws of physics, thermodynamics, and chemistry that govern the energy processes and, on the other hand, the design and operational constraints related to the above-mentioned disciplines, and the laws of the countries in which the energy systems operate. Eventually, these models represent the society in its entirety because of their capability to describe the relationship between energy problems and society [70].

Given the potentially huge size of the optimization problem, the degree of detail of the models will necessarily have to decrease as the size of the geographical area under consideration increases. Thus, if the size is that of an entire country or region, plants of the same type may be aggregated into categories, users may be aggregated by types (e.g., low-temperature thermal, high-temperature thermal, electric), and networks may be considered by common characteristics (e.g., high, medium, and low-pressure gas network, or high-, medium-, low-voltage electric networks). Conversely, if the size of the geographic area is narrower, such as housing or industrial districts, all individual energy systems (i.e., energy conversion and storage units) and interconnections (i.e., electric, thermal and gas grids) can be modeled precisely, without approximations. For municipal governments, the boundaries of analysis could be whole municipalities or parts of them, in which it will be possible to model in detail not only the associated plants and distribution networks with each specific existing constraint, but also the utilities, proposing aggregation mechanisms to create benefits for both individual members and the community.

In such a complex reality, it is certainly useful for the individual (or entity, company,..) to decide on the "energy interventions" that are most convenient locally, but it is difficult to think that these local interventions can always be consistent with the search for the overall optimum of the society in which they are implemented.

Thus, there is a clear need to operate both locally and globally, so that local interventions are consistent with those of a global nature, i.e., relating to the region-state, or in general to the overall context/society in which they are carried out.

This coherence highlights the pressing need to start from global models, which give the general guidelines for appropriate energy policies, within which local interventions fit.

Several questions can be asked here as well:

What kind of structure, equations, variables, and what kind of evaluations can this model perform? Is it possible to build models that include all the variables involved without becoming overly complex and such that they

require excessive computational time, preventing their simple use, and such that the benefits that can be achieved at the overall level can be immediately assessed? What are the objectives in using these models and what is the actual utility of the evaluations produced?

Below an attempt to answer:

- The overall model must certainly include sub-models that are capable of evaluating the behavior of all the conversion and storage systems included in them, both under design and off-design conditions. These sub-models include mass and energy balances of these components and the chemical and physical properties of the fluids involved, and should be included in databases that can be used by the overall model.

- The model arranges these sub-models so that the individual conversion and storage units can be aggregated not only with each other but with the distribution networks in order to form the model of the overall system;

- The model must include time series of users' energy demands, evaluated on a deterministic or stochastic basis when necessary. The model must also be capable of "managing" these demands according to utility aggregation criteria [71] and demand-response programs [72].

- The overall model is part of an optimization problem that must be solved by an algorithm capable of considering different sets of decision variables.

- The model must consider also all constraints other than energy-technology constraints, i.e. those associated with the economic environment (investment costs, costs and prices of different forms of energy and their variability over time,..) and the natural and regulatory environment (limitations on emissions, incentives,..) as well as arising from social issues (acceptability and acceptance and consequent time for installation, use of labor, working conditions, etc....).

- Goals (objective function(s)) should be clearly established (Section 4) and properly expressed in mathematical terms.

Figure 9 shows the conceptual scheme of a computational platform capable of building an energy system model that includes the above-mentioned features.

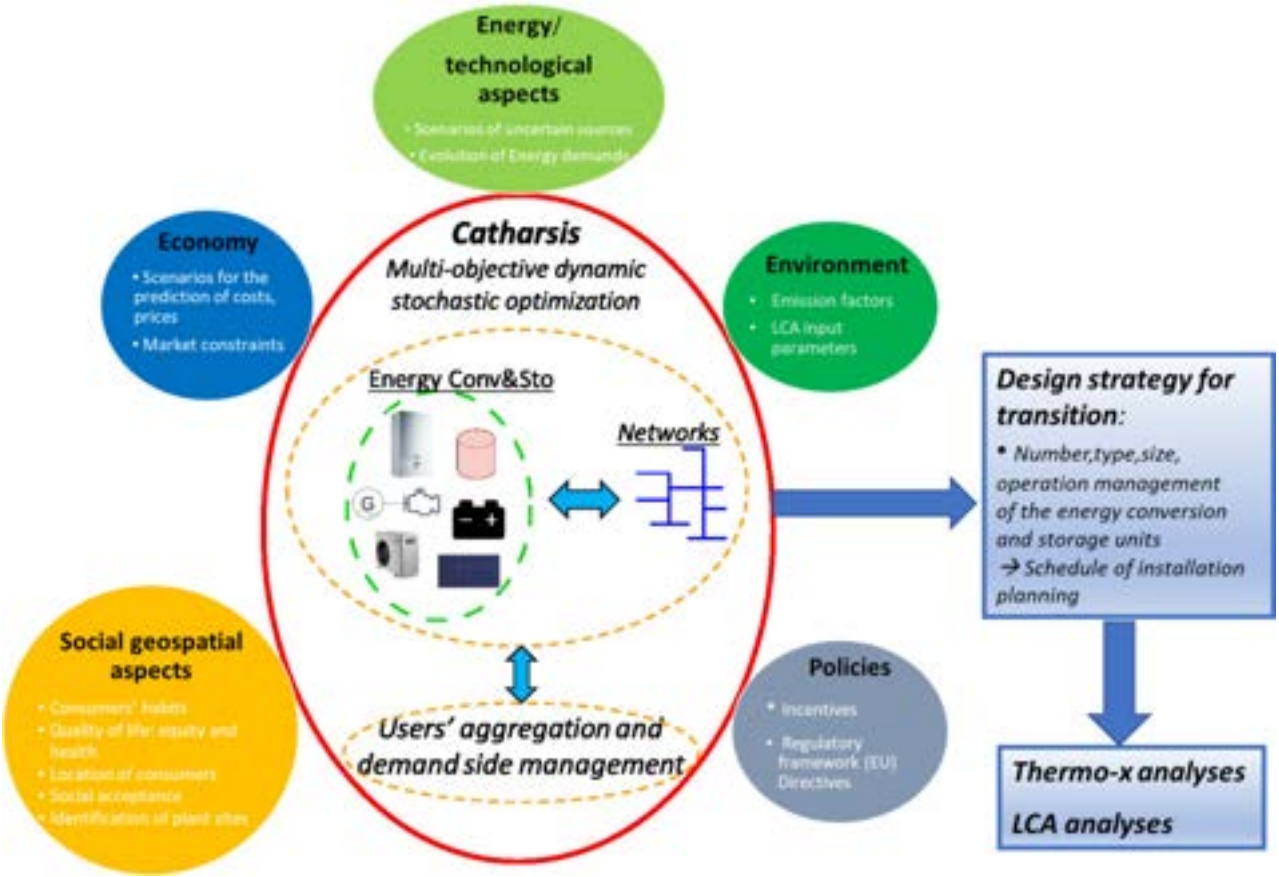

Figure 9. Calculation platform to evaluate the schedule of installation planning of new energy conversion/storage systems and network in the future.

The platform builds the model of the considered system from a superstructure (red part in the center) containing (in a database) all available conversion and storage units in the considered geographical area. The platform chooses the optimal number, type, and size of these units and builds the network to connect them together and distribute power to users according to the optimal value (minimum or maximum) of one or more target functions.. The same central part (red) of the superstructure includes the optimization procedure driven by an appropriate algorithm capable of evaluating the objective function for each set of values of the system's independent/decision variables. The construction of the model requires setting all constraints arising not only from the technological-energy limitations of individual conversion and storage facilities, but also economic (investment costs, costs and prices of energy consumed and sold,...), environmental (limitations on emissions, materials to be used...), social (acceptability of renewable and fossil fuel based plants, occupation of areas intended for other uses,...), political-legislative (restrictions imposed by legislation, incentives, taxes,...) constraints. The nature of the model is dynamic, since all variables involved are time-dependent. As highlighted in Section 4, this feature is crucial given the need to shape the energy system of the future, especially in the "energy transition", by progressively choosing the energy conversion units that best fit to a specific location at a specific time. The model has a Mixed-Integer Linear Programming formulation, where integer variables are used to decide the inclusion or exclusion of conversion and storage units in design problems, and their activation or deactivation in operation problems. General features of the models have been presented in [73,74]. The last stage of development of the platform [75] concerns the contextual search for the optimal configuration of the energy generation and storage system and the configuration of the networks that distribute the energy produced. This comprehensive view of the system can also include utility management, through organization into energy communities or membership in demand-response programs. Once the optimal configuration and design variables of the generation/accumulation units and energy networks are defined, a final thermoeconomic/environmental or life-cycle assessment of the overall system is performed to obtain a complete picture of its performance and environmental compatibility (bottom right in Fig. 9). In this way, the platform stands as an essential tool for designing and managing the energy system, from generation to demand for the portion of "society" under consideration.

7. Conclusions

This paper is an attempt to trace in a simple way the extraordinary evolution in the research on energy conversion systems that has taken place in recent years. In particular, the purpose was to see how thermoeconomic analyses have played a pioneering role in expanding energy-only analyses toward the whole set of disciplines that are necessarily involved in the design and use of an energy system, starting with economics. The initial focus on increasing the exergetic efficiency of large fossil fuel plants that supplied almost all of the energy for end uses necessarily shifted to the simultaneous search for the best trade-off between this increase and cost reduction, taking into account all the environmental issues involved in the conversion and use of the energy generated. It is precisely this necessary consideration of the "environment," understood not only as “nature” but also as "humanity" inhabiting the world, that has shifted the focus from the individual plant to larger geographic portions in which there are different individuals with different energy needs. These portions of the universe, and ultimately the whole world, require that we design the overall energy system of the future in the most sustainable way possible, to give future generations the same or even better opportunities for consumption and well-being as existing ones. To this end, the work of the energy engineer must not be concerned with the individual plant but with all the plants included in the geographical portion under consideration and the distribution networks to users, integrating closely with that of all the actors involved in the design of the society of the future. Thus, the paper shows that other types of "X" analysis should be added to exergoeconomic analyses to include all aspects involved in energy use, with the ultimate goal of reducing overall consumption and distributing it more evenly around the world as the only means of achieving a truly sustainable system. In this direction, the paper also demonstrates the importance of forecasting models that are capable of predicting and optimizing the design and operation of the energy system of the future by considering the real physical processes involved along with all the external constraints, while maintaining a simple structure. This feature allows useful and realistic results to be obtained quickly and in a way that is easily understood even by non-"insiders." The ambition is for these models to become commonly used, especially in public administrations and private companies, to build an overall system that is as consistent as possible with the sustainability needs of society as a whole.

Nomenclature

c	cost per monetary unit (*$/kJ*)
$\dot{C}$	total cost flow rate (*$/s*)
CHP	Combined Heat and Power
e	specific exergy (*kJ/kg*)
$\dot{E}$	exergy flow rate (*kJ/s*)
$\dot{m}$	mass flow rate (*kg/s*)

$MINLP$ Mixed-Integer Non-Linear Programming

$\dot{W}$ mechanical power (*kW*)

$\dot{Z}$ amortization cost flow rate (*$/s*)

ε energetic efficiency

η exergetic efficiency

Subscripts and superscripts

$e, 2$ exit

F related to a fuel stream

$i, 1$ inlet

k related to k-th component

P related to a product stream

q heat

w work

On the Future of Exergy-based Methods

George Tsatsaronis

Chair of Energy Engineering and Environmental Protection
Technische Universität Berlin, Berlin, Germany
georgios.tsatsaronis@tu-berlin.de

Abstract:

In 1984 the author coined the term *exergoeconomics* to replace the term *thermoeconomics* when *exergy costing* is used in the combination of an exergetic analysis with a cost analysis and to emphasize the role of exergy in the efforts to reduce the product cost. He also developed a general exergoeconomic methodology based on appropriate definitions of the "product" and "fuel" for each component of an energy conversion system and on exergy-based variables. These definitions and the application of exergoeconomics were generalized by A. Lazzaretto and the author in 2006 in an approach based on specific costs (*SPECO approach*).

Mayer and the author coined in 2009 the term exergoenvironmental analysis for a combination of an exergy analysis with a life-cycle analysis when exergy is used to assign environmental impacts to streams. An exergoenvironmental analysis uses the methodological background of the above exergoeconomic methods.

Starting in 2002, the author and later, in cooperation with T. Morosuk and co-workers at TU Berlin, developed the advanced exergy-based methods, which are based on the notion that the inefficiencies (exergy destruction and exergy loss), the costs, and the environmental impacts can be split into avoidable/unavoidable and endogenous/exogenous parts, to improve understanding of the formation process of inefficiencies, costs and environmental impacts within an energy conversion system, to reduce the limitations of the conventional exergy-based methods, and to facilitate system optimization.

As often happens, after their introduction, all the above terms and methods have been misused and misinterpreted by some other authors.

This paper very briefly reviews past contributions by the author and some other exergy practitioners and discusses future developments.

The exergy-based methods allow for a comprehensive and consistent simultaneous evaluation of the performance of an energy conversion system from the thermodynamic, economic, and environmental viewpoints. However, the advanced exergy-based methods need further investigations to be generalized, integrated and to reduce their subjectivity as well as the efforts and time required for their application. Development of appropriate software and short-cut methods will facilitate their use by researchers and engineers in industry and the applications of exergy-based methods in energy-intensive industrial processes for multiobjective optimization purposes.

Keywords:
Thermoeconomics; Exergoeconomics; Exergoenvironmental analysis; Advanced exergy-based methods; Optimization of energy systems.

1. Introduction

In the analysis, evaluation and optimization of energy-conversion systems (ECS), progress has been made every time the limitations of an existing method have been identified and solutions for overcoming at least some of these limitations have been developed. Thus, after realizing that an energy-based method can lead to misleading results and conclusions, the exergetic analysis, which combines the concepts of energy and entropy, was adopted as the appropriate method for analyzing and evaluating ECS from the thermodynamic viewpoint. All alternative terms used to characterize an exergetic analysis (e.g., the term "second-law analysis") are not accurate, because this analysis combines the second *and* the first laws of Thermodynamics.

An exergetic analysis identifies the location, magnitude and causes of inefficiencies within an ECS. The inefficiencies are measured in terms of exergy destruction and exergy loss [1]. Based on the results received by an exergetic analysis, changes in the design and operation of an ECS can be identified to improve its exergetic efficiency, which is the best variable for evaluating the thermodynamic performance of an ECS. An exergetic analysis can be applied also to very complex systems and is the most effective method for evaluating and improving the thermodynamic performance of a system. Various variables can be used to measure the performance of an ECS (for example, thermodynamic efficiency, cost of product(s), environmental impact, rate of return on investment, and payback time). An exergy-based method should be able to consider all of these measures of performance. Finally, an exergetic analysis can stimulate and guide creativity and innovation [2].

In order to predict future developments, we must first understand and evaluate what has happened up to now. Therefore, the following two sections refer to past contributions to the exergy-based methods by the author and his co-workers as well as by other authors, before in section 4 the needs for future developments are discussed. It is important to keep in mind that all analyses of an ECS should consider the entire life time of the system.

This is a brief review paper. Because of space limitations no equations to describe the methods are given. The equations are available in the literature cited for each method. Also the mathematical cost minimization methods developed for an ECS are not discussed here (even the ones using exergy) because in these methods (a) we need to know the investment costs of components as functions of thermodynamic variables and such information is not readily available, and (b) we cannot include in the optimization considerations related to safety, maintainability, and operability of the plant, considerations that could be easier incorporated into an iterative improvement approach, such as the approaches discussed here.

2. Contributions by the author and his co-workers: From exergetic analysis to the advanced exergy-based methods

An exergetic analysis assists in the *thermodynamic* optimization of an ECS. In real-world applications, however, realization of the thermodynamic optimum would result in very high investment and product costs. Therefore, we are interested in a solution that minimizes the product cost and not in a solution that maximizes efficiency. Thus, an economic analysis must be considered in parallel and in addition to the exergetic one. From a combination of the two analyses, we obtain the maximum useful information, when both following conditions are fulfilled: (a) the two methods are combined using the exergy-costing principle [1], and (b) the analysis is conducted at the system component or a lower level. The term *thermoeconomics* was initially used for this combination (e.g., [3]). However, after noticing that the term “thermoeconomic analysis” was used also in publications that were not employing the exergy-costing principle, which is essential here, the author introduced in 1984 the term *exergoeconomics* (or *exergoeconomic analysis*) to more accurately characterize this combination, to emphasize the role of exergy in cost minimization, and to clearly distinguish the different approaches [4]. In the same publication, the terms *fuel* and *product* were generalized, the variables *cost per unit of exergy for fuel and product*, *cost difference* (which later was replaced by the *relative cost difference*) and *exergoeconomic factor* were introduced, and the formulation of the exergy balances and cost balances was generalized. These generalizations allowed later a consistent evaluation of the thermodynamic, economic, and environmental performance of an ECS. For a long time the terms thermoeconomics and exergoeconomics were used in parallel as synonyms by the author (e.g., [1]). Unfortunately the term exergoeconomics has been used in the past by some other authors in cases where only an exergetic analysis and an economic one were conducted without using the exergy costing principle and without using an appropriate combination of the two analyses, thus contributing to a certain confusion surrounding the meaning and use of these terms.

Purpose plays a central role in exergy-based analyses, where a *product* is defined unambiguously for every system component and process according to its purpose [4-8]. The ratio between *product* and *fuel* is the exergetic efficiency of the thermodynamic system being considered. An exergetic analysis provides the most rigorous definition of thermodynamic efficiency and the foundation for assigning costs (in an exergoeconomic analysis, e.g., [1, 4-9]) and environmental impacts (in an exergoenvironmental analysis [10,11]) to energy carriers. The definitions of exergetic efficiency have been generalized in the SPECO method [9].

The continuously increasing interest in environmental considerations in the last decades led to the development of the exergoenvironmental analysis, which identifies the location, magnitude and causes of environmental impacts associated with an ECS [10-12]. Thus, using an appropriate definition for *product* and *fuel* for each component of an ECS [9], engineers obtain *consistent*, informative, and powerful analyses and evaluations from the viewpoints of thermodynamics, economics and envirnmental impact.

A conventional exergy-based method, however, does not assess (a) the parts of exergy destruction, cost and environmental impact that can be realistically avoided in a component or a process (by increasing the capital investment), and (b) the interactions among components with respect to exergy destruction, cost and environmental impact. These drawbacks of a conventional analysis are corrected in the *advanced exergy-based methods* (AEBM) (see, for example, [13-19]). By considering the avoidable/unavoidable values, the endogenous/exogenous values and their combinations (endogenous avoidable, exogenous avoidable, etc.) and by applying these concepts to the exergetic, exergoeconomic, and exergoenvironmental analyses, we obtain the most comprehensive set of analyses and evaluations of an ECS available today.

When dealing with exergy streams carrying a significant amount of *useful* chemical exergy, a distinction in the costs and environmental impacts associated with chemical and physical exergy might be meaningful. In addition, the chemical exergy should sometimes be split into reactive and non-reactive exergy [1] (e.g., in a gasification or chemical process), and the physical exergy, into thermal and mechanical exergy [20] (e.g., in a refrigeration process) to enable the definition of meaningful efficiencies, to improve the accuracy of calculations, to make fairer the calculation of costs and environmental impacts, and to improve the quality of conclusions drawn from the results of applications of exergy-based methods to an ECS.

Recently R. Castillo developed the *thermodynamic cost accounting* (TCA) approach, a novel exergy-based approach to determine the cost formation process and the formation of environmental impacts within an ECS [21]. Compared to the approaches discussed above, this approach emphasizes the boundaries to the overall system (instead of the component level), takes a different approach to the interactions among components, extracts useful conclusions from the Castillo Paz diagram, and clearly reveals the importance of recirculating streams to the thermodynamic, economic, and environmental performances (see, for example, the application of the TCA to the CGAM problem [7, 21]).

3. Contributions by other authors

Based on the ratio between the cost per unit of exergy of a stream and the cost per unit of exergy of fuel to the overall ECS when only fuel costs (but no investment or operation and maintenance costs) are considered (cases the author studied, for example, in [6] and [22]), the Zaragoza group under the leadership of Antonio Valero developed the *exergetic cost theory* (ECT) [7, 23-24], which calculates the amount of exergy needed to provide each exergy stream in an ECS. The contributions of ECT complement the ones by the author and his co-workers. The group from Zaragoza also developed a method for the *diagnosis of malfunctions and disfunctions* around the operating point of an ECS [25-26].

The approach of *cumulative exergy consumption* (CEC) considers all thermodynamic inefficiencies that occur in the entire chain between the point where all natural resources used in the process are obtained from the natural environment to the point where the final product is generated [27]. This approach extends the system boundaries of the thermodynamic analysis to include all processes that previously were used to provide the feeds to the process under investigation. CEC accounts for how the inefficiencies of the process being analyzed affect the inefficiencies of the processes that provide the feeds, and vice versa. This information is used in calculating environmental impacts associated with the process that is being considered.

The *extended exergy accounting* (EEA) method is also based on the calculation of the cumulative exergy consumption, but takes into consideration additional aspects such as the exergy associated with capital (investment costs) and human activity (labor) [28-29]. The *extended cumulative exergy consumption* associated with the investigated system is minimized.

Environomics, *thermoecology*,and *exergoenvironmental analysis* deal with the reduction of the environmental impact. [30-37]. When more than one pollutant (e.g., CO2, CO, NOx, SO2, and solid particles) are considered in the analysis, the question arises how to compare (to establish the equivalence of) 1 kg of one pollutant with 1 kg of another. A common currency is needed here: In *environomics* [30, 31], monetary values (costs) are assigned to the environmental impact associated with each pollutant, then an exergoeconomic model is extended to include the costs of pollutants, and finally a cost minimization problem is solved. In *thermoecology* [32], or *exergoecology* [33], the depletion of non-renewable natural resources and the effects of pollutants are expressed in exergy terms. The resulting thermoecological (or exergoecological) cost (expressed in exergy units) is based on the cumulative consumption of non-renewable exergy, and includes the cost associated with the rejection of harmful substances to the natural environment. In the *exergoenvironmental analysis* [10-12, 34, 35], a one-dimensional characterization indicator is obtained using a *life cycle assessment* (LCA); this indicator is used in the *exergoenvironmental analysis* in a similar way as the cost is used in *exergoeconomics*.

An index (a single number), for example, the Eco-indicator 99 describes the overall environmental impact associated with each exergy carrier and with the manufacturing of each system component.

4. Future developments

Before discussing any future development we must point out that all methods mentioned in sections 2 and 3 have not yet received the same acceptance and reception by the scientific, engineering, and political communities as other methods, for example the pinch method and the method of LCA. The reasons for this lie probably in the facts that (a) exergy, not being introduced and discussed properly or sufficiently in engineering curricula, remains a variable and a concept that is not understood and used easily, and (b) the extraction of useful information from an exergy-based method requires good understanding of the limitations of the method being used and critical thinking, contrary to other more popular methods that can be applied as "recipes". Finally, the disagreements among the exergy practitioners, the plethora of available approaches, the misinterpretations and misuses of these methods certainly have not contributed to their wider acceptance. In 2007 the author coordinated the responses received from several exergy practitioners in an effort to standardize the definitions and nomenclature in exergy-based methods [36]. The applications that followed showed a very limited success of this effort.

One development is certain for the future: The number of cases in which exergy-based methods could be applied will be lower because more electricity will be generated using direct energy conversion, for example, photovoltaics, wind energy, and hydropower, and more electricity will be used in the sectors of transportation, industry, and buildings in every future year. Thus, the exergy-based methods, which show their strength and are more useful when thermal energy is involved, will follow the decline in relative importance we have experienced for thermodynamics and thermal sciences in the engineering curricula in the last years.

The diversity of the methods mentioned in sections 2 and 3 indicates that there is not a single generally accepted method for evaluating the design and the performance of an ECS. All methods have weak points: For example, the *advanced exergy-based methods* often use some subjective estimates, *the exergetic cost theory* does not explicitly consider the investment cost, the assignment of costs to environmental impacts in *environomics* is more or less arbitrary, as is the conversion of monetary values (e.g., capital investment and salaries) and environmental impact into exergy values in the *extended exergy accounting method*. In addition, it is very time consuming to apply most of the above methods. All these weak points reduce the usefulness of the corresponding methods. In the future we should expect developments that will reduce the weak points associated with each approach.

It should be emphasized that the evaluation of costs, which will incur in the future, and of environmental impacts will always be somehow subjective and associated with limitations because of the uncertainties involved in their estimation. However, even the imperfect information extracted from an exergoeconomic or an exergoenvironmental analysis is always useful for reducing the costs and the environmental impacts associated with an ECS.

The *advanced exergy-based methods* are expected to be further developed in the future, so that their subjectivity and the time required for their application will be reduced. Through applications to different ECS, we should expect a higher degree of method generalization and the development of short-cuts to reduce the time required for their application. Also the development of new software specialized in the application of these methods will facilitate application of the methods to many different energy-intensive processes. Because environmental considerations will become more important on future applications, a further integration of these methods (see, e.g., [37, 38]) will enable a fast and consistent multiobjective optimization of an ECS, for example an optimization (improvement procedure) that will simultaneously consider costs and environmental impacts in the optimization to reveal actions that could decrease the cost(s) of the overall product(s), while, at the same time, enhancing the efficiency, and decreasing the environmental impact of the ECS being evaluated. Finally, decision making procedures referring to an ECS will be further improved through applications of advanced exergy-based methods.

5. Conclusions

Various methods have been developed using exergy for the evaluation and improvement of an ECS from the viewpoints of thermodynamics, economics and ecology. Brief reviews of the methods show that all of them have some limitations while focusing on specific aspects of the ECS being considered. The *advanced exergy-based methods* provide the most comprehensive and powerful set of methods available today for evaluating

and improving an ECS. All these methods have not yet received from the industry and politicians the recognition they deserve as tools for decision making.

Future work is expected to include the reduction of the limitations associated with each method, a generalization and integration of the methods and the development of appropriate software and short-cut approaches to reduce the time required for the applications.

Abstract:

Research on carbon capture is increasing interest due to its impact in the search of net-zero carbon economy. In this sense, amine solutions play an important role in the post-combustion CO_2 capture, using them as chemical absorbents. There are different amines or mixed amines that are studied to substitute MEA, which is the best well-known despite some drawbacks such as its high energy demand or its low potential of CO_2 absorption. On the other hand, key properties such as density, viscosity or heat capacity are necessary for the design and optimization of the separation plant; the accuracy of the calculations is directly related to the accuracy of the properties. In this work, these properties, which were determined by means of experimental techniques of low uncertainty, are presented and compared for three tertiary amines: Triethanolamine (TEA), N-Methyldiethanolamine (MDEA) and 2-Dimethylaminoethanol (DMAE). Densities were measured using a commercial vibrating tube densimeter that was completed with different devices allowing the determination of density with a standard uncertainty of 0.35 kg/m^3. A falling body viscometer was used for viscosity measurements with a standard uncertainty of 1.6%. Finally, a flow calorimeter, developed in our laboratory, measured isobaric heat capacities with a standard uncertainty of 0.5%. The comparison is done in a temperature range from 293.15 K to 353.15 K and pressures up to 25 MPa. In addition, different mass fractions of amine in the mixture (amine +water) are studied (w_{amine} = 0.1 to 0.4).

Keywords:

Density; Viscosity; Heat capacity; 2-Dimethylaminoethanol (DMAE); N-Methyldiethanolamine (MDEA); Triethanolamine (TEA).

1. Introduction

The objective of a net-zero carbon economy is fostering the research on carbon capture as a measure to promote the energy transition. In this context, alkanolamine solutions play an important role as chemical absorbents for CO_2 capture in the post-combustion. Although this technology is industrially mature, there are some key points to address to reduce the associated cost such as the search for solvents with less energy requirements, better stability, and less harmful emissions, in addition to the process optimization, and integration with the CO_2-emitting plant [1].

There are different amines or mixed amines that are studied to substitute MEA, which is the best well-known despite some drawbacks such as its high energy demand or its low potential of CO_2 absorption. However, the design and optimization of the separation plant require the knowledge of key properties such as density, viscosity or heat capacity of these new potential absorbents. Moreover, the accuracy of the calculations is directly related to the accuracy of the properties.

Our research group has been involved during the last decade in the accurate measurement of these properties as can be seen in previous papers. Density and viscosity of different aqueous solutions of alkanolamines were already measured at wide ranges of temperature and pressure: Ethanolamine (MEA) and N-Methyldiethanolamine (MDEA) in [2]; Diethanolamine (DEA), Triethanolamine (TEA) and 2-Dimethylaminoethanol (DMAE) in [3]; Piperazine (PZ) in [4] and blended amines (PZ+ DMAE) in [4] and (MDEA+DEA) in [5]. Heat capacities of 30% weight of amine up to 25 MPa for aqueous solutions of MEA, DEA and TEA were presented in [6], and heat capacities of aqueous solutions of six different amines are reported in [7].

In this work, a comparison of the behaviour of the three tertiary amines: Triethanolamine (TEA), N-Methyldiethanolamine (MDEA) and 2-Dimethylaminoethanol (DMAE) in terms of density, viscosity and heat capacity is presented and discussed. The comparison is done in a temperature range from 293.15 K to 353.15 K and pressures up to 25 MPa. In addition, different mass fractions of amine in the mixture (amine +water) are studied (w_{amine} = 0.1 to 0.4).

2. Experimental section

2.1. Materials

The materials used in the measurements were purchased from Sigma-Aldrich of the highest purity available and used without further purification. Their purities in mass fraction (as stated by the supplier) were: Triethanolamine (TEA) ≥ 0.99, N-Methyldiethanolamine (MDEA) ≥ 0.99, and 2-Dimethylaminoethanol (DMAE) ≥ 0.995.

A precision balance (RADWAG PS750/C/2) was used to make the mixtures by weighting, estimating an expanded uncertainty (k=2) of 0.0002 in mass fraction.

2.2. Equipment

Three accurate techniques are used to perform the measurements: densities are determined using a commercial vibrating tube densimeter, viscosities by means of a falling body viscometer and heat capacities using a flow calorimeter. All the techniques are calibrated and checked regularly. A brief description of the main features of these techniques is explained below.

An Anton Paar DMA HPM densimeter is employed to carry out the density measurements, the technique is completed with an automatization system in such a way that, through the computer program, ramps of pressures and temperatures can be programmed, and the frequency measurements are recorded for the sample. The technique can measure density in a temperature range from 240 K to 420 K and up to 140 MPa with a relative standard uncertainty of 0.35 kg/m^3. Details of the technique and the uncertainty budget are published in [8].

Density, ρ, of a fluid is related to the vibration period, τ, through (1):

$$\rho(T,p) = A(T)\tau^2(T,p) - B(T,p) \quad (1)$$

where $A(T)$ and $B(T,p)$ are two characteristic parameters of the apparatus which can be determined by a calibration procedure, in this case, water and vacuum were used for calibration.

Viscosity measurements are undertaken in a falling body viscometer whose principle of measure is based on the fall time of a body in a vertical tube filled with the sample [3,9]. The apparatus can perform measurements between 240 K to 475 K and up to 140 MPa, with a relative expanded uncertainty (k = 2) of 3%.

The model used for this viscometer is given by (2):

$$\eta = a + b\Delta\rho\Delta t \quad (2)$$

Where viscosity (η) is related to fall time (Δt) and the difference of density between the falling body and the liquid ($\Delta\rho$) and the parameters a and b are obtained by calibration using water and dodecane.

Finally, an automated flow calorimeter, fully developed in our laboratory, is used for isobaric heat capacity measurements. Its working principle lies in balancing the heating and cooling power of the calorimetric cell to maintain a fixed difference between the inlet and exit temperatures of the circulating fluid. at constant flow rate and, heat capacity is calculated by the determination of the net power exchanged.

The value of net power ($\dot{Q}_{net}$) is directly related to the isobaric heat capacity as shown in equation (3):

$$C_p = \dot{Q}_{net}/(\dot{V} \times \rho \times \Delta T) = \left[a + b\left(\dot{Q}_{base} - \dot{Q}_{measured}\right)\right]/(\dot{V} \times \rho \times \Delta T) \quad (3)$$

where $\dot{V}$ is the volumetric flow of the fluid, ρ is the density of the fluid at the pump temperature, ΔT is the temperature decrease and, a and b are the calibration constants calculated by an electric calibration. The relative expanded uncertainty of the heat capacity obtained with this technique is 1%. This equipment works in the temperature range from 240 K to 420 K and up to 25 MPa, the details are described in [6,10].

3. Results and discussion

This work is focus on the thermophysical behaviour of aqueous solutions of three ternary amines (TEA, MDEA, DMAE), based on the experimental data of densities, viscosities, and isobaric heat capacities. These properties will be compared in the range of temperatures from 293.15 K to 353.15 K, pressures from 0.1 MPa to 30 MPa and mass fractions from 0.1 to 0.4.

Experimental values of density and viscosity for (TEA+ water) and (DMAE+ water) are published in [3] at mass fractions from 0.1 to 0.4, in the range of temperatures from 293.15 K to 393.15 K and pressures up to 140 MPa for density and up to 100 MPa for viscosity. On the other hand, data for (MDEA + water) mixtures (w_{amine} = 0.1 to 0.4) can be found in [2] where densities from 293.15 K to 393.15 K and pressures up to 140 MPa and viscosities from 293.15 K to 353.15 K and pressures up to 120 MPa are reported.

Data of isobaric heat capacities of the aqueous solutions of the three ternary amines of this study (w_{amine} = 0.3) from 313.15 K to 353.15 K and up to 25 MPa are given in [6].

Although the experimental values can be found in different papers [2,3,6,7], to report the complete information, Tables 1-3 contains the experimental values of heat capacities, viscosities and densities of the amine solutions under study.

To better illustrate the comparison in the behaviour of the mixtures under study, some experimental results are presented graphically. Figure 1 presents the density as a function of pressure at different temperatures for the aqueous solutions of MDEA, DMAE and TEA at mass fractions of 0.2 and 0.4 as an example.

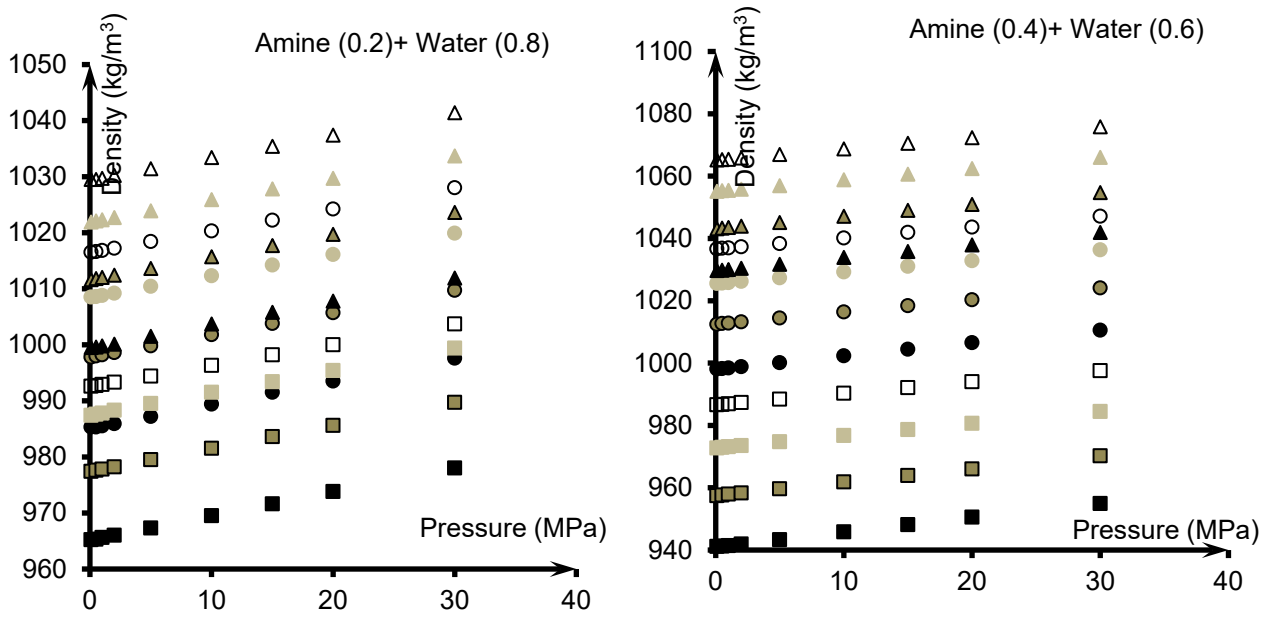

Figure. 1. Densities of the amine + water mixtures, TEA (triangle), MDEA (circle) and DMAE (square), as a function of pressure at different temperatures: (empty symbol) 293.15 K, (clear grey) 313.15 K, (dark grey) 333.15 K and (black) 353.15 K.

As can be seen in Figure 1, whether the aqueous solutions of amines are compared at the same conditions of temperature, pressure and compositions, densities follow the following sequence ρ(TEA) > ρ(MDEA) > ρ(DMAE) which is the same as the pure amines. TEA and MDEA have densities higher than water whereas DMAE density is lower than water, therefore, when the mixture is enriched in amine the density is enhanced for TEA and MDEA solutions and is decreased for DMAE mixtures. When the mass fraction of the amine is changed from 0.1 to 0.4, the increase of density ranges from 1.9% up to 2.9% for MDEA solutions and from 4.4% up to 5.1% for TEA solutions, the maximum effect is obtained at 293.15 K. In the case of DMEA solutions, the decrease of density varies from 0.8% up to 2.5%, and the maximum decrease is found at 353.15 K.

Concerning the effect of pressure, the density increases lineally with pressure, in the range of this study; this increment varies between 1% and 1.5% when the pressure is changed from 0.1 MPa to 30 MPa, being similar, regardless the amine or its amount. This effect is well quantified since the uncertainty in density is less than 0.1%.

On the other hand, density decreases with increasing temperature as expected. When temperature is increased from 293.15 K to 353.15 K, the density for the mixtures under study decreases between 2.7% up to

4.5%. In this case, a slightly different behaviour between the amines is observed. The density of TEA mixtures decreases between 2.7% up to 3.3% whereas the decrease ranges from 3% up to 3.6% for MDEA solutions and from 3.4% up to 4.5% for DMAE solutions. For the three amines, the highest effect is observed for the mixture of the highest amine content (w_{amine} = 0.4).

Results for viscosity are illustrated in Figure 2 in a similar way than for density. Viscosity is presented as a function of pressure at different isotherms for two mixtures of amine mass fraction of 0.2 and 0.4. It should be clarified that isotherm at 293.15 K for the system {MDEA (0.4) + water (0.6)} was not measured.

If the viscosities are compared for the different amine solutions at the same conditions (p, T, and w), TEA solutions are less viscous than MDEA solutions in the whole ranges of studied, and the same is true in comparison to DMAE solutions except at w_{amine} = 0.4 and T = 353.15 K; at these conditions, viscosity of DMEA mixture is less than TEA mixture. Moreover, the comparison of TEA and DMAE solutions at w_{amine} = 0.4 and T = 333.15 K, indicates that viscosity of DMAE mixture is less than TEA up to 10 MPa and above 15 MPa TEA solutions are less viscous but the differences in viscosity at this isotherm are below the uncertainty of the measurements.

The comparison between MDEA and DMAE solutions in terms of viscosity, let conclude that viscosity of DMAE solutions is higher than MDEA solutions for w_{amine} = 0.1 and 0.2 at T = 293.15 K, 313.15 K and 333.15 K, and w_{amine} = 0.3 at T = 293.15 K, and the whole pressure range (0.1 MPa to 30 MPa). On the contrary, viscosity of MDEA solutions is higher than DMAE solutions for w_{amine} = 0.2 and T = 353.15 K; w_{amine} = 0.3 and 0.4 and T = 313.15 K, 333.15 K and 353.15 K; and the whole pressure range (0.1 MPa to 30 MPa).

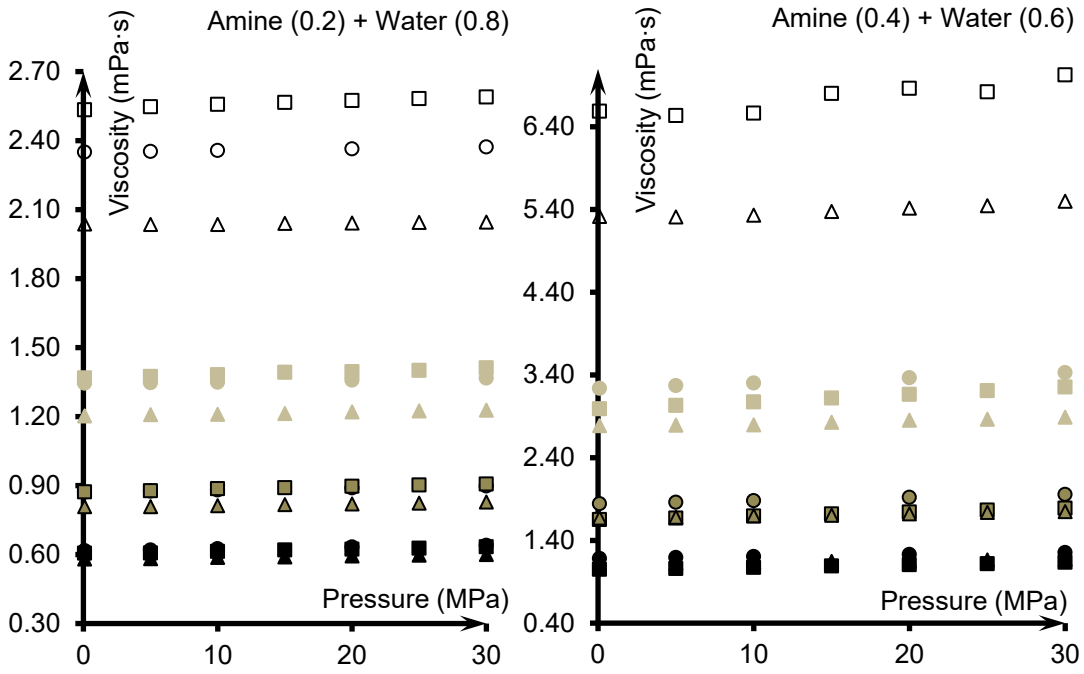

Figure. 2. Viscosities of the amine + water mixtures, TEA (triangle), MDEA (circle) and DMAE (square), as a function of pressure at different temperatures: (empty symbol) 293.15 K, (clear grey) 313.15 K, (dark grey) 333.15 K and (black) 353.15 K.

If we compare the effect on viscosity of increasing the amine composition from 0.1 to 0.4, the result is a remarkable increase: from 145% (at 353.15 K and 0.1 MPa) up to 280% (293.15 K and 30 MPa) for TEA, from 195% (at 333.15 K and 0.1 MPa) up to 271% (313.15 K and 30 MPa) for DMAE and, from 127% (at 353.15K and 0.1 MPa) up to 349% (293.15K and 30 MPa) for MDEA.

Analysing the effect of increase pressure from 0.1 MPa up to 30 MPa in the viscosity, the results are as follows: There is an increase in viscosity whose value depends on the amine and its quantity in such a way that the highest increased is observed for w_{amine} = 0.4. For the mixtures with this composition, the increase of viscosity ranges from 3.4% to 4.6% for TEA, 5.9% to 6.1% for MDEA and 6.7% up to 8.8% for DMAE, whereas the increase ranges from 1.2% to 3.6% for TEA, 2.9% to 4.7% for MDEA and 4.6% up to 6.2% for DMAE, for the w_{amine} = 0.3 mixtures. In contrast with the mixtures with w_{amine} = 0.1, whose increments in viscosity are between -1.1% up to 3.2%, being these values within the uncertainty of the measurements.

As clearly shown in Figure 2, the higher the temperature, the lower the viscosity, being the average decrease, when temperature is increased from 293.15 K up to 353.15 K, between 68.5% and 83.8% for w_{TEA} = 0.1 and

w_{DMAE} = 0.4, respectively. Moreover, the effect is greater for solutions richer in amine, for example the average decrease is 69.9 % for w_{DMAE} = 0.1 and 78.7% for w_{TEA} = 0.4.

Finally, it can be concluded that the viscosity of DMAE solutions is the most sensitive to pressure and temperature changes. For example, the viscosity varies, at T=353.15 K, from 1.050 mPa/s at *p*=0.1 MPa to 1.135 mPa/s at p= 30 MPa, and, at T=293.15 K, from 6.587 mPa/s at p=0.1 MPa to 7.027 mPa/s at p= 30 MPa, for the w_{DMAE} = 0.4 mixture.

The last comparison refers to the isobaric heat capacity that is shown in Figure 3, where this property is represented for the three amines at different conditions.

At the same conditions of temperature, pressure and composition, the isobaric heat capacity of the amine solutions studied is ordered as follows: c_p (DMAE) > c_p (MDEA) > c_p (TEA) which is the opposite to the behaviour of density and different from viscosity, as well.

When the effect of increasing pressure from 0.1 MPa to 25 MPa is quantified, the general trend is a slight decrease which is within the uncertainty of the measurements (1%) except for the mixtures w_{DMAE} = 0.3, w_{MDEA} = 0.3; and w_{TEA} = 0.4. The average decrement of isobaric heat capacity is 1.8%, 2.2% and 8.2%, respectively. This remarkable effect for the w_{TEA} = 0.4 solution is clearly shown in Figure 3.

In relation to the variation of the heat capacity with the temperature, it should be noted that for mixtures of composition 0.1, a minimum is observed at 313.15 K for TEA and at 333.15 K for MDEA and DMEA; for the other compositions, the heat capacity increases with increasing temperatures.

In order to discuss the effect of temperature on the isobaric heat capacity values, this is computed when the temperature is changed from 313.15 K to 353.15 K: The heat capacity of TEA aqueous solutions increases an average of 2.2% (w_{TEA} = 0.2), 4.1% (w_{TEA} = 0.3) and 2.8% (w_{TEA} = 0.4); the effect for MDEA solutions is an average increment of 3.1% (w_{MDEA} = 0.2), 5% (w_{MDEA} = 0.3) and 4.5% (w_{MDEA} = 0.4); and for DMAE mixtures is 3.2% (w_{DMAE} = 0.2), 5% (w_{DMAE} = 0.3), and 4% (w_{DMAE} = 0.4).

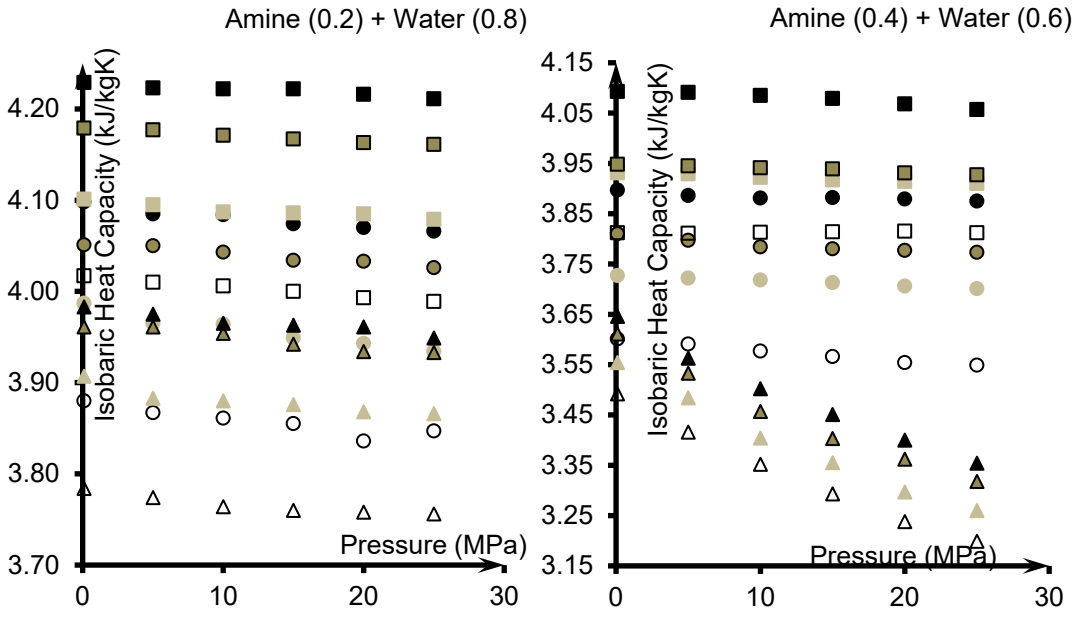

Figure. 3. Isobaric heat capacities of the amine + water mixtures, TEA (triangle), MDEA (circle) and DMAE (square), as a function of pressure at different temperatures: (empty symbol) 293.15 K, (clear grey) 313.15 K, (dark grey) 333.15 K and (black) 353.15 K.

Therefore, no significant differences are observed for the three amines, at a given composition, in relation to the effect of temperature, however, it is the amount of amine that matters. If the mass fraction of amine is increased from 0.1 to 0.4, the heat capacity of the mixtures decreases between 4% and 9% for DMAE solutions, 6% and 9% for MDEA solutions and 10% and 20% for TEA solutions.

Besides, the experimental data are fitted to semiempirical equations. The modified Tammann-Tait equation (Eq. 1) is used for density for each composition:

$$\rho(T,p) = (A_0 + A_1 T + A_2 T^2)/1 - C\, ln\left(\frac{B_0+B_1 T+B_2 T^2+p}{B_0+B_1 T+B_2 T^2+0.1MPa}\right) \quad (1)$$

On the other hand, viscosity data are correlated using the modified VFT (Vogel-Fulcher-Tammann) model, Eq. (2), for each composition, that was used by other authors [11]:

$$\eta(T,p) = \exp\left[\mathrm{a} + \mathrm{b}p + (\mathrm{c} + \mathrm{d}p + \mathrm{e}p^2)/(T - \mathrm{f})\right] \quad (2)$$

Regarding isobaric heat capacities, the following empirical correlation is used [7]:

$$c_p(p,T) = a_0 + a_1 p + a_2 T + a_3 p^2 + a_4 T^2 + a_5 pT \quad (3)$$

The fitting parameters are reported in [2,3,7], and the standard deviations obtained for the three thermophysical properties under study are summarized in Table 5.

Table 5. Results of the standard deviations σ obtained by the different fitting equation of the experimental data: density Eq. (1), viscosity Eq. (2) and isobaric heat capacity Eq. (3).

MDEA (1) + H_2O (2)	w_1 = 0.1	w_1 = 0.2	w_1 = 0.3	w_1 = 0.4
Density, Eq. (1): σ (kg/m^3)	0.029	0.018	0.0046	0.026
Viscosity, Eq. (2): σ (mPa·s)	0.0042	0.0035	0.017	0.026
Heat capacity, Eq. (3): σ (kJ/kgK)	0.023	0.006	0.008	0.013
TEA (1) + H_2O (2)	w_1 = 0.1	w_1 = 0.2	w_1 = 0.3	w_1 = 0.4
Density, Eq. (1): σ (kg/m^3)	0.164	0.146	0.130	0.0915
Viscosity, Eq. (2): σ (mPa·s)	0.0022	0.012	0.015	0.057
Heat capacity, Eq. (3): σ (kJ/kgK)	0.005	0.004	0.002	0.005
DMAE (1) + H_2O (2)	w_1 = 0.1	w_1 = 0.2	w_1 = 0.3	w_1 = 0.4
Density, Eq. (1): σ (kg/m^3)	0.162	0.119	0.0849	0.0881
Viscosity, Eq. (2): σ (mPa·s)	0.0080	0.0122	0.0213	0.0190
Heat capacity, Eq. (3): σ (kJ/kgK)	0.029	0.004	0.005	0.027

Table 5 shows that the standard deviations obtained are always lower than the expanded uncertainty of the experimental measurements: 0.7 kg/m^3 for density; 3% for viscosity or 1% for heat capacity, proving the goodness of these equations.

4. Conclusions

Experimental thermophysical properties, for amine aqueous solutions of MDEA, TEA and DMAE (at amine mass fractions of 10%, 20%, 30% and 40%) are reported and the behaviour is compared. Whether the aqueous solutions of amines are compared at the same conditions of temperature, pressure and compositions, the density of the mixtures follows the same behaviour than the pure amines: ρ(TEA) > ρ(MDEA) > ρ(DMAE) which is the same as the pure amines and wide ranges of temperature and pressure. Densities increase for richer amine solutions for MDEA and TEA but decrease for DMEA. In contrast, the heat capacity of the mixtures varies in a different order: c_p (DMAE) > c_p (MDEA) > c_p (TEA), and the heat capacity decreases for richer amine solutions for the three amines being TEA more sensitive. Finally, viscosity shows different tendencies and some differences observed are within the uncertainty of the measurements, however, viscosities of these mixtures increase with increasing amine weight fraction.

Finally, it should be noted the importance of having accurate data of these properties, since the results of these calculations will be as accurate as the properties involved in them. These measurements enrich data bases and allow to check the models which are used in the software for designing and optimizing industrial plants.

Abstract :

The valorisation of waste heat to respond to the increase demand on electricity and cooling is an important energetic challenge. For this purpose, an original hybrid thermochemical cycle is proposed: this sorption cycle is based on reversible endothermic/exothermic solid-gas reactions, and its originality lies in the integration of an expander on the gas line to provide mechanical work. This tri-thermal discontinuous cycle is able to recover medium grade waste heat (between 150 and 250 °C) to valorise it in a second step by providing cold production at its endothermic component and mechanical work - thanks to the expander - on the gas flow. Moreover, its two step operation leads to a storage functionality. While a previous study holds the thermodynamic stationary analysis of this cycle (Godefroy et al., ECOS 2019), this paper presents the experimental study part. A prototype of the hybrid thermochemical cycle, with $MnCl_2(6/2)NH_3$ (solid-gas reactants) and 1 kWe scroll expander, is developed at the laboratory. First experimentations on the prototype proved on a side the hybrid thermochemical concept by the simultaneous cold and mechanical productions during the whole reaction of the production phase, and on the other side they showed experimentally the mass coupling behaviour between the reactor and the expander in several operating conditions.

Keywords: Hybrid thermochemical cycle; Heat waste recovery; Cold and work productions; Experimental prototype.

1. Introduction

1.1. Background and state of the art

Sustainable development that meets the needs of the present without promising the ability of future generations to meet their own needs has been announced in 1987 by the World Commission on Environment and Development [1]. The acceptance and reliability of solar energy and waste heat come in the same context while considering such sources of energies as emerging sources since they are always free, endless and convertible [2]. Waste heat is highly discharged at the industrial sectors in a wide temperature range and thus participating in the increase of greenhouse gas emissions and more resource consumptions while left useless. As a step in responding to this issue, the United Nations Environment Program proposed industrial ecology, which involves studying the relationships and interactions within and between industrial systems and natural ecological systems from a systems-oriented perspective [3]. On this way also, conversion technologies and cycles based on the wide temperature ranges of the released heat at the industries were developed and set under study. Absorption chillers, adsorption beds, thermochemical reaction processes were exploited in this theme showing their adaptability in such temperature ranges (even low and medium) as chemical heat pumps for temperature upgrading. Besides, steam and organic Rankine cycles were investigated also but for power generation purposes.

As industrial waste heat has an intermittent regime, processes like thermochemical attract attention due to the storage functionality they offer.

Among such solid-gas thermochemical processes, ammoniated ones have a large diversity due to the variety of solid salts that can react with ammonia – especially the chlorides [4]. Being integrated with an expander, hybrid thermochemical cycles were defined to valorise mass and heat transfers in thermal and electrical productions. In [5], a novel "resorption" (two-salt bed reactors) cycle for cogeneration of electricity and refrigeration was proposed featuring a turbine between the high and low temperature salt reactors. Numerical analysis of a single sorption cycle was performed and investigated in [6]. Results showed a limited performance of the cycle resulted from the mutual constraint between the expansion device and the sorption unit with a detectable mismatch between them. Experimentally, by having $CaCl_2$ and activated carbon as the sorbent unit and a scroll expander, the challenges were confirmed by [7] where only unstable and weak work production was achieved during the experiment. A second experiment was performed in [8], the resorption pairs was $MnCl_2$ & $CaCl_2$, and similarly unstable work production was noticed during the short process. Such challenges haven't stopped the research, so that in [9] the use of phase change material in a heat storage system combined with a thermochemical hybrid process was addressed. In [10], more than one hundred reactive ammoniated salts were scanned and analysed in a hybrid thermochemical cycle that can recover heat below than 250 °C. Moreover, it was shown that these hybrid thermochemical cycles offer inherent cogeneration and storage capabilities, as demonstrated in [11] and [12], representing an added value compared to more traditional solutions. This paper continues the research in hybrid thermochemical processes, where an experimental prototype is developed at CNRS-PROMES permitting to validate the hybrid concept by continuous cold and mechanical productions during the production phase, and to analyse the cycle's behaviour and the coupling between the expander and the reactor in different operating conditions.

1.2. The proposed cycle

Several architectures were defined for the hybrid thermochemical cycle [13] depending on the preferred energy production: cold or mechanical. In this study, the simultaneous mode is chosen for the developed prototype: it allows a cogeneration of cold and mechanical energy as presented on the Clausius Clapeyron diagram, Figure. **1**. Figure. **2** shows the main components of the prototype: thermochemical reactor, condenser, evaporator, volumetric expander and fluid tank. The decomposition reaction of the solid-gas reactant is the charging phase where heat Q_h is supplied to the reactor at T_{hot} and the gas desorbs toward the condenser to be condensed and stored at ambient conditions T_{amb}. During the discharging phase (synthesis reaction), cold is produced by the evaporation of the condensed liquid at T_{cold} at the evaporator. This vapor flow produces then mechanical work at the expander, and after it is then involved in the synthesis reaction occurring at ambient conditions (or at a medium temperature). $MnCl_2$, (6/2) NH_3 is the chosen reactive ammoniated salt, based on its interesting thermodynamic properties and stability as shown in the analysis of [10]. The thermochemical reaction that takes place is:

$$MnCl_2.6NH_3 + \Delta h_r \rightleftarrows MnCl_2.2NH_3 + 4NH_3 \qquad (1)$$

The diagram, Figure. **1**, presents the NH3(L/G) and MnCl2(6/2) NH3 equilibrium lines for ammonia and the reaction respectively, based on the Clausius Clapeyron equilibrium equation:

$$\ln\left(\frac{p}{p_0}\right) = -\frac{\Delta h_r}{RT_r} + \frac{\Delta s_r}{R} \qquad (2)$$

where, p is the equilibrium pressure, p_0 is the reference pressure (1 bar), R is the ideal gas constant, Δh_r and Δs_r are respectively the enthalpy and the entropy of the solid gas reaction or the phase change of ammonia and T_r is the reactant temperature.

A scroll expander is integrated within the thermochemical cycle between the evaporator and the reactor. The control parameter of the bench are the temperatures and flowrates of all heat transfer fluids (HTF), with the electrical resistance at the generator bounds. Temperatures are measured with PT100 probes for the inlet/outlet of HTFs, and by numerous thermocouples inside the reactor (in the reactive solid (12 thermocouples), at the reactor wall (8 thermocouples) and in the HTF (8 thermocouples)). The pressure of the main components (evaporator, expander, condenser and reactor) and the level of liquid ammonia in the tank (linked to the reaction advancement) are also monitored.

In what follows, experimental analysis of cycle is done showing the proved concept of the hybrid thermochemical cycle and the coupling between its components.

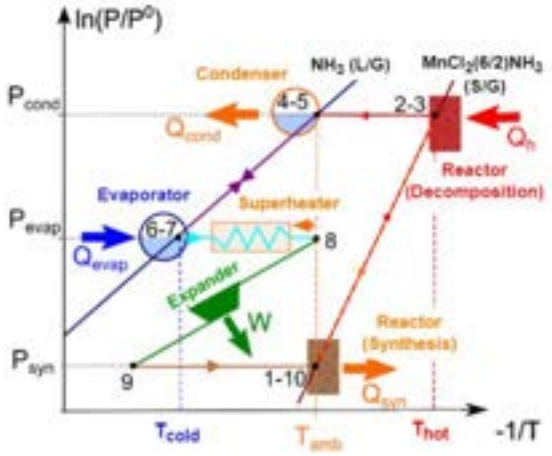

Figure. 1. Simultaneous hybrid thermochemical cycle described on the Clausius Clapeyron diagram.

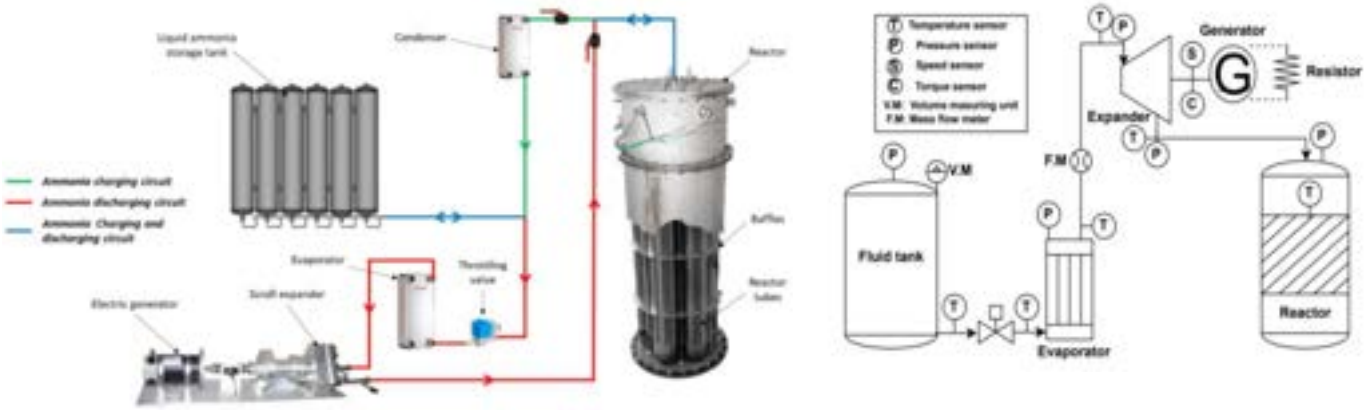

Figure. 2. Left: Schematic description of the developed prototype: reactor with 29 Kg of $MnCl_2$ & 23 kg of NH_3, 1 kWe scroll expander (bought from Air squared), condenser, evaporator, throttling valve & fluid tanks. Right: Process flow diagram: cold and mechanical productions phase.

2. Numerical analysis of the expander/reactor coupling

To analyse from a theoretical point of view the coupling between the expander and the reactor, a simplified modelling of these components has been developed.

The main hypotheses of this analysis are as follows:

- Steady state operation;
- The working fluid is considered as an ideal gas with constant heat mass capacity;
- Uniform pressure, temperature and composition are considered in each component;
- Heat losses and pressure drops are neglected;
- Variation of kinetic and potential energy are neglected.

By applying the first law on the expander, the expansion power of the working fluid can be expressed as:

$$\dot{W}_{NH_3} = \dot{m}_{swept} \cdot \Delta h_{swept} \tag{3}$$

Having the mass flow rate expression as:

$$\dot{m}_{NH_3} = \dot{m}_{swept} + \dot{m}_{leak} = \frac{p_{adm} . M_{NH_3}}{R \cdot T_{adm}} \left(\dot{V}_{swept} + \dot{V}_{leak} \right) = \frac{p_{adm} . M_{NH_3}}{R \cdot T_{adm}} \left(V_{swept} \cdot \omega + K_{leak} \cdot \sqrt{p_{adm} - p_{exh}} \right) \tag{4}$$

With p_{adm} and T_{adm} are the pressure and temperature at the expander admission, V_{swept} is the swept volume and ω the rotational speed, K_{leak} is the coefficient of internal leakage of the expander and p_{exh} is the pressure at the expander exhaust.

The enthalpy variation is expressed, considering a constant isentropic efficiency:

$$\eta_{is} = \frac{\Delta h_{swept}}{\Delta h_{is}} \rightarrow \Delta h_{swept} = \eta_{is} \cdot \Delta h_{is} \tag{5}$$

With the ideal gas assumption and a constant Cp, the swept enthalpy variation is as:

$$\Delta h_{swept} = \eta_{is} \cdot Cp_{NH3} \cdot T_{adm} \cdot \left(\left(p_{adm} / p_{exh} \right)^{\frac{1-\gamma}{\gamma}} - 1 \right) \tag{6}$$

The exhaust pressure can be expressed, thanks to the kinetic law of the reactor, as:

$$\dot{m}_{NH3} = M_{NH_3} \cdot n_{sal} \cdot \nu_r \cdot \tilde{k}_{cin} \cdot \frac{p_{exh} - p_{eq}\left(T_r\right)}{p_{exh}} \text{ and thus: } p_{exh} = \frac{p_{eq}\left(T_r\right)}{\left(1 - \frac{\dot{m}_{NH3}}{M_{NH_3} \cdot n_{salt} \cdot \nu_r \cdot \bar{k}_{cin}} \right)} \tag{7}$$

Where:

- $n_{salt,}$ $\nu_{r,}$ and $\bar{k}_{cin}$ are the number of mole of the reactive salt in the reactor, the stoichiometric coefficient of the reaction (eq. 1), and the average kinetic coefficient of the reaction;

- the solid/gas equilibrium pressure is calculated, thanks to the Clausius-Clapeyron equation (eq. 2), as a function of the reactant temperature (T_r).

The temperature T_r is calculated by applying the 1st law on the reactor wall and on the reactants:

$$\dot{m}_{NH3} \cdot \left(\frac{\Delta h_r}{M_{NH3}} - Cp_{NH3}\left(T_r - T_{exh}\right) \right) = \left(UA\right)_r \cdot \left(T_r - \bar{T}_{htf;r}\right) \quad \text{with } \bar{T}_{htf;r} = \frac{T_{out;htf;r} + T_{in;htf;r}}{2} \tag{8}$$

$$\dot{m}_{NH3} \cdot \left(\frac{\Delta h_r}{M_{NH3}} - Cp_{NH3}\left(T_r - T_{exh}\right) \right) = \left(\dot{m}Cp\right)_{htf;r} \cdot \left(T_{out;htf;r} - T_{in;htf;r}\right) \tag{9}$$

Taking into account that $\frac{\Delta h_r}{M_{NH3}} >> Cp_{NH3}\left(T_r - T_{exh}\right)$:

$$T_r \approx T_{in;htf;r} + \frac{\dot{m}_{NH3}.\Delta h_r}{M_{NH3}} \cdot \left(\frac{1}{2.\left(\dot{m}Cp\right)_{htf;r}} + \frac{1}{\left(UA\right)_r} \right) \tag{10}$$

Where $T_{out;htf;r}$ and $T_{in;htf;r}$ are the outlet and inlet temperatures of the reactor heat transfer fluid; $\left(\dot{m}Cp\right)_{htf;r}$ is the heat capacity flow of the reactor HTF; $\left(UA\right)_r$ is the heat transfer parameter of the reactor.

By combining eq.3, 6, 7 and 10, the power of working fluid expansion can be expressed as:

$$\dot{W}_{NH_3} = \dot{m}_{swept} \cdot \eta_{is} \cdot Cp_{NH3} \cdot T_{adm} \cdot \left(\left(\frac{p_{adm} \cdot \left(1 - \frac{\dot{m}_{NH3}}{M_{NH_3} \cdot n_{salt} \cdot \nu_{react} \cdot \tilde{k}_{cin}} \right)}{p_{eq}\left(T_r\right)} \right)^{\frac{1-\gamma}{\gamma}} - 1 \right) \qquad (11)$$

The eq. 4, eq.10 and eq.11 show that the power of working fluid expansion $\left(\dot{W}_{NH_3}\right)$ is mainly a function of two operating parameters: the admission pressure (p_{adm}), the expander rotational speed (ω), and one design parameter which is the heat transfer parameter $\left(UA\right)_r$ of the reactor HTF. An analysis of the evolution of $\dot{W}_{NH_3}$ by varying these 3 parameters has been carried out. All other parameters are kept constant and their values represent the characteristics of the prototype (design values or values identified from the first experiments), as shown below in Table 1.

Table 1. Main design and operating parameters for the numerical coupling analysis

Expander parameter	Value	Reactor parameter	Value
Swept volume V_{swept}	1.45×10^{-5} m^3	Number of mole of salt n_{salt}	235.9 mol
Coef. of internal leakage K_{leak}	1×10^{-6} m^{3}s^{-1}.Pa$^{0.5}$	Kinetic of the reaction $\overline{k}_{cin}$	1.5×10^{-4} s^{-1}
Isentropic efficiency η_{is}	0.6	Enthalpy of the reaction Δh_r	50.59 kJ.mol^{-1}
Admission temperature T_{adm}	20 °C	HTF heat capacity flow $\left(\dot{m}Cp\right)_{htf;r}$	1000 W.K^{-1}
		HTF inlet temperature $T_{in;htf;r}$	40 °C

The increase of the expander rotation speed (ω), (Figure. **2**), induces an increase of the swept flow and thus an increase of the working fluid mass flow $\left(\dot{m}_{NH_3}\right)$, (cf. eq. 4). This increase in the mass flow rate causes a decrease of the pressure ratio (R_p) due to the increase of the reactor's temperature (T_r), (cf. eq. 10), and an increase of the pressure difference between the exhaust pressure and the equilibrium pressure of the reaction, (cf. eq. 7). These two antagonism evolutions generate an optimum of the expansion power $\left(\dot{W}_{NH_3}\right)$. For a given rotation speed, the swept mass flow rate $\left(\dot{m}_{swept}\right)$ is fixed, and thus the increase of the total mass flow rate $\left(\dot{m}_{NH_3}\right)$ with the rise of $\left(UA\right)_r$ is related to the increase in the leaked flow $\left(\dot{m}_{leak}\right)$ generated by the higher pressure ratio. While the admission pressure is fixed (p_{adm} =1.5×10^5 Pa), the enhancement of the reactor heat transfer parameter $\left(\left(UA\right)_r\right)$ allows the decrease of the reactor temperature (T_r), (cf. eq. 10), and thus a decrease of the exhaust pressure (p_{exh}) resulting in a higher-pressure ratio. Thus, this higher-pressure ratio generates a rise in the power output with $\left(UA\right)_r$.

On the other hand, increasing the inlet pressure of the expander (Figure. **3**) induces an increase of the mass flow (cf. eq. 4). As for the previous analysis, this higher mass flow generates a decrease in the pressure ratio (Figure. **3** centre). In the case of low heat transfer parameter $\left(UA\right)_r$ at the reactor, these two behaviours lead to a decrease in the produced power, but for higher heat transfer parameters, an optimum of power production is detected (Figure. **3** right).

This coupling between the expander and the reactor has also been analysed experimentally, and presented in the following section. Experimentally, the rotational speed of the expander is modulated by a variable electrical resistor

which is connected to the electrical generator at the expander's extremities. The variation of the admission pressure is generated by a modification of the cold source temperature T_{cold}.

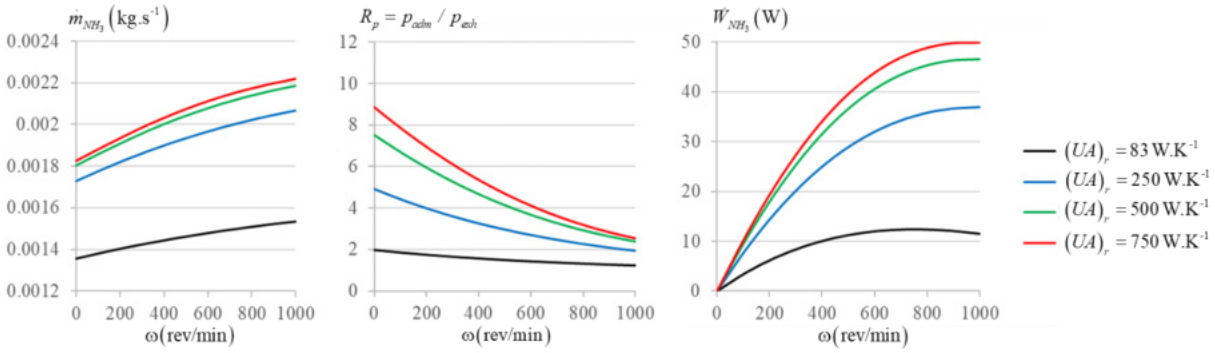

Figure. 2. Evolution of the working fluid flow rate (left), the pressure ratio (centre), the power of working fluid expansion (right) as function of the expander rotational speed for different reactor heat transfer parameter with p_{adm} =1.5×10^5 Pa.

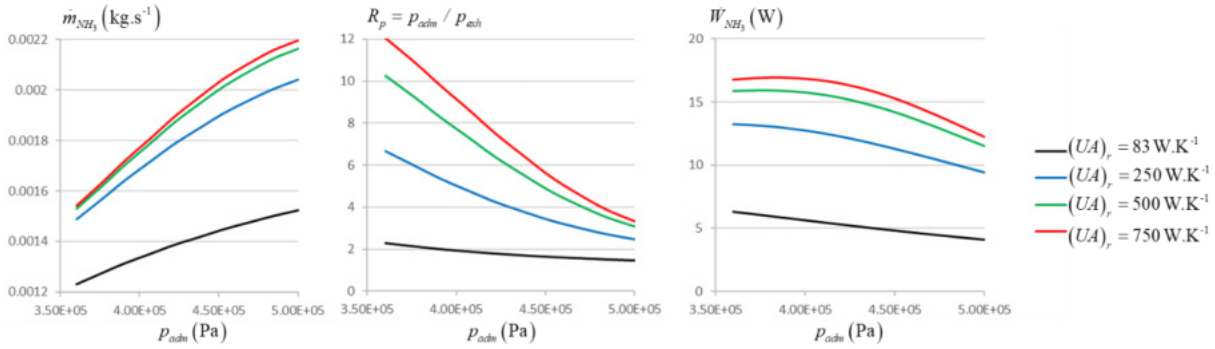

Figure. 3. Evolution of the working fluid flow rate (left), the pressure ratio (centre), the power of working fluid expansion (right) s function of the admission pressure for different reactor heat transfer parameter with ω =200 rev/min.

3. Experimental Analysis

The thermochemical cycle (reactor – condenser – evaporator) was set firstly under experimentations, by bypassing the expander. Several decomposition and synthesis reactions were done to check the reproducibility and the kinetics of the phases. Once validated [14], the expander was integrated to exploit the hybrid cycle in the discharging phase, where ammonia passes from the liquid tank to the evaporator, expander, and then to the reactor. Two protocols are set to be followed during the test of the hybrid cycle:

- The first is to fix the inlet pressure at the expander (and thus T_{cold} i.e. T^{in} and P^{in} of the expander) while varying the electrical load at the generator which will vary the coupling force with the expander, and its mechanical power. While the mechanical power is expressed as function of the pressures at the extremities of the expander, as shown in the following equation, this protocol leads to vary the outlet pressure at the expander with the electrical load and thus permits to analyse the behaviour of the cycle in such conditions.

$$\dot{W}_{mec} = \mathbf{T}_{mec}.\omega = \dot{W}_{NH_3}.\eta_{mec}$$

where $\dot{W}_{mec}$is the produced mechanical power, $\mathbf{T}_{mec}$ is the torque force between the generator and the expander, ω is the rotational speed, η_{mec} is the mechanical efficiency of the expander.

- The second is to vary the inlet pressure at the expander (and thus T_{cold}), permitting to analyse the behaviour of the expander during the discharging phase while coupled to a fixed electrical load, and thus the same coupling force with the generator.

3.1. Fixed Tcold and variable electrical charge

A first experiment with an electrical resistor of 7 Ω, connected to the generator, is done while exploiting the expander in the hybrid cycle, for a fixed T_{cold} at 10 °C at the evaporator's inlet. The inlet temperature at the reactor is set to be maintained at a medium temperature 40 °C. After the concept's validation in this experiment, more experiments are done with changing the electrical resistance to: 3.4, 31, 57, 85, 100 Ω. An experiment with a blocked expander is conducted to simulate short circuit electrical conditions, and another one without electrical charge to simulate open circuit electrical conditions, i.e. a resistor of ∞ Ω, leading to define the behaviours of the cycle at the electrical condition boundaries. In Figure. **4**, results of this first experiment are presented. The expander is rotating continuously during the whole synthesis reaction stage i.e. for a reaction advancement X between 0.1 and 0.9, proving the concept of the hybrid thermochemical cycle. After the start-up phase, the rotational speed ω of the expander decreases from 600 tr/min (i.e. the classical peak of a reaction at its beginning) till 80 tr/min for an advancement X < 0.3. Behind, an acceleration in the production is noticed where the rotational speed increased to reach 300 tr/min. Such two-level profile is also repeated in the other experiments, where the cold production and the mechanical work have always two levels during the reaction – under actual analysis. For this system analysis, results are treated as average values between the minimum and the maximum level production limits that correspond to an average of the production during an advancement of the reaction between 0.2 & 0.8.

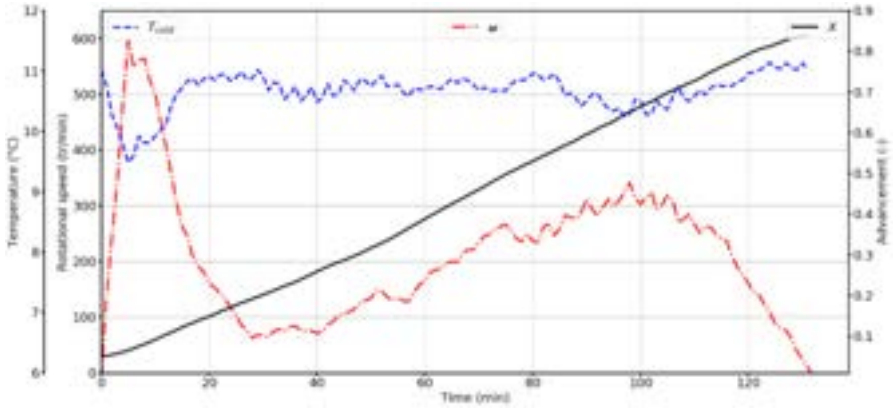

Figure. 4. Cold temperature, rotational speed of the expander during the discharging phase.

Figure. **5**, Figure. **6**, and Figure. **7** present the behaviour of the hybrid cycles for different electrical resistances. Figure. **5** presents the variation of the rotational speed ω_{av} of the expander, and the torque force $T_{mec,av}$ with the generator as function of the electrical resistor. When the expander is free, or the generator is in an open circuit electrical condition, the rotational speed reaches its maximum value while the torque force has its minimum. Coupling the electrical resistor to the generator increases the torque force on the expander and decreases its rotational speed. The maximum average rotational speed achieved by the expander was at 480 tr/min in an open circuit electrical condition. Regarding the average torque force, its maximum was at 1 N.m for a blocked expander, while the minimum was at 0.1 N.m for the open circuit experiment.

Figure. **6** shows the variation of the average mass flow rate of ammonia $\dot{m}_{av}$ and the average pressure ratio $R_{p,av}$ at the expander as function of the electrical resistor. The average mass flow rate has an increasing profile as the electrical resistance increases, whereas the pressure ratio has a decreasing one. The maximum pressure ratio achieved during the experiments is for the blocked case experiment, where $R_{p,av}$ = 1.5 and the minimum is for an open circuit electrical condition experiment, $R_{p,av}$ = 1.2. Regarding the mass flow rate of ammonia, the difference between experimental boundaries (blocked and open circuit conditions) is of 0.175 g/s. On the other side, concerning the productions of the cycle, Figure. **7**, the cold production has a negligible variation between the boundaries of the experiments, but although it shows an increasing profile while the electrical resistance increases ($Q_{c,av}$ from 1.98 to 2.1 kW). This slight increase in the cold production results from the slight increase in the mass flow rate of ammonia as the conditions changes from blocked to an open circuit. No mechanical productions are achieved while the expander is blocked, an average of 6 W is produced in open circuit conditions, and a maximum of 10.5 W is reached for a resistance of 7 Ω. The mechanical production increases to reach a maximum and then decreases while the electrical load at the generator increases presenting an optimum of the mechanical production between the blocked conditions and the experiment with an electrical resistor of 31 Ω, contrary to the cold production that increases always with the electrical resistance. This cycle's behaviour, shows the antagonistic coupling behaviour between the cold production and the mechanical power as the electrical resistance varies,

determining an optimum of the mechanical power production dependent on the mass flow rate of the gas, the coupling force and the pressure ratio at the expander.

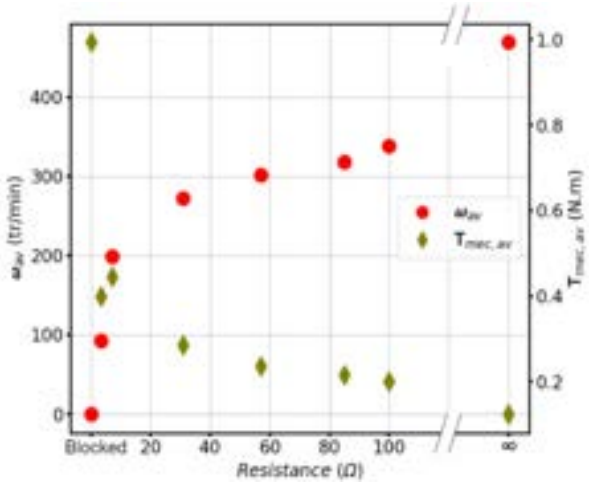

Figure. 5. Variation of the rotational speed and the mechanical torque at the expander with the electrical resistance.

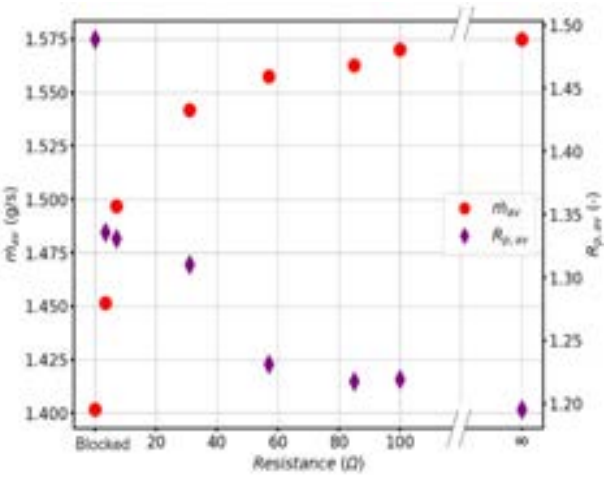

Figure. 6. Average ammonia flow rate and pressure ratio variations with the electrical resistance.

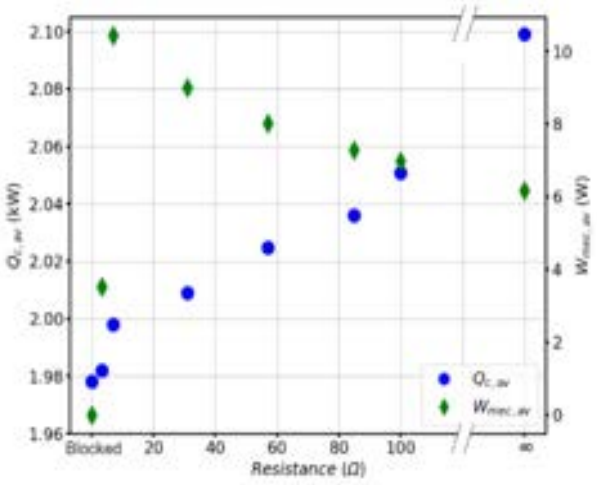

Figure. 7. Variation of the average cold and mechanical productions with the electrical resistance.

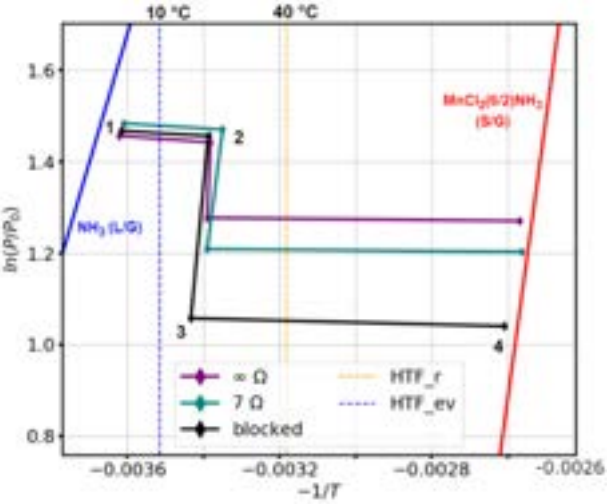

Figure. 8. Clausius Clapeyron diagram: experiments with constant Tcold but variable electrical conditions.

Whereas, the cold production is shown to be dependent on the mass flow rate as the evaporating pressure is set to be fixed by T_{cold}. These experimental results that show weak pressure ratios and mechanical productions highlight the importance of the expander's technology necessary for such hybridization objective, where such results determine an important internal leakage inside the scroll expander that affects the mechanical behaviour and the mass coupling between the components. Additionally, Figure. **5**, Figure. **6** and Figure. **7**, show that experiments done between a blocked resistor and a resistor of 31 Ω, have more important and interesting evolution of the cycle's behaviour since after this boundary its seems that the behaviour don't have a significant change - stable. Therefore, this demands to define operating electrical conditions more adaptable to the range of production of the expander in such cycles of small gas flow rates.

Within such limitation and weak productions, Clausius Clapeyron diagram in Figure. **8** still shows the mass coupling between the components of the hybrid cycle at the electrical boundary conditions and at 7 Ω (chosen since it's the cycle that achieved the maximum mechanical power). For each experiment representation on this diagram:

HTF_ev and HTF_r represents the heat transfer fluid conditions at the evaporator and the reactor respectively, points 1, 2, 3, represent respectively the temperature and pressure of ammonia at the evaporator, at the inlet of the expander, at the outlet of the expander and point 4 represents the salt's temperature and pressure during the reaction. This diagram presents clearly the difference with the classical one (where the synthesis pressure is the same as the evaporating pressure in a classical cycle but different in a hybrid one - points 1 & 4) and shows the expansion of ammonia at the expander (points 2 – 3) even with its weak ratio. Furthermore, it sheds attention to the importance of the heat sink and exchange at the reactor (to evacuate the heat of the synthesis reaction) while the salt's temperature is closer to the equilibrium temperature of the reaction than the heat transfer fluid temperature at the reactor's level.

3.2. Variable cold temperature and fixed electrical charge

Three experiments were done at three different cold temperatures: 5, 10, and 15 °C (by the glycolic water heat transfer fluid loop of the evaporator) corresponding to $P_{sat,evap}$: 5.12, 6.12, and 7.28 bar respectively. An electrical resistor of 7 Ω is connected to the generator that's coupled to the expander. The inlet temperature at the reactor is set to be maintained at a medium temperature of 40 °C (by an oil HTF loop). The following figures (Figure. **9** and Figure. **10**) present the behaviour of the hybrid cycles for these 3 cold temperatures. For a better analysis, the experimental operating conditions are plotted on the Clausius Clapeyron diagram, Figure. **11**.

The average cold production $Q_{c,av}$ at the evaporator and the average mass flow rate of ammonia $\dot{m}_{av}$ are shown in Figure. **9** and Figure. **10** for the three experiments. As T_{cold} increases (i.e. P_1 in Figure. **11**), the average mass flow rate of ammonia increases. This is due to a larger deviation from the equilibrium conditions of the synthesis reaction (i.e. the difference between $T_{HTF\text{-}r}$ and $T_{eq}(P_3)$ in Figure. **11**). This increase in the flow rate of the gas increases the average cold power production, as expected. Despite in these experiments the minimum cold temperature is fixed at 5 °C and the maximum at 15 °C, corresponding to 2.16 bar as a pressure difference between the minimum and maximum operating conditions at the evaporator' level, the difference between the average cold productions slightly changed where the average production increases from 1.85 to 2.25 kW with the increase of the average mass flow rate from 1.4 to 1.75 g/s as the cold temperature increases. At the level of the expander, the average mechanical production $\dot{W}_{mec,av}$ and the average pressure ratio $R_{p,av}$ between the inlet and the exhaust pressures are shown in Figure. **9** and Figure. **10**. The average mechanical power decreases from 10.2 to 9.6 W and the average pressure ratio from 1.55 to 1.22, as the cold temperatures increases from 5 to 15 °C. The Clausius Clapeyron diagram Figure. **11** shows for the three experiments that the salt's temperature is mostly close to its equilibrium and far from the imposed heat transfer fluid temperature HTF_r. This increase of the temperature difference between the reactive medium and the HTF, that's proposed to be a result of the weak heat transfer parameters at the reactor, imposes a higher pressure at the expander's exhaust. In the ideal case, without heat transfer limitations at the reactor, the pressure in the reactor P_3 would be smaller for the 3 cases and thus the pressure ratio of the expander $R_p = P_{in}/P_{out} = P_2/P_3$ would increase with T_{cold}, but, the experimental results show the inverse ($R_{p,av}$ = 1.49, 1.26, 1.19 for T_{cold} = 5, 10 and 15 °C respectively).

Therefore, while T_{cold} and the evaporating pressure P_1 increases, the mass flow rate of ammonia increases, which must favour in terms the mechanical power at the expander, but while on the other hand the pressure ratio of the expander decreases, the mechanical power is reduced. This behaviour demonstrates the coupling between the reactor and the expander, and numerical studies are in progress to deeper analyse this coupling, thanks to these experimental results. Besides the effect of the hot reactive medium temperature, the decrease in the pressure ratio while the evaporating pressure increases results from an important internal leakage through the scroll expander. Therefore, the leaked flow rate which flows directly to the reactor is significantly higher than the effective mass flow rate, rising the pressure at the reactor inlet, and thus resulting in low pressure ratios and an unexpected decrease in the mechanical work. This analysis, in this protocol, highlight again the important mass coupling between the expander and the reactor, with an attention to the expander's technology and the heat exchange at the thermochemical reactor during the synthesis reaction.

4. Conclusion

A hybrid thermochemical prototype was developed at CNRS-PROMES laboratory, providing the reliability and concept validation of such hybrid cycles. Such cycle is able to recover heat at low and medium ranges below 250 °C, showing its adaptability to the integration in industrial parks for heat waste recovery. After a steady state analysis of the coupling between the expander and the reactor, first experimental tests at the laboratory showed this mass coupling behaviour between the expander and the reactor in several operating conditions. At their limits, the experiments highlight the importance of the heat sink and thermal exchanges at the reactor's level and shed attention on the technology of the expander regarding its internal leakage, as concluded from the experiments done with a fixed electrical load and variable evaporating pressures. On the other side, the experiments with a fixed evaporating pressure and variable electrical resistances defined an optimum of the mechanical production at the expander's level and showed the possibility of a control methodology at the generator's level to maintain the pressure of the synthesis reaction (or the expander's exhaust). While it could be noted that such hybrid cycle achieves the first experimental success based on what's presented in the literature, motivations to perform experimental tests on other hybrid thermochemical architectures are considered. In parallel, a numerical model developed in a previous study is set to be validated in order to go deeper in the energetic and exergetic analysis of the cycle.

Abstract:

- This paper deals with the optimal integration of power plants including a storage device such as concentrated solar power plants. For such systems, numerous structures are possible, involving different number of heat exchangers, and for each of them, optimal operating temperatures to be found. Moreover, the heat storage system can be located at different temperature levels offering another degree of freedom when optimizing the whole system. If process simulators are nowadays very powerful tools for optimizing complex processes, they require to propose a primary design before any optimization steps. Finite-Dimension Thermodynamics (FDT) could help engineers to propose this primary design, close to the optimal one. To this aim, FDT method have been generalized for power generation systems including a storage device and any number of heat exchangers. An model of thermal storage system is also proposed which can be included in the FDT modelling. The optimization step consists in maximizing the power generation submitted to the thermodynamics constraints (first and second Laws) related to each heat exchangers, power block and thermal storage system. Remarkable results have been found: i) all the studied structures lead to the Curzon-Ahlborn efficiency when optimized, ii) for the same driving source (same temperature and same power), the output power production varies with N^{-2}, N being the number of the heat exchangers, iii) Charge and discharged times scenarios have a big impact on the optimal operating temperatures and on the resulting daily energy production.

Keywords:

Finite dimension thermodynamics, optimal integration, thermal storage, solar power plant.

1. Introduction

Finite-Time Thermodynamics aims to overpass the assumption of reversible, and consequently infinitely slow, transformations inherent to the Carnot cycle definition [1]. Chambadal [2] and Novikov [3] were the pioneers in 1957, proposing a power plant model that associates a reversible Carnot cycle driven by a heat source at high temperature T_H through an irreversible thermal resistance. These works were rediscover and completed by Curzon and Ahlborn [4] in 1975, who added a second thermal resistance coupling the reversible power block with the heat sink at low temperature T_L. All these previous studies were seeking the optimal temperatures between which the Carnot cycle must operate to ensure maximum power production. They demonstrated that at this maximum power point (MPP), the efficiency is equal to the so called 'nice radical efficiency' $\eta_{MPP} = 1 - \sqrt{T_L/T_H}$. De Vos [5] and Bejan [6] extended the Finite-Time Thermodynamics (FTT) to the Finite-Size or Finite-Dimension Thermodynamics (FDT) [7], [8]. The main difference is that the energy and entropy balances are here applied to the power plant itself, operating in a steady state, and not to the working fluid evolving in time over a cycle as done in FTT studies. Consequently, the method is no longer limited to Carnot engines, but can be applied for all types of engines. This leads to define endoreversible engine [5] for those internal entropy production is null or negligible. In that case, FTT and FDT lead to similar results, in particular to the nice radical efficiency at the MPP.

From these first studies, FTD/FDT methods have been successfully applied to a wide variety of systems such as refrigerators and heat pumps [9], distillation systems [10], chemical reactions [11] , wind power [12] or solar power [13]

However, the reliability of the results is often subjected to much criticism due to the assumptions underlying the FTT/FDT:

1. Linear driving force.
2. Endoreversible nature of the cycle.
3. Availability of powerful tools for industrial process optimization such as Aspen, Dymola or TRNSYS.

We obviously agree with these limitations. However, process simulators/optimisers require a mandatory first step: to propose a guessed design for initiating the optimisation process. This is the main objective of the FTT/FDT methodology: to define an initial design, deduced from thermodynamics, which could be used as a basis for further optimisation. Following this objective, the two first items seems reasonable: linear laws are commonly used in engineering pre-design, and endoreversible cycles are quite close to actual cycles as main irreversibility sources appear in the heat exchangers linking the process with the external heat sources . Moreover, Meunier et al. [14] and Castaing et al. [15] showed that an equivalent endoreversible cycle could be substituted to any sorption refrigeration irreversible cycles. This result also applies to any thermodynamics cycles. Conversely, passing from an endoreversible cycle to an actual cycle is also possible: in Reference [16], FDT method was used in order to find the optimal operating conditions of a endoreversible cycle, from which the optimal operating conditions of an actual Hirn cycle were deduced (i.e condensing and evaporating pressures and inlet turbine temperature). Nevertheless, FDT models are restricted to basic architectures of power plant: a single power cycle exchanging heat with two reservoirs through two heat exchangers (HX) whereas actual power plants often include more heat exchangers. PWR nuclear power plants use a primary heat transfer fluid (HTF), that induces two heat exchangers in the hot side: the reactor and the steam generator. In contrast, BWR use a single heat exchanger in the hot side: the reactor itself. The cooling loop can also involve one (condenser for direct through cooling) or two HXs (condenser and cooling tower for indirect cooling). A question then rises: does the HX number affect the optimal operating temperatures, the output power, and the efficiency of the cycle at the MPP? Similar issue appears for Concentrated Solar Power (CSP) plants, which can also involve one (Direct Steam Generator, DSG) or two (indirect heating) hot HXs. In addition, most of CSP plants include a thermal energy storage (TES) system, which adds complexity and diversity in possible architecture: the storage system can be direct (same fluid acts as HTF and storage medium) or indirect (two different HTFs flow in the solar loop and in the power block hot loop). Consequently, thermal storage device should be integrated in the FDT analysis. Therefore, the objectives of this work are twofold:

1. Extend the FDT methodology to processes that include a heat storage device.
2. Investigate the impact of TES and number of HX on the power plant optimal temperatures, power output and efficiency at the MMP.

In addition to these two original contributions, the optimization problem is solved without any assumption concerning the endoreversibility of the TES and the power block: the second law is treated here as an inequality while endoreversibility is usually assumed in FDT studies.

2. Problem definition

The FDT formalism requires to substitute a thermodynamic equivalent system to the real components involved in the power plant. The method is detailed in [16] and is briefly outlined here for heat exchangers and power blocks. An equivalent system is then proposed for TES systems. Finally, the optimisation problem is defined.

2.1. Equivalent heat exchanger and power block

Heat exchangers can be modelled by a thermal conductance K, transferring the heat flux $\dot{q}$ between two thermostats whose temperatures are equal to the mean entropic temperatures ($\tilde{T} = \Delta h/\Delta s$) of the cold and hot fluids. The heat flux can then be simply expressed by a Newton law:

$$\dot{q} = \mathrm{K}\left(\tilde{T}_H - \tilde{T}_L\right) \tag{1}$$

For power blocks, the same concept applies: any power cycle can be assessed through an equivalent cycle operating between two reservoirs à $\tilde{T}_H$ and $\tilde{T}_L$. For Rankine or Hirn cycles, these two temperatures are the entropic mean temperatures related to the working fluid when crossing respectively the steam generator and the condenser. First and Second Laws then write:

$$\dot{q}_H - \dot{q}_L = \dot{w} \tag{2}$$

$$\frac{\dot{q}_H}{\tilde{T}_H} - \frac{\dot{q}_L}{\tilde{T}_L} = -\dot{\sigma}_i \leq 0 \tag{3}$$

with $\dot{\sigma}_i$: internal entropy production (W/K)

$\dot{w}$: output power (W)

Notice that if $\dot{\sigma}_i$ = 0, Eqs. (2) and (3) define the endoreversible cycle.

2.2. Equivalent Thermal Energy Storage system

A two-tank heat storage device is considered (**Figure 1a**). Upstream, $\dot{m}^H$ flow enters the high temperature loop at temperature T_{out}^H, and returns to the TES system at higher temperature T_{in}^H. Downstream, $\dot{m}^M$ flow enters the medium temperature loop at T_{out}^M, and returns to the TES system at lower temperature T_{in}^M. The difference between the two mass flows is stored in or taken from either of the two tanks, hot at T^H. and cold

T^C. **Figure 1b** presents the operation scenario. Constant thermal powers are assumed here, but the method applies also for varying power. Hot loop operates during the duration t^H and the user demand is active during the duration t^M.

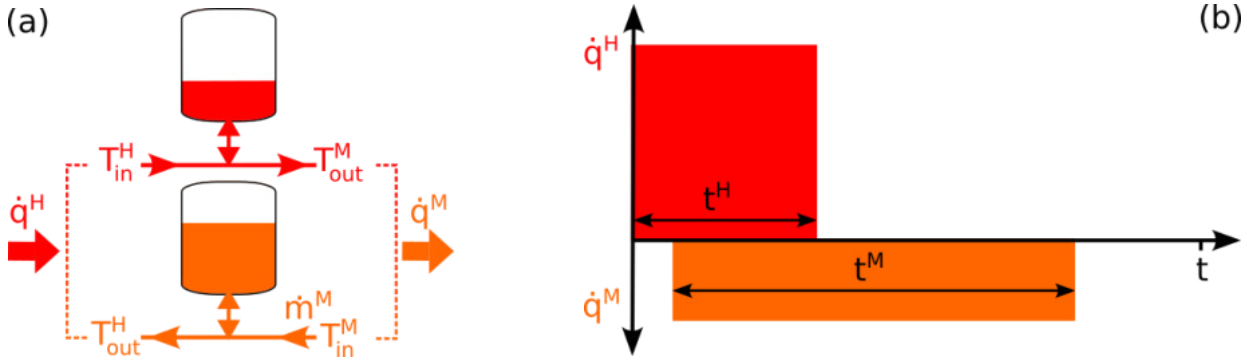

***Figure 1**. (a) 2-Tank TES system, (b) operation scenario*

Assuming a periodic stationary regime and no heat losses, energy and entropy balances related to the TES system write, on a period t:

$$\Delta U = \int_{t^H} \dot{m}^H \, (h^H_{in} - h^H_{out}) \, dt + \int_{t^M} \dot{m}^M \, (h^M_{in} - h^M_{out}) \, dt = 0 \tag{4}$$

$$\Delta S = \int_{t^H} \dot{m}^H \, (s^H_{in} - s^H_{out}) \, dt + \int_{t^M} \dot{m}^M \, (s^M_{in} - s^M_{out}) \, dt + \int_{t} \dot{\sigma}_{irr} \, dt = 0 \tag{5}$$

Posing

$$\dot{q}^H = \frac{1}{t^H} \int_{t^H} \dot{m}^H \, (h^H_{in} - h^H_{out}) \, dt \qquad \dot{q}^M = \int_{t^M} \dot{m}^M \, (h^M_{in} - h^M_{out}) \, dt \tag{6}$$

$$\tilde{T}^H = \frac{\int_{t^H} \dot{m}^H \, (h^H_{in} - h^H_{out}) \, dt}{\int_{t^H} \dot{m}^H \, (s^H_{in} - s^H_{out}) \, dt} \qquad \tilde{T}^M = \frac{\int_{t^M} \dot{m}^M \, (h^M_{in} - h^M_{out}) \, dt}{\int_{t^M} \dot{m}^M \, (s^M_{in} - s^M_{out}) \, dt} \tag{7}$$

Eqs. (3) and (4) simplify in:

$$\dot{q}^H t^H - \dot{q}^M t^M = 0 \tag{8}$$

$$\frac{\dot{q}^H t^H}{\tilde{T}^H} - \frac{\dot{q}^M t^M}{\tilde{T}^M} = - \int_{t} \dot{\sigma}_{irr} \, dt \leq 0 \tag{9}$$

Energy conservation (Eq. (8)) permits to express the 2nd law inequality according to the equivalent temperatures $\tilde{T}^H$ and $\tilde{T}^M$:

$$\tilde{T}^M - \tilde{T}^H \leq 0 \tag{10}$$

2.3. Equivalent power plant

The equivalence models allow any heat transfer fluid that undergoes a temperature change to be replaced by a thermostat whose temperature corresponds to the equivalence temperatures defined above. As an example, **Figure 2** presents the flowsheet of a CSP plant with indirect storage and its related equivalent model. All heat exchangers are replaced by a conductance, and every heat transfer fluid inlet/outlet by a thermostat. The process can be divided in three loops:

In the high temperature (HT) loop, the solar thermal flux $\dot{q}^H$ is collected and transferred to the TES system. The medium temperature (MT) loop picks up the thermal flux $\dot{q}^M$ from the TES system and transfers it to the power block. The power block consumes $\dot{q}^M$, and converts it in power $\dot{w}$ and thermal flux $\dot{q}^L$. The low temperature (LT) loop cools the power block and transfers the thermal flux $\dot{q}^L$ to the air through the cooling tower.

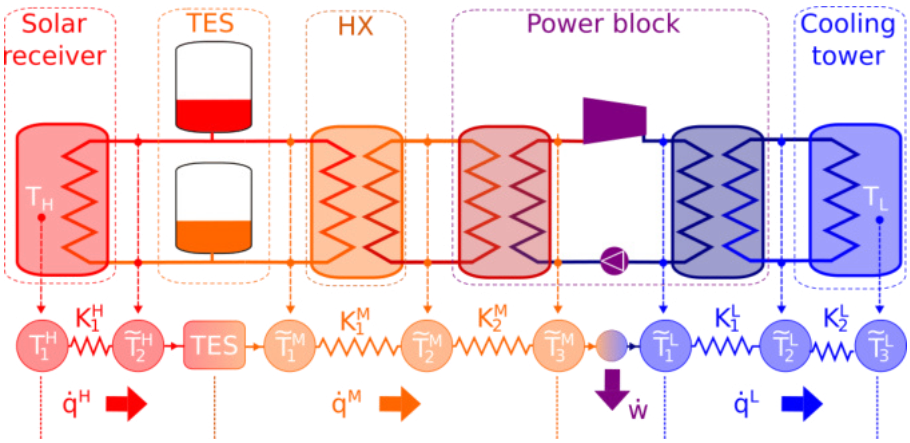

***Figure 2**. CSP plant with indirect storage. Schematic flowsheet and related equivalent system.*

2.3. Optimisation problem

To be as general as possible, the problem is defined for any number of heat exchangers in each loop. Thence, the power plant to be optimised includes (**Figure 3**):

- h heat exchangers in the HT loop,
- m heat exchangers in the MT loop,
- l heat exchangers in the LT loop.

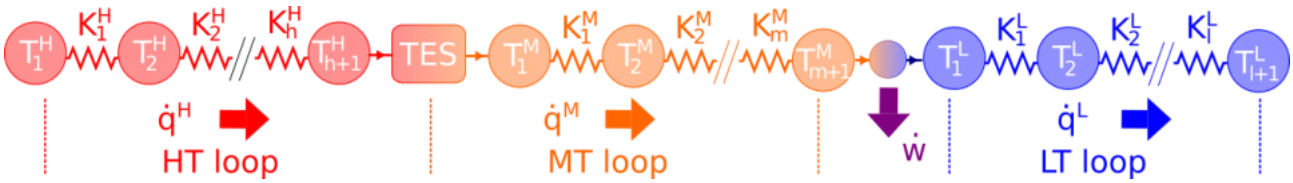

***Figure 3**. Equivalent system to be optimised.*

According to the operation scenario displayed **Figure 1b**, the mechanical energy produced per cycle is:

$$w = \dot{w}\, t^M \tag{11}$$

This quantity is maximised subjected to the following equality constraints:

1. conservation of energy for the TES, Eq. (8),
2. Newton's Law, Eq. (1), for each heat exchanger, in each loop,
3. conservation of energy for the power block, Eq. (2),
4. Equality of T_1^H and T_l^L with the temperature of the hot and cold sources,

$$T_1^H = \mathrm{T_H}, \qquad T_{l+1}^L = \mathrm{T_L} \tag{12}$$

Three inequality constraints also apply:

5. 2nd law related to the power block, Eq. (3),
6. 2nd law related to the TES system, Eq. (10),
7. Finite dimensions constraint: as each conductance must be finite, their sum is necessary also finite. Then, there exists a finite positive number K_Σ such as:

$$\sum_{i=1}^{h} K_i^H + \sum_{i=1}^{m} K_i^M + \sum_{i=1}^{l} K_i^L - K_\Sigma \leq 0 \tag{13}$$

The resolution of this optimisation problem is detailed in Appendix A. It involves $7 + 2 \cdot (h + m + l)$ optimisation variables (output power $\dot{w}$, heat fluxes $\dot{q}^H, \dot{q}^M$ and $\dot{q}^L$, $h + m + l$ conductances K_i^J, $h + m + l + 3$ temperatures T_i^J), and four optimisation parameters (durations t^H and t^M related to the operating scenario, and temperatures

of the heat source T_H and heat sink T_L). An optimal solution exists whatever the number of heat exchanger is. The main results are presented and discussed in the next section.

3. Results and discussion

The optimal solution is obtained for saturated inequality constraints (Eq. (A 31)-(A 33)).This shows logically that the TES system and the power block must be endoreversible, and that a higher K_Σ implies a higher output power. This last item appears clearly through the expression of the optimal power output (Eq. (A 66)):

$$\dot{w}^* = \frac{1}{\left(h\sqrt{t^M/t^H} + m + l\right)^2} K_\Sigma \left(\sqrt{T_H} - \sqrt{T_L}\right)^2 \tag{14}$$

which depends linearly on K_Σ. Equation (A 14) also shows how the number of heat exchangers affects the output power $\dot{w}^*$. As t^H and t^M are of same order of magnitude, the denominator represents approximatively the total number of heat exchangers $N_{HX} = h + m + l$. Thence, output power produced by the plant is approximately inversely proportional to N_{HX}. Impact of the TES can also be analysed. Increasing the ratio t^M/t^H, (i.e., increasing the storage capacity), reduces the capacity of the power block, but increases the mechanical energy provided during a cycle given by Eq. (11). **Figure 4** presents the evolution of output power $\dot{w}^*$ and mechanical energy $\dot{w}^*$ produced per day according to the production duration t^M and assuming t^H = 10 h (sunny hours in the case of CSP plant) for K_Σ = 10 MW/K, T_H = 30°C and T_H = 400°C. Three architectures are compared, all integrating an indirect cooling (cooling tower):

- Direct Steam Generation with direct storage, involving 3 HXs (h = 1, m = 0, l = 2)
- Indirect Steam Generation with direct storage, involving 3 HXs (h = 1, m = 1, l = 2)
- Indirect Steam Generation with indirect storage, involving 4 HXs (h = 1, m = 2, l = 2)

As t^H = 10h, t^M = 10 h correspond to no TES and t^M = 24 h to a continuous production implying a 14 h storage capacity.

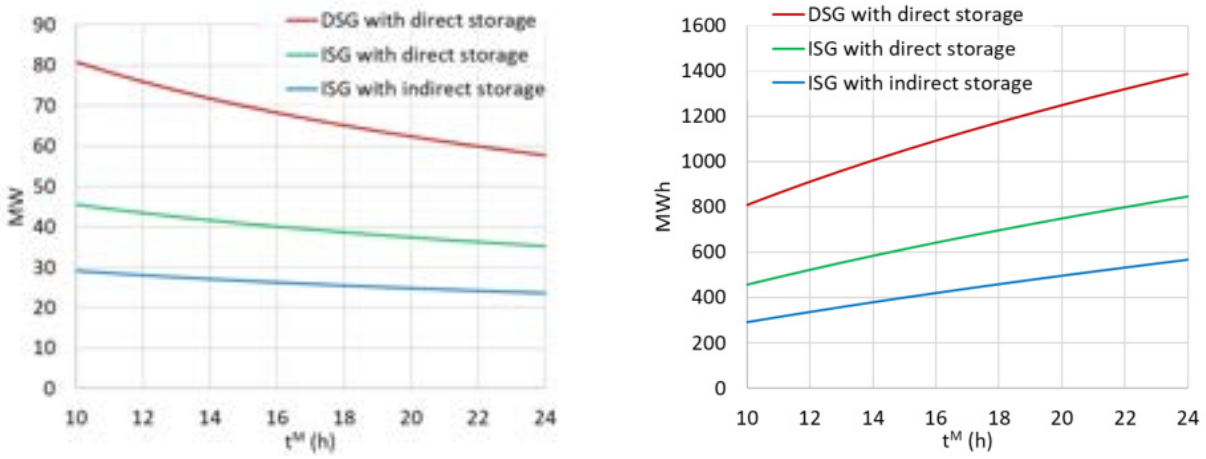

Figure 4. *Output power $\dot{w}^*$(a) and mechanical energy per day (b) according to the production duration.*

Influence of the number of HX is clearly displayed. For a constant K_Σ, which reflects the cost of the HXs, the output power or energy production evolves approximately with N_{HX}^{-2}, as mentioned above. Concerning the production duration, it decreases the power block capacity, but increases the daily production due to a longer production duration.

Another interesting result concerns the optimal conductances and driving forces. In each loop, all conductances (and consequently all driving forces because of Newton's Law) are equal. From Eqs. (A 43),(A 46) and (A 55) we have:

$$K^{L*} = K^{M*} \qquad \Delta T^{L*} = \sqrt{T_L/T_H}\ \Delta T^M \qquad \dot{q}^{L*} = \sqrt{T_L/T_H}\ \dot{q}^M \tag{15}$$

$$K^{H*} = \sqrt{t^M/t^H}\ K^* \qquad \Delta T^{H*} = \sqrt{t^M/t^H}\ \Delta T^M \qquad \dot{q}^{H*} = (t^M/t^H)\ \dot{q}^M \tag{16}$$

For the MT and LT loop downstream the TES, conductances are equal. Heat flux $\dot{q}^{L*}$ is lower $\dot{q}^{M*}$ because part of $\dot{q}^{M*}$ has been converted in power $\dot{w}^*$. Consequently, the driving force ΔT^{L*} is also lower than ΔT^{M*}.

For the HT loop, heat flux $\dot{q}^{H*}$ is higher then $\dot{q}^{M*}$, but here, the optimal solution shares equally this increase between the driving force ΔT^{K*} and the conductances K^{H*}

Finally, the energy efficiency of the plant can be deduced from (A 65) and (A 66):

$$\eta^* = \frac{\dot{w}^* t^M}{\dot{q}^{H*} t^H} = \frac{\dot{w}^*}{\dot{q}^{M*}} = 1 - \sqrt{\frac{T_L}{T_H}} \tag{17}$$

Thus, the optimal efficiency neither depends on the number of HXs, nor on the operating scenario, and is equal to the Curzon-Ahlborn efficiency. **Figure 5** compares the efficiency given by Eq.(17) with experimental efficiencies evaluated from available data sets covering many power plant architectures. The ORCs [17] correspond to the simpler structure: no TES ($t^M = t^H$), no MT loop ($m = 0$), direct or indirect cooling ($l = 1\ or\ 2$). Most of those displayed are laboratory prototypes. This could explain efficiencies sometimes much lower than η^*. For nuclear power plants [18], the hot source temperature (cladding maximum temperature) has been supposed to be 50°C higher than the reactor outlet temperature. Two architectures are presented, BWR ($h = 1$) and PWR ($h = 2$), the other parameters being similar ($t^M = t^H, m = 0, l = 1\ or\ 2$). Most of them reach or even overcome the optimal efficiency. Solar power plant [19] are also commercial plants, all including a TES, with various storage capacity ($2\ h\ < t_{storage}\ < 13\ h$), storage technology (m = 1 or 2), and involving a cooling tower (l = 2). Similarly to nuclear, the only hot temperature available in database was the solar field outlet temperature. Hot source temperatures (maximum temperature of the receiver wall) have been supposed to be 20°C (parabolic trough) or 50°C (tower) higher than the solar field outlet temperature. This figure clearly displays the fact that commercial plants, which have benefited for more than 40 years (solar) or 70 years (nuclear) of R&D fit quite well the η^* curve. That proves that Eq. (17) gives a good approximation of the efficiency of heat engines that have benefited from several decades of research and development. Therefore, we can reasonably assume that it also gives a good assessment of what the efficiency of emerging technologies will be in their future commercial form.

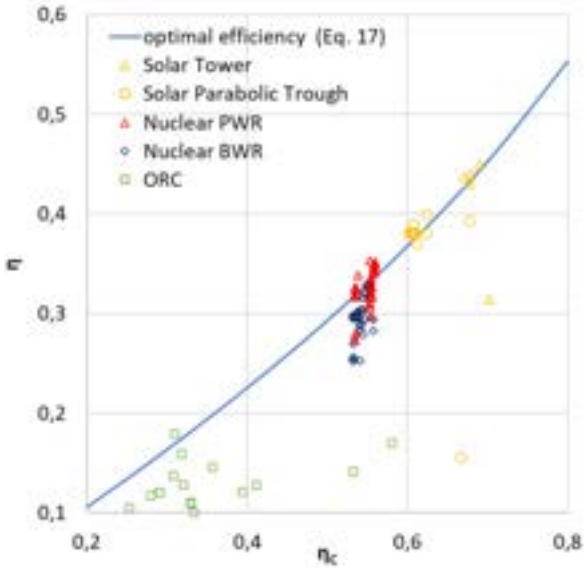

***Figure 5** : Energy efficiency of power plants from [17], [18], [19] data.*

4. Conclusion

This study aimed to extend FDT results to many power plant structures that may involve different numbers of heat exchangers and may operate with or without a TES. A general model was developed that determined the operating temperatures maximizing the power plant's output energy. A remarkable result is that the optimal efficiency is equal to the Curzon-Ahlborn efficiency, regardless the architecture of the plant and the operation scenario. However, the architecture of the plant impacts a lot the output power which varies approximatively with N_{HX}^{-2}. Concerning the operation scenario, increasing the storage capacity decreases the installed capacity of the power block but increases the daily energy output. Finally, the comparison of the actual efficiency of power plants shows that technologies that have benefited from several years of R&D achieve the Curzon Ahlborn efficiency. The latter could then be used to estimate the future performance of emerging technologies, such as combined cycles, or supercritical cycles. These technologies could take advantage of a higher temperature provided by generation IV nuclear reactors or future solar towers. Integrating these new technologies in the present analysis is one of the perspectives of this work.

Appendix A

The optimization problem is:

$\min(-\dot{w}\ t^M)$

s.t. $\dot{q}^H\ t^H - \dot{q}^M\ t^M = 0$ (A 1)

$K_i^J\left(T_i^J - T_{i+1}^J\right) - \dot{q}_i^J = 0\ , \forall\ J\ \in \{H,\ M, L\}, \forall\ i\ \in\ [1 \cdots n^J]$ (A 2)

$\dot{q}^H\ -\ \dot{q}^L -\ \dot{w} = 0$ (A 3)

$T_1^H = \mathrm{T_H}$ (A 4)

$T_{l+1}^L = \mathrm{T_L}$ (A 5)

$T_1^M - T_{h+1}^H \leq 0$ (A 6)

$\dot{q}^M/T_{m+1}^M - \dot{q}^L/T_1^L \leq 0$ (A 7)

$$\sum_{J=H,M,L}\left(\sum_{i=1}^{n^J} K_i^J\right) - K_\Sigma \leq 0 \quad \text{(A 8)}$$

The durations (t^H, t^M), the heat source temperatures ($\mathrm{T_H}$,$\mathrm{T_L}$) and the numbers of heat exchangers $n^H = h$, $n^M = m,\ n^L = l$) being taken as parameters, the Lagrangian function of this optimization problem writes:

$$\mathcal{L}\left(\dot{w}, \dot{q}^J, K_i^J, T_i^J, \lambda_i^J, \lambda_k, \mu_n\right) = \left\{\begin{array}{l} -\dot{w}\ t^M + \lambda_1(\dot{q}^H\ t^H -\ \dot{q}^M\ t^M) + \sum_{J=H,M,L}\left\{\sum_{i=1}^{n^J}\lambda_i^J\left[K_i^J\left(T_i^J - T_{i+1}^J\right) - \dot{q}^J\right]\right\} \\ +\lambda_2(\dot{q}^M -\ \dot{q}^L -\ \dot{w}) + \lambda_3(T_1^H - \mathrm{T_H}) + \lambda_4(T_{l+1}^L - \mathrm{T_L}) \\ +\mu_1(T_1^M - T_{h+1}^H) + \mu_2(\dot{q}^M/T_{m+1}^M - \dot{q}^L/T_1^L) + \mu_3\left[\sum_{J=H,M,L}\left(\sum_{i=1}^{n^J} K_i^J\right) - K_\Sigma\right] \end{array}\right\} \quad \text{(A 9)}$$

where $J\ \in \{H,\ M, L\}$, $i\ \in\ [1 \cdots n^J]$, $k\ \in\ [1 \cdots 5]$, $n \in\ [1 \cdots 2]$. The optimal conditions are:

$$\frac{\partial \mathcal{L}}{\partial \dot{w}} = -t^M -\ \lambda_2 = 0 \quad \text{(A 10)}$$

$$\frac{\partial \mathcal{L}}{\partial \dot{q}^H} = \lambda_1\ t^H - \sum_{i=1}^{h}\lambda_i^H = 0 \quad \text{(A 11)}$$

$$\frac{\partial \mathcal{L}}{\partial \dot{q}^M} = -\lambda_1\ t^M - \sum_{i=1}^{m}\lambda_i^M + \lambda_2 + \mu_2/T_{m+1}^M = 0 \quad \text{(A 12)}$$

$$\frac{\partial \mathcal{L}}{\partial \dot{q}^L} = -\sum_{i=1}^{l}\lambda_i^L - \lambda_2 - \mu_2/T_1^L = 0 \quad \text{(A 13)}$$

$$\frac{\partial \mathcal{L}}{\partial K_i^J} = \lambda_i^J\left(T_i^J - T_{i+1}^J\right) + \mu_3\ = 0, \forall\ J\ \in \{H, M, L\}, \forall\ i\ \in\ [2 \cdots n^J] \quad \text{(A 14)}$$

$$\frac{\partial \mathcal{L}}{\partial T_i^J} = \lambda_i^J K_i^J - \lambda_{i-1}^J K_{i-1}^J = 0, \qquad \forall\ J\ \in \{H, M, L\}, \qquad \forall\ i\ \in\ [2 \cdots n^J] \quad \text{(A 15)}$$

$$\frac{\partial \mathcal{L}}{\partial T_1^H} = \lambda_1^H K_1^H + \lambda_3 = 0 \quad \text{(A 16)}$$

$$\frac{\partial \mathcal{L}}{\partial T_{h+1}^{H}} = -\lambda_h^H K_h^H - \mu_1 = 0 \quad \text{(A 17)}$$

$$\frac{\partial \mathcal{L}}{\partial T_1^M} = \lambda_1^M K_1^M + \mu_1 = 0 \quad \text{(A 18)}$$

$$\frac{\partial \mathcal{L}}{\partial T_{m+1}^M} = -\lambda_m^M K_m^m - \mu_2 \, \dot{q}^M / (T_{m+1}^M)^2 = 0 \quad \text{(A 19)}$$

$$\frac{\partial \mathcal{L}}{\partial T_1^L} = \lambda_1^L K_1^L + \mu_2 \, \dot{q}^L / (T_1^L)^2 = 0 \quad \text{(A 20)}$$

$$\frac{\partial \mathcal{L}}{\partial T_{l+1}^L} = -\lambda_l^L K_l^L + \lambda_4 = 0 \quad \text{(A 21)}$$

$$\dot{q}^H \, t^H - \, \dot{q}^M \, t^M = 0 \quad \text{(A 22)}$$

$$K_i^J \left(T_i^J - T_{i+1}^J\right) - \dot{q}^J = 0, \qquad \forall \, J \in \{H, M, L\}, \qquad \forall \, i \in [1 \cdots n^J] \quad \text{(A 23)}$$

$$\dot{q}^H - \dot{q}^L - \dot{w} = 0 \quad \text{(A 24)}$$

$$T_1^H - \mathrm{T_H} = 0 \quad \text{(A 25)}$$

$$T_{l+1}^L - \mathrm{T_L} = 0 \quad \text{(A 26)}$$

$$\mu_1 (T_1^M - T_{h+1}^H) = 0, \qquad \mu_1 \geq 0, \quad \text{(A 27)}$$

$$\mu_2 (\dot{q}^M / T_{m+1}^M - \dot{q}^L / T_1^L) = 0, \qquad \mu_2 \geq 0 \quad \text{(A 28)}$$

$$\mu_3 \left(\sum_{J=H,M,L} \left(\sum_{i=1}^{n^J} K_i^J \right) - K_\Sigma \right) = 0, \qquad \mu_3 \geq 0 \quad \text{(A 29)}$$

We first demonstrate that μ_1, μ_2 and μ_3 cannot be null and then solve this system.

1. $\mu_3 = 0$

Equation (A 14) shows that all the λ_i^J should be zero, as $T_i^J - T_{i+1}^J = 0$ would imply, from (A 23), $\dot{q}^J = 0$ which is not acceptable. Therefore, $\mu_2 = 0$ from (A 19) or (A 20), and (A 13) implies that $\lambda_2 = 0$,which is forbidden from (A 10), the duration t^M being strictly positive:

$$\lambda_2 = -t^M \quad \text{(A 30)}$$

Hence, $\mu_3 \neq 0$

2. $\mu_1 = 0$

Equation (A 18) shows that λ_1^M should be zero as $K_1^M = 0$ would imply, , from (A 23), $\dot{q}^M = 0$, which is not acceptable. Therefore, Eq. (A 15) implies that all $\lambda_i^M = 0$ because $K_{\mathrm{j}}^M = 0$ would also implies $\dot{q}^M = 0$. Thence, $\mu_2 = 0$ from Eq. (A 19), which is not acceptable as seen above. Hence, $\mu_1 \neq 0$

3. $\mu_2 = 0$

Equations (A 19) shows that $\lambda_m^M = 0$ as $K_m^M = 0$ is not acceptable, because it would imply, from (A 23), $\dot{q}^M = 0$. Therefore, $\mu_2 = 0$ from (A 14), which is forbidden as seen above. Hence, $\mu_2 \neq 0$

4. $\mu_1 \neq 0$ and $\mu_2 \neq 0$ and $\mu_3 \neq 0$

Equations (A 28) and (A 29) then write:

$$T_1^M = T_{h+1}^H = \mathrm{T_{TES}}, \qquad \mu_1 \geq 0 \quad \text{(A 31)}$$

$$\frac{\dot{q}^M}{T_{m+1}^M} - \frac{\dot{q}^L}{T_1^L} = 0, \qquad \mu_2 > 0 \quad \text{(A 32)}$$

$$\sum_{i=1}^{h} K_i^H + \sum_{i=1}^{m} K_i^M + \sum_{i=1}^{l} K_i^L - K_\Sigma = 0, \quad \mu_3 > 0 \tag{A 33}$$

Equations (A 31) and (A 32) demonstrates that, quite logically:

- the optimal TES system operates reversibly,
- the optimal power block is an endoreversible engine.

Equations (A 14) and (A 23) imply:

$$\lambda_i^J = -\frac{\mu_3}{\left(T_i^J - T_{i+1}^J\right)} = -\mu_3 \frac{K_i^J}{\dot{q}^J}, \qquad \forall\, J \in \{H, M, L\}, \qquad \forall\, i \in [2 \cdots n^J] \tag{A 34}$$

Replacing λ_i^J in Eq. (A 15) gives:

$$-\frac{\mu_3}{\dot{q}^J}\left[\left(K_i^J\right)^2 - \left(K_{i-1}^J\right)^2\right] = 0, \qquad \forall\, J \in \{H, M, L\}, \qquad \forall\, i \in [2 \cdots n^J] \tag{A 35}$$

showing that, in each loop (i.e., HT, MT, or LT loops), all the conductances are equal.

$$K_i^H = K^H, \quad K_i^M = K^M, \quad K_i^L = K^M, \qquad \forall\, i \tag{A 36}$$

That also implies, from Eq. (A 34):

$$\lambda_i^H = -\mu_3 \frac{K^H}{\dot{q}^H} = \lambda^H, \qquad \lambda_i^M = -\mu_3 \frac{K^M}{\dot{q}^M} = \lambda^M, \qquad \lambda_i^L = -\mu_3 \frac{K^L}{\dot{q}^L} = \lambda^L, \qquad \forall\, i \tag{A 37}$$

$$T_i^H - T_{i+1}^H = \frac{\dot{q}^H}{K^H} = \Delta T^H, \quad T_i^M - T_{i+1}^M = \frac{\dot{q}^M}{K^M} = \Delta T^M, \quad T_i^L - T_{i+1}^L = \frac{\dot{q}^L}{K^L} = \Delta T^L, \quad \forall\, i \tag{A 38}$$

Introducing the expressions of λ_i^J in Eqs.(A 11) (A 16),(A 17),(A 18) and (A 21) gives:

$$\lambda_1 = -\mu_3 \frac{h\, K^H}{\dot{q}^H\, t^H} \tag{A 39}$$

$$\lambda_3 = \mu_3 \frac{(K^H)^2}{\dot{q}^H} \tag{A 40}$$

$$\mu_1 = \mu_3 \frac{(K^H)^2}{\dot{q}^H} = \mu_3 \frac{(K^M)^2}{\dot{q}^M} \tag{A 41}$$

$$\lambda_4 = -\mu_3 \frac{(K^L)^2}{\dot{q}^L} \tag{A 42}$$

Equations (A 22), (A 41) and (A 38) imply:

$$\dot{q}^H = \tau\, \dot{q}^M, \qquad K^H = \sqrt{\tau}\, K^M, \qquad \Delta T^H = \sqrt{\tau}\, \Delta T^M \tag{A 43}$$

with $\tau = t^M / t^H$

Expressing μ_2 from Eqs. (A 19) and (A 20), and using (A 36) and (A 37) gives:

$$\mu_2 = \mu_3\, (K^M)^2 \left(\frac{T_{m+1}^M}{\dot{q}^M}\right)^2 = \mu_3\, (K^L)^2 \left(\frac{T_1^L}{\dot{q}^L}\right)^2 \tag{A 44}$$

showing that, using (A 32):

$$K^M = K^L = K^* \tag{A 45}$$

Introducing Eqs. (A 43) and (A 45) in Eq. (A 33) gives the optimal values of the conductance K^*:

$$\mathrm{h} \cdot \sqrt{\tau}\, \mathrm{K}^* + \mathrm{m} \cdot\, \mathrm{K}^* + \mathrm{l} \cdot\, \mathrm{K}^* = K_\Sigma \implies \mathrm{K}^* = \frac{K_\Sigma}{\mathrm{h} \cdot \sqrt{\tau} + m + l} \tag{A 46}$$

Introducing the expression of λ_1(A 39), λ_2 (A 30), μ_2(A 44) and λ_i^J(A 37) in Equations (A 12) and (A 13) gives:

$$\mu_3 \left[h \frac{K^H}{\dot{q}^H} \frac{t^M}{t^H} + \mathrm{m} \ \frac{K^M}{\dot{q}^M} + T_{m+1}^M \left(\frac{K^M}{\dot{q}^M} \right)^2 \right] = t^M \tag{A 47}$$

$$\mu_3 \left[-l \ \frac{K^L}{\dot{q}^L} + T_1^L \left(\frac{K^L}{\dot{q}^L} \right)^2 \right] = t^M \tag{A 48}$$

Using (A 38) and (A 43), Equations (A 47) and (A 48) write:

$$\frac{\mu_3}{\Delta T^M} \left[h\sqrt{\tau} \ + \mathrm{m} + \frac{T_{m+1}^M}{\Delta T^M} \right] = t^M \tag{A 49}$$

$$\frac{\mu_3}{\Delta T^L} \left[-l \ + \frac{T_1^L}{\Delta T^L} \right] = t^M \tag{A 50}$$

Thence,

$$\mu_3 = \frac{t^M (\Delta T^M)^2}{\left(h\sqrt{\tau} \ + m \right) \Delta T^M + T_{m+1}^M} = \frac{t^M (\Delta T^L)^2}{-l \ \Delta T^L + T_1^L} \tag{A 51}$$

Combining (A 43), (A 25) and (A 31) gives:

$$\left(h\sqrt{\tau} \ + m \right) \Delta T^M = h \ \Delta T^H + \ m \ \Delta T^M = T_1^H - T_{h+1}^H + T_1^M - T_{m+1}^M = T_H - T_{m+1}^M \tag{A 52}$$

In a similar way, we have, using (A 26)

$$l \ \Delta T^L = T_1^L - T_{l+1}^L = T_1^L - T_L \tag{A 53}$$

Thence, Eq. (A 51) simplifies in:

$$\mu_3 = \frac{t^M (\Delta T^M)^2}{T_H} = \frac{t^M (\Delta T^L)^2}{T_L} \tag{A 54}$$

showing that:

$$\Delta T^L = \sqrt{\frac{T_L}{T_H}} \ \Delta T^M \ . \tag{A 55}$$

Combining (A 38), (A 44) and (A 55) gives:

$$\mu_2 = \mu_3 \left(\frac{T_{m+1}^M}{\Delta T^M} \right)^2 = \mu_3 \left(\frac{T_1^L}{\Delta T^L} \right)^2 \implies T_1^L = \frac{\Delta T^L}{\Delta T^M} \ T_{m+1}^M = \sqrt{\frac{T_L}{T_H}} \ T_{m+1}^M \tag{A 56}$$

Introducing (A 55) and (A 56) in (A 53) gives

$$l \sqrt{\frac{T_L}{T_H}} \ \Delta T^M = \sqrt{\frac{T_L}{T_H}} \ T_{m+1}^M - T_L \ \Rightarrow \ T_{m+1}^M = \sqrt{T_H T_L} + l \ \Delta T^M \tag{A 57}$$

Thence, (A 52) writes :

$$\left(h\sqrt{\tau} \ + m \right) \Delta T^M = T_H - \sqrt{T_H T_L} - l \ \Delta T^M \tag{A 58}$$

which gives the optimal expressions of ΔT_M^*:

$$\Delta T^{M*} = \frac{T_H - \sqrt{T_H T_L}}{h\sqrt{\tau} \ + m + l} \tag{A 59}$$

ΔT^{H*} and ΔT^{L*} are deduced respectively from (A 43) and (A 55):

$$\Delta T^{H*} = \sqrt{\tau} \frac{T_H - \sqrt{T_H T_L}}{h\sqrt{\tau} \ + m + l}, \qquad \Delta T^{L*} = \frac{\sqrt{T_H T_L} - T_L}{h\sqrt{\tau} \ + m + l} \tag{A 60}$$

All the optimization variables can be now deduced.

Conductances

Optimal conductances are given by Eqs (A 43), (A 45) and (A 46):

$$K_i^{L*} = K_i^{M*} = K^* = \frac{K_\Sigma}{\mathrm{h}\cdot\sqrt{\tau}+m+l}, \qquad K_i^{H*} = \sqrt{\tau}\,K^* = \frac{\sqrt{\tau}\,K_\Sigma}{\mathrm{h}\cdot\sqrt{\tau}+m+l} \tag{A 61}$$

Temperatures

The optimal temperature bounding the power block write, using (A 56) and (A 57):

$$T_{m+1}^{M*} = \frac{l\,T_H + \left(h\sqrt{\tau}\,+m\right)\sqrt{T_H T_L}}{h\sqrt{\tau}\,+m+l}, \qquad T_1^{L*} = \frac{l\,\sqrt{T_H T_L} + \left(h\sqrt{\tau}\,+m\right)T_L}{h\sqrt{\tau}\,+m+l}, \tag{A 62}$$

The optimal temperature of the TES ($T_{TES} = T_{h+1}^{H} = T_1^{M}$) can be deduced from (A 59) and (A 62) reminding that $m\,\Delta T^M = T_1^M - T_{m+1}^M$:

$$T_{TES}^* = \frac{(l+m)\,T_H + h\sqrt{\tau}\,\sqrt{T_H T_L}}{h\sqrt{\tau}\,+m+l} \tag{A 63}$$

General expressions for the temperatures are:

$$\begin{aligned} T_{i+1}^{H*} &= T_H - i\;\Delta T^{H*}, & i &= 0..h \\ T_{i+1}^{M*} &= T_{TES} - i\,\Delta T^{M*} & i &= 0..m \\ T_{i+1}^{L*} &= T_L + (l-i)\,\Delta T^{L*}, & i &= 0..l \end{aligned} \tag{A 64}$$

Heat flows and mechanical power

The heat flows are obtained using (A 43), (A 45),(A 46),(A 59) and (A 60):

$$\dot{q}^{H*} = \tau\,K_\Sigma\frac{T_H - \sqrt{T_H T_L}}{\left(h\sqrt{\tau}\,+m+l\right)^2}, \quad \dot{q}^{M*} = K_\Sigma\frac{T_H - \sqrt{T_H T_L}}{\left(h\sqrt{\tau}\,+m+l\right)^2}, \qquad \dot{q}^{L*} = K^*\frac{\sqrt{T_H T_L} - T_L}{\left(h\sqrt{\tau}\,+m+l\right)^2} \tag{A 65}$$

Mechanical power is obtained from (A 24). Using (A 65), we get:

$$\dot{w}^* = K_\Sigma\frac{\left(\sqrt{T_H} - \sqrt{T_L}\right)^2}{\left(h\sqrt{\tau}\,+m+l\right)^2} \tag{A 66}$$

Lagrange multipliers

Combining Eqs. (A 41), (A 54) and (A 56) gives:

$$\mu_1^* = t^M\frac{\dot{q}^{M*}}{T_H} > 0 \qquad \mu_2^* = \frac{t^M}{T_H}(T_{m+1}^{M*})^2 > 0 \qquad \mu_3^* = \frac{t^M}{T_H}(\Delta T^{M*})^2 > 0 \tag{A 67}$$

From Eqs. (A 37) to (A 42), combined with (A 54),(A 55) and (A 61) , we get

$$\begin{aligned} &\lambda_1^* = -\,h\,\frac{\Delta T^{H*}}{T_H}, \qquad \lambda_2^* = -t^M, \qquad \lambda_3^* = t^M\frac{\dot{q}^{M*}}{T_H}, \qquad \lambda_4^* = -t^M\frac{\dot{q}^{L*}}{T_L} \\ &\lambda_i^{H*} = -\,t^H\frac{\Delta T^{H*}}{T_H}, \qquad \lambda_i^{M*} = t^M\frac{\Delta T^{M*}}{T_H}, \quad \lambda_i^{L*} = -\,t^M\frac{\Delta T^{L*}}{T_L}, \qquad \forall\, i \end{aligned} \tag{A 68}$$

Nomenclature

Abstract:

Providing energy services can be achieved by various technologies or combinations of technologies and it is important to be able to characterize the quality of these different options. In practice, different indicators of the quality of energy processes can be defined: the effectiveness based only on the First Law of thermodynamics or the exergy efficiency based on the exergy balance, thus accounting for both the First and the Second Laws of thermodynamics. While the exergy efficiency definition is general and applies to all systems with values always ≤1, it is not the case of the effectiveness. Today, there is no general definition and formulation of effectiveness that can be applied to all technologies and/or energy conversion systems. The most general formulation of effectiveness given in the literature is indeed mainly valid for processes that take place above the atmospheric temperature. It must however be adapted for refrigeration systems and also for any conversion systems providing simultaneously energy services for both heating and cooling. In this article, we propose a new approach for a general expression of the effectiveness suitable for any energy conversion systems including heat pumps and cogeneration systems with combined heating and cooling. The main advantage of such a method is therefore to provide simple and generic expressions of global exergy losses and efficiencies of any systems in relation to the conventional performance indicator (the effectiveness) most commonly used by engineers to estimate energy losses of a system.

Keywords:

Thermodynamics; Exergy losses; Exergy efficiency; Effectiveness; Explicit relations of exergy

1. Introduction

Energy services can be provided by a variety of types of processes, technologies or combinations of technologies, including boilers, powerplants and heat pump/refrigeration systems with or without cogeneration(combining power, heating and/or cooling). The energy processes can take place in various forms, accompanied by different losses: internal and external losses. The internal losses are resulting from various irreversibilities (dissipations, thermal devaluation and others) while the external losses are related to the energy released to the atmosphere (heat losses, exhaust losses, energy evacuated by a cooling media). In practice, different indicators of the quality of energy processes can be defined [1,2]: the effectiveness based only on the First Law of thermodynamics or the exergy efficiency based on the exergy balance, thus accounting for both the First and the Second Laws of thermodynamics. Different approaches, formalisms and nomenclatures of the exergy analysis to identify losses in a system are reported in [3]. The exergy method applied by some authors [4, 5] consists of quantitatively evaluating the global exergy losses $\dot{L}$ on the basis of internal exergy losses $\dot{L}_D$ called also exergy destruction inside the strictly defined system and external exergy losses $\dot{L}_E$ or exergy destroyed between the system and the atmosphere and calculating the overall exergy efficiency. A general approach of exergy formulation has also been proposed in [1, 2] on the basis of an exergy balance carried out on the boundary of the system extended to the atmosphere in order to internalize and attribute all losses to the system and also by subdividing $\dot{L}$ in two subcategories: the dissipation exergy losses inside the system and the heat transfer exergy losses. Based on this approach, the performance of a system can be determined using a general formulation of efficiency by identifying all exergy services (work, heat and flow exergies) received or provided by the system. All these approaches or methods are equivalent in term of using entropy to estimate the global exergy losses and are still not frequently used in industrial sectors, as it may seem too theoretical. Besides, its application, although ideal for comparing different technologies and locating losses, is not easy for practitioners for different reasons: the concept of entropy and the potential maximum of work associated to a flow-energy (co-enthalpy) are not well understood [1].

The effectiveness (based on the First Law of thermodynamics) is most commonly used by partitioners because of the simplicity of using the energy balance equation to identify external energy losses without any knowledge of entropy. It is however not applicable to compare different technologies because of the multiple definitions that exist (engine efficiency, efficiency based on Lower Heating Value or on Higher Heating Value, heating coefficient of performance, cooling coefficient of performance). Today, there is no general definition and formulation of effectiveness that can be applied to all technologies. The most general formulation of effectiveness given in [5] is indeed only valid for processes that take place above the atmospheric temperature. It must therefore be adapted for refrigeration systems but also for any conversion systems providing simultaneously energy services for both heating and cooling.

In this article, we propose a **new approach for a general expression of the effectiveness** applied to all technologies including heat pumps when used in cogeneration with combined heating and cooling. This new approach facilitates the use of exergy theory in a way to highlight, with explicit equations, the existing link and relationship between energy and exergy losses of any system. Results of using such a method are shown for different examples of cogeneration systems with integrated technologies but also for particular basic components like boilers, heat exchangers and air-coolers. The overall exergy losses and efficiencies explicitly are expressed in function of the effectiveness and the energy services balance which can be determined in any case without any knowledge of the entropy. This can be useful for practitioners to determine and know the exergy performance of any energy system based solely on energy balance terms and the effectiveness of the system.

2. Commonly used indicators of the quality of energy processes

In practice, two different indicators of the quality of energy processes can be defined: the effectiveness (ε: so-called "thermal efficiency" or "coefficient of performance") based only on the First Law of thermodynamics or, better, the exergy efficiency (η) based on the exergy balance, thus accounting for both the First and the Second Laws of thermodynamics. The basic idea of the exergy performance indicator given in [1,2] is to use:

$$\eta = \frac{\sum_t \left[\dot{E}^-_{u,t}\right]}{\sum_t \left[\dot{E}^+_{u,t}\right]} \tag{1}$$

Where $\sum_t \left[\dot{E}^-_{u,i}\right]$ represents the total exergy services provided or delivered by the system to consumers in the form of work ($\dot{E}^-_w$), heat ($\dot{E}^-_q$) and transformation ($\dot{E}^-_y$) exergies and $\sum_t \left[\dot{E}^+_{u,t}\right]$ represents the total exergy services received by the system from utilities in the form of work ($\dot{E}^+_w$), heat ($\dot{E}^+_q$) and transformation ($\dot{E}^+_y$) exergies. All terms here are numerically positive. Considering the global exergy loss ($\dot{L}$) in the system, the ***exergy efficiency*** can then simply be formulated as follows:

$$\eta = \frac{\dot{E}^-_w + \dot{E}^-_q + \dot{E}^-_y}{\dot{E}^+_w + \dot{E}^+_q + \dot{E}^+_y} = 1 - \frac{\dot{L}}{\sum_t \left[\dot{E}^+_{u,t}\right]} \tag{2}$$

When any exergy term of the numerator exits the system without being used, the boundary of the system needs to be extended to the atmosphere and this exergy term becomes zero, but the corresponding exergy losses are still accounted for in $\dot{L}$ since the denominator has not changed. We can say that the related exergy loss is internalized and attributed to the system. For example, if the system is a combustion engine with a generator, its main service is to provide electricity, even though the cooling network has exergy that could potentially be used by others. However, if the exergy of the cooling network is not used but is destroyed in a cooling tower, it is automatically included in the exergy losses $\dot{L}$. Some authors [4, 5] subdivide $\dot{L}$ into:

$$\dot{L} = \dot{L}_D + \dot{L}_E$$

Where $\dot{L}_D$ includes the exergy destruction inside the strictly defined system and $\dot{L}_E$ includes the exergy destroyed between the system and the atmosphere. For example, if the designer knows that there is no use of the heat of an engine thermal cycle he should not only try to limit the exergy destruction inside the cycle itself but also design the cycle in such a way to try to minimize the heat exergy exiting the system.

Although different definitions of exergy efficiency can be found in the literature, a simple example will show the interest of having introduced the transformation exergy concept in its formulation. Take the heat exchanger of Figure 1 used to heat a substance (c) such as cold milk with another substance (h) e.g. hot water (two-stream heat transfer process with no phase-change).

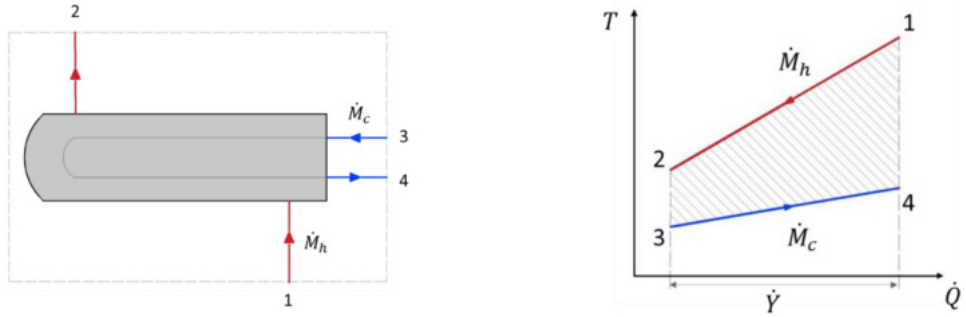

Fig. 1: Example of a heat transfer process through a heat exchanger
a) Schematic heat exchanger process, b) T-Q diagram of the hot and cold streams

The transformation (also called flow) energy ($\dot{Y}_h^+$) received by the system from the hot stream at a given temperature (T_h) is transferred through the heat exchanger to a cold stream ($\dot{Y}_c^-$) at a useful temperature (T_c). The above formulation of efficiency Eq. (2) reduces to:

$$\eta = \frac{\dot{E}_{yc}^-}{\dot{E}_{yh}^+} = \frac{\dot{M}_c\,(k_4 - k_3)}{\dot{M}_h\,(k_1 - k_2)} \leq 1 \tag{3}$$

Where $\dot{E}_{yh}^+$ is the exergy received from the hot stream (water), $\dot{E}_{yc}^-$ represents the one transferred to the cold stream (milk) through the heat exchanger and $k_j = h_j - T_a s_j$ represents the coenthalpy of the fluid in State j. That is coherent with the services provided and avoids discrepancies due to the fact that different thermodynamic references exist for the substances milk and water. Therefore an efficiency defined like:

$$\eta^* = \frac{\dot{M}_c\,k_4 + \dot{M}_h\,k_2}{\dot{M}_h\,k_1 + \dot{M}_c\,k_3} \tag{4}$$

would not be adequate to provide a coherent view of the exergy service to be provided. Furthermore, if two users refer to different thermodynamic databases they would get, for the same system, different values for the efficiency η^*. Such a confusion is avoided when using the definition η (Eq.3). It is interesting to note that the general exergy efficiency Definition (Eq.2) remains valid when a refrigeration service is demanded. In Figure 1 the milk could be cooled typically from the atmospheric temperature to a lower temperature by a water or brine achieving thus the required refrigeration service. Equation (3) remains unchanged since the cooled milk leaves with a higher exergy level while, on the other side the water loses some of its exergy from inlet to exhaust of the heat exchanger. This results from the fact that, as was shown in [1], the further the thermodynamic state of a substance, at a given pressure, is away from the dead state (atmosphere) the higher is its exergy level represented here by the coenthalpies.

It is not the same for the energy terms that do not change sign below and above the atmospheric temperature, with the exception of the heat losses to the atmosphere. The basic idea of the effectiveness is that all energy exchanges between a system and its atmospheric environment (taken from and/or released to the environment) are considered as losses. The general formulation of the ***effectiveness*** given in [1,2] (based on First Law only) in a similar manner to what has been done for the exergy efficiency would give:

$$\varepsilon = \frac{\dot{E}_w^- + \dot{Q}_i^- + Y_n^-}{\dot{E}_w^+ + \dot{Q}_i^+ + Y_n^+} \qquad T > T_a \tag{5}$$

This expression is indeed only valid for processes that take place above the atmospheric temperature and can take values between 0 and ∞. The effectiveness, as defined from the general Equation (Eq.2), is not an absolute quality indicator like the exergy efficiency is. It is still commonly used but mainly for relative comparison between system alternatives providing the same service. To illustrate this, let us consider the case of a simple heat pump for heating (a) and cooling (b) applications given in Figure 1.

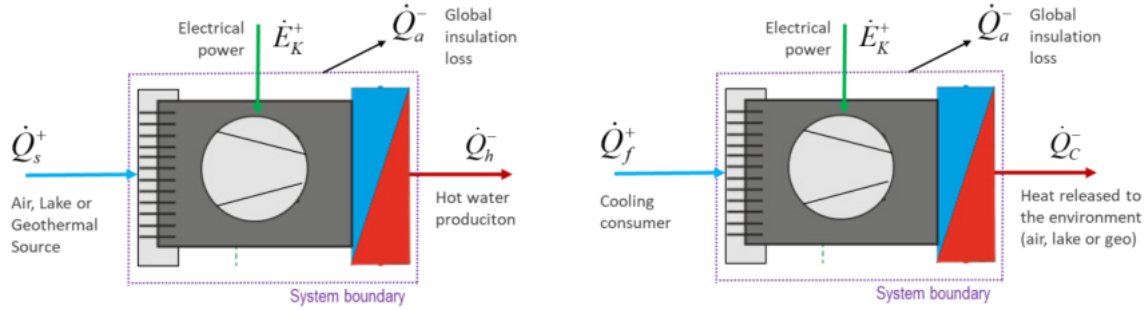

Fig. 2: Example of a vapor compression simple heat pump system: (a) for a heating, (b) for a cooling

For this case of a heat pump, the system boundary is defined by the closed cycle refrigerant (working fluid), so that the thermal energy exchanges with the exterior (with the user and/or the environment) are represented by thermal-heat only ($\dot{Q}$); there is no flow-energy ($\dot{Y}$) exchanged between the system and the exterior.

For the **heating** application, the system receives electricity ($\dot{E}_w^+ = \dot{E}_K^+$) and captures heat-energy ($\dot{Q}_s^+$) from the environment to deliver thermal heat ($\dot{Q}_h^-$) to a user for hot water production. Knowing that $\dot{Q}_s^+$ heat energy comes from the environment and is therefore "free" and thus not accounted for, the heating effectiveness $\boldsymbol{\varepsilon_h}$ obtained from Eq. (5) becomes:

$$\varepsilon_h = \frac{\dot{Q}_h^-}{\dot{E}_w^+} \geq 1 \quad (6)$$

Because the numerical value of this indicator is always higher than one and thus can no more semantically be called an "efficiency", this heating effectiveness is commonly called "coefficient of performance of heating (COP_h)".

The situation is different for the heat pump with **cooling** application of Figure 2b. The system receives electricity ($\dot{E}_w^+ = \dot{E}_K^+$) and provides cooling service to consumer by extracting energy ($\dot{Q}_f^+$) at low temperature and rejecting heat ($\dot{Q}_c^-$) to the environment at higher temperature. For this basic application, the cooling effectiveness $\boldsymbol{\varepsilon_f}$ is commonly defined in the literature by the following equation (Eq. 7) and is therefore not coherent for an effectiveness determined from the Eq. (5):

$$\varepsilon_f = \frac{\dot{Q}_f^+}{\dot{E}_w^+} \geq 1 \quad (7)$$

It can also take any numerical value between 0 and ∞, reason why it is commonly called *coefficient of performance of cooling* (COP_f) instead. For both applications of heating and cooling, the exergy efficiency based on Eq. (2) can be applied and the numerical value of these indicators are always lower than one, reason why we use the term of efficiency with the difference of the effectiveness:

$$\eta_h = \frac{\dot{E}_{qh}^-}{\dot{E}_w^+} < 1 \quad (8)$$

$$\eta_f = \frac{\dot{E}_{qf}^-}{\dot{E}_w^+} < 1 \quad (9)$$

While the exergy efficiency definition Eq. (2) is general and applies to all systems, it is not the case of the effectiveness (Eq. 5). The latter cannot be applied to all technologies and/or energy conversion systems. It is indeed only valid for processes that take place above the atmospheric temperature ($T \geq T_a$) and therefore must be adapted for refrigeration systems and also for any conversion systems providing simultaneously energy services for both heating and cooling.

3. New approach for a general expression of the effectiveness

3.1. A general expression of effectiveness applied to all technologies

To circumvent some of the difficulties to define a general expression for the effectiveness we propose the following expression in such a way to highlight $(\dot{U}_{0t})$ which represents the difference between the inlet services (work, gas, biomass…) expended for the system and the outlet services (work, heating and/or cooling) delivered by the system:

$$\varepsilon = \frac{\sum_t [\dot{U}_t^-]}{\sum_t [\dot{U}_t^+]} = 1 - \frac{\dot{U}_{0t}}{\sum_t [\dot{U}_t^+]} \quad (10)$$

Where $\sum_t [\dot{U}_t^-]$ is the total energy services provided or delivered by the system to users and $\sum_t [\dot{U}_t^+]$ represents the total energy services received by the system from utilities. Considering the different form of outlet energy services, the inlet/outlet ***energy services balance*** ($\dot{U}_{0t}$) can then clearly be formulated as follows:

$$\dot{U}_{0t} = \sum_t [\dot{U}_t^+] - \left(\sum_w [\dot{E}_w^-] + \sum_h [\dot{U}_h^-] + \sum_f [\dot{U}_f^+] \right) \quad (11)$$

Where each term (given in bracket) is a numerically positive value and the indices w, h and f refer to the types of energy services delivered or supplied by the system:

- $\sum_w [\dot{E}_w^-]$ mechanical or electrical energy services that can be **delivered** by the system
- $\sum_h [\dot{U}_h^-]$ hot services **delivered** by a system for a heating application
- $\sum_f [\dot{U}_f^+]$ cold services **supplied** by a system for a cooling application

This later term corresponds to a positive value because the main service in a cooling application is not to deliver heat but to capture heat at a temperature T_f lower than that of the ambient like in a fridge or any refrigeration system.

The inlet/outlet ***energy services balance*** ($\dot{U}_{0t}$) could also be obtained by using the First Law equation [1] and by separating the energy service terms from the total energy exchanged with the environment ($\dot{Q}_a^-$):

$$\sum_k \dot{E}_{w_k}^+ + \sum_i \dot{Q}_i^+ + \sum_n \dot{Y}_n^+ = \dot{Q}_a^- \quad (12)$$

$\dot{Q}_a^-$ may be exchanged in different forms such as heat transferred between the system and the environment, e.g. water, soil, air ($\dot{Q}_0^-$) and/or flow energy evacuated to the atmosphere, e.g. exhaust gases ($\dot{Y}_0^-$). The term $\dot{Q}_0^-$ may also include thermal losses due for example to the imperfection of the insulation.

A distinction is made because the terms $\dot{Q}_0^- and\ \dot{Y}_0^-$ may include some valuable energies taking into account that the level of temperature of the fluid T_0 could be higher or lower than the ambient temperature T_a. This expression of the First Law Eq. (12) could also be reformulated by using the numerically positive values of energy services defined above and by highlighting the balance of energy exchanges with the environment:

$$\sum_t \left[\dot{U}_t^+\right] - \left(\sum_w \left[\dot{E}_w^-\right] + \sum_h \left[\dot{U}_h^-\right] + \sum_f \left[\dot{U}_f^-\right]\right) = \dot{Q}_0^- + \dot{Y}_0^- \quad (13)$$

By subtracting the First law equation Eq. (13) from the inlet/outlet energy services equation Eq. (11), the inlet/outlet energy services balance ($\dot{U}_{0t}$) can lead to the following general equation, as function of the total energy exchanged between the system and its environment:

$$\dot{U}_{0t} = \dot{Q}_0^- + \dot{Y}_0^- - 2\sum_f \left[\dot{U}_f^+\right] \quad (14)$$

This result shows clearly the difference between the heating and cooling application in term of the effectiveness. In a heating application, $\dot{U}_{0t}$ is equal to the total energy exchanged with the environment ($\dot{Q}_a^- = \dot{Q}_0^- + \dot{Y}_0^-$) but it is not the case for a cooling application where $\dot{U}_f^+ \neq 0$. This result can be interpreted by the fact that the cold utility (or refrigerant) in the system is considered in the balance for both capturing heat from the user and providing cooling services to the same user.

Example of a simple heat pump system for heating application

Let us apply this definition to the previous examples, starting with the case of the heat pump for heating (Figure 2a). The energy service provided to customers corresponds to $\dot{Q}_h^-$ and the energy service received by the system is the electrical power ($\dot{E}_k^+$). There are no cooling services and no work or electric production for this application:

- $\sum_h \left[\dot{U}_h^-\right] = \dot{Q}_h^-$ Heating service
- $\sum_f \left[\dot{U}_f^+\right] = 0$ No cooling service for this application
- $\sum_w \left[\dot{E}_w^-\right] = 0$ No work or electrical production

There is no flow exchanged with environment ($\dot{Y}_0^- = 0$) and the heat exchanged with environment is represented by $\dot{Q}_0^- = \dot{Q}_s^-$. The energy balance based on the two equations of energy services Eq. (11) and energy exchange between the system and the environment Eq.(14) can be done as:

$$\dot{U}_{0t} = \dot{E}_k^+ - \dot{Q}_h^- = \dot{Q}_a^- - \dot{Q}_s^+ \quad (16a)$$

Therefore, the effectiveness of the general Equation Eq. (10) corresponds to COP_h according to:

$$\varepsilon_h = 1 - \frac{\dot{E}_k^+ - \dot{Q}_h^-}{\dot{E}_K^+} = \frac{\dot{Q}_h^-}{\dot{E}_K^+} = COP_h \quad (16b)$$

$$\varepsilon_h = 1 + \frac{\dot{Q}_s^+}{\dot{E}_K^+} \quad (16c)$$

A same result can be obtained by using Eq. 5 for this process of heating services which takes place above the atmospheric temperature.

Example a simple refrigeration system for cooling application:

In the case of the refrigeration unit of Figure 2b, the energy service provided to customers corresponds to $\dot{Q}_f^+$ and the energy service received by the system is the electrical power ($\dot{E}_k^+$). There are no heating services and no work or electric production for this application:

- $\sum_f \left[\dot{U}_f^+\right] = \dot{Q}_f^+$ Cooling service
- $\sum_h \left[\dot{U}_h^-\right] = 0$ No heating service for this application

- $\sum_w[\dot{E}_w^-] = 0$ No work or electrical production

There's no flow exchanged with environment ($\dot{Y}_0^- = 0$) and the heat exchanged with environment is represented by $\dot{Q}_0^- = \dot{Q}_c^-$. The energy balance based on the two equations of energy services Eq. (11) and energy exchange between the system and the environment Eq. (14) can be done as:

$$\dot{U}_{0t} = \dot{E}_k^+ - \dot{Q}_f^+ = \dot{Q}_c^- - 2\,\dot{Q}_f^+ \tag{17a}$$

Therefore, the effectiveness of the general Equation (Eq.10) corresponds to COP_f according to:

$$\varepsilon_f = 1 - \frac{\dot{E}_k^+ - \dot{Q}_f^+}{\dot{E}_K^+} = \frac{\dot{Q}_f^+}{\dot{E}_K^+} = COP_f \tag{17a}$$

$$\varepsilon_f = 1 - \frac{\dot{Q}_c^- - 2\,\dot{Q}_f^+}{\dot{E}_K^+} \tag{17a}$$

This result could not be obtained with Eq. (5) for this process of refrigeration that take place at a temperature level below the atmospheric temperature and also for any energy conversion processes providing simultaneously energy services for both heating and cooling (for example with heat pumps in cogeneration). For such cogeneration applications, the energy balance based on Eq. (11) and Eq. (14) can be done as:

$$\dot{U}_{0t} = \dot{E}_k^+ - \dot{Q}_h^- - \dot{Q}_f^+ = -2\,\dot{Q}_f^+ \tag{18a}$$

Therefore, the effectiveness of the general Equation Eq. (10) corresponds to $\varepsilon = \varepsilon_h + \varepsilon_f$ according to:

$$\varepsilon = 1 - \frac{\dot{E}_k^+ - \dot{Q}_h^- - \dot{Q}_f^+}{\dot{E}_K^+} = \frac{\dot{Q}_h^- + \dot{Q}_f^+}{\dot{E}_K^+} = \varepsilon_h + \varepsilon_f \tag{18b}$$

$$\varepsilon = 1 + \frac{2\,\dot{Q}_f^+}{\dot{E}_K^+} = 1 + 2\,\varepsilon_f \tag{18c}$$

Considering Eq. (18b) and Eq. (18c), we can deduce the well-known simple relation between the effectiveness for heating (ε_h) and cooling (ε_f):

$$\varepsilon_h = \varepsilon_f + 1 \tag{19}$$

3.2. A general relationship between energy and exergy indicators

From the equations of exergy efficiency (Eq.2) and effectiveness (Eq.10), a generic relationship can be deduced for the overall exergy losses and efficiencies of any energy conversion technologies as a function of the conventional performance indicators (engine efficiency, efficiency based on Lower Heating Value or on Higher Heating Value, heating coefficient of performance, cooling coefficient of performance) most commonly used by engineers to estimate various energy losses of a system:

$$\frac{\dot{L}}{\dot{U}_{0t}} = \frac{1-\eta}{1-\varepsilon}\,.\,R_{E/X} \tag{20}$$

Where $R_{E/X}$ represents the ratio of exergy services received by the system ($\sum_t[\dot{E}_{ut}^+]$) to the energy services expanded for the system ($\sum_t[\dot{U}_t^+]$). This ratio of exergy/energy is generally known for different sources and/or technologies. For electric vapor compression heat pumps, it is equal to the unity ($R_{E/X} = 1$); for thermal power cycle units, it corresponds to the Carnot factor related to the temperature level of the source ($R_{E/X} = 1 - T_a/\bar{T}_g$); For industrial fuels in combustion boilers, it can be determined by the coefficients given in [6, 7].

Such a general formulation of Eq. (20) can be applied to develop explicit relations between the global exergy losses ($\dot{L}$) and the external energy exchanges ($\dot{U}_{0t}$) with the environment (taken from and/or released to environment) and for any energy conversion technologies.

In fact, $\dot{U}_{0t}$ represents the difference between the inlet and the outlet energy services and can be determined or estimated in any case without any **knowledge of the entropy**. This can be very useful for practitioners to determine and know the exergy performance of any energy system based solely on energy balance terms and the effectiveness of the system.

4. Explicit relations of exergy losses for cogeneration technologies

4.1. Combined heat and power cogeneration systems

Any energy conversion system receiving heat-energy services ($\dot{Q}_g^+$) from a **hot** source at a given temperature level ($\bar{T}_g$) to both produce mechanical or electrical energy services ($\dot{E}_w^-$) and supply heat energy services ($\dot{Q}_h^-$) to a heating system at a lower temperature level ($\bar{T}_h$) is considered as a combined heat and power system.

There are many types of power-heat cogeneration plants based on steam turbine (ST) or organic fluid turbine (ORC), gas turbine (GT) and combined gas-steam cycle power plant technologies (CC), which can be found in particular in the chemical or food industry, in household waste incineration plants and of course in district heating thermal power stations. Figure 3 shows an example of a cogeneration plant with a power plant combining electricity and heat using the thermal energy of combustion gases in a boiler to generate steam which drives a power generation turbine. Steam extraction at an intermediate enthalpy level is used to provide energy services for the production of superheated water for a district heating network.

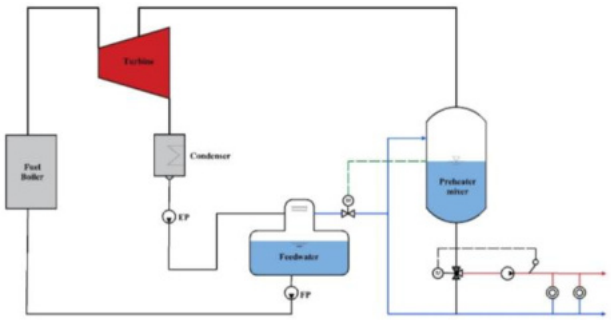

Figure 3: Schematic diagram of the example of steam turbine cycle cogeneration system

Other more decentralized cogeneration systems based on internal combustion engine or fuel cell technologies are used for small scale applications, e.g. in building.

For the example of the cogeneration system given in figure 3: the hot source is represented by the combustion gases ($\dot{Q}_g^+$) in the boiler, the output energy services are the net electricity production ($\dot{E}_w^- = \dot{E}_T^- - \dot{E}_P^+$, meaning the balance between the production in the turbine and the consumption in the various pumps) and the heat energy ($\dot{Q}_h^-$) obtained from the vapor extraction is to supply the heating circuit in the network.

Let us consider the general case of cogeneration where $\dot{Q}_a^-$ represents the heat losses to the atmosphere because of non-perfect insulated components, $\dot{Q}_0^-$ the quantity of energy released from the condenser and $\dot{Y}_0^-$ the exhaust energy out of the boiler. In this case, $\dot{U}_{0t}$ can be expressed by the following relations for steady state operation and based on Eq. (11) and Eq. (14):

$$\dot{U}_{0t} = \dot{Q}_g^+ - \left(\dot{E}_w^- + \dot{Q}_h^-\right) \qquad \dot{U}_{0t} = \dot{Q}_a^- + \dot{Q}_0^- + \dot{Y}_0^- \tag{21}$$

Thus, the effectiveness for cogeneration (ε) based on Eq. (10) can be given by:

$$\varepsilon = 1 - \frac{\dot{U}_{0t}}{\dot{Q}_g^+} = \frac{\dot{E}_w^- + \dot{Q}_h^-}{\dot{Q}_g^+} = \varepsilon_e + \varepsilon_h \tag{22}$$

Where $\varepsilon_e = \dot{E}_w^- / \dot{Q}_g^+$ represents the effectiveness for electricity production and $\varepsilon_h = \dot{Q}_h^- / \dot{Q}_g^+$ represents the effectiveness for heating. A same result can be obtained by using Eq. 5 for this process of cogeneration which takes place above the atmospheric temperature.

Same reasoning can be applied to determine the overall exergy efficiency (η) by the general equation (Eq. 2):

$$\eta = \frac{\dot{E}_w^- + \dot{E}_{qh}^-}{\dot{E}_{qg}^+} \tag{23}$$

Where $\dot{E}_{qg}^+$ represents the heat-exergy received by the system from the hot source and $\dot{E}_{qh}^-$ represents the heat-exergy provided by the system to the user for heating.

The exergy efficiency can then be determined by considering the Carnot factors related to the temperature levels of the hot source ($\bar{T}_g$) and of the heating system ($\bar{T}_h$):

$$\eta = \frac{\dot{E}_w^- + \left(1 - \frac{T_a}{\bar{T}_h}\right) \dot{Q}_h^-}{\left(1 - \frac{T_a}{\bar{T}_g}\right) \dot{Q}_g^+} = \frac{\varepsilon_e + \left(1 - \frac{T_a}{\bar{T}_h}\right) \varepsilon_h}{1 - \frac{T_a}{\bar{T}_g}} \tag{24}$$

In general, these temperature levels of the source and the heating system are initially known. Thus, improving the exergy performance of a cogeneration system shall involve also improving the effectiveness ($\varepsilon = \varepsilon_e + \varepsilon_h$) and therefore minimizing the total energy released to the environment Eq. (21). To illustrate this, we can apply the general expression for exergy losses Eq. (10) by replacing the exergy efficiency η by its value defined in Eq. (24). We can thus express the exergy losses in the most general form by the following relations:

$$\dot{L}_g = \left[1 + \frac{T_a}{1 - \varepsilon}\left(\frac{\varepsilon_h}{\bar{T}_h} - \frac{1}{\bar{T}_g}\right)\right] \dot{U}_{0t} \tag{25}$$

Or on the basis of the system input energy:

$$\dot{L}_g = \left[1 - \varepsilon + T_a\left(\frac{\varepsilon_h}{\bar{T}_h} - \frac{1}{\bar{T}_g}\right)\right] \dot{Q}_g^+ \tag{26}$$

Two components of exergy losses can be distinguished: external exergy losses that are exactly equal to the energy releases to the environment (and therefore become zero for a system without energy exchange with the atmosphere) and internal exergy losses (exergy destruction) that are related to the temperature difference between source and user. The exergy losses by destruction in the system increase not only with the temperature difference but are lower the higher the source and user temperature levels are. The lower the temperature levels, the higher the losses for the same temperature difference.

Equation (24), Eq. (25) and Eq. (26) are general for any cogeneration system with or without combustion exhaust gases, using for example boiler, gas turbine or internal combustion engine technologies for which the overall effectiveness is less than unity (ε<1) taking into account the exhaust losses to the chimney ($\dot{Y}_0^-$) as well as the possible heat losses to the atmosphere ($\dot{Q}_a^-$) because of the high gas temperature. They can also be used for various particular or supposed cases for power generation only (powerplants), for small organic ranking cycles with cogeneration effectiveness close to unity (ε<1) and/or for simple heating applications with boilers or network substations with a perfectly insulated heat exchanger.

Case of **a powerplant:** Zero effectiveness for heating (ε_h=0) corresponds to a **power system** where the energy received from the hot source is only for producing mechanical or electrical energy and all energy that can be recovered from the cold source at lower temperature Th is destroyed to the atmosphere. This is the case for example for many **power-plants**. Thus, Eq. (24) and Eq. (26) become:

$$\eta = \frac{\varepsilon_e}{1 - T_a/\bar{T}_g} \qquad \dot{L}_g = \left[1 - \varepsilon_e - \frac{T_a}{\bar{T}_g}\right] \dot{Q}_g^+ \tag{27}$$

This is a well-known and particular relationship between the exergy efficiency of a power system, the effectiveness and the ideal effectiveness based on the Carnot factor.

Case of **a cogeneration system** based on **Organic Rankine Cycle:** Effectiveness of cogeneration equal to unity (ε=1) corresponds to a perfectly insulated–cogeneration system ($\dot{Q}_a^- = 0$) without any exhaust energy to the atmosphere ($\dot{Y}_0^- = 0$) and where the energy received from the hot source is totally used for producing mechanical or electrical energy and all residual and available energy of the cold source at lower temperature $\bar{T}_h$ is recovered for cogeneration. The external energy losses are zero ($\dot{U}_{0t} = 0$) and part of the exergy received is destroyed in the system. It is the case for example for cogeneration systems using **closed power-cycles e.g. with organic rankine cycles** which are supposed to be perfectly insulated. Equations (24) and Eq. (26) become:

$$\eta = \frac{1 - T_a/\bar{T}_h\,(1 - \varepsilon_e)}{1 - T_a/\bar{T}_g} \qquad \dot{L}_g = \left[T_a\left(\frac{1 - \varepsilon_e}{\bar{T}_h} - \frac{1}{\bar{T}_g}\right)\right] \dot{Q}_g^+ \tag{28}$$

Case of a **heating system with boiler or heat exchanger only:** Zero effectiveness for electricity (ε_e=0) corresponds to a **heating system** where the energy received from the hot source is only for supplying heat energy services ($\dot{Q}_h^-$) to a heating system at a lower temperature level ($\bar{T}_h$). Losses to the atmosphere ($\dot{U}_{0t}^-$) can take place in different forms, due for example to a defect in the insulation of system components ($\dot{Q}_a^- = 0$) or for exhaust gases ($\dot{Y}_0^- = 0$). This is the case for example for **heat transfer process with boiler or heat exchanger**. Thus, Eq. (26) and Eq. (28) become:

$$\eta = \frac{1 - T_a/\bar{T}_h}{1 - T_a/\bar{T}_g}\,\varepsilon_h \qquad \dot{L}_g = \left[1 - \varepsilon_h + T_a\left(\frac{\varepsilon_h}{\bar{T}_h} - \frac{1}{\bar{T}_g}\right)\right]\dot{Q}_g^+ \tag{29}$$

For all these above applications, one can show the important role of the temperature in the assessment of the overall exergy losses or efficiencies. To illustrate this, let us consider for example Eq. (31) by using the temperature difference ($\Delta T = \bar{T}_g - \bar{T}_h$) between the hot gases and the heating process. The following expressions are obtained:

$$\dot{L}_h = \left[(1 - \varepsilon_h)\left(1 - \frac{T_a}{\bar{T}_g}\right) + \varepsilon_h\,\frac{T_a}{\bar{T}_g}\,\frac{\Delta T}{\bar{T}_h}\right]\dot{Q}_g^+ \tag{30}$$

$$\eta_h = \varepsilon_h\left[1 - \frac{T_a}{\bar{T}_g - T_a}\,\frac{\Delta T}{\bar{T}_h}\right] \tag{31}$$

Two components of exergy losses can be distinguished: external heat transfer exergy losses that are rather related to the temperature level of the source (and therefore become zero for a system without energy exchange with the atmosphere) and internal heat losses (devaluation of energy) that are related to the temperature difference between source and user. The exergy losses by external transfer do increase with the temperature level of the source while the exergy losses by internal heat devaluation increase not only with the temperature difference but are lower the higher the source and user temperature levels are. The lower the temperature levels, the higher the exergy losses for the same temperature difference. The temperature therefore plays an important role in the assessment of the overall exergy losses and irreversibilities.

These expressions of exergy losses Eq. (30) and efficiency Eq. (31) for a heat transfer process not only classify but also define the qualities that any heat transfer system between a source and a user must have. Figures 4 show for a given effectiveness like in a heat exchanger ($\varepsilon_h = 1$) the influence of temperature difference between hot and cold streams on the specific exergy loss and efficiency in the heat transfer process, by considering respectively the parametric curves of the consumer's useful temperature ($\bar{T}_h$) and the temperature level of the hot source ($\bar{T}_g$). The specific exergy loss is given by the following $\alpha_L = \dot{L}_g/\dot{Q}_g^+$.

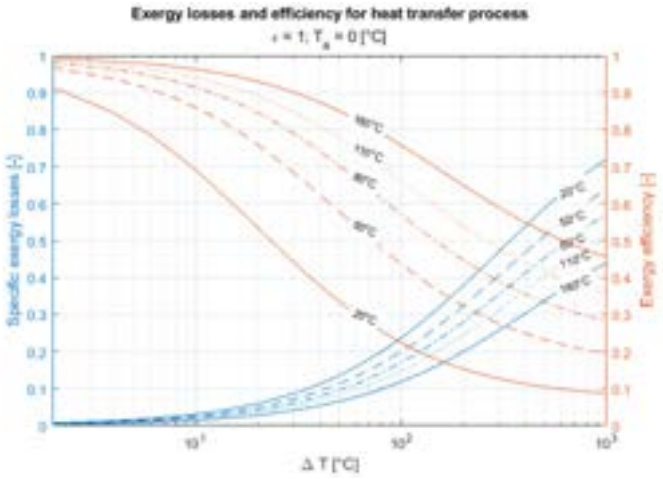

Fig. 5: The effect of the differential temperature on the exergy performance of a heat transfer process with parametric curves corresponding to the consumer's useful temperature ($\bar{T}_h$)

Zero heating effectiveness ($\varepsilon_h = 0$) corresponds to a heat transfer system where all energy received from the hot stream is destroyed to the atmosphere. It is the case for example for an **air-cooler**. Thus, Eq. (24) and Eq. (26) become:

$$\dot{L}_g = \left[\left(1 - \frac{T_a}{\bar{T}_g}\right)\right]\dot{Q}_g^+ \qquad \eta = 0 \tag{32}$$

In the case of a **perfectly insulated heat exchanger**, the effectiveness is assumed to be equal to unity ($\varepsilon_h = 1$). The external heat transfer losses are zero and part of the exergy received is destroyed by internal heat devaluation. Equation (32) and Eq. (33) become:

$$\dot{L}_g = \frac{T_a}{\bar{T}_g}\,\frac{\Delta T}{\bar{T}_g - \Delta T}\,\dot{Q}_g^+ \qquad \eta_t = 1 - \frac{T_a}{\bar{T}_g - T_a}\,\frac{\Delta T}{\bar{T}_g - \Delta T} \tag{33}$$

For the same temperature difference between the hot source (hot gases) and user (heating system), the heat exchange is better for a hot source at higher temperature. This is why, for the same temperature difference, the exergy losses in a heat exchanger for domestic hot water production or for LT heating system are greater than those in a substation of a HT district heating system.

This is also the case for example with heat exchangers for the production of domestic hot water, for heating in district heating substations between the superheated water and the water for heating or for heat production in water-cooled boilers.

4.2. Heating and cooling with heat pump cogeneration systems

Heating and/or cooling installations are often composed of many components that exchange energy with a thermodynamic circuit. These energy exchanges can take place in various forms, involving different processes, including vapor compression and absorption heat pump/refrigeration cycles most commonly investigated by engineers. Modern installations of heat pumps are used in cogeneration with combined heating and cooling. Figure 6 shows an example of such a system with a heat pump combining heating and cooling. It allows to capture low temperature energy from the environment $\dot{Q}_s^+$ (i.e. Lake or geothermal) at a certain temperature level ($\bar{T}_0$), to transfer heat to a fluid (principal circuit) via a heat exchanger and to use it as a cold source in a heat pump to provide a heating service ($\dot{Q}_h^-$) necessary for hot water production ($\bar{T}_h$). The cold fluid out of the heat pump is transported through a network of pipes to supply cooling energy to the consumer and returns back to the heat exchanger. The cooling service are represented with the flow or transformation energy service ($\dot{Y}_f^+$) at temperature level ($\bar{T}_f$).

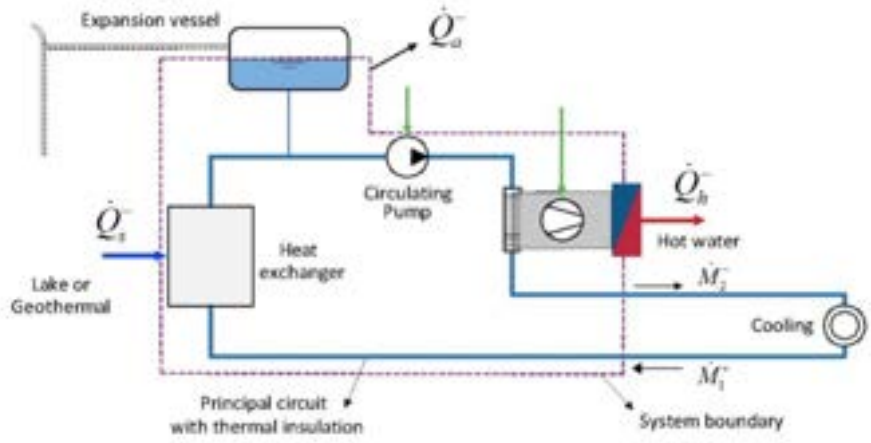

Fig. 6 *Example of a combined heating and cooling system*

The circulation of the heat transfer fluid is ensured by a circulating pump that overcomes the total pressure losses of the network. $\dot{E}_P^+$ represents the electrical power consumed by the circulating pump and $\dot{E}_K^+$ is the electrical power consumed by the heat pump. The input energy services are the net electricity consumption ($\dot{E}_w^+ = \dot{E}_P^+ + \dot{E}_K^+$). There is no work or electric production for this application:

- $\sum_f [\dot{U}_f^+] = \dot{Y}_f^+$ Cooling service, $\dot{Y}_f^+ = \dot{M}\left(h_{cz_1} - h_{cz_2}\right)$
- $\sum_h [\dot{U}_h^-] = \dot{Q}_h^-$ Heating service for this application
- $\sum_w [\dot{E}_w^-] = 0$ No work or electrical production

As the system is considered perfectly insulated (heat losses to the atmosphere are null) and there is no flow exchanged with environment ($\dot{Y}_0^- = 0$), the heat exchanged with environment is represented by $\dot{Q}_0^- = \dot{Q}_s^-$. The energy balance based on the two equations of energy services Eq. (11) and energy exchange between the system and the environment Eq. (14) can be done as:

$$\dot{U}_{0t} = \dot{E}_w^+ - \dot{Q}_h^- - \dot{Y}_f^+ \qquad \dot{U}_{0t} = -\left(\dot{Q}_s^+ + 2\,\dot{Y}_f^+\right) \tag{34}$$

Therefore, the effectiveness of the general Equation Eq. (10) corresponds to the total effectiveness according to:

$$\varepsilon = 1 - \frac{\dot{U}_{0t}}{\dot{E}_w^+} = \frac{\dot{Q}_h^- + \dot{M}\left(h_{cz_1} - h_{cz_2}\right)}{\dot{E}_w^+} = \varepsilon_h + \varepsilon_f \tag{35}$$

$$\varepsilon = 1 + \frac{\dot{Q}_s^+ + 2\,\dot{M}\left(h_{cz_1} - h_{cz_2}\right)}{\dot{E}_w^+} = \varepsilon_0 + 2\varepsilon_f \tag{36}$$

Where $\varepsilon_h = \dot{Q}_h^- / \dot{E}_w^+$ and $\varepsilon_f = \dot{Y}_f^+ / \dot{E}_w^+$ respectively represent the effectiveness for heating and cooling and the term given by the following $\varepsilon_0 = 1 + \dot{Q}_s^+ / \dot{E}_w^+$ characterizes the amount of energy taken from the environment.

When considering equation Eq. 34, one also can demonstrate that ε_0 represents the difference between the effectiveness for heating and cooling ($\varepsilon_0 = \varepsilon_h - \varepsilon_f$). In the case of adiabatic components with no heat transfer losses and no energy withdrawal from the source ($\dot{Q}_s^+ = 0,\ \varepsilon_0 = 1$), we find the same relation Eq. (19) between the effectiveness of heating (ε_h) and cooling (ε_f) for a simple heat pump. This shows that the total effectiveness (ε) of such a combined heating/cooling cogeneration system also depends on this percentage of energy taken from the environment ($1 - \varepsilon_0$). These results based on Eq. (35) and Eq. (36) could not be obtained by using Eq. (5) for this process of cogeneration involving cooling services which take place at a temperature level below the atmospheric temperature.

Same reasoning can be applied to demonstrate that, the exergy performance of the system not only depends on the effectiveness of heating (ε_f) and cooling (ε_f) but also on the energy exchanged the environment ($1 - \varepsilon_0$). To illustrate that, let us first apply the general expressions of exergy efficiency Eq. (2) by considering the Carnot factors related to the temperature level of heating ($\bar{T}_h$) and cooling ($\bar{T}_f$). The overall exergy efficiency for heating/cooling cogeneration (η) is:

$$\eta = \frac{\dot{E}_{qh}^- + \dot{E}_{yf}^-}{\dot{E}_w^+} = \left(1 - \frac{T_a}{\bar{T}_h}\right) \varepsilon_h + \left(\frac{T_a}{\bar{T}_f} - 1\right) \varepsilon_f \tag{37}$$

Or then:

$$\eta = \varepsilon_0 - T_a \left(\frac{\varepsilon_h}{\bar{T}_h} - \frac{\varepsilon_f}{\bar{T}_f}\right) \tag{38}$$

Where $\dot{E}_w^+$ represents the work-exergy received by the system, $\dot{E}_{qh}^-$ represents the heat-exergy provided by the system to the user for heating and $\dot{E}_{yf}^-$ represents the flow-exergy provided by the system to the user for cooling.

By replacing the exergy efficiency η by its value defined in Eq. (20). We can thus express the exergy losses in the most general form by the following relations:

$$\dot{L}_g = \left[1 - \varepsilon_0 + T_a \left(\frac{\varepsilon_h}{\bar{T}_h} - \frac{\varepsilon_f}{\bar{T}_f}\right)\right] \dot{E}_w^+ \tag{39}$$

Two components of exergy losses can be distinguished: external exergy losses that are exactly equal to the energy taken from the environment and internal exergy losses (with irreversibilities) that are related to the temperature difference between heating and cooling consumers. The internal exergy losses in the system increase not only with the temperature difference but are lower the higher the temperature levels.

Equations (38) and (39) are general for any combined heating and cooling system using a heat pump technology with additional energy taken from the environment e.g. $\varepsilon_0 \neq 1$. For a particular case of a simple heat pump cogeneration application without any energy captured from the environment ($\dot{Q}_s^+ = 0, \varepsilon_0 = 1$), Eq. (38) and Eq. (39) become:

$$\eta = 1 - T_a \left(\frac{\varepsilon_h}{\bar{T}_h} - \frac{\varepsilon_f}{\bar{T}_f}\right) \qquad \dot{L}_g = \left[T_a \left(\frac{\varepsilon_h}{\bar{T}_h} - \frac{\varepsilon_f}{\bar{T}_f}\right)\right] \dot{E}_w^+ \tag{40}$$

Equations (38) and (39) can also be used for particular cases of a thermopump for heating only ($\varepsilon_0 = 1, \bar{T}_f = T_a$) or of a frigopump for cooling only ($\varepsilon_0 = 1, \bar{T}_h = T_a$). For example, by combining Eq. (20) and Eq. (38), we found the well-known and particular relationships between the exergy efficiency of a heat pump cycle, the coefficient of performance (effectiveness) and the ideal effectiveness based on the Carnot factor:

For a thermopump ($\bar{T}_f = T_a$):

$$\eta_h = \varepsilon_h \left(1 - \frac{T_a}{\bar{T}_h}\right) \qquad COP_h = \eta_h \cdot \frac{\bar{T}_h}{\bar{T}_h - T_a} \tag{41}$$

For a frigopump ($\bar{T}_h = T_a$):

$$\eta_f = \varepsilon_f \left(\frac{T_a}{\bar{T}_f} - 1\right) \qquad COP_f = \eta_f \cdot \frac{\bar{T}_f}{T_a - \bar{T}_f} \tag{42}$$

5. Conclusion

A general expression of the effectiveness applied to all technologies is proposed in this study. It is based on the First Law of thermodynamics by separating the energy service terms (inlet services in term of work, gas and/or biomass expended for a system and outlet services in term of work, heating and/or cooling delivered by the system) from the total energy exchanged with the environment. A clear difference between the heating and cooling processes is observed based on a general formula of energy services balance. In the case of a heating process, the difference between the inlet and outlet energy services is exactly equal to the total energy exchanged with the environment but it is not the case for a cooling application for which the energy exchanged with the refrigerant (cold utility) need properly to be considered in the balance by accounting for both the cooling services supplied by system to the user and the same quantity of energy received or captured by the system from the user.

Based on this new approach of effectiveness and the existing exergy efficiency formulation, a generic relationship between energy and exergy losses has been proposed. It allows to provide simple and generic expressions of exergy losses and efficiencies of any energy systems in relation to the conventional performance indicators (thermal efficiency, heating coefficient of performance, cooling coefficient of performance) most commonly used by engineers to estimate the various losses of a system. Such a method has been applied for complex cogeneration systems (combining power, heating and/or cooling) but also for single energy components, e.g. boilers, heat exchangers and air-coolers to show the benefit. The overall exergy efficiency and losses of such systems explicitly are given in function of the effectiveness.

Main results and advantages of such an approach are: Having a unique formula of effectiveness for both heating and cooling applications and creating the link between the known performance indicators; Providing a general relationship between exergy efficiency and effectiveness of any system; Performing the exergy analysis of common installations without any knowledge of entropy; Providing simple and generic relations of exergy efficiencies and losses and/or estimating the detailed distribution of the exergy losses of a system according to the different forms of energy losses (heat losses, exhaust gases, heat energies taken from or released to the environment, e.g. water, soil and air).

These can be very useful for practitioners to determine and know the exergy performance of any energy system based solely on energy balance terms and thus the effectiveness of the system.

Abstract:

Efficiency of a gas turbine engine is directly impacted by the turbine inlet temperature and the corresponding pressure ratio. A major strategy, aside from use of costly high-temperature blade materials, is increasing the turbine inlet temperature by internally cooling the blades using pressurized air from the engine compressor. Understanding the fluid mechanics and heat transfer of internal blade cooling is therefore, of paramount importance for increasing the temperature threshold, hence increasing engine efficiency. This paper presents results of a novel cooling approach, i.e., the use of Ranque-Hilsch vortex flow for first row gas turbine blade cooling. Test results clearly demonstrate the successful formation of continuous Ranque-Hilsch vortex flow by injecting compressed air into a cylindrical chamber equipped with seven air inlets. Separated boundaries of the reversed flow with detectable boundaries were accompanied by a significant drop in temperature on the cold stream side. At inlet pressure of 63 kPa, the outlet temperature from the vortex tube dropped below 0°C, which allowed blade temperature drop of about 200 °C. The thermal efficiency of the gas turbine increased from 40% to 43% by vortex-cooling the blades with 10% mass of compressed air extracted at about 910 kPa. For the tested scenario of a 17 MW engine, the partial extraction had a better efficiency increment than extraction at full compression which was 1200 kPa.

Thermodynamics; Gas turbine engine, internal blade cooling, thermal efficiency, power output, Ranque-Hilsch vortex flow, experiment.

1. Introduction

The life cycle of a gas turbine engine blade is most affected by high the operating temperature, constant centripetal loading, and thermally induced stresses, particularly during start-up and shutdown. The thermal efficiency of the engine increases with the increase of the pressure ratio and the firing temperature which increases the turbine rotor inlet temperature (TRIT). As the firing temperature increases, the heat transferred to the turbine also increases, rising above the material temperature threshold which requires mitigation measures of material failure if upholding the high temperature is desired to maintain high efficiency. This requires internal cooling of the rotor blades. Significant research has been going on for decades to design an internal cooling system particularly for the first-stage blades, to achieve higher firing temperature. Effective internal cooling of the rotating blades is a significant challenge, compounded by wake-induced turbulence and unfavorable area ratios between inner and outer surfaces [1] [2]. This can cause formidable challenges to turbine internal cooling.

Various cooling techniques are applied on the turbine blade to keep the working temperature within a safety limit [3] [4] [5]. It is a common practice to cool high-pressure turbine blades using air from the compressor which is routed through the turbine blades thereby lowering its temperature. Swirl cooling is one of the many techniques used for such cooling. The idea is to route swirling air from the compressor through the turbine blade's internal passages [6]. The first rows of turbine blades typically operate at a temperature that exceeds 1,200 °C [7] [8] [9], and therefore, may greatly benefit from internal cooling if higher firing temperature is to be entertained.

Analytical and experimental modeling in the leading-edge area of the blade, with regard to internal swirl cooling systems, could result in optimization of turbine blade designs with respect to heat transfer, cost, and performance, as well as reduced downtime [10] [11] [12]. Adding complexity to the demanding task of managing high temperature without its accompanying penalties is the driving desire for a long-term life cycle without frequent inspections and overhauls. Turbine blades withstanding high temperatures and constant mechanical stresses, which limit the turbine blade life cycle, may also cause permanent material deformation

[13] [14]. These can also cause local plastic yielding while contributing to material creep [15]. Some innovative techniques have been proposed to improve the convective heat transfer for internal cooling of gas turbine airfoils, including rib turbulators, pin fins, dimpled surfaces, impingement cooling, and swirl flow cooling [16] [17] [18] [19] [20].

Of particular interest here, the topic of our research, is “swirl cooling” which induces a reverse flow. One such innovative approach is discussed by Glezer et al. [14] who present experimental results comparing three separate studies. The research provided a better understanding of the screw-shaped swirl cooling technique for heat transfer in internal swirl flow, where heated walls were applied and a screw-shaped cooling swirl was generated, introducing flow through discrete tangential slots. The authors mention that the Coriolis forces play an important role in enhancing the internal heat transfer when their direction coincides with a tangential velocity vector of the swirl flow.

Another paper on the same subject of swirl cooling, [21] states that the local surface Nusselt numbers increase when increasing the Re number (the range in this study was from 6,000 to about 20,000). As a result, the local swirl chamber heat transfer and flow structure are linked to increased advection as well as notable alterations to vortex behavior near the concave surfaces of the swirl chamber. One key result was that, along with the Nusselt number, the changes of surface heat transfer downstream of each inlet increased sharply when compared to other locations. Hedlund et al. [21] observe that as the turbulent flow becomes more pronounced, the axial and circumferential velocities get larger and intensify the turning of the flow from each inlet.

Other studies show that blade internal swirl cooling is effective and can afford long term life to blades especially if employed in tandem with advanced blade alloys [22] [23]. Experiments conducted by Ligrani et al. [3], Moon et al. [1], and Glezer et al. [13] introduced an internal cooling structure as one way to attend to high temperature management in gas turbine cooling, Fig. 1.

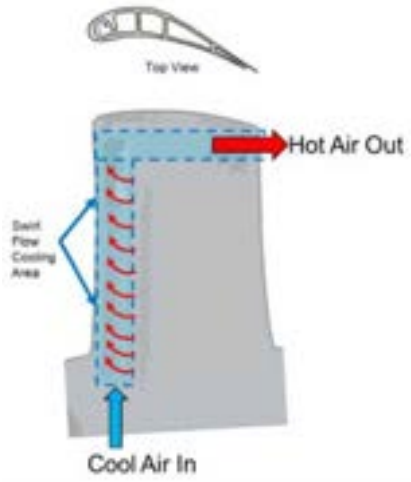

Figure 1: Turbine blade leading edge internal cooling design, [4].

The above summaries of recent developments in turbine blade internal cooling show advances in several fronts. However, the idea of applying the Ranque-Hilsch vortex flow for internal blade cooling has never been investigated. Thus, the focus of this study is to conclusively prove that sustained reverse flow with accompanying temperature drop can be produced, which allows the use of the cold stream for a gas turbine blade internal cooling. The vortex flow is injected tangentially through holes to induce the vortices, as shown in Fig. 2.

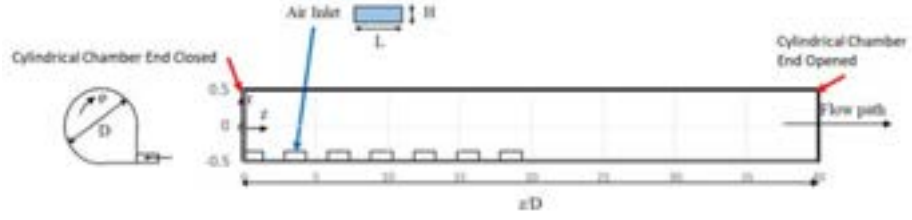

Figure 2: Cylindrical chamber geometry with seven air inlets, [24].

2. Experimental setup

The main piece of the lab setup for the vortex flow cooling experiment is LaVision Stereo-PIV system, which includes a LaVision PC, two ImagerproX cameras, two Nd-YAG lasers, and LaVision particle seeder as shown in Fig. 3. The cameras are mounted on a stand equipped with stepper motors, allowing it to travel freely along the chamber length. The fluid is seeded with olive oil particles that have diameters in the range of 1-3 μm and specific gravity of 0.703. These oil tracer particles are chosen because they are small enough that they have little inertia; validating the tracer particle motion best reflects the actual flow path. The seeding particles in the fluid distribute the laser light, which is captured by the video acquisition system. The Nd-YAG laser is a Pegasus PIV with a wavelength of 527 nm and maximum energy of 20 mJ per pulse. The Nd-YAG laser serves as the illumination source for the PIV system and is manipulated through the appropriate use of optical instruments to produce a laser sheet of 2 mm thickness on the chamber's bottom wall. This setup allows the illumination of planes parallel to the vertical axis. Two high-speed and high-resolution CCD cameras (Phantom v7.3. 800_600 pixels, 12 bit) capture images of the illuminated PIV particles at a rate of 100 frames per second. With that frame rate, 2000 images are acquired over a period of 10 seconds, similar to the measurement duration in the experiment conducted by others [12-13].

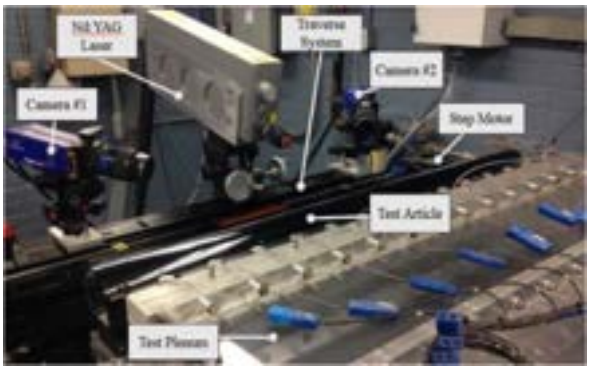

Figure 3: Hardware setup.

DaVis is utilized to collect PIV data, all data points are taken and collected in one file set which exports time-average velocity and is post-processed in DaVis to be transferred into MATLAB. MATLAB cleans up DaVis raw data and allows the calculation of crucial flow field variables. All velocity calculations are conducted in MATLAB, followed by a file structure that prepares data for visualization in Tecplot 360, which is used for data visualization. One advantage of using Tecplot 360 is that it provides powerful flow visualization options. Created some macros to automate visualization procedures. To create smooth transitions in between data points, a data interpolation scheme was employed.

3. Generating a Ranque-Hilsch vortex flow

Before committing to the use of the cold stream of the Ranque-Hilsch flow, it would behoove us to first scrutinize its occurrence within the theoretical scope presented above, with an accompanying temperature drop - significant enough to cool the gas turbine blades.

3.1. Theoretical justification, Navier Stokes Eq. and CFD

The Navier-Stokes, centrifugal force, and centrifugal velocity equations can be used to show prevalence of the reverse flow in the cylindrical chamber. Once preliminary values were entered, the results show a radial pressure drop of about 140 Pa, which spans from the gauge pressure at the inlet of approximately 340 Pa, as clearly illustrated in Fig. 4.

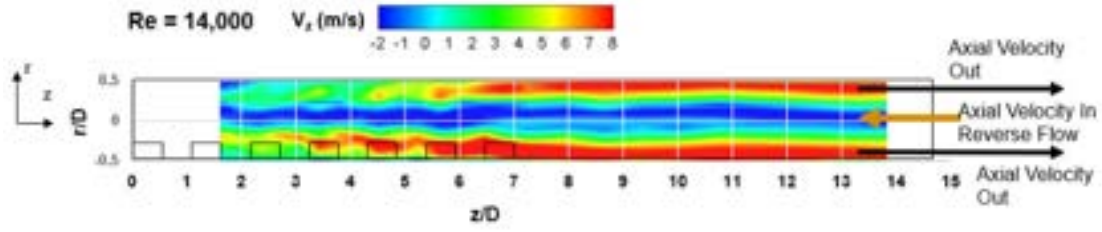

Figure 4: Radial pressure drop estimate.

CFD simulations can further lay evidence to predict the loadings and flow distributions of blade rows, including for end-wall regions. As a tool, CFD can produce valuable outputs, albeit its limitations in predicting turbine heat transfer, mainly because of constraints in modeling turbulence and vortices, uncertainty of boundary conditions, and the inherent flow unsteadiness in turbomachinery. Here we simulate velocity, temperature, and pressure distributions to show if their profiles support the notion of existence of a reverse flow, and if the continuity equation is satisfied.

Velocity: The velocity streamline for the entire fluid domain is presented in **Error! Reference source not found.**5. The largest velocity value is noticed at inlet 7 at 30.457 m/s. There are three reversed flow cases at the inlets 1, 2 and 3. The velocity is minimum near the end of the chamber.

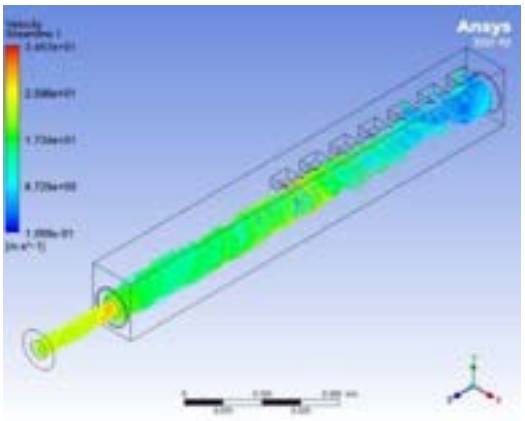

Figure 5: Velocity streamline of the fluid domain.

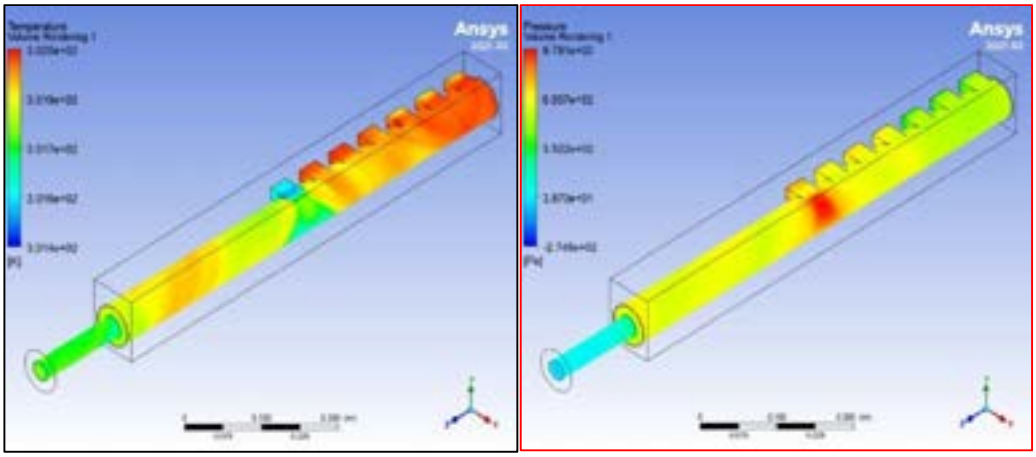
Temperature and Pressure: The temperature and pressure distribution along the cylindrical chamber are given in Fig. 6. The highest pressure is observed in front of inlet seven reading 979 Pa. However, after air inlet seven the cross-section of the chamber, the pressure distribution shows significant drop resulting in -30.870 Pa. The temperature contour indicates separated cold and hot streams. These temperature and pressure show existence of a reverse flow with a temperature drop.



(a) (b)

Figure 6: Temperature (a) and pressure (b) contour of the vortex chamber and tube

Continuity Eq.: To confirm the mass is balanced, we assess the mass flow rate at some distance “z” downstream of the flow. The goal here is to plot the mass flow rate at the three assumed Re numbers to confirm that the mass flow rate going into the cylindrical chamber matches the total mass flow rate going out of the chamber as cold and hot streams. Figure 7 shows that the mass flow rate going into the chamber matches the sum of reversed and unreversed flows leaving the chamber, which proves the reverse vortex flow takes place inside the cylindrical chamber.

The total mass inflow rate through the system is 0.0535 kg/s. This is also the sum of the flow rate through each inlet, which again is the same as the flow rate at the outlet, as shown in Tab 2.

Table 2: Summary of mass flow rate at the inlets and outlets.

Location	Inlet 1	Inlet 2	Inlet 3	Inlet 4	Inlet 5	Inlet 6	Inlet 7	Outlet
Flow Rate, kg/s	-0.0085	-0.0088	-0.0075	0.0096	0.0033	0.0063	0.0343	0.0287

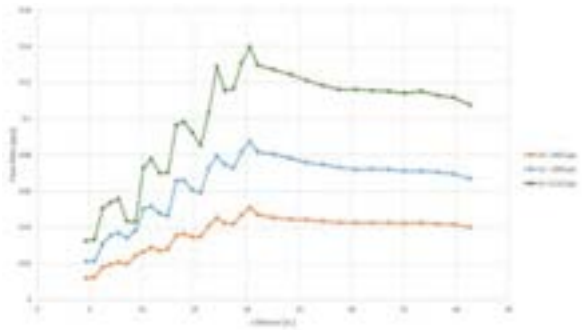


Figure 7: Mass flow rate vs. z-Distance at all three Re numbers of cylindrical chamber.

4. Evidence of prevalence of reverse flow

4.1. Thermochromic Liquid Crystal (TLC)

The cylindrical chamber is made of clear acrylic material, painted with TLC to allow visualization of color changes within the required time range. As the air enters the plenum, Fig. 8, it passes into a rectangular heating mesh, leading to rectangular cross-sectional air inlets with individual hydraulic diameters (D_H) of 0.011 m. These inlets are connected to the principal vortex chamber so that one surface is tangent to the chamber inner circumference.

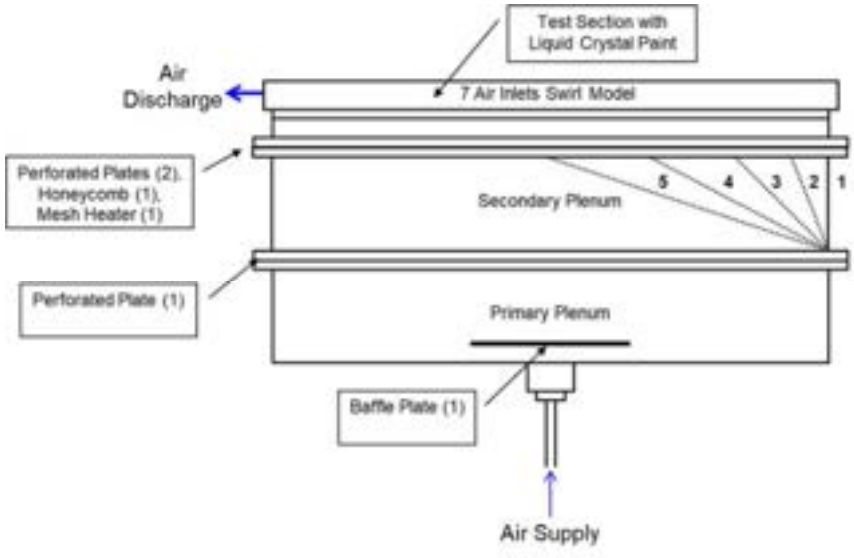

Figure 8: TLC painted test stand with plenums attached.

The surface area optics suitable for the spatial resolution are painted, first the cylindrical chamber is coated with liquid crystal paint, followed by black paint. A coupon is built, following the same process for calibration purposes, coated with liquid crystal paint, and followed by black paint.

TLC Data Collection: An in-house software is used to synchronize the entire liquid crystal experiment. The data is collected by continuously polling after the system is heat-soaked to the required temperature. The data acquisition step size is 0.5 seconds and the VXI is set to a time interval of 0.2 seconds. The video file is converted to an AVI file, imported into the “Liquid Crystal Image Analyzer (LCIA),” as shown in Fig. 9. Contact resistance and temperature drop through the wall are determined experimentally from the calibration process

and green time is measured simultaneously. Using seven calibrated thermocouples equally separated across the length of the cylindrical chamber, the temperature of the air entering the cylindrical chamber is measured. All measurements are collected when the cylindrical chamber is at steady state and when the heating mesh on the plenum reaches 35°C.

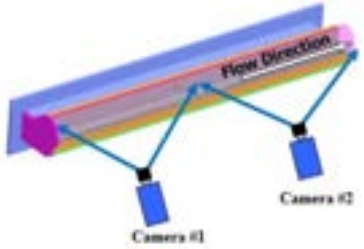

Figure 9: heat transfer data collection by two cameras for the painted test stand.

Once the green time image is calculated, then the probe locations are associated with columns of temperature readings in the temperature probe data file. Noise is edited out with an eraser image mask, followed by the region of interest definition using a polygon mask. These final images are then exported as JPEG image files. Cameras recording in DV format are set up to view the liquid crystal coated surface of the test stand, capturing 10 samples per second. The air flow rate is set as the liquid crystal transitions at 35°C and regulator pressure at 6.89 KPa. Once the system is heat soaked, cameras start recording. When the paint has fully transitioned to blue, the cameras and data acquisition system are stopped manually.

The data points were taken at 33 locations at a distance of 19.81 mm from each other, as shown in Figure 10 and Fig. 11. Data were collected at both locations, in between air inlets and at the middle of the air inlets (i.e., data point #2 and data point #4, respectively) to show the complicated flow and its variation.

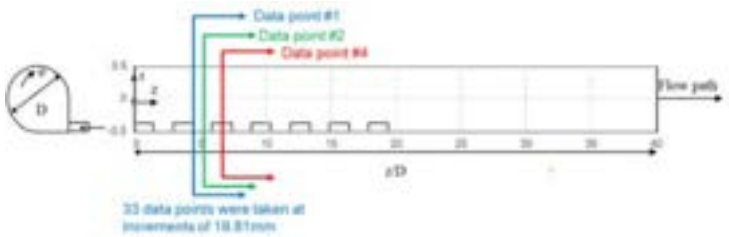

Figure 10: Data point locations in increments of 19.81 mm.

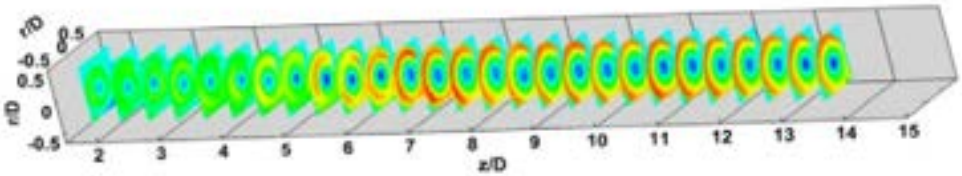

Figure 11: Cross-sectional area of data points.

4.1.1. Axial Velocity Distribution

As the Re number increases, the axial velocity, V_Z, intensifies, measuring higher on the outer wall region, as shown in Figure 12. From upstream to downstream, the V_Z ranges from -2 to 7 m/s in all three Re numbers, as is expected in a cylindrical chamber. The outer wall region velocity increases across the length, reaching a maximum velocity at the second half of the vortex chamber. Another observation is the high V_Z in the direction of the outer wall region. Between the core and the chamber wall in the outer wall region, an inertia-driven vortex was observed and measured a flow field pattern that is critically different between high to low Re numbers.

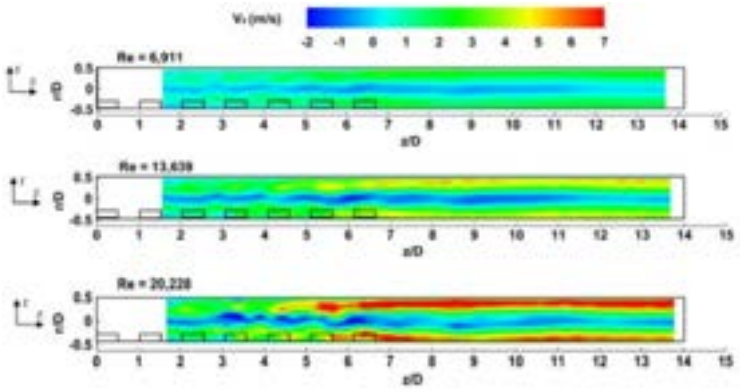

Figure 12: Axial velocity distribution of cylindrical chamber at all three Re numbers.

4.1.2. Reverse Vortex Flow at the Center of the Cylindrical Chamber

With this geometry, the vortex flow cooling has important axial and circumferential components of velocity, and the overall flow pattern through the cylindrical chamber behaves similar to a vortex tube, also known as the Ranque-Hilsch vortex tube, a mechanical device that separates a compressed air into hot and cold streams with temperature difference reaching over 250°C. Although unintended, the detailed flow behavior inside a Ranque-Hilsch vortex tube and flow reversal in the cylindrical chamber share similitudes. The velocity profile was measured for both air and water operated Ranque-Hilsch vortex tube. Based on this study, there was a remarkable agreement between theoretical estimation and experimental results. Furthermore, the unintended consequence of the vortex flow behavior needed more analysis; utilizing 3-D stereo-PIV at the nominal Re = 13,639, three cross-sectional areas were chosen. **Error! Reference source not found.** 10 shows the three cross-sectional areas z/D = 3, 6, and 13 carefully studied looking for evidence of the reverse flow and captured it and all three cross-sectional areas to show reverse flow. Stereo-PIV is a powerful tool able to capture in great detail how each droplet behaves and map the axial velocity field flow. The discovery of this unintended behavior is so astronomically important that more research and analysis had to be completed to satisfy the minds of the experts. The next step is to understand the vortex flow behavior where the reverse flow exists.

Figure 13 presents the normalized axial velocity against the cylindrical chamber length, downstream of the flow. The pressure decreases downstream on the outer chamber wall, the reverse flow at the centerline is increasingly visible.

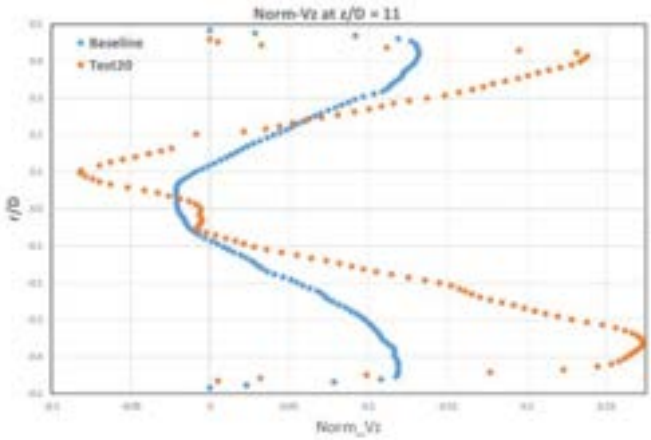

Figure 13: Normalized V_z at z/D = 11 of cylindrical chamber.

4.2 Video Evidence

In addition to the above listed techniques, the existence of a reverse flow was also validated using a video. For this purpose, we prepared a wire with a piece of light string, rag attached at the end of the wire. The wire is then inserted at three different locations to see its motion. The string moved in the direction of the flow in all the three locations. The string changes direction as it is moved across the internal boundary of the reversed flow.

Figure 14: Video evidence of the reverse vortex flow using a wire and a soft yarn attached.

5. Conclusion

The results show that for an incoming air of 100kPa, the temperature and pressure drops are significant. The exit temperature depends on the input pressure with a nearly linear relationship. As the input pressure increases, the outlet temperature of the cold stream decreases. For validation purposes, the compressed air temperature at inlet was kept constant at a value of 28°C for the simulation. When the air at 1kPa was admitted to the vortex chamber, the exit temperature remained the same for both the simulation and the experimental test. However, at 63kPa inlet pressure, the stream temperature cooled to 0°C i.e., yielding a temperature drop of about 29°C.

Experimental data collected from the cylindrical vortex chamber which models internal cooling passage of a blade located near the leading edge of a gas turbine blade, for Re range of 7,000 to 21,000 show outstanding accuracy and 3-D resolution obtained with the Stereo-PIV imaging techniques employed here. The combination of CFD and experimental data reveal distinct advantages of the vortex cooling concept introduced here, over other cooling methods.

The versatility of the vortex cooling design to redistribute a different path of heat load profile without major casting changes was demonstrated by using seven air inlets. The span of the outer-wall velocity flow fields increases, due to the enlargement of the vortex flow core. The TLC heat transfer test results exemplify how the Nu were measured favourably at the middle length of the chamber and values decline downstream.

The primary objective of this research has been met by performing tests to prove prevalence of a reverse flow in the swirl chamber. The channel served as a Ranque-Hilsch vortex tube. As a result, the compressed air was separated into hot and cold streams with temperature difference reaching over 250°C. The detailed flow behaviour inside a Ranque-Hilsch vortex tube and flow reversal in the cylindrical chamber share similarities. Based on this study there was an impressive and conclusive presence of reverse axial flow at the core as illustrated in the experimental results. Simulation results correlated the experiment results and validated the reverse flow with similar mass flow rate and pressure gradients of 0.0535 kg/s and 979 Pa, respectively. The CFD recreated the reverse flow at Re = 14,000. The results affirm that higher pressure input can contribute to lowering the temperature at the exit from the chamber, favouring the cooling process. The thermal efficiency increased by about 3% when the blade is cooled by extracting 10% partially compressed air. This is a significant gain.

Abstract:

Several advanced energy systems include less standard fuel oxidation conditions. This is particularly true when partial oxy-combustion, post-combustion of anodic gases of SOFC or CO_2 gas separation are considered. This paper reviews the theoretical basis for the determination of the heating values and of the exergy values of various fuels. As a reminder, the exergy value of fuels is developed using Gibbs free energies of formation and is illustrated with a van't Hoff box with compressors and turbines. The paper also discusses the molar exergy of diffusion which is important when assessing various CO_2 separation technologies as well as the relative importance of the reference environment. The concepts of fuel exergy for fuels and exergy of diffusion for inert species is clearly established. The choice of the value of the exergy of diffusion of liquid water is particularly sensitive when calculating the exergy value of hydrocarbon fuels in systems with gas condensation.

Keywords:

Thermodynamics; Fuel; Heating value; Exergy; Oxidation.

1. Introduction

In practice processes occurring within real energy system take place in a given surrounding environment (e.g. the atmosphere characterized by the pressure P_a, the ambient temperature T_a and its chemical composition). The latter is considered large enough for its main features like the pressure, the temperature and the mass concentrations to remain constant. Whatever resources are considered in energy systems their ultimate fate will end up to be in equilibrium with the environment.

Combustion gases from a fuel boiler will reach an equilibrium with the atmosphere after passing through the chimney exhaust. Energy and masses are conserved, but their potential to do work is ultimately degraded to be cancelled when the equilibrium with the atmosphere is reached, a thermodynamic state that is called the dead state. Therefore, every technical energy system, aim at exploiting at its best the potential of a resource from its original state to the ultimate state of the environment. For example, a fuel is interesting because its initial thermodynamic state is different from that of the one from the stable inert gasses of the atmosphere. The objective of the energy system designer is therefore to make the most of the chemical potential of the fuel for delivering energy services. The challenge lies on the manner that the fuel energy or the exergy potential can be coherently represented in the expressions of the Laws of thermodynamics.

Most publications like [2] apply the terminology of chemical exergy for fuels as well as for inert gases like molecular N_2. The objective of this paper is to reformulate a coherent and concise approach of the problem of the comparison between energy and exergy evaluation of fuels in modern energy systems. The paper advocates a clear differentiation between diffusion and reactive phenomena in the exergy analysis of fuel-based energy systems. It also expresses the interest of having a symmetry between energy and exergy approaches of fuels. In so doing the paper also highlights the importance of an existing model of reversible combustion for a proper understanding of the main concepts.

2. Combustion

Combustion is an oxidation process, air oxygen (O) being the dominant oxidizer used. The input mixture (M) is made of fuel and oxidizer, called "reactants" in chemistry, while the output combustion or oxidation gases (G) are the reaction "products", generally emitted directly to the atmosphere. When all fuel components are fully oxidized (reactants in *stoichiometric* proportions, see below) the combustion or oxidation is said to be complete and the reaction products are designated by Gc.

For simplicity of analysis, the most common fuels are often reduced to their main component only, i.e. natural gas to methane CH_4, gasoline to octane C_8H_{18} and diesel fuel (or heating oil) to dodecane $C_{12}H_{26}$. More

generally, a generic molecule $\boldsymbol{C_aH_bO_cN_d}$ can be used. The stoichiometric coefficients, stoichiometric air amount and volume ratio of the combustion products for such a generic molecule are given below. Note that for energy analyses a simple composition of air is assumed, with a molar fraction of O_2 of 0.21, the rest being essentially nitrogen with a molar fraction of 0.79.

2.1 Energy (heating value of fuel)

A convenient way to assess the energy that can be obtained from a fuel in basic energy analyses is the concept of "Heating Value, HV". Although there are several different heating value concepts that can be developed [1], heating and cooling systems are usually open systems, such as typical burners, and the combustion can be considered to take place at constant pressure (isobaric). Heating values are defined with respect to a given reference state (standard conditions) that is usually:

$$Standard\ pressure\ P^0 = 1\ atm = 1.01325\ bar \text{ and } standard\ temperature\ T^0 = 25°C$$

However, most fuels include hydrogen atoms that oxidize to give H_2O vapor in the combustion products. When cooling the combustion gases to recover their heat energy, this water vapor can condense - totally or partially- depending on its partial pressure in the gases P_v and the lowest temperature of the cooling medium. In fact, water vapor starts to condense as soon as its partial pressure corresponds to the saturation pressure P_v'' at what is called the ***dew point***. In calorimeters, condensation takes place each time that the dew point temperature is higher than the standard temperature. This corresponds to:

$$\frac{P_v}{P} = \tilde{c}^G_{H2O}\ with\ P_v = P_v''(T)\ at\ the\ dew\ point \quad (1)$$

In which $\tilde{c}^G_{H2O}$ is the molar fraction of H_2O in the combustion gases.

The saturation pressure of water $P_v''(T)$ can be calculated on the basis of the following approximation of the Clausius-Clapeyron Eq. (2) [1]:

$$ln\left(\frac{P_v''}{140974}\right) = \frac{-3928.5}{231.667+T} \quad (2)$$

Where P_v'' is in bar and T in degree Celsius. Equation valid for the temperature range from 0°C and 150°C.

2.1.1. Air factor and its influence on gas condensation

A minimum proportion of oxygen, called ***stoichiometric,*** is required to achieve a complete combustion of the fuel. When air is the oxidant source the ratio between the input air amount (A) and the stoichiometric amount (Ast) is the ***air factor*** λ defined by:

$$\lambda = \frac{N_A}{N_{Ast}} = \frac{M_A}{M_{Ast}} \quad (3)$$

Another parameter called ***equivalence ratio*** ϕ is also often used; it is defined by:

$$\phi = \frac{1}{\lambda} \quad (4)$$

Note that the quantity of air corresponding to the stoichiometric quantity of oxygen is also called ***theoretical air*** [2].

Another ratio commonly used is the air-fuel ratio that is the ratio between the amount of air and the amount of fuel in mass (AF) or molar ($\widetilde{AF}$) units. The conversion between the mass and the molar air-fuel ratios corresponds to:

$$AF = \widetilde{AF}\ \frac{\tilde{m}_A}{\tilde{m}_F} \quad (5)$$

2.1.2. Isobaric heating values

Heating values are typically measured in calorimeter at constant volume or at constant pressure [1]. In order to simplify the discussion in this paper and since the majority of oxidation-based energy systems are open systems in quasi-steady operation this paper focusses on constant pressure (isobaric conditions).

For hydrocarbons the dew point is higher if the hydrogen/carbon ratio is higher and lower if the degree of dilution of water vapor is high in combustion gases (high air factor λ). This is the reason why there is a need to introduce two different isobaric heating values:

- ***higher heating value HHV*** when all H_2O formed during combustion is condensed;
- ***lower heating value LHV*** when none of H_2O formed during combustion is condensed

Those are defined by the following equations:

Specific isobaric Heating Value. $HHV(or\ LHV) = \Delta h^0 = \frac{H_M^0 - H_{Gc}^0}{M_F}\ \left[\frac{J}{kgF}\right]$ (6)

Molar isobaric Heating Value. $HHVm\ (or\ LHVm) = \Delta \tilde{h}^0 = \frac{H_M^0 - H_{Gc}^0}{N_F}\ \left[\frac{J}{kmolF}\right]$ (7)

The exponent $()^0$ reminds that those values are determined at a given reference state and H_{Gc}^0 varies depending on whether there is full or no condensation of the formed vapor from hydrogen. The following relation links the higher and lower heating values:

$$HHV = LHV + \dot{M}_{H2Op}\, q_{vap}^0 / \dot{M}_F \quad (8)$$

In which:

- $\dot{M}_{H2Op}$ is the total mass flow of H_2O produced during combustion,
- q_{vap}^0 is the latent heat of H_2O at the standard temperature.

The heating values of most common fuels can be found in the literature with specific or molar values.

The energy balance with all terms numerically positive can be expressed by:

$$\sum_k \dot{E}_k^+ + \sum_i \dot{Q}_i^+ + \dot{\boldsymbol{Y}}_{\boldsymbol{comb}}^+ + \sum_n \dot{Y}_n^+ - Q_a^- = \sum_k \dot{E}_k^- + \sum_i \dot{Q}_i^- + \sum_n \dot{Y}_n^- \quad (9)$$

Considering separately the network denominated with the subscript $()_{comb}$ in which combustion takes place:

$$\dot{\boldsymbol{Y}}_{\boldsymbol{comb}}^+ = \dot{M}_F\left(HHV + \hat{h}_F\right) + \dot{M}_A \hat{h}_A - \dot{M}_G \hat{h}_G - \sum(\dot{M}_I\, HHV_I) - (\dot{M}_{H2Op} - \dot{M}_{cond}) q_{vap}^0 \quad (10)$$

Where:

- $\hat{h}_F = \int_{T^0}^{T^F} dh_F$ (11) and $\hat{h}_A = \int_{T^0}^{T^A} dh_A$ (12) and $\hat{h}_G = \int_{T^0}^{T^G} dh_G$ (13) are accounting for the fact that the entering reactants and exiting products in practice have a temperature different from that of the reference standard state,
- $\dot{M}_I$ and HHV_I are the mass-flows of unburned hydrocarbons and their higher heating value, in the case of incomplete combustion,
- $\dot{M}_{H2Op}$ is the total mass-flow of H_2O produced during combustion,
- $\dot{M}_{cond}$ is the mass-flow of H_2O effectively condensed.

Figure 1 illustrates the heat gains that can be obtained by condensing the combustion gases in a condensing boiler for various fuels. The same applies to the exhaust gases of cogeneration units (engines or gas fed fuel cells) and gas fired heat pumps. The more diluted the resulting water vapor is (high λ), the less heat can be recovered from condensation and the lower is the dew point temperature. The higher the H/C ratio, the higher the dew point temperature. We can see, for example, that stoichiometric gas engines ($\lambda = 1$) allow to potentially recover more condensation heat and at a higher temperature than lean burn gas engines ($\lambda \cong 1.6$).

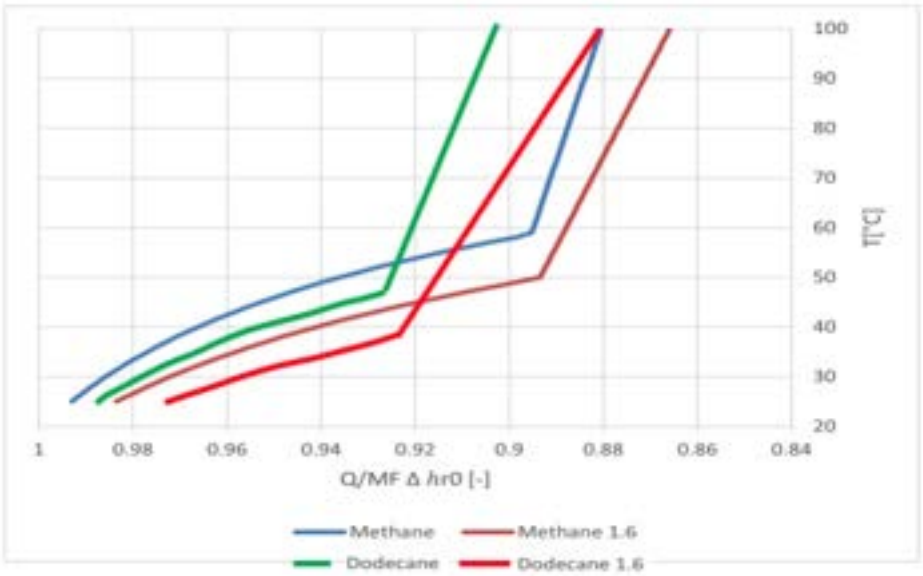

Figure. 1. Parts of the higher heating value recoverable when cooling the combustion gases from a condensing boiler down to 25°C with $\boldsymbol{\lambda = 1}$ (blue &green) or $\mathbf{1.6}$ (red & brown) for methane CH_4 (close to natural gas) and $C_{12}H_{26}$ (close to fuel oil). Here Q is the heat rate obtained, MF is the mass flow rate of fuel and $\Delta hr0$ is the isobaric higher heating value.

2.1.3. Enthalpies of formation and absolute entropies

In processes that do not involve chemical reactions, no species is modified and therefore all are considered inert, thus the reference of each of their thermodynamic state properties cancels out between inlet et outlet in energy or exergy balances. This is not the case anymore when reactions take place and new species are formed. In such conditions it becomes important to define coherent references. Hence the use of the definition of ***standard enthalpies of formation***, given per molar units in thermodynamic tables. Since entropy is also

essential in the Second Law and exergy analyses, the use of ***absolute entropies*** for all species is also of prime importance.

The values of enthalpies of formation of species that can be considered stable in the environment are arbitrarily assigned a zero value at the standard state. When this is not the case, they are determined either from calorimetric experiments or based on methods of statistical thermodynamics using spectroscopic measures. The fact that the reactions are exo- or endo-thermic influences the sign of the enthalpies of formation. For example, the reaction $2H_2 + O_2 \rightarrow 2H_2O$ is exothermic, which implies that heat needs to be extracted to come down to the standard temperature after reaction. Therefore, the enthalpy of formation of H_2O is negative, which is coherent with the convention of "positive entering" in a calorimeter for example.

The isobaric molar $\Delta\tilde{h}^0$ and specific heating value Δh^0 can then be determined by the following generic equations:

$$\Delta\tilde{h}^0 = \sum_i \left[\frac{N_i\ \tilde{h}^0_{fi}}{N_F}\right] - \sum_j \left[\frac{N_j\ \tilde{h}^0_{fj}}{N_F}\right] \qquad \left[\frac{J}{kmol_F}\right] \tag{14}$$

$$\mathrm{HHV} = \Delta h^0 = \sum_i \left[\frac{N_i\ \tilde{h}^0_{fi}}{M_F}\right] - \sum_j \left[\frac{N_j\ \tilde{h}^0_{fj}}{M_F}\right] \qquad \left[\frac{J}{kg_F}\right] \tag{15}$$

In which all the H_2O formed during combustion is condensed and, as before:

- subscript i refers to all compounds of the reactants (fuel and air)
- subscript j refers to all compounds of the reaction products (combustion gases)

3. Exergy value and exergy of diffusion (also called chemical exergy)

The **advantage of the heating values based on the First Law of thermodynamics is that they are independent from the presence of inert gases as long as enough oxygen is provided to allow for a complete combustion**. As such they do not account for the level of purity of the oxygen (pure or mixed with air) or for the concentration of CO_2 in the combustion gases. These parameters however play an increasing role in all energy systems that include CO_2 separation or oxy-combustion for example. Then the Second Law starts to be of primary importance and exergy analyses can provide a more coherent framework to evaluate advanced systems.

3.1 Convention regarding the exergy value

The objective is not only to consider thermomechanical equilibrium with the environment (P^0, T^0) (thermo-mechanical dead state) but also physico-chemical equilibrium (P^{00}, T^0, s^{00}) (dead states of each species). Hence, the need to precise a more complete reference of the environment considered, as described in Table1.

Table 1. Partial pressure and molar fractions of the main gaseous constituents of the standard atmosphere (at the standard conditions with $P^0 = 1.01325\ bar$ and $T^0 = 25°C$)

Substance	$P_i\ [bar]$	$\tilde{c}_i^A\ [kmol_i/kmol_A]$
N_2	0.7665	0.7565
O_2	0.2056	0.2030
Ar	0.0091	0.0090
$H_2O(g)$	0.0316	0.0312
CO_2	0.0003	0.0003

One further component to account for is liquid water resulting for example from condensation of combustion gases. It will be discussed later.

Furthermore, a convention is established to clarify the following conditions for the evaluation of the exergy value resulting from reactive processes:

- The fuel F and the air A enter separately (no premixing with the fuel)
- Each constituent of the reaction products Gc (combustion gases) ends up physically mixed with the standard atmosphere, i.e. at its partial pressure P_i^{00}
- Water exists in the final combustion products Gc either in liquid or vapor form at the limit of saturation, i.e. at the partial pressure of saturation in the standard atmosphere.

These conditions being set, the corresponding values for the **exergy value of a fuel** are the following:

$$\widetilde{EXV} = \Delta\tilde{k}^0 = \sum_i \left[\frac{N_i\ \tilde{k}^{00}_{fi}}{N_F}\right] - \sum_j \left[\frac{N_j\ \tilde{k}^{00}_{fj}}{N_F}\right] \qquad \left[\frac{J}{kmol_F}\right] \tag{16}$$

$$\mathrm{EXV} = \Delta k^0 = \sum_i \left[\frac{N_i\ \tilde{k}^{00}_{fi}}{M_F}\right] - \sum_j \left[\frac{N_j\ \tilde{k}^{00}_{fj}}{M_F}\right] \qquad \left[\frac{J}{kg_F}\right] \tag{17}$$

In accordance with the basic definition of exergy, the specific exergy value Δk^0 corresponds to the maximum work e^F_{max} that can be recovered from a fuel in an open reversible combustion in steady state, like in Figure 2. In principle, we should also consider whether or not there is condensation of the water formed during combustion. However as shown in [1] the difference between a higher and a lower exergy value is negligible, in particular when $T_a = T^0$. This is logical since the Carnot factor $(1 - {}^{T_a}/_{T^0})$ is zero. Hence t**he advantage of the exergy analysis of systems including oxidation processes is that a single exergy value can be considered in first approximation for fuels.**

Table 2. Features of the main species involved in combustion [5]

Species	Symbol	State	Molar mass [kg/kmol]	Enthalpy of formation [kJ/kmol]	Absolute entropy [kJ/(kmol K)]	Standard free enthalpy* [kJ/kmol]	**Exergy value** or Exergy of diffusion

*also called Gibbs function of formation or Gibbs free energy of formation

Table 2 provides the molar masses $\tilde{m}$, the enthalpies of formation $\tilde{h}_f^0$,the absolute entropies $\tilde{s}^0$, the standard free enthalpies $\tilde{g}_f^0$, the exergy values $\widetilde{EXV}(= \Delta\tilde{k}^0)$, resp. the exergies of diffusion $\tilde{e}_d^0$ of a number of compounds considered in practice. For reference, the calculator [12] provides slightly different values with a fairly high value for the entropy of diffusion of H_2O liquid, reason why we kept here the original values of [5].

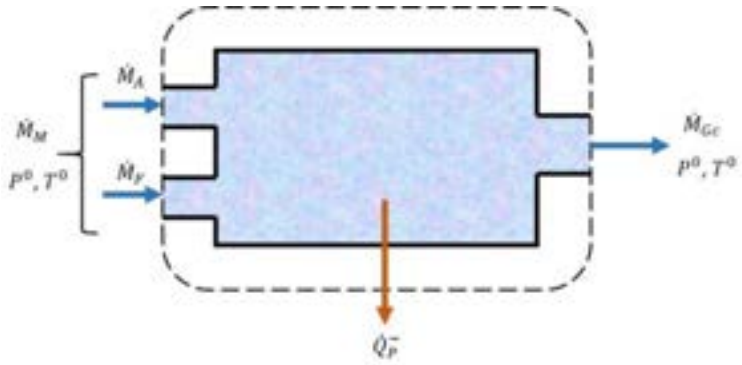

Figure. 2. Example of combustion in steady-state operation at constant pressure

3.2 Model of reversible combustion or oxidation

According to the definition of exergy the maximum work to be considered is the ideal work that could be recovered from reversible processes. In this context the idea of a ***reversible combustion*** is not obvious but can be explained with the use of a so-called van't Hoff box (cited in [3]) with compressors and turbines and semi-permeable membranes (Figure 3). Semi-permeable membranes are membranes that let only one species go through when the partial pressure of that species is not balanced on both sides of the membrane. One practical example of semi-permeable membrane is the solid electrolyte of a Solid Oxide Fuel Cell (ionic conductor) that, in certain conditions of temperatures, let only oxygen go through. The principle of a van't Hoff box is that the species inside the box are near the chemical equilibrium when reactions occur in the direction of the arrows shown in Figure 3, but the process can be reversed with only a slight change in the pressure between inlet and outlet with in this case arrows being reversed. For example, the species i2 in Figure 3 could be oxygen taken from the atmosphere and i1 a gaseous fuel like CH_4. Then j2 could be CO_2 and j1 would be H_2O according to the well-known reaction:

$$CH_4 + 2O_2 \rightleftarrows CO_2 + 2H_2O \tag{18}$$

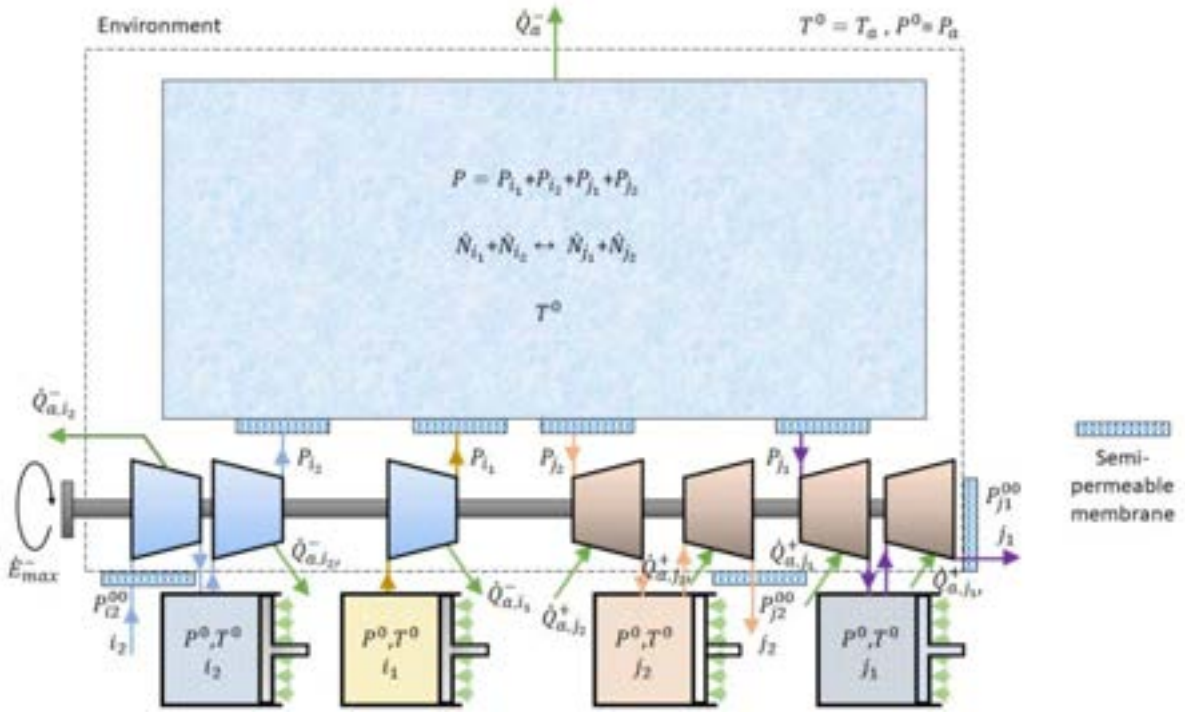

Figure. 3. Schematic representation of the reversible combustion of a fuel

The double arrow in the above equation indicates that the reaction is reversible close to equilibrium. Mechanically the first compressor is used to suck O_2 from its partial pressure P_{i2}^{00} in the atmosphere to a dedicated storage at pressure P^0, and the second compressor is pushing O_2 into the box at pressure *P*. The third compressor is pushing CH_4 from pressure P^0 to pressure *P* in the box. Then, on the same shaft one could imagine 4 turbines, 2 for CO_2 and 2 for H_2O, all gases ending up at their partial pressure in the atmosphere. All these machines are supposed to be isothermal, exchanging heat only with the atmosphere. Reversing the processes would mean that the turbines become compressors and the compressors become turbines. The net

mechanical power $\dot{E}^{-}_{max}$ that can be obtained from the process corresponds to an exergy rate equal to the specific exergy value of the fuel multiplied by the mass flow of fuel.

Through this representation one sees that if the oxidant is pure oxygen, more work can be obtained since the work required by the first compressor is not needed. On the other end if the concentrated CO_2 or H_2O exiting the system are just mixed with the atmosphere, then an opportunity to recover more work is lost. It is interesting to note that the theoretical work delivered by the second CO_2 turbine is equivalent to the minimum amount of work required to separate the same amount of CO_2 from the atmosphere for separate storage.

Let us first calculate the work recovered in steady-state operation for the simple case without the first compressor and the two turbines adapting the state of the exhaust gases to the atmospheric conditions:

$$\dot{E}^{-} = \dot{Q}^{+}_{a} + \sum_i [\dot{M}_i \, h^0_{fi}] - \sum_j [\dot{M}_j \, h^0_{fj}] \tag{19}$$

Assuming that the processes are reversible, then the Second Law gives:

$$\dot{Q}^{+}_{a} = T^0 \, (\sum_j [\dot{M}_j \, s^0_j] - \sum_i [\dot{M}_i \, s^0_i]) \tag{20}$$

Therefore:

$$\dot{E}^{-} = \dot{E}^{-}_{max} = \sum_i [\dot{M}_i \, (h^0_{fi} - T^0 s^0_i)] - \sum_j [\dot{M}_j \, (h^0_{fj} - T^0 s^0_j)] \tag{21}$$

$$\dot{E}^{-} = \dot{E}^{-}_{max} = \sum_i [\dot{M}_i \, g^0_{fi}] - \sum_j [\dot{M}_j \, g^0_{fj}] \tag{22}$$

Where g^0_f is the Gibbs free energy (also called free enthalpy) of formation.

For ideal gases the reversible mechanical power of an isothermal compressor is known to be:

$$\dot{E}^{+} = \dot{N} \int_{P_{in}}^{P_{out}} \tilde{v} dP = \dot{N} \int_{P_{in}}^{P_{out}} \tilde{\boldsymbol{r}} T^0 \frac{dP}{P} = \dot{N} \tilde{\boldsymbol{r}} T^0 ln\left(\frac{P^{out}}{P_{in}}\right) \tag{23}$$

Where $\tilde{\boldsymbol{r}}$ is the molar universal gas constant and the species behave like an ideal gas.

Inversing the integral limits give the equivalent equation for turbine.

Therefore, the net maximum work of the case of Figure 3 corresponds to:

$$\dot{E}^{-}_{max} = \sum_i [\dot{N}_i \, \tilde{g}^0_{fi}] - \sum_j [\dot{N}_j \, \tilde{g}^0_{fj}] + \dot{N}_{j1} \tilde{\boldsymbol{r}} T^0 ln\left(\frac{P^0}{P^{00}_{j1}}\right) + \dot{N}_{j2} \tilde{\boldsymbol{r}} T^0 ln\left(\frac{P^0}{P^{00}_{j2}}\right) - \dot{N}_{i2} \tilde{\boldsymbol{r}} T^0 ln\left(\frac{P^0}{P^{00}_{i2}}\right) \tag{24}$$

Let us also introduce the ***molar exergy of diffusion*** $\tilde{e}^0_{dk}$ for a species k:

$$\tilde{e}^0_{dk} = \frac{\dot{N}_k}{\dot{N}_F} \tilde{\boldsymbol{r}} T^0 ln\left(\frac{P^0}{P^{00}_k}\right) \tag{25}$$

The ratio $\frac{\dot{N}_k}{\dot{N}_F} = \nu_k$ is called stoichiometric coefficient and the ***molar exergy value of a fuel*** can be written in the following compact form:

$$\frac{\dot{E}^{-}_{max}}{\dot{N}_F} = \Delta\tilde{k}^0 = \sum_i [\nu_i \, \tilde{g}^0_{fi}] - \sum_j [\nu_j \, \tilde{g}^0_{fj}] + \sum_j [\tilde{e}^0_{dj}] - \sum_i [\tilde{e}^0_{di}] \tag{26}$$

$$\widetilde{EXV} = \Delta\tilde{k}^0 = \Delta\tilde{g}^0_f + \sum_j [\tilde{e}^0_{dj}] - \sum_i [\tilde{e}^0_{di}] \tag{27}$$

The absolute free enthalpy $\tilde{g}^0_f$ can be calculated from the absolute enthalpies and the absolute entropies according to the following relation:

$$\tilde{g}^0_f = \Delta\tilde{h}^0_f - T^0 \sum(\tilde{s}^0_P - \tilde{s}^0_R) \tag{28}$$

Note that in the literature [4], [2] all terms of the equation (3.114) are called **standard chemical exergies** although they refer to chemically stable substances and their exergy potential only lies in their partial pressure relative to the environment. Hence our terminology of ***exergy value*** $\widetilde{EXV} = \widetilde{\Delta k}^0$ of the fuels and ***exergy of diffusion*** for the other terms like the oxidants (i.e. O_2) or the stable combustion products like CO_2 or H_2O(g). In that way the symmetry between the heating values of fuels and their exergy value is kept, since the expression “heating value” is not to be used for inert components.

We also have the relation [2]:

$$\tilde{s}^{00}_i(T, P_i) = \tilde{s}^0_i(T) - \tilde{\boldsymbol{r}} ln\left(\frac{P_i}{P^0}\right) = \tilde{s}^0_i(T) - \tilde{\boldsymbol{r}} ln\left(\frac{\tilde{c}^A_i P}{P^0}\right) \tag{29}$$

Note that, in practice, real fuels are often mixtures of monomolecular fuels. Natural gas being the most common example. Since mixing implies diffusion losses, the exergy value of such a real fuel cannot be the simple addition of the relative exergy values of the n fuel components but corresponds to:

$$\Delta\tilde{k}^0 = \sum_1^n \tilde{c}_i \, \Delta\tilde{k}^0_i + \tilde{\boldsymbol{r}} T_a \sum_1^n \tilde{c}_i \ln \tilde{c}_i \tag{30}$$

3.3 Exergy values of more complex technical fuels

However, the exergy value of most solid or liquid technical fuels, which are complex mixtures of chemical compounds, is often difficult to determine. Various evaluations have been made on the basis of statistical

methods [4] using the concentration of basic components in the fuel like C, H, O, N and S as well as their LHV or HHV.

Table 3. Energy (heating) and exergy values of common fuels at the standard conditions of 1 atm and 25°C [5]

Fuel	State	LHV $= \Delta h_i^0$ [kJ/kg]	HHV $= \Delta h_s^0$ [kJ/kg]	$\widehat{LHV} = \Delta \tilde{h}_i^0$ [kJ/kmol]	$\widehat{HHV} = \Delta \tilde{h}_s^0$ [kJ/kmol]	$\mathrm{EXV} = \Delta k^0$ [kJ/kg]	$\widehat{EXV} = \Delta \tilde{k}^0$ [kJ/kmol]
C	Solid	32765	32765	393510	393510	34183	410545

C_2H_6	Gas	47512	51903	1428698	1560710	49678	1493418
C_7H_{16}	Liquid	44559	48072	4464778	4816810	47460	4757253
C_2H_6	Gas	47512	51903	1428698	1560710	49678	1493418
C_8H_{18}	Liquid	44788	48255	5116144	5512150	47435	5408656
$C_{12}H_{26}$	liquid	44574	47838	7592289	8148246	47169	8034431
CH_3OH	Gas	21110	23850	676364	764154	22544	720516
CH_3OH	Liquid	19936	22683	638762	726770	22367	716122
C_2H_5OH	Gas	27720	30590	1277060	1409281	29605	1360790
C_2H_5OH	Liquid	26818	29683	1235498	1367510	29386	1354514

However, a simplified approach to evaluate the chemical exergy of common combustible raw materials has been also proposed by [4].

$$\Delta k^0 = \alpha(LHV) \quad or \quad \Delta k^0 = \beta(\mathrm{HHV}) \tag{31}$$

Table 4. Coefficients to evaluate the exergy value of fuels [4]

Fuel	Coefficient	
	$\boldsymbol{\alpha}$	$\boldsymbol{\beta}$
Wood	1.15	1.05
Fuel oil	1.07	0.99
Natural gas (high methane)	1.04	0.99
Hard coal	1.09	1.03
Coke	1.06	1.04
Lignite	1.17	1.04
Coke-oven gas	1	0.89
Blast furnace gas	0.98	0.97

The following more detailed approach is also proposed for wood by [4].

$$\beta = \frac{1.0412+0.2160\left(c_{H_2}^F/c_C^F\right)-0.2499\left(c_{O_2}^F/c_C^F\right)\left[1+0.7884\left(c_{H_2}^F/c_C^F\right)\right]+0.0450\left(c_{N_2}^F/c_C^F\right)}{1-0.3035\left(c_{O_2}^F/c_C^F\right)} \qquad \text{valid for } \frac{c_{O_2}^F}{c_C^F} \le 2.67 \tag{32}$$

3.4 Exergy balance for a generic fuel molecule $C_aH_bO_cN_d$

$$C_aH_bO_cN_d + \left[a+\frac{b}{4}-\frac{c}{2}\right]O_2 \rightarrow a\ CO_2 + \frac{b}{2}H_2O(g) + \frac{d}{2}N_2 \tag{33}$$

$$\frac{\dot{E}^-}{\dot{N}_F} = \frac{\dot{Q}^+}{\dot{N}_F} + \tilde{h}_F^0 + \left[a+\frac{b}{4}-\frac{c}{2}\right]\tilde{h}_{O_2}^0 - a\tilde{h}_{CO_2}^0 - \frac{b}{2}\tilde{h}_{H_2O}^0 - \frac{d}{2}\tilde{h}_{N_2}^0 \tag{34}$$

Second Law for steady-state operation:

$$0 = \frac{\dot{Q}^+}{\dot{N}_F T^0} + \tilde{s}_F^{00} + \left[a+\frac{b}{4}-\frac{c}{2}\right]\tilde{s}_{O_2}^{00} - a\tilde{s}_{CO_2}^{00} - \frac{b}{2}\tilde{s}_{H_2O}^{00} - \frac{d}{2}\tilde{s}_{N_2}^{00} + \frac{\dot{s}^i}{\dot{N}_F} \tag{35}$$

By substituting the value $\frac{\dot{Q}^+}{\dot{N}_F}$ in Equation (34) one gets:

$$\frac{\dot{E}^-}{\dot{N}_F} = \tilde{h}_F^0 + \left(a+\frac{b}{4}-\frac{c}{2}\right)\tilde{h}_{O_2}^0 - a\tilde{h}_{CO_2}^0 - \frac{b}{2}\tilde{h}_{H_2O}^0 - \frac{d}{2}\tilde{h}_{N_2}^0 - T^0\left[\tilde{s}_F^{00} + \left(a+\frac{b}{4}-\frac{c}{2}\right)\tilde{s}_{O_2}^{00} - a\tilde{s}_{CO_2}^{00} - \frac{b}{2}\tilde{s}_{H_2O}^{00} - \frac{d}{2}\tilde{s}_{N_2}^{00}\right] - T^0\frac{\dot{s}^i}{\dot{N}_F} \tag{36}$$

The transition of the absolute entropy from the thermomechanical dead state to the global dead state is given by Equ.(34).

For a generic molecule, Equ. (36) can also be written as:

$$\Delta\tilde{k}^0(or\ \tilde{e}_d^0) = \left[\tilde{g}^0_{f\,C_aH_bO_cN_d} + \left(a + \frac{b}{4} - \frac{c}{2}\right)\tilde{g}^0_{f\,O_2} - a\tilde{g}^0_{f\,CO_2} - \frac{b}{2}\tilde{g}^0_{f\,H_2O} - \frac{d}{2}\tilde{g}^0_{f\,N_2}\right] + \tilde{\boldsymbol{r}}T^0 ln\left[\frac{\left(\tilde{c}^A_{O_2}{}^{\left(a+\frac{b}{4}-\frac{c}{2}\right)}\right)}{\left(\tilde{c}^A_{CO_2}\right)^a\left(\tilde{c}^A_{H_2O}\right)^{\frac{b}{2}}\left(\tilde{c}^A_{N_2}\right)^{\frac{d}{2}}}\right] \quad (37)$$

All data from species involved in combustion (Table 2), either exergy values for fuels or exergies of diffusion for inert species can typically be generated by Eq. (37).

3.5 Liquid water as a special case

Table 1 provides the values for a standard gaseous environment. We all know, however, that the environment consists of various equilibria like the equilibrium between surface water and the local gaseous atmosphere that usually shows a temperature difference. When dealing in particular with heating and cooling services, but also with power plants, the gaseous atmosphere is the most important environment since heat losses or gains as well as oxidant input and gas exhausts take place with the atmosphere. Because of that practical choice it is logical to also define the exergy of diffusion of liquid water by the exergy required for its release to the standard atmosphere.

Equation (37) can also be used to calculate the exergy of diffusion of liquid water. Even though there is no chemical change involved, the expression of the generic molecule can be used. Note that various attempts have been made in the literature [10], [4], [2] to find a global equilibrium between gaseous, liquid and solid species on Earth even going as far as considering various depth in the Earth crust[1].

Song et al. [9] developed new correlations based on a broad range of data bases. As a result of these various analyses the exergy of diffusion of liquid water varies between 5 et 950 kJ/kmol. Using the higher values results in a variation of the exergy values of fuels like hydrocarbons. From a practical standpoint this introduces complications that are not worth the efforts and we propose to limit the exergy of diffusion (chemical exergy in the literature) to the lower bound following the calculation shown below.

Example: Calculation of the exergy of diffusion of liquid water

We consider a system in which the water is evaporated and expanded in an isothermal turbine. For liquid water, a=0, b=2, c=1 and d=0. Equ. (37) becomes:

$$\tilde{e}_{d,H_2Oliq} = \left[\tilde{g}^0_{f\,H_2Oliq} - \frac{b}{2}\tilde{g}^0_{f\,H_2Og}\right] + \tilde{\boldsymbol{r}}T^0 ln\left[\frac{1}{\left(\tilde{c}^A_{H_2O}\right)^1}\right] = 5.1\ \text{[kJ/kmol]}$$

Conclusions

The concepts of fuel lower and higher heating values are compared with the fuel exergy value that has the advantage of being independent from the amount of condensation taking place in combustion or oxidation gases. The mechanistic model of reversible combustion presented allows a better interpretation of phenomena than a blind application of the concept of fuel exergy. Furthermore, and by coherence with First Law approaches it is recommended to separate the notions of exergy values for fuels from the concept of exergy of diffusion for chemically stable substances. In these definitions, one uncertainty remains that is linked to the broad range of exergy of diffusion of liquid water found in the literature.

Liquefaction of natural gas in offshore installations: effects of irreversibilities and composition of natural gas

Rafael Dias Assunção[a], Waldyr Luiz Ribeiro Gallo[b]

[a] University of Campinas, Campinas, Brazil, rafassunc@gmail.com
[b] University of Campinas, Campinas, Brazil, gallo@fem.unicamp.br ***(CA)***

Abstract:

The use of natural gas in the energy matrix has been gaining prominence on the world scenery, due to being a fuel with available reserves and being less pollutant than other fossil fuels. Gas pipelines can be hard to build when oil and gas production takes place in deep waters and at a great distance from the coast. An alternative is to liquefy natural gas at the production site (LNG). The LNG can then be transferred to land by methane tankers. Offshore natural gas liquefaction is strongly limited by weight and available space on vessels. In this work, three natural gas liquefaction processes are evaluated (Joule-Thomson cycle, reverse Brayton cycle and Claude cycle). The main objective is to evaluate the sensitivity of each type of technology to the main irreversibilities present: isentropic efficiencies, pressure drop and minimum temperature differences in heat exchangers. Each system is modeled in the ASPEN-Hysys environment, with Peng-Robinson equations of state. After validating the modeled systems, sensitivity studies are performed on the main sources of irreversibility for each system. The effect of the composition of the natural gas to be liquefied on the performance of the systems was also analyzed. The obtained results showed that design parameters (and the irreversibilities associated with them) produce enormous effects on the performance of the liquefaction systems, indicating that compromises between weight and space available in the FPSO may imply the adoption of non-optimized systems in terms of exergy efficiency.

Keywords:

Offshore oil and gas production; Natural gas liquefaction systems; LNG; Exergy efficiency.

1. Introduction

Natural gas (NG) is increasing it's participation in the world energy matrix. Among the fossil fuel, NG is the less pollutant and have the smaller CO_2 footprint. Although the COVID-19 pandemic decreased the economic activities in the world, the war among Russia and Ucrania introduced large concerns on NG availability and energy security. The international trade of NG was greatly affected, specially in Europe.

As any gaseous fuel, NG presents difficulties concerning its transport and distribution. The most used form of transport today is the use of gas pipelines as a link between producers, intermediaries and consumers. However, this solution has as its main disadvantage the fact that when the distances involved are large, the risks involving gas pipelines, such as leaks, increase significantly [1]. This problem is amplified when the production is made offshore, due to the difficulties associated with the launching pipelines at deep water and at long distances from the coastline. This is the case for NG produced in the Brazilian Pre-Salt oil and gas fields. Today, most of the gas produced (associated gas) is re-injected in the oil field. Although this is positive to maintain the pressure in the oil field, the gas is not delivered to the market and is not monetized.

There are a considerable international experience in the transport and trade of NG in liquefied form (LNG) using specialized ships. Various LNG production and export facilities are distributed in producing countries and various re-gasification facilities exists in importing countries. This is the only viable form to deliver natural gas for long distances. LNG production facilities are positioned aside the production fields, onshore. However, when the gas field is offshore, some specialized floating production units (FLNG) were proposed and constructed. An analysis presented by [2] points to this option as a "game changer" in the same way that FPSO enabled oil production in deep water. However, this will depend on the performance and economics of the few pioneer FLNG in operation. There are great challenges to be overcome: weight, topside deck available space, meteorologic and oceanographic conditions. Figure 1 shows preliminary CAPEX and capacity figures of some FLNG units. As for 2022, there are six units in operation: Prelude (Australia), Satu and Dua (Malaysia), Hilli Episeyo (Cameroon), Coral Sul (Mozambique) and Tango (Congo Brazzaville - a barge).

Figure 1. CAPEX and capacity for FLNG in operation or construction. Source: [3]

The heart of a FLNG is the cryogenic system. There are many different cryogenic cycles being proposed to LNG production, both for land or offshore units. The cycles can be classified by the type of refrigerating fluid (pure substances, or mixed substances) and by the type of expansion adopted: Joule-Thomson effect obtained by expansion valves, or adiabatic expansion obtained by turbo-expanders. There is also the possibility to use both effects, like in the Claude cycle.

For land systems, weight, size and complexity are not great concerns, and various researchers presented comparison among different system [4], or optimization of systems [5,6]. A comprehensive review for cryogenic cycles can be found in [7]. Due to the restrictions posed by floating production, specific FLNG systems have been explored. A simplified mixed refrigerant cycle (N_2, CH_4, C_2H_6 and C_3H_8) with dual pressure is proposed in [8] and a good specific power consumption of 1150 kJ / kg of LNG was obtained. A cryogenic cycle based on a reverse Brayton cycle is presented and analyzed in [9]. This cycle uses N_2 as working fluid.

Usually the NG to be liquefied is also pressurized, to reduce the size of the equipment. Using this characteristic, [10] proposes that the last stage for LNG production uses of an expansion valve in the NG line to obtain the final product, LNG at near atmospheric pressure.

Looking for small systems, [11] compares three cycles: one with mixed refrigerant and dual expansion, and two reverse Brayton cycles also with dual expansion, one of them with N_2 and another with CH_4 as working fluids. Based on the hypothesis adopted, the mixed refrigerant presents a better performance: ~1500 kJ / kg of LNG versus 2500 and 2100 kJ / kg of LNG for mixed refrigerant, dual expansion with N2 and dual expansion with CH4. Another work [12] uses data from a Brazilian FPSO gas production and composition, and obtains similar results.

It is difficult to compare the performance of the various systems due to different hypothesis adopted by each author. Some papers does not present all hypothesis adopted, specially those associated with the main irreversibilities: compressors and expanders isentropic efficiencies, pressure losses in the heat exchangers and pipes, approach temperatures in heat exchangers. This work intends to evaluate the effect of irreversibilities and the effect of NG composition on the performance of three cryogenic cycles.

2. Methodology

The cryogenic systems analyzed in this work are described in the next section. All equipment are supposed to operate in the steady-state. Mass and energy conservation was the first step in the simulation of each control volume identified in the flowsheets. Using the entropy balance, entropy generation was calculated to avoid thermodynamic pitfalls in heat exchangers. The exergy balance was used to calculate the irreversibilities and exergy components to obtain performance parameters.

Aspen-Hysys software was adopted to calculate thermodynamic properties of the different flows, using the Peng-Robinson equation of state. All simulated cycles were validated using the same cycles, hypothesis and values of parameters present in [7].

Equation (1) shows the exergy balance for a control volume in the steady-state

$$0 = \dot{Ex}_Q - \dot{Ex}_W + \sum_{in}(\dot{Ex}) - \sum_{out}(\dot{Ex}) - \dot{ExD}, \quad (1)$$

where $\dot{Ex}_Q$ is the exergy associated with a heat flow, $\dot{Ex}_W$ is the available power, $(\dot{Ex})$ are the exergy flow associated with the masses crossing the control surface and $\dot{ExD}$ is the destroyed exergy inside the control volume, also known as irreversibility. The exergy flow $(\dot{Ex})$ is determined by the Eq.(2):

$$\dot{Ex} = \dot{m}[h - h_0 - T_0(s - s_0) + ex^{ch}], \quad (2)$$

where ex^{ch} is the chemical exergy per mass unit. The environment is supposed at 25ºC and 1 atm and the chemical exergy, when needed, was obtained according to [13] methodology.

Three performance parameters were calculated: the exergy efficiency, shown in the Eq. (3), the liquid power needed to produce 1 kg of LNG in the Eq.(4), and the energy needed to produce LNG as a percentual of the Lower Heating Value (LHV) of LNG, Eq. (5):

$$\eta_{Ex} = \frac{\dot{Ex}_{LNG} - \dot{Ex}_{NGin}}{|\dot{W}_{net}|} \quad (3)$$

$$\frac{W}{m} = \frac{\dot{W}_{net}}{\dot{m}} = \frac{\dot{W}_{compressors} - \dot{W}_{expanders}}{\dot{m}_{LNG}} \left[\frac{kJ}{kg\ LGN}\right] \quad (4)$$

$$\%\text{LHV} = \frac{\dot{W}_{net}}{\dot{m}_{LNG} * LHV} \ . \quad (5)$$

3. Simulated cycles and its validation

Three cycles were selected in this study: one based in the Joule-Thomson effect, one reverse Brayton cycle and one Claude cycle. All cycles chosen were compatible with [7], which was the reference for model validation.

3.1. Joule-Thomson cycle

The J-T cycle flowsheet in presented in the Fig. 2. The working fluid is compressed in three stages K- , with water cooling E- , and the expansion valve VLV-100 produces the final cooling effect. The working fluid in the cycle is a mixture of components, with the composition given in the Table 1. The composition of the mixture can be changed if desired, to obtain a better match with the NG cooling temperature path. The NG to be liquefied enters the cold box LNG-100 in the state 10 at 5 MPa and 298 K and exits in state 11 at 5 MPa and 113 K.

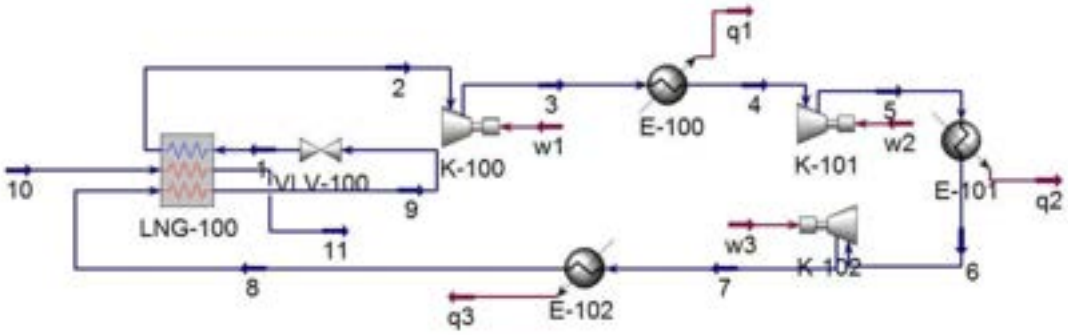

Figure 2. Joule-Thomson cycle.

Table 1. Mixed refrigerant composition for the J-T cycle

Substance	Molar fraction (%)
N_2	8.6
CH_4	30.1
C_2H_6	24.3
C_3H_8	37.0

3.2. The reverse Brayton cycle

The flowsheet of this cycle is presented in the Fig.3. In the reverse Brayton cycle, the working fluid is N_2. The refrigerant in compressed in three stages, with water cooling. The expansion is done by a turbo-expander (K-103). The NG to be liquefied enters the first heat exchanger LNG-100 and is pre-cooled. The final liquefaction occurs in the heat exchanger LNG-101. Again, the NG is at a constant pressure of 5 MPa, enter the system at 298 K and exits at 113K.

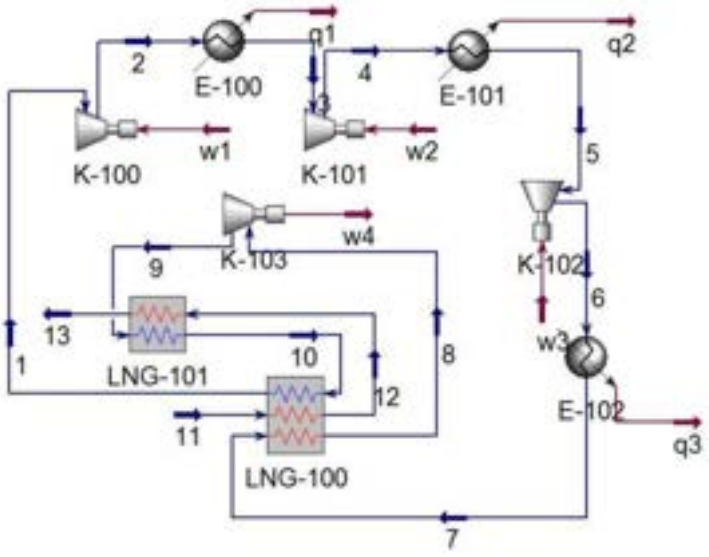

Figure 3. Reverse Brayton cycle

3.3. The Claude cycle

The Claude cycle is shown in the Fig.4. The NG to be liquefied is cooled through the heat exchangers LNG-100 to LNG103. The inlet and outlet conditions of the NG is the same as the two previously presented cycles: 5 MPa, constant, 298 K at inlet and 113 K at outlet. The cooling cycle is somewhat more complex, with four stages of compression, with water cooling, and the expansion process is made by expansion valves and turbo-expanders. The working fluid is pre-cooled in the heat exchanger LNG-100 and then is splitted in two streams. One of them goes to the turbo-expander K-104, mixes with the return stream in the MIX-100 and then passes in the heat exchanger LNG-101. The second stream passes LNG-101, LNG-102 where is cooled, goes to the expansion valve VLV-100 and finally enters the heat exchanger LNG-103. The return stream goes to LNG-102, LNG-101 and LNG-100 to close the cycle.

This cycle uses a NG as the working fluid, with composition given in the Table 2, which is the same adopted for the NG to be liquefied.

Table 2. Natural gas composition adopted for model validation.

Substance	N_2	CH_4	C_2H_6	C_3H_8	$n-C_4H_{10}$	$i-C_4H_{10}$
Molar composition (%)	1.0	91.0	5.0	2.0	0.6	0.4

3.4. Validation of the simulation

It is important to mention that [7] presents results for a great number of **ideal** cycles, always considering the production of 1 kg/s of LNG. Pressure losses, minimum approach temperatures and isentropic efficiencies for compressors and expanders are not considered. The cycles simulated in this work were validated against the values presented in [7] for the simplest cycle of each type (J-T, Brayton, Claude) using the same data, and good results were obtained. The relative deviations on exergy efficiency, Eq. (3), were -1.2% for the J-T cycle, +0.2% for the reverse Brayton cycle and 0,0% for the Claude cycle. Main results of the validation of this work are presented in the Table 3, showing also the exergy efficiency of [7].

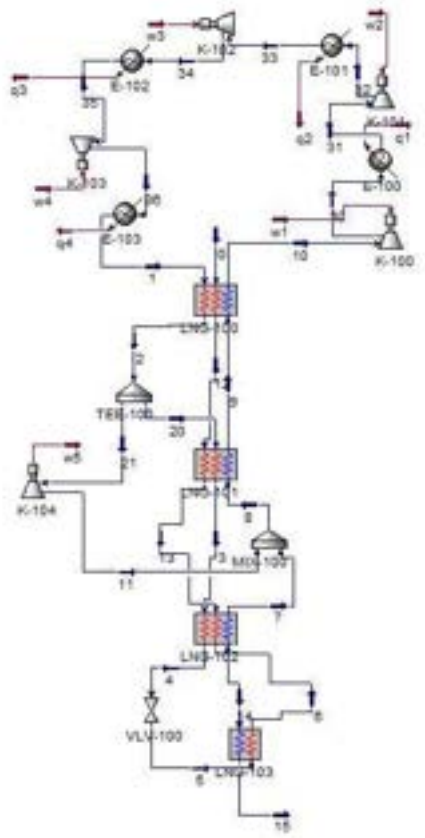

Figure 4. The Claude cycle

The obtained results are overestimated, since important sources of irreversibility were not considered. The use of exergy efficiency is not usual outside academic circles. The most usual parameter to define a good performance for LNG production is presented in the third column in the Table 4: energy expressed in kWh needed to produce 1 kg of LNG. The best practical systems developed for onshore complex installations are in the range of 0.2545 - 0.3572 [4] and for offshore values in the range of 0.400 to 0.474 according to one equipment provider [14].

Table 3. Main results from the validation process

Parameter Cycle	W/m [kJ / kg LNG]	W/m [kWh / kg LNG]	Energy/ LHV %	η_{Ex} %	η_{Ex} % [7]
J-T	795.9	0.2211	1.64	56.4	57.1
Reverse Brayton	743.4	0.2065	1.53	60.4	60.3
Claude	752.8	0,2091	1.56	59.7	59.7

4. Results and discussion

This section shows the effects of irreversibilities as well as the effects of the NG composition on the performance of the basic cryogenic cycles presented.

4.1. Influence of the irreversibilities on cycle performance

This work evaluates three types of irreversibilities: isentropic efficiencies of compressors and expanders, pressure losses in heat exchangers, and minimum approach temperatures in heat exchangers. To evaluate the isolated effect of each irreversibility source, a parametric study was made. The isentropic efficiency was varied in the range from 80-100%; pressure losses were evaluated in the range 0-5% as a percentage of

inlet pressure of each stream; minimum approach temperatures in the heat exchangers were evaluated in the range 0-10°C. Ideal cycles have 100% isentropic efficiencies, 0% pressure losses and minimum approach temperatures of 0°C. To analyze each parameter, the other ones were maintained at the ideal values.

It is important to note that the results for exergy efficiency presented in this section for ideal (base) cycles are different from the results presented for the same ideal cycles presented in the Table 3. This is due the fact that the NG composition is different from the one adopted in [7] and presented in Table 2. To this study, a typical composition of the NG produced in the Brazilian Pre-Salt was adopted. So, to obtain the maximum exergy efficiency a new optimization should be made. This is a clear proof of the dependency of the performance of each cycle to the NG composition, effect which will be analyzed in the next section.

Table 4 presents the results of the parametric analysis for the Joule-Thomson cycle. This cycle uses mixed refrigerant with the composition given in Table 1 and reaches a maximum pressure of 5,0 MPa. From the results, it is clear that the minimum approach temperature is the main irreversibility effect, followed by the isentropic efficiency of the compressors. Pressure losses are also relevant, although less important than the other effects. The importance of the minimum approach temperature is due to the mismatch among the NG composition and the composition of the mixed refrigerant, and emphasize the importance of the adjustment of the working fluid composition to each NG composition.

Table 4. Parametric analysis for the Joule-Thomson cycle.

Parameter	Value	Exergy Efficiency	W/m [kJ/kg LNG]	W/m [kWh/kg LNG)	Energy / LHV %
Isentropic efficiency	100%	49.5	720.1	0.2000	1.49
	90%	44.6	800.1	0.2223	1.65

	2%	48.0	738.7	0.2052	1.53
	5%	45.9	766.9	0.2130	1.58
Approach T (°C)	0.0	49.5	720.1	0.2000	1.49
	5.0	30.1	1185.3	0.3293	2.45
	10.0	22.2	1604.0	0.4455	3.31

The results obtained for the reverse Brayton cycle are presented in the Table 5. This cycle operates with N2 as working fluid and its maximum pressure is very high: 10 MPa. The cycle adopts a turbo-expander to obtain the desired minimum temperature. Due to the high pressure needed from compressors and the use of the turbo-expander, the main irreversibility in this cycle is the isentropic efficiency of the rotating machines. Minimum approach temperatures and pressure losses are clearly secondary effects, although important.

Table 5. Parametric analysis for the reverse Brayton cycle.

Parameter	Value	Exergy Efficiency	W/m [kJ/kg LNG]	W/m [kWh/kg LNG)	Energy / LHV %
Isentropic efficiency	100%	52.2	683.4	0.1898	1.41
	90%	31.7	1124.0	0.3122	2.32

	2%	47.5	742.9	0.2064	1.53
	5%	41.7	833.9	0.2316	1.72
Approach T (°C)	0.0	52.2	683.4	0.1898	1.41
	5.0	48.4	736.8	0.2047	1.52
	10.0	44.9	794.6	0.2207	1.64

Table 6 presents the results obtained for the Claude cycle. The working fluid for the Claude cycle is NG, but with composition as given by Table 2. There is a mismatch among composition of the NG as working fluid and the NG to be liquefied. This cycle also operates with very high pressure (10 MPa) and uses a turbo-expander as well as a expansion valve to obtain the needed minimum temperature. Since there are rotating machines, mismatch among the working fluid and NG to be liquefied, and a great number of heat exchangers, all irreversibilities are important, including pressure losses.

As seen in Tables 4 to 6, the irreversibilities can have a huge effect on the performance of the cycles.

Table 6. Parametric analysis for the Claude cycle.

Parameter	Value	Exergy Efficiency	W/m [kJ/kg LNG]	W/m [kWh/kg LNG)	Energy / LHV %
Isentropic efficiency	100%	44.3	805.1	0.2236	1.66
	90%	30.9	1154.4	0.3207	2.39
	80%	21.4	1662.2	0.4617	3.43
Pressure loss	0%	44.3	805.1	0.2236	1.66
	2%	41.6	839.6	0.2332	1.73
	5%	37.9	893.8	0.2483	1.85
Approach T (°C)	0.0	44.3	805.1	0.2236	1.66

	10.0	39.5	903.7	0.2510	1.87

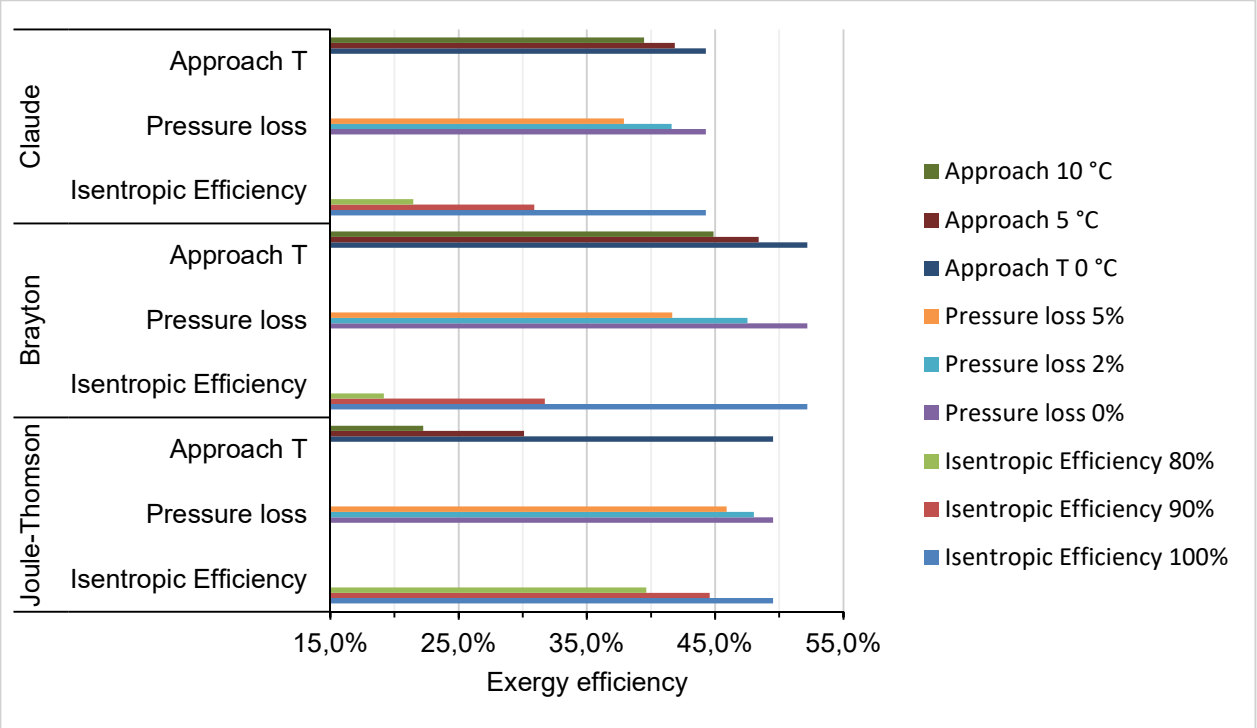

Figure 5. Effects of irreversibilities on the exergy efficiency for the three cycles.

Figure 5 shows the effects of irreversibilities on the exergy for the three cycles. As can be observed, each cycle presents different impacts from each parameter. Since all cycles use compressors, the isentropic efficiency is relevant for all of them. The mismatch of working fluid and NG properties can induce a great impact on performance due to high values of minimum approach temperatures.

4.2. Influence of the natural gas composition

The operation of a FLNG is foreseen to 20 to 25 years in a given gas oil and gas field. The composition of the NG to be liquefied varies during the field operation, even after the needed treatment before liquefaction. As became clear in the previous section, NG composition impacts the performance of the cryogenic cycles.

To evaluate the effect of NG composition, five NG compositions were adopted. These compositions are presented in the Table 7 and are associated to different years of a typical production curve. The first one corresponds to the third year, when occurs the maximum production of oil and gas. The second composition is for the production year 12. The third composition corresponds to the year 15, when the oil and gas production begins to fall and water content increases. The fourth composition occurs at the 50% BSW (Basic Sediment and Water) condition. Finally, the fifth composition corresponds to year 21, in a condition with maximum water and CO_2 in the oil field. It must be said that all compositions are obtained after the pretreatment phase.

Table 7. NG composition for five field operation conditions.

Three scenarios for irreversibilities effects were explored. The Base Case is the ideal condition: isentropic efficiencies of 100% for all rotating machines, no pressure loss, and minimum approach temperature of 0°C whenever possible. For the Case 1, irreversibility parameters are in an intermediate value. Isentropic efficiencies are 90%, pressure losses are 2% of the inlet pressure for each heat exchanger, and minimum approach temperature is 5°C. Case 2 represents the worst condition for all parameters: isentropic efficiencies are 80%, pressure losses are 5% of the inlet pressure for each heat exchanger, and minimum approach temperature is 10°C.

As an example of the thermodynamic states for each stream, Table 8 presents the results for condition 1 (NG composition for the third year of field operation) for the three scenarios using Joule-Thomsom cycle. The streams are numbered according to Fig.2.

The thermodynamic states for the reverse Brayton and Claude cycle are not presented here due to space limitation for the paper.

The effect of NG composition and degree of irreversibilities on the performance of the Joule-Thomson cycle is presented in the Table 9. The degree of irreversibility is the dominant effect, causing huge reductions on the exergy efficiency, whatever is the NG composition. As an example, for NG composition 2, the exergy efficiency falls from 52.5% (base case) to 27.6% for case 1 and to 14.4% to case 2. The effect of NG composition, however, for the same level of irreversibility (case), is also relevant. In the example, the exergy efficiency vary in the range from 5 to 17% depending on the NG composition. And it must be remembered that the NG composition didn't vary so much, as can be seen in the Table 7. The J-T cycle uses mixed refrigerant. To improve the performance of the cycle, the molar percentage of the constituents of the working fluid should be optimized for each NG composition, bringing operational complexity for the FLNG.

	Case 2	17.50%	2105.0	0.585	4.35

Table 10 shows the performance for the reverse Brayton cycle. The overall tendencies are similar to J-T cycle - that is, the degree of irreversibility is the main effect. Since the working fluid for this cycle is N_2, the effects of NG composition is near 3.5%, not so great as for J-T cycle. Since this cycle operates with very high pressures and uses various rotating machines, the effects of irreversibilities on exergy efficiencies are even greater than for the J-T cycle: from 54% (base case) to 28% in case 1 and 14% in the case 2.

The performance of the Claude cycle is presented in the Table 11. The effect of irreversibilities on performance is again the predominant: the exergy efficiency drops from 45% in the base case to 31.5% in case 1 and to 20.3% for case 2. The effect of the NG composition for a given level of irreversibility is in the range of 3.7 to 6.0%.

Table 10. Performance of the reverse Brayton cycle for different NG compositions and different degrees of irreversibilities

NG Composition	Degree of irreversibility	Exergy eff	W/m [kJ /kg LNG]	W/m [kWh/kg LNG]	Energy / LHV %

	Case 2	20.6%	1714.9	0.476	3.54

Figures 6 and 7 present comparisons among the three cycles, focusing on exergy efficiency and work to produce 1 kg of LNG respectively. As expected, the work needed increases (and the exergy efficiency decreases) when the irreversibilities increases. It is interesting to note, however, that for a given cycle and a given level of irreversibility, the NG composition can produce a higher exergy efficiency associated with a smaller work to produce 1 kg of LNG. Mass, energy and approach temperatures details can explain this.

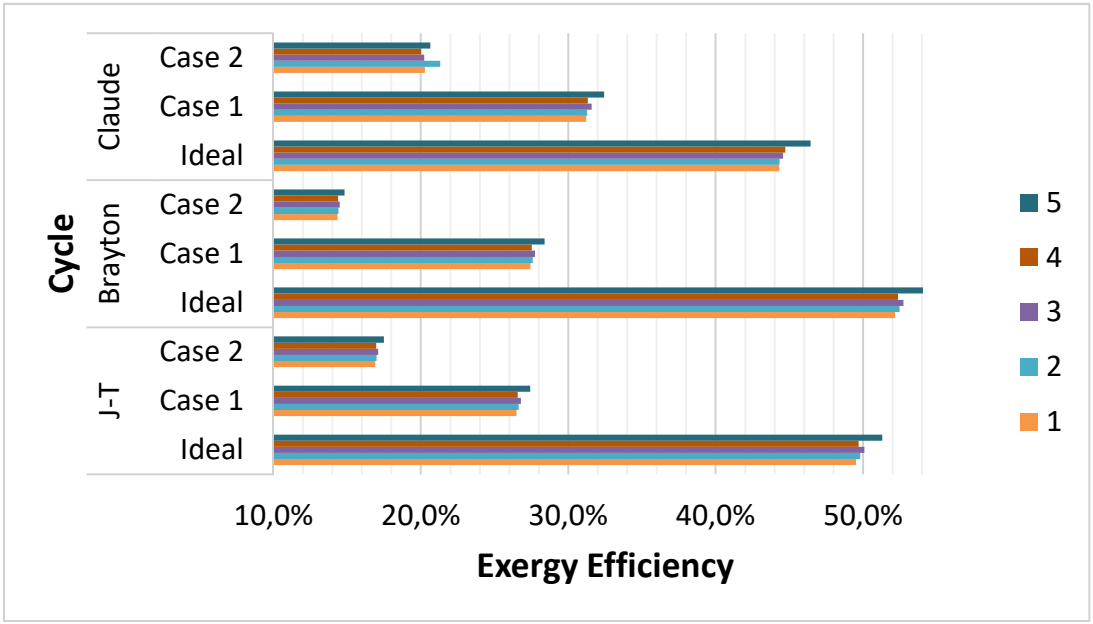

Figure 6. Performance comparisons among the three cycles: exergy efficiency.

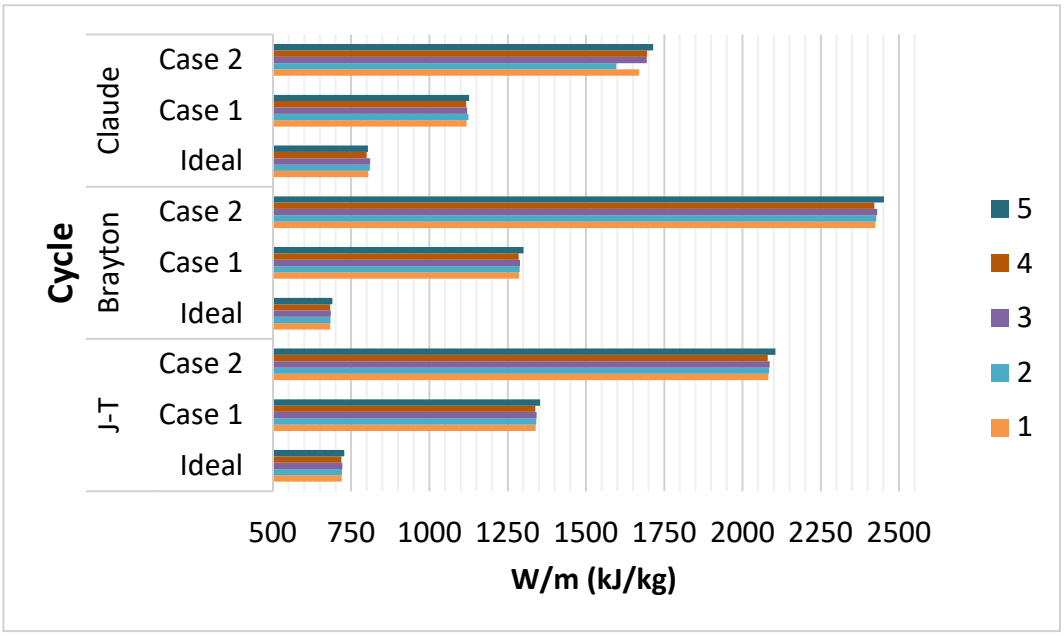

Figure 7. Performance comparisons among the three cycles: work to produce 1 kg of LNG.

5. Concluding remarks

The analysis developed in this work showed the huge influence of the irreversibility level on the performance of three cycles proposed to produce LNG offshore. The limitation of weight and size induces a design which uses as few components as possible. Then, the three cycles studied were the simplest of each class. The influence of the NG composition, although smaller, is also relevant.

The use of mixed refrigerants is interesting to reduce the internal heat transfer irreversibilities in heat exchangers, but requires an optimization of the working fluid composition (molar fractions of the components) associated with the NG composition. This is the case for the analyzed J-T and Claude cycles.

The use of N_2 in a reverse Brayton cycle presented less dependency of the NG composition. However, this cycle proved to be the most sensitive to the isentropic efficiencies of the rotating machines - that is, the design of highly efficient compressors and turbo-expanders must be the focus for a better performance of this cycle.

The prime movers to run the compressors can be electrical motors, or thermal machines as gas turbines. The work needed to produce 1 kg of LNG didn't take into account the use of fuel to run the prime mover or to generate the electricity. As an example, if a gas turbine fueled by NG, with 35% of efficiency, is used as mechanical drive, the use of fuel can be in the range of 5-15% of the available NG, depending on the cycle and level of irreversibilities.

To reduce the volume of the equipment, the NG to be liquefied was assumed at 5 Mpa to increase its density. The power needed to compress the NG to this pressure was not taken into account. Depending on details of the FLNG design and pretreatment processes, the NG can be at some pressure grater than atmospheric.

For the cycles analyzed, in the conditions specified in this work, the exergy efficiency varied from 43 to 52% for the ideal cycles, to 14 to 17% for cycles with high level of irreversibilities. This indicates that the feasibility of FLNG is quite sensible to a balance among high efficiency and cycles as simple as possible to save size, weight and economic costs.

Nomenclature

h -	Enthapy [kJ/kg]	LHV -	Lower heating value [kJ/kg]	$\dot{E}x$	Exergy flow [kJ/s]
$\dot{m}$ -	Mass flow [kg/s]	$\dot{E}x_Q$ -	Exergy flow -heat transfer [kJ/s]	η_{Ex}	Exergy efficiency
s -	Entropy [kJ/(kg.K)]	$\dot{E}x_W$ -	Exergy of power [kJ/s]	NG	Natural gas
T -	Temperature [K]	$\dot{E}xD$ -	Destryed exergy [kJ/s]	LNG	Liquified natural gas
$\dot{W}$ -	Power [kW]	ex^{ch} -	Chemical exergy [kJ/kg]	FPSO	Oil and gas platform

Abstract:

In this work, the annual performance of a solar thermal power system in Greece is numerically studied. The system consists of a field of Evacuated Tube Collectors and a Trilateral Flash Cycle engine. The main target of this study is to assess the potential of the Trilateral Flash Cycle, a promising higher efficiency alternative to the Organic Rankine Cycle, for solar energy exploitation. The effects of the solar irradiance, the temperature of the heat source, and the flashing efficiency on the total solar energy conversion efficiency are monitored. The economics of the system is preliminarily studied taking into account its scale and the anticipated annual power output. Simulations indicate that the combined Solar-Trilateral Flash Cycle system can achieve an average annual total solar energy conversion efficiency of 5%, outperforming a Solar-Organic Rankine Cycle system of similar architecture at the examined location. It is demonstrated that the efficiency of the Trilateral Flash Cycle engine is highly dependent on the quality of the Working Fluid at the onset of expansion, and the operating pressure ratio. Moreover, the Trilateral Flash Cycle can achieve a thermal efficiency of up to 11%. The Levelized Cost of Electricity of the power system is estimated to lie in the region of 0.26 - 0.32 €/kWh, based on its scale, indicating that it may be a competitive solution for solar energy exploitation.

Solar Energy; Trilateral Flash Cycle; Two-Phase Expansion; Evacuated Tube Collectors; Solar Efficiency; Thermal Efficiency.

1. Introduction

Solar energy presents a huge potential for green power generation, especially in locations with low to middle latitudes, and it may be efficiently exploited by solar thermal power systems. In these systems, solar thermal collectors generate heat that is utilized for power production by a heat-to-power conversion technology. Several types of solar thermal collectors, with different ranges of applications each, have been developed [1], and they are currently considered to be at a mature technological level [2]. These collectors provide heat at rather low temperatures (<400^{o}C), a range where the traditional water-steam Rankine power cycles of centralized power stations cannot operate efficiently. The overall solar energy conversion efficiency of solar thermal power systems depends on the collectors' efficiency and the thermal efficiency (heat-to-power ratio) of the power generation technology. Bottoming power cycles are a widely applied solution for the efficient exploitation of low-temperature heat, with the Organic Rankine Cycle (ORC) indicated as a robust solution because of its flexible design, low maintenance cost, and nearly unsupervised operation [3].

Many works have been published in the literature (e.g. [4–7]) assessing the potential and efficiency of the ORC, both numerically and experimentally, with different heat sources. The main drawback of the ORC is the drop in its thermal efficiency at lower heat source temperatures. Several studies have been published in the literature (e.g. [8]) aiming to identify the causes for this efficiency drop. The consensus is that the energy losses in the ORC are mainly ought to the isothermal vaporization process of the Working Fluid (WF) at the evaporator of the cycle. During this process, the temperature of the WF remains constant while the temperature of the Heat Transfer Fluid (HTF) drops, leading to a sub-optimal match between the finite heat source and the WF. The optimal match between the heat source and the WF may be accomplished when the power cycle obtains

a trilateral shape [8], where the vaporization of the WF is omitted. One such possible high-efficiency power cycle variant is the Trilateral Flash Cycle (TFC), initially conceptualized by Smith et al. [9].

The TFC consists of the same components as the ORC but the WF enters the power generator in the saturated liquid state, or partially evaporated in the generalized version of the TFC, where it undergoes two-phase expansion, also known as flashing. The TFC is not technologically mature, mainly because of the lack of fundamental knowledge about the complex flashing phenomenon in the expander. Only a few experimental works ([10–12]) have been performed in two-phase expansion until now, with the quality of the WF at the onset of expansion identified as the most significant factor affecting the efficiency of the two-phase expander. Higher vapor qualities result in increased efficiencies of the two-phase expansion, which can reach 80% [11]. Furthermore, only a few numerical models [13–16] have been developed to simulate two-phase expansion, all of which simulate flashing in twin-screw expanders. In the work of Skiadopoulos et al. [16], a semi-empirical thermodynamic low-order model was developed to simulate two-phase expansion in twin-screw expanders. In this model, a segmental approach is applied to monitor the evolution of flashing in the expansion chamber. Moreover, the liquid and vapor phases are assumed to be in thermal non-equilibrium and a two-fluid model approach is followed for the formulation of the governing equations.

The purpose of this work is to assess the performance of a small-scale solar thermal power system in Athens, Greece, driven by low-temperature solar heat, which is provided by a field of Evacuated Tube Collectors (ETCs), and exploited by a TFC bottoming power cycle. To the best of the authors' knowledge, this is the first work in the literature systematically investigating the promising TFC power cycle for solar heat exploitation. The ETCs are selected for the system, because of their increased efficiency in comparison to Flat Plate Collectors, which are typically preferred for small-scale systems because of their lower cost. An integrated numerical tool simulating the annual performance of the combined Solar-TFC system is developed, in the software environment of Matlab (R2022b). The numerical model utilizes meteorological data for the installation site, provided by the National Observatory of Athens. Another novel feature of this work is that in TFC modeling, the performance of the two-phase expander, under varying operating conditions, is accurately monitored, by applying the novel thermodynamic low-oder model developed by Skiadopoulos et al. [16]. This approach in two-phase expansion modeling comes to fill a gap in the relevant literature since several theoretical works studying the performance of the TFC have been published, but the two-phase expander is usually treated as a black box with isentropic efficiencies achieved in the dry-vapor region [17,18]. R245fa is selected as the WF of the TFC, because it has been tested as a WF in Solar-ORC systems, numerically and experimentally, demonstrating very good thermodynamic behavior within the range of temperature and operating pressure ratios of low-temperature solar systems [6,7].

This paper is organized as follows. In Section 2, the architecture of the integrated system, the governing equations, and the numerical methodology are presented in detail. Moreover, the methodology for the economic assessment of the Solar-TFC system is presented. In Section 3, the performance of the ETCs, the TFC, and the integrated system are investigated in detail. Thereafter, the annual electricity output of the unit and the achievable total solar energy conversion efficiency, along with the thermal efficiency of the TFC and the second law efficiency of the Solar-TFC system, under optimal operating conditions, throughout the year are estimated. Finally, a short economic analysis of the Solar-TFC system is presented. General conclusions and remarks are presented in Section 4.

2. Materials and Methods

2.1. Description of the Solar-TFC system

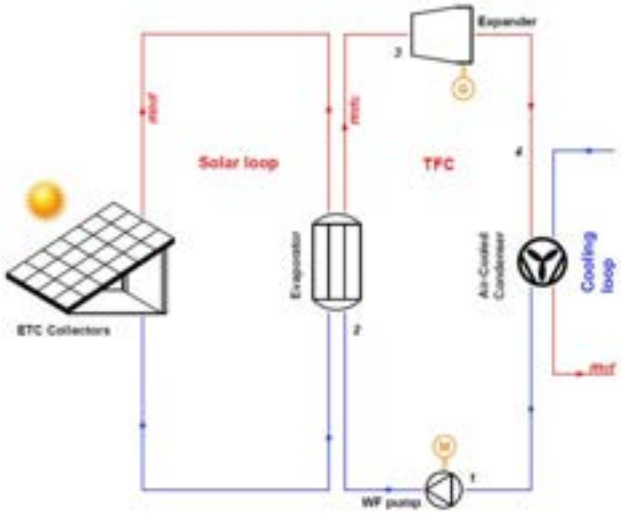

Figure 1. Schematic layout of the Solar-TFC system.

A schematic layout of the modeled Solar-TFC system is presented in Figure 1. The unit operates in HTF mode, i.e. solar thermal energy is transferred from the field of the ETC to the evaporator of the TFC through an HTF. In the evaporator of the TFC, the WF is heated up, at high pressure, reaching the state of the saturated liquid or the two-phase mixture. Thereafter, it flows through the two-phase expander, where flashing occurs and power is generated. The two-phase mixture at the expander's discharge dissipates heat to the environment through the air-cooled condenser. Finally, the WF is pumped to the operating pressure of the evaporator, and the power cycle starts anew. The thermodynamic states of the WF in the TFC (numbered 1÷4) are presented in Figure 1. Details regarding the thermodynamic processes of the WF in the TFC are given in Section 2.2.2. The thermodynamic properties of the HTF, the WF, and the CF are calculated by utilizing the CoolProp library [19] wrapper for Matlab.

2.2. Modeling

2.2.1. ETC collectors

The Thermomax DF 100 30, developed by Kingspan Thermomax, ETCs are selected for the solar field. The technical specifications of the selected ETCs are listed in Table 1. The inclination angle β is selected to maximize the annually absorbed solar energy at the installation site [7]. The values of T_{min} and T_{max} are typical of low-temperature solar power systems, ensuring low thermal losses towards the ambient, and, at the same, subcritical operation of the power cycle (taking into consideration that the critical temperature of R245fa is equal to 154 °C). Based on T_{max}, H_2O pressurized at 4 bar, to avoid boiling in the solar loop, is selected as the HTF. Finally, $\dot{m}_{htf}/A_{col}$ takes the average value of the recommended, by the collectors' developer, mass flowrate range for the solar cooling loop.

Table 1. Technical specifications of the ETCs.

Parameter	Symbol	Value [Units]
Aperture area	A_{ap}	3.228 [m^2]
Optical efficiency at normal incidence	η_o	0.779 [-]
First-order losses coefficient (based on A_{ap})	a_1	1.07 [W/m^2-K]
Second-order losses coefficient (based on A_{ap})	a_2	0.0135 [W/m^2-K^2]
Heat Transfer Fluid	HTF	H_2O [-]
Collector Area- Specific HTF flowrate	$\dot{m}_{htf}/A_{col}$	$2.95 \cdot 10^{-2}$ [kg/m^2-s]
Inclination angle	β	32 [°]
Minimum collectors' temperature	T_{min}	80 [°C]
Maximum collectors' temperature	T_{max}	130 [°C]

The thermal efficiency η_{col} of the collectors is calculated by Eq. (1). This empirical formula is applied commonly in solar collectors' modeling because the value of the coefficients η_o, a_1, and a_2 are available from the collectors' certification experiments.

$$\eta_{col} = \eta_o - a_1 \cdot \frac{(T_m - T_{amb})}{G_{tot}} - a_2 \cdot \frac{(T_m - T_{amb})^2}{G_{tot}} \quad (1)$$

In Eq. (1) G_{tot} is the total solar irradiance on the collectors' surface, T_m is their average temperature, and T_{amb} is the ambient temperature. The heat gain $\dot{Q}_{col}$ of the collectors is then given by Eq. (2), where A_{col} is the total area of the collectors.

$$\dot{Q}_{col} = \eta_{col} \cdot A_{col} \cdot G_{tot} \quad (2)$$

A common assumption in solar power system simulations is that T_m is equal to the average temperature of the HTF flowing in the solar loop. This assumption is expressed by Eq. (3), where $T_{htf,in}$ and $T_{htf,out}$ are the temperatures of the HTF flowing in and out of the solar cooling loop, respectively.

$$T_m = \frac{T_{htf,in} + T_{htf,out}}{2} \quad (3)$$

During steady-state operation of the Solar-TFC system, and if the heat losses at the HTF circuit are assumed negligible, $\dot{Q}_{col}$ is equal to the heat transfer rate $\dot{Q}_{ev}$ to the evaporator of the TFC engine. $\dot{Q}_{ev}$, on the HTF side, is given by Eq. (4), with $c_{p,htf}$ representing the specific heat capacity, under constant pressure, of the HTF, calculated at T_m.

$$\dot{Q}_{ev} = \dot{m}_{htf} \cdot c_{p,htf}\left(T_{htf,out} - T_{htf,in}\right) \quad (4)$$

The total irradiance G_{tot} on the inclined surface of the collectors is given by Eq. (5), where G_b and G_d are the beam irradiance normal on the collectors, and the diffuse irradiance, respectively (ground-reflected irradiance is not considered).

$$G_{tot} = G_b + G_d \quad (5)$$

G_b is calculated based on the available meteorological data at the installation site. Specifically, G_b is given by Eq. (6), where G_h is the beam irradiance on a horizontal surface, and R_b is the beam radiation tilt factor.

$$G_b = G_h \cdot R_b \tag{6}$$

R_b is given at each instance by applying Eq. (7), where L is the local latitude, δ the solar declination, and hr the hour angle. Detailed methodology concerning the calculation of R_b is presented by Kalogirou [20].

$$R_b = \frac{\sin(L-\beta)\cdot\sin(\delta) + \cos(L-\beta)\cdot\cos(\delta)\cdot\cos(hr)}{\sin(L)\cdot\sin(\delta) + \cos\cdot(L)\cdot\cos(\delta)\cdot\cos(hr)} \tag{7}$$

2.2.2. TFC

A qualitative Temperature- Entropy (T-s) diagram of the TFC power cycle with R245fa as the WF is presented in Figure 2, where the thermodynamic processes undergone by the WF, the HTF, and the Cooling Fluid (CF) are drawn. The thermodynamic processes of the TFC are the following:

- 1→2: Adiabatic pumping
- 2→3: Heat absorption in the evaporator at constant pressure p_{ev}
- 3→4: Adiabatic expansion in the two-phase expander
- 4→1: Heat rejection in the condenser at constant pressure p_{con}

The WF is sub-cooled at the suction port of the pump to prevent cavitation. Heat is transferred to the evaporator of the TFC engine by the HTF of the solar cooling loop, leading to a drop in its temperature from $T_{htf,out}$ to $T_{htf,in}$. Heat is dissipated from the TFC in the condenser, resulting in the temperature rise of the CF from $T_{cf,in}$ to $T_{cf,out}$. Herein, the term TFC is generalized to engulf the power cycle architectures where the WF at the onset of expansion can be in a state ranging from saturated liquid to saturated vapor.

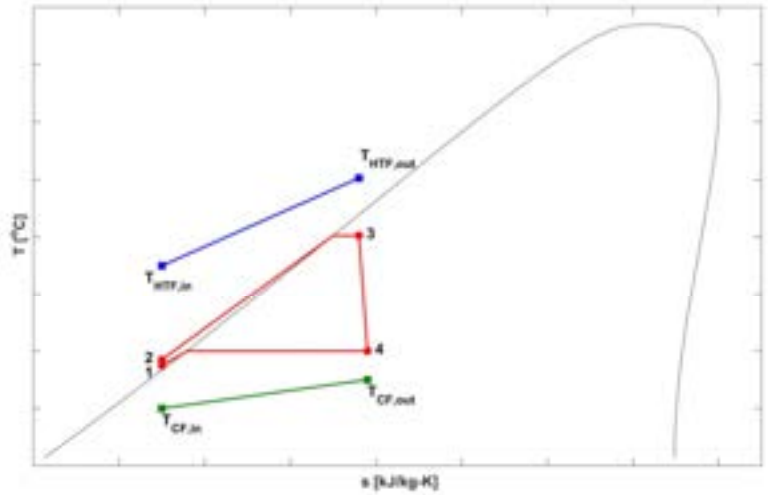

Figure 2. T-s diagram of the TFC with R245fa as the WF.

The parameters, along with their values and symbols, for the numerical modeling of the TFC are listed in Table 2. Assuming negligible heat losses at the TFC evaporator, $\dot{Q}_{ev}$ will be equal to the heat absorbed by the WF of the TFC, equality expressed by Eq. (8), where $\dot{m}_{wf}$ is the mass flowrate of the WF, whereas h_3 and h_2 are the specific enthalpies of the WF at thermodynamic states 2 and 3 of the power cycle, respectively.

$$\dot{Q}_{ev} = \dot{m}_{wf} \cdot (h_3 - h_2) \tag{8}$$

Table 2. Modeling parameters of the TFC cycle.

Parameter	Symbol	Value [Units]
Pinch point temperature difference at the evaporator	PP_{ev}	5 [°C]
Pinch point temperature difference at the condenser	PP_{con}	5 [°C]
Pump isentropic efficiency	$\eta_{pu,is}$	0.75 [-]
Working Fluid	WF	R245fa
Cooling Fluid	CF	Air [-]
Temperature rise of the Cooling Fluid	ΔT_{cf}	10 [°C]
Working fluid sub-cooling at pump suction	ΔT_{sub}	5 [°C]

The temperature T_4 of the WF at the onset of condensation is derived from PP_{con}, as in Eq. (9)

$$T_4 = T_{cf,out} + PP_{con} \tag{9}$$

where $T_{cf,out}$ is the temperature of the CF at the outlet of the condenser's cooling loop, given by Eq. (10). In Eq. (10), $T_{cf,in}$ is the temperature of the CF at the inlet of the cooling loop, equal to T_{amb} for the modeled case of the air-cooled condenser in this work.

$$T_{cf,out} = T_{cf,in} + \Delta T_{cf} \tag{10}$$

After applying Eq. (9), p_{con} is readily calculated, as the saturation pressure of the WF at T_4. The coupling between the TFC and the solar cooling cool is accomplished by PP_{ev}, as expressed by Eq. (11), where $T_{htf,pr}$ is the temperature of the HTF at the end of the preheating stage, and $T_{sat,wf}(p_{ev})$ is the saturation temperature of the WF at p_{ev}. In the ideal trilateral cycle, $T_{htf,pr}$ becomes equal to $T_{htf,out}$.

$$T_{htf,pr} = T_{sat,wf}(p_{ev}) + PP_{ev} \tag{11}$$

Equation (12) must be satisfied along with Eq. (8). In Eq. (12), $\dot{Q}_{pr}$ is the heat transfer rate from the HTF to the WF during the preheating stage, and $h_{l,sat}(p_{ev})$ is the enthalpy of the saturated liquid at p_{ev}.

$$\dot{Q}_{pr} = \dot{m}_{wf} \cdot \left(h_{l,sat}(p_{ev}) - h_2\right) = \dot{m}_{htf} \cdot c_{p,htf} \cdot \left(T_{htf,pr} - T_{htf,in}\right) \tag{12}$$

The numerical procedure for the determination of $\dot{m}_{wf}$ and p_{ev}, for a desired quality x_3 of the two-phase mixture at the onset of expansion is as follows. The value of p_{ev} is varied iteratively in a stepwise manner. For a guess intermediate value of p_{ev}, the saturation temperature $T_{sat,wf}(p_{ev})$ of the WF is calculated, and, subsequently, $T_{ht\ ,pr}$ is derived by applying Eq. (11). Thereafter, two values for $\dot{m}_{wf}$ are calculated by simultaneously applying Eqs. (8) and (12). The iterations on p_{ev} terminate when the two values of $\dot{m}_{wf}$ converge.

After the values of $\dot{m}_{wf}$ and p_{ev} have been determined, the thermodynamic low-order two-phase expansion model (details about the methodology applied in the two-phase expansion model can be found in Ref. [16]), is run. The outcome of the simulation is the rotational speed of the expander for the given mass flowrate, and the specific enthalpy h_4 of the WF at the discharge port. Thereafter, the isentropic efficiency $\eta_{ex,is}$ of expansion is calculated by Eq. (13), where $h_{4,is}$ is the specific enthalpy of the WF corresponding to an isentropic expansion from state 3 at p_{ev} to p_{con}.

$$\eta_{ex,is} = \frac{h_3 - h_4}{h_3 - h_{4,is}} \tag{13}$$

The power $\dot{w}_{ex}$ generated by the two-phase expander is given by Eq. (14)

$$\dot{w}_{ex} = \dot{m}_{wf} \cdot (h_3 - h_4) \tag{14}$$

whereas the power $\dot{w}_{pu}$ absorbed by the pump is calculated by Eq. (15), in which h_1 is the specific enthalpy of the WF at its suction.

$$\dot{w}_{pu} = \dot{m}_{wf} \cdot (h_2 - h_1) \tag{15}$$

h_2 is derived by applying the formula for the isentropic efficiency $\eta_{pu,is}$ of the pump, as in Eq. (16).

$$\eta_{pu,is} = \frac{h_{2,is} - h_1}{h_2 - h_1} \tag{16}$$

In Eq. (16), $h_{2,is}$ is the specific enthalpy of the WF corresponding to its isentropic pumping from state 1 at p_{con} to p_{ev}. The thermal efficiency η_{th} of the TFC is given by Eq. (17), where $\dot{w}_{net}$ is the net power generated by the TFC engine.

$$\eta_{th} = \frac{\dot{w}_{net}}{\dot{Q}_{ev}} = \frac{\dot{w}_{ex} - \dot{w}_{pu}}{\dot{Q}_{ev}} \tag{17}$$

The heat transfer rate $\dot{Q}_{con}$ at the condenser is calculated by Eq. (18), leading to the evaluation of the necessary mass flowrate $\dot{m}_{cf}$ of the CF. In Eq. (18) $c_{p,cf}$ is the specific heat capacity, under constant pressure, of the CF.

$$\dot{Q}_{con} = \dot{m}_{wf} \cdot (h_4 - h_1) = \dot{m}_{cf} \cdot c_{p,cf} \cdot \Delta T_{cf} \tag{18}$$

2.2.3. Solar-TFC system

At any operating instance of the Solar-TFC system, the overall solar energy conversion efficiency η_{tot} is given by Eq. (19).

$$\eta_{tot} = \eta_{col} \cdot \eta_{th} = \frac{\dot{Q}_{col}}{A_{col} G_{tot}} \cdot \frac{\dot{w}_{net}}{\dot{Q}_{ev}} = \frac{\dot{w}_{net}}{A_{col} \cdot G_{tot}} \quad (19)$$

Moreover, the exergy efficiency η_{II} of the unit is given by Eq. (20)

$$\eta_{II} = \frac{\dot{w}_{net}}{\left(1 - \frac{T_{amb}}{T_{sol}}\right) A_{col} \cdot G_{tot}} \quad (20)$$

where T_{sol} is the solar reference temperature, taken equal to 5770 K for this work [7].

The average thermal efficiency $\eta_{th,av}$ of the TFC engine, and the average solar energy conversion efficiency $\eta_{tot,av}$ and average exergy efficiency $\eta_{II,av}$ of the combined unit over a period are calculated by integrating Eqs. (17), (19), and (20), respectively.

2.3. Economic analysis

The economics of the Solar-TFC system is assessed by evaluating the Levelized Cost of Electricity ($LCOE$), an estimation of the average cost that the owner-operator of the system will have to pay for every kWh produced during its anticipated lifetime N. $LCOE$ is given by Eq. (21)

$$LCOE = \frac{C_{inv} + \sum_{i=1}^{N} \frac{M}{(1+i)^r}}{\sum_{i=1}^{N} W} \quad (21)$$

where C_{inv} is the total initial investment cost, W is the total electricity produced at year i, M is the annual maintenance cost at year i, and r is the annual discount rate. In this work, it is assumed that W, as well as M and r remain constant throughout N. C_{inv} is given by Eq. (22), where sc_{tfc} and sc_{col} are the specific costs of the TFC and the ETC collectors, respectively, whereas P_{tfc} is the nominal electric capacity of the TFC.

$$C_{inv} = sc_{tfc} \cdot P_{tfc} + sc_{col} \cdot A_{col} \quad (22)$$

The values of the parameters for the economic analysis are listed in Table 3. Analysis concerning the estimation of sc_{tfc}, based on the nominal capacity of the TFC is presented in Section 3.3.3.

Table 3. Parameters of the economic analysis.

Parameter	Symbol	Value [Units]
Lifetime	N	20 [yr]
Annual discount rate	r	5 [%] [7,21]
Annual maintenance cost	M	$0.01 C_{inv}$ [€]
Specific cost of collectors	sc_{col}	260 [€/m^2] [6]

3. Results & Discussion

3.1. Solar field

The performance of the solar field is assessed based on the achievable values for η_{col} as a function of G_{tot}, T_{amb}, and T_m for a clear-sky day at the installation site. The variation of G_{tot}, G_d, and T_{amb} from sunrise to sunset, with an hourly time step, as a function of solar time for the reference day is presented in Figure 3. The fluctuation of η_{col} and $\dot{Q}_{ev}/A_{col}$ versus solar time for the reference day and different desired operating temperatures T_m is presented in Figure 4. It is assumed that the TFC engine operates when the temperature of the collectors reaches the desired value of T_m, and, thereafter, T_m remains constant for as long as possible, based on the values of G_{tot} and T_{amb}. Therefore, during the heating up of the collectors, it is assumed that the solar irradiance is exploited initially only to increase T_m ($\dot{Q}_{ev} = 0$) until its desired value has been reached. Subsequently, (and for as long as $\dot{Q}_{col} > 0$) all the heat gain $\dot{Q}_{col}$ is delivered to the TFC engine ($\dot{Q}_{col} = \dot{Q}_{ev}$), and T_m is kept constant. When $\dot{Q}_{col} < 0$, the collectors are cooled down, and the operation of the TFC engine stops.

After sunrise, the temperature of the collectors begins to increase, with a gradual drop in η_{col} because the temperature difference $T_m - T_{amb}$ rises and the heat losses towards the ambient are increased. After the desired operating temperature T_m has been reached, η_{col} rises as G_{tot} and T_{amb} increase, and it drops gradually after solar noon. The maximum values of η_{col} and $\dot{Q}_{ev}/A_{col}$ (while the TFC engine is operating), equal to 0.664 and 676.84, respectively, are obtained for T_m equal to 80 °C. Increasing T_m reduces η_{col} and $\dot{Q}_{ev}/A_{col}$ because the heat losses towards the ambient are also higher. However, reducing T_m may harm η_{th}, as the

operating pressure ratio of the TFC will drop. The effect of T_m, along with other identified crucial parameters, on the efficiency of the TFC is described in detail in Section 3.2.

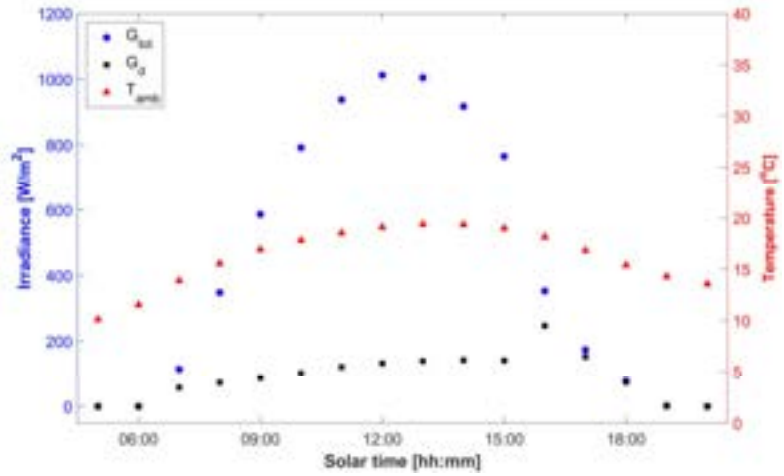

Figure 3. Irradiance on ETC collectors and T_{amb} as a function of solar time on a clear-sky spring day.

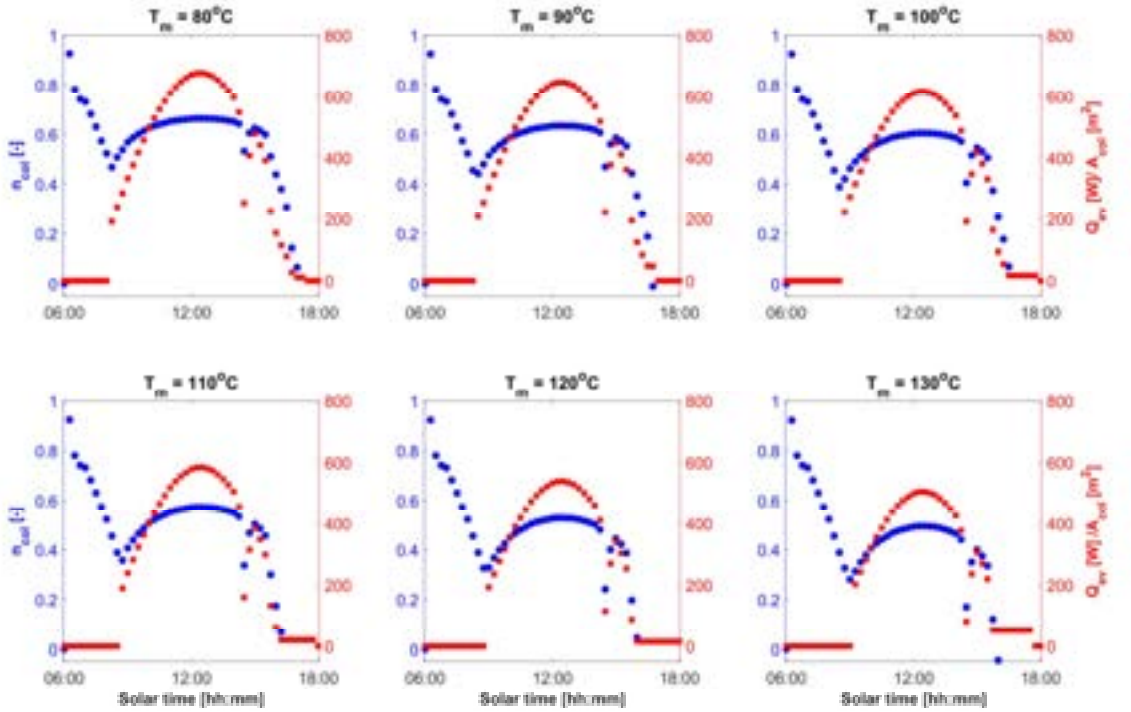

Figure 4. η_{col} and $\dot{Q}_{ev}/A_{col}$ as a function of solar time for different values of T_m.

3.2. TFC

The performance of the TFC is assessed based on its efficiency at solar noon, when the irradiance on the collectors is maximized, of the reference day presented in Section 3.1. The value of η_{th} depends on the isentropic efficiency $\eta_{ex,is}$ of the two-phase expansion, which, in turn, is directly related to x_3 and T_m, as can be seen in Figure 5. Low vapor quality at the suction port of the two-phase expansion leads to very low values of $\eta_{ex,is}$. This is attributed to the increased pressure losses at suction and the increased mass flowrates $\dot{m}_{wf}$ of the WF, which cannot be accommodated by the modeled expander [11,16]. Furthermore, as T_m and x_3 vary, the deviation of the WF volume ratio from the built-in volume ratio of the two-phase expander varies as well. For every T_m there is a value of x_3 for which an optimal match between the two values is obtained, and the over-under expansion losses are minimized.

Increasing $\eta_{ex,is}$ has an obvious positive effect on η_{th}, and values as high as 0.11 can be achieved. The variation of $\eta_{ex,is}$ and η_{th} with x_3, for the range of values for T_m, indicates that the optimal operating point of

the unit lies always within the two-phase region, as their values are systematically reduced towards the saturated vapor state.

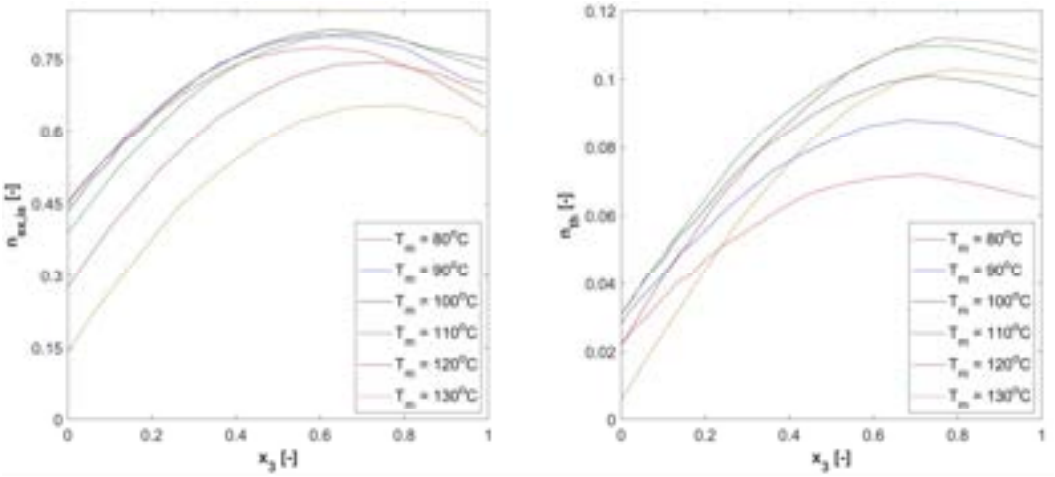

Figure 5. $\eta_{ex,is}$ and η_{th} versus x_3 for different values of T_m.

3.3. Solar-TFC

3.3.1. Performance optimization

The analysis presented in Sections 3.1 and 3.2 highlighted that there are two degrees of freedom, i.e. T_m and x_3, in the Solar-TFC system, the determination of which leads to the maximization of η_{tot} for given irradiance and T_{amb} values. The system of Eqs. presented in Sections 3.1, 3.2, and 3.3 is formulated in Matlab, wherein a native genetic algorithm, which leads to the determination of the global optimum, is applied aiming to maximize η_{tot}, with T_m and x_3 the iteration variables. The optimization problem is solved throughout the year with a fifteen minute interval.

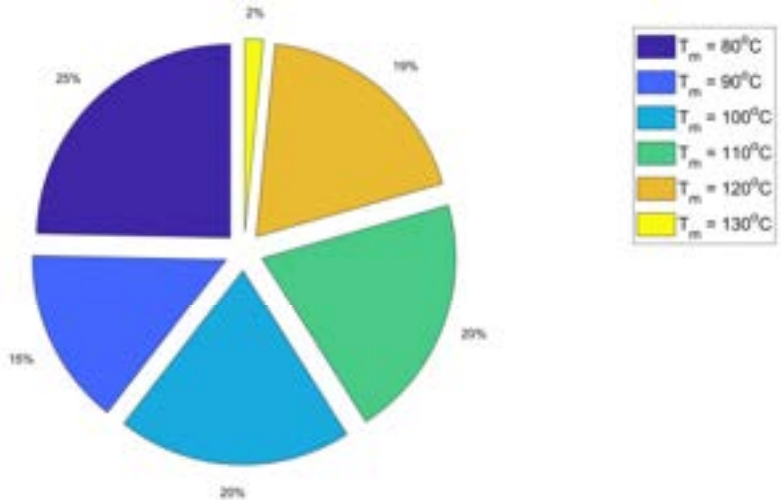

Figure 6. Frequency distribution of optimal T_m value per year.

The simulations reveal that the Solar-TFC system can be operational for a total of 2835 hours per year in Athens. The frequency distribution of the optimal T_m on the annual basis is presented in Figure 6. It can be deduced that T_{min} is the most frequent optimal operating temperature of the collectors. This is justified since an annual optimization is undertaken, and days with low values of irradiance and T_{amb} are also considered. On the other hand, it must be stressed that it is optimal to operate the system at T_{max} for only about 2% of the unit's operating time around the year. This is because, as analyzed in Sections 3.1 and 3.2, the heat losses of the solar field towards the ambient are very high, and, at the same time, the efficiency of the TFC is rather low, because of low $\eta_{ex,is}$ values. T_{max} is optimal only in a few instances during summer, when $\dot{Q}_{ev}/A_{col}$ is maximized because of the high irradiance, and, T_{amb} is high enough to ensure a favorable WF volume ratio, and, therefore, an operating pressure ratio for the TFC. The variation of the optimal x_3 throughout the year is presented in Figure 7, and it ranges from 0.59 to 0.83. As analyzed in Section 3.2, high values of x_3 ensure satisfying $\eta_{ex,is}$, and, as a result, increased η_{th}, a finding consistent with experiments [11].

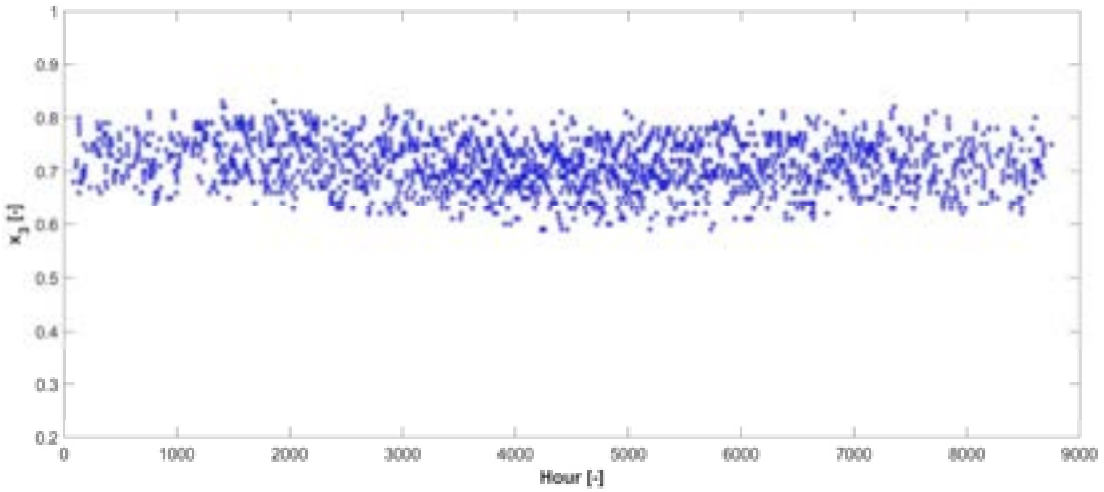

Figure 7. Optimal vapor quality x_3 at the suction port of the expander throughout the year.

3.3.2. Annual yield and efficiency

The total collectors' area- specific solar energy E_{sol}/A_{col} incident on the ETCs monthly, for the operational time of the Solar-TFC system, along with the average monthly $\eta_{tot,av}$ are presented in Figure 8.

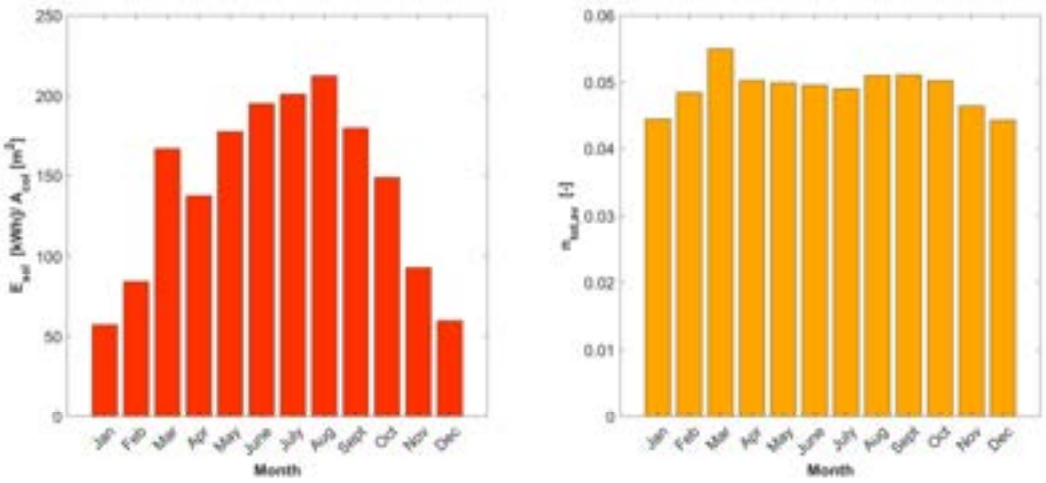

Figure 8. Monthly variation of E_{sol}/A_{col} and $\eta_{tot,av}$.

E_{sol}/A_{col} is maximized in August, however, the combined system is most efficient in solar energy harvesting during March. This can be explained as follows. The irradiance on the collectors may be higher during summer, but the utilization of an air-cooled condenser increases the condensation temperature and pressure (see Eqs. (9) and (10)), and the operating pressure ratio p_{ev}/p_{con} of the TFC is reduced, with adverse effects on the power generation potential. If the condensation temperature was kept constant throughout the year, it is expected that $\eta_{tot,av}$ would be higher in summer.

The average annual solar energy conversion efficiency $\eta_{tot,av}$ of the Solar-TFC system is equal to 0.05, which is substantially higher than the one estimated (0.03) for a small-scale Solar-ORC system at the installation site [6], which consists of the same ETCs and two scroll expanders, installed in series, as power generators. The monthly distribution of the total collectors' area-specific W/A_{col} electricity produced by the TFC, and the values of $\eta_{II,av}$ and $\eta_{th,av}$ are presented in Figure 9. The annual yield of electricity is equal to 86 kWh per m^2 of collectors, with an average $\eta_{th,av}$ equal to 0.10. This average annual efficiency is again higher than the calculated (0.089) from the simulations of the aforementioned small-scale Solar-ORC system at the same location, demonstrating the potential of the TFC for higher-efficiency solar thermal power systems. The annual average exergy efficiency $\eta_{II,av}$ is approximately 0.05, a value slightly lower than the one simulated for a small-scale Solar-ORC system with R245fa as the WF in Athens [7]. However, that unit utilizes Parabolic Trough Collectors, which achieve higher values of η_{col}, but are most costly.

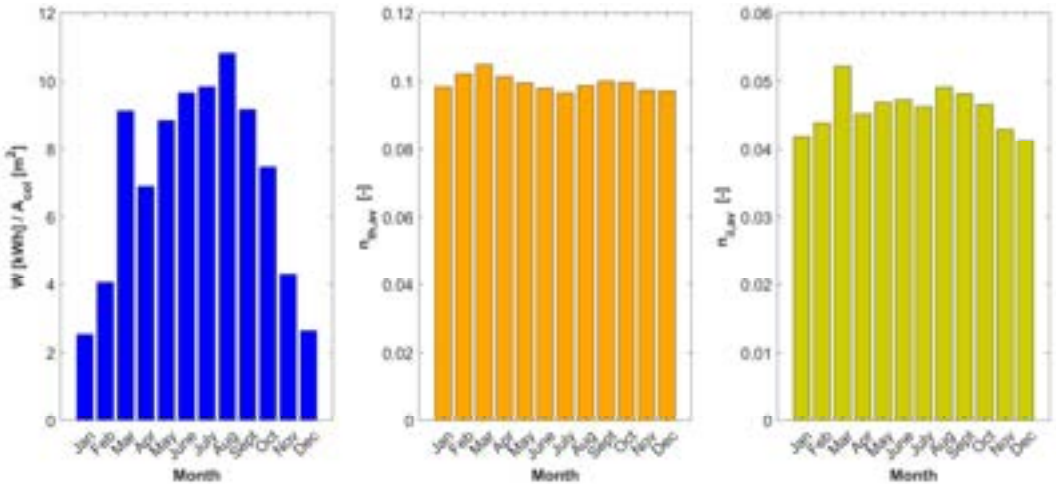

Figure 9. Monthly variation of W/A_{col}, $\eta_{th,av}$, and $\eta_{II,av}$.

3.3.3. Economic assessment

The economics of the Solar-TFC system is assessed by performing a parametric analysis, with A_{col} and sc_{tfc} the degrees of freedom. A_{col} implicitly determines the value of P_{tfc}. It is assumed that G_t, T_m, and T_{amb} are equal to 1000 W/m^2, 110 ^{o}C, 20 ^{o}C, respectively, at the design point of the unit. By applying Eq. (1), η_{col} is calculated and, assuming a gross value, i.e. neglecting $\dot{w}_{pu}$, of η_{th} equal to 0.08, the value of P_{tfc} may be readily calculated. Thereafter, sc_{tfc} is estimated based on the values of P_{tfc}, the nominal heat capacity, and the temperature of the heat source, according to the work of Braimakis et al. [22]. The values of P_{tfc} and sc_{tfc} as a function of A_{col} are listed in Table 4. It must be noted that the parametric values of A_{col} were selected to ensure that P_{tfc} lies within the operating nominal electric capacities of twin screw expanders [23].

$LCOE$ versus A_{col} is plotted in Figure 10. As A_{col} increases, $LCOE$ drops because sc_{tfc} is diminished. The estimated $LCOE$ values are considered competitive against the current electricity prices at the European Union, and also against the reported $LCOE$ values of Solar-ORC systems in the literature, that range between 0.25 and 0.95 €/kWh [6,7,24]. The penetration of the Solar-TFC system in the market could be further assisted in the future, considering the European policies to assist the participation of renewables in the energy mix and promote decentralized energy production.

Table 4. Parametric values of A_{col}, P_{tfc}, and sc_{tfc} at the Solar-TFC system design point.

A_{col} [m^2]	200	300	400	500	600
P_{tfc} [kW$_{el}$]	9	14	18	23	28
sc_{tfc} [€/kW$_{el}$]	4850	4300	3800	3300	3000

4. Conclusions

In the present work, the annual performance of a Solar-TFC power system located in Athens was numerically studied. The operation of the system was optimized throughout the year to maximize solar energy conversion efficiency. Particular attention was paid to the two-phase expansion efficiency, which mainly affects the thermal efficiency of the TFC, with flashing simulations indicating that higher vapor qualities (59-83%) of the WF at the onset of expansion have a positive effect on the power cycle performance. The numerical results indicated that 86 kWh of green power per m^2 of collectors can be generated by the Solar-TFC system annually, with the average solar energy conversion efficiency reaching 5%, higher than the one estimated for a Solar-ORC system with similar architecture in Athens. The average annual thermal efficiency of the TFC and exergy efficiency of the combined Solar-TFC system were calculated approximately equal to 10% and 5%, respectively.

The preliminary economic analysis of the Solar-TFC system demonstrated the potential of the TFC as a competitive replacement of the ORC for solar heat recovery. Indeed, $LCOE$ values in the range of 0.26 - 0.32 €/kWh can be anticipated for an operation reaching 20 years. The economics of the system is better as its size increases, because of the TFC engine's lower specific cost at higher capacities.

Concluding, the analysis presented in this work highlighted the potential of the TFC for efficient solar energy conversion, and its competitiveness compared to the ORC. However, it must be noted that additional research work is necessary for the TFC to reach a technologically mature level. This research work must mainly focus on the comprehension of the flashing phenomenon and the development of expanders that will operate efficiently in the two-phase region.

Abstract:

Circular thermoeconomics encompasses the physical principles of the circular economy (strictly spiral economy), industrial symbiosis, and second law costing and diagnosis of complex energy systems.
This article describes a new software tool for circular thermoeconomics distributed as a MATLAB package. The software implements the algorithms described in the latest revisions of the exergy cost theory. In addition to production cost calculation and diagnostics functions, TaesLab incorporates new ones for determining energy savings due to waste recovery and process integration. The production structure model makes it possible to analyse different plant configurations, integrating other processes for waste recovery or energy storage. For demonstration purposes, the article presents a short example of a cogeneration plant with waste recovery and describes its data model and the functionality of this software tool.

Keywords:

thermoeconomics, waste cost allocation, circular economy, software tools.

1. Introduction

Thermoeconomics, an energy analysis methodology combining thermodynamics and economics, support energy systems' design, synthesis, and operation with higher efficiency and lower production costs. Thermoeconomics methods are usually applied to assess the energy and monetary cost of energy systems' internal flows and final products. These methods detect inefficiencies and evaluate their economic effects using thermoeconomic diagnosis [1]. Environmental issues have been incorporated into the analysis [2] to consider waste treatment and emission cost allocation. Classic exergy cost theory [3] has been recently revisited to include general waste cost allocation methods [4].

This methodology, called Circular Thermoeconomics [5], is based on the theory of exergy cost and its generalisation, the *structural theory*, which allows the accounting of physical or thermodynamic costs, both of functional products and waste generated in parallel. It makes it possible to identify which part of these costs are due to internal irreversibilities and which are due to the waste produced or external irreversibilities. Each of these irreversibilities can be reduced to certain limits: Internal irreversibilities by improving the efficiency of the processes or changing the technology, but always up to a specific limit; External irreversibilities by recycling waste. Internal irreversibilities are, at the same time, also the cause of waste and their transfer and disposal increment costs.

The word "recycling" is used interchangeably by Thermoeconomics, Circular Economy and Industrial Symbiosis. One may wonder if it means the same thing in all three fields of activity. Recycling means efficient use of resources. What is different is the type of systems it studies. In general, the objective of the circular economy is the recovery of any solid waste, while the system analysed is the recovery plant. Industrial symbiosis deals with reusing waste or by-products from one plant by other plants. In this case, the system under study is the set of interacting plants. Thermoeconomics cover the general use, no matter how complex the subsystems and flow interconnections are.

If a waste leaves the boundaries of a plant, it is dissipated into the environment, but its formation and disposal costs must be accounted for by identifying its origin. Some of this waste could be reused in other processes or plants. This theory allows for calculating its formation costs and providing a target cost as a basis for discussion with other plants interested in using it.

There is a wide range of software for the modelling, process integration, simulation, and optimisation of energy systems, such as EES [6], HSC Chemistry [7], or ASPEN PLUS [8]. Still, in general, they do not include thermoeconomic analysis. Torres et al. [9] provide the guidelines for developing thermoeconomic

analysis software and present an Excel-based application [10] that implements these ideas. These ideas are applied in some specific tools for energy analysis software [11].

This paper describes a new software tool, called TaesLab, that implements the algorithms described in [4], including waste cost allocation and recycling analysis. The software is presented as a MATLAB package or as a stand-alone application. TaesLab provides a set of functions and tools that allow a complete thermo-economic analysis of an energy system, starting from the definition of its thermoeconomic model, a collection of plant states defined by the exergies of its mass and energy flows, and the costs of its external resources. The main functions are:

- Read and Check the Thermoeconomic Data Model.
- Compute Exergy Balances and Fuel Product table.
- Compute Exergy Cost.
- Analyse the Cost Formation Process of Products and Waste.
- Recycling Analysis.
- Thermoeconomic Diagnosis.

The results are presented in the form of graphs and tables. These can be saved in Excel sheets or text files for further analysis.

An Organic Rankine Cycle (ORC) is used as an example to illustrate the application's functionality. It uses waste heat to produce electricity. Part of the heat dissipated in the condenser could be recycled and used to produce air conditioning in another plant process, for example, an ejector refrigeration cycle [12].

2. Thermoeconomic Data Model

To make a thermoeconomic analysis of an energy system. a set of information that constitutes the thermoeconomic data model is needed.

2.1. Physical structure

For a given level of aggregation, an energy system can be represented by a directed graph, whose nodes are the thermodynamic processes and edges are the flows of matter and energy exchanged. Figure 1 depicts the physical structure of the plant used as example.

2.2 Thermodynamic model

To perform the thermoeconomic analysis of an energy system, it is necessary to define the exergy of each flow specified in the physical structure. The thermodynamic model of the plant is described by a set of equations (including mass, energy and entropy balances) that allow the determination of each mass, heat and work stream involved in the physical structure of the plant from a set of input variables, which define a thermodynamic state of the plant. In this example, an EES model obtains the exergy flows. The main parameters of the plant are also shown in Figure 1.

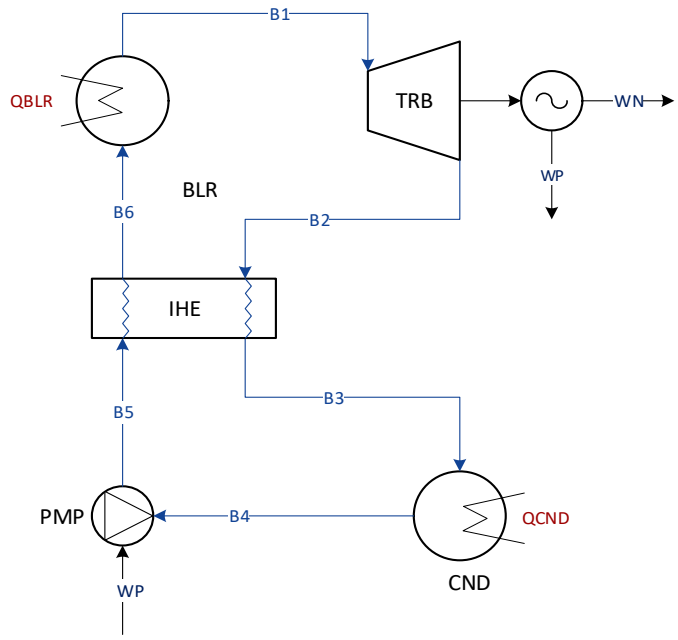
2.3 Productive structure

Each component or process of the system has a productive purpose established by its exergy efficiency, defined as the amount of exergy produced per unit of exergy of resources used, and which measures the quality of the process. Thus, for each process of the system, it is necessary to identify which flows constitute the product or products of the process and which resources or fuels are used to produce them. In this definition, it is also necessary to indicate which flows are waste and which processes are used to eliminate them, called dissipative processes [13]

2.4 Waste Cost Allocation

How the waste cost is allocated to the production processes of a system depends on the type and nature of the waste. There is no general criterion for assigning the cost of system waste. For example, in the case of heat dissipated in the condenser of a Rankine cycle, we can distribute the cost proportionally to the entropy generated by each process. On the other hand, the flue gases removed by the stack of the combined cycle are allocated to the combustion process. Therefore, the allocation of the residual costs should be based on the following criteria:

- The waste cost must be allocated to the production units that have generated it. Here, it is essential to establish a conceptual difference between the exergy of waste and its cost. Costs also encompass exergy consumption to be involved in eliminating the system waste. Therefore, the cost, not its exergy, is of actual interest. It raises a need that is expressed in the second premise.
- It is needed to identify the process of cost formation of waste. It parallels the production cost formation process because the residues are removed in the dissipative components but are formed together with the production processes. The responsibility of a productive component for waste generation lies in its contribution to the formation cost of waste.



Parameter	Value
ORC fluid	R245fa
Generator pressure P_{blr} (bar)	20
Inlet waste gases temperature T_G (ºC)	160
Generator pinch point ΔT_{blr} (ºC)	20
Condenser outlet temperature T_{cnd} (ºC)	30
Turbine isentropic efficiency η_{trb} (%)	80
Pump isentropic efficiency η_{pnp}(%)	85
Internal Heat Exchange efficiency ε_{ihe}(%)	80
Net Power (kW)	50
Reference temperature T_0 (ºC)	15.94
Reference pressure P_0 (bar)	1.013

Figure. 1. Thermodynamic diagram of the ORC plant and main operational parameters,

To identify waste flows at the process level, relating each flow with the physical and chemical processes in dissipative units is necessary. We must define as many dissipative units as waste flows. Dissipative units are defined in such a way that the output product stream is a waste flow, and input fuel streams are these flows that one wants to be eliminated and the resources required to do that. The irreversibility carriers allow one to identify the waste stream's origin, path, and end. The Fuel-Product and the Irreversibility-Cost tables can help to determine the cost formation process of products and wastes.

TaesLab uses the following methods, described in detail in reference [4]

- EXERGY: This method looks for the immediate cause and distributes the waste's costs to the components that have produced it directly and in proportion to their exergy.
- COST: This allocation method is like the previous one but distributes the cost proportionately to its exergy cost instead of its exergy. It should be noted that, in many cases, a waste's exergy is irrelevant, but its cost is relevant.
- RESOURCES: This method is based on the definition of cost, i.e. the cost of a waste is the amount of external resources expended to produce it. The method internalises the waste cost to the external resources proportionally to the amount used to make it. This is the DEFAULT method used by TaesLab if no waste definition is provided.
- IRREVERSIBILITY: This method identifies the waste cost formation process from the cost-irreversibility table and distributes the cost according to the irreversibility carriers of waste streams.
- HYBRID: This method combines the IRREVERSIBILITY and EXERGY methods. The method considers the full path of the waste cost formation. See reference [14]

2.5. Economic and environmental model

The exergy cost is relative to the limits of the system. Therefore, we must define the thermodynamic system's boundaries that constitute the installation and its environment. The exergy cost, also called direct exergy cost, only considers the irreversibility of the processes (both internal and external) within the system boundaries.

From the viewpoint of natural resource management, the system boundaries should be set at the level of extraction of non-renewable resources from nature [15]. The exergy cost of natural gas processed in a gas turbine will be higher than its exergy due to the extraction, storage and transportation processes required to use it. Moreover, the direct exergy cost does not consider that the installation processes have their own exergy cost because additional exergy will be needed to keep them in operation. On the other hand, when considering the economic aspects, the perspective is broadened by the introduction of two additional factors: the market prices of fuels (€/MWh) that are not linked to the exergy of the resources processed and the cost of investment, maintenance and operation of the facility necessary for the production process (€/h) For these

reasons, the concept *generalised exergy cos*t is presented as a broader view of the exergy cost, in which the costs of the system flows take into account the interactions with the physical and economic environment. Therefore, the external valuation of resources could be measured in mass, energy or monetary units per unit of time; and the costs of the plant processes, measured in terms of mass, energy or monetary units and levelized per unit of time, must be considered.

Some examples of generalised exergy costs are the thermo-ecological cost [16] or the exergoeconomic cost [17], which assesses the monetary cost of internal flows and outputs of complex plants.

2.6 Thermoeconomic Data Model

Defining this thermoeconomic model requires a collection of structured data or tables that provide the information needed to analyse a system using TaesLab. The data model can be saved in an XLSX spreadsheet workbook, but other formats, such as CSV, JSON or XML, can also be used. The required tables, defined for the ORC plant in Appendix A, are:

- *Flows*: Enumerate the flows of the system. See Table A1 (a). The *type* field indicates if the flow connects to the plant process (INTERNAL), is an external resource (RESOURCE), is a final product (OUTPUT) or a waste leaving the system (WASTE).
- *Processes*: Enumerate the process of the system. See Table A1 (b). The *type* field indicates if the process is PRODUCTIVE or DISSIPATIVE. The productive structure is defined in the fields: *fuel* and *product*. We show which flows, described in the previous table, constitute the fuel and which flows are the product. For example, in the case of the Steam Generator (BLR), the fuel is the waste heat (QBLR), and the product is (B1-B6), the exergy difference between flows B1 and B6.

  These two tables define the productive structure of the plant.
- *Format*: The numerical format used for the results tables and the units in which the different quantities appear are indicated. For example, exergy values (EXERGY) are expressed in (kW) and are shown with up to ten significant digits and three decimal places. See Table A4
- *Exergy*: It contains the values of the flow exergies for different plant states or simulations. See Table A2. Each column represents a plant state. The first column of values is used as the reference state, and the column name serves as a key to identify that state. TCND45 use T_{cnd}=45ºC, ETAT75 simulates the plant with η_{trb}=75%, PBLR15 use P_{blr}=15 bar, noIHE bypasses the internal heat interchange, and n-Butane uses that fluid instead R234fa.

The rest of the tables described below are optional:

- *WasteDefinition*: Defines how the waste cost is allocated; see table A3. The different types of waste cost allocation have been described in section 2.5
- *WasteAllocation:* It manually defines the ratios for allocating waste costs to production processes. See also Table A.5
- *ResourcesCost*: Values of external resource costs, both flow costs (FLOW) and process costs (PROCESS). The units must be those indicated in the Format table for GENERALIZED_UNIT_COST and GENERALIZED_COST, respectively. Table A5 shows the economic costs of the processes in c€/kWh, according to the reference [18]. In the case of waste gases, they are considered amortised in the plant that produces them. Therefore the unit cost of the external resource flow QBLR is zero.

3. The TaesLab Application

TaesLab is a MATLAB package compatible with Octave, which provides a set of functions to perform the thermoeconomic analysis of a plant interactively from the MATLAB console. It also provides an application with a graphical user interface, see Figure 2, where the essential functions can be performed. See reference [10] for complete information on the use of the package, the user guide and its download.

TaesLab GUI has three panels. In the left panel, select the status to be calculated and the rest of the parameters. In the right panel, select the tables and graphs of the current state to be displayed in the central panel.

TaesLab has three groups of functions.

- Read and check the thermoeconomic model files.
- Cost analysis and thermoeconomic diagnosis.
- Show and save the results.

There are five blocks of results:

- Productive Structure.
- Thermoeconomic State.

- Thermoeconomic Analysis
- Thermoeconomic Diagnosis
- Summary Results

For each of these blocks, we can show the tables obtained, graph representations, and see internal information of the calculations using the workspace inspector. All the results could be saved into text files or XLSX spreadsheet workbooks for further analysis. The complete list of tables and graphs that could be obtained is explained in the user manual [10] mentioned above.

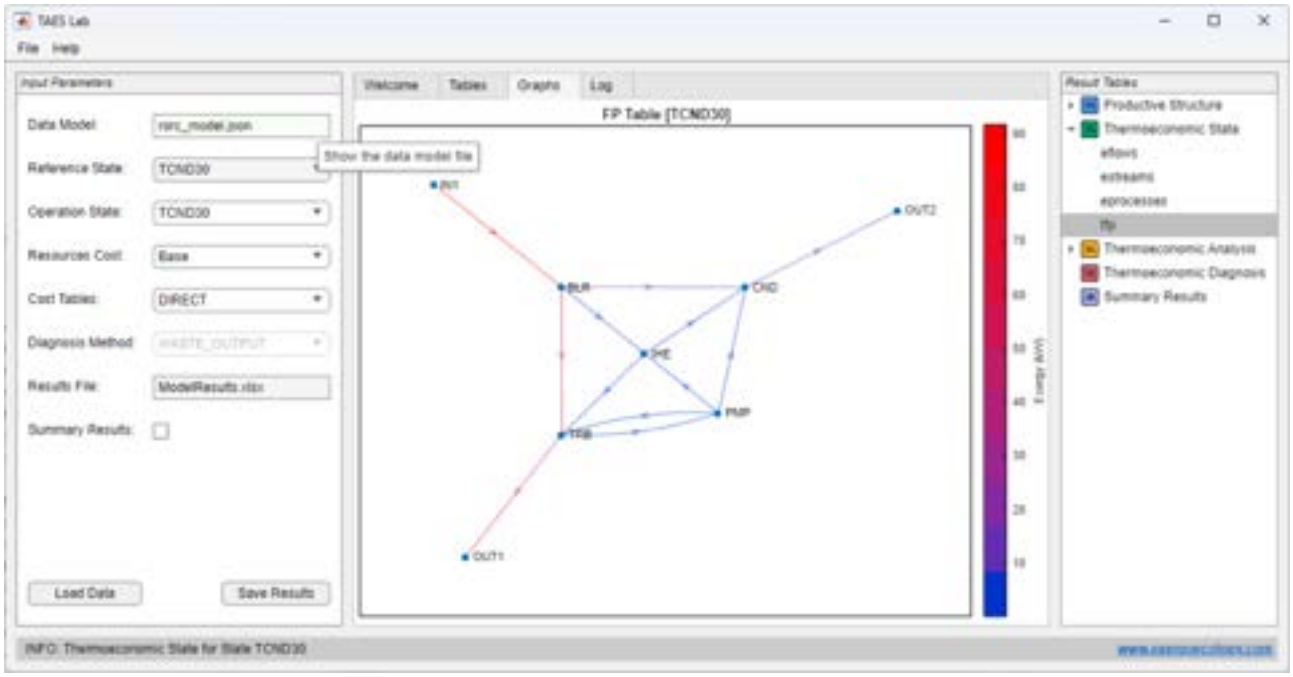


Fig.2 Screenshot of the GUI Application of TaesLab

3.1. Input Parameters

The application has several parameters that can be modified interactively.

- *State*: Indicates the state where we want to perform the analysis.
- *CostTables*: Indicates which types of tables we want to generate.
  - DIRECT: Only direct exergy costs are calculated
  - GENERALIZED: If external resources data are available, obtain generalised exergy costs
  - ALL: Both cost types are selected.
- *ResourcesCost*: Allows selecting the data to calculate the generalised costs.
- *ReferenceState*: Indicates which state will be used as the reference when running the thermoeconomic diagnosis.
- DiagnosisMeth*od*: Indicates the method used to make the thermoeconomic diagnosis.
  - NONE: The thermo-economic diagnosis calculations are deactivated.
  - WASTE_OUTPUT: Waste is considered as plant output flows.
  - WASTE_INTERNAL: The cost of waste is assessed according to the chosen waste cost allocation.
- Summary Results: Activate Summary Results tables and graphs.

Appendix B shows the Live Script used to obtain the tables and figures obtained below.

3.2. Productive Structure

In this block of results, the information on the production structure graph, including the production groups, also called streams, is shown. The construction of the adjacency matrix of the production structure graph is explained in detail in reference [4]. Figure 3 shows the production structure of the example plant. It has been drawn with yEd graph software [19] from a file obtained by the app function `SaveProductiveDiagram`.

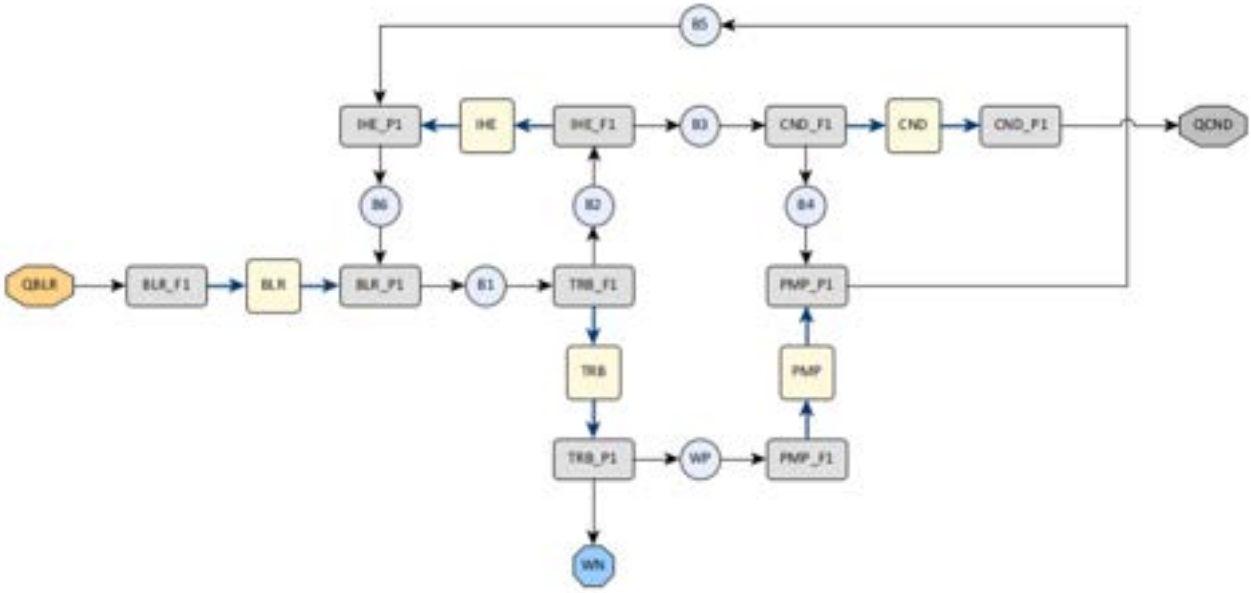

Figure 3. *Productive structure graph of the ORC plant,*

In this graph, the yellow squares represent the processes, the gey rectangles the productive groups, and the blue circles the flows. Resources are drawn as an orange octagon, waste as a grey octagon, and Final products as a blue octagon. Each Internal flow connects two productive groups, and each process connects to one or several fuel and product groups.

3.3 Thermoeconomic State

This results block shows the plant's exergy balances and its Fuel-Product table. Table 1 shows the exergy balance of the example ORC plant.

Table 1. Process Exergy Balance of ORC plant

Key	F(kW)	P(kW)	I(kW)	k(J/J)	η (%)
BLR	99.53	73.70	25.84	1.3506	74.04
TRB	65.67	52.43	13.24	1.2525	79.84
IHE	2.07	1.51	0.57	1.3754	72.71
PMP	2.43	2.08	0.35	1.1698	85.49
CND	9.54	9.54	0.00	1.0000	100.00
ENV	99.53	50.00	49.53	1.9906	50.24

The application checks if fuel (F), product (P) and irreversibility (I) are non-negative values. If both fuel and product are zero, the component is bypassed and not considered in the calculation. It permits to analyse of several plant configurations in the same data model.

Table 2. Fuel-Product Exergy Table (kW)

Key	BLR	TRB	IHE	PMP	CND	ENV	Total
BLR	0.00	62.62	1.97	0.00	9.10	0.00	73.70
TRB	0.00	0.00	0.00	2.43	0.00	50.00	52.43
IHE	0.00	1.28	0.04	0.00	0.19	0.00	1.51
PMP	0.00	1.77	0.06	0.00	0.26	0.00	2.08
CND	0.00	0.00	0.00	0.00	0.00	9.54	9.54
ENV	99.53	0.00	0.00	0.00	0.00	0.00	99.53
Total	99.53	65.67	2.07	2.43	9.54	59.54	238.78

Table 2 shows the Fuel-Product table of the plant. This table shows the role of each plant's processes. The most important ones are the steam generator (BLR) and the turbine (TRB), while the IHE and the pump (PMP) recover a small part of the exergy.

3.4. Thermoeconomic analysis

This section presents the results of calculating a plant state's direct and generalised energy costs. There are several types of tables:

- Summary tables of costs for flows and processes.
- Fuel-Product Cost Tables
- Irreversibility Cost Tables

The values of direct exergy costs are decomposed between the part due to internal irreversibilities B^*_{IN} and the costs due to waste B^*_{EX}, applying the selected criterion for waste cost allocation.

$$B^* = B^*_{IN} + B^*_{EX} \quad (1)$$

In the case of generalised exergy costs, they are broken down into the part due to the cost of external resources C_e, the costs associated with processes, C_z, and the cost due to waste, C_r, see Table 3.

$$C = C_e + C_z + C_r \quad (2)$$

Table 3. *Generalised (exergoeconomic) cost of ORC flows.*

Key	B(kW)	C(c€/h)	Ce(c€/h)	Cz(c€/h)	Cr(c€/h)	c(c€/kWh)	ce(c€/kWh)	cz(c€/kWh)
B1	82.99	37.96	0.00	20.96	17.01	0.4574	0.0000	0.2525
B2	17.32	7.92	0.00	4.37	3.55	0.4574	0.0000	0.2525
B3	15.25	6.98	0.00	3.85	3.12	0.4574	0.0000	0.2525

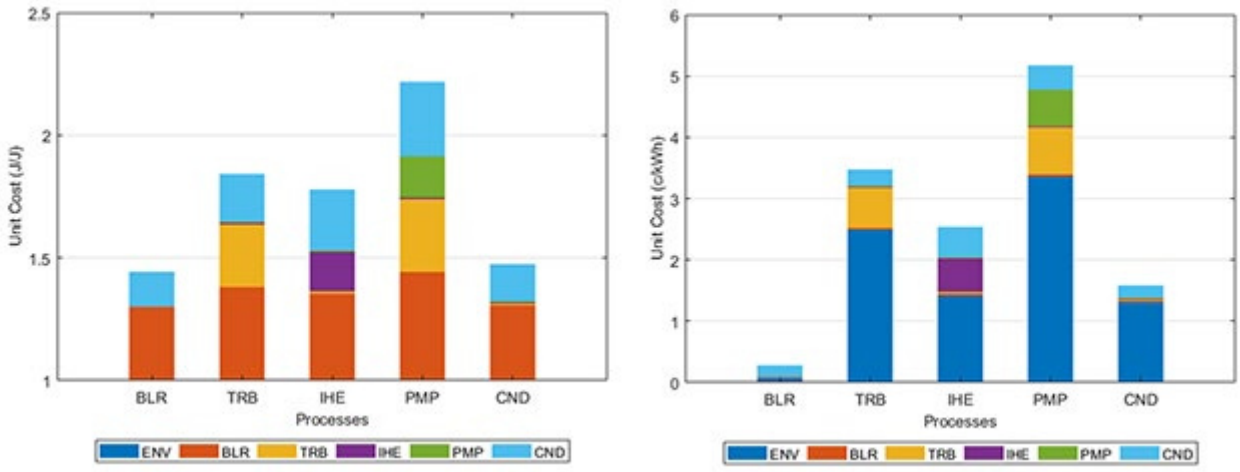

Fig. 4 *Direct and Generalized irreversibility cost graphs*

Table 3 shows the generalised cost of flows. The main contribution is the investment and maintenance costs of the equipment. Here the cost of waste does not reach 10%, and it is assumed that the heat used in the steam generator has no cost. Then the electricity cost is 34.73 €/MWh and the heat 15.84 €/MWh.

The irreversibility cost charts analyse the cost formation process, considering the effect of each process's internal and external irreversibilities. In the case of generalised cost, the impact of the cost of external resources associated with flows and processes is also considered. See Fig. 4.

In the case of direct cost, the main contribution to the cost of each component is the steam generator, as it is the least efficient component located at the beginning of the production chain, also noting that waste costs have a significant weight. In the case of exogenous economic costs, an essential part, as already mentioned, is the equipment costs, together with the irreversibilities of the turbine, due to its high cost.

The application provides an additional function (Summary of Results) that allows the generation of comparative tables and graphs for the different states of the plant.

3.5. Waste Recycling Analysis

As long as residual streams have exergy, they can be retrieved in *recovery units*; the condenser/heat exchange is in the ORC example. These recovery units are integrated into the plant and constitute productive units. Instead of expending exergy to dispose of waste, their exergy is recovered to produce another by-product. In the case of the ORC plant, the recovery unit could produce steam for an ejector refrigeration system. The potential savings from waste recycling can be estimated if one knows the production costs due to external irreversibilities. The production cost due to waste k^*_{EX} indicates the maximum amount of resources that could be saved if waste were recycled.

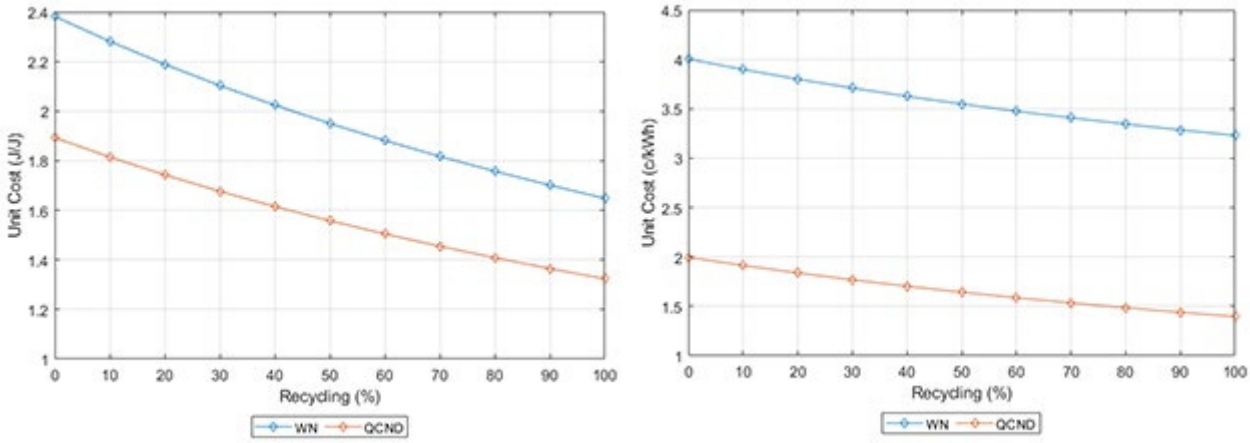

Fig. 5 *Direct and Generalized cost of output flows as a function of waste QCND recycled for TCND45 state.*

It is well known that not all waste can be saved for technical and economic reasons. But, using process integration and Industrial Symbiosis[21], other systems may convert this waste into resources. The exergy cost theory allows for evaluating the waste cost, accounting for resource savings, and providing fair prices to waste becoming by-products.

TaesLab allows computing the production costs if a part of the waste stream is recycled. Figure 6 shows the plots of the output system flows as a function of the portion of waste recycled for the TCND45 state. In the case of recycling up to 66% of the heat, the cost of electricity is 34.35 €/MWh, which is lower than operating the plant under reference conditions.

3.6 Thermoeconomic Diagnosis

The thermoeconomic diagnosis allows for comparing two states of the plant, identifying the causes of the increase in resource consumption between a reference state and another state (operating state). It also allows for evaluating the cost of production increase and the increase of the waste cost.

Diagnosis results are generated when `DiagnosisMethod` is active, and the `ReferenceState` and `State` parameters have different values. The application provides two methods for the analysis of waste cost variation. The first one, WASTE_OUTPUT, is the standard method of thermoeconomic diagnosis, in which the impact on fuel is the sum of the cost of malfunctions caused by the variation of internal irreversibilities MF_i^*, plus the cost of the variation of external outputs, including final products and wastes. The increase in the waste cost implies a useless consumption of resources but not an increase in the final product.

$$\Delta F_T = \sum_i MF_i^* + \sum_i k^*_{P,IN}\Delta\omega_s \tag{3}$$

The second method, WASTE_INTERNAL, addresses this limitation. It is a new implementation of the fuel impact calculation. The cost of waste variation is reallocated to the plant's production processes and final products, according to the defined waste cost allocation criteria.

$$\sum_j k^*_{IN,j}\Delta\omega_{R,j} = \sum_i MR_i^* + \sum_j k^*_{EX,j}\Delta\omega_{T,j}\ , \tag{4}$$

where MR_i^* is the cost of process malfunctions due to the external irreversibility increase, and $\Delta\omega_T$ is the variation of the final products. In such a case, the fuel impact formula is rewritten as follows:

$$\Delta F_T = \sum_i MF_i^* + \sum_j MR_i^* + \sum_j k_{P,j}^* \Delta\omega_{T,i} \quad (5)$$

If we compare the waste heat consumption of the plant in the reference state with that used in the TCND45 (66% recycling) state condition, we can see a fuel impact of 19.47 kW. However, in Table 4 and Figure 8, it can be seen that there is also an extra production of 18.17 kW and a real exergy saving of 7.398 kW.

4. Conclusions

This paper presents a new software application for the thermoeconomic analysis of energy systems. The application follows the methodology described in [9]. It is an evolution of the TAESS application [web], which implements the new algorithms for circular thermoeconomics described in [4], with particular emphasis on analysing the waste cost formation process and its effect on production costs.

The application is presented as a MATLAB package, which includes both applications with a graphical user interface (GUI) and interactive functions that can be used in the MATLAB environment. The fact that it is written in MATLAB language facilitates the calculations of mathematical structures and provides an efficient environment for visualising the results obtained. Through notebooks or Live Scripts, it is possible to use TaesLab for educational purposes and applications adapted to users' needs. In addition, a library of classes is available, allowing new applications and functions to be developed by reusing the source code already generated. Most of the functionality of this software is also compatible with Octave, the open-source alternative to MATLAB.

TaesLab allows focusing on obtaining results without defining the cost equations as in other methodologies. The paper describes the data model, including its physical and productive structure and thermodynamic, economic and environmental data, and shows with an example its capabilities.

As future perspectives for TaesLab, besides adding new functionalities such as aggregation and integration of systems and models with energy storage..., is to integrate it with other simulation packages of energy systems such as Simulink [22], ASPEN or HSC.

Advanced Exergy Analysis of the Flash Ironmaking Process

Jannik Neumann, Frank Dammel, Peter Stephan

Institute for Technical Thermodynamics, Technical University of Darmstadt, Darmstadt, Germany, (neumann, dammel, pstephan)@ttd.tu-darmstadt.de

Abstract:
The growing demand for renewable energy highlights the importance of green energy carriers in mitigating the temporal and geographic imbalances between renewable energy supply and demand. Iron, as a metal fuel, offers a promising solution by enabling the storage of electrical energy from renewables through the thermochemical reduction of iron oxides with green hydrogen. This stored energy can be later converted back into electricity via thermochemical oxidation, such as in retrofitted coal-fired power plants. Transporting the iron/iron oxide in a closed cycle allows for spatial and temporal separation of renewable energy storage and release. To maximize the system efficiency of this energy-iron cycle, it is crucial to achieve high storage efficiencies during the thermochemical reduction of iron oxides. The flash ironmaking process is a promising method for this, as it allows for the reduction of fine iron oxide particles with green hydrogen without the need for pre- or post-treatment. Conventional exergy analyses, as well as advanced exergy analysis, are used to analyze the flash ironmaking process. The results reveal an exergetic system efficiency of 53.7 % for a defined base case, with the largest share of exergy destruction attributed to unavoidable exergy destruction at 82.2 % of the total exergy destruction. Additionally, most of the exergy destruction was endogenous at 89.4 % of the total exergy destruction. These assessments indicate that the overall potential for improvement of the reduction plant is moderate, and component improvements should be prioritized over structural improvements to reduce avoidable endogenous exergy destruction.

Keywords:
Direct Reduction of Iron; Exergy Analysis; Green Iron; Iron as Energy Carrier; Metal Fuels.

1. Introduction

The impact of climate change on both ecosystems and humans is becoming increasingly concerning, with approximately 3.3 to 3.6 billion people residing in highly susceptible areas [1]. Governments worldwide are facing the challenge of balancing electricity security and meeting the rising demand for electricity while simultaneously reducing emissions. This becomes even more challenging due to the recent global energy crisis triggered by Russia's invasion of Ukraine which highlights the vulnerability of the current energy system [2]. At the center of the required clean energy transition is the significant increase in renewable energy soruces paired with the electrification of end-uses. However, due to the inherent variability of renewable energy sources, a secure and decarbonized power sector requires much larger-scale flexible resources than currently exist [3]. One cornerstone of future energy systems might be the use of carbon-free chemical energy carriers (ECs), which can convert clean electricity into stable media for energy storage and transport. By connecting various low-cost production regions with users of green ECs through global value chains, the future energy supply security can be ensured [3]. Iron is being considered as a potential alternative to frequently discussed ECs such as hydrogen and hydrogen-based ECs for the global transport and seasonal storage of renewable energy [4–7]. The energy-iron cycle consists of the storage of electrical energy via thermochemical reduction of iron oxides using green hydrogen, which can subsequently be converted back into electricity through thermochemical oxidation. This conversion process can take place in coal-fired power plants that have been retrofitted for this purpose [8]. This reuse of existing assets and infrastructure can lead to significantly reduced implementation times and costs compared to alternative ECs [7]. Furthermore, the transport and storage of iron/iron oxide is comparatively easy and does not require liquefaction or elevated pressures, which is an advantage over other ECs. The round trip efficiency and the cost of such an energy-iron cycle depend strongly on the regeneration (thermochemical reduction) of the iron oxides [7].
Thermochemical reduction of iron oxide is a well-established process that primarily utilizes coal in blast furnaces, resulting in a significant contribution of 7 % to global CO_2 emissions [9]. However, an alternative method is to employ shaft furnace processes that use natural gas instead of coal, which offer a promising solution to reduce associated CO_2 emissions from ironmaking [9]. This approach is particularly useful in regions with access to cheap natural gas.

Among various routes towards carbon-neutral ironmaking, the shaft furnace process is considered the most promising due to its ability to operate with green hydrogen instead of natural gas and its comparatively high technological readiness level [10]. One drawback of the shaft furnace reduction process is the necessity of iron oxide pellets as feedstock, which must be prepared beforehand and adds to the costs and emissions (although the potential for carbon neutrality exists through the use of hydrogen or bio-mass [11]). Further processing is needed to obtain the required iron powder [8], typically by melting the reduced iron pellets in an energy-intensive electric arc furnace and subsequently water-atomizing the melt.
At the University of Utah a promising alternative technology called the flash ironmaking process [12, 13] has been developed, which can reduces energy consumption and capital investment requirements. This innovative process allows for the direct utilization of fine iron oxide particles without requiring additional pre- and post-treatment, eliminating the need for pelletization and iron powder production. The reaction rate is rapid, and residence times are short, typically just a matter of seconds [12, 14], compared to the minutes to hours required in shaft furnace reactors, thanks to the small particle size (ranging from 10 to 100 microns). The flash reactor reduction technology is a high-intensity process that is free from problems associated with operating at high temperatures, such as particle sticking, unlike other gas-based ironmaking processes that use fluidized bed or shaft furnace reactors. As a result, the process can be operated at elevated temperatures (i.e. above 1150 °C), resulting in a more intensive process. The flash ironmaking process offers several advantages, including dispensing with the requirement for pre- and post-treatment, low energy consumption and capital investment, and high-intensity. Given these advantageous features, the flash ironmaking process aligns perfectly with the described energy-iron cycle as a promising reduction process.
To improve the understanding, identify the sources of irreversibility, and estimate the real improvement potential of this energy-intensive process, exergy-based analyses are performed. For this purpose the methodology and process are described in detail before the analyses are performed.

2. Methodology

The flash ironmaking process will be analyzed using both conventional and advanced exergy analyses. These two analyses will be briefly summarized subsequently before the flash ironmaking process is described in more detail.

2.1. Exergy Analysis

An exergetic analysis is widely recognized as the most efficient method for evaluating the efficiency of energy conversion processes [15–17]. It provides insights by analyzing the real thermodynamic inefficiencies in a system and its components, which are not available by means of an energetic analysis. These can greatly enhance energy-intensive processes from a thermodynamic, an economic, and an ecological perspective. When evaluating systems that involve chemical reactions, the total specific exergy e_{tot} of a material stream, is a combination of both physical exergy e_{ph} and chemical exergy e_{ch}, as represented by

$$e_{\text{tot}} = e_{\text{ph}} + e_{\text{ch}} \,. \tag{1}$$

Physical exergy is calculated based on the current enthalpy h and entropy s as well as their reference state values (h_0 and s_0), using the following equation

$$e_{\text{ph}} = (h - h_0) + T(s - s_0) \,. \tag{2}$$

Chemical exergy, on the other hand, has two components: a reactive part, which is represented by the standard chemical exergies, and a non-reactive part due to mixing. This can be expressed as

$$e_{\text{ch}} = \sum_l \omega_l e^0_{\text{ch},l} + T_0 \sum_l R_l x_l ln(x_l) \,. \tag{3}$$

The standard chemical exergy $e^0_{\text{ch},l}$ for each species l can be obtained from tables for standard reference environments [15, 18, 19] or it can be calculated for a process-specific reference environment. In this case, the latter approach is used, with the reference species being liquid H_2O, Fe_2O_3, and ambient air. For iron and hydrogen, the standard chemical exergies based on the process-specific reference environment are 6448 kJ kg^{-1} and 118 246 kJ kg^{-1}, respectively.

The exergy balance of a generic open control volume can be expressed by

$$\dot{E}_{\text{D}} = P + \dot{E}_{\text{Q}} + \sum_{in,i} \dot{m}_i e_{i,\text{tot}} - \sum_{out,j} \dot{m}_j e_{j,\text{tot}} - \dot{E}_{\text{L}} \,, \tag{4}$$

where $\dot{E}_{\text{Q}}$ and P correspond to the time rates of exergy transfer associated to heat and work transfer, respectively. The exergy loss rate $\dot{E}_{\text{L}}$ and exergy destruction rate $\dot{E}_{\text{D}}$ depend on the chosen system boundary. For

this evaluation, the system boundaries extend into the environment with the constant reference temperature T_0. Therefore, any exergy reduction due to heat losses to the environment is considered as exergy destruction, and only the material streams leaving the system correspond to exergy losses. To determine the exergetic efficiency of a system or component, it is necessary to define a fuel (F) and a product (P) for the analyzed system or component. Then, the overall exergy balance can be expressed by

$$\dot{E}_\mathrm{D} = \dot{E}_\mathrm{F} - \dot{E}_\mathrm{P} - \dot{E}_\mathrm{L}\,, \tag{5}$$

where the definition of the product must be consistent with the purpose of the system/component. The exergetic efficiency is defined as the ratio of the rate of exergy transfer associated with the product to the rate of exergy transfer associated with the fuel

$$\epsilon = \frac{\dot{E}_\mathrm{P}}{\dot{E}_\mathrm{F}} = 1 - \frac{\dot{E}_\mathrm{D} + \dot{E}_\mathrm{L}}{\dot{E}_\mathrm{F}}\,. \tag{6}$$

To compare the exergy destruction $\dot{E}_{\mathrm{D},k}$ of individual components k and losses associated to material streams leaving the system $\dot{E}_\mathrm{L}$ to the total fuel exergy $\dot{E}_{\mathrm{F,tot}}$ of the overall system, exergy destruction $y_{\mathrm{D},k}$ and exergy loss y_L ratios can be defined

$$y_{\mathrm{D},k} = \frac{\dot{E}_{\mathrm{D},k}}{\dot{E}_{\mathrm{F,tot}}}\,, \qquad y_\mathrm{L} = \frac{\dot{E}_\mathrm{L}}{\dot{E}_{\mathrm{F,tot}}}\,. \tag{7}$$

This allows for the assessment of the relative contribution of each component to the total exergy destruction of the system and can be used to define the total exergetic system efficiency

$$\epsilon_\mathrm{tot} = 1 - \sum_k y_{\mathrm{D},k} - y_\mathrm{L}\,. \tag{8}$$

Conventional exergy analysis provides valuable insights into how energy systems can be improved, but it falls short in illustrating the impact of interactions among components within the overall system and the real potential (including technological limitations) for improvement [20, 21]. To overcome these limitations, advanced exergy analysis has been developed. This approach provides a more comprehensive view of the origin of exergy destruction, taking into account the interactions between components and offering a clearer picture of the potential for improvement.

2.2. Advanced Exergy Analysis

An advanced exergy analysis goes beyond conventional analysis by breaking down the exergy destruction within each component into its endogenous and exogenous parts, as well as its avoidable and unavoidable parts and their combinations. Determining the unavoidable and endogenous fractions of exergy destruction entails making certain discretionary judgments, and thus, is somewhat subjective. Nonetheless, the insights obtained from this division surpasses the drawbacks of partial subjectivity [22]. The methodology of advanced exergy analysis was developed at the Institute for Energy Engineering of Technical University Berlin [20–25] and will be briefly summarized before been applied to the flash ironmaking process.

2.2.1. Unavoidable and Avoidable Exergy Destruction

Although it may be possible to mitigate a fraction of the exergy destruction rate in a component, there is usually a residual amount that cannot be avoided due to a variety of limitations. These limitations can include techno-economic constraints such as material availability and cost, as well as thermodynamic restrictions. For instance, the maximum achievable efficiencies of turbo-machinery or electrolyzers may be limited by current or future technology, resulting in unavoidable exergy destruction. By segregating the exergy destruction into two distinct parts – unavoidable $\dot{E}^{\mathrm{UN}}_{\mathrm{D},k}$ and avoidable $\dot{E}^{\mathrm{AV}}_{\mathrm{D},k}$ – in the k$^{\mathrm{th}}$ component

$$\dot{E}_{\mathrm{D},k} = \dot{E}^{\mathrm{UN}}_{\mathrm{D},k} + \dot{E}^{\mathrm{AV}}_{\mathrm{D},k}\,, \tag{9}$$

a more precise evaluation of the potential to enhance the component's thermodynamic efficiency can be achieved. To estimate the value of $\dot{E}^{\mathrm{UN}}_{\mathrm{D},k}$ within each system component, the most favorable operating conditions that just cannot be achieved in the near future are assumed.

2.2.2. Endogenous and Exogenous Exergy Destruction

Additionally, the impact of interdependencies of the system component can be analyzed by separating the total exergy destruction within the k$^{\mathrm{th}}$ component into endogenous $\dot{E}^{\mathrm{EN}}_{\mathrm{D},k}$ and exogenous $\dot{E}^{\mathrm{EX}}_{\mathrm{D},k}$ parts

$$\dot{E}_{\mathrm{D},k} = \dot{E}^{\mathrm{EN}}_{\mathrm{D},k} + \dot{E}^{\mathrm{EX}}_{\mathrm{D},k}\,. \tag{10}$$

The endogenous share refers to the exergy destruction that takes place within the kth component while all other components are ideal, and the component under assessment is performing at its designated efficiency. In contrast, the exogenous fraction represents the discrepancy between the overall exergy destruction and the endogenous exergy destruction for the specific component. Determining exogenous and endogenous exergy destruction values for individual components is a critical aspect of advanced exergy analysis. Traditionally, two methods, based on thermodynamic cycles and the engineering approach, have been employed [24]. However, these approaches have limitations such as computational difficulties, theoretical deficiencies, and the need for a large number of non-standard simulations, rendering them impractical [21, 25]. To overcome these limitations, a novel decomposition-based approach was recently developed [25] and successfully applied [26] by Penkuhn and Tsatsaronis. This method involves calculating the exogenous exergy destruction for a given component by applying a modified exergy balance equation

$$0 = \sum_j \dot{E}^{\mathrm{EN}}_{\mathrm{Q},j,k} + P^{\mathrm{EN}}_k + \sum_i (\dot{m}e)^{\mathrm{EN}}_{i,k} - \sum_o (\dot{m}e)^{\mathrm{EN}}_{o,k} - \dot{E}^{\mathrm{EN}}_{\mathrm{D}k} \,. \tag{11}$$

This equation takes into account the endogenous operation parameters, which include composition, pressure, temperature, mass flow rate, and exergy transfer to or from the components. It is crucial to define these endogenous parameters for each component in relation to the remaining idealized system. Additionally, the exergetic efficiency ϵ_k of the component must be identical in both the endogenous case and the base case design. By using this novel approach, the drawbacks of previous methods can be avoided, providing a more accurate and practical solution to determine endogenous and exogenous exergy destruction values.

2.2.3. Combination of the Exergy Splitting Approaches

The combination of the two previous concepts results in the following equation for exergy destruction

$$\dot{E}_{\mathrm{D},k} = \dot{E}^{\mathrm{UN,EN}}_{\mathrm{D},k} + \dot{E}^{\mathrm{UN,EX}}_{\mathrm{D},k} + \dot{E}^{\mathrm{AV,EN}}_{\mathrm{D},k} + \dot{E}^{\mathrm{AV,EX}}_{\mathrm{D},k} \,. \tag{12}$$

When optimizing a system based on the results of an advanced exergy analysis, it is important to focus on reducing the avoidable endogenous (that can be reduced by improving the efficiency of the component being considered) and avoidable exogenous (that can be reduced by changes to the system topology) exergy destruction. With these considerations in mind, the exergetic efficiency given in 6 can be adjusted

$$\epsilon^{\mathrm{AV,EN}}_k = \frac{\dot{E}_{\mathrm{P},k}}{\dot{E}_{\mathrm{F},k} - \dot{E}^{\mathrm{UN}}_{\mathrm{D},k} - \dot{E}^{\mathrm{AV,EX}}_{\mathrm{D},k}} \,. \tag{13}$$

Similarly to the differentiation of different parts of exergy destruction (see 12), the exergy destruction ratios can be further differentiated as follows

$$y_{\mathrm{D},k} = y^{\mathrm{UN,EN}}_{\mathrm{D},k} + y^{\mathrm{UN,EX}}_{\mathrm{D},k} + y^{\mathrm{AV,EN}}_{\mathrm{D},k} + y^{\mathrm{AV,EX}}_{\mathrm{D},k} \,. \tag{14}$$

The important information is conveyed through the unavoidable, endogenous exergy destruction $\dot{E}^{\mathrm{UN,EN}}_{\mathrm{D},k}$, which represents the smallest possible endogenous exergy destruction resulting from techno-economically constraints of the component as well as its interactions with other components [21, 26].

$$\dot{E}^{\mathrm{UN,EN}}_{\mathrm{D},k} = \dot{E}^{\mathrm{UN}}_{\mathrm{D},k} \frac{\dot{E}^{\mathrm{EN}}_{\mathrm{D},k}}{\dot{E}_{\mathrm{D},k}} \,. \tag{15}$$

The remaining different parts of exergy destruction can then be calculated by the introduced set of equations.

3. Flash Ironmaking

As prevousliy mentioned the utilization of green hydrogen for green ironmaking is an emerging technology. This section provides a brief overview of the thermochemical reduction of iron oxides using hydrogen, followed by a detailed introduction to the flash ironmaking process.

3.1. Reduction of Iron Oxides with Hydrogen

The step-wise direct reduction of iron oxides with hydrogen at temperatures above 843 K proceeds through a series of intermediate stages, starting from hematite Fe_2O_3, then magnetite Fe_3O_4, followed by wüstite $Fe_{(1-z)}O$, and finally to metallic iron Fe [27]. The global reaction for the reduction of hematite is described by

$$\mathrm{Fe_2O_3} + 3\,\lambda_{\mathrm{H_2}}\mathrm{H_2} \longrightarrow 2\,\mathrm{Fe} + 3\,\lambda_{\mathrm{H_2}}\mathrm{H_2O} + 3\,(\lambda_{\mathrm{H_2}}\text{-}1)\,\mathrm{H_2} \qquad \Delta H_{\mathrm{r}}(\lambda_{H_2} = 1) = 98.77\,\mathrm{J\,mol^{-1}} \,. \tag{R1}$$

Here, λ_{H_2} represents the hydrogen equivalence ratio. However, to achieve full conversion of the iron oxides to iron, an overstoichiometric ($\lambda_{H_2} > 1$) amount of hydrogen is required, since the reaction is limited by the chemical equilibrium [27]. It should be noted that the applied thermodynamic data [28] assume that wüstite exists only as $Fe_{0.947}O$ ($z = 0.053$). The progress of reduction can be quantified by the reduction degree, denoted as X, which is given by

$$X = 1 - \frac{N_O}{1.5 \cdot N_{Fe}}, \tag{16}$$

where N_{Fe} represents the molar amount of iron and N_O corresponds to the molar amount of oxygen bound to the iron. For example, the reduction degree of pure iron would be 1 ($N_O = 0$), and for a mixture of wüstite and iron ($\omega_{Fe} = 0.83$, $\omega_{Fe_{0.947}O} = 0.17$), the reduction degree is 0.9.

3.2. Process Description, Modeling, and Parameterization

Figure 1 illustrates the flowsheet of the flash ironmaking process under investigation. The process begins with fine iron oxide powder (the product of the prior oxidation process) as feedstock which is preheated in an iron oxide preheater. The powder is then directed to the flash reactor, where it reacts with a hydrogen stream to iron and water, as represented by R1. Due to the endothermic nature of the reduction reaction, an external heat source is required. This heat can be generated internally by burning a portion of the reducing agent through partial oxidation, a technique commonly used in various industrial processes, such as natural gas reforming. The reactor effluent is separated through a cyclone, with the hot iron leaving the cyclone being cooled down by an air heater, which utilizes the available heat to preheat the iron oxide feed using a secondary fluid (air). The hot hydrogen leaving the cyclone is then utilized in a regenerative heat exchanger (hydrogen preheater) to preheat the gaseous reactants before entering the flash reactor. The majority of the water in the recycle stream is removed through a simple condenser and the remaining hydrogen is merged with hydrogen generated by the electrolyzer.

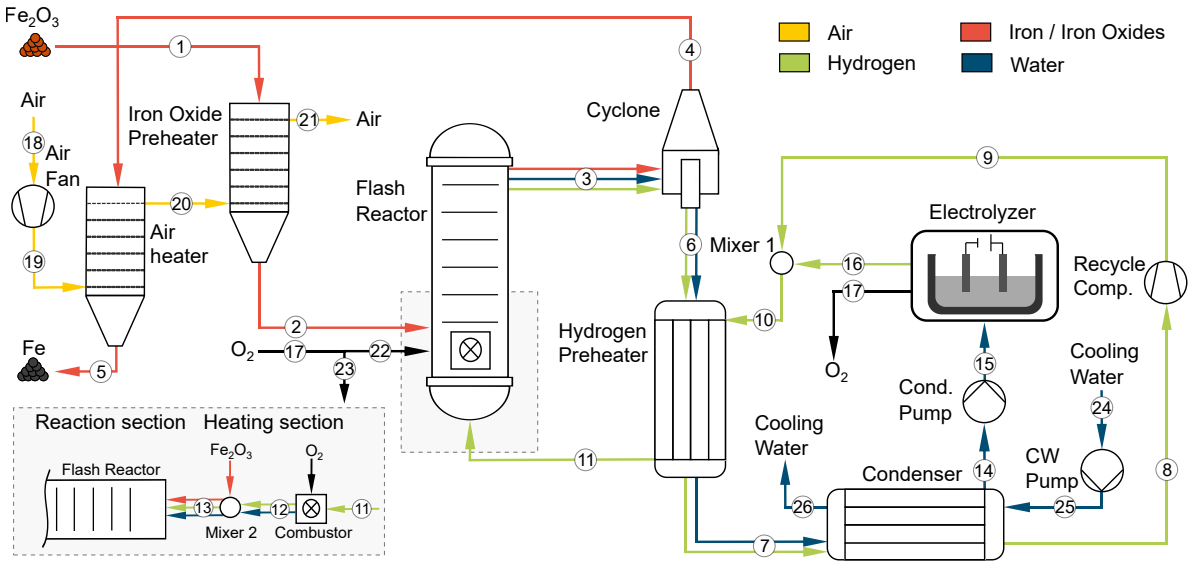

Figure 1: Flowsheet of the investigated flash ironmaking process

3.2.1. Modeling and Assumptions

The flash reactor is the key component of the investigated process. Experimental and numerical evidence suggests that it is possible to fully convert iron oxides to iron using hydrogen at atmospheric pressure [13]. However, for the reference design, a reduction degree of $X = 90\,\%$ is assumed. The flash reactor is modeled as a sequence of a combustor, a heating section (adiabatic mixer), and a reaction section (adiabatic yield reactor), as highlighted in Fig. 1. The adiabatic mixing of the heating section is a reasonable simplification since the heating period is very brief, as supported by numerical investigations [14]. The oxygen flow into the combustor is adjusted to achieve a defined temperature of 1300 °C at the reactor section inlet (Stream 13). In addition, the hydrogen equivalence ratio is set to $\lambda_{H_2} = 3$, so there are no conversion restrictions due to chemical equilibrium limitations. The mass flow rate of solid product leaving the process (Stream 5) is set to $\dot{m}_5 = 35\,\mathrm{kg/s}$, which corresponds to an annual production of approximately 1 million tons (industrial plant scale). All heat exchangers are assumed to have a pressure drop of $\Delta p = 0.15\,\mathrm{bar}$ and a relative heat flow loss $\dot{Q}_{rel}$ equivalent to 2.5 % of the heat flow of combustion/transferred heat flow, is introduced to account for heat losses in both the combustor and heat exchangers. Additional details on the process components are presented in Table 2, and the corresponding stream table is provided in Appendix A.

To enable comparisons between energy-based and exergy-based analyses, a system efficiency parameter is defined, denoted as η_{tot}, for the given process. This parameter is calculated using the following equation

$$\eta_{tot} = \frac{\dot{m}_5 \cdot HV_5}{\sum_k P_k}, \tag{17}$$

where the numerator simply represents the product of the mass flow rate and the corresponding heating value of the product stream, and the denominator accounts for the sum of all energy supplied to the system.

The required definition of fuel and product for the exergy analyses, taking into account the splitting of chemical and physical exergy, for each component and at the system level is defined in Table 1. The unavoidable exergy destruction for each component is calculated individually at the component level, under the best conditions possible, to define the unavoidable exergy destruction. The technological limitations and associated assumptions are given in Table 2. For components where an exergetic efficiency cannot be defined (such as mixer 1 and the cyclone), as they do not serve any meaningful purpose from a thermodynamic perspective, the unavoidable exergy destruction is set equal to the endogenous exergy destruction. The same assumption was made for the flash reactor (consisting out of the combustor, mixer 2 and the reaction section). Another approach to defining unavoidable conditions for the flash reactor could be to assume full conversion ($X = 1$) at the minimum possible hydrogen equivalence ratio. However, such an assumption would result in higher specific exergy destruction due to the inherent irreversibilities associated with the chemical reactions involved. Consequently, this approach would lead to negative avoidable exergy destruction, the interpretation of which is not clear.

To calculate the endogenous and exogenous exergy destruction, individual components with their corresponding exergetic efficiency are simulated in conjunction with an idealized system [25]. The real process takes into account factors such as incomplete conversion of iron oxides in the reactor, incomplete separation of water from the residual gaseous stream in the condenser, and a higher hydrogen equivalence ratio than thermodynamically required. In contrast, in the idealized process, full conversion is achieved ($X = 1$), complete separation of water out of the recycle stream, and the minimal possible hydrogen equivalence ratio are assumed. The minimal hydrogen equivalence ratio $\lambda_{H_2} = 2.6$ is obtained using chemical equilibrium calculation for the idealized system under the corresponding conditions ($t = 1300\,^{\circ}\mathrm{C}, \omega_{H2} = 57\,\%$, $\omega_{H2O} = 43\,\%$). These idealizations result in different mass flow rates and compositions. To ensure a fair comparison, the overall main product of the process is kept constant, corresponding in this case to the chemical exergy in stream 5 leaving the system ($\dot{E}_{ch,5} = 196.4\,\mathrm{MW}$). Due to the full conversion and the corresponding higher specific chemical exergy of the product, the material flow is reduced to meet the same main product for both the idealized and real processes. To determine the endogenous exergy destruction within the air heater, we assume that the upstream air fan is operating isentropically and adjust the pressure accordingly, as pressure drops downstream should not be attributed to the air heater. The inlet of the hot stream is determined by the idealized reactor ($X = 1$), while the approach temperature is adjusted to achieve the same exergetic efficiency as in the base case design. Similarly, the endogenous exergy destruction of the other heat exchangers are determined by using the streams of the idealized system and adjusting the approach temperature to achieve the same exergetic efficiency as in the base case design. For the reaction section and the combustor, the hydrogen equivalence ratio and the associated heat losses are adjusted to meet the same exergetic efficiency between the base case design and the idealized system in conjunction with the component, respectively. Since the reactor operates at atmospheric pressure, the pressure levels generated by the turbo-machinery are not required for the overall process and are associated with pressure drops in other components. Therefore, the entire exergy destruction within the turbo machinery is exogenous. The specifications for the calculation of endogenous exergy destruction and the resulting streams are given in Appendix B.

The results are derived using EBSILON® *Professional* [30] applying the thermodynamic data given in [28] and user defined routines for the calculation of physical and chemical exergies. The reference temperature and pressure is set to $T_0 = 298.15\,\mathrm{K}$ and $p_0 = 1.013\,\mathrm{bar}$, respectively.

4. Results and Discussion

The energetic system efficiency of the base case design was determined to be $\eta_{tot} = 61.7\,\%$ based on a conventional mass and energy-based analysis (not explicitly shown here). The energetic analysis identified the electrolyzer as the component with the highest losses, followed by the residual energy of the material streams leaving the system, and the heat losses of the combustor and heat exchangers. To get an impression of the achievable energetic system efficiency, the process was parameterized according to the assumed unavoidable technological constraints given in Table 2. This resulted in an energetic system efficiency of $\eta_{tot} = 68.5\,\%$, a significant improvement potential from the base case design.

Based on the conventional exergy analysis presented in Table 3, the exergetic system efficiency of $\epsilon_{tot} = 53.7\,\%$ indicates significant inefficiencies within the process. The electrolyzer is responsible for the largest exergy de-

Table 1: Definition of fuel and product according to [29] for each component given in Fig. 1

struction, followed by the condenser, hydrogen preheater, reactor, combustor, and the other heat exchangers. Figure 2 illustrates the exergy destruction ratios of all components, starting from the overall process fuel, in descending order leading to the defined product of the process. The analysis reveals that the turbo-machinery and the cyclone only cause insignificant exergy destruction. The exergy losses associated with streams leaving the system result in an exergy loss ratio of y_L = 1 %, with the chemical exergy of the oxygen leaving the system having the highest share. In contrast to the energetic analysis, which pointed to the material streams leaving the system, the exergy analysis quantifies the low quality of the energy within these streams due to the low associated temperatures. The exergetic efficiencies of the different components are mostly high, with the exception of the flash reactor, which suffers from the high inherent irreversibilities associated with the reduction reaction. Interestingly, the exergetic efficiency of the combustor is comparatively high, which is due to the partial oxidation and the high temperature of stream 11 entering the combustor.

Based on the analysis of unavoidable and avoidable exergy destruction, it is concluded that the total unavoidable and avoidable exergy destruction account for 82.2 % ($\dot{E}^{UN}_{D,tot}$ = 136.1 MW) and 17.8 % ($\dot{E}^{AV}_{D,tot}$ = 29.4 MW) of the exergy destruction, respectively. After factoring in the unavoidable exergy destruction, a modified exergetic efficiency of 85.8 % can be determined for the base case (cf. Table 3). The highest unavoidable exergy destruction is associated with the electrolyzer, the condenser, the flash reactor and the combustor, while the highest avoidable exergy destruction is related to the elctrolyzer, the hydrogen preaheater, the combustor and the iron oxide preheater. The share between endogenous and exogenous exergy destruction is even more one-sided, with endogenous exergy destruction accounting for 89.4 % and exogenous exergy destruction for 10.6 % of the total exergy destruction. These findings suggest that a large share of the exergy destruction is unavoidable. However, the assessments point out that improving individual components should have a higher priority over structural improvements.

When combining the two exergy splitting approaches, the total share of avoidable endogenous and avoidable exogenous exergy destruction in relation to the total avoidable exergy destruction is 87.1 % and 12.9 %, respectively. The electrolyzer, hydrogen preheater, and the combustor exhibit the highest potential for reducing endogenous avoidable exergy destruction. This highlights the potential for improvement through technological

advances in water-electrolysis, heat recovery measures, and the importance of proper reactor design and operation, including internal combustion.

The exergy-based evaluations presented here demonstrate the potential for enhancement of the analyzed flash ironmaking process. While technological advancements in water-electrolysis and lower approach temperatures lead to obvious improvements in overall performance, it is evident that there is still potential for improvement of the flash reactor (sequence of combustor, mixer 2, and reaction section). The attained conversion and reaction conditions (reaction temperature, hydrogen equivalence ratio) result in exergy destruction upstream and downstream of the reactor, which could be reduced. However, it should be noted that although these assessments are thermodynamically correct, economic considerations remain the driving force in real-world process synthesis.

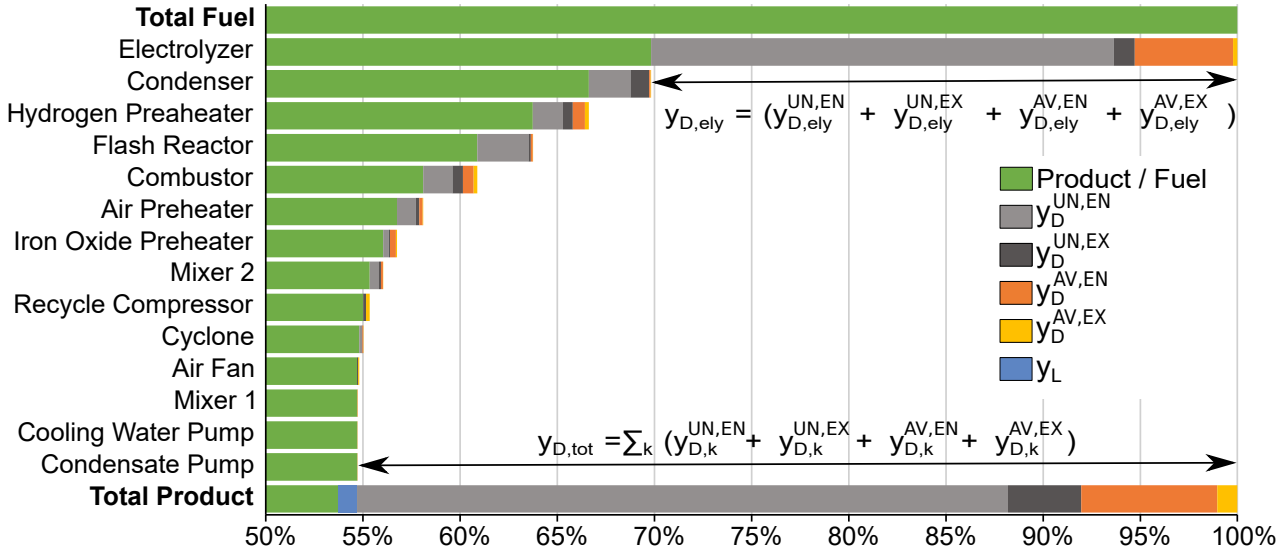

Figure 2: Waterfall diagram to visualize the results of the conventional and advanced exergy analysis

5. Conclusion

The present study focuses on the thermodynamic assessment of flash ironmaking, a promising method for sustainable iron oxide reduction using green hydrogen. To this end, conventional energy and exergy analyses, as well as an advanced exergy analysis, are conducted. A defined based case is used to determine an energetic efficiency of 61.7 % and an exergetic efficiency of 53.7 % for a given parameterization. For a scenario with foreseeable best case technological constraints, an energetic efficiency of 68.5 % and an exergetic efficiency of 59.7 % can be determined.

The informative value of the employed methods can be demonstrated by the assessment of the condenser, which separates the undesired water out of the recycle stream. While the energetic analysis points to the high energy content of the cooling water leaving the condenser, the exergetic analysis indicates significantly lower potential, which is further deemed as mainly unavoidable exergy destruction by the advanced exergy analysis. The overall potential for improvement of the plant is found to be moderate, mainly due to the high unavoidable exergy destruction (i.e. 82.2 % of the total exergy destruction), and the improvement potential is primarily associated with the internal operational conditions of the components. The highest avoidable exergy destruction is observed in the electrolyzer, the hydrogen preheater, and the combustor, which is also endogenous.
The findings of these analyses confirm that the flash ironmaking process is a promising alternative to the conventional shaft furnace process, particularly in the context of a circular energy-iron economy, given its dispensation of the requirement for pre- and post-treatment of iron oxides (required for the shaft furnace process), low energy consumption, and high-intensity. The performed assessments provide insights into the sources of irreversibility and estimate the potential for improvement in this energy-intensive process. However, for a more comprehensive assessment, it is crucial to consider economic factors in the synthesis of the analyzed flash ironmaking process. In addition to reliable techno-economic models, this requires a comprehensive reactor model that takes reaction kinetics and transport phenomena into account.

Abstract:

The most severe reason for global warming is the release of anthropogenic CO_2 emissions to the atmosphere. One way to mitigate these emissions is to capture CO_2 directly at an emitting source using carbon capture technologies. An important process in the carbon capture value chain is to condition the captured CO_2 to the following transportation. In this study, a system for liquefaction and purification of CO_2 is of focus and an exergoeconomic analysis is made. In the system, CO_2 is compressed through two-stage compression with intercooling, while water condensate is removed. The liquefaction is performed using an external two-stage refrigeration cycle. The compressors were found to be the greatest source of exergy destruction and were the greatest cost contributors. An overall exergy efficiency of 39 % was found and it was seen that 13 % of the fuel supplied was lost in external coolers. To improve the system and utilise the exergy loss, two configurations for district heat integration were investigated. It was found to increase the exergy efficiency to 45 % and 50 %, respectively, depending on the configuration. Integration of district heating in the intercoolers could be made without additional costs for the system. A cost increase of the overall system of 11 % was seen when the heat discharged in the refrigeration cycle was also utilised for district heat production. This shows that there is a potential for utilising the waste heat from the system and adding revenue from district heat sales.

Keywords:

CO_2 liquefaction and purification; CO_2 conditioning; District heat integration; Exergoeconomic analysis; Thermoeconomic analysis.

1. Introduction

In 2016, anthropogenic CO_2 emissions accounted for 75 % of the total greenhouse gas emissions in the world [1]. Some of the sectors responsible for the majority of the CO_2 emissions are the electricity and heating sector and the manufacturing and construction sector accounting for 41 % and 17 %, respectively. Carbon capture technologies are expected to play an important role in reducing emissions from these sectors, as the technology allows for continuous utilisation of existing fossil-based facilities and can provide deep emission reductions that are difficult to mitigate with technological advances (e.g. for production of iron, steel, cement, and various chemicals) [2]. Furthermore, the technology can be used to achieve negative emissions by capturing and storing CO_2 from biogenic sources. A capture capacity of 7.6 Gt CO_2 per year is expected in 2050 [3], of which only 0.5 % was realised in 2021 [4]. This indicates that all process steps of the carbon capture value chain must be scaled up and become more cost-effective to reach the required capacity. The focus of this study is the liquefaction and purification process, which ensures that captured CO_2 is conditioned to the correct state and quality before transport. The process is highlighted in the carbon capture value chain in Fig. 1. The conditioning process accounts for between 20 % and 70 % of the costs when also considering the following transportation [5, 6, 7]. Therefore, an improvement of this process step can potentially have a significant influence on the overall costs.

The captured CO_2 is typically in a gaseous state after separation. To reduce the cost of transportation, the density can be increased. This can be achieved in the conditioning process by increasing the pressure or decreasing the temperature of CO_2. In the food and beverage industry today, CO_2 is transported in a liquid state at 15 bar and –30 °C [8]. Furthermore, impurities such as water, volatiles, and incondensable gasses could be removed before transportation [9].

Several studies have compared different layouts of the liquefaction and purification system on energy [10, 11]

Figure 1: Position of the liquefaction and purification process in the carbon capture value chain.

and economic [12, 13] performance parameters when different requirements for the end-state of CO_2 exist. At a delivery pressure of 15 bar, a system with an external refrigeration cycle generally shows the best performance. The effects of impurities and final quality requirement are investigated by Deng et al. [8], they find that the process costs increase when impurities in the source increase at lower delivery pressures. Aspelund and Jordal [9] investigate the effects of impurities and pressure level of the CO_2 feed gas. They find that a decrease in the inlet pressure and an increase in impurities increase power consumption. Energy, exergy, and economic analyses have been performed on different layouts of a CO_2 liquefaction system by Chen and Morosuk [14], showing that the majority of the exergy destruction ($>$80 %) occurs in coolers and compressors and that it is equally distributed between these two types of components. The highest exergy efficiency of 67 % was found for a system with an external refrigeration cycle. An exergoeconomic analysis was made on a liquefaction system using an absorption refrigeration cycle by Aliyon et al. [15] having an exergy efficiency of 86 % with heat exchangers showing the highest cost improvement potential. Exergy analyses have also been performed on liquefaction systems by Muhammad et al. [16, 17] resulting in total exergy efficiencies of 68 % and 56 %, respectively. It is seen that the highest exergy destruction occurs during compression of the captured CO_2 and that potential for utilisation of heat from intercooling exists. It is of interest to determine where cost inefficiencies exist in a liquefaction system using an external refrigeration cycle to deliver purified liquid CO_2 at 15 bar, and whether it is possible to recover heat through the integration of district heat (DH) production. Therefore, an exergoeconomic analysis of a liquefaction and purification system was made in the present study. It was investigated which components were of most importance for the overall costs of the system and whether thermodynamic inefficiencies or capital expenses were dominating sources of costs. The potential of DH integration was evaluated to determine the economic benefit for the system.

2. Methods

2.1. System description

A process flow diagram of the baseline liquefaction and purification system is illustrated in Fig. 2. The CO_2 product stream is compressed through two-stage compression (COMP) with intercooling (COOL). During intercooling, the remains of water in the captured CO_2 are condensed and removed in gas-liquid separators (SEP). The compressed and purified CO_2 is then liquefied in a heat exchanger (LIQHEX) which works as the evaporator of an external transcritical CO_2 refrigeration cycle. Finally, the liquid CO_2 is pumped to the transport pressure. The incoming mass flow rate of 1.8 th^{-1} of gaseous CO_2 was at 40 °C and 1.7 bar containing 4.3 %(mol) water. Remaining impurities were neglected. The system should deliver liquid CO_2 at 15 bar and 2 K subcooling, and the liquefaction was set to occur at 14.5 bar. In the baseline system, cooling water was heated from 20 °C to 70 °C in the intercoolers, while air was heated from 15 °C to 40 °C in the gascooler (GC). DH was integrated in two alternative ways; in all intercoolers and the gascooler (COOL1, COOL2, COOL3, and GC), and only in intercoolers (COOL1, COOL2, and COOL3). DH water was assumed to be heated from 35 °C to 70 °C. The high pressure in the refrigeration cycle was optimised to the temperature of the available cooling media through cost minimisation. The optimal pressure with air as cooling media in the GC was 75 bar, while the optimal pressure was 110 bar when DH was integrated in the GC. In two-stage compression, the same pressure ratio was applied for each stage, and the intermediate pressure levels (p_{int}) were given by: $p_{int} = \sqrt{p_{low} \cdot p_{high}}$ [18].

2.2. Energy analysis

The system was modelled in steady state by applying mass and energy balances to control volumes for all components. Pressure and heat losses were neglected in pipelines, heat exchangers, and separators. The model was implemented in Engineering Equation Solver [19], and the thermodynamic properties of the CO_2 stream with water impurities were determined using Dalton's law and an ideal gas mixture assumption.

Reciprocating compressors were used in the system and were modelled using a heat loss factor, an isentropic efficiency (η_s), and a volumetric efficiency (η_{vol}). A heat loss factor of 3 % was applied and defined as the ratio of the compressor heat loss to the supplied compressor power. The estimated efficiencies for compressors and pump are presented in Table 1.

The heat exchangers were modelled with a minimum temperature approach of 5 K^1 and a constant overall heat transfer coefficient (U), as shown in Table 2.

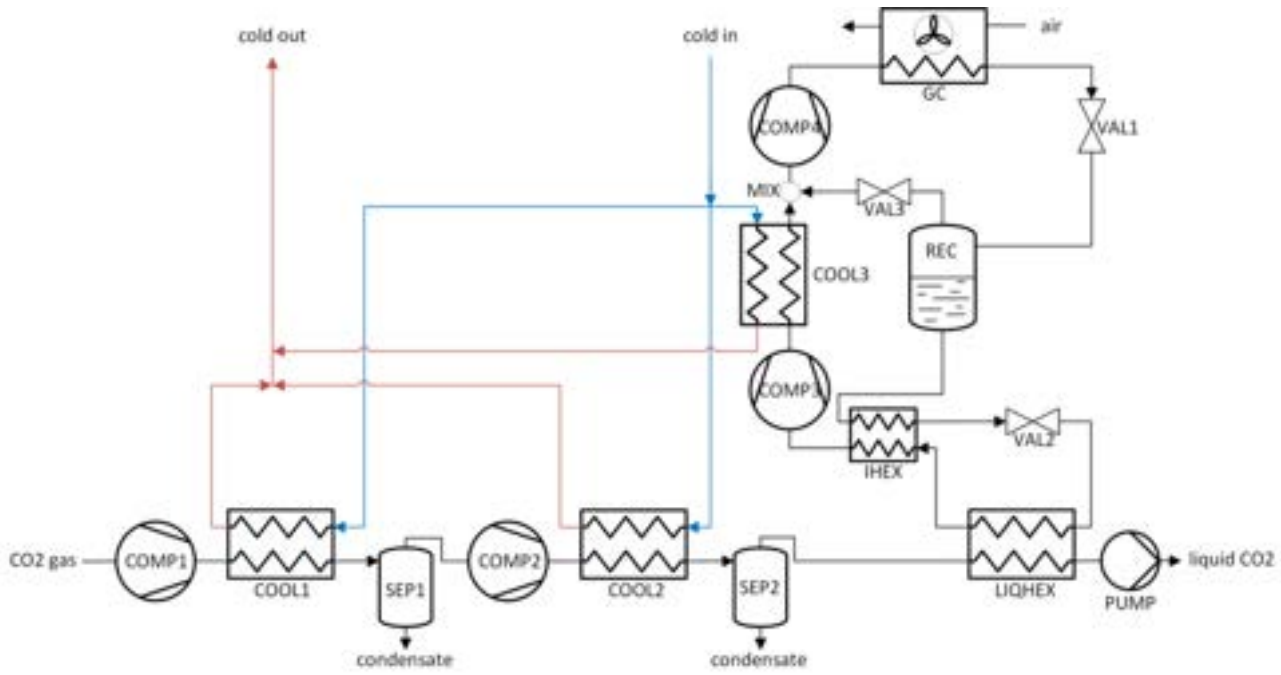

Figure 2: Process flow diagram of the baseline liquefaction and purification system.

Table 1: Assumed efficiencies. Component names refer to Fig. 2.

Component	η_s [%]	η_{vol} [%]
COMP1, COMP2	65	80
COMP3, COMP4	67	83
PUMP	85	100

The gas-liquid separators were assumed to collect all liquid from the two-phase mixture at the bottom of the tank by gravitational forces. The vertical velocity (v) was assumed to be 0.30 ms^{-1} for SEP1, 0.05 ms^{-1} for SEP2 and, 0.13 ms^{-1} for the receiver in the refrigeration cycle (REC). SEP2 in the CO_2 product stream was assumed to remove all remains of water so that pure CO_2 entered the liquefaction heat exchanger.

The required size of each component was determined using the relations given in Table 3. The compressors and pump were defined by a displacement volume ($\dot{V}_{disp}$) required to deliver the actual volume flow rate at the suction line ($\dot{V}_{in}$). The required heat transfer area (A) of the heat exchangers were determined from the required heat transfer rate ($\dot{Q}$), the overall heat transfer coefficient and the logarithmic mean temperature difference of the process (ΔT). The gas-liquid separators had a cross-sectional area (A_{cross}) which ensured the assumed vertical velocity of the volume flow of gas ($\dot{V}_{gas,out}$).

Table 2: Assumed overall heat transfer coefficients. Component names refer to Fig. 2.

Component	U [$kW(m^2K)^{-1}$]	**Source**

IHEX	0.46	[20]
COOL1	0.46	*NDA*
COOL2, COOL3	0.68	*NDA*
GC (air as cooling media)	0.04	[21]
GC (DH water as cooling media)	2.30	*NDA*

2.3. Exergy analysis

The exergy of a given system is the useful work that can potentially be utilised in a process where the system interacts and reaches equilibrium with the surroundings, while heat transfer only occurs to the surroundings [22].

[1] To allow the model to reach the optimal pressure of 110 bar when DH was integrated in the GC, the pinch point temperature difference in the internal heat exchanger (IHEX) was increased from 5 K to 8 K.

Table 3: Relations for calculation of required component sizes.

Component type	Size relation
Compressors and pump	$\dot{V}_{\text{disp}} = \dot{V}_{\text{in}}/\eta_{\text{vol}}$
Heat exchangers	$A = \dot{Q}/U\Delta T$
Gas-liquid separators	$A_{\text{cross}} = \dot{V}_{\text{gas,out}}/v$

An exergy analysis helps identify which components and material streams are the cause of inefficiencies and losses in the system. The surroundings (denoted state 0) were defined with a temperature and pressure of 15 °C and 1 atm. An exergy reference environment was chosen and the standard chemical exergy (e_0^{CH}) of CO_2 and H_2O was given as 19 870 kJ/kmol and 9500 kJ/kmol, respectively [22]. The specific exergy (e) was calculated by Eq. (1) [22] taking the physical (PH) and chemical (CH) exergy into account. This was used together with the mass flow rate ($\dot{m}$) to determine the exergy flow rates ($\dot{E}$) through the system: $\dot{E} = e \cdot \dot{m}$.

$$e = \underbrace{(h - h_0) - T_0\,(s - s_0)}_{e^{\text{PH}}} + \underbrace{\sum_n \left(y_n e_{0,n}^{\text{CH}}\right) + \left(h_0 - \sum_n y_n h_{n,0}\right) - T_0 \left(s_0 - \sum_n y_n s_{n,0}\right)}_{e^{\text{CH}}} \tag{1}$$

The exergy destruction within the system was determined using the product (P) and fuel (F) concepts [23]. The rate of fuel exergy should be sufficient to generate the product and overcome the exergy destruction (D) and exergy losses (L), as given by Eq. (2) [22]. Losses were considered as material streams which transfer exergy directly to the surroundings without further use and were only considered on a system level. Therefore, the last term of Eq. (2) was omitted on a component level.

$$\dot{E}_{\text{F}} = \dot{E}_{\text{P}} + \dot{E}_{\text{D}} + \dot{E}_{\text{L}} \tag{2}$$

The definitions of product and fuel exergy flow rates are given in Table 4. The external coolers, mixer and valves were considered to be dissipative components, therefore no product was defined. The overall product of the baseline system was the increase in exergy of the CO_2 product stream, while the exergy fuel accounted electricity consumption and cooling water (denoted COOL). When DH was integrated in the system, the heating of the cooling water was also considered as a product and the fuel reduced to only being the electricity consumption. For the baseline system, the overall losses were given as the sum of the condensate of water leaving the separators, all leaving streams of cooling water, and the air stream leaving the GC, as given by Eq. (3).

$$\dot{E}_{\text{L}} = \sum \left(\dot{E}_{\text{liq,out}} + \dot{E}_{\text{COOL,out}}\right) + \dot{E}_{\text{GC,out}} \tag{3}$$

Table 4: Definitions of fuel and product exergy rates. Component names refer to Fig. 2.

Component type	$\dot{E}_{\text{F}}$	$\dot{E}_{\text{P}}$
COMP	$\dot{W}$	$\dot{E}_{\text{out}} - \dot{E}_{\text{in}}$
PUMP	$\dot{W}$	$\dot{E}_{\text{out}} - \dot{E}_{\text{in}}$
SEP	$\dot{E}_{\text{in}} - \dot{E}_{\text{liq,out}}$	$\dot{E}_{\text{gas,out}}$
REC	$\dot{E}_{\text{in}}$	$\dot{E}_{\text{gas,out}} + \dot{E}_{\text{liq,out}}$
LIQHEX (cooling across T_0)	$(\dot{E}_{\text{ref,in}} - \dot{E}_{\text{ref,out}}) + \dot{E}_{\text{CO2,in}}$	$\dot{E}_{\text{CO2,out}}$
IHEX (cooling at $T < T_0$)	$\dot{E}_{\text{cold,in}} - \dot{E}_{\text{cold,out}}$	$\dot{E}_{\text{hot,out}} - \dot{E}_{\text{hot,in}}$
COOL (cooling at $T > T_0$)	$\left(\dot{E}_{\text{CO2,in}} - \dot{E}_{\text{CO2,out}}\right) - \left(\dot{E}_{\text{COOL,out}} - \dot{E}_{\text{COOL,in}}\right)$	–
GC (cooling at $T > T_0$)	$\left(\dot{E}_{\text{ref,in}} - \dot{E}_{\text{ref,out}}\right) + \dot{W} - \dot{E}_{\text{a,out}}$	–
MIX	$\dot{E}_{\text{hot,in}} + \dot{E}_{\text{cold,in}} - \dot{E}_{\text{out}}$	–
VAL	$\dot{E}_{\text{in}} - \dot{E}_{\text{out}}$	–
Baseline system	$\sum \left(\dot{W} + \dot{E}_{\text{COOL,in}}\right)$	$\dot{E}_{\text{CO2,out}} - \dot{E}_{\text{CO2,in}}$
DH integration	$\sum \dot{W}$	$\left(\dot{E}_{\text{CO2,out}} - \dot{E}_{\text{CO2,in}}\right) + \sum \left(\dot{E}_{\text{COOL,out}} - \dot{E}_{\text{COOL,in}}\right)$

For the system with DH integration in the intercoolers, the losses reduced to only account the condensate of water leaving the separators and the air stream leaving the GC, as given by Eq. (4).

$$\dot{E}_{\mathrm{L}} = \sum \dot{E}_{\mathrm{liq,out}} + \dot{E}_{\mathrm{GC,out}} \tag{4}$$

When DH was integrated in all external coolers, the losses only included the condensate of water leaving the separators, as given by Eq. (5).

$$\dot{E}_{\mathrm{L}} = \sum \dot{E}_{\mathrm{liq,out}} \tag{5}$$

A set of exergy performance indicators can be defined to evaluate individual components and the system as a whole. An exergy destruction ratio (γ_{D}) was defined for each component and on a system level, see Eq. (6) [22]. An exergy loss ratio (γ_{L}) was similarly defined for each material stream considered as a loss and on a system level as seen in Eq. (7). An exergy efficiency (ε) was defined for all non-dissipative components and on a system level and was given as the ratio of the exergy product rate to the exergy fuel rate: $\varepsilon = \dot{E}_{\mathrm{P}}/\dot{E}_{\mathrm{F}}$. For the dissipative components, no exergy efficiency was defined.

$$\text{component level}: \quad \gamma_{\mathrm{D}} = \frac{\dot{E}_{\mathrm{D}}}{\dot{E}_{\mathrm{D,sys}}}, \qquad \text{system level}: \quad \gamma_{\mathrm{D,sys}} = \frac{\dot{E}_{\mathrm{D,sys}}}{\dot{E}_{\mathrm{F,sys}}} \tag{6}$$

$$\text{stream level}: \quad \gamma_{\mathrm{L}} = \frac{\dot{E}_{\mathrm{L}}}{\dot{E}_{\mathrm{L,sys}}}, \qquad \text{system level}: \quad \gamma_{\mathrm{L,sys}} = \frac{\dot{E}_{\mathrm{L,sys}}}{\dot{E}_{\mathrm{F,sys}}} \tag{7}$$

2.4. Economic analysis

For each component, the purchased equipment cost (PEC) was estimated by the cost relation in Eq. (8) [22]. The PEC of a component with a given size (X) was estimated using the list price of a similar component (denoted z) with a known size. The scaling exponent (α) is specific for each component type and is given in Table 5. The PEC of the reference components are presented in Table 6. All monetary values are given in 2022€.

$$\mathrm{PEC} = \mathrm{PEC}_z \left(\frac{X}{X_z} \right)^{\alpha} \tag{8}$$

Table 5: Scaling exponents used for different types of components.

Component type	**Scaling exponent** (α)	**Source**
Compressors	0.77	[24]
Pump	0.59	[25]
Heat exchangers with CO_2 or water	0.78	[25]
External cooler with air	0.39	[25]
Gas-liquid separators	0.30	[22]

To account for additional costs besides the investment of the component, the PEC was adjusted to a total capital investment of TCI = 4.16 · PEC [22]. The levelised cost rate associated with the capital investment ($\dot{Z}^{\mathrm{CI}}$) was then given by Eq. (9). Here, the TCI was discounted and annualised using a real discount rate (i) of 3 % and a lifetime (L) of 25 years. An annual operating time (H) of 8000 h was assumed. The cost rate of operation and maintenance was given by $\dot{Z}^{\mathrm{OM}} = 0.15 \cdot \dot{Z}_k^{\mathrm{CI}}$ [25]. The total costs associated with owning a component ($\dot{Z}$) was the sum of capital investment and operation and maintenance: $\dot{Z} = \dot{Z}^{\mathrm{CI}} + \dot{Z}^{\mathrm{OM}}$.

$$\dot{Z}^{\mathrm{CI}} = \frac{\mathrm{TCI}\left(\frac{i(1+i)^L}{(1+i)^L-1}\right)}{H\,3600\mathrm{sh}^{-1}} \tag{9}$$

The electricity price was assumed to be 0.08 €kWh^{-1} based on [29] and [30]. The cost of the cooling media was 7.83 €kWh^{-1} and was calculated from the TCI and operational costs of a drycooler required to discharge the heat to the surroundings. The entering gaseous CO_2 and the entering DH water were assumed to be free of charge.

Table 6: Purchased equipment cost and size of reference component for all components in the system. Component names refer to Fig. 2.

Component	PEC of reference [€]	Size of reference (X)	Source
COMP1, COMP2, COMP3	34 393	150.5 m^3h^{-1}	[26]

Range of cost function: *0.07 m^3 to 150 m^3, †8.3 m^2 to 373 m^2. It was assumed that prices were still representative.

2.5. Exergoeconomic analysis

An exergoeconomic analysis is a way to determine cost flows throughout a thermal energy system and to investigate how inefficiencies in the system affect the cost of the final product [22]. The cost rates ($\dot{C}$) were determined throughout the system, and are given as the product of the average cost per unit of exergy (c) and the exergy flow rate: $\dot{C} = c \cdot \dot{E}$ [22]. The cost balances applied to all types of components are given in Table 7. Auxiliary cost equations were made for components with more than one exiting exergy stream using the product and fuel principles according to the approach in [23]. The cost balances of dissipative components (coolers, mixer, and valves) were adjusted so that all costs were assigned to an auxiliary variable ($\dot{C}_{\mathrm{dif,dc}}$), which was added to the final product. The costs of all loss streams were set to 0 €s^{-1} in the analysis, thereby the costs were assigned directly to the overall product. On a system level, the economic value of the losses was estimated by assuming an overall constant product rate and that changes in losses result in changes in the fuel supply: $\dot{C}_{\mathrm{L}} = c_{\mathrm{F}} \cdot \dot{E}_{\mathrm{L}}$, where c_{F} is the average cost per unit of exergy fuel. A similar assumption was used for estimating the costs of exergy destruction: $\dot{C}_{\mathrm{D}} = c_{\mathrm{F}} \cdot \dot{E}_{\mathrm{D}}$ [22].

The cost balance of the general form: $\dot{C}_{\mathrm{P}} = \dot{C}_{\mathrm{F}} + \dot{Z}$ was applied on a system level with the definitions of product and fuel costs given in Table 8. For the systems with DH integration, the cost rate of the total product was given as the sum of the cost rate of CO_2 and DH production: $\dot{C}_{\mathrm{P}} = \dot{C}_{\mathrm{P,CO2}} + \sum \dot{C}_{\mathrm{P,DH}}$. The definition of product and fuel exergy used for the external coolers was the same in both the baseline system and with DH integration, as this allowed for allocation of the component costs to both DH production and the CO_2. When DH was produced

Table 7: Cost balances and auxiliary equations for each component. Component names refer to Fig. 2.

Component type	Cost balance	Auxiliary equation (*F/P principle*)
COMP	$\dot{C}_{\mathrm{out}} = \dot{C}_{\mathrm{in}} + \dot{C}_{\mathrm{w}} + \dot{Z}$	–

GC	$\dot{C}_{\mathrm{dif,dc}} + \dot{C}_{\mathrm{ref,out}} = \dot{C}_{\mathrm{ref,in}} + \dot{C}_{\mathrm{w}} + \dot{Z}$	(F) $c_{\mathrm{ref,in}} = c_{\mathrm{ref,out}}$
MIX	$\dot{C}_{\mathrm{dif,dc}} + \dot{C}_{\mathrm{out}} = \dot{C}_{\mathrm{hot,in}} + \dot{C}_{\mathrm{cold,in}} + \dot{Z}$	(F) $c_{\mathrm{out}} = \frac{\dot{E}_{\mathrm{hot,in}} c_{\mathrm{hot,in}} + \dot{E}_{\mathrm{cold,in}} c_{\mathrm{cold,in}}}{\dot{E}_{\mathrm{hot,in}} + \dot{E}_{\mathrm{cold,in}}}$
VAL	$\dot{C}_{\mathrm{dif,dc}} + \dot{C}_{\mathrm{out}} = \dot{C}_{\mathrm{in}} + \dot{Z}$	(F) $c_{\mathrm{in}} = c_{\mathrm{out}}$

Table 8: Cost flow rates for the overall system.

System	$\dot{C}_F$	$\dot{C}_{P,CO2}$	$\dot{C}_{P,DH}$
Baseline	$\sum \dot{C}_w + \sum \dot{C}_{COOL,in}$	$\dot{C}_{CO2,out} + \sum \dot{C}_{dif,dc}$	–
DH integration	$\sum \dot{C}_w$	$\dot{C}_{CO2,out} + \frac{\dot{E}_{CO2,out} - \dot{E}_{CO2,in}}{\dot{E}_P} \sum \dot{C}_{dif,dc}$	$\dot{C}_{COOL,out} + \frac{\dot{E}_{COOL,out} - \dot{E}_{COOL,in}}{\dot{E}_P} \sum \dot{C}_{dif,dc}$

in a cooler, the fuel principle was applied to both the CO_2 stream and the DH water stream, to keep all costs in the auxiliary variable. The allocation of the total sum of $\dot{C}_{dif,dc}$ was made using the exergy value of the CO_2 product and DH as weighting factors in the absence of other valuation methods.

A set of exergoeconomic performance indicators were defined to evaluate the system. The relative cost difference (r) indicates the increase in average cost per exergy unit between fuel and product of a productive component or system, relative to the average cost of fuel supplied [22]. It is given by Eq. (10), here c_P is the average cost per unit of exergy product.

$$r = \frac{c_P - c_F}{c_F} = \frac{1-\varepsilon}{\varepsilon} + \frac{\dot{Z}}{c_F \dot{E}_P} \tag{10}$$

An exergoeconomic factor (f) was defined, as given in Eq. (11). It is the ratio between the costs coming from investment and operation to the total costs of the component or system. By using this factor, the dominating source of costs in a component can be evaluated [22]. Since costs of losses were only considered on a system level, the last term of the denominator was omitted on a component level.

$$f = \frac{\dot{Z}}{\dot{Z} + \dot{C}_D + \dot{C}_L} \tag{11}$$

3. Results

3.1. Baseline system

The baseline system had a total power consumption of 210 kW and a cooling load on the refrigeration cycle of 177 kW. Furthermore, the total cooling load in COOL1 and COOL2 was 137 kW. The total capital investment of the system was 1.7 M€. The results of the exergy and exergoeconomic analyses of the baseline system are shown in Table 9. The greatest exergy destruction was seen in the compressors and the GC, with the three highest rates of exergy destruction in COMP4 (15.1 kW), COMP1 (14.2 kW), and the GC (14.2 kW). The four compressors accounted for 56 % of the exergy destruction in the system, while the GC accounted for 14 %. Less significant contributions were found in the LIQHEX, COOL1, COOL2, VAL1, and VAL2 ranging between approx. 3 % to 8 %, while the remaining components each contributed less than 1 % to the overall exergy destruction. The results for the PUMP and the MIX were excluded from Table 9 as these components only accounted for a total of less than 0.4 % of the total exergy destruction, and less than $6 \cdot 10^{-3}$ % of the total capital investment.

The results for all material streams considered as losses are seen in Table 10. The greatest exergy losses were discharged in the GC (9.9 kW) and COOL1 (7.6 kW) accounting for 32 % and 24 % of the total losses, respectively. Losses related to cooling accounted for 85 % of the total losses in the system, while the removal of water constituted the remaining 15 %. On a system level, an exergy efficiency of 39 % was found, while 46 % of the fuel exergy being supplied was destroyed through irreversibilities in the system. The exergy losses constituted 15 % of the fuel supply on a system level.

The results of the exergy analysis indicated that the performance of the system could be improved by reducing exergy destruction, with the highest reduction potential seen in compressors and the GC and somewhat lower reduction potentials in the LIQHEX, COOL1, and COOL2. By increasing the efficiencies of compressors and decreasing the temperature difference in the LIQHEX, the exergy efficiency of the system could be directly improved. However, an improvement of the GC, COOL1, and COOL2, would reduce the destruction in these components while increasing the exergy losses. The temperature of the working media at the outlet of the components would in such case decrease and therefore a greater cooling load would be needed in the components, resulting in a greater discharge of heat to the cooling media. The analysis also showed a potential for utilising losses associated with cooling, as approx. 13 % of the fuel supply was lost in the cooling water.

Table 9: Exergy and exergoeconomic results of the baseline system. Component names refer to Fig. 2.

The results of the exergoeconomic analysis seen in Table 9 showed that the highest cost sources were the compressors and the GC, as these components had both relatively high costs associated with exergy destruction and capital investment. The CO_2 product compressors, COMP1 and COMP2, showed high relative cost differences of 250 % and 130 % meaning that the specific cost of the product stream was significantly increased compared to the fuel costs in these two components. Furthermore, COMP1 and COMP2 showed exergoeconomic factors of 86 % and 73 %, respectively, indicating that the highest cost sources in these components were capital investment. The relative cost increase in COMP3 and COMP4 of 74 % were less significant. The costs of irreversibilities and capital investment in these two components were well balanced with exergoeconomic factors of 47 % and 52 %, respectively. Looking at the heat exchangers in the system, these were generally dominated by costs associated with exergy destruction, with the greatest contributions in the GC, COOL1, COOL2, and COOL3 showing exergoeconomic factors ranging between 2 % to 14 %. At a system level, the cost rate of the product was 32 €h^{-1}, corresponding to 18.3 €t^{-1} CO_2 at the liquid product mass flow rate of 1.77 th^{-1}. The exergoeconomic factor of the overall system was 56 % indicating, that the costs associated with capital investment and inefficiencies were balanced.

The exergoeconomic analysis showed that the components in which fuel was supplied to the system were of most importance for the overall costs. The analysis indicated that the overall product cost could be reduced if the costs associated with the CO_2 product stream compressors, COMP1 and COMP2, were decreased. The

greatest cost contribution in these components was the capital investment, therefore, this could be decreased to potentially reduce the costs of the overall product. The external coolers showed moderate cost contributions stemming from inefficiencies. However, a reduction in exergy destruction and thereby costs associated with inefficiencies would result in increased costs of exergy losses. An alternative way of reducing the costs of inefficiencies in the external coolers could be to reduce the average cost of fuel supply to the components. This could be done if the costs of the available cooling media could be reduced.

3.2. Integration of district heat

Based on the results of the exergy and exergoeconomic analyses, it was chosen to implement DH in the external coolers to utilise the exergy loss associated with cooling and to eliminate the costs of the cooling water. The effects on the overall system costs were evaluated when DH was integrated in all coolers (COOL1, COOL2, COOL3, and the GC) and when it was only integrated in the intercoolers (COOL1, COOL2, and COOL3).

The results of the exergy and exergoeconomic analyses for the overall systems are presented in Table 11. It is seen, that the overall exergy product was increased for both DH integration options compared to the baseline system because the heating of water was now considered a product for the overall system. Therefore, the total losses were reduced to 5.0 kW and 16 kW when implementing DH in all external coolers and only in intercoolers, respectively. As a consequence, also the exergy efficiency increased for both integration options, with the highest exergy efficiency seen for the system with DH integration in all coolers because this option also utilised the heat discharged in the GC. The cooling was provided at a higher temperature with DH water. Therefore, an increase in exergy destruction was seen for both integration options which was primarily caused by increased exergy destruction in compressors and in the LIQHEX, because the temperatures at the component inlets increased. A significantly higher total exergy destruction was seen for the integration of DH in all coolers. This was caused by an increase in the optimal high pressure in the refrigeration cycle when the GC should use DH water for cooling (see Section 2.1). This significantly increased the load on COMP4, and also increased the throttling losses in VAL1.

Considering the overall system costs in Table 11, it was seen that the costs of the total system increased 11 % to 36 €h^{-1}, when DH was integrated in all coolers. This was caused by the increase of the high pressure in the refrigeration cycle, resulting in higher electricity consumption in compressors. This was also seen from the higher cost of exergy fuel of 22 €h^{-1}. The costs of the total system remained constant when DH was only implemented in intercoolers. In this integration option, the costs associated with cooling water were eliminated and outweighed the increased power consumption of compressors, meaning that the overall fuel costs remained closed to constant. The increased temperature at the suction line of COMP2 and COMP4 increased the volume flow rates, which led to greater component sizes and increased capital investment. This resulted in a cost rate of capital investment of 14.3 €h^{-1} when DH was integrated in intercoolers. For the alternative option, the capital investment showed an overall small decrease to 13.9 €h^{-1} which was caused by the GC being significantly smaller when water was used as cooling media.

When considering the costs assigned to the liquefaction and purification of CO_2, it was reduced for both implementation options. For the system with DH integration in all coolers, the CO_2 product cost was found to be $\dot{C}_{P,CO2}$ = 31.1 €h^{-1}, while it was $\dot{C}_{P,CO2}$ = 30.9 €h^{-1} when only integrating DH in existing water coolers. These costs corresponded to a specific cost of liquefaction and purification of 17.6 €t^{-1} CO_2 and 17.5 €t^{-1} CO_2, respectively. The remaining costs were assigned to the DH product. The total DH production was 168 kW at 10.1 €MWh^{-1} and 160 kW at 9.2 €MWh^{-1} when implementing DH in all coolers and only in intercoolers, respectively.

The results showed that integration of DH in the existing water coolers could be made without increasing the costs of the overall system, when assuming that the DH operators would pay for additional components needed to operate the DH. The increase in available cooling temperature increased the power consumption and the required size of the subsequent compressors, which increased the costs associated with these components. However, the costs associated with cooling were reduced, thereby reducing the costs stemming from ineffi-

Table 11: Exergy and exergoeconomic results for systems with DH integration.

DH integration	$\dot{E}_F$ [kW]	$\dot{E}_P$ [kW]	$\dot{E}_D$ [kW]	ε [%]	γ_D [%]	$\dot{C}_F$ [€h^{-1}]	$\dot{C}_P$ [€h^{-1}]	$\dot{C}_D$ [€h^{-1}]	$\dot{Z}$ [€h^{-1}]	r [%]	f [%]
COOLs and GC	272	137	130	50.2	48	22	36	11	13.9	220	56
COOLS only	224	101	107	45.2	48	18	32	8.6	14.3	300	59

ciencies in the system. The results also showed that integration of DH in the GC increased the overall system costs, due to an increased load on the high-pressure compressor. Therefore, this integration option would only be more feasible than the baseline system, if the revenue from DH sales was greater than the additional costs of the electricity consumption.

4. Discussion

The definitions of product and fuel for all components were chosen as total exergy streams. In some components and on the system level it would be more correct to divide the streams of exergy into thermal, mechanical, and chemical parts. As an example, the correct product definition of the CO_2 liquefaction and purification would be the sum of the thermal exergy in the liquid outlet stream and the increase in mechanical and chemical exergy from inlet to outlet, while the thermal exergy in the gaseous inlet stream should be considered as a fuel. This would give a negligible increase in the overall exergy product rate to 85 kW and the exergy efficiency to 39.7 %. It would result in a slightly lower product cost rate, as the costs of fuel and capital investment would not be affected by a split in exergy streams. Furthermore, it would affect the systems with DH integration in a similar way. The higher level of detail would significantly increase the computational effort of the model, and would not affect the overall conclusions of the study.

The cost balances for the external coolers were the same for both the baseline system and the systems with DH integration, even though a useful exergy product could be defined with DH integration. This approach allowed for allocation of the cooler costs between the liquefaction and purification of CO_2 and the DH production. Alternatively, all costs could be assigned to the DH product in each cooler. This would not affect the overall costs of the system, but reduce the costs assigned to the liquefaction and purification of CO_2. Furthermore, alternative methods for allocation of the costs could be used, which could distribute the costs of coolers and dissipative components in a different way between the DH product and the CO_2 product.

In both systems with DH integration, it was expected that the DH can generate positive revenue. DH integration in intercoolers would make the system more economically feasible than the baseline system, while the revenue from DH should at least exceed the additional expenses when implementing DH in all coolers. The additional costs of this system corresponded to a minimum selling price of DH of 21 €MWh^{-1}. In 2022, around 100 of the Danish DH networks had heat prices higher than 21 €MWh^{-1} [31], assuming that the heat price constituted 25 % of the price paid by consumers [32]. This indicated that the feasibility of integrating DH in all coolers depends on the local DH network. To make the conclusions on DH integration more robust, a sensitivity analysis of the ambient temperature and the yearly operating hours of the plant could be made.

The analysis also showed that the compressors were a major cost source. If the components of the systems should be changed, these should be of focus. In the systems with DH integration, it could also be beneficial to improve the performance of the coolers, as these showed moderate costs associated with inefficiencies. This would increase DH production and revenue. It would also result in a reduction of the exogenous contribution to exergy destruction in COMP2, COMP4, and the LIQHEX because the temperature at the inlet of these components would be reduced. To investigate the interdependencies between components, it could be of interest to perform an advanced exergy analysis [33]. In the present study, it was assumed that all water was removed from the CO_2, however, the amount of water that can be removed by condensation is limited by the temperature of the available cooling water. It would be relevant to also consider this influence when evaluating the effect of DH integration.

5. Conclusion

An exergoeconomic analysis of a system for liquefaction and purification of CO_2 was made. The system consisted of two-stage compression with intercooling and an external two-stage refrigeration cycle used for liquefaction. The analysis showed an exergy efficiency of 39 %, while 15 % of the supplied exergy fuel was considered as losses with the dominating part associated with external cooling. The compressors throughout the system were responsible for 56 % of the total exergy destruction and were found to be the most significant for costs. The analysis suggested that the capital investment of the two-stage compressors in the CO_2 product stream should be reduced to reduce the costs of the overall process.

It was found that integration of DH could increase the exergy efficiency to 45 % and 50 % and that the highest efficiency was achieved when all external coolers were used for DH production. However, it was seen that implementation of DH in the gascooler of the refrigeration cycle resulted in an 11 % increase in the total system costs, while DH could be integrated only in the water coolers without affecting the total costs of the system. Integration of DH increased the costs associated with compressors but reduced the costs of cooling. The analysis of the initial system also suggested that the performance of the coolers should be improved, which was expected to have a positive impact on the overall system only if DH was integrated. The study showed, that production of DH from the waste heat of the liquefaction and purification process could potentially have a positive economic impact on the system and that this was depending on the choice of integration.

Nomenclature

Roman Letters

$\dot{C}$	Cost rate [€s^{-1}]
$\dot{E}$	Exergy flow rate [kW]
$\dot{m}$	Mass flow rate [kgs^{-1}]
$\dot{Q}$	Heat transfer rate [kW]
$\dot{V}$	Volumetric flow rate [m^{3}s^{-1}]
$\dot{W}$	Power [kW]
$\dot{Z}$	Cost rate of owning component [€s^{-1}]
A	Area [m^2]
c	Average cost per exergy unit [€kJ^{-1}]
e	Specific exergy [kJkg^{-1}]
f	Exergoeconomic factor [%]
H	Annual operating hours [h]
h	Specific enthalpy [kJkg^{-1}]
i	Real interest rate [%]
L	Lifetime [y]
r	Relative cost difference [%]
s	Specific entropy [kJ(kgK)$^{-1}$]
T	Temperature [℃]
U	Overall heat transfer coefficient [kW(m^{2}K)$^{-1}$]
v	Velocity [ms^{-1}]
X	Primary design variable
y	Mass fraction [–]

Greek Letters

α	Scaling exponent [–]
η	Efficiency [%]
γ	Exergy ratio [–]
ε	Exergy efficiency [%]

Subscripts and superscripts

n	Chemical component
0	Reference state
a	air
CH	Chemical
CI	Capital investment
cross	Cross-sectional
D	Destruction

Clear paths to teach exergy

Daniel Favrat[a], Malick Kane[b],

[a] Ecole Polytechnique Fédérale de Lausanne (energy center), Lausanne, Switzerland, daniel.favrat@epfl.ch

Abstract:

This paper proposes a clear path to the exergy balance by subtracting the second Law balance (multiplied by Ta) to the first Law that let appear all the exergy terms. In each exergy terms it is shown that it is essential to clearly distinguish the process-dependent entities from the state functions and how the latter can be visualized in parametric representations including 3D. An opportunity is shown to superpose the various dead states (thermo-mechanical or physicochemical equilibrium). The typical First Law indicators (Effectiveness, coefficient of performance) are compared with the corresponding exergy efficiency for integrated processes including house heating with cogeneration and heat pumps or the valorization of LNG evaporation. From this strong basis the development of both First Law and Exergy efficiencies is shown for a variety of systems providing different energy services in the whole range of temperatures. A much greater coherence of the exergy approach for modern systems including co-or tri-generation is highlighted. The power of the notion of exergy efficiency is further illustrated by comparing various heating or air-conditioning energy systems in urban areas with the possibility to multiply the exergy efficiency of the subsystems to get a coherent ranking of the active technology options. Ultimately, we briefly show how one specific emerging platform (nolej) based on AI could simplify the work of teachers in thermodynamics in general.

Keywords:

Thermodynamics; Teaching; Exergy; Entropy; Exergy efficiency; Effectiveness.

1. Introduction

Exergy is too complicated! That is the too frequent comment coming from practitioners or even physics colleagues. One potential explanation is the fact that, to start with, the entropy concept is often not well understood. In many studies in physics, entropy is essentially introduced in relation to closed system. However, most of the energy systems the engineers deal with, are open systems with the importance of considering the entropy of the masses transiting through the boundaries of the system. As a matter of fact, when asked if they, themselves, have seen their own entropy increase in average during the last year, many would answer yes instead of considering that it is vital for them to keep their entropy constant (at least at constant weight!!). They are also unable to explain why human can still live by 45°C atmospheric temperature or more, while their own body is at 37°C. Heat transfer is not the only way to get rid of one's entropy creation.

One second potential explanation is that while, in the First Law of thermodynamics, the distinction between state functions and process-dependent entities is clearly done with differentiated names, it is often not done with the exergy balance where all terms are called exergy.

One third potential explanation is that the exergy efficiencies, in particular for combustion systems, are numerically much lower than the performance indicators based on the First Law of thermodynamics, reason why the practitioners do not like it. This is in particular relevant for condensing fuel boilers, where First Law "efficiencies" are sometimes quoted with values above 100% due to their use of the Lower Heating Value to characterize the fuel energy input while they condense part of the vapor produced during combustion.

Other obstacles might also be a confusion with the many First Law performance indicators that exist (engine efficiency, efficiency based on Lower Heating Value or on Higher Heating Value, heating coefficient of performance, cooling coefficient of performance) that can be replaced by a single indicator, the exergy efficiency. Also comes into play the potential maximum work that is easily associated to work but not well understood for the other energy outputs like those linked to exiting masses.

2. Exergy balance

2.1. Definition of exergy

The historical path that resulted in a correct and complete interpretation of the First and Second Laws of thermodynamics and their implications has been a lengthy one. It ultimately led to the following definition of exergy, a fundamental concept in the modern approach of the management and proper use of energy:

Exergy: the potential of maximum work that could ideally be obtained from each amount of energy being transferred or stored, using reversible cycles with the environment (atmosphere) as one of the energy sources, either hot or cold.

2.2. Equation of exergy balance

Let us look at a given system surrounded by an environment characterized by its temperature T_a and its pressure P_a.

The First Law of thermodynamics (energy balance) is given by:

Energy storage work heat energy of transiting masses

$$\frac{d(U_{cz}+P_aV)}{dt} = \sum_k \dot{E}^+_{wk} + \sum_i \dot{Q}^+_i - \dot{Q}^-_a + \sum_j \dot{M}^+_j h_{cz_j} \quad (1)$$

Or to express the energy conservation:

$$\sum_k \dot{E}^+_{wk} + \sum_i \dot{Q}^+_i - \dot{Q}^-_a + \sum_j \dot{M}^+_j h_{cz_j} - \frac{d(U_{cz}+P_aV)}{dt} = 0 \quad (2)$$

$$\underbrace{\sum_k \dot{E}^+_{wk} + \sum_i \dot{Q}^+_i - \dot{Q}^-_a + \sum_j \dot{M}^+_j h_{cz_j} - \frac{d(U_{cz}+P_aV)}{dt}}_{\dot{Y}^+} = 0$$

Power transformation

The state functions U_{cz} and h_{cz_j} are defined here as:

$$U_{cz} = U + M\frac{C^2}{2} + MgZ \quad (3)$$

$$h_{cz_j} = h_j + \frac{C_j^2}{2} + gZ_j \quad (4)$$

Where U_{cz} is the total internal energy including the internal energy *U*, as well as the kinetic and potential energies. h_{cz_j} is the total enthalpy per unit mass of the flowing fluid including the specific enthalpy *h* as well as the specific kinetic and potential energies at the specified state *j*.

The specific enthalpy *h* accounts for the specific internal energy and the specific work required to push it into or out of the system, *C* represents the absolute velocity and *Z* the altitude. In most practical cases the kinetic and potential terms can be neglected, except when the conditions vary significantly through time or in off-design conditions.

In the above equations, the entities $\dot{E}^+_w, \dot{Q}^+, \dot{M}^+$ can be numerically positive or negative using the convention positive entering indicated by the exponent $()^+$. This allows very compact formulations of the laws. (Later when defining the performance indicators requiring only numerically positive terms the convention positive exiting $()^-$ will also be introduced for some entities).

- $\dot{E}^+_w$ represents the mechanical energy rate ("work") given to or retrieved from the system (through volume change or rotating shaft for examples),
- $\dot{Q}^+$ represents the heat rate entering or retrieved from the system from any hot source different from the atmosphere,
- $\dot{M}^+$ is the input or output (fluid) mass flow of the system,

The notion of *power transformation* $\dot{Y}$ introduced here allows to group all terms concerned with similar masses in networks [1], making sure that the thermodynamic references are coherent, and allowing a simpler definition of the energy services received or provided. A network groups all the masses in a subsystem that are in direct contact with each other. For example, a simple heat exchanger has two networks, one for the fluid being heated and one for the fluid being cooled.

The Second Law of thermodynamics is given by:

Entropy storage entropy of heat entropy of masses entropy creation

$$\frac{dS}{dt} = \sum_i \frac{\dot{Q}^+_i}{T_i} - \frac{\dot{Q}^-_a}{T_a} + \sum_j \dot{M}^+_j s_j + \dot{S}^i \quad (5)$$

Where:

- S is the entropy of the system and is a state function while *s* is a specific state function attached to each mass of the system or moving through its boundary.

- $\dot{S}^i$ is the creation of entropy inside the system, exponent i for internal or irreversibility, and is not a state function but a process-dependent entity. As such $\dot{S}^i$ cannot be determined at a time t, since it needs to be integrated over a time lapse like for work or heat.

In both formulas, the energy or entropy exchanges with the surrounding (atmosphere) have been separated from the other entities, in the same way as Carnot did not include them in his definition of the Carnot efficiency. In quasi-steady operation of open systems, the time derivatives of the state functions *S*, U_{cz} and *V* are equal to 0. However, it is not the case for the rate of entropy creation $\dot{S}^i$ since it is not a state function but a process-dependent entity, that requires an integration over time to be quantified. Equation 2 then allows to highlight that any open system needs, not only a cold source but an entropy bin for the entropy of both the heat and the entropy of masses crossing the boundary to compensate for its entropy creation. In quasi-steady operation the entropy of an adiabatic steam turbine does not change, thanks to the fact that the exiting steam has a higher entropy and therefore carry with it the entropy creation occurring in the turbine itself. The same applies to humans or other living creatures that can get rid of their entropy creation through mass transfer [2,3].

Let us multiply the two members of the entropy balance of Equ. (5) by the environmental (atmospheric) temperature T_a so that each term is expressed in energy per unit of time (W), like in the energy balance. Furthermore, since entropy is not conserved in real processes, the term of entropy creation is moved to the right member of the equation:

$$T_a \sum_i \frac{\dot{Q}_i^+}{T_i} - \dot{Q}_a^- + T_a \sum_j \dot{M}_j^+ s_j - T_a \frac{dS}{dt} = -T_a \dot{S}^i \qquad (5)$$

Subtracting the latter from the energy balance (Equ. (2)) leads to the ***exergy balance*** for a system including n networks:

$$\sum_k \dot{E}_{wk}^+ + \sum_i \dot{Q}_i^+ - \dot{Q}_a^- + \sum_j \dot{M}_j^+ h_{cz_j} - \frac{d(U_{cz} + P_a V)}{dt} = 0$$

$$-\left\{ T_a \sum_i \frac{\dot{Q}_i^+}{T_i} - \dot{Q}_a^- + T_a \sum_j \dot{M}_j^+ s_j - T_a \frac{dS}{dt} = -T_a \dot{S}^i \right\}$$

$$\sum_k \dot{E}_{wk}^+ + \sum_i \left(1 - \frac{T_a}{T_i}\right) \dot{Q}_i^+ + \sum_n \left[\sum_j \dot{M}_j^+ (h_{cz_j} - T_a s_j) - \frac{d(U_{cz} + P_a V - T_a S)}{dt} \right] = T_a \dot{S}^i \qquad (6)$$

Coenthalpy coenergy

Work exergy Heat exergy Flow exergy Storage exergy Exergy loss

Exergy transformation $\dot{E}_y^+$ for each of n network

In Equ. (6) all the terms are now ***exergy*** terms in the same way as all the terms of the First Law are energy terms. However, there is the need to clearly differentiate between state functions and process-dependent entities with a clear denomination. For systems with only work exchange and heat exchanges, these state functions can be expressed as a function of two other state functions (in a given atmosphere for exergy state functions)

Table 1. State functions

First Law and Second state functions	Exergy state functions
Internal energy *U* or *u*	*Coenergy* $J = U + P_aV - T_aS$ or $j = u + P_av - T_as$
Total internal energy U_{cz} or u_{cz}	Total coenergy $J_{cz} = U_{cz} + P_aV - T_aS$ or $j_{cz} = u_{cz} + P_av - T_as$
Enthalpy *H* or *h*	Coenthalpy $K = H - T_aS$ or $k = h - T_as$
Total enthalpy H_{cz} or h_{cz}	Total coenthalpy $K_{cz} = H_{cz} - T_aS$ or $k_{cz} = h_{cz} - T_as$

The rate of mechanical (or electric) energy, $\dot{E}_w^+$, represents a transfer of energy of the highest thermodynamic quality, such as technical work or electricity, with the system, and as long as such a transfer is done without friction.

According to the definition of exergy given in the introduction, the quantitative values of energy and exergy, for mechanical work or electricity for example, $\dot{E}_w^+$, are identical. Let us emphasize that, in this paper, the E_w terms represent the energy terms with the highest potential to provide all kinds of energy services (in this case, equivalent in quantity to exergy). Therefore, it applies to work or electricity terms. The letter *E*, contrary to many books, is not used to express the total internal energy, which is defined here as U_{cz}. In most practical cases the kinetic and potential terms can be neglected, except when the conditions vary significantly through time or space, or in off-design conditions. This way of writing has also the advantage that the same subscript $()_{cz}$ can be applied to the total enthalpy by symmetry.

The ***heat exergy*** term $(1 - T_a/T_i)\dot{Q}_i^+$ is the work equivalent of the thermal energy given to the system from a heat reservoir at temperature T_i different from T_a. This expression highlights the multiplicative factor $(1 - T_a/T_i)$ that is nothing other than the so-called *Carnot factor*. This one determines the maximum work that can be produced from a heat rate $\dot{Q}_i^+$ at temperature T_i when working in an environment at temperature T_a (*Carnot cycle*) with $T_i > T_a$. One key element that needs to be highlighted is that as soon the temperature of the source at T_i is below T_a then $\dot{E}_q^+$ becomes numerically negative which means that for the system to accept heat, it must provide work, like typically for cooling or refrigeration.

The ***flow exergy*** term $\dot{M}^+(h_{cz} - T_a s)$, in the absence of chemical reactions, is the maximum work that can be recovered if the considered flow is reversibly brought to a thermal and mechanical equilibrium with the atmosphere. This fact is not obvious at first sight and deserves a demonstration. Figure 1 illustrates the reversible processes that could be used to verify that this expression is the maximum potential work that can be recovered. Those consist first of an isentropic expansion in a turbine until the exit temperature corresponds to T_a, followed by a further expansion in an isothermal turbine until P_a is reached.

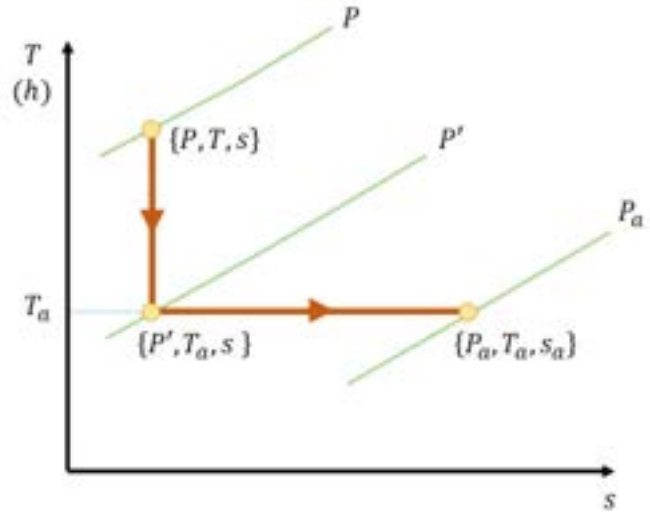

Figure 1. Reversible processes to illustrate that the coenthalpy ($k = h - T_a s$) corresponds to the maximum specific work (exergy) that can be recovered from a mass flow.

The ***storage exergy term,*** *the total coenergy* $J_{cz} = U_{cz} + P_a V - T_a S$ is the maximum work that is stored in the system and could be recovered at a later stage. It accounts for the internal energy (*U*), including the kinetic and potential energy (*cz*), and the mechanical exergy linked to the exchange at the flexible system boundary (like with a piston) with the atmosphere. Again, this concept is not obvious and needs a demonstration to accept it.

Figure 2 illustrates in a (T-s) diagram the reversible processes that could be used to verify that this expression is the maximum potential work that can be recovered from a mass stored in the system. Those consist first of an isentropic expansion in an expander until the exit temperature corresponds to T_a, followed by a further expansion in an isothermal heated expander until P_a is reached. The term $T_a s$ corresponds to the heat received from the atmosphere during these processes. Finally, if the downstream pressure in a general case does not correspond to the atmospheric pressure, then an isentropic compressor might be required as illustrated in Figure 2. Releasing or capturing heat to or from the atmosphere does not, in-itself, imply any exergy exchange since $T = T_a$ and the Carnot factor is null. When it comes to $P_a V$ it should be easy to understand that when the piston of an engine moves downwards, some of the work from the expanding gas is used to push the surrounding atmosphere ($-P_a\, dV$) but is recovered when the piston goes up, the atmosphere helping. Therefore, it is a true form of energy storage and can be associated to any of the networks in the system.

The ***exergy loss term*** $T_a \dot{S}^i = \dot{L}$ includes all the exergy losses taking place in the system.

In the same way that the notion of *power transformation* was introduced in the First Law, the corresponding notion of *exergy transformation* grouping the flow exergy and storage exergy terms for each network is also quoted.

Demonstration that the exergy transformation between two different pressures of a gas bottle corresponds to the maximum work that could be retrieved. This case of energy storage with an inert gas, like air, initially pressurized, can be represented by the cylinder-piston device of Figure 2. Equations are the same as for the case of Figure 1 except that the end point is not the state of the atmosphere and we have thus to add a compression process from 2' to 2. The kinetic and potential energies $()_{cz}$ are neglected.

a) *isentropic* expansion in an adiabatic expander from $\{P_1, v_1, T_1, s_1\}$ to $\{P_{1'}, v_{1'}, T_a, s_1\}$, that is until the temperature T_a is reached:

$$E_w^- = -(U_{1'} - U_1) - P_a(V_{1'} - V_1) = -M\big((u_{1'} - u_1) - P_a(v_{1'} - v_1)\big) \tag{7}$$

b) *isothermal* expansion in a diabatic compressor from $\{P_{1\prime}, v_{1\prime}, T_a, s_1\}$ to $\{P_{2\prime}, v_{2\prime}, T_a, s_2\}$, heat being received from the atmosphere:

$$E_w^- = -(U_{2'} - U_{1'}) + Q_a^+ - P_a(V_{2'} - V_{1'}) = (U_{1'} - U_{2'}) + T_a(S_2 - S_1) + P_a(V_{1'} - V_{2'}) \quad (8)$$

c) *isentropic* compression in an adiabatic compressor from $\{P_{2\prime}, v_{2\prime}, T_a, s_2\}$ to $\{P_2, v_2, T_a, s_2\}$:

$$E_w^+ = (U_2 - U_{2\prime}) + P_a(V_2 - V_{2\prime}) \quad (9)$$

Hence the maximum work that can be recovered is:

$$E_{wmax}^- = -(U_{1'} - U_1) - P_a(V_{1'} - V_1) + (U_{1'} - U_{2'}) + T_a(S_2 - S_1) + P_a(V_{1'} - V_{2'})\ (U_2 - U_{2'}) + P_a(V_2 - V_{2'})$$
$$= (U_1 - U_2) - T_a(S_1 - S_2) + P_a(V_1 - V_2) = J_1 - J_2 = E_y^- \quad (10)$$

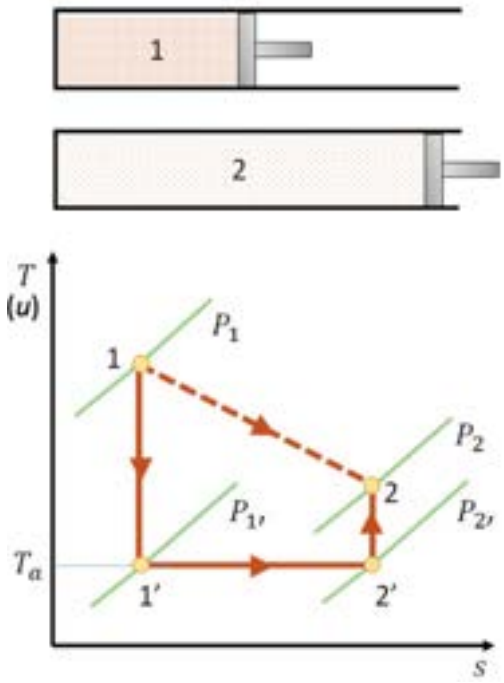

Figure 2. Reversible processes leading to the production of maximum work from the expansion of a given mass of gas in a closed system.

The net maximum work is therefore also the difference of the total coenergies. This is typically the term that will allow us to assess the work that can ideally be recovered in compressed air storage schemes, or from a compressed inert gas in a compressed air car, a technology that some researchers are presently developing for urban driving [4].

2.3 State functions versus process-dependent entities

Note that in the above equations the symbol δ is used in derivatives for process-dependant entities while d is used for state functions.

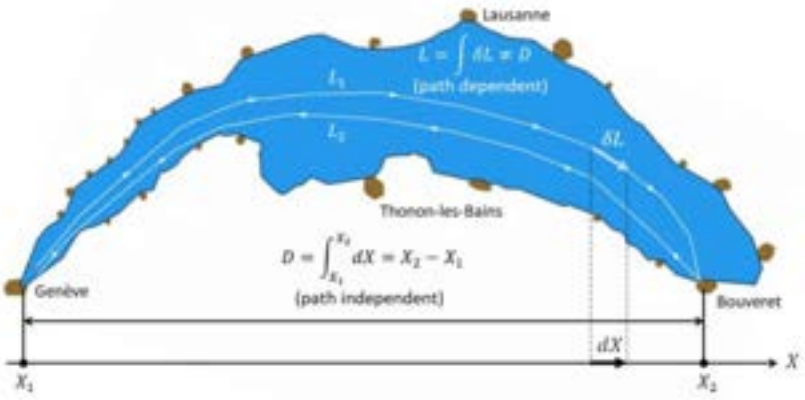

Figure 3. Illustration of the difference between a state function and process-dependent entity

State functions can be defined in any position during a process while process-dependant entities require an integration over the chosen thermodynamic path. Figure 3 symbolically illustrates this difference in the simple example of a boat going from point 1 ("Geneva") to point 2 ("Bouveret") and return following a different path, thus of different length ($L_1 \neq L_2$) while the "distance as the crow flies" D between the two cities remains of course unchanged.

In this case the length of the path L is a process-dependent entity while the reference of its horizontal position X is a state function. X_1 and X_2 can be clearly defined, but this is not the case for L that will depend on the path chosen by the skipper that day.

One interesting feature is: $\oint dX = 0$ while $\oint \delta L > 0$

Therefore, we will also have: $\oint dS = 0$ while $\oint \delta S^i > 0$

It is important to realize that, even though we are in both cases speaking of entropy, the entropy *S* within the system is a state function while the creation of entropy **inside** the system S^i is a process-dependent entity.

Q, E_w are also process dependent entities while S, U, H with their specific mass counterparts s, u, h are state functions.

When expressed in function of time we have:

$$\dot{Q}^+ = \frac{\delta Q^+}{dt} \quad (11) \; ; \qquad \dot{E}_w^+ = \frac{\delta E_w^+}{dt} \quad (12) \; ; \qquad \dot{S}^i = \frac{\delta S^i}{dt} \quad (13)$$

Figures 4 and 5 show the state function *coenergy* of air in function of the temperature and its specific entropy. Similar diagrams can be made for any substance or mixtures of substances.

Energy and masses are conserved, but their potential to do work is ultimately degraded to be cancelled when the equilibrium with the atmosphere is reached, a thermodynamic state that is called the *dead state*.

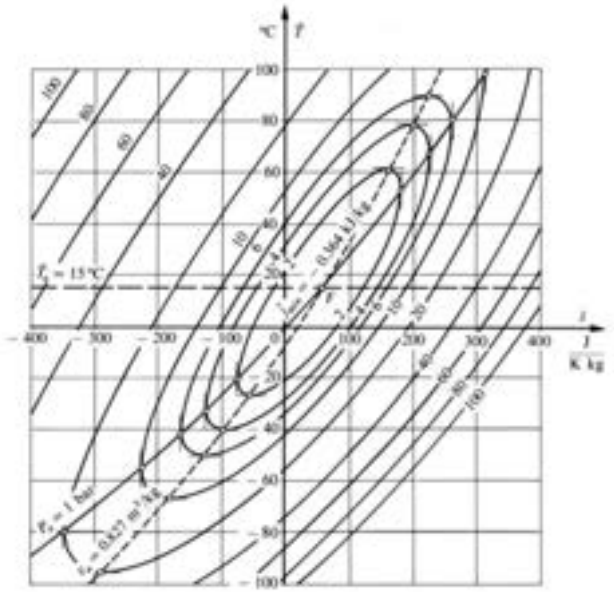

Figure 4. Coenergy of air in a T-s diagram [1]

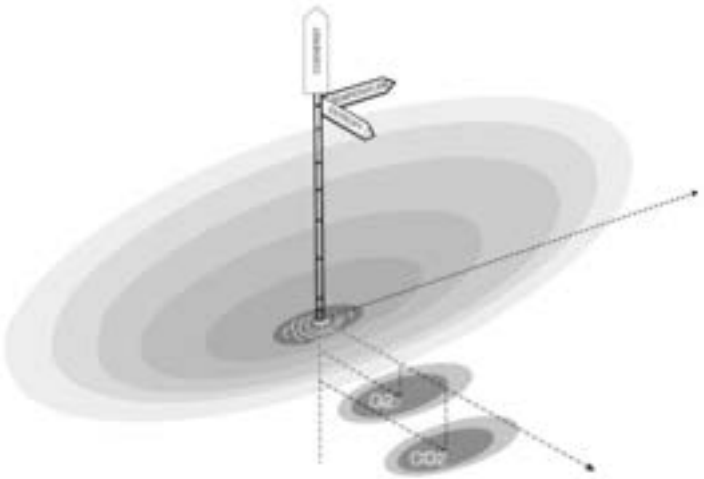

Figure. 5. Approximate representation of the coenergy function (here for air) with the thermomechanical dead state at the centre of the bowl, as well as the individual dead states for O_2 and CO_2

Those diagrams illustrate the existence of different *dead states*:

- The *dead state* of the mixture corresponding to the thermo-mechanical equilibrium with the environment (atmosphere). It corresponds to the bottom of a bowl where the coenergy has a minimum value. The higher the difference between the absolute value of (s-s_a) or the difference (T-T_a), the higher is the value of the coenergy.
- Two other *dead states* are approximatively represented, one for the physico-chemical equilibrium of the component H_2O of the air mixture and one other for the physico-chemical equilibrium of the component CO_2.The exergy analysis requires then the definition of a reference composition of the atmosphere shown in Table 2. The latter illustrates the minimum work required to separate CO_2 from air that is now discussed in the context of CO_2 separation for either reuse or storage.

3. Extension to chemical processes

Chemical processes like combustion or oxidation in fuel cells imply a change of substance between the input substances and the products of the reactions. While the sum of the enthalpies of the flows through an open adiabatic system with a combustion process does not change, the reference states for each products have lower values.

Table 2. Partial pressure and molar fractions of the main gaseous constituents of the standard atmosphere (at the standard conditions with $P^0 = 1.01325$ bar and $T^0 = 25°C$)

Substance	$P_i\ [bar]$	$\tilde{c}_i^A\ [kmol_i/kmol_A]$
N_2	0.7665	0.7565
O_2	0.2056	0.2030
Ar	0.0091	0.0090
$H_2O(g)$	0.0316	0.0312
CO_2	0.0003	0.0003

3.1. Fuel exergy value

The analysis of reactive processes, like combustion, can be dealt with by introducing a combustion network with a power transformation term $\dot{Y}_{comb}^{+}$ in the energy balance et a combustion exergy transformation term $\dot{E}_{y\,comb}^{+}$ in the exergy balance. For the latter not only the standard atmosphere (Table 2) should be considered but also the following set of hypotheses:

- The fuel F and the air A enter separately (no premixing with the fuel)
- Each constituent of the reaction products Gc (combustion gases) ends up physically mixed with the standard atmosphere, i.e. at its partial pressure P_i^{00}
- Water exists in the final combustion products Gc either in liquid or vapor form at the limit of saturation, i.e. at the partial pressure of saturation in the standard atmosphere.

These conditions being set, the corresponding values for the **exergy value of a fuel** EXV are the following:

$$\mathrm{EXV} = \Delta k^0 = \sum_i \left[\frac{N_i\ \tilde{k}_{fi}^{00}}{M_F}\right] - \sum_j \left[\frac{N_j\ \tilde{k}_{fj}^{00}}{M_F}\right] \qquad \left[\frac{J}{kg_F}\right] \tag{14}$$

In accordance with the basic definition of exergy, the specific exergy value Δk^0 corresponds to the maximum work e_{max}^F that can be recovered from a fuel in an open reversible combustion in steady state (Fig.6).

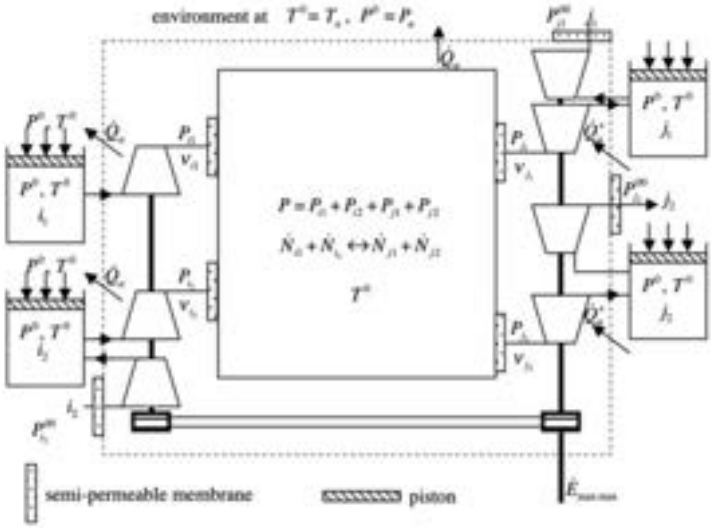

Figure 6. Mechanistic model of a reversible combustion using a van'Hoff's box [1,5]

3.2. Energy and exergy balances including power- or exergy- transformation for the combustion network

In principle, we should also consider whether or not there is condensation of the water formed during combustion. However as shown in [1] the difference between a higher and a lower exergy value is negligible in particular when $T_a = T^0$. This is logical since the Carnot factor $(1 - \frac{T_a}{T^0})$ is zero. Hence t**he advantage of the exergy analysis of systems including oxidation processes is that a single *fuel exergy* value can be considered in first approximation.**

Energy balance

$$\sum_k \dot{E}^-_{w_k} + \sum_i \dot{Q}^-_i \left(+\dot{Q}^-_a\right) + \sum_n \dot{Y}^-_n = \sum_k \dot{E}^+_{w_k} + \sum_i \dot{Q}^+_i \left(+\dot{Q}^+_a\right) + \sum_n \dot{Y}^+_n + \dot{Y}^+_{comb} \quad (15)$$

$\dot{Y}^+ = \sum_l \left[\dot{M}^+_l h_{cz_l}\right] - \mathrm{d}(U_{cz} + P_a V)/dt$ (16) for each of the n system networks, except for the combustion network that is treated separately:

$$\dot{Y}^+_{comb} = \dot{M}_F\left(HHV + \hat{h}_F\right) + \dot{M}_A \hat{h}_A - \dot{M}_G \hat{h}_G - \sum(\dot{M}_I\, HHV_I) - (\dot{M}_{H2Op} - \dot{M}_{cond}) q^0_{vap} \quad (17)$$

Where:

- $\hat{h}_F = \int_{T^0}^{T^F} dh_F$ and $\hat{h}_A = \int_{T^0}^{T^A} dh_A$ and $\hat{h}_G = \int_{T^0}^{T^G} dh_G$ are the enthalpy differences between the state of the entering or exiting entities considered in the power transformation $\dot{Y}^+_{comb}$ and the standard conditions. The species in $\hat{h}_A$ and $\hat{h}_G$ are considered to be perfect gases
- $\dot{M}_I$ and HHV_I are the mass-flows of unburned hydrocarbons and their higher heating value, in the case of incomplete combustion,
- $\dot{M}_{H2Op}$ is the mass-flow of *H₂O* produced during combustion,
- $\dot{M}_{cond}$ is the mass-flow of *H₂O* effectively condensed.

Exergy balance

$$\sum_k \dot{E}^-_{w_k} + \sum_i \dot{E}^-_{q_i} + \sum_n \dot{E}^-_{y_n} = \sum_k \dot{E}^+_{w_k} + \sum_i \dot{E}^+_{q_i} + \sum_n \dot{E}^+_{y_n} + \dot{E}^+_{y,comb} - \dot{L} \quad (18)$$

$$\dot{E}^+_y = \sum_l \left[\dot{M}^+_l (h_{cz_l} - T_a s_l\right] - \mathrm{d}(U_{cz} + P_a V - T_a S)/dt = \sum_l \left[\dot{M}^+_l k_{cz_l}\right] - \mathrm{d}J_{cz}/dt \quad (19)$$

for each of the *n* system networks except for the combustion network that is treated separately:

$$\dot{E}^+_{y,comb} = \dot{M}_F\left(\mathrm{EXV} + \hat{k}_F\right) + \dot{M}_A \hat{k}_A - \dot{M}_G \hat{k}_G - \sum\left[\dot{M}_I \Delta k^0_I\right] \quad (20)$$

(Specific isobaric) fuel exergy value

$$\mathrm{EXV} = \Delta k^0 = \sum_i \left[\frac{N_i\ \tilde{k}^0_{fi}}{M_F}\right] - \sum_j \left[\frac{N_j\ \tilde{k}^0_{fj}}{M_F}\right] \quad \text{in } \left[\frac{J}{kg_F}\right] \quad (21)$$

or

$$\Delta\tilde{k}^0 = \Delta\tilde{g}^0_F + \sum_j [\,\tilde{e}^0_{dj}] - \sum_i [\,\tilde{e}^0_{di}] \text{ in } \left[\frac{J}{kmol_F}\right] \text{ with } \tilde{e}^0_{dk} = \frac{\dot{N}_k}{\dot{N}_F} \tilde{r} T^0 ln\left(\frac{P^0}{P^{00}_k}\right) \quad (22)$$

Where $\Delta\tilde{g}^0_F$ is the Gibbs free energy (free enthalpy) of the fuel based on the enthalpies of formation and the absolute entropies. $\tilde{e}^0_{dk}$ is the exergy of diffusion (often called chemical exergy of the inert species).

4. Energy and exergy performance indicators

Historically Carnot developed its engine efficiency based only on energy terms. When the process is reversed this definition of efficiency becomes higher than 1 for heating or $\lessgtr 1$ for cooling, reason why COP heating or COP cooling have been introduced. We prefer the introduction of the concept of effectiveness adapted to all cases even if there is still the need to differentiate between heating and cooling effectivenesses when dealing with First Law energy terms.

This issue is not a problem with the notion of exergy efficiency where one definition only can be used for all systems with values remaining lower or equal to 1.

Providing energy services can be achieved by various technologies or combinations of technologies and it is important to be able to characterize the quality of these different options. In practice, two different indicators of the quality of energy processes can be defined: the *(energy)* ***effectiveness*** (so-called "thermal efficiency" or "coefficient of performance") based on the First Law of thermodynamics only or, better, the ***exergy efficiency*** based on the exergy balance, thus accounting for both the First and the Second Laws of thermodynamics. The basic idea of these sets of performance indicators is to use:

$$\varepsilon\ (or\ \eta) = \frac{energy\ (or\ exergy)\ services\ \boldsymbol{provided\ by}\ the\ system}{energy\ (or\ exergy)\ services\ \boldsymbol{received\ by}\ the\ system} \quad (22)$$

The *energy* ***effectiveness*** can be formulated as follows:

$$\varepsilon = \frac{\sum_k \dot{E}^-_{w_k} + \sum_i \dot{Q}^-_i + \sum_n \dot{Y}^-_n}{\sum_k \dot{E}^+_{w_k} + \sum_i \dot{Q}^+_i + \sum_n \dot{Y}^+_n} \quad \text{valid for processes at } T \geq T_a \quad (23)$$

Written that way, this expression is indeed only valid for processes that take place above the atmospheric temperature and can take values between 0 and ∞. This formulation can be directly used for engine or heating heat pump cycles. An exception needs to be done for refrigeration for which the refrigeration service $\dot{Q}_f^+$ or $\dot{Y}_f^+$ with temperature values lower than T_a must be only considered in the numerator as an energy service provided by the system.

The ***exergy efficiency*** can then simply be formulated as follows:

$$\eta = \frac{\sum_k \dot{E}_{w_k}^- + \sum_i \dot{E}_{q_i}^- + \sum_n \dot{E}_{y_n}^-}{\sum_k \dot{E}_{w_k}^+ + \sum_i \dot{E}_{q_i}^+ + \sum_n \dot{E}_{y_n}^+} = 1 - \frac{\dot{L}}{\sum_k \dot{E}_{w_k}^+ + \sum_i \dot{E}_{q_i}^+ + \sum_n \dot{E}_{y_n}^+} \leq 1 \quad (24)$$

Note that we consider in the numerator only the exergy services provided to users of the system. When any exergy term of the numerator exits the system without being used, the boundary of the system needs to be extended to the atmosphere and this exergy term becomes zero, but the corresponding exergy losses are still accounted for in $\dot{L}$ since the denominator has not changed. We can say that the related exergy loss is internalized and attributed to the system. For example, if the system is a combustion engine with a generator, its main service is to provide electricity, even though the cooling network has exergy that could potentially be used by others. However, if the exergy of the cooling network is not used but is destroyed in a cooling tower, it is automatically included in the exergy losses $\dot{L}$. Some authors like [6] subdivide $\dot{L}$ into:

$$\dot{L} = \dot{L}_D + \dot{L}_E \quad (25)$$

Where $\dot{L}_D$ includes the exergy destruction inside the strictly defined system and $\dot{L}_E$ includes the exergy destroyed between the system and the atmosphere. We do not consider this subdivision as useful in practice, since the objective is in fine the reduction of the total exergy loss $\dot{L}$.

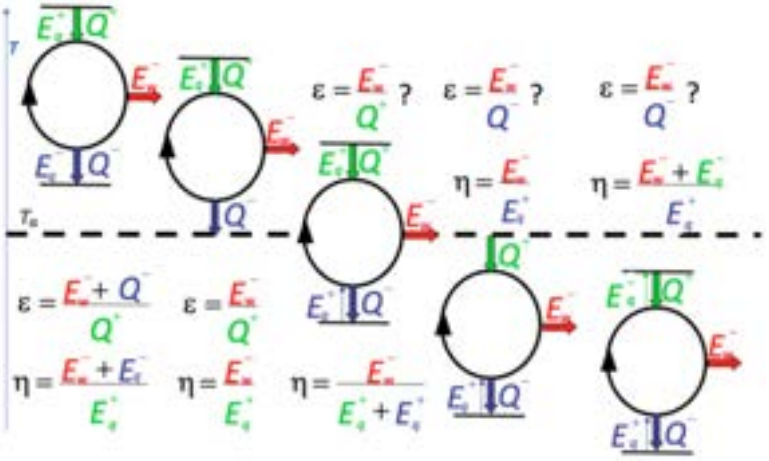

Figure 7. Simple representation of the energy effectiveness and the exergy efficiency of engine cycles in function of the temperature range [1]

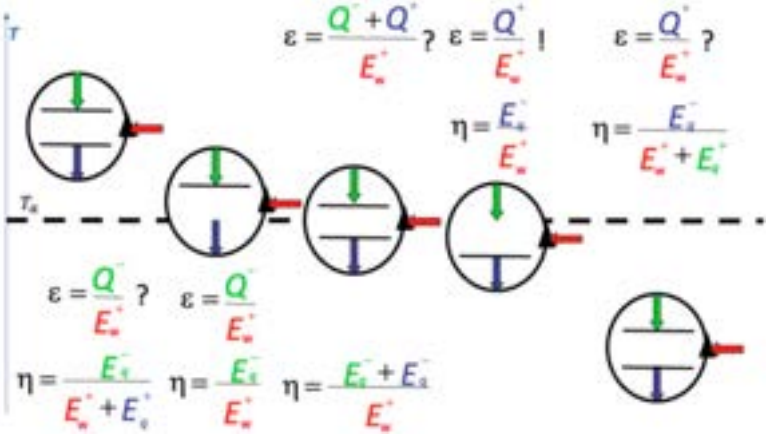

Figure 8. Simple representation of the energy effectiveness and the exergy efficiency of heat pump cycles in function of the temperature range [1]

Figures 7 and 8 show the performance indicators for simple engine cycles and heat pumps cycles in the various temperature ranges. There are clearly situations where defining an effectiveness is problematic while exergy efficiencies are coherent for all cases.

Figure 9 shows a symbolic representation of some common technologies in a 3D bowl diagram. This is inspired from the earlier representations of [1] with an analogy between exergy levels and the gravity field. Mass units are represented by little men. The red arrows show a typical fuel boiler situation starting with a high exergy level fuel combined to give combustion gases at relatively high temperature and specific exergy to provide

heat for a building at low exergy level. Finally heat losses through the walls of the building let energy leak to the dead state. The green arrows represent the processes of an engine requiring, to elevate some of the little men to the high exergy level of electricity some little men need to be going to the dead state all the greater as the initial exergy level is low. An alternative is shown with the downward little men being deviated at the level of the house heating and that corresponds to a cogeneration system. The blue arrows illustrate a direct electric heating based on Joule's effect. The yellow arrow illustrates an electrical heat pump. Finally on the left of the figure is a representation of a sub-atmospheric temperature Rankine engine cycle using the environmental heat as a heat source and the lower temperature of liquid natural gas (LNG) to be evaporated as a cold source.

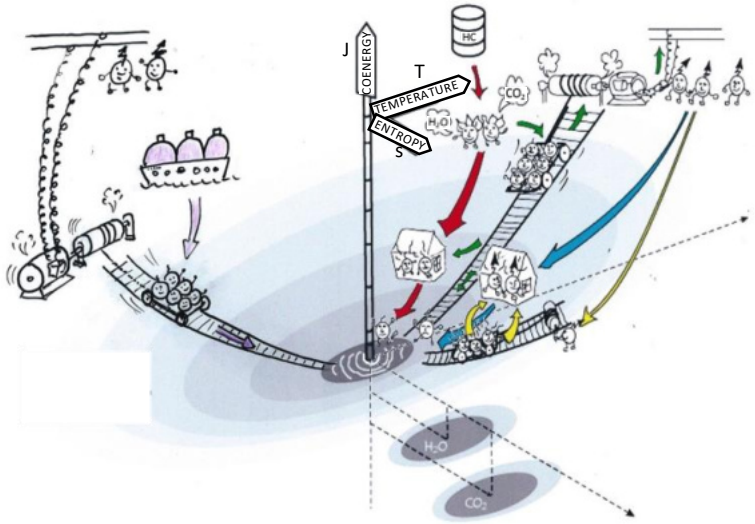

Figure 9: Symbolic representation of the exergy bowl with different heating and power generation technologies [7]. (Rigorously the coenergy bowl should be redrawn for each change of substance)

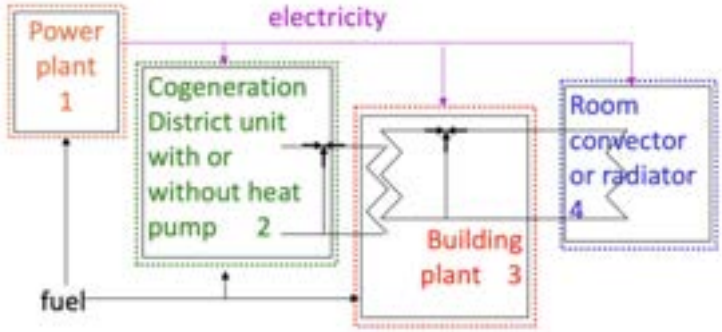

Figure 10. Division in 4 subsystems of the problem of heating or cooling of a building with a multiple choice of technologies [8].

Table 2: Examples of overall technologies for heating

Technologies	Power plant	DH plant	Building plant		Room convector		Overall exergy efficiency (%)	
Supply/return temperatures			45°/35°	65°/55°	45°/35°	65°/55°	45°/35°	65°/55°
Direct electric heating (hydro power)	0.88				0.07	0.07	6.0	6.0
Building non-condensing boiler			0.11	0.16	0.53	0.38	6.1	6.1
Building condensing boiler			0.12		0.53		6.6	
District heat pump (combined cycle plant)	0.54	0.61	0.54	0.76	0.53	0.38	9.4	9.4
Domestic heat pump (cogeneration combined cycle power)	0.54		0.45	0.45	0.53	0.38	12.9	9.2
District heat pump(hydropower)	0.88	0.61	0.54	0.76	0.53	0.38	15.4	15.4
Domestic heat pump (hydropower	0.88		0.45	0.45	0.53	0.38	21.2	15.1

Figure 10 and Table 2 responds to a basic question asked by the architect. Since exergy is higher at a higher heating temperature why is it interesting to use low temperature heating systems like floor heating? Exergy

analysis provides a coherent answer. As shown in [7] the overall exergy efficiency can be obtained by multiplying the exergy efficiencies of each subsystem.

$$\eta = \eta_1 \eta_2 \eta_3 \eta_4 \tag{26}$$

Example: Combined cycle power plant without cogeneration (1) + District heating heat pump (2) + DH heat exchanger in the building (3) + Convector (4).

$$\eta = \left(\frac{\dot{E}^-_{el,1}}{\dot{E}^+_{y,1}}\right)\left(\frac{\dot{E}^-_{y,2}}{\dot{E}^+_{el,2}}\right)\left(\frac{\dot{E}^-_{y,3}}{\dot{E}^+_{y,3}}\right)\left(\frac{\dot{E}^-_{q,4}}{\dot{E}^+_{y,4}}\right) = \frac{\dot{E}^-_{q,4}}{\dot{E}^-_{y,1}} \tag{27}$$

Table 11 illustrates the case for cooling.
The net conclusion from such analysis and which corresponds well to the second Law of thermodynamics is:

Heat at the lowest temperature as possible and cool at the highest temperature as possible

Table 11 Examples of overall technologies for air-conditioning [8]

Power plant technologies	Power plant	Dist. plant	Building plant			Room convector			Overall exergy efficiency [%]		
Supply/return temperatures			*10°/15°*	5°/10°	0°/5°	*10°/15°*	5°/10°	0°/5°	*10°/15°*	5°/10°	0°/5°
Nuclear power	0.32		*0.4*	0.4	0.4	*0.56*	0.43	0.34	*7.1*	5.4	4.3
Gas motors	0.36		*0.4*	0.4	0.4	*0.56*	0.43	0.34	*8.1*	6.2	4.9
Combined cycle power plant without cogeneration	0.54		*0.4*	0.4	0.4	*0.07*	0.07	0.07	*12.1*	9.3	7.3
Hydropower	0.88		*0.4*	0.4	0.4	*0.53*	0.38	0.33	*19.8*	15.2	12.0

Further application of the concept of exergy efficiency that is often motivating students is the application to vehicle drives as shown in [9,10] where alternative of power drives from electric to liquid nitrogen cars and others are compared. Estimates of exergy efficiencies of electric cars of the order of 69% (without accounting for the efficiency of power generation) are compared with an average of 18% for thermal engine cars based on road tests. In [10] these values are introduced into regional energy scenarios to estimate the future influence on the electricity consumption for example.

5. AI platform for teaching exergy

An attempt was made to apply an AI emerging platform [11] to assist educators. It was applied to the first part of this paper noticing that this beta version did not yet allow equations in a MS Word environment so those had to be described in a written format. However, this early approach illustrates the potential interest of this fast-developing tool at a time where ex-cathedra courses are recognized to be inefficient. The platform proposes a number of tools including automatically generated glossary, concept cards, Quiz, Drag the word, flash cards and crosswords that the author can then freely modify to increase the accuracy or the pertinence.

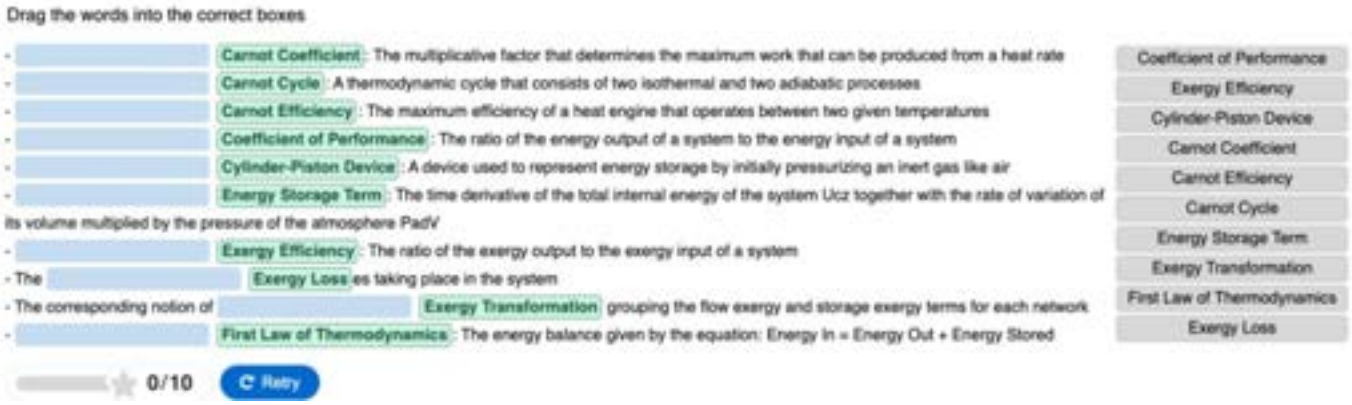

Figure 10. Non modified proposal from the platform for a “drag the word” exercise

Figure 10 shows one of the “Drag the word” proposal with here the solution superposed in green. Some of the definition obviously need to be improved but the structure is there and the effort from the educator is significantly reduced. Figure 11 provides another presentation with the crossword that can break the monotony during the course. Here again some definitions need to be improved. Of particular interest is the 40 questions with multiple choice of answers among which about one third still need to be discarded, mainly because they refer to the descriptive of equations that are not ideal at this stage.

One additional benefit for the educator could be to highlight the parts of his paper that are not clear enough and need to be improved.

Conclusions

Teaching exergy for a broad range of users is still a challenge. The approach proposed in this paper tries to have a rigorous symmetry between the First Law balance and the exergy balance in cases of open systems with a clear distinction between state functions and process-dependent entities. Applications linked to the ranking of technology combinations for heating and air-conditioning are, among others, good examples for the use of the exergy concept. Finally, an attempt is made to exploit for teaching purposes the fast-developing use of AI tools with the present limitations.

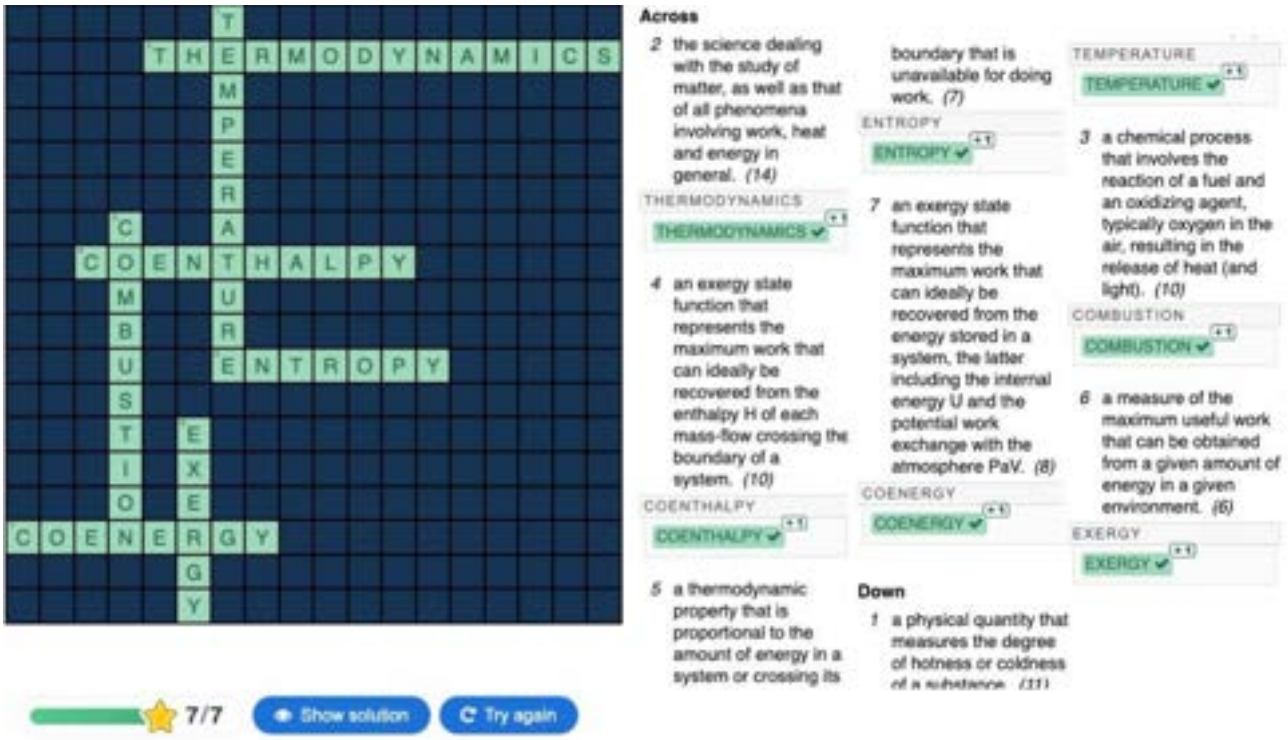

Figure 11. Example of crossword generated by the platform (text yet unmodified)

Abstract:

The idea of a Thermodynamic cost associated with flows in a network of irreversible thermodynamic processes is widely developed in the context of energy engineering, but the general formulation of the Exergy Cost Theory-ECT allows in principle its application also to the biochemical networks.
This paper describes the application of the exergy analysis to a generic metabolic network and an approach for calculating the exergy costs associated with all the flows present in the network, according to the ECT. The main perspective is to use the exergy cost information for defining additional constraints in the Flux Balance Analysis- FBA of the bacterial metabolic network. Which could help identifying directions for the optimization of the biomass production process, and the enhancement of the biofuel use in industry. In fact, this approach mainly relays on the maximization of the produced biomass, for identifying all metabolites fluxes in a biochemical network, with the constraints expressed by the stoichiometric relations of all reactions within the network. Therefore, some additional constraints have to be introduced, in order for guiding the optimization algorithm towards thermodynamically feasible solutions.
The expectation is that, by introducing the actual exergy cost, with their clear physical meaning, the results would be more consistent with the experimental finding, reported in literature, for a wide range of possible environmental conditions.
By applying the unit exergy cost concept, a deeper understanding of the reason why the reaction paths of the same metabolic network changes, in different environmental conditions, is also expected to be achieved.

1. Introduction

Living cells are known as complex and dynamic systems that play a vital role in maintaining the balance of life on Earth. They are composed of various subsystems that interact with each other in a coordinated manner, with each subsystem contributing to the overall functioning of the cell.

Understanding the behavior and performance of these systems is critical for comprehending the underlying mechanisms of cellular processes and for improving the efficiency of biotechnological processes. One approach to analyzing the behavior and performance of living cells is exergy analysis. Exergy analysis is a thermodynamic method that quantifies the amount of energy available for conversion from one form to another and has been widely used in the analysis of energy systems, such as power plants and industrial processes.

In recent years, exergy analysis has been applied to the study of living cells, it has been widely used in the study of living cells, providing a comprehensive understanding of the thermodynamics of these complex and dynamic systems. The application of exergy analysis to living cells has resulted in new insights into cellular behavior and performance, and has led to improvements in the design and operation of bioreactors and bioprocesses. One of the key areas where exergy analysis has been applied to the study of living cells is in the analysis of metabolic pathways.

By quantifying the energy inputs, outputs, and losses in cellular processes, exergy analysis can provide a detailed understanding of the efficiency of metabolic pathways, and identify areas for improvement. This

information can be used to optimize cellular processes, leading to improved performance and greater sustainability. Another area where exergy analysis has been applied to the study of living cells is in the analysis of ion transport processes, such as ion pumps and channels. By quantifying the energy inputs and outputs of these processes, exergy analysis provides a valuable framework for assessing their efficiency and optimizing their performance.

In this context, exergy analysis has also been used in the study of bioreactors and bioprocesses, providing a thermodynamic framework for the analysis of energy and matter exchange in these systems.

In this paper, we describe the application of exergy analysis to a generic metabolic network, with a focus on calculating the exergy costs associated with all the flows present in the network.

The Exergy Cost Theory (ECT) provides a framework for this analysis, allowing for the formulation of a thermodynamic cost associated with flows in a network of irreversible thermodynamic processes. While the ECT has been widely used in energy engineering, this paper explores its application to biochemical networks. Our main perspective is to use the exergy cost information to define additional constraints in the Flux Balance Analysis (FBA) of the bacterial metabolic network, which is a powerful technique in bioinformatics, used for identifying directions for the optimization of biomass production processes and the enhancement of biofuel use in industry. Nevertheless, the approach mainly relies on the maximization of the produced biomass, with the constraints expressed by the stoichiometric relations of all reactions within the network. This approach requires the introduction of additional constraints for guiding the optimization algorithm towards thermodynamically feasible solutions.

We expect that by introducing the actual exergy cost, with their clear physical meaning, the results would be more consistent with experimental findings reported in literature for a wide range of possible environmental conditions. We also expect to achieve a deeper understanding of why the reaction paths of the same metabolic network change in different environmental conditions by applying the concept of unit exergy cost. Overall, our paper demonstrates the potential of exergy analysis, and the ECT in particular, for optimizing metabolic networks in bioengineering.

2. Exergy analysis of cellular process

Exergy analysis of cellular processes starts with a thermodynamic analysis of the energy exchanges that take place in the cell, including the inputs and outputs of energy, matter, and entropy[1].

The exergy of a process is defined as the maximum useful work that can be obtained from a system, and it is calculated as the difference between the actual enthalpy of the system and the reference enthalpy[2]. The reference enthalpy is the enthalpy of the system in a state of equilibrium at a reference temperature and pressure, usually taken to be the temperature and pressure of the environment.

Exergy analysis can be used to assess the efficiency of various cellular processes, such as metabolic pathways, ion transport, and biochemical reactions[3]. For instance, it is possible to use it to determine the energy conversion efficiency of metabolic pathways, as well as the exergy losses due to internal irreversibilities, [4] [13] such as entropy production.

Additionally, exergy analysis can be used to assess the efficiency of ion transport processes, such as ion pumps and channels, by quantifying the inputs and outputs of these processes from an energetic point of view [5]. By quantifying the energy inputs, outputs, and losses in cellular processes, exergy analysis could be utilized for assessing theefficiency of various metabolic pathways [6].

The late mentioned method provides a valuable framework for the optimization of cellular processes, by identifying areas for improvement in energy and matter exchange. This information can be used to improve the efficiency of cellular processes [7].

3. Exergy Analysis of Biotechnological Processes

Evaluating the potential for energy utilization and efficiency in a given system or process is a key point to fulfill optimization. In the context of biotechnology, exergy analysis is a suitable tool to evaluate the performanceof bioprocesses such as fermentation, biorefining, and biogas production, etc..

The basic principle of exergy analysis is to calculate the maximum useful work that can be obtained from a system or process, based on the availability of energy in the system and the environment.
In bioprocesses,[7] the exergy of the process inputs (such as substrates and nutrients) and the exergy losses (such as waste heat and other by-products) can be quantified. These information can then be employed to identify areas for improvement in terms of energy efficiency and sustainability.

There are several benefits to using exergy analysis in biotechnology. One of the main benefits is that it provides a comprehensive and quantitative assessment of the energy utilization and efficiency of a bioprocess.

Such information is quite useful for enhancement the process conditions, reduce energy costs, and minimize environmental impact.

These kind of analysis is indeed, a valuable tool for evaluating the performance of bioprocesses in terms of energy utilization and efficiency. As the information obtained from an exergy analysis could provide meaningful insights to optimize the process conditions, reduce energy costs, and minimize environmental impact, making bioprocesses more sustainable and environmentally friendly.

4. Glycolysis pathway of Escherichia coli

Escherichia coli is a type of bacterium that uses glycolysis as its primary source of energy, which is a metabolic pathway that breaks down glucose (a simple sugar) into pyruvate, producing energy in the form of ATP [9]. The following is a summary of the glycolysis pathway in *E. coli*:

• Conversion of glucose to fructose-1,6-bisphosphate: Glucose is converted to fructose-1,6-bisphosphate through the action of hexokinase, which adds a phosphate group to the molecule.

• Cleavage of fructose-1,6-bisphosphate: The next step is the cleavage of fructose-1,6- bisphosphate into two three-carbon molecules, glyceraldehyde-3-phosphate and dihydroxyacetone phosphate, by the action of aldolase;

• Phosphorylation and isomerization: Both glyceraldehyde-3-phosphate and dihydroxyacetone phosphate are converted to their isomer, 1,3-bisphosphoglycerate, by the action of triose phosphate isomerase. This reaction is also accompanied by the addition of a phosphate group, producing energy in the form of ATP.

• Conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate: The next step is the conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate through the action of phosphoglycerate kinase, which adds another phosphate group, producing more ATP.

• Conversion of 3-phosphoglycerate to 2-phosphoglycerate: The next step is the conversion of 3-phosphoglycerate to 2-phosphoglycerate through the action of phosphoglycerate mutase.

• Conversion of 2-phosphoglycerate to phosphoenolpyruvate: The final step of glycolysis is the conversion of 2-phosphoglycerate to phosphoenolpyruvate (PEP) through the action of enolase. This reaction releases energy in the form of ATP.

• Conversion of phosphoenolpyruvate to pyruvate: The conversion of phosphoenolpyruvate to pyruvate is catalyzed by the enzyme pyruvate kinase. This final step of glycolysis completes the degradation of glucose to pyruvate, producing a net gain of two ATP molecules.

In addition to producing ATP, the degradation of glucose in glycolysis also generates the building blocks for other metabolic processes, including the citric acid cycle, which generates more energy.

Figure. 1. Glycolysis pathway of *Escherichia. Coli*.

4.1. Exergy analysis and exergy cost of the glycolysis metabolic pathway of *Escherichia coli*

Exergy analysis is a thermodynamic method that assesses the maximum useful work that can be obtained from a system. In the context of the glycolysis metabolic pathway of *E. coli*, the exergy analysis would involve calculating the change in exergy (useful work potential) for e each step of the reaction sequence.

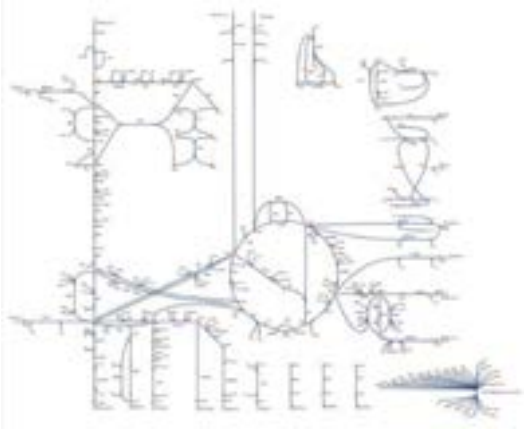

Figure. 2. ESCHER map of the metabolic pathway of *E.coli*. core (**a simplified model**).

(https://escher.github.io/#/app?map=e_coli_core.Core%20metabolism&tool=Builder&model=e_coli_core)

Performing the exergy analysis of the glycolysis pathway involves estimating the change in exergy (by representing the useful work potential) at each step of the whole reaction sequence.

In order to perform exergy analysis, it is necessary to determine the chemical exergy values of the involved compounds in the metabolic pathway. These values represent the maximum amount of work that can be obtained from each compound through chemical reactions under standard conditions.

By taking into account the exergy inputs and outputs of each reaction, the exergetic cost associated with the targeted pathway could be calculated.

Identifying possible relevant compounds in the pathway is also possible through the exergy of the metabolic compounds. (Figure3)

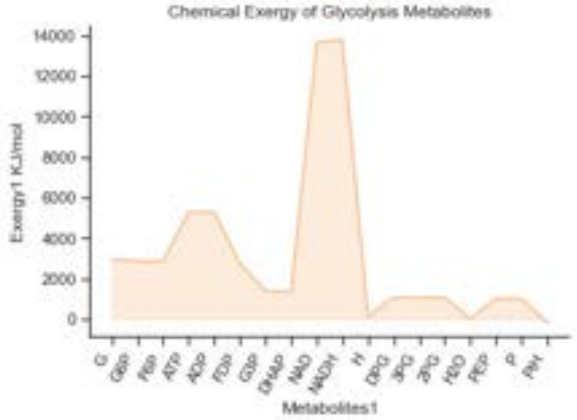

Figure. 3. The chemical exergy of the glycolysis metabolites in standard conditions.

The chemical exergy values in the plot represent the maximum amount of work that can be obtained from the metabolites through chemical reactions, and under standard conditions (298 K, 1 atm, pH 7). The data used toproduce the plot was originally extracted from literature [11].

It demonstrate that the higher the chemical exergy value of a metabolite, the greater its potential for doing useful work. Based on the plot, we can see that glucose-6-phosphate (G6P) has the highest chemical exergy value among all the metabolites in the glycolysis pathway, followed by fructose-6-phosphate (F6P) and 3-phosphoglycerate (3PG).

Which could suggests that these metabolites have the greatest potential for performing useful work in the pathway. In contrast, the lowest chemical exergy values are observed for pyruvate and ATP, indicating that these metabolites have less potential for performing useful work in the pathway.

However, it is important to note that ATP is a crucial energy carrier in the cell and plays a key role in energy metabolism, as showed, the plot gives insight into the chemical potential of the metabolites in the glycolysis pathway and can be used to guide the optimization of the pathway for increased efficiency and energy utilization. (View Figure.3)

The exergy cost represents the irreversibilities or inefficiencies within a giving system and it is a good tool to quantifies the amount of available work that is lost or degraded during the process. Exergy cost calculation involves the comparison between the exergy values of the reactants and the exergy of the products for each reaction in the metabolic pathway.

For accurate K* calculations, reliable chemical exergy values for the compounds involved in glycolysis are crucial as a primary step.

By applying exergy analysis approach and calculating the exergetic cost for each compound in the glycolysis pathway, it is possible to determine the steps with the highest exergy losses.

This sort of information is a suitable way to guide efforts for the optimization of certain pathways and improvement of the overall efficiency and energy utilization of the whole process.

Using the exergy analysis and exergy cost calculation of compounds in the glycolysis metabolic network may be a way to provide valuable insights into the thermodynamic efficiency and sustainability of this essential metabolic process. Furthermore, It enables researchers to evaluate the performance of the pathway, determine areas for potential improvement, and to develop more efficient strategies, especially for metabolic engineering and optimization.

Through the optimizing the glycolysis pathway based on exergy analysis, it is possible to enhance energy efficiency, reduce waste, and improve the utilization of resources in *Escherichia coli* metabolism.

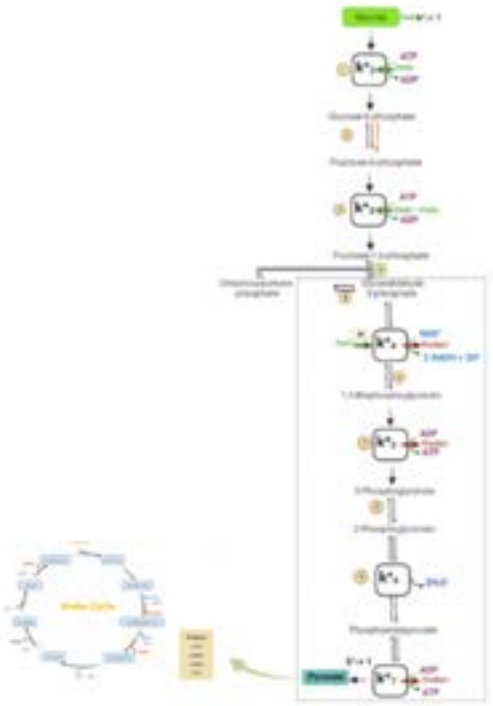

Figure. 4. Reproductive structure of the glycolysis pathway.

K* represents the exergy cost

In this context, glycolysis pathway can be seen as a reproductive structure within cellular metabolism, where the participated metabolic compounds act as fuels and products.

This pathway is one of the important and relevant pathways in most metabolic networks, as it serves as a central hub for energy generation and the production of essential molecules that sustain cellular functions.

In glycolysis, glucose, is regarded as a primary fuel source, it is initially converted into two molecules of pyruvate through a series of enzymatic reactions. This breakdown of glucose generates energy in the form of ATP and NADH. These energy-rich compounds are considered as vital fuels for various cellular processes in biology.

Moreover, the selected pathway is responsible for the production of other important metabolic compounds (that act as products). For instance, during the conversion of glucose to pyruvate, intermediates such as glucose-6-phosphate (G6P), fructose-6-phosphate (F6P), and 3-phosphoglycerate (3PG) are formed and regarded as “internal products” in this process. These compounds play crucial roles in biosynthetic pathways, providing building blocks for the synthesis of essential molecules such as nucleotides, amino acids, and lipids, etc..

The reproductive nature of the glycolysis metabolic network is evident in the recycling of metabolic compounds, where NADH, generated during glycolysis, is further oxidized to NAD+ in a subsequent cellular processes, such as oxidative phosphorylation. This recycling mechanism ensures the continuous availability of key cofactors and maintains the energy flow within the metabolic network.

The identification of metabolites as fuels and products highlights the dynamic and interconnected nature of cellular metabolism.

Glycolysis not only generates ATP, the primary energy currency of the cell, but also provides essential precursors for the synthesis of biomolecules involved in the cellular growth.

Consequently, understanding the reproductive structure of the glycolysis pathway and the roles of its compounds (By its identification as fuels and products in the process) is vital for comprehending cells from an energetic point of view, optimizing certain metabolic pathways, and also designing strategies for metabolic engineering and biotechnological applications.

Therefore, by manipulating the glycolysis pathway and its associated metabolic compounds, it would make possible to ameliorate energy production, redirect metabolic fluxes, and achieve desired cellular outcomes.

4.2. Exergy and exergy cost analysis of biochemical networks in living systems far from equilibrium

These kind of analyses represents a potential approach to understand the thermodynamic behavior of biological systems and to identify the most energetically efficient pathways for energy conversion and utilization. In living systems, biological processes often occur far from thermodynamic equilibrium, which means that traditional exergy analysis approaches may not be applicable.

For this matter, it is important to develop new methods and theoretical frameworks for exergy analysis in far from- equilibrium systems. One example of a theoretical framework is the concept of exergy efficiency, which is utilized to quantify the efficiency of energy conversion and utilization in living systems. This framework takes into account the entropy production of the system, as well as the exergy changes that occur in the system. Another important area of research is the application of exergy and exergy cost analysis to specific biological systems, such as metabolic pathways, cellular respiration, and photosynthesis. As these sort of studies can provide wider insights into the energetics of these processes and furthermore, help in the identification of potential targets for improvement in terms of energy and energy efficiency.

Despite that the approach of exergy analysis of biochemical networks in living systems far from equilibrium is still developing, it has already produced valuable insights into the energetics of these systems and has the potential to provide important guidance for energy-efficient design and operation in a wide range of biological and biotechnological application.

5. Analogical analysis: Industrial system (Engine) vs Biological system (Bacterial environment)

One of the fascinated things about nature is that it is the origin of all human kind works, same as industrial systems that has been inspired from the biological system present in our environment, as understanding the nature of the work process in a biological environment could be the key to make a development and a step forward in Human work, and vice- versa. In an engine, the exergy analysis would involve quantifying the energy losses and inefficiencies that occur as fuel is converted into useful work. This analysis can help identify areas where energy is being wasted, such as through heat losses or frictional losses, and guide efforts to optimize the engine for improved efficiency.

Similarly, in a bacterial environment, the exergy analysis would involve quantifying the energy losses and inefficiencies that occur as nutrients are converted into biomass or other bioproducts. This analysis can help identify areas where energy is being wasted, such as through the production of useless bi-products, and guide efforts to optimize the metabolic pathways of the bacteria for improved efficiency.

A key difference between the two mentioned systems is that an engine is a closed system, whereas a bacterial environment is an open system that interacts with its surroundings.

This means that the exergy analysis of a bacterial environment must take into account the energy inputs and outputs from the surrounding environment, such as through the exchange of nutrients, gases, and heat. To say better, the analogy between the exergy analysis of an industrial system and a biological system highlights the importance of understanding the thermodynamic efficiency of systems, whether they are designed by humans or evolved through natural selection.

By optimizing the efficiency of these systems, we can minimize energy losses and waste, and improve our ability to produce useful work or bioproducts.

6. Microbial production of fuels

Microbial production of fuels refers to the process of using microorganisms, such as bacteria and yeast, to convert biomass into biofuels. The most common type of biofuel produced using this method is bioethanol, which is made from sugars or starches in crops such as corn, sugarcane, and wheat.

The process of microbial production of bioethanol involves the fermentation of sugars by yeast or bacteria to produce ethanol and carbon dioxide. In addition to bioethanol, other biofuels such as butanol and biomethane can also be produced using microbial processes. Butanol, for example, can be produced by the

fermentation of sugars and starches by bacteria such as Clostridium. Biomethane can be produced by the anaerobic digestion of organic matter by microorganisms, producing methane that can be used as a fuel source. Microbial production of biofuels has gained increasing attention as a sustainable and renewable alternative to traditional fossil fuels.[13]

The use of biomass as a feedstock reduces the carbon footprint of biofuels and helps to reduce dependence on finite fossil fuel resources. However, the efficiency and scalability of microbial production of biofuels still pose challenges, and further research and development is needed to make this technology more economically viable.

7. The challenges

The efficiency and scalability of microbial production of biofuels are two important factors that determine the commercial viability of this technology. Efficiency refers to the amount of biofuel produced per unit of biomass used as a feedstock. Improving the efficiency of the process is crucial in order to make it economically viable, as it directly affects the cost of production.

The efficiency of microbial production of biofuels is influenced by a number of factors, such as the type of microorganisms used, the composition of the feedstock, and the conditions of the fermentation process. The efficiency and scalability of microbial production of biofuels are two important factors that determine the commercial viability of this technology.

Efficiency refers to the amount of biofuel produced per unit of biomass used as a feedstock. Improving the efficiency of the process is crucial in order to make it economically viable, as it directly affects the cost of production. The efficiency of microbial production of biofuels is influenced by a number of factors, such as the type of microorganisms used, the composition of the feedstock, and the conditions of the fermentation process.

Scalability refers to the ability to increase the production of biofuels as demand increases. Scalability is a challenge for microbial production of biofuels, as the process is often limited by factors such as the availability of suitable feedstocks, the cost and availability of the microorganisms used, and the cost of the necessary equipment and infrastructure. Additionally, scaling up the production process can also affect the efficiency of the process, as the conditions required for optimal growth and fermentation of microorganisms may change at larger scales.

Despite these challenges, research and development in the field of microbial production of biofuels continues, with the goal of improving both the efficiency and scalability of the process. Advances in genetic engineering and synthetic biology have led to the development of more efficient microorganisms, and the development of new technologies such as consolidated bioprocessing and metabolic engineering have the potential to significantly improve the efficiency and scalability of the process in the future.

Conclusion

Exergy analysis is a powerful tool for the analysis of living cells and biotechnological processes. It provides a thermodynamic framework for quantifying the efficiency of cellular processes and biotechnological systems, and it has been widely applied to the study of energy systems, such as power plants and industrial processes. lately, exergy analysis has been applied to the study of living cells, providing new insights of the metabolic behavior, and offering new avenues for optimization and improvement.

It has been used to assess the efficiency of metabolic pathways, ion transport, and biochemical reactions, and to identify areas for improvement in bioreactor design and operation. The application of exergy analysis to living cells and biotechnological processes continues to grow, as researchers seek to gain deeper insights into the complex and dynamic nature of these systems. With its ability to provide a thermodynamic framework for the analysis of energy and matter exchange, exergy analysis is poised to play an increasingly important role in the study of living cells and biotechnology in the years to come.

The application of exergy analysis to living cells and biotechnological processes continues to grow, as researchers seek to gain deeper insights into the complex and dynamic nature of these systems. With its ability to provide a thermodynamic framework for the analysis of energy and matter exchange, exergy analysis is poised to play an increasingly important role in the study of living cells and biotechnology.

Abstract:

In energy or chemical engineering, a representation of highly complex processes is often only possible through a simulation. Conducting experiments or building demonstrators is far too costly and time-consuming. Applying exergy-based methods is beneficial to reveal thermodynamic inefficiencies and to propose appropriate optimization approaches for energy conversion processes. Therefore, teaching theory and software-based application of such methods are essential in engineering study programs.

This paper presents a didactic concept for open educational resources on exergy analysis covering the introduction to the exergy method, its distinction from the energy analysis, and its application to various case studies. The course aims to combine thermodynamic understanding with numerical mathematics and object-oriented programming. Students learn to build and run models of energy conversion systems and conduct respective exergy analyses using the software Thermal Engineering Systems in Python (TESPy). The course material is developed using Jupyter notebooks, which offer a flexible connection between theory and code. Results are reproducible and can be tested and developed further by the open-source community.

The advantages of exergy-based methods can be illustrated by evaluating and visualizing real thermodynamic losses using Grassmann or waterfall diagrams. Process understanding can be deepened further by parameter analysis showing their impact on components and the overall process. Finally, the acquired knowledge is transferred to more complex problems with multiple components or more than one product.

1. Introduction and Motivation

In the last years, particularly since the start of the COVID-19 pandemic, the need for using electronically-based teaching materials has increased. Nevertheless, the didactic concepts for teaching events have also changed fundamentally in a concise time [1, 2]. Specific methods, e.g., flipped/inverted classroom, were previously only used by an interested group of lecturers and played a subordinate role. The pandemic has significantly accelerated the development and led to the increased use of numerous previously underrepresented didactic methods. As a result, the didactic quality of teaching courses was improved almost imperceptibly, especially in the field of engineering.

But what principles should be applied to the design of a lecture or seminar at a university today? Von Thun [3] gives some advice on this. He considers the development of one's own design principles as fundamental, which correspond to the requirements and possibilities of your subject, your contents, and your person. The lecture or seminar should not only be given but also created. Developing those design principles is an exciting and valuable part of the professional biography of a university teacher.

When designing a course, it is necessary to determine which competency goals are to be achieved. According to Anderson and Krathwohl [4] there are six categories of cognitive process dimensions to choose from: first remember, second understand, third apply, fourth analyze, fifth evaluate, sixth create. Many courses at universities, especially introductory classes, usually are within the third category. However, the study's goal should be to reach the 6th level, i.e., to plan a research paper on a given topic, i.e., to work scientifically on one's own. Concerning engineering sciences, it is, therefore, essential to get into independent practice-relevant action as early as possible in the curriculum, e.g., to be able to program independently.

In engineering programs, especially in the field of energy and chemical engineering, thermodynamics is a fundamental discipline. In many of these courses, the exergy concept [5–9] is taught to aspiring engineers as a helpful and powerful tool. In this context, the conclusive teaching of the concept is one of the major challenges for the lecturers. There needs to be more than a conventional thermodynamics lecture to make the students apply the exergy concept and explore exergy. Following the previous remarks, we need at least one more advanced course for teaching the exergy concept. Independent activities such as programming should be included. The students must be enabled to apply general principles of thermodynamics independently, evaluate them, and finally, create energy conversion processes independently according to the given requirements and check them with the help of exergy-based methods.

In today's highly interconnected and globalized world, it should be widely accepted that research and teaching are not the exclusive preserve of established societies or segregated groups with limited social access. Indeed, even in the beginnings of the universities in the Middle Ages, admission restrictions were unusual [10, 11]. Ultimately, the composition of the student body was shaped by social realities, such as the exclusion of women. Of course, numerous social barriers have been dismantled in the meantime. That it is nevertheless not self-evident is shown by the 4th United Nations Sustainable Development Goal[1]: "Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all." Addressing lifelong learning shows a need to make knowledge and knowledge transfer accessible to all without barriers, even outside appropriate institutions. For example, this can be made possible through a digital offering independent of end devices. Free and open-source access should be a standard feature.

Furthermore, in research projects funded by third parties, work is often expected today to be transdisciplinary. Consequently, social shareholders are also involved, and data and results should be available to everyone for subsequent use. For such cooperative collaboration across spatial or temporal distances, several technical solutions (cloud, git, web) exist today that enable participation and curation in various forms simultaneously. Remember, understand, apply, analyze, evaluate, and create no longer necessarily have to take place in the lecture hall or seminar room on the chalkboard.

An online course was developed based on the findings formulated up to this point. The open educational resources on exergy analysis covering the introduction to the exergy method, its distinction from the energy analysis, and its application to various case studies. The interactive digital learning experience offered to students in the course described here is a building block in the development of professional competencies for future engineers.

The present contribution is structured as follows: A didactic concept for the developed online course is presented in the next section. Information about the online implementation based on Python and Jupyter Notebooks is collected in Section 3. Some illustrative results from the course material are shown in the results section, followed by the conclusions.

All developed materials and used libraries are available on a free and open-source basis. If researchers, practitioners, teachers, or students use the content, the CC BY 4.0 guidelines[2] should be respected. The prepared content can be accessed online in a textbook format.[3] Furthermore, everyone is invited to join the developer team, share ideas and suggestions, or even bug reports via the GitHub repository.[4]

2. Didactic Concept

2.1. Target Group, Prerequisites and Integration into Curriculum

The course is intended for students in undergraduate engineering programs, especially power engineering, process engineering, and chemical engineering. In addition, the course can be a possible advanced training, since it is available in an open-source form. Nevertheless, the content is not primarily aimed at that, meaning that examples could seem too simple for a practitioner.

Students should already completed coursework in basic mathematics, thermodynamics, and object-oriented programming knowledge. Furthermore, they should be familiar with the purpose of using apparatus and machines as well as processes of energy engineering. Finally, they are expected to be interested in going deeper into the exergy concept.

Consequently, the course fits into the curriculum of the study program according to Figure 1. In deviation from the illustration, it is conceivable that the course is offered in the third or fourth semester. In any case, the stated prerequisites should be taken into account. The advantage of an early start of the course is the practice-oriented relevance of the contents. Thus, a hands-on mentality is developed, and the students are taught the relevant engineering skills at an early stage. They learn to solve problems in teams and practice modeling, programming,

[3] https://fwitte.github.io/TESPy_teaching_exergy/
[4] https://github.com/fwitte/TESPy_teaching_exergy

and scientific computing. Also, they get familiar with from scratch process design and find alternative solutions. Finally, the students further develop existing structures.

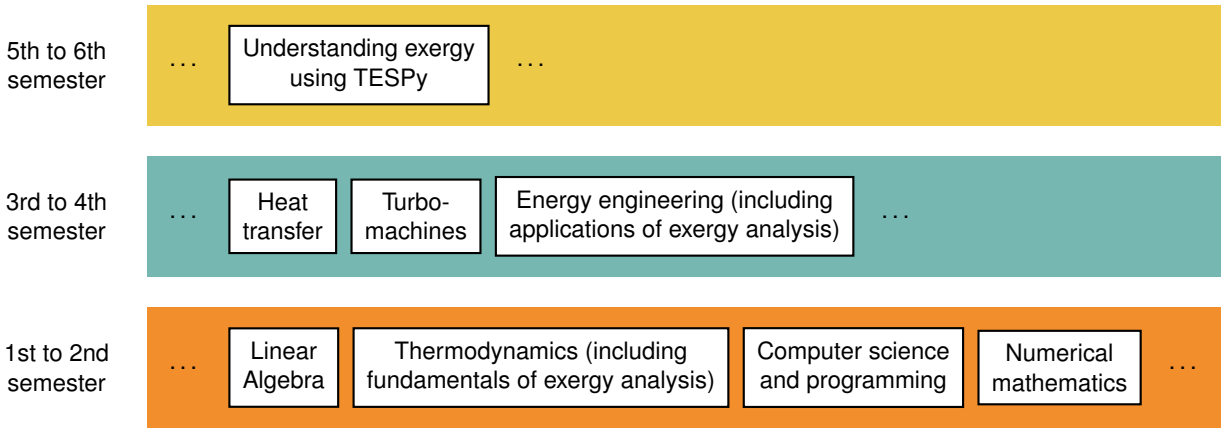

Figure 1: Integration into the curriculum of a typical engineering undergraduate program

2.2. Learning Outcomes

After finishing the course, the students are familiar with the basics of steady-state process simulation and know different methods for calculating the thermodynamic properties of substances. Also, they can build, initialize and solve process flowsheets independently, using the software Thermal Engineering Systems in Python (TESPy) as a process simulation tool for modeling, calculating, and analyzing complex energy engineering processes and interpreting the results obtained. The participants identify and solve problems that occur during process simulation and can independently use aspects of the exergy concept for their future research questions. They are familiar with physical and chemical exergy and the splitting of physical exergy. They can evaluate processes and components with the help of exergy analysis and exergy-based parameters and present the analyses graphically. Finally, using a version control system, the students apply group work methods such as team communication, milestone processing, and cooperative programming.

In their best efforts, students complete the module by adding new elements to the existing course, and thus reach the highest level of competence according to Anderson and Krathwohl [4], see Section 1.

2.3. Content and Competencies

Following the course content of fundamentals of thermodynamics and energy conversion, the focus is on simulating single state changes, simple cycles, and complex energy conversion systems. At the same time, the participants will practice methods of exergetic process evaluation.

The mathematical representation of individual components of energy engineering processes, e.g., heat exchangers, pumps, turbines, waste heat boilers, steam generators, condensers, is subsequently combined into the representation of overall processes, e.g., gas turbines, gas and steam turbine power plants, steam power processes, and integration of renewable energy sources. The methods of setting up process simulations, solving mass and energy balances, and calculating thermodynamic property data are covered. The simulation program used is the free and open-source software TESPy, see Section 3.

The work can be done individually or in small groups. We recommend working in teams of 2 to 3 people to intensify social skills and test suitable collaboration methods. Figure 2 shows the distribution of the competence fields addressed during the course. Depending on the individual characteristics of the course, shares may shift slightly.

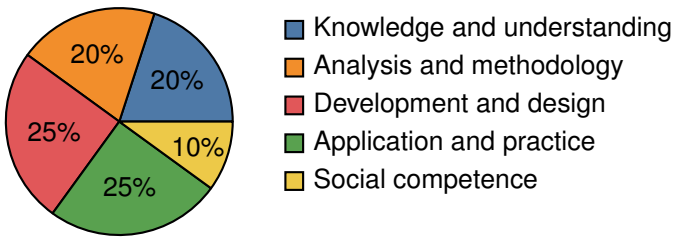

Figure 2: Pie chart showing the competency fields addressed in the progress of the course.

2.4. Schedule

The Gannt chart in Figure 3 shows a sample schedule for designing the class for one semester (2 contact hours per week). In its first version, the course includes four sections and three milestones. The kick-off meeting can include a get-to-know-you and orientation session if the students work in teams. Afterward, there is the possibility to configure the own hardware and run tests regarding the functionality of the libraries to be used.

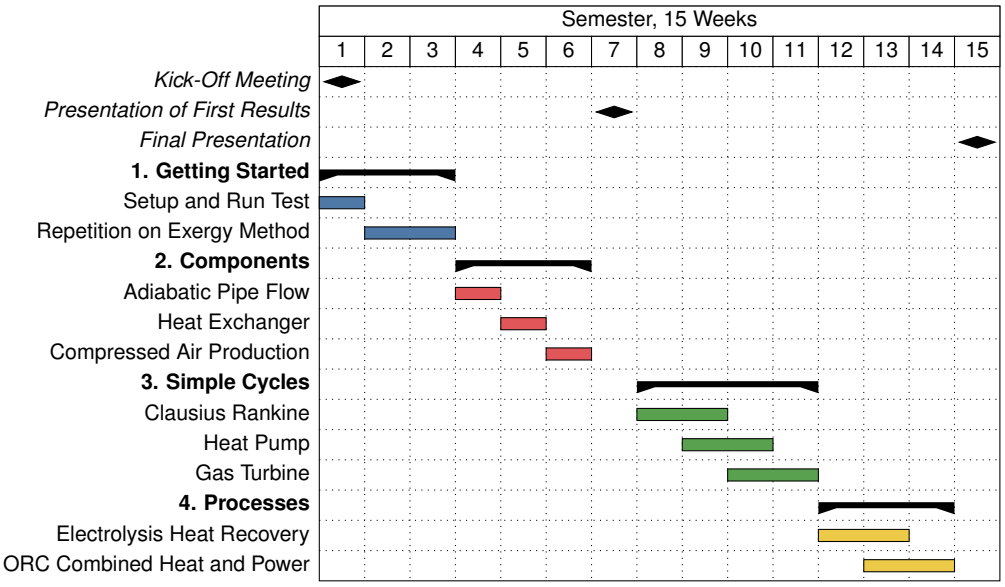

Figure 3: Gannt chart showing the possible progress of the course in one term.

In the second section, students are encouraged to investigate thermodynamic fundamentals for simple applications and program them independently. All analyses are carried out at the component level and usually involve exactly one thermodynamically describable change of state. With the help of simple exergetic analyses based on the solution of the mass and energy balances and simple graphical evaluations, differences between energetic and exergetic descriptions can be made easily understandable.

In the second section, the students will partially write down the correlations in an elementary way and later moving forward to a object-oriented programming. The advantages of a Python library (e.g., TESPy) become clear with the transition from the second to the third section.

In the third section of the course, the exergy analysis is to be applied to simple multi-component systems. At the latest in this section, the students should be aware of the advantages of the exergy-based evaluation compared to a purely energetic consideration. A further focus is then on the graphical evaluation of the results. How can the findings be visualized in the best possible way? The students can try out various approaches independently here.

Since the interaction of several components is now being investigated, the focus is on how the components' properties impact the overall process. For instance, which components significantly influence the exergy destruction of the overall process and why. It is necessary to determine which thermodynamic parameters are the most important for improving the overall process.

The last section examines complex processes with more than one product. If a process provides different forms of energy as products, for example electricity and district heating, an energy-based assessment of the quality of the overall process is misleading. Exergy is the only way to ensure comparability of the different material and energy flows. The students are to conduct these evaluations for processes such as heat recovery in electrolysis or processes with combined heat and power.

2.5. Further Reading, Online Tutorials, Hardware, Software

During their work the students can use several textbooks or online tutorials for fundamental or further reading. We recommend the following:

- Thermodynamic fundamentals [12, 13]
- Exergy concept [6–9]
- Python [14] and Jupyter Notebooks [15]
- TESPy [16–18]

For scientific computing in Python environments, it is a convenient option to use ready-made distributions that integrate relevant packages and library management in a user-friendly way. A simple start succeeds with miniforge[5], available for all current operating systems. To edit and run the code students can install a code editor such as Pycharm[6] (free of charge for university members) or Visual Studio Code[7] or run a local server allowing them to work in a browser. The online documentation of the course includes all relevant installation instructions.

3. Implementation

In recent years, there has been a concern [19] in the energy system analysis community, among others, with the public provision of data and publicly funded research's traceability. Various initiatives are engaging in this area, developing free and open-source work paradigms and taking them into other domains. Aspects initially discussed only in research are spilled into teaching. For example, the Journal of Open Source Education [20] specifically addresses lecturers to publish online educational resources connected with free and open-source software. In a proposal, Morrison [21] formulates the idea of combining publicly available data and voluntary contributions from experts into a "student-centered" energy system model for education. The actual energy system model will be programmed in Julia, and the workflow will be set up in Jupyter. It is explicitly not a web-based scenario generator or gamification exercise. The students will perform exercises in a curated way and develop the code of the energy system model piece by piece.

Inspired by these ideas, the present course for energy technology and exergy analysis was developed. In particular, the idea for the structural content and the technical project architecture is based on Morrison's proposal. The entire content of the course is embedded in a Python-based structure. The prepared content can be accessed online in a textbook format[8] and the source files are available through the respective GitHub repository.[9] Figure 4 shows the implementation.

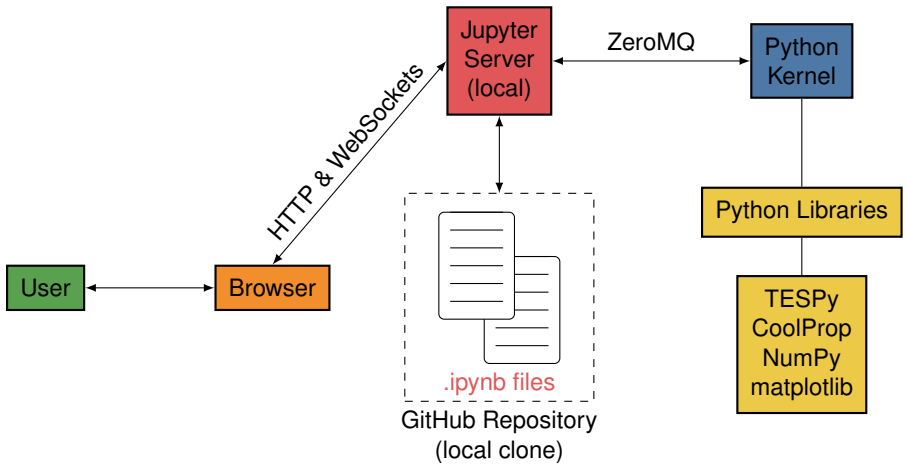

Figure 4: Implementation of the resources into a Python-based architecture including a powerful and user-friendly front-end

The files[10] are provided as a Jupyter notebook. It is an editable format where not only Python code is stored and can be executed, but visualization, markdown, and collaboration capabilities exist. Consequently, this format is particularly suitable for course formats like the one presented here. Outlines can be created, and text can be formatted, images and videos can be added, mathematical formulas and referencing can be used.

To create their own code, students can download the Jupyter files to their machine and locally run a Jupyter server, which allows to access a Python kernel and run their code in the browser or in code editors.

The open-source software TESPy [16] is used for the component-based simulation of the considered energy conversion processes. The software is developed as part of the open energy modeling framework (oemof) in the scientific field and by industrial users.[11] The user can build up arbitrary thermodynamic processes from single predefined components like heat exchangers, compressors, valves, or turbines. In addition to heat pumps, geothermal or solar thermal power plants, heat networks, or chillers can also be mapped. The software

[5] https://github.com/conda-forge/miniforge

[8] https://fwitte.github.io/TESPy_teaching_exergy
[9] https://github.com/fwitte/TESPy_teaching_exergy
[10] file extension .ipynb
[11] https://oemof.org

accesses the likewise open-source substance properties database CoolProp [22]. Detailed documentation with more examples and tutorials is available for the software.[12]

Following process simulation and design, exergy analysis can be used to identify sources of thermodynamic losses. The exergy analysis is performed automatically. Only the exergetic fuel, product, and loss of the overall process have to be passed to the tool [17, 18]. Furthermore, the simulation models can be combined with optimization methods [23].

4. Featured Course Material

The course is based on three relevant pillars whose approach enables change management and innovation processes in their respective disciplines or application areas. The three pillars are

- object-oriented programming with Python,
- steady-state power plant simulation with open-source software (TESPy, CoolProp), and
- thermodynamic evaluation using exergy-based methods.

As a consequence, the contents of the course lead to the conclusion that these three pillars can be interlinked with each other exceptionally well for prospective engineers to teach the exergy concept. We want to summarize this by presenting selected tasks from the course and illustrating the results comprehensibly.

Within all listed thermodynamic models below we assume steady-state processes, all components are adiabatic, there are no pressure losses in the heat exchangers, and changes in kinetic and potential energies can be neglected. Ambient conditions are set to $T_0 = 25\,^\circ\mathrm{C}$ and $p_0 = 1.013\,\mathrm{bar}$. For the calculation of chemical exergies the model of Ahrendts [24] is used. The corresponding flow diagrams and parameters of the processes can be found in Figures 5, 8, 11, and 12 as well as Tables 1, 2, and 3. Due to space limitations, not all source codes are given below. All tasks and solutions can be obtained from the git repository.

4.1. Highlight 1: Adiabatic Pipe Flow

Consider a well insulated pipeline transporting a fluid, i.e., water steam or air. The state change from 1 to 2 because of friction can be described as an adiabatic throttling valve as shown in 5.

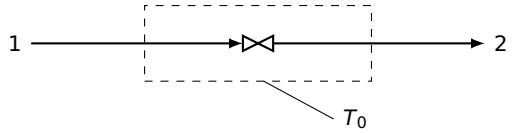

Figure 5: Flowchart of adiabatic pipe flow

Table 1: Adiabatic pipe flow parameters

Parameter	Symbol	Unit	Value
Inlet temperature	T_1	°C	195
Inlet pressure	p_1	bar	10
Constant (or varying) outlet pressure	p_2	bar	6 (or p_1 ... p_0)
Mass flow rate	m_1	kg/s	1

First, setting up the parameters of the pipe flow and calculating the inlet enthalpy, if necessary install CoolProp.[13]

```
from CoolProp.CoolProp import PropsSI as PSI
fluid = "water"
p_in = 10 * 1e5
T_in = 195 + 273.15
h_in = PSI("H", "P", p_in, "T", T_in, fluid)
p_out = 6 * 1e5
```

Considering the above assumptions, and the energy balance, we determine the outlet temperature for isenthalpic throttling using CoolProp.

```
h_out = h_in
PSI("T", "P", p_out, "H", h_out, fluid) - 273.15
```

[12] https://tespy.rtfd.io

[13] As an alternative a simple, full-featured, lightweight CoolProp wrapper for Python is available via https://pypi.org/project/pyfluids/.

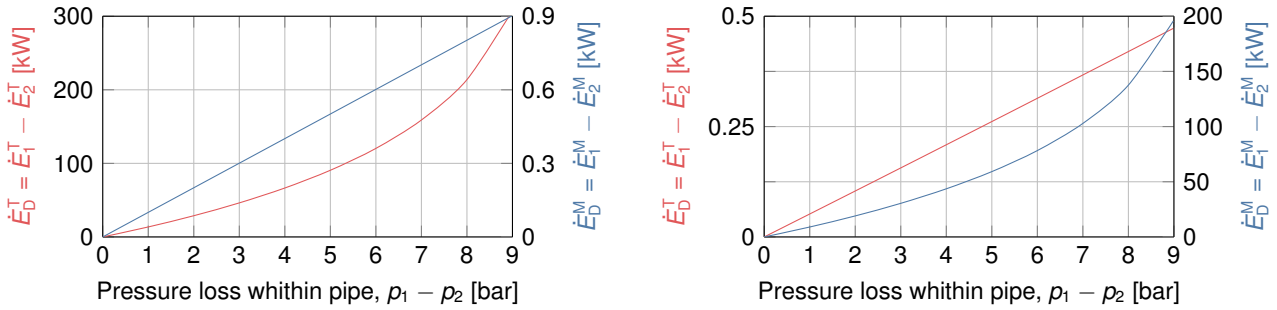
Subsequently, the following exercises, among others, can be performed. Implementing a function that splits the physical exergy in its thermal and mechanical parts [25]. Creating a plot showing how the thermal and mechanical exergies are affected within a range from ambient pressure to inlet pressure. And re-performing the tasks by using air instead of water steam.

Using a Python function the calculation of thermal and mechanical exergy can be performed for different temperatures, pressures and fluids.

```
def calc_splitted_physical_exergy(p, h, p0, T0, fluid):
    r"""Calculate specific physical exergy according to splitting rule."""
    s = PSI("S", "P", p, "H", h, fluid)
    h_T0_p = PSI("H", "P", p, "T", T0, fluid)
    s_T0_p = PSI("S", "P", p, "T", T0, fluid)
    ex_therm = (h - h_T0_p) - T0 * (s - s_T0_p)
    h0 = PSI("H", "P", p0, "T", T0, fluid)
    s0 = PSI("S", "P", p0, "T", T0, fluid)
    ex_mech = (h_T0_p - h0) - T0 * (s_T0_p - s0)
    return ex_therm, ex_mech

ex_T_in, ex_M_in = calc_splitted_physical_exergy(p_in, h_in, p0, T0, "water")
```

Figure 6a and 6b show the difference in the values between inlet and outlet of the thermal and mechanical exergies, representing the corresponding exgery destruction in the pipe flow for varying pressure ratios. Note the different scales of the y-axes. The thermal exergy of water steam changes by up to 300 kW, while the mechanical exergy difference is 0.9 kW at maximum. For air the thermal exergy difference reaches a maximum of around 0.5 kW, the mechanical exergy changes up to 200 kW.



(a) Water steam

(b) Air

Figure 6: Thermal and mechanical exergy destruction within the the pipe for varying pressure losses

The fundamental difference of the substance characteristic leads to the fact that the exergy destruction for water steam in the pipe flow is mainly triggered by a decrease of the thermal exergy. In the case of air, the mechanical exergy decreases significantly more.

A comparison of the exergy destruction rate for the pipe flow of water steam and air is shown in Figure 7. The ratio of both exergy destruction rates is almost constant and is about 1.5.

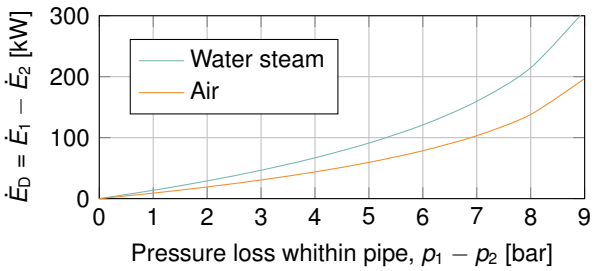


Figure 7: Exergy destruction for water steam and air within the adiabatic pipe flow

Lessons Learned from this task:

- Physical exergy of a mass flow can be split into a thermal and a mechanical part.
- At the same pressure and temperature, the shares of thermal and mechanical exergies depend on the working fluid.

4.2. Highlight 2: Open-Cycle Gas Turbine

A simple gas turbine model should be developed within this task. Compressed ambient air is mixed up with methane. The gases after the combustion are used in a gas turbine expander to supply mechanical, respectively electrical energy.

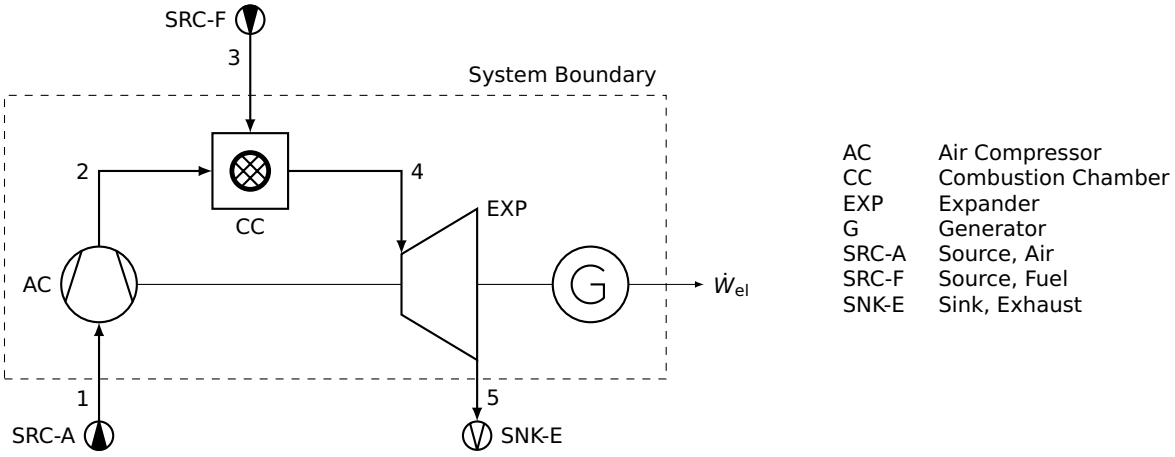

Figure 8: Flowchart of open-cycle gas turbine

Table 2: Open-cylce gas turbine parameters

Parameter	Symbol	Unit	Value
Net power output	$\dot{W}_{net}$	MW	150
Air compressor, isentropic efficiency	$\eta_{s,AC}$	–	0.85
Air compressor, pressure ratio	$r_{p,AC}$	–	18
Combustion chamber, thermal efficiency	η_{CC}	–	0.98
Combustion chamber, pressure ratio	$r_{p,CC}$	–	0.95
Expander, isentropic efficiency	$\eta_{s,AC}$	–	0.9
Expander, inlet temperature	T_4	°C	1400
Expander, outlet pressure	p_5	bar	1.013
Fuel, inlet pressure	p_3	bar	20
Fuel, inlet temperature	T_3	°C	25
Fuel, mass analysis[a]	$y_{i,fuel}$	–	$(\dots, 1.0)$
Air, mass analysis[a]	$y_{i,air}$	–	$\begin{pmatrix} 0.7551 \\ 0.2314 \\ 0.0129 \\ 0.0006 \\ 0.0 \\ 0.0 \end{pmatrix}$

[a] All fluid compositions are given as $y_i = \left(y_{N_2}, y_{O_2}, y_{Ar}, y_{CO_2}, y_{H_2O}, y_{CH_4}\right)^T$

TESPy is used to set up the thermodynamic model of the gas turbine. The solution is carried out for the full load case. The documentation of the source code can be found in the appendix.

A parameter study should be performed based on the results for the air compressor pressure ratio and expander inlet temperature. The solution is a multiple run of the simulation above, while varying pressures and temperatures.

Figure 9 depicts a parameter plot for the given gas turbine system varying expander inlet temperature from 900 °C to 1400 °C and the air compressor pressure ratio from 5 to 30. The reference point corresponds to the data from Table 2. For the plot only the marked points were calculated, the lines in between are linear regressions. If necessary, the accuracy of the graph can be increased by performing more calculations. An optimal combination of expander inlet temperature and pressure ratio exists to maximize the specific work and the efficiency of the gas turbine.

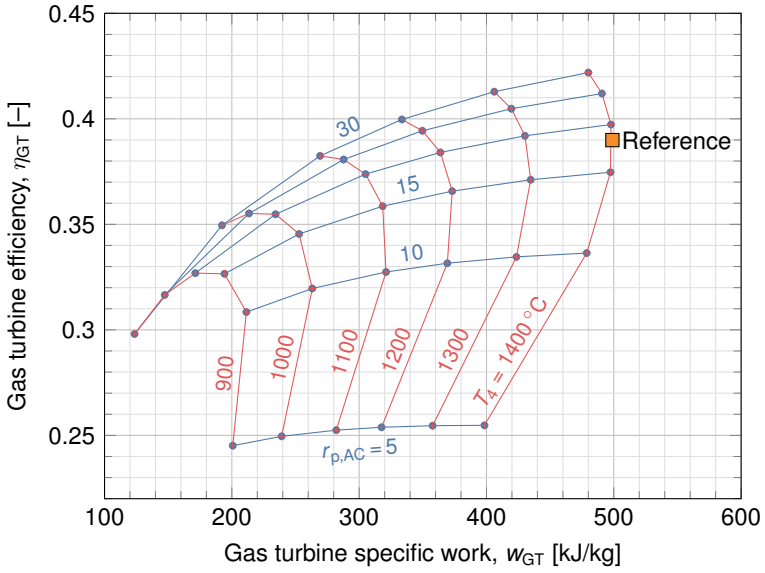

Figure 9: Gas turbine parameter plot for varying expander inlet temperature air compressor pressure ratio

However, with this initially only energetic evaluation of the process, based on the specific power and the net efficiency, the real thermodynamic losses cannot be quantified and the performance of the system components cannot be compared with each other. The exergy analysis answers these open questions.

In case TESPy is used for the simulation of the thermodynamic performance, an exergy-based evaluation can be carried out using the class ExergyAnalysis. The students have to set up the exergy flow rates crossing the system boundary and define the exergetic fuel, the exergetic product and the exergetic loss of the overall process.

The busses for the net work rate and the fuel input are already defined. In case of fuel the chemical exergy must be considered. Additionally, an exergy loss bus must be defined for the exhaust gas.

The generic exergy analysis of TESPy can be set up within a few lines of code, defining the above mentioned exergy flow rates and the ambient conditions.

```
from tespy.tools import ExergyAnalysis
ean = ExergyAnalysis(gas_turbine, E_P=[work_net], E_F=[ex_fuel], E_L=[ex_loss])
ean.analyse(pamb=1.013, Tamb=25)
```

The graphical evaluation of the exergy analysis can be done, for example, with a waterfall diagram. Penkuhn et al. [26] show this for a cogeneration plant. Another form of visualization is the representation of exergy rates in a Sankey diagram, often called a Grassmann diagram.[14] The exergy analysis results are linked to the representation of the process flow diagram. The different material and energy streams of the flowsheet are brought to a uniform basis with the help of the exergy. The width represents the exergy rate. In addition, the exergy destruction is directly assigned to each component. Figure 10 shows this for the gas turbine process under investigation. The highest exergy destruction rate occurs in the combustion chamber, followed by the expander and air compressor. The exhaust gases represent an exergy loss for the overall process.

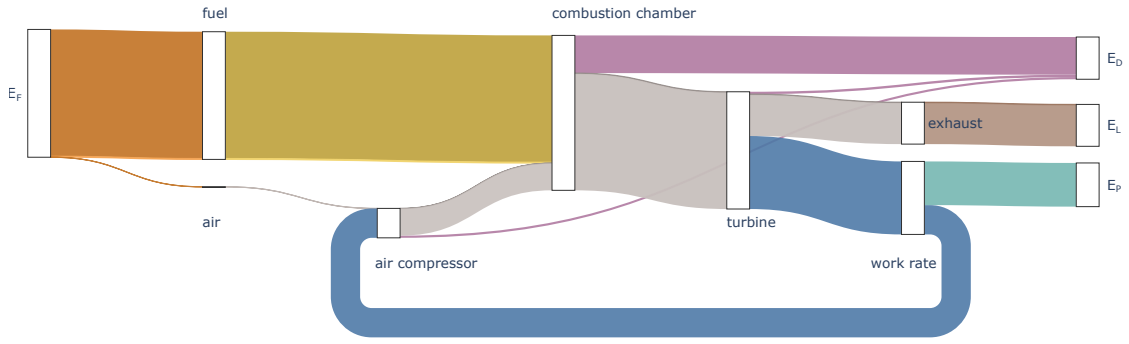

Figure 10: Grassmann diagram of gas turbine process showing the results of the exergy-based assessment

[14] Grassmann [27] transferred the idea of Sankey to the exergy concept. Exergy flow diagrams are therefore associated with his name.

The light tint indicates physical exergy, and the dark tint indicates chemical exergy, for example, visible in the fuel exergy flow rate or the exergy flow rate between the combustion chamber and the expander. It can be observed that all flows are either nearly pure chemical or pure physical exergy.

Lessons Learned from this task:

- Learn that TESPy can do a lot of work for you.
- Relevant thermodynamic process parameters identified and numerically evaluated.
- Applied exergy analysis for a simple process for the first time, and identified the locations and magnitudes of real thermodynamic inefficiencies.

4.3. Highlight 3: Process Design Study for a Combined Heat and Power Plant

This example contains a process design study. A proposal for a power plant to supply electricity and district heating is to be developed. The heat source is a geothermal field.

The design proposal is to be modeled, simulated, and evaluated independently by the students. The design based on the principle of cogeneration is to be compared with a process design with complete condensation operation (without heat extraction). For this purpose, the energetic and exergetic efficiency of the overall process will be defined.

$$\eta = \frac{\dot{W}_{\text{net}} + \dot{Q}_{\text{DH}}}{\dot{H}_1 - \dot{H}_2} \tag{1}$$

$$\varepsilon = \frac{\dot{W}_{\text{net}} + \left(\dot{E}_{\text{FL}} - \dot{E}_{\text{RL}}\right)}{\dot{E}_1 - \dot{E}_2} \tag{2}$$

All predefined parameters and boundary conditions can be found in Figure 11 and Table 3.

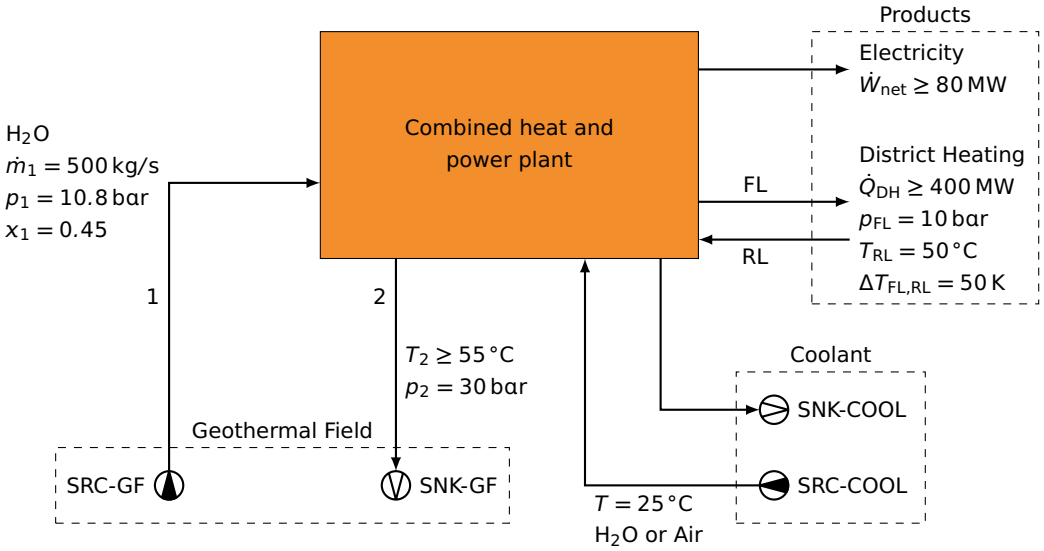

Figure 11: Process design study for a combined heat and power plant to provide electricity and district heating.

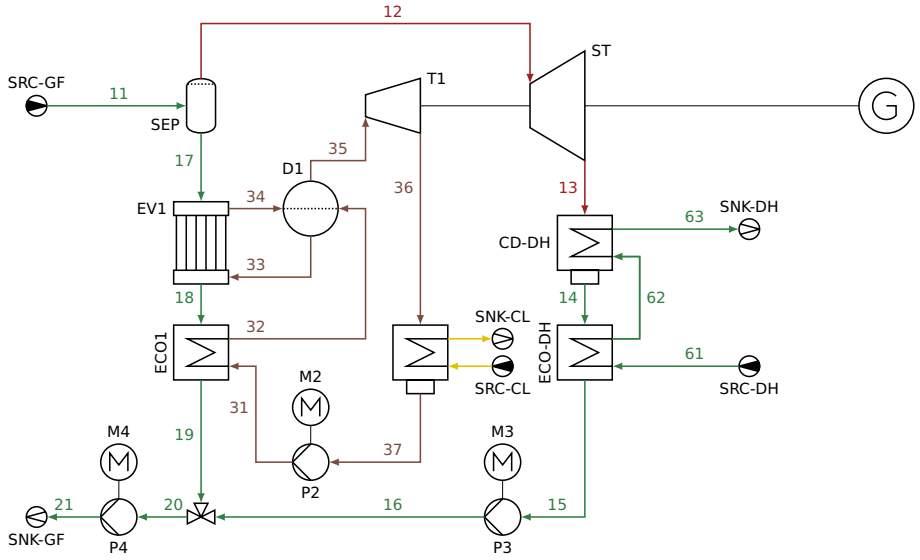
The following subtasks are to be solved within the scope of the assigned problem: Selection of suitable working fluids and selection and reasoning of the use of thermodynamic properties models for the simulation; creation of a process design, modeling, and simulation in TESPy; definition and use of relevant variables for the evaluation of the process designs and subsequent comparison and discussion.

There is no generally valid standard solution for solving this task. Two possible designs with and without heat extraction are shown in Figure 12. In both variants, the heat flow of the liquid part of the geothermal fluid is absorbed by an upstream organic Rankine cycle (ORC) and used to produce electricity. The steam phase is expanded in a steam turbine. In the case of simultaneous provision of district heating, a heating condenser with preheating follows before the geothermal fluid is returned. In the design for electricity generation only, a second ORC is inserted after the steam turbine.

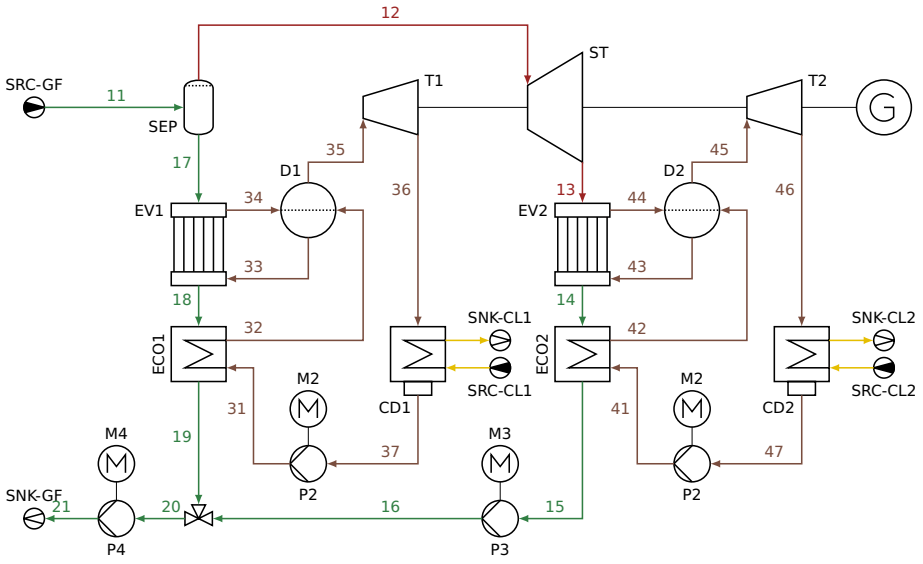
Both process designs are simulated and compared both energetically and exergetically. The results are shown in Table 4. According to Eq. (1), the energetic evaluation treats two different energy flows (electricity and heat)

Table 3: Process design study specifications and constraints

Component	Parameter		Unit	Value
Auxiliary installations	Electrical power requirements		MW	3
Generators	Mechanical-electrical efficiency		–	0.985
Motors	Electrical-mechanical efficiency		–	0.975
Steam turbines	Isentropic efficiency		–	0.9
	Mechanical efficiency		–	0.99
	Minimum steam quality		–	0.9
Pumps	Isentropic efficiency		–	0.8
	Mechanical efficiency		–	0.99
Heat exchangers	Minimal temperature difference	liquid–liquid	K	10
		liquid–condensing	K	5
		liquid–steam	K	20
		liquid–gaseous	K	25



(a) Geothermal combined heat and power plant



(b) Geothermal power plant

Figure 12: Flowcharts of possible process designs

equally. The efficiency is significantly higher in the case of heat extraction. It gives the impression that the process is much closer to the thermodynamic optimum, which is not the case, as the comparison of the exergetic efficiencies shows. Here, both exergetic products can be directly converted into each other. The result is that the process designs have approximately similar range of exergetic efficiencies, and therefore the misestimation of the energetic evaluation can be revealed.

Table 4: Comparison of energetic and exergetic efficiency for developed process designs

Process design	Energetic efficiency η [%]	Exergetic efficiency ε [%]
Geothermal combined heat and power plant	80.4	70.3
Geothermal power plant	19.0	62.8

Lessons Learned from this task:

- The exergy analysis assists in the selection and improvement of a suitable process design.
- Different material and energy streams can be consistently evaluated based on exergy.
- Various process designs with different fuels or products remain comparable with the help of exergy.

5. Conclusion

The idea presented in this article is based on the notion that research and teaching should be accessible to all with as few barriers as possible. At the same time, the paper addresses the exergy concept, one of the essential analysis tools of thermodynamic engineering. Object-oriented programming with Python, particularly steady-state power plant simulation with open-source software, is linked to exergy as an established thermodynamic quantity in the concept presented.

A modular structure is developed to facilitate the integration of the resources into existing courses and for self-learners to choose their appropriate entry point. The modular structure covers exergy analysis of single component operation as the entry-level, where the fundamental understanding of the exergy concept is conveyed. Based on that, students will learn to model simple thermodynamic cycles and to carry out first and second-law analyses by evaluating the simulation results. It is further supported by applying parametric analysis to understand the connection between individual component parameters to the thermodynamic performance of the overall process.

Further processing possibilities arise from the potential integration of additional exercises, the extension to the exergoeconomic analysis [28], the exergoenvironmental analysis [29], or the advanced exergy analysis [30]. At the same time, all interested students, researchers, and practitioners are invited to try the course, and to contribute by making comments or reporting bugs and developing it further collaboratively.

Abstract:

An exergy analysis is carried out on the negative CO_2 emission gas power plant (nCO_2PP), which integrates the process sections of fuel preparation, power generation and carbon capture. Processes of exergy destruction are studied with particular focus on the process in the gasification unit of the fuel preparation section, where a large amount of exergy is destroyed in various chemical reactions from sewage sludge to producer gas conversion. The largest exergy losses are observed in the wet combustion chamber and in the fuel line with the gasification process and water condensation in the gas scrubber, amounting to 126 kW, 43-45 kW and 56 kW respectively, which corresponds to efficiencies of 62%, 89% and 84% of these units, while the exergy efficiency of the power plant is 29.5%. The integration of the gasification unit with the gas scrubber is investigated, and a heat exchanger combination is considered. Ambient air changes in relative humidity and, due to increasing global greenhouse gas emissions, CO_2 concentration are analysed. Insight into the theoretical operation of the power plant through exergy analysis allows energy efficiency to be increased by improving areas of highest exergy destruction. To represent real power plant operation, the analysis is based on an optimised process simulation calculated using the most accurate published equations of state, verified with experimental thermophysical property data from the literature.

Exergy Analysis; Efficiency; Gasification; Sewage Sludge; CO_2; Process Simulation; Integration; Power Plant.

1. Introduction

The Negative CO_2 emission Gas Power Plant (nCO_2PP) shown in Figure 1 is the subject of intensive research in a project dedicated to the disposal of sewage sludge with simultaneous generation of electricity and CO_2 capture [1]. The nCO_2PP cycle has already been described in several articles [2–4] as it offers the hope of simultaneously disposing of the harmful products of human activity (e.g., sewage sludge), then allowing the production of useful electricity, and finally allowing the capture of carbon dioxide in a dedicated part of the CCS. A contribution to the field was made in [5], where an exergy analysis of the nCO_2PP system was conducted, investigating aspects of energy efficiency and CO_2 capture. The basic equipment includes: (1) the working medium generator - i.e., the wet combustion chamber (WCC), the steam-gas expander ($GT+GT^{bap}$), the spray-ejector condenser (SEC), and the gasifier in which the sewage sludge is converted into syngas by means of a converter, which is a bleed stream (Fig.1.). Additional equipment includes oxygen, fuel and CO_2 compressors, water pumps and heat exchangers. It is extremely important not only to test the syngas production experimentally, but also to model the gasification process correctly to indicate its contribution to the energy conversion chain.

The nCO_2PP cycle is consistent with the idea of a bioenergy with a carbon capture and storage (BECCS) power cycle. This involves using a renewable energy source in the form of biomass in combustion processes and then capturing the carbon dioxide produced in this way, ultimately achieving negative CO_2 emissions. However, in addition to carbon performance, an important parameter for the sustainable conversion of fuel energy is exergy destruction. One of the critical parameters influencing exergy destruction are ambient parameters such as temperature, humidity and pressure, which have already been classified in many works by some well-known authors on the subject [6,7]. It is worth noting that the effect of CO_2 in the air is also beginning to play an increasingly important role in exergy analyses, while the issue of determining the chemical exergy of individual elements still lacks a sufficiently reliable physical basis, and most scholars rely on Szargut

[7] in this area. The situation is even more complicated when determining the chemical exergy of different types of biomass [8]. First of all, there is a lack of a clear chemical and physical foundation to move from well-established methods to determine the composition of the ultimate and proximate type to the exergy, because here, entropy relating to the atomic level plays a role [9]. In the case of the present work, the analyses will focus on a significantly challenging biomass, which is sewage sludge. Attempts to model this process appropriately are being developed particularly intensively in the Aspen Plus environment, where, using mass, momentum and energy balance and the entropy production equation, the exergy destruction due to gasification can be determined [10]. Using these models, it is important to determine the components of the syngas at the reactor outlet and the input supplied to the gasifier. Due to the varying composition of sewage sludge, depending on the region of the world, the calorific value of the sludge and thus, the exergy that is stored in it, also changes [11]. In addition, there is great hope in the production of alternative fuels using sewage sludge, where exergetic analyses supplement information on the quality of energy conversion to useful products such as hydrogen [12] or methanol [13]. With respect to exergetic efficiency, it is possible to provide feedback about sustainable energy conversion. This is because it is necessary to identify possible ways of reducing the destruction of exergy, especially in devices where an alternative solution can be proposed.

In the case of the oxyfuel cycle, which is the subject of this study, it is also important to determine the impact of exergy destruction in separation processes either in an air separation unit (ASU) and a spray-injection condenser (SEC). Industrial ASUs rely on cryogenic methods in order to be able to supply the required amount of oxygen, and methods to reduce power consumption are also found in this part of the system [14]. Thus, exergetic analyses undoubtedly provide an opportunity to study technical and environmental aspects related to energy systems [15]. Therefore, this approach was chosen to analyse the nCO_2 cycle integrated with syngas production in the sludge gasification process.

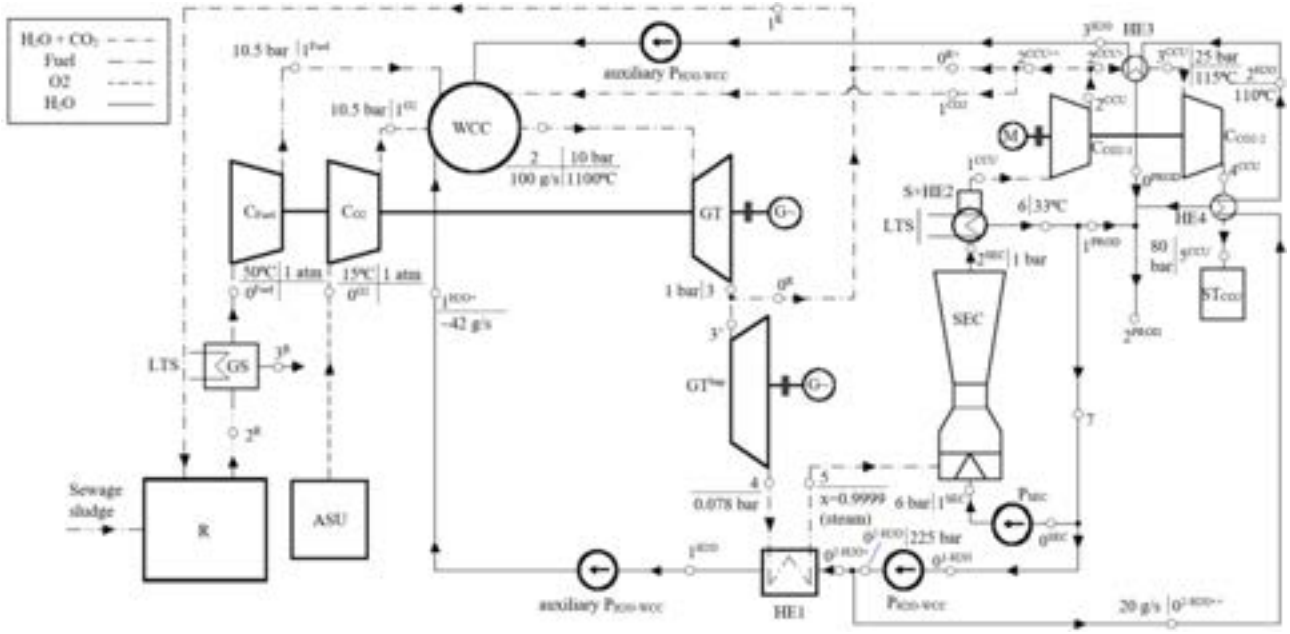

Figure. 1. nCO_2PP process flow diagram [16] where main devices are: WCC – wet combustion chamber, GT – gas turbine, GT^{bap} – low-pressure turbine, R – gasifier, SEC – spray-ejector condenser. Additional devices includes: C_{O2} – oxygen compressor, C_{fuel} – fuel compressor, HE1 – heat exchanger 1, G – generator, $P_{H2O\text{-}WCC}$ – WCC water pump, P_{SEC} – SEC pump, S+HE2 – separator connected with heat exchanger 2, $C_{CO2\text{-}1}$ and $C_{CO2\text{-}2}$ – CO_2 compressors, HE3 – heat exchanger 3, HE4 – heat exchanger 4, GS – gas scrubber, ASU – air separation unit, LTS – lower temperature source.

2. Methodology

2.1. Principal equations

The flow exergy is usually split into a thermomechanical part and a chemical exergy. The latter consists of a mixing part and the chemical exergy component.

$$E^{tot} = E^{th} + E^{ch} \tag{1}$$

The chemical exergy of sewage sludge was calculated as [13]

$$E_{ss}^{ch} = \dot{m}_{ss} \cdot LHV_{ss} \frac{1.0412+0.2160\cdot\left(\frac{H}{C}\right)-0.2499\cdot\left(\frac{O}{C}\right)\cdot\left[1+0.7884\cdot\left(\frac{H}{C}\right)\right]+0.0450\cdot\left(\frac{N}{C}\right)}{1-0.3035\cdot\left(\frac{O}{C}\right)} \tag{2}$$

The power plant was simulated using Aspen Plus with REFPROP equations of state. A part of the exergy was derived from this software. However, due to the lack of proper documentation of exergy in Aspen software, it was investigated whether this was total exergy, thermomechanical exergy or some part of it. Essentially, total flow exergy is the reversible work done when a flow is brought into equilibrium with its environment. The "Aspen exergy" is the reversible work done when the flow is brought from the relevant state to the Aspen dead state. Due to condensation and phase separation when the flow contains H_2O, the mixture is partially separated. This means that the Aspen exergy calculation includes part of the mixing exergy together with the thermomechanical component. The remaining flow exergy is the reversible work obtained when the flow is brought from the Aspen Plus restricted dead state to equilibrium with the environment:

$$W_{\text{rev}} = T_0 \cdot \bar{R} \cdot \left[\sum_{i \neq H_2O} n_i \cdot ln \frac{n_i}{n - n_{H_2O(liq0)}} + \left(n_{H_2O(\text{g0})} + n_{H_2O(\text{liq0})}\right) \cdot ln \frac{p_{s0:\,H_2O}(T_0)}{p_0}\right] + n_{H_2O(\text{liq0})} \cdot (p_0 - p_{s0}) \cdot \bar{v}_{f:\,H_2O}(T_0) + \sum_i n_i \cdot \bar{e}_i^{\text{ch}} \quad (3)$$

For streams consisting only of liquid water, the equation reduces to the chemical exergy:

$$W_{\text{rev}} = n_{H_2O(liq0)} \cdot \bar{e}_{H_2O(liq0)}^{\text{ch}} \quad (4)$$

Including the exergy part calculated by Aspen Plus, the total exergy is as follows:

$$E^{\text{tot}} = E^{\text{Aspen}} + W_{\text{rev}} \quad (5)$$

For the purposes of analysis, exergy destruction was obtained from the steady-state exergy balance,

$$E_d = \sum E_{in}^{\text{tot}} - \sum E_{out}^{\text{tot}} + \sum W_{in} - \sum W_{out} \quad (6)$$

The exergy efficiency of a unit is expressed as the outflow-to-inflow ratio of exergy rates,

$$\eta_{ex} = \frac{\sum E_{out}^{\text{tot}} + \sum W_{out}}{\sum E_{in}^{\text{tot}} + \sum W_{in}} \quad (7)$$

A benefit of the outflow-to-inflow efficiency (compared to the “task efficiency”) is that the efficiency of two or more combined units (subsystems) is simply the product of the efficiencies of the individual units. The exergy efficiency of the power plant is then expressed as

$$\eta_{ex|nCO_2PP} = \frac{\sum W_{out} - \sum W_{in}}{E_{fuel,in} + E_{O_2,in}} \quad (8)$$

Here, to appreciate the CO_2 capture, the thermodynamic value (pressure and chemical exergy) of the captured CO_2 could be added in the denominator.

2.2. Input data

For exergy analysis, the Aspen Plus dead state was set to the T_0 temperature of 15ºC and p_0 pressure of 1 atm (at sea level 0), which corresponds to most standards. Thus, read values from Aspen Plus with REFPROP equations of state, such as saturation pressure $p_{s0:\,H_2O}(T_0)$ was 0.0170579 bar and $\bar{v}_{f:\,H_2O}(T_0)$ was 0.018031 m^3/kmol. The exergy calculation also uses the universal gas constant $\bar{R}$ equal to 8.31433 kJ/(kmol K). The chemical exergy calculations used the composition of dry air [17] based on the US Standard Atmosphere, with the CO_2 concentration assumed to be 375 ppm [6] for the year 2004. For comparison, a global average of 417 ppm was used for the year 2022 [18] and a worst-case scenario of 1000 ppm was predicted for the year 2100 [19].

The composition of sewage sludge digested in the gasification unit and fueling the whole power plant, was assumed as mass fractions 27.9% C, 6.7% H, 28.9% O, 4.4% N, 32.2% Ash, with an LHV of 9.8 MJ/kg. The synthesis gas produced by gasification in a steam atmosphere at 760 °C and, after cleaning in the gas scrubber, a volumetric composition of 9.3% CO, 46.8% H_2, 13.9% CH_4, 26.4% CO_2 and 3.5% C_3H_8.

Table 1. Assumptions for the thermodynamic cycle

Parameter	Symbol	Unit	Value
Temperature exhaust after WCC (before GT)	t_2	ºC	1100
Mass flow of the exhaust gas from the WCC	$\dot{m}_2$	g/s	100
Exhaust pressure after WCC	p_2	bar	10
Oxygen-fuel excess ratio in WCC	λ	-	1
Initial syngas temperature, after gas scrubber	t_{fuel}	ºC	50
Initial oxygen temperature	t_{O2}	ºC	15

Syngas fuel pressure before C_{fuel} compressor	p_{0-fuel}	bar	1
Oxygen pressure before C_{O2} compressor	p_{0-O2}	bar	1
Fuel to WCC pressure loss factor	δ_{fuel}	-	0.05
Oxygen to WCC pressure loss factor	δ_{O2}	-	0.05
Regenerative water pressure to WCC	p_{1-H2O}	bar	225
Exhaust vapor quality after HE1	x_5	-	0.999
Exhaust temperature after HE1, before SEC	t_5	ºC	33
CO_2 pressure after compressor C_{CCU1}	p_{2-CCU}	bar	25
CO_2 pressure after compressor C_{CCU2}	p_{4-CCU}	bar	80
H_2O temperature after HE4	t_{2-H_2O}	ºC	110
CO_2 temperature after HE3	t_{3-CCU}	ºC	115
Water vapor from Separator in 1^{CCU} mixed with CO_2 vapor	-	%	100% humid
Pressure after GT^{bap}	p_4	bar	0.078
Temperature after SEC	t_6	ºC	35
Turbine GT, internal efficiency (η_i)	η_{iGT}	-	0.89
Turbine GT^{bap}, η_i	$\eta_{iGT-bap}$	-	0.89
Fuel compressor C_{fuel}, η_i	$\eta_{iC-fuel}$	-	0.87
Oxygen compressor C_{O2}, η_i	η_{iC-O2}	-	0.87
WCC water pump $P_{H2O-WCC}$, η_i	$\eta_{iP-H2O-WCC}$	-	0.8
SEC water pump P_{SEC}, η_i	η_{iP-SEC}	-	0.8
CO_2 compressor C_{CO2-1}, η_i	$\eta_{iC-CO2-1}$	-	0.87
CO_2 compressor C_{CO2-2}, η_i	$\eta_{iC-CO2-2}$	-	0.87
Mechanical efficiency for all devices	η_m	-	0.99

3. Results and discussion

Table 2. Calculated chemical components exergy in changing air relative humidity or CO_2 concentration according to [6] and based on Szargut model [7].

Parameter	Symbol	Unit	Value				
Relative Humidity	RH	%	40	50	60	50	50
Atmospheric CO_2 concentration	X_{aCO_2}	ppm	375	375	375	417	1000
Chemical exergies of substances	$\bar{e}^{ch}_{O_2}$	kJ/kmol	3762	3766	3770	3766	3766
	$\bar{e}^{ch}_{CO_2}$	kJ/kmol	18915	18920	18924	18665	16570
	$\bar{e}^{ch}_{H_2O(liq0)}$	kJ/kmol	2195	1661	1224	1661	1661
	$\bar{e}^{ch}_{H_2O(g0)}$	kJ/kmol	11980	11446	11009	11446	11446
	$\bar{e}^{ch}_{H_2}$	kJ/kmol	239121	238585	238146	238585	238585
	$\bar{e}^{ch}_{CO}$	kJ/kmol	275120	275122	275124	274868	272772
	$\bar{e}^{ch}_{CH_4}$	kJ/kmol	836442	835368	834491	835114	833019
	$\bar{e}^{ch}_{C_3H_8}$	kJ/kmol	2157893	2155747	2153991	2154984	2148697

To complete the exergy analysis, the next step was to calculate the chemical exergy of the sludge and calculate the total exergy and efficiency by substituting the chemical exergies from Table 2 above, with the Aspen Plus exergy known from the models. Relative humidities of 40%, 50% and 60% were used for the chemical exergy calculations. For comparison, the changing atmospheric CO_2 concentration of 417 ppm for the global near-surface average in 2022 and the worst-case scenario of 1000 ppm predicted for 2100 were added.

The following tables (Tables 3-13) show the change in exergy rates as a function of the change in dead state parameters. Note that the parameters in Table 1 do not change.

For the gasification unit shown in Table 3, the syngas composition results came from the experiment presented in the authors' other work [2]. Some simplifications were applied: neglecting the exergy of moisture, ash, nitrogen and sulphur, focusing only on the most important aspect from the power generation point of view. A special attention to this process was due to the high water content in the producer gas and its subsequent treatment in a gas scrubber, the exergy analysis of which is shown in Table 4. While applying the simplifications mentioned above, the gas scrubber is simply a condenser in this case. While the producer gas has a high temperature, the waste heat can be recovered during the condensation process, which was not foreseen in the nCO_2PP concept, as the power plant efficiency of BECCS was usually calculated in the literature without

the gasification unit and gas scrubber and overlooked, thus opening a way to increase the overall energy efficiency of the power plant. The exergy efficiency of the gasification unit decreases with higher humidity or CO_2 concentration, and the same is true for the gas scrubber. The exergy destruction had among the largest exergy destruction rates after the WCC, amounting to 43-45 kW and 56 kW for the gasification unit and the gas scrubber, respectively. The exergy efficiency of the gasification unit was close to 89%, while that of the gas scrubber was 84%. The latter can be increased together with the exergy efficiency of the power plant by using water condensation waste heat for the power plant processes.

The following points show the exergy rates as a function of the relative humidity and as a function of the CO_2 content in the air. As can be seen from Tables 5 and 6, the variation of the above parameters did not affect the compressors. In the whole range of the analyzed parameters, the O_2 compressor exergy destruction remained at the level of 0.45 kW, giving an exergy efficiency of 94.6%, while for the fuel compressor the exergy destruction was 0.67 kW and the exergy efficiency 99.8%. It is worth noting that the influence of the environment on the operation of the compressors was reduced to a negligible level due to the lowest exergy rates. Table 7 applies to water pumps, where the effect of the dead state was much more significant. Despite the constant value of exergy destruction, there is a decrease in exergy efficiency with increasing relative humidity. This is related to the change in the value of the exergy rates carried in the water pumped by the pumps. In contrast, a “task efficiency” would give identical results, independent of atmospheric composition.

Heat exchanger 1 (HE 1) results are given in Table 8, with a heat load of 48.6 kW. In this case, the changes in exergy flux were not only for water, but also for the mixture of water vapour and CO_2. A mixture flowed on one side of the exchanger, so the exergy efficiency decreased as both the relative humidity and the proportion of CO_2 in the dead state increase. Also here, a “task efficiency” would be independent of the atmospheric composition.

Table 9, which refers to the water-injected oxy-fuel combustor, is of particular interest as it has several functions in this power plant. Apart from producing working medium with desired parameters for gas turbines, it has oxy-combustion destined for CCU unit, also it reuses water collecting waste heat from other parts of the power plant and cools down the oxy-combustion flame to desired temperature. Hence, it is called a 'wet' combustor. The combustion was assumed stoichiometric with perfect mixing of oxygen and fuel. In reality, some dissociation and kinetics (non-completed reactions) will give a somewhat lower adiabatic flame temperature. The exergy destruction rate of this unit was the largest in the whole power plant yielding about 126 kW, and its exergy efficiency was about 62%, indicating that special attention needs to be paid to improving this process. In relation to the exergy of the sewage sludge fed to the system, this exergy efficiency was 50% when taking into account the whole process from gasification through water condensation in the gas scrubber, compression and mixing effects in the WCC before ignition and after flame generation. It is worth noting that while oxygen mixing with fuel did not cause significant exergy destruction, water mixing into the flame exhaust caused the largest exergy drop in the range of 64-67 kW. Therefore, to increase efficiency, solutions should be sought in the area of water injection to the WCC.

Tables 10 and 11 refer to the main useful energy generator, the high pressure (GT) and low pressure (GT^{bap}) expander with output power of 90.4 kW and 65.7 kW, respectively. The total exergy rates depended slightly on the amount of CO_2 and relative humidity of the atmosphere at dead state. Increasing these parameters gave insignificant changes and virtually no effects on the exergy destruction rates, which were 4.7 kW and 4.8 kW, respectively. In addition, as expected, the gas turbine expanders were characterized by high exergy efficiencies of 97.9% (GT) and 95.6% (GT^{bap}), respectively, at RH=0.4 and 375 ppm CO_2.

Despite significant exergy rates flowing into the SEC, the exergy destruction within this device was negligible. The value of the exergy efficiency, as shown in Table 12, varied from 99.5% to 99.7% in inverse proportion to the increase in relative humidity. It can also be seen that the increase of CO_2 to 1000 ppm in the dead state did not affect the exergy efficiency.

One of the main objectives of the nCO_2PP cycle is to capture carbon dioxide. Therefore an indispensable part is to determine the exergy conversion in the Carbon Capture Unit (CCU) island, where the following should be distinguished: heat exchangers HE3 and HE4 (heat duty 12.3 kW), compressors C_{CO2-1} and C_{CO2-2} (power consumption 10.1 kW). The results of the analysis of the exergy destruction rates and the exergy efficiency are presented in Table 13. It can be noted that for the CCU island, there was a clear effect of the amount of CO_2 in the dead state on the exergy efficiency, which decreased from 74.8% for 375 ppm CO_2 (RH=0.5) to 73.2% for 1000 ppm CO_2. This is due to the definition of the efficiency, as the inflow and outflow exergies both decrease with the chemical exergy when increasing atmospheric CO_2. A task efficiency (changed exergy rate by input power) would be unaltered.

3.6. nCO₂PP exergy efficiency

While the cumulative efficiency of the power plant in the studied combination is 27.88% [16], its exergy efficiency according to Eq. (8) is 29.48% when related to the exergy of the sewage sludge used as input and is constant for varying RH or CO_2 concentration, although the value starts to vary when related to the producer gas.

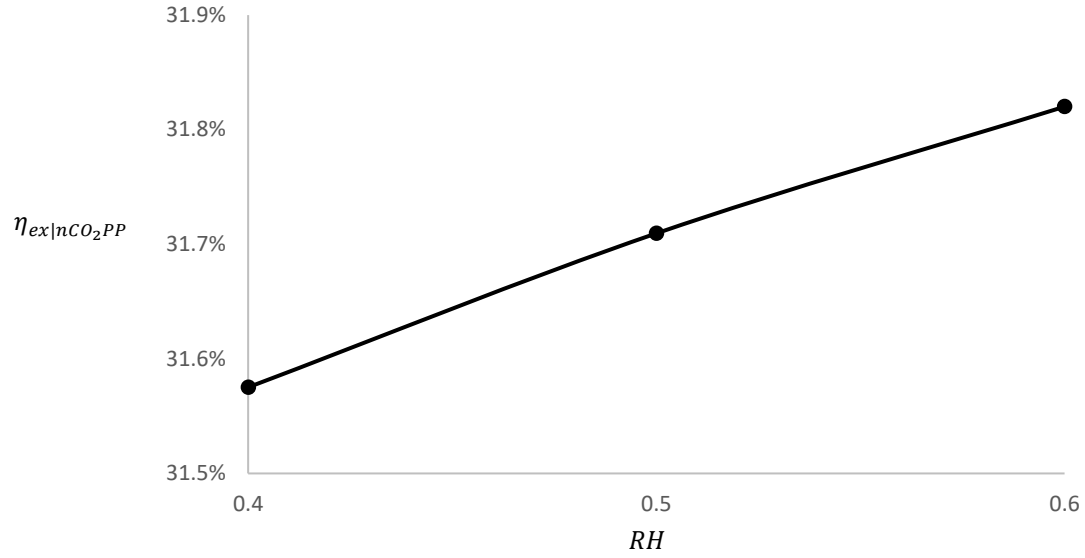

Figure. 2. nCO₂PP exergy efficiency in changing air humidity conditions

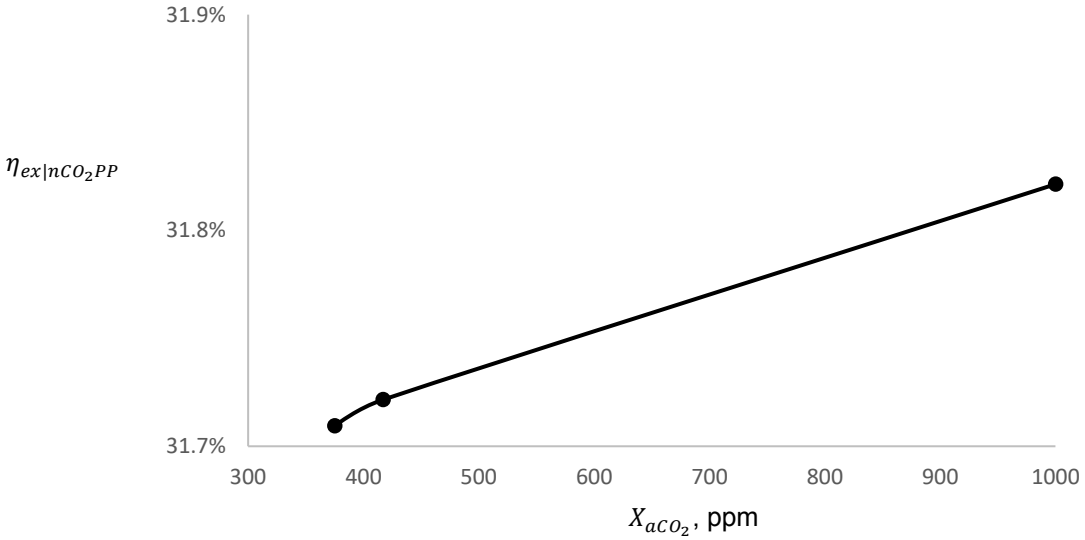

Figure. 3. nCO₂PP exergy efficiency in changing air CO_2 concentrations

4. Conclusions

Second law analysis has been conducted on nCO₂PP. The analyses gave an insight into the integrated system of the gasifier and the nCO₂PP cycle, taking into account the influence of relative humidity and CO_2 content in the air, which translated into chemical exergy of the components in relation to the dead state. The conducted analyses showed that the lowest exergy efficiency is characterized by a wet combustion chamber with a value of about 62%. However, exergy losses affecting the efficiency of this device are unavoidable. Another significant loss is the CO_2 conditioning system for later storage with an exergy efficiency value of 75%. Also, in this set of devices, the possibilities of reducing exergy destruction are limited. Another device with a relatively low exergy efficiency is the gasifier unit and the heat exchanger of gas scrubber with efficiencies of 89% and 84%, respectively. Significant prospects for reducing exergy destruction are offered by the Heat exchanger of Gas Scrubber because the waste heat from this device can be used to drive organic Rankine cycles or to produce oxygen in oxygen transport membranes.

Abstract:

In view of the energy transition, it is important that engineering students are familiar with the concept of exergy and the added value of exergy analysis compared to energy analysis. Exergy analysis tells the truth about energy efficiency and exergy is directly related to sustainable development. This paper focuses on teaching exergy to students at the Delft University of Technology (TU Delft), but the contents are valuable to other engineering students as well. To encourage the teaching of exergy, the basics of exergy and exergy analysis are presented, as well as examples and ideas for teaching exergy to BSc students that are related to the topics of their BSc programme. It is recommended that the contents of this paper be discussed with many teachers of BSc programmes, especially teachers of BSc programmes that do not yet seem to include the teaching of exergy, and that attention be paid to teaching exergy to MSc students as well.

Keywords:

Teaching; Exergy; Academia; Energy Transition; Added Value; Basics; Examples.

1. Added value of exergy

In view of the energy transition, it is of utmost importance that students graduating from technical universities are well aware of energy-related concepts such as heat, work, energy conservation and the work potential, or quality, of energy. This work potential is important since it is needed for all processes and activities to take place. Preferably, all students who become policy makers, whether they graduate from technical or from non-technical universities, are familiar with these concepts. The work potential of energy is known as exergy; a term proposed in 1953 by Z. Rant [1].

According to the Science Europe Physical, Chemical and Mathematical Sciences Committee, our society does not have an energy crisis, but an exergy crisis [2]. As they put it [2, p.2]: “It is, however, not energy per se that needs to be secure, affordable and sustainable but rather exergy.” and “Exergy analysis not only tells the truth about energy efficiency, but, in an extended perspective, potentially leads to resource accounting on a global scale: a common scale for our common future.”

Exergy analysis tells the truth about energy efficiency because it, in contrast with energy analysis, takes into account the work potential of the ingoing and outgoing flows of a process or system, and shows where work potential is lost. This loss of work potential cannot be made visible with energy analysis. Besides, the law of energy conservation tells that energy cannot be lost nor created. It can only change forms.

Knowing that work potential is needed for all processes and activities and that each process and activity is accompanied with the loss of work potential raises the question whether enough work potential is available to current and future generations. Sources of work potential are fossil fuels such as gas and oil, but these are not renewable and their use causes carbon dioxide emissions. An example of an infinite and renewable source of work potential is solar energy. Solar radiation is also essential for photosynthesis; for plants and trees to grow and to produce the substances necessary in living organisms. Like human processes and activities, photosynthesis and related natural processes involve loss of work potential as well.

Exergy analysis can be used to investigate the causes of the loss of work potential and whether there are possibilities to limit this loss, and thus limit the amount of work needed for the process or activity to take place. In this way, exergy analysis can also be helpful in the choice of which product(s) must preferably be produced,

in the assessment of the reparability, reusability of products and the selection of, e.g., minerals that are used to produce a product.

The results of energy and exergy analyses may very well indicate different parts of processes or systems that have the largest room for improvement. For example, the results of an energy analysis of a methanol production process show that the distillation section needs improvement, while the results of an exergy analysis of the same process clearly indicate that the reforming section causes the highest exergy loss [3].

Furthermore, according to Dincer and Rosen [4, p.61]: “Many suggest that mitigating the environmental impact of energy resource utilization and achieving increased resource-utilization efficiency are best addressed by considering exergy. The relations between exergy and both energy and the environment make it clear that exergy is directly related to sustainable development.”

The calculation of exergy values of amounts of mass and/or energy is based on thermodynamic equations, which makes it a more fundamental method than other sustainability assessment methods because, e.g., the environmental impact is calculated by making use of models and weighting factors, the economic performance is based on costs that vary over time because of market developments, and the calculation of the societal impact of processes or systems is hampered by the limited availability and qualitative nature of data.

This paper focuses on teaching exergy to students at Delft University of Technology (TU Delft), Delft, Netherlands, because all authors have graduated from this university and are, or were, employed by this university. Chapter 2 considers the current status of exergy teaching at TU Delft. Chapter 3 deals with teaching exergy in general, while chapter 4 provides examples and ideas dedicated to students taking specific BSc programmes at TU Delft. This is followed by discussion, conclusions and recommendations.

2. Current exergy teaching at TU Delft

In the academic year 2022-2023, TU Delft offers 16 BSc programmes and more than 30 MSc programmes. The TU Delft study guide [5] was used to determine which of these programmes discusses exergy in one or more of their courses by searching the study guide for courses with the search text “exerg*”, thus with a wildcard at the end. This search resulted in the following eight programmes.

The BSc Mechanical Engineering includes the course Process Engineering & Thermodynamics (WB2543), with the ability to perform energy and exergy calculations of energy and process equipment being one of the learning objectives. The BSc Molecular Science & Technology comprises the course Energy, Recycling and Safety (4052ENRV6), where exergy is mentioned in the Dutch description (not in the English version) of the course contents as part of the topic energy, i.e. together with the energy balance of the earth, greenhouse effect and climate change. The BSc Systems Engineering, Policy Analysis & Management offers the course Processes in the Energy Sector (TB242EB), of which one of the learning objectives is dedicated to exergy, i.e. to be able to explain what exergy and exergy loss is and to calculate exergy losses, values and efficiencies. The BSc minor programme Engineering for Large-scale Energy Conversion and Storage (ELECS) comprises two courses that deal with exergy: the course Energy Conversion: Devices, Systems and Efficiencies (WB3575) applies exergy analysis to energy conversion systems, devices and processes and the course Assessment of Energy Systems (WB3585) applies several assessment methods, i.e. life cycle assessment and exergy analysis, to large scale energy conversion and storage systems. The MSc Applied Earth Sciences contains a course Energy Transition (AESM1315), of which exergy analysis belongs to the course contents, but in 2022/2023 only exam opportunities are offered because this course is discontinued. The MSc Architecture, Urbanism and Building Sciences offers the course User-centred Sustainability Studio (AR3B015), where exergy is mentioned in one of the titles listed as literature and study materials, i.e. Energy Potential Mapping - Visualising Energy Characteristics for the Exergetic Optimisation of the Built Environment [6]. The MSc Mechanical Engineering includes the course Equipment for Heat & Mass Transfer (ME45165), which deals with the principles of heat integration, exergy analysis and pinch technology for heat exchanger networks. The MSc Sustainable Energy Technology programme’s course The Necessity of Storage Technology (SET3080) investigates energy densities, efficiencies, capacities, exergies of thermal storage and combined heat and power possibilities.

This does not mean that teaching exergy is part of the aforementioned programmes only, since exergy could be taught in other programmes without mentioning it in the study guide. E.g. it is expected that the BSc Architecture, Urbanism and Building Sciences pays attention to exergy by means of the Exergy guidebook for building professionals [7]. Because of the strong relationship between exergy and thermodynamics, especially entropy (Section 3.1.1), the study guide was used to find programmes that contain courses in this field by using the search texts “thermodynamic*” and “entrop*”. This has been complemented with a search for courses dealing with “energ*” for BSc programmes which don’t seem to teach exergy, thermodynamics nor entropy. The reason for looking in more detail at the BSc programmes is that TU Delft offers 16 BSc programmes, while the number of MSc programmes is considerably larger, i.e. more than 30. This makes it more feasible to start with all BSc students being well aware of work potential, exergy, in view of the energy transition. Table 1 presents an overview of the results of the search for courses and programmes.

Table 1. Overview of exergy and/or exergy related education per BSc and/or MSc programme according to the TU Delft study guide 2022-2023.

[1] The course Mathematical Physical Models (AM3510) contains the derivation of differential equations from physical laws such as mass and energy conservation
[2] Several courses (codes with BK*) deal with energy use, in-house climate etc.
[3] Several courses (codes CTB*) deal with energy, e.g. energy balances, energy dissipation etc.
[4] The course Computer Organisation (CSE1400) deals with the design of digital computers and their energy use.
[5] E.g. the course Electrical Energy Conversion (EE2E11).
[6] The course Sustainable Impact (IOB3-5) considers the energy effectiveness in products, energy efficiency etc.

It can be concluded from the results in Table 1 that nine of the sixteen BSc programmes teach exergy and/or thermodynamics and that teaching entropy is part of the BSc Nanobiology. The other six BSc programmes do at least pay attention to energy, though it sometimes seems quite specific. Nevertheless, the contents of all BSc programmes provide starting points for teaching exergy.

3. Teaching exergy in general

General information about exergy can be found in literature (section 3.1). As an alternative, this chapter provides basic knowledge about thermodynamics (section 3.2), exergy calculations (section 3.3) and methods that apply exergy analysis (section 3.4).

3.1. Where to start?

Several textbooks about thermodynamics pay attention to exergy, e.g. the books by Moran and Shapiro [8], Smith, Van Ness and Abbott [9] and Cengel and Bowles [10]. Textbooks about exergy have been published as well, e.g. by Dincer & Rosen [4], Szargut, Morris & Steward [11], Kotas [12] and Sankaranarayanan, Van der Kooi and De Swaan Arons [13]. PhD theses may also be a valuable source of information, e.g. [3,14-16]. Many scientific papers about exergy have been published and even a journal dedicated to exergy analysis exists: the International Journal of Exergy [17]. More informal information can be found on websites such as

the website ‘Do more with the quality of energy’, which explains in plain words, in Dutch, what exergy is [18] and the website tudelft.nl/exergy.

3.2. Basic thermodynamics

The concepts of energy, energy conservation, heat and work can in plain words be explained by an example from daily practice, such as the following example about bicycling. When someone wants to make a ride on their bike, they must exert a continued force on the pedals, in other words: they perform work. The larger the friction with the road, the larger the force that they need to exert on the pedals of the bicycle (be it by keeping the same speed, or by lowering the force and distance per revolution and making more revolutions). On the other hand, without friction, they would not start moving forward because the friction between the tires of the bicycle and the road is essential to start riding. Once started bicycling, it would be possible to bike at constant speed without using the pedals in case of a flat and frictionless road and the absence of any other friction effects. In reality, different types of friction occur and they must continue to exert a force on the pedals to continue biking, i.e. a continual work input is necessary. This work input is a form of energy. The law of energy conservation states that the total amount of energy remains the same. So, where does this work input go to? The exerted work causes deformation of the tires and road, and finally becomes heat at the temperature of the environment. Thus, the work input is transformed into other types of energy. This degradation of work is a general characteristic of processes that occur in reality.

The law of energy conservation is also known as the first law of thermodynamics. However, being more precise: the first law of thermodynamics results from applying the law of energy conservation to a system and its surroundings. Another important law of thermodynamics related to the concept of work is the second law of thermodynamics. This 2nd law can be expressed as follows: in every real process degradation of work takes place, only in the limiting case of a reversible process the amount of work remains the same. In reality, reversible processes cannot take place because it is impossible to return both the system and the surroundings to the state before the process started. Examples of irreversibilities and driving forces are the following [7]: friction, heat transfer through a finite temperature difference, spontaneous chemical reactions and spontaneous mixing of substances with different compositions and unrestrained expansion of a gas or liquid to a lower pressure.

The transfer of energy between a system and its surroundings can be classified as work or as heat. The latter is caused by a temperature difference between the system and surroundings and always occurs in the direction of decreasing temperature. Examples of forms of energy that are different from work and heat are the following: kinetic energy, potential energy due to gravity, chemical potential energy, electrical energy etc.

3.3. Basic exergy calculations

This section is a selection of what 2nd year BSc students Systems Engineering, Policy analysis & Management is taught about exergy analysis. After an introduction about the difference between energy and exergy and the added value of exergy, they learn how to calculate exergy values of mass and/or energy, which starts with the definition of exergy. Exergy is defined as the maximum theoretical amount of work that can be obtained when an amount of energy or mass is brought into total equilibrium with the reference environment. It follows from this definition that energy in the form of work resembles 100% exergy. The same holds for kinetic energy, potential energy due to gravity and electrical energy. To be able to calculate the maximum amount of work that can be obtained from other forms of energy, the reference environment needs to be defined. This reference environment is a model of the atmosphere, oceans and earth’s crust. It consists of components in total equilibrium with each other and at a certain pressure, p_0, and temperature, T_0, mostly 1 atm. and 25 °C, respectively. In some applications, e.g. in analyses related to the built environment, the actual pressure and temperature are used. The composition of the reference environment is chosen in such a way that by no means work can be obtained from the reference environment. A well-known and commonly used model of the reference environment has been developed by Szargut et al. [11].

3.3.1. Calculation of exergy values

The exergy value of heat is calculated from its energy value and the Carnot efficiency. Assuming a constant temperature of the heat, the exergy value of heat at a higher temperature than the temperature of the reference environment is calculated as shown in Eq. (1). N.B.: when temperature T is lower than T_0 the absolute value of the Carnot factor has to be used.

$$Ex_{\mathrm{Q}} = Q \cdot \left(1 - \frac{T_0}{T}\right) \quad (1)$$

with:
Ex_{Q} = exergy value of heat [J]
Q = energy value of heat [J]
T = temperature of the heat (assumed constant) [K]
T_0 = temperature of the reference environment [K]

The exergy value of mass flows consists of a physical contribution, Eq. (2), a chemical contribution, Eq. (3) and/or a contribution due to mixing, Eq. (4), when the mass flow consists of more than one substance.

$$Ex_{\mathrm{m,phys}} = (H - H_0) - T_0(S - S_0) \quad (2)$$

with:
$Ex_{\mathrm{m,phys}}$ = physical exergy value of the substance [J]
H = enthalpy of the substance at its conditions [J]
H_0 = enthalpy of the substance at the pressure and temperature of the reference environment [J]
S = entropy of the substance at its conditions [J/K]
S_0 = entropy of the substance at the pressure and temperature of the reference environment [J/K]
T_0 = temperature of the reference environment [K]

$$ex^0_{\mathrm{ch},i}(T_0) = \sum(N_e ex^0_{\mathrm{ch},e}(T_0)) + \Delta_{\mathrm{f}} g^0_i(T_o) \quad (3)$$

with:
$ex^0_{\mathrm{ch},i}(T_0)$ = standard chemical exergy value of substance i at T_0 [J/mol]
$ex^0_{\mathrm{ch},e}(T_0)$ = standard chemical exergy value of element e at T_0 [J/mol]
$\Delta_{\mathrm{f}} g^0_i(T_o)$ = Gibbs energy of formation of substance i at T_0 [J/mol]
N_e = number of moles of element e per mole of substance i [-]

$$ex_{\mathrm{mixing}} = RT_0 \sum(x_i \ln(x_i)) \quad (4)$$

with:
ex_{mixing} = mixing contribution in case of ideal mixing [J/mol of mixture]
R = universal gas constant, 8.314 [J/mol·K]
T_0 = temperature of the reference environment [K]
x_{i} = molar fraction of substance i

3.3.2. Calculation and presentation of exergy losses and efficiencies

The loss of exergy can be subdivided into internal exergy loss and external exergy loss. The internal exergy loss, Eq. (5), is caused by irreversibilities (Section 3.2) and is also known as exergy destruction. The external exergy loss is the exergy that is lost with waste flows.

$$Ex_{\mathrm{loss,internal}} = \sum Ex_{\mathrm{in}} - \sum Ex_{\mathrm{out}} \quad (5)$$

Universal as well as functional exergy efficiencies of a system can be calculated. Where the universal exergy efficiency compares all ingoing and outgoing amounts of exergy, Eq. (6), the functional exergy efficiency takes into account the purpose of the system [19], e.g. the exchange of heat in a heat exchanger, Eq. (7).

$$\Psi_{\mathrm{univ}} = \frac{\sum Ex_{\mathrm{out}}}{\sum Ex_{\mathrm{in}}} \quad (6)$$

$$\Psi_{\mathrm{funct,heat\ exchanger}} = \frac{(Ex_{\mathrm{p,out}} - Ex_{\mathrm{p,in}})}{(Ex_{\mathrm{s,in}} - Ex_{\mathrm{s,out}})} \quad (7)$$

with:
Ex_{p} = exergy amount of the mass flow that is heated in the heat exchanger [J]
Ex_{s} = exergy amount of the mass flow that is cooled in the heat exchanger [J]

Besides numerical representation of the results of exergy analyses, the loss of exergy can be shown in a Grassmann diagram, i.e. the exergy variant of the Sankey diagram, and/or in a value diagram. Originally, value diagrams were used for heat transfer processes, as they show the $(1-T_0/T)$ value of heated and cooled flows versus the amount of heat that is transferred, but they can be used for the evaluation of thermal power plants as well [16].

3.4. Exergy methods

Scientists from all over the world have developed assessment methods that pay attention to exergy losses [3]. The following presents a brief overview of some important exergy analysis methods. The Cumulative Exergy Consumption (CExC) method was introduced in 1988 by Szargut et al. [11] and takes into account all exergy needed to produce a product, i.e. attention is paid to the exergy needed in its supply chains as well. A method that is considered equivalent [1] is the Exergetic Cost method developed by Valero et al. [20] in 1986. The CExC method was extended in 2001 with the abatement of emissions and the system itself by Dewulf et al. [21] resulting in the Cumulative Exergy Consumption for Construction and Abatement (CExCA) method. Around the same time, Sciubba [22] introduced the Extended Exergy Accounting (EEA) method which expands the CExC method by integrating thermo-economic methods and the inclusion of labour and environmental impact. The Cumulative Exergy Extraction form the Natural Environment (CEENE) method extends the CExC method with land use and was developed in 2007 by Dewulf et al. [23] to be used in combination with the ecoinvent database [24]. Examples of assessment methods related to the standard Life Cycle Assessment (LCA) method [25] are the following: Exergetic Life Cycle Analysis (ELCA) developed in 1997 by Cornelissen [26] includes the calculation of internal exergy losses, Life Cycle Exergy Analysis (LCEA) developed around the same time by Gong and Wall [27] calculates the exergetic pay-back time and the Exergoenvironmental analysis method introduced in 2009 by Meyer et al. [28] combines LCA with the Exergoeconomic analysis method by Tsatsaronis and Winhold [29]. This Exergoeconomic analysis method was introduced in 1984 for the combined exergetic and economic analysis of energy conversion processes and determines the costs of the exergy losses in the components of a system. The method was the basis of the Advanced exergoeconomic analysis method introduced in 2008, which splits the internal exergy losses into avoidable and unavoidable exergy losses and makes a distinction between exergy losses caused by the component itself and exergy losses caused by connected components [30]. The Total Cumulative Exergy Loss (TCExL) method can be regarded as combination of, or extension to, the CExC, CExCA, CEENE and ELCA methods and calculates all exergy losses caused by a technological system during its life cycle [3].

4. Examples and ideas for teaching exergy at TU Delft

The examples and ideas for teaching exergy presented in this chapter vary in difficulty, i.e. for students with no background in thermodynamics at all, for students with a background in thermodynamics but who are unfamiliar with exergy and some illustrative examples for students who have been taught how to carry out exergy analysis. Section 4.1 provides an overview of which examples/ideas are recommended for students from which BSc programme. Sections 4.2 to 4.8 introduce and explain these examples/ideas. Many more examples and applications of exergy analysis can be found in textbooks about exergy, e.g. [4].

4.1. Overview of examples/ideas and educational programmes

The results of the search for current education in the field of exergy, thermodynamic, entropy and/or energy presented in chapter 3 has been used as the starting point for providing examples/ideas for the teaching of exergy at TU Delft. The goal was to find examples/ideas that are related to the subjects the students are being taught during their BSc programme. The examples/ideas mentioned in Table 2 are based on examples used by the authors when teaching exergy to their students, complemented with examples that are expected to be interesting to students from other BSc programmes.

The authors recommend teachers to make the lectures interesting by interacting frequently with the students and to visualise the theory as much as possible, e.g. by visualising the difference between physical and chemical exergy or how the chemical exergy of a substance can be calculated from the standard exergy values of the elements. It is also recommended to alternate between explaining theory and letting the students make calculations based on the examples/ideas provided in this chapter during the lectures. The assessment can consist of theoretical questions about the concept of exergy as well as questions that require calculations by the students. The students may be expected to know the equations by heart before taking the exam, but another option would be to provide a formula sheet. In the latter case, it can still be tested whether the students understand the theory correctly, e.g. by providing a schematic overview of an energy system including the thermodynamic properties of the flows and asking the students to calculate the internal and external exergy losses, which implies that they e.g. need to understand which temperature and enthalpy and entropy values should be used for the calculation of the physical exergy of a mass flow.

Table 2. Overview of examples per BSc programme.

BSc programmes	Section(s)	Example(s)
Aerospace Engineering	4.7	Hydrogen combustion
Applied Earth Sciences	4.6	Heat exchanger
Applied Mathematics	4.2, 4.3.2	Energy/exergy, Electricity to heat
Applied Physics	4.6	Heat exchanger
Architecture, Urbanism and Building Sciences	4.2, 4.3.1, 4.6	Energy/exergy, Mixing hot/cold water, Heat exchanger
Civil Engineering	4.2, 4.3.1, 4.4, 4.6	Energy/exergy, Mixing hot/cold water, Iron production, Heat exchanger
Clinical Technology	4.2, 4.5	Photosynthesis
Computers Science & Engineering	4.2, 4.3.2	Energy/exergy, Electricity to heat
Electrical Engineering	4.2, 4.3.2	Energy/exergy, Electricity to heat
Industrial Design Engineering	4.2, 4.4	Energy/exergy, Iron production
Life Science & Technology	4.2, 4.5	Photosynthesis
Marine Technology	4.2, 4.4, 4.7	Iron production, Hydrogen combustion
Mechanical Engineering	4.6, 4.8	Heat exchanger, Heat pump
Molecular Science & Technology	4.7	Hydrogen combustion
Nanobiology	4.2, 4.5	Photosynthesis
Systems Engineering, Policy analysis & Management	4.2, 4.6, 4.7	Heat exchanger, Hydrogen combustion

4.2. Energy versus exergy

The teaching of exergy could start with the following example, which proved to be insightful to students who have never heard of exergy before (and maybe think the “x” is just a typo).

This example starts with telling that different types of energy exist and that one type of energy may be more valuable, or useful, than another type of energy. This could be followed by the teacher asking the students to mention some types of energy, i.e. electrical energy, heat, kinetic energy etc. Then the teacher tells the students that the valuable or useful part of energy has its own name: exergy.

After that, the teacher shows a sandwich, or a picture of a sandwich, and asks the students whether they know how many calories the sandwich provides and where these calories come from, i.e. from carbohydrates, proteins and oils/fats. Finally, the teacher tells the students that you could look at energy and exergy like the following: the energy represented by the sandwich are the calories and one of the components, e.g. the carbohydrates, is the exergy (although in reality all three components contain more or less exergy). So, exergy is a part of energy. The amount of exergy could be large or even 100%, i.e. many calories and many or all, in this case, carbohydrates such as with a sugar cube. And the amount of exergy could be small or even zero, i.e. calories without these carbohydrates such as with a piece of fish.

4.3. Energy conservation versus exergy loss

4.3.1. Mixing of hot and cold water

The difference between energy and exergy analysis can easily be shown with the following example about the mixing of hot and cold water. The example is about filling a bath tub, but of course the teacher can think of another situation that is applicable.

An empty and well-isolated bath tub is filled with two buckets of hot water of 60 °C and two buckets of cold water of 20 °C, resulting in warm bath water with a temperature of 40 °C, i.e. there are no heat losses from the hot or warm water to the bathroom. The temperature in the bathroom equals 20 °C. Table 3 presents an overview of the energy and exergy values of the water in the buckets.

Table 3. Energy and exergy values of buckets filled with water.

Water temperature [°C]	Energy [kJ/bucket]	Exergy [kJ/bucket]
60 °C (hot)	2511	105
20 °C (cold)	839	0
40 °C (warm)	1675	28

The question to be asked to the students would be: calculate the total amounts of energy and exergy before the mixing of water and after the mixing of the water, and compare the results. The answer is quite straightforward since the total amount of energy before mixing equals 2*2511+2*839 = 6700 kJ, which is the same as the amount of energy after mixing, i.e. 4*1675 = 6700 kJ. In case of exergy, these values are different, i.e. 2*105+2*0 = 210 kJ before mixing and only 4*28 = 112 kJ after mixing. With this example, the teacher can let the students experience that the total amount of energy stays the same, is conserved, but that this does

not hold for the total amount of exergy. The mixing of hot and cold water causes exergy loss. This exergy loss is of the type internal exergy loss, also known as exergy destruction, and the driving force that causes this exergy loss is the difference in temperature between the hot and cold water (Section 3.2).

4.3.2. From electricity to heat

The following example is about a laptop, but it is applicable to many more electrical devices, such as an electrical heater, a television, a vacuum cleaner etc. The only thing is that the power of the device and the temperature of the emitted heat will be different.

Assume that a laptop is used to write a conference paper about teaching exergy, that the power of this laptop equals 50 W and that the room in which the author writes their paper has a constant temperature of 18 °C. The laptop gets warm during the writing of the paper and constantly emits heat of 60 °C.

The question to be asked to the students would be: perform an energy and exergy analysis of this warm laptop. The answer to the first part of the question is, again, quite straightforward since the power consumed by the laptop will be fully converted into heat, i.e. the heat generation equals the electric power and both equal 50 W. The results of the exergy analysis are, again, different, since electric power represents 100% exergy, while the exergy content of heat depends on the temperature of the heat and the temperature of the reference environment (Section 3.3.1), in this case the temperature of the room since no other information is available. The amount of heat represents an exergy amount of (1-(18+273.15)/(60+273.15))*50 = 0.13*50 = 6.3 W. Thus, the internal exergy loss equals 50-6.3 = 44 W, i.e. 87% of the exergy input, which is very different from the 0% loss according to the energy analysis.

4.4. Iron production

The usual way of producing iron, e.g. to be used in parts of a bicycle or for large constructions, is the blast furnace process, which converts iron ore into pure iron by burning coke (carbon) and results in the emission of carbon dioxide, Eq. (R1). The reactants are at 298 K and the products at 1809 K.

$$\mathrm{Fe_2O_3(s) + 5.7C(s) + 4.2O_2(g) + 17N_2(g) \rightarrow 2Fe(l) + 5.7CO_2(g) + 17N_2(g)} \quad \text{(R1)}$$

In view of the energy transition, attention is paid to an alternative way of producing iron, i.e. with hydrogen instead of coke, Eq. (R2).

$$\mathrm{Fe_2O_3(s) + 8.1H_2(g) + 2.5O_2(g) + 10N_2(g) \rightarrow 2Fe(l) + 8.1H_2O(g) + 10N_2(g)} \quad \text{(R2)}$$

Table 4 provides the exergy values of the reactants and products of Eqs. (R1) and (R2). The question to be asked to the students would be: calculate the total exergy input of the original blast furnace process and the alternative process with hydrogen, the percentage of exergy that is lost and compare the results with regard to exergy and emitted components.

Table 4. Chemical exergy values of the substances of Eqs. (R1) and (R2) [31,32].

Reactants at 298 K	Exergy [kJ/mol]	Products at 1809 K	Exergy [kJ/mol]
Fe_2O_3(s)	12.4	Fe(l)	415
C(s)	411	CO_2(g)	73
O_2(g)	3.97	H_2O(g)	51
N_2(g)	0.72	N_2(g)	33
H_2(g)	236		

The exergy inputs of the original and alternative processes equal 2384 kJ/mol iron ore and 1941 kJ/mol iron ore, resp., and are obtained by multiplying the exergy values of the components with the stoichiometric coefficients shown in the reaction equation. The total exergy of the products is calculated analogously and comparing the exergy input with the exergy output results in exergy losses of 24% and 19%, respectively.

4.5. Photosynthesis

Each and every process is accompanied with exergy losses: technological processes as well as natural, biological processes such as photosynthesis. In his PhD thesis [14], Lems provides a detailed exergy analysis of photosynthesis. He assesses the light and dark reactions of photosynthesis separately and combines them into the following overall reaction equation, Eq. (R3):

$$\mathrm{6CO_2 + 6H_2O + 6P + 24h\nu_{680nm} + 24h\nu_{700nm} \rightarrow 6C_6H_{12}O_6 + 6O_2 + 6P_{ATP}} \quad \text{(R3)}$$

with:

$h\nu_{680nm}$ and $h\nu_{700nm}$ = photons with a wavelength of 680 nm and 700 nm, respectively

P = inorganic phosphate

P_{ATP} = terminal phosphate group of ATP (adenosine triphosphate)

Table 5 shows the exergy values of the substances. The exergy value of photons can be calculated in the same way as the exergy value of heat, i.e. from the energy value of the photons times the Carnot factor, with T_{low} and T_{high} being the surface temperatures of the earth (298.15 K) and the sun (5762 K), respectively. The Planck constant equals 6.626×10^{-34} Js.

Table 5. Exergy values of the substances occurring in the overall photosynthesis reaction.

Substance	Exergy [kJ/mol]	Comment [14]
$C_6H_{12}O_6$ (glucose)	2955	
CO_2	≈ 0	almost in equilibrium with the concentration in the atmosphere
H_2O	0	taken at zero
O_2	≈ 0	considered to be in equilibrium with air
P_{ATP}	306	compared to P

The question to be asked to the students would be: calculate the exergy loss caused by the overall photosynthesis reaction.

The answer can be calculated as follows. The exergy value of one mole of photons with a wavelength of 680 and 700 nm equals 6.26x10-34*680/1E9*(1-298.15/5762)* 6.022x10^23 = 162 kJ and, analogously, 167 kJ, respectively. This results in a total exergy input of 24*162 + 24*167 = 7896 kJ. The total exergy output equals 2955 + 6*306 = 3261 kJ. Combining these answers results in an exergy loss of 7896 – 3261 = 4635 kJ per mole of glucose formation.

4.6. Energy and exergy analysis of a heat exchanger

An interesting example of the differences between energy and exergy analysis and between universal and functional efficiencies (Section 3.3.2) is the assessment of an ideal counter current heat exchanger. Table 6 shows the enthalpy (i.e. energy) and entropy values of the primary and secondary flows, i.e. steam and flue gas, respectively. The steam is heated from 138 to 234 °C, the flue gas cooled from 436 to 220 °C and the temperature of the reference environment equals 15 °C. The chemical exergy value of flue gas equals 69 kJ/kg.

Table 6. Enthalpy and entropy values of flue gas (41 kg/s) and steam (29 kg/s).

Substance	h_{in} [MJ/kg]	h_{out} [MJ/kg]	h_0 [MJ/kg]	s_{in} [kJ/kg·K]	s_{out} [kJ/kg·K]	s_0 [kJ/kg·K]
Flue gas	-3.5	-3.8	-4.3	7.9	7.5	6.0
Steam	0.58	1.0	0.063	1.7	2.6	0.22

The question to be asked to the students would be: calculate and compare the universal and functional energy and exergy efficiencies of the heat exchanger. Table 7 shows the results obtained by using the enthalpy values of the in- and outgoing flows to calculate the energy flows, Eq. (2) to calculate the exergy flows and Eqs. (6) and (7) for the calculation of the universal and functional efficiencies. The differences between the energy and exergy efficiencies as well as between the universal and functional exergy efficiencies are remarkable.

Table 7. Universal and functional energy and exergy efficiencies of the heat exchanger.

	Universal [%]	Functional [%]
Energy	100	99
Exergy	82	62

4.7. Hydrogen combustion

One of the energy carriers that has gained interest in view of the energy transition is hydrogen, since it can be produced when there is an excess of wind energy, stored, and combusted in a power plant when there is a shortage of electricity from renewable energy sources, although the round-trip efficiency is low.

The following example is about calculating the exergy loss during hydrogen combustion with pure oxygen. It is assumed that the combustion temperature equals 1100 °C. The temperature of the reference environment is set at 25 °C and the Gibbs energy of formation of water at 25 °C equals -237 kJ/mol. Table 8 shows the other thermodynamic data needed for this example.

Table 8. Exergy values of the substances related to hydrogen combustion, at 1 atm [31].

Substance	Enthalpy at 1100 °C [kJ/mol]	Enthalpy at 25 °C [kJ/mol]	Entropy at 1100 °C [J/mol·K]	Entropy at 25 °C [J/mol·K]	Standard chemical exergy [kJ/mol]
H_2 (hydrogen)	32	0	176	131	236
O_2 (oxygen)	36	0	255	205	3.97
H_2O (water)	-200	-286	246	70	to be calculated

The question to be asked to the students would be: calculate the exergy loss caused by the combustion of hydrogen when the effect of mixing is neglected. The solution to this example consists of the following steps: 1) calculate the physical exergy values of the reactants (H_2, O_2) and product (H_2O) with Eq. (2), 2) calculate the chemical exergy value of H_2O with Eq. (3), 3) calculate the total exergy value of the reactants and product, 4) calculate the amount of heat that is released during combustion and calculate its exergy value with Eq. (1), 5) calculate the exergy loss by subtracting the total amount of exergy out from the total amount of exergy in. Table 9 shows the results.

Table 9. Results of the example about hydrogen combustion.

	Energy [kJ/mol H_2]	Physical exergy [kJ/mol]	Chemical exergy [kJ/mol]	Total exergy [kJ/mol]	Total exergy [kJ/mol H_2]	**Total**
IN						**268**
H_2		19	236	255	255	
O_2		21	3.97	25	13	
OUT						**203**
H_2O		34	0.99	35	35	
Heat of combustion	214			168	168	
Exergy loss						**65**

4.8. Energy and exergy analysis of a heat pump

The implementation of electric heat pumps in industry and households is very relevant in view of the energy transition. In this example, operational costs are allocated to the exergy destruction in the heat pump components. Assume that the heat pump operates 8.000 hrs per year, during 5 years at an electricity price of 0.041 €/kWh. The efficiency of the compressor drive, η_m, equals 85%. The temperature of the reference environment is set at 20 °C. Table 10 shows the mass flows and thermodynamic data of the flows.

Table 10. Mass flows and thermodynamic data needed for the heat pump example.

Component[1]	Working medium (2.1 kg/s)		Source or Sink (30 kg/s)			
	h_{in} [kJ/kg]	s_{in} [J/kg·K]	h_{in} [kJ/kg]	s_{in} [J/kg·K]	h_{out} [kJ/kg]	s_{out} [J/kg·K]
Evaporator	322	1,421	126	437	108	378
Compressor	581	2,305	n/a	n/a	n/a	n/a
Drive	n/a	n/a	n/a	n/a	n/a	n/a
Condenser	626	2,347	168	572	189	639
Expansion valve	322	1,406	n/a	n/a	n/a	n/a

[1] The working medium leaving the evaporator has the conditions of the working medium entering the compressor, etc.

The question to be asked to the students would be: calculate per component the amount of energy transferred, the exergy destruction and the related operational losses (costs). Table 11 presents the results, which have been calculated as follows. The energy transfer by the evaporator, compressor, condenser and expansion valve follows from the difference in enthalpy of the ingoing and outgoing working medium. The energy transfer by the drive has been calculated with $W_D = W_C/\eta_m$. The exergy destruction caused by the evaporator, compressor, condenser and expansion valve has been calculated with Eqs. (2) and (5), where H_0 and S_0 cancel out. The exergy destruction caused by the drive is taken as the difference with the compressor duty, i.e. W_D minus W_C. The operational losses are calculated by multiplying the exergy destruction with the number of operating hours per 5 years and the costs per kWh.

Table 11. Results of the heat pump example.

Component	Energy transfer [kW]	Exergy destruction [kW]	Operational losses [k€]
Evaporator	544	21	35
Compressor	95	26	42
Drive	111	16	27
Condenser	638	18	30
Expansion valve	0	9	15

5. Discussion and conclusions

It is said that our society does not have an energy crisis, but an exergy crisis, and that exergy is directly related to sustainable development. Despite the added value of exergy analysis compared to energy analysis, it is

important to pay attention to all three pillars of sustainability, i.e. to the environmental, economic as well as the social sustainability of processes and activities.

The reader of this paper may get the impression that exergy losses should be avoided by all means, but the loss of exergy is unavoidable; it is needed to overcome friction and to achieve a reasonable speed of processes and activities. However, too large driving forces, e.g. differences in pressure and/or temperature, should be avoided because this would lead to a too large input of work.

Although exergy analysis, paying attention to the loss of work potential, is relevant in view of the energy transition, it seems that teaching exergy is not common practice at TU Delft. It was learnt from the TU Delft study guide that probably just 4 of the 16 BSc programmes, 1 BSc minor programme and 4 of the more than 30 MSc programmes pay attention to exergy and exergy analysis. However, a more detailed investigation is needed before firm conclusions can be drawn about the extent to which teaching exergy is part of the TU Delft educational programmes.

The basics of thermodynamics and exergy calculations presented in this paper are meant as a first step in teaching exergy in academia, but it cannot be ruled out that (essential) information is missing. The same holds for the brief overview of exergy methods.

The authors like to emphasize that the understanding of the exergy concept is highly valuable for both engineering professionals and policy makers that have to decide about the energy transition. Exergy analysis provides a more thorough understanding of the improvement potential of processes and systems. It helps to better understand how to reach sustainability goals such as the reduction of carbon dioxide emissions and improving resource efficiency.

6. Recommendations

It is recommended that a more detailed investigation of the teaching of exergy at TU Delft be carried out and that the contents of this paper be discussed with many teachers of BSc programmes, especially teachers of BSc programmes that do not yet seem to include the teaching of exergy. Based on these discussions, dedicated examples and ideas can be developed for teaching exergy as part of BSc programmes. It is recommended that attention be paid to teaching exergy to MSc students as well.

Abstract:
Hydrogen is considered a promising alternative as an energy carrier for the transition to a renewable energy matrix. However, most of the hydrogen is currently produced using fossil fuels, making it essential to develop green hydrogen production routes. Therefore, this study aims to perform an exergoeconomic analysis of the high-temperature electrolysis (HTE) process for hydrogen production using solar and wind energy. To this end, it is proposed novel plant arrangements for solid oxide electrolysis cells (SOEC). To supply the plant's electrical demand, two options are considered: a wind farm (WF) and a photovoltaic system (PV). A solar concentration system is considered for the thermal demand. As another contribution to the area, the analysis is carried out considering the Brazilian scenario, specifically Pecém (Ceará), a coastal district located in the northeast of Brazil. It was selected due to the high availability of solar and wind resources and the existing industrial and port infrastructure. Energy and exergy analyses are performed to identify the components with the highest level of irreversibility. Finally, an exergoeconomic assessment is accomplished to determine the exergy costs of hydrogen production. For the WF-SOEC arrangement, the total exergy efficiency obtained is 26.53%, and the unit exergy cost of hydrogen is 3.89 kJ/kJ. For the PV-SOEC arrangement, the corresponding values are 13.74% and 7.53 kJ/kJ, respectively. Overall, the results demonstrate that HTE route using solar and wind energy can be a viable and sustainable alternative to produce hydrogen from 100% renewable sources and without direct CO_2 emissions.

Keywords:
Exergoeconomic assessment; Green hydrogen; Solar energy; Wind energy.

1. Introduction

Hydrogen plays an important role in the chemical industry. Industrial hydrogen is utilized for various purposes such as producing fertilizers and ammonia, refining petrochemicals, processing food, cooling power generators in power plants, metallurgical processes, as a fuel for space exploration, and manufacturing semiconductors [1][2].

In addition to being an important industrial raw material, hydrogen has the potential to become a key energy source for achieving sustainable decarbonization, particularly in sectors where electrification is difficult [3][4] From a total cost perspective (including production, distribution and retail costs), hydrogen could be the most cost-effective low-carbon solution for more than twenty different applications, including long-distance transportation by road and sea, urban vehicles, trains, the steel industry, energy storage, and residential heating [5][6].

Hydrogen can be produced using different non-renewable (coal, oil, nuclear and natural gas) or renewable (biomass, solar, wind, hydro, geothermal, wave energy, etc.) resources through a wide variety of technological routes (reforming, gasification, electrolysis, etc.) [7]. To be considered low-carbon hydrogen, it must be produced from renewable electricity, nuclear, biomass or fossil fuels with carbon capture, storage and utilization (CCUS). However, almost all the hydrogen is currently generated from fossil fuels without CCUS [8].

Electrolysis is one of the oldest and most mature processes and has the versatility to use electricity from different renewable sources to produce H_2. Alkaline electrolysis stands out for being the one with the greatest maturity and the greatest commercial reach [9]. PEM (polymer electrolyte membrane) electrolysis have many advantages such as lower gas permeability, high proton conductivity, and high pressure operation [10]. However, as the temperature rises, the electrolysis process becomes more endothermic and a greater proportion of the total energy needed for the system can be provided in the form of heat, leading to increased efficiency in the process [11].

In this way, high-temperature electrolysis (HTE) offers higher efficiency by operating at reduced electrical potentials, thereby minimizing irreversibilities. The high operating temperature is an important feature of this process, giving rise to its two main advantages over alkaline and polymeric membrane electrolyzers: higher exergy efficiencies and faster chemical kinetics [12]. Despite being a process under development, it is approaching maturity. HTE occurs through solid oxide electrolyzer cells (SOEC) operating in the range of 600°C to 900°C. SOECs can convert steam (H_2O), carbon dioxide (CO_2), or a combination of both, directly into hydrogen (H_2) or syngas (H_2+CO), respectively. HTE can be integrated with various renewable energy sources and industrial processes. These can serve as feedstocks for fuel synthesis plants and the chemical industry, thus enabling different Power-to-X scenarios. They can also be integrated with various chemical synthesis processes for the recycling of captured CO_2 and H_2O into synthetic fuels such as methane, methanol, and ammonia. When operating in reverse, the electrolyzer cell acts as a solid oxide fuel cell (SOFC) [13].

Some authors [14][15][16][17][18][19] have previously proposed plant layouts for solid oxide electrolyzer cells that operate from renewable sources, specially solar energy. However, these studies have mainly focused on technical and economic analysis, with an emphasis on energy and capital costs. In general, energy balances treat all energy forms as equal without distinguishing between different degrees of energy that pass through the system boundary and do not provide information on internal losses. Exergy analysis, which is an alternative technique based on the concept of exergy, can be used to address this limitation [20][21]. And from the perspective of modeling, simulating, and optimizing energy systems, exergoeconomic assessment is also important in determining the average cost per unit of exergy of each exergy stream [22].

Based on this background, the present study makes a significant contribution to the area by employing a comprehensive evaluation methodology based on energy, exergy, and exergoeconomic assesment for two novel plant arrangements for H_2 production based on the HTE route, powered by solar and wind energy. This assessment provides a comprehensive thermodynamic evaluation of the plant processes. In addition, the study focuses on the Brazilian scenario, specifically Pecém (Ceará), which is a location in northeastern Brazil with high availability of solar and wind resources and existing industrial and port infrastructure - optimal conditions for a hydrogen production plant.

2. Method

2.1. SOEC modelling

The process of electrolyzing water to produce hydrogen and oxygen gases is a long-standing and established method. The basic principle of an electrolyzer is to use electricity to split water molecules. This phenomenon was initially demonstrated by Nicholson and Carlisle in 1800, and further expounded upon by Faraday in the 1820s, who coined the term "electrolysis" in 1834. However, it was only in 1902 that the Oerlikon Engineering Company began the commercial use of electrolysis [11]. The reaction for water electrolysis can be represented by the Eq. (1):

$$H_2O \rightarrow H_2 + 1/2\, O_2 \tag{1}$$

Solid oxide electrolyzer models can be classified into several types. Geometrically, they are categorized into zero-dimensional (0D), one-dimensional (1D), two-dimensional (2D), and three-dimensional (3D) models. They can also be classified as physical models (white-box), empirical models (black-box), and semi-empirical models (gray-box). Additionally, in terms of length scale, SOEC models can be classified into microscale, mesoscale, and macroscale models, with the latter further subdivided into cell-level, stack-level, and system-level models [23]. In this study, a semi-empirical SOEC (zero dimension) system model was developed according to the studies of O'Brien [12], Petipas, Brisse and Bouallou [24], and Hansen [25].

The minimum electrical energy (W_{min}) required for electrolysis (reversible process) is equal to the change in Gibbs free energy (G), shown in Eq. (2), where H represents the enthalpy, T is the absolute temperature and S the entropy of the reactants and products of the chemical reaction. With increasing temperature, the electrolysis process becomes progressively endothermic.

$$\dot{W}_{min} = \Delta G = G_{prod} - G_{react} = H_{prod} - H_{react} - T(S_{prod} - S_{react}) \tag{2}$$

For the electrolysis process to take place, the minimum voltage required is the standard state open-cell voltage or reversible voltage (V_0) given by Eq. (3), where ΔG is the Gibbs free energy change, F is the Faraday constant (96,486 C/mol) and j is the number of electrons transferred per molecule of hydrogen produced.

$$V_0 = \frac{\Delta G}{jF} \tag{3}$$

When reactants and pure products are separated, the reversible voltage (V_0) is applicable [26]. However, to account for the variety of gas compositions present in real electrolyzers, the Nerst open cell potential (V_N) must

be considered, as given by Eq. (4), where R_u is the universal gas constant, y represents the molar fractions and T is the absolute temperature during the reaction.

$$V_N = \frac{\Delta G}{jF} - \frac{R_u T}{jF} ln\left(\frac{y_{H_2O}}{y_{H_2} y_{O_2}^{0,5}}\right) \quad (4)$$

The thermoneutral voltage (V_{TN}), as a function of the enthalpy of reaction (ΔH), is given by Eq. (5). The electrolysis of water is an endothermic process. Therefore, the heat flux of the reaction ($q"_R$) is negative. However, the heat flux resulting from irreversibilities ($q"_{OHM}$), is positive. At thermoneutral voltage, the net heat flux is zero, as these heat fluxes cancel each other out [26]. Their values can be calculated using Eq. (6) where i is the current density (A/m²).

$$V_{TN} = \frac{\Delta H}{jF} \quad (5)$$

$$q"_R = -q"_{OHM} = i(V_N - V_{TN}) \quad (6)$$

The electrical power ($\dot{W}_{TN}$) required for the electrolysis process considering the thermoneutral voltage can be calculated using Eq. (7), where I is the current (A) in the electrolyzer and $\dot{m}_{H_2}$ is the mass flow rate of hydrogen.

$$\dot{W}_{TN} = V_{TN} I = \dot{m}_{H_2} \Delta H \quad (7)$$

The modelling and simulation of the electrolysis process is performed via Python using the suite Cantera [27] and the Coolprop library [28].

2.2. Proposed plants

An electrolysis plant is basically composed of electrolyzers and the Balance of Plant (BoP), which includes energy supply, water supply and purification, compression, processing, and storage of gases. Figure 1 illustrates two hydrogen production plants. The first involves a wind farm supplying electricity to solid oxide electrolysis cells (WF-SOEC), proposed initially in a previous study [29]. In the second plant, photovoltaic panels (PV-SOEC) supply all the electrical energy needed. In both cases, to provide the necessary thermal energy, a solar tower system is used, whereby solar radiation is collected by heliostats in the solar field and reflected to superheat steam at a temperature of 850°C in the solar receiver (SR).

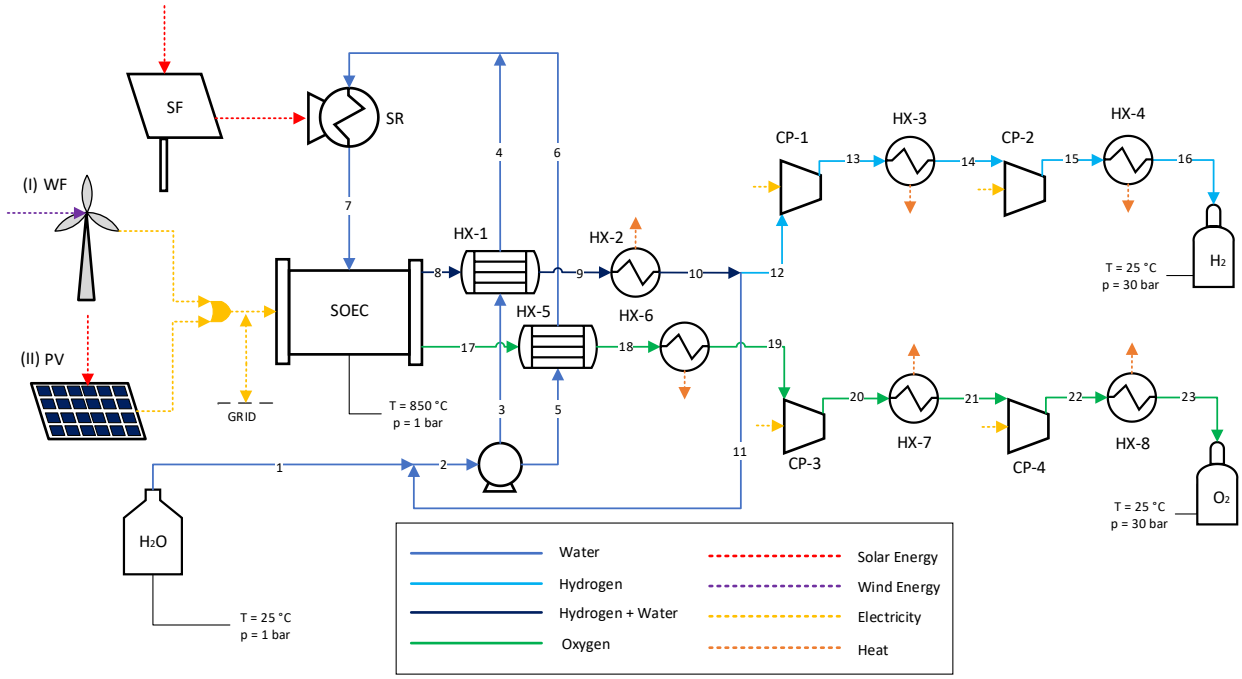

Figure 1. Proposed plants: (I) WF-SOEC (II) PV-SOEC

The electrolyzer produces two streams, one containing a mixture of hydrogen (H_2) and steam, and the other containing oxygen (O_2), which are then directed to recovery heat exchangers (HX-1 and HX-5, respectively) to preheat the water used in the process. The H_2/H_2O mixture is then cooled in HX-2, and the condensed steam is separated from hydrogen and recycled. Finally, hydrogen and oxygen are compressed (H_2 in CP-1 and CP-2, and O_2 in CP-3 and CP-4) and cooled (H_2 in HX-3 and HX-4, and O_2 in HX-6, HX-7, and HX-8)

before being stored at a pressure of 30 bars. The main differences in relation to other arrangements proposed in the literature are related to the direct recovery of heat from the electrolyzer outlet gases and the processing and storage of oxygen as a co-product.

The wind farm (or photovoltaic panels) also provides the necessary electricity to power the compressors, but due to the intermittent nature of electricity production, a connection to the electrical grid is also included. For the analysis of the proposed systems, the following conditions are considered:

- The hydrogen production plant is designed to operate for eight hours a day according to the supply of concentrated solar energy [30].
- In the WF-SOEC arrangement, the installed capacity of the wind farm is 10 MW (five Vestas V100-2MW wind turbines) [31].
- In the PV-SOEC arrangement, the installed capacity is considered the minimum necessary to produce the equivalent amount of H_2 in the WF-SOEC arrangement.
- The efficiency of PV system, defined as the ratio between the output electricity and the input of solar energy, is 15%.
- The AC-DC electricity conversion efficiency is 95%.
- The solar field (SF) has an energy efficiency of 60% [17], which means that only 60% of the solar energy reaching the heliostats is directed to the receiver (the remaining 40% are heat and optical losses).
- The solar receiver (SR) has an energy efficiency of 85% [32], which is the percentage of energy absorbed by the steam in the component (the remaining 15% are heat and optical losses).
- The electrolyzer operates at a thermoneutral voltage to minimize thermal stress [12]. Consequently, the process is isothermal at T = 850ºC and p = 1 bar.
- The molar steam conversion ratio (SC) is 75%, i. e., the molar fraction of H_2 at the SOEC outlet is 0.75 [24].
- Each compressor has an isentropic efficiency of 80%.
- Heat recovery exchangers HX-1 and HX-5 do not transfer heat to the environment, and pinch point is 10°C. The thermodynamic state of the water is the same at the outlet of these both heat exchangers.
- Pressure losses, as well as changes in kinetic and potential energy are not considered.

3.3. Solar and wind data

The study is being carried out for Pecém, a coastal district located in north-eastern Brazil. This location was selected due to its established industrial, electrical, and port infrastructure, as well as its abundance of solar and wind energy resources. Furthermore, there is a project to establish a green hydrogen hub in the area [33].

Data for solar resource evaluation are taken from The National Solar Radiation Data Base (NRSDB) through System Advisor Model (SAM) software considering a typical meteorological year (TMY) [34][35]. The average daily global horizontal irradiation (GHI) is estimated at 6.19 kWh/m²/day and the average daily direct normal irradiation (DNI) is estimated at 5.95 kWh/m²/day.

For the wind resource evaluation, it was used the data from the atlas of Brazilian wind potential [36]. The wind speed distribution can be represented by the Weibull density probability function, given by Eq. (8), where v is the wind speed, c is the scale factor and k is the form factor [37]. The main wind parameters for Pecém considering a height of 100 meters are presented in Tab. 1.

$$f(v) = \frac{K}{C}\left(\frac{v}{C}\right)^{K-1} e^{-(v/C)^K} \tag{8}$$

The monthly mean values of direct normal irradiance (DNI) and global horizontal irradiance (GHI) for Pecém in a TMY are shown in Figure 2a. The annual wind speed distribution is shown in Figure 2b, considering the number of annual hours for different speed intervals.

Table 1. Main wind parameters

Parameter	Unit	Value
Average wind speed ($\bar{v}$)	m/s	8.87
Scale factor (C)	-	9.76
Form factor (K)	m/s	4.20
Average air density (ρ)	kg/m³	1.17

Source: [36]

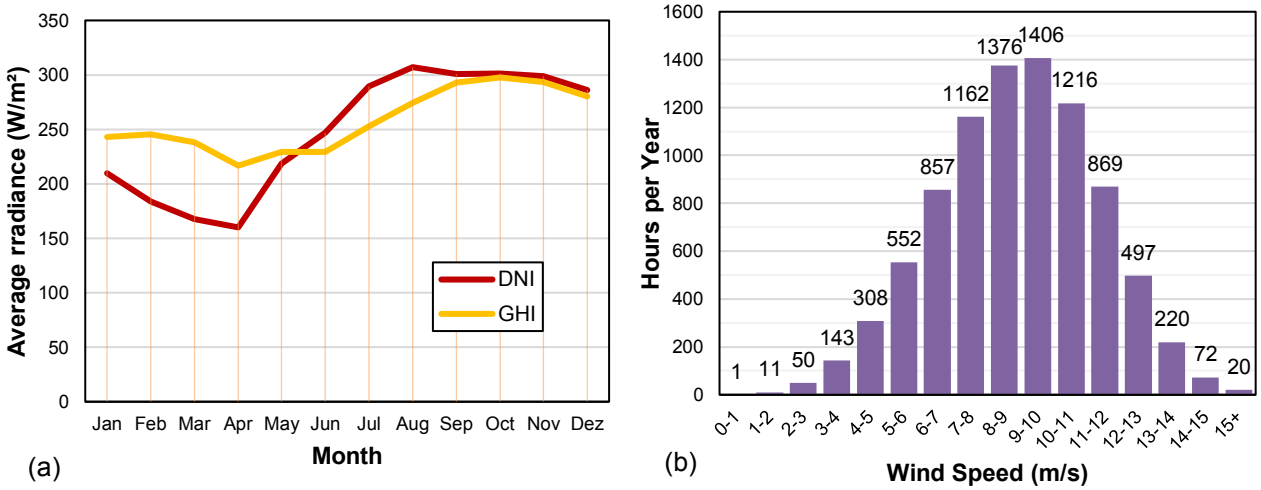

Figure 2. Solar and wind data for Pecém: (a) Solar irradiance [34][35] *and (b) Wind speed distribution* [36].

3.4. Energy and exergy analysis

The efficiency of energy conversion in SOEC system (η_{SOEC}) can be defined analogously to the definition for fuel cells in terms of the enthalpy of reaction according to Eq. (9) and the solar/wind-to-hydrogen conversion efficiency can be calculated in terms of the higher heating value of hydrogen (HHV) with Eq. (9):

$$\eta_{SOEC} = \frac{\dot{m}_{H_2} \Delta H}{\dot{W}_{SOEC}} \tag{9}$$

$$\eta_{solar/wind\_H_2} = \frac{\dot{m}_{H_2} HHV_{H_2}}{\dot{W}_{WF/PV} + \dot{Q}_{SF}} \tag{10}$$

The exergy efficiency of the electrolysis process can be defined according to the expression of Eq. (11), called the degree of perfection, being the ratio between the exergy of the products and the input exergy:

$$\eta_{B,SOEC} = \frac{B_{prod}}{B_{input}} = \frac{\dot{B}_8 + \dot{B}_{17}}{\dot{B}_7 + \dot{W}_{SOEC}} \tag{11}$$

The wind turbine exergy ($\dot{B}_{WF,in}$) is expressed by Eq. (12), which is a function of the air specific mass (ρ), the turbine swept area (A), and the wind speed (v) [38]. For the exergy analysis of solar field (SF) and photovoltaic panels (PV), the relation between energy and exergy fluxes in Eq. (13) is considered [39], where *T* is the solar surface temperature (5778 K) and T_0 is the ambient temperature (298 K). For these specific values, the ratio between exergy and energy fluxes is 0.9312.

$$\dot{B}_{WF,in} = \frac{1}{2} \rho A v^3 \tag{12}$$

$$\frac{\dot{B}_{SF/PV,in}}{\dot{E}_{SF/PV,in}} = 1 - \frac{4}{3}\frac{T_o}{T} + \frac{1}{3}\left(\frac{T_0}{T}\right)^4 \tag{13}$$

The exergy efficiencies for the solar field (SF), solar receiver (SR), wind farm (WF), photovoltaic panels, electrolyzer (SOEC), and heat exchangers HX-1 e HX-5 are defined as the ratio between output and input exergy. As for the compressors, their exergy efficiencies were determined by the ratio of the exergy change and the power provided. The total exergy efficiency of the plant was calculated as a function of the total fluids exergy rates and the solar radiation exergy rates with Eq. (14):

$$\eta_{B,total} = \frac{\dot{B}_{H_2.16} + \dot{B}_{O_2.23}}{\dot{B}_{WF/PV,in} + \dot{B}_{SF,in} + \dot{B}_{water.1}} \quad (14)$$

3.5. Exergoeconomic assessment

Based on Fig. 3, the exergoeconomic balance can be written according to Eq. (15), where $\dot{C}_{inp,i}$ and $\dot{C}_{prod,i}$ are the cost rates of inputs and products, respectively.

Figure 3. Exergoeconomic balance components

$$\sum_i \dot{C}_{inp,i} = \sum_i \dot{C}_{prod,i} \quad (15)$$

Eq. (15) can be rewritten, inserting the unit exergy cost, c_i, (in kJ/kJ) for each stream, according to Eqs. (16) and (17). It represents the amount of exergy required to produce a unit of the respective exergy stream. In this way, it is considered that the input used in the first process of a plant has an exergy cost equal to the unit.

$$c_i = \frac{\dot{C}_i}{\dot{B}_i} \quad (16)$$

$$\sum_i (c_{inp} \cdot \dot{B}_{inp})_i = \sum_i (c_{prod} \cdot \dot{B}_{prod})_i \quad (17)$$

When necessary, partition methods are applied, as proposed by [40]: Equality method: the costs are divided among the products according to their exergy content; (ii) Extraction method: the costs are discharged in a single exergy stream.

The product of multiplying the unit exergy cost (kJ/kJ) by the specific exergy of a given stream (kJ/kg) produces an exergy intensity indicator in kJ/kg that specifies the amount of exergy required to obtain a unit of mass of a certain stream [41], according to Eq. (18):

$$\varphi_i = c_i b_i \quad (18)$$

4. Results and Discussion

Figure 4a illustrates the wind exergy and generated electricity for the analysed wind farm as function of wind speed. Figure 4b shows the corresponding exergy efficiencies. The maximum net power output of 10 MW is achieved only when wind speed exceeds 11.6 m/s, which happens 12.7% of the time, or approximately 1110 hours per year. The average net power output is estimated as 6.38 MW. The total yearly electricity generation in the wind farm is estimated as 55.88 GWh. Considering a total of 170.5 GWh of wind exergy available annually, this represents an average exergy efficiency of 32.8%.

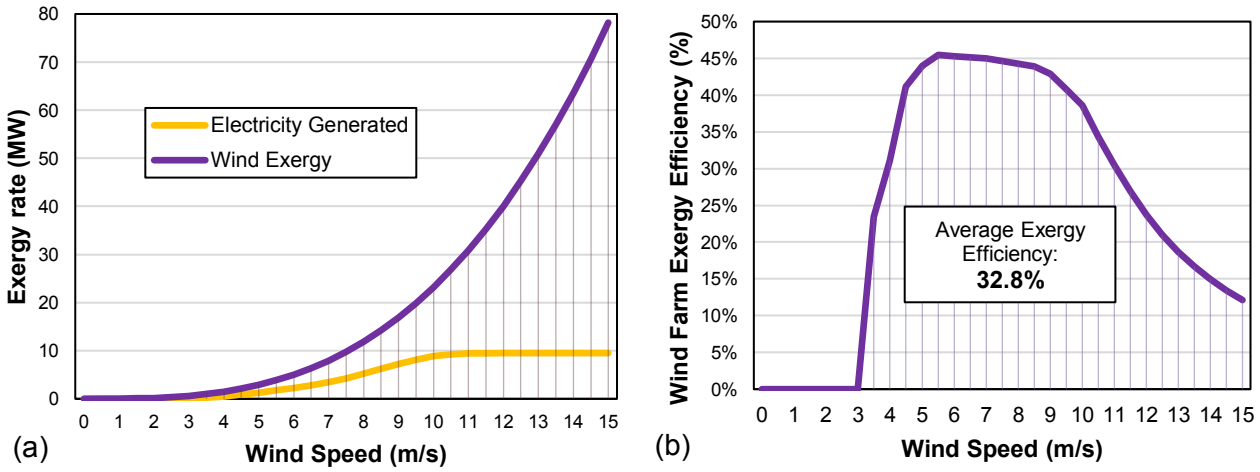

Figure 4. Wind farm results: (a) Wind exergy and electricity generated and (b) Exergy efficiency

The estimated electricity generation over a typical meteorological year (TMY) is shown in Fig. 5 in GWh for the two considered systems (WF and PV). The months with the highest and lowest levels of generation coincide for both forms of generation. However, the variability of wind energy is slightly higher. Fig. 6 illustrates the hydrogen production of the proposed plant. The estimated average daily production of hydrogen is 4.13 t, which results in a daily production of 23.7 t of oxygen and a water consumption of 36.8 m³/day. Due to the variation in direct irradiation throughout the year, the production in April tends to be 48% lower than in August. In practice, it means that the plant would operate at about half of its capacity during this month.

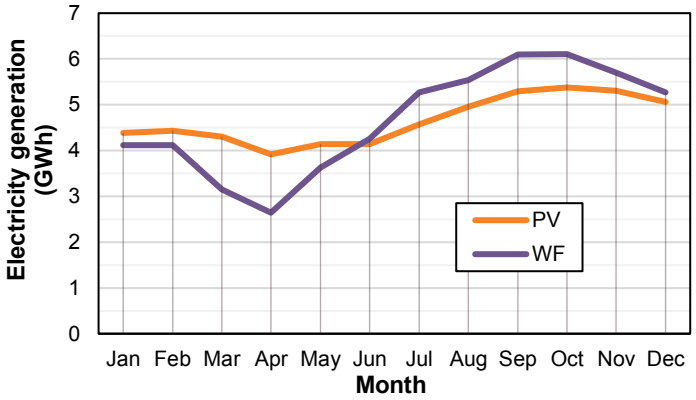

Figure 5. Estimated electricity generation over a typical meteorological year (TMY)

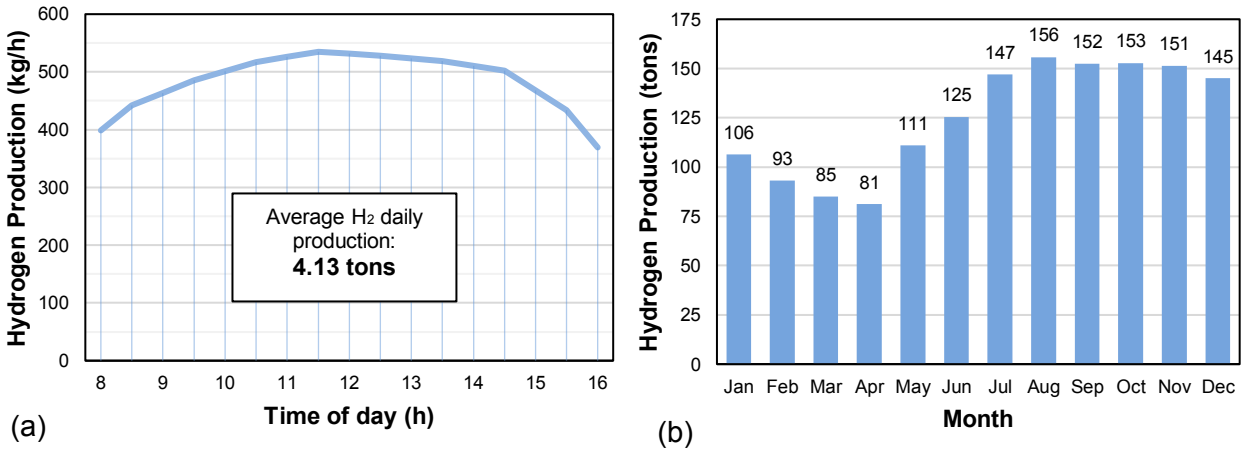

Figure 6. Hydrogen production: (a) Average hourly production and (b) Average production per month

Table 2 summarizes the results of the energy and exergy analysis conducted for the plant's power and heat supply components. The irreversibilities observed in wind turbines are associated with the interaction between air and blades, as well as the efficiencies of mechanical and electrical conversion. In the PV panels and solar concentrators there are optical losses such as attenuation, blocking, or shadowing, as well as losses related to heat convection and conduction [39]. For the wind farm, the values from the energy and exergy analysis are the same since wind exergy and electrical work are equal to the values in the exergy balance. For the PV panel, solar field and solar receiver, the ratio between exergy and input energy is given by Eq. (13). Specifically for the solar receiver, the exergy efficiency is much lower than the energy efficiency due to the irreversibility of the process of converting solar radiation into exergy of the steam.

Table 2. Energy and exergy analysis: power supply components

Components[1]	Energy Analysis			Exergy Analysis		
	Received (MWh/day)	Delivered (MWh/day)	Energy Efficiency (%)	Received (MWh/day)	Delivered (MWh/day)	Exergy Efficiency (%)
Wind Farm (WF)	467.19	153.09	32.8	467.19	153.09	32.8
Photovoltaic System (PV)	1020.63	153.09	15.0	950.41	153.09	16.1
Solar Field (SF)	55.67	33.40	60.0	51.84	31.10	60.0
Solar Receiver (SR)	33.40	28.39	85.0	31.10	13.78	44.3[2]

[1] The wind farm is part of the arrangement (I) WF-SOEC, and the photovoltaic system is part of the arrangement (II) PV-SOEC.
[2] Only physical exergy of the steam was considered for the calculation for the solar receiver.

The results of the analysis conducted for the electrolyzer, heat exchangers, and compressors are presented in Tab. 3. The SOEC exergy efficiency is 89.4%. The losses in the electrolyzer occurs due to overvoltage at the anode and cathode, as well as ohmic resistance of the cells [26]. The thermoneutral voltage (V_{TN}) is 1.288 V, the ohmic heat flux ($q"_R$) is 0.163 W/cm², and the average power consumed ($\dot{W}_{TN}$) is 17.67 MW, which corresponds to 92.3% of the electricity demanded in the plant.

Table 3. Energy and exergy analysis: SOEC, heat exchangers, and compressors

Components	Energy Analysis			Exergy Analysis		
	Power (kW)	Rejected (kW)	Energy Efficiency (%)	Destroyed (kW)	External Losses (kW)	Exergy[(2)] Efficiency (%)
Electrolyzer (SOEC)	17671.20	0	100.0	1864.69	0	89.4

Compressor 4 (CP-4)	245.28	0	100.0	28.72	0	88.3
Heat Exchanger 8 (HX-8)	-	257.42	-	0	67.50	-
Total	19137.10	2372.86	87.6	3096.80	551.97	80.9

[(2)] Only physical exergy was considered for the calculation of the heat exchangers.

Heat recovery exchangers HX-1 and HX-5 achieved low exergy efficiencies due to the high mean temperature difference between the fluids. Therefore, one of the enhancements that can be made in this plant involves modifying the configuration of these exchangers or changing the method of heat recovery. In the other exchangers, the heat is rejected to the environment, which represents an exergy rate of 552 kW, enough to feed at least one of the compressors. Despite this, the efficiency of the set of electrolyzer, exchangers and compressors is 80.9%.

The overall energy efficiency for the WF-SOEC configuration is 31.08%, and 15.10% for the PV-SOEC arrangement. The overall exergy efficiency is 26.53% and 13.74%, respectively. The energy losses and exergy destroyed are detailed in the Sankey and Grassmann diagrams in Fig. 7 and 8 for both configurations.

Regarding other studies, Lin and Haussener [14] obtained an energy efficiency of 9.9% for a different PV-SOEC arrangement. Restrepo et al. [17] obtained an efficiency of 31.8% for a PV-SOEC system but used PV panels with solar concentration (CPV) that achieve efficiencies far above conventional PV cells (36.3% versus 15.0%). Nasser and Hassan [19] obtained an efficiency value of 18.6% considering a WF-SOEC plant configuration. However, it is difficult to make direct comparisons among these studies due to variations in plant configuration, modes of operation, and locations considered for the analyses.

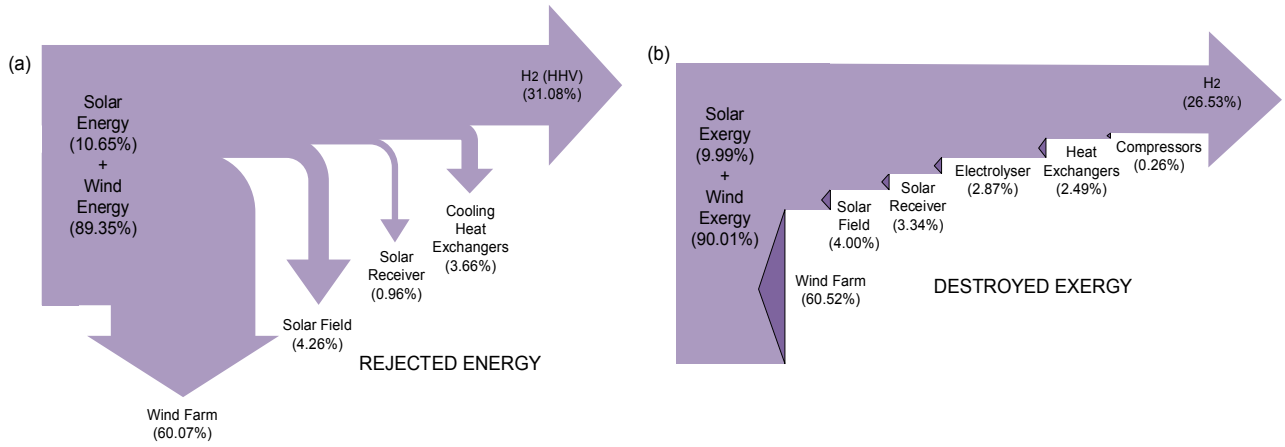

Figure 7. Energy and Exergy Diagrams for the WF-SOEC plant: (a) Sankey and (b) Grassmann

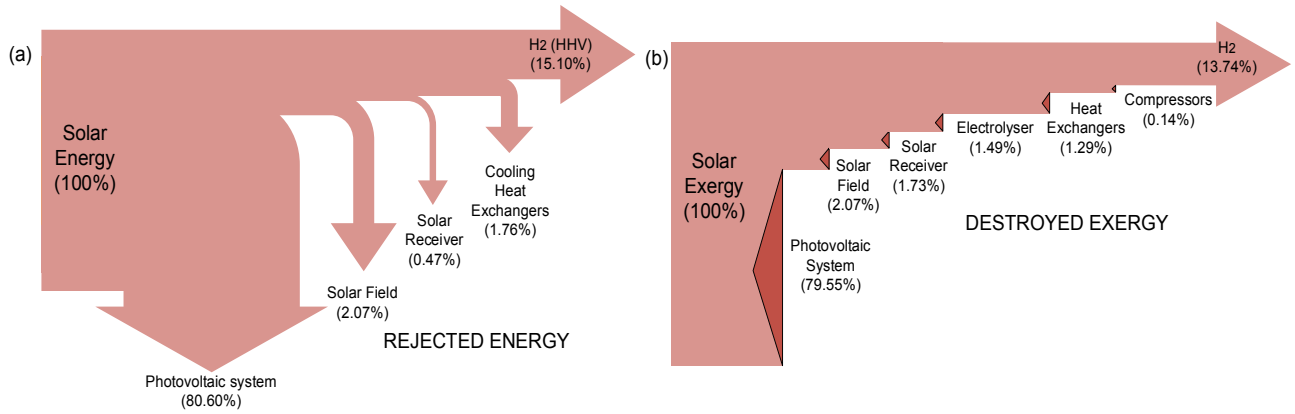

Figure 8. Energy and exergy diagrams for the PV-SOEC plant: (a) Sankey and (b) Grassmann

In the exergoeconomic analysis, the extraction method is adopted in the electrolyzer since hydrogen is considered the main product of the plant. However, as the total exergy of hydrogen at the electrolyzer outlet is almost 30 times higher than the total exergy of oxygen, there will be no significant differences in costs if the equality method is applied.

The unit exergy costs for each stream are presented in Fig. 9a for the WF-SOEC arrangement, where A and B are the exergy fluxes of solar irradiation, C is the flow of wind exergy, and D is the electricity generated by the wind turbines. As the streams A, C, and 1 are the inputs used in the first process of the plant, their exergy costs are considered equal to the unit. The unit exergy costs obtained for solar exergy in the solar receiver, electricity, and steam are 1.67, 3.30, and 4.26 kJ/kJ, respectively. For oxygen, the estimated unit exergy cost is 4.78 kJ/kJ, and for hydrogen at the end of the process, it is 3.89 kJ/kJ.

The unit exergy costs for the PV-SOEC plant are presented in Fig. 9b. As the efficiency of the photovoltaic system is less than half that of the wind system, the exergy costs are significantly higher. The unit cost of electricity is 6.72, steam is 6.35, and for oxygen, it is 9.61 kJ/kJ. For hydrogen, it is 7.53 kJ/kJ, which is 94% higher than in the previous configuration.

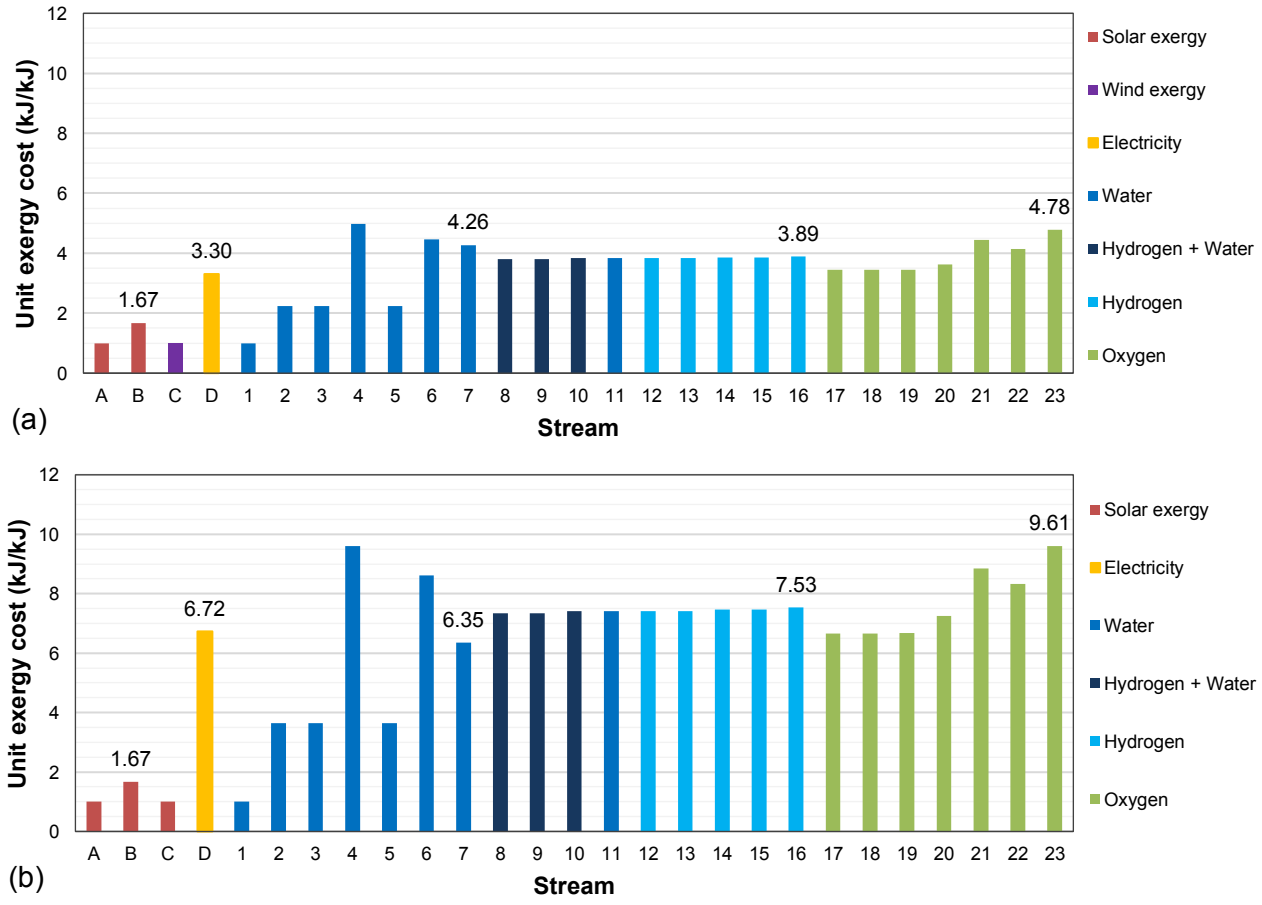

Figure 9. Unit exergy costs: (a) WF-SOEC and (b) PV-SOEC

Finally, Tab. 4 shows the exergy intensity values for the superheated steam used in the electrolysis process and the gases oxygen and hydrogen produced. In the WF-SOEC plant, 471.96 MJ of exergy is necessary to produce 1 kg of hydrogen, while for the PV-SOEC plant, it is 913.69 MJ. Although these values are high compared to the chemical exergy of H_2, in both cases, the exergy used is 100% obtained from renewable resources and without direct CO_2 emissions, which gives a significant advantage compared to the currently predominant production processes in the hydrogen industry. Moreover, these arrangements can be optimized to achieve higher levels of efficiency and lower exergy costs.

Table 4. Exergy Intensity

Plant	Stream	Exergy intensity (MJ/kg)
WF-SOEC	H_2O (850ºC, 1 bar)	8.00
	O_2 (25ºC, 30 bar)	1.84
	H_2 (25ºC, 30 bar)	471.96
PV-SOEC	H_2O (850ºC, 1 bar)	11.91
	O_2 (25ºC, 30 bar)	3.69
	H_2 (25ºC, 30 bar)	913.69

5. Conclusions

This study provides a comprehensive energy, exergy, and exergoeconomic assessment for two hydrogen production plants based on the high-temperature electrolysis (HTE) route. The analyses were carried out for Pecém, a coastal district located in north-eastern Brazil. In the proposed plants, the thermal demand is supplied by solar energy from a solar tower system. For the electrical demand, wind turbines and photovoltaic panels were evaluated.

Assuming the generation of a wind farm with 10 MW of installed capacity as a reference, the daily H_2 production was estimated at 4.13 t. The SOEC exergy efficiency was 89.4%. The overall energy efficiency for the WF-SOEC configuration was 31.08%, and 15.10% for the PV-SOEC arrangement. The overall exergy efficiency was 26.53% and 13.74%, respectively. In the exergoeconomic analysis, the unit exergy cost of hydrogen was 3.89 for the WF-SOEC, and 7.53 for the PV-SOEC configuration.

Regardless the efficiencies and the exergy costs achieved, it is important to note that in both arrangements evaluated, the exergy used is obtained 100% from renewable resources and without direct CO_2 emissions. This gives a significant advantage over the predominant production processes in the hydrogen industry. The SOEC technology, while still undergoing research and development, offers a promising alternative for hydrogen production with the potential for further optimization of efficiency levels and lower exergy costs. Furthermore, this study provides a basis for future investigations into HTE-based hydrogen production plants and serves as a contribution to the transition towards sustainable energy systems.

Thermodynamic assessment of Latin American cities applying exergetic efficiency: effects of information availability on efficiency evaluation

Ricardo Morel Hartmann[a], Luis Evelio Garcia-Acevedo[a], Amir Roberto De Toni Jr[b]

Abstract:

Energetic analysis of cities is a challenging task, due to the lack of a concise, general thermodynamic parameter to evaluate energetic output streams that is applicable to every city. Therefore, exergetic efficiency was applied as a comparative index, given that it encompasses concepts of first and second laws of thermodynamics, thus providing a figure of merit similar to those applied to thermal systems. The proposed concept was employed to assess five metropolitan areas in Latin America: Bogotá, Buenos Aires, Rio de Janeiro, Santiago de Chile and São Paulo. Comparisons among the five cities show a linear trend of increasing per capita CO_2 emissions with increasing *per capita* inlet exergy, as well as the importance of electric mobility to the overall exergetic efficiency. Also noteworthy is the complexity of observing and assessing internal exergetic streams and the evaluation of a usefulness of industrial production in terms of thermodynamic properties. According to the analysis, São Paulo presented the highest exergetic efficiency, 22.43 %, while Santiago de Chile presented the lowest, 17.94 %. This result is somewhat unexpected, since São Paulo is a warmer city, with significant HVAC use during Spring and Summer, but at the same time reflects São Paulo's exergetic data availability, thus allowing a more detailed evaluation.

Thermodynamics of cities; Smart cities; Exergetic efficiency, Data availability.

1. Introduction

Around 5,000 BC the first cities were formed as primitive centers for trade and religious activities [1] and, as time elapsed, certain cities became specialized centers, e.g., Sidon and Tyre, in modern-day Lebanon, which were well established maritime cities circa 2,000 BC. Since then, urban centers evolved as *locus* for several economic activities like shipping, manufacturing, mining, education, finance, health and many others, with capitals and metropolitan areas being relevant in one or more of these economic sectors. According to the United Nations [2], in 2014, urban dwellers were 54 % of the global population, and this share is projected to be 66 % by 2050. Such an increase in urban density will demand better solutions for mobility, water supply, and waste management, all of which are related to energetic and exergetic efficiency and sustainable development.

Eger [3] and Susanti et. al. [4] pointed out that only in the last four decades have cities been analyzed from a multidisciplinary perspective, instead of being an exclusive subject of demography, and, currently, economic discussions involving concepts such as circular economy [5-7] provide additional tools for the study of cities. Beyond these views in terms of economic roles and sectors, cities can also be seen as living organisms that consume and discard mass and energy, thus being amenable to the laws of conservation which underpin the science of thermodynamics.

Issues with municipal solid waste (MSW) and sewage management are much older than the formal statements of mass and energy conservation, which may help explain why these problems are seldom investigated from a thermodynamics standpoint. Though the number of studies exploring thermodynamics of cities increased in recent years, such assessments are sparse compared to analysis focused on Information and Communication Technology (ICT), which is one of the features of so-called Smart Cities (SC). The

concept of Smart City is not unequivocal [8,9] but there is consensus regarding the key role of ICT, Artificial Intelligence (AI), and Internet of Things (IoT) to enhance governance, transparency, and mobility, among other interactions of citizens with the urban environment. Albino et. al. [9] argue that a comprehensive approach to SC must also include personal and community needs, considering sustainability in a broader sense. Also relevant is the role of renewable energy, distributed generation and electrical mobility, aiming to improve exergetic efficiency and to achieve net zero emissions.

1.1. Thermodynamic assessment of cities

In this subsection a brief overview of recent studies regarding thermodynamic assessments of cities is provided. Pelorosso et al. [10] presented a discussion involving the concepts of circular economy, low-entropy city and complex socio-ecological systems. The authors also discuss the role of urban green infrastructure (UGI) to increase exergetic efficiency and the possibility of devising a generic strategy applicable to every city. Purvis and Mao [11] examined the application of entropy as an indicator of urban sustainability, by means of assessing exergy and generation of irreversibilities. Cities were analyzed as dynamic entities consisting of dissipative structures, thus showing the limits of a straightforward evaluation of entropy in urban systems. The authors argued that it is not possible to use entropy to assess material flows and degradation in a meaningful way, given the absence of 'utility' or 'usefulness' metrics in thermodynamics, which only has exergy, that corresponds to energetic availability. Regardless, Purvis and Mao agree with the use of exergetic assessments and circular economy strategies to improve urban sustainability.

Bristow and Kennedy [12] presented a nonequilibrium thermodynamics evaluation based on the concept of dissipative structures as stated by Kondepudi and Prigogine [13]. The authors conducted a macro-scale analysis, presenting results of energetic intensity as function of population density for 22 global cities. Results showed that energy intensity increases at a higher rate than population growth, which is a characteristic behavior of dissipative structures. Additionally, Bristow and Kennedy emphasized the need for further studies, with a consistent methodology, to assess exergetic flows in cities, especially regarding micro-scale processes occurring within their control volume.

Regarding Smart Cities, Zheng et al. [8] reported a scientometric review of smart city literature between 1990 and 2019, encompassing 7,380 articles. Publications were classified according to Web of Science criteria, with 35.05 % of studies being in the 'engineering electrical electronics' area, 21.98 % in 'computer science information systems', 20.18 % in 'telecommunications', and 19.95 % in 'computer science theory methods', with no category dedicated to thermodynamics. Yu and Zhang [14] evaluated the energetic efficiency in 251 Chinese cities, given their adoption of smart city policies, between 2003 and 2016. The authors developed a non-convex metafrontier data envelopment analysis to examine energy consumption data, but no analysis of thermodynamic behavior was conducted. Yu and Zhang claim to present the first systematic analysis of energetic efficiency of cities in China and concluded that the adoption of SC policies positively affected energetic efficiency.

Hartmann et al. [15] assessed the exergetic efficiency of a coastal city in Brazil (Florianópolis), focused on the effect of MSW management, showing that a proper waste separation combined with waste-to-energy generation could increase exergetic efficiency by 1.5 %, resulting in a yearly mitigation of 15,761 tons of carbon dioxide. Hartmann and Garcia-Acevedo [16] further developed the methodology for evaluation of the exergetic efficiency of urban centers, presenting results for five cities with different main economic sectors: electricity generation (Foz do Iguaçu), manufacturing (Ingolstadt), services/ICT (Florianópolis), tourism (Hawaii), and oil refining (Singapore), the latter also being a Smart City. The results indicate a linear trend of increasing per capita CO_2 emissions with increasing per capita production of MSW. Also noteworthy is the impact of electric mobility to reduce exergy destruction within the city.

Given this brief overview, the present paper aims to add to the scientific literature by reporting an assessment of the exergetic profile of five major cities in Latin America, thus providing subsidies to improve their exergetic performances. Additionally, it intends to compare and discuss the influence of available data on exergetic evaluation of the cities, given that availability of reliable data is one of the key issues of smart cities [3,4,8,9,14].

2. Theoretical background

Among the reasons to employ exergetic efficiency as an 'energy smartness index' one can emphasize that i) it encompasses both the first and second laws of thermodynamics; ii) it can be related to carbon dioxide emissions and fuel savings; iii) it is a positive number between zero and one, thus easy to communicate. Purvis and Mao [11] pointed out that an energetic efficiency analysis based only on the first law of thermodynamics is not adequate to every urban center, given the impossibility to evaluate the 'usefulness' of intangible products such as software and services. On the other hand, every city consumes exergy through

internal irreversibilities, thus it is possible to apply exergetic assessments regardless of the main economic sector.

The thermodynamic analysis applied here involves: a) definition of the metric to be evaluated; b) setting of adequate control volume; c) description of simplification hypothesis; d) mathematical model; and e) analysis of results. The preceding sections have shown that exergy is the thermodynamic property that fulfils a). Regarding b), a proper control volume, which includes streams of energy, enthalpy, entropy, exergy, heat, mass, water, pollutants, among others, is illustrated in Fig. 1.

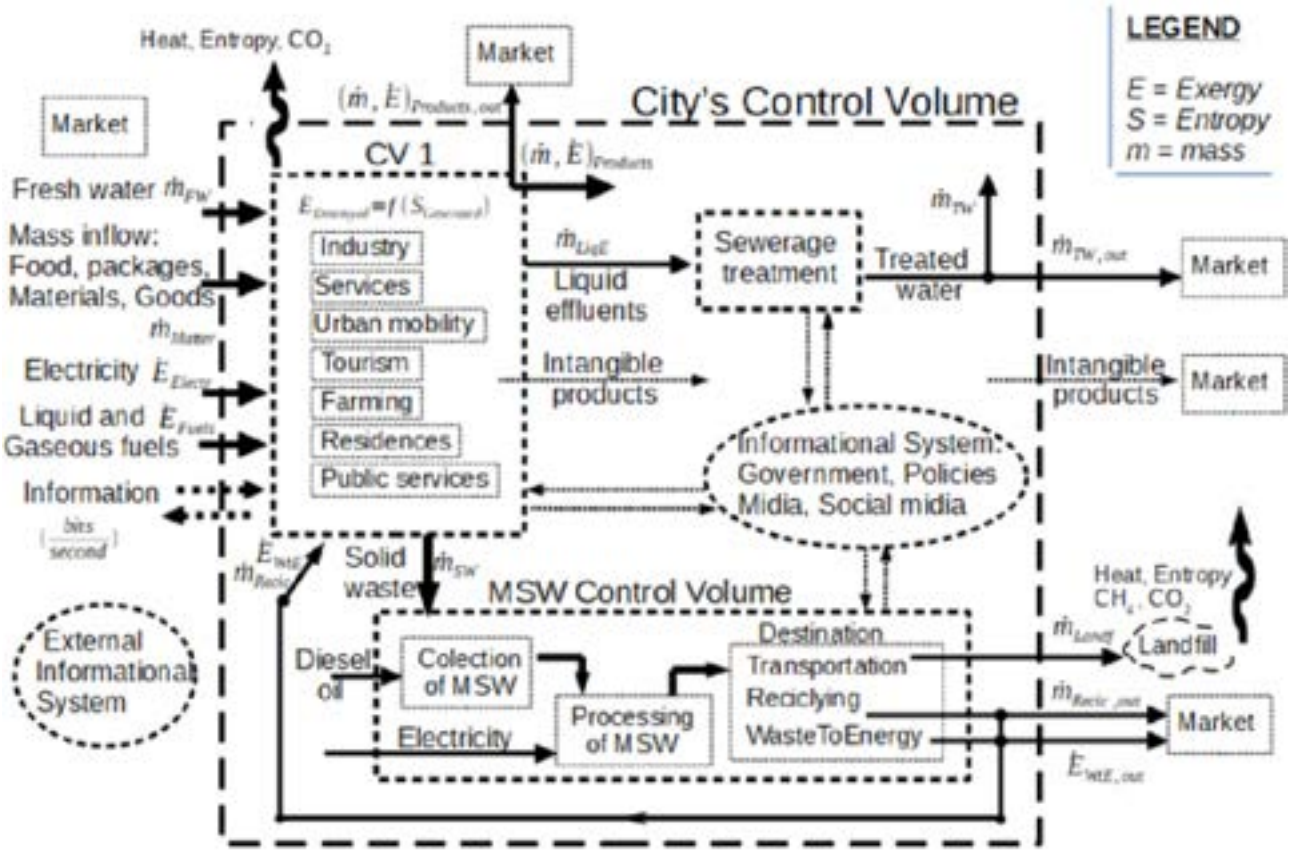

Fig. 1. Representative control volume for the thermodynamic assessment of cities.

The proposed simplification hypothesis are as follows:

(i) Inlets and outlets are considered in terms of yearly average, steady-state streams of exergy;
(ii) Exergy streams are limited to the concepts presented in Hartmann et al. [15], Moran et al. [17] and Szargut et al. [18], i.e., exergy related to altitude, kinetic exergy, electrical exergy, physical exergy related to temperature difference, and chemical exergy (heating value of fuels);
(iii) Vehicles, house appliances and other equipment are considered in terms of annual exergy consumption;
(iv) Analysis will be limited to classical thermodynamics, thus information streams will not be assessed.

2.1. Mathematical formulation

Given the proper control volume and the set of hypotheses, the mathematical model can be formalized. Exergetic efficiency is calculated in terms of inlet and outlet streams,

$$\eta_{II} = \frac{\dot{E}_{out}}{\dot{E}_{inlet}} \qquad (1)$$

$$\eta_{II} = 1 - \left(\frac{\dot{E}_{dest}}{\dot{E}_{inlet}} \right) \qquad (2)$$

where η_{II} is exergetic efficiency, $\dot{E}_{out}$ is produced exergy, $\dot{E}_{inlet}$ is inlet exergy and $\dot{E}_{dest}$ is exergy destroyed within the control volume. Equation (1) is convenient for evaluating cities which export exergy, like ones with an oil refinery or a power plant, while Eq. (2) shows a general case. The inlet rate of exergy, $\dot{E}$, is simply the sum of all exergetic streams, e.g. electricity, coal, oil, liquid and gaseous fuels, as well as river streams. The exergy rate for electricity is equal to its power, while that for water and other mass streams includes kinetic exergy, physical exergy due to temperature difference in relation to a dead state, and potential exergy [17]. Chemical exergy of liquid and gaseous fuel is calculated following Szargut et al. [18],

$$\dot{E}_{fuel,i} = \dot{E}_{chem} = \beta_{fuel,i} \cdot LHV_{fuel,i} \qquad (3)$$

where $\dot{E}_{chem}$ is the rate of chemical exergy, LHV is the lower heating value, and β is the ratio of chemical exergy to LHV, which is given by Rakopoulos and Giakoumis [19], for liquid and gaseous fuels, respectively, as,

$$\beta_{liq} = 1.0334 + 0{,}0144\left(\frac{H}{C}\right) \qquad (4)$$

$$\beta_{gas} = 1.0334 + 0{,}0144\left(\frac{H}{C}\right) - 0.0694\left(\frac{1}{N_C}\right) \qquad (5)$$

where H/C is the hydrogen to carbon ratio in the fuel, and N_C is the number of carbon atoms in the fuel molecule. Exergy outlet evaluation is analogous to the exergy inlet one, plus the streams of wastewater and MSW, when useful data is available. The evaluation of the rate of exergy destruction is expressed as,

$$\dot{E}_{dest,i} = \left(1 - \eta_{II,i}\right)\dot{E}_{Inlet,i} \qquad (6)$$

where $\eta_{II,i}$ is the exergetic efficiency of a process i. Representative values of exergetic efficiencies of processes and appliances, as well as the source of data are presented in Tab. 1.

Table 1. Exergetic efficiencies for processes and appliances

Process/Appliance	Exergy type	%	Reference
Motors (industrial, mobility)	electric	76.00	[20,21]
Air conditioner	electric	01.90	[22]
Personal computer	electric	75.00	[22]
Lighting	electric	20.00	[22]
Refrigerator	electric	07.20	[22]
Cooking oven	electric	24.20	[22]
Television	electric	80.00	[22]
Vacuum cleaner	electric	70.00	[22]
Water heater	electric	10.50	[22]
Heater/boiler	combustion	06.00	[23]
Internal combustion engines/vehicles	combustion	25.00	[19,20]
Ovens	combustion	14.88	[24]
Combustion/chemical reactions	combustion	70.00	[25]

Assessment of carbon dioxide emissions due to combustion considered stoichiometric combustion [26] with dry air, thus the emissions, in kilograms of CO_2 emissions per kilogram of fuel, are: 3.09 for gasoline, 3.12 for Diesel oil, 1.91 for hydrated ethanol, 3.02 for liquefied petroleum gas (LPG), and 2.75 for natural gas. Emissions from coal, when necessary, were obtained from data available for each analysed city.

3. Results and discussions

The proposed methodology [16] was applied to assess five global cities in Latin America: Bogotá, Buenos Aires, Rio de Janeiro, Santiago de Chile and São Paulo. The selection of these cities considered their presence in the IMD-SUTD Smart City Index Report 2021 [27], and the energy data used as input for the present analysis were obtained from their respective open data/transparency websites and reports, which are referenced in each subsection. However, the availability and specificity of municipal data varied significantly between cities, thus hampering a thorough assessment. In order to check the reliability and consistency of some metrics calculated in the present assessment, like per capita emissions, data available at the US Energy Information Agency [28], the Our World in Data Project [29] and the International Energy Agency [30] served as baseline values. Each of the following subsections provides details regarding these differences of available information. The analysis was carried out based on data of the year 2019, before the Covid-19 pandemic.

3.1. Bogotá

Bogotá is the capital and largest city of Colombia, with 7.2 million inhabitants in the city proper (Geoportal del DANE - Geovisor CNPV 2018) and 10.7 million in the metropolitan area. The urban centre covers 307.3 km², resulting in a population density above 24,000/km². Bogotá is located in a high plateau of the Andes, with an average altitude of 2,640 metres and typical temperatures between 5 and 20 °C. The metropolitan region is responsible for 24.7 % of national gross domestic product and the El Dorado International Airport handles the largest cargo volume in Latin America.

According to the Smart City Index [27], Bogotá ranks 116 out of 118, with a 'D' rating, in a tier shared with Nairobi, Lagos, Rio de Janeiro and São Paulo. Energy and emissions data for Bogotá are available on open data websites <http://www.sui.gov.co/web/energia> [31] and <https://public.tableau.com/app/profile/upme> [32]. It is worth noting that the website hosted by the government [31] has many features, allowing detailed searches considering income level (in Spanish, *estrato*), rural and urban locations, government buildings, and many others. On the other hand, the website was frequently offline, usually at night and during weekends. Table 2 summarizes the results of the exergetic assessment of Bogotá.

Table 2. Exergetic assessment of Bogotá, year 2019.

Energy source	Exergy input, TJ/yr	Exergy destroyed, TJ/yr	$CO_{2,\ equi}$, Mton/yr
Gasoline	30,552.7	22,761.8	2.253
Diesel oil	33,926.1	25,274.9	2.353
Ethanol	416.1	310.0	0.028
LPG	1,765.4	1,502.7	0.109
Natural gas	25,201.8	23,689.7	1.844
Electricity	27,273.7	24,137.2	1.287
Total	**119,135.8**	**97,676.3**	**7.874**
Exergetic efficiency	**18.01 %**	**$CO_{2,\ equi}$, ton/person-yr**	**1.096**

From data on Tab. 2, one can notice how the inhabitants of Bogota have an almost equal reliance on gasoline and Diesel for urban mobility, as well as a limited use of LPG. It is important to note that per capita emissions available elsewhere [29] include all emissions sources. In the case of Colombia, more than 50 % of emissions are associated with land-use changes and agriculture, which are not included in our assessment.

3.2. Buenos Aires

Buenos Aires is the capital and largest city of Argentina, with 2.9 million inhabitants in the city proper and 12.8 million in the metropolitan area. The city covers 20,300 km², resulting in a population density above 14,000/km². The metropolitan area has Argentina's two main maritime ports and represents around a quarter of the country's gross domestic product. Buenos Aires has a humid subtropical climate, with typical temperatures between 10 and 25 °C, though summers have highs above 35 °C and record highs reaching 43 °C, while record lows are near -5 °C.

According to the Smart City Index [27], Buenos Aires ranks 98 out of 118, with a 'CC' rating, in a tier shared with Mumbai, Jakarta, Istanbul, Lisbon, and Budapest. Energy and emissions data for Buenos Aires are supposedly available on open data website <estadisticaciudad.gob.ar>, though it has been down/inaccessible for several months. Therefore, the authors had to use national level data [33-36] to evaluate municipal values, which is likely to produce biased results. Table 3 presents the exergy assessment for Buenos Aires.

Table 3. Exergetic assessment of Buenos Aires, year 2019.

Energy source	Exergy input, TJ/yr	Exergy destroyed, TJ/yr	$CO_{2,\ equi}$, Mton/yr
Gasoline	16,458.6	12,261.7	1.214
Diesel oil	22,478.9	16,746.8	1.559
LPG	2,463.0	2,096.5	0.153
Natural gas	71,949.8	61,229.3	5.265
Electricity	31,880.5	23,910.4	3.099
Total	**145,230.8**	**116,244.6**	**11.290**
Exergetic efficiency	**19.96 %**	**$CO_{2,\ equi}$, ton/person-yr**	**3.690**

From the data in Tab. 3 one can notice Buenos Aires', hence Argentina's, reliance on natural gas, which corresponds to 64 % of the electric mix [29]. It is also noteworthy that about 1.72 million vehicles in Argentina, roughly 17 % of the passenger fleet, are fuelled by compressed natural gas (CNG). Electricity generation in Argentina consumed approximately 590,000 TJ of natural gas in 2019, followed by industries, with a consumption close to 523,000 TJ [34]. Regarding emissions, the electricity generation in Argentina is more carbon intensive than natural gas burning for final uses.

3.3. Rio de Janeiro

Rio de Janeiro is the second-most populous city in Brazil, with a population of 6.72 million, while its metropolitan area is home to 12.28 million. The city proper covers 1,221 km², with a population density around 5,500/km². The city is known for its tropical, humid climate, with daily means above 20 °C, record lows around 10 °C and record highs above 42 °C, thus having significant demand for HVAC.

According to the Smart City Index [27], Rio de Janeiro ranks 118 out of 118, with a 'D' rating, in a tier shared with Nairobi, Lagos, Bogotá and São Paulo. Energy and emissions data for Rio de Janeiro were obtained from its open data website <www.data.rio> [37] and also from state level data [38]. The Data Rio website is not user friendly, since it does not offer data visualization on graphs or tables online, thus working more like a repository of spreadsheets. Table 4 presents the exergetic assessment for Rio de Janeiro.

Table 4. Exergetic assessment of Rio de Janeiro, year 2019.

Energy source	Exergy input, TJ/yr	Exergy input, %	Exergy destroyed, TJ/yr	$CO_{2,\ equi}$, Mton/yr
Gasoline	23,451.4	15.6	17,471.3	1.729
Diesel oil	24,575.5	16.3	18,308.8	1.704
Ethanol	6,936.1	4.6	5,167.4	0.468
LPG	5,568.1	3.7	4,739.6	0.345
Natural gas	35,575.0	23.6	26,532.3	2.603
Electricity	54,453.6	36.2	51,186.4	2.508
Total	**150,559.8**	**100.0**	**123,405.7**	**9.357**
Exergetic efficiency	**18.03 %**		**$CO_{2,\ equi}$, ton/person-yr**	**1.393**

Regarding data on Tab. 4, it is important to note that Brazilian gasoline, available at the pump, is mixed with ethanol, in proportions up to 27.5 %. Hydrated ethanol is also available in gas stations, and most passenger vehicles produced in Brazil since 2006 can run on any mixture between E20 gasoline to E100. Also noteworthy are the low emissions associated with electricity, which are due to Brazil's reliance on hydropower.

3.4. Santiago de Chile

Santiago is the capital and largest city of Chile, and its population of 6.3 million people corresponds to some 32 % of the country. The city has an area of 641 km² with a population density close to 10,000/km². Santiago is located in a valley, with an average elevation of 570 metres, and has a cool, semi-arid climate, with daily averages between 7 and 21 °C, record lows below -5 °C and record highs around 40 °C. According to the Smart City Index [27], Santiago ranks 110 out of 118, with a 'C' rating, in a tier shared with Cape Town, Bucharest, Sofia, Mexico City, Athens, and Rome.

Energy statistics for Santiago de Chile and its metropolitan region are available in reports [39] and on an open data website <energiaregion.cl> [40], which is very user friendly even though it mostly presents per

capita data, thus lacking the extensive searching features of its Colombian counterpart. Table 5 presents the exergetic assessment for Santiago.

Table 5. Exergetic assessment of Santiago de Chile, year 2020.

Energy source	Exergy input, TJ/yr	Exergy destroyed, TJ/yr	$CO_{2,\ equi}$, Mton/yr
Gasoline	50,141.0	37,355.0	3.697
Diesel oil	53,816.3	40,093.1	3.732
LPG	22,839.1	19,440.6	1.415
Natural gas	25,201.8	23,689.7	1.844
Electricity	64,317.0	56,920.5	19.777
Total	**216,315.2**	**177,499.0**	**30.465**
Exergetic efficiency	**17.94 %**	**$CO_{2,\ equi}$, ton/person-yr**	**4.859**

From Tab. 5 one can notice that Santiago, in comparison with Rio de Janeiro, has a similar population, but its population density is 80 % higher than Rio's and its exergy input is 43 % higher. Per capita emissions are quite high since half of the Chilean electricity generation comes from fossil fuels (22 % coal, 15 % oil, and 14 % gas) [29,30].

3.5. São Paulo

São Paulo is the largest city in Brazil and the Southern Hemisphere, with 12.4 million inhabitants and a population density of 8,000/km². The city comprises around 5.8 % of the country's population but it represents some 10.7 % of the national GDP. São Paulo is located on a plateau close to the Atlantic Ocean, with an average elevation of 800 metres, and has a humid subtropical climate, with daily averages between 12 and 30 °C, record lows around 0 °C and record highs around 40 °C.

According to the Smart City Index [27], São Paulo ranks 117 out of 118, with a 'D' rating, in a tier shared with Nairobi, Lagos, Bogotá and Rio de Janeiro. Energy statistics for the city of São Paulo are available on the São Paulo state open data website [41], though only as a repository for reports and spreadsheets. Table 6 shows the exergetic assessment of São Paulo.

Table 6. Exergetic assessment of São Paulo, year 2019.

Energy source	Exergy input, TJ/yr	Exergy input, %	Exergy destroyed, TJ/yr	$CO_{2,\ equi}$, Mton/yr
Gasoline	61,789.5	20.0	46,033.2	4.556
Diesel oil	64,263.1	20.8	47,876.0	4.456
Ethanol	56,944.7	18.4	42,423.8	3.842
LPG	13,907.9	4.5	11,838.4	0.862
Natural gas	19,753.5	6.4	14,738.6	1.446
Electricity	92,516.0	29.9	76,912.7	4.221
Total	**309,174.7**	**100.0**	**239,882.7**	**20.828**
Exergetic efficiency	**22.43 %**		**$CO_{2,\ equi}$, ton/person-yr**	**1.707**

Regarding data on Tab. 6, it is noteworthy the relevance of ethanol in the São Paulo energy mix, due to the state being Brazil's largest producer of sugarcane, thus making E100 price competitive with gasoline.

The state government of São Paulo publishes monthly data of its energetic profile, which allows more comprehensive analysis compared to the other four cities. Table 7 shows a detailed exergetic profile of natural gas use and Tab. 8 shows a detailed exergetic profile of electricity consumption in São Paulo for the year 2019.

Table 7. Exergetic assessment of natural gas utilization in São Paulo, year 2019.

Energy source	Exergy input, TJ/yr	Exergy input, % of city	Exergy destroyed, TJ/yr
Residential	5,781.8	1.9	5,178.2
Commercial	2,241.9	0.7	1,908.3
Industrial	5,481.9	1.8	3,837.4
Automotive	2,042.0	0.7	1,521.3
Cogeneration	131.7	0.0	52.7
Thermogeneration	4,074.2	1.3	2,240.8

Table 8. Exergetic assessment of electricity consumption in São Paulo, year 2019.

Energy source	Exergy input, TJ/yr	Exergy input, % of city	Exergy destroyed, TJ/yr
Residential	41,313.5	13.4	37,430.0
Commercial	32,788.1	10.6	28,525.7
Industrial	8,718.0	2.8	2,615.4
Rural	6.8	0.0	2.0
Public lightning	1,643.3	0.5	1,339.3
Public buildings	8,046.3	2.6	7,000.3

It is possible to observe in Tab. 7 that there is no prominent sector using natural gas, since none of them represents more than 2 % of inlet of exergy into São Paulo's control volume. Observation of Tab. 8, on the other hand, reveals that, in the case of electricity use, there are some sectors more suitable for exergetic improvements. Residential and commercial sectors presented higher shares of electricity use, thus offering more opportunities for improvements related to renewable energy microgeneration, wall insulation, smart building management, and general strategies for energy efficient buildings. These initiatives are also applicable to public buildings.

Regarding urban mobility, São Paulo presents a higher share of ethanol use, about 18.4 %, compared to 4.6 % in Rio de Janeiro. On the other hand, Rio de Janeiro has a higher share of vehicular natural gas, about 18.8 %, while in São Paulo it is only 0.7 %. These differences are due to the distinct energetic profile of the states, e.g. São Paulo is the main producer of ethanol, while Rio de Janeiro is the main producer and industrial centre of petroleum and natural gas in Brazil.

Regarding electromobility, both cities present a very low percentage of electric vehicles, lower than 0.05 %. It is important to note that for Rio de Janeiro and São Paulo summation of all fuels for mobility (ethanol, Diesel oil, gasoline and natural gas) is in the range of 55 – 60 %, thus offering a significant room for exergetic improvement by means of electromobility adoption. In fact, this observation is also valid for Bogotá, Buenos Aires and Santiago de Chile. Table 9 presents the comparison of exergetic efficiency, CO_2 emissions and population of the five cities analyzed.

Table 9. Exergetic comparison of the five assessed cities.

City	Population, Million people	Total Exergy input, TJ/yr	Exergetic efficiency, %	CO_2 Emission, Ton/person-yr
Bogotá	7.2	119,135.8	18.01	1.096
Buenos Aires	2.9	145,230.8	19.96	3.690
Rio de Janeiro	6.7	150,559.8	18.03	1.393
Santiago de Chile	6.3	216,315.2	17.94	4.859
São Paulo	12.4	309,174.7	22.43	1.707

In Tab. 9 one can notice that, even though Buenos Aires has less than half of the population of Bogotá, it presents higher input of exergy. Also, comparing the Brazilian metropoles, São Paulo presents noticeably higher exergetic efficiency compared to Rio de Janeiro. The likely culprit for this difference is Rio de Janeiro's warmer climate, which increases electricity consumption by very exergetic inefficient (1.9 %) air conditioners.

3.6. Effects of geographic location and data availability on the calculation of exergetic efficiency

Geographic location has a strong influence on the exergetic performance of cities, mainly due to different HVAC needs of each climate. According to Table 1, comparing electric devices, exergetic efficiency of air conditioners is 1.9 % while for water heaters the value is 10.5 %. For gas boilers applied for water heating, the exergetic efficiency is around three times higher, which means that colder cities are likely to present higher exergetic efficiencies, but the present assessment does not reproduce this expectation. For instance, the exergetic efficiency of São Paulo, located in Köppen's 'Cwa' (dry winter) climate zone, was evaluated as 22.43 %, while Buenos Aires, located in Köppen's 'Cfa' (humid year round) climate zone, has an exergetic efficiency of 19.93 %. This discrepancy could be due to differences in mobility systems, which has been previously observed by Hartmann and Garcia-Acevedo [16] when evaluating the exergetic efficiency of Ingolstadt, Germany, where an extensive system of electric trams operates. However, in the current

comparison, Tables 3 and 6 shows that Buenos Aires and São Paulo present similar amounts of combustion exergy on their transportation sectors. It is noteworthy that combustion exergetic efficiency of any fuel is almost the same because of the dynamic behaviour of machines for mobility, as pointed out by Rakopoulos and Giakoumis [19]. Thus the unexpected difference in the results for Buenos Aires and São Paulo must be related to a different source of exergy destruction.

One possible reason for such difference could be attributed to errors on data collection and/or miscalculations. In order to check for possible discrepancies, some results were compared to the literature, e.g., Figure 2 shows the plot of *per capita* CO_2 emission as function *per capita* inlet exergy.

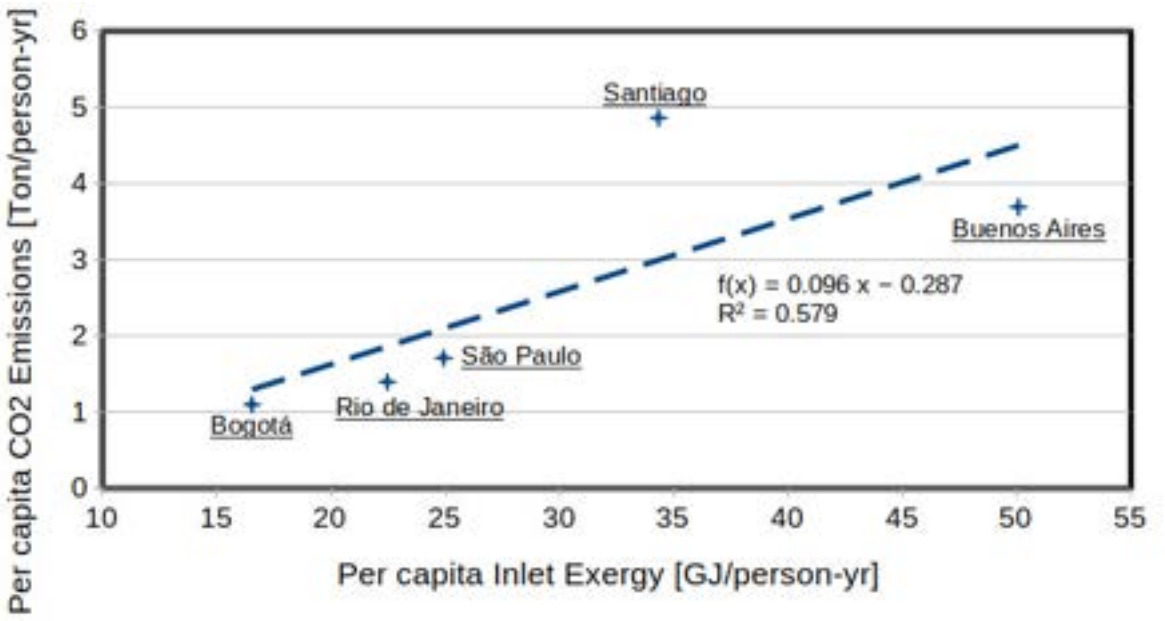

Fig. 2. Plot of per capita CO_2 emission as function per capita inlet exergy.

Figure 2 shows a linear trend of increasing *per capita* CO_2 emission with increasing *per capita* inlet exergy, with a similar trend being reported by Hartmann and Garcia-Acevedo [16]. It is noteworthy that Santiago de Chile presented the highest *per capita* emission of CO_2, of 4.859 Mton of CO_2 per person-year, visible as an 'outlier' well above the trend line on Fig. 2. This high volume of emissions is due to significant consumption of coal and Diesel oil for electricity generation.

Thus, the exergetic efficiency comparison between Buenos Aires and São Paulo, considering their distinct climates, further comparisons with literature data, and with the observed lack of reliable exergetic data for Buenos Aires, as discussed in section 3.2, allows us to conclude that the differences on exergetic efficiency between these two cities is mainly due the lack of comprehensive and reliable exergetic information for the city of Buenos Aires. For instance, data presented on Tables 7 and 8 for São Paulo allowed a better assessment of São Paulo, being on accordance with a previous analysis carried out for a well established Smart City, Singapore [16]. Therefore, one can expect that, as smart grids and smart city initiatives are implemented in the major metropolitan areas of Latin America, it will be possible to improve the quality and thoroughness of this kind of exergetic assessment.

4. Conclusions

An exergetic assessment of five Latin American cities was carried out by comparing their inlet and outlet exergetic fluxes and then calculating the exergetic efficiency and carbon dioxide emissions in CO2 equivalent ton by person per year.

The methodology for evaluation of the exergetic efficiency of urban centers takes as a metric to be evaluated the major energetic fluxes, i.e. gas and liquid fuels as well as electricity; it assumes the city border as a control volume; applies the mathematical model developed by Hartmann and Garcia-Acevedo [16], which follows the basic principles for the evaluation of machines and thermal systems, resulting in an overall exergetic efficiency for each analised city.

São Paulo, rated "d" in the smart index, has the highest exergy efficiency among the cities studied, 22,43%. This result is likely due to the highest participation of ethanol in its mobility-related consumption, since ethanol's share is of the same order of magnitude as gasoline and diesel, as shown on Table 6. Other cities also rated "d" in the smart index, as Bogotá (18,01%) and Rio de Janeiro (18,03%), have medium value of exergy efficiency. On the other hand, Santiago de Chile has the lowest exergy efficiency (17,94%) and

highest carbon dioxide emissions index (30,46 MTon CO2 per year), even though its population is about half of Sao Paulo's. This result is probably due to the low use of ethanol combined with the extensive use of natural gas as a main fuel of the automobile fleet.

It is also possible to observe a relationship between the cities' high temperatures and their low exergetic efficiency. This phenomena could be explained due to the massive use of air conditioning systems while also related to the type of primary source for the electricity production. Such a scenario presents an opportunity to improve the city's Smart City Index, by means of investing, for example, in constructive systems aimed at improving the energy efficiency of buildings. The methodology has been demonstrated to be applicable for an initial assessment of the smartness of cities, but further data granularity is required to provide a thorough analysis.

Abstract:

Thermoeconomics is a branch of engineering that combines concepts from thermodynamics and economics to tackle problems that are hard or cannot be solved by these sciences, separately. The main applications of thermoeconomics are cost allocation, optimization, and malfunction diagnosis of energy systems. Defining the productive structure plays a critical role in thermoeconomic modeling, and exergy is a highly appropriate thermodynamic quantity to correlate with costs. For systems containing dissipative equipment, the use of total exergy in conventional productive diagrams need a subsequent decision, by the analysts, on how to define its fuel and product. In some applications, exergy disaggregation can be elegant options, mostly to deal with dissipative components. Nevertheless, all of them increase the complexity in thermoeconomic modelling. In this work, thermoeconomic cost allocation approaches in a simultaneous heating and cooling heat pump system were performed from the application of some thermoeconomics methodologies. The studied system has one dissipative component (valve) and generates no waste. There are three specific objectives. Firstly, to present the different possibilities to treat and isolate the valve in the thermoeconomics modelling. Secondly, to compare the methodologies presented from the thermoeconomic point of view through the cost allocation in a simultaneous heating and cooling heat pump system. And finally, to show the pros and cons of each methodology applied in this study to support future decision-makings in thermoeconomic modelling. The research demonstrates that the differences between the methodologies used were not significant, and the choice of methodology should depend on factors such as the need for disaggregated equipment. In conclusion, the findings of this study indicate that without certain models that may overestimate the cost of particular components, the thermoeconomic results fall within a narrow range of 4% of the solution line. This suggests that the methodologies used did not yield significantly different results.

Keywords:

Thermoeconomic Approach, Cost Allocation, Physical Exergy Disaggregation, Modelling Complexity, Dissipative Component.

1. Introduction

Thermoeconomics is a branch of engineering that combines concepts from thermodynamics and economics to tackle problems that are hard to solve or cannot be solved by these sciences, separately. The main applications of thermoeconomics are cost allocation, local and global optimization, and malfunction diagnosis of energy systems.

Historically, Keenan [1] was the first researcher to associate the exergy (availability) of the final products of an energy system with their respective costs [2]. Since then, this idea has been applied to several different problems [3], including optimisation of energy systems [4,5]. However, it was only in the late 1980s and early 1990s that modern thermoeconomic methodologies were proposed. In 1994, the CGAM problem was defined to compare results by the application of such methodologies [6]. Since then, thermoeconomics has been widely applied to many energy system problems.

Frangopoulos proposed the Thermoeconomic Functional Analysis (TFA) [7,8], which is originally a methodology for energy systems optimisation. Nevertheless, TFA can be adapted to solve cost allocation problems. Von Spakovsky proposed the Engineering Functional Analysis (EFA) [9], which is an optimisation methodology, but it can be used for cost allocation as well as TFA. Lozano and Valero proposed the Theory

of Exergy Cost (TEC) [10,11] which was originally developed for cost allocation and malfunction diagnosis, but it can be also applied to formulate optimisation problems. Tsatsaronis and co-workers proposed some exergoeconomic methods [12,13] that became the SPECO method [14], which is a methodology for cost allocation and energy systems optimisation. The methodologies were adapted to deal with environmental impact problems in the same energy systems as well [15–17].

Other thermoeconomic approaches were proposed besides the ones. Erlach et al. proposed the Structural Theory [18], which is a unification approach of the methodologies applied to the CGAM problem. Santos et al. proposed the H&S model [19], which is a modification of the Structural Theory regarding the application of negentropy. Lourenço et al. proposed the UFS model [20], which is an extension of the H&S model. Recently, a method of localized physical disaggregation [21] was proposed to isolate dissipative equipment with less complexity when compared with total disaggregation. However, it can incur a loss in the accuracy of the results. Finally, the latest thermoeconomic methodology presented in the literature is the A&F model [22], a methodology proposed to isolate dissipative components with less modelling complexity.

A key concept used in most thermoeconomic methodologies and approaches is the functional diagram, also known as the productive diagram. The productive diagram is a graphical representation of the inter-relations between the subsystems of the global system and its surroundings. Subsystems are connected according to their respective purposes. Frangopoulos [7] proposed this key concept first in the 1980s, but it has been applied since then until nowadays. The way in which the productive structure is defined is a key point of thermoeconomic modelling. One of the most adequate thermodynamic magnitudes to be associated with the cost is exergy since it contains information from both the first and the second laws of thermodynamics. Most thermoeconomicists agree that exergy is the most appropriate thermodynamic magnitude to associate with cost since it contains information from both the first and the second laws of thermodynamics, qualifies the energy streams, and identifies the irreversibility of the subsystems [23].

The utilization of total exergy in conventional productive diagrams can become a hard task when the systems include dissipative equipment, such as valves. This is because the analyst needs to decide on how to define the fuel and product for the dissipative component, which can be challenging. One solution to this issue is the use of physical exergy disaggregation. Despite the improvement in result accuracy, when the exergy streams are disaggregated, the modelling complexity is increased [14].

In this study, different thermoeconomic methodologies are applied to a simultaneous heating and cooling heat pump system, which contains a dissipative valve and generates no waste. The study has three specific objectives. Firstly, the research presents the different methodological possibilities for treating and isolating the valve. Secondly, it compares the various thermoeconomic methodologies based on cost allocation in the simultaneous heating and cooling heat pump system. Finally, it demonstrates the advantages and disadvantages of each methodology, which can help guide future decision-makings in thermoeconomic modelling.

By presenting and comparing different cost allocation approaches, this study provides guidance for analysts in their future work and contributes to the development of more effective thermoeconomic modelling.

2. Physical exergy disaggregation

Since 1990, thermoeconomics has used physical exergy disaggregation, which was initially introduced by Kotas [24]. In agreement with [14], disaggregate exergy components enhance the precision of results in thermoeconomics. Physical exergy, disregarding kinetic, potential, and other energy forms, is expressed by Eq. (1), as used by H&S Model approach. It is worth mentioning that all components of exergy presented in this study depend solely on the thermodynamic properties of the flows, previously known.

$$\dot{E}_i^{PH} = \dot{E}_i^{H} - \dot{E}_i^{S} = \dot{m}_i \cdot \left[\left(h_i - h_0 \right) - T_0 \cdot \left(s_i - s_0 \right) \right] \tag{1}$$

Applying the definition of specific enthalpy in Eq. (1), h = u + Pv, Eq. (2) is written. Rearranging Eq. (2), the three terms of UFS Model are obtained and given by Eq. (3).

$$\dot{E}_i^{PH} = \dot{m}_i \cdot \left\{ \left[\left(u_i + P_i \cdot v_i \right) - \left(u_0 + P_0 \cdot v_0 \right) \right] - T_0 \cdot \left(s_i - s_0 \right) \right\} \tag{2}$$

$$\dot{E}_i^{PH} = \dot{E}_i^{U} + \dot{E}_i^{F} - \dot{E}_i^{S} = \dot{m}_i \cdot \left[\left(u_i - u_0 \right) + \left(P_i \cdot v_i - P_0 \cdot v_0 \right) - T_0 \cdot \left(s_i - s_0 \right) \right] \tag{3}$$

Furthermore, Eq. (4) can be obtained by rearranging Eq. (2) in a different way, specifically by combining the first and third terms of Eq. (3).

$$\dot{E}_i^{PH} = \dot{m}_i \cdot \left\{ \left[\left(u_i - T_0 \cdot s_i \right) - \left(u_0 - T_0 \cdot s_0 \right) \right] + \left(P_i \cdot v_i - P_0 \cdot v_0 \right) \right\} \tag{4}$$

The specific Helmholtz energy of a closed system under a heat bath (reservoir at T_0) is given by $a = u - T_0 s$. This can be applied for both i-th and dead states. Eqs. (5) and (6) show the Helmholtz energy term and flow

work term, respectively. Thus, the physical exergy could be written as in Eq. (7), according to the A&F Model. It is important to highlight that the principle used in applying the A&F Model to disaggregate physical exergy into its Helmholtz energy terms (Eq. (5)) and flow work term (Eq. (6)) is similar to that used in the H&S and UFS Models.

$$\dot{E}_i^A = \dot{m}_i \cdot (a_i - a_0) = \dot{m}_i \cdot \left[(u_i - T_0 \cdot s_i) - (u_0 - T_0 \cdot s_0) \right] \tag{5}$$

$$\dot{E}_i^F = \dot{m}_i \cdot (P_i \cdot v_i - P_0 \cdot v_0) \tag{6}$$

$$\dot{E}_i^{PH} = \dot{E}_i^A + \dot{E}_i^F = \dot{m}_i \cdot \left\{ \left[(u_i - T_0 \cdot s_i) - (u_0 - T_0 \cdot s_0) \right] + (P_i \cdot v_i - P_0 \cdot v_0) \right\} \tag{7}$$

3. Thermoeconomic modelling

The productive structure is a representation that elucidates the purpose of subsystems by explicitly revealing their input (fuels) and output (products) components in terms of productive flows. In thermoeconomic methodologies, physical or/and productive flows are conventionally utilized to graphically illustrate the productive interconnections among subsystems. This study employs productive and physical flows to construct productive/physical diagrams that facilitate the visualization of the productive structure. Fictitious units (junctions and bifurcations) are used to assist the drawing up of the productive diagrams.

After the definition of the productive structure, each subsystem is represented by means of a cost equation balance relating a thermodynamic magnitude and the unit cost of external resources, and internal flows. The mathematical model lists a set of cost equation balances in each subsystem to calculate the unit costs. A thermoeconomic model should be performed by using Eq. (8).

$$\sum (k_{out} \cdot Y_{out}) - \sum (k_{in} \cdot Y_{in}) = k_F \cdot E_F \tag{8}$$

In Eq. (8), E_F is the external fuel exergy consumption (in kW); and Y_{out} and Y_{in} means the generic thermodynamic magnitude of the internal flows at inlet and outlet (including final products) of each subsystem. The solution of the set of equations results in the unit exergy costs of each internal flow and each final product. In this paper, *Y* assumes the thermodynamic magnitudes, such as power (W), total exergy (E), Helmholtz energy term (E^A), flow work term (E^F), internal energy (E^U), and entropic term (E^S). The unknown k_{out} and k_{in} are the unit exergy costs of the internal flows at the outlet and the inlet of each subsystem. The unit exergy cost of a flow is the amount of external exergy unit required to obtain one unit of this flow, meaning that the unit exergy costs of a flow is a measure of the thermodynamic efficiency of the production process when producing this flow [25]. Each subsystem provides a single cost balance equation, thus auxiliary equations are necessary when several products are obtained in a component. Thermoeconomic models which use physical exergy disaggregation, based on the productive diagrams, consider the equality criteria [8,14,26], where productive flows exiting the same productive unit must have the same unit cost. It is worth mentioning that for all the methodologies studied in this research, in the absence of external assessment, the exergy cost of the mass and energy streams entering the plant equals their exergy *(k_w = 1 [kJ/kJ]).*

4. Case study

A simultaneous heating and cooling heat pump system is studied to exemplify the proposal of this paper. This is the same system studied by Nguyen et al. [27]. The flowsheet of the system is shown in Figure 1. The heat pump consists of four components: evaporator, motor-compressor, condenser, and valve. The working fluid of the system is ammonia. The evaporator and the condenser are two water-coupled systems designed for district cooling and heating, respectively. In Figure 1, 'H', 'C', 'r' and 's' correspond to hot, cold, return and supply, respectively, and 'em' corresponds to electric motor.

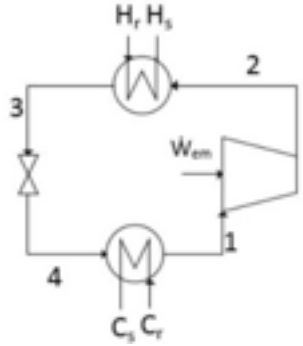

Figure. 1. The physical structure of the heat pump system

Certain assumptions have been made, including the assumption that the processes are in a steady state. Additionally, it is assumed that ammonia is a saturated vapor at state 1 and a saturated liquid at state 3, there is no heat exchange with the environment, there are no changes in kinetic and potential energy, there is no pressure drop for flow through heat exchangers, and chemical exergy is not considered.

Table 1 shows the parameters of the heat pump system.

Table 1: System parameters

Parameter	Symbol	Value	Unit
Condensation temperature	T_{cnd}	70	°C
Evaporation temperature	T_{evp}	7	°C
Evaporator heat transfer rate	$\dot{Q}_{evp}$	250	kW
Compressor isentropic efficiency	η_{cmp}	75	%
Electric motor efficiency	η_{em}	90	%
Water streams pressure	P_{H2O}	300	kPa
Environment pressure	P_0	100	kPa
Environment temperature	T_0	20	°C

Avoiding pinch problems, Eqs. (10)-(13) are used to model the condenser and the evaporator:

$$T_{Hs} = T_{cnd} + 0°C \tag{10}$$

$$T_{Cs} = T_{evp} + 3°C \tag{11}$$

$$T_{Hr} = T_{Hs} - 30°C \tag{12}$$

$$T_{Cr} = T_{Cs} + 6°C \tag{13}$$

Conventional mass, energy and exergy balance equations are applied from the data to each control volume. The simulation is done in Engineering Equation Solver [28]. Table 2 shows the values of electrical power input and mass flow rates of ammonia, hot water, and cold-water streams.

Table 2. Electrical power input and mass flow rates

Variable	Symbol	Value	Unit
Electrical power	$\dot{W}_{cmp}$	110.181	kW
Ammonia mass flow rate	$\dot{m}_{NH3}$	0.271	kg/s
Hot water mass flow rate	$\dot{m}^{H}_{H2O}$	2.783	kg/s
Cold water mass flow rate	$\dot{m}^{C}_{H2O}$	9.958	kg/s
Hot water stream exergy	$\dot{E}_{Qcond}$	37.026	kW
Cold water stream exergy	$\dot{E}_{Qevp}$	6.125	kW

Table 3 shows the thermodynamic properties of ammonia.

Table 3. Thermodynamic properties of the main physical flows of the heat pump system

Flow	P [kPa]	T [°C]	E [kW]	E^A [kW]	E^F [kW]	E^S [kW]	E^U [kW]
1	554	7.00	64.50	68,76	-4,27	-82,50	-13,74
2	3312	179.80	147	129,95	17,04	-65,84	64,11
3	3312	70.00	86.17	122,73	-36,57	-354,08	-231,39
4	554	7.00	76.09	105,58	-29,51	-344,08	-238,47

5. Thermoeconomic methodologies

In this Section, five thermoeconomic methodologies will be studied for the case study presented in this work. One of these methodologies will be presented in a physical diagram (TEC), while the others will be presented using a productive diagram (E Model, UFS Model, A&F Model, and localized physical exergy disaggregation). The aim is to develop the methodologies for the exergy cost allocation of the electrical power to the final products of the system, i.e., heating and cooling. In agreement with [29], this work also concurs that the best productive structure would be one that explains with the greatest depth and simplicity the productive function of the subsystems and flows present in the physical structure of the plant under examination.

5.1. TEC

According to original formulation of TEC [10], one can apply the exergy cost balance equation to each control volume of the system. In addition, it is considered that the final products of the system are the exergy flow increase of both hot and cold-water streams, respectively. In this methodology, the sum of the inlet cost streams is equal to the sum of the exit cost streams for each control volume shown, such as Eq. 8. However, the interpretation of which flows are fuels or products for each subsystem is not a trivial task. Therefore, equations Eqs. (14) - (17) are formulated with the aim of performing the proposed study and Figure 2 shows the physical structure of the heat pump system using TEC.

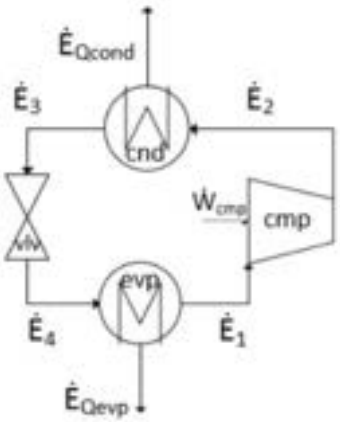

Figure. 2. Physical structure of the heat pump system using TEC

$$k_w \cdot \dot{W}_{cmp} + k_1 \cdot \dot{E}_1 = k_2 \cdot \dot{E}_2 \tag{14}$$

$$k_2 \cdot \dot{E}_2 = k_3 \cdot \dot{E}_3 + k_{cnd} \cdot \dot{E}_{Qcond} \tag{15}$$

$$k_3 \cdot \dot{E}_3 = k_4 \cdot \dot{E}_4 \tag{16}$$

$$k_4 \cdot \dot{E}_4 = k_1 \cdot \dot{E}_1 + k_{evp} \cdot \dot{E}_{Qevp} \tag{17}$$

Whether there is removal of exergy from a mass stream within the control volume being considered then the unit exergy cost of the output stream is equal to the unit exergy cost of the correspondent input stream. Therefore, Eqs. (18)-(19) are written.

$$k_3 = k_2 \tag{18}$$

$$k_1 = k_4 \tag{19}$$

According to the authors [29], a limitation of the theory of exergetic cost, as it was originally formulated, consisted of defining the productive structure in relation to the same flows and components present in the physical structure. One of the resulting difficulties lies mainly in the adequate treatment of the dissipative units and of the residues of the plant [29].

5.2. E Model

The E Model utilizes total exergy to define fuels and products of the subsystems of the plant. However, when a valve is present in the system as a dissipative equipment, the analyst must decide how to treat the valve. It is not possible to assign a productive purpose to the valve using only total exergy. Usually, dissipative equipment is combined with other subsystems to aid in the production of the final product. Moreover, this plant has the characteristic of having two products, which makes the analyst's decision more difficult. Therefore, this study presents three options to treat the valve using total exergy, as illustrated in Figure 3. The first option (Figure 3a) is to combine the valve with the condenser (where the valve's irreversibility is entirely attributed to heat), the second (Figure 3b) is to combine it with the evaporator (where the valve's irreversibility is entirely attributed to cold), and the third option (Figure 3c) is to separate it until temperature T_0 (ambient temperature), where the valve's irreversibility up to that point will be attributed to the condenser, and below temperature T_0, it will be attributed to the evaporator. This third option appears to be more reasonable since it is consistent to consider (from a thermodynamic point of view) that until temperature T_0, the valve contributes to the heat production and below the ambient temperature, it contributes to the cooling production.

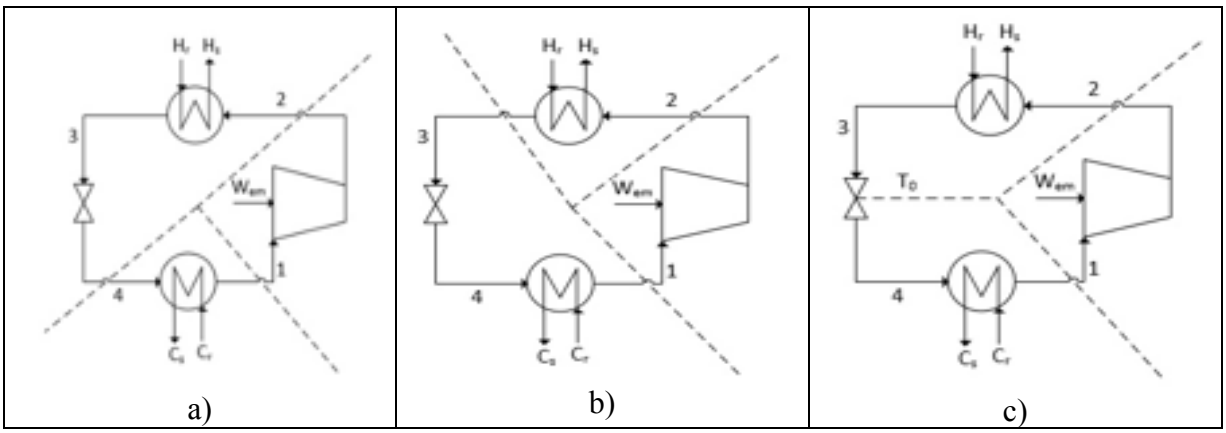

Figure. 3. Three physical structure layouts for the treatment of the valve: a) *valve with the condenser; b) valve with the evaporator; c) valve until T_0 with condenser, below T_0 with evaporator.*

Figures 4 to 6 depict the production diagram for the three possible treatments of the valve using Model E. It is worth noting that the main difference between the three diagrams is the input of the subsystem where the valve is merged. As previously explained, however now represented in the productive diagram, in Figure 4 the valve is merged with the Condenser (*E Model - CV*), in Figure 5 it is merged with the evaporator (*E Model – VE)*, and in Figure 6 the irreversibility of the valve is divided between the condenser and the evaporator.
In all the productive diagrams analysed in this research, the rectangles represent the actual units or subsystems that correspond to the physical equipment of the system. The rhombus and circles are fictitious units utilized to connect and/or divide the productive streams. Each subsystem includes input arrows to indicate its fuel or resources, and output arrows to indicate its products. The determination of productive streams is based on the specific exergy term variation between the inlet and outlet, with positive variation classified as a product and negative variation as fuel [19]. In this research, the auxiliary equation for each bifurcation is formulated using the multiproduct method, which assumes that the same unit costs apply to all productive streams that leave the same subsystem, owing to shared resources and irreversibilities inherent within the subsystem [30].

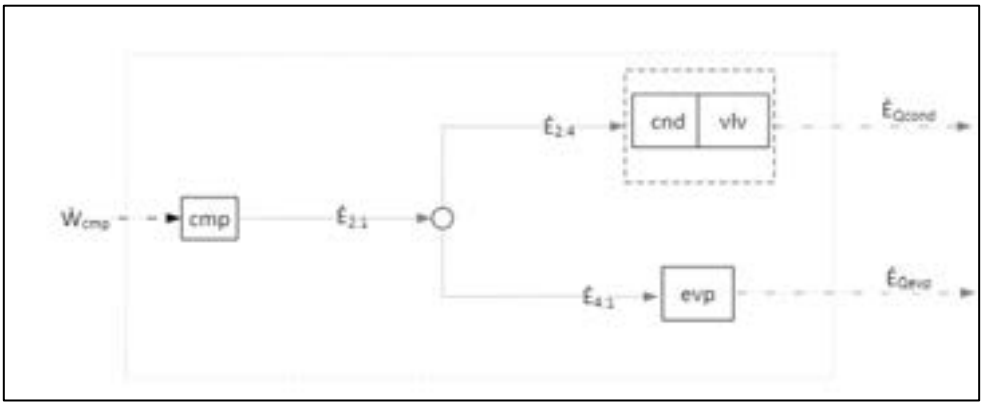

Figure. 4. Productive diagram for the heat pump system using E Model - CV.

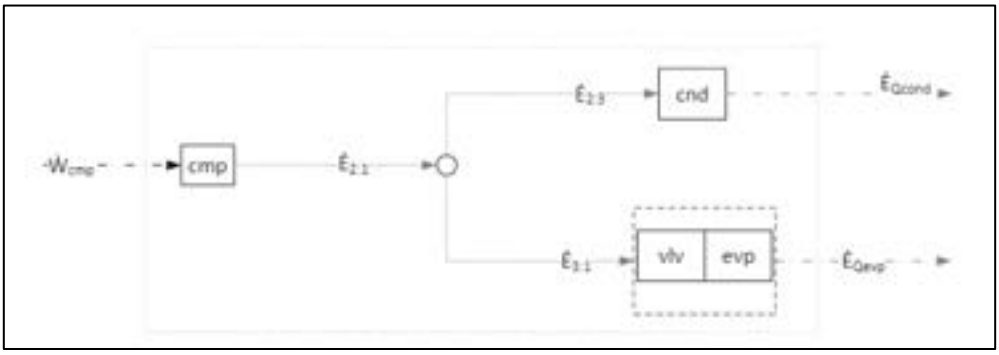

Figure. 5. Productive diagram for the heat pump system using E Model - VE.

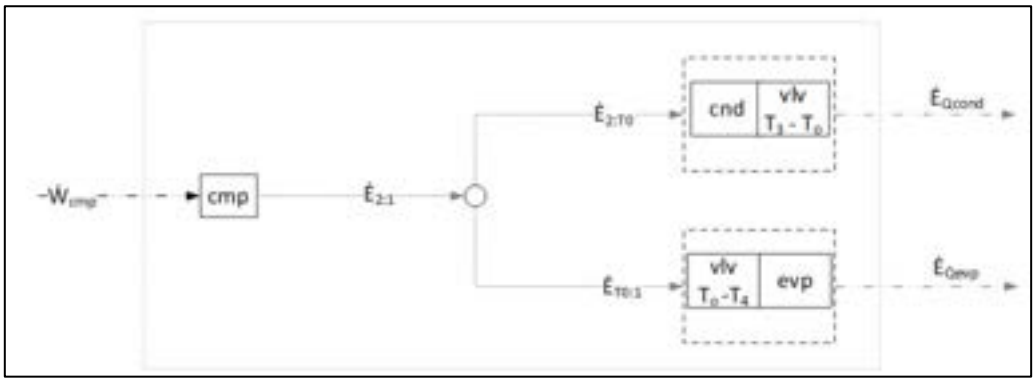

Figure. 6. Productive diagram for the heat pump system using E Model - CVE.

5.3. UFS Model

Despite the increased computational effort required and modelling complexity compared with the E Model, the application of the UFS Model [20] is justified because there is a valve in the system. To be more specific, there are two additional exergy terms for every equipment in the productive diagram to define fuel and product, compared to the E Model. The valve is now isolated, and there is no longer a need to merge this component with another to achieve its intended production purpose. Figure 7 represent the productive diagram of the heat pump system using the UFS Model. As already explained, this model utilizes physical exergy disaggregated into internal energy (E^U), flow work (E^F), and entropic term (E^S).

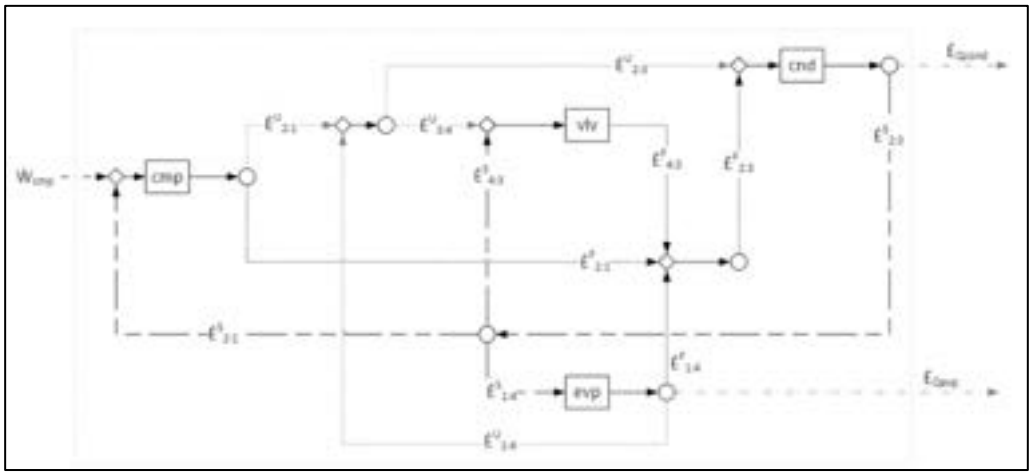

Figure. 7. Productive diagram for the heat pump system using UFS Model.

5.4. A&F Model

The diagram depicted in Figure 8 showcases the use of the A&F Model [22] in the heat pump system for the isolation of valves and the determination of their products and fuels via the utilization of Helmholtz energy (E^A) and flow work (E^F) terms.

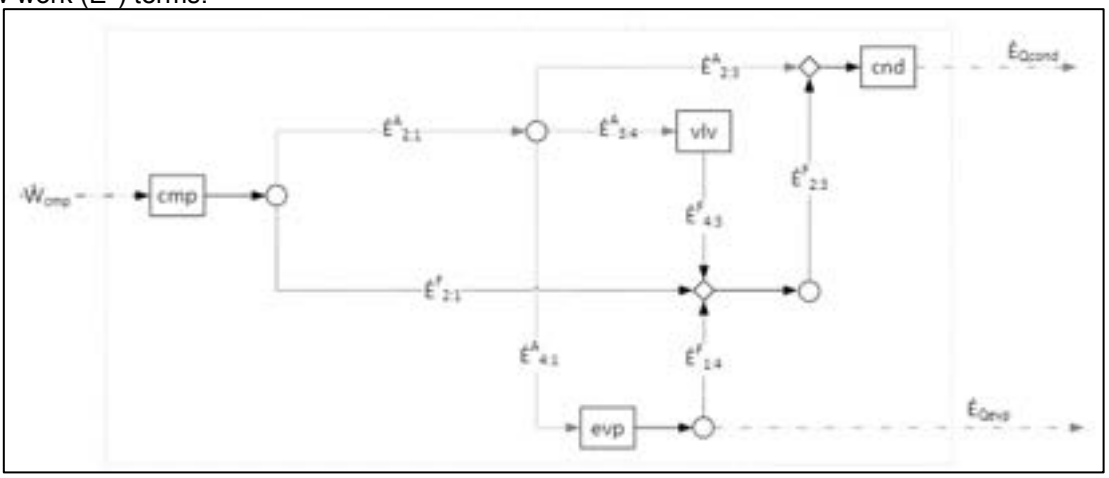

Figure. 8. Productive diagram for the heat pump system using A&F Model.

By employing these terms, the model allows for the appropriate handling of this dissipative component. The pro of the A&F Model over the E Model, in this study, is attributed to its ability to isolate valves. Regarding the UFS model, both models can isolate dissipative components, but the A&F Model achieves this via a simpler exergy disaggregation using only two terms, as opposed to the three terms used by UFS. Consequently, the A&F Model's simplicity and universality are its main advantages. Furthermore, compared to the UFS Model, the A&F Model reduces the number of flows, junctions-bifurcations, and cost equations, resulting in a significantly lower degree of complexity and computational requirements.

5.5. Localized physical exergy disaggregation (E Model – LD).

The localized physical exergy disaggregation [21] is used to disaggregate physical exergy only in dissipative equipment where the total exergy is not enough to define a productive purpose for the equipment. In this case study, the valve is a dissipative equipment, and therefore, the disaggregation of physical exergy into its Helmholtz energy (E^A) and flow work (E^F) terms was only used in the definition of fuel and product for this equipment. It should be noted that other methodologies could be used to isolate the valve as long as fuel and products could be defined. However, in this work, the A&F model was chosen, which is the thermoeconomic model with the fewest exergy terms capable of defining input and output for the valve. In other words, where total exergy can be used, it is used; where it is not possible, the disaggregation of physical exergy is a viable solution. This model has an advantage over other models that use physical exergy disaggregation, as it can isolate the valve with fewer flows. The Figure 9 shows the productive diagram for the heat pump system using localized physical exergy disaggregation.

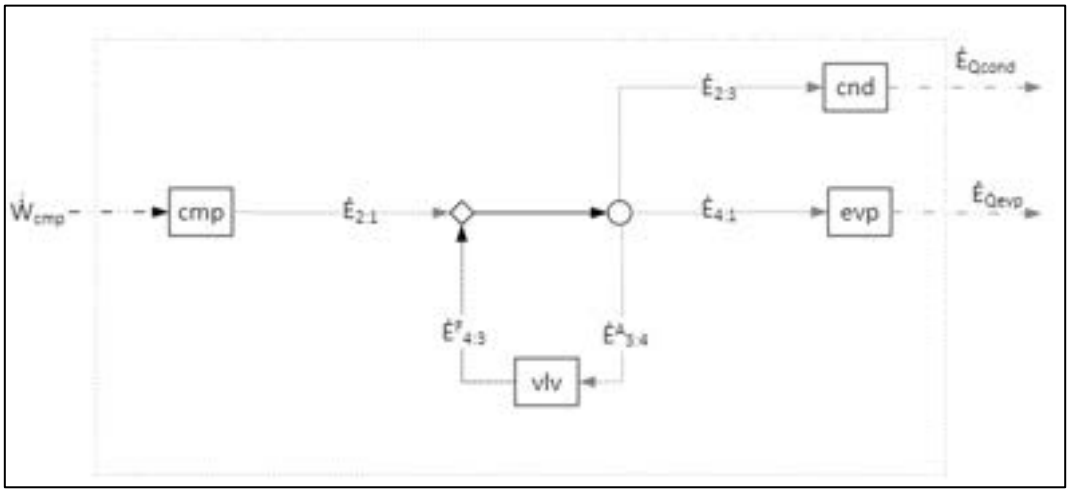

Figure. 9. Productive diagram for the heat pump system using localized physical exergy disaggregation.

6. Results and discussions

The cost allocation models had to determine the unit exergy cost for both heating and cooling, which was a challenge. Regardless of the method used for allocation, the result was a pair of unit exergy costs for both final products that lie along a defined straight line, which can be mathematically represented by Eq. (20).

$$\dot{W}_{cmp} = k_{E_{Qcond}} \cdot \dot{E}_{Q_{cond}} + k_{E_{Qevp}} \cdot \dot{E}_{Q_{evp}} \rightarrow k_{E_{Qcond}} = -\frac{\dot{E}_{Q_{evp}}}{\dot{E}_{Q_{cond}}} \cdot k_{E_{Qevp}} + \frac{\dot{W}_{cmp}}{\dot{E}_{Q_{cond}}} \quad (20)$$

Thus, for each model, as the unit exergy cost of heating increases (k_{EQcond}), the unit exergy cost of cooling (k_{EQevp}) decreases. The six points in Figure 10 represent pairs of unit exergy costs for heating and cooling obtained from the different methods analysed in the study, and they are consistent from a thermoeconomic point of view since they belong to the same straight-line solution.

In Figure 10, it can be observed in the upper corner that when assigning the entire cost of the fuel of the system to a single final product, the unit exergy costs will be (0;2.98) and (17.99;0) for the separately produced of heating and cooling, respectively. In this same region of the Figure 10, it is possible to identify a green square that delimits an area where the costs allocation corresponding to all thermoeconomic methodologies presented in this work are contained, highlighting that the results obtained for the unit exergy costs do not present significant differences. More specifically, when considering all possible thermoeconomic results for the unit exergetic costs of heating and cooling, it is possible to notice that the employed methodologies are concentrated within a specific range, with a variation of around 17.5% for heating and cooling. This observation can be interpreted as an additional indication that these methodologies demonstrate yield similar results with respect to the values found.

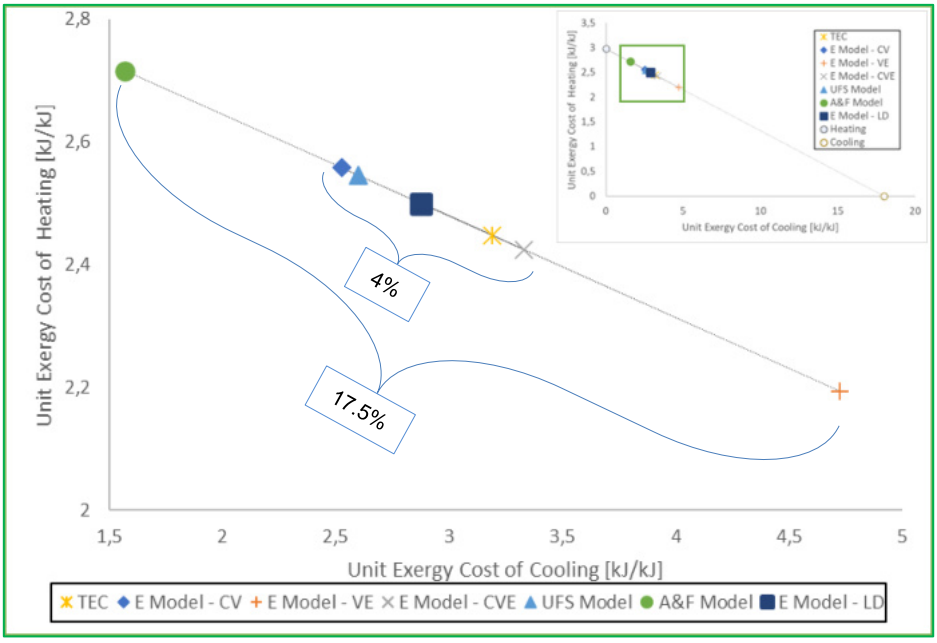

Figure. 10. Results of final unit exergy costs of products

It is not possible to determine which methodology presents the best/right cost through cost allocation, as all the methodologies presented in this study produce coherent results. However, some comparative analysis can be made such as among the three possibilities for using Model E presented in the study. It is observed that associating the valve with the condenser results in the highest cost of heating among the three possibilities, which was expected because all the irreversibility related to the valve is associated with heat, which increases his cost. Associating the valve with the evaporator leads to an increase in the cost of cooling, as all the valve irreversibility is associated with the evaporator. When there is a rational criterion for dividing the irreversibility of the valve (Model E-CVE), an intermediate value is obtained for the costs. It can be observed that the A&F model exhibits the highest unit exergy cost of heating. This can be attributed to the fact that all the irreversibility of the valve is associated as fuel to the condenser, along with a portion of the irreversibility of the evaporator that is also linked as fuel to the condenser (see Figure 8). This is similar to the UFS model. However, in the UFS model diagram, a part of the irreversibility of the condenser returns to the cycle as fuel to the compressor, which slightly reduces the cost of the condenser product.

When analysing the TEC, E Model - CVE, and E Model - LD, it is noted that all of them have an implicit or explicit rule for dividing the irreversibility of the valve for both final products, which results in intermediate costs for these products. It is worth noting that it is more thermodynamically reasonable for the irreversibility of the valve to be divided between both final products. However, not all methodologies presented in this study follow this procedure, possibly due to the subjectivity of the productive diagram, regarding the productive unit interconnection, adopted by the analyst during the implementation of these methodologies. By conducting a more detailed analysis of cost allocation, excluding methodologies that overload the cost of heating (A&F Model and E - CV Model) or cooling (E Model - VE), it can be observed that the methodologies that apply a more rational criterion for dividing valve irreversibility among final products (TEC, E Model - VCE, E MODEL - LD, and UFS Model) are concentrated within a specific range, with a variation of about 4% for heating and cooling. This conclusion is the result of a more rigorous and precise analysis, which allowed for a clearer identification of the methodologies that may be more effective in allocating these costs.

The information presented in Tables 4 – 5 displays the values of fuel (Fu), product (Pr) and irreversibility (Ir) for each individual component of the plant, for each used methodology. It should be noted that although different productive structures (fuel and product) are defined, no matter the methodology, the irreversibility (fuel-product difference) of each component remains the same. Irreversibility is one of the responsible for generating costs in thermoeconomics. However, the methodologies obtain different results since different fuels and products are used for the productive units. It is important to highlight that the costs generated by each productive units depend on the product-fuel ratio (efficiency). Thus, different cost values are obtained for each methodology.

Table 5 presents a comparison between the subsystems merged in the E model. It is observed that, in the E-Model-CV, the irreversibility of the Condenser-Valve subsystem is exactly equal to the sum of the irreversibility of the equipment when they are separated in the other thermoeconomic methodologies. Similarly, the same result can be observed in the E-Model-VE. For the E-Model-CVE, two inputs, two outputs, and two irreversibilities were presented, as the valve is partly merged with the condenser and partly with the valve. Nevertheless, it is still possible to compare the irreversibility, as the sum of the two irreversibilities presented in the E-Model-CVE is the same as the sum of the irreversibility of these subsystems when separated in the other thermoeconomic methodologies.

7. Conclusions

This study aimed to present and compare different thermoeconomic methodologies for unit exergy cost allocation in a heat pump system with a dissipative valve. The study focused on presenting different options for treating the valve in thermoeconomic modelling and comparing the advantages and disadvantages of each methodology. The methodologies presented in this study were TEC, E Model, UFS Model, A&F Model, and localized physical exergy disaggregation.

Different models can be used to define fuels and products of subsystems in the presence of a dissipative equipment like a valve. The E Model uses total exergy, but it can be challenging to assign a productive purpose to the valve. The UFS Model is more complex but allows for the isolation of the valve. The A&F Model isolates valves using Helmholtz energy and flow work terms, reducing complexity and computational requirements when compared with UFS Model. Finally, localized physical exergy disaggregation can disaggregate physical exergy only in dissipative equipment, like valves, where total exergy is not enough to define a productive purpose. It is important to observe that while the models define different productive structures, with different fuels and products utilized in each production unit, the irreversibility of each component remains constant. Therefore, it can be concluded that the models are consistent with thermodynamic principles.

The results demonstrate that although each methodology presents different results, the differences are not significant. Therefore, the methodology to be used will depend on various factors, such as the need to have disaggregated equipment or not. Regarding the E Model - CV and E Model - VE, it was observed that they tend to overload the cost of heating and cooling, respectively. Conversely, the UFS and A&F Models disaggregate the valve but were presented in this study using the productive diagram, which may have some arbitrariness in relation to connections, due to the use of productive flow only. Thus, for these methodologies, the use of the comprehensive diagram, which combines both productive and physical flows, may be a more appropriate option, since the TEC method, which uses physical flows, presents an intermediate cost.

When considering all possible thermoeconomic results, i.e., all the solution straight line, the obtained results are concentrated within approximately 17.5% of the line. However, excluding methodologies that overload the cost of heating or cooling, this value would drop to 4%, which indicates that these methodologies did not produce significantly distinct results.

In conclusion, this study provides valuable insights for future decisions in thermoeconomic modelling and highlights the importance of a suitable productive structure to explain the productive function of the subsystems and flows present in the physical structure of the plant.

Abstract:

An experimental study has been carried out to characterise a laboratory-scale cooling tower (CT) intended to provide water to a high temperature radiant cooling system during night-time. The present study evaluates the possibility of broadening its operation during daytime to precool the outdoor airflow required for ventilation during occupation periods. The performance of the CT combined with a water-to-air coil demonstrates that its operation within a water-economiser cycle would result into energy savings and better indoor air quality (IAQ) for most summer conditions studied, with the only exception of humid tropical climates. The few non-interesting locations can be easily identified regarding the corresponding Köppen-Geiger climate classification, and relative energy efficiency of the system at different climates is rather foreseeable through the local wet bulb depression (WBD) bin data. This leads to the conclusion that a CT designed to fed TABS during night-time can efficiently operate during diurnal occupation periods to remove ventilation loads of the required dedicated outdoor air system (DOAS) or support the additional mechanical cooling if required, with little initial cost.

Cooling Tower; Free cooling; Water-side economiser; Ventilation air cooling; ANOVA.

1. Introduction

Current research and policies being developed towards less energy-consuming buildings aim for energy efficient strategies to achieve indoor comfort. Improvements in cooling systems are key steps on this path, given the growing trends on energy consumption for space cooling due to global warming and urban heat islands, in addition to the quality of life expectations of a population that spends more and more time indoors.

Ventilation rates have such an impact on buildings energy requirements that it may result appealing to try to minimise them. However, it is essential to avoid compromising IAQ, and in this sense strategies such as heat recovery, demand control or free cooling are targeted as possible solutions (1).

Research conducted on Thermally Activated Building Systems (TABS) for space cooling is gaining interest due to higher cool water temperatures required, but a Dedicated Outdoor Air System (DOAS) would be always required to fulfil ventilation rates established in the standards (2).

Among the number of existing alternatives designed to simultaneous and efficiently achieve indoor thermal comfort and IAQ, those based in the free-cooling potential of outdoor conditions are particularly appealing. Low temperature cooling towers (CT) can efficiently exploit this free-cooling potential for either cool ventilation air or fed high temperature water cooling systems, though to date little research work has been focused on the characterisation of these CT (3,4). In the present paper it is aimed to maximise this free-cooling potential by enabling a CT designed to operate during favourable night-time outdoor conditions for TABS cooling, to extend its operating hours during daytime within a water-economiser cycle for ventilation air cooling.

1.1. Water-Economiser cycles

The simplest solution of directly use cool outdoor air as ventilation air is the only one that could simultaneously improve energy efficiency and IAQ when higher airflows are supplied (5,6). The implementation of this all-air free-cooling solution is called air-side economiser cycle, and in principle it is always interesting in ventilation

systems because it can minimise or even avoid mechanical cooling requirements if outdoor conditions are favourable. However, it incurs in also higher fan requirements.

Some research work focused on this particular issue. Wang and Song (7) approached it considering a steady-state study in terms of operating conditions and auxiliary fan power consumption, to design the optimal control for an air handling unit (AHU) equipped with an economiser cycle. They determined the optimal supply temperature and airflow for three different operating zones of (I) 100% free-cooling, (II)partially assisted mechanical cooling and (III) minimum airflow supplied, obtaining energy savings of up to 90%. Rackes and Waring (8) also defined ranges of optimal temperature set-points and airflows for different building zones and periods along a representative day in different seasons. On contrary, from their analysis of the impact of changing the ventilation rate on the energy demand, Santos and Leal (1)obtained for the European climatology a general lowering of the yearly cooling demand if ventilation rates are increased. Hence, their results showed variations on the cooling demand from -0.01 to -0.16 kWh/(m^2·year) when ventilation rate was changed in 1m^3/(h·person). Besides being favourable for every case studied, they concluded that, although results depended on the building type and use, climate is the determinant factor in the case of new buildings in general. They all nonetheless agreed in combining different systems with an adequate control to optimise energy savings at each operating conditions.

Control is the core in economiser cycles, which can be on a temperature or enthalpy basis. Although the latter can in principle be more energy-saving, its further complexity and relative precision make temperature control generally more interesting, provided that climate is not excessively humid. A fixed-dry bulb temperature control can then be interesting if set-temperatures are adequately defined according to the climate (5). Hence, limitations of these systems are intrinsically related to climate conditions. When outdoor conditions are beyond the psychrometric region of interest for air-side economisers applicability, they can still be interesting for water-side economisers operation. This is because water-side economisers exploit outdoor air free-cooling potential indirectly, by cooling water in a CT that later passes through a coil where ventilation air is cooled. However, additional electric power requirements due to fans and pumps would have considerable weight in this case, thus restricting the range of applicability more importantly.

Although free-cooling potential for different climate conditions and the related energy savings have been extensively studied for air-side economisers for different locations and cases (9), water-economisers have not been so widely approached.

Kim et al. (10) proposed a water-side free-cooling system to provide cooling water required in a liquid desiccant system assisted with evaporative cooling that operates with 100% outdoor air. A range of hot and humid conditions of dry bulb temperature (DBT) between about 20 and 32°C, and wet bulb temperature (WBT) from about 20 to 25°C were tested for the CT operation. With this combined system they obtained COPs of 3 to 20 times those expected for a conventional chiller. They also obtained important reductions in the chilling demand through a similar system proposed for a Data Centre (11).

Most research work on economisers applications focused on Data Centres, due to the large cooling demands involved in these applications, which lead to the existence and development of further numerous technologies to efficiently provide the required cooling (12–14). Air-side economisers are particularly appealing for higher energy savings are expected, as demonstrated by Cho et al. (15) for subtropical climates. However, some authors have directed their studies to specific implementations of water-side economisers because of the requirements on air cleanliness and humidity, besides the advantages on the system's integration within the central cooling system (16). Ham and Jeong (16) demonstrated through an annual simulation of a water-side economiser modelled in EnergyPlus, that this system would always result into energy savings with respect to cooling consumptions in Data Centres. If a proper design of the Data Centre is developed (that is, an aisle contained instead of uncontained Data Centre) higher supply temperatures could be set, thus enlarging the number of operating hours and consequently the energy savings. Agrawal et al. (17) compared various strategies to improve efficiency in air cooling for Data Centres at different locations of 17 climate types. Among them, they proposed configurations of 1 or 2 cooling towers to provide cooling water that is later used to precool water used in the AHU. Results showed that interest of water-side economisers increased for colder climates and that a two-cooling tower configuration would improve energy savings in some cases. Interest of water-side economiser over indirect evaporative cooling strategies focused on its less water consumptions.

As could be expected, efficiency of water-side economisers also depends on the season. Durand-Estebe et al. (18) obtained, through simulation in TRNSYS of different water-side economiser strategies in a Data Centre, optimal temperature set-points of 20°C during Winter, whereas it rises to 24°C for mid-season operation at a Mediterranean mild climate. However, these optimal set-points would differ for different case studies in terms of air-cooling production or control strategy. Hence, they proposed a control that adapts to the outdoor climate operating conditions.

On the overall, water-side economisers have been demonstrated to be effective. However, as also stated for air-side economisers, actual energy savings may not always be significant due to extra fan and pump power consumption. Durand-Estebe et al. (18) disregarded the power required by water pumps in water-side

economiser cycles, though payed close attention to extra fan power required when air temperature set is raised. They in fact obtained an increase in the fan energy consumption of 43% when air temperature is modified from 16°C to 24°C to optimise energy savings by reducing heat pump energy requirements by 78%.

Besides, the installation is voluminous and costly, so it would be only reasonable if energy savings obtained balance out the initial investment, costs of water consumption and maintenance of the CT (17–19). Nonetheless, initial cost can be justified through the expected energy savings (10).

The aim of the present study is to assess the energy savings potential of expanding the operation of a CT designed for TABS, towards daytime operation in a water-economiser cycle, either to remove ventilation loads or to precool supply air when thermal comfort is not achieved by means of the TABS and additional cooling is required.

2. Methodology

A laboratory-scale device has been designed and constructed. It consists of a low temperature CT combined with an external finned coil as a water-to-air heat exchanger. This system would permit the pre-cooling of ventilation air through the coil with water previously cooled in the tower.

The target was to experimentally characterise the operation of this system in diurnal summer air conditions, to study the possibilities of expanding the operating period of low temperature cooling towers implemented for night-time water cooling for TABS, to daytime operation for cooling ventilation air.

2.1. Cooling tower

The experiments are conducted with the open, forced draft wet cooling tower shown in Figure 1.

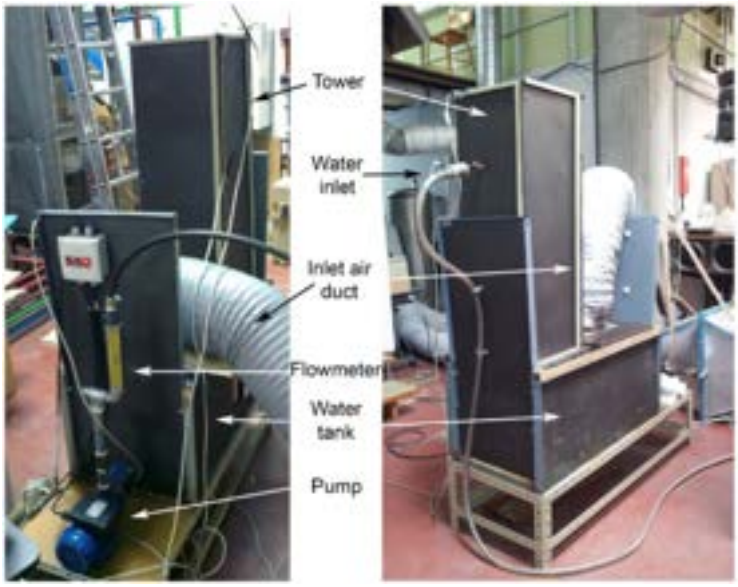

Figure. 1. Low temperature cooling tower used for the tests.

Water is sprayed from the upper part of the tower with the aid of a set of nozzles. The tower is equipped with a droplet separator at the air outlet to avoid generation of aerosols and unnecessary water losses. The packing consists of polycarbonate panels with a structure of hexagonal cells, offering a total exchange area of 13,5 m^2, which results in a surface density of 370 m^2/m^3. The water tank has a total capacity of 100 l; water level can be controlled with a level-viewer in the tank and is maintained at 60 l. Air enters the tower through a separate orifice in the same water tank, generating the desired counter-flow through the tower filling. Cooled water in the tank is then driven to the coil by a water pump placed at the water tank exit, and from the coil to the tower nozzles.

A copper-tube aluminum-fin coil is employed to pre-cool ventilation air with the aid of water cooled in the tower. It consists of staggered tubes of 3/8'' and 3.2mm separation between fins, arranged in 4 columns and 12 rows. Its total dimensions are 320x320x90mm. The coil is assembled within a structure to which the air ducts for ventilation air are connected.

The approach of the tower results to be about 5°C, which falls within the expected achievable range in practice (20). This high value is due to the also high outdoor air operating temperatures tested in the study, which has an important influence on the CT performance owing to results in existing literature (3,10). The outdoor DBT is also decisive for the approaching temperature, according to the Analysis of Variance (ANOVA) performed from the experimental results obtained in the present work (figure 2.a). However, the approaching temperature could be reduced by increasing the air flow rate (3,4), as observed in figure 2.b.

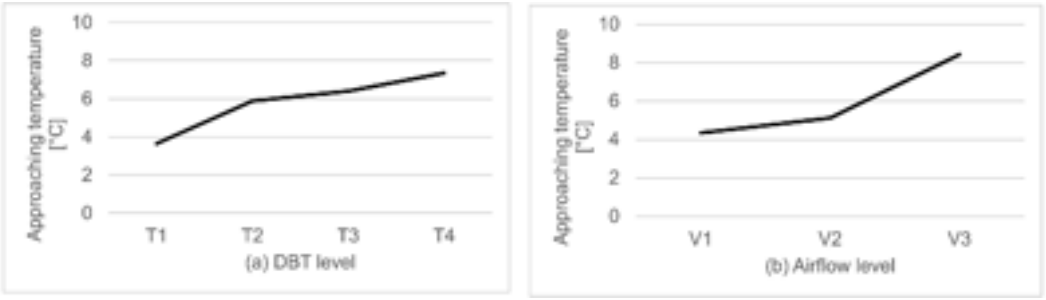

Figure. 2. Average approaching temperatures in the CT for increasing (a) outdoor air DBT; and (b) air flow rate.

This high approach justifies the limited effectiveness obtained in the tower (figure 3), as the effectiveness of the tower is calculated from the water temperature drop achieved in the tower to the maximum temperature drop achievable (1):

$$\varepsilon_T = (T_{Tw\,i} - T_{Tw\,o})/(T_{Tw\,i} - \mathrm{T}_{wb\,Ta\,i}) \quad (1)$$

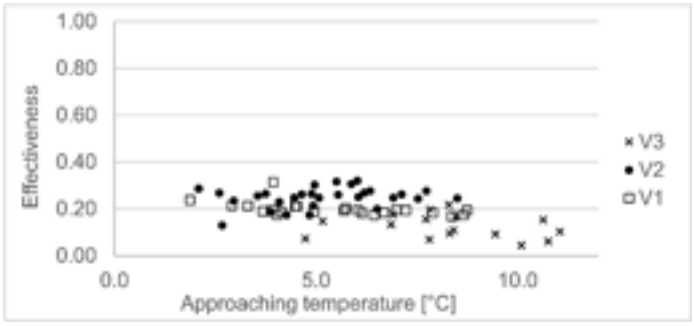

Figure. 3. CT effectiveness to approaching temperatures obtained for different air flows.

2.2. Test bench

The cooling tower and the coil are connected together as illustrated in figure 4. Air supplied to both the CT and the coil is conditioned by an Air Handling Unit that enables the system to operate at the different outdoor conditions defined in the design of experiments. Water cooled in the tower would be automatically driven to the TABS during night-time, and to the coil for diurnal operation, switched when the building becomes occupied. Ventilation air pre-cooled in the coil would be supplied to the conditioned space.

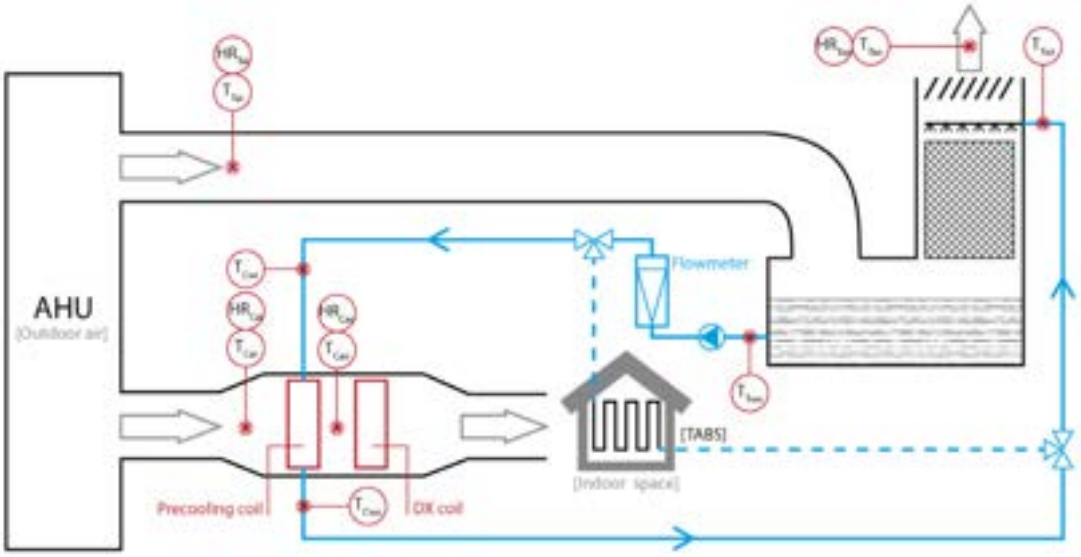

Figure. 4. Configuration of the combined system.

Measurements of air DBT and RH are acquired at the air inlet and outlet of the CT and the coil, as indicated in figure 4. Also, water temperatures are measured in the water circuit at the inlet and outlet of both the coil

and the tower. Water flow is measured with a variable area flowmeter at the outlet of the water tank, with ±2% accuracy and range from 1.5 to 10 l/min. Air flow is measured through the pressure drop obtained in orifice plates placed in the air ducts downstream the AHU plenum for air distribution.

Temperature sensors are 4-wired Pt-100 with accuracy of ±0.1°C and range from 50 to 250°C. They have been calibrated before the tests with a calibration oven.

RH sensors are capacitive type, ±2% stability and 0 to 100% range, also previously calibrated to a reference sensor.

Pressure drop is measured with differential pressure sensors placed upstream and downstream enough of the two orifice plates. These orifice plates have been previously calibrated with a reference nozzle.

2.3. Design of experiments

Table 1 presents the design of experiments. Three levels of airflow are studied, while the water flow is fixed at 4 l/min (and thus not reflected in table 1). This is because only water-to-air flow ratios are of interest (3). The consequent operating water-to-air ratios are of about 1.5, 0.9 and 0.8 for levels V1, V2 and V3, respectively. Four levels of outdoor air DBT and another four levels of wet bulb temperature (WBT) are proposed. These levels are selected to cover the widest range of probable diurnal outdoor air conditions during summer period. Conditions for the set T1-W4 belong to the fog region and are thus disregarded; consequently, a total of 90 tests have been developed.

Table 1. Design of experiments.

FACTORS					
V	(m^3/h)	DBT	(°C)	WBT	(°C)
V1	150	T1	25	W1	18
V2	250	T2	30	W2	21
V3	300	T3	35	W3	24
		T4	40	W4	27

An AHU is used to reproduce the desired outdoor conditions, as shown in figure 4. Because the variable controlled in the AHU was the relative humidity, for each pair of DBT – WBT the corresponding RH was calculated, then established as the set condition in the AHU together with the DBT. These operating conditions are tested in an arbitrary order and twice to check repeatability. Those tests where repeatability was not observed, were developed again and the less reliable tests were disregarded.

3. Results and discussion

3.1. Ventilation and cooling potential

3.1.1. Air temperature drop in the coil

Figures 5.a) to c) show the air temperature drop obtained in the coil for the different inlet airflow rate, DBT and WBT. It can be observed that ventilation air cooling in the coil is influenced by its initial DBT (T_{Cai}) and WBT ($T_{wb\ Cai}$). Higher T_{Cai} result into larger temperature drops because the air DBT at the inlet determines the logarithmic mean temperature difference (LMTD). But, to understand how $T_{wb\ Ca\ i}$ affects air cooling achieved in the coil, it must be noticed that outdoor air is used both as operating air in the tower and as ventilation air in the coil ($T_{Cai}=T_{Tai}$; $T_{wb\ Cai}=T_{wbTai}$). Because the WBT determines the water temperature achieved at the outlet of the cooling tower (T_{Two}), then driven to the coil, $T_{wb\ Ca\ i}$ also influences the LMTD, though indirectly. Increasing T_{ai} yields larger air-to-water temperature differences in the coil. Likewise, both higher T_{ai} and lower $T_{wb\ a\ i}$ foresee larger water cooling in the tower, hence larger air-to-water temperature differences and then air temperature drops in the coil.

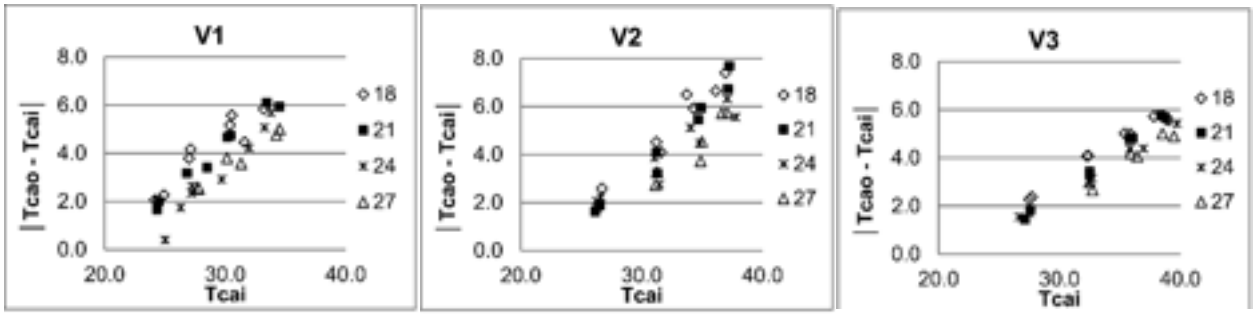

Figure. 5. Experimental air temperature drop through the coil for airflows (a) V1, (b) V2, and (c) V3.

The ANOVA demonstrate a main contribution of T_{Cai}, of 65% on the temperature drop, and a contribution of $T_{WB\ C\ ai}$ of 15%. Effect of airflow is limited to 8%, and the remaining effect comprehends the effect of dual and three factors interactions, as well as a remaining non-determined contribution.

3.1.2. Ventilation air cooling capacity

Because only sensible cooling is performed through the coil, x_{Ca} would be constant and ventilation air cooling can be obtained as expressed in equation (2):

$$\dot{Q}_{Ca} = \dot{m}_{Ca} \cdot (Cp_a + Cp_v \cdot x_{Ca}) \cdot \Delta T_{Ca} \quad (2)$$

Figure 6 represents air cooling achieved in the coil in terms of the the wet bulb depression (WBD), which is defined as the difference between the outdoor air DBT and its WBT. For the same reason derived from previous figures 5.a) to c), it can be observed that increasing the outdoor air WBD result in larger heat transferred from the air cooled in the coil. This is due to better evaporative cooling potential in the tower under larger WBD, hence larger water temperature range, which is afterwards used to cool the ventilation airstream in the coil. In this case, there is greater influence of the airflow rate, due to the same definition of equation (2).

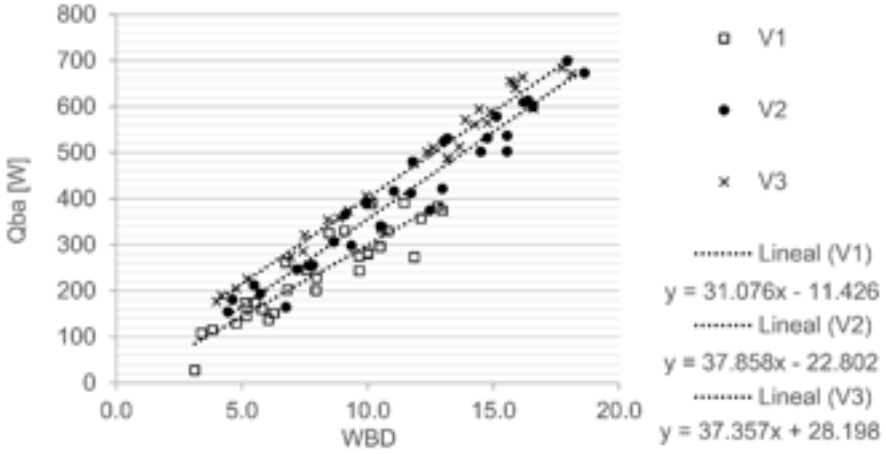

Figure. 6. Air cooling achieved in the coil at different outdoor air conditions and ventilation airflows.

The ANOVA developed on this parameter showed a main dependency on airflow, of 50%, being the contribution of T_{Cai} a 35% whereas $T_{wb\ Ca\ i}$ accounts for only 8%. The remaining effect is similarly distributed between the effect of the three possible pairs of factors interaction and a non-determined error.

Consequently, although harsher outdoor air conditions entrain larger thermal loads, they also yield better performance. This point agrees with the idea stated by Ma et al. (21) that the external environment at the same time hinders the building autonomy and benefits the building homeostasis.

3.1.3. Coil thermal effectiveness.

Another interesting parameter to be considered concerning the coil operation is its thermal effectiveness. According to the ε-NTU method, thermal effectiveness of the coil can be defined as (3):

$$\varepsilon_c = (T_{Cao} - T_{Cai})/(T_{Cao} - T_{Cwi}) \quad (3)$$

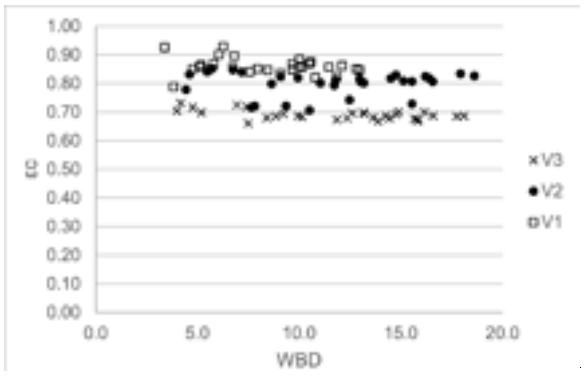

Figure. 7. Thermal effectiveness in the coil.

Figure 7 shows that the difference between T_{Cai} and the $T_{wb\ Ca\ i}$ has no effect. However, higher airflows imply shorter residence times and thus lower air temperature drops, hence smaller thermal efficiencies. This idea agrees with the results of the ANOVA on this parameter, as the contribution of the airflow rate is 82%.

3.2. Total cooling application

In this section, daytime operation of the cooling tower is studied as a mean to remove the ventilation loads generated by the required DOAS for TABS. The TABS are cooled with the night-time operation of the CT as the only cooling source and no further mechanical cooling is required during occupation times. The adaptive thermal comfort criteria can be fairly considered under these conditions.

The adaptive thermal comfort criteria is regarded in the existing European standards on indoor environment ([23] EN 16798-1:2019 Standard: Energy Performance of Buildings. Ventilation for Buildings. Part 1: Indoor Environmental Parameters for Design and Assessment of Energy Performance of Buildings Addressing Indoor Air Quality, Thermal Environment, Lighting and Acoustics. Module M1-6., n.d.) as suitable when there is no mechanical cooling and occupants can adapt to the thermal conditions by operating windows or modifying their clothing.

Some authors conceive adaptive comfort for buildings where TABS are implemented for thermal mass cooling, if water cooling demand is supported through low energy means. Whether considering adaptive or conventional thermal comfort models for TABS is thoroughly studied by Sourbron and Helsen (23). According to these authors every criterion would be valid in these cases, but they highlight that the key of the decision among existing models lays on the conflict between energy savings and strict comfort requirements. Pfafferot et al. (24) state that buildings with TABS fed by ground cooling should be considered as ‘‘mixed-mode buildings’’, and decide to consider the adaptive models. They nonetheless concede that further research on their applicability for these cases would be needed. The suitability of adaptive thermal comfort models for radiant cooling panels with water cooled in a CT is evaluated by Memon et al. (25), obtaining adequate indoor conditions in naturally ventilated spaces.

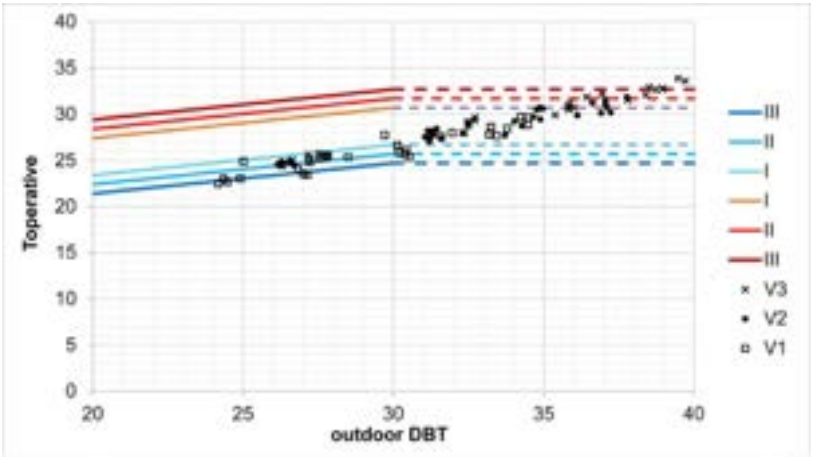

Figure. 8. Temperatures achieved in the ventilation air precooled in the coil and adaptive comfort ranges to be expected.

To study whether the cooling tower could support ventilation loads during its daytime operation, it would be enough to pay attention to supply air temperatures reached in the coil. These are represented in figure 8 within the ranges of adaptive comfort defined in the European standard ([23] EN 16798-1:2019 Standard: Energy Performance of Buildings. Ventilation for Buildings. Part 1: Indoor Environmental Parameters for Design and Assessment of Energy Performance of Buildings Addressing Indoor Air Quality, Thermal Environment, Lighting and Acoustics. Module M1-6., n.d.). Because comfort ranges for the adaptive criterion are not defined for outdoor air DBT over 30°C, trends have not been extrapolated, and the corresponding limits for 30°C have been considered for temperatures over this value. Besides, cases between 25°C and 30°C are scarce, being anyhow limited the validity of its application.

Figure 8 shows that supply air temperatures are maintained within the comfort ranges, except from the cases when the harshest outdoor conditions occur working with the highest airflow rate. For these cases, as well as for those when TABS and the night-time operation cooling tower as the only cooling source are insufficient, additional cooling would be needed during daytime occupation, and adaptive comfort criteria would not be acceptable.

3.3. Air precooling application

If additional mechanical cooling is required to achieve comfort, then the adaptive thermal comfort criteria would no longer be applicable, and the water-economiser cycle would just reduce the energy demand required by the conventional chilling system.

The energy savings achievable through the water-economiser cycle are calculated for various locations at different summer climate types. Four cities Worldwide and then seven Spanish cities have been selected and compared to assess the climate applicability of the CT. The considered cooling season spans from May to September for the Northern Hemisphere and from November to March for the Southern Hemisphere.

Worldwide cities selected correspond to the following Köppen-Geiger climate classification (26): (a) London, UK (Cfb: Temperate climate without dry season, warm summer); (b) Sydney, Australia (Cfa: Temperate climate without dry season, hot summer); (c) Las Vegas, US (Bwh: Arid, desert, hot climate); and (d) Singapore (Af: Tropical, rainforest). Climate data used in the study is obtained from Meteonorm databases (27).

Results obtained for the three airflow levels tested are gathered in table 2. Operating periods are calculated for a base temperature of 25°C, as an upper limit set-temperature for indoor thermal comfort in offices in summer ([23] EN 16798-1:2019 Standard: Energy Performance of Buildings. Ventilation for Buildings. Part 1: Indoor Environmental Parameters for Design and Assessment of Energy Performance of Buildings Addressing Indoor Air Quality, Thermal Environment, Lighting and Acoustics. Module M1-6., n.d.). Consequently, number of operating hours corresponds to the summer occupation periods (May to September between 8 a.m. and 8 p.m.) when outdoor DBT is over 25°C. If outdoor air DBT falls below 25°C, the system would operate under an air-economiser cycle, while for temperatures above 25°C, the water-economiser cycle would start operating. This temperature control is considered over enthalpy control due to its simplicity and less cost; however, enthalpy control would be recommendable in humid climates (S. K. Wang, 2001).

Energy savings are calculated through the correlations obtained for the total air-cooling capacity (Figure 6) applied to the climate data at each location on an hourly basis. The corresponding electric energy savings in the conventional water chilling system are estimated for a seasonal COP of 2.5.

Finally, actual energy savings are calculated deducting the electric energy consumption of the circulation devices: the water pump and the additional fan power required to support the pressure drop in the cooling tower. No additional fan requirements are considered through the coil because it is part of the existing ventilation system.

The power of the water pump (W_{pump}) used in the tower is of 46W. To obtain the additional fan power requirements (W_{fan}), equation (4) is used:

$$W_{fan} = \Delta P_T \cdot \dot{V}_T \tag{4}$$

The pressure drop in the cooling tower has been experimentally characterised through equation (5) for different air volume flows in the tower. A constant of K_T=200 has been obtained, for the pressure drop ΔP_T in [hPa]:

$$\dot{V}_T = K_T \cdot \sqrt{\Delta P_T} \tag{5}$$

Table 2. Operating periods and expected energy savings (World)

CITY	Water-economiser cycle operating period No. hours / % summer	Air cooling [kWh]	Energy savings (no aux.)* [kWh$_e$]	Energy savings [kWh$_e$]	Airflow level
LONDON	58	11.6	4.6	1.8	V1
(Cfb)	2.9%	13.6	5.4	2.1	V2
		16.3	6.5	2.8	V3
SYDNEY	540	91.6	36.6	10.5	V1
(Cfa)	27.5%	106.8	42.7	12.0	V2

(Af)	92.8%	177.8	71.1	-34.0	V2
		268.6	107.4	-12.4	V3

*Without considering additional power consumption of the auxiliary devices.

Table 2 shows how harsh climate conditions may enable the cooling tower to operate during longer daytime periods with larger energy savings. Indeed, the system would operate during around 90% of the summer -daytime occupation- period at Las Vegas. However, particularly humid climates like Singapore would have long operating periods but low effectiveness, yielding negative energy savings. It can also be observed that increasing airflows always allow larger energy savings, despite also larger pressure drops in the CT and the consequent extra fan power requirements.

A second study has been conducted for seven Spanish climates according to the Spanish building code (28) and the Köppen-Geiger classification (26): (i) Avila – E1/Csb (Temperate climate, dry warm summer); (ii) Barcelona – C2/ Csa (Temperate climate, dry hot summer); (iii) Bilbao – C1/ Cfb (Temperate climate without dry season, warm summer); (iv) Madrid – D3/ Csa (Temperate climate, dry hot summer); (v) Sevilla – B4 / Csa (Temperate climate, dry hot summer); (vi) Valencia – B3/ Csa (Temperate climate, dry hot summer); (vii) Valladolid – D2 / Csb (Temperate climate, dry warm summer). Concerning the Spanish building code climate index (composed by a letter and a number), only the number is of interest here, which refers to the summer climate harshness. Climate data used in this study has been obtained from the Spanish building code. Results are gathered in Table 3.

Table 3. Operating periods and expected energy savings (Spain)

CITY	Water-economiser cycle operating period No. hours / % summer	Air cooling [kWh]	Energy savings (no aux.)* [kWh]	Energy savings [kWhe]	Airflow level
Avila (E1/ Csb)	323 16.2%	133.1	53.3	37.6	V1
		159.4	63.7	45.4	V2
		173.6	69.5	48.5	V3
Bilbao (C1/ Cfb)	288 14.5%	65.0	26.0	12.1	V1
		76.6	30.6	14.2	V2
		90.2	36.1	17.4	V3
Barcelona (C2/ Csa)	579 29.1%	120.5	48.2	20.2	V1
		141.7	56.7	23.7	V2
		169.2	67.7	30.1	V3
Valladolid (D2/ Csb)	715 35.9%	280.9	112.4	77.8	V1

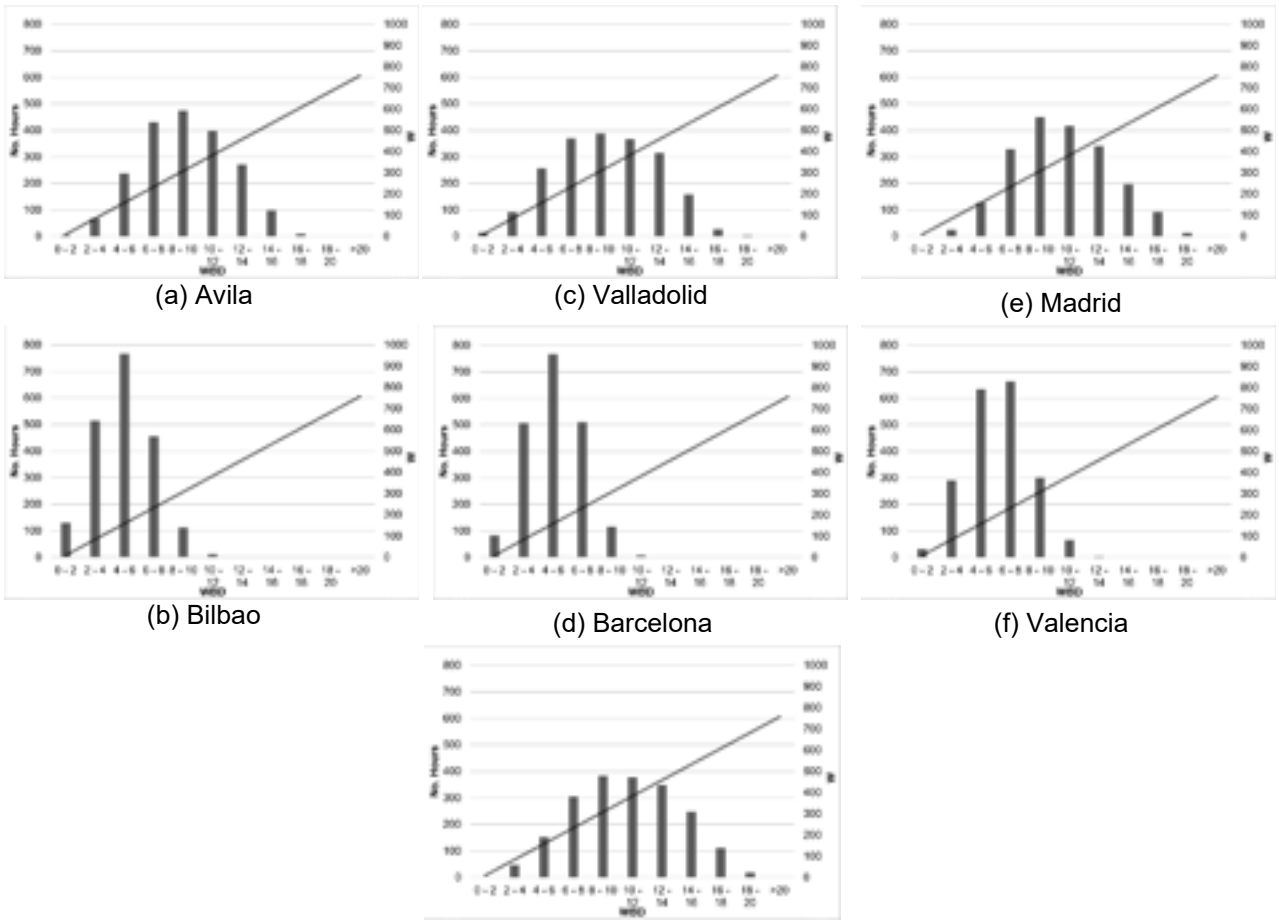
		423.3	169.3	119.6	V2
		462.0	184.8	128.1	V3
Sevilla (B4/ Csa)	1405 70.6%	519.1	207.7	139.7	V1
		620.1	248.1	168.0	V2
		683.2	273.3	182.1	V3

*Without considering additional power consumption of the auxiliary devices.

Again, increasing airflow levels entrain larger energy savings, despite additional consumption of the fan. On the other hand, longer operating periods do not necessarily involve larger savings. This is because a simple fixed DBT control is performed whereas it has been demonstrated that the system performance is highly dependent on the WBD. However, despite an enthalpy control of the cooling tower operating periods would provide more coherent results concerning number of operating hours and energy savings achieved, it would not be interesting due to its greater complexity and given that energy savings are anyway positive.

Hence, the achievable energy savings cannot be foreseen in detail if only the climate harshness index of the Spanish building code and the operating hours are considered. More humid climates incur into worse results than those expected regarding the operating hours. The cases of Madrid and Valencia, Avila and Bilbao, and Valladolid and Barcelona have the same climate classification in summer, but Valencia, Bilbao, and Barcelona are more humid climates. Hence, energy savings are of about 2.5, 3, and near 4 times higher for Madrid, Avila, and Valladolid, respectively. This lack of direct connection among operating hours and energy savings highlights the importance of carefully considering the climate of the location, to avoid excessive energy

consumptions of the circulation devices. For this reason, summer climate classification in the Spanish building code would be insufficient to foresee the applicability of this system. Consequently, to better study the interest of the cooling tower diurnal operation, the WBD bin-data of the target location rises as a key point of study, if faced to the experimental results of the system (9). This comparison is illustrated in figures 9 (a) to (g).



(a) Avila (c) Valladolid (e) Madrid

(b) Bilbao (d) Barcelona (f) Valencia

(g) Sevilla

Figure. 9. WBD-bin data of the selected Spanish cities compared to the system's cooling capacity.

In these figures, WBD of up to 20°C are considered, for being these the ones experimentally characterised. The cooling capacity of the system at V3 is represented, deducting the additional fan and pump power requirements. It can be seen how climates with larger WBD ranges would enable more energy savings, thereby justifying the values obtained in table 3. Therefore, from figure 9 Avila, Valladolid, Madrid and Sevilla would appear to be the most interesting locations for day-time operation of the cooling tower to pre-cool ventilation air, and actually are the ones with better results (table 3).

4. Conclusions and future work

A low temperature cooling tower has been experimentally characterised at a laboratory scale. Water cooled in the CT is used for ventilation air cooling in a water-to-air coil through a water-economiser cycle.

The performance of the CT is studied for three water-to-airflow rates of 0.8, 0.9 and 1.5, keeping the water flow constant, four DBT and four WBT. An ANOVA demonstrates that the airflow factor has the largest contribution to the water-economiser cycle thermal effectiveness and cooling capacity. Increased airflow yields larger energy savings, together with better IAQ expectations, despite higher fan power requirements.

Energy savings have been calculated for 4 cities Worldwide (London, Sydney, Las Vegas and Singapore) and seven Spanish cities. It was seen that, although the best results were obtained for the driest climates, broadening the operation period of the CT would result into positive energy savings for all cases studied but for Singapore.

Non-interesting humid climates can be easily identified regarding the WBD-bin data. On contrary, the Spanish building code climate classification for summer is not detailed enough to foresee the locations where the system proposed would have better potential, as it does not consider the humidity of the summer season.

At those climates where the water-economiser cycle is effective, the use of fixed DBT control is enough to switch between an air or a water-economiser cycle. This option is preferable over an enthalpy control, due to its higher simplicity and the positive energy savings obtained at these climates.

Thanks to positive energy savings and no significant investment required, it is interesting in most cases to expand to daytime operation of an existing CT for night-time TABS cooling, either to simply supply ventilation loads or to pre-cool air if auxiliary mechanical cooling is needed.

Abstract:

Most of the literature models for condensation heat transfer prediction are based on specific experimental parameters and are not general in nature for applications to fluids and non-experimental thermodynamic conditions. Nearly all correlations are created to predict data in normal HVAC conditions below 40°C. High temperature heat pumps operate at much higher parameters. This paper aims to create a general model for the calculation of heat transfer coefficients during flow condensation which could be applied to a wide range of fluids and thermodynamical parameters up to the vicinity of the critical point. To achieve this goal authors present a model based on Feed Forward Neural Network. The designed neural network consists of 5 hidden layers and utilizes ReLu and linear activation functions. The first four layers consist of 50 neurons, and the last layer consists of 1 neuron. The network was trained on a consolidated database which consists of 4659 data points for 25 fluids and covers a range of reduced pressure from 0.1 to 0.9 for various mass velocities and diameters. Two input variants were considered. For randomly selected test data Mean Square Root achieved 0.1093 and Mean Absolute Error MAE achieved 0.2243 for the first configuration which consist of 4 parameters. For the second variant, which consists of 17 parameters, MSE achieved 0.0452 MAE achieved 0.1028.

Keywords:

condensation; heat transfer coefficient; high value of reduced pressure; increased saturation pressure; artificial neural network.

1. Introduction

The condensation process in high temperature heat pumps occurs at temperatures higher than 80˚C. There is a knowledge gap in the literature for increased saturation temperatures above 90˚C. There is sparse data for the corresponding high reduced pressures for lower values of saturation temperature. Most of existing experimental data is collected for temperatures below 40 ˚C, which is related to the refrigeration applications of low boiling agents. For temperatures higher than 120 ˚C most refrigerants operate around the thermodynamic critical point, where rapid changes in viscosity and density of the liquid and vapor phases occur, which has a significant impact on interfacial interactions. During the 2022 energy price crisis increased demand could be observed for industrial high temperature heat pumps (HTHP). These devices enable energy recovery and further utilization in industrial processes. High temperature heat pumps operate in the vicinity of the critical point. Among the others, the thermal and hydraulic issues close to the critical point are the least recognized. The larger amount of works are related only to carbon dioxide, much smaller to water. Studies for other fluids are very scarce. The ones published are presented in a consolidated database. Only a few experiments regard condensation at high saturation temperatures in the near critical area. The basic characteristics in flows through the channels at close to critical parameters have been studied since the 50s of last century. Nevertheless, the phenomena presenting the specific challenges for the successive researchers have been observed and can be outlined as follows: 1) The fluid is very expandable, while the thermal diffusivity tends to zero due to very low thermal conductivity and high specific heat. 2) The thermal properties change nonlinearly, which is different from the normal liquid or gas flow and leads to new flow structures. 3) The absence of surface tension and a capillary effect leads to low pressure loss and low flow friction. 4) The buoyancy effect can be more complex. 5) There are expected thermal-mechanical effects and

several time and spatial scales, related to thermal equilibrium or stability evolution in confined spaces. Recently, because of environmental protection requirements, it's an obligation to look for new working fluids, in the case in which physical characteristics are not sufficiently studied. In addition, a large group of these fluids are mixtures. In such a case, the issue is further complicated. It's hard to define the close to the critical area due to the temperature glide effect as well as the different thermal and flow properties of the mixture components. As a result, there is a risk of the formation of vapor-liquid mixtures with dynamics difficult to control. This may happen when one (or more) of the mixture components passes the critical point, while the other components remain in the subcritical area. The situation is similar for media containing additives, i.e. refrigerant oils, air, or inert gases. Untypical character and high dynamics of phenomena taking place in the area close to critical require the selection of working parameters of installation to be chosen very carefully. The authors aim to create a general model which can accurately predict the heat transfer coefficient during condensation at various values of reduced pressure. A special focus on parameters in the vicinity of critical point is a novelty of this research. The authors utilized Feed forward Neural Network which has a different structure than the neural network presented by other authors. The new FNN is also significantly smaller.

Work carried out by other researchers is described in paragraph 1. The consolidated database is described in the second paragraph. Feed-forward network model is presented in the next paragraph. The results are discussed in the fourth paragraph.

1.1. Prediction methods that utilize neural networks.

The study presented by [1] uses machine learning (ML) methods to predict heat transfer coefficients (HTCs) for flow condensation in horizontal tubes. A database with a wide range of fluids and experimental conditions is compiled to evaluate five ML models. Using XGBoost models, a new universal correlation is developed based on the analysis of the most important parameters. The study finds that the ML models perform well in predicting the 1213 test data points, with convolutional neural network CNN achieving the best mean absolute relative deviation (MARD) of 5.82% and the coefficient of determination (R2) of 0.98 or higher for both XGBoost models. XGBoost is better at extrapolating data with reliable performance and the lowest MARD of 19.64%. They also created a conventional correlation which mean absolute relative difference achieved 19.21%. Qiou et al. [2] gathered a consolidated database of 16953 data points. The consolidated database was divided into training and testing data, and an optimization is performed to create the final model architecture consisting of dimensionless input parameters and hidden layers. The artificial neural network (ANN) model demonstrates excellent accuracy in predicting the test data with a mean absolute error (MAE) of 14.3%, and 92.0%, and 97.4% of the predicted data fall within ±30% and ±50%, respectively. The performance of the ANN model was compared with universal correlations for saturated flow boiling heat transfer which was outperformed by ANN. Zhou et al. [3] proposed a new method for predicting heat transfer coefficients in flow condensation in mini/microchannels using a consolidated database of 4,882 data points from 37 sources. The data includes various parameters such as working fluid, reduced pressures, hydraulic diameters, and mass velocities. Four machine learning models were developed and compared, and the ANN and XGBoost models showed the best predicting accuracy. These models were able to predict test data with MAEs of 6.8% and 9.1%, respectively. The models were also compared to a highly reliable universal correlation and were found to perform better in predicting heat transfer coefficients for individual datasheets and different condensation flow regimes. The models were able to accurately predict heat transfer coefficients for datasets outside their training database when fluid specific information was available. The study shows that machine learning algorithms can be used to develop a robust new tool for predicting heat transfer coefficients in flow condensation in mini/micro channels. Moradkhani et al. [4] presented a study which focused on the creation of accurate models for estimating the condensation heat transfer coefficient (HTC) inside conventional and mini/micro channel heat exchangers using machine learning methods. The study evaluated the performance of three different models: gaussian process regression (GPR), hybrid radial basis function (HRBF), and interpolating-based radial basis function (RBF). The study also presented a new general correlation using the least square fitting method (LSFM). The study evaluated the accuracy of earlier HTC models and found a lack of more accurate models for condensation heat transfer coefficient (HTC) in conventional and mini/micro channels. Among the intelligent method-based models, the GPR model showed the highest accuracy for the testing dataset with an average absolute relative deviation of 4.50%, and it was selected as the most reliable model for predicting the HTC in different channels. The study also developed a new conventional general HTC correlation.

2. Consolidated database

The consolidated database is presented in the Table 1. It consists of data presented in 28 publications for 21 fluids. Mass velocity varies from 75 to 1400 kg/(m^2 ·s), reduced pressure varies from 0.1 to 0.9 and diameters vary from 0.76 mm to 15 mm. The first 22 sources which consist form almost 2900 data points were used to train neural networks. 6 last sources are intended for ANN testing

3. Neural network model

The previously cited studies [1–4]show that the use of the artificial intelligence method can give better results than conventional correlations for predicting the heat transfer coefficient. During the initial tests, 3 methods were investigated: Feedforward Neural Networks (FNN), Convolutional Neural Networks (CNN), and the k-means clustering algorithm. The results provided by FNN were the most promising and the authors decided to

pursue this approach. Artificial Neural Network ANN showcased high quality results also in [34,35]. A multi-layer neural network was developed to train the prediction of the heat transfer coefficient during flow condensation. The scheme of this network is presented in the Figure 1.

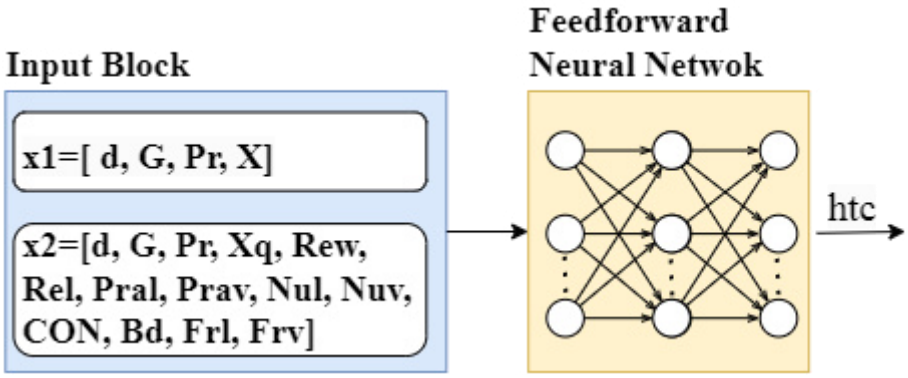

Figure. 1. Scheme of designed neural network.

The applied neural network uses activation functions (FA), such as ReLu (fR) $fR(x) = \max(0, x)$ and Linear $fL(x) = x$. ReLu is used on 4 first layers, and the last layer utilizes linear function. The authors of the work tried to make the architecture of the network used as simple as possible, and at the same time give the best results. Finally, 5 hidden layers were used with 50 neurons in the first layer (M=50), 50 neurons in the second layer (N=50), 50 neurons in the fourth layer (D=50), 50 neurons in the third layer (P=50), and 1 neuron in the last layer (Q=1). The output (y_{out})signal from the network is described by the relation:

$$y_{out}(x,\omega) = fL\left(\sum_{i=1}^{Q} \omega_{ji}^{I} \cdot x_i \left(\sum_{l=1}^{P} \omega_{out} fL\left(\sum_{k=1}^{D} \omega_{lk}^{III} fR\left(\sum_{j=1}^{N} \omega_{kj}^{II} fR\left(\sum_{i=1}^{M} \omega_{ji}^{I} \cdot x_i + \omega_{j0}^{I}\right) + \omega_{k0}^{II}\right) + \omega_{l0}^{III}\right) + \omega_{0utO}^{iv}\right) + \omega_{l0}^{III}\right) \quad (1)$$

Signals $x(k) = [x_1, \ldots, x_M]$ given to the input k neuron multiplied by sets of weights $\omega(k)$ are sent to the next fully connected layer. The vector of initial weights $\omega(k) = [\omega_1, \ldots, \omega_M]$ is randomized from the range (0,1). Given the research results described in [36] the Adam algorithm was used to teach the networks under study. The network performance error was calculated as the difference between expected y and output $\hat{y}$ based on Mean Squared Error (MSE) and Mean Average Error (MAE) for all n observations i;i = 1.. n;

$$MSE(y, \hat{y}) = 1/n \sum_{i}^{n} (y(i) - \hat{y}(i))^2 \quad (1)$$

4. Results

FNN was trained for two input data configurations. The first one consisted only of basic thermodynamical parameters: diameter, flow rate, quality, and reduced pressure (in comparison to critical pressure). The second configuration feature also a set of criteria numbers. From the learning database, nearly 800 measurements were randomly selected to test the database. A comparison of the two input configurations is presented in the Table 2. Both configurations achieved good results for the test dataset. Case 1 with only 4 basic input parameters achieved accurate output data of its limited input data. The second configuration achieved significantly better results., which are lower than the measurement errors of most experiments. Most experiments regarding measurement of HTC during condensation have measurement errors between 10 and 20%. It is worth mentioning that the presented ANN was much smaller than the artificial intelligence networks presented by [1–4]. Values of MSE and MAE have achieved thanks to data preparation and curation for FNN. The expected value was turned into a logarithmic value and rescaled, which enabled FNN to achieve formidable results.

Table 2. FNN evaluations on the test dataset for different input combinations.

case	number of input parameters	input parameters	MSE	MAE
1	4	d, G, Pr, X	0.1093	0.2243
2	17	d, G, Pr, X, Rev, Rel, Pral, Prav, Nul, Nuv, CON, Bo, Frl, Frv, Frlf, Frvf, Wevf	0.0452	0.1028

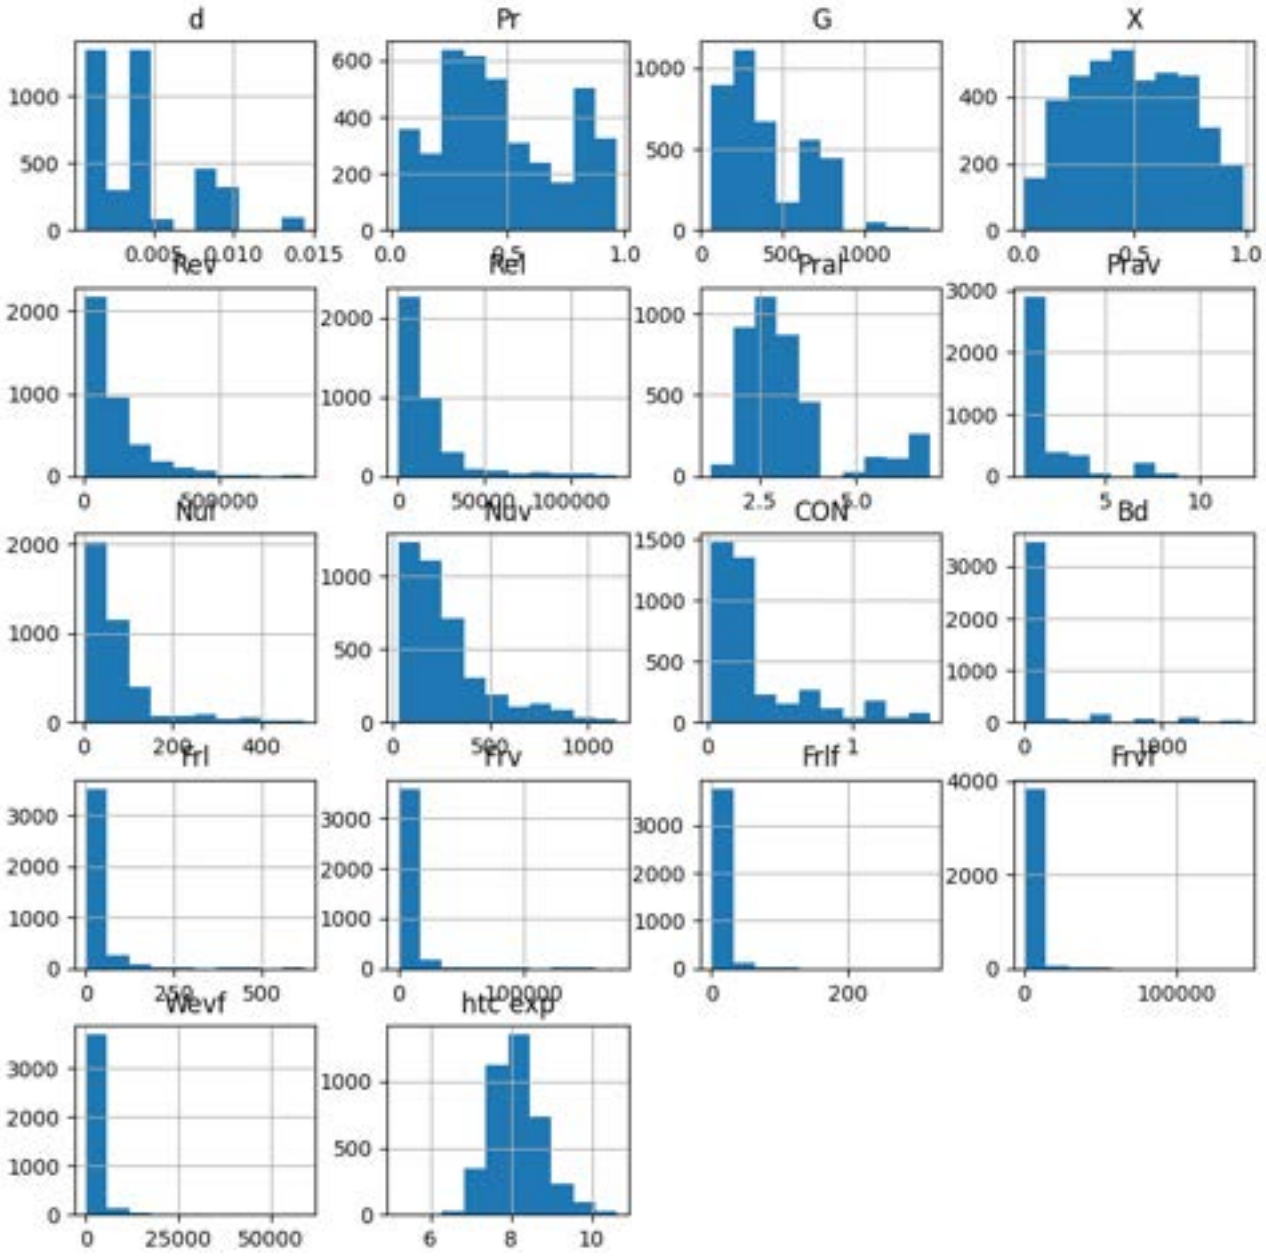

Figure. 2. Histograms that present the distribution of input parameters.

Histograms which present the distribution of input parameters are present in the Figure 2. Parameters are described in the nomenclature section. Most important are diameter, mass velocity, reduced pressure and quality which are measured during the experiment. The rest of the parameters are criteria numbers which are calculated using fluid properties and mentioned experimental parameters. The learning process of the first dataset can be observed in the Fig. 3. Comparison of experimental and calculated values of HTC can be observed in the Fig. 4 and the Fig. 5. Value of the expected value and output value for the training dataset provides good results for sparse input data. Both variants were trained for 100 epochs.

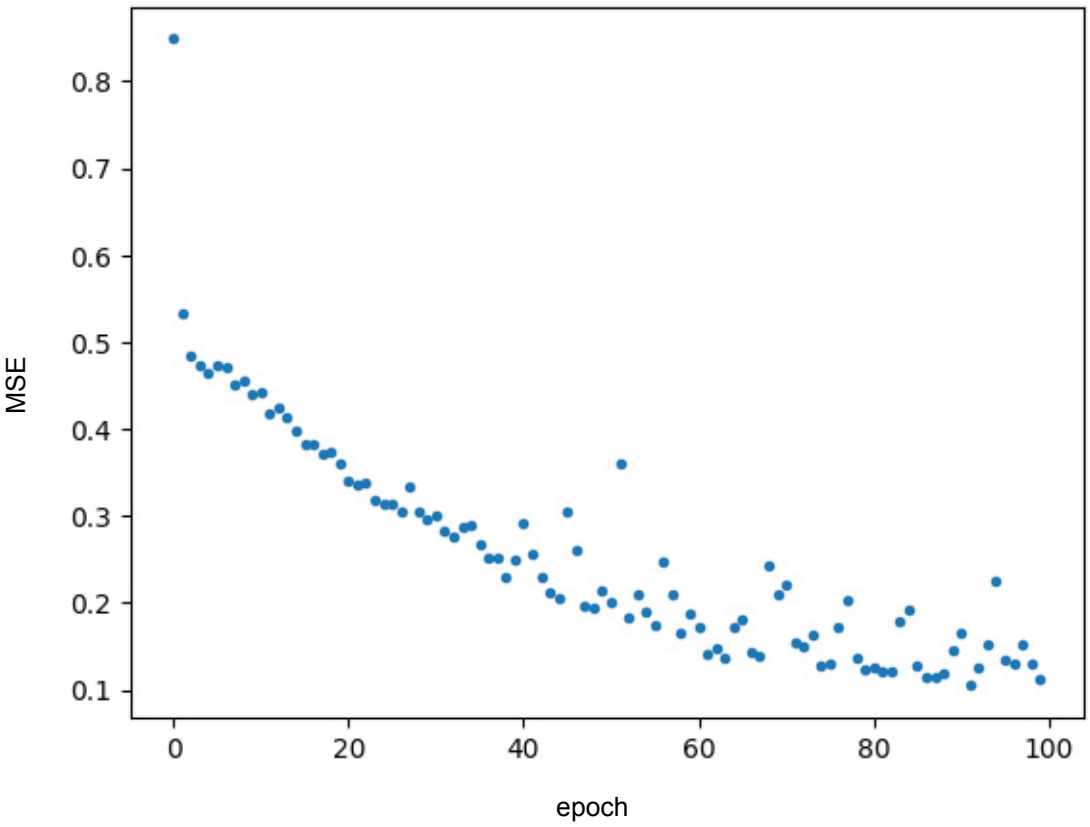

Figure. 3. Learning graph for the first input configuration

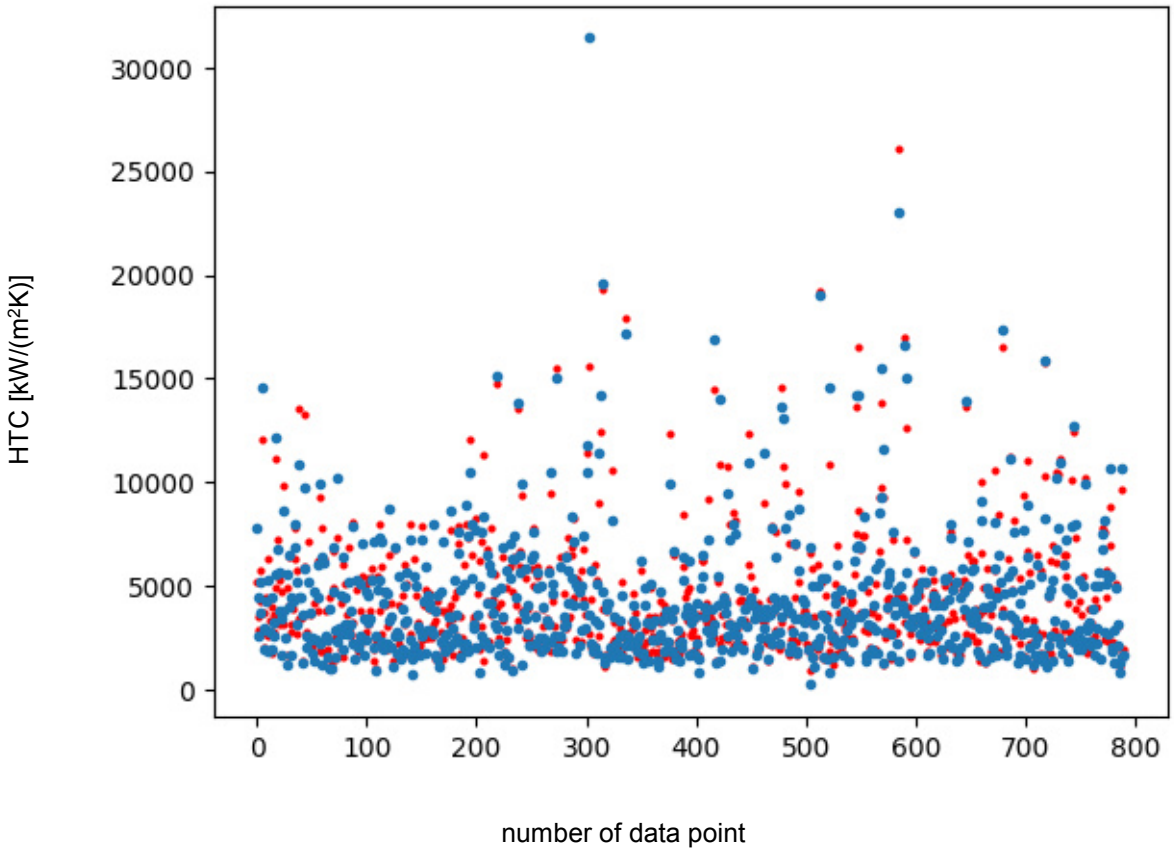

Figure. 4. Comparison of experimental heat transfer coefficient and results for the first input configuration. Experimental values are blue and FNN output values are red.

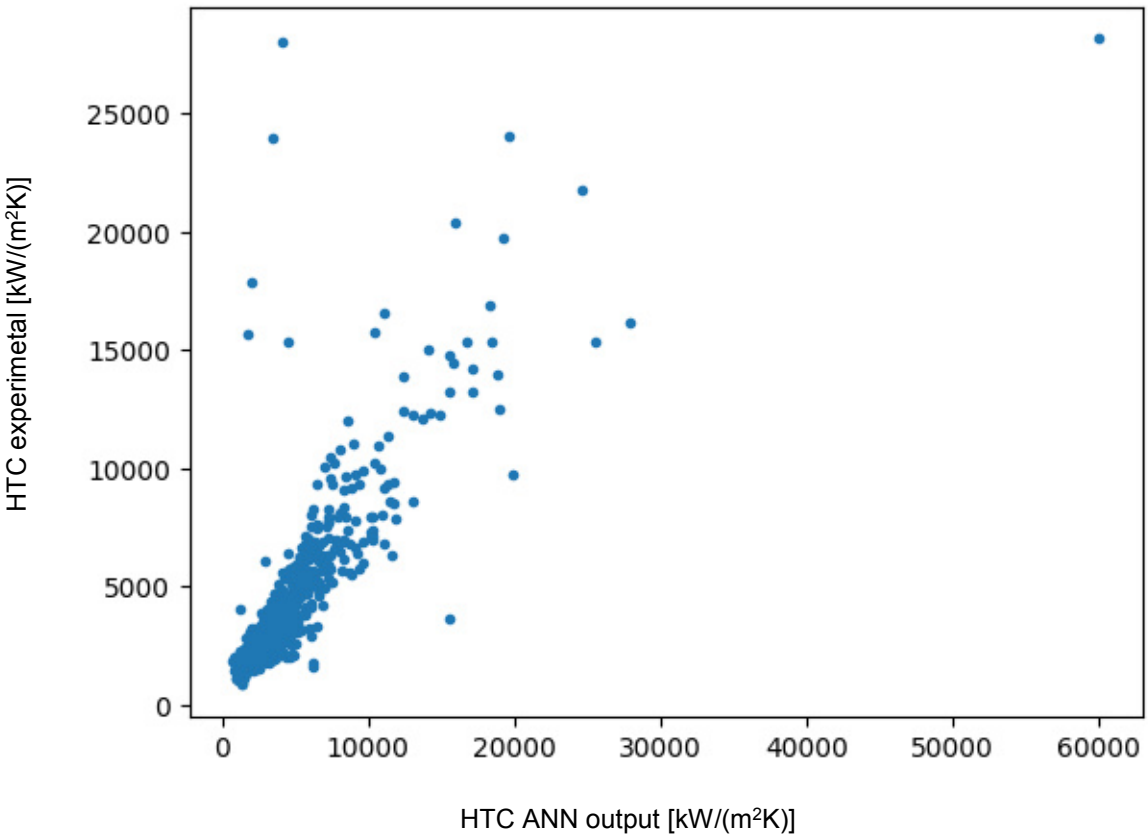

Figure. 5. Comparison of HTC value measured during the experiment and ANN output data for the first input configuration

The learning process of the second dataset can be observed in the Fig. 6. Comparison of experimental and calculated values of HTC can be observed in the Fig. 7 and in the Fig. 6. Better results can be observed in the Fig. 8. than in the Fig. 4. Learning process is significantly faster f second configuration.

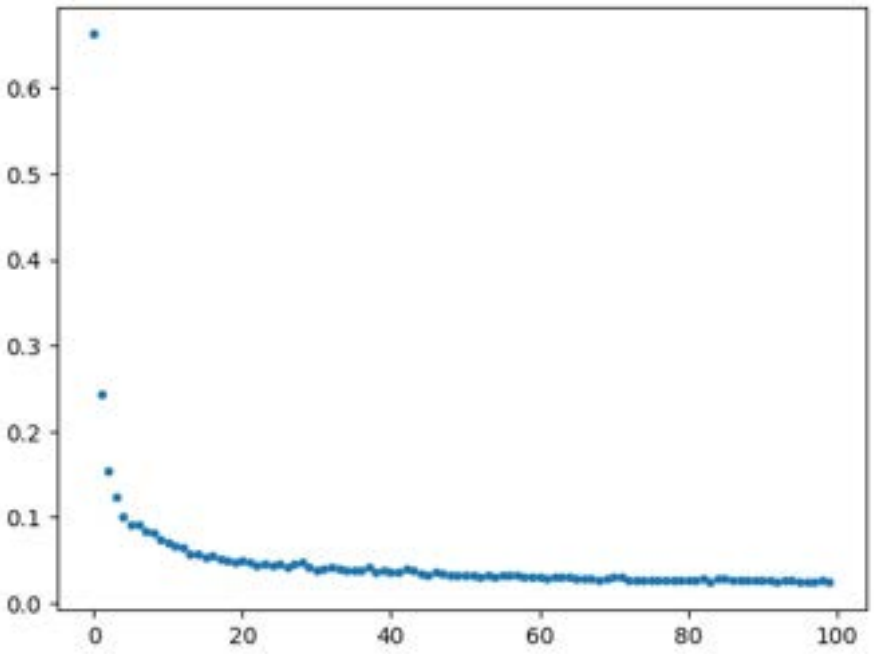

Figure. 6. Learning graph for the second input configuration

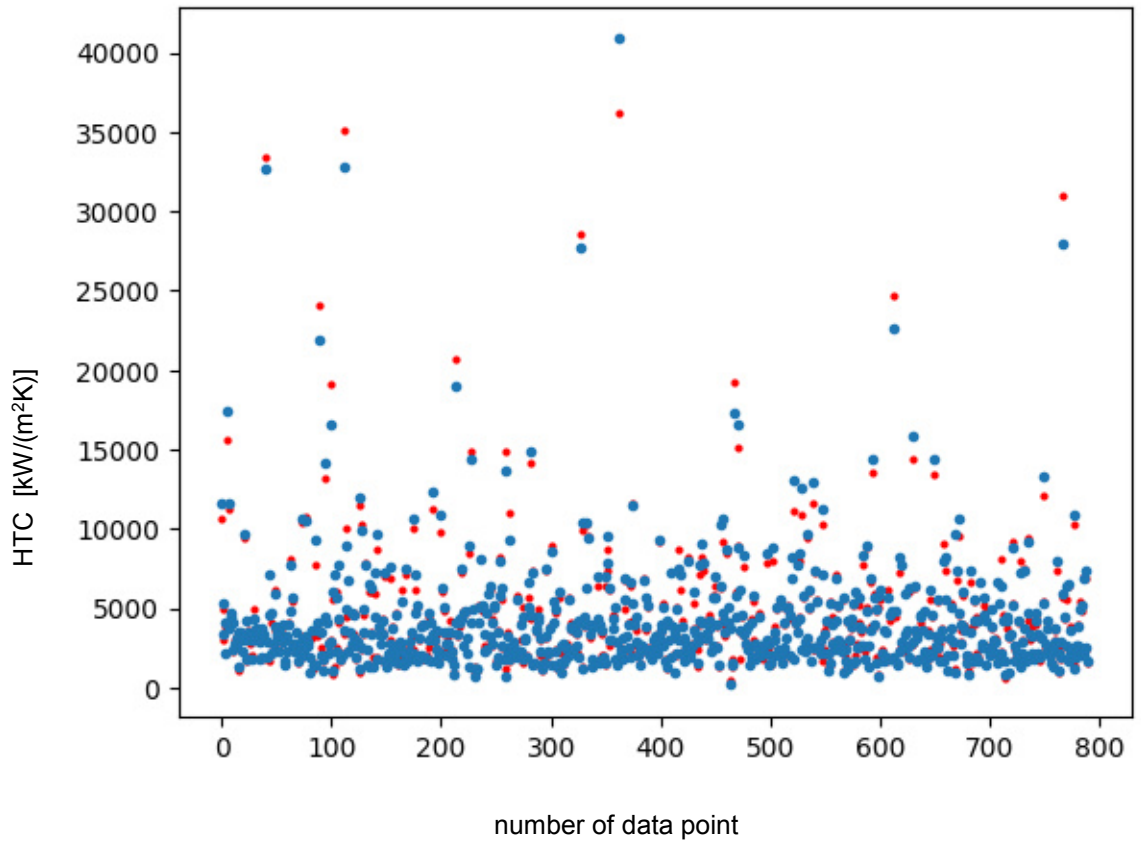

Figure. 7. Comparison of experimental heat transfer coefficient and results in for the second input configuration. Experimental values are blue and FNN output values are red.

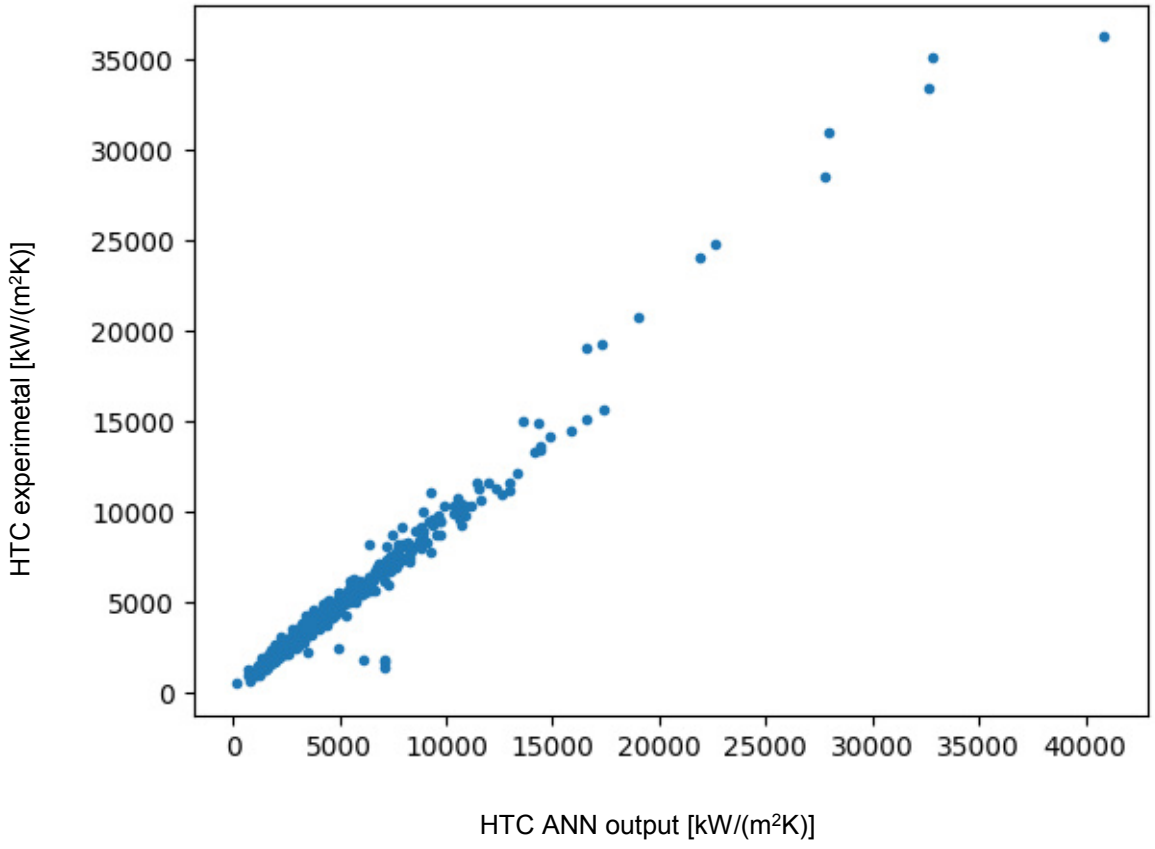

Figure. 8. Comparison of HTC value measured during the experiment and ANN output data for the second input configuration

4. Conclusions

The authors created a model which can predict heat transfer coefficient during flow condensation. The model utilizes Feed Forward Neural Network (FNN). The method was trained on the consolidated experimental database which consists of 4659 data points. The consolidated database covers various parameters of diameter, mass velocities, and reduced pressures ranging from 0.1 to 0.9. The proposed Feed Forward Neural network achieved very good results for randomly selected data points. Designed FNN consists of 5 hidden layers and utilizes ReLu and linear activation functions. ADAM algorithm was used for training. Mean Square Root MSE achieved 0.1093 and Mean Absolute Error MAE achieved 0.2243 for the first variant. For the second variant, MSE achieved 0.0452 MAE achieved 0.1028. The value of MAE achieved by the second configuration is lower than the measurement error of most experiments. It is important to mention that created FNN is relatively small, but it managed to provide good results. The created network consists of 5 layers. Further development of work is required to gather more experimental data points from different experiments than used in testing data and testing created FNN on a new dataset. This will allow to test the new method in a real-case scenario.

Nomenclature

ANN Artificial Neural Network,

Abstract:

Moisture control is essential for appropriate indoor air quality, mainly in humid regions. Liquid desiccant dehumidification system is among the latest techniques used to minimize the humidity indoors and maintain thermal comfort, requiring less energy than dehumidification through conventional refrigeration. In the current work, a four-stage dehumidifier is constructed, which consists of a dynamic packing soaked in the solution containing the desiccant. The linear motion of packing is induced by a cam spring follower mechanism powered by a motor. Celdek 7090 is used as packing along with Calcium Chloride of different concentrations as desiccant. Experiments are conducted for varying air velocity, desiccant concentration, and inlet dry bulb temperature. Input parameters are noted and performance parameters such as coefficient of performance, moisture removal rate, dehumidification efficiency, and humidity and temperature drops are evaluated. Results indicate that an increase in the desiccant concentration yields larger dehumidification, though 40% desiccant concentration led to adverse effects on the system components and hindered the flow. Rise in the inlet temperature slightly raised the dehumidification. System gave maximum moisture removal rate, dehumidification efficiency, and coefficient of performance equal to 4.83 g/s, 72.74%, and 4.35 respectively. Results also showed that increasing air velocity reduced the dehumidification efficiency. Air quality check conducted on the exit air, it is found that air quality is good and meets ASHRAE standards.

Keywords:

Multistage dehumidifier; desiccant; coefficient of performance; dehumidification effectiveness; air quality.

1. Introduction

Due to the rise in the world's population, there is a significant increase in the energy consumption. Air conditioning (AC) alone comprises 50% of the overall building energy utilization [1]. It is thus critical to improve the energy efficiency when controlling the temperature and humidity within the occupied spaces. In AC, the temperature is maintained below dew point temperature to remove moisture by condensation [2]. Due to water collection, there is a risk of growth of the mold and bacteria, with the consequent undesirable health effects. Therefore, to remove more moisture, reheater is required [3]. Desiccant dehumidification is an alternative approach which can provide high air quality and meet thermal comfort conditions [4]. Liquid desiccant dehumidification system (LDDS) is an alternative option where that dehumidifies the air with the use of liquid desiccant. Humid air is driven through the duct and interacts with the packing, where there moisture condensates [5]. This is due to the vapor pressure difference between the desiccant and the air. As the concentration of the desiccant increases, there is a drop in the vapor pressure of the desiccant and the moisture diffuses from the higher to the lower concentration [6]. Some of the packings which are commercially available are Celdek and Aspen packing. Celdek packing gives high wettability value. Wettability is the desiccant holding capacity of the packing. Lithium bromide (Li Br) and Lithium Chloride (Li Cl) are commonly used desiccants which yielded good dehumidification, but they are corrosive [7]. This issue can be overcome using less corrosive desiccants such as Calcium Chloride ($Ca\ Cl_2$) and potassium formate (HCO_2K) [8]. Thickness of the packing and desiccant concentration are decisive on the dehumidification performance [9].

Outside climate is another factor which determines the dehumidifier performance. In the majority of the systems, the packing is static, single stage, and the type of flow between the air and the desiccant is either counter or cross flow [10]. Counter flow can result into higher performance. Some articles in the literature focus on multistage and dynamic dehumidifiers.

Air can be driven through one or more packings. Similarly, the packing may be static or dynamic. Dong et al. [11] studied a corrugated, S-shaped, PVC, and a globular shaped, polypropylene packing. the performance of the dehumidifier was evaluated for the inlet air flow rate and temperature. In terms of the moisture effectiveness, corrugated packing gave better results than S-shaped packing. Globular packing gave the least performance among all. Wang et al. [12] worked on a counterflow liquid desiccant dehumidifier which used structured packing with wettability of 650 m^2/m^3. Experiments were conducted for variable packing height, climatic conditions, and air velocity. The system gave a moisture effectiveness of 0.6 and moisture removal rate of 0.9 g/s. Jain et al. [13] built a dehumidifier unit which comprised a cooling tower, heat exchanger, regenerator and control unit. The desiccant used by the unit was Ca Cl_2 and Li Cl, and the desiccant concentration and air flow rate were varied. Results indicated that change in the specific humidity of Lithium Chloride and Calcium Chloride was found to be 5.86 and 1.77 g/kg. Bouzenada et al. [14] developed a desiccant air conditioning system which used Ca Cl_2 as desiccant. Operating parameters such as air temperature, humidity and air velocity were varied and found that absorption mass rate varied linearly with the inlet air humidity. Results indicated that the system gave a vapor pressure of 20 Pa. Lu et al. [15] worked on LDDS where the inlet air humidity ratio and temperature were varied. Experimental test rig was developed and found that outlet desiccant and air temperature increased with the inlet conditions. Solution fraction increase gave a drop in the outlet humidity. Seenivasan et al. [16] compared the performance of single and two stage dehumidifiers. Air flow rate were varied and found that there was a drop in the dehumidification effectiveness. There was a rise in the condensation rate with the increase in the desiccant flow rate. Also, the performances varied with the desiccant concentrations and found that moisture removal rate increased significantly. Results inferred that two-stage dehumidifier performed better than single stage dehumidifier. Cheng et al. [17] worked on a multistage dehumidifier and conducted experiments for different number of packing stages. The system used Li Cl solution which interacted with the humid air in cross flow direction. Results indicated that dehumidification efficiency was mainly affected by air flow rate and solution flow rate, and the system gave a dehumidification efficiency of 80%. Li et al. [18] performed an experimental study on a multistage planar membrane dehumidifier both counter and parallel flow arrangements. Nafion 212 membranes were used, and the inlet operating conditions were initially maintained at 27ºC, then varied. Performance parameters were obtained by varying the temperatures, relative humidity, and air flow rate. Results indicated that counter flow dehumidifier gave better performance compared to the parallel type.

After reviewing the literature, it is found that most of the papers used counter and cross flow types, while desiccant used were Li Cl and Ca Cl_2. Celdek packing is widely used, which gave high wettability. Few works focused on the variation of the climatic conditions and the solution flow rate. Most research focus on single stage static dehumidifiers, while research related to multistage dynamic dehumidifiers is scarce. Also, the study of the influence of the desiccant concentration variation and the climatic conditions on the system performance are limited. To overcome these gaps, a multistage reciprocating dehumidifier is constructed where the desiccant concentration and inlet climatic conditions were varied to obtain the performance parameters such as moisture removal rate and moisture effectiveness. Energy efficiency is also studied and expressed in the form of the COP.

2. Methodology

Figure.1 shows the psychrometric process in the desiccant dehumidification system.

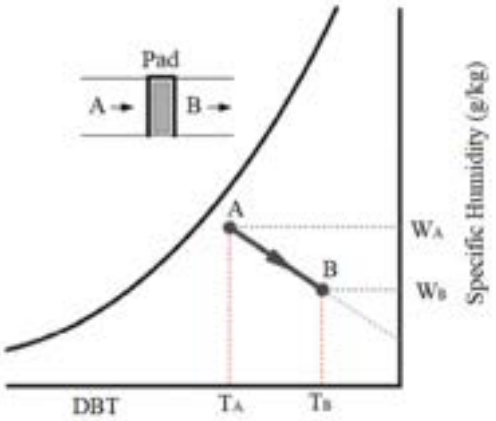

Figure.1. Psychometric process representing dehumidification.

The air gets dehumidified as it passes through the reciprocating packing system. W_A, T_A are the air specific humidity and temperature at the inlet, while W_B, T_B are the air specific humidity and temperature at the outlet. In the dehumidification process, the temperature of air increases as the specific humidity drops.

The moisture removed from the air (MRR) is given by equation (1), which is evaluated by the product of air flow rate and difference in specific humidity.

$$MRR = (\omega_i - \omega_o)\, \dot{m}_a \tag{1}$$

The dehumidification efficiency given in equation (2) is defined as the ratio of the difference between the inlet and outlet specific humidity to the inlet specific humidity and equilibrium specific humidity.

$$\varepsilon = \frac{\omega_i - \omega_o}{\omega_i - \omega_{eq}} \tag{2}$$

The mass transfer coefficient is defined as the product of the MRR to the product of the surface area and the specific humidity difference of average and equilibrium points. It is given by equation (3).

$$K = \frac{MRR}{A\,(\omega_{av} - \omega_{av,eq})} \tag{3}$$

The Coefficient of Performance (COP) is defined as the ratio of the enthalpy difference or heating effect to the total energy required. It is shown in equation (4).

$$COP = \frac{HE}{Energy\ consumed} \tag{4}$$

All the performance parameters are determined using equations (1) to (4) and represented in section 3 in the form of graphical representation.

2.1. Multistage dehumidifier test rig construction and operation

Figure 2 shows the experimental test rig constructed. It mainly consists of an absorber unit where the dehumidification process is carried out, composed by four packings at different positions that reciprocate inside the desiccant solution.

The evaporator of a vapour compression refrigeration system is integrated in the absorber to regulate the desiccant temperature. Celdek 7090 is used for the multistage packing, which rotates thanks to a 0.3HP motor that powers a cam spring follower mechanism. A blower drives the air through a 25cm×25cm and 2.5 m length duct, where it interacts with the packing soaked with desiccant. As the air gets dehumidified, the desiccant concentration drops due to the water condensation. To regain the due concentration, the desiccant is driven to a preheater tank, where it is heated up to approximately 65°C, then driven to the heater tank equipped with an electric coil that supplies 1 kW. A separator consisting of baffled structured plates enables the mass transfer and the hot desiccant is pumped to a contact device system. The contact device consists of four further reciprocating packings where air interacts with the hot desiccant, removing the moisture and cooling it. The desiccant at the original concentration is pumped to a radiator where it is further cooled, then supplied to the absorber unit. The connection of the different systems is represented in Figure 3.

In this system, the reciprocating packing gets dipped inside to increase the wettability. The reciprocating action is enhanced due to cam follower mechanism powered by a 0.3 HP motor. Air is blown by a 0.5 HP blower and interacts with the Ca Cl_2 desiccant, which leads to moisture condensation. High desiccant concentration has low vapor pressure; hence the air moisture diffuses towards the concentrated desiccant. Low concentration desiccant is driven through a regenerator to regain the original concentration. The regenerator consists of a preheater, separator, heater and a contact device. Weak desiccant is preheated using the waste condenser heat from a VCR cycle. It is driven through the heater where the desiccant is heated to the boiling temperature, then enters the separator to eliminate moisture from the solution. The separator contains baffle plates and is insulated using Asbestos covering. This completes a first stage of dehumidification. The desiccant moves into the contact device where it is in contact with the reciprocating packing. Due to the vapor pressure difference between hot desiccant and the fresh air entering the contact device, a second stage dehumidification takes place. In the second stage regeneration, due to the packing action, the temperature of the desiccant slightly drops down. The high temperature concentrated desiccant is made to pass through the radiator to reduce the temperature drastically and the warm desiccant enters the absorber unit where the temperature of the desiccant is in equilibrium temperature due to the evaporator coil. Table.1 gives the operating conditions of the system.

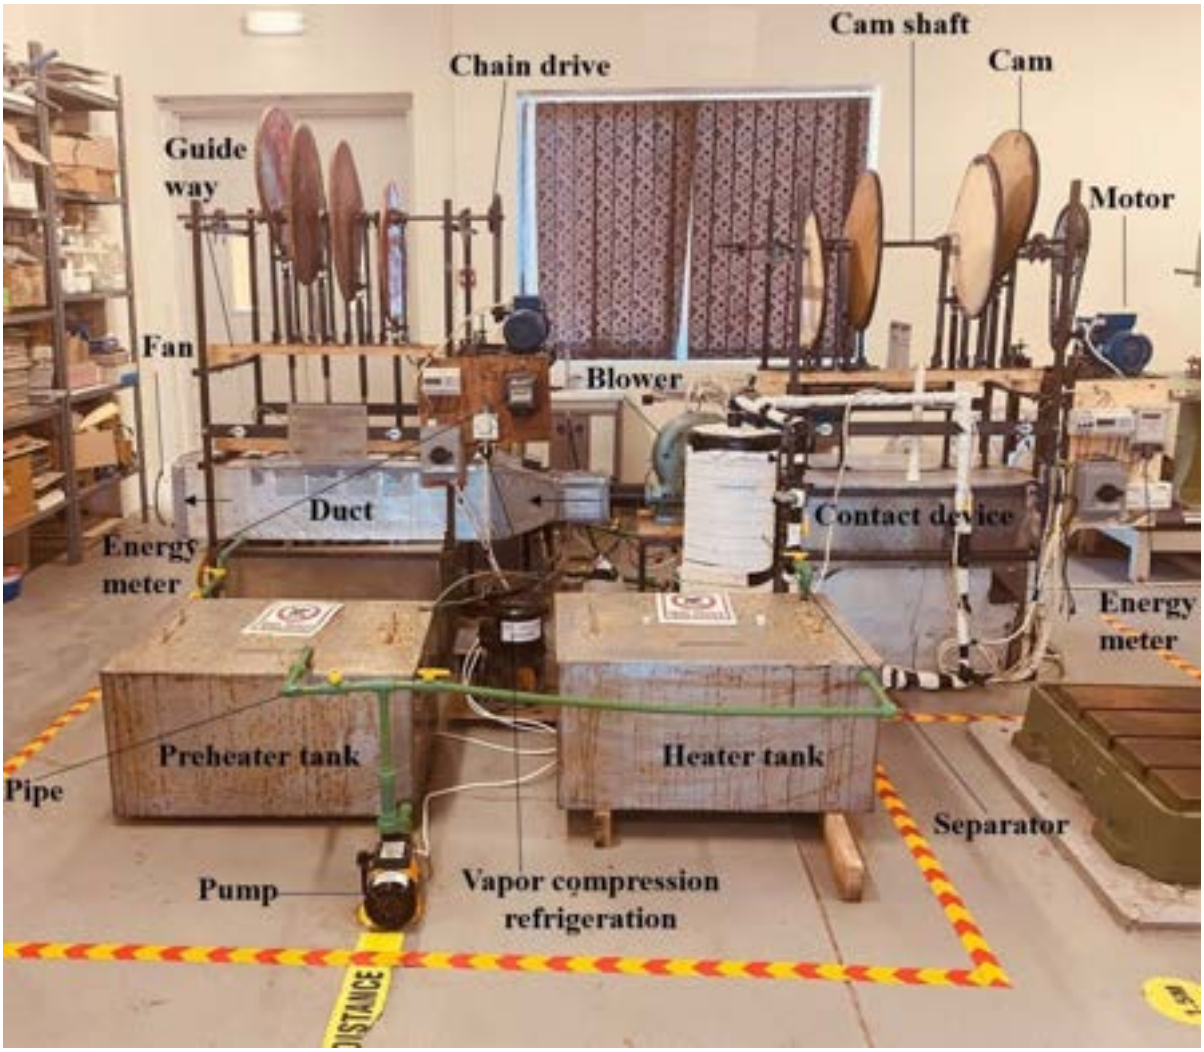

Figure.2: View of the multistage dehumidifier test rig

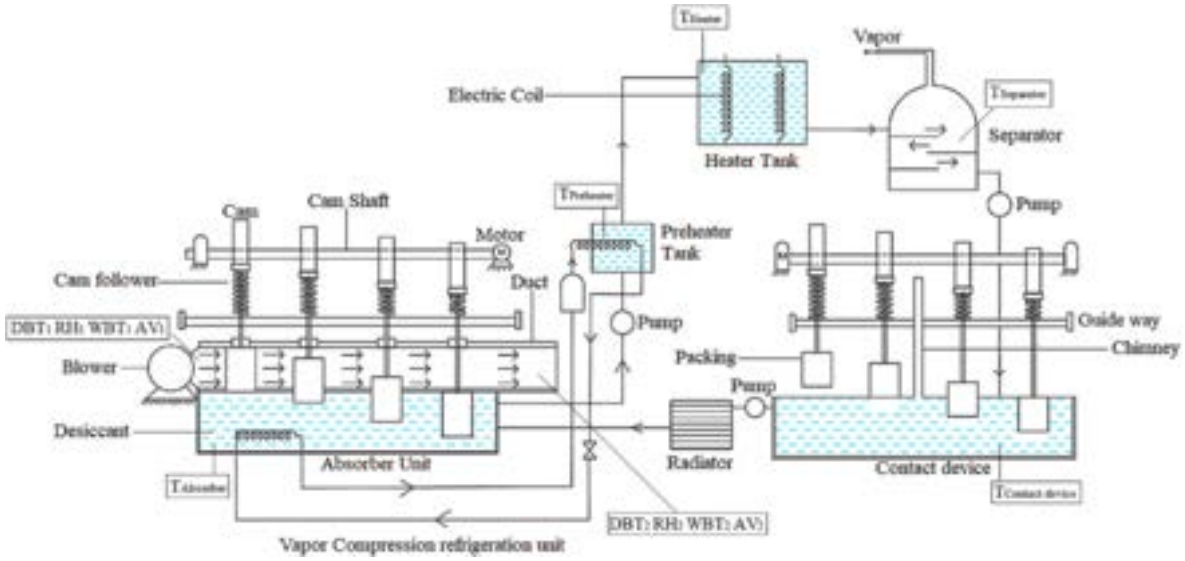

Figure.3: Scheme of the multistage dehumidifier test rig

Table.1. Experimental conditions and parameters studied

Packing, wettability, type of flow and fluids	Inlet conditions	Measuring parameters	Performance parameters
Packing: Celdek 7090, Wettability: 632 m^2/m^3 Type of flow: cross flow Fluids: Air and Calcium Chloride desiccant Cam shaft speed: 10 rpm	Inlet temperature: 30 to 42ºC Mass flow rate: 0.23 to 0.62 kg/s Desiccant concentration: 20%, 30% and 40%	Outlet temperature, relative humidity, wet bulb temperature	Moisture removal rate, COP, dehumidification efficiency, mass transfer coefficient

2.2. Measuring instruments

Several instruments are used to measure the operating parameters. A refractometer is used to measure the concentration of the salt. It measures the salinity range between 1 to 100% and has a resolution of 1%. The desiccant flow is measured using a flow meter which has a range of flow between 10 to 120 LPM and has a pressure value of 20 bar. Dry bulb temperature is measured using Pt100 thermometers with a range from -20 to 80°C, accuracy ± 0.1˚C, and resolution of 0.1˚C. To measure the wet bulb temperature, a Pt100 thermometer with similar specification is used, where the bulb is covered with a soaked cloth. Capacitive hygrometers are used to measure the relative humidity, which has a range of 0 to 99%. Anemometer measures the air velocity of air which has the range of 0.3 to 30 m/s and resolution 0.1 m/s. Tachometer measures the cam shaft speed of rotation which has range of 10 to 9999 rpm and resolution 0.1 rpm. Energy meter measures the total energy consumed by the unit during the operation period. It has voltage of 220 V, frequency 50 Hz and current 80 A.

3. Results and discussion

Experiments have been conducted by varying the mass flow rate of air and desiccant concentration. For a particular concentration, mass flow rate of air is varied from 0.23 kg/s to 0.62 kg/s with an increment of 0.1 kg/s. Air and desiccant conditions such as air temperature, specific humidity, desiccant concentration, and air velocity are measured at the inlet and exit of the system.

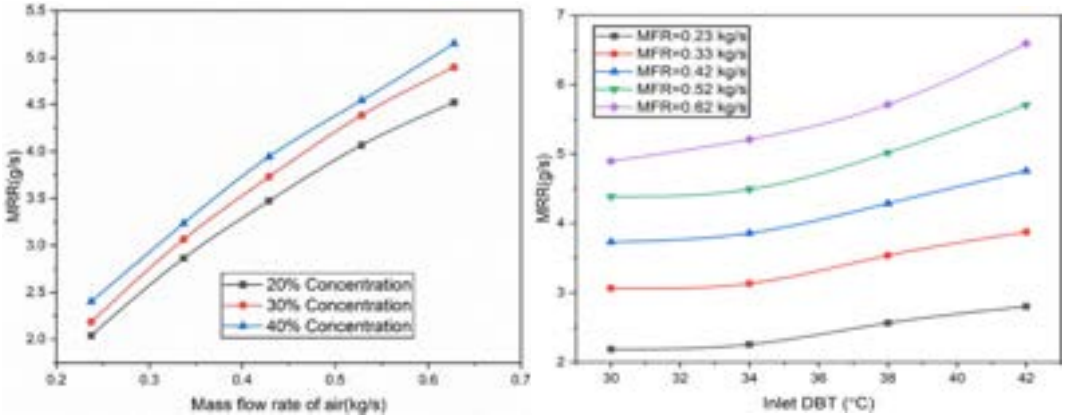

Figure. 4. Variation of MRR with mass flow rate of air and inlet DBT

Figure 4 shows the variation of MRR with the flow rate for different desiccant concentrations. As the concentration and mass flow rate increases, MRR also increases. Higher air velocities have higher mass flow rates. Even though difference in the humidity ratio decreases for higher mass flow rates, increased mass helps to remove more moisture per time unit. This increases the MRR (g/s). As the concentration is increased, vapour pressure difference between air and the desiccant also increase. Higher vapour pressure difference increases the ability to remove more moisture. Hence, 40% concentration desiccant absorbs more moisture than 20 %.

Figure 4 also shows the variation of MRR with the inlet air temperatures. For any value of fixed air relative humidity, as the air temperature increases, humidity ratio also increases. This increases the dehumidification capacity of the air sample. Hence, as the inlet air temperature increases, higher MRR is observed. The results show that for 0.52 kg/s air flow rate, MRR increases by 11.79% for 40% desiccant concentration, as compared to that of 20% concentration. Similarly, when the inlet temperature varies from 30 to 42°C, MRR increases by 30.2%.

3.1. Outlet DBT

Figure 5 shows the variation of the exit DBT with the mass flow rate and the inlet DBT for different desiccant concentrations. Higher concentrated desiccant can absorb more moisture from the air, or, in other words, higher heat of condensation is released. This heat increases the temperature of both the air and the desiccant. This leads to a rise in the exit air temperature for all tested cases. As the mass flow rate of the air increases, the amount of moisture being condensed reduces, which in turn reduces the exit air temperature.

Figure 5 also depicts the variation of the exit DBT for different air inlet temperatures. Higher inlet temperature increases the temperature rise for any fixed air mass flow rate. This is because higher inlet temperature is responsible for higher dehumidification, hence enhanced heat transfer rate, which also increases the air temperature. From the tested values, it is observed that the air exit temperature is 4.5% higher for 40 % desiccant concentration than for 20% concentration and 0.52 kg/s air flow rate. When the inlet temperature varied from 30 to 42°C, exit DBT raises by 83%.

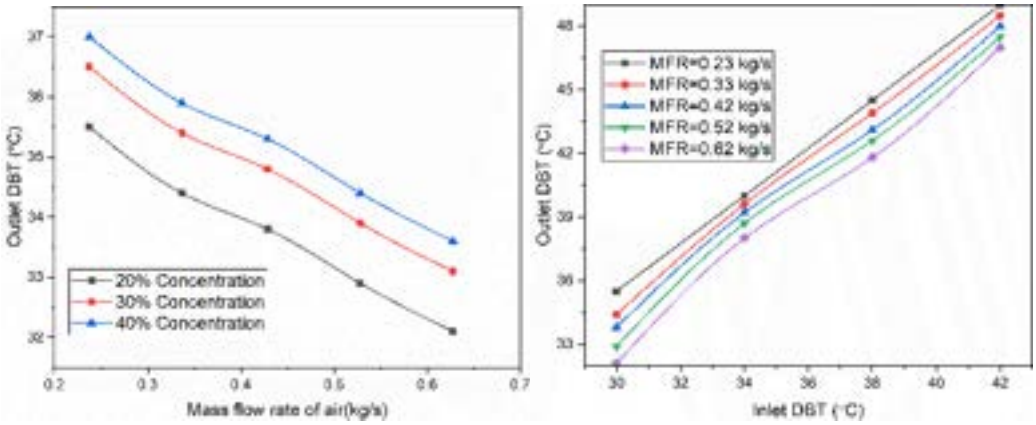

Figure. 5. Variation of outlet DBT of air with mass flow rate and inlet DBT

3.2. Dehumidification or moisture effectiveness (DE)

Dehumidification or moisture effectiveness (DE) is the ratio of moisture absorbed by the desiccant to the difference between the inlet and equilibrium moisture. Equilibrium moisture is the moisture contained by the air sample at the desiccant inlet conditions. It is clearly seen from figure 6 that higher desiccant concentrations show higher moisture effectiveness. This is because as the concentration increases, dehumidification also increases. For a constant value of equilibrium moisture, higher DE will be observed. As the mass flow rate of the moisture increases, DE value decreases resulting in reduced DE.

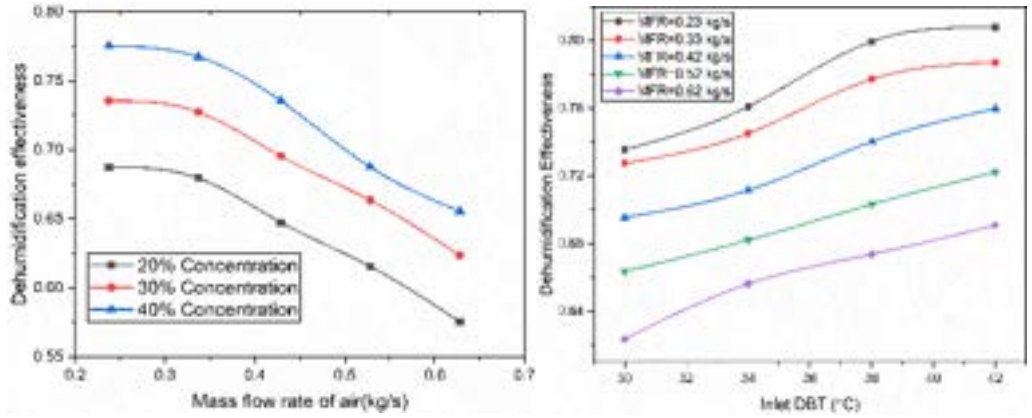

Figure. 6. Variation of Dehumidification effectiveness with mass flow rate and inlet DBT

Figure 6 also depicts the variation of DE for various inlet air temperatures. As the air inlet temperature increases, DE also increases. Similarly, as the inlet temperature increases, dehumidification capacity of air sample increases. For any constant RH condition, specific humidity values are higher for higher temperatures. This increases the dehumidification capacity. Hence higher temperature will have higher tendency for dehumidification. When the concentration is increased from 20% to 40%, DE increases 11.5% for 0.52 kg/s air flow rate. For the same air mass flow rate, when the inlet temperature increases from 30 to 42°C, DE increases by 10.6%.

3.3. COP

COP is the ratio of enthalpy change due to the dehumidification to the total energy input to the system. Total energy input includes the work supplied to the blower and the motor that runs the cams. It is observed from figure 7 that desiccant concentration significantly influences the COP, as the dehumidification values increase when increasing the desiccant concentration. Furthermore, as the air mass flow rate increases, COP tends to rise. Even though energy input to the blower increases for higher mass flow rates, the increased enthalpy difference contributes to higher COP values. It is also seen that higher inlet temperatures tend to enhance the COP. This is mainly due to the higher moisture absorbing capacity of the air sample at higher temperatures with fixed RH conditions. Concerning the energy requirements, these are independent from the inlet temperatures. Consequently, higher inlet DBT increases the enthalpy difference and hence the COP. The experimental results reveal that when the desiccant concentration is enhanced from 20 % to 40%, COP rises by 48%. Similarly, when the inlet temperature increased from 30 to 42°C, the COP is increased by 45% for 0.53 kg/s air flow rate.

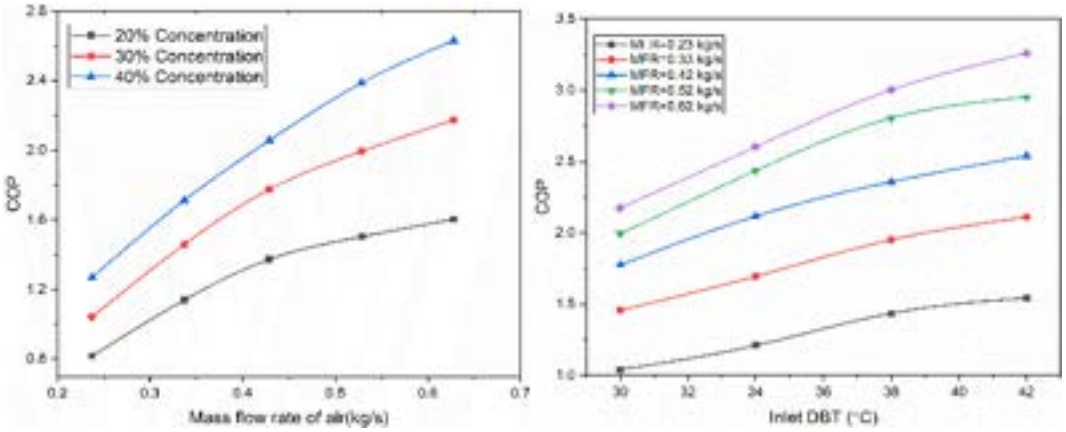

Figure 7. Variation of COP with mass flow rate and inlet DBT

4. Conclusions

Experimental investigations are conducted in a reciprocating multistage dehumidification unit to assess the dehumidification performance for different $CaCl_2$ desiccant concentrations and different air inlet temperatures. The results obtained can be summarized as follows:

- Multistage reciprocating dehumidification shows better performance as compared to that of a single stage stationary type, with higher values of MRR and moisture effectiveness.
- Increasing the concentration from 20 to 40% increases the MRR, DE, and COP by 17.6%, 13.2% and 53.6%, respectively, for 0.23 kg/s air flow rate.
- When the inlet temperature increased from 30 to 42°C, the performance parameters MRR, DE, and COP increased by 27.2%, 34.5% and 49 %, respectively, for 0.23 kg/s air flow rate.
- When the mass flow rate is increased from 0.23 kg/s to 0.72 kg/s, the DBT, humidity ratio, and DE decrease by 9.5%,7.2%,16.1%; whereas the MRR and the COP increase by 80% and 95%, respectively, for 20% desiccant solution and inlet temperature of 34°C.

Hence, it is seen that a multistage reciprocating dehumidification unit offers benefits such as higher performance with reduced desiccant consumption, as the desiccant remains stationary unlike the conventional dehumidification systems. As the four pads are intermittently in contact with air, pressure drop and energy consumption are lower. This contributes to more sustainable dehumidification technologies with minimum energy consumption and environmental pollution.

Abstract:
Concentrated Solar Power plants are commonly recognized as one of the most attractive options within carbon free power generation technologies because their high efficiency and also because implementation of hybridization and/or storage is feasible. In this work a small-scale system focused on distributed production, in the range of kW_e (5 kW_e to 30 kW_e), is modeled. A parabolic dish collects direct solar power towards a receiver located at its focus. There, the heat transfer fluid increases its temperature for thermal storage or for directly producing electricity at the power block. Thus, this is a crucial component in CSP systems since it greatly influences global efficiency. There is a trade-off in the energy balance within the thermal receiver, since the higher the temperatures it achieves, the higher the radiation losses could be. In this work, a heat transfer analysis for an air volumetric receiver coupled to a parabolic dish is carried out. The solar receiver is modeled under steady-state conditions using a detailed set of equations. The model considers the main losses by convection, conduction and radiation at the glass window and the surrounding insulator. The temperatures and heat transfers along the different receiver zones are computed with a built from scratch in-house code programmed in Mathematica®. The thermal efficiency mainly depends on the incoming solar irradiance at the glass window, the receiver geometry and the type of materials considered, as well as on the ambient temperature. It is expected that this model (precise but not too expensive from the computational viewpoint) could help to identify the main bottlenecks, paving the way for optimization when designing solar volumetric receivers in this kind of systems.

Concentrated Solar Power, Solar receiver, Heat transfer, Parabolic dish, Distributed energy.

1. Introduction

A key element in any concentrated solar power (CSP) system is the solar receiver. It can be considered as a special type of heat exchanger with the aim to convert the input direct solar irradiance into heat for a thermal fluid. Receiver efficiency is essential to obtain a high efficiency in the overall CSP plant and so, commercial interest. Heat transfer processes in the solar receiver are very complicated and during the last years many experimental or simulation studies were conducted in order to propose optimized designs. A recent compilation of those studies is due to Sedighi *et al.* [1].

A particularly interesting application of CSP systems is the possibility of producing distributed electricity at the scale of kW_e, close to the consumption place. Solar dishes, for instance, are capable to perform this task with good efficiencies. A collecting parabolic dish reflects the input solar radiation into a solar receiver located at parabola focus, where it is transferred to a fluid that uses to be a gas running a thermodynamic cycle.

Particularly, Brayton cycles are being investigated due to their promising features as high efficiency, versatility, compactness, and possibility to integrate hybridization or storage schemes. Requirements for solar receivers designed to operate together with Brayton cycles include the necessity to operate at high temperatures (over about 800°C) and relatively high pressures [2].

Pressurized volumetric receivers use closed loops, can be compact and reach large efficiency at large temperatures and pressures adequate for Brayton cycles [3]. Moreover, can operate with gases different from air, as helium, argon, nitrogen or CO_2. Their design continue being a challenge nowadays in order to set the basis for new evolutions of CSP systems, increasingly interesting from an economic perspective. These receivers

are usually closed with a quartz glass window that can reach temperatures about 1200°C and its cooled by the thermal fluid itself or through an extra cooling system [4]. Behind the glass, there is a cavity containing a porous media, the absorber, that is directly impinged by solar radiation. The gas flows through its pores getting a high temperature. Foam can be metallic or ceramic [5]. The first are more economic and can reach temperatures about 1450°C, for instance with Nickel compounds. Other advantages of metal foams include high porosity and specific surface area, as well as, high mechanical strength. Outer walls of the receivers are usually thermally isolated from the ambient to minimize heat losses. Aluminum silicate is a usual material with a low thermal conductivity (around 0.06 W/(m.K) [6]. Bellos *et al.* [7] have reviewed the most recent technologies and advances on cavity receiver designs for solar dish concentrators.

Studies and analysis of solar receivers for solar dish applications include experiments and simulations at different levels. Zhu *et al.* [4, 6] performed both studies for an own design. The experimental study was conducted at Hangzhou, China, and consisted of a compressor, a dish and a receiver with a Ni foam absorber [4]. Variations with time of different parameters as energy and exergy efficiencies, heat losses, temperatures, pressures were performed at real solar conditions in a period with approximately constant direct normal irradiance (DNI). Subsequently, a simplified stationary model for heat transfer in receiver zones was presented [6]. A good agreement between experimental and calculated receiver efficiency (with values about 82%) was obtained.

At a different level of refinement, Wang *et al.* [8] developed a Computational Fluid Dynamics (CFD) model that was validated against experimental measures. A SiC (silicon carbide) absorber was utilized and different porous parameters were analyzed. Maximum temperatures of the outlet air slightly exceeded 1000 K. Solar to thermal efficiencies over 63% were obtained.

The aim of this work is to accurately predict the thermal efficiency of the system made up of a Parabolic Dish Collector (PDC) and a solar volumetric receiver placed at its focus. This system subsequently could be coupled to a thermal cycle, as Stirling or Brayton ones, to produce electric energy for distributed applications. This work is part of a series of studies by our group devoted to a complete modeling of the overall system, including the optics of the parabolic dish, the thermal efficiency of the receiver and the efficiency of the thermodynamic cycle. The methodology intends to be capable of making precise computations for each subsystem at a similar physical level, making clear the bottlenecks of all involved efficiencies with the aim to propose improved designs and operation schemes on the whole system [9]. Special emphasis on subsystems integration is envisaged. For instance, CFD analysis would be an alternative analysis method [10]. However, this would an extensive computational effort and the key physical factors affecting global system efficiency (and the corresponding efficiency bottlenecks) are not always easy to extract. Due to space limitations, in this paper only the model for the efficiency of the solar receiver is exposed.

A detailed set of equations for the heat transfer model in each of the stages during gas heating will be employed. The model includes some features not considered and/or barely touched in previous works, as the volumetric (instead of superficial) heat transfer coefficient for the porous media, different temperatures inside and outside of the glass window, losses across the receiver insulator, more accurate expressions for thermal radiation exchanges and a more complete set of view factors. All these factors are included in appropriate energy balance equations. Most important losses are also incorporated to the model. The models presented in the following paragraphs pursue to be realistic enough to precisely determine the thermal efficiency within a reasonable computational time. They include a comprehensive set of equations with a relatively large number of parameters, but all of them are controllable and with a clear physical origin and meaning.

2. Modelling

The solar receiver model was originally inspired in that from Zhu *et al.* [6], although significant modifications are introduced in order to enlarge its capabilities and to improve model accuracy. The solar receiver model is exposed in the following subsections.

2.1. Energy efficiency equation

The receiver thermal efficiency is the ratio between the heat absorbed by the fluid and the total heat flux impinging at the receiver aperture area, as it is shown in Eq. (1):

$$\eta_{th,rcv} = \frac{\dot{Q}_r}{I_b} = \frac{\dot{m}\,(\bar{h}_o - \bar{h}_i)}{\eta_d\, A_d\, DNI} \tag{1}$$

where $\dot{Q}_r$ stands for the heat flux absorbed by the fluid at the receiver. It can be calculated in terms of the fluid mass flow through the receiver, $\dot{m}$, and the difference between the outlet and inlet fluid specific enthalpies, $\bar{h}_o$ and $\bar{h}_i$, respectively. I_b is the solar radiation power impinging at the solar receiver window. This parameter can be expressed as the product of the parabolic dish optical efficiency, η_d, dish aperture area, A_d, and direct solar irradiance (DNI) [6, 11]. Thus, Eq. (1) encompasses solar receiver efficiency associated with heat losses and parabolic dish optical efficiency.

2.2. Solar volumetric modelling: Heat transfer equations

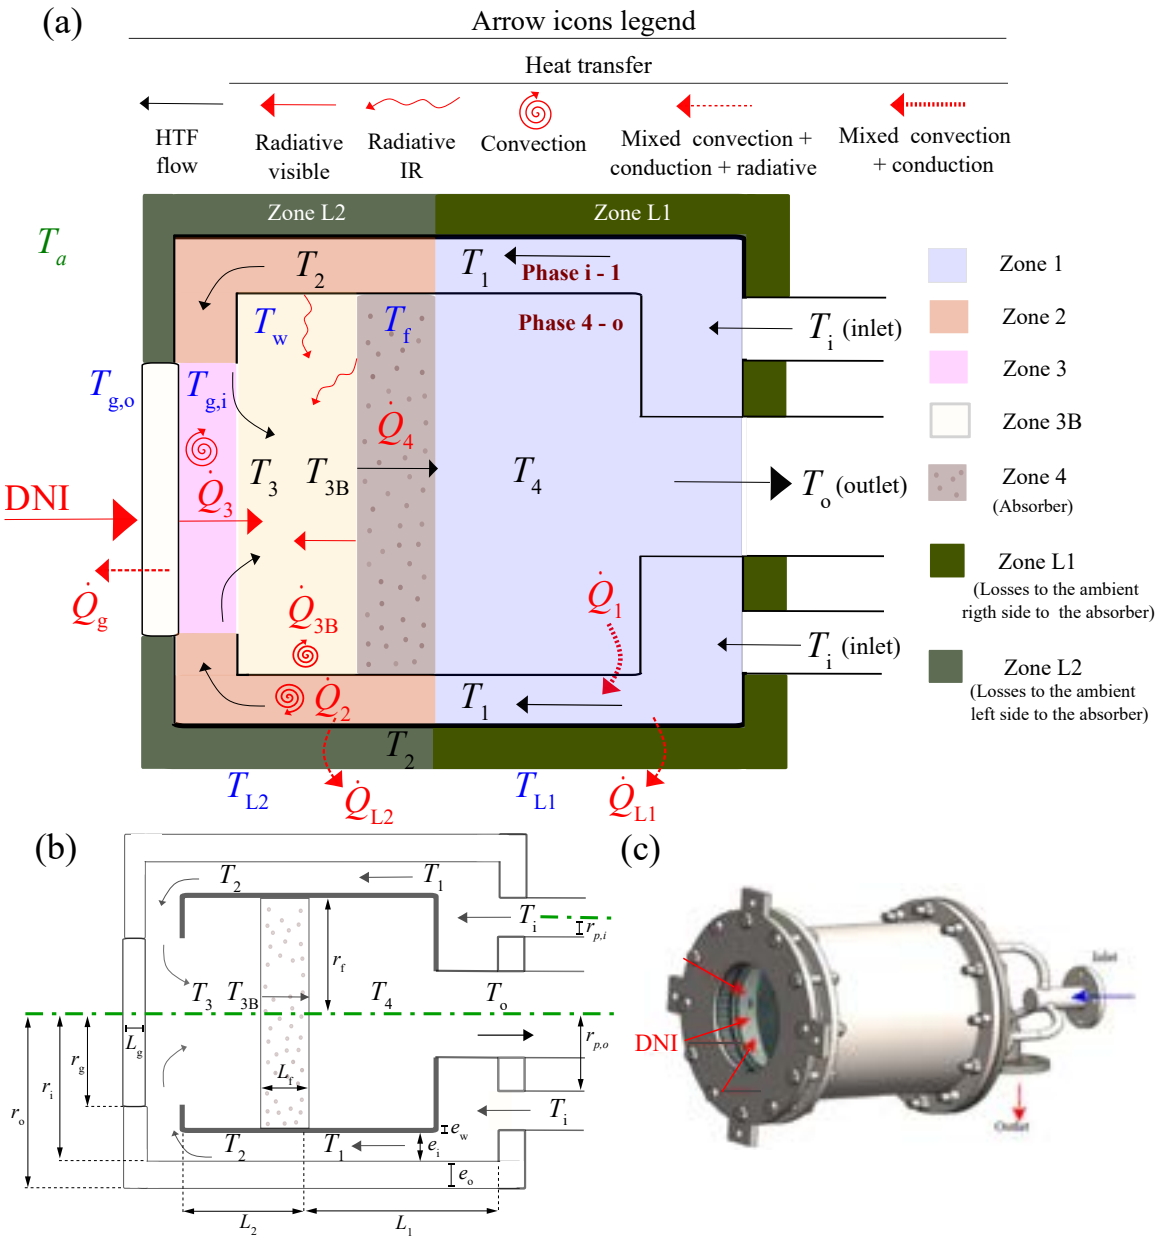

Figure 1: (a) Scheme of the receiver used for this work [6]. Air temperatures (T_i, T_1, T_2, T_3, T_{3B}, T_4 and T_o) are depicted in black. Surfaces temperatures related to glass, internal wall, absorber foam, front external insulator, and back external insulator (T_g, T_w, T_f, T_{L1} and T_{L2}, respectively) in blue and ambient temperature (T_a) is depicted in green. (b) Geometrical parameters used in the heat transfer model of the receiver. (c) 3D image of the receiver (taken from Zhu *et al.* [6]).

The solar receiver model presented hereby considers an axially cylindrical pressurized volumetric receiver with a geometrical design as shown in Fig. 1. For validation and numerical applications the design by Zhu *et al.* [6] will be considered, but the models developed in this paper could be applied to other designs and dimensions in a straightforward manner. The symmetry axis goes through the window centre and it is normal to the window surface. As commented in the Introduction, this kind of receivers are especially interesting for high-temperature applications because aperture quartz glasses can reach temperatures quite above 1000 °C and receiver thermal efficiency at such conditions can be very high. Usually, the heat transfer fluid (HTF) is pressurized air and the receiver core is a metal or ceramic foam that will be considered as a uniform medium with a given porosity (Zone 4 in Fig. 1).

All the temperatures and heat exchanges involved are included and shown in Fig. 1(a). Figure 1(b) displays the main geometric parameters considered. The HTF (air) enters the receiver at T_i temperature and crosses different zones until it arrives at the outlet, at temperature T_o. Next, a brief description of all zones is given.

- Zone 1: It can be split in two parts: phase $i-1$ (from the receiver inlet until the end of Zone 1), and phase $4-o$ (from Zone 1 after the absorbing foam until the receiver outlet). The colder air (at temperature T_i) receives heat ($\dot{Q}_1$) from the flux of air which is crossing the receiver outlet, since the latter has a higher temperature (T_o). Thus, the air arrives at Zone 2 at temperature T_1. Due to this heat exchange, the temperature at the receiver exit, T_o, is slightly lower than the air temperature just after crossing the absorber foam (T_4). The heat transfer can be modeled as a mixed convection and conduction process (similar to a heat exchanger).
- Zone 2: There is a heat transfer ($\dot{Q}_2$) through the inner cylinder wall (at temperature T_w) to the air, which rises its temperature from T_1 to T_2. $\dot{Q}_2$ comes from the thermal and visible radiation emitted by the absorber foam and the glass window to the inner cylinder wall.
- Zone 3: The air receives a heat flux $\dot{Q}_3$ by means of convection with the inner glass surface (at temperature $T_{g,i}$). Thus, the air achieves temperature T_3. Besides, the heat balance at the glass window has to be considered, and it will be further explained in detail in the following paragraphs.
- Zone 3B: The air exchanges a heat flux, $\dot{Q}_{3B}$, through convection with the inner wall surface (at temperature T_w). Hence, the air arrives at the absorber foam at temperature T_{3B}. $\dot{Q}_{3B}$ influences the energy balance at Zone 2.
- Zone 4: Here, the fluid crosses the absorber foam (at temperature T_f), receiving thus a heat flux $\dot{Q}_4$. In this stage, the air rises its temperature up to T_4. The heat transfer corresponds to a convection with the pores inside the absorber foam.

The previous brief explanation serves as an introduction to the set of equations employed for simulating the receiver. The equations are exposed in the following paragraphs but first, some considerations should be noticed:

- This work presents a steady-state model. Hence, mass balance equations ($\dot{m}_i = ... = \dot{m}_o = \dot{m}$) will be indirectly included within heat balance equations.
- Absorber foam (T_f) temperature is considered uniform along the whole material. This assumption means that T_f is the left, right and inside temperature for the absorber foam.
- The wall of the inner cylinder is considered a grey body under thermal-balance conditions. Then, its absorptivity (α_w) and emittance (ϵ_w) are equivalent. This element also possesses a uniform temperature T_w.
- It has been considered negligible the glass thermal radiation transmittance. Thus, there are no radiation losses across the glass (greenhouse effect).

As in any heat transfer process, three equations should be taken into account: heat transfer mechanisms, and mass and energy balances. As previously mentioned, mass balance is included within enthalpy balance. Regarding the pressure, it has been considered a global pressure drop of 0.2 bar [11] across the receiver. However, for each heat transfer, the pressure drop is small enough for considering it constant. Thus, within the equations, the isobaric heat capacity, $\bar{c}_p$, will be considered instead of enthalpies. The following equations describe the volumetric solar receiver model:

2.2.1. Zone 1

The heat exchange in this zone is modeled as a heat exchanger (Logarithmic Mean Temperature Difference, LMTD, expression will be considered). Then, the energy balance can be written as:

$$\dot{Q}_1 = \dot{m}\,\bar{c}_p(T)(T_1 - T_i) + \dot{Q}_{L1} = \dot{m}\,\bar{c}_p(T)(T_4 - T_o) \tag{2}$$

Here, $\dot{Q}_{L1}$ stands for the thermal losses through the insulator (Zone L1, see Fig. 1). Besides, as a heat exchanger, the heat transfer should meet the following relation:

$$\dot{Q}_1 = U_1 A_1 \frac{(T_o - T_i) - (T_4 - T_1)}{\log \dfrac{(T_o - T_i)}{(T_4 - T_1)}} \tag{3}$$

where $\bar{c}_p(T)$ stands for the average isobaric thermal capacity between temperatures T_i and T_1, or between T_4 and T_o. $\bar{c}_p(T_m)$ is calculated through REFPROP coupled with Mathematica® [12, 13]. Regarding U_1, it represents a global conduction and convection heat transfer coefficient, while A_1 stands for the effective Zone 1 area.

2.2.2. Zone 2

The heat transfer in this zone, $\dot{Q}_2$, is also modeled as a heat exchanger, where the air and the inner wall cylinder are involved. The energy balance can be written as:

$$\dot{Q}_2 = \dot{m}\bar{c}_p(T)(T_2 - T_1) + \dot{Q}_{L2} = h_{wo}A_w \frac{(T_w - T_1) - (T_w - T_2)}{\log \frac{(T_w - T_1)}{(T_w - T_2)}} \tag{4}$$

where $\dot{Q}_{L2}$ represents the thermal losses through the insulator (Zone L2 in Fig. 1) and T_1, T_2 are the air temperatures at Zone 1 and Zone 2, respectively. h_{wo} is the convective coefficient at the inner cylinder outer surface wall. A_w stands for the inner cylinder wall area, but it only comprises the wall area in between the absorber foam and the glass window. Temperature T_w is the inner wall temperature.

Finally, heat flux $\dot{Q}_2$ emitted by the wall comes from the absorber foam and from the glass window. The absorber foam releases thermal and visible radiation due to the reflection of the direct sun beam radiation (I_b) impinging on it. It also receives visible radiation from the glass window. At the same time, the wall losses energy due to the convection with the air crossing Zone 3B, and thermal radiation to the glass window are considered. Then, the following heat balance equation can be written:

$$\dot{Q}_2 = \overbrace{\tau_g\, I_b\, F_{gf}\cdot \rho_f\, F_{fw}}^{\text{Visible radiation from foam}} + \overbrace{\tau_g\, I_b\, F_{gw}(1 - \rho_w\, F_{wf} - \rho_w\, F_{wg})}^{\text{Visible radiation from glass window}} + \frac{\overbrace{\sigma(T_f^4 - T_w^4)}^{\text{Thermal radiation from foam}}}{\frac{1-\epsilon_f}{A_f\,\epsilon_f} + \frac{1}{A_f\,F_{fw}} + \frac{1-\epsilon_w}{A_w\,\epsilon_w}} - \frac{\overbrace{\sigma(T_w^4 - T_{g,i}^4)}^{\text{Thermal radiation to the glass}}}{\frac{1-\epsilon_w}{A_w\,\epsilon_w} + \frac{1}{A_w\,F_{wg}} + \frac{1-\epsilon_g}{A_g\,\epsilon_g}} - \underbrace{\dot{Q}_{3B}}_{\text{Convection with air}} \tag{5}$$

where ϵ_w, ϵ_f and ϵ_g are the wall, absorber foam and glass window emissivities, respectively. Note that the wall is being considered as a grey body in thermal equilibrium. Thus, the wall absorptivity (*i.e.* the share of energy that the wall will absorb and transfer to the air) is the same as the wall emissivity ($\alpha_w = \epsilon_w$). The share of visible radiation reflected by the foam and by the wall are represented as ρ_f and ρ_w, respectively, while τ_g is the glass window transmissivity. A_f is the cross-sectional foam area, and σ is the Stefan-Boltzmann constant. The term F_{fw} is the '*view factor*' between the foam and the wall. It represents the ratio between the amount of thermal radiation leaving the foam that hits the wall [14]. Similarly, F_{wg} is the wall-to-glass view factor, and F_{gf} is the glass-to-foam view factor. Finally, T_f and $T_{g,i}$ are the absorbing foam and the inner glass surface temperatures, respectively. $\dot{Q}_{3B}$ is the convection heat exchange between the inner wall and the fluid, which will be defined later.

2.2.3. Zone 3

Here, the air fluxes over the internal surface of the glass window. This prevents the window breakage, since the air flux lowers its temperature. On one hand, there is a convection heat transfer between the air and the inner window surface, which can also be modeled as a heat exchanger. Thus, the following equations can be used:

$$\dot{Q}_3 = \dot{m}\bar{c}_p(T)(T_3 - T_2) = h_{gi}A_g \frac{(T_{g,i} - T_3) - (T_{g,i} - T_2)}{\log \frac{(T_{g,i} - T_3)}{(T_{g,i} - T_2)}} \tag{6}$$

where h_{gi} is the convective coefficient at the glass inner surface, A_g is the cross sectional glass area, T_g is the glass window temperature and T_3, T_2 are the Zone 3 and Zone 2 air temperatures, respectively.

Besides, some other heat transfers occurs at the glass window. It receives visible radiation directly from the Sun (I_b) as well as from the absorber foam ($\sim F_{fg}\,\rho_f\,\tau_g\,I_b$). The window also receives thermal radiation from the wall and the foam. However, it also suffers convection and radiation losses with the ambient. The convection heat transfer with the air can be also considered a 'loss' at the glass window inner surface. All these phenomena can be summarized in the following expression:

$$\begin{aligned}\overbrace{\alpha_g \cdot I_b + \tau_g\, I_b\,(F_{fg}\,\rho_f\,F_{fg} + F_{gw}\,F_{wg}\,\rho_w)}^{\text{Visible radiation}} + \frac{\overbrace{\sigma(T_f^4 - T_{g,i}^4)}^{\text{Thermal radiation from foam}}}{\frac{1-\epsilon_f}{A_f\,\epsilon_f} + \frac{1}{A_f\,F_{fg}} + \frac{1-\epsilon'_g}{A_g\,\epsilon'_g}} + \frac{\overbrace{\sigma(T_w^4 - T_{g,i}^4)}^{\text{Thermal radiation from wall}}}{\frac{1-\epsilon_w}{A_w\,\epsilon_w} + \frac{1}{Aw\,F_{wg}} + \frac{1-\epsilon'_g}{A_g\,\epsilon'_g}} = \\ = \underbrace{\dot{Q}_3}_{\text{Convection with air}} + \underbrace{h_{go}\,A_g\,(T_{g,o} - T_a)}_{\text{Convection with ambient}} + \underbrace{\epsilon'_g\,A_g\,\sigma\,(T_{g,o}^4 - T_a^4)}_{\text{Radiation with ambient}}\end{aligned} \tag{7}$$

where α_g is the glass absorptance at visible wavelength. ϵ'_g is the glass emissivity at long wavelength and F_{fg} is the foam-to-glass view factor. Finally, h_{go} stands for the convective coefficient at the outer glass surface.

2.2.4. Zone 3B

Aiming to model the solar receiver as realistic as possible, it has been considered a convection heat exchange between the internal wall, on the inner side, with the fluid. This heat transfer is not considered in [6]. The energy balance equations describing this phenomena will be related to the energy balance at Zone 2 ($\dot{Q}_{3B}$ in Eq. (5)):

$$\dot{Q}_{3B} = \dot{m}\bar{c}_p(T)(T_{3B} - T_3) = h_{wi}A_w \frac{(T_w - T_3) - (T_w - T_{3B})}{\log \dfrac{(T_w - T_3)}{(T_w - T_{3B})}} \tag{8}$$

where h_{wi} is the convective coefficient at the wall inner surface, A_w is the internal wall area, T_w is the wall temperature and T_{3B}, T_3 are the Zone 3B and Zone 3 air temperatures, respectively.

2.2.5. Zone 4

At this stage, the absorbing foam exchanges heat with the air crossing through it. This occurs through convection, so the energy balance equations are:

$$\dot{Q}_4 = \dot{m}\bar{c}_p(T)(T_4 - T_3) = V_f \cdot h_{vf} \frac{(T_f - T_3) - (T_f - T_4)}{\log \dfrac{(T_f - T_3)}{(T_f - T_4)}} \tag{9}$$

where V_f is the absorber foam vacuum volume $V_f = A_f L_f \phi$. The parameters ϕ and L_f are the foam porosity and foam width, respectively. Zhu *et al.* [4, 6] only provides the pore diameter, d_p, and the Pores Per Inch, (PPI). Thus, Fu *et al.* [15] expression was used for obtaining the absorbing foam porosity: $\phi = (\pi/4)(\text{PPC}\, d_p)^2$ where PPC refers to 'Pores Per Centimeter'. It can be calculated by means of PPI.

The volumetric convective coefficient, h_{vf}, is obtained by following Barreto *et al.* [10], Wu *et al.* [16] and Fu *et al.* [15] works. Similarly to previous equations, T_4 stands for the air temperature at the foam outlet. Besides, an energy balance for the absorber foam system must be established. The foam absorbs the visible radiation coming from the glass window, but it also suffers some losses: visible radiation reflected, convection heat transfer with the air, and thermal radiation emitted to the wall and glass. So, the following equation can be written:

$$\overbrace{\tau_g\, I_b\, F_{gf}(1-\rho_f)}^{\text{Visible from glass to foam}} + \overbrace{\tau_g\, I_b\, F_{gw}\cdot F_{wf}\,\rho_w}^{\text{Visible from wall to foam}} = \dot{Q}_4 + \frac{\overbrace{\sigma(T_f^4 - T_w^4)}^{\text{Thermal radiation to the wall}}}{\frac{1-\epsilon_f}{A_f\,\epsilon_f} + \frac{1}{A_f\,F_{fw}} + \frac{1-\epsilon_w}{A_w\,\epsilon_w}} + \frac{\overbrace{\sigma(T_f^4 - T_{g,i}^4)}^{\text{Thermal radiation to the glass}}}{\frac{1-\epsilon_f}{A_f\,\epsilon_f} + \frac{1}{A_f\,F_{fg}} + \frac{1-\epsilon_g}{A_g\,\epsilon_g}} \tag{10}$$

The air temperatures at all the stages are perfectly characterized by those previous equations. However, losses through the receiver insulator must be modeled in order to obtain more precision when analyzing the system.

2.2.6. Heat losses at the insulator: Zone L1

This zone refers to the cylindrical insulator from the inlet pipes until the absorber foam plane. It also considers the plane surface surrounding the inlet and outlet pipes, as depicted in Fig. 1. The heat transfer across the insulator surfaces will be modeled as a heat exchanger. So, the heat transferred from the air to the insulator (convection and conduction) must be the same as the heat flux from the outer insulator surface to the surroundings (convection and radiation).

$$\dot{Q}_{L1} = A_{iL1}\, U_{L1} \frac{(T_1 - T_{L1}) - (T_i - T_{L1})}{\log \dfrac{(T_1 - T_{L1})}{(T_i - T_{L1})}} \tag{11}$$

where $\dot{Q}_{L1}$ denotes the heat flux that is lost through the Zone L1. A_{iL1} stands for the internal insulator area, including the cylindrical and the circular sectors ones. U_{L1} is an effective heat transfer coefficient, which accounts for the cylindrical and plane zones. Thus, $A_{iL1}\, U_{L1}$ can be written as:

$$A_{iL1}\, U_{L1} = A_{iL1.cyl}\, U_{cyl.L1} + A_{iL1.flat}\, U_{flat.L1} \tag{12}$$

where:

$$A_{iL1.cyl} = 2\,\pi\, r_i\, L_1; \qquad A_{iL1.flat} = \pi\,(r_i^2 - r_{p,o}^2 - 3r_{p,i}^2) \tag{13}$$

$$U_{cyl.L1} = \left[\frac{1}{h_{L1,in}} + \frac{r_i \cdot \log(r_o/r_i)}{k_i}\right]^{-1}; \qquad U_{flat.L1} = \left[\frac{1}{h_{L1,in}} + \frac{e_o}{k_i}\right]^{-1} \tag{14}$$

$U_{cyl.L1}$ and $U_{flat.L1}$, represent two global conduction and convection heat transfer coefficients for the cylindrical and flat areas, respectively. The insulator thermal conductivity (0.06 W/(m.K) for aluminium silicate) is denoted by k_i, e_o stands for the insulator thickness and $h_{L1,in}$ represents an average convection coefficient for the inner insulator surface. r_i denotes the inner insulator cylinder radius while r_o accounts for the external insulator radius, respectively. $r_{p,i}$ and $r_{p,o}$ are the inlet and outlet pipes radius. The effective flat area, $A_{iL1.flat}$, does not include the three inlet pipes nor the outlet pipe (see Eq. (13)). The last heat exchange occurs at the outer insulator surface, where convection and radiation with the surroundings has been considered. Thus, this phenomenon can be described through the following expression:

$$\dot{Q}_{L1} = A_{o1}\,(h_{c,L1} + h_{r,L1})\,(T_{L1} - T_a) \tag{15}$$

where A_{o1} represents the insulator outer surface area in Zone L1, including cylindrical and flat ones:

$$A_{o1} = A_{o1,cyl} + A_{o1,flat} = 2\,\pi\,r_o\,L_1 + \pi\,(r_o^2 - r_{p,o}^2 - 3r_{p,i}^2) \tag{16}$$

$h_{c,L1}$ is the convection coefficient between the outer insulator surface temperature (T_{L1}) and ambient temperature (T_a), while $h_{r,L1}$ stands for the radiation coefficient under the same conditions. This radiation coefficient can be written as follows [17]:

$$h_{r,L1} = \epsilon_{L1}\,\sigma\,(T_{L1} + T_a)(T_{L1}^2 + T_a^2) \tag{17}$$

where ϵ_{L1} is the outer insulator surface emissivity.

2.2.7. Heat losses at the insulator: Zone L2

This zone refers to the cylindrical insulator from the absorber foam plane until the glass window plane. It also takes into account the plane surface surrounding the glass window, as depicted in Fig.1. Similarly to Zone L1, the heat transfer across the insulator surfaces will be considered as heat exchangers.

$$\dot{Q}_{L2} = A_{iL2}\,U_{L2}\,\frac{(T_2 - T_{L2}) - (T_1 - T_{L2})}{\log\dfrac{(T_2 - T_{L2})}{(T_1 - T_{L2})}} \tag{18}$$

where $\dot{Q}_{L2}$ denotes the heat flux lost through the insulator front side. $A_{iL2}\,U_{L2}$ is an effective heat transfer coefficient, which accounts for the cylindrical and flat zones.

The coefficients are analogous to those explained for Eqs. (11) and (13). The only difference is that here, the temperatures involved are T_2, T_1 and T_{L2} (the outer insulator surface temperature in Zone L2) as depicted in Fig. 1. r_g stands for the receiver glass window radius.

Again, the heat released from the outer insulator surface to the surroundings, can be described by:

$$\dot{Q}_{L2} = A_{o2}\,\left(h_{c,L2} + h_{r,L_2}\right)\,(T_{L2} - T_a) \tag{19}$$

where A_{o2} represents the insulator outer surface area within Zone L2, including cylindrical and flat ones.

$h_{c,L2}$ is the convection coefficient between the outer insulator surface temperature (T_{L2}) and ambient temperature (T_a), while $h_{r,L2}$ stands for the radiation coefficient under the same conditions.

2.3. Receiver thermal energy efficiency

All previous equations allow for calculating the receiver efficiency by means of Eq. (1) through the resolution of T_o. However, $\eta_{th,rcv}$ can also be estimated by means of the heat fluxes as follows:

$$\eta_{th,rcv} = \frac{\dot{Q}_1' + \dot{Q}_2' + \dot{Q}_3 + \dot{Q}_{3B} + \dot{Q}_4 - \dot{Q}_1}{I_b} \tag{20}$$

where $\dot{Q}_1' = \dot{Q}_1 - \dot{Q}_{L1}$ and $\dot{Q}_2' = \dot{Q}_2 - \dot{Q}_{L2}$. Within Zone 1, a wall temperature, T_w, it is not considered, and the inner cylinder wall is assumed to be a heat exchanger. So, note that $\dot{Q}_1$ is not a net flux since it is gained by the fluid at the inlet (phase $i-1$) but it is lost at the output (phase $4-o$). Considering this, Eq. (20) can be rewritten as:

$$\eta_{th,rcv} = \frac{\dot{Q}_2 + \dot{Q}_3 + \dot{Q}_{3B} + \dot{Q}_4 - \dot{Q}_{L1} - \dot{Q}_{L2}}{I_b} \tag{21}$$

Finally, the efficiency can also be expressed as a function of heat losses as follows:

$$\eta_{th,rcv} = 1 - \frac{\dot{Q}_g + \dot{Q}_{L1} + \dot{Q}_{L2} + \rho_g I_b}{I_b} \tag{22}$$

where the term $\rho_g I_b$ accounts for the share of solar energy radiation reflected by the glass window.

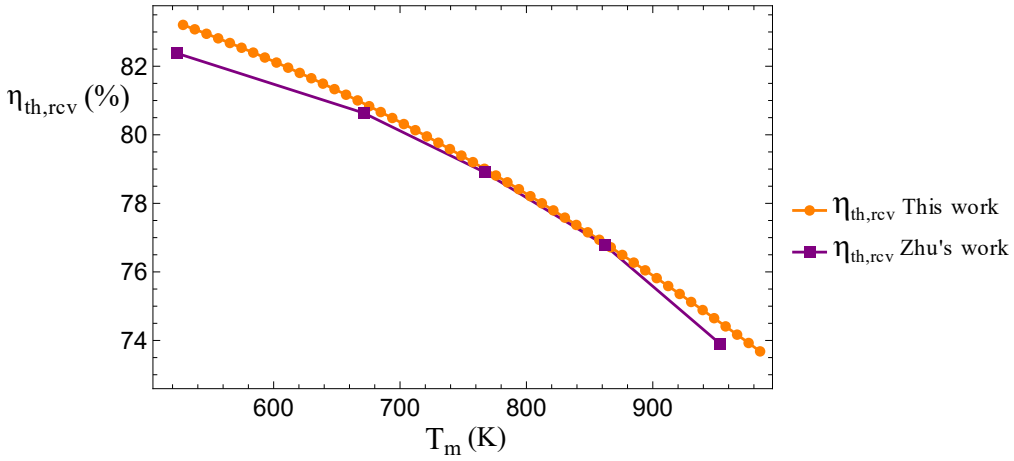

Figure 2: Solar receiver thermal efficiency as a function of mean receiver temperature, T_m: Comparison between Zhu's model (purple) [4] and this work (orange).

3. Validation

In this subsection, the validation of the solar receiver model is presented. As mentioned before, the geometry has been mainly taken from Zhu's work [4]. The optical efficiency will be taken as the same that Zhu *et al.* provide (η_d = 0.8645). In Table 1, the value of the parameters employed for the validation process are exposed. In Fig. 2, a comparison between the values obtained in this work and Zhu *et al.* [6] results is depicted. It shows a good agreement, especially in the medium zone of the temperature interval. The smallest relative difference (0.05%) is found at 861.8 K. The greater relative differences are found at the lowest temperature (1.06% at 523.9 K) and at the highest temperature (0.83% at 953.3 K). The relative difference is below 1.5% for all the cases. Thus, it can be considered that the model presented here has been validated.

4. Application

The model presented here can be used to predict the thermal receiver efficiency at specific locations with different meteorological conditions. In Fig. 3, the receiver thermal efficiency for two days is presented. The mass flow rate remains constant in these simulations. The location selected is Ouarzazate (Morocco) and the days are one day in summer (June 24th, 2021) and one day in winter (December 22th, 2021). The variation of DNI and ambient temperature (T_a) are also attached.

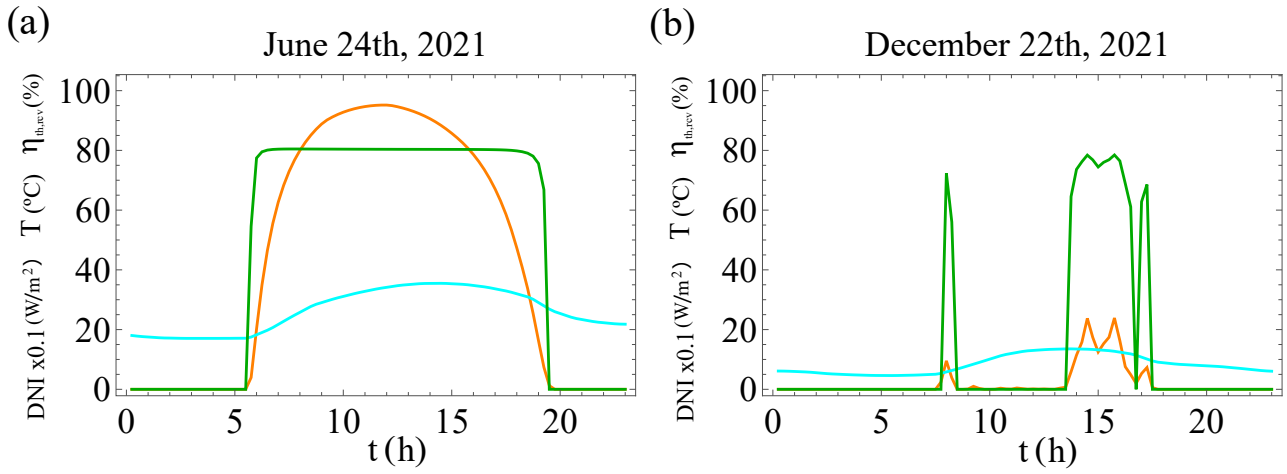

Figure 3: Solar receiver thermal efficiency along one day at Ouarzazate (Morocco). The thermal receiver efficiency, ($\eta_{th,rcv}$, (%), green), DNI (W/m^2) multiplied by 0.1 (orange) and ambient temperature (°C, cyan) are depicted together. (a) June 24th, 2021. (b) December 22th, 2021. December month is exposed for proving that, if DNI overcome a minimum value, receiver's thermal efficiency could achieve values close to the ones obtained in summer.

Table 1: Solar receiver parameters for the validation with Zhu's [6] work.* These parameters are not made explicit within Zhu's work.

Nomenclature	Value (unit)	
DNI	600 W/m^2	Solar heat flux impinging at the glass window
σ	5.67 10^{-8} W/(m^2 K^4)	Stefan Boltzmann constant
$\dot{m}$	0.04 kg/s	Mass flow rate
η_d	0.8645	Dish optical efficiency
A_d	44 m^2	Dish aperture area
Glass window		
ρ_g	0.136	Reflectivity at visible wave
τ_g	0.851	Transmissivity at visible wave
α_g	0.013	Absorptivity at visible wave
$^*\alpha'_g$	1	Absorptivity at long wave (perfect)
r_g	0.125 m	Radius
$^*L_g$	0.015 m	Glass thickness
Inner cylinder wall		
ρ_w	0.2	Reflectivity at visible wave
ϵ_w	0.8	Emissivity (grey body at thermal equilibrium)
A_w	0.1788 m^2	Total wall area (only the share of wall placed in between porous matrix and glass window)
$^*e_w$	0.001 m	Wall thickness
Foam porous matrix		
ρ_f	0.05	Reflectivity at visible wave
ϵ_f	0.95	Emissivity (grey body at thermal equilibrium)
r_f	0.182 m	Radius
L_f	0.065 m	Foam width
ϕ	0.792 (-)	Porosity
PPI / PPC	75 / 29.53	Pores Per Inch / Pores Per Centimeter
d_p	3.40·10^{-4} m	Pore diameter
d_c	1.86·10^{-3} m	Average pore cell diameter
l_s	6.58·10^{-4} m	Strut length
Geometrical parameters*		
L_1	0.195 m	Receiver length for the phase i – 1 (to the right of the foam)
L_2	0.1079 m	Receiver length for the phase 1 – 2 (to the left to the foam)
e_i	0.014 m	Radius difference between inner wall and insulator cylinders
r_i	0.136 m	Internal insulator radius
e_o	0.003 m	Insulator thickness
r_o	0.2 m	External insulator radius
Inlet and outlet pipes		
$r_{p,i}$	0.01 m	Inlet pipe radius
$^*r_{p,o}$	0.042 m	Outlet pipe radius
View factors		
F_{fg}	0.4193	Foam porous matrix to glass window
F_{fw}	0.5807	Foam porous matrix to inner wall
F_{gf}	0.8891	Glass window to foam porous matrix
F_{gw}	0.1109	Glass window to inner wall
F_{wf}	0.6069	Inner wall to foam porous matrix

Meteorological data were taken from MERRA (Modern-Era Retrospective Analysis) for the ambient temperature and from Copernicus Europe's eye on earth for the DNI data. Both of them were provided by Solar Radiation Data (SoDa) Service [18, 19]. If the DNI overcomes the minimum value of 30 W/m^2 (necessary for the set of equations to converge), the receiver thermal efficiency ranges between 80.47 % and 54.57 % in June, and between 78.45 % and 56.01 % in December.

The results in Fig. 3(a) shows an almost constant value for $\eta_{th,rcv}$ during the central hours of the day (a sunny day without DNI oscillations), reaching values above 82%. The day selected in December is a cloudy day with strong oscillations of DNI. Mean temperature is quite lower than in June. In spite of this, maximum thermal efficiency value is 78.45 % (only 2.42 % below the maximum for June, achieved at a DNI value of 768 W/m^2).

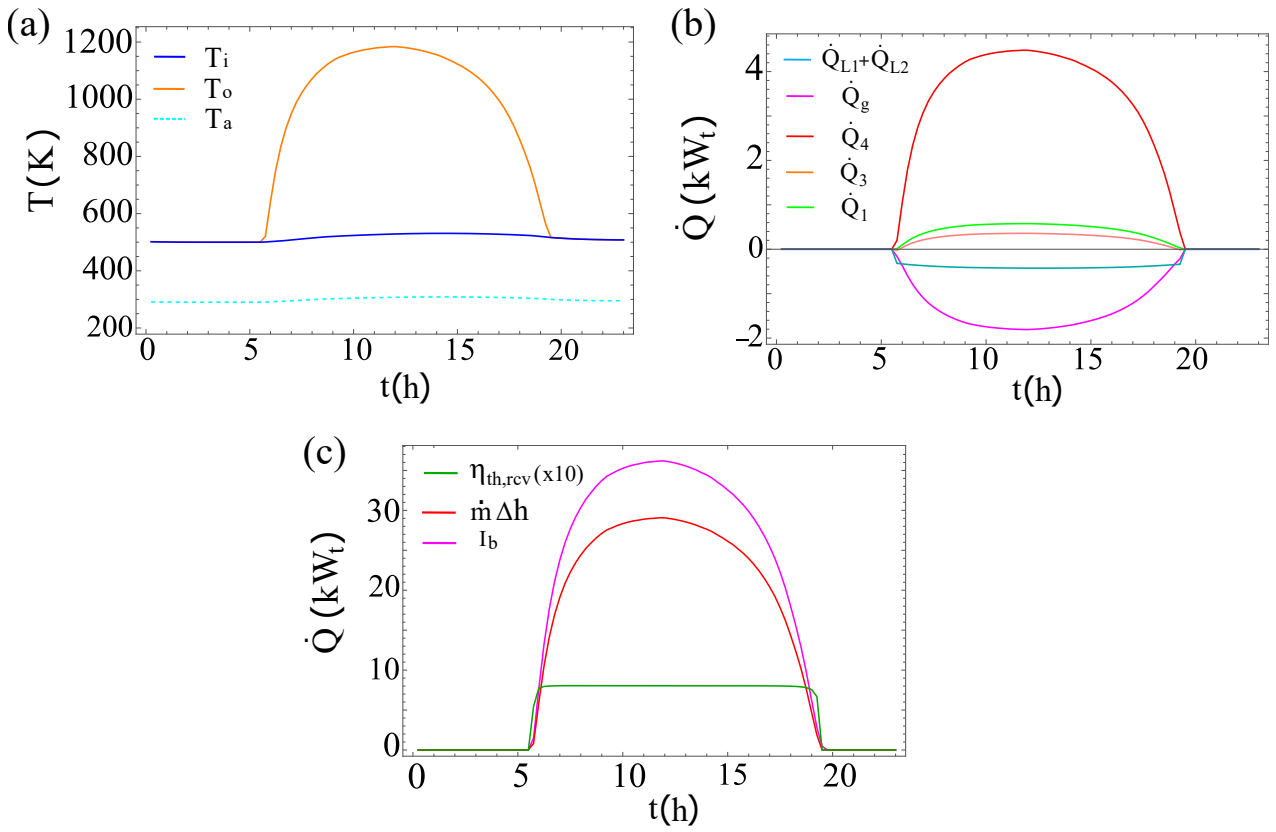

Figure 4: Solar receiver outputs throughout the day June 24th, 2021, at Ouarzazate (Morocco). (a) Inlet (orange), outlet (blue) and ambient temperatures (cyan) in K (T_i,T_o and T_a, respectively). (b) Fluid Heat fluxes ($\dot{Q}_1$ (green), $\dot{Q}_3$ (orange), $\dot{Q}_4$ (red) and losses trough the glass window ($\dot{Q}_g$ (magenta) and trough the insulator $\dot{Q}_{L1}$ + $\dot{Q}_{L2}$ (dark cyan)). $\dot{Q}_4$ is multiplied by $0.2 \cdot 10^{-3}$ and $\dot{Q}_g$ is multiplied by 10^{-3}. (c) Thermal receiver efficiency, ($\eta_{th,rcv}$ in green), is multiplied by 10. The product of mass flow and enthalpy increase ($\dot{m} \cdot \Delta h$) (red) and the solar power at the receiver window, I_b (magenta) are depicted together.

In Fig. 4, some of the output indicators of the receiver model throughout June 24th, 2021 are presented. It has been considered that during night hours, and also for DNI values below 30 W/m^2, the system is turned off. Fig. 4(a) depicts the inlet and outlet temperature (T_i (blue) and T_o (orange), respectively). While T_i seems to follow ambient temperature (T_a) shape (plotted in cyan), the outlet temperature resembles the shape of DNI during the sunlight hours. In Fig. 4(b) it is clear that the heat absorbed inside the porous foam, $\dot{Q}_4$ (red), is the highest heat flux contribution to the fluid for raising its temperature. At the same time, the heat losses through the glass window, $\dot{Q}_g$ (magenta), account for the main losses within the receiver. In Fig. 4(c), aiming to explain the receiver efficiency plateau during the day, the numerator of the Eq. 1 , $\dot{m}(\bar{h}_o - \bar{h}_i)$ was depicted in red, along with the denominator, I_b (magenta). Since the ratio between the numerator and the denominator is almost the same throughout the sunlight hours, the receiver efficiency, $\eta_{th,rcv}$, is also approximately constant during the same hours as it is seen in Fig.4(c) and Fig. 3(a).

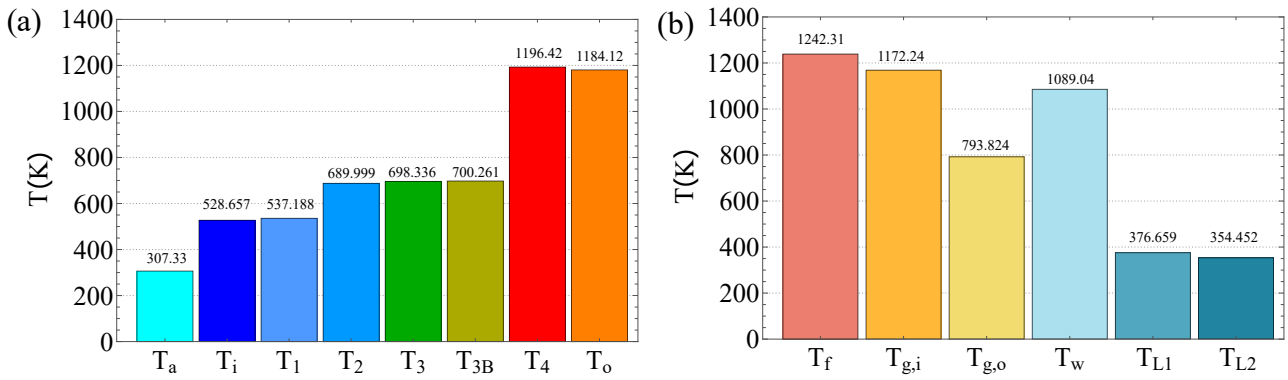

Figure 5: (a) Fluid temperatures during its flow through the receiver (see Fig. 1(a)) for notation. (b) Temperatures on receiver surfaces at the same conditions: June 24th, 2021 at noon.

Finally, in Fig. 5, the profile of the fluid (Fig. 5(a)) and receiver surfaces temperatures (Fig. 5(b)) are shown. These temperature values correspond to June 24th, 2021 at noon (12 h). In Fig. 5(a), it is depicted how the air rises its temperature from 528.7 K (T_i ,temperature at the outlet of the initial compressor) until 1196.42 K (T_4, the temperature after crossing the porous foam). The outlet temperature (T_o) is approximately 12.3 K below T_4, due to the heat exchange between the receiver outlet and inlet (Zone 1). As depicted in Fig. 5(b), the highest temperature among the surfaces is achieved at the porous foam, T_f, (1242.31 K). There is a difference of 378 K between the inner and outter glass surfaces ($T_{g,i}$ and $T_{g,o}$, respectively). This temperature difference is proportional to the heat losses across the glass window ($\dot{Q}_g$). The insulator surface temperatures for Zone L1 (376.66 K) and Zone L2 (354.45 K), are about 70 K above ambient temperature. The wall surface temperature (1089.04 K) is close to the inner glass window surface temperature, but it never overcomes it.

5. Conclusions

A physical model for heat transfers and losses in a closed pressurized solar receiver associated to a parabolic dish, small-scale, CSP system was presented. It can be applied to different receiver geometries and materials at stationary conditions. Particularly, a quartz glass on the window and a metallic foam in the absorber were considered. All the main heat transfer efficiencies are modeled and computed, allowing for a precise estimation of receiver thermal efficiency without paying an excessive computational effort. The physical mechanisms influencing receiver efficiency are identified and modeled within realistic hypotheses. This permits to calculate, for any value of DNI and ambient temperature, the temperatures of the heat transfer fluid and receiver surfaces at any stage, and also, to quantify heat transfer flows and losses to the ambient.

The ultimate goal of this kind of models is to couple it with submodels for the optical efficiency of the dish, for instance by means of a ray tracing software like Tonatiuh [20] and also with thermodynamic models for the power unit associated, as Brayton of Stirling cycles. Thus, it would be possible to analyze the behaviour of the whole system and to propose improvements for design or operation with enough precision and without applying to techniques requiring a huge computational effort.

Abstract:

The storage of cryogenic fuels such as liquid hydrogen (LH_2) or liquefied natural gas (LNG) poses significant thermal and mechanical loads to the tanks that store them because of the considerable temperature gradients produced during filling operation and sloshing. This work presents a numerical investigation of the transient heat conduction within the walls of an insulated cryogenic tank undergoing sloshing. The unsteady heat conduction is analyzed by modeling the sloshing as a spatially distributed and time-varying boundary condition on the inner side of the tank. The scaling laws of the problem are analyzed by combining the characteristic time scale of heat conduction with the characteristic time scales of the sloshing. The modulation of sloshing-induced thermal fluctuations is then analyzed across the wall thickness and in the circumferential direction. The resulting dimensionless modulation map allows for analyzing the tank's thermal response for different designs.

Keywords:

Cryogenics, Cryogenic liquid storage, Heat transfer and thermal insulation, Sloshing,

1. Introduction

Cryogenic tanks store liquefied fuels such as liquid hydrogen (LH_2) or liquefied natural gas (LNG) at extremely low temperatures, ranging from 20 to 110 K. Consequently, the walls of these tanks experience significant temperature gradients during all the phases of their operating cycle (e.g., chill-down, filling, pressurization), and the design and optimization of their thermal response raise many challenges. The tank wall and the insulation layers should minimize the heat ingress to minimize the boil-off of the cryogenic liquid and, thus, the need for venting to avoid overpressurizing the tank. Moreover, the tank weight should be minimized in all transport applications to maximize the payload without compromising its mechanical resistance. The need for these compromises has motivated various experimental and numerical investigations on the thermo-mechanical analysis of these tanks.

Heathman et al. [1] experimentally characterized a cryogenic tank for space applications and measured the effect of boil-off and different insulation strategies on the wall temperature. Murugan, Starvin, and Dhas[2], the authors studied the behavior of a hydrogen tank during the chill-down process using thermo-structural finite elements analysis to estimate the heat transfer and induced deformations. Similarly, Rao and Jagadeesh [3], and Ko [4] used finite elements to characterize the structural and thermal stress of a hydrogen tank under high-pressure loads and heating/cryogenic cooling. Craig and Hanna [5] studied the thermal response of a LH_2 tank subjected to extreme heating profiles using 1D/2D finite differences models to determine the boil-off level as a function of the insulation strategy.

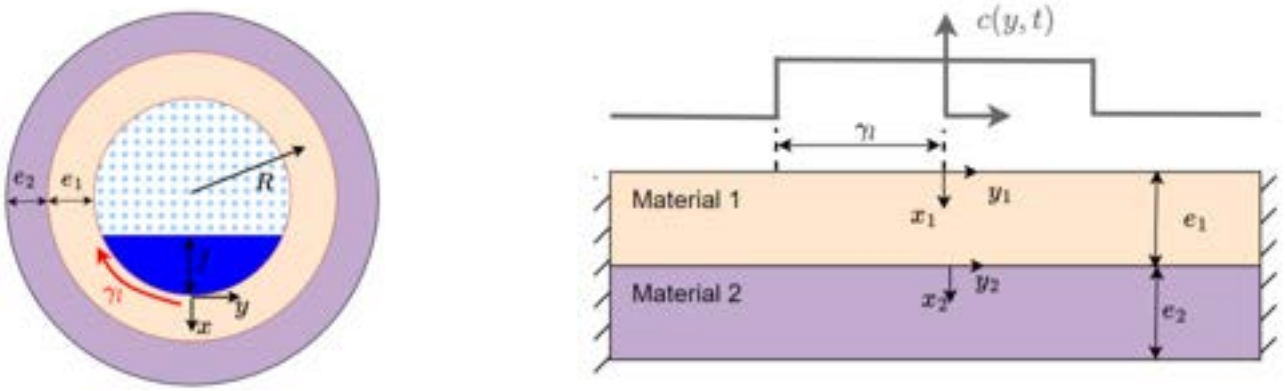
Furthermore, the inner tank material in contact with the fluid must be carefully chosen, especially for hydrogen storage, as its molecules are likely to penetrate through the solid [6] and embrittle the materials [7, 8]. This has promoted using metallic materials such as stainless steel, aluminum alloys, and nickel alloys, combined with multilayer and vacuum insulation [9]. The latter consists of alternating layers of reflective and insulating materials to minimize radiation and conduction heat transfer. For hydrogen tanks, an aluminum alloy inner layer offers a slow permeation rate and is less subject to embrittlement [10]. Such an approach was also shown to minimize boil-off due to "hot spots" by spreading the localized heat leaks through the metal's high conductivity [11]. In the aforementioned studies, the effect of sloshing has not been considered by focusing either on static storage or a perfectly mixed tank. However, an appreciable temperature difference (up to 15 K, [12, 13]) can be produced between the liquid and the ullage gas. Sloshing can thus induce additional time-varying thermal loads on the tank's wall [14]. This is especially critical in metallic alloys, which are known to suffer from crack propagation and *thermal fatigue* when undergoing repeated thermal cycles [15].

This work investigates the thermal response of a horizontal cylindrical tank undergoing lateral sloshing. We consider a simplified model in 2D, leveraging the large aspect ratios in most common tank designs and allowing for fast numerical integration of the heat conduction problem. The thermal response is analyzed in a dimensionless form to link the modulation of temperature fluctuations to the dimensionless numbers scaling the problem.

The rest of the article is structured as follows. Section 2. introduces the problem set, with its simplifying assumptions and the numerical methods and investigated test cases. Section 3. collects the results regarding thermal propagation across the wall's thickness and along the circumferential direction. Finally, section 4. collects conclusions and perspectives for future work.

2. Problem set

The configuration investigated in this work is illustrated in the schematic of Fig. 1a. We consider a horizontal cylindrical tank with radius R and thickness e_1, insulated with a cylindrical shell of thickness e_2 and filled with a liquid up to a level f. The extension of the tank along its axis (i.e. orthogonal to the paper) is large enough to allow considering the problem in 2D, in the plane (x, y) introduced in the figure.



(a) Cross view of the cylinder

(b) Two-dimensional simplification of the tank wall geometry

Figure 1: Schematic views of the tank geometry and 2D domain considered in this work.

Assuming that the tank's thickness is much smaller than its circumference (i.e. $e_1, e_2 \ll 2\pi R$), we replace the curvilinear coordinates with Cartesian ones and construct a 2D domain by unwrapping the cylinder and the shell (see Fig. 1b). We treat the heat conduction problem in the cylinder and the insulation shell with two distinct domains, herein distinguished with subscripts 1 and 2.

On the inner side of the wall, in contact with the liquid and ullage gas, we define the fluid temperature as $T_f(y_1, t) = T_l c(y_1, t) + T_g(1 - c(y_1, t))$, where T_l and T_g are the (constant) temperatures on the liquid and the ullage gas respectively and $c(y_1, t) \in [0, 1]$ is a color function equal to 1 where the solid is contact with the liquid and 0 when it is contact with the gas. The temperature difference $\Delta T = T_g - T_l$ is encountered in cryogenic tanks because of heat leaks and/or pressurization as well as evaporation and the natural tendency of the liquid to be subcooled with respect to the interface [12, 13]. By keeping the temperature of the fluids constant in time, we assume no thermal mixing and no mass exchange (evaporation/condensation) between the two phases, at least within the sloshing time scale of interest.

The 2D heat conduction problem and the boundary conditions considered in this work for the two domains $\Omega_1 := x_1 \in [0, e_1] \times y_1 \in [-\pi R, \pi R]$ and $\Omega_2 := x_2 \in [0, e_2] \times y_2 \in [-\pi R, \pi R]$ are

$$
\begin{cases}
\partial_t T_1(x_1, y_1, t) & = \alpha_1(\partial^2_{x_1} T_1 + \partial^2_{y_1} T_1) \\
T_1(0, y_1, t) & = T_f(y_1, t) \\
\quad \text{or} & \\
\kappa_1 \partial_x T_1(0, y_1, t) & = h_f(T_1(0, y_1, t) - T_f(y_1, t)) \\
T_1(e_1, y_1, t) & = T_2(0, y_2, t) \\
T_1(x_1, -\pi R, t) & = T_1(x_1, \pi R, t)
\end{cases}
\quad \text{and} \quad
\begin{cases}
\partial_t T_2(x_2, y_2, t) & = \alpha_2(\partial^2_{x_2} T_2 + \partial^2_{y_2} T_2) \\
T_2(0, y_2, t) & = T_1(e_1, y_1, t) \\
\kappa_2 \partial_x T_2(e_2, y_2, t) & = h_a(T_2(e_2, y_2, t) - T_a) \\
T_2(x_2, -\pi R, t) & = T_2(x_2, \pi R, t)
\end{cases}
\tag{1}
$$

where α_1, α_2 are the heat diffusivities, and κ_1, κ_2 are the thermal conductivities for the two materials. On the inner condition problem, we consider two scenarios for the boundary conditions on the surface in contact with the fluid: (1) a Dirichlet boundary condition or (2) a Robin boundary condition with heat transfer coefficient h_f. The assumption of Dirichlet conditions on the inner wall is purely demonstrative and rather unphysical. Considering the large differences in the thermal effusivities of the fluid (whether liquid or gas) and the solid, the surface temperature at the contact between the two is expected to be much closer to the latter than the former. However, from the thermal loading point of view, the two investigated problems can be seen as the two extremes between the actual loads are expected.

The two solid domains communicate with a Dirichlet boundary condition at $x_1 = e_1$, $x_2 = 0$ while a Robin boundary condition is considered on the external surface of the insulation, with heat transfer coefficient h_a. Periodic boundary conditions are introduced in $y = -\pi R$ and $y = \pi R$ for both domains, as both locations are at the top of the cylinder.

To model the occurrence of a sloshing event, we treat the color function with an imposed variation in space and time (see Fig. 1b). This is a square wave with half-width γ_l, oscillating with an amplitude A_f and an angular frequency ω. Focusing on lateral sloshing, the oscillation frequency is taken as the one corresponding to the first sloshing mode in potential flow theory [16]. This is usually the first to be triggered and most prominently present in the sloshing response. According to Lamb[17] for an horizontal tank this is $\omega = \sqrt{1.37g/(R - e_1)}$, with g the gravitational acceleration. Concerning the sloshing amplitude A_f and width γ_l, computed from the filling level. Throughout the modeling of the sloshing, we focus on planar waves [16]. Furthermore, the temperature of the fluids is kept constant, thus assuming no thermal mixing between the two phases. Finally, evaporation due to heat ingress or condensation due to thermal mixing are not considered.

2.1. Scaling and dimensionless formulation

To scale the problem, we consider the dimensionless coordinates $\hat{x}_j = x_j/e_j$ and $\hat{y}_j = y_j/2\pi R$, with $j = 1, 2$, the dimensionless temperatures $\theta_j = (T_j - T_l)/(T_g - T_l)$, and the dimensionless time $\hat{t} = \omega t/2\pi$. The resulting dimensionless problem in $\hat{\Omega}_1 := x_1 \in [0,1] \times \hat{y}_1 \in [-1/2, 1/2]$ and $\hat{\Omega}_2 := \hat{x}_2 \in [0,1] \times \hat{y}_2 \in [-1/2, 1/2]$ becomes:

$$
\begin{cases}
\partial_t \theta_1(\hat{x}_1, \hat{y}_1, \hat{t}) & = Fo_1(\partial^2_{\hat{x}_1}\theta_1 + \varepsilon_1^2 \partial^2_{\hat{y}_1}\theta_1) \\
\theta_1(0, \hat{y}_1, \hat{t}) & = 1 - c(\hat{y}_1, \hat{t}) \\
\quad \text{or} & \\
\partial_{\hat{x}_1}\theta_1(0, \hat{y}_1, t) & = Nu_f(\theta_1(0, \hat{y}_1, t) - 1 + c(\hat{y}_1, \hat{t})) \\
\theta_1(1, \hat{y}_1, \hat{t}) & = \theta_2(0, \hat{y}_2, \hat{t}) \\
\theta_1(\hat{x}_1, -1/2, \hat{t}) & = \theta_1(\hat{x}_1, 1/2, \hat{t})
\end{cases}
\quad \text{and} \quad
\begin{cases}
\partial_t \theta_2(\hat{x}_2, \hat{y}_2, \hat{t}) & = Fo_2(\partial^2_{\hat{x}_2}\theta_2 + \varepsilon_2^2 \partial^2_{\hat{y}_2}\theta_2) \\
\theta_2(0, \hat{y}_2, \hat{t}) & = \theta_1(1, \hat{y}_1, \hat{t}) \\
\partial_{\hat{x}_2}\theta_2(1, \hat{y}_2, \hat{t}) & = Nu_a(\theta_2(1, \hat{y}_2, \hat{t}) - \theta_a) \\
\theta_2(\hat{x}_2, -1/2, \hat{t}) & = \theta_2(\hat{x}_2, 1/2, \hat{t})
\end{cases}
\tag{2}
$$

where $Fo_j = 2\pi\alpha_j/(e_j^2\omega)$ are the Fourier numbers in the two domains, $Nu_f = h_f e_1/\kappa_1$ and $Nu_a = h_a e_2/\kappa_2$ are the Nusselt numbers in the inner and outer surfaces, and $\varepsilon_j = e_j/2\pi R$ are the thickness to circumference ratio of the two domains.

The Nusselt number on the outer surface was computed using a classic correlation of natural convection over on horizontal cylinder [18]:

$$
Nu_a = \left(0.6 + \frac{0.387 Ra_a^{1/6}}{[1 + (0.559/Pr_a)^{9/16}]^{8/27}}\right)^2 \tag{3}
$$

where $Ra_a = g\beta_a(T_a - T_2(e_2)(D_o)^3)/(\nu_a^2)Pr_a$ is the Rayleigh number based on the outer diameter $D_o = 2R + e_1 + 2e_2$ as a reference length, the external wall temperature $T_2(e_2)$. This is computed during the simulation and the air properties at ambient temperature while the air's Prandtl number at ambient temperature Pr_a is constant.

The Nusselt number on the inner surface is computed using two correlations depending on the inner Richardson number :

$$
Ri_f = \frac{Gr_f}{Re_r^2} = \frac{g\beta_f(T_a - T_1(0))(R_i)^3)}{A_f^4\omega^2} \tag{4}
$$

where the Reynolds number was defined as in [19] and the properties β_f and ν_f and Pr_f are computed using the color function $c(y_1, t)$ for weight-averaging liquid and gas properties. Natural convection is considered $Ri > 10$, while forced convection is assumed if $Ri_f < 0.1$ [20]. A mixed regime appears between these two boundaries.

Therefore, depending on Ri_f the Nusselt number on the inner surface is

$$\begin{cases} Nu_f = Nu_{f,F} = 0.680 Re^{1/2} Pr^{1/3} & \text{if } Ri < 0.1 \\ Nu_f = Nu_{f,N} = 0.605 Ra_f^{1/3} & \text{if } Ri > 10 \\ Nu_f = (Nu_{f,F}^3 + Nu_{f,N}^3)^{1/3} & \text{if } Ri \in [0.1, 10] \end{cases} \tag{5}$$

All fluid properties used in the above correlations were computed from the library *CoolProp* [21] using air for the ambient side and liquid/gaseous hydrogen or methane for the fluid side. Typical values for the thermophysical properties of the materials considered in this work are summarized in Table 1 while the usual ranges for the Nusselt numbers are given in Table 2.

Table 1: Properties and typical thickness of the materials considered in the composition of the walls.

Material	κ [W/m/K]	α [mm^2/s]	e [mm]
Al 6061 (domain 1) [22]	162	65.4	1-20
SST 316 (domain 1) [22]	16.3	4.1	1-20
Polyurethane foam (domain 2) [23]	0.05	2.2	10-200
High Density Polyethylene (domain 2) [24]	0.04	0.02	10-200

Table 2: Typical Nusselt number range

Fluid	Gas phase	Liquid phase
Air	70-140	-
Hydrogen	100-2500	6000-10000
Oxygen	100-1200	6800 - 7300
Methane	100-800	3800 - 4300

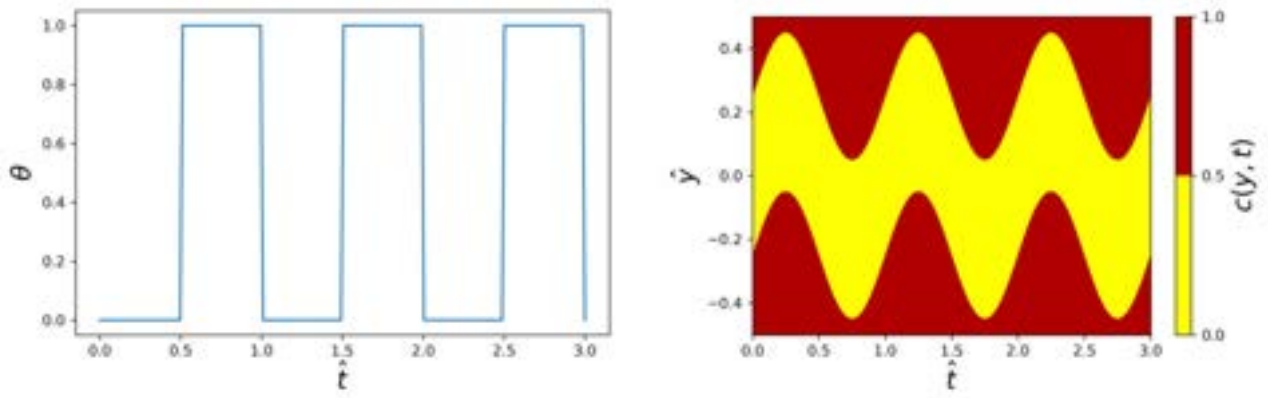
2.2. Numerics and selected test cases

The problems in (2) were solved using the method of lines. This approach consists of discretizing the equation's spatial derivatives and transforming the resulting expressions into a system of ordinary differential equations (ODEs) in time. The spatial derivatives were computed using second-order finite difference while the time integration was carried out using the LSODA solver [25] from the ODEINT package in SciPy [26]. Prior to introducing the sloshing perturbation, the thermal field is initialized with the steady solution at rest, i.e., without fluid motion.

We consider two aspects of the tank's thermal response. First, we focus on the thermal response across the wall thickness. To this end, we reduce the problem to a 1D domain by setting $\varepsilon_1, \varepsilon_2 \to 0$ in (2) and study the dimensionless temperature evolution at the height of the interface at rest, that is $\hat{y}_1 = \gamma_l$). For the half-filled tanks considered in this work, this is $\hat{y}_1 = 1/4$ (or $\hat{y}_1 = -1/4$). In this location, the oscillation of the color function in the dimensionless domain $c(\gamma_l/(2\pi R), \hat{t})$ produces a square wave of unitary amplitude, unitary period and 50% duty cycle (see Fig. 2). Second, we focus on the circumferential propagation of heat by analyzing the full 2D problem. Considering a half-filled tank, the interface is centered at $\hat{y}_1 = \pm 1/4$ and oscillates harmonically in time with unitary period and dimensionless amplitude $\hat{A}_f$. An example of the corresponding spatiotemporal evolution for an amplitude $\hat{A}_f = 0.2$ is shown in Fig. 2.

Table 3: Test matrix summarizing the main parameters for the 1D and 2D simulations presented in this work.

Case	Model	θ_a	ε_1	ε_2	Fo_1	Fo_2	Fluid BC	No. layers
1	1D	28.8	0	0	[7e-5, 300]	-	Dirichlet	1
2	1D	28.8	0	0	[7e-5, 300]	-	Robin	1
3	1D	28.8	0	0	[1e-3, 80]	[1e-5, 30]	Robin	2
4	2D	28.8	1e-3	7e-3	5e-2	6	Robin	2



(a) (b)

Figure 2: (a) Dimensionless temperature evolution at $\hat{y}_1 = \gamma_l$ in the 1D problem and (b) spatiotemporal evolution of the color function used to simulate sloshing $c(y, t)$ in the 2D problem. In both cases, the tank is considered to be half-filled.

The simulations were carried out with n_x = 100 grid points across the thickness ($\hat{x}$) and n_y = 70 points across the circumferential coordinate ($\hat{y}$) for a total of 10 oscillation periods. A grid dependence study proved that this discretization was sufficient for our needs. Four test cases are considered, and their settings are reported in Table 3. Case 1 considers a 1D problem with a single layer, with Fourier numbers ranging from 7×10^{-5} to 300. To give an order of magnitude, a representative Al6061 tank from [27], with R = 0.5 m and e_1 = 5 mm (see Table 1), shielded by a shell of e_2 = 3 cm thick Polyurethan foam leads to $Fo_1 \approx 6$ and $Fo_2 \approx 5 \times 10^{-3}$. Dirichlet boundary conditions are considered in Case 1, with a dimensionless ambient temperature of θ_a = 28.8. This represents a test case with T_l = 20K, T_a = 293K, and $\Delta T = T_g - T_l$ = 10 K. Case 2 is identical to Case 1 but considers Robin boundary conditions in the inner wall. Case 3 considers a multi-layer problem, maintaining the 1D formulation, while Case 4 considers the multi-layer problem using a 2D formulation.

To quantify the dimensionless thermal response of the tank wall to the sloshing-induced thermal excitation, we define the dimensionless thermal modulation as

$$\mathcal{H}(\hat{x}, \hat{y}) = \max(\theta(\hat{x}, \hat{y})) - \min(\theta(\hat{x}, \hat{y})). \tag{6}$$

This is only a function of $\hat{x}$ in the 1D problem (having fixed $\hat{y} = \pm 1/4$). Moreover, we define the thermal penetration depth as the distance from $\hat{x}_1 = 0$, or $\hat{x}_2 = 0$, along the wall thickness, within which $\mathcal{H} > 0.1$, hence $\mathcal{H}(\hat{x} = \hat{d}) = 0.1$.

3. Results and discussion

The results for the one-dimensional simulations (Cases 1,2,3 in Table 1) are presented in section 3.1. while the results for the two-dimensional simulations (Cases 4 in Table 1) are presented in section 3.2..

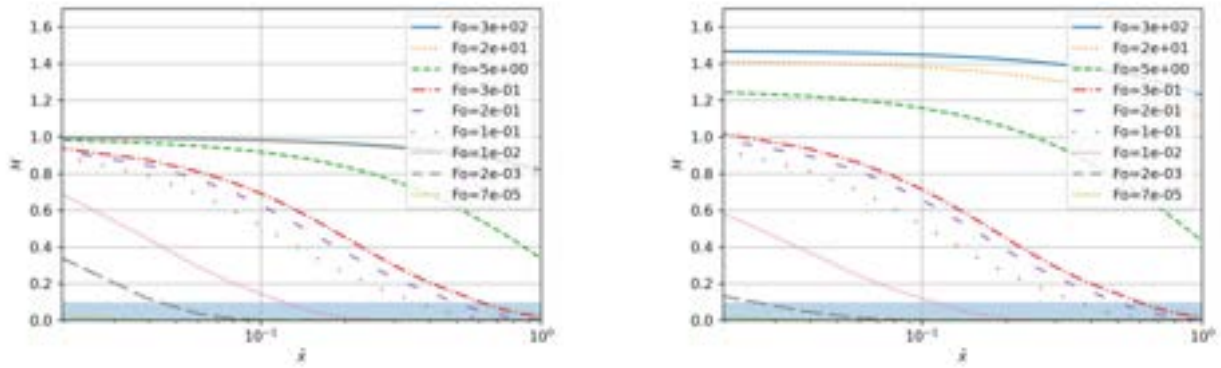
3.1. One-dimensional model

3.1.1. Single layered tank wall response to sloshing excitation

Focusing on the single-layered wall (Cases 1 and 2 in Table 1), Fig. 3a and 3b show the distribution of $\mathcal{H}$ across the tank's thickness $\hat{x}$ with the Dirichlet and Robin boundary conditions on the inner wall, respectively, for a broad range of Fourier numbers. Since only one layer is considered, no subscripts are used in the legends. The colored area in both figures defines the region $\mathcal{H} < 0.1$, indicating where the sloshing-induced thermal oscillations are considered negligible.

These figures show that the penetration depth $\hat{d}$ remains identical with both boundary approaches. Furthermore, in both cases, for $Fo > 3 \times 10^{-1}$, the sloshing perturbation causes the thermal oscillations to propagate through the entire thickness, producing $\mathcal{H}(1) \sim 1$. Then, as $Fo \to 0$, the thermal fluctuations are increasingly damped, pushing the penetration depth to zero (i.e., $\hat{d} \to 0$). In such a case, the time scale of the sloshing excitation is negligible compared to the time scale of diffusion. In fact, as $Fo < 10^{-2}$, the perturbations are significantly damped in the close vicinity of the wall.

The key difference between Cases 1 and 2 is the value of the thermal modulation in the vicinity of the inner wall (i.e., $\mathcal{H}(0)$). While the Dirichlet condition imposes the perturbation to be bounded between 0 and 1, the convective boundary condition can amplify it beyond these bounds. This means that the inner wall becomes



(a) (b)

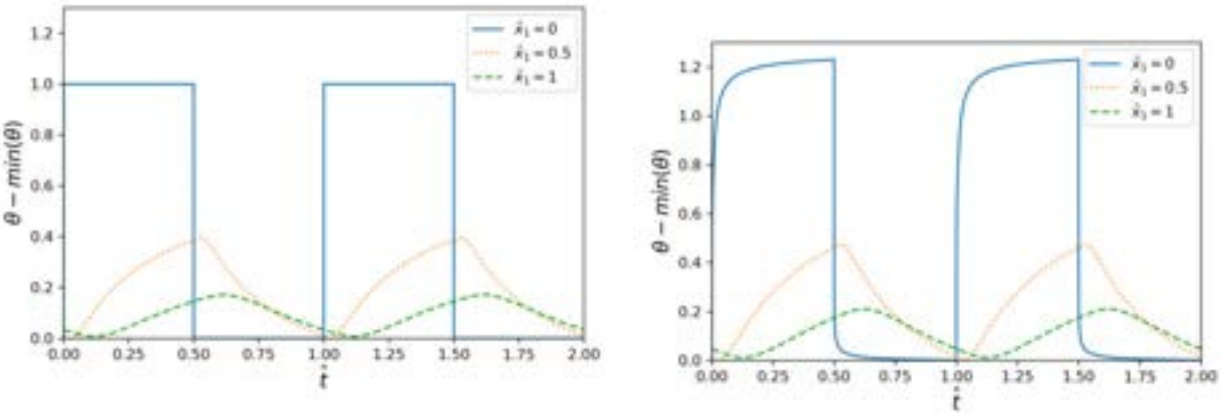
Figure 3: One-dimensional transfer function along non-dimensional wall thickness for different *Fo* numbers. (a) Dirichlet boundary condition on the fluid side and (b) Robin boundary condition on the fluid side.

warmer than the gas. One can show that the steady state solution of the 1D heat equation (2) with Robin boundary conditions on both ends leads to the following inner wall temperature:

$$\overline{\theta}(0) = \frac{(Nu_f Nu_a - Nu_f)\,(1 - \overline{c}(\gamma_l)) + Nu_a \theta_a}{Nu_f Nu_a + Nu_a - Nu_f}. \tag{7}$$

Therefore, provided that $\theta_a > 1$, the inner temperature is always warmer than the fluid at equilibrium, i.e. $\overline{\theta}(0) > 1 - \overline{c}(\gamma_l)$ with $\overline{c}(\gamma_l) = 0$ for the gas and 1 for the liquid. From Equation (7), it is clear that temperature overshoot increases as Nu_f decreases. Thus, since the Nusselt number of the gas is one order of magnitude lower than the liquid's (see Table 2), the temperature overshoot in the regions in contact with the gas is larger than in the liquid phase. Consequently, as shown in Fig. 3b, the thermal modulation reaches values greater than unity for $Fo > 3 \times 10^{-1}$.

This phenomenon is more evident in Fig. 4, which shows the dimensionless evolution of temperature in time at $\hat{x}_1 = 0, 0.5, 1$ with Dirichlet (a) and Robin (b) boundary conditions for $Fo = 3.9$. This case is representative of an aluminum layer within the typical thickness in Table 1. The Robin boundary condition introduces a delay in the transfer of the perturbation to the inner side of the wall, as depicted by the solid line in Fig. 4b. This delay further attenuates the perturbation when the time scale of the excitation is much smaller than the one of diffusion, i.e. $Fo << 1$, compared to the Dirichlet approach. This effect can be visualized for $Fo = 10^{-2}$ and $Fo = 2 \times 10^{-3}$ on Fig. 3.



(a) (b)

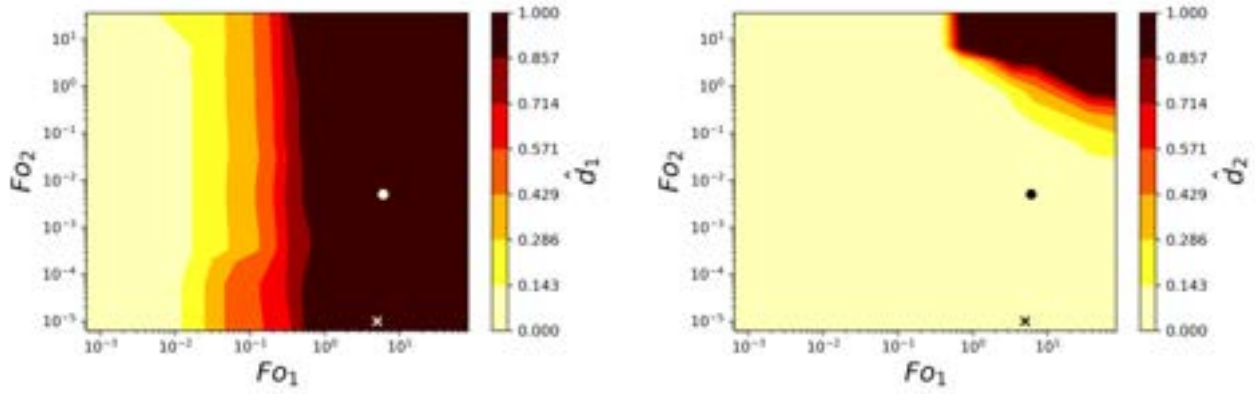
Figure 4: Evolution of the temperature with dimensionless time at different depths of the single-layered wall, $Fo = 3.9$. (a) Dirichlet boundary condition on the fluid side and (b) Robin boundary condition on the fluid side.

While the Dirichlet simplification provides a good estimate of the penetration depth and allows for identifying the critical Fourier number above which the perturbation reaches the ambient side as $Fo = 3 \times 10^{-1}$, it fails

at representing the amplification/attenuation phenomena. Indeed, as this approach forces the inner side of the wall to be at the fluid temperature, the wall overheating due to external heat flux cannot be considered. In addition, the delay introduced by the thermal inertia is under-predicted. In the following, we focus on the convective boundary condition on the fluid side.

3.1.2. Multi-layered tank wall response to sloshing excitation

As cryogenic tanks are usually made of multi-layered materials, we investigate the influence of the different layer compositions and thicknesses for the dual-layered tank (Case 3 in Table 3). To represent the state-of-art tank layout, a conductive material is placed on the fluid side while an insulating material is placed on the ambient side. Thus, we study the thermal response of the two layers as a function of their respective Fourier numbers for the ranges indicated in Table 3. Figure 5 shows contour maps of the penetration depth within the two layers as a function of the Fourier number combination. Similarly, Fig. 7 represents the maximum value of thermal modulation encountered in each layer, i.e. $\mathcal{H}_1(0)$ and $\mathcal{H}_2(0)$. In these figures, the circle and cross points locate existing hydrogen tanks of respective dimensions $R \approx 0.5$ meters [27] and $R \approx 1.5m$ [28]. The dimensionless temperature evolution of the circle point is depicted in Fig. 6.



(a) (b)

Figure 5: Contour plot of dimensionless penetration depths of a dual-layered cryogenic tank wall as a function of the layer *Fo* numbers. (a) Penetration depth on the fluid side material and (b) penetration depth on the ambient side material

Figure 5a shows the penetration depth in the first layer (material 1 in Figure 1), computed as in the previous condition, while Figure 5b shows the same quantity in the second layer (material 2 in Figure 1). The thermal fluctuation reaches the second layer by traveling the first layer only if $Fo_1 > 3 \times 10^{-1}$. When this occurs, the fluctuation can travel through the second layer if $Fo_2 > 10^{-1}$ (note that one has $\hat{d}_2 > 1/3$ for $Fo_2 > 10^{-1}$ 5b).

Figures 6 shows the dimensionless temperature fluctuation at $\hat{x}_1 = 0, 0.5, 1$ for the multilayer condition in the case of $Fo_1 = 3.9$, $Fo_2 = 10^{-5}$ (configuration labelled with a circle in figures 5). In this condition, the oscillation period is large enough to let the wall reach equilibrium before the solid comes into contact with a different

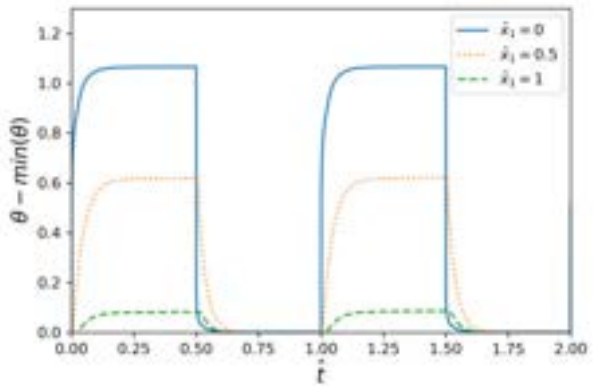


Figure 6: Evolution of the temperature with dimensionless time at different depths of the fluid side material for a dual-layered wall, $Fo_1 = 3.9$, $Fo_2 = 10^{-5}$ (circle marker in Figure 5).

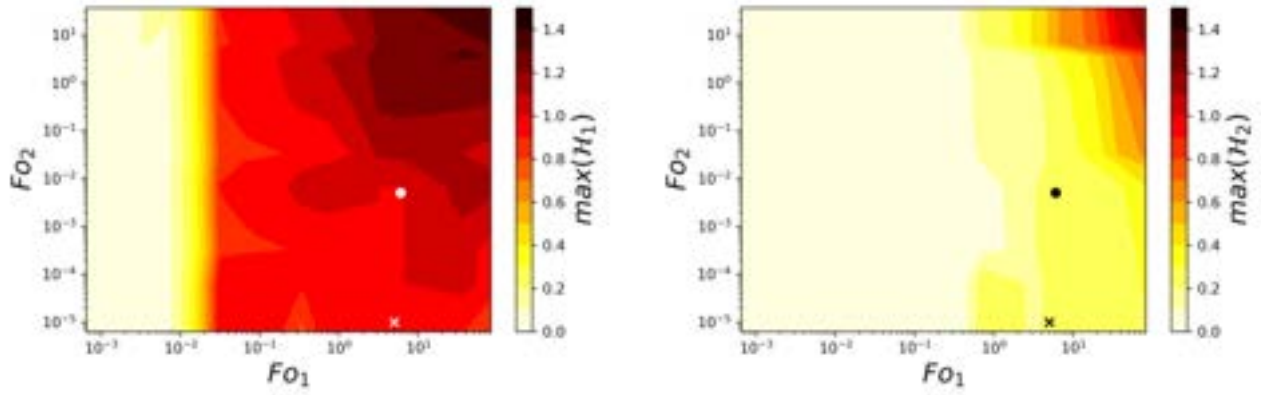
phase. Figures 7a and 7b show the maximum value of the dimensionless modulation $\mathcal{H}$ in both materials for the same range of Fourier numbers considered in the previous figures. These figures show that the penetration length for the inner material is almost independent of the outer one, but the amplification in the inner (more conductive) material is influenced by the Fourier number of the outer (insulation) layer. The amplification of the thermal oscillation is reduced as $Fo_2 \to 0$. As Fo_2 tends to 0, the ambient side material mitigates the external heat ingress, thus tempering the overheating of the inner side with respect to the ullage gas. It is interesting to note that the insulation layer always receives an attenuated perturbation, as depicted in Fig. 7b, except for extreme Fourier number values, i.e. $Fo_{1,2} > 10$.



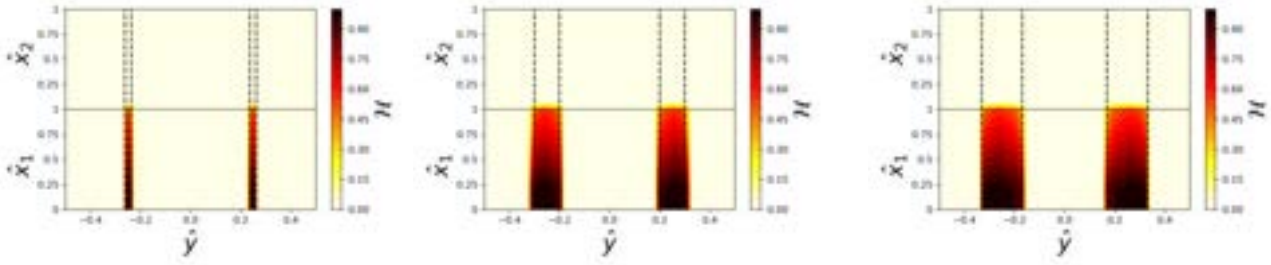
(a) (b)

Figure 7: Contour plot of dimensionless thermal modulation of a dual-layered cryogenic tank wall as a function of the layer *Fo* numbers, (a) maximum value in fluid side material, and (b) maximum value in the ambient side material

3.2. Two-dimensional model

We conclude this investigation with the two-dimensional response of the wall to sloshing with varying dimensionless excitation amplitudes $\hat{A}_f$. We focus on the configuration with $Fo_1 = 3.9$, $Fo_2 = 10^{-5}$ (circle marker in Fig. 5) because similar results were found for the one with $Fo_1 = 3.9$, $Fo_2 = 10^{-5}$ (cross marker in Fig. 5).

The resulting thermal modulation maps in 2D are depicted in Fig. 8a. The boundary between the two materials is represented by a horizontal solid line, while vertical dashed lines delimit the region spanned by the oscillation of the temperature distribution (color function). The results of the 2D approach align with the maps 7 and 5. Indeed, while the perturbation enters the insulation layer with a thermal modulation $\mathcal{H}_2 \approx 0.4$, it is quickly damped so that $\hat{d}_2 \approx 0$. Regardless of the oscillation amplitude, and despite the large diffusivity of the inner layer, we observe that the response of the wall remains extremely localized to the region covered by the sloshing. In other words, at the scale of the sloshing, heat conduction in the circumferential direction can be neglected.



(a) $\hat{A}_f = 0.016$ (b) $\hat{A}_f = 0.064$ (c) $\hat{A}_f = 0.087$

Figure 8: 2D contour plot of transfer function value of a dual-layered cryogenic tank wall subjected to sloshing excitation of different non-dimensional amplitudes.

4. Conclusions

This study analyzed the transient heat conduction with cryogenic sloshing perturbation within a multi-layered tank, considering both one and two-dimensional cases. A dimensionless analysis was performed to identify the scaling parameters on the thermal behavior of the tank.

The study identified a threshold on the Fourier number for inner layer material, namely $Fo_1 \approx 3 \times 10^{-1}$, above which the thermal excitation is amplified and crosses the entire layer thickness. This amplification is attributed to the inner wall overheating due to heat ingress from the outside. It can be minimized by increasing the insulation, i.e. decreasing the Fourier number of the ambient side material Fo_2. This finding suggests that careful consideration must be given to the thermal properties of the tank walls and the operating conditions to minimize the effects of sloshing on the thermal cycling of the inner tank shell.

Furthermore, the study revealed that the perturbation caused by sloshing remains localized in the excitation region and barely spreads along the circumference of the inner shell. This means that the time scale of the sloshing is usually much shorter than the time scale for the heat conduction in the circumferential direction for most material combinations considered in this work.

Overall, the single and multi-layered tank walls' dimensionless analysis has provided an understanding of the thermal behavior of cryogenic storage tanks subjected to sloshing. In particular, thermal modulation and penetration depth maps are valuable tools for designers. The maps can be used to determine the tank's response to such perturbation excitation as a function of the Fourier number of each layer and can help optimize the design of the tank walls by minimizing the effects of sloshing on the temperature distribution within the tank. The findings of this study can be used to improve the design and operation of cryogenic storage systems, to enhance their safety and efficiency. Further research will be focused on extending this work to a complete thermodynamic model accounting for fluid phase and temperature changes.

Abstract:

Unlike the standard materials, metallic nanoparticles offer enhancing the heat convertion rate which implies the maximum and average temperature boost significantly in the considered system. The work's purpose is to examine heat transfer in the metallic nanoparticles which have been deposited on a glassy substrate, enabling the nanostructures thermoablation. Furthermore, the functionalized substrate is irradiated with multicolor-laser-sources, with a future perspective to develop a solar model. This is particularly crucial at improving efficiency in solar-collectors-based renewable energy sources. On the other hand, the theoretical investigations which have been previously verified for a single laser source aim to demonstrate the unsteady temperature and entropy increase in selected geometry cross-sections. The produced heat and the appropriate boundary conditions are calculated based on the advanced optics (Mie-Lorentz and Rayleigh-Drude theories) using an analytical approach. On the other hand, the temperature field and entropy production for the case study is being achieved via CFD simulations. The obtained results will be subsequently being applied in order to optimize the appropriate nanoparticle size and shape in operational work conditions.

heat transfer, light ablation, energy convertion, nanostructures

1. Introduction

The world sources of energy were grounded on fossil fuels above one hundred years ago due to their efficiency and common availability. It has been discovered, however, that their exploitation and extensive utilization is contributing to have the greenhouse effect accelerated. Therefore, the diligent search of new alternate energy sources and their diversification has been a burning issue nowadays. Nonetheless, the majority of the renewable sources of energy do not provide the instant and powerful temperature increase at the same time, which may last either long hours or explode the costs of usage. Regrettably, many of the available techniques are based on the heat flux supply to the fluid-solid boundary, which implies a slow temperature increase in the whole system [1].

On the other hand, since the COVID-19 pandemic situation began, the peoples have realized the necessity of hand and room disinfections. Unlike the powerful chemical compounds, the overheating of viruses by reaching an appropriate temperature may reduce number of germs in a selected volume to virtually zero. In a similar way, tumors and cancers could be damaged completely, however there is the same problem with penetration in order not to kill healthy cells at the same time and in order to provide the noninvasiveness [2–3].

In this moment, metallic nanoparticles emerge as a new strategy by using their own radiative properties. Their advantage is that they may freely travel through a microscale pipe, which increases temperature much faster than it is performed with a standard metal sheet. The future perspective is to apply them as an agent for solar collectors, steam production or germs inactivation. Although there are several papers which propose the nanofluidic flows in the context of mass and heat transfer [4 – 5], heat generation and nanoparticles' shape optimization are an abstruse issue and require to compute sophisticated formulas and equations that would be calculated numerically.

Therefore, this work introduces and offers step by step some theoretical methods which are joined following the available models, which is Cattaneo-Vernotte equation for nanoparticles, Rayleigh-Drude approximation, Royer-Yamaguchi approach for a surface effect and the electromagnetic energy convertion into heat, which has been developing in authors' papers. Likewise, the proposed theory is capable of being shifted for bulbs

and solar models. Moreover, the obtained results for the selected theory are revealed for the specially-prepared system which was thermoablated using three lasers and which enables to study both convection moves and microscale heat transfer effects.

2. Theoretical models

Heat transfer of light-ablated metallic nanoparticles is calculated in different methods, depending on the considered model. Nevertheless, most of them require using the hyperbolic energy equation, which is known as Cattaneo-Vernotte equation [7 – 8], and frequently is dedicated for pulsed light sources where temperature inside nanoparticles cannot be written as constant the whole time. For AuNRs, this equation is presented as follows:

$$\mathrm{r}\cdot\frac{\partial^2}{\partial t^2}(\rho\cdot e)+\frac{\partial}{\partial t}(\rho\cdot e)=\mathrm{div}\big(k_{\mathrm{eff}}\cdot\mathrm{grad}(T)\big)+S_e^{\mathrm{np}} \tag{1}$$

$$\mathrm{r}=3\cdot\frac{k_{\mathrm{eff}}}{\rho\cdot c_p}\cdot\frac{1}{{v_{\mathrm{sound}}}^2} \tag{2}$$

On the other hand, for the continuous light sources, like CW-lasers, the delivered heat is sufficiently low so as to have the hyperbolic energy equation reduced into the standard parabolic one. In this work, including gravity forces and Boussinesq approach, the utilized continuity, momentum and energy, turbulence and dissipation equations are written by [5]:

$$\frac{\partial}{\partial t}\begin{Bmatrix}\rho\\ \rho\vec{v}\\ \rho e\\ \rho\mathbb{k}\\ \rho\epsilon\end{Bmatrix}+\mathrm{div}\begin{Bmatrix}\rho\vec{v}\\ \rho\vec{v}\otimes\vec{v}\\ \rho e\vec{v}\\ \rho\mathbb{k}\vec{v}\\ \rho\epsilon\vec{v}\end{Bmatrix}=\mathrm{div}\begin{Bmatrix}0\\ \overleftrightarrow{\tau}-p\overleftrightarrow{I}\\ \left(\overleftrightarrow{\tau}-p\overleftrightarrow{I}\right)\cdot\vec{v}+(k_{\mathrm{eff}}+k_{\mathrm{t}})\cdot\mathrm{grad}(T)\\ \left(\mu+\frac{\mu_{\mathrm{t}}}{\mathrm{Pr}_{\mathbb{k}}}\right)\cdot\mathbb{k}\\ \left(\mu+\frac{\mu_{\mathrm{t}}}{\mathrm{Pr}_{\epsilon}}\right)\cdot\epsilon\end{Bmatrix}+\begin{Bmatrix}0\\ (\rho-\rho_o)\cdot\vec{g}\\ S_e^{\mathrm{f}}+S_e^{\mathrm{np}}\\ G_{\mathbb{k}}-\rho\epsilon+G_{\mathrm{Б}}\\ C_{1\epsilon}\cdot\frac{\epsilon}{\mathbb{k}}\cdot\left(G_{\mathbb{k}}+C_{3\epsilon}\cdot G_{\beta}\right)-C_{1\epsilon}\cdot\rho\cdot\frac{\epsilon^2}{\mathbb{k}}\end{Bmatrix} \tag{3}$$

where:

$$\overleftrightarrow{\tau}=\mathrm{grad}\left(\overrightarrow{X^{\dagger}}\right)-\frac{2}{3}\mu I_{\vec{d}}\overleftrightarrow{I}+2\mu\overleftrightarrow{d}-\frac{2}{3}(\rho\mathbb{k}+\mu_{\mathrm{t}}\cdot I_{\vec{d}})\cdot\overleftrightarrow{I}+2\mu_{\mathrm{t}}\cdot\overleftrightarrow{d} \tag{4}$$

$$G_{\mathbb{k}}=2\mu_{\mathrm{t}}\cdot\overleftrightarrow{d}\cdot\overleftrightarrow{d^{\dagger}} \tag{5}$$

$$G_{\mathrm{Б}}=\mathrm{Б}\cdot\frac{\mu_{\mathrm{t}}}{\mathrm{Pr}}\cdot\vec{g}\cdot\mathrm{grad}(T) \tag{6}$$

The most relevant factors, however, estimate this part of energy which is directly converted into heat from the incident light. Likewise, the formulas may be presented for fluids (and solids as well) and particles, respectively as follows:

$$S_e^{\mathrm{f}}=A_{abs_M}\cdot I_{abs_M}=A_{abs_M}\cdot I_o(\vec{r})\cdot(1-R_M)\cdot\left(1-\exp\left(-A_{abs_M}\cdot\delta\right)\right) \tag{7}$$

$$S_e^{\mathrm{np}}=\sum_{i=1}^{N}A_{abs_i}\cdot I_{abs_i}=\sum_{i}^{N}w_i\cdot\left(\xi\cdot C_{abs_i}\cdot I_o(\vec{r})\cdot(1-R_i)\cdot\left(1-\exp\left(-A_{abs_i}\cdot l_{ph}\right)\right)\right) \tag{8}$$

The difference is visible as well in the absorption coefficient whose value is calculated via different ways. For continuous media, like homogeneous fluids or solids, the formula may be described by:

$$A_{abs_M}=\frac{4\pi\cdot\mathbb{im}\left(n_M(\lambda)\right)}{\lambda} \tag{9}$$

For particles, however, the formula implies counting particle by particle, which obviously cannot be performed. This is the reason why N refers to the number of the grouped particles which possess the same or similar dimensions. The commonly utilized theory, which solves the problem, is based on Rayleigh-Drude approximation whose advantage is the simplicity in adjusting both size, shape and distance effects [9 – 10]. The general formula are followed by [11 – 12]:

$$A_{abs_i}=\xi\cdot\left(\left(C_{ext_i}\right)-\left(C_{sca_i}\right)\right)=\xi\cdot\left(\left(4\pi\cdot\left(\frac{2\pi}{\lambda}\right)\cdot\mathbb{im}(\alpha_i)\right)-\left(\frac{8\pi}{3}\cdot\left(\frac{2\pi}{\lambda}\right)^4\cdot|\alpha_i|^2\right)\right) \tag{10}$$

Nevertheless, the situation which significantly distinguishes the converted rate is how far from the surface nanoparticles are located. For microsize pipes this effect is relevant only near walls, and here only nanofluidic theories are utilized based on the heat transfer coefficient between fluid and particles [4 – 5]. Amongst many theories where the topic has been investigated, Smoluchowski theory, which is presented in [13 – 14], provides satisfactory solutions.

On the other hand, when nanoparticles are deposited on a surface, the interaction should be included with the surface effect which generally increases the optical cross sections, especially for elongated shapes, like nanodisks or nanorods. Here, Royer-Yamaguchi approach [15 – 16] appears to be a perfect solution due to the fact it includes both the surface and distance effect. In this work, the adjusted polarizabilities for rods are presented in the Appendix A. Nevertheless, it should be mentioned that this method is immature for prolate structure, and provides the validity only for the symmetrical alignment of nanoparticles to each other. The other configurations, although they correspond much more to reality, are not supported with the abovementioned formulas, and this aspect would be under further investigations.

Furthermore, total entropy generation, $\mathbb{S}$, is investigated using formula [21,33 – 35] for Boussinesq and turbulent approach:

$$\mathbb{S} = \left(\frac{k_{\mathrm{eff}} + k_{\mathrm{t}}}{T^2}\right) \cdot \left(\mathrm{grad}(T)\right)^2 + \left(\frac{\mu}{T}\right) \cdot \left(-\frac{2}{3} I_{\vec{a}} \cdot \overrightarrow{I} + 2\overrightarrow{d}\right) + \left(\frac{1}{T}\right) \cdot \left(-\frac{2}{3}(\rho \mathbb{k} + \mu_{\mathrm{t}} I_{\vec{a}})\overrightarrow{I} + 2\mu_{\mathrm{t}}\overrightarrow{d}\right) \tag{11}$$

This parameter determines the irreversibility rate of each process, and may reveal which irreversible processes, friction in movement or heat transfer with conduction and forced or natural convection is dominant at each stadium of the simulations.

3. Numerical proceedings

3.1. Considered system

In order to reduce the number of examined systems and to investigate the heat and mass transfer particularly at the same time, it has been decided to create the model which is both simple to prepare, to simulate and to be proceeded in the target application. Fig. 1. outlines the system's scheme from two sides. Gravitational forces works along the x direction in this model.

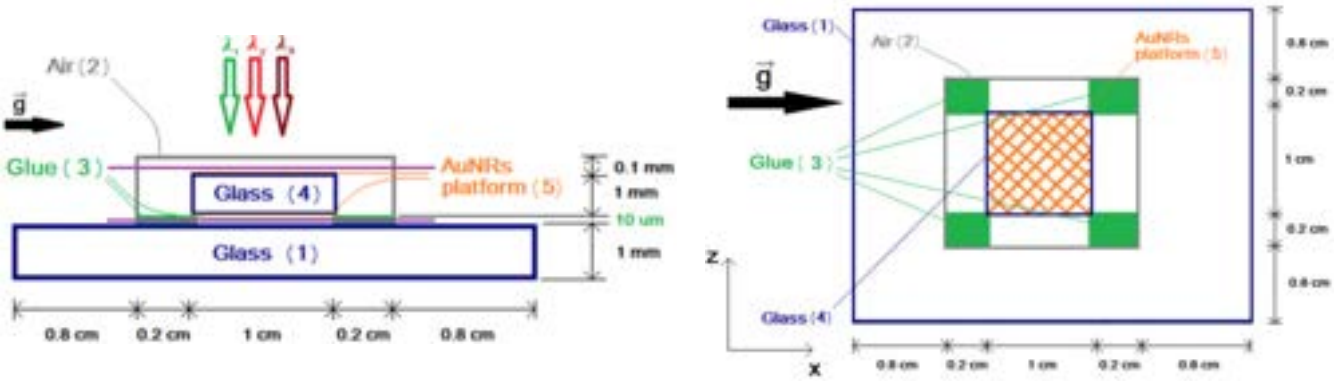

Figure. 1. Scheme of the created geometry and domains with boundary conditions applied in the simulations (scale has not been saved). Violet lines highlight the considered planes in section "Results".

3.2. Boundary conditions

In order to compute the results numerically, the considered system has been discretized into three grids. The calculations have been performed via *Ansys.Fluent* software (version 22.1) on the *Tryton* supercomputer of the TASK resources consisted of 72 cores (Intel®Xeon®Processor E5 v3 @ 2,3GHz) using the SIMPLE algorithm and the second-order scheme for the (2) – (9) equations. The control parameters have been established on 0.5 excepting pressure and density whose values equals 0.3. The space and time tests are based on Roacher's and Richardson's extrapolations [17] so as to verify and minimize the numerical error. The utilized mesh for results is visible in fig. 2.

Likewise, boundary conditions are specified assuming the system is kept in the adiabatic conditions, excepting the irradiated walls where mixed conditions are expected. Moreover, diffusive momentum flux, although they are coated on the glassy base, require using Marangoni's stress for gold nanoparticles due to the presence of the organic compound (CTAB):

$$\overrightarrow{X^{\dagger}} \rightarrow \frac{d\vec{\sigma}}{dT} \cdot \mathrm{grad}(T) \tag{13}$$

where surface tension coefficient equals $\frac{d\vec{\sigma}}{dT} = -0.00005263\ \mathrm{N} \cdot \mathrm{m}^{-1} \cdot \mathrm{K}^{-1}$ [21].

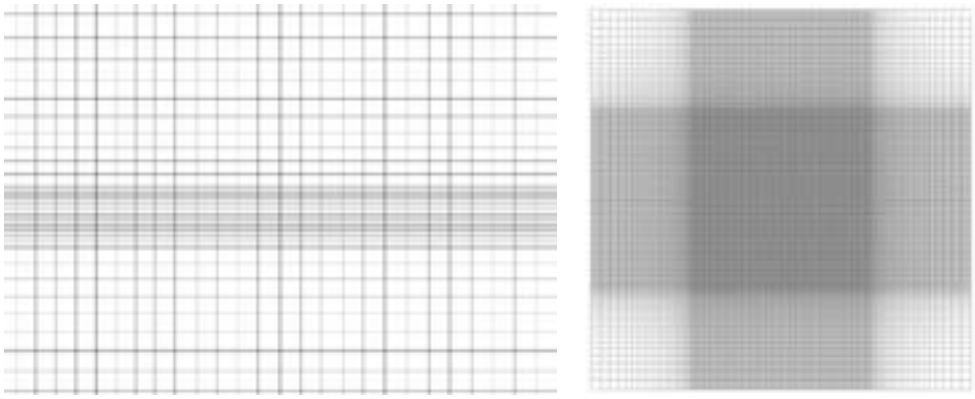

Figure. 2. Applied discretized grid in the simulations from two sides.

Furthermore, heat source, which are three lasers here with the incident wavelengths, $\lambda_{L=1} = 532\ \mathrm{nm}$, $\lambda_{L=2} = 640\ \mathrm{nm}$, $\lambda_{L=3} = 808\ \mathrm{nm}$, undergo the gaussian distribution in the space regime, accordingly:

$$S_e^{\mathrm{np}} = \sum_{L=1}^{3}\left(\sum_{i}^{N} w_i \cdot \left(\xi \cdot C_{abs_i}(\lambda_L) \cdot I_{oL} \cdot \exp\left(-2\left(\frac{\vec{r}}{R_{\phi L}}\right)^2\right) \cdot \left(1 - R_i(\lambda_L)\right) \cdot \left(1 - \exp\left(-A_{abs_i}(\lambda_L) \cdot l_{ph}\right)\right)\right)\right) \tag{14}$$

where each laser output power has been established on $80\ \mathrm{mW}$. These three lasers deliver the heat flux during 90 seconds (irradiation time). After this time, the system is being cooled.

Table 1. details all mentioned assumptions, whereas table 2. reveals material thermal properties from literature.

Table 1. Specified boundary conditions in the considered simulations

No.	Material	Type of boundary conditions	Details
(1)	Bottom borosilicate glass	Mixed	$T_o = 297.15\ \mathrm{K}\ (75.20^{\mathrm{o}}\mathrm{F})$ $h = 13.6\ \mathrm{W \cdot m^{-2} \cdot K^{-1}}$ $\delta = 0.001\ \mathrm{m}$ $S_e^{\mathrm{f}} \approx 0\ \mathrm{W \cdot m^{-3}}$ $R_{\phi L} = 0.0015\ \mathrm{m}$

4. Results

Heat transfer results may be described by the mathematical functions whose solutions are determined by specified boundary conditions. Some results are based on Green's or gaussian functions and are presented in [19 – 20]. The presence of forced and natural convection, however, which occurs in this work, implies the major functions' complicity and therefore numerical methods are advisable.

Results are being considered 5 μm above (top) (red color) and under (bottom) (blue color) glassy base, near the AuNRs platforms respectively. Fig. 3a. highlights maximum temperature vs time response, fig. 3b. presents the entropy changes, whereas fig. 3c outlines maximum velocity fluctuations. As may be noticed, maximum temperature reaches 33.225°C and 31.795°C above and under the top glass respectively, which is a promising temperature increase since the operating laser power is quite low. It is expected that higher values of power would significantly increase the maximum temperature of the system. On the other hand, this work assumes using the three wavelengths which do not correspond perfectly for the sun spectrum distribution.

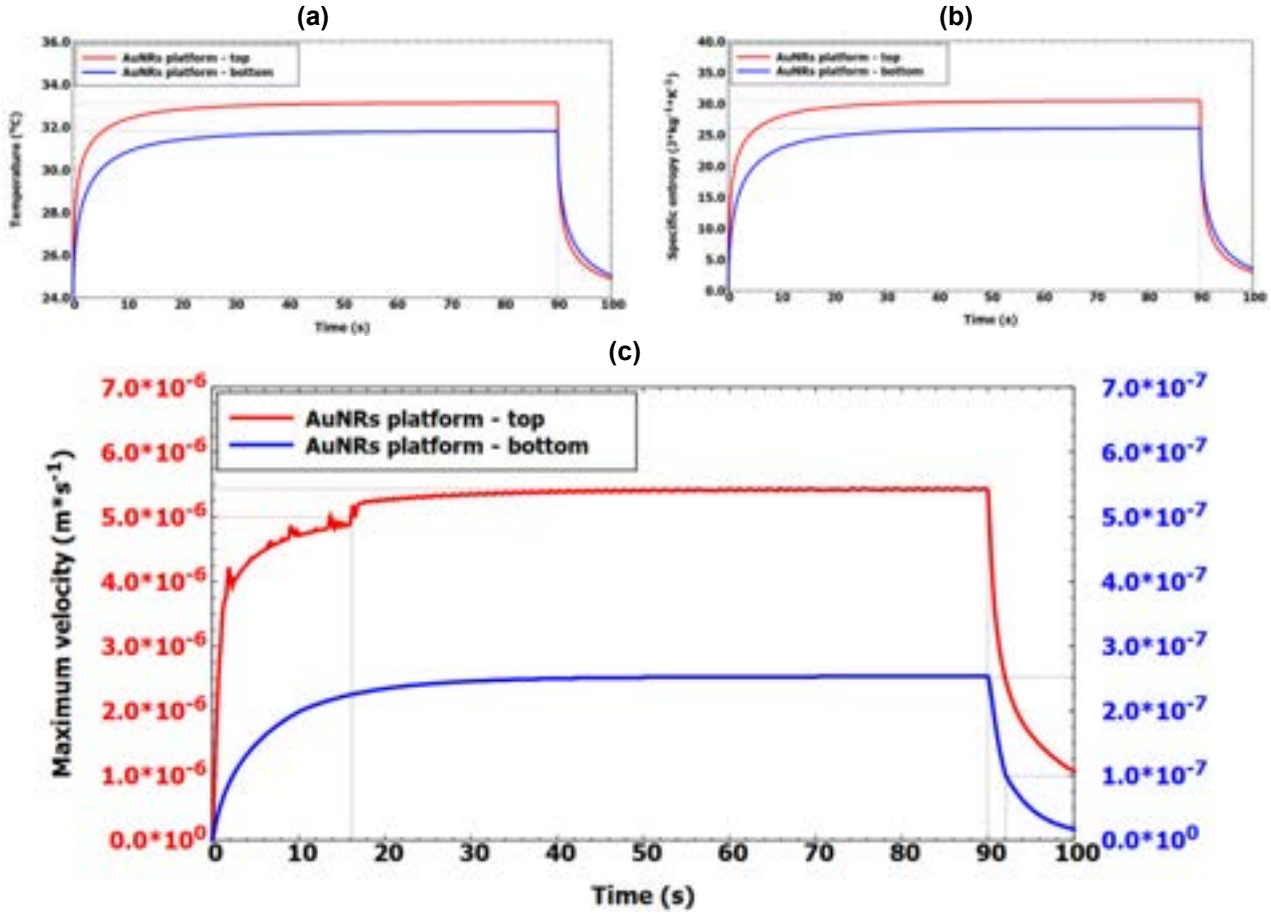

Figure. 3. (a) Maximum temperature, **(b)** specific total entropy and **(c)** maximum velocity vs. time results 5 μm above (top) (red color) and 5 μm under (bottom) (blue color) glassy base of the AuNRs platforms respectively. Using dotted lines, sensitive moments in time are raised.

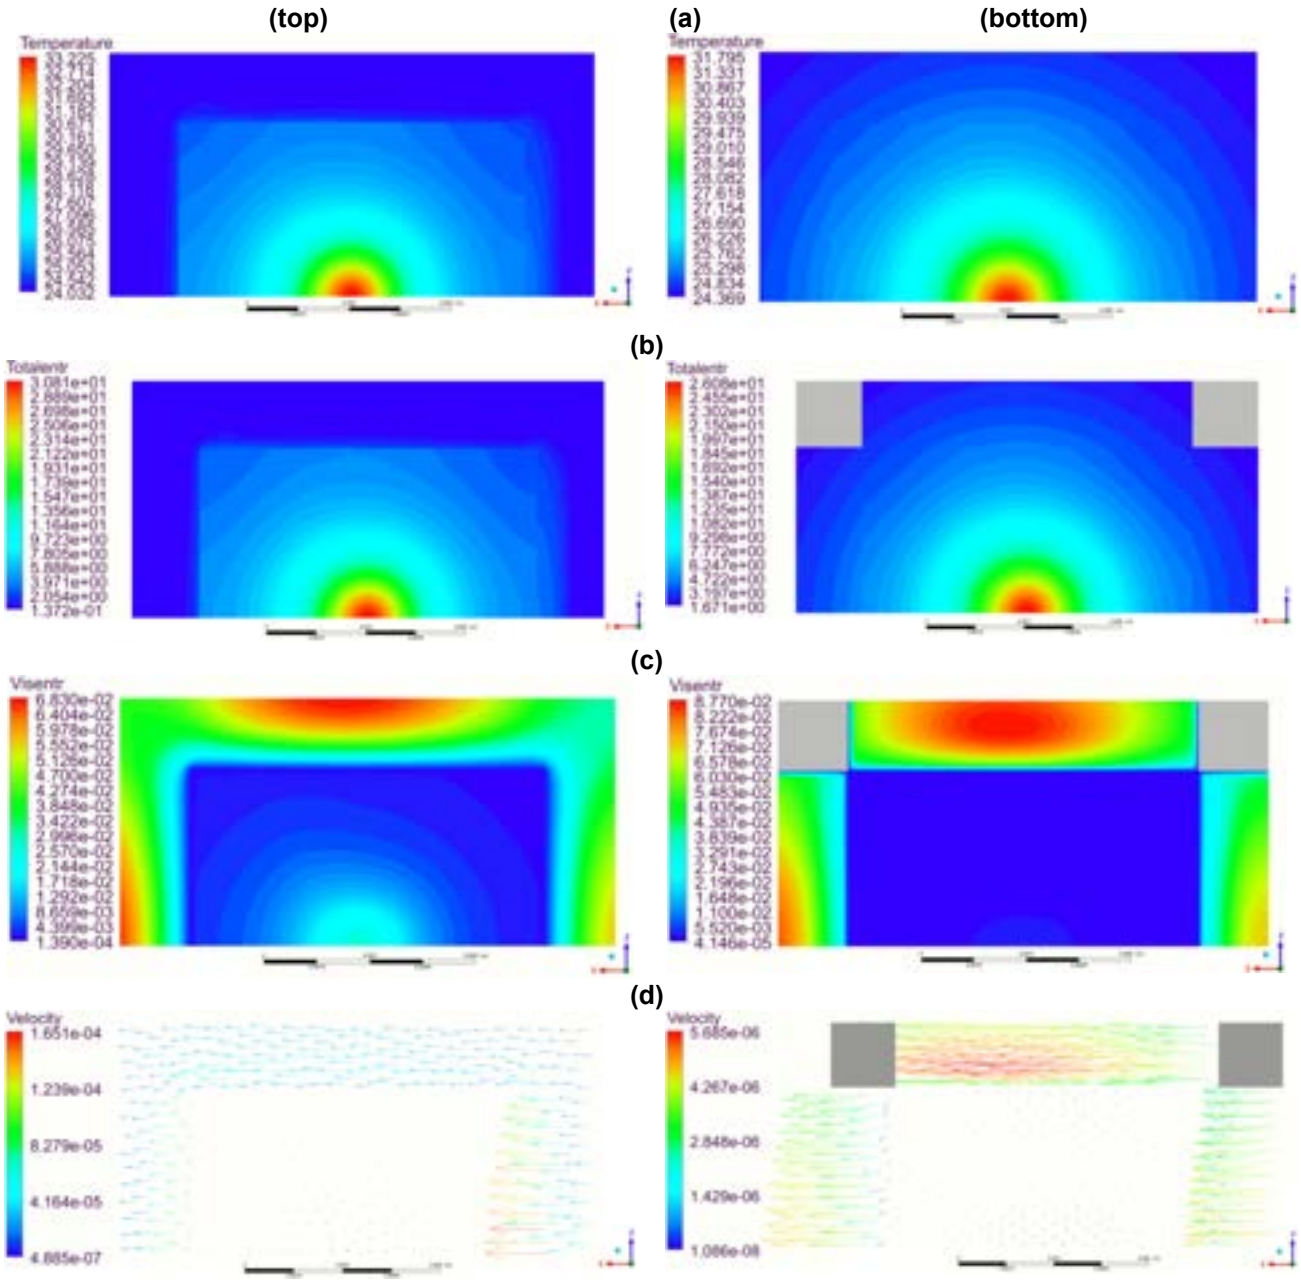

Figure. 4. (a) Temperature, **(b)** specific total and **(c)** dynamic entropy, **(d)** velocity contour plots 5 μm above (top) (red color) and 5 μm under (bottom) (blue color) glassy base of the AuNRs platforms respectively after 90 seconds of the system irradiation.

Furthermore, curve shapes are responsible for the heat rate and thermal properties of that the considered system consisted. As long as the quick temperature increase is explained via high value of material's thermal diffusivities compared to gold, the steady state is obtained as a result of assumed adiabatic and insulated conditions at walls and of the air domains, respectively. Nonetheless, under the discussed theory in Appendix A, many parameters, like nanoparticle's dimensions or surface material, can be adjusted ensuring different temperature changes and curve shapes. Each of these aspects should be examined particularly in the near future.

Likewise, the obtained low values of velocity imply weak impact on the heat rate. As a matter of fact, thermal effects may have triggered the natural convective movement of the fluid associated with the distribution of the plate. Moreover, the results are expected to be distinguishable in the microscale region between glass and above the AuNRs-platform respectively. This may be noticed peering into both the differences of the maximum temperature and specific entropy for the considered surfaces. The explanations are searched in the thickness of the AuNRs platforms and the heat transfer coefficient which implies a lower value if the flow is weaker, which is clearly visible in fig. 3c. The flow, however, is governed by different phenomena. The top-AuNRs-platform is exhibited for the forced convection and turbulence effects which is due to the gravity forces.

This is the reason why dynamic entropies, which are presented in figs. 4c and 5c, are distinguishable to each other, and why are visible only very close to AuNRs platforms. In order to enforce the flow inside the microscale region, significantly higher pressures should be applied, which is not necessary for the top-AuNRs-platform due to the assumed outlet condition. On the other hand, dynamic entropy is not a dominant process, which may be realized from total entropy contours which implies that and mainly heat transfer does the lion's share in the whole simulation.

Hence, heat is generally transported by conduction, whereas natural convection is directly responsible for the entropy generation. Dynamic entropy, which is caused by friction, is a few ranks lower than the static one. However, asymmetrical heat wave front, which is visible in the figures 4c and 5c, appears to be due to the natural convection, both near the top- and bottom-AuNRs-platforms.

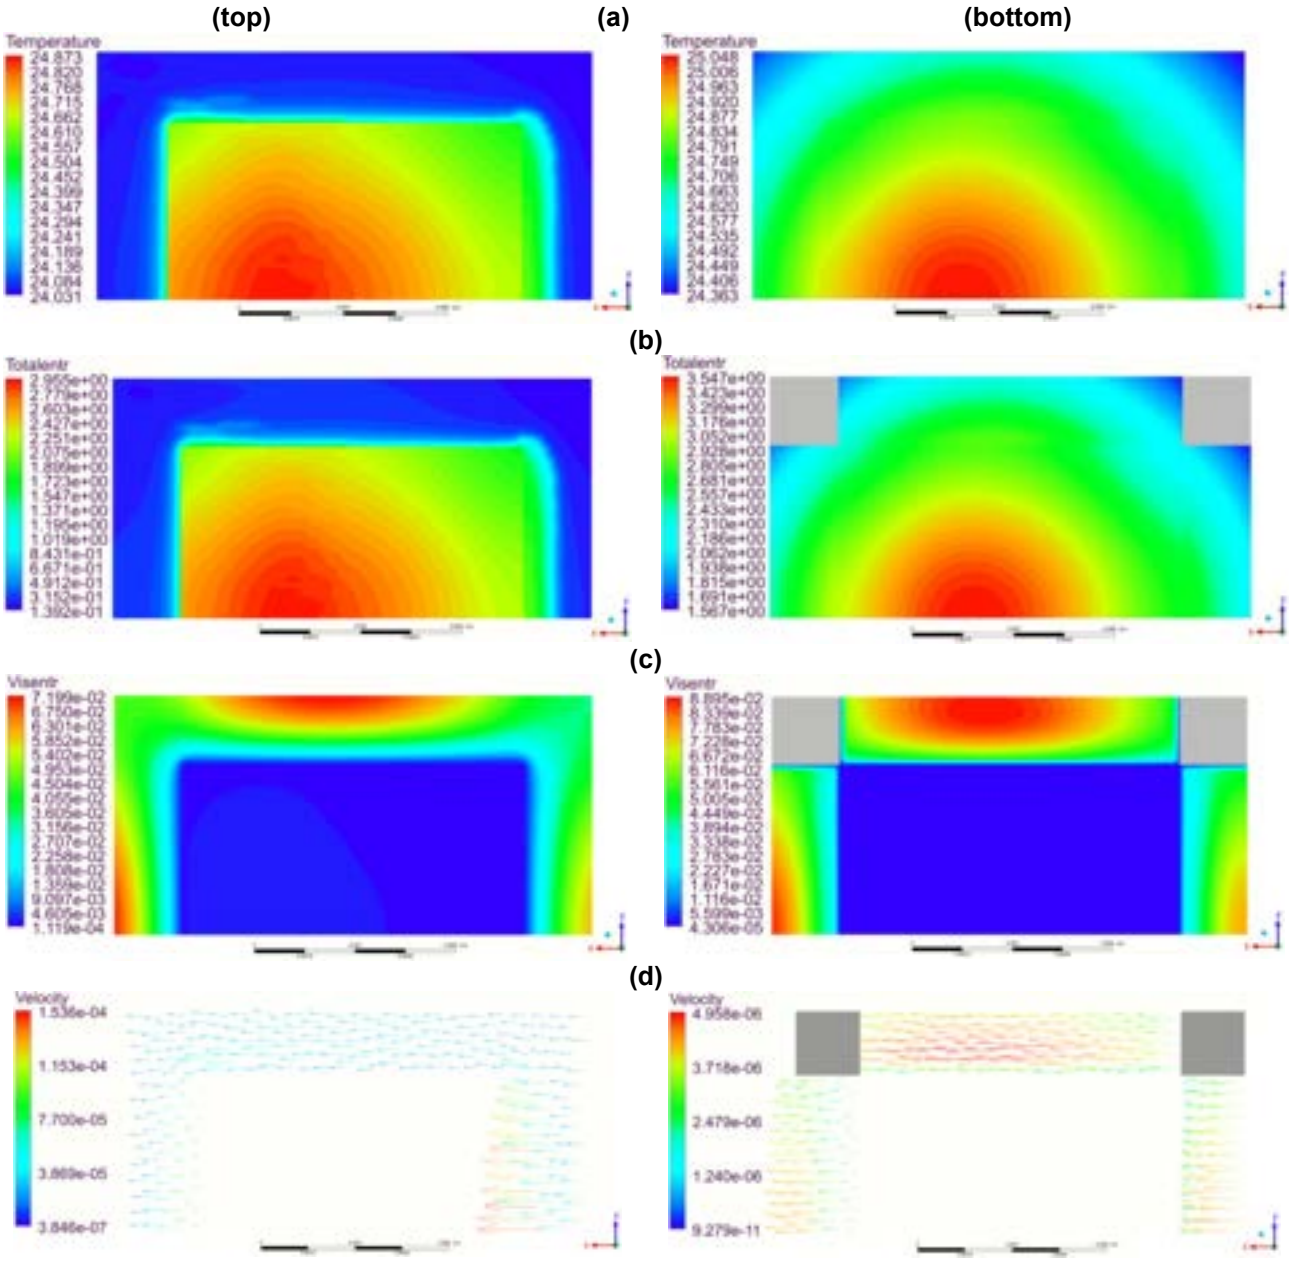

Figure. 5. (a) Temperature, **(b)** specific total and **(c)** dynamic entropy, **(d)** velocity contour plots 5 μm above (top) (red color) and 5 μm under (bottom) (blue color) glassy base of the AuNRs platforms respectively after 10 seconds of the system cooling.

Jagged contours may be explained following that Marangoni's stress is responsible for the fluctuations presence which are intensified as a result of the turbulence effects due to convection forces. Moreover, it is supposed that heat is transported as a result of the convection processes which implies the turbulence influence, even if the flow takes low values. Another issue occurs at the rectangular boundaries where the contours appear to be discontinuous due to the fact that there are located the material boundaries, and the material properties abruptly vary. These discontinuities are common phenomena manifested at the micro- and

nanoscale, with velocity slip, transpiration mobility and Marangoni's stress among the dominant effects [36-39].

Furthermore, the jumpy variations may be noticed in the velocity vs time plot where the curve does not possess a smooth character. This is not observed in the bottom-AuNRs platform where the curve is deprived of the discontinuities, and where the turbulence is significantly weaker. It is also worth mentioned that the curves have been improved via decreasing mesh size as long as the satisfactory quality obtains, and every simulation has provided a similar feedback.

5. Summary

Metallic nanostructures, although they are followed with standard Boltzmann transport equations, require utilizing sophisticated mathematics which implies the problem complexity in boundary conditions. In this work, microscale heat transfer and convection moves have been raised and discussed. This paper suggests that there is a possibility to apply metallic nanoparticles in real energy or biomedical applications. Their unquestionable advantage is heating them inside pipes, which omits the problem of the low heat transfer coefficient of the exterior surfaces. Moreover, the utilized model, although NRs are not truly present, the interaction between NRs and light is the response based on the physical phenomena. The approach, however, does not require to calculate many equations, which definitely may accelerate the simulation compared to the available full optical approaches, like DO model.

Furthermore, the outlined theoretical results reveal that even relatively low values of the laser powers are sufficient so as to obtain a significant temperature increase. In this work, the maximum value has reached ΔT=9.225^{o}C. Although higher temperature may be provided by manipulation of nanoparticle's properties or stronger light sources, it should be taken into account the heat transfer is strictly conjugated with the conduction where heat spreads decreasing the maximum value supporting the average one. On the other hand, the competition between force and natural convection also is not trivial, which has been present and been studied thoroughly in this work as well. In this work, the forced convection influence has been discovered not to do the lion's share due to the weak flow near the AuNRs platforms.

It is being predicted, however, this effect would be much more visible e.g. in solar collectors where AuNRs shall move freely and be exposed to the high stresses due to the forced convection. Nonetheless, the considered topic takes the advantage and encourages further investigations due its promising temperature increase in the imitating-systems which may be used in energy or biomedical applications.

Acknowledgments

The work was supported by the National Science Centre, Poland, under research project „Shape and displacement optimization of gold nanorods in the killing chamber in order to phototermoablation processes", no UMO-2021/43/D/ST8/02504.

Computations were carried out using the computers of Centre of Informatics Tricity Academic Supercomputer & Network (CI TASK) in Gdansk.

Appendix A

This part studies the applied formula for electrical polarizabilities applied for the substrate effect of the used nanostructures. Due to the surface effect and anisotropy of considered nanostructures, several formulas are calculated and specified for 130 x 130 different sizes of d_{s_i} and d_{l_i}. The general boundary condition for the total polarizability is described as follows:

$$\alpha_i = \frac{2}{3}\left(\frac{2}{3}\cdot\left(\left(\alpha_{i,y}\right)_{Ya}+\left(\alpha_{i,z}\right)_{Ya}\right)+\frac{1}{3}\cdot\left(\left(\alpha_{i,x,dl}\right)_{Ya}\right)\right)+\frac{1}{3}\cdot\left(\frac{2}{3}\cdot\left(\left(\alpha_{i,y,ds}\right)_{Ya}+\left(\alpha_{i,z,ds}\right)_{Ya}\right)+\frac{1}{3}\cdot\left(\left(\alpha_{i,x}\right)_{Ya}\right)\right) \tag{A.1}$$

The substrate and distance effects are described by Royer-Yamaguchi approach [15 -16], where the anisotropic factor, β_i, is perpendicular along the y-axis, as follows:

$$\left(\alpha_i\right)_{Yam} = \frac{\left(\alpha_i\right)_{sur}}{1+\left(\frac{\left(\alpha_i\right)_{sur}}{\frac{4}{3}\pi\cdot {d_{s_{1i}}}^2\cdot d_{l_{1i}}}\right)\cdot\beta_i} \tag{A.2}$$

Surface polarizabilities are assumed for the prolate ellipsoids which are the complex functions, as follows:

$$\left(\alpha_{i,x,z}\right)_{sur}\rightarrow\left(\alpha_{i,x,z}\right)_{sur}\left(\mathbb{p}_{11},\mathbb{q}_{11},\mathbb{e}_{11},\varepsilon_h,\varepsilon_{sur},d_{s_{1i}},d_{s_{2i}},d_{l_{1i}},u_l\right) \tag{A.3}$$

$$\left(\alpha_{i,y}\right)_{sur}\rightarrow\left(\alpha_{i,y}\right)_{sur}\left(\mathbb{p}_{10},\mathbb{e}_{10},\varepsilon_h,\varepsilon_{sur},d_{s_{1i}},d_{s_{2i}},d_{l_{1i}},u_l\right) \tag{A.4}$$

Contrary to ellipsoids, rods possess the flat long dimension which contributes to appear new dipole configurations. It was discovered by Fuchs publication [18] in which the charge arrangements of edgy shapes (triangles, cubes, octahedrons etc.) The publication implies that the dipole arrangement in a nanoparticle may be

specified by a certain parameter in order to solve and establish the other dipole configurations. As long as the along axes tend to spherical distribution, $(\phi_i(d_{s_i}, d_{l_i}) \rightarrow \phi_i(d_{s_i}, d_{s_i}) \rightarrow 0)$, the situation changes in rods. It is assumed to exist the new configuration where dipoles are arranged at the very opposites diagonal indicating $\phi_i(d_{s_i}, d_{l_i}) \rightarrow \phi_{i,d_l}\left(d_{l_i} - d_{s_i}, \sqrt{(d_{l_i} - d_{s_i})^2 + (d_{s_i})^2}\right)$ and $\phi_i(d_{s_i}, d_{l_i}) \rightarrow \phi_{i,d_s}\left(d_{s_i}, \sqrt{(d_{l_i} - d_{s_i})^2 + (d_{s_i})^2}\right)$, which are projected on the main space diagonal of a rod for y- and x-, z- axes respectively. Fig. A.1 demonstrates these four assumed charge arrangements which have been adjusted to the x-oriented particles than are deposited on the y-axis surface. The assumed parameters and properties for the abovementioned formulas are highlighted in tables A.1 and A.2.

Table A.1: Nanorods assumed parameters

General parameters	**Assumed value**
NPs general size, d_s x d_s x d_l	15 x 15 x 55 nm
Coating thickness, d_{s_2}	4 nm
Average NP – NP distance, u_l	140 nm
Nanoparticles concentration, ξ	$8.67 \cdot 10^{21}$ m^{-3}

Nomenclature

Roman letters

A_{abs_i}	absorption coefficient of the i-particle, m^{-1}
A_{abs_M}	absorption coefficient of the continuous material, m^{-1}
C_{abs_i}	absorption cross section of the i-particle, m^2
C_{ext_i}	extinction cross section of the i-particle, m^2
C_{sca_i}	scattered cross section of the i-particle, m^2
c_p	specific heat capacity, $\mathrm{J} \cdot \mathrm{K}^{-1} \cdot \mathrm{kg}^{-1}$
$\overleftrightarrow{d}$	symmetric rate of deformation, s^{-1}
d_{l1_i}	longer diameter of the i-nanoparticle, m

d_{s1_i}	shorter diameter of the i-nanoparticle, m
d_{s2_i}	size of the nanoparticle's coating, m
e	specific energy, $\mathrm{J} \cdot \mathrm{kg}^{-1}$
$G_{\mathbb{k}}$	turbulence kinetic energy generation due to velocity gradients, $\mathrm{kg} \cdot \mathrm{m}^{-1} \cdot \mathrm{s}^{-3}$
$G_{\text{Б}}$	turbulence kinetic energy generation due to buoyancy forces, $\mathrm{kg} \cdot \mathrm{m}^{-1} \cdot \mathrm{s}^{-3}$
$\vec{g}$	gravity, $\mathrm{m} \cdot \mathrm{s}^{-2}$
h	heat transfer coefficient, $\mathrm{W} \cdot \mathrm{m}^{-2} \cdot \mathrm{K}^{-1}$
$I_o(\vec{r})$	initial intensity laser profile, $\mathrm{W} \cdot \mathrm{m}^{-2}$
I_{abs_i}	absorbed part of the i-particle, $\mathrm{W} \cdot \mathrm{m}^{-2}$
$I_{\vec{d}}$	first invariant of the strain rate, s^{-1}
$\overleftrightarrow{I}$	unit tensor, -
k_{eff}	effective thermal conductivity coefficient, $\mathrm{W} \cdot \mathrm{m}^{-1} \cdot \mathrm{K}^{-1}$
L	subsequent laser source
l_{ph}	light-NR interaction thickness, m
$Pr_{\mathbb{k}}$	turbulent Prandtl number for kinetic energy, -
Pr_{ϵ}	turbulent Prandtl number for rate of dissipation, -
Pr	Prandtl number, -
p	pressure (Pa)
R_i	reflection coefficient of the i-nanoparticle, m
R_M	reflection coefficient of the continuous material, m
$R_{\phi L}$	beam sizes of laser sources, m
$\overleftrightarrow{R}$	Reynolds stress tensor
$\vec{r}$	radius – spherical coordinate, m
S_e^f	source of energy for fluids, $\mathrm{W} \cdot \mathrm{m}^{-3}$
S_e^{np}	source of energy for the i-particle, $\mathrm{W} \cdot \mathrm{m}^{-3}$
T	temperature, K
T_o	initial temperature at the $t = 0\ \mathrm{s}$, K
t	time, s
u_l	distance between particles, m
$\vec{v}$	velocity of the fluid, $\mathrm{m} \cdot \mathrm{s}^{-1}$
v_{sound}	speed of sound, $\mathrm{m} \cdot \mathrm{s}^{-1}$
$\overrightarrow{X^{\dagger}}$	diffusive momentum flux, $\mathrm{kg} \cdot \mathrm{m} \cdot \mathrm{s}^{-2}$
x, y, z	Cartesian's coordinates, -

Greek letters

α_i	polarizability of the i-particle, m^3
β	anisotropic factor for distance and surface effects, -
δ	thickness of the considered material, m
ε_h	permittivity of the host medium, -
ε_{sur}	permittivity of the base where NRs are embedded, -
ϵ	turbulent energy dissipation, $\mathrm{m}^2 \cdot \mathrm{s}^{-3}$
λ	incident wavelength, m
μ	molecular viscosity, $\mathrm{Pa} \cdot \mathrm{s}$
μ_{t}	eddy viscosity, $\mathrm{kg} \cdot \mathrm{m}^{-1} \cdot \mathrm{s}^{-1}$
ξ	nanoparticles concentration, m^{-3}
ρ	density of a material, $\mathrm{kg} \cdot \mathrm{m}^{-3}$
$\overleftrightarrow{\sigma}$	surface tension parameter, $\mathrm{N} \cdot \mathrm{m}^{-1}$
ψ	prolation parameter, -

Slavic letters

Б	thermal expansion coefficient, K^{-1}
г	relaxation time, s

Abstract:

In many thermal processes, elements with high temperatures are distributed in a non-uniform way, whose internal surface temperatures must be known. Intrusive through-wall sensors are commonly used, but this technique is not possible in some cases. In addition, it requires numerous sensors distributed over the entire surface to know the temperature of the entire surface adequately. This is the case with the inner surfaces of the cylinder and cylinder head of reciprocating internal combustion engines, where it is relatively easy to measure the external temperature of the surfaces but not the temperature distribution of the inner surfaces. The accurate evaluation of this interior temperature is relevant for the determination of inner processes, such as the rejected heat from the combustion chamber.

In this work, a methodology for the estimation of the average temperature of the interior surfaces of elements is presented. Starting from the experimental measurement of the temperature distribution of the exterior surfaces and measuring the total energy transferred from the interior to the exterior surface, the proposed methodology uses an iterative sequence of simulations using finite element methods. The result is a distribution of temperatures on the interior surfaces, whose average temperature is taken as the temperature of the interior surfaces. The minimum mean square error (MSE) value achieved is of the order of 50. The method converges when an improvement of the MSE by less than 5% is achieved. The convective heat transfer coefficients from the finned surface to the atmosphere is $1{,}4 \cdot 10^{-4}$ W/mm^{2}K, which are normal values associated with natural convection.

This methodology has been validated by building a prototype in the laboratory. The methodology has achieved a high agreement between the measured and the predicted values.

Keywords:

Sensors, Infrared thermal images, thermal engine, temperature indirect measurement

1. Introduction

In thermal systems that are composed of mechanisms and thermal generation within them, the prediction of heat transfer is important as it influences heat losses. An accurate prediction of heat losses are essential to know the performance, power, emissions and stress field [1]. Examples of such systems are heat engines, such as reciprocating internal combustion engines, or thermal storage systems based on thermochemical reactions. Knowing the temperature distribution inside these systems is important to characterise the behaviour of these thermal systems.

Measuring the interior temperatures of walls that are not accessible is quite costly and difficult. Intrusive techniques are normally used, with holes drilled to install the sensors, which can modify the phenomenon and render the model useless [2]. Measurements based on optical techniques are also common [3] but require specific windows or special preparation of the model to be measured, with optical access. An example would be the diode laser sensor [4] or coherent anti-Stokes Raman spectroscopy [5].

Directly measuring temperatures on indoor surfaces using sensors can be complicated and intrusive [6]. In addition, the spatial variation of temperatures on indoor surfaces is important [7,8]. If the measurement is reduced to a few points, the averages can be non-representative of the whole assembly. Moreover, it is challenging for small systems to install a relevant number of sensors on the inner surfaces, with the risk of affecting inner flows. This is especially important for measuring the inner surface of combustion chambers of reciprocating internal combustion engines or high-temperature energy storage systems where the gas temperature could be considered constant for many analyses, but for the purpose of mechanical calculations and heat transfer calculations, the assumption of constant surface temperature is not valid. The smaller the

volume and the higher the temperature, the more complicated the installation and the more intrusive the measurement method.

In addition, when the outer surface of the system whose inner surface temperature is to be measured is not uniform, for instance, air cooling internal combustion engines with an external finned surface, measurement becomes even more difficult due to the more difficult installation conditions of the sensors.

There are indirect methods for the determination of these temperatures based on heat transfer mechanisms. Some authors use resistance-capacitance models [9]. Other authors use models that solve by finite element methods, in stationary or transient regimes. For both types of models, the boundary conditions are varied: constant temperatures on the inner and outer surface, constant heat transfer coefficients on the inner wall and temperature of the outer wall equal to that of the coolant or heat transfer coefficients in different areas of the outer surface of the piston [10, 11, 12].

It should also be noted that the derivation of the values of the boundary conditions for these simulations is varied. In many cases, the authors use values of conditions from the literature, which do not ensure their validity if extrapolated to different engines or systems. Other authors obtain these values through previous simulations of the combustion cycle or the internal process within the system. Obtaining accurate boundary condition values from experimental measurements is challenging [13].

In general, the most usual boundary condition for the outer surface side is to impose either the surface temperatures, the heat transfer coefficient or the coolant temperature. In the literature, most of the studies applied to internal combustion engines are directed to the study of water-cooled systems, in which the water temperature is almost constant or varies slightly, and the outer surfaces are smooth and do not have extended surfaces, unlike the case of air cooling. This work presents a methodology for an accurate evaluation of the inner temperature of high-temperature thermal energy systems. It is a non-intrusive methodology, requiring only infrared imaging, measurement or estimation of total heat and the use of CFD software for heat transfer analysis. Unlike other methodologies, no contact or drilling is required for thermocouple or heat flow meter placement. It is developed for being applied to hard-to-monitor systems, such as internal combustion engines or high-temperature energy storage systems. The methodology is demonstrated in an air-cooled internal combustion engine but is fully applicable to any other thermal system with the characteristics described.

2. Preliminary considerations

Several considerations have to be made before proposing a methodology for the indirect determination of the inner temperature of systems, inside which there is thermal generation or gases at high temperatures and cannot be accessed by simple methods. These considerations are related to the use of the finite element method (FEM), appropriate selection of the boundary conditions, analysis of the theoretical basis of heat transfer through extended surfaces; available experimental techniques; election of the resolution method and setting of admissible errors.

2.1. Application of the finite element method to problems in conduction and convection heat transfer

The following steps are required to solve a thermal problem using FEM:

- Phase 1 "Preprocessing": meshing, development of the equations for each element, creation of the total conductivity matrix and application of the boundary conditions and loads.
- Phase 2 "Equation solving": solving the set of linear algebraic equations to obtain the results at the nodes.
- Phase 3 "Post-processing": extraction of the information required for this research. For example, the total heat loss of a body under study or the temperature distribution on selected surfaces of this system.

Equation (1) is the form of the equations characterizing heat transfer by convection and conduction under stationary conditions:

$$[K]\{u\} = \{P\} + \{N\}, \tag{1}$$

Where [K] is the total conductivity matrix, {u} is the vector of temperatures of the nodes to be known, {P} is the vector of heat loads that are constant and {N} is the vector of nonlinear heat fluxes that depend on temperature. The vector {P} is associated with the heat transfer occurring at the surface of the element as well as the generation within the element. The vector {N} is associated with convection at the surface of the solid and temperature-dependent heat loads.

The chosen software is NC/NASTRAN and uses an iteration scheme based on the Newton-Raphson method. It is useful to follow the following two recommendations so that the iterative process can converge properly:

- Initial temperature estimation: for highly nonlinear problems, the iterative solution is very sensitive to the assumed initial temperature.

- Convergence criterion: the first time a problem is solved, it is advisable to keep the default values of the parameters that control the iterative process. For problems with poor convergence, it is possible to increase the values of the tolerances, although this decreases the accuracy.

2.2. Analytical resolution of heat transfer by conduction and convection of finned surfaces

As a previous step to the determination of the methodology, it is necessary to study the theoretical basis of heat transfer on extended surfaces. This study will allow us to justify the methodology and better interpret the results.

In the conduction analysis for a generic annular fin, Figure1, the following assumptions are adopted:

- One-dimensional conduction in the radial direction of the fin. If the longitudinal dimensions are much larger than the fin thickness t, then the temperature changes in the longitudinal direction are much larger than those in the transverse direction.
- Steady-state conditions.
- Constant and non-temperature-dependent conductivity.
- Radiative transfer from the fin surfaces is negligible.
- There is no energy generation in the volume considered.
- The heat transfer coefficient is constant over the entire surface.

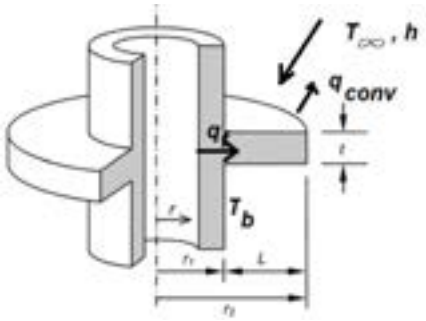

Figure. 2. Fin model and characteristic dimensions.

The conduction equation in the fin is a zero-order modified Bessel equation, Eq. (2):

$$\frac{d^2\theta}{dr} + \frac{1}{r}\frac{d\theta}{dr} - m^2\theta = 0, \tag{2}$$

where $m^2 = 2h/kt$ y $\theta = T - T_\infty$.

The temperature distribution is obtained once the boundary conditions have been chosen. The following four sets of possible boundary conditions can be applied:

- CC1, where heat arriving by conduction at the beginning of the fin is transmitted by convection along the fin;
- CC2, in which the heat arriving at the end of the fin is negligible and, therefore, the fin edge can be considered adiabatic;
- CC3, in which the temperature of the fin edge is known and;
- CC4 represents the ideal case in which the fin extension is so large that it can be considered infinite, and therefore, the temperature at the fin edge is equal to the ambient temperature.

Figure 3 illustrates the temperature distribution for an annular ring case of the inner and outer radius of 50 and 100 mm, respectively, with a heat transfer coefficient equal to 150 W/m^{2}K, the thickness of 5 mm and end temperatures of 100 ºC and 80 ºC, ambient temperature of 50 ºC. The heat fluxes for boundary conditions CC1, CC2, CC3 and CC4 are 244, 238, 230 and 387 W/m^2, respectively. As can be seen, the last boundary condition CC4 differs quite a lot from the remaining ones, as the ratio of the exterior to interior radius is not high.

Considering the objective of this work, the most appropriate boundary condition is CC1 because the transmission at the tip is by convection. However, for the characteristic dimensions of the fins, CC2 and CC3 would also be valid. The distribution can be approximated by straight lines to achieve zero errors at the base and tip of the fin.

In a first approximation, the solution for boundary conditions CC1, CC2 and CC3 can be approximated by straight lines to achieve zero errors at the base and the tip of the fin. The maximum relative approximation

error is 6.5% and occurs at the midpoint of the fin. Because these are small errors, the fins can be made independent, in terms of temperature, of the body to which they are attached.

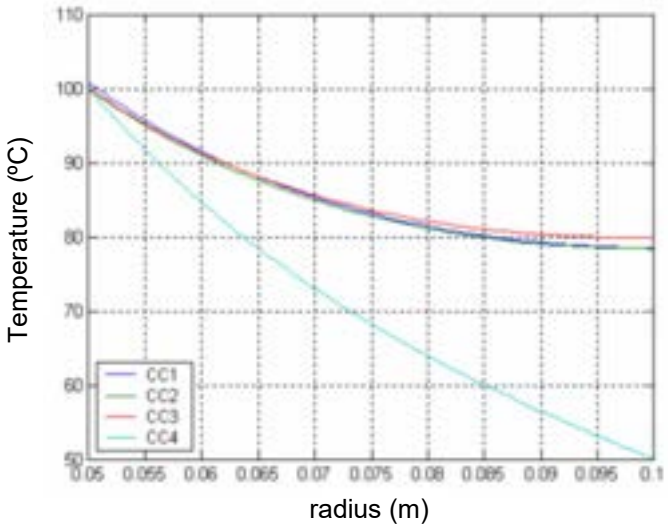

Figure. 3. Evolution of temperatures along an annular fin for different boundary conditions.

2.3. Finite element method (FEM) resolution of conduction and convection heat transfer of extended surfaces

A simple model of a trapezoidal fin is initially simulated to validate and understand the FEM resolution of heat transfer. Figure 3 shows the fin and conditions and simulation results.

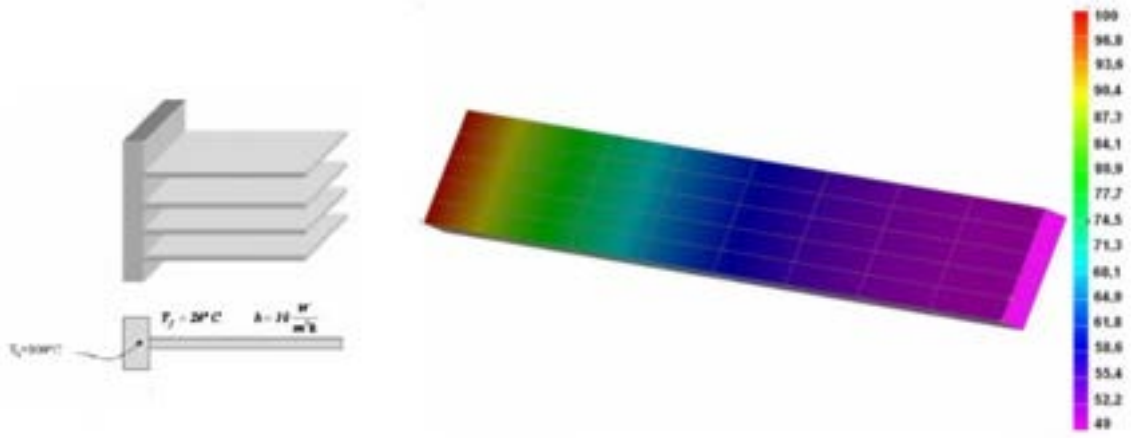

Figure. 3. a) Fin model; b) Simulation results

The temperatures obtained by analytical resolution and by FEM are compared and show divergences of less than 0,5%, which are smaller the more elements the model meshing has, although its complexity and computational load also increase.

2.4. Experimental setup

An experimental installation for the measurement of inner temperatures of systems by means of the methodology proposed in this work and for its validation is carried out., which consists of a large box, in comparison with those of the system to be tested, totally hermetic and thermally isolated from the outside. Inside this box, electrical resistors were placed. On the upper surface of the box, there is an opening in which the inner surface of the component to be tested is fitted. In this way, the box simulates the combustion chamber of the engine in which the electrical resistors generate the released energy. The thermal power chosen is similar to that which would be produced in the real operating conditions of the components to be tested. They simulate the conditions of energy generation by combustion. Thermocouples are placed on the inner and outer surfaces of the system to be tested. Figure 4 shows the installation scheme, and Figure 5 shows photographs of the installation and a detail of the location of thermocouples on the inner surfaces. Thermographs are also taken of the external surfaces, which are the ones visible to the camera. Figure 6 shows thermographs taken from the experiments.

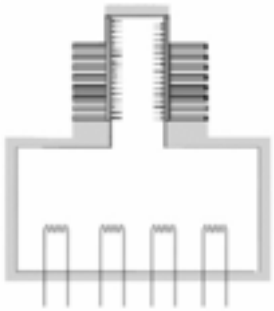

Figure 4. Installation scheme for methodology validation.

Tests were carried out with electrical powers of 150, and 600 W and the cylinder and cylinder head of an air-cooled reciprocating internal combustion engine with finned outer surfaces were chosen as parts. When the temperatures at the thermocouples and the temperature and pressure inside the case reached a steady state, approximately 30 minutes, the thermocouple temperatures and thermographs of all visible surfaces were recorded (Figure 6), and the values of the ambient conditions were also recorded.

3. Selection of the set of boundary conditions

Several sets of boundary conditions can be imposed to estimate the temperature of the inner surface of the cylinder head or cylinder. The proposed ones are:

a) The temperature at the outer surfaces and heat flux at the inner surface.
b) Convective heat transfer coefficient on the outer surfaces and heat flux on the inner surface, such that the temperatures of the outer surfaces match the measured temperatures.
c) The temperature at the outer surfaces and heat flux due to convection at the outer surface.

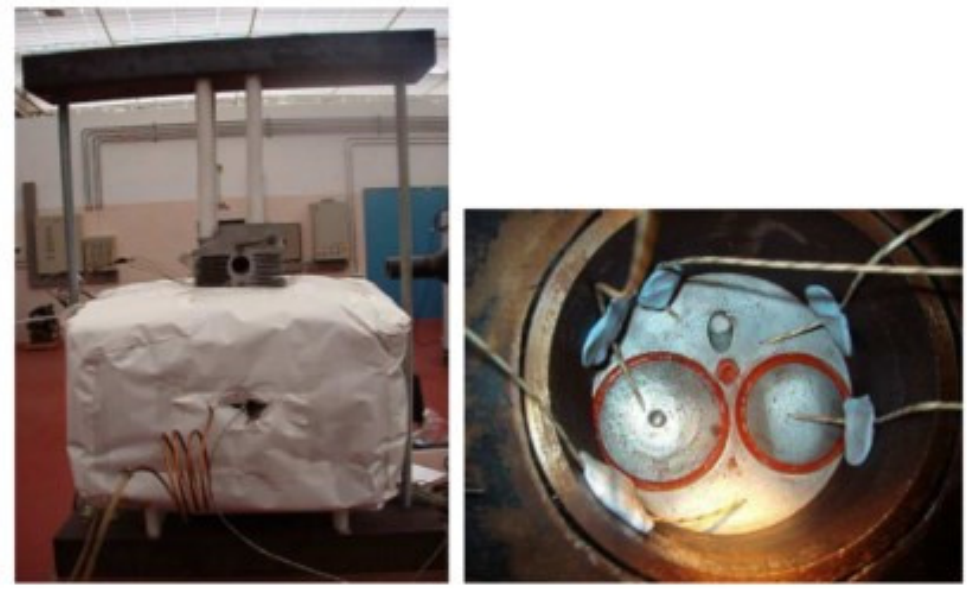

Figure 5. a) Installation setup; b) thermocouples on inner surfaces.

The set of boundary conditions c) is discarded because of the need to impose boundary conditions on all finned surfaces for FEM resolution, which is impossible from a practical point of view.

The two possible sets of boundary conditions, a) and b), are applied to the two chosen components.

3.1 Previous analysis of the boundary conditions

In this case, the set of boundary conditions a) is applied. The external surface temperature field is imposed from the temperature measurements obtained in the test. This field is of the logarithmic type, as shown in Section 2.2:

Step 1: This step intends to obtain a logarithmic-type temperature distribution on the fins by imposing on the bottom and end nodes of the fins the temperatures measured in the test. As discussed in Section 2.2, the errors in the temperature distribution are small regardless of whether a linear or logarithmic distribution is applied. However, the errors in the flow distribution through the surface are relevant. It should be noted that

these are the only boundary conditions applied and that the rest of the surfaces (lateral surface of the fins, inner surface of the cylinder head and non-finned surfaces of the cylinder head) are adiabatic. A scheme of Step 1 is shown in Figure 7.

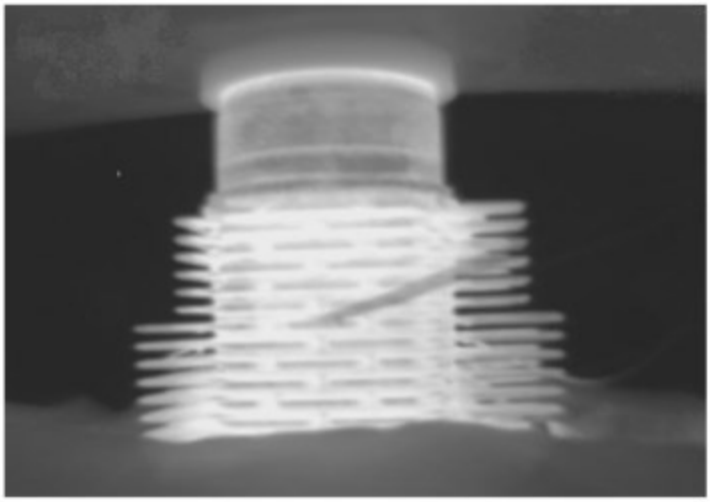

Figure 6. Extended surface cylinder thermograph.

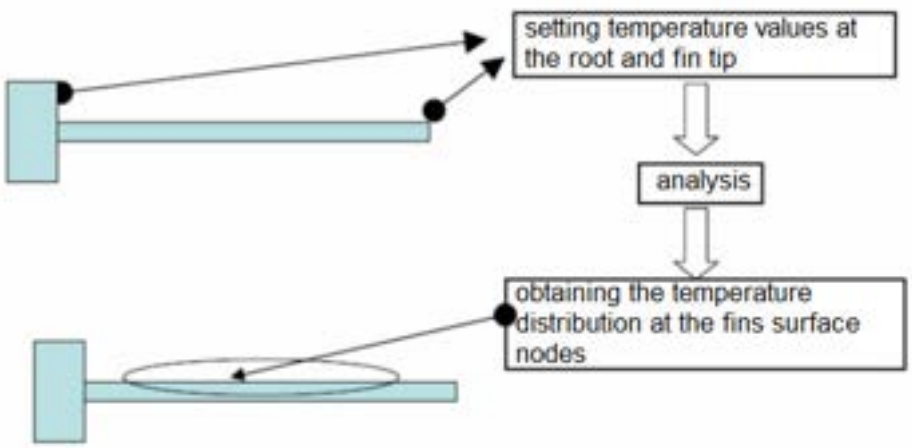

Figure 7. Step 1 of the boundary conditions set election.

Step 2: in this step, the temperatures of the finned surfaces obtained in Step 1 are imposed as a boundary condition; other boundary conditions modelling the test are also imposed, Figure 8:

- heat flow through the inner surface of the cylinder head,
- free convection transfer coefficient from the non-finned outer surfaces to the environment,
- other surfaces are considered adiabatic

3.2. Analysis of the simulation results

The temperature distribution is obtained from the resolution of this model and matches the measured values. However, the heat flux distribution is not valid since it results from solving a one-dimensional conduction problem in the fin in Step 1. This model forces the appearance of local heat fluxes that are transferred from the environment to the root of the fin, called auxiliary fluxes. A scheme of such auxiliary flows is shown in Figure 9. This situation is unrealistic and persists in Step 2 of this resolution and cannot be cancelled.

Therefore, although the temperature field on the outer surfaces is adequate, the heat flux distribution is not. This is the reason why this set of boundary conditions cannot be imposed on the simulation of the cylinder head and cylinder when the engine is under load. The second set of boundary conditions and their validity for the estimation of the average inner surface temperature of the two systems tested is presented below.

In view of the conclusions of the analysis of the application of the set of conditions a), which advise against its use, the set of boundary conditions b), which imposes free convection transfer on the surfaces, is applied. The measured heat power is uniformly distributed on the inner surface.

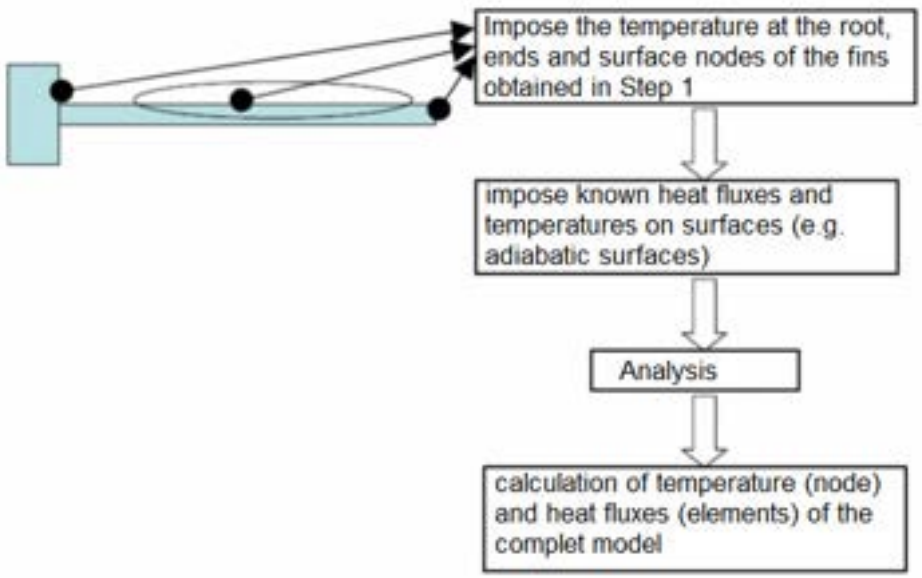

Figure 8. Step 2 of the boundary conditions set election.

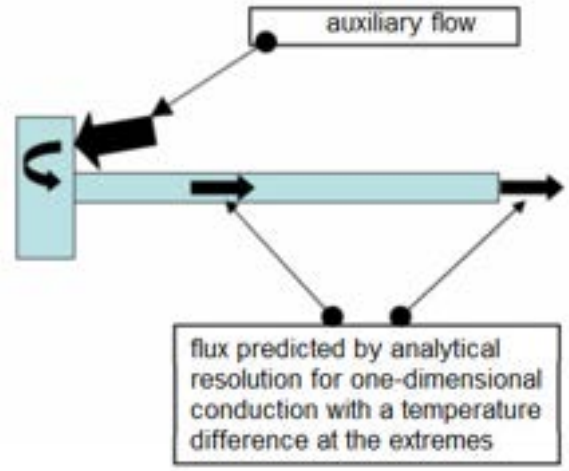

Figure 9. Auxiliary flows representation.

Once the boundary conditions are imposed: uniform heat flux over the elements of the inner surface of the cylinder, which is equal to the heat power generated by the electrical resistors, and the convection coefficient over the elements of the finned surfaces, the model with the applied loads is sent to the NX/NASTRAN solver module.

The temperatures measured on the external surfaces by thermographs and thermocouples will be compared with the temperature field on the external surfaces obtained from the FEM simulation from an initial heat transfer coefficient. If this correspondence does not occur, the comparison is iterated with FEM simulation results with another heat transfer coefficient value.

4. Methodology proposed

A comprehensive review of heat transfer on extended surfaces has been carried out in the previous sections, and the best selection of boundary conditions for temperature determination has been studied. This work aims to determine the average inner surface temperature of systems with extended outer surfaces inside which there is power generation. An inverse method that solves the heat transfer in these systems by means of finite elements is then proposed and described, taking into account the previous considerations exposed in Sections 2 and 3. The main difficulty of this kind of approach is the correct imposition of the boundary conditions in the models and the value of these boundary conditions, whose considerations have been discussed in Section 3. A flow diagram of this methodology is presented in Figure 10.

In the proposed method, the following boundary conditions are chosen:

- Heat flow through the inner walls of the system to the outside, $\dot{Q}_{heat}$

- The heat transfer coefficient on the outer surfaces h_{ext}, which is obtained from an iterative process that converges when the temperatures on the outer surfaces resulting from the FEM model match the measured ones,
- The temperatures of the selected points of the external surfaces and whose values are obtained from the thermographs and those recorded in the thermocouples during the tests, $T_{meas,k}^{outer}$.

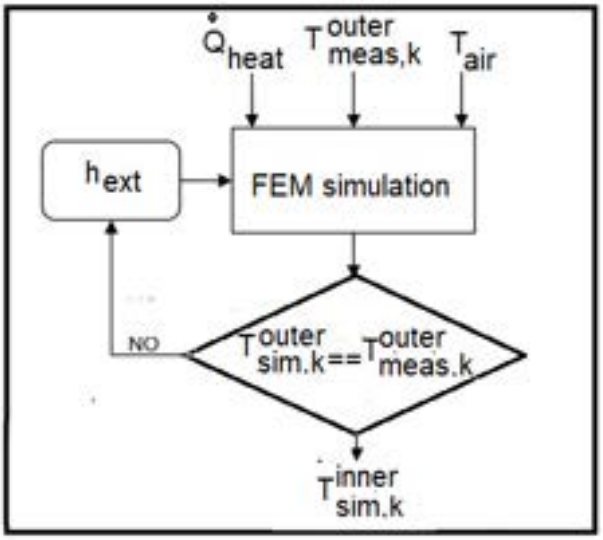

Figure. 10. Methodology flow diagram.

The value of the heat flow through the inner walls of the system, $\dot{Q}_{heat}$, is the heat released by the electrical resistances, whose total value is known but not its distribution along the inner surface. The FEM model requires the heat per unit area and time as a boundary condition. The heat distribution is assumed to be uniform, and the inner surfaces whose outer equivalent are not finned, which is also adiabatic, are considered adiabatic.

The second boundary condition imposed is the convective heat transfer from the outer extended surface to the surrounding air. The heat transfer coefficient h_{ext} is constant and the air temperature is constant.

The cylinder head is an example of those components where there are several parts, and the interaction between surfaces must be considered. In this case, it is considered that the bond between the contact surfaces is perfect and the conductivity is infinite.

Once the boundary conditions have been applied, the model is sent to the NX/NASTRAN solver module.

Once the boundary conditions have been successfully applied, the model is sent to the NX/NASTRAN solver module.

When the simulation is finished, the temperatures of the outer finned surfaces are obtained in the FEMAP post-processing module. Due to the large surface area, points were chosen to compare the measured temperature with the temperature resulting from each simulation. The values of the 9 thermocouples and 10 points on the thermographs were chosen, in total 19 points. The 19 measured temperature values, $T_{meas,k}^{outer}$., are compared with those resulting from the simulation, $T_{sim,k}^{outer}$. k indicates the temperature point being compared. The mean square variation, called MSE, is defined according to Equation (2):

$$MSE = \frac{1}{n}\sum_{k=1}^{k=n}\left(T_{sim,k}^{outer} - T_{meas,k}^{outer}\right)^2, \quad (2)$$

The method attempts to identify the value of h_{ext} that minimizes the mean square error with the temperature measurements MSE_{min}, Figure 11. To calculate such an optimal value of h_{ext} an iterative search process is followed based on interpolations of $MSE(h_{ext})$ as a Cubic Spline type curve. The search is initialized by taking three sufficiently distant values of h_{ext} and calculating the MSE values, they produce.

These $MSE(h_{ext})$ curve values are then interpolated by Spline, and the minimum of the interpolated curve and the corresponding hext,CIL value are calculated. The model is then simulated with this value, and the MSE it produces is calculated. If no significant improvement of MSE is achieved, relative difference below 5%, it is considered to have converged to MSE_{min}. If the improvement is significant, it is incorporated into the interpolation of MSE_{min} by Cubic Spline and iterated again.

As an example, the method when the extended surface cylinder is tested, and the internal thermal generation is equal to 150 kW is illustrated in Figure 12.

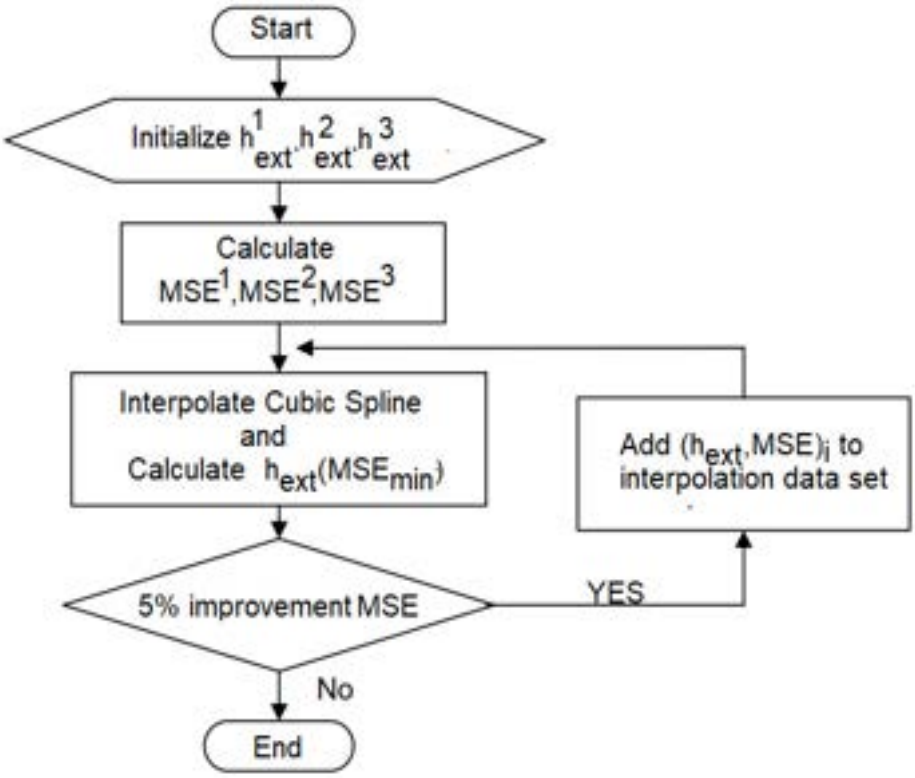

Figure. 11. Heat transfer coefficient iterative method.

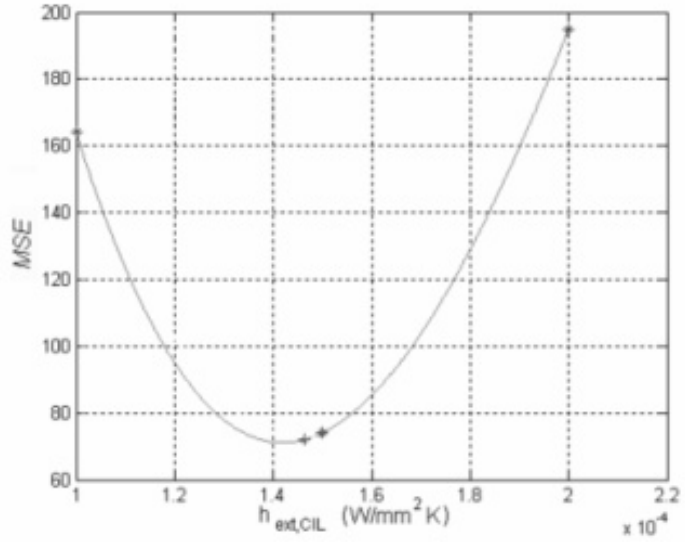

Figure. 12. MSE for different heat transfer coefficients values according to the iteration method

A representation of the temperatures at the chosen points, resulting from experimentation and simulations, for the internal and external surfaces is shown in Figure 13. As can be seen, the difference between the simulation and measured temperatures is quite small. Figure 14 shows a comparison of FEM simulation results with thermography measurements, proving the great similarity between the two.

It is verified that the resulting inner surface temperatures correspond to those measured with thermocouples in the tests. As for the distribution of the heat flows, it is verified that, in all cases, on the whole external surface they are transferred from the environment to the cylinder head and that on the internal surface, the flows are incoming. There are no auxiliary heat flows from the environment to the fins, as in the previous case. The total power transferred through each of the surfaces is also obtained, and it is found that the power transferred through the outer surfaces is equal to that generated by the electrical resistors. It should be noted that the proportion of power transferred to the environment from the finned surfaces is much higher than that associated with the non-finned surfaces. Once this correspondence has been achieved, it is verified that the resulting interior surface temperatures correspond to those measured with thermocouples in the tests.

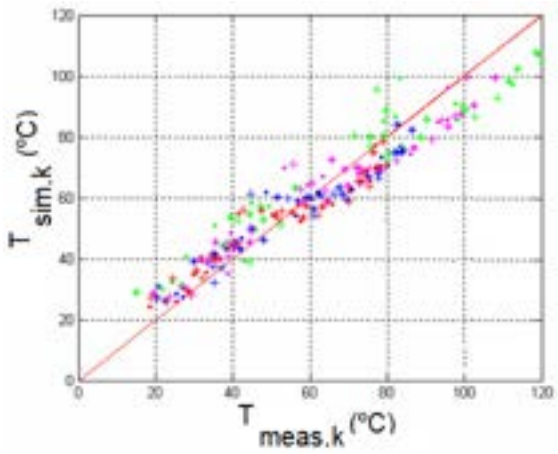

Figure. 13. Representation of temperatures at the points of comparison.

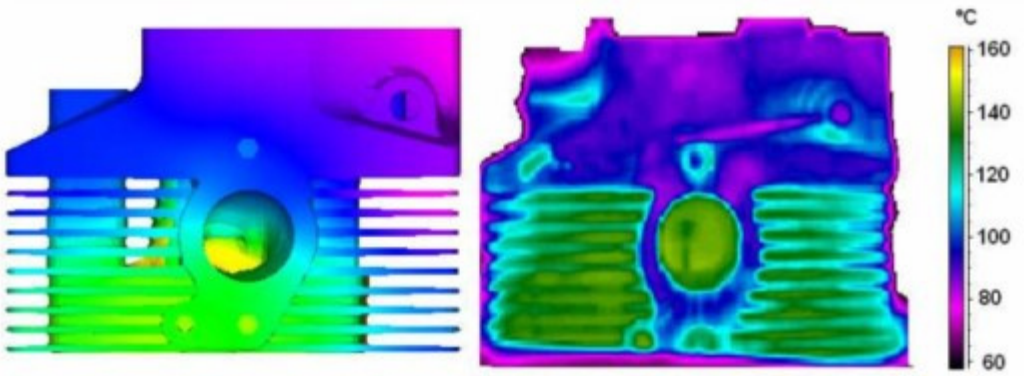

Figure. 14. Comparison of FEM simulation results with thermographs, for tests at 150 W and cylinder head as a component.

5. Conclusions

This work presents a methodology for an accurate evaluation of the inner temperature of high-temperature thermal energy systems. It is developed for being applied to hard-to-monitor systems, such as internal combustion engines or high-temperature energy storage systems. The methodology is demonstrated in an air-cooled internal combustion engine but is fully applicable to any other thermal system with the characteristics described.

Regarding the distribution of the heat flows, it is verified that, for all cases, in all the external surfaces, these are transferred from the environment to the cylinder head and that in the internal surface, the flows are incoming. There are no auxiliary heat flows from the environment to the fins, as in the previous case. The total power transferred through each of the surfaces is also obtained, and it is found that the power transferred through the outer surfaces is equal to that generated by the electrical resistors. It should be noted that the proportion of power transferred to the environment from the finned surfaces is much higher than that associated with the non-finned surfaces.

Therefore, the inverse methodology for determining internal surface temperatures by non-intrusive means has been validated.

Direct vaporization ORC-evaporator heat transfer model for thermal degradation risk assessment

João S. Pereira* and José B. Ribeiro

Univ Coimbra, ADAI, Department of Mechanical Engineering, Coimbra Portugal,
joao.pereira@dem.uc.pt

Abstract:

For the last decades, Organic Rankine Cycle has been the technological choice of numerous large-scale systems. Due to its characteristics, mainly its simplicity and reliability, the ORC is pointed to be one of the most promising technologies to fulfil the gap of cogeneration systems in domestic dwellings. However, bringing the technology to the domestic scale can raise some difficulties related to its restricted requirements which can go from the system size to the response time. To deal with these questions, the use of direct evaporators is been referenced as an imperative path to follow. The use of these direct evaporators excludes the intermediate circuit that is frequently implemented. The introduction of this is usually justified by the direct exposition of the organic fluid to the high temperatures of the heat source which can degrade it. When the author's objective is to individually study the organic fluid and its properties (including its thermal stability), all the information regarding the system becomes irrelevant. The evaluation of the risk that this option may put to the organic fluid thermal degradation requires the determination of the temperature of the heat-transfer surfaces with which the organic fluid is in contact. As its experimental measure is extremely difficult to accomplish, such determination requires the development of a detailed physical model of the combustion and heat-transfer processes in the ORC-evaporator.Taken this into consideration, the development and validation of such model is presented. This will allow a detailed evaluation of several key features of the combustion and heat-transfer processes as a function of some ORC operating parameters. Among those features is the temperature of the internal surface of the tubes with which the organic fluid is in contact. This temperature, which can be used to assess the risk of the thermal degradation of the organic fluid, has shown to be highly affected by the thermal resistances and by the combustion gases temperature. To reduce that risk, the operating conditions of the ORC should be those allowing the vaporization process to start as early as possible and reducing the superheating phase to the minimum possible.

Keywords:

Organic Rankine cycle, Heat-transfer model, ORC-evaporator, Direct vaporization arrangement, Thermal degradation risk assessment.

1. Introduction

Given the huge dimension of its potential market and the expected economic and environmental benefits associated with its use, the research and development activities on a domestic scale combined heat and power systems (CHP) have increased over the last two decades [1,2]. For the particular case of the systems that are attempting to retrofit the current wall-hang combi-boilers, the most promising solutions involve the use of Organic Rankine Cycles (ORC) [3,4]. Furthermore, due to the extremely demanding requirements imposed on these systems, especially in what refers to the (short) response time and (small) dimensions, it is suggested that the vaporization of the working fluid of the ORC should be done using the high-temperature combustion gases directly [5,6]. One of the major risks associated with this option is the thermal degradation of the organic working fluid [7,8]. The high temperature that these fluids may reach when in contact with the heat transfer surfaces can lead to the disruption of the chemical bonds of its molecules and to the subsequent degradation of their physical properties. In an attempt to minimize this problem, ORC-based micro-CHP systems may be reconfigured into a hybrid arrangement in which the combustions gases are firstly cooled in a combustion gases-water heat exchanger before crossing through the organic fluid heat exchanger [9]. Even so, the evaluation of the magnitude of this problem demands the calculation of the heat-transfer surfaces' temperature with which the organic fluid will be in contact. That risk will be minimum if the temperature of those surfaces is kept below the one of thermal degradation. This limiting temperature,

however, is normally determined by standard tests where the fluid is at rest and in thermal equilibrium with the wall of its container [10–14]; a quite different situation from what happens in real working conditions [15]. Besides the bulk temperature of the organic fluid at the exit of the evaporator (a well-known parameter since it is easy to measure and required for the evaluation of the cycle efficiency), it is also important to know the temperature of the heat-transfer surfaces with which the fluid is in contact. Contrary to the organic fluid temperature, this is very difficult to measure but it can, and should, be controlled. Despite its importance, heat-transfer surface temperatures are rarely measured or calculated. Since its direct measure is very difficult, as are those of any tubes' internal surface, the only option left is its calculation. That, however, is far from being trivial as it results from the mutual dependency of the internal and external heat-transfer mechanisms and demands for the development of an appropriated heat-transfer model. The development of such model, that is crucial for the determination of the operation conditions that should keep the risk of thermal degradation of the organic fluid at an acceptable level, however, is not yet described in the literature.

Acknowledging that the thermal degradation of the organic fluid is the key feature opposing the use of direct vaporization in ORC-based micro CHP systems, the main objective of this paper is to show how the operating conditions of those systems (e.g. the organic fluid mass flow rate or the natural-gas burner combustion power) affect the organic fluid vaporization process and the temperatures of the heat-transfer surfaces. These are compared to the temperature limits referenced in the literature to evaluate the risk of organic fluid thermal degradation. This will be illustrated on a particular ORC-evaporator design but the analysis will be kept as general as possible. Given the importance that the evaluation of the heat-transfer surface temperatures may have on the definition of boundaries for the operating conditions, and given the scarcity of heat-transfer models intended to calculate those temperatures, it is also an objective of this manuscript to contribute to the disclosure and widespread of these type of models through the presentation of the approach followed in its development, namely: disclosing the correlations used for the determination of the heat-transfer coefficients and duly presenting the underlying simplifications, calibration and validation.

2. ORC-evaporator heat-transfer model

The ORC-evaporator domain to be simulated in this study comprises the gas-burner and two heat-exchanger sections: one to complete the water heating process initiated in the ORC-condenser, named the water post-heater section (PH), and the other for the organic fluid vaporization, simply named evaporator heat-exchanger (EHE). A 3-D representation of these two sections can be seen in Figure 1.

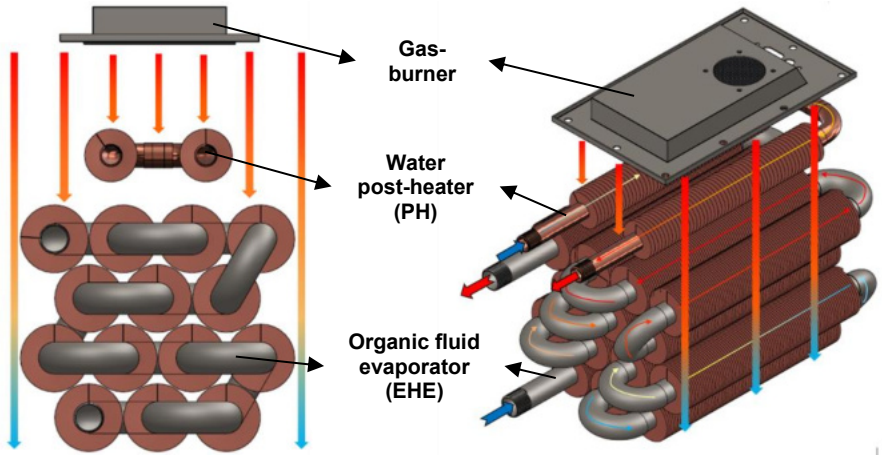

Figure 1. Schematic representation of the two heat-exchanger sections and the natural-gas burner of the ORC-evaporator.

As the PH and the EHE heat-transfer models demand, as input parameters, several combustion gases' characteristics, the thermochemical calculations of the natural gas (NG) combustion process were also included in the overall model. Thus, the overall model includes three different sub-models: i) the gas-burner/combustion model, ii) the PH heat-transfer model and iii) the EHE heat-transfer model. These models were implemented in MatLab® coupled with the RefProp thermodynamic database [16]. According to the physical arrangement, as depicted in Figure 1, the models are run sequentially since the outputs of the combustion model are used as inputs for the PH model and its outputs are used as inputs for the EHE model, as shown in Figure 2.

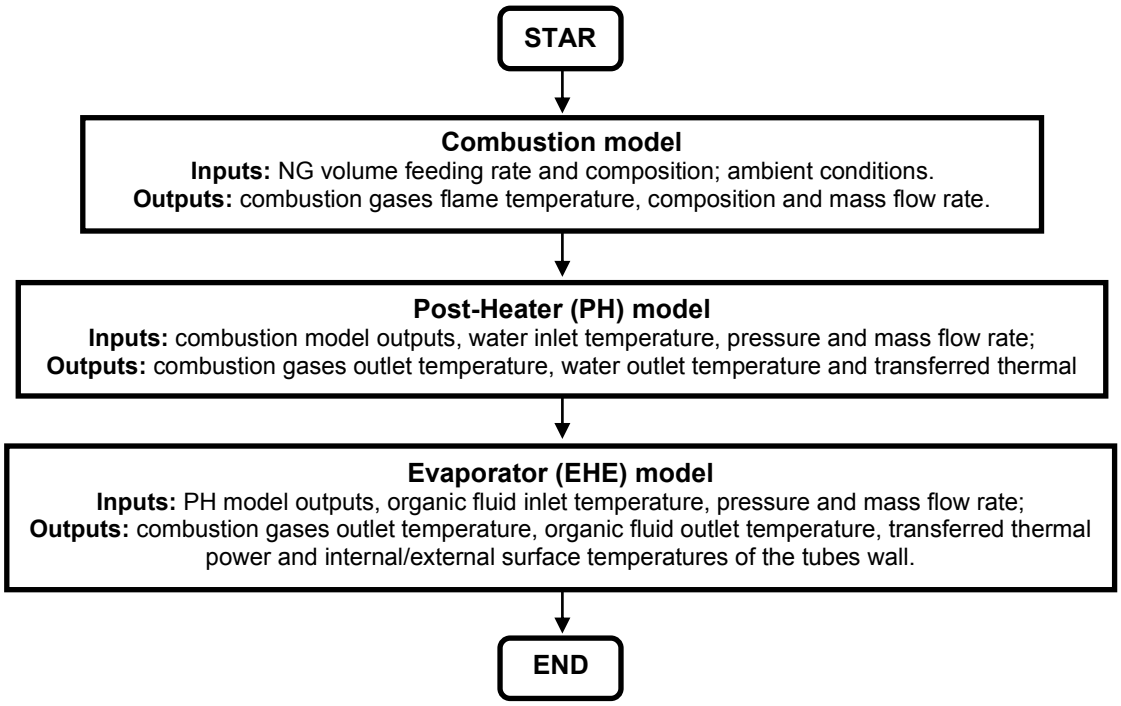

Figure 2. General flowchart of the entire ORC-evaporator model with the main inputs and outputs.

The Post-Heater (PH) is a cross-flow heat exchanger placed between the gas burner and the EHE (see Figure 1). It is composed of a pair of finned tubes within which water, previously heated in the ORC condenser, flows. To calculate the outputs described in Figure 2, the overall heat-transfer coefficient must be determined. This demands the calculation of the heat-transfer coefficient for the water and combustion gases sides. In order to make that determination easier and since it is known that the water inside the PH tubes will remain in the liquid state and its temperature will not drastically rise, the water's physical domain was divided into two control volumes (CV) – one for each tube. For the combustion gases side, however, the physical domain was not divided and the temperature is assumed to have a uniform/ homogeneous distribution in the horizontal direction. The CVs in which the PH domain is divided are illustrated in Figure 3.

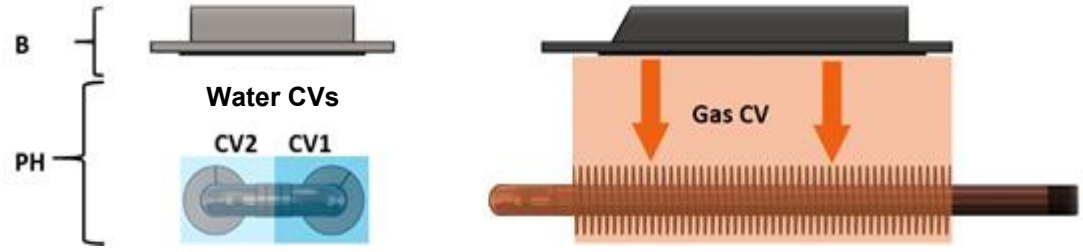

Figure 3. 2D view of the gas-burner (B) and PH assembly with the CVs defined for the water and the combustion gases flow.

The EHE is a compact heat exchanger made of stainless-steel tubes with copper fins presenting a mixed configuration regarding the interaction between the external and internal flows since it can be classified neither as a counter-flow nor as a cross-flow arrangement. Figure 4 shows a detached schematic representation of the EHE with the flow directions for both fluids.

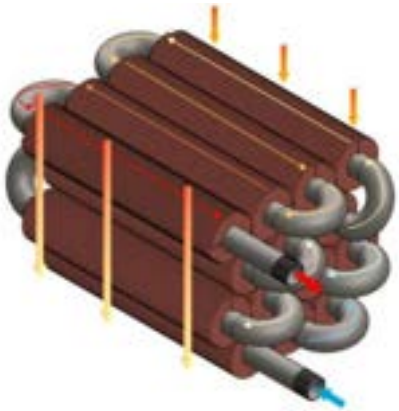

Figure 4. Schematic representation of the (detached) EHE section.

The EHE contains four levels of stainless-steel tubes with copper fins. Each level contains a different number of tubes, as shown in Figure 5. Since the variation of the organic fluid properties is expected to be much bigger than those observed for the water in the PH section (mainly due to the vaporization process), the volume occupied by this inside the EHE tubes was split into a large number of CVs. On the other hand, the volume occupied by the combustion gases was split into as many CVs as levels of tubes.

All the equations and details regarding the model developed are shown in [17].

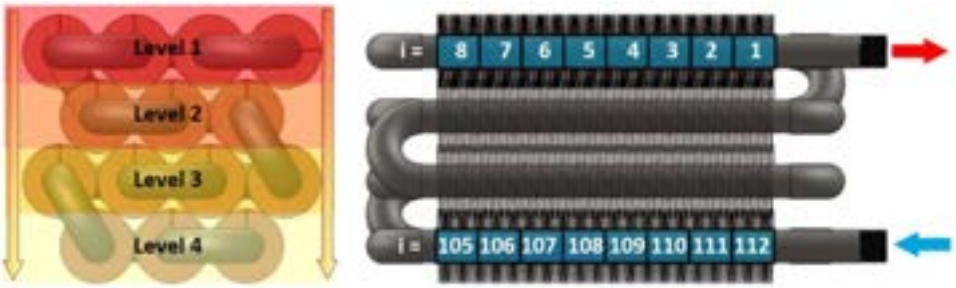

Figure 5. 2D view of the EHE section with the discretization of the gas and organic fluid per CV.

3. Experimental test rig

In order to verify and validate the options taken and the simplification made in the development of the ORC-evaporator physical-mathematical model, a comparison needs to be done between the results retrieved with it and those obtained from the experimental tests. To perform such a task, the designed ORC-evaporator was integrated into a test rig emulating a micro-scale ORC-based CHP system. A schematic diagram, including the instrumentation used, is presented in Figure 6.

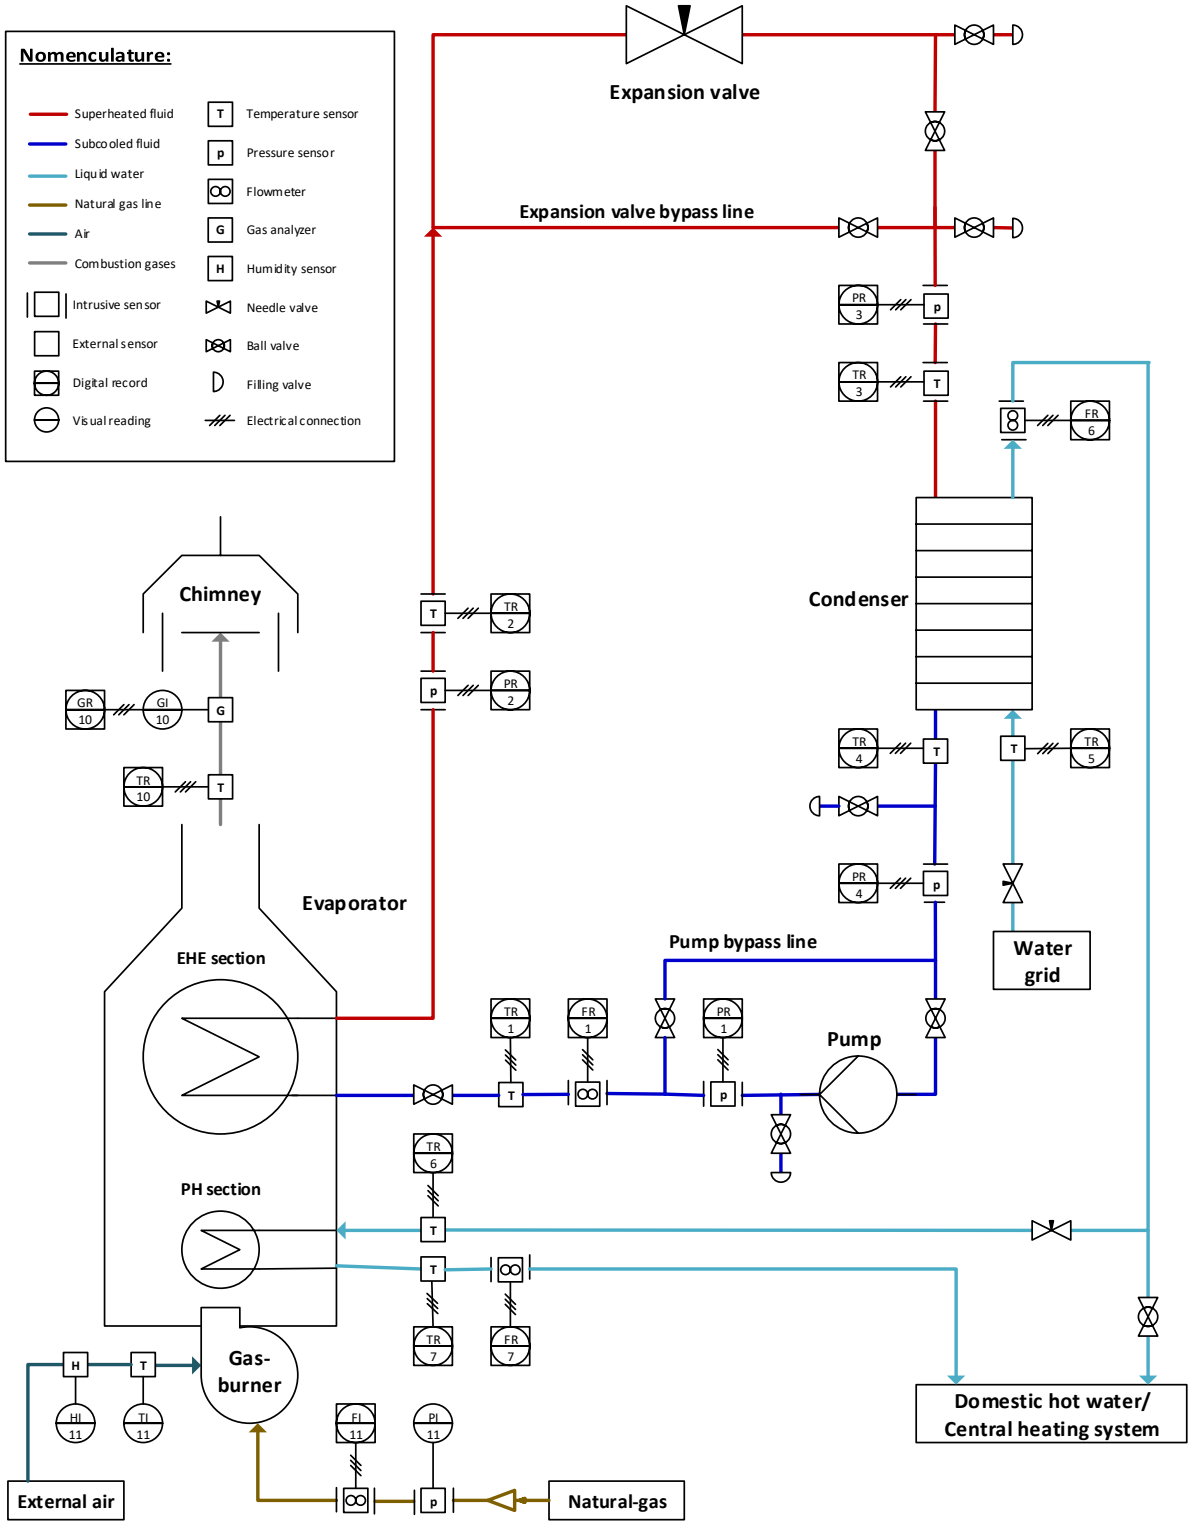

Figure 6. Schematic diagram of the hybrid CHP configuration with the new ORC-evaporator.

As there is a particular interest in the characterization of the ORC-evaporator behaviour, this component is specially monitored and, in addition to the instruments presented in Figure 6, both of its sections have a series of contact thermocouples partially embedded in the wall of the elbows that connect their finned tubes. These thermocouples are kept out from the direct exposition of the combustion gases and are externally surrounded by a quasi-adiabatic media, as is shown in Figure 7. The main characteristics of the instruments used are presented in Table 1.

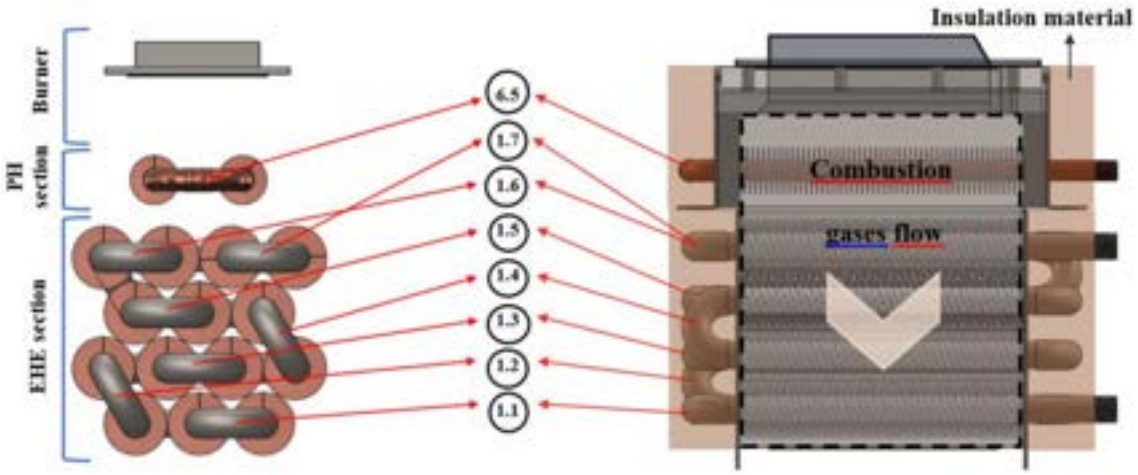

Figure 7. Schematic representation of the ORC-evaporator with the location of the contact thermocouples alongside the PH and EHE sections.

Table 1. Main characteristics of the instruments used in the experimental test rig.

Line number (see Figure 6)	**Measurement**	**Stream**	**Type**	**Range**	**Accuracy**
1	Mass flow rate	Organic fluid	Coriolis	[0 – 2.2] kg/s	0.4 %
[1-4]	Pressure	Organic fluid	Diaphragm	[0 - 10] bar	0.05 % FS
[All]	Temperature	Organic fluid / PH water / combustion gases	Thermocouple type T	[-40 - 300] ºC	0.0075.|T| or 1 °C
7	Volumetric flow rate	PH water	Turbine	[1 - 25] L/min	2 %
10	Oxygen sensor	Combustion gases	Infra-red	[0 - 25] %	1 %
11	Temperature / humidity	Ambient air	Thermistor/ polymer film	[-20 - 40] ºC / [20 - 80] %	5 %
11	Volumetric flow rate	Natural-gas	Diaphragm	[0 – 1.7] dm^3/s	1 %

4. Model validation

The comparison between the experimental and the model results will be done for the water and organic fluid temperatures gathered along the PH and EHE sections of the ORC-evaporator (see Figure 8), respectively. Besides those temperatures, the transferred thermal power in each section will also be used to assess the match between the experimental and the model results as it allows solving the problems arising from the use of temperatures to compare the heat-transfer process when a two-phase state is presented (see Figure 9).

The data shown reveals differences between the calculated and the experimental results smaller than 2% regarding the transferred thermal power, for both sections and, concerning the temperatures, values smaller than 2% and 8% for the PH and EHE sections, respectively. These results end up reflected in the model's capacity to predict the starting point of the organic fluid vaporization process within the ORC-evaporator tubes. This can be seen in Figure 10, in which the measured and calculated temperatures of the organic fluid retrieved along the EHE section are shown for one specific operating point. The error in the identification of the beginning of the phase transition process is less than 1 tube.

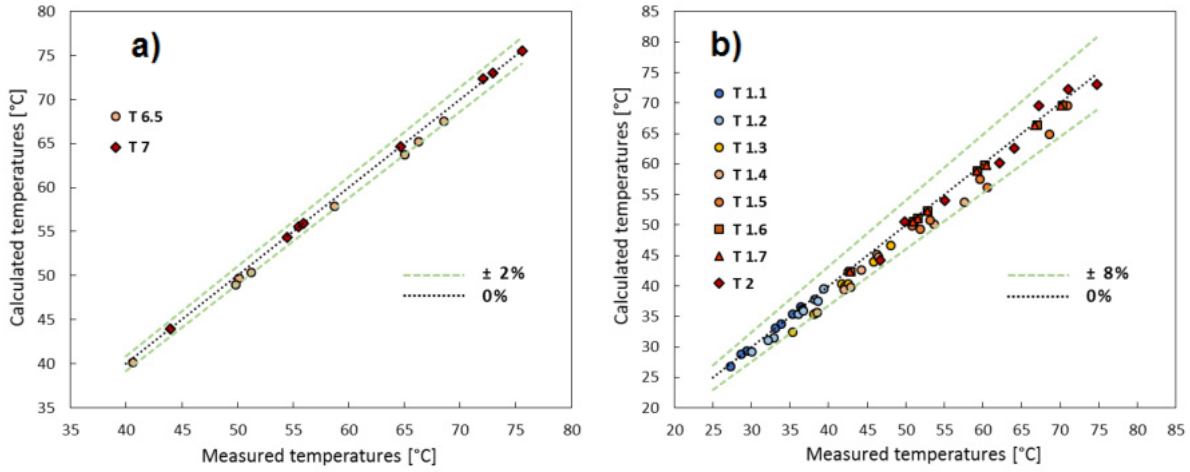

Figure 8. Calculated versus measured temperatures for a) PH and b) EHE.

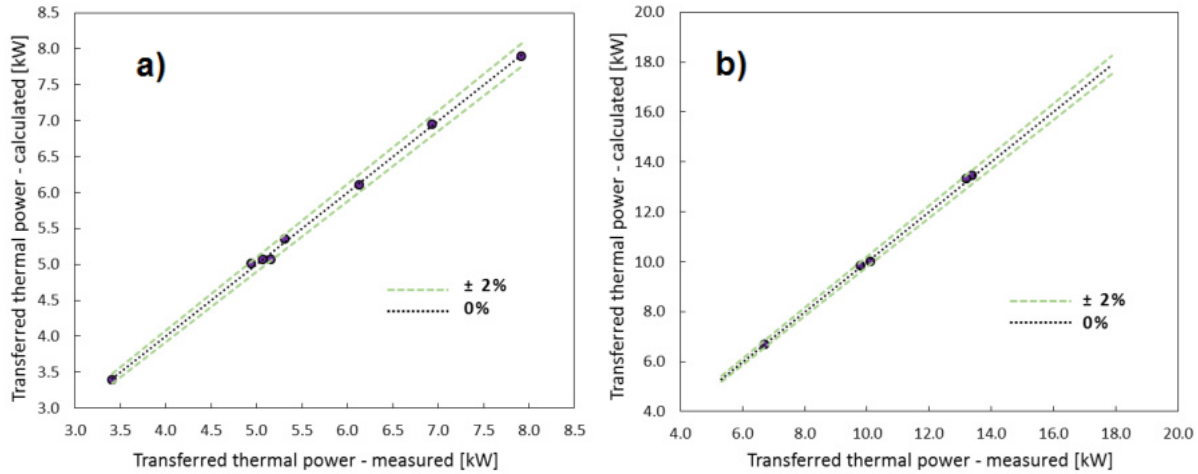

Figure 9. Calculated versus measured transferred thermal power for a) PH and b) EHE.

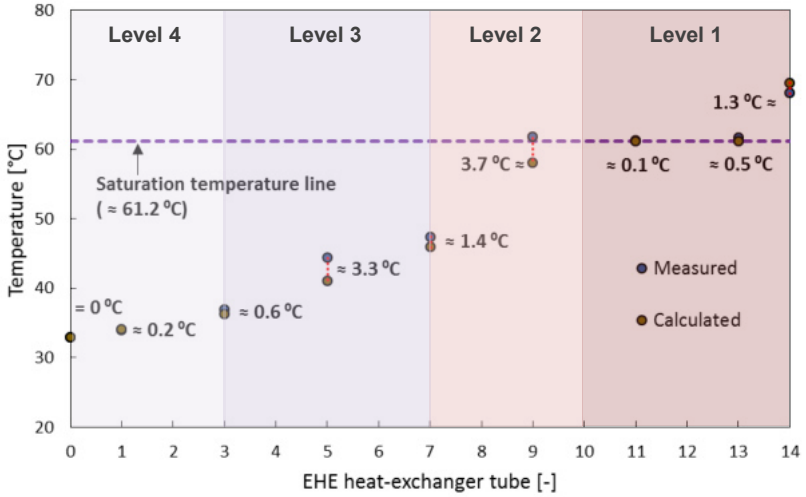

Figure 10. Calculated and measured values of the organic fluid temperatures along the EHE section.

5. Model exploration and conclusions

It is presumed that the reliability shown by the model on the prediction of the organic fluid temperature and of the transferred thermal power is inferable for the prediction of the temperatures of the inner surface of the evaporator tubes since they are mutually dependent. Thus, it will be possible to use it to identify what is and where occurs the maximum value of the inner surface temperature of the evaporator tubes, so that considerations about the risk of thermal degradation of the organic fluid may be taken into account. This temperature, together with both the outer surface and the organic fluid temperatures, is shown in Figure 11 for one specific operating point, as an example. The combustion gases' temperature values, for each of the

levels in which their domain is divided, are also shown in that figure. As their behaviour is essentially determined by the thermal resistances involved in the heat-transfer process, the values of those, evaluated for each of the EHE control volumes, are shown in Figure 12 together with the cumulative transferred thermal power.

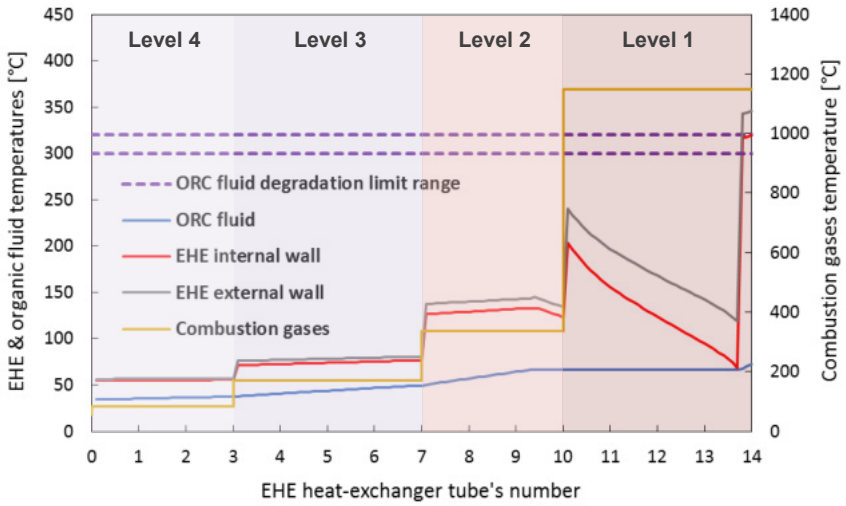

Figure 11. Combustion gases, organic fluid (bulk) and tubes internal and external wall temperatures along the EHE tubes.

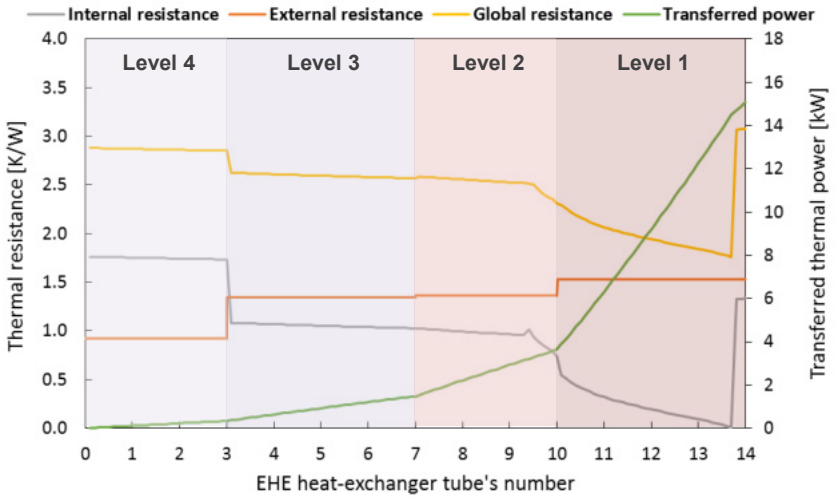

Figure 12. Internal, external and overall thermal resistances and cumulative transferred thermal power along the EHE tubes.

From this analysis, it can be said regarding the main objective of this work, the characterization of the temperature of the internal surface of the EHE tubes, that this parameter is essentially determined by the internal thermal resistance (since the external is essentially constant) and by the combustion gases' temperatures. As the non-boiling heat-transfer processes, occurring when the organic fluid is either in liquid or in gaseous phases, are characterized by similar values of the internal thermal resistance (see Figure 12), the combination of these heat-transfer regimes with high temperatures of the combustion gases may originate very high internal surface temperatures of the EHE tubes (see Figure 11). Therefore, efforts should be made to avoid or, if not possible, to minimize those. That means, reducing the superheating degree to the minimum value possible and avoiding the presence of the organic fluid in a liquid phase on the 1st level of the tubes. It is also important to notice that any reduction in the temperature of the combustion gases in contact with the tubes of this 1st level, as the one induced by the PH section in this case, will help to reduce the maximum temperature of the inner surface of the tubes' wall and with that, the risk of fluid degradation.

Exergy cost analysis of bifurcated circular vessels with permeable walls: beyond the Hess-Murray law

Enrico Sciubba
Università Niccolò Cusano – Roma, Italy
enrico.sciubba@unicusano.it
ORCID 0000-0003-2220-1762

Abstract

Since bi- and trifurcated structures are ubiquitous in nature (from trees to rivers to bronchial alveoli to veins and arteries etc.), the idea that their striking topological similarity originates from a physical principle is appealing and stimulated a great number of theoretical and experimental investigations. The concepts of "nature's economy" and of "goal-driven evolution" can been invoked to conjecture that there must be some "reward" for the effort placed by a biological system to build a bifurcated structure, in the sense that the evolutionary advantage gained by the system must more than compensate the additional resource consumption. The interest of engineers, botanists and biologists in this matter is justified by the expectation that linking the "shape" of these structures to their "function" would allow for better aimed interventions in the case of malfunctions (overflow of rivers and channels, tree roots rotting, poor soil exploitation, circulatory diseases…). Furthermore, provided the quite different boundary conditions are properly taken into account, such an insight may be translated into more accurate and efficient design guidelines of artificial (manufactured) branched structures like pipelines, heat exchangers, biological implants etc..

In the early XX century two physiologists, Walther R. Hess in 1903 and Cecil B. Murray in 1926, independently derived a general correlation between the successive radii of bi- and trifurcated vessels: since their derivation was based on a first-order "energy budget" of the operation of the bifurcated system, their result ($r_{i+1}/r_i=2^{-1/3}$) was seen as a confirmation of the evolutionary biology, then in its infancy. The Hess-Murray Law has undergone since a series of critical reviews both in biology and in engineering, and different researchers strived on the one side to reinforce its physical foundation and on the other side to justify the obvious disagreement of its predictions with experimental data.

In this paper, after a brief discussion of Hess' and Murray's original derivations, experimental evidence and physical considerations are used to argue that the "cubic root of 2" allometry cannot apply to the blood flow in arteries and veins. Its application to capillary flows must be corrected by introducing wall suction. On the same basis, it is argued that the law accurately represents the flow in sap-carrying vessels in leaves, but cannot be applied to tree branchings where the bifurcations are originated by a different sort of evolutionary trade-off.

It is then shown that an exergy cost analysis leads to a more credible quantification of the cost/benefit ratio of creating a bifurcation: an application to realistic models of permeable blood vessels indicate that a) the onset of a bi- or trifurcation always requires a larger use of resources w.r.t. the equivalent non-bifurcated configuration; b) the existence of an optimal radius ratio is not guaranteed; and c) the H-M optimal ratio can be seen as a limit value obtained by neglecting some of the relevant physical variables.

1- Introduction

1.1 - The problem

Bifurcated structures in fluid carrying channels and vessels are ubiquitous in nature: as shown in (Figure 1) the shape of tree roots and branches, leaf veins, circulatory systems in animals, air vessels in the respiratory systems, river deltas…display an amazing degree of geometric similarity, so pervasive to suggest the conjecture that their creation can be explained by some common evolutionary principle. Understanding the underlying physics might lead to a better comprehension of natural evolution and linking the "shape" of these structures to their "function" would allow for better aimed interventions in the case of malfunctions (overflow of rivers and channels, poor health of tree roots and tips, poor soil exploitation, circulatory diseases…). And a clearer insight on the physics of natural bifurcations may pave the way to the formulation of more accurate and efficient design guidelines of artificial (manufactured) branched structures (provided proper provision is made for the quite different boundary conditions).

It is therefore not surprising that a multitude of studies have been -and still are being- published on the topic. In fact, engineers, botanists and biologists have devoted substantial time and resources to search for a general model of bi-, tri- and polyfurcated fluid carrying vessels. From a careful consultation of the archival literature [9,18,24,27,28] it is though apparent that there remain questions to be answered:

a) Why do bifurcated structures appear in nature?
b) Why is the geometry of such structures apparently similar at all scales and in different instantiations?
c) How and to what measure is the shape of a bifurcation independent of the prevailing boundary conditions?
d) Does the functional advantage obtained by repeated bifurcations decrease with the number of splittings?

One of the goals of this paper is to clarify the current state of affairs and suggest possible paths to a solution. To place this study in the correct perspective, it is useful to begin by examining the available empirical evidence collected over decades of valuable experimental campaigns:

1) Although different types of branchings display an amazing degree of large-scale geometric similarity, the specific details (radius- and length ratio of daughter and parent branches, branching angle, complanarity) depend on the type of fluid being transported (newtonian or non-newtonian, pure substance or particle laden), on the material of the channel walls (lignine, muscle fibers, gravel, sand…), and on the flow features (creeping, laminar or turbulent);
2) Although a branched network resembles a fractal structure, there is no indication that the fractal exponent remains constant over successive branching levels. Thus, Fractal models are not considered here;
3) While in plants the flow can be accurately modeled as stationary, in blood and air systems as well as in rivers the non-stationarity of the flow has a substantial influence on the geometry of the bifurcations.

1.2 – The currently most popular physical model: the Hess-Murray law

In 1903 the Swiss physiologist Walter Rudolf Hess formulated a model of blood flow in arteries and capillaries that results in an allometric correlation between the radii of successive branchings in bi/trifurcated vessels: the original concept is presented and discussed in Hess' doctoral thesis published in 1903, with expanded versions published in 1914 and 1917 [7,8]. The same correlation was "rediscovered" by the American physiologist Cecil Dunmore Murray in 1926 using a slightly different approach, and later refined and extended in the same year in two other papers [12,13,14]. Since the numerical result, i.e., the allometric rule, is the same, the law came to be referred to as "the Hess-Murray law".

The method proposed by Hess and Murray is described in detail in several review papers [4,20,24,28], and what is of interest here is to underline the novelty of their approach: they assumed that blood or lymph circulation in living organisms is governed by a "work minimization" principle. Although the legacy of the H-M law is considered to be the derivation of an "optimal branching ratio" $\delta = \frac{d_{i+1}}{d_i} = \frac{1}{\sqrt[3]{2}} = 0.7937$ between the daughter-to-parent diameters of symmetrical branchings, the real merit resides in the "energy cost" methods they adopted. As we shall see, their conjecture is in fact only a first approximation of the energy balance of bifurcated systems, but due to the simplicity of their "cubic root of 2" correlation and of its apparent universality, the "H-M radius ratio" is widely employed in biology and even in engineering as a modelling criterion. What goes often unmentioned is that extensive experimental assessments performed in the second half of the 20th century indicate that while the correlation is sufficiently accurate for the smallest vessels (capillaries), it fails for the larger ones (large veins and arteries); moreover, it can be extended to turbulent flows only by changing the exponent of the root [27]. Recent comparisons with numerical investigations of branched flows led to similar conclusions

[2,11,15,16]. It is argued in section 4 here below that this depends on intrinsic limitations of the H-M law and on some hitherto little explored restrictions to its theoretical foundation.

3 – A Brief description of Hess' and Murray's original derivations

3.1 – Hess' problem position and solution

In 1903, in a preparatory paper for his M.D. thesis [7], the Swiss physiologist Walter Rudolf Hess proposed the existence of a physical "optimization criterion" that guides the branching of arterial vessels. This idea was also the topic of later work in his "Habilitation" thesis [8], but the 1903 work already contains a complete derivation of his "cubic root of 2" law. Hess' interest was motivated by previous work by Roux [17] who postulated a "dynamic mechanical principle" to be the driver of vessel bifurcations in animal circulatory systems. To extract physical meaning from Roux' experimental data, Hess suggested that nature would adopt a "minimum resource consumption" criterion to build the human circulatory system and proceeded to calculate how this task can be attained ("*Wie kann die Aufgabe des Blutes mit dem kleinsten Kraftverbrauch erledigt werden*" [7, p.5]). Hess' idea is that the optimal radius of a vessel carrying a given volumetric blood flowrate is the one that minimizes a cost function given by the sum of the pumping work and the metabolic cost of the volume of the pumped blood. Since the former is inversely proportional to the fourth power of the radius and the latter to the square of the radius, an "optimal radius" exists and is proportional to the cubic root of the flowrate. Furthermore, if a vessel splits symmetrically and the mass flowrate is each of the branches is equal to the half of that in the mother vessel, imposing optimality on the daughter branches leads to the allometric law:

$$\delta = \frac{r_1}{r_0} = \frac{1}{\sqrt[3]{2}} \qquad 1)$$

A detailed description of Hess' derivation is provided in [20]: for the purpose of this paper, it suffices here to list the conditions under which the derivation is valid:

a) The flow in arteries, arterioles, veins and capillaries can be described by Poiseuille's law for steady laminar flow in circular vessels with rigid walls;
b) Blood is a Newtonian fluid with constant viscosity;
c) Blood has a metabolic cost proportional to the pumping work performed by the heart (neglecting its thermal content);
d) Since flowrate and pumping power are directly proportional, a larger radius would decrease the pressure drop (and the pumping power) but increase the flowrate. The two effects are opposite, and the problem can be reformulated as a Lagrangian minimization:

$$\mathcal{L}_{Hess} = K_1 \frac{m^2}{r^4} + K_2 r^2 \qquad (2)$$

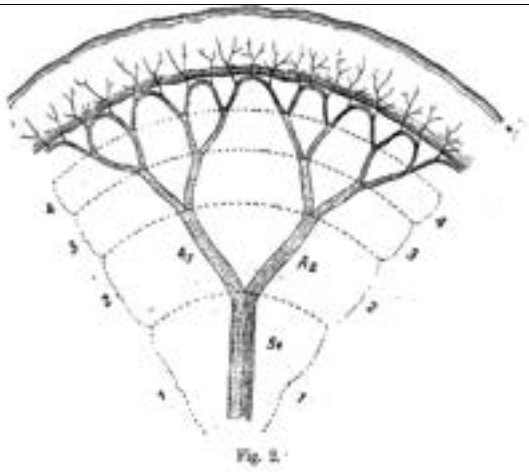

Figure 2 – Hess' concept (original drawing from [8])

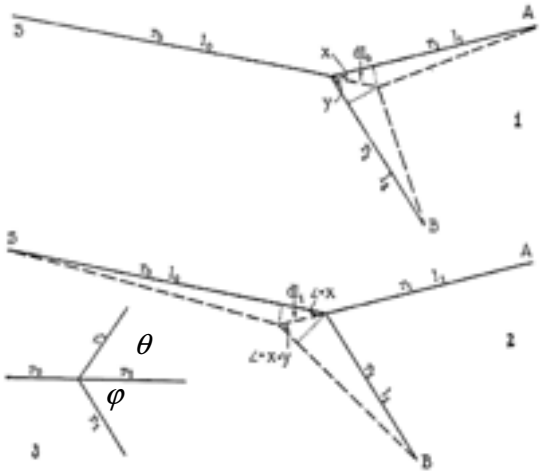

Figure 3 – Murray's calculation of the optimal splitting angle (original drawing from [12])

Which results in:

$$r_{opt} = \left(\frac{2K_1}{K_2}\right)^{1/6} m^{1/3} = \kappa m^{1/3} \quad (3)$$

Where the constant κ depends on the fluid properties and on the metabolic rate.

e) If a vessel bifurcates symmetrically (Figure 2), $m_1=m_2=m_0/2$, the optimality can be extended to the daughter branches:

$$r_0 = \kappa m_0^{1/3}; \quad r_1 = r_2 = \kappa \left(\frac{m_0}{2}\right)^{1/3} \quad (4)$$

Whence equation (1).

Throughout his papers Hess repeatedly states that his result depends on the assumption of validity of Poiseuille pressure drop formula and flow stationarity, and makes reference to selected contemporary literature to support his belief that *i)* a branching does not generate turbulence and *ii)* the low-frequency pulsations do not affect the flow in such a way as to invalidate Eq. (1).

3.2 – Murray's problem position and solution

Murray was aware of Hess' work, and makes his goal explicit in the first lines of his 1926 paper [12]: "*If we examine the arterial system bearing in mind the question of economy, we find that there are two main antagonistic factors. If the vessels are too small, the work required to drive the blood through them becomes too great; if the volume of the vessels is too large, the volume of blood, being equally large, becomes a burden to the whole body*". Murray maintained that his calculation of the blood cost was more accurate than Hess' and based on the latest experimental results. He also derived the "optimal angles" for a symmetric bifurcation using the principle of the minimum virtual work. Again, a detailed description of the mathematical steps is provided in [20].

Proceeding along the same path previously proposed by Hess, Murray obtained an expression for the power required to pump a given mass flowrate of blood in a straight vessel with rigid walls, $P_{pump} = K_1 \frac{m^2}{r^4}$, where K_1 is the same constant as in Hess' formulation. He then proceeded to calculate the metabolic cost of the pumped blood:

$$C_{blood} = bL\pi r^2 = K_3 r^2 \quad (5)$$

Where b is the "cost of blood" calculated on the basis of the then available data on heart rates and varies between 980 and 1980 W/m^3 as per Murray's estimates. For the purpose of this paper, the accuracy of the value of b is though irrelevant.

The optimal radius is again obtained by solving the corresponding Lagrangian:

$$\mathcal{L}_{Murray} = K_1 \frac{m^2}{r^4} + K_3 r^2 \quad (6)$$

Which results in:

$$r_{opt} = \left(\frac{2K_1}{K_3}\right)^{1/6} m^{1/3} = \xi m^{1/3} \quad (7)$$

Where the constant ξ depends on the fluid properties and on the power absorbed by the heart. If a vessel bifurcates symmetrically (Figure 2), i.e., if $m_1=m_2=m_0/2$, the optimality can be extended to the daughter branches and the "cubic root of 2" law $\delta = \frac{r_1}{r_0} = \frac{1}{\sqrt[3]{2}}$ is recovered.

In a second paper [13], Murray calculates the optimal branching angle by applying again the principle of minimum work: as shown in Figure 3, among the possible path lengths the one that minimizes the total work displays branching angles given by:

$$cos\theta = \frac{r_0^4 + r_1^4 - r_2^4}{2r_0^2 r_1^2}; \quad cos\varphi = \frac{r_0^4 + r_2^4 - r_1^4}{2r_0^2 r_2^2} \quad (8)$$

That is:

$$\theta = arccos\left[\frac{r_0^4 + r_1^4 - \left(r_0^3 - r_1^3\right)^{4/3}}{2r_0^2 r_1^2}\right]; \quad \varphi = arccos\left[\frac{r_0^4 + r_2^4 - \left(r_0^3 - r_2^3\right)^{4/3}}{2r_0^2 r_1^2}\right] \quad (9)$$

Introducing the optimal radius ratio δ (Eq. 1):

$$\theta = \varphi = arccos\left[\frac{1 + \delta^4 - \left(1 - \delta^3\right)^{4/3}}{2r_0^2 \delta^2}\right] \sim 37.5° \quad (10)$$

The above result predicts that symmetrical branches should have a total branching angle ($\theta+\varphi$) of about 75°.

If the vessel trifurcates as shown in Figure 4, with two side daughter branches being symmetrical with equal radii $r_1=\gamma r_0$ and the third coaxial with the main and also of radius $r_2=r_1$, the optimal value of the radius ratio is $\gamma = \frac{1}{\sqrt[3]{3}} = 0.6934$ and Murray's optimization procedure provides:

$$\psi = arccos\left[\frac{r_0^2 - \left(r_0^3 - 2r_1^3\right)^{2/3}}{2\gamma^2 r_0^2}\right] \quad (11)$$

with the splitting angle ψ=57°.

Although not mentioned by Murray, Eq. (8) leads to an interesting corollary: if $r_1=r_2$, it reduces to

$$cos\theta = \frac{1}{2\delta^2} \quad (12)$$

Which implies that larger daughter branches ought to form higher angles with the parent vessel.

For future record, consider that Murray's angle formulae (8) and (12) retain their validity if applied to branching ratios different from the "canonical value" ($\delta = 0.7937$; $\theta = 37°$): for example, a $\delta = \frac{1}{\sqrt{2}} = 0.707$ that ensures constant fluid velocity in the parent and daughter branches corresponds (Figure 7) to an angle $\theta=0°$, i.e., to no splitting, while the $\delta=0.5$ derived from a constant Reynolds assumption in parent and daughter branches leads to impossible solutions of Eq. (12): this does though not agree with empirical evidence.

4 – SOME REFLECTIONS ON THE PHYSICS OF FLUID-CARRYING VESSELS

As certified by an impressive experimental database [9,18,23,24,25,27,28,30], the "cubic root of 2" correlation is reasonably accurate in small capillaries and in the small sap-carrying channels of leaves, but it fails in predicting branching ratios in human arteries (typical diameters 0.005-0.025 m) and veins (0.006-0.03 m), as well in smaller vessels in case of turbulent flow [27]. The discrepancies have been traditionally explained by considering that the blood flow is pulsatile, that the vessel walls are non-rigid, that blood is a non-Newtonian fluid with shear thinning characteristics, and that the junctions inevitably generate turbulence in the flow. In fact, in his original paper Hess made a point in stressing that his model was derived by neglecting all of the above.

A possible explanation of the reason for the popularity of the H-M law in spite of its lack of generality may be found in its "robustness" with respect to both the radicand and the exponent of the root: as shown in Figures 5 and 6, changing the radicand from 1.5 to 3.5 results in a maximum difference of about 20% w.r.t. the H-M radius ratio, while changing the exponent 1/n of the root from 0.66 (=1/1.5) to 0.3 (=1/3.3) leads to a maximum derangement of about 17%. Translating these relative values into absolute measurement of the daughter branches, this means that the differences are of the order of fractions of a millimeter and can often be absorbed by the inevitable averaging over large series of *in vivo* measurements.

It is therefore legitimate to question the validity of the H-M model itself: is it missing some relevant variables? Or is its "universality" being overestimated? The remaining sections of this paper present a critical analysis of different physical instantiations.

5 – DIFFERENT TYPES OF BIFURCATED STRUCTURES IN NATURE

5.1 – River flows

The claim that the H.M law ought to apply to river flows appears at least as an arbitrary extrapolation of the principles on which the law is based. First, the flow in rivers is rarely laminar; second, it is an open channel flow rather than a genuinely internal flow; third, the flow characteristics are essentially determined by several factors not contemplated in the H-M derivation: hydraulic head, type of the river bed, structure of the banks, presence of obstacles on the water path; permeability of the terrain. In the absence of a physical model that includes all of the above effects, the similarity between a river delta and -for instance- tree roots is purely topological and the existence of an underlying common physical principle is not justifiable.

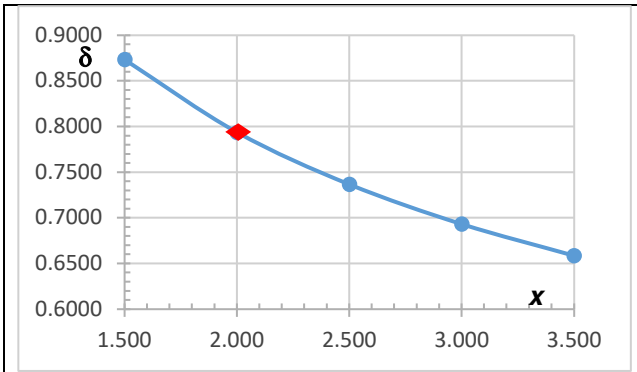

Figure 5 – H-M radius ratio $\delta=r_1/r_0$ vs radicand in $1/x^{1/3}$

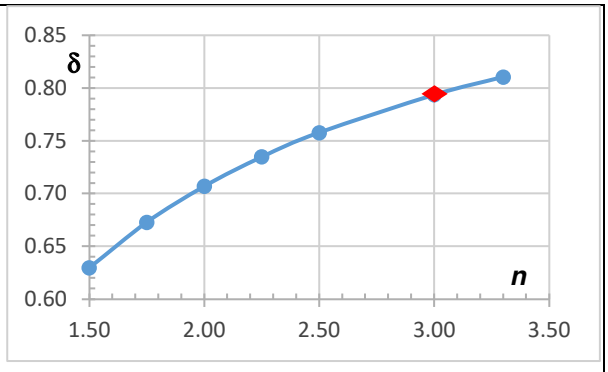

Figure 6 – H-M radius ratio $\delta=r_1/r_0$ vs exponent *n* in Eq. (1).

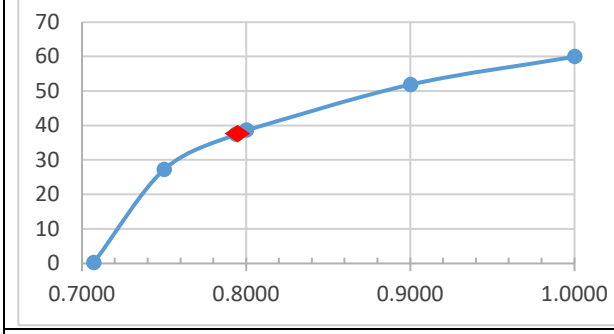

Legenda:
δ=0.707, constant velocity;
δ=0.7937, H-M value;
δ=1, constant vessel radius

Figure 7 - Murray's splitting angle for symmetric branches as f(δ)

5.2 – Blood flow in arteries and veins

Experimental evidence demonstrates that we are dealing here with the unsteady turbulent flow of a non-newtonian fluid in vessels of variable diameter and with non-rigid walls. Again, the H-M model does not account for any of these characteristics. It is therefore legitimate to conclude that the apparent success of "semi-empirical exponent adjustment" of the H-M law is to be abscribed to its arithmetical "robustness" mentioned in section 4.

5.3 – Blood flow in arterioles, venules and capillaries

In these smaller vessels, the flow is with good approximation laminar, and the unsteadiness is strongly damped by the upstream circuit capacity (Figure 8). The H-M law ought to apply here, with a small modification to take into account the effects of permeable walls described in section 6 below.

5.4 – Sap flow in leaves capillary tubules

This is perhaps the most suitable instantiation of H-M flow: laminar, steady, very small flowrates and Reynolds numbers. As for the capillaries, a correction to the H-M model to account for the (significant) amount of wall permeability is in order: the treatment being the same as for blood capillaries, both the model and the results are shown in section 6.

5.5 – Tree branchings, including roots

The attempt to apply the H-M law to these systems is based on wrong premises. To begin with, there is no "fluid branch splitting" here, because the carrying vessels (xylems and phloems) do not bifurcate. The splitting of the woody structure seems to obey some sort of reproducible rule, probably linked to the advantage the plant obtains from a larger crown, that depends in turn on the number of branchings, since the final twigs carry the most leaves. A possible non H-M model is described in [21].

6 – A MODEL BASED ON THE EXERGY COST OF A BIFURCATION

6.1 –Theoretical justification

As stated in the Introduction, the major merit of the Hess-Murray approach is the idea of the existence of an "energy cost" principle that guides the creation of a branching: in essence, a vessel bifurcates in such a way that the energy budget of the main- and of the daughter branches is "optimal". There are two energy cost items in the H-M budget: the energy rate required to overcome friction (pumping power) and that needed to "create" the blood (its metabolic cost). This is a very reasonable physical principle and in fact leads to accurate predictions for the class of flows it has been originally derived for.

It is likely that in capillary flows the permeability of the walls has some influence on the shape of the structure, and in this section we shall examine a model that accounts for these effects. Before doing that though, it is important to consider that when we deal with problems in which different forms of energy are involved (in this case, material energy and pumping work) the proper thermodynamic quantifier is eXergy. The model discussed in the next sections is in fact based on a comparison of the exergy cost [26] of a bifurcated structure w.r.t. to its non-bifurcated counterpart. The results presented here apply to capillary blood flow and sap flow in leaf tubules and -most likely with lesser accuracy- to blood flow in arterioles and venules.

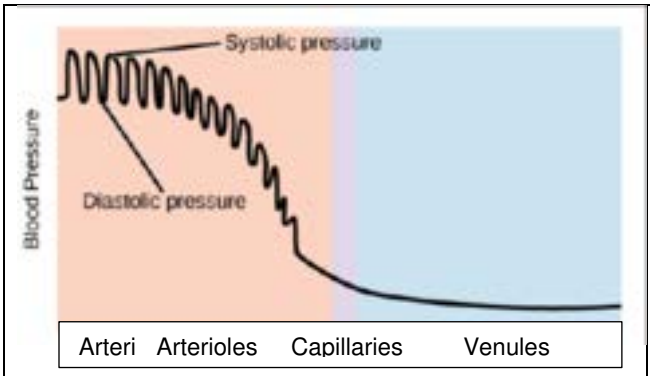

Figure 8 – Representative diagram of the pressure in human blood circulation system

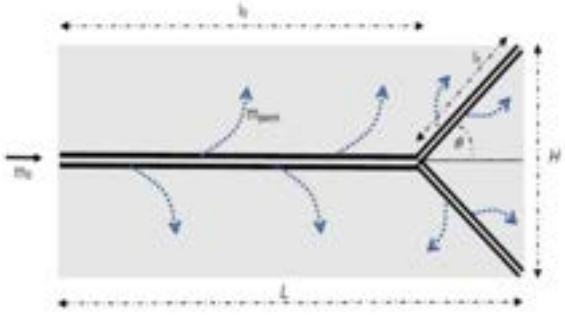

Figure 9 – Conceptual illustration of the proposed model

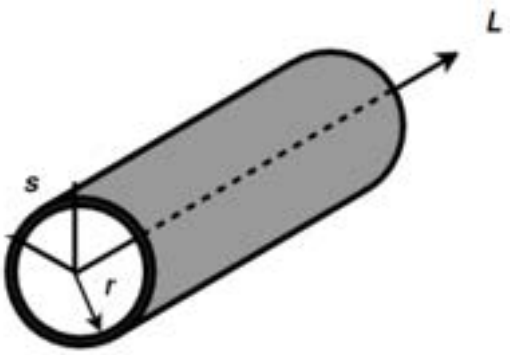

Figure 10 – For the calculation of the tubule volume

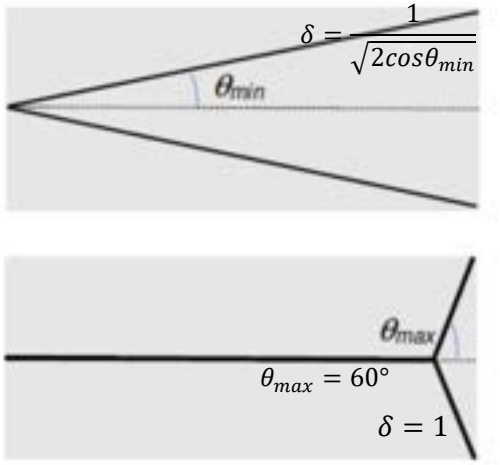

Figure 11 – Minimum- and maximum allowed splitting angles

Consider a straight portion of vessel of length *L* and uniform radius r_0: it will "feed" a domain *H*x*L* as shown in Figure 9. Under steady state conditions, the amount of fluid mass permeated through the wall is proportional to the vessel external surface:

$$m_{perm} = 2\pi r_0 L\xi \tag{13}$$

where ξ [kg/(m^{2}s)] is the wall permeability coefficient.

This mass flowrate must be equal to the difference between the inlet and outlet mass flowrates: for ease of calculation, let us assume that the length *L* is a "terminal" portion and the outlet flowrate is zero:

$$m_{metab} = \gamma HLs \tag{14}$$

where γ [kg/(m^{3}s)] is the local metabolic rate and *s* is the thickness of the surrounding tissue, assumed constant over the domain *H*x*L*.
The inlet mass will be thus equal to:

$$m_0 = m_{metab} = \gamma HLs \tag{15}$$

There are three terms in the exergetic cost of the structure: the first is equal to the pumping power required to propel the fluid through the length *L*:

$$\dot{E}_p = \frac{f m_0^3 L}{4\pi^2 \rho^2 r_0^5} \tag{16}$$

where *f* is the friction factor (in the following calculations the value *f=64/Re* has been assumed throughout). The second cost is the amount of exergy required of the main system (the body, the tree…) to generate the blood or the sap:

$$\dot{E}_f = e_{fluid} m_0 \tag{17}$$

where e_{fluid} [J/kg] is the specific exergy of the blood or sap. The third cost term is the exergy embodied into the walls of the vessel (Figure 10):

$$\dot{E}_{mat} = \frac{e_{fluid} \varphi \pi L r_0^2 (\sigma^2+2)}{\tau} \tag{18}$$

where τ [s] is the assumed operational life of the vessel, φ is a coefficient that accounts for the ratio of the "vessel construction time" to τ and σ=s_0/r_0 is the ratio of the wall thickness to the radius. Thus the total exergy cost (in W) of the "linear vessel segment" of length *L* is:

$$\dot{E}_L = \frac{f m_0^3 L}{4\pi^2 \rho^2 r_0^5} + e_{fluid} m_0 + \frac{e_{fluid} \varphi \pi L r_0^2 (\sigma^2+2)}{\tau} \tag{19}$$

For a symmetrically branched structure the above calculations can be repeated separately for the unsplit length l_0 and for the two branches l_1. The result is:

$$\dot{E}_{BIF} = \frac{f m_0^3 L}{4\pi^2 \rho^2 r_0^5}\left(\lambda_0 + \frac{\lambda_1^4 cos^3(\theta)}{4\delta^5}\right) + e_{fluid} m_0 + \frac{e_{fluid} \varphi \pi L r_0^2 (\sigma^2+2)}{\tau}(\lambda_0 + 2\lambda_1 \delta^2) \tag{20}$$

where $\lambda_0=\ell_0/L=1-a/(2\tan\theta)$; $\lambda_1=\ell_1/L=a/(2\sin\theta)$, $\delta=r_1/r_0$ and $a=H/L$ is the domain aspect ratio.
The difference $\dot{E}_L - \dot{E}_{BIF}$ represents the additional resource cost the main system incurs into when developing a bifurcation in the domain *H*x*L*. It is convenient to use Eq. (12) to eliminate the radius ratio δ and obtain an expression in the angle θ:

$$\Delta\dot{E}_{BIF} = \dot{E}_L - \dot{E}_{BIF} = K_P\left(\frac{a^3 cos^{1.5}(\theta)}{2^{0.5} tan^4(\theta)} - \frac{1}{\tan(\theta)}\right) + K_M\left(\frac{1}{sin(\theta)\cos(\theta)} - \frac{1}{\tan(\theta)}\right) \tag{21}$$

With

$$K_P = \frac{a f m_0^3 L}{8\pi^2 \rho^2 r_0^5}; \qquad K_M = \frac{a e_{fluid} \varphi \pi L r_0^2 (\sigma^2+2)}{2\tau} \tag{22}$$

Plots of ΔE_{BIF} as a function of θ for different aspect ratios are shown in Figures 12 and 13: only the graphs for a=0.25 and a=1 are shown, since the general shape remains similar for the intermediate aspect ratios. As expected, the results are somewhat different for blood and sap:

I. <u>Blood flow</u>

a) The $\Delta\dot{E}_{BIF}$ is always positive, i.e., the construction of a bifurcation <u>always</u> leads to a reduction of the exergy cost born by the system;
b) The cost reduction is of the order of few percentage points for each single bifurcation (see Table 2), with the absolute exergy savings in the range 10^{-7} W/bifurcation: it is clear that the

savings at system level make sense only if the number of branchings is sufficiently high (an estimate of the number of bifurcations in the human blood circulation system is of the order of billions [25]);

c) The aspect ratio of the domain has a direct influence on the resource savings because it sets a limit to the possible splitting lengths: $\theta_{min} = \arctan\left(\frac{a}{2}\right)$ and $\theta_{max} = arccos(0.5)$ as shown in Figure 11;
d) The curve of the saved resource is rather flat and it is shows an optimal value (i.e., maximum resource savings) towards the lowest allowed splitting angles;
e) The optimal radius ratio d lies between 0.715 (narrowest domain, a=0.25) and 0.759 (square domain, a=1): it is interesting that not only these values are consistently lower than the Hess-Murray 0.7937 value, but also that they do not reproduce either the constant Re value (0.5) or the constant velocity (0.707);
f) The value of the ratio K_P/K_M has an important influence on the numerical results (i.e., on the percentage savings), but since all physical quantities in both K_P and K_M are rather rigidly determined for blood and sap (Table 1), this value has a reasonably small variability.

II. <u>Sap flow</u>

a) The $\Delta\dot{E}_{BIF}$ is three orders of magnitude higher than in blood capillaries, with the average value being about 10^{-2}W;
b) Here, too, the aspect ratio plays a significant role in determining the range of θ;
c) The curve of the saved exergy resource is clearly skewed towards the lowest allowed splitting angles;
d) The value of the ratio K_P/K_M has an important influence on the numerical results, but it is rather rigidly determined for the known physical properties of sap and has a small variability.

The above results are somewhat less “deterministic” as those of previously published allometric models [3,4,18,24,28], and lead to an interesting interpretation:

i- The advantage of a single bifurcation is very small, and it becomes relevant at system level only if a sufficiently high number of branchings exist;
ii- While every angle between θ_{min} and θ_{max} leads to exergy savings that differ by few percent points- Blood and sap display different savings for different splitting angles, but the optimal values in both cases are skewed towards the lowest allowable angles (daughter branch length ℓ_1 as long as possible);
iii- For each aspect ratio, the radius ratio δ has a lower limit set by the domain shape and grows with the splitting angle to an upper limit δ=1 (established by experimental evidence) that corresponds to θ_{max}=60°;
iv- Within θ_{min} and θ_{max} thus, solutions are in practice almost equivalent (see Table 2), and different values of the radius ratio are acceptable, possibly influenced by the external boundary condition. For comparison with previous works [1,3,4,19,24,28,29], the H-M solution $\delta = \frac{1}{\sqrt[3]{2}}$ with θ_{max}=35.5°is also shown on the graphs;
v- There is no general allometric rule that governs the branching in ALL blood and sap carrying vessels! The solutions displayed here apply only to capillaries and small leaf tubules. The balance of larger vessels (arteries, veins, larges sap tubes) is much more complicated, due to several other relevant variables that enter the game.

7 - CONCLUSIONS

The paper presents a new model to predict the splitting angle and the radius ratio of a single, symmetric bifurcation in small blood vessels and sap tubules. The model consists in the calculation of the exergy cost difference between an unsplit vessel of length L in a domain HxL and the bifurcated configurations in the same domain. The balance is obtained by imposing that the fluid mass flowrate at the inlet is completely permeated to feed the surrounding tissue with the metabolically necessary nutrients. Three "cost terms" are identified: the pumping exergy rate, the exergy rate of the transported fluid and the exergy rate equivalent to the amount embodied in the construction of the vessel structure. The concept is clearly borrowed from the 20th century seminal works of Hess and Murray, but the use of exergy instead of energy and the inclusion of the permeation lead to substantially different results. In conclusion, it can be said that the creation of a bifurcation is -under the boundary conditions specified here- always convenient for the system, in the sense that a bifurcated structure reduces the overall exergy consumption. Furthermore, the resource savings depend on the aspect ratio of the domain, i.e., on the extension of the surrounding tissue the vessels deliver nutrients to. Finally, the concept of "optimal splitting radius ratio" does not apply, because there is a rather wide range of legitimate splitting angles all of which are "convenient" for the system and each one of which corresponds to a different radius ratio. The H-M value falls within the range of allowable angles, but is not optimal in any sense. The advantage for sap vessels is of 3 orders of magnitude higher than for blood capillaries, and this is compensated by a much larger number of capillary junctions w.r.t. those experimentally detectable on leaves and other sap carrying vessels. It must be stressed however that the model does not apply to xylems and phloems that do not bifurcate.

The analysis is performed under rather stringent specifications: laminar flow, rigid permeable walls with constant diameter and constant wall thickness, and an exact balance of the inlet mass flowrate with the permeated one. The inclusion of different levels would imply a major complication in the modelling effort.

Abstract:

There is a gap in knowledge regarding the flow pattern of low-boiling working fluids in the range of high saturation temperatures (above 120°C) and medium and high reduced pressures (0.5-0.9). Data are present in the literature for similar values of reduced pressures, but for lower values of saturation temperature. This is due to the existing refrigeration applications of these working fluids. At high values of reduced pressure, the density of the gas phase is relatively high, and the density of the liquid phase is low. There is a low specific volume difference between the liquid and gas phases. The liquid phase has a low surface tension value. The gas phase has a relatively high viscosity, and the liquid phase has a reduced value of viscosity. These changes in the parameters of refrigerants cause significant differences in flow structures. At a low value of reduced pressure, 0.2, the occurrence of annular flow was observed already at a quality of 0.07 for a mass velocity of G=355 [kg/(m^2·s)], while for a reduced pressure of 0.8, annular flow occurs much later, at a quality of 0.47 for the same mass velocity. Mass velocity flow maps in a function of quality for constant values of reduced pressure and flow maps for reduced pressure as a function of quality at constant mass velocity are presented. Flow maps are compared with correlations for transition lines between intermittent and annular flow structures from literature. Authors new correlation for transition line for researched conditions is presented. New prediction method is the only one which managed to predict transition to annular flow at high values of reduced pressure for collected experimental data.

two-phase flow; flow patterns; flow maps; R1233zd(E); high value of reduced pressure; annular flow transition line prediction

1. Introduction

An important trend in the development of new technologies is the miniaturization of technical objects. This effort requires extensive basic knowledge of fluid mechanics and heat transfer in single-phase convection and boiling and condensation in flow. The ability to accurately predict pressure drops and heat transfer, as well as the selection of geometry and operating conditions, are important factors in the design and selection of optimal heat exchanger settings. There is now a growing interest in low global warming potential (GWP) refrigerants. New European regulations require that air conditioning and refrigeration applications cannot be manufactured using fluorinated greenhouse gases with a GWP greater than 150 (EU directive 2019/1937). This leads to the use of new, environmentally friendly agents such as CO2, which operates in the near-critical and supercritical areas. Other applications, such as high-temperature heat pumps or ORC cycles, operate at much higher parameters than refrigeration systems. In 2022 energy price crisis resulted in immense demand for industrial high temperature heat pumps. Data available in the literature on heat transfer by refrigerants at high saturation temperatures are scarce. Studies of structures and flow maps are even more scarce. Many heat transfer correlations such as [1,2]created for specific flow pattern. It is essential to predict flow pattern to accurately calculate heat transfer coefficient.

1.1. Previous research on flow pattern maps

Cheng et al [3]conducted a study of heat transfer coefficients and CO2 flow maps during boiling. The medium was tested for reduced pressure Pr from 0.21 to 0.87, mass velocity G from 170 kg/(m^2·s) to 570 kg/(m^2·s), and temperature from -28°C to 25°C. Nema et al. [4]studied the flow structures of R134a during condensation and proposed a new criterion for the transit of flow structures. Charnay et al. [5] studied the flow structures of R245fa during boiling at 60°C, which corresponds to a pressure of 4.6 bar for a mass velocity of 100 to 1,500 kg/(m^2·s) with an inner diameter of a 3mm round tube. Charnay et al. [6] conducted additional tests for a

saturation temperature of 120°C. They compared the results obtained with annular flow transition lines available in the literature. Although the flow structures more closely resembled those observed at the macroscale, the transition line was similar to that observed in minichannels. Barberi et al.[7] presented research on R134a boiling in in smooth brass tubes for various diameters form 6.2 mm to 12.6 mm for mass velocities from 25 to 500 kg/(m^2·s). El Hajal et al. [8]presented flow pattern map and flow pattern based heat transfer model for condensation inside horizontal plain tubes for CO2 for reduced pressure up to 0.8. Kim et al. [1,9] conducted research on flow maps and heat transfer during condensation of FC-72. They proposed flow patter prediction method which was development of Soliman method [10]Zhang et al. [2] further developed this correlation to predict low patterns for R170 for high saturation pressures from 1.5 to 2.5 MPa what correspond to reduce pressure up to 0.51 MPa. Revelin and Thome [11]in et al presented research of flow patterns of R134a ad R245fa for 26, 30 and 35 °C saturation temperatures inside 0.5 mm and 0.8 mm diameter glass tube. They proposed correlation for pattern prediction method. Ong and Thome [12]proposed new method for pattern flow prediction for R134a, R236fa and R245fa during flow boiling in small channels of 1.03, 2.20 and 3.04 mm diameter.

2. Methodology and laboratory equipment

A study was conducted to visualize the flow of two-phase modern refrigerant R1233zd for reduced pressure values from 0.2 to 0.6. and for mass velocity G [kg/(m^2·s)] from 180 to 445. The critical temperature of the tested refrigerant is 156.6°C, and the critical pressure is 21.4 bar. Its GWP (Global Warming Potential) is 1, and its ODP (Ozone Depleting Potential) is 0 according to the NIST database of Acree et al. (2022). A schematic of the test rig is shown in Figure 1. The prevailing pressure in the system is established through a pressurized nitrogen tank connected to a membrane hydroaccumulator. The main pump ensures that the medium is pumped through the system and overcomes the flow resistance. Behind the pump is a Coriolis mass flow meter. Next is the preheater, followed by a section for measuring heat transfer coefficients during boiling. Behind the measuring section is the visualization section, which is shown in Fig. 2. It consists of a borosilicon tube with an inner diameter of 3mm, a wall thickness of 3mm and a length of 200mm. Behind the visualization section is a condensation section with an intermediate oil system that provides constant condensation conditions. Images were taken with a Photron Fastcam Mini UX100 high-speed camera.

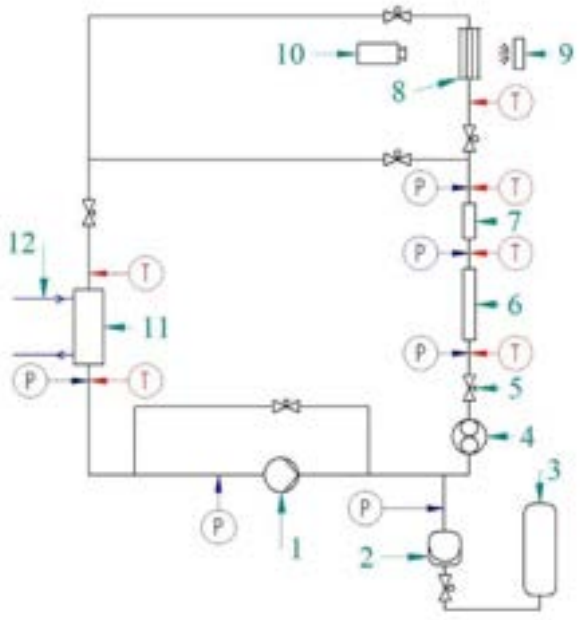

Figure 1. Test stand: 1 - piston diaphragm pump, 2 - diaphragm hydroaccumulator, 3 - pressurized nitrogen tank, 4 - Coriolis flow meter, 5 - control valve, 6 - heater, 7 - heat exchange measurement section, 8 - visualization section, 9 - led light source, 10 - high-speed camera, 11 - condenser, 12 - oil loop.

Figure 2. The visualization section with the Photron Fastcam Mini UX100 high-speed camera. Behind the visualization section is an led light source.

3. Flow patterns

Tests were conducted for reduced pressures Pr from 0.2 to 0.8 of the critical pressure value. The mass velocities tested were 180, 265, 355 and 445 kg/(m^2·s). Figure 3 shows the flow structures for Pr=0.2, while Figure 4 shows the flow structures for Pr=0.4, Figure 5 shows the structures for Pr=0.6, Figure 6 shows the structures for Pr=0.7 and Figure 7 show flow structures for Pr=0.8. All figures show the same mass velocity of G=355 kg/(m^2·s), which makes it possible to compare the differences in flow structures. Due to the large difference in the specific volume ratio of the liquid and gas phases at a reduced pressure of 0.2, annular flow already occurs at a dryness degree of x=7%, while for a quality of 0.8, annular flow occurs at x=45%. Bubble flow was defined as when bubbles alone are present. Slug flow was defined as when single plugs are present. When the flow is dominated by multiple plugs that are close to merging into a ring, or when the ring was not continuous the flow was defined as intermittent. In Fig. 3, one can observe the slug and annular flow. In Fig. 4 and Fig. 5, bubble, plug, intermittent and annular flows can be observed. Fig. 5, Fig. 8, Fig. 9, Fig. 10 show the flow structures for Pr=0.6 and for mass velocities of G=355 kg/(m^2·s), G=180 kg/(m^2·s), G=265 kg/(m^2·s) and G=445 kg/(m^2·s), respectively. In particular, one can observe the later appearance of ring structure for lower mass velocities. This trend is shown in the flow maps in the next section. For reduced pressures 0.7 and 0.8 bubbles can be observed even when annular follow emerged. This is unique structure which can be only observed at vicinity of thermodynamical critical point.

Figure 9. Flow Patterns Pr=0,6 G=265 kg/(m²·s) Quality respectively: 19,6%, 27%, 35,2%, 55,6%

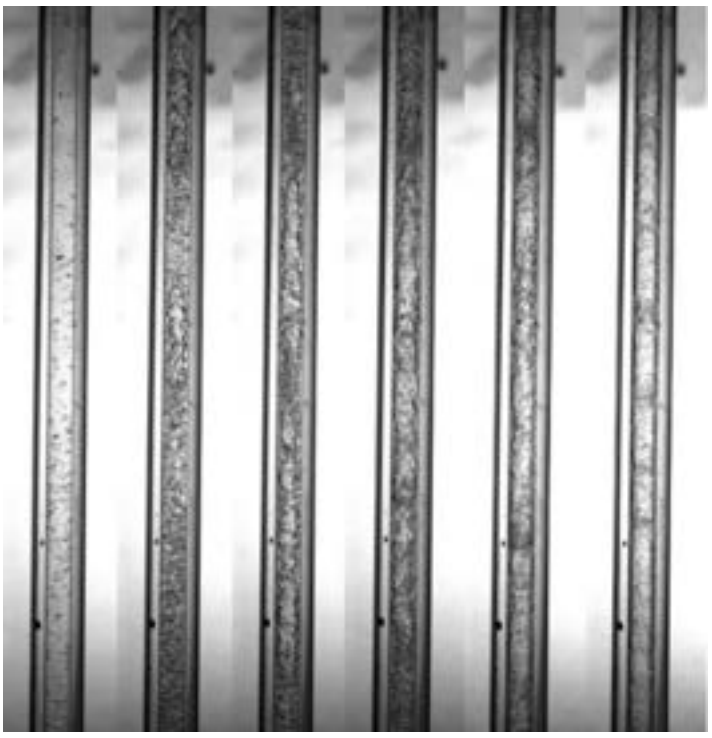

Figure 10. Flow Patterns Pr=0,6 G=445 kg/(m²·s) Quality respectively: 8,5%, 15,9%, 23,7%, 36,5%, 52,4%, 67,6%

4. Flow maps and new annular flow prediction method

In recent years flow maps were primarily presented as Mass flow in function of quality. This presentation method allow to easily compare patterns with experiment and heat transfer coefficient measurements.

4.2. New correlation to determine transition line to annular flow

A new prediction method for determination of flow pattern transition into annular flow is proposed. Its is modification of correlation proposed by Revelin et al. [13] Original correlation presented good prediction at lower values of reduced pressure 0.3 and 0.4 what can be observed in the Figures 12 and 13. Is is good result we take in into account that this method was created for different fluid and different diameter. That correlation is based on fluids R134a and R245fa at 26, 30 and 35 °C saturation temperatures inside 0.5 mm and 0.8 mm diameter glass tube. In the Figure 18 it can be observed that method proposed by Ravelin do not follow trend of annular transition line for different values of reduced pressure. In fact it showed that annular flow occurs fasters at high reduced pressure. Experimental data show opposite trend. Because of that Bond number was introduced to the equation. Bond number represents effect of gravitational forces compared to surface tension forces for the movement of liquid. When significance of surface tension value of this criterial number is higher. Surface tension decreases for higher value of saturation temperature. This change allowed to adapt transition line for all reduced pressures what can be observed in the Fig 18. Formula for transition line between intermittent flow and annular flow is:

$$x_{i/a} = Rel^{1.47}/Wel^{1.23} \cdot Bo^{1.9} \cdot 3.5 \cdot 10^{-7} \quad (1)$$

4.3. Flow maps with transition lines for R1233zd(E)

Fig. 11 shows the flow map for reduced pressure of 0.2, Fig. 12 shows the flow map for Pr=0.3, Fig. 13 shows the flow map for Pr=04, Fig. 14 shows the flow map for Pr=0.5, Fig. 15 shows the flow map for Pr=0.6 Fig. 16 shows the flow map for Pr=0.7, and Fig. 16 shows the flow map for Pr=0.6. Fig. 17 shows the flow map for mass velocity G=355 kg/(m^2*s) as a function of reduced pressure and quality. In Figures 11 through 16, an inverse correlation can be observed between mass velocity and the occurrence of annular flow. Annular flow occurs fastest for a reduced pressure of 0.2, and latest for Pr=0.8. This is a result of the smaller difference between the unit specific volume of the gas phase and the liquid phase, and the lower surface tension of the liquid phase. The delayed occurrence of annular flow also occurs for lower values of mass velocity. 7 correlations for transition of flow pattern into annular flow is presented in the flow maps for various values of reduced pressure and mass velocity. This correlations are proposed by Ong and Thome[12], Revelin and Thome [11],Cheng et al. [3], El Hajal et al. [8]Zhuang et al. [2], Kim and Mundawar [9] and last one is the one

proposed in this article. None of this correlations was created for exact conditions as in experiment conducted by authors. Correlations of El Hajal and Cheng were created for CO_2 for high values of reduced pressure up to 0.8. Zhuang proposed correlation for medium values of reduced pressure for ethane. Other correlations were created for low values of reduced pressure. Correlations proposed by Revelin and Thome and by Ong and Thome showed good results for Pr around0.3 and 0.4. Method proposed by Kim and Mundawar was second best correlation and predicted flow correctly from 0.2 up to 0.5 value of reduced pressure. All correlations expressed correct trend between mass velocity and transition line except from Correlations proposed by El Hajal and Cheng. New correlation correctly predict trends for various value of reduced pressure and various mass velocities.

Table 1. Comparison of correlations which predict annular flow for collected database for R1233zd(e).

Correlation	number of experimental data points correctly calculated	percentage of experimental data points correctly calculated
Ong and Thome [12]	238	78.81%
Revelin et al. [11]	214	70.86%
New corelation	276	91.39%
Cheng et al. [3]	236	78.15%
El Hajal et al. [8]	215	71.19%
Zhuang et al. [2]	227	75.17%
Kim and Mundawar [1]	262	86.75%

Comparison of all tested correlations is presented in Table 1. Authors correlation managed to correctly predict 91,39% of collected experimental data points. Second best is correlation presented by Kim and Munawar [1] which predicted 86.75% points. Other correlations managed to predict from 70% to 75% of data point despite not being able to follow experimental transition lines.

4.3. Applicability of new correlation for different fluids.

Applicability of new correlation for different fluids was tested on data collected by Charnay et al.[5,6]. Authors correlation follow experimental transition trend also for this fluid. Experimental lines for all correlations are presented in the Fig 19. Data is presented as function of Reduced pressure and quality

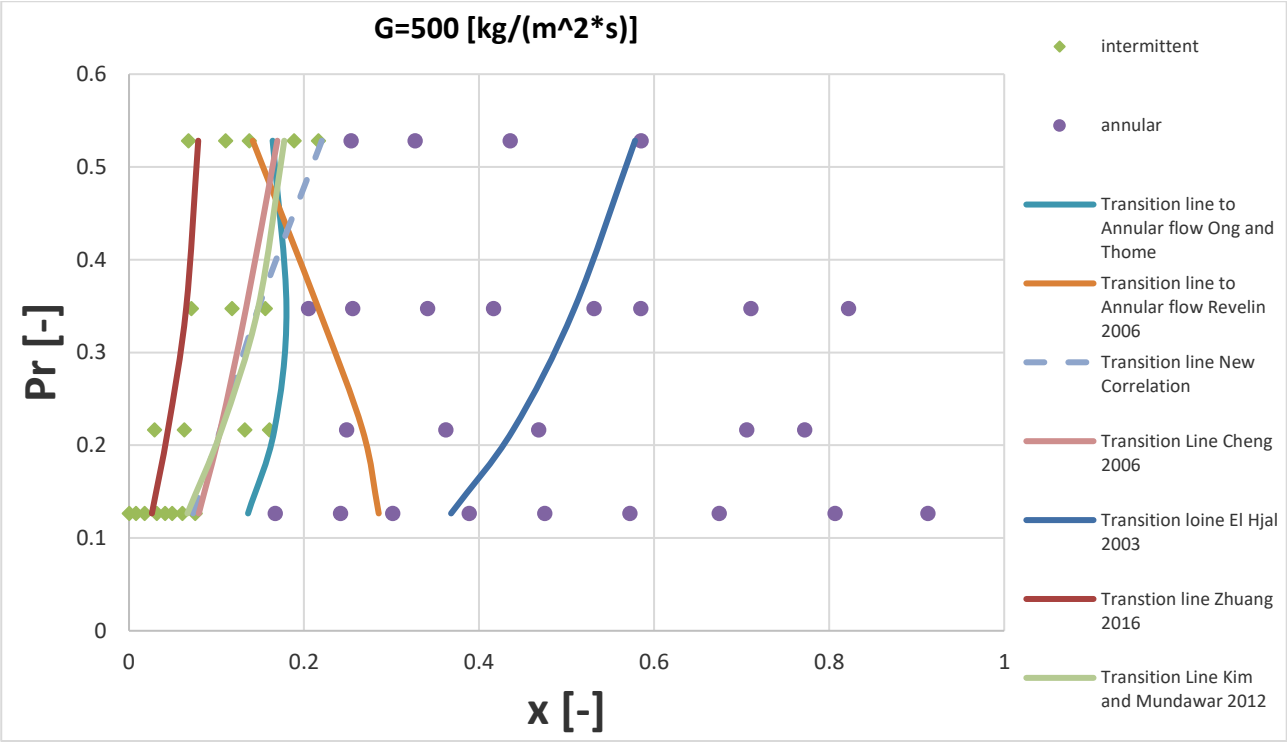

Figure. 19. Flow map for reduced pressure ranging from 0.13 to 0.53 for mass flow 500 [kg/(m^2*s)] for R245fa collected by Charnay et al. [5,6]

5. Conclusions

The change in the physical properties of refrigerants as the saturation temperature increases has a major impact on structures and flow maps. At high values of reduced pressure, the density of the gas phase is relatively high, and the density of the liquid phase is low. There is a low specific volume difference between the liquid and gas phases. These properties cause a delay in the occurrence of annular flow. For reduced pressure 0.8 annular flow occurred at 45% of quality for G=355 [kg/(m^2*s)] and for reduced pressure 0.2 it was visible at 7% of quality. Since the presence of bubbles in the flow occurs for much higher quality at higher reduced pressures nucleation as a heat transfer mechanism is more important for boiling at high saturation temperatures. It is also worth noting the delayed occurrence of annular flow for lower values of mass velocity. Further work should focus on expanding the experimental database. Old correlations for annular transitions lines prediction did not manage correctly to predict transition of flow pattern to annular flow for high reduced pressures. Most of them predicted trend opposite to measured for increasing saturation pressure. They predicted that annular flow occurs faster for high values of reduced pressure, but in fact annular flow occurs later for high saturation pressure. New correlation for annular flow transition line is able to predict transition form intermittent flow into annular flow for all measured reduced pressures and mass velocities. Authors correlation managed to correctly predict 91,39% of collected experimental data points what is best results of all tested correlations.

Nomenclature

Abstract:
Thermal variation is assumed to be one of the main source of uncertainty in dimensional measurements and must be controlled in order to analyse and quantify its possible effects. Therefore, as the analysis of temperature control is influenced by different complex non-linear heat transfer effects, the study of this variable is considered a highly application dependent measurement problem. However, temperature measurement devices are often designed primarily to increase their durability, so they remain vulnerable to transient effects. Hence, improvements in mathematical models of general purpose temperature sensors through the knowledge of its response in the application would significantly improve their performance and accuracy.

Keywords:
Thermistor response, Heat transfer, Dynamic response, First-order models.

1. Introduction

One of the coins used to determine the macroscopic state of a system is determined by means of an intensive property known as temperature. This variable has an important dependence on statistical concepts and, for the moment, we shall regard the temperature to be an empirical quantity, measured by a device, such that temperature is proportional to the expansion [1] that occurs whenever energy is added to matter by means of heat transfer. This concept can be understood by imagining a thermometer, where thermal expansion is: liquid metal in a long glass tube, bending of a bimetallic strip or resistivity variation of a semiconductor, among others.
Thermal variation [2] is assumed to be the main source of uncertainty in dimensional measurements and, given these influences, the control of this variable is considered to be a highly application-dependent measurement problem. In fact, it is also known that heat transfer analysis and temperature control is very useful in many engineering systems and that, under stationary conditions, its value does not vary with time at a given point. In contrast, under non-stationary [3] or transient conditions, the temperature varies with time. However, under stationary conditions, effects such as self-heating can occur. For this reason, Darkhaneh [4] proposes a way to quantify the error caused by thermistor self-heating, as it is a problem that generates uncertainty in temperature measurement. In addition, there are areas of thermistor operation that it is preferable to avoid due to certain effects such as blowup, as pointed out in their respective studies by Antontsev and Chipot [5] and Barabanova [6].
On the other hand, nowadays, the precise measurement of the thermal properties of materials is mainly done on the centimetre or millimetre scale [7,8]. It is clear that the miniaturisation of sensors brings undeniable advantages, such as: lower thermal inertia; limited invasiveness of the system to be characterised, which is therefore less disturbed by the sensor; and the possibility of using small amounts of material, which is highly desirable in nanotechnologies, for example. Thus, in this document we refer to miniature sensors as sensor elements whose main dimensions are of the order of a millimetre.
Other problems has been observed that for certain applications involving convection mechanisms, especially in the study of turbulent flows, phenomena are detected during temperature monitoring that introduce uncertainty and lead to confusion in the processes to be analysed. The measurement of transient heat transfer is very important in various areas of scientific importance including the determination of engine temperature,

aerodynamic vehicle temperature in a high velocity flow environment, mentioned by Sanjeev and Kumar [9,10]. From the point of view of analysing the turbulent effects that can occur and generate uncertainty in the temperature measurement, we can refer to the smallest known scale, the Kolmogorov scale. This is the smallest turbulent motion [11] present in a flow and is the scale at which energy is dissipated by molecular viscosity. Taking into account the formation of vorticity at certain points close to the measurement points, near-wall turbulence effects can be considered, as well as the ratio of the velocity and thermal boundary layer established by the Prandtl number.

Hence, improvements in the response of general-purpose temperature sensors through the compensation for response delay would significantly improve their performance and applicability, like mention Tagawa et al. [12]. Thus, this work proposes an experiment to study the turbulence and vorticity generated through the stagnation of a device exposed to an air stream. A device inmersed into the airstream has two built-in thermistors that will measure the stagnation temperature and the static temperature (Fig. 3). In these experiments, it can be seen that an effect is produced that goes against the theory presented and this phenomenon can be associated with a fraction of energy that is dissipated through the leads of the thermistor. This is then corroborated by a series of additional tests in different media with different heat transfer coefficients. Then, this experiment is presented from a mathematical point of view, studying and analysing the effectiveness of first-order models for cases where the sensors are in an airstream. These models provide the necessary tools to approximate real behaviour and by means of a developed algorithm (depending on the selected conditions) it is possible to simulate a thermistor response similar to that of the experiment. However, as will be contrasted with the other tests performed, in certain applications they do not have the necessary precision and induce error in the measurements.

One of the main motivations for the development of this work is that temperature measurement devices are often vulnerable to these transient effects, as they are primarily designed to increase their durability. However, the moderating industry demands smaller and smaller, non-invasive measuring devices for many applications. More accurate measurements of thermal conditions are therefore a real challenge as these companies are demanding more and more complex and precise systems. Accordingly, identifying a suitable mathematical model and the effects that occur in temperature sensors will allow us to evaluate a way to study the effects of turbulence and heat transfer and to be more aware of transient effects.

In the current paper, as a first point of departure, a series of theoretical concepts involved in the test carried out will be described. This is followed by a detailed explanation of the general first-model with the formulation of the governing equations. Next, the description of experiment that has led to the hypotheses put forward in relation to the observed phenomena. Then, the results obtained from such equations will be compared with those of real measurements, thus explaining the phenomena that cause such behaviours. Finally, some perspectives of future are exposed with the conclusions obtained.

1.1. Boundary layer: hidrodynamic and thermal

It is obvious to think that the temperature distribution obtained around a body immersed in a stream will have a similar character to the distribution of velocities in the various layers of a fluid. Therefore, in a flow over a heated surface, both the velocity boundary layer and the thermal boundary layer develop simultaneously (Fig. 1).

This concept of boundary layer was introduced into the science of fluid mechanics by L. Prandtl at the begining of the last century: it has probed to be very fruitful.

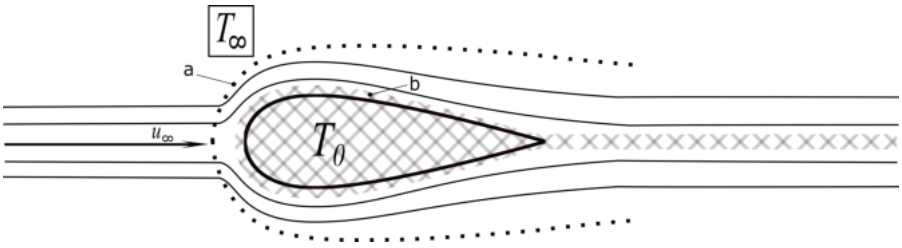

Figure 1: Analogy between temperature and vorticity distribution in the neighbourghood of a body placd in a stream of fluid.

In the Fig. 1, **a** and **b** correspond to the limits of the temperature increase; **a** for low speeds and **b** for high speeds. It should be noted that in the convective transport mechanism two processes take place, the diffusion of heat by the randomly moving molecules in the fluid and the advection of heat due to the overall motion of the fluid. As the molecules of the whole maintain their random motion, the total heat transfer is due to a superposition of the energy transport due to the motion of the molecules and the global motion of the fluid that takes place. Thus, if we imagine a solid body placed in a fluid stream and heated so that its temperature

remains above the surrounding environment, then it is clear that the temperature of the stream will increase only in the layer closest to the boda and in a narrow wake behind it, as shown in Fig. 2. Therefore, the greatest diffusion from the hot body to the surroundings occurs in the layers closest to the hot body, which, in accordance with the flow phenomenon, can be called the thermal boundary layer.

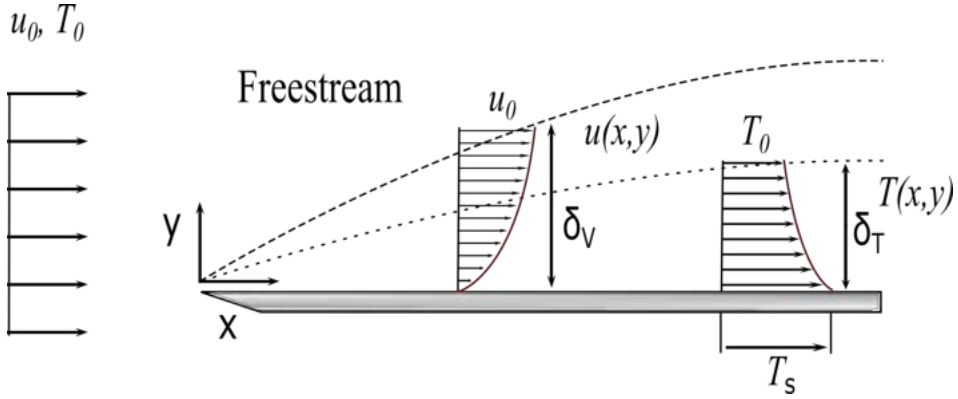

Figure 2: Hidrodynamic and thermal boundary layer.

The thickness of the thermal boundary [13] layer (ΔT) at any location along the surface is defined as the distance from the surface at which the temperature difference ($T - T_s$) is equal to $0.99 \cdot (T_0 - T_s)$, which establishes some relationship to the velocity boundary layer. So, it can be said that the rate of convective heat transfer anywhere along the surface is directly related to the temperature gradient at that location. Hence, the shape of the temperature profile of the thermal boundary layer imposes convective heat transfer between the solid surface and the fluid flowing over it. Since the fluid velocity will have a strong influence on the temperature profile, the development of the velocity boundary layer relative to the thermal boundary layer will have a strong effect on the convective heat transfer. So, it is evident that flow phenomena and thermal phenomena interact to a high degree.

1.2. Temperature increases through adiabatic compression; stagnation temperature.

Temperature changes caused by dynamic pressure variation in a compressible fluid are important from the point of view of heat transfer. In particular, it seems useful to compare the difference in temperatures resulting from heat generation by friction with those caused by compression. For this reason, if we look at Fig. 1, it is logical to think that if the velocity varies along the contour, the temperature will also vary along the shape. If we assume an adiabatic and reversible process due to the low value of conductivity and the high right rate of change in the thermodynamics propierties of state will, in general, prevent any apreciable exchange of heat with the sorroundings. Then, the temperature increase (ΔT) which occurs at the stagnation point of a body in a fluid stream and that is due to the compression that is generated when the fluid makes contact with the solid, as can be deduced from Fig. 1.

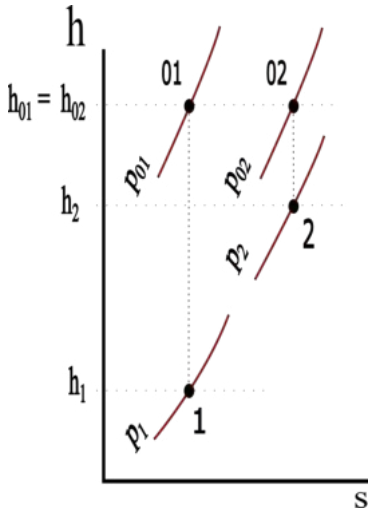

Figure 3: h-s diagram.

The h-s diagram indicates that the stagnation enthalpies - total energy level - are constant, but the area of interest focuses on the static variables and the kinetic energy terms. Thus, it is possible to know the energy state of the fluid and to determine the conditions that are introducing uncertainty into the temperature measurements.

2. First-order model

As mentioned in the introduction, the first model corresponds to the classical approach proposed by the manufacturer to obtain the thermistor properties. It is therefore a generic model that encompasses any situation to which the sensor is subjected. In other words, this type of proposal does not focus on the heat flow through the wires, as well as other thermophysical parameters.
Accordingly, a scenario showing a thermistor immersed in airstream and the heat transfer due to convection process between sensor and surrounding is shown in Fig. 4. In this schematic, it can be seen that the thermistor is in an environment whose fluid temperature is (T_∞) and surrounding temperature (T_{sur}). Also, the boundary layer around of thermistor (control volume) has an associated a convective resistance (R_h).
On the other hand, at this point, it is important to point out that the influences of radiation heat transfer ($\dot{q}_r$) , as well as the self heating (S_h) producing in the thermistor are of minimal relevance in this study, as will be discussed in the conclusions section. Therefore, for now we will focus on the determination of the convection ($\dot{q}_h$) phenomena.

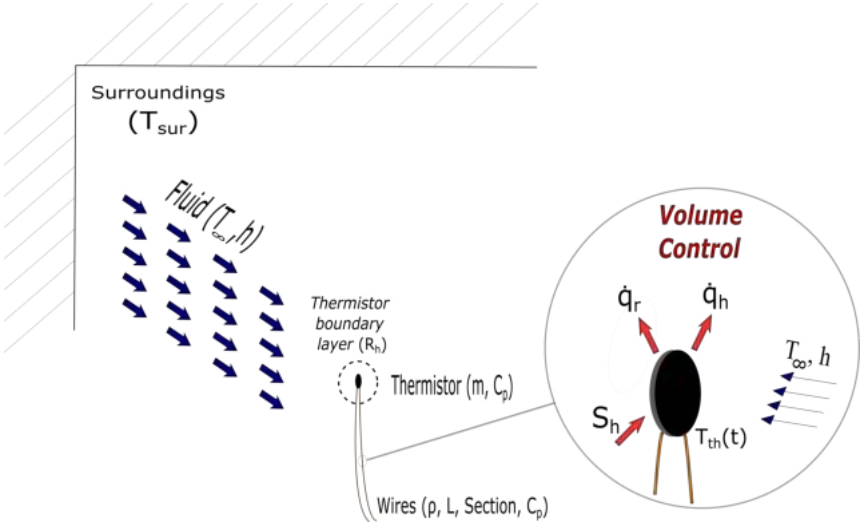

Figure 4: First-order model diagram.

Then, from the energy balance in the control volume (CV) of the last diagram, is deduced:

$$-\dot{q}_h = m \cdot c_p \cdot \frac{dT_{th}}{dt} \tag{1}$$

Keep in mind the minus sign of the equation means that the heat transfer is gave up to surrounding area.
By the other hand, the Newton´s cooling law is:

$$\dot{q}_h = h \cdot A \cdot (T_{th}(t) - T_\infty) \tag{2}$$

So, substituting Eq. (2) into Eq. (1) and developing, it is obtained:

$$-h \cdot A \cdot (T_{th}(t) - T_\infty) = m \cdot c_p \cdot \frac{dT_{th}}{dt} \tag{3}$$

$$(T_{th}(t) - T_\infty) + \frac{m \cdot c_p}{h \cdot A} \cdot \frac{dT_{th}}{dt} = 0 \tag{4}$$

$$(T_{th}(t) - T_\infty) + \tau \cdot \frac{dT_{th}}{dt} = 0 \tag{5}$$

At this point, a linear time-invariant system (LTI) is founded. By this:

$$\frac{1}{\Delta T_{th}} \cdot dT = -\frac{1}{\tau} \cdot dt \tag{6}$$

$$\Delta T_{th_1} = \Delta T_{th_2} \cdot e^{-t/\tau} \tag{7}$$

$$T_{th_1} = (T_{th_2} - T_\infty) \cdot e^{-t/\tau} + T_\infty \tag{8}$$

If $t = \tau$, the equation is:

$$\frac{(T_{th_1} - T_\infty)}{(T_{th_2} - T_\infty)} = 0.632 \tag{9}$$

That is, the time period during which temperature effectiveness ($T_{th_1} - T_\infty$) becomes 63.2% of the temperature width ($T_{th_2} - T_\infty$) is taken as τ.

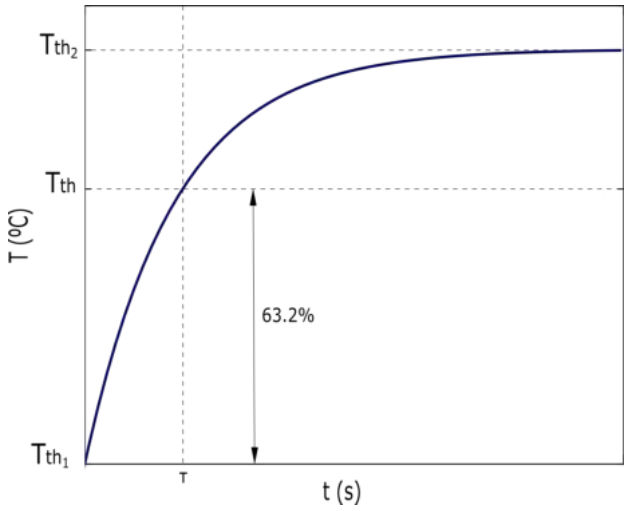

Figure 5: Thermal time constant.

2.1. Thermal-electrical analogy for first-order model

Generally, the manufacturer proposes a first order system as the characteristic response of a temperature sensor. This kind of representation makes it possible to show mathematically and in a simple manner how the thermistor (T_A) behaves over time when an external heat source (E_s) is applied to it. However, this model omits some effects that may be of special interest for the phenomena described in the previous paragraphs. Nevertheless, as a first analysis, to which certain terms will later be introduced and compared, this model is presented in which a series of conditions will be taken into account. Thus, as proposed by Sanjeev and Kumar in [7], the one-dimensional (1D) heat transfer equation for a semi-infinite solid body can be a starting point to obtain the value of the transient temperature at the sensor surface. So, from the schematic shown in Fig. 4, does not involve heat flow through the wires ($\dot{q}_c$), radiation heat transfer ($\dot{q}_r$) and the self heating (S_h). Thus, using the electrical analogy for the study of the heat transfer of a system, this first-order model results as follows:

For this case, initially only convective resistance of the CV (R_h) and heat capacity of thermistor (C_1) will be taken into account.
Therefore, from the energy balance at point A it is obtained:

$$E_s - \dot{q}_h = C_1 \cdot \frac{dT_A}{dt} \tag{10}$$

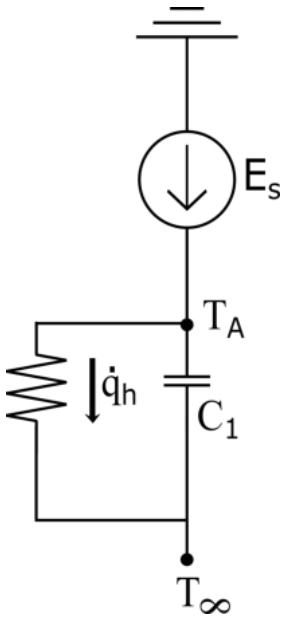

Figure 6: Thermal-electrical diagram for first-order model.

The Newton´s cooling law is:

$$\dot{q}_h = h \cdot A \cdot (T_A - T_\infty) \tag{11}$$

Then, substituting the Eq. (11) into Eq. (10) and developing the result according ours considerations it is obtained:

$$\frac{C_1}{h \cdot A} \cdot \frac{dT_A}{dt} + (1 + \frac{1}{h \cdot A \cdot R_1}) \cdot T_A - \frac{1}{h \cdot A} \cdot H_s = 0 \tag{12}$$

Where the term ($\frac{C_1}{h \cdot A}$) is the known thermal time constant (τ). The form of which is as follows:

$$a_2 \cdot y' + a_1 \cdot y + a_0 = 0 \tag{13}$$

Each coefficient accompanying the variable corresponds to those in Eq. (12), so they must be taken into account in the solution. Also, the b term in the following equation is related to the amplitude of the external heat source (E_s). This turns out to be a first order linear ordinary differential equation, the solution of which is:

$$T_A = b \cdot e^{(-a_1/a_2) \cdot t} - \frac{a_0}{a_1} \tag{14}$$

As mentioned in the section on the thermal time constant, this Eq. (14) can be divided into a heating and a cooling stage, thus obtaining two responses with corresponding time constants. Obviously, this depends on the external source, among other factors, so we will focus on the generic equation as such.

3. Overview of experimental procedure.

The way to relate the study of turbulence and heat transfer is for the thermistor to be excited by an external source that causes the same disturbances and uncertainties as the vortices in an air current. Thus, in order to identify the limitations to which these temperature sensors are subject, a device and an experiment are designed to study their behaviour. This test consists of placing two thermistors in a small tube so that each sensor measures a different temperature: static temperature (T_1) and stagnation temperature (T_{01}). This refers to the diagram presented in Fig. 3.
Finally, this device is placed inside an isolated tube through which an airstream circulates.
The morphology of the described device is schematically represented in the following image.

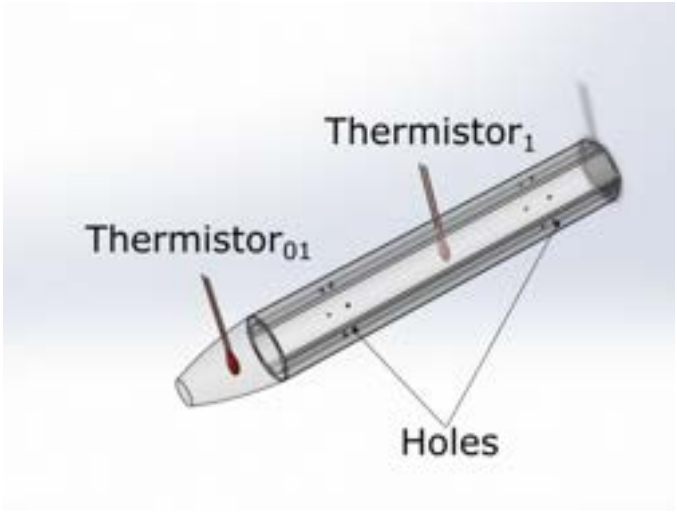

Figure 7: Sensor.

Figure 8: Sensor.

Fig. 8 below shows the actual assembly of the device:
Some parameters of the thermistor used in the experiment are shown in the Table 1 but, the most important one is the thermal time constant that will be compared with the numerical solution proposed.

The airstream is produced by fan controlled by a microcontroller. Inside of the tube there is the device with two thermistors NTC that read the different temperature changes (T_{01}) and (T_1). Also, there is an additional thermistor outside that reads atmosphere temperature but is not integrated in the system as its value is merely informative. These values, are reading using an integrated development environment. With this, it is possible to collect and show data comming from microcontroller.
Regarding to data acquisition, we have these devices:

- An adaptative stage of signal (Voltage divider): consists of $10k\Omega$ resistors and the power supply ensures a constant voltage of 5V.
- An analogical to digital converter of 16 bits (ADS1115 Texas Instruments): will allow a higher accuracy of

Table 1: Parameters of NTC thermistor used.

Parameter	Value
Resistance at 25 ºC	10.000Ω ± 1%
Temperature rating	-30º to 90 ºC
β (25º to 85ºC)	3.435 K nominal
Dissipation constant	0,7 mW/ºC nominal (Still air)
Thermal time constant	5 seconds nominal (air)

the temperature values read. It is also powered by the 5V power supply.

- A microcontroller ATmega328 (Atmel) implemented in an embebed system (Arduino): to prevent the microcontroller that records the data from crashing, another one is available to control the shutter. In turn, both are managed by an external application developed that allows real-time reading of the data.

Although, other devices are used in this experiment and keeping in mind all system described, Fig. 9 shows a schema of this:

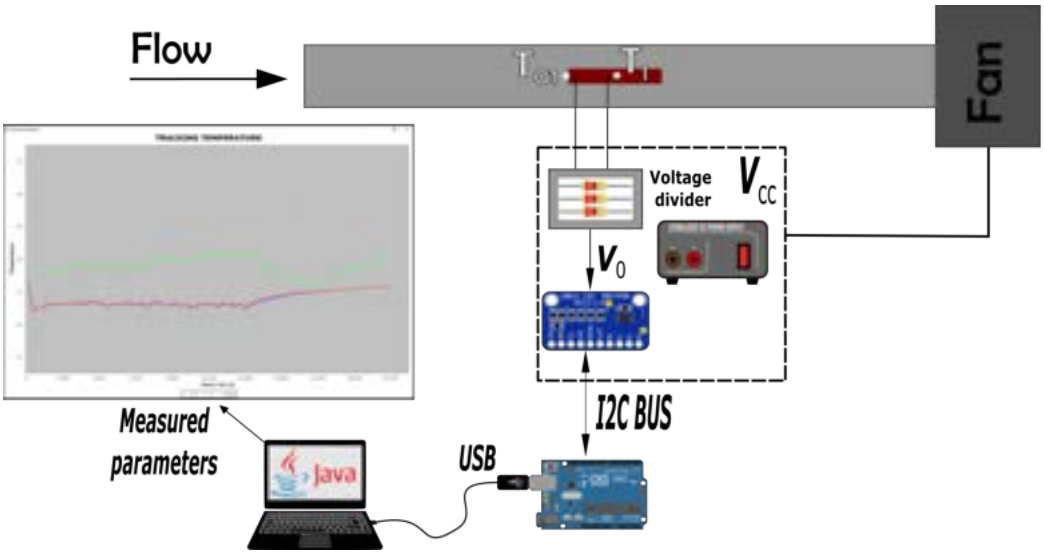

Figure 9: Acquisition and data capture for the experiment.

In Fig. 10, the response obtained during an experiment is shown. As can be seen, the temperature gradient value is proposed on the vertical axis and the test time on the horizontal axis. When the measurement is started, the fan is started and the evolution of the data is analysed in real time. This information is also stored for later study.

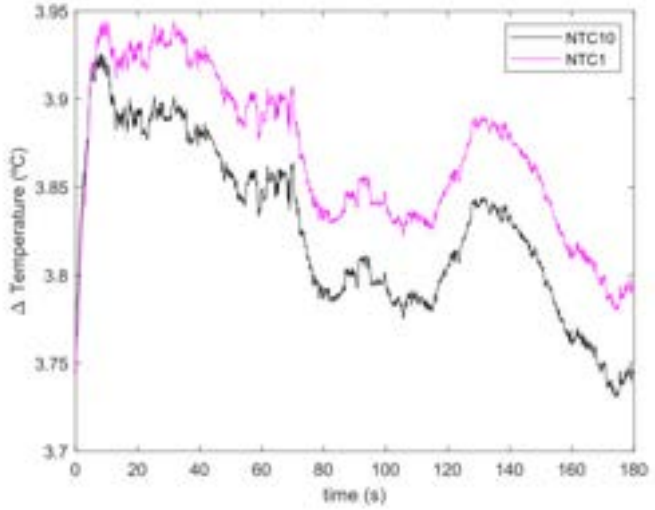

Figure 10: Response with tube experiment and two thermistors.

4. Results and discussion.

4.1. Response of thermistor in airstream

In this section, the results carried out in the tube with the device to measure temperatures will be presented. It should be noted that each test has a sample frequency of 10 data per second. The duration of the tests can be variable. This depends on the amount of data to be collected. Generally, however, tests last between 60 and 300 seconds.
For example, the two experiments shown below (Fig. 11 and Fig. 12) have a duration of 80 seconds. As soon as the temperature reading begins, the fan starts running and the data is recorded. In both tests, the magenta line corresponds to the static temperature (thermistor inside the device) and the black line to the stagnation temperature (thermistor at the tip of the device).

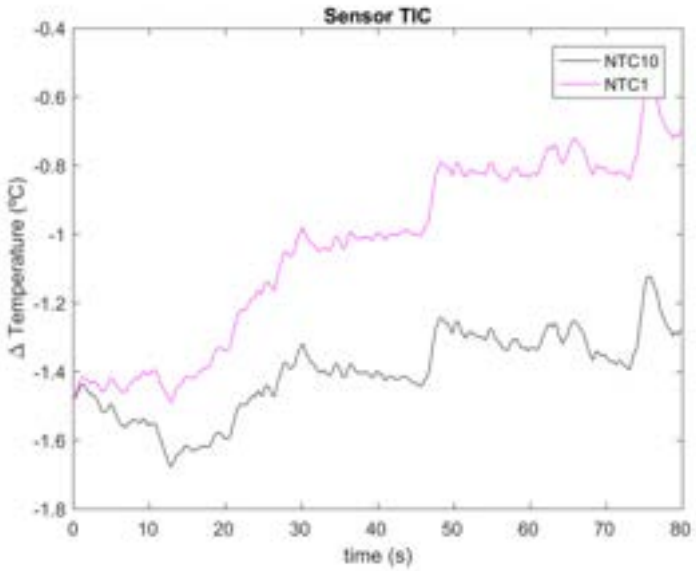

Figure 11: Response with tube experiment and two thermistors.

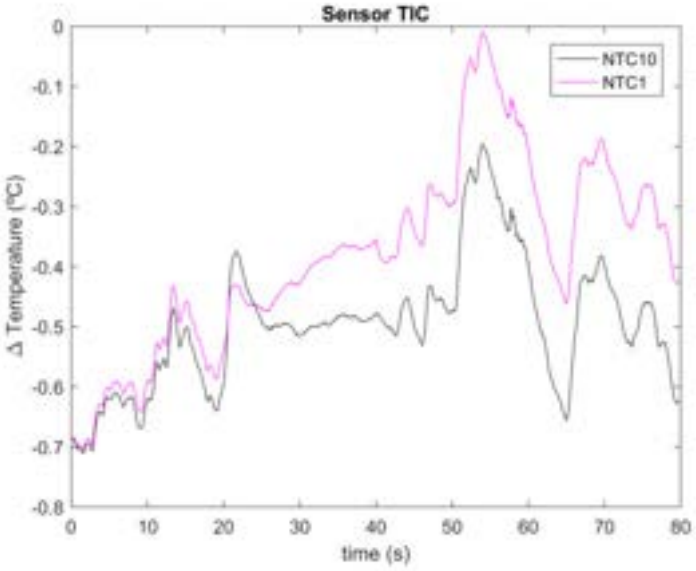

Figure 12: Response with tube experiment and two thermistors.

As can be seen in the previous graphs, the difference in temperature of both variables reaches maximums of 0.2 ºC. However, the most curious thing is the value that the stagnation temperature takes, when it is supposed to increase due to friction effects. This was later corroborated by a simple experiment that simulated the behaviour of the fluid inside the tube. This test consisted of exciting the isolated thermistor with an external heat source in a chamber in which two completely different fluids were introduced separately. This heat source allowed different excitation powers to be applied to the thermistor, thus contrasting the different media. Then, the typical response of the thermistor used to an external heat source that is applied for a certain time and then disappears is shown. It should be noted that these experiments are carried out in still fluids and under controlled conditions. Also, what is demonstrated is that the response of the sensor itself is simply reproducible from Eq. (14), as can be seen in the graph below.

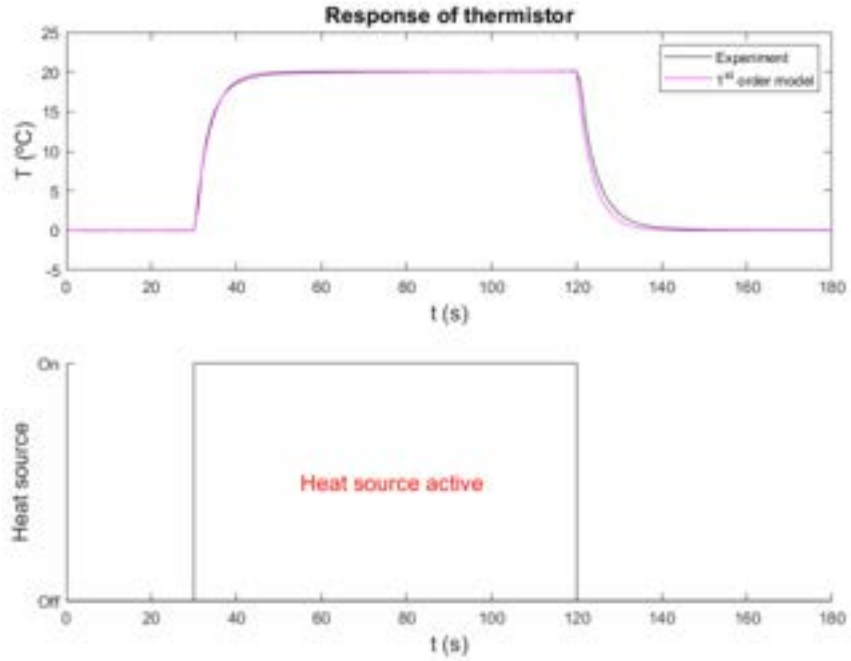

Figure 13: Response of thermistor during experiment using external heat source.

The following table shows the temperature gradient reached by the thermistor for each of the four powers during the tests with different fluids. Also, a quality estimator (QE) is shown to assess the accuracy with which

the first-order model is adapted to the response obtained. Fluid 1 has a lower heat transfer coefficient and after the tests a time constant of 3.57 s was obtained. For fluid 2, which has a higher heat transfer coefficient, the time constant was found to be 1.29 s.

Table 2: Temperature gradient results in different fluids and excitation powers.

	Fluid 1			Fluid 2		
Power	ΔT_1 ($^\circ C$)	STD_1	QE_1	ΔT_2 ($^\circ C$)	QE_2	STD_2
P_1	25,41	0,1	230,81	11,77	0,03	87,77
P_2	20,19	0,01	85,67	10,07	0,002	17,54
P_3	10,47	0,01	40,57	4,43	0,001	13,18
P_4	9,80	0,04	50,89	4,38	0,05	18,99

With all this, it is understood that there is an important fraction of heat flow that is lost through the cables and that is not analysed accordingly. Thus, from the first test in which the stagnation temperature and the static temperature were measured, results were obtained that suggested that certain phenomena related to the turbulent behaviour of the fluid were taking place and that heat flow through the cables was being generated.

4.2. Discussion.

Due to minimal surface of thermistors in a gaseous medium, there is a behaviour with a high dynamic responses. This high dynamic response of sensors proves to be a great advantage in several applications, in which temperature evolution measurements are sought with great precision in phenomena that occur in a short period of time, in which the temperature undergoes very abrupt variations. Also, due to the high transient response to which both thermistors are subjected in the temperature measurement during the experiment, it is unfeasible to obtain such behaviour by means of a first-order mathematical model. However, for applications where the measurements are more stable and are not constantly changing abruptly, such as Fig. 13, it is possible to resort to first-order mathematical models.

On the other hand, even if it is possible to find a model that fits the response obtained in the conditions of the tube experiments (Fig. 11 and Fig. 12), it must be stressed that there are other phenomena that are not considered. As mentioned above, the stagnation temperature will tend to increase its value due to the friction generated in the layers closest to the thermistor. But as can be seen, the opposite is true. This suggests that there is a fraction of energy that is flowing through the conductors and is inducing this contradictory behaviour. Therefore, it is necessary to have tools that allow us to discern the applications, models and sensors to be used in order to obtain more precise measurements.

5. Conclusions.

This article presents experiments carried out under specific conditions that have allowed conclusions to be drawn about first-order models and their accuracy in real applications.

Therefore, the existence of conduction phenomena through the cables is evident, which in certain applications introduce uncertainty in the measurements. Thus, all this leads us to consider that in order to use this type of sensors in temperature control systems, it is important to take into account the conditions of the fluid to be monitored. Thus, as mentioned, due to the high dynamic responses offered by these sensors, it is necessary to know the uncertainties introduced by boundary layer effects and vorticity. These phenomena can lead to errors in high-precision processes in terms of temperature knowledge, as we have seen.

However, not everything should be seen from a negative point of view, as this type of device could be used to determine the turbulence near the wall or to detect the boundary layer detachment zone in order to improve aerodynamics. Thermistors, knowing their influence, have an attractive application in this type of field due to their small size and the reduced instrumentation required. Therefore, the development of measuring devices that implement this type of sensors to study the conditions of a fluid is not ruled out. Likewise, the quantification of the energy lost through the cables could be a future motivation, as the introduction of tools would allow more detailed processes to be obtained.

Predictive models for the "optimal" radius ratios in natural bi- and trifurcated vessels: beyond the Hess-Murray law

Enrico Sciubba
Università Niccolò Cusano – Roma, Italy
enrico.sciubba@unicusano.it

Abstract

Bifurcated structures are ubiquitous in nature, both in living and non-living systems. The modern approach to their physical modelling starts from the recognition that in plants and animals the substitution of (a portion of) a straight vessel length with a branched one serves a biological "goal" that requires some energy and material "expenditure". Such expenditure must be justified by a compensating gain for the resulting evolved structure. A great number of studies addressed this topic, mainly from a biomedical science perspective, but since all of them indicate a weak agreement with experimental data, it is useful to explore the matter in some more detail. The purpose of the vessels considered in this study is to "transport" material flows like sap, blood or air, and the striking geometrical similarity of the forked structures found in plants, circulatory systems, bronchial alveoli and river deltas suggests indeed the presence of a single underlying physical principle. Experimental evidence indicates that the topology of bifurcated blood, air and sap vessels (e.g., their "shape") is amazingly similar under quite different external constraints, and this might imply that the shape of a bifurcation is at least to some extent independent of the boundary conditions. Furthermore, it is unclear if and to what measure the functional advantage obtained by repeated bifurcations decreases with the number of splitting levels. This paper presents a critical review of the most popular physical model formulated for the description of bifurcated structures, the so-called Hess-Murray law ("H-M" in the following). It is first shown that, under a very restrictive set of assumptions, the H-M law can be obtained by the assumption of constant wall stress in the parent and daughter branches. Then both Hess' and Murray's original derivations are discussed from a physical point of view, and the extension of the rule to the case of non-symmetrical bi- and trifurcations is presented.
It is then argued that in real branched networks the actual optimality criteria (i.e., in an evolutionary sense the "driving force") may be quite different from the assumptions posited in the H-M law literature, which explains the weak predictive value of the law. Some adjustments to the model that include a resource-based cost/benefit of the formation of a bifurcation are presented and discussed.

1. Introduction

1.1 The problem

Bifurcated structures in fluid carrying channels and vessels appear in tree roots and branches, leaf veins, circulatory systems in animals, air vessels in the respiratory systems, corals, river deltas… (Figure 1). At first sight, such structures display an amazing degree of geometric similarity, and understanding the underlying physics is important for three reasons: first, if the existence of a unifying physical principle can be convincingly identified, this knowledge may lead to a better comprehension of natural evolution. Second, linking the "shape" of these structures to their "function" would allow for better aimed interventions in the case of malfunctions (overflow and flooding of rivers and channels, poor tree health, poor soil exploitation, circulatory diseases…). Third, a clearer insight on the physics of natural bifurcations may lead to the formulation of more accurate and efficient design guidelines of artificial (manufactured) branched structures, for example, in pipelines, heat exchangers, biological implants etc.
It is therefore not surprising that a large number of studies have been devoted to this topic. Leaving aside engineering applications, which require a separate discussion and are subject to quite different external constraints, botanists and biologists have dedicated substantial time and resources to the search for a general model of bi-, tri- and polyfurcated fluid carrying vessels. A brief list of the main questions to be answered can be extracted from a careful consultation of the archival literature[1]:

a) Why do bifurcated structures appear in nature?
b) Why is the geometry of such structures apparently similar at all scales and in different instantiations?

[1] To the best of my knowledge, the first modern systematic inquiry into this matter was performed by Wilhelm Roux in his dissertation in 1878 [25]. The original text being not easily accessible, I had to rely on later citations.

c) How and to what measure is the shape of a bifurcation independent of the prevailing boundary conditions?
d) Does the functional advantage obtained by repeated bifurcations decrease with the number of splittings?

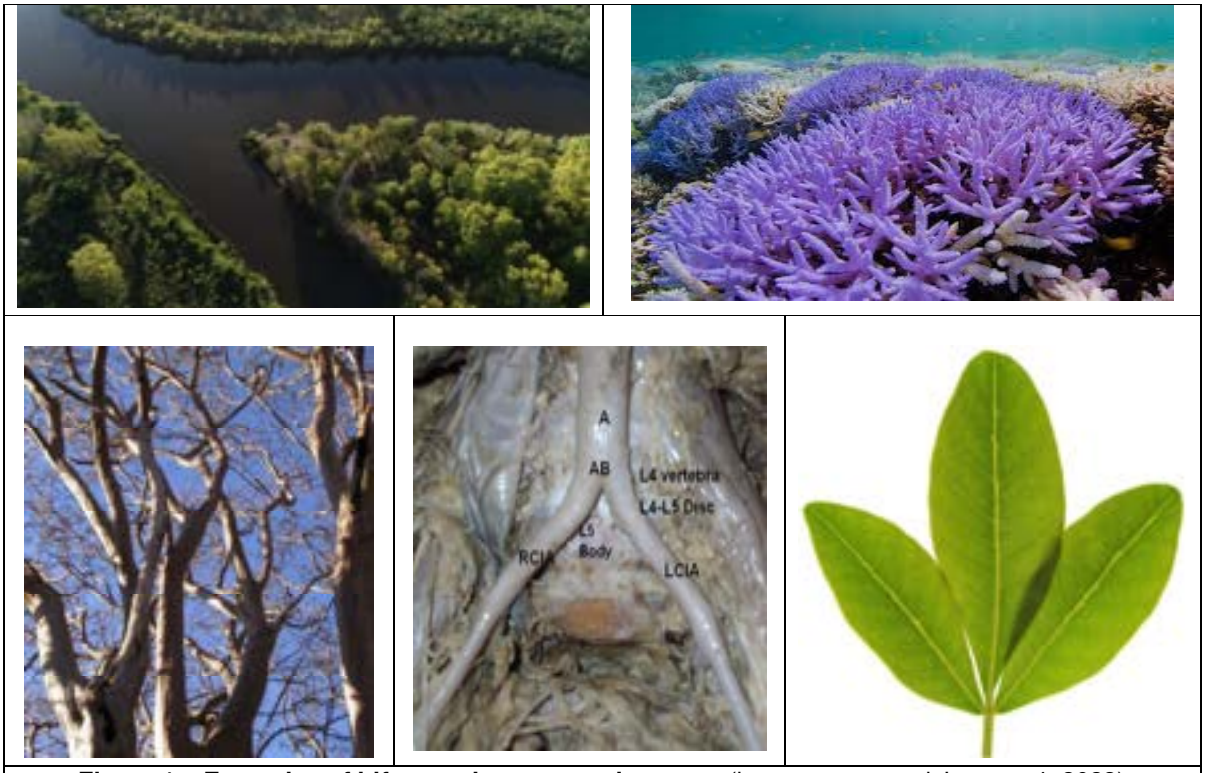

Figure 1 – Examples of bifurcated structures in nature (images accessed January 4, 2023)

A final answer to the above questions is yet to be found, and one of the goals of this paper is to clarify the current state of affairs and suggest possible paths to a solution.
To place this study in the correct perspective, it is useful to begin by examining the available empirical evidence collected over decades of valuable experimental campaigns. A summary of the knowledge that can be inferred from the large set of available data is the following:

1) Different types of branchings display an amazing degree of geometric similarity at large scales, but the exact geometric details (radius- and length ratio of daughter-to-parent branches, branching angle, complanarity) depend on the type of fluid being transported (newtonian or non-newtonian, pure substance or particle laden) [39,41], on the material and/or state of the channel walls (lignine, muscle fibers, gravel, sand…) [13,14,24,28,39,], and on the flow features (creeping, laminar or turbulent) [2,13,22,23,40,42];
2) Although a branched network resembles a fractal structure, there is no indication that the fractal exponent remains constant over successive branching levels [35];
3) While in plants the sap flow can be accurately modeled as stationary[2], in blood and air systems as well as in rivers the non-stationarity of the flow has a substantial influence on the geometry of the bifurcations [39,40].

1.2 – A very popular physical model: the Hess-Murray law

Over a century ago, the Swiss physiologist Walter Rudolf Hess formulated a model of blood flow in arterioles and capillaries that resulted in an allometric correlation between the radii of successive branchings in bi/trifurcated vessels: the original concept is presented and discussed in Hess' doctoral thesis published in a little known 1903 paper, with two further extended versions published (in german) in 1914 and 1917 [10,11]. Using a similar approach, the American physiologist Cecil Dunmore Murray "rediscovered" the same correlation in a 1926 article, and later refined and extended it in two other papers [16,17,18]. Since the

[2] Here and in the following, a significant distinction in the nomenclature must be made: while in blood- and air circulation systems one refers in fact to individual vessels (capillaries, veins, arteries etc.), in plants the "vessels" are either the mesoscale ducts of leaves and roots (the "veins") or the large scale twigs and branches. At the smallest xylem scale there is no bifurcation.

numerical result, i.e., the allometric rule, is the same, the law came to be referred to as "the Hess-Murray law".

The methods proposed by Hess and Murray are described in detail in sections 3 and 4 below: it is important to underline the novelty of both approaches, based on the assumption that the circulation of blood, lymph and air in living organisms is governed by a "work minimization" principle. The popularity of the H-M law is though not due to the "energy cost" methods they adopted (for a documented critique, see sections 3 and 4 below), but rather to the derivation of an "optimal branching ratio" $\delta = \frac{d_{i+1}}{d_i} = \frac{1}{\sqrt[3]{2}} = 0.7937$ between the diameters of two successive symmetrical branches. This "cubic root of 2" correlation underwent extensive theoretical and experimental reassessment in the second half of the 20th century, and the results indicate that while it is sufficiently accurate for the smallest vessels (capillaries), it fails for the larger ones (large veins and arteries); moreover, it does not apply to turbulent flows [42]. Recent comparisons with numerical investigations of branched flows led to similar conclusions [22,24,39,40].

In 1997 Bejan [4] published a very ingenious generalization of the H-M law: he reasoned that, if the law holds, then every bifurcated stream that carries a material or immaterial flow from one point (the *source*) to two others (the *sinks* or *end-users*) should -in an evolutionary sense- develop along a global structure exactly specified by the "cubic root of 2" rule. This intuition forms the basis for his Constructal Theory ("CT"), which has since seen a great number of applications in the most diverse fields (see also [5,6,15] for the Authors' own reassessment). Not by chance, the very name "constructal" was conceived to be an antonym of "fractal", to signify that real structures follow from goals and physical laws, in line with Hess' & Murray's teleology, rather than from abstract "shape factors" or Lyapunov exponents (borrowing Bejan's words: "*Nature is not fractal*" [4]). The goals are in turn determined by external influences related, in nature, to evolutionary pressures [5], and in engineering, to design specifications. In this sense, CT represents a "closed" scientific paradigm, not only *qualitative* but *quantitative*: it proposes a novel interpretation and classification of natural (abiotic and biological) structures and leads to measurable and repeatable design procedures for engineered artefacts. The entire body of its results depends though on the applicability of the H-M law, and more precisely on the general validity of the "cubic root of 2" correlation (or any other correlation of the form 2^{-n}).

The real legacy of the H-M law is not its (doubtful) universal accuracy, but rather its conceptual foundations: it states that biological organisms can be described by means of an allometric scaling arising from an "energy costing" approach. As noted in [36] and later by [5,27,31], this in turn implies the existence of a similar allometry between different species: if the relative sizes of the respective blood or sap vessels scale according to a 2^{-n} rule then, whatever the value of n, the average physical dimensions of the individual organism depend on the radius of the main branch, which in turn depends on the metabolic rate of the species.

On the engineering side, in spite of Sherman [36] argument that -if the hydraulic diameter d_h is substituted for d- the H-M law should also hold with minimal corrections for human artefacts (pipelines, fluid carrying networks, porous media), the matter is more complex, because heat exchangers and fluid networks are designed under several "non-natural" constraints, some of which derive from purely technical requirements (entry length in a HE, material compatibility, vessel wall mechanical resistance, etc.) and others are cost-related (minimal material costs, optimal thermal insulation, minimum pumping work, etc.). The analysis of the applicability of the H-M law to engineered structures is outside of the scope of the present study.

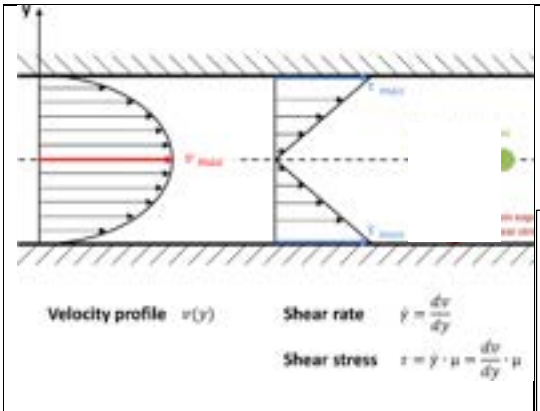

Figure 2 – Flow of a newtonian fluid in a circular channel: velocity and viscous stress profiles

2- Young's Constant Wall Stress Law

2.1 -Theoretical model

It is interesting to remark that, as reported by Thomas Young in its Croonian lecture 1809 [44], presented well before Hess' study, an exact form of the radius ratio in branched tubes was already known to hydraulic engineers. This formula also reads $\delta = \frac{d_{i+1}}{d_i} = \frac{1}{\sqrt[3]{2}} = 0.7937$, but its derivation does not depend on the approximations introduced by Hess on the "regulatory power of the blood flow" nor on the inaccurate "metabolic cost of blood volume" calculated by Murray.

2.2 - The mathematical derivation

Consider the steady laminar and isothermal flow of a Newtonian fluid in a symmetrically branched circular channel (Figure 3, top left). Assuming that the flow can be described by Poiseuille formula and remains laminar in the daughter branches (i.e., neglecting the possible onset of turbulence at the junction), the wall stress calculated in the parent (ℓ_0) and daughter (ℓ_1, ℓ_2) branches takes the form:

$$\tau_w = \frac{4\nu m_j}{\pi r_j^3} \quad (1)$$

with *j=0* for the main and 1 and 2 for the splits. Let us impose the constancy of the wall stress throughout the bifurcation:

$$\tau_{w,0} = \frac{4\nu m_0}{\pi r_0^3} = \tau_{w,1} = \frac{4\nu m_1}{\pi r_1^3} = \tau_{w,2} = \frac{4\nu m_2}{\pi r_2^3} \quad (2)$$

If the split is symmetrical, then $m_1 = m_2 = m_0/2$, and we obtain:

$$\delta = \frac{r_1}{r_0} = \frac{r_2}{r_0} = \frac{1}{\sqrt[3]{2}} = 0.7937 \quad (3)$$

i.e., the same value prescribed by the H-M rule.

The validity of Eq. (3) rests of course upon the assumptions of steady Poiseuille flow, and therefore there is no reason for the exponent $n=-1/3$ to apply under turbulent- or non-stationary flow conditions. It is to be expected though that in leaf tubules, blood capillaries and in the smallest tubules of the respiratory tract, where diameters are well below 1 mm and the Reynolds number of the flow is very low, the above correlation should apply.

An interesting consequence of Eq. (3) can be derived if we prescribe the Δp in the main- and in the daughter branches to be the same. This implies:

$$\lambda = \frac{l_1}{l_0} = \frac{l_2}{l_0} = 2 \quad (4)$$

Eq. (4) would suggest that at each bifurcation the length of the daughter branches doubles, a condition not supported though by experimental evidence.

The above calculation can be adapted to non-symmetric branchings (Figure 3 top right). To close the calculation, we need to know the ratio of the mass flowrates through the daughter branches, $k_1 = m_1/m_0 = x$, $k_2 = m_2/m_0 = 1-x$. We obtain:

$$\delta_1 = \frac{r_1}{r_0} = x^{1/3}$$

$$\delta_2 = \frac{r_2}{r_0} = (1-x)^{1/3} \quad (5)$$

In this case the pressure drops through the daughter branches are different, unless one selects a proper ℓ_1/ℓ_2 ratio:

$$\Delta p_1 = \Delta p_2 \quad iff \quad \frac{l_1}{l_2} = \left(\frac{1-x}{x}\right)^2 \left(\frac{\delta_1}{\delta_2}\right)^4 \quad (6)$$

3 – Hess' original model

3.1 - Problem position

In 1903, in a preparatory paper for his M.D. thesis [10], the Swiss physiologist Walter Rudolf Hess proposed the existence of a physical "optimization criterion" that guides the branching of arterial vessels. This idea was also the topic of later work in his "Habilitation" thesis [11], but the 1903 work already contains -albeit in a convolute way and with some debatable assumptions- a complete derivation of his "cubic root of 2" law. Hess was clearly inspired by previous work by Roux [25] who postulated a "dynamic mechanical principle" to be the driver of vessel bifurcations in animal circulatory systems. Trying to interpret the large mass of experimental data presented by Roux, Hess starts by assuming that nature would adopt a "minimum resource consumption" criterion to build the human circulatory system and proceeds to calculate how this task can be attained ("*Wie kann die Aufgabe des Blutes mit dem kleinsten Kraftverbrauch erledigt werden*" [10], p.5). In spite of his convolute writing style, Hess' approach emerges clearly: the optimal radius of a vessel carrying a given volumetric blood flowrate is the one that minimizes a cost function given by the sum of the pumping work (inversely proportional to the fourth power of the radius) and the metabolic cost of the volume of the pumped blood (proportional to the square of the radius).

3.2 - The mathematical derivation

In modern terms, Hess' procedure can be reformulated as follows:

a) Assume the flow in arteries can be described by Poiseuille's law for steady laminar flow in circular vessels with rigid walls;

b) Calculate the pumping power in W/(meter of vessel) required of the heart to process a flowrate m [kg/s]:

$$P_{pump} = K_1 \frac{m^2}{r^4} \quad (7)$$

where K_1 is a constant that depends on the fluid viscosity and density;

c) Calculate the metabolic cost of the pumped blood, neglecting its thermal content:

$$C_{blood} = K_2 r^2 \quad (8)$$

Where C_{blood} is also in W/m of vessel and K_2 is a constant depending on the metabolic rate;

d) Find the optimal radius by solving the corresponding Lagrangian[3]:

$$\mathcal{L}_{Hess} = P_{pump} + C_{blood} = K_1 \frac{m^2}{r^4} + K_2 r^2 \quad (9)$$

Which results in:

$$r_{opt} = \left(\frac{2K_1}{K_2}\right)^{1/6} m^{1/3} = \kappa m^{1/3} \quad (10)$$

Where the constant κ depends on the fluid properties and on the metabolic rate. If a vessel bifurcates symmetrically (Figure 4), i.e., if $m_1=m_2=m_0/2$, the optimality can be extended to the daughter branches:

$$r_0 = \kappa m_0^{1/3}; \quad r_1 = r_2 = \kappa \left(\frac{m_0}{2}\right)^{1/3} \quad (11)$$

Whence

$$\delta = \frac{r_1}{r_0} = \frac{1}{\sqrt[3]{2}} \quad (12)$$

Throughout his papers Hess repeatedly stresses that he is aware that his result depends on two critical assumptions, namely Poiseuille flow and stationarity, and makes accurate reference to selected contemporary literature that reinforces his belief that a branching does not generate turbulence and that the low-frequency pulsations do not affect the flow in such a way as to invalidate Eq. (12).

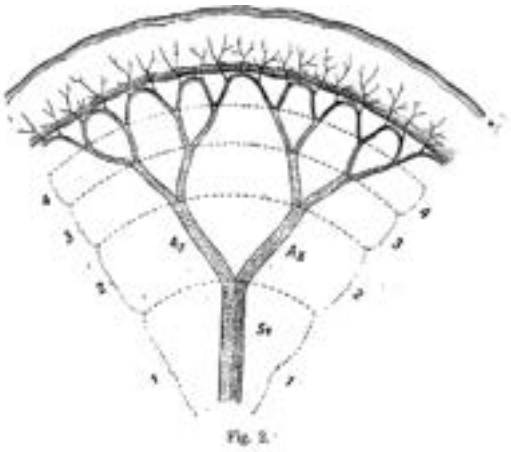

Figure 4 – Hess' original concept [11]

Figure 5 – Asymmetric trifurcation of a corkbark tree tip ($r_1=r_2\neq r_3$)

4 – MURRAY'S model

4.1 - Problem position

Between 1926 and 1927, Cecil B. Murray, an American physiologist, published a set of papers aimed at the identification of the most "economic" oxygen supply to the human limbs via blood transport through the vessels. He demonstrated that such an optimal value can be derived by minimizing a cost function consisting of two terms: the power needed to overcome friction and the "metabolic cost" of the blood flowing through the vessel. The premises are similar to those posited by Hess, but the calculation of the blood cost function is different. He, too, arrived at a "cubic root of 2" formula. Murray -as Hess- assumed the blood flow to be

[3] In fact, Hess only presents a graphical derivation, because the expression he derives for K_2 is not explicit in the variable "r", and thus he must use an approximation to make the dependence explicit

described by the stationary Poiseuille formula, and explicitly stated that his derivation ought to be considered a statistically valid theoretical guideline and that his model represents a "theoretical approximation" of the more complex physiology of blood transport. In his own words [16]: "*If we examine the arterial system bearing in mind the question of economy, we find that there are two main antagonistic factors. If the vessels are too small, the work required to drive the blood through them becomes too great; if the volume of the vessels is too large, the volume of blood, being equally large, becomes a burden to the whole body*". Murray was aware of Hess' previous work but maintained that his calculation of the blood cost was more accurate and based on the latest experimental results. Besides reformulating the theory, Murray also derived the "optimal angles" for a symmetric bifurcation using the minimum virtual work principle (Figures 6, 7).

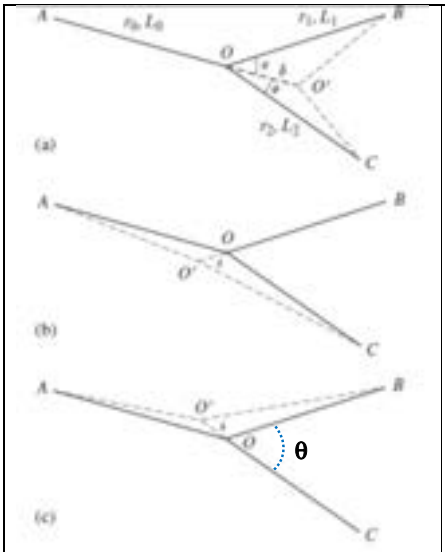

Figure 6 - Murray's derivation of the optimal branching angle [16]

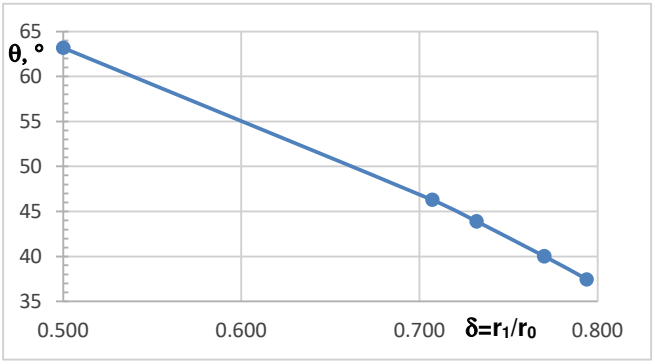

n	1.00	2.00	2.22	2.65	3.00
$\delta=r_1/r_0$	0.500	0.707	0.732	0.770	0.794
theta °	63	46	44	40	37
$\lambda=\ell_1/\ell_0$	0.25	1.00	1.15	1.41	1.59

Figure 7 – Branching angle θ as a f(δ) for symmetrical bifurcations. $\delta=2^{-1/n}$, $\theta=arcos(0.5/\delta^2)$

4.2 - The mathematical derivation

Proceeding along the same path previously proposed by Hess, Murray obtained an expression identical to Hess' for the power required to pump a given mass flowrate of blood in a straight vessel with rigid walls, Eq. (7): $P_{pump} = K_1 \frac{m^2}{r^4}$,

where K_1 is the same constant as in Hess' formulation.

He then proceeded to calculate the metabolic cost of the pumped blood:

$$C_{blood} = b\rho l\pi r^2 = K_3 r^2 \qquad (13)$$

Where b is the "cost of blood" calculated on the basis of the then available data on heart rates, and varies between 980 and 1980 W/m^3 according to the adopted calculation method. For the purpose of this paper, the accuracy of the value of b is though irrelevant.

The optimal radius is again obtained by solving the corresponding Lagrangian:

$$\mathcal{L}_{Hess} = P_{pump} + C_{blood} = K_1 \frac{m^2}{r^4} + K_3 r^2 \qquad (14)$$

Which results in:

$$r_{opt} = \left(\frac{4K_1}{K_3}\right)^{1/6} m^{1/3} = \xi m^{1/3} \qquad (15)$$

Where the constant ξ depends on the fluid properties and on the power absorbed by the heart. If a vessel bifurcates symmetrically (Figure 3, top left), i.e., if $m_1=m_2=m_0/2$, the optimality can be extended to the daughter branches and the "cubic root of 2" law $\delta = \frac{r_1}{r_0} = \frac{1}{\sqrt[3]{2}}$ is recovered.

In a second paper [17], Murray calculates the optimal branching angle by applying again the principle of minimum work: as shown in Figure 6, among the possible paths the branching angles that minimize the total work are given by:

$$cos\theta = \frac{r_0^4+r_1^4-r_2^4}{2r_0^2r_1^2}; \quad cos\varphi = \frac{r_0^4+r_2^4-r_1^4}{2r_0^2r_2^2} \qquad (16)$$

Now Murray argued that, since according to Eq. 10 the mass flow rate at optimal configuration is proportional to the cube of the radius, the correlation between the radii of the main- and the daughter branches is:

$$r_0^3 = r_1^3 + r_2^3 \qquad (17)$$

So that the final relationship between the splitting angles becomes:

$$\theta = arccos\left[\frac{r_0^4+r_1^4-\left(r_0^3-r_1^3\right)^{4/3}}{2r_0^2r_1^2}\right];\quad \varphi = arccos\left[\frac{r_0^4+r_2^4-\left(r_0^3-r_2^3\right)^{4/3}}{2r_0^2r_1^2}\right] \tag{18}$$

Introducing the optimal radius ratio δ (Eq. 12):

$$\theta = \varphi = arccos\left[\frac{1+\delta^4-\left(1-\delta^3\right)^{4/3}}{2\delta^2}\right] \sim 37° \tag{19}$$

The above result predicts that symmetrical branches should have a total branching angle ($\theta+\varphi$) of about 75°.
If the vessel trifurcates as shown in Figure 5, with two side daughter branches being symmetrical with equal radii $r_1=\gamma r_0$ and the third coaxial with the main and also of radius $r_2=r_1$, the optimal value of the radius ratio is $\gamma = \frac{1}{\sqrt[3]{3}} = 0.6934$ and Murray's optimization procedure provides:

$$\psi = arccos\left[\frac{r_0^2-\left(r_0^3-2r_1^3\right)^{2/3}}{2\gamma^2r_0^2}\right] \tag{20}$$

with the splitting angle ψ=57°.
Murray did not elaborate on the fact that Eqs. (16) & (20) retain their validity under <u>any</u> law of the type 2^{-n}. Figure 7 displays the branching angle θ as a function of the radius ratio δ for n=1, 2, 3 and two experimentally & numerically validated values, namely 2.22 and 2.45 [13,26,34,41,42].
Another consequence of the H-M law (or of any similar allometric correlation) is that the length of the branches may also be derived as a function of *n*: for example, imposing a constant pressure drop across all branches (i.e., $\Delta p_0=\Delta p_1=\Delta p_2$, not necessarily an "optimal" choice) one obtains

$$\lambda_1 = \frac{\ell_1}{\ell_0} = 2^{\left(2\frac{n-2}{n}\right)} \tag{21}$$

The λ_1 are also shown in Figure 7: in spite of their not being optimal in any sense, these values can be used as a yardstick for assessing field-measured values. In fact, the largest majority of field data report ℓ_1 values lower than 1, which indicates that the "constant Δp" is not a preferred configuration in nature.

5 – Limitations of the Hess-Murray Law

5.1 - Theoretical analysis

The applicability of the H-M law depends on several assumptions, the more stringent being:

a) *Validity of the Poiseuille flow*
While in plants the sap flow is so slow that it can be modelled as a creeping flow, in animals laminarity is the exception rather than the rule. Notice though that this fact *per se* does not affect the value of the branching ratio: the <u>necessary</u> condition for the H-M law to apply is that a phenomenon can be modeled as emerging from the combined influence of two competing "forces", one proportional to the square of the mass flowrate and to the inverse fourth power of the radius, and the other to the square of the radius.

b) *Validity of the steady state flow conditions*
This is a major simplification, and both experimental [12,20,21,34,45] and numerical [2,13,22,23,24,33,34,40] studies demonstrated that the inherent unsteadiness in blood vessels has a major impact on the exponent of the allometric correlation.

c) *Independence on the type of fluid*
Both sap and blood are non-Newtonian fluids, and experimental and numerical studies demonstrate that releasing the newtonianity condition results in a different value of the exponent *n* in Eq. (15).

d) *Validity of the assumption of rigid walls*
On this point one must differentiate between application of the law to plants and animals: in the former case, the lignino-cellulosic walls are for all practical purposes rigid, while in the latter the compliant muscle-structure of arteries and veins may even invalidate the non-slip condition.

Allometric branching models exist that are not derived from a Hess-Murray perspective (for details see [7,43]), but their treatment is outside of the scope of this paper.

5.2 – Comparison with experimental results

Given the convenience of a simple correlation like the H-M law, several experimental campaigns have been conducted over the years to verity its applicability, especially in biology. The verified experimental evidence may be summarized as follows:

a) As anticipated by Murray, both *in vitro* and *in vivo* tests convincingly demonstrate the validity of a H-M-like allometry in capillaries and arterioles, with exponent values in the range $2^{-0.16}$ through $2^{-0.43}$ [2,23,26,36,41]. In larger vessels (veins, arteries) a $2^{-0.47}$ value is more appropriate [26,41].

b) More importantly, several independent experiments on animal circulatory systems [12,45] conclude that radius-dependent *slenderness factors* appear to be correlated by a power law of the type $\ell/(2r)=\alpha r^n$, with $0.47<n<1.1$ and α a case-dependent function of r_0: this implies that the dimensionless splitting length $\lambda_0=\ell_0/L$ (see Figure 7) is also a relevant parameter.

c) Although, for the reasons discussed in the previous sections, the agreement is expected to be better in plants, independent studies report vessels ratios between 0.47 and 0.85 for both leaves and soft twigs [1,25]. Following Murray [19] and in spite of a critique by Savage [27], some Authors assume bough-to-trunk and twig-to-bough radius ratios to follow the "cubic root of 2" rule: as we shall see in section 6.4, it is possible to formulate a physical model for such a case also by assuming a volume conserving law that leads to an exponent $n=2$. Some Authors prefer to use a log/log fit for the branch lengths and the radius [12,20].
Referring the reader to [29,31] for a more detailed discussion, it is fair to conclude this analysis by saying that the Hess-Murray's law:

a) Has the great merit of introducing the idea that the growth of branches in a tree or in epithelial tissue is dictated by a "balance" of material and metabolic energy cost;
b) It is valid in a first approximation for all processes in which the two contrasting "forces" are friction and fluid volume;
c) Displays an acceptable agreement for small, rigid-walled vessels and laminar flow, but fails significantly to describe branching ratios observed in real structures for any other condition (larger vessels, compliant walls, non-newtonian fluid, turbulent flow).

6 - Models based on a different "cost" structure

All of the hitherto formulated alternative models maintain the physical approach suggested by Hess and Murray: the formation and operation of a branched configuration must serve some physiological goal and therefore it ought to "minimize" in some sense the resources invested by the system in generating the bifurcation. Adam [1] proposes some alternative cost functions, all of them confirming the "cubic root of 2" correlation but having different values for the constant ξ in the solution of the "optimal" radius (Eq. 15). The unsatisfactory agreement of the H-M law has stimulated further research in the topic, and it is instructive to examine some other Lagrangians that have been explicitly or implicitly proposed in relatively recent archival publications. In this section we shall discuss three alternative models based on the consideration that a bifurcation must be created with an investment of both material and energy.

6.1 – Minimal pumping power in a target volume

The simplest cost function considers only the "system operation cost", i.e., the pumping power required to overcome friction losses. Simply imposing minimum P_{pump} (Eq. 7) leads of course to the trivial and unphysical result $r\to\infty$. It is though interesting to investigate the existence of geometrically constrained values for the radius ratio and for the branching angle. Consider Figure 8: in real instantiations a branching takes place within a "volume" (here, area) defined by the origin "O" and the final points A and B, and if the splitting point moves along the parent branch, ℓ_0 varies and so does $\ell_1=\ell_2$ (if the branching is symmetrical). The Poiseuille pressure loss along the three vessels is:

$$\Delta p_0 = \frac{8\nu l_0 m_0}{\pi r_0^4}; \qquad \Delta p_1 = \Delta p_2 = \frac{4\nu l_0 m_0}{\pi r_1^4} \tag{22}$$

The corresponding pumping powers:

$$P_{pump,0} = q_0\Delta p_0 = \frac{8\nu l_0 m_0^2}{\pi\rho r_0^4}; \qquad P_{pump,1} = P_{pump,2} = q_1\Delta p_1 = \frac{2\nu l_1 m_0^2}{\pi\rho r_1^4} \tag{23}$$

The lengths ℓ_0 and ℓ_1 are subject to the constraints:

$$L = l_0 + l_1 cos\theta; \text{ or } \qquad \lambda_0 = 1 - \lambda_1 cos\theta \tag{24}$$

The ratio P_{bif}/P_0 is less than unity (i.e., it brings an advantage in terms of pumping power) only above a certain splitting angle of about 61°, i.e. for an exponent $n\cong 2$ and a radius ratio very close to $\frac{1}{\sqrt{2}} = 0.707$ (Figure 9). There is no minimum.
Notice that the application of Eq. (23) results in an implicit correlation between the radius ratio and the aspect ratio $a=H/L$ of the 2D domain defined by the branching, because the splitting lengths l_0 and l_1 depend on the aspect ratio and θ as per Eq. (24). This is a useful outcome, and shows that different values of the exponent n may accommodate more closely the deviations from the H-M law in real plants and blood vessels.

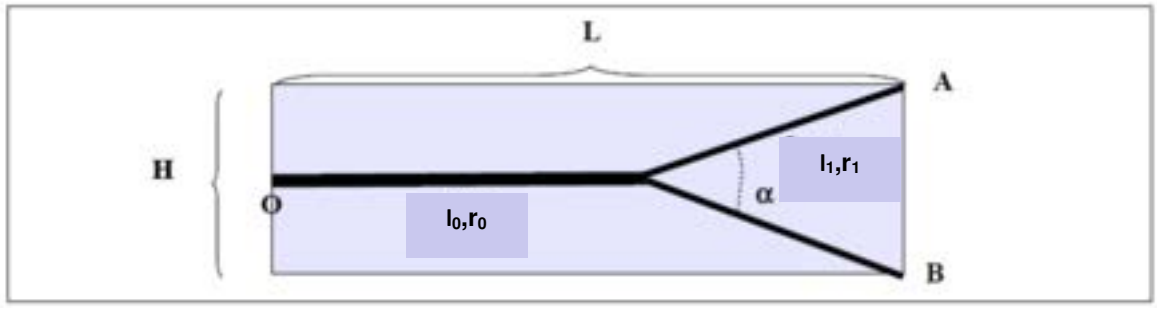

Figure 8 – Definition of the influence area of a bifurcation (adapted from [30])

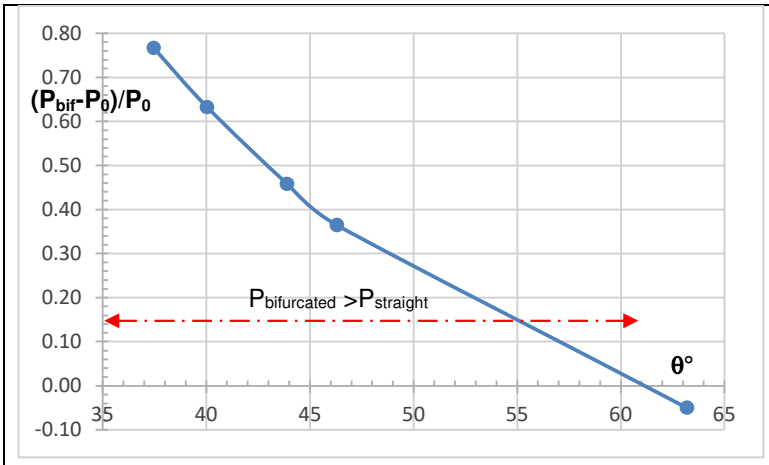

Figure 9 – Symmetric bifurcation: dimensionless pumping power vs. splitting angle θ

Figure 10 – Vessel vs. twig radius in a tree bifurcation

6.2 - Minimal entropy generation

Another very useful paradigm used to optimize bifurcated structures, pioneered by Bejan [3], is the Entropy Generation Minimization (EGM). True to its name, EGM is based on the idea that the "optimal" shape of a branched fluid-carrying conduit ought to minimize the total irreversibility occurring during its operational window (the lifetime of the vessel). EGM was formulated earlier than CT, is undoubtedly more comprehensive than the latter and -more important- it generates richer insight. Contrary to common belief, it can be proven that the two approaches do not consistently lead to the same results [30,31]. Since the flow of sap and blood can be assumed as isothermal and single phase, the only entropy generation is caused by friction, and the lagrangian becomes:

$$\mathcal{L}_{\dot{s}} = K_s \dot{s}_{visc} \tag{25}$$

It turns out that, since the rate of viscous entropy generation is directly proportional to the lost work due to friction, the solution to Eq. (25) leads to the same results as in section 6.1 [29].

6.3- Minimal pumping power and material formation cost

This model, formulated by researchers investigating tree growth, [8,9], is based on the premise that the growth of a bifurcation carries a cost equal to the biological production expenditure required of the tree to produce the volume of the material (lignine) of the new sap carrying vessels. This cost is assumed to be proportional to the Net Primary Production of the plant (NPP), a measure of the efficiency of the tree to transform its global resource input into "new wood" [20,21,37,38]. This expenditure must be added to that required to pump the sap. It is readily seen that the new volume is proportional to the square of the vessel radius, and thus the Lagrangian takes the same form as Hess' one, although with a different value for the constant K_5.

$$\mathcal{L}_{material} = K_1 \frac{m^2}{r^4} + K_5 r^2 \tag{26}$$

Thus, while the optimal radius that carries a given mass flow rate of sap is of course different than that predicted by the H-M law, still the radius ratio of the daughter branches to the parent one follows the cubic root of 2 rule, because the solution of (28) is again $r_{opt}^3 = \left(\frac{K_1}{K_5}\right)^{1/2} m$.

6.4- Minimal pumping power, material formation and fluid cost

It is useful to address the problem from a different viewpoint: it is correct that the system "resource expenditure" is proportional to the pumping power and to the material cost require for building the vessel's envelope, one ought to consider that the scope of circulating the nutrients is to allow the system to "grow". Therefore, there is another expense required, namely that of the generation and maintenance of the material that surrounds the vessel: in a tree, the twig, and in an animal system, the surrounding tissue. The additional cost is proportional to the metabolic rate required by this "growth", and it dictates the mass flowrate[4]. Denoting as R the radius of the twig or bough (or of the organic tissue surrounding a blood vessel), the mass flow of sap or blood depends on the growth rate, and at steady state can be expressed as:

$$m = K_3 R^2 \tag{27}$$

Where K_3 is a function of the metabolic rate of nutrients needed to build a cylinder of radius R and unit length. The Lagrangian becomes:

$$\mathcal{L}_{ex} = K_4 \frac{R^4}{r^4} + K_5 r^2 \tag{28}$$

With $K_4 = K_1 * K_3$. Experimental evidence shows that the volume per unit length of the two splits is equal to that of the root trunk[i5]:

$$V_{root} = V_{b1} + V_{b2} \tag{29}$$

i.e., that (Figure 10):

$$R_{root}^2 = R_{b1}^2 + R_{b2}^2 \tag{30}$$

And in a symmetric bifurcation:

$$\frac{R_{b1}}{R_{root}} = \frac{1}{\sqrt{2}} \tag{31}$$

The radius R of the twig or epithelial system is obviously much larger than the radius r of the xylems or of the capillaries, and thus the constant K_5 must also contain the number N of the vessels participating to the feeding of R, a constant not affected by the differentiation. Minimizing the Lagrangian leads to:

$$\delta = \frac{r_1}{r_0} = 2^{-2/3} = 0.63 \tag{32}$$

Since the correlation between θ and δ is derived on the basis of the minimization of virtual work, Murray's formula still applies, and for a symmetric bifurcation we obtain:

$$\theta = \arccos\left(\frac{1}{2\delta^2}\right) = \arccos\left(2^{-1/3}\right) = 37.5° \tag{33}$$

i.e., a value almost equal to that prescribed for a symmetric bifurcation before introducing the cubic correlation between the vessel radius and the mass flowrate (Eq. 19). Notice that in this type of model it is necessary to take into account the permeability of the vessel walls: a more detailed description is provided in [32].

7 - Conclusions

In spite of its being overcelebrated -especially in biosciences- the Hess-Murray law does not display a satisfactory agreement with experimental results. Furthermore, most of the assumptions on which the $n=3$ exponent has been derived are far from being realized in nature. Nevertheless, its fruitful legacy is the concept that th*e creation and maintenance of a bifurcation serves an evolutionary criterion of minimal energy cost*. The idea underlying the study discussed in this paper is that it is not the allometry itself, but the "cost/benefit" evaluation that is worthy of further analysis. In fact, a different model based on a different form of the Lagrangian "cost function" leads to a different "optimum" (or to no optimum altogether).

This suggests to extend the horizon of the investigation: in line of principle, it would be very satisfactory if the "construction" of a bifurcation could be derived by a single principle of minimization of the amount of resources needed to create and maintain the branched structure so that it serves the scope for which it was generated. The mass- and energy balances of a living system (be it a plant or an animal) depend on the amount of resources the system can avail itself of, and these "costs" include "nutrients", thermal and chemical flows, water and solar radiation. It is likely that the benefits could be expressed in terms of "more effective access to resources" or "higher productivity", and in such a perspective the most convenient quantification of both resource cost and evolutionary benefit is the equivalent amount of primary exergy resources consumed for each given "task". The resulting models become somewhat more involved and are left for a future study.

Abstract:
The proposed study presents preliminary design guidelines for vortex-induced vibration energy harvesting devices. In particular, this study combines high-quality computational fluid dynamics techniques to systematically examine the oscillatory behaviour of flow-induced vibration cylinders in cross-flow configurations. Simple cylinders are examined and modelled in terms of masses, damping, and stiffness. The design maps are derived after a comprehensive validation of the numerical model. The maps link the most important flow characteristics at which the device should be installed to the foundational variables relevant to energy recovery and the most important flow properties on which the device must be installed. The results show that the lock-in conditions are achieved with a reduced velocity value of about 5. Additionally, the analysis revealed that the density ratio is a key design parameter, since the functional properties of the device are ensured only for modest values, roughly around 10. In essence, the results provide significant insights into the fluid mechanics of the system, direct indications of the nondimensional groups that regulate system physics, and practical tips for its design.

Keywords:
vortex-induced vibrations, energy harvesting, mini-hydro, virtual design.

1. Introduction

Since the beginning of civilisation, the harvesting of energy from waterways has played a fundamental role in the implementation of human society. In fact, water flows are generally easily accessible and provide a constant energy supply to help with several human activities. However, today, the scientific community recognises that the most profitable water resources for electricity generation have already been fully exploited with standard and well-established technologies. Therefore, novel and disruptive ideas are needed in the hydroelectric landscape. In particular, the mini-hydro aims to generate electricity from tiny/minimal water sources using innovative concepts. These prototypes are a long way different from canonical turbine/watermill plants, the latter requiring significant financial investments and long payback periods. Thus, in a world that is moving from fossil to renewable resources and from concentrate to distributed generation, mini- and microhydro technologies will play a crucial role, especially if the new devices/systems will generate electricity from untapped water flows in an appealing way for building, industrial, and tertiary sectors.

One of the most relevant innovations in this field is related to energy harvesters. Generally speaking, these devices consist of electrofluid-mechanical systems designed to convert the energy content of water flowing into pipes, canals, and conduits into electricity, mainly inducing a vibration on a bluff body linked to an electric generator. In this context, in-depth study and understanding of the Vortex-Induced Vibration (VIV) phenomenon become fundamental, especially concerning its application to energy harvesting systems. Therefore, several studies have made great progress in understanding the causes and characteristics of VIV. This need comes from the fact that vibrations induced by fluid flows on bluff bodies can be particularly dangerous in many engineering situations, such as projects that involve bridges, offshore structures, and cables, in particular if the lock-in state is reached. However, vibrations can also be seen as an energy source and can be used for energy production.

In particular, from the pioneering work of Goswami et al. [1], which presented the experimental results of the properties of the vortex-induced response of a spring-mounted circular cylinder in a low-speed wind tunnel, several other contributions appeared in the literature. Blackburn and Henderson [2], for instance, addressed the free vibration behaviour and wake models in vortex-induced and free oscillations through a numerical model, showing that the method is a valid alternative to experimental setups. Later on, Zhao et al. [3], investigated the steady and oscillatory flow of VIV systems by numerically solving the two-dimensional Reynolds-Averaged Navier-Stokes (RANS) equations. The main finding is that the combination of steady flow and oscillatory pattern widens the lock-in regime, achieving a twice broader lock-in regime concerning the pure steady or pure

oscillatory flow.

The works mentioned above can be considered to be the foundation of VIV fundamental physics, while the use of VIV systems to harvest energy became a hot research topic only in recent years. In particular, the idea at the base of energy harvesting with VIV systems refers to the combination of bluff bodies with piezoelectric generators or coil-magnet electromagnetic systems. In this regard, [4] found that the inviscid component of the fluid is responsible for the instability and that the viscous drag has a dual influence on energy harvesting. In particular, at a given flow speed, its dissipative action reduces the power output while leading to a sustained limit cycle of oscillations. Molino-Minero-Re et al. [5] examined the energy harvesting performance of different cylinder sizes. The results show that the frequency of oscillation decreases as the diameter of the cylinders increases, whereas the power supplied does not follow a clear trend. Also Abdelkefi et al. [6] focused on the motion of a rigid cylinder, providing a mathematical model that accounts for the coupled lifting force, the movement of the cylinder, and the harvested voltage, describing the lift with a modified van der Pol equation. As a result, the influence of the load resistance of the coupled circuit influences the onset synchronisation, shifting it to higher free-stream velocities. As Abdelkefi et al. [6] stated, Mehmood et al. [7] found the same results regarding the effects of the load of the coupled electromechanical circuit. Andrianne et al. [8] developed an energy harvester based on the phenomenon of wind galloping. More recently, Zhu et al. [9] introduced a new perspective in the field of energy harvesting research by proposing a particular configuration with a circular cylinder combined with a free-rotating pentagram impeller. Cylinder vibration and impeller rotation energy are harvested simultaneously. The result shows an efficiency of 22.6% and an expected power output of 885.53 W/m^3. Finally, Nitti et al. [10] studied the coupling mechanism between cross-flow translation and rotation, providing a single degree of freedom cylinder system. The research findings underlined that the rotation maintains the lock-in condition.

Despite the extensive numerical and experimental contributions inherent in the research and development of VIV devices, no investigations have provided detailed and precise design criteria that can be considered valid for maximising the exploitation of the water-fluid dynamics. In particular, literature contributions typically focus on specific configurations, frequently offering laboratory testing, with few hints about the influence of the flow field conditions on the choice of the design parameters such as mass and control circuit settings (i.e., stiffness and damping).

The present research investigates in detail the mutual relationship between fluid dynamics and body behaviour and attempts to offer design guidelines for a VIV energy harvester, with the aim of maximising the energy production by ensuring the lock-in condition. For this purpose, a database of configurations is considered and virtually analysed under different fluid-dynamic operating conditions using Computational Fluid Dynamics (CFD) tools. In this preliminary investigation, only a basic cross-flow cylinder arrangement is addressed, and the influence of the control system mass and stiffness on the device displacements depending on the flow characteristics is explored, the latter being unambiguously connected to electrical power generation.

The rest of the work is organised as follows. Section 2. describes the model and its validation procedure, while Section 3. presents the results of the analysis. Finally, Section 4. makes conclusive remarks.

2. Model description and validation

The configuration, investigated in this study, is represented by a cross-flow cylinder arrangement, whose behaviour under different water flow conditions was thoroughly analysed to establish the basis for an innovative design strategy aimed at maximising energy production. In this Section, the mathematical description of the mechanical model of the device is first presented. Then, the numerical CFD model and its validation are outlined.

2.1. Mechanical model description

The interaction between the flow stream and the cylinder displacement was modelled by a 2D model concerning an elastically mounted circular cylinder immersed in a cross-flow. The cylinder can undergo vertical displacement; therefore, the single degree-of-freedom system is governed by a forced second-order oscillator equation.

$$m\ddot{\tilde{y}} + c\dot{\tilde{y}} + k\tilde{y} = F_y \tag{1}$$

where F_y is the resulting lift force on the surface of the cylinder, m is the mass of the cylinder, while c and k are the damping and stiffness parameters, respectively. $\tilde{y}$, $\dot{\tilde{y}}$ and $\ddot{\tilde{y}}$ denote vertical dimensional movement, velocity, and acceleration. Since the aim of the study is to propose a design strategy not customised to specific conditions, Eq. (1) was transformed into an equivalent nondimensional formulation by casting $y = \tilde{y}/D$ and $t = \tilde{t}U_\infty/D$, being D the diameter of the cylinder, U_∞ the free stream speed of the flow and $\tilde{t}$ the dimensional time. Thus, the following equation holds:

$$\rho d\ddot{y} + \mu\dot{y} + \xi y = 2c_y \tag{2}$$

where $\rho = \rho_s/\rho_\infty$ is the solid-to-fluid density ratio, $d = A/D^2$ is a geometric parameter in which A is the cylinder area, $c_y = F_y/q_\infty$ is the lift coefficient, with $q_\infty = 1/2\rho_\infty U_\infty^2 D$ the free stream pressure load, while $\mu = c/(\rho_\infty U_\infty D)$ and $\xi = k/(\rho_\infty U_\infty^2)$ are the nondimensional damping and stiffness, respectively.

Equation (2) highlights the relevant design criteria for the system. In particular, body motion is affected by the density ratio (ρ), the geometrical characteristic of the body (d) and the nondimensional damping and stiffness (μ, ξ). However, it is also affected by the lift coefficient (c_y), which in turn depends on the interaction between the fluid motion and the cylinder itself. So, to establish the above-mentioned design parameters, it is necessary to define the fluid-dynamics around the cylinder, but this fluid-dynamics can be only determined once the geometry is defined.

To face this challenge by providing useful design guidelines, it is hence necessary to combine the mechanical model with a CFD 2D model, described in the next section, allowing one to determine the fluid-dynamics for a given geometry.

2.2. CFD simulation settings and model validation

To describe the dynamics of the system within a fluid force field, in this study, the numerical model of the cylinder was built in such a way that it can be free to move vertically. In particular, the ANSYS Fluent platform is used to fill the CFD database. The software, in particular, is specifically used to solve the fluid equation of motion, while Python scripts are employed to postprocess the results.

To analyse the behaviour of the cylinder under free flow conditions, the two-dimensional model consists of a rectangular box of size $(50 \times 30)D$, where D indicates the diameter of the cylinder, in which the cylinder is set at $15D$ from the inlet and is subtracted from the entire fluid domain using a Boolean operation to form a solid part (Figure 1).

Regarding the boundary conditions, the *velocity inlet*, which is a known parameter in the design procedure, is imposed on the left side of the domain to obtain a precomputed free stream Reynolds number, $Re = \rho_\infty u_\infty D/\mu_\infty$. A *wall-type* boundary is enforced at the edge of the cylinder, resulting in a non-slip condition for the velocity components. The upper and lower edges correspond to a *symmetry* condition, and the right domain side imposed a homogeneous pressure distribution according to the *pressure outlet* Fluent option.

The initial dynamics is predicted through *hybrid initialisation*, which implies the solution of simplified equations during ten iterations.

Regarding the pressure-velocity coupling algorithm, the recommendations of the ANSYS Fluent user guide have been followed, and the *PISO* algorithm is used. The method provides stable calculations despite a more significant time step and optimal under-relaxation factor for both momentum and pressure. Default options are used. The discretisation process of the spatial terms accounts for second-order upwind formulas.

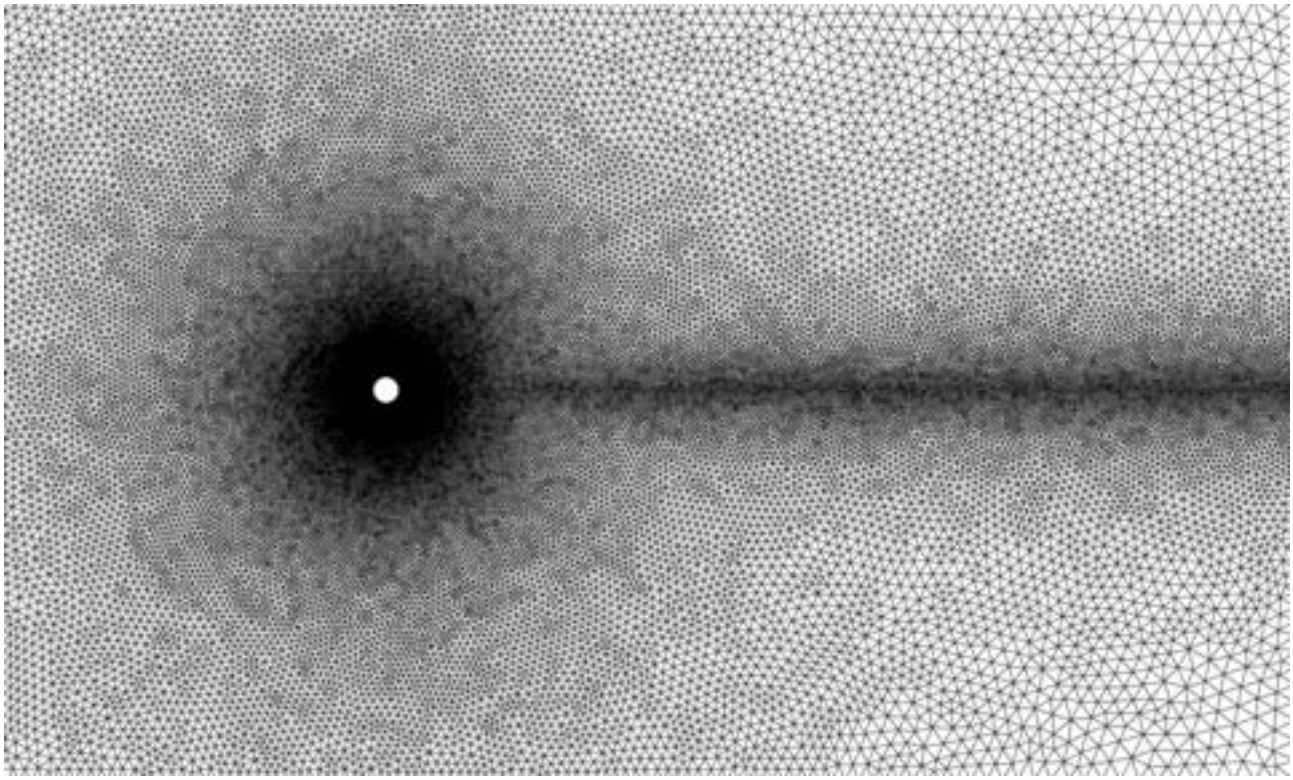
The system dynamics is simulated according to a RANS approach in both steady and unsteady versions.

In order to identify the most appropriate numerical model to reproduce most of the critical flow properties of the investigated geometry, the turbulence model and the mesh refinement level are defined by comparison with experimental results and validated numerical results.

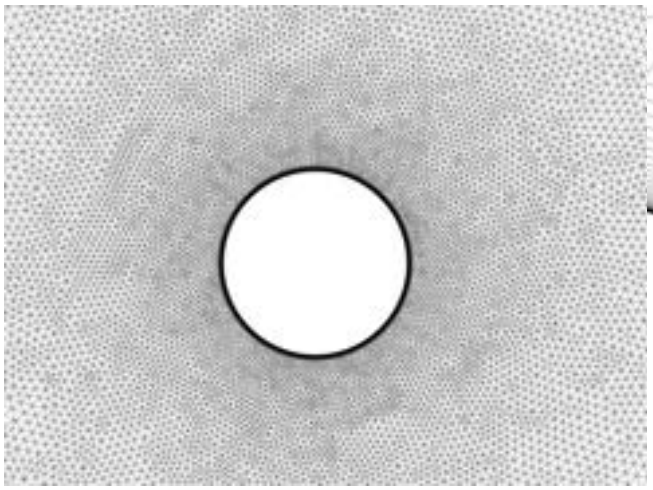
Regarding mesh size, three hybrid meshes with increasingly refined dimensions with a size of approximately 20k, 40k, and 90k elements are used. The grids will be referred to as coarse (C), medium (M), and fine (F). In all the three cases, the meshing process has been performed with the built-in meshing software available in ANSYS. A hybrid structured/unstructured approach is used to ensure a reasonable approximation near the cylinder wall region and, simultaneously, reduce the calculation time.

Figure 1 provides a mesh overview and some zooms around the cylinder region for the fine grid of 90k elements. In particular, structured cells are located in the near-wall area (Figure 1c) to capture velocity gradients in the boundary layers. Construction lines are also used to cluster most of the computational cells in the wake region and around the cylinder. The entire meshes are built on the basis of the maximum investigated Reynolds number, i.e. $Re = 10^6$, and keeping the wall Y plus distribution, $y_w^+ = \rho_w u_\tau y_w/\mu_w$, below the unit. This ensures that a sufficient number of cells are used to resolve the near-wall velocity gradients throughout the Reynolds spectrum. Note that ρ_w and μ_w are the wall fluid density and molecular viscosity, y_w is the first-off-the-wall cell distance, while $u_\tau = \sqrt{\tau_w/\rho_w}$ denotes the wall friction velocity, with $\tau_w = \mu_w \partial u_p/\partial y$ the wall shear stress.

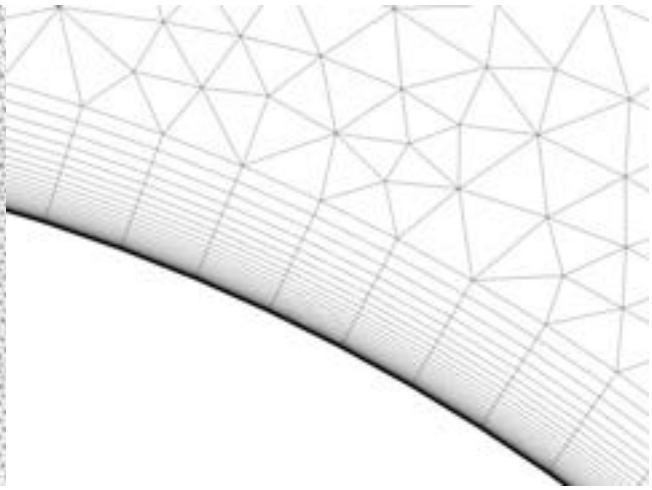
Regarding turbulence models, three increasingly sophisticated models are considered: the one equation Spalart-Allmaras (SA) model by Spalart and Allmaras [11], the two equations k-ω Shear Stress Transport (SST) model by Menter [12] and the four equations Transition SST (TSST) model by Menter et al. [13]. The convergence of the flow under steady conditions was monitored, granting 10^{-6} residual drop tolerance of all flow parameters.



(a) Mesh overview



(b) Near cylinder details



(c) Near wall details

Figure 1: Mesh overview (a) and details (b,c). The figures refers to the fine grid of 90k elements.

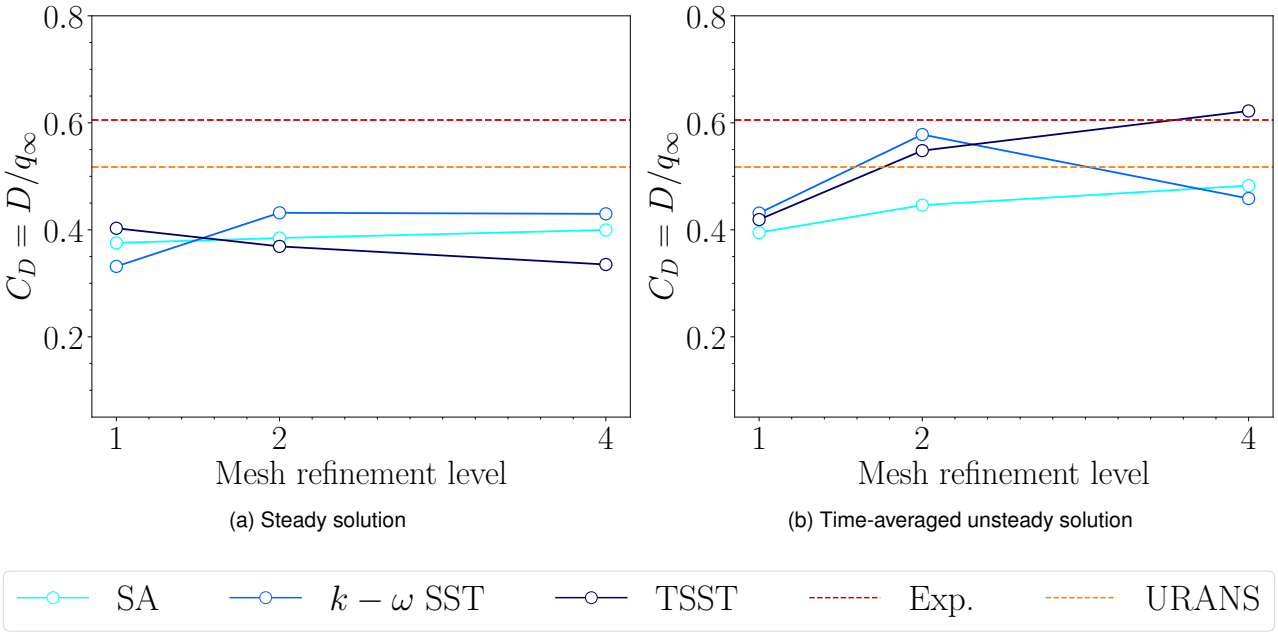
To define the most suitable numerical approach, according to the best CFD practises (see, e.g., [14]), the three sets of meshes and the three turbulence models are compared in terms of the cylinder drag coefficient, $C_D = D/q_\infty$, with the experimental results by Warschauer and Leene [15] and with the time average drag value of the unsteady RANS simulations by Ong and Wallace [16] (Figure 2). D denotes the drag force per unit length. In all cases, the Reynolds number of the flow is set to 10^6, which is the maximum Reynolds number that will be used in the following analyses.

As can be seen in Figure 2, the medium and fine arrangements yield little discrepancies, both in the steady- and time-averaged versions of the drag coefficient. A C_D error of around 5% is observed for steady setup, while a 0.4% mismatch is observed in medium arrangements combined with the k-ω SST model.

The results suggest that the medium mesh gives a good compromise between computational performance and accuracy, while adopting the fine mesh would increase the computational time of the simulation drastically, particularly with respect to the unsteady setup, without introducing appreciable accuracy effects.

To fully validate the numerical model, the proper resolution of the boundary layer gradients is also verified. In this regard, we focus on the y_w^+ distribution on the cylinder. Figure 3 shows the y_w^+ distribution as a function of

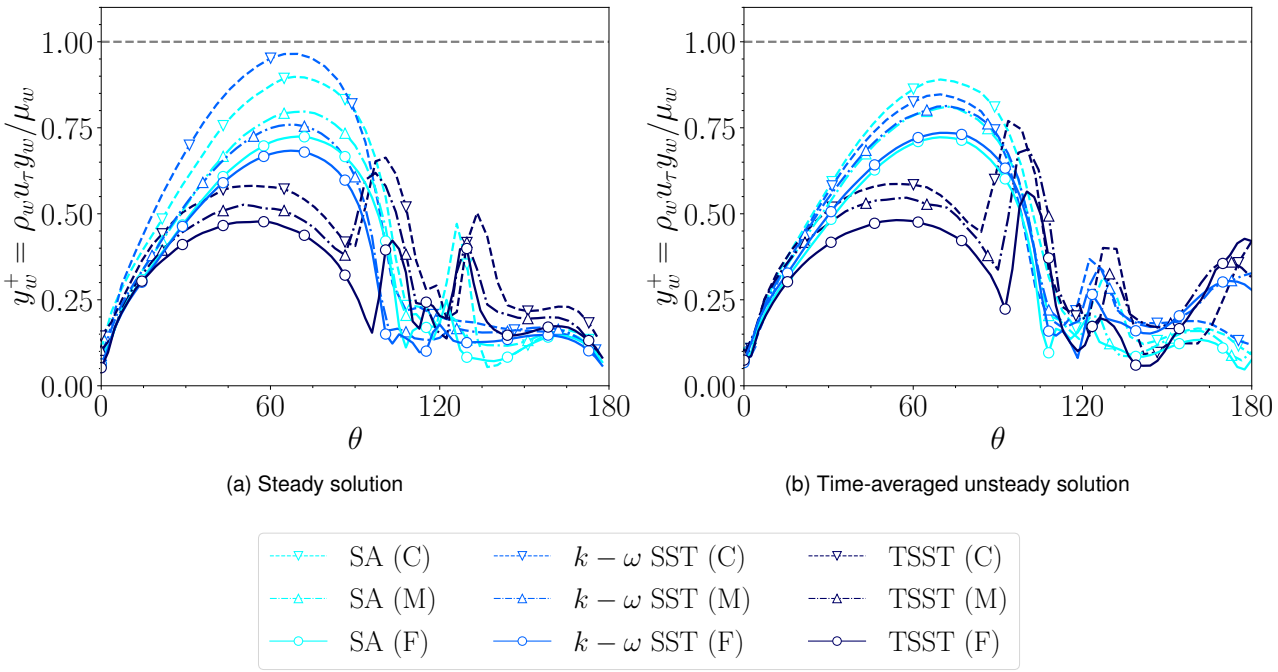
the angular cylinder coordinate, of the mesh refinement and the turbulence model.



(a) Steady solution

(b) Time-averaged unsteady solution

Figure 2: Comparison between cylinder drag coefficient at Re=10^6 as a function of turbulence model and mesh refinement level. Results are compared with the time average drag value of the unsteady RANS simulations by Ong and Wallace [16] and the experimental results by Warschauer and Leene [15].



(a) Steady solution

(b) Time-averaged unsteady solution

Figure 3: y_w^+ distribution on the upper half of the cylinder as a function of the mesh refinement level and the turbulence model.

Both time-averaged unsteady case (Fig. 3a) and steady results are provided (Fig. 3b). Note that all the built meshes provide results close to the suggested threshold for wall-resolved RANS simulations, i.e., $y_w^+ \leq 1$, giving an average Y plus value around the cylinder from $y_w^+ = 0.46$ for the coarse mesh to $y_w^+ = 0.33$ for the fine setup. Thus, this result confirms that the proposed numerical model provides a good representation of

the velocity profiles near the cylinder surface. Discrepancies between distributions have to be ascribed to turbulence modeling only.

2.3. The database

VIV components can generate a significant amount of energy only when their fundamental frequency matches the natural frequency of the rigid system in a vacuum environment, a condition known as the lock-in state. To characterise the system the non-dimensional parameters are: *(i)* the Strouhal number associated with the body motion, $St_y = f_y D/U_\infty$, where f_y denotes the first harmonic frequency associated with the body motion in the flow, *(ii)* and the Strouhal number of the flow, $St_v = f_v D/U_\infty$, where f_v denotes the frequency associated with the vortex shedding. This system nondimensional dynamics is conveniently described as a function of the so-called reduced velocity, $U_r = U_\infty/(f_n D)$, representing the relationship between the convective time scale of the flow, U_∞/D, and the natural time scale of the motion of the body in a vacuum environment, $1/f_n$, being $f_n = 1/(2\pi)\sqrt{k/m}$ the natural frequency of the cylinder.

The lock-in state is achieved when $St_y \approx 1/U_r$. On the contrary, outside of the lock-in state, body movement tends to follow the vortex shedding frequency, that is, $St_y \approx St_v$.

According to Equation (2), the system dynamics depends on the design parameters but also on the fluid-body interaction, and hence, to choose the design parameters it is necessary to know beforehand the fluid-dynamic behaviour.

To solve this problem, a database of numerical CFD simulations is created, by determining the fluid-cylinder interaction for different values of the diameter of the cylinder D, of the density ratio, of the control stiffness, of the water velocity, and of the Reynolds number.

The resulting database was then organised as follows. Given a certain geometry, the dynamics of the system was parametrically organised to the density ratio and the nondimensional stiffness, setting for simplicity μ equal to zero. However, since ξ depends on the Reynolds regime of the flow, the results are given as a function of the following modified stiffness:

$$k^* = \frac{kD}{mg} \tag{3}$$

where mg is a reference force, with g denoting gravity acceleration. Obviously, ξ is linked to k^* as follows:

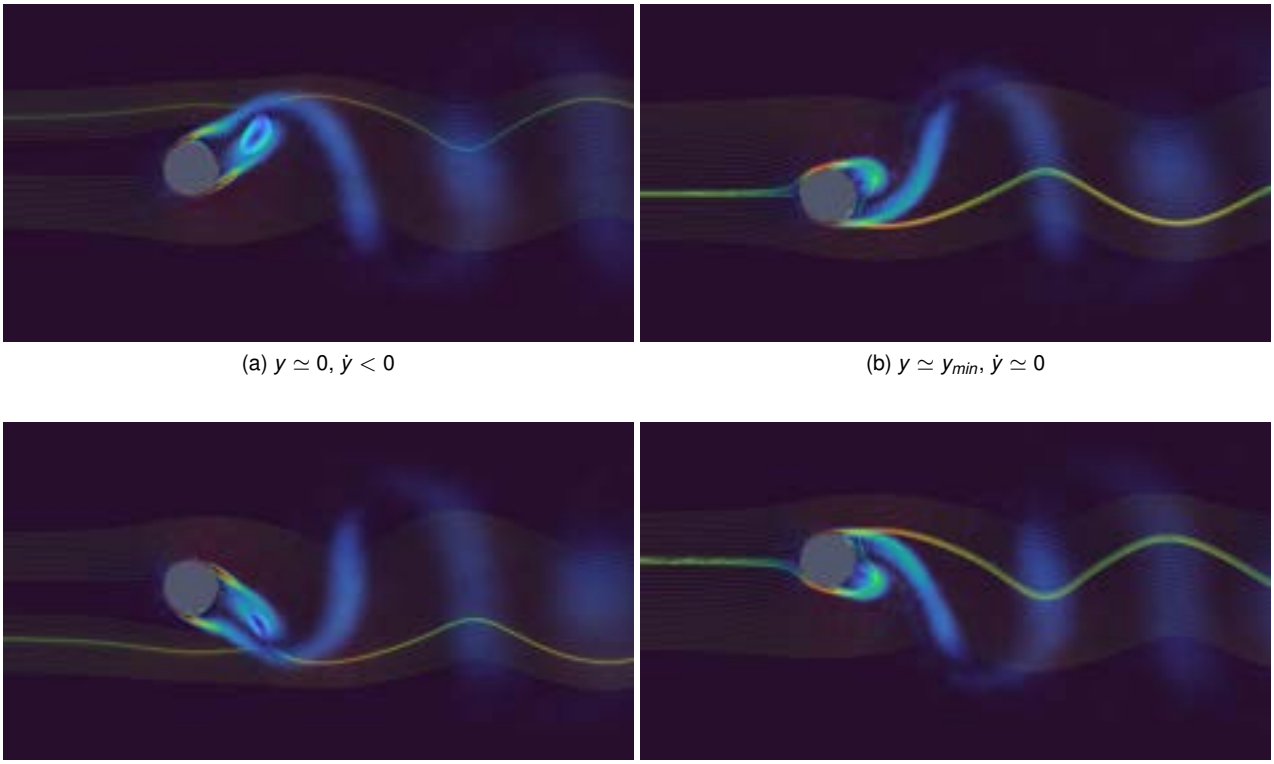
$$\xi = k^* \frac{mg}{\rho_\infty U_\infty^2 D} \tag{4}$$

These organised results will be presented in the following section together with an insight of the fluid dynamics in the lock-in state.

3. Results and discussion

3.1. The fluid mechanics of the system in the lock-in condition

As a first step, we analyse fluid mechanics of the system in lock-in condition. Figure 4 shows the non-dimensional vorticity contours as a function of the cylinder location in a lock-in state. The results refer to $Re = 4 \cdot 10^3$, $\rho = 10$ and $k^* = 6.5$. In particular, Fig. 4a shows the location of $y \simeq 0$ in a negative speed framework, $\dot{y} < 0$. Fig. 4b shows the cylinder flow field around its minimal excursion ($y \simeq y_{min}$, $\dot{y} \simeq 0$). Fig. 4c provides the location of the $y \simeq 0$ cylinder in a positive speed framework, $\dot{y} > 0$). Finally, Fig. 4d shows the flow field where the cylinder reaches the dead top location ($y \simeq y_{max}$, $\dot{y} \simeq 0$).



(a) $y \simeq 0$, $\dot{y} < 0$ (b) $y \simeq y_{min}$, $\dot{y} \simeq 0$

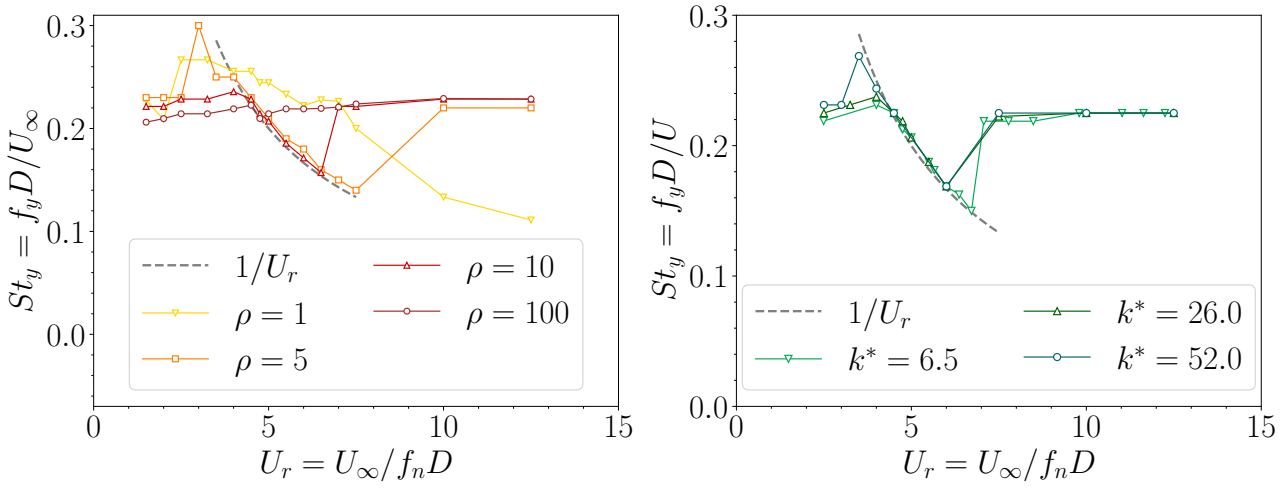
(c) $y \simeq 0$, $\dot{y} > 0$ (d) $y \simeq y_{max}$, $\dot{y} \simeq 0$

Figure 4: Instantaneus ω_z vorticity contours and pathlines in four dynamical locations of the cylinder. Present results refers to $Re = 4 \cdot 10^3$, $\rho = 10$ and $k^* = 6.5$.

According to Guilmineau and Queutey [17], the lock-in state is maintained by a vortex pattern near the tail of the cylinder. In particular, the main vortex of the cylinder determines the location of the lower pressure, the value of which is significantly related to the act of motion of the cylinder. The lower and upper dead locations (Fig. 4b and Fig. 4d) indicate that the vortex is quite close to the surface of the cylinder. This state significantly desymmetrises the force field surrounding the cylinder, which is pushed back to the side opposite the tail vortex. The states in which the cylinder passes through the zero displacement location (Figs. 4a and 4c), on the other hand, indicate how the main vortex detaches the surface, allowing the cylinder motion to reach maximum speed.

3.2. Design guidelines and energy production

This section aims to understand the interaction between the frequency of the body motion and the natural frequency of the cylinder when ρ and k^* change in light of the optimisation of the mechanics and fluid dynamics of the system. Indeed, as explained above, the lock-in state is not obvious as a priority, preventing the adoption of a simple and straightforward design procedure. Figure 5 shows the trend of the Strouhal number associated with body movement, St_y, as a function of the reduced speed, U_r, parametrically with respect to the density ratio (Fig. 5a), setting the modified stiffness at 6.5, and the modified stiffness (Fig. 5b), setting the density ratio at 10.



(a) Density ratio effect

(b) Reduced frequency effect

Figure 5: Strouhal number of the body motion as a function of the reduced velocity. Results are reported parametrically to (a) the solid-to-fluid density ratio, fixing $k^* = 6.5$ and (b) the reduced stiffness with $\rho = 10$.

As already explained above, the reduced speed U_r is an excellent self-similarity coordinate since it can be used to compare the convective time with the natural oscillation scale of the cylinder: for certain conditions, as the physical speed increases, a variation in ρ or k^* keeps the curves collapsing in the same intervals. Furthermore, such a representation is extremely useful, as it highlights the lock-in region (grey-shaded branch of the hyperbola in Figure 5).

In Figure 5a, the dynamics of the system is explored with a density ratio of $\rho = \{1, 10, 100\}^T$. The lock-in regime fails for both small and large density ratios. In particular, the $\rho = 1$ arrangement lacks a real lock-in state, and the system tends to a hyperbolic trend but with a systematic error; this indicates that the cylinder oscillates at a frequency primarily determined by the flow, and in general, it is difficult to control. Conversely, high density ratios make the lock-in area mostly disappear, collapsing in a narrow range of reduced speed values. As a result, it is evident that ρ must be kept within a reasonable range, restricting the choice of the VIV material in certain ranges of density, which can be optimised for the specific characteristic of the fluid flow.

In Figure 5b, the analysis is carried out by adjusting ρ to 10 and varying the reduced stiffness within the sample $k^* = \{6.5, 26, 52\}^T$. On the contrary to the density ratio, the stiffness variation preserves the lock-in regime, which always occurs in the same range of reduced velocity, suggesting the existence of an optimal value of the cylinder diameter depending on the fluid velocity.

After grasping the effect of density and stiffness on the lock-in condition, it is also interesting to analyse the system response in terms of displacement in this condition and outside. This analysis is of fundamental importance, as the nondimensional root mean square displacement of the cylinder, y_{rms}/D, is directly related to the amount of energy that the VIV system can extract from the flow.

Figure 6 shows the y_{rms}/D trend as a function of the reduced speed (Fig. 6a) and of the Reynolds number of the flow (Fig. 6b). Data are provided parametrically to the density ratio ρ, with a fixed reduced stiffness of $k^* = 6.5$.

All curves exhibit bumped-like behaviour, clustering non-trivial cylinder displacements in the $U_r = 3 \div 10$ range.

The reduced speed at which the highest displacement is centred is essentially independent of the density ratio and is limited to a band around $U_r \approx 5$, in agreement with the results presented in Figure 5a. On the other hand, the extension of the bump is heavily affected by ρ, and the lower ρ, the higher the operating range of the VIV device.

Analysing the simulation results as a function of the Reynolds number, significant insights can be derived in terms of the flow regime in which the device is supposed to be installed. In fact, as ρ increases, the peak of the displacement moves to a lower Reynolds regime. This is an important information at the design level since it highlights that the higher the device mass with respect to the flow, the lower the Reynolds number tolerated in the system.

In conclusion, the density ratio is a very tricky design parameter, since as ρ increases, the operational range of the lock-in state narrows dramatically, thus reducing the flexibility of the VIV device, but also requires higher Reynolds, which are not so easy to reach in the water flows targeted by the VIV device. Therefore, keeping ρ in

the range of 10 seems to represent a good compromise between flexibility and applicability, in the hypothesis of reduced stiffness of 6.5.

To verify the influence of reduced stiffness k^* on these conclusions, the results were analysed, fixing the density ratio equal to 10 and varying the reduced stiffness. Figure 7 shows the y_{rms}/D trend as a function of the reduced speed (Fig. 7a) and the Reynolds number of the flow (Fig. 7b).

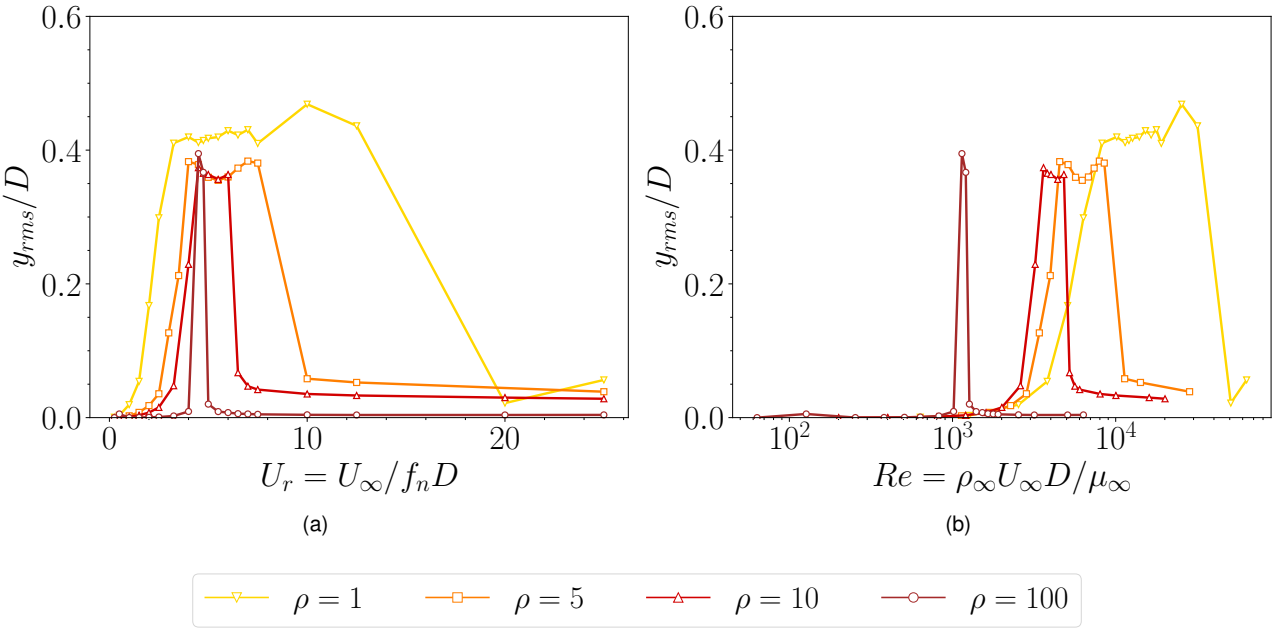


Figure 6: Density ratio effect on the non-dimensional root-mean-square cylinder displacement as a function of (a) the reduced velocity and (b) the flow Reynolds number. Present results are obtained with a reduced stiffness equal to k^* = 6.5.

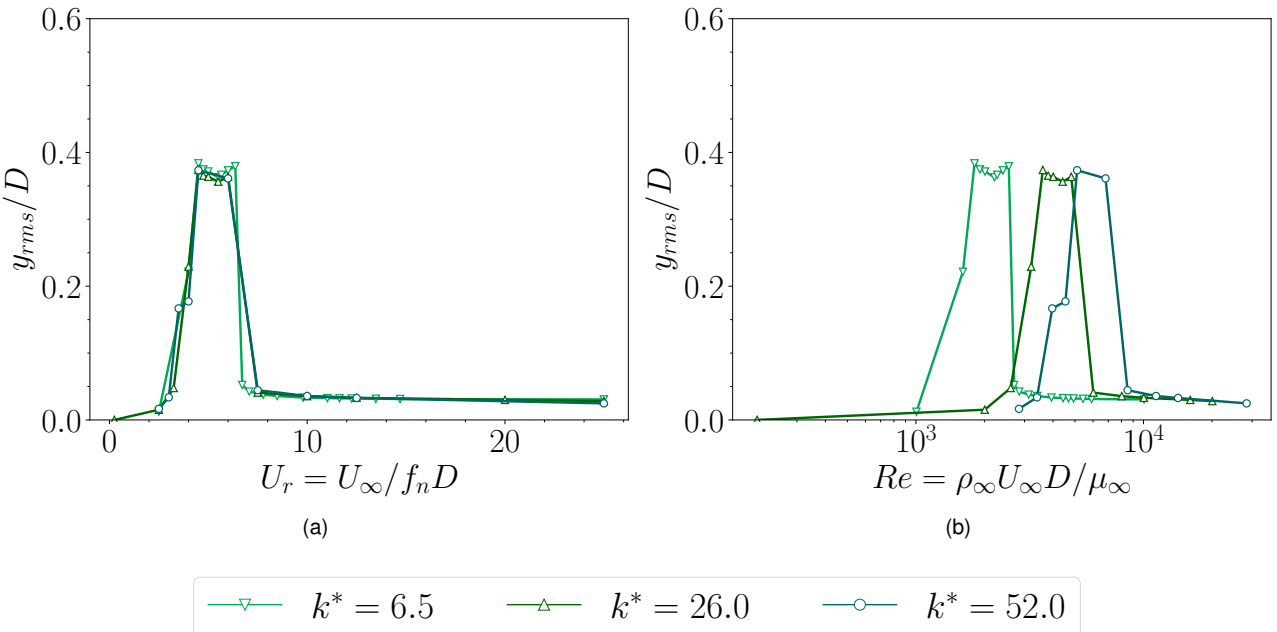

Figure 7: Reduced stiffness effect on the non-dimensional root-mean-square cylinder displacement as a function of (a) the reduced velocity and (b) the flow Reynolds number. Present results are obtained with a density ratio equal to ρ = 10.

It can be seen that the reduced stiffness keeps the displacement amplitude constant as a function of the Reynolds regime without narrowing or widening the lock-in region (Fig. 7b). Subsequently, in terms of reduced velocity (Fig. 7a), this causes the system lock-in in the same U_r range, clustered around 5. Therefore, another important design guideline for VIV devices can be deduced: controlling the stiffness of the system is the key to match the lock-in condition (and hence the maximum displacement) with the flow regime of the installation site.

Note that in the lock-in state, the cylinder oscillates with mean square displacements of $\approx 0.4D$ (Fig. 7); thus performing harmonic oscillations of amplitude $\approx 0.4\sqrt{(2)}D$. This result is independent of the Reynolds regime and of the mechanical characteristics of the system, which is a really interesting starting point for the preliminary design of the system.

Finally, it is also possible to estimate the mechanical power that can be extracted by the VIV device in the different configurations (reduced stiffness, density ratio, etc.). In particular, the non-dimensional mechanical power (power coefficient) is determined according to the following equation:

$$P^*_{rms} = \sqrt{\frac{1}{\Delta T}\int_{t+\Delta T}\left[\frac{\dot{y}(t)}{U_\infty}\frac{F_y(t)}{1/2\rho_\infty D U^2_\infty}\right]^2 dt} \tag{5}$$

where $F_y(t)$ and $\dot{y}(t)$ are the instantaneous lift force and cylinder velocity respectively.

Figure 8 shows the trend of the mechanical power coefficient, P^*_{rms}, as a function of the reduced speed and parametrically with the density ratio and the reduced-stiffness.

As shown in Figure 8, P^* is significant only in the lock-in area ($U_r \approx 5$) where values around 0.2 are reached. In particular, if the density ratio increases, the power coefficient decreases (Fig. 8a); while, as the modified stiffness varies, the power output remains practically constant.

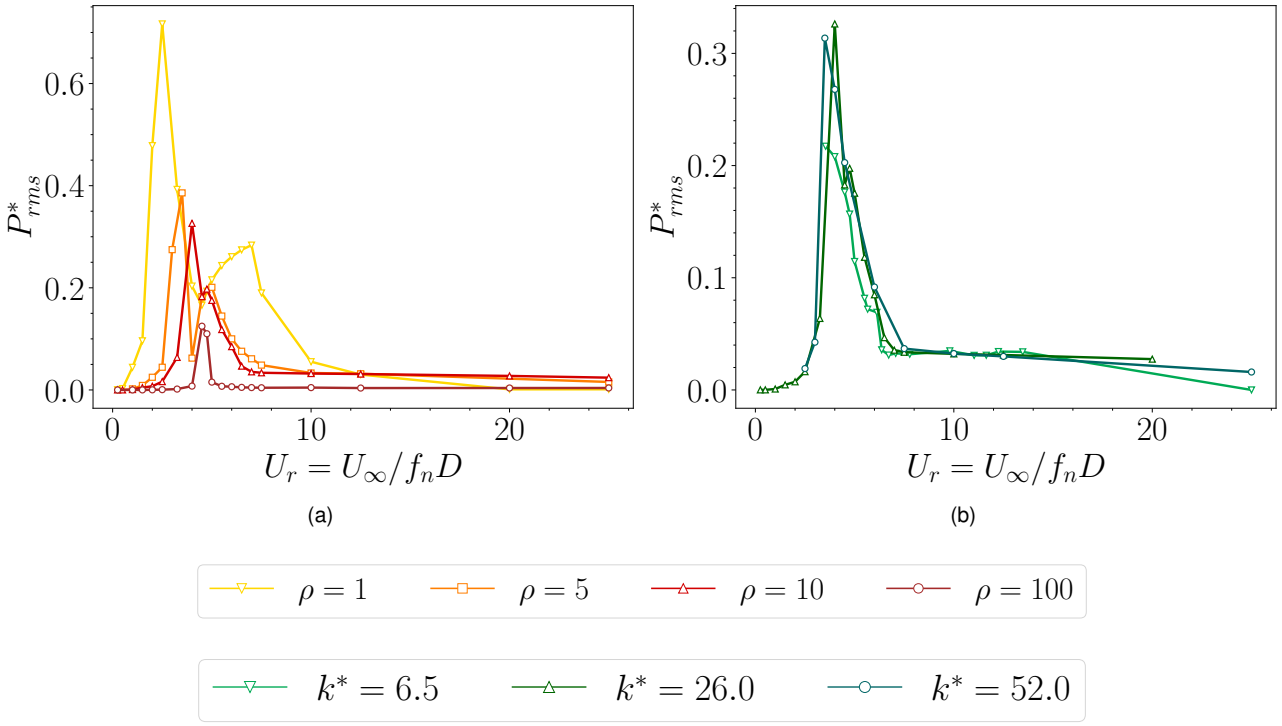

Figure 8: Non-dimensional power coefficient associated to the cylinder body motion as a function of the density ratio, ρ and the reduced stiffness, k^*.

4. Conclusions

The proposed investigation addresses the critical aspects of the design of VIV devices for energy harvesting, with the aim of providing some preliminary design guidelines and estimation of the mechanical power that can be extracted.

In particular, a simple cylinder configuration in cross-flow conditions is investigated and modelled in terms of mass, damping, and stiffness. This model was combined with a numerical CFD model to estimate the

fluid-body interaction. By means of these models, the system behaviour was investigated in several configurations, by parametrically varying the system fundamental mechanical properties (solid-to-fluid density ratio and stiffness of the control system), the cylinder geometry (diameter), and the flow regime in which it is immersed.

The resulting database was analysed to highlight the influence of the different parameters on the achievement of the lock-in conditions, which results to be achieved for a reduced velocity value of about 5.

The analysis also revealed that the density ratio is a key design parameter, since the functional properties of the VIV device are ensured only for modest values of it, roughly around 10. Smaller values of the density ratio make the system lose its ability to attain the lock-in state by creating a difficult-to-control oscillation pattern with optimal Reynolds values between 10^4 and 10^5. On the other hand, high density ratio values dramatically shrink the lock-in zone, limiting the flexibility of the VIV device to maintain lock-in conditions even in operating conditions close to the optimal one.

Concerning the stiffness effects, this well fits the system modulation, especially to match the maximum displacements on a specific Reynolds regime. In fact, if the density ratio is kept constant, the control system stiffness can retain the cylinder displacements and lock-in state at different Reynolds regimes.

Future analyses will investigate a broader spectrum of density ratios and reduced stiffness to build an extensive database in view of system sizing. The damping effect and other geometrical configurations will also be analysed to further investigate the VIV devices behaviour and their best design practises.

Abstract:

The paper presents a procedure for a systematic numerical optimisation of a Venturi tube for water treatment using cavitation conditions. The numerical method employs computational fluid dynamics techniques within a Reynolds-Averaged Navier-Stokes framework in conjunction with an optimisation procedure to improve a baseline Venturi configuration. To define the numerical model associated with the baseline solution, a reliable meshing method is given. The procedure evaluates various mesh sizes and turbulence closure to determine the ideal balance between processing time and accuracy. The model is then used as a starting point for an optimisation procedure. The optimised arrangement improves the mean vapour quality of the tube by approximately 130% compared to the original geometry.

Keywords:

Hydrodynamic cavitation; Venturi tube; CFD investigation; wastewater treatment.

1. Introduction

Hydrodynamic cavitation is a well-known phenomenon gaining prominence due to its use in various technical and chemical processes, such as emulsification, oxidation, nanomaterial production, and wastewater treatment. Hydrodynamic cavitation aims to induce cavitating microbubbles into the water flow, and the Venturi tube is a commonly adopted device for this purpose.

The Venturi tube is a simple device that consists of a converging section where the flow is accelerated, a throat zone where the pressure reaches its lowest value, and a diverging segment where the tube recovers the cross section of the pipe in which it is placed. If the ratio between the Venturi throat diameter and the diameter of the external pipe is small enough, the increase in velocity induced by section reduction can lead to cavitating conditions in the throat flow. When the static pressure falls below the vapour pressure, cavitation is defined as the development, growth, and collapse of microbubbles or vapour cavities in a liquid. Due to the adiabatic compression of the cavities, the collapse occurs at various points. Consequently, a substantial amount of energy is quickly released, generating a supercritical state with high temperature and pressure (5000 K and 500 bar) similar to those on the solar surface. These conditions accelerate chemical and physical transformations, which can be used for a variety of practical applications, including the destruction of chemical contaminants in water (Gogate et al. [1], Dular et al. [2], Sarc et al. [3], Biasiolo et al. [4]).

Carpenter et al. [5] sum up the theory of cavitation, focussing on the hotspots of collapsing cavities, and discuss the available approaches to generate the multiphase phenomena and the corresponding uses of the technology in different contexts. Researchers emphasised the importance of the specific geometric characteristics of the Venturi tube.

Using Computational Fluid Dynamics (CFD) techniques, Dastane et al. [6] numerically analysed the cavitating flow in a Venturi tube, comparing various mesh sizes and performing single- and multiphase simulations. They observed that the single-phase method underestimates the value of the input pressure. Bashir et al. [7] offer a CFD-based optimisation technique for the geometry of cavitating Venturi tubes. Using experimental tests and simulations, Li et al. [8] explored the impact of Venturi geometries on cavitation.

Despite the already published work, the prediction of cavitating flows using computational methods is still a critical issue, and only few results are available in the literature. In particular, the most advanced CFD strategies, such as Large-Eddy Simulations (LES) and Direct Numerical Simulations (DNS), can hardly be adopted in multiphase and complex flow conditions, such as those about a deep cavitating wall-bounded flow. Therefore, digital prototyping of such devices is still demanded by Reynolds-Averaged Navier-Stokes (RANS) based models, albeit with all the limitations that such strategy embeds.

The present work aims to determine the most critical parameters that influence the RANS CFD simulation results for flow cavitation inside Venturi tubes and to provide optimisation suggestions to enhance the Venturi baseline design. A RANS model has been built and used to predict the two-phase flow and to make a comparison between various model resolutions in terms of grid discretization level. The results indicate that high grid resolutions are required for numerically insensitive outcomes. Finally, the baseline model is used as a starting point for an optimisation procedure devoted to design a novel tube shape capable of improving steam generation.

The paper is organised as follows: Section 2. presents the numerical model and provides a description of the numerical settings. Section 3. summarises and discusses mesh sensitivity analysis with the aim of finding the optimal mesh size. Section 4. provides hints regarding the Latin Hypercube Sampling (LHS) method implemented to optimise the Venturi geometry and gives quantitative information concerning the characteristics of the tube shape. Finally, Section 5. gives the concluding remarks.

2. Computational setup

The development of a Venturi tube optimised configuration requires the development of a properly calibrated numerical model of the device. To this end, the University of Padova research group (Turbomachinery and Energy Systems - TES Group), after an in-depth review of the literature, has selected the baseline geometry of the Venturi tube (see De Vanna et al. [9]). The developed model reproduces the geometry proposed by Shi et al. [10]. The baseline geometry is used to (i) correctly set the numerical model, (ii) determine the most appropriate grid dimension, and (iii) choose the reliable turbulence model.

Figure 1 shows the shape of the baseline configuration, while Table 1 lists the dimensions of the Venturi tube. The device has a throat diameter (d) of 3.18 mm, while the diameter of the pipe (D) is equal to 12.7 mm. The converging angle slopes is of 19° while the diverging one is equal to 5°. The CFD model is extended by 30 and 80 mm before and after the L_1 and L_5 segments to achieve fully developed turbulent flow and prevent unphysical recirculations. The axial symmetry of the tube limits the task to a 2D domain. Ansys-Workbench 2020 R1 is used to build both geometry and grids, while Ansys-Fluent is used to solve the flow field [11].

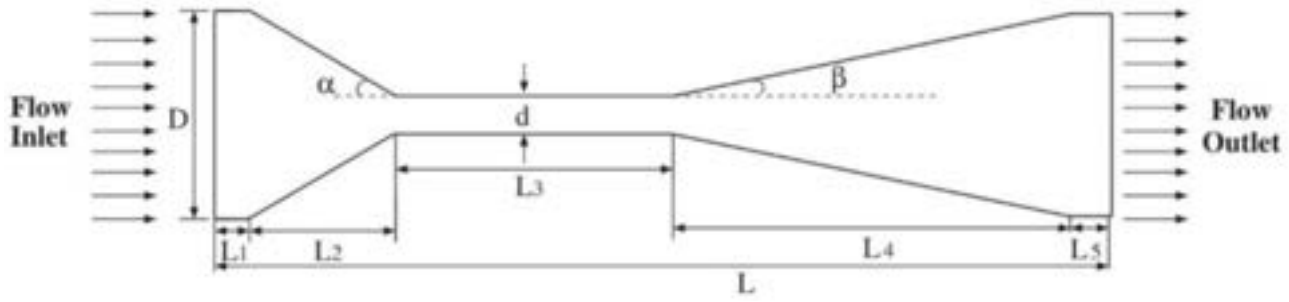

Figure 1: Schematic view of the Venturi tube geometry. Dimensions are listed in Table 1.

Table 1: Geometry characteristics of the baseline shape of the Venturi tube as given by Shi et al. [10].

D (mm)	d(mm)	L_1 (mm)	L_2 (mm)	L_3 (mm)	L_4(mm)	L_5 (mm)	α (°)	β (°)
12.7	3.18	6.00	14.0	20.0	54.0	6.00	19.0	5.00

Based on the experience of the research team in the field of CFD, three structured meshes of 100′000 (100k), 200′000 (200k) and 300′000 (300k) elements have been built and tested with the aim of finding the dimension of the grid that guarantees a good compromise between the accuracy of the results and the efficiency of the computation.

Adopting the internal software suites, each computational grid is quality validated to ensure a maximum skewness value below 0.22, an inflation growth rate between 1.05 and 1.20, and an orthogonality quality value above 0.99. Inflation is placed close to the walls to improve the resolution in the boundary layer and ensure that the wall Y plus (defined as $y^+ = y_w/\delta_\nu$, $\delta_\nu = \mu_w/(\rho_w u_\tau)$) values are accurate. δ_ν is the wall viscous length while ρ_w and μ_w are the fluid density and viscosity at the location of the wall, respectively. u_τ is the friction velocity, while y_w is the first-off-the-wall cell distance. Specifically, the objective is to address a y^+ value lower than 1. Table 2 reports the mean aspect ratio, the mean skewness and the mean orthogonal quality of the three developed meshes while Figure 2 shows an extent zoom of the 300k grid in the Venturi inflowing corner.

Table 2: Grid quality parameters.

Mesh	Mean aspect ratio	Mean Skewness	Mean Orthogonal quality
100k	4.194	$2.80 \cdot 10^{-2}$	0.996
200k	4.508	$2.73 \cdot 10^{-2}$	0.996
300k	6.091	$2.21 \cdot 10^{-2}$	0.997

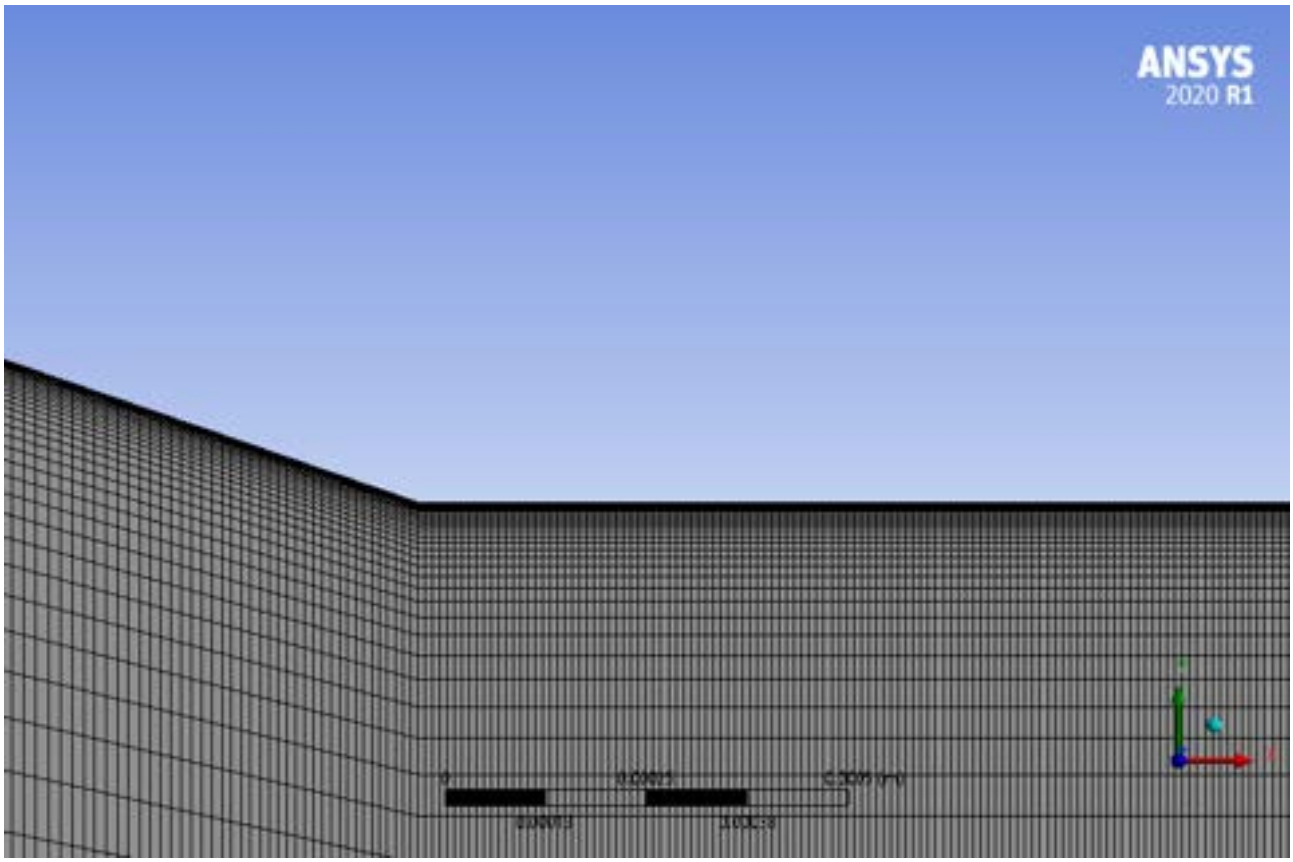

Figure 2: Detailed view of the 300k mesh in the inflowing Venturi corner.

The system's dynamics is simulated by finding solutions to an incompressible RANS system of equations in a steady-state framework. The flow field dynamics is solved using four different turbulence models. As said, the test of different turbolence models is used to find the best compromise between accuracy and calculation time.

The complexity of the model gradually increases from first to last: the one-equation Spalart-Allmaras (SA) model, the two-equations k-epsilon realisable model, the two-equations k-omega shear stress transport (SST) model, and the four-equation transition SST (TSST) model.

To solve the mass and momentum conservation equations related to the behaviour of the cavitating flow in the mixture model, the pressure-velocity coupled method is adopted. Thus, to satisfy the requirements of the coupling algorithms, the equations include implicit discretization of the pressure gradient terms and the mass flow.

To discretise the convective components in the transport equations for the vapour volume fraction, the Quadratic Upwind Interpolation for Convection Kinematics (QUICK) technique is used. The PREssure STaggering Option (PRESTO) method is adopted in the computation of the pressure. To discretize the convection terms that are included in the momentum equations, the second-order upwind technique is selected. Finally, the "water-vapor" mixture model is adopted to mimic two-phase cavitation flows for multiphase flow solutions. The phase transition is computed according to the Schnerr-Sauer cavitation model. As boundary conditions, the "pressure inlet" and "pressure outlet" conditions are enforced at the inflowing and outflowing edges, respectively; this means setting the total and static pressure. Additionally, "adiabatic no-slip wall" conditions are enforced at the Venturi internal surfaces. In the nameplate conditions, a condition that embeds cavitating events in the throat of the tube is set. This means an inlet total pressure, p°_{in}, of 180'000 Pa and a static pressure at the

outlet, p_{out}, of 101'325 Pa.

3. Baseline Venturi model validation procedure

The validation process of the developed model aims to define the most suitable turbolence model and grid size. First, mesh sensitivity analysis is performed with the total intake pressure set at its design value (180 kPa). The process follows CFD best practises according to De Vanna et al. [12]. Figure 3 provides the freestream-scaled axial velocity, u/u_∞, and pressure, p/p_∞, distributions along the throat-scaled axial coordinate, $x^* = x/d$, as a function of both the grid resolution and the turbulence model. As shown in Figure 3, results are clustered in a really narrow band, except for the results obtained with the SA model and in the coarser cases. Therefore, the comparison allows to certainly exclude the simplest turbulence model as well as the mesh with the lower resolution.

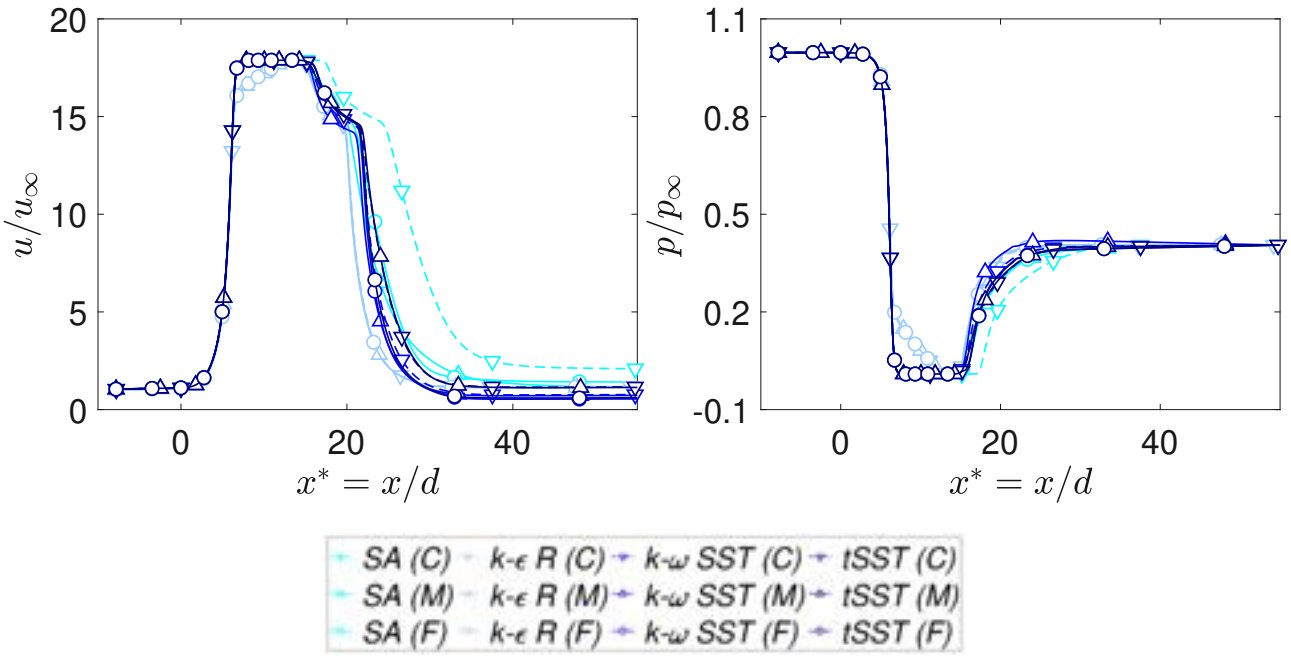

Figure 3: Axial velocity and pressure distributions as a function of the grid refinement and turbulence model. The lighter to darker tone of the colour refers to gradually more complex turbulence models, i.e. SA, $k-\epsilon$ realisable, $k-\omega$ SST and TSST, respectively.

The global parameters are compared to fine-tune the grid and assess the influence of the discretization level on the investigation results. Figure 4 depicts the non-dimensional Venturi pressure drop and the coarse-scaled drag force as a function of the grid resolution. The 100k element mesh somewhat underestimates the drop in pressure, but the model saturates the value after 200k grid refinements. Instead, the drag coefficient data are exactly matched as the grid size changes. This implies that an excessive number of mesh elements would be unreasonable, which would only result in stressing computer resources. Based on the evaluation of global parameters, the 200k configuration seems to be the ideal trade-off between numerical accuracy and computing load. Thus, the 200k mesh arrangement, combined with the k-omega SST, is selected and used for the upcoming analyses.

4. Latin Hypercube Sampling and optimisation results

In this work, the Latin Hypercube Sampling (LHS) technique is used to improve the design of the Venturi geometry regarding a priori specified goals. The LHS technique has been proposed by McKay et al. [13] as a sampling mechanism to fill a design variable space. The importance of sampling is derived from the need to correctly choose the input variables of a mathematical model that describes real occurrences, thus gathering the necessary information about the probability distribution of the output with the fewest number of inputs. Swiler et al. [14] define Latin Hypercube Sampling as a technique to examine the probability distribution of a multivariate function with k variables by selecting n different values for each variable. Using the equal probability reasoning, the values are selected by dividing each variable into n different pieces. As a result, after randomly selecting a value from each layer, the values collected for each variable are randomly paired, producing n evaluations of the input variables. Loh [15] provided a more detailed examination of the theoretical

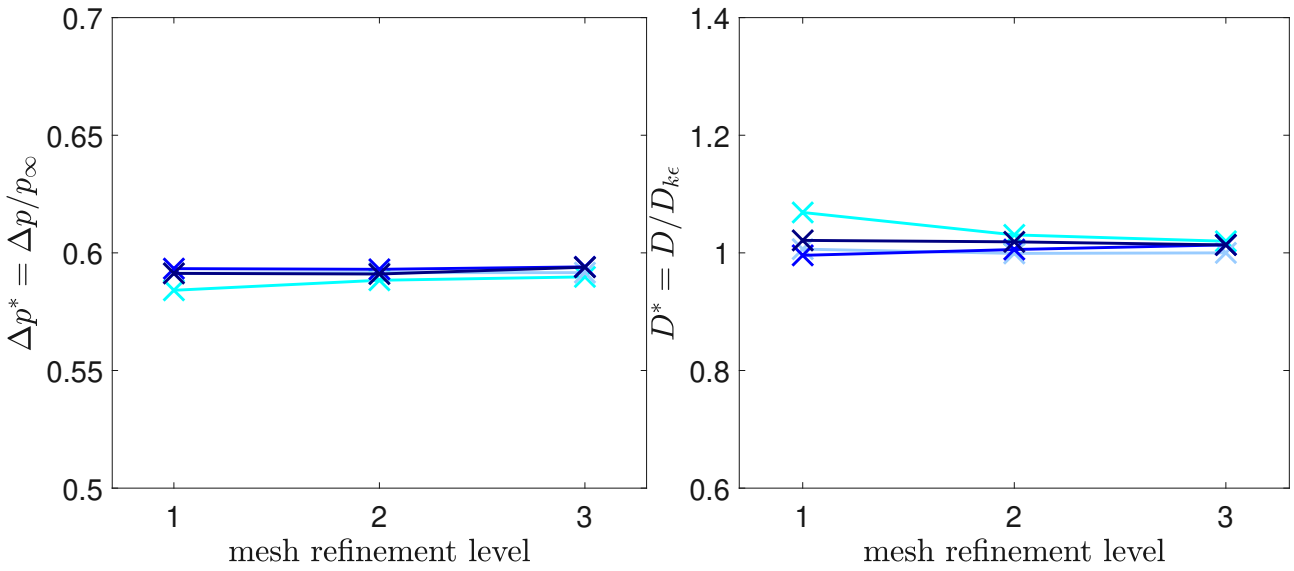

Figure 4: Model validation as a function of the grid refinement and turbulence model. From lighter to darker tones colours refer to gradually more complex turbulence models, i.e., SA, $k-\epsilon$ realisable, $k-\omega$ SST and TSST, respectively. The refinement level refers to the 100k, 200k, and 300k mesh, respectively.

background of the LHS approach, as well as the fundamental mathematical formulation of the method. As presented by Helton et al. [16], this technique has been widely used in complex system analyses, with its main characteristics highlighted, such as its simplicity and ability to result in more uniform stratification than other random sampling strategies, revealing to be a suitable method for selecting input variables or having a rough estimate of optimal locations. In this study, the Latin Hypercube Sampling technique is employed using the Matlab "lhsdesign" function, which generates an LHS matrix of size $k \times n$, where k and n are again variables and different values for each variable, respectively. In particular, each configuration generated by the LHS method consists of a variation of the baseline solution reconstructed through Beziér splines. The approach allows to obtain different Venturi tube geometries in terms of shape angles, inlet, throat, and discharge lengths, as well as it ensures a smooth profile of the tube.

To assess the performance of the geometric configurations of the Venturi tube in terms of the ability to generate cavitation events, each configuration has been assigned a performance parameter related to the generation of steam in the discharge portion of the pipe. Five stations (named *stat*1, *stat*2, *stat*3, *stat*4, *stat*5) are placed beside the tube discharging section to sample the radial distribution of the vapour quality. The average integral value of the steam quality, X_v, is derived for each distribution according to Equation 1:

$$X_v(x_i) = \frac{1}{R}\int_0^R X_v(x_i, r)dr, \quad i = 1, \dots, N_{stats} \tag{1}$$

where r and R denote the radial coordinate and the maximum radius associated with each station, respectively, while x_i are the axial coordinates of the samples. As a result, this value indicates how much steam is connected to each station. Finally, the five measurements associated with each station are averaged to provide a single performance parameter for each geometric arrangement, i.e.,

$$X_v = \frac{1}{N_{stats}}\sum_{i=1}^{N_{stats}} X_v(x_i) \tag{2}$$

When applied to the baseline Venturi's configuration, this method produces a performance metric of X_v = 0.1421. Instead, the LHS optimisation process produces a set of 12 configurations capable of greatly enhancing the performance inherent in steam generation compared to the baseline (see Table 3).

Table 3: Results of the optimisation analysis.

Configuration	Vapor performance index	Improvement [%]
baseline	0.1421	-
1	0.2688	89.11
2	0.2382	67.59
3	0.2825	98.75
4	0.1734	22.01
5	0.1933	36.02
6	**0.3321**	**133.7**
7	0.2138	50.40
8	0.1627	14.48
9	0.1455	2.38
10	0.2275	60.05
11	0.1931	35.88
12	0.1451	2.10

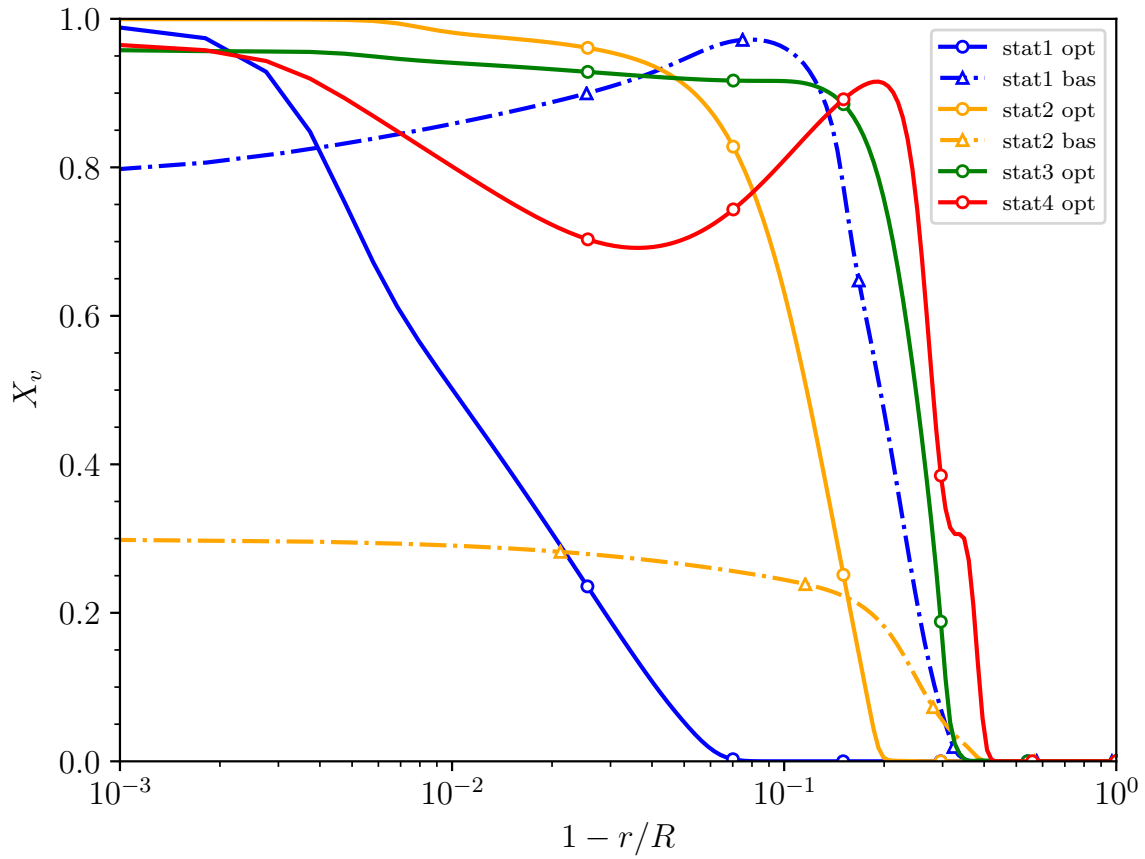

Figure 5: Baseline and optimal solutions comparison in terms of steam production distribution in the Venturi discharging sections.

Although all factors considered result in a significant boost in steam production performance, individual 6 is unquestionably the best. In fact, it is observed a 133% increase in the steam generation on average when compared to the baseline solution. Figure 5 compares the trend in steam quality at the five stations in configuration 6 with the same data acquired in the baseline situation. The solid curves represent the optimal case, while the dashed-dotted curves report the baseline solution. It can also be seen that the baseline configuration tends to cluster the vapour production in the early stations, with the first station having a clear advantage. Furthermore,

stations 1 and 2 of the baseline solution (in Figure 5 (named *stat*1 and *stat*2) concentrate the quality of the vapour along the wall of the pipe. Instead, the optimal solution not only improves the steam distribution in *stat*1 and *stat*2, but also generates a significant amount of steam in *stat*3 and *stat*4 (see Figure 5), whereas the baseline does not. For completeness, it is reasonable to claim that stations with a vapour quality less than 10^{-2} are not meaningful and, therefore, are not reported.

5. Conclusions

The proposed investigation examines a baseline and an improved Venturi tube geometry for applications involving hydrodynamic cavitation. After building the numerical model of the device, it is first calibrated as a function of grid resolution and turbulence model, with a focus on the independence of the results from mesh refinement. The baseline model is then used as the leading configuration in an LHS-based automatic optimisation process. Compared to the baseline configuration, the method can increase the steam production of the Venturi tube by almost 130%. In addition, the improved design concentrates steam production along the channel axis, while the baseline design directs steam production toward the wall. Therefore, the study demonstrates that by modifying the Venturi tube design, the hydrodynamic system performance can be improved. Without chemical components, solvents, and/or addition of man-made substances, the optimised geometry can be an economic solution to abate contaminants in water systems. In future studies, experimental campaigns will be conducted in both baseline and optimised configurations to validate numerical findings and/or design new, more efficient Venturi tube configurations. In addition to optimisation and numerical simulations, alternative configurations, including numerous Venturi tubes or asymmetrical nozzles, will be designed and tested.

Abstract:

Fuel cells have proved to be promising alternatives for Internal Combustion Engines (ICEs) with higher efficiency and lower harmful environmental impact. Among different types, Proton Exchange Membrane Fuel Cell (PEMFC) has proved to be the best option to reach zero adverse emissions at low temperatures, which enables the operation of the PEMFC for mobility applications. However, cost, durability, and thermal/water management should be further considered to better commercialize PEMFCs. Durability and water/thermal management of the PEMFC can be improved by increasing the liquid removal from the gas diffusion layers (GDL) inside each stack of the PEMFC. However, there are no efficient simulation methods to analyze water removal based on experimental efforts. The goal of this study is to use the Lattice Boltzmann Method (LBM) to precisely capture the characterization of the GDLs that have been scanned by the Computed Tomography (CT) scans. Once the three-dimensional CT scans of the GDL are performed, the segmentation and reconstruction will be made to provide the needed geometry for fluid flow simulation. The geometry will be then used to characterize the effective parameters of the thermal/water management of the PEMFC. This study can also be a valid reference for future computational fluid dynamic analyses in the GDL using the numerical modeling with the conservative equations or the Lattice Boltzmann modeling (LBM) with the kinetic and particle distribution equations.

Keywords:

Proton exchange membrane fuel cell (PEMFC); Gas Diffusion layer (GDL); Lattice Boltzmann Method (LBM); Computed Tomography (CT) scan.

1. Introduction

The harmful environmental impacts of fossil fuels and the low efficiency of combustion engines have motivated the decision-makers to find alternative fuels [1]. In this regard, methanol, ethanol, bio-fuels, ammonia, hydrogen, etc. have been suggested as possible candidates having advantages/disadvantages for each of them [2]. Among the mentioned alternative fuels, hydrogen has been suggested as the most promising option for a wider spectrum of usages [3]. This means that hydrogen production methodologies should be developed to provide the required demand of fuel for different industries [4].

As a promising technology to facilitate the transition from fossil fuels to hydrogen, fuel cells are proposed [5]. Among the introduced fuel cell variants, the Proton Exchange Membrane Fuel Cell (PEMFC) is considered the most commercialized and efficient type in low-temperature operations [6]. The basis of PEMFC's operation is to use hydrogen as fuel and produce water and electricity as outputs [7]. Although significant developments have been achieved to improve the performance of the PEMFCs, the main barriers toward further commercialization of the PEMFCs are water/thermal management, cost, and durability [8].

Considering the low-temperature operation of the PEMFCs, a concentrated effort should be made to keep the operating conditions such as humidity and temperature in the desired range to manage the highest lifetime [9]. The PEMFC is a composition of different layers, namely, membrane, Catalyst Layer (CL), Gas Diffusion Layer (GDL), Micro-Porous Layer (MPL), and Bipolar Plate (BP) [10]. The desired operating temperature range of the membrane should be around 65 to 85 degrees Celsius to prevent drying or flooding the cell in addition to a humid condition to prevent drying the membrane [11]. However, high humidity results in the formation of water droplets/columns in the GDL, which acts as a diffusing medium to split the hydrogen and a backing layer to support the CL [12]. To improve water management and reduce the water columns (breakthroughs) inside the GDL, the MPL is being used [13]. The remaining water droplets in the GDL and MPL result in filling the pores and difficulties in cold start, that is starting the PEMFC from sub-zero temperatures [14]. In addition to the usage of MPL, controlling the capillary pressure in those regions are proven efficient method to prevent the formation of breakthroughs [15]. To control the capillary pressure, the microstructure and the wettability of the porous regions can be modified [16]. In other words, water management and the formation of breakthroughs in the GDL can be improved by the changes in the microstructure of the GDL [17]. Although these concepts are supported by the I-V characteristic curves and the experimental setups, novel simulation methods based on experiments should be developed to facilitate the quantitative measurements of each GDL's breakthroughs.

Although experimental methods are unable to calculate the number of each GDL's breakthroughs, the computational fluid dynamic (CFD) is able to present quantitative amounts in different applications [18]. The significant developments of the CFD commercial softwares such as ANSYS, and COMSOL have enabled the researchers to have a better vision of the fluid flow inside the porous media [19]. However, these softwares are developed based on conservation equations such as mass, energy, and momentum. This means that this commercial softwares cannot be used to simulate the fluid flow inside the GDL/MPL since the dominating driving force in those regions is the capillary pressure [20]. In this regard, CFD models that are based on the kinetics of the particles, such as the Lattice Boltzmann Method (LBM), rather than the conservation equations should be used to characterize the fluid flow inside the GDL/MPL and to quantitatively measure the formation of the breakthroughs in these regions [21]. Although the structure of the GDL and MPL can be obtained using different prediction methods, the exact structure can be observed using novel microscopy and tomography techniques [22].

To obtain the exact structure of a porous region, it is common to either use Focused Ion Beam-Scanning Electron Microscopy (FIB-SEM) or Computational Tomography (CT) scans [23]. Although FIB-SEM is an efficient method to characterize the structure of the GDL/MPL, it is a destructive method and demands special procedures to embed the samples to minimize the destruction of the samples through microscope imaging [24]. Additionally, FIB-SEM imaging demands more operation time to detect the structure of the same porous regions in comparison to the CT scan. CT scans [25] are also non-destructive and they are the best options considering the thickness of the GDL which is approximately around 200 μm. FIB-SEM is capable of measuring up to the resolution of 3 *nm* while CT scans reach 1 μm. Concerning the mentioned information, the combination of CT scans, which produce the exact geometry of the GDL, accompanied by the LBM CFD simulation will enable the quantitative measurement of the amount of water breakthroughs inside the GDL.

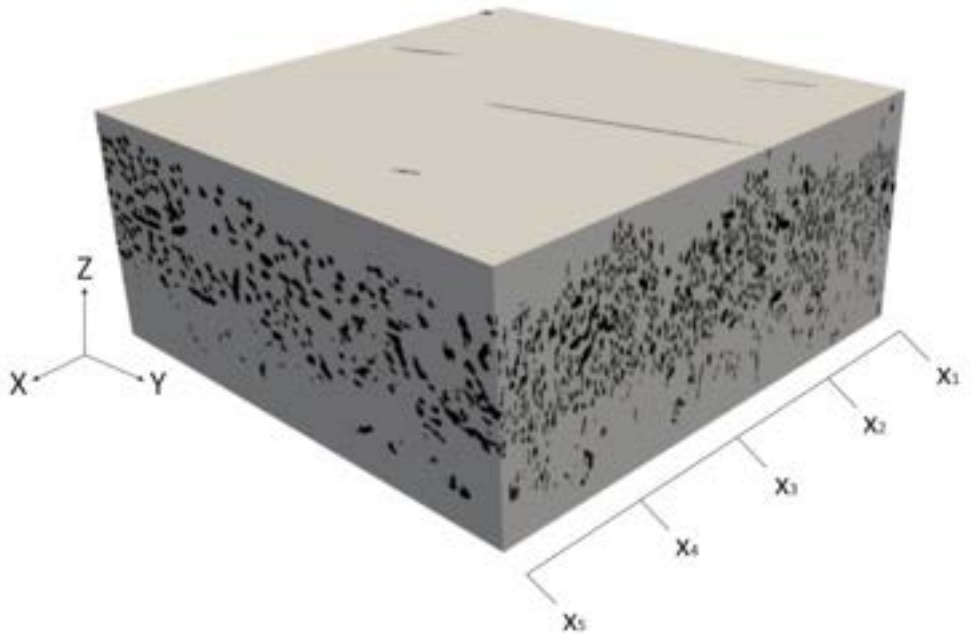
This study aims to provide a methodology to calculate the amount of water breakthroughs in an arbitrary GDL. The suggested methodology is based on using CT scan imaging to segment and reconstruct the exact geometry of the GDL in the PEMFCs. The reconstruction of the GDL provides the exact geometry of the GDL to be used for CFD simulations. This study benefits from LBM concepts, which are based on the kinetics of the particles rather than conservation principles in the CFD commercial softwares. The novelty of this study is to perform the quantitative measurement and characterization of the breakthroughs inside an arbitrary GDL using the LBM and CT scans. The results of this study can be used as a reference methodology to analyze the characteristics of the GDL considering the water/thermal management.

2. Problem description

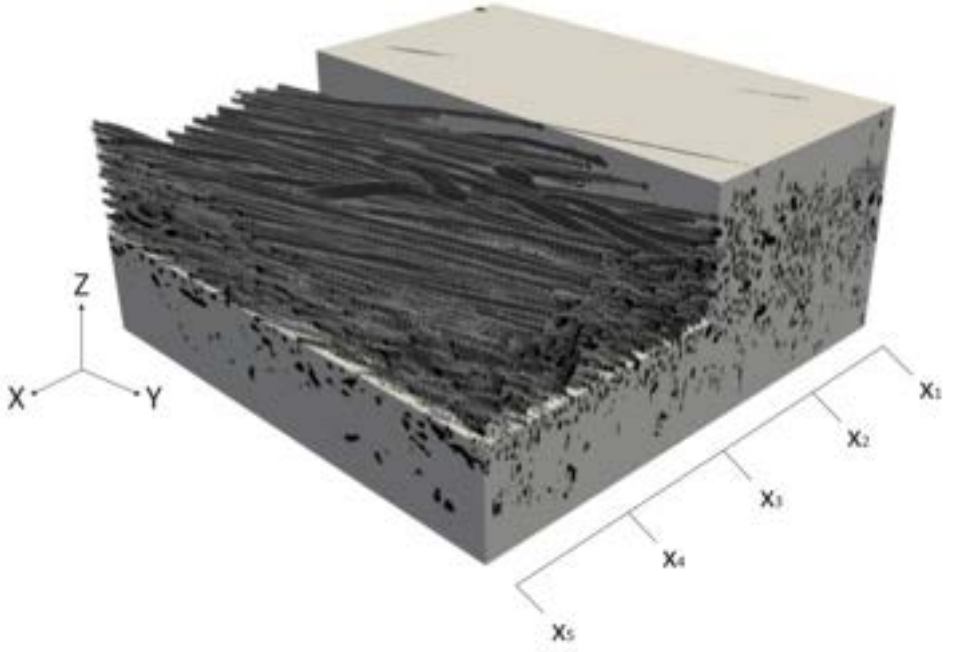
This study aims at providing a reference method to characterize the water management of GDLs in PEMFC applications. In this regard, an arbitrary GDL sample has been used followed by the required CT scan to obtain the precise geometry of the carbon fibers for simulation purposes.

Figure 1 (a) shows the whole domain of the considered GDL sample while Figure 1 (b) illustrates the carbon fibers with more details. The mentioned geometry in Figure 1 has been obtained using $\mu - CT$ scan imaging with the operating conditions indicated in Table 1. The size of the sample is $1.685 \times 1.464 \times 0.225$ (mm^3) and the image resolution is 1 μm. The segmentation and reconstruction of the images have been done using Dragonfly software, Version 2020.2 developed by Object Research Systems (ORS) Inc in Montreal (Canada).

Once the segmentation and reconstruction of the GDL images are done, the reconstructed model was used to perform the Lattice Boltzmann Method (LBM) simulation to analyze the water flow in the GDL. The required governing equations to develop the LBM simulation model are presented in Section 3.. The results of the LBM



(a)



(b)

Figure 1: The schematic of the scanned, segmented, and reconstructed GDL to be analyzed using the LBM: (a) the whole considered region, (b) the clipped image to show the GDL inside the boundary condition.

simulation provide the three-dimensional flow distribution of the flow inside the GDL, hence the existence of breakthroughs (water columns) in the GDL can be predicted. It is believed that the formation of the water columns in the GDL is a form of degradation that fills the GDL pores and increases the possibility of remaining the water at sub-zero temperatures, leading to difficulties for the cold-start.

3. Governing equations

To implement the Multiple Relaxation-Time (MRT) model of the Lattice Boltzmann Method (LBM), the LBM can be developed based on the MRT collosion equation considering the force term as of Eq. 1 [26]:

Table 1: The operating conditions to perform the CT scans and the characteristics of the analyzed GDL sample

Parameter	Value	Parameter	Value
Acceleration voltage	40 kV	Averaging frames	10
Current	120 μA	Exposure time	500 ms
Image resolution	1 μm	Rotation step	0.22 degrees
Sample size (X-direction)	1.685 mm	Sample size (Y-direction)	1.464 mm
Sample size (Z-direction)	0.225 mm	Stage temperature	21 Celsius degrees
Voxel size (X-direction)	1685	Voxel size (Y-direction)	1464
Voxel size (Z-direction)	225		

$$f(x + e\Delta t, t + \Delta t) = f(x, t) - M^{-1}[SM(f^{eq}(x, t) - f(x, t)) + (I - \frac{1}{2}S)MF] \tag{1}$$

here, the density distribution function is shown with f (see Eq. 2 while Δt is the time step. M indicates the orthogonal matrix [27], which transfers the distribution functions and S is the diagonal matrix designed for D3Q19 as $S = \omega I$ [28]. As required in LBM, the discretized velocity is obtained using a D3Q19 lattice model, which is shown by e [29].

$$f_i^{eq}(\rho, u) = \rho w_i[1 + \frac{e_i.u}{c_s^2} + \frac{(e_i.u)^2}{2c_s^4} - \frac{u^2}{2c_s^2}] \tag{2}$$

where, F represents the body forces based on the Guo's model [30, 31]:

$$F_i = \omega_i(\frac{e_i - u}{c_s^2} + \frac{(e_i.u)e_i}{c_s^4}).F \tag{3}$$

The indicated sound speed, c_s in 3 is considered to be $\frac{1}{\sqrt{3}}$. Each velocity direction is attributed with a weighting factor of ω_i based on ref. [26]. The respective values of the density and velocity can be obtained in Eqs. 4 and 5:

$$\rho = \Sigma_i f_i \tag{4}$$

$$u = \frac{1}{\rho}\Sigma_i e_i f_i + \frac{F\Delta t}{2\rho} \tag{5}$$

3.1. The magic parameter

Although in the Single Relaxation Time (SRT) LBM, the impacts of magic parameter is negligible on the results due to not being a parameter of viscosity, the MRT-LBM model demands the determination of magic parameter. For instance, the magic parameter can be calculated using Eq. 6 for Two Relaxation Time (TRT) LBM model:

$$\Lambda = \Lambda^+\Lambda^- = (\frac{1}{\omega^+\Delta t} - \frac{1}{2})(\frac{1}{\omega^-\Delta t} - \frac{1}{2}) \tag{6}$$

where, ω^- can be selected arbitrary while ω^+ should be computed through Eq. 7:

$$\vartheta = c_s^2(\frac{1}{\omega^+} - \frac{1}{2}) \tag{7}$$

In the MRT model, multiple frequencies correspond to the relaxation times and can be divided into symmetric, Λ_j^+, and anti-symmetric, Λ_k^-, groups. The combination of the mentioned two groups creates a single magic parameter that modifies the simulation error as follows [32]:

$$\Lambda_{j,k} = \Lambda_j^+\Lambda_k^- j = e, \pi, \varepsilon, \vartheta k = q, m \tag{8}$$

$$\Lambda_{j,k} = [\Lambda_\vartheta^+\Lambda_q^-, \Lambda_e^+\Lambda_q^-, \Lambda_\varepsilon^+\Lambda_q^-, \Lambda_\pi^+\Lambda_q^-, \Lambda_\vartheta^+\Lambda_m^-, \Lambda_e^+\Lambda_m^-, \Lambda_\varepsilon^+\Lambda_m^-, \Lambda_\pi^+\Lambda_m^-] \tag{9}$$

Considering the 9, there are eight different magic parameters for the D3Q19 model. As all the magic parameters are considered identical, the presented MRT can be assumed as TRT model. Thus, the existing frequencies of the symmetric group ω^s can be considered equal to the calculated frequency from the viscosity as of Eq. 10:

$$\omega^s = \frac{1}{\frac{\vartheta}{c_s^2\Delta t} + \frac{1}{2}} \tag{10}$$

where, the superscript "*s*" indicates the existing frequencies of the symmetric part. the related superscript for the anti-symmetric part is "*as*" and the corresponding frequency can be calculated using Eq. 11:

$$\omega^{as} = \frac{4 - 2\omega^{s}}{(4\Lambda - 1)\omega^{s} + 2} \tag{11}$$

3.2. Mean velocity computation

Considering the Darcy model, the permeability tensor is defined as follows:

$$K_{ij} = \frac{\mu}{\Delta P_j}\bar{U}_i; i, j = 1, 2, 3 \tag{12}$$

here, ΔP_j is the pressure gradient in j-direction while $\bar{U}_i$ is the mean volumetric velocity in the i-direction as follows [33]:

$$\bar{U}_i = \frac{1}{V_t}\int_{\Omega} u_i d\Omega \tag{13}$$

where, V_t is the total volume of the sample while $d\Omega$ is the volumetric element in the pore domain. Using the trapezoidal discrete form, Eq. 14 can be solved as follows:

$$\bar{U}_x = \frac{\sum_k^{N_k}\sum_j^{N_j}\sum_i^{N_i} u_{x_{ijk}}}{N_i N_j N_k} \tag{14}$$

Accounting the form of Eq. 14, error will be produced, which can be controlled using the magic parameter, and by using high-order interpolations to solve the Eq. 13. The effective permeability can be presented as follows [34]:

$$K_{eff} = K_{ideal} + \frac{2}{3}\Lambda - \frac{1}{12} \tag{15}$$

where, K_{ideal} is the exact value of the permeability in the ideal boundary condition.

4. Results and discussion

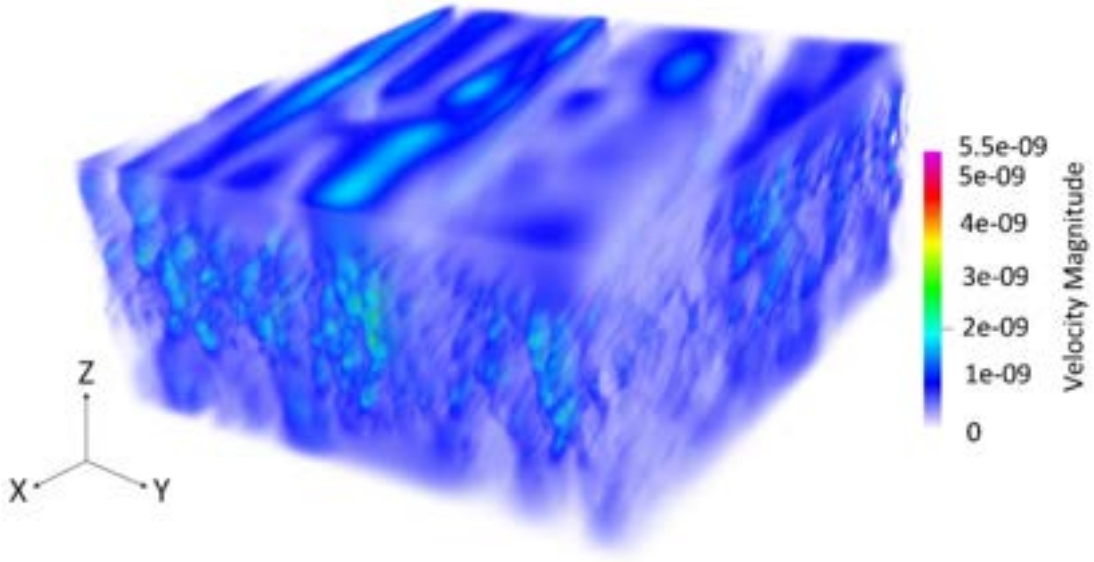
In the first step, the GDL sample, shown in Figure 1, is scanned with $\mu - CT$ imaging to enable the segmentation and reconstruction of the sample for CFD analysis. Furthermore, the $\mu - CT$ imaging enables the calculation of the porosity and the mean pore diameter that can be needed for the LBM simulation. Using the Dragonfly software and after the reconstruction of the images, the respective values of the porosity and the mean pore diameter were calculated to be 0.8516 and 2.894 μm, respectively.

As mentioned in Section 3., there are three methods to use the LBM, Single-Relaxation Times (SRT), Two-Relaxation Times (TRT), or Multi-Relaxation Time (MRT). Among these methods, the MRT-LBM benefits from the highest accuracy and precision, hence this study has utilized this model to simulate the scanned GDL sample by the $\mu - CT$ imaging. Each of the Lattice vectors is located in the position of x and the time of t, which enables the transient simulation of the fluid flow inside the GDL. In this study, the D3Q19 discretization model has been used, that means each of the lattice vectors has 19 different components in the momentum space.

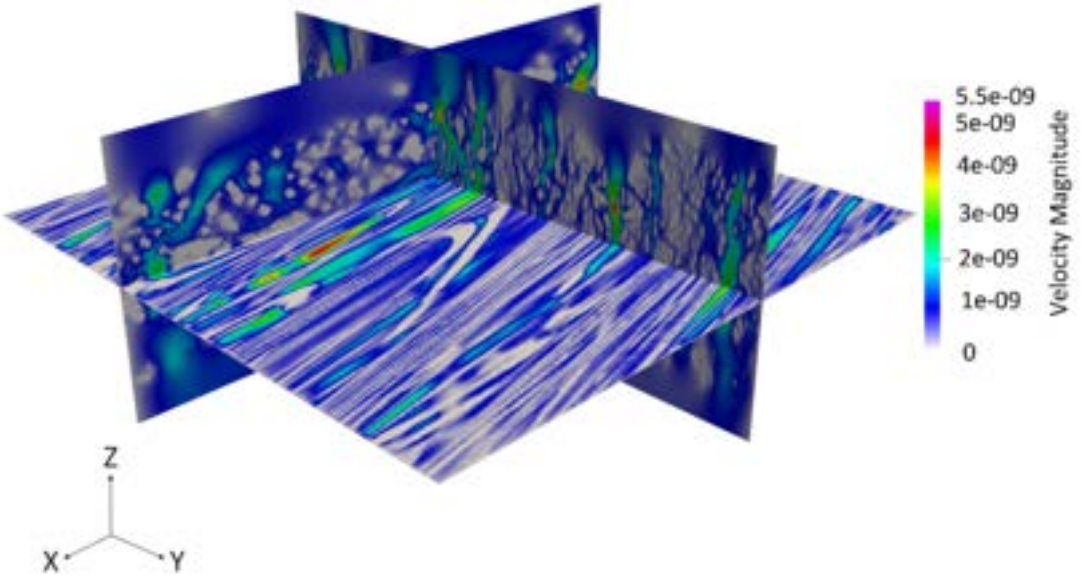
Accounting for the boundary conditions, the fluid flow is at low speeds (laminar flow) and Darcy conditions and the aim is to consider the capillary pressure as well. The implemented pressure gradient as the driving force for the fluid flow in the Z-direction, shown in Figure 1, is 0.1 $\frac{Pa}{m}$. The four surfaces of the GDL sample shown in Figure 1 parallel to the ZY and XZ planes are considered walls with no-slip boundary conditions.

A simplification has been made and pure water has been selected for the working fluid. In this regard, the kinematic viscosity of the fluid is 0.802 $\frac{mm^2}{s}$ while the fluid density is 995.7 $\frac{kg}{m^3}$. The maximum number of iterations for flow simulation is 80,000,000 while the Navier-Stokes relaxation time is 1. Additionally, the frequency that the convergence being checked is 0.5 s while the convergence criteria for the flow field is 10^{-4}. The inflation parameter regarding the LBM simulation, which considers the surface mesh before the visualization is 0.1.

Once the required parameters for the LBM simulation are provided, the fluid flow analysis is done. Figure 2 presents the results of the LBM simulation for the GDL sample shown in Figure 1. As can be seen, there are regions with higher velocities in the three-dimensional domain with red, yellow, and green colors. These regions are indicators of the possibilities for the formation of breakthroughs inside the GDL. Notably, the analyzed GDL by the $\mu - CT$ scan has not gone through aging and is a pristine sample. To have a better visualization of the breakthroughs inside the GDL, Figure 3 is provided, which illustrates the fluid flow inside the GDL considering



(a)



(b)

Figure 2: The three-dimensional results of the performed CFD analysis using the LBM method on the presented sample in Figure 1: (a) The three-dimensional changes in the velocity in the considered domain, (b) The changes in the velocity considering three different slices in the X-, Y-, and Z- directions.

the X_1, X_2, X_3, X_4, and X_5 slices shown in Figure 1. Specifically, in Figure 3(c) and 3(e), the breakthroughs can be seen, as the green regions (indicating the breakthrough) pass through the GDL carbon fibers. The GDL carbon fibers in Figure 3 are shown with while values since the velocity vectors are zero if there exist solid materials.

As Figure 2 illustrates, the visualization of the breakthroughs inside the GDL is not a straightforward procedure and better quantification measurements are required. In this regard, each voxel that has velocity values of more than 2×10^{-9} in the domain given by Figure 2 (a) is considered as a region of breakthrough. In this regard, 9.13% of the GDL porous region, which is illustrated in Figure 2(a), is consisted of the breakthroughs. This means that 50,675,060 voxels are labeled as breakthroughs inside the whole domain with 555,039,000 voxels. In other words, 0.051 mm^3 of the illustrated domain in Figure 1 is prone to create breakthroughs in the whole domain of 0.555 mm^3.

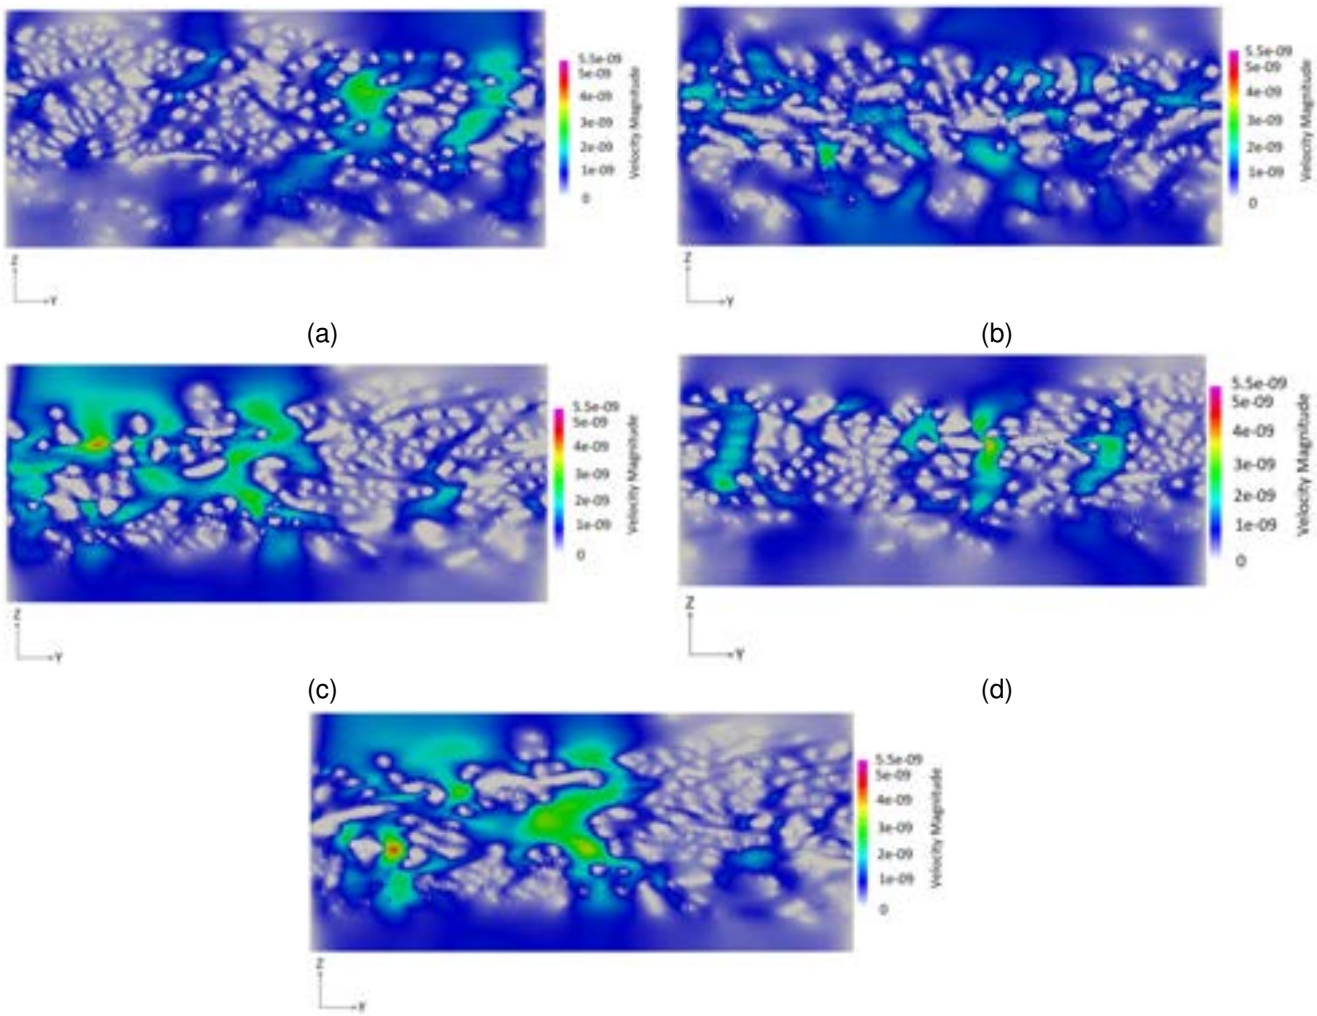


Figure 3: The two-dimensional velocity contours in the X-direction after performing the LBM simulations on the analyzed samples shown in Figure 1: (a) Slice X_1 depicted in Figure 1, (b) Slice X_2 depicted in Figure 1, (c) Slice X_3 depicted in Figure 1, (d) Slice X_4 depicted in Figure 1, (e) Slice X_5 depicted in Figure 1

5. Conclusion

This study could analyze the formation of the water columns inside the GDL of the PEMFC. The formation of water columns, which is also famous as breakthroughs, is known as a degradation phenomenon that fills the pores and leads to difficulties in starting the cell from sub-zero temperatures. As the driving force of the fluid flow in the GDL is the capillary pressure, the conventional conservation principles such as momentum, energy, and mass are not the governing equations, and methods based on the kinetics of the particles should be used. In this regard, LBM formulation, which is considered a powerful CFD methodology based on the kinetics of the particles to simulate the fluid flow at the interfaces between the gas/solid/liquid and at low-velocity conditions, has been used using the obtained $\mu - CT$ images of the GDL. $\mu - CT$ images could provide the exact geometry of the GDL followed by the porosity and the mean pore diameter that is required for the LBM simulation.

The results of the LBM simulation could provide the velocities of the water passing through the GDL. The illustrated contours visualized the locations of the breakthroughs followed by the corresponding voxels. To enable the quantitative measurement of the breakthroughs, the voxels with higher velocity values of 2×10^{-9} were considered to be a part of the breakthroughs in the domain. In this regard, it was calculated that 50,675,060 voxels are labeled as breakthroughs among the whole 555,039,000 voxels. In other words, considering the whole size of the domain, which is 0.555 mm^3, the created breakthrough is equal to 0.051 mm^3. The LBM simulation could also provide a quantitative percentage of 9.13% as the share of the breakthrough in the whole domain.

The output results of this study proved that the performance of the GDLs can be characterized without experimental testing and novel GDLs can be analyzed before assembly to reduce the costs and time. The current novelty of this study can be used in future studies to facilitate GDL characterization. Additionally, the following

topics can be accounted for future studies:

- This study only analyzed an arbitrary pristine GDL to analyze the possibility of the GDL characterization using the LBM simulation and CT scan imaging. It is suggested to consider aged or degraded samples of GDL and evaluate the impacts of different types of degradation phenomena on the amount of created breakthroughs.
- To facilitate the LBM simulations, simplifications were made and only pure water was considered as the fluid flow in the GDL. However, in reality, the fluid is either hydrogen or oxygen in a humid environment with the possibility of water formation.
- LBM simulation is also a powerful tool to analyze the droplet formation and movement in porous media, which is the exact electrochemical phenomenon inside the GDL. In this regard, further details can be added to this model to obtain the highest precision in the simulation results.

Acknowledgments

This project has received funding from the European Union's Horizon 2020 research and innovation program under the Marie Sklodowska-Curie grant agreement No. 754354.

The segmentation and reconstruction of the images have been done using the Dragonfly software, Version 2020.2 developed by Object Research Systems (ORS) Inc in Montreal, Canada. The required link to the company's website is: http://www.theobjects.com/dragonfly.

Abstract:

Ejectors are devices that expand a primary flow through a nozzle to entrain and compress a secondary flow without moving parts. They can be modelled in 1D as two streams exchanging momentum. However, the engineering modelling of this exchange is based on closure parameters such as friction coefficients that must be calibrated against experimental or numerical data. This work proposes a general machine learning framework for calibrating engineering models governed by Ordinary Differential Equations (ODEs) and presents its application to the 1D modelling of an ejector. We combine a physics-separated approach with a physics-integrated approach, with the first acting as an initial guess for the second. The first approach calibrates shear and friction coefficients from their counterpart extracted via post-processing of an axisymmetric CFD simulation. The second consists of calibrating these coefficients from the prediction of physical quantities (pressures, temperatures, and cross-sections), thus making the training process aware of the ODEs driving the forecast.

Keywords:

1D ejector modelling, closure modelling, physics-constrained machine learning

1. Introduction

Ejectors are flow devices that expand a primary flow to entrain and compress a secondary flow into a mixing pipe. These 'compressors' have no moving parts and are thus robust and without limitations on the working fluid (gas, liquid, two-phase). Their applications include aeronautics, the chemical and processing industry, power generation and refrigeration [1].

Ejectors are commonly modelled with 0D lumped parameter formulations [2–6], meaning that conservation laws are expressed between key sections such as the throat and the exit of the primary nozzle, the constant area section of the mixing pipe and the exit of the diffuser. These models give fast predictions of the global performance in the form of mass flow rates but require calibration of several closure coefficients accounting for the isentropic efficiencies of key components. On the other hand, classic CFD provides detailed flow fields [7,8], but requires more computational time and effort for meshing and setting up the solver, which is generally too expensive at system scale. A compromise consists of 1D models, which discretize the flow field in the axial direction. The mixing pipe can be modelled with a single domain [9], or with two interacting domains [10–12]. These models still require calibration, for example, for modelling wall friction and shear. Nevertheless, they provide local information and resolve more physics related to entrainment than 0D models, at a fraction of the cost of 2D/3D CFD.

Closure relations mapping these closure coefficients to physical quantities (e.g., a friction coefficient which depends on the Reynolds number) could make these models self-standing and thus more useful in early design stages, but their derivation is particularly challenging. This work proposes a machine learning formalism to discover such closure relations from data. By training the model on reliable CFD data, the intricacies of the 2D flow field can be lumped into the closure coefficients of the lower dimensional 1D model to maximize the accuracy of these models. This data-driven approach has been successfully applied in other branches of fluid mechanics such as heat transfer or and turbulence modelling. These can be classified as physics-separated (as in [14]) or physics-integrated (as in [15, 16]) depending on whether the learning process is carried out on data extracted from a simulation or during a simulation. These approaches are briefly reviewed in the next section. None of these have been implemented for the calibration of ejector models.

In this work, we propose a general formulation for machine learning-based closure of a system of ordinary differential equations (ODEs), and we apply it to a 1D ejector model with two streams (1D-2s hereafter). The

general framework is presented in section 2. and its application on the ejector model in section 3.. The results are discussed in section 4., leading to the conclusions in section 5..

2. A general framework for machine learning-based calibration

We consider a physical problem governed by a system of ordinary differential equations (ODEs) in the state variables $\boldsymbol{u} \in \mathbb{R}^{n_u}$ and a set of parameters $\boldsymbol{p} \in \mathbb{R}^{n_p}$ to be linked to the state variables. In this work, we focus on boundary value problems in $x \in [0, L]$, and denote the sought-after closure relation as $\boldsymbol{p} = g(\boldsymbol{u}, x)$. Thus the closure problem can be written as

$$f\left(\boldsymbol{u}, \frac{d\boldsymbol{u}}{dx}, \frac{d^2\boldsymbol{u}}{dx^2}, ..., x, \boldsymbol{p} = g(\boldsymbol{u}, x)\right) = 0\,, \tag{1}$$

with boundary conditions $\boldsymbol{u}(0) = \boldsymbol{u}_L$ and $\boldsymbol{u}(L) = \boldsymbol{u}_R$. This framework is general enough to encompass many physical systems, from turbulence modelling [15–18] to general inverse modelling [13]. This work presents the first implementation of this framework for the closure of 1D ejector models.

The problem of finding the unknown function is generally a difficult variational problem. Machine learning offers an alternative approach by approximating the unknown function using a parametric model $\boldsymbol{p} = g(\boldsymbol{u}, x; \boldsymbol{w})$ which depends on a finite set of weights $\boldsymbol{w} \in \mathbb{R}^{n_w}$. This could range from a simple linear relation to artificial neural networks (ANNs), and the range of possible functions that the given model can represent defines the 'hypothesis set' in the machine learning formalism [21]. Following [19], the identification of the weights $\boldsymbol{w}$ can be carried out using physics-separated and physics-integrated approaches (see also [14], and [13, 15–18]).

The physics-separated approach is a classic supervised learning formulation which assumes that a set of instances $(\tilde{\boldsymbol{u}}_i, x_i)$ and the associated parameters $\tilde{\boldsymbol{p}}_i$ are available. Therefore, the optimal set of weights is the one that minimizes a cost function $J(\boldsymbol{w})$ such as, for example:

$$J_1(\boldsymbol{w}) = \sum_i \sum_r \frac{\left(\tilde{\boldsymbol{p}}_{i,r} - g(\boldsymbol{u}_{i,r}, x_i; \boldsymbol{w})\right)^2}{\tilde{\boldsymbol{p}}_{i,r}^2}\,, \tag{2}$$

where i is the index spanning the instances $\tilde{\boldsymbol{p}}_i$ at coordinates x_i and r is the index spanning the entries in each vector of parameters (i.e. the closure coefficients that make up $\boldsymbol{p}$).

This regression problem is shown schematically in block II of figure 1 and starts with an initial guess $\boldsymbol{w}_0$. The gradient of the cost function $d_{\boldsymbol{w}}J$ only requires the gradient of the parametric function $d_{\boldsymbol{w}}g$; this is easily available for usual machine learning models (e.g. using backpropagation in ANNs) hence classic gradient-base optimizer such as the BFGS algorithm [20] can be implemented efficiently. However, this approach requires that both the parameters $\tilde{\boldsymbol{p}}_i$ and the full states $\tilde{\boldsymbol{u}}_i$ can be extracted from a sufficiently rich dataset with sufficient accuracy (cf. block I in figure 1). This is rarely possible from experimental data. Moreover, the trained model g is unaware of the underlying physical problem in (1) since the model is never called during training.

The physics-integrated approach includes the physical problem in (1) during the learning process (cf. block III in figure 1). Note that both approaches are self-standing, but can be applied successively. The extraction of the model parameters from data is not required, and the training is based on some observation of the states and the prediction that the model f can achieve for a given set of weights $\boldsymbol{w}$. Considering the simplest case of full observation of the states $\tilde{\boldsymbol{u}}_i$ and denoting the solution of (1) as $\boldsymbol{u}_i(g(\boldsymbol{u}_i, x_i; \boldsymbol{w}))$ when the closure is achieved with the weights $\boldsymbol{w}$, the optimal set of weights minimizes a cost function of the form

$$J_2(\boldsymbol{w}) = \sum_i \sum_r \frac{\left(\tilde{\boldsymbol{u}}_{i,r} - \boldsymbol{u}_{i,r}(g(\boldsymbol{u}_{i,r}, x_i; \boldsymbol{w}))\right)^2}{\tilde{\boldsymbol{u}}_{i,r}^2} \tag{3}$$

where i is the index spanning the instances $\tilde{\boldsymbol{u}}_i$ at coordinates x_i and r is the index spanning the entries in each state vector (i.e. the variables considered for the cost function definition).

The relative error is preferred here due to the composite nature of common state vectors (e.g., pressures and temperatures). Using the chain rule, it is easy to see that in this formulation, the gradient of the cost function $d_w J$ requires the gradient of the problem solution with respect to the parameters and the gradient of the parameters with respect to the weights, i.e. $d_w J(\boldsymbol{u}(g(\boldsymbol{w}))) = d_u J d_p \boldsymbol{u} d_w g$. Computing this gradient symbolically is challenging and requires adjoint differentiation (cf. [13, 15–18]), but for a computationally inexpensive solver of f and a small number of parameters, a simple finite difference implementation is feasible. Besides avoiding the need for extracting the parameters $\tilde{\boldsymbol{p}}$ from data, this approach has the main merit of pairing the closure

with the solver with which it is later deployed. On the other hand, the model sensitivity to the parameters ($d_p\boldsymbol{u}$) strongly influences the cost function gradient and often results in more poorly behaved and multimodal cost functions.

In this work, we propose a combination of the two approaches, whereby the solution of a physics-separated approach is used as a starting point for a physics-integrated approach (hence successively following blocks I to III in figure 1). This offers an excellent balance between accuracy, robustness and computational cost.

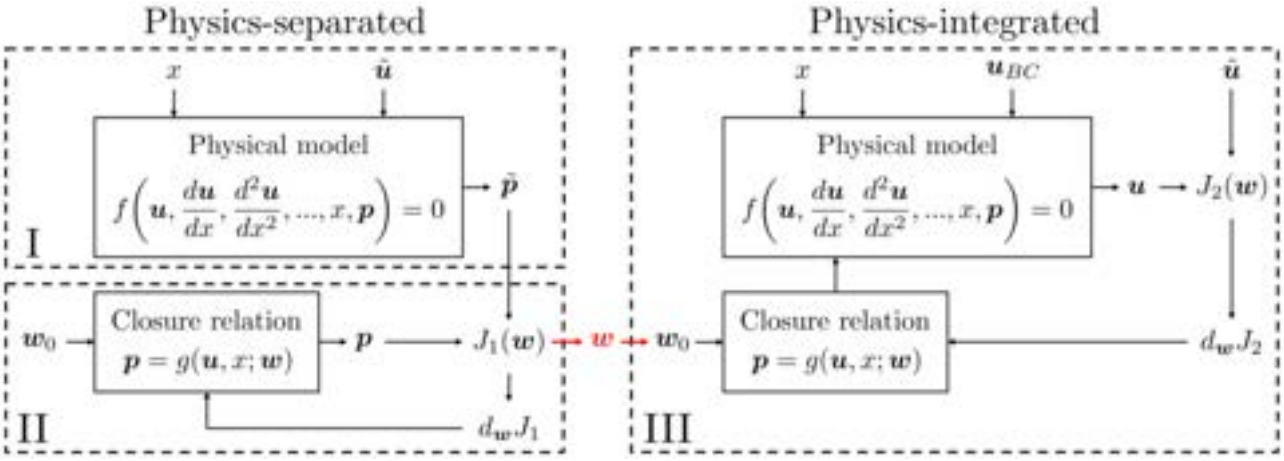

Figure 1: Schematic overview of the physics-separated and the physics-integrated approach for calibrating a physical model f through a closure relation g, given data $\tilde{\boldsymbol{u}}$. The physics-separated approach consists of (I) extracting the reference parameters $\tilde{\boldsymbol{p}}$ from data and (II) applying a classic supervised machine learning technique for regressing $\boldsymbol{p}$. The physics-integrated approach (III) includes the physical model in the training process and thus requires the sensitivity of the model with respect to its parameters $d_{\boldsymbol{p}}\boldsymbol{u}$. Both methods are self-standing, but this work proposes to apply them successively (I-III) as indicated in red.

3. Application to a 1D ejector model

The previously introduced model calibration framework is applied to the modelling of a supersonic ejector using a 1D and two streams formulation. The calibration is based on data from a 2D axisymmetric CFD simulation presented in [22]. This is briefly reviewed in section 3.1.. The model formulation is presented in section 3.2. while the procedure for the calibration is reported in section 3.3..

3.1. The CFD Dataset

We consider an ejector with a converging primary nozzle, operating with total pressures p_{tp} = 5 bar, p_{ts} = 1 bar and static back pressure p_b = 2.2 bar. Herein, the subscripts p and s are used for variables related to the primary and the secondary flows, respectively (see list of symbols at the end of the article). The total temperatures equal T_{tp} = T_{ts} = 293K. The numerical domain and a contour of the Mach number field are shown in figure 2. The primary jet is under-expanded due to the large pressure difference between the inlets, which leads to a shock train in the mixing pipe. This is evidenced by the dividing streamline as indicated by the full red line in figure 2. The ejector operates in off-design conditions, so the maximal flow rate is not reached, and the mixed flow remains subsonic. Consequently, no shock train is present in the diffuser as would be the case in on-design conditions [7]. Interested readers are referred to [22] for further numerical details and the validation against experiments.

The data assimilation in this work focuses on the mixing pipe since the primary and secondary inlets can be accurately described with classic quasi-1D flow theory. The mixing pipe features complex flow phenomena, mixing the two streams and shock trains interacting with shear layers. This portion of the ejector is the one where closure relations are required the most.

The first step in the data preparation consists of calculating the dividing streamline in the mixing pipe. This is defined as the line bounding the primary mass flow rate. Hinging on the axisymmetry of the problem, this is the radius r_{div} such that:

$$\dot{m}_p(x) = \int_0^{r_{div}} \rho(x,r)u(x,r)\, 2\pi r\, dr, \quad \text{and} \quad \dot{m}_s(x) = \int_{r_{div}}^{R} \rho(x,r)u(x,r)\, 2\pi r\, dr, \tag{4}$$

The dividing streamline is also used to average the relevant flow variable across the ejector's section, i.e.

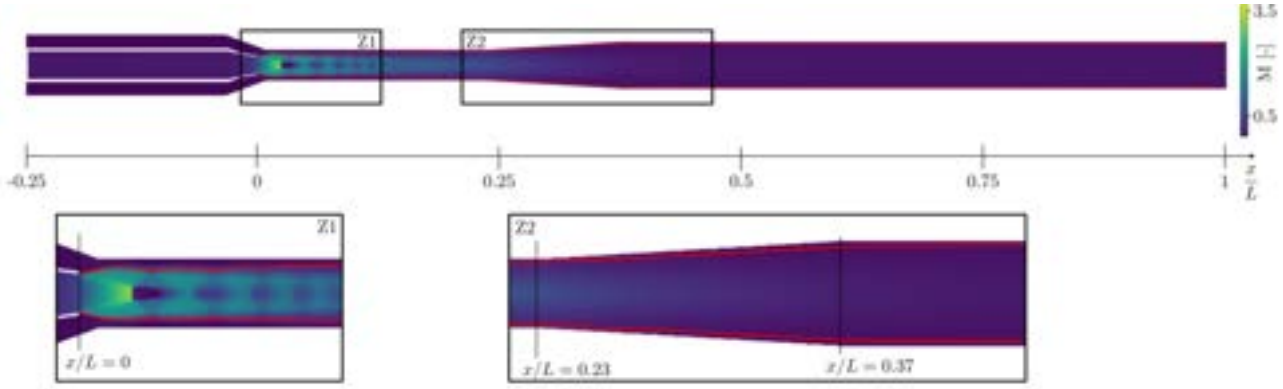

Figure 2: Mirrored Mach number field of an ejector operating in off-design conditions, obtained through classic axisymmetric CFD [22]. A shock train is present in the mixing pipe due to the different static pressures of both streams at the exit of the primary nozzle. The red line indicates the dividing streamline. The reference 1D data in the rest of the work is obtained through averaging over the resulting cross-sections with equations (5).

$$\hat{\rho}_{p,s}(x) = \frac{1}{A_{p,s}} \int_{A_{p,s}} \rho \, dA_{p,s}, \quad \hat{u}_{p,s}(x) = \frac{1}{\hat{\rho}_{p,s} A_{p,s}} \int_{A_{p,s}} \rho u \, dA_{p,s}, \quad \text{and} \quad \hat{e}_{t\,p,s}(x) = \frac{1}{\hat{\rho}_{p,s} A_{p,s}} \int_{A_{p,s}} \rho e_t \, dA_{p,s}, \tag{5}$$

where the hat $\hat{\cdot}$ denotes the cross-section averaged variables and the subscripts p, s denote the primary and the secondary stream. Therefore, the areas $A_{p,s}$ are the portion of the domain corresponding to $r \in [0, r_{div}]$ and $r \in [r_{div}, R]$ respectively. It is worth noticing that the specific choice of density average is arbitrary, but the other two equations enforce that the 1D variables keep the same mass flow rate and total internal energy as the CFD [23]. The final dataset consists of the cross-sections $A_{p,s}$ and the flow variables obtained with equation 5 at 1530 spatial coordinates x of the single CFD simulation shown in figure 2. Hence, the available data is locally rich, but limited to a single geometry and a single operating condition. Therefore, the resulting calibration in section 4. can not be expected to generalize to different operating conditions.

3.2. Model definition

The main idea of the 1D- two stream ejector model is to treat the inlets as 1D domains with the variable area along the axial coordinate x (as in the 1D modelling of nozzle flows). The mixing pipe is modelled as a 1D domain with 2 streams that exchange momentum through shear and with the wall. The division of the complete section between the two streams remains a degree of freedom, e.g., the same primary mass flow rate can pass through a narrow or a wide flow passage, with the secondary cross-section adapting accordingly. Therefore, the static pressure is assumed to be equal in both streams as an additional constraint. This set of equations is known as the compound flow theory, originally proposed by Bernstein [24] and adopted later in ejector modelling [6, 10, 23, 25]. The set of ODEs (1) consists of the following governing equations:

$$\frac{d_x p}{p} = \frac{1}{\beta}\left(d_x A + \frac{1}{2} f_{ps} l_{ps} \frac{\left(M_p^2 - M_s^2\right)^2}{M_p^2 M_s^2} - \frac{1}{2} f_w l_w \left(1 + (\gamma - 1) M_s^2\right)\right), \tag{6}$$

$$\frac{d_x p_{tp}}{p_{tp}} = -\frac{1}{2} \frac{f_{ps} l_{ps}}{A_p} \gamma \left(M_p^2 - M_s^2\right), \tag{7}$$

$$\frac{d_x p_{ts}}{p_{ts}} = \frac{1}{2} \frac{f_{ps} l_{ps}}{A_s} \gamma \left(M_p^2 - M_s^2\right) - \frac{1}{2} \frac{f_w l_w}{A_s} \gamma M_s^2, \tag{8}$$

$$\frac{d_x T_{tp}}{T_{tp}} = 0 \text{ and } \frac{d_x T_{ts}}{T_{ts}} = 0, \tag{9}$$

$$\frac{d_x A_p}{A_p} = \left(\frac{1 - M_p^2}{\gamma M_p^2}\right) \frac{d_x p}{p} + \frac{1}{2} \frac{f_{ps} l_{ps}}{A_p} \left(1 + (\gamma - 1) M_p^2\right) \left(1 - \frac{M_s^2}{M_p^2}\right), \tag{10}$$

$$\frac{d_x A_s}{A_s} = \left(\frac{1 - M_s^2}{\gamma M_s^2}\right) \frac{d_x p}{p} - \frac{1}{2} \frac{f_{ps} l_{ps}}{A_s} \left(1 + (\gamma - 1) M_s^2\right) \left(\frac{M_p^2}{M_s^2} - 1\right) + \frac{1}{2} \frac{f_w l_w}{A_s} \left(1 + (\gamma - 1) M_s^2\right), \tag{11}$$

where

$$\beta = A_p \frac{1 - M_p^2}{\gamma M_p^2} + A_s \frac{1 - M_s^2}{\gamma M_s^2}, \tag{12}$$

and with the constraint that $A_p + A_s = A$. It is worth noticing that eq. (6) implies that the static pressure is equal on both primary and secondary sides, i.e. $p_p = p_s = p$. The derivation of these equations from conservation principles is presented in appendix A. We refer to the list of symbols for the definition of all variables.

The two closure parameters to be identified in a data-driven model calibration are the shear coefficient f_{ps} between the streams and the wall friction coefficient f_w. These are linked to the shear forces acting on the perimeter of the primary cross-section (l_{ps}) and the wall's perimeter (l_w), respectively. Therefore, in the formalism introduced in section 2., these variables constitute the model parameters $\boldsymbol{p} = [f_{ps}, f_w]^T$ to be provided by the closure function g while the state variables are $\boldsymbol{u} = [p, p_{tp}, p_{ts}, T_{tp}, T_{ts}, A_p, A_s]^T$. The local Mach numbers can be computed from these variables (e.g. the static and total pressures) or the local densities using the ideal gas law. Note that the constraint on the cross-sections can be imposed by first calculating the gradient of the primary cross-section A_p and subtracting it from the gradient of the total cross-section.

It is worth stressing that the assumption of equal static pressure is problematic at the inlet of the mixing pipe because the primary flow is generally under-expanded (cf. figure 2). Therefore, the proposed model cannot be used from the exit of the primary nozzle ($x = 0$) unless a pressure equalization mechanism is introduced in the model. Alternatively, the areas for the primary and secondary flows must be provided at the inlet of the mixing channel: in this case, the pressures naturally equalize within a short distance from the inlet; this is akin to what happens through the shock cells in the CFD simulation. The development of the first approach is left to future work. In this work, we use the dividing streamline identified from the CFD up to the point where the pressures equalize, and downstream, we use the compound equations (6)-(12) (this is further discussed in Section 4.)

The research question addressed in this work is the feasibility of deriving the spatial distribution of shear and friction coefficients that makes the 1D model comply with the post-processed CFD data. Moreover, in this work, we do not (yet) link the closure parameters to the state, which is a more complex task and should be studied across a wide range of operating conditions. We focus on the parameters' spatial distributions and their derivation by implementing the physics-separated and physics-integrated approaches.

3.3. Calibration

Physics-separated approach

Following the framework in Section 2., the physics-separated approach consists of calculating the closure coefficients from the processed CFD data. To this end, equations (7) and (8) can be used to compute the 1D shear and friction coefficients (f_{ps} and f_w) if all the other terms are extracted from data via appropriate processing. These two equations give:

$$f_{ps} = -\frac{2A_p}{l_{ps}\gamma\left(M_p^2 - M_s^2\right)}\frac{d_x p_{tp}}{p_{tp}} \quad \text{and} \quad f_w = -\frac{2A_s}{l_w \gamma M_s^2}\left(\frac{d_x p_{ts}}{p_{ts}} - \frac{1}{2}\frac{f_{ps} l_{ps}}{A_s}\gamma\left(M_p^2 - M_s^2\right)\right). \tag{13}$$

Both definitions rely on the differentiation of pressure evolution, computed using finite differences on a smoothed version of the signal. The derivation was carried out with a second-order centred scheme, while the smoothing was carried out with a Savitzy-Golay filter with a second-order polynomial. The resulting closure coefficients are, therefore, functions of the spatial coordinate x and could be linked to the local value of the state variables $\boldsymbol{u}$, or local values of dimensionless numbers such as Reynolds and Mach numbers in each stream, or pressure and temperature ratios. However, this regression has a high risk of overfitting because the flow field (and thus the closure coefficients) can change drastically with the operating conditions. This challenging regression requires a large dataset and is foreseen for future work. This work focuses on a single off-design operating point, with regression as a function of the axial coordinate x. Practically, we minimize the cost function (2) separately for the shear and the wall friction coefficient with a parametric function g heuristically constructed after analyzing the data. The specific choice is provided in Section 4.1.. Note that we can split the regression in two smaller problems because the predicted closure coefficients $\boldsymbol{p}$ can be evaluated independently against their references $\tilde{\boldsymbol{p}}$.

Physics-integrated approach

The closure coefficients derived in the previous section are those that minimize the error in the definitions (13), but this does not guarantee that the model prediction is the most accurate. The complex interplay of this parameter with the other equations in the model (6)-(11) introduces additional sensitivities to the model prediction. The physics-integrated approach seeks to account for all of these using the cost function (3) to penalize model prediction (that indirectly depends *also* on the parameters). In the investigated calibration problem, the observed quantities included in the cost function are the pressures p_{tp} and p_{ts} and the cross-sections A_p and A_s. The static pressure p is not included because the shock trains make p_p and p_s oscillate. Since the 1D model can only reproduce the mean trends due to the assumption of equal static pressures, this oscillation could unfairly penalize the model prediction and produce local minima in the cost function landscape. Moreover, the total temperature is excluded because it is assumed to be constant in the mixing pipe and

thus does not contribute to accentuating the cost function gradient distribution along the spatial coordinate. Finally, an additional term is added at the exit ($x = L$) to penalize the potential error on the back pressure. This penalization helps enforce the boundary condition of the model. Therefore, the cost function (3) for this approach becomes

$$J_2(\boldsymbol{w}) = \sum_i \left[\frac{(\tilde{p}_{tp,i} - p_{tp,i}(g))^2}{(\tilde{p}_{tp,i})^2} + \frac{(\tilde{p}_{ts,i} - p_{ts,i}(g))^2}{(\tilde{p}_{ts,i})^2} + \frac{(\tilde{A}_{p,i} - A_{p,i}(g)^2}{(\tilde{A}_{p,i})^2} + \frac{(\tilde{A}_{s,i} - A_{s,i}(g))^2}{(\tilde{A}_{s,i})^2} \right] + \frac{\tilde{p}(L) - p(g, L)}{\tilde{p}(L)} \tag{14}$$

where the summation is carried out over the available instances (e.g. grid points in x), the functional dependency on g denotes the model prediction based on the closure g and the summation over the index r is made explicit over the four variables involved. We recall that the closure function depends on weights $\boldsymbol{w}$, i.e. $g := g(x, \boldsymbol{w})$. For a given guess of the weights, hence a given closure law $\boldsymbol{p} = g(x, \boldsymbol{w})$, the cost function $J_2(\boldsymbol{w})$ in (14) is computed by first solving numerically the set of equations in (6)-(11) using a shooting method.

4. Results

4.1. Physics-separated approach

Figure 3 shows the original and filtered 1D distributions of the total pressure in both streams from the post-processed CFD, from the exit of the primary nozzle at $x/L = 0$ to the exit of the numerical domain at $x/L = 1$ (cf. equations (5)). The total pressures equalize for $x/L > 0.4$, as a result of the mixing process and the growth of the shear layer separating the two streams. After this equalization, the two streams are fully mixed and indistinguishable, driven by a common total pressure and temperature. The zoom Z1 (shown on the right) displays a sharp drop in total pressure at $x/L = 0.025$. This corresponds to the Mach disk in figure 2. This is a 2D effect which can not be reproduced by the 1D model and is thus better filtered out before the data is used for calibration. The filtered signal thus 'averages' the shock train for the computation of the closure coefficients. The window length of the Savitzky-Golay filter has been tuned to this end.

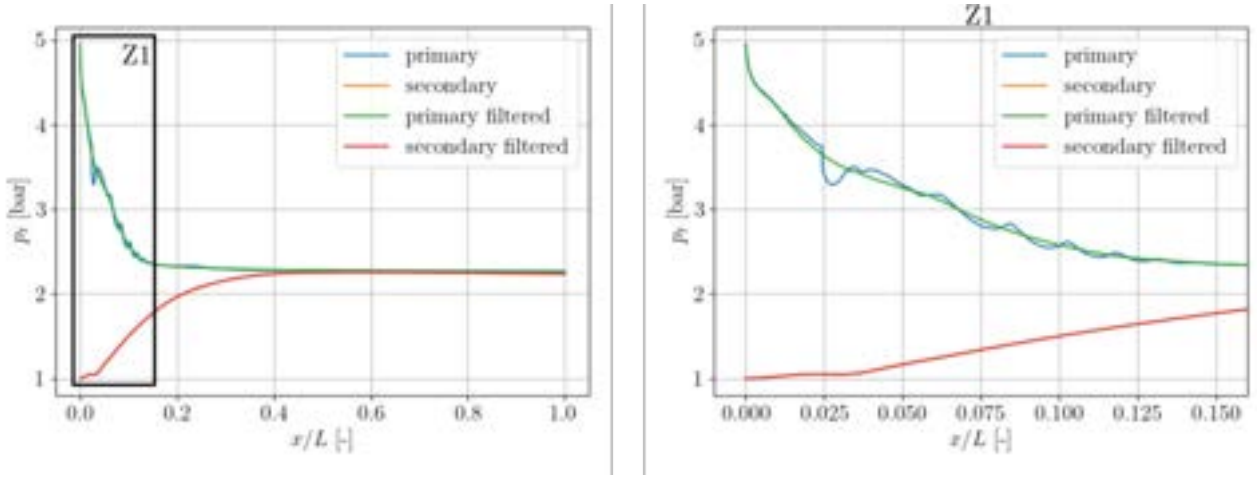

Figure 3: Filtering of the 1D total pressure field obtained through post-processing the CFD simulation in figure 2. The total pressures tend towards a common value as the primary and secondary streams exchange momentum. The shock train at the inlet of the mixing pipe strongly affects the primary total pressure, which is therefore filtered with a Savitzky-Golay filter before being differentiated (cf. equations (13)). The filtered secondary total pressure coincides with its raw counterpart since it is already quite smooth.

The shear and friction coefficients computed with equations (13) are shown in figures 4 and 5 respectively. The unfiltered coefficients show a sharp peak at the position of the Mach disk, as the primary total pressure changes suddenly at this point. This artefact is avoided through filtering. Still, both results indicate large coefficients at the inlet of the mixing pipe, especially in the wall friction f_w, which reaches an extreme value of 25 (with values expected to be of the order 0.01). A possible explanation could be the separation region behind the wall between the exit of the primary nozzle and the secondary inlet. This trailing edge is not sharp, so it is followed by a region of separated flow which slows down both the primary and the secondary stream through shear. This effect is locally quite strong for the primary flow due to a momentum deficit between the sonic flow and the stagnant flow in the bubble, hence a large value of the shear coefficient f_{ps}. However, this force is applied equally but with an opposite sign on the secondary flow, which therefore tends to *accelerate* rather than *decelerate*. In turn, a high wall friction coefficient is thus needed to overcome this numerical acceleration and still represent the actual friction forces on the secondary stream.

The peak at the inlet of the mixing domain shows an exponential decay, so an exponential function is chosen in the parametric closure function g for the calibration. Downstream, the evolution is rather flat, except for the oscillations induced by the shock train. Therefore, the closure function g is parametrized with a linear trend downstream. This leads to the following parametric function with 5 weights:

$$\begin{cases} y = w_1 + w_2 \exp(-w_3 x) & \text{if} x \leq w_0 \\ y = w_1 + w_2 \exp(-w_3 w_0) + w_4 x & \text{if} x > w_0 \end{cases} \tag{15}$$

This function is used for both closure coefficients, bringing the number of weights to 10. The mismatch with the post-processed coefficients is minimized using the summed squared error as a cost function and with the BFGS algorithm available in SciPy [20]. The gradient computation is performed with finite differences, which is affordable due to the low cost of the function to be called and the low number of weights. The resulting regression is shown alongside the raw and the filtered signals in figures 4 and 5.

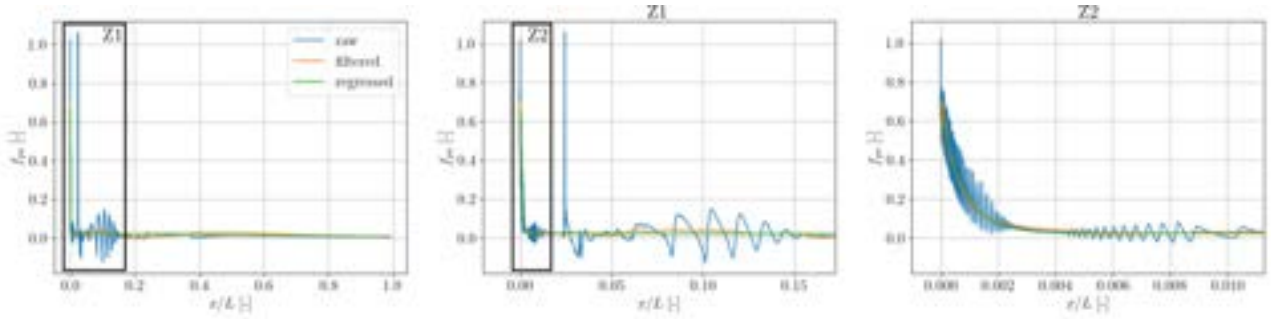

Figure 4: Shear coefficient calculated from the raw and filtered total pressure field from figure 3 with equation (13). The exponential decay at the inlet is attributed to a separation bubble at the exit of the primary nozzle. The calculation on the raw signal suffers from sharp gradients in the shock train and the Mach disk ($x/L = 0.025$). The physics-separated regression is carried out with equation (15) on the filtered shear coefficient f_{ps}.

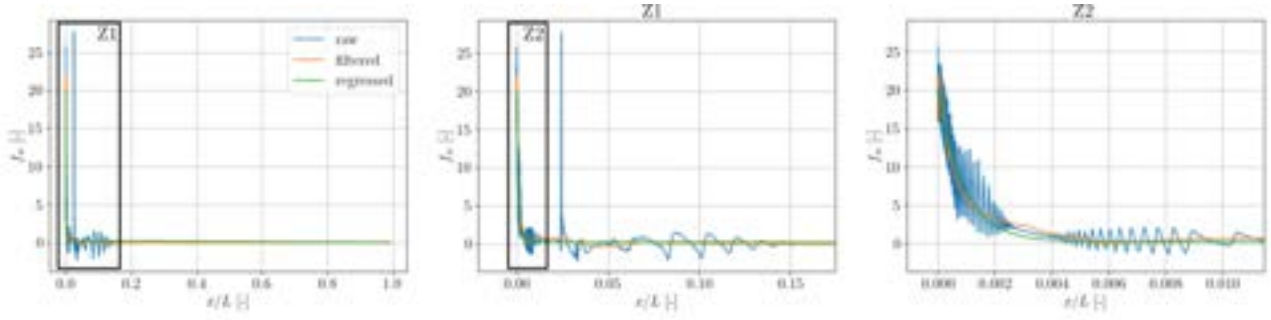

Figure 5: Wall friction coefficient calculated from the raw and filtered total pressure field from figure 3 with equation (13). The same trends are observed for the shear between the streams (cf. figure 4), so the same parametric function is used for the regression.

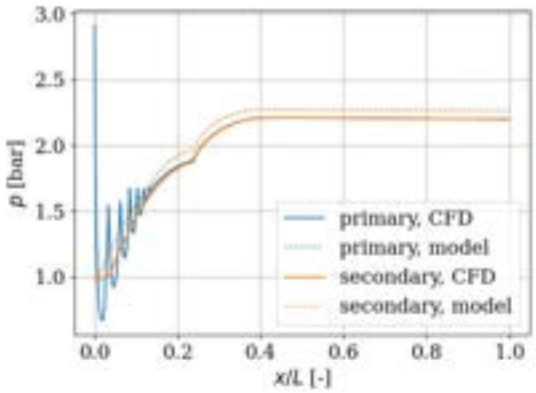
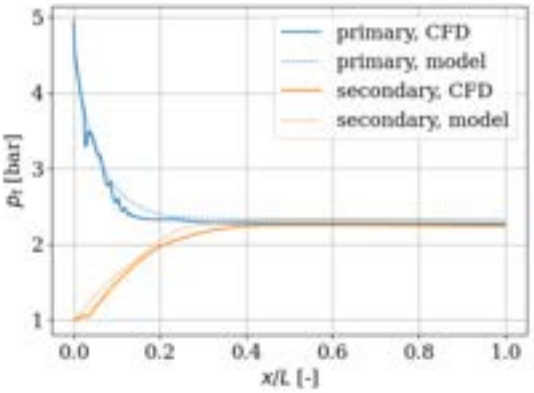
Next, we use the regressed closure relation to predict the flow field of the ejector with the 1D model. The resulting flow field compares well to the post-processed CFD (cf. figure 6). Upstream, the cross-section is imposed by the CFD, leading to a close match. Downstream, the unique pressure deviates from the values in the CFD due to the shock train (the primary stream is particularly affected). Nevertheless, the 1D model captures the global rising trend. This pressure increase arises from the momentum exchange between the two streams of the compound flow (cf. equation (6) with $\beta > 0$). The pressure rises more strongly in the diffuser from $x/L = 0.23$ and reaches a constant value where the streams reach the same total pressure. The constant total temperature in the 1D-2s model matches the post-processed CFD within 3 K. The deviation is attributed to the low enthalpy in the separation bubble at the exit of the primary nozzle, which influences the total temperature field downstream near the dividing streamline. The constant total temperature remains a good approximation for the bulk of the streams. Thermal mixing through different inlet temperatures is foreseen as a future extension of the 1D-2s model.

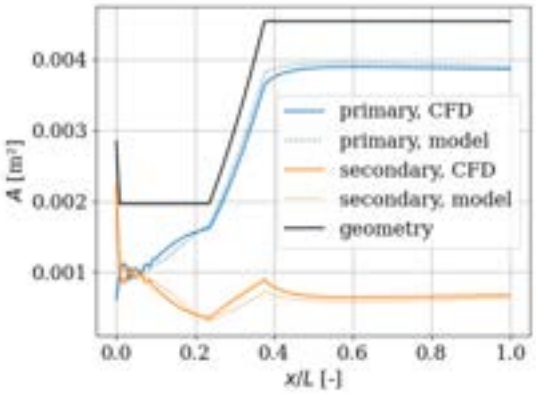
Despite the indirect penalization on the closure coefficients, an excellent match is obtained. The assumption of equal static pressure in both streams proves to be an acceptable assumption to close the system of equations (6)-(11) (at least in this off-design operating point). The match of the cross-sections between the 1D model and the CFD best validates the model. However, the 1D model shows a mismatch in back pressure (2.3 bar in the model and 2.2 bar in the CFD). The formulation with the ODEs always requires a shooting method to match a boundary condition at the exit of the domain ($x = L$), but none of the flow quantities is penalized in the physics-separated approach. Therefore, we apply the physics-integrated method in the next section to improve the prediction in the flow quantities both in the internal domain and the boundary condition for the static pressure.



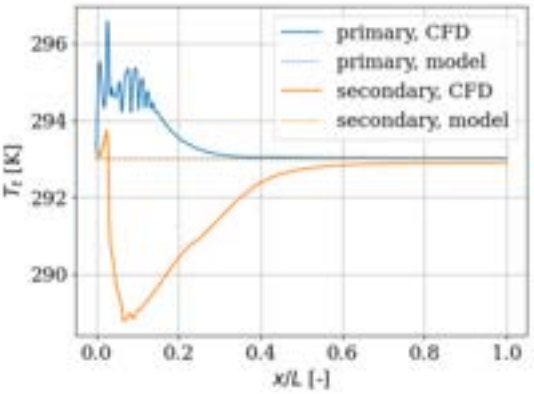
(a) Static pressure p



(b) Total pressure p_t



(c) Cross-section A



(d) Total temperature T_t

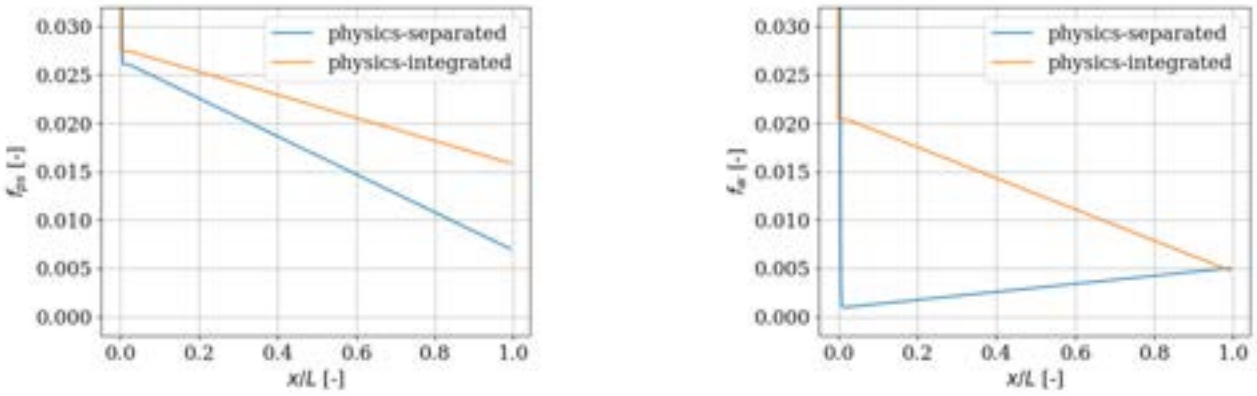
Figure 6: Model predictions with the regressed closure relation from the physics-separated approach (cf. figures 4 and 5). All variables match the post-processed 1D data quite well (the cost function (14) equals 0.0044). However, the boundary condition of the static pressure at the outlet is not met due to the indirect regression on the post-processed closure coefficients instead of on the physical quantities (cf. equations (2) and (14)).

4.2. Physics-integrated approach

The closure relation from the section above serves as an initial guess for the physics-integrated approach, where the prediction error on the physical quantities is minimized (including the back pressure as a boundary condition, cf. equation (14)). The resulting evolution of the shear and friction coefficients is shown in figure 7. The wall friction coefficient increased significantly, resulting in lower static pressure and a satisfied boundary condition (cf. figure 8a). An increased shear coefficient compensates for the corresponding loss in secondary total pressure. Finally, we note that the exponential decay between the inlet and $x/L = 0.01$ from figures 4 and 5 has sharpened, which results in a flat plateau in the coefficients in figure 7. This indicates the extreme values found with the physics-separated approach were not necessary.

The physics-integrated approach has decreased the value of the cost function (equation (14)) from 0.0044 with the initial guess from the physics-separated approach to 0.0036. This significant improvement can be appreciated visually by comparing figures 6 and 8. However, the integrated approach is less straightforward

a priori; one does not know which type of parametric function allows a close match. Additionally, initializing the weights is also non-trivial. For example, an excessive wall friction coefficient could decrease the static pressure enough to choke the flow and lead to problems in the integration of the system of ODEs (which becomes singular if $\beta = 0$). Therefore, the initialization through the physics-separated approach followed by fine-tuning with the physics-integrated proves an effective strategy for the model calibration, profiting from their complementary advantages.



(a) Shear coefficient f_{ps}

(b) Wall friction coefficient f_w

Figure 7: Comparison of the regressed closure relations of the physics-separated and the physics-integrated approach. The first serves as initial guess for the latter method and is optimized to minimize cost function (14) (final value of 0.0036). A significant increase of the wall friction coefficient has allowed to decrease the static pressure in the mixing duct, leading to a satisfied boundary condition (cf. figure 8a).

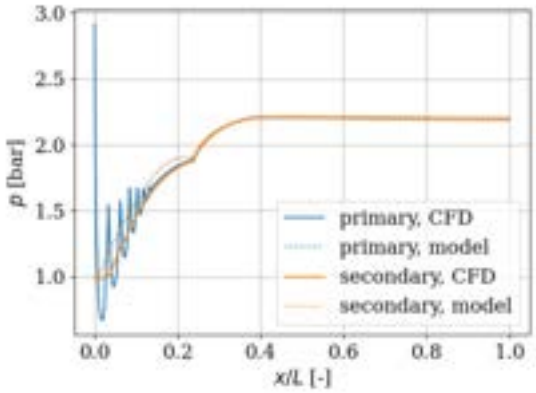
5. Conclusion

This work proposes a general machine learning framework for calibrating physical models governed by a system of ODEs. We have explored a physics-separated approach, which consists of calculating the closure coefficients from higher resolution data (CFD) and then regressing the post-processed coefficients, and a physics-integrated approach, where the model is called upon during the optimization (training) phase to minimize the prediction error on the observed physical quantities. Both approaches have been applied successfully on a 1D ejector model to find the shear and wall friction coefficients as a function of the spatial coordinate.

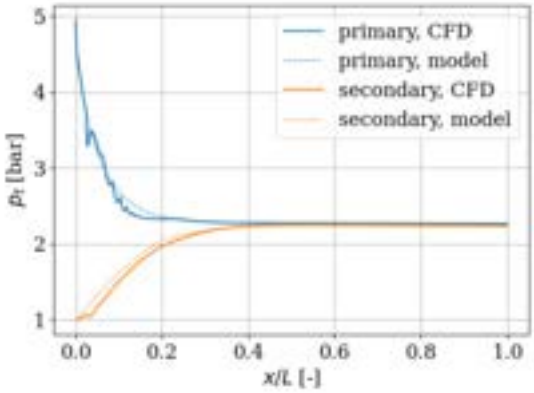
The results show that a successive application of both approaches proves to be a convenient and robust method to calibrate the 1D model. The physics-separated approach guides the choice of the parametric function and provides a valid initial guess for the physics-integrated approach,. This then acts as a refinement tool to further minimize the prediction error by *directly* penalizing mispredictions in the state variables.

The proposed methodology is robust and flexible: it is compatible with state-of-the-art optimizers and leaves a free choice of the regressor. Any parametric tool fits the framework, ranging from linear regression to artificial neural networks. Furthermore, the method brings physical insight through closure relations for low-order but highly interpretable models. Finally, the framework can be categorized as physics-*constrained*, as opposed to physics-*informed*, machine learning since the conservation equations are always respected. From a more global perspective, splitting the problem in a set of physical equations f and closure relations g (cf. equation (1)) allows the continued use of dedicated solvers for the physical problem f, which are conservative and efficient, and simplifies the machine learning task by restricting its scope to the closure problem g. In this sense, the framework is an extension of neural ODEs, which solve the combined problem of f and g with neural networks without including prior physical knowledge. Consequently, less complex regressors may suffice for solving the problem, reducing the amount of required data or improving the performance on a fixed dataset.

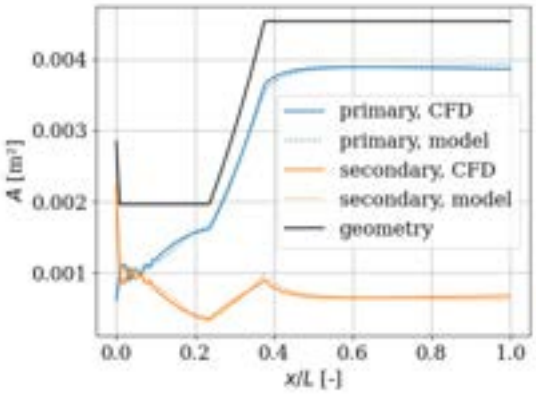
Improvements are foreseen on two fronts. Firstly, the 1D ejector model is currently being extended to on-design operation with a pressure equalization mechanism to remove the requirement of imposing the cross-section from CFD at the inlet of the mixing pipe. Secondly, the adjoint method is being explored to handle closure laws requiring many weights (e.g., neural networks). Finally, the closure coefficients can be linked to the state variables rather than space coordinates to discover more universal closure relations for the 1D ejector model. This will require an extensive study on operating conditions and various geometries.



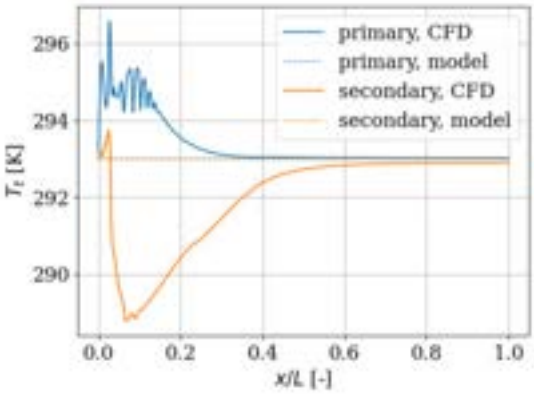
(a) Static pressure p



(b) Total pressure p_t



(c) Cross-section A



(d) Total temperature T_t

Figure 8: Model predictions with the regressed closure relation from the physics-integrated approach (cf. figure 7). The agreement improved compared to the physics-separated approach in figure 6 (the cost function (14) equals 0.0036). Moreover, the boundary condition of the static pressure at the outlet is now respected.

Appendix A Derivation of the 1D ejector model from first principles

The base equations of the 1D model are the quasi-1D Euler equations with a force term F:

$$d_x(\rho_i A_i V_i) = 0; \quad d_x(\rho_i A_i V_i^2) = -A_i d_x p_i + F_i; \quad d_x(\rho_i A_i V_i h_{ti}) = 0 \tag{16}$$

where the index i denotes either the primary (p) or the secondary stream (s). The following equivalent system can be derived from these conservation equations (cf. [26] for a detailed derivation):

$$\frac{d_x p_i}{p_i} = \left[\frac{1+(\gamma-1)\,M_i^2}{1-M_i^2}\right]\frac{F_i}{A_i p_i} + \left[\frac{\gamma M_i^2}{1-M_i^2}\right]\frac{d_x A_i}{A_i}; \quad \frac{d_x p_{ti}}{p_{ti}} = \frac{F_i}{A_i p_i}; \quad \frac{d_x T_{ti}}{T_{ti}} = 0 \tag{17}$$

The wall friction force acts on the secondary stream and is defined through a classic friction coefficient:

$$F_w = -\frac{1}{2} f_w \rho_s v_s^2 = -\frac{1}{2} f_w \gamma p_s M_s^2 \tag{18}$$

The shear force is defined in a similar way and depends on the difference in dynamic pressure:

$$F_{ps} = \frac{1}{2} f_{ps} \left(\rho_p v_p^2 - \rho_s v_s^2 \right) = \frac{1}{2} f_{ps} \gamma p \left(M_p^2 - M_s^2 \right) \tag{19}$$

The primary and secondary forces are given by $F_p = -F_{ps}$ and $F_s = F_{ps} + F_w$. Combining the equations above results in equations (7) and (8). The equation for the static pressure results from the assumption of equal static pressure in both streams. The first step is to inverse equation (17) in terms of the area:

$$d_x A_i = \left[A_i \frac{1 - M_i^2}{\gamma M_i^2} \right] \frac{d_x p}{p} - \left[\frac{1 + (\gamma - 1) M_i^2}{\gamma M_i^2} \right] \frac{F_i}{p} \tag{20}$$

where the static pressure p lost the index because we assume $p_p = p_s$. Equations (10) and (11) for the gradient of the cross-sections follow from the equation above after filling in the forces. We sum the equation above for both streams and obtain the gradient of the known geometry $A = A_p + A_s$:

$$d_x A = \left[A_p \frac{1 - M_p^2}{\gamma M_p^2} + A_s \frac{1 - M_s^2}{\gamma M_s^2} \right] \frac{d_x p}{p} - \left[\frac{1 + (\gamma - 1) M_p^2}{\gamma M_p^2} \right] \frac{F_p}{p} - \left[\frac{1 + (\gamma - 1) M_s^2}{\gamma M_s^2} \right] \frac{F_s}{p} \tag{21}$$

The first term corresponds to the compound choking indicator β from equation (12). We reverse the equation above, to obtain the following expression of the pressure gradient:

$$\frac{d_x p}{p} = \frac{1}{\beta} \left(d_x A + \left[\frac{1 + (\gamma - 1) M_p^2}{\gamma M_p^2} \right] \frac{F_p}{p} + \left[\frac{1 + (\gamma - 1) M_s^2}{\gamma M_s^2} \right] \frac{F_s}{p} \right) \tag{22}$$

Equation (6) follows after filling in the forces and some simplifying operations.

Nomenclature

Letter symbols

e	specific internal energy, J/(kgK)
f_{ps}	shear coefficient, $-$
f_w	wall friction coefficient, $-$
l_{ps}	perimeter of the primary cross-section, m
l_w	perimeter of the wall, m
$\dot{m}$	mass flow rate, kg/s
p	pressure, Pa
r	radial coordinate, m
t	time, s
u	axial velocity, m/s
x	axial coordinate, m
A	cross-section, m^2
F	force per unit length, N/m
L	length of the ejector, m
M	Mach number, $-$
R	wall radius, m
T	temperature, K
$\boldsymbol{p}$	vector of closure parameters, $-$
$\boldsymbol{u}$	state vector, $-$
$\boldsymbol{w}$	weight vector, $-$

Greek symbols

β	compound choking indicator, m^2
γ	ratio of specific heat capacities (air: 1.4), $-$
ρ	density, kg/m^3

Subscripts and superscripts

$\hat{\cdot}$	cross-sectional average of a variable
$\tilde{\cdot}$	observation of a variable
b	back, outlet of the ejector
p	primary stream
s	secondary stream
t	total quantity (pressure, temperature, internal energy)

Abstract:
Sound generated by air diffusers is a factor that affects a productive working environment and therefore plays an important role in the operation of HVAC systems. A reliable prediction of sound sources and levels offers the potential to minimise noise emissions by modifying geometric features in the early design stage of air diffusers. The research field of aeroacoustics yielded many approaches to compute not only sound propagation but also sound generation in airflows. Based on the prominent Lighthill analogy the Curle analogy and Proudman analogy were developed. In this work, we investigate a commercially available slot diffuser. The airflow through the diffuser is calculated using steady-state simulations at diffuser outlet velocities of 4, 6 and 8 m/s, which corresponds to roughly 181, 267 and 351 m^3/h, respectively. To evaluate the influence of the solid surfaces we compute the emission according to Curle's analogy. We further use Proudman's analogy to assess the effect of the freestream. Based on the flow simulation geometric optimisations are proposed. By design, a steady-state simulation is not able to capture time-resolved phenomena, such as periodic vortex shedding. But since they are far less demanding in regards to computational resources, we can simulate a wider variety of flow conditions. By identifying the primary sound source regions we not only increase the awareness towards the impact of certain flow structures, such as large scale vortex systems, but also offer a first indicator of possible design optimisations. The computed flow field is to be validated with near-field Laser-Doppler-Anemometry (LDA) measurements.

Aeroacoustics, Slot Diffuser, Flow Simulation, Aeroacoustics Analogy.

1. Introduction

In addition to thermal comfort, the acoustic environment also affects the general perceived comfort in buildings. Since legislation and increasing public awareness require the ventilation of public buildings, the associated acoustic emissions are gaining importance. While ventilation noise is desirable to some degree to mask other noise sources, the ventilation system should generally be as quiet as possible. The components transmitting the ventilation noise into the occupied room are air diffusers.

Typical air diffusers can be divided into two common groups: swirl and slot diffusers. In this work, we focus on the investigation of a commercially available two-slot diffuser, which is shown in Figure 1. To gain insight on the flow field, we use a detailed flow simulation which provides us the strength of acoustic sources based on a steady-state solution.

In his PhD thesis Tautz [13] performed a detailed investigation of an automotive ventilation system. He was able to reproduce not only the acoustic spectrum but also the location of the acoustic sources. The computation however required significant computational ressources.

Ravichandran et al. [11] investigated a generic automotive diffuser with disturbed inflow conditions. They used detailed transient flow simulations to compute the acoustic emissions. Although not explicitely evaluated, the main features contributing to the acoustic emissions were the guiding flaps inside the diffuser.

Kusyumov et al. [7] succesfully applied a steady-state simulation to an isolated helicopter fuselage to predict broadband noise sources. Their case included Mach numbers greater than in our case, but it demonstrates the ability of Proudman's model to predict noise emissions.

For a generic slot diffuser we already showed, that the main acoustic sources are located near sharp edges [9]. Here a steady-state simulation indicated the same regions as a transient simulation. Therefore we deem it possible to identify the main noise source regions by steady-state simulations, if the spectral distribution of the noise is not of greater interest.

Although some researchers have adressed the acoustic emissions of air diffusers in the automotive sector, a

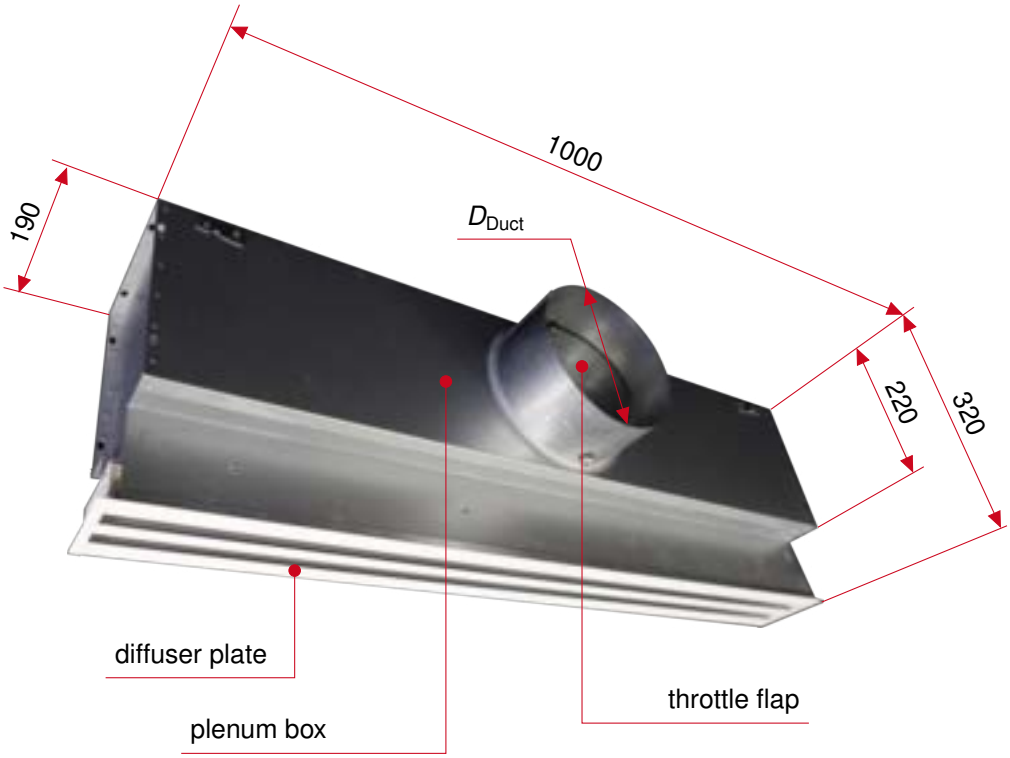

Figure 1: Picture of the investigated diffuser, dimensions given in mm

detailed investigation of the acoustic emissions of air diffusers applied in buildings have not been investigated. In this work we aim to investigate the acoustic behaviour of a slot diffuser while reducing the computational cost to locate the geometric features mainly responsible for the acoustic emission. A transient simulation offers a detailed investigation of acoustic phenomena (see [11, 13]). However the lower fidelity of a steady-state simulation is sufficient, if one is only interested in determining the main source locations (see [7, 9]).

2. Methodology

In this section we first describe the geometry of the slot diffuser and explain certain simplifications we made. We then explain the numerical and experimental setup, where the latter is needed to validate our simulations. We then present our method to rate the broadband noise emission. The slot diffuser is investigated at three diffuser outlet velocities $v_D = 4$, 6 and 8 m/s, which correspond to volume flow rates of $\dot{V} = 181$, 267 and 351 m^3/h. The diffuser outlet velocity is defined as the maximum occuring velocity within the diffuser.

2.1. Description of the geometry

Figure 1 shows the slot diffuser consisting of a circular connection duct with diameter D_{Duct}, that is connected to a plenum box. In order to limit the volume flow, an additional, perforated throttle flap is implemented in the connecting section between duct and plenum box. Preliminary simulations show, that the perforation has a negligible impact on the flow and aeroacoustic results, which is why we simplify the throttle flap by a solid round plate. The beams visible in Figure 2a, which are required to attach the diffuser plate to the plenum box, are also omitted to reduce the model size. Using the length of the plenum box l_{Plenum}, the diffuser plate features two rectangular slots with length $l_{Slot} = l_{Plenum}$ and width b_{Slot} (see Fig. 2c). Both slot channels are separated by a wall (see Fig. 2b), resulting in a total diffuser width of $b_{diffuser}$.

To alter the outlet flow pattern, both slots feature adjustable flaps, which are visible in Figure 2b. By changing the flap angle α_{Flap}, the exit flow angle can be varied between a ceiling-attached or ceiling-normal direction. In our study we only investigate the ceiling-attached case, since this is the most common setting. The geometric parameters are summarised in Table 1 and a detailed view of the simplified geometry used for the simulation is shown in Figure 2c.

2.2. Modelling of the flow and broadband noise

The slot diffuser is modelled in the commercially available software package STAR-CCM+ (17.06.008) from Siemens [12]. Although acoustic phenomena are by definition of transient nature, several models have been developed in the past to capture at least the acoustic sources from steady-state simulations. The use of

Table 1: Geometric parameters of the prepared slot diffuser

Parameter	Value	Unit	Description
D_{Duct}	198	mm	Connection duct diameter
l_{Slot}	997	mm	Length of the rectangular slots
b_{Slot}	20.5	mm	Width of one rectangular slot
α_{Flap}	43.5	°	Angle of the slot flaps

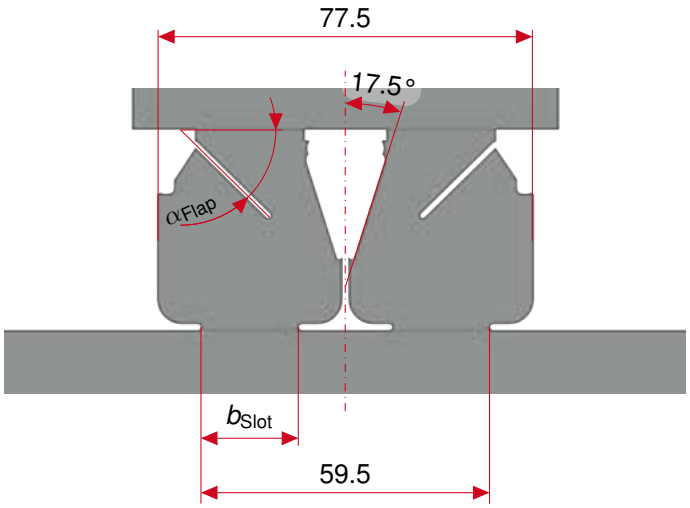
(b) Picture of the diffuser plate



(c) Prepared geometry for the simulation model, dimensions in mm

Figure 2: Detail view of the diffuser outlet region

steady-state simulations offers significant savings in computational effort.

To accurately resolve all important geometric features, we employ an unstructured polyhedral mesh with a resolution up to $\Delta = 0.25\,\text{mm}$ near the curvatures of the flaps. Inside the plenum, the average resolution is kept close to $\Delta \approx 1.5\,\text{mm}$. We resolve the boundary layer with $n_{\text{Prism}} = 7$ prism layers with a total thickness of $\Delta_{\text{Prism}} = 2\,\text{mm}$ which results in $y^+ < 1$ in all important areas. To prevent steep gradients of mesh resolution, we set both the surface and the volumetric growth rate to 1.05. The total mesh size is $n_{\text{Cells}} \approx 61 \cdot 10^6$ cells. We use the same mesh for all simulations, since only the inlet mass flow changes.

We assume the air flow to be incompressible with a constant density ρ (see Tab. 2). The steady-state simulation is computed using a segregated flow solver. We use a pressure-velocity coupling scheme (SIMPLE), which is designated for incompressible flows [12]. In addition to incompressibility, we assume the air to be isothermal. As turbulence model we select the realizable $k-\varepsilon$ - model with all y+ wall treatment, since in our case it gives a more accurate solution of the ceiling-attached flow than e.g. the $k-\omega$ - model.

We define the inlet boundary condition with a constant mass flow condition $\dot{m} = \rho \cdot \dot{V}$ and low turbulence intensity v'/v (see Tab. 2). The diffuser is connected to a large volume which represents part of a room. While the ceiling is modelled as a no-slip wall, the other faces of the room are modelled as a pressure outlet with $p_{\text{out}} = 0\,\text{Pa}$.

Two broadband noise source models are used to calculate the aeroacoustic sources. The first model computes

broadband noise from dipole sources as a surface acoustic power P^{a}_{Curle}, which are most dominant in the vicinity of solid boundaries. It evaluates the turbulent boundary layer and was first developed by Curle [2, 3] based on the work of Lighthill [8].

$$P^{a}_{\text{Curle}} = \frac{1}{12\,\pi\overline{\rho}\overline{c}^{3}} \cdot 4\pi^{3}\,\overline{(u')^{2}}\,\left(p'_{\text{Wall}}\right)^{2} \tag{1}$$

The fluctuations $\overline{(u')^{2}}$ and p'_{Wall} can be further simplified according to Hinze [6, pp. 668-680]. The simplification yields expressions that only depend on the turbulent kinetic energy k and the wall shear stress τ_{Wall}.

$$\overline{(u')^{2}} = \frac{2}{3}\max\left(k;\ \frac{3.3\,\tau_{\text{Wall}}}{\overline{\rho}}\right) \qquad \left(p'_{\text{Wall}}\right)^{2} = \max\left(3\,\tau_{\text{Wall}};\ 0.7\,\overline{\rho}\cdot\frac{2}{3}k\right)$$

The second model was developed by Proudman [10] based on the work of Lighthill [8] and computes broadband noise from quadrupole sources originating from free stream turbulence as a volumetric acoustic power P^{a}_{Proudman}. Here u_{t} and L are the turbulent scales for the velocity and length.

$$P^{a}_{\text{Proudman}} = \alpha\rho\frac{\left(\overline{u_{\text{t}}}^{2}\right)^{4}}{c^{5}\,L} = \alpha\rho\frac{\overline{u_{\text{t}}}^{3}}{L}\frac{\overline{u_{\text{t}}}^{5}}{c^{5}} \qquad \text{with } u_{\text{t}} = \sqrt{\frac{2}{3}k} \tag{2}$$

Both models assume isotropic turbulence, which is consistent with turbulence modelling assumptions.

2.3. Laser-Doppler-Anemometry setup

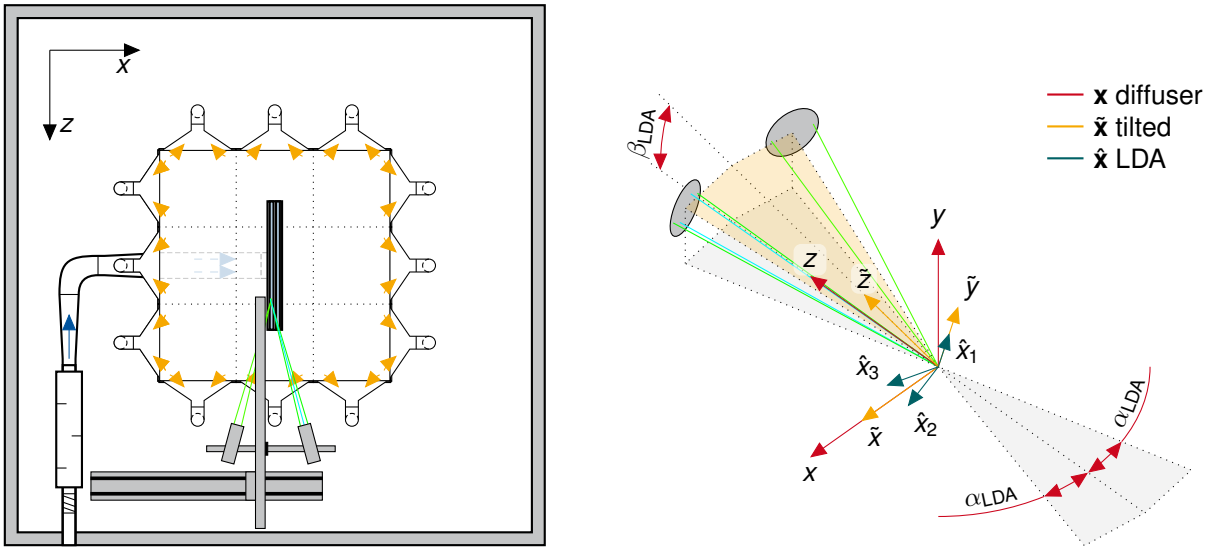
We use a 3D-LDA system from *Dantec* that consists of a 2D *FiberFlow* and a 1D *FlowLite* probe. With proper arrangment both probes form a 3D-setup that allows us to measure all three velocity components. All optical measurements are performed in a separate chamber, which allows for a completely dark environment. The required volume flow $\dot{V}$ is delivered by a supply unit located outside of the chamber. We calculate the volume flow by measuring the pressure drop over an orifice. This method is calibrated by using a reference orifice as specified in DIN EN ISO 5167 - 2.

A schematic view of the setup in the chamber is given in Figure 3a. The diffuser is fed with air by utilising existing openings in the chamber walls to allow a connection to the supply unit. When feeding the required DEHS particles the chamber quickly fills up with fog, which renders the LDA system unable to produce good results. To mitigate this problem, we install a special exhaust system that provides an additional volume flow $\dot{V}_{\text{ex}} > 1200\,\text{m}^3/\text{h}$ to ventilate the whole chamber (depicted by → in Fig. 3a). The exhaust system draws air from the test hall environment outside the chamber through an opening in the chamber ceiling. It is then distributed using a suspended ceiling such that the exhaust volume flow is guided downwards along the chamber wall until it is captured by the exhaust hoods. We use 12 hoods that are evenly distributed around the diffuser frame. All hoods feed into a collection plenum below the frame from which an additional fan draws the exhaust volume flow. The exhaust system ensures, that the LDA probes have clear sight on the target location and no fog accumulates during the course of the whole measurement.

The 2D probe is connected to a laser which generates wavelengths of 488 nm (blue laser) and 514.5 nm (green laser), while the 1D probe utilises a laser with a wavelength of 532 nm (green laser). Each velocity component is recorded separately in non-coincident mode, since a measurement in coincident mode requires much more time to acquire a sufficient number of samples. We use beam expanders to allow the mounting of lenses with a focal length of $f_{\text{LDA}} = 500\,\text{mm}$. We attach the probes to a movable traverse system, which allows us to automatically measure a wide range of locations. Both probes are aligned along the z-direction of the diffuser with an angle of $\alpha_{\text{LDA}} = 15°$ and therefore enclose an angle of 30°. We further tilt the whole probe system by $\beta_{\text{LDA}} = 15°$ to allow for a measurement at $y = 0\,\text{mm}$. The diffuser coordinate system, that we use in this paper, is colored red in Figure 3b.

Table 2: Parameters of the flow and aeroacoustic models

Parameter	Value	Unit	Description
ρ	1.18415	$\text{kg}\,\text{m}^{-3}$	Density of the air
T	25	°C	Temperature of the air
v'/v	0.01	-	Inlet turbulence intensity
c	343	$\text{m}\,\text{s}^{-1}$	Speed of sound
$P_{\text{ac,ref}}$	$1 \cdot 10^{-12}$	W	Reference value of the acoustic power



(a) Schematic of the LDA setup in the measurement chamber

(b) Sketch of the coordinate transformation

Figure 3: Setup of the LDA measurement and definition of the diffuser coordinate system

For each measured velocity component u_i, we acquire $N_i \geq 5000$ samples over a maximum duration of 5 min per evaluation point. The averages are calculated by using the arithmetic average, where $N_1 \neq N_2 \neq N_3$ due to non-coincident measurement.

$$\overline{u_i} = \frac{1}{N_i} \sum_{k=1}^{N_i} u_i(k) \tag{3}$$

To calculate the velocity components within the diffuser coordinate system $\mathbf{x} = (x, y, z)$, two transformations are required. A sketch of the coordinate transformations is given in Figure 3b. The first transformation $\mathbf{A}$ is used to translate the probe signals from their coordinate system $\hat{\mathbf{x}} = (\hat{x}_1, \hat{x}_2, \hat{x}_3)$ into a tilted, intermediate coordinate system $\tilde{\mathbf{x}} = (\tilde{x}, \tilde{y}, \tilde{z})$.

The blue laser (488 nm) is oriented vertically and measures u_1. Both green lasers (514.5 nm and 532 nm) are aligned horizontally and measure u_2 and u_3 respectively. We then apply another rotation transformation $\mathbf{B}$ about the $\tilde{x}$-axis to acquire the velocity components in the diffuser coordinate system.

$$\tilde{\mathbf{x}} = \mathbf{A} \cdot \hat{\mathbf{x}} \quad \text{, with } \mathbf{A} = \begin{bmatrix} 0 & \frac{1}{2\cos(\alpha_{\mathrm{LDA}})} & \frac{1}{2\cos(\alpha_{\mathrm{LDA}})} \\ 1 & 0 & 0 \\ 0 & -\frac{1}{2\sin(\alpha_{\mathrm{LDA}})} & \frac{1}{2\sin(\alpha_{\mathrm{LDA}})} \end{bmatrix} \tag{4}$$

$$\mathbf{x} = \mathbf{B} \cdot \tilde{\mathbf{x}} \quad \text{, with } \mathbf{B} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(\beta_{\mathrm{LDA}}) & -\sin(\beta_{\mathrm{LDA}}) \\ 0 & \sin(\beta_{\mathrm{LDA}}) & \cos(\beta_{\mathrm{LDA}}) \end{bmatrix} \tag{5}$$

$$\mathbf{x} = \mathbf{B} \cdot \mathbf{A} \cdot \hat{\mathbf{x}} = \mathbf{C} \cdot \hat{\mathbf{x}} \tag{6}$$

We use the combined transformation matrix $\mathbf{C}$ to transform the velocity components and their respective variances.

2.4. Validation of the computed flow-field

To validate the flow field, the computed average velocity magnitude $\overline{|\mathbf{v}|}$ and the turbulent kinetic energy (TKE) k are compared with the LDA measurements. The steady-state simulation calculates time-averaged results only but directly reports the necessary values for $\overline{|\mathbf{v}|}$ and k.

In the case of the LDA measurements both values need to be computed from the recorded samples. For the velocity components, we can directly apply the coordinate transformation from equation 6 to the averaged probe signals $\overline{u}_{\mathrm{LDA}} = (\overline{u}_1, \overline{u}_2, \overline{u}_3)$.

$$\overline{\mathbf{v}} = \mathbf{C} \cdot \overline{u}_{\mathrm{LDA}} \tag{7}$$

Since we measure the variance of the velocity in the skewed LDA-coordinate system, we need to apply the transformation directly to the measured values. The transformation of the variances of u_i onto the x-direction

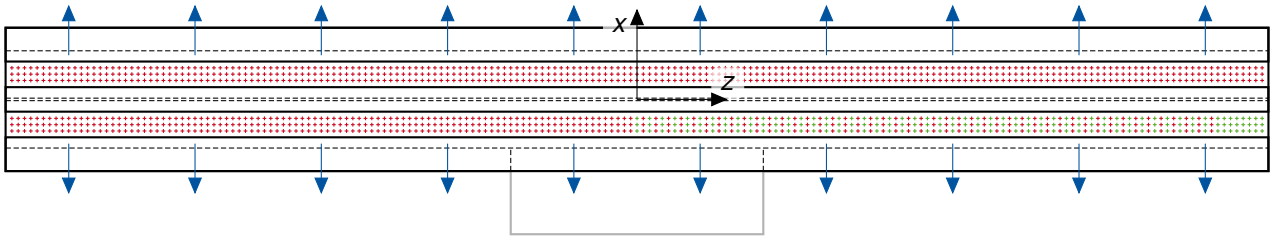


Figure 4: Evaluation points for the velocity field validation (green: LDA, red CFD)

is illustrated by equation 8, the other velocity components are treated similarly.

$$\overline{v_x'^2} = \left[\frac{1}{N_1}\sum_{i=1}^{N_1}\Big((u_1(i)-\overline{u_1})\cdot c_{11}\Big)^2\right] + \left[\frac{1}{N_2}\sum_{j=1}^{N_2}\Big((u_2(j)-\overline{u_2})\cdot c_{12}\Big)^2\right] + \left[\frac{1}{N_3}\sum_{k=1}^{N_3}\Big((u_3(k)-\overline{u_3})\cdot c_{13}\Big)^2\right] \tag{8}$$

Since the data rate for a full or semi-coincident measurement is too low, we are however not able to validate this approach yet. Finally, we use the transformed values to calculate the average velocity magnitude $\overline{|\mathbf{v}|}$ and TKE k according to equations 9 and 10.

$$\overline{|\mathbf{v}|} = \sqrt{\overline{v_x}^2 + \overline{v_y}^2 + \overline{v_z}^2} \tag{9}$$

$$k = \frac{1}{2}\left(\overline{v_x'^2} + \overline{v_y'^2} + \overline{v_z'^2}\right) \tag{10}$$

We validate the flow-field on the diffuser outlet plane at specific points on a x-z-plane at $y = 0\,\mathrm{mm}$. We spatially discretise the outlet section by $\Delta x = \Delta y = 5\,\mathrm{mm}$. The positioning of the validation points is displayed in Figure 4. Due to the limited spatial range of the LDA traverse system, we only measure points below $x < 0$ and above $z \geq 0$. We further reduce the number of points to be measured by downsampling the points towards the centre of the outlet and investigating only one slot. This is applicable as the flow field is symmetrical. Consequently, we measure the green points + with LDA. In the simulation, we additionally capture all red points +. In total, the outlet is discretised by 1194 points, of which 162 are measured with LDA.

The manufacturer's data sheet specifies certain operating points which are you used to validate the total-to-static pressure drop between the diffuser inlet $p_{\mathrm{tot,in}}$ and the ambient pressure in the chamber $p_{\mathrm{st,amb}}$. The inlet pressure is measured at the same section for the simulation and the experiment.

$$p_{\mathrm{tot,in}} = p_{\mathrm{st,in}} + \frac{\rho}{2}v^2 \tag{11}$$

$$\Delta p = p_{\mathrm{tot,in}} - p_{\mathrm{st,amb}} \tag{12}$$

Since the volume flow rates given in the data sheet do not match the simulated flow rates, the pressure drop is approximated.

$$\Delta p_{\xi,x} = \xi \cdot \dot{V}^x \tag{13}$$

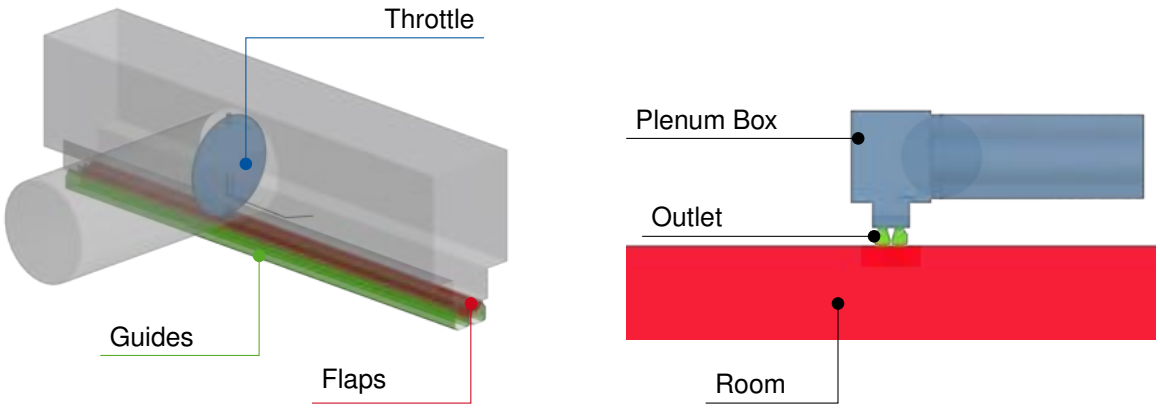
$$\min \sum_{i=1}^{N}\left(\frac{\Delta p_{\mathrm{data}} - \Delta p_{\xi,x}}{\Delta p_{\mathrm{data}}}\right)^2 \tag{14}$$

The pressure loss coefficient ξ and the exponent x are calulated by using a regression model, which minimises the sum of the squared errors. Using $\xi = 4.18 \cdot 10^{-4}$ and $x = 1.91$, we can approximate the data sheet values with a maximum relative error of MAE = $4.195 \cdot 10^{-2}$. By using the approximated pressure $\Delta p_{\xi,x}$ we can assess the error of the flow model regarding the pressure losses at the respective volume flow $\dot{V}$.

$$\Delta p_{\mathrm{error}} = \frac{\Delta p_{\mathrm{sim}}(\dot{V}) - \Delta p_{\xi,x}(\dot{V})}{\Delta p_{\xi,x}(\dot{V})} \tag{15}$$

2.5. Evaluation of aeroacoustic broadband noise

To evaluate the total broadband noise predicted by both aeroacoustic broadband noise models, we integrate their respective acoustic power values. The Curle model predicts noise emitted from surfaces, which is why we integrate its power on representative boundary surfaces (see Fig. 5a). Since Proudman's model computes



(a) Evaluation surfaces for the Curle calculation

(b) Evaluation volumes for the Proudman calculation

Figure 5: View on the surfaces and volumes used for the aeroacoustic broadband noise evaluation

a volumetric acoustic power, we apply a volume integral to specific subregions of interest (see Fig. 5b).

$$P_{\text{int,Curle}} = \int_S P^{\text{a}}_{\text{Curle}} \cdot ds \tag{16}$$

$$P_{\text{int,Proudman}} = \int_V P^{\text{a}}_{\text{Proudman}} \cdot dv \tag{17}$$

All integrated acoustic powers are then converted into the dB scale using the reference value $P_{\text{ac,ref}}$ (see Tab. 2).

$$P_{\text{ac,Curle/Proudman}} = 10 \cdot \log_{10}\left(\frac{P_{\text{int,Curle/Proudman}}}{P_{\text{ac,ref}}}\right) \tag{18}$$

By comparing the individual subsets, we can assign high noise emissions to individual geometric features. The selected subsets are shown in Figure 5. To evaluate the acoustic emissions from solid boundaries with Curle's model, we select three boundary subsets (see Fig. 5a). We further define three volumes in which we evalute the emissions from Proudman's model (see Fig. 5b). In both cases we also evaluate the overall emission from all boundaries (including the plenum box and the ceiling) and from the entire fluid region.

3. Results

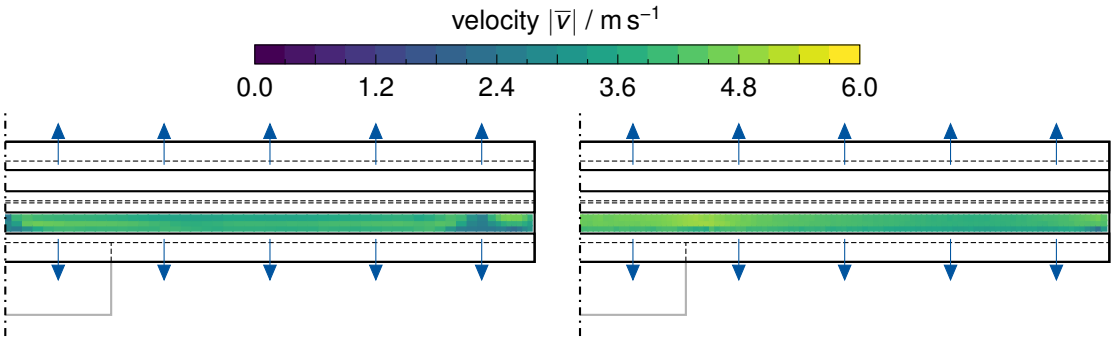
We give a detailed discussion and validation of the results for the medium diffuser velocity $v_{\text{D}} = 6\,\text{m/s}$ which corresponds to a volume flow of $\dot{V} = 267\,\text{m}^3/\text{h}$.

3.1. Flow field validation

To validate the flow field we reduce the evaluation to the half of the lower slot ($x < 0, z > 0$) that was measured with LDA (see Sec. 2.3.). The sampled fields are shown in Figure 6 with their respective available spatial sampling resolution (see Sec. 2.4.).

By applying the sampling we calculate the computed average velocity to $|\overline{v}|_{\text{avg,CFD}} = 4.13\,\text{m/s}$, which is slightly higher than the measured value of $|\overline{v}|_{\text{avg,LDA}} = 3.80\,\text{m/s}$. The relative deviation of the average velocity is $|\overline{v}|_{\text{avg,CFD}}/|\overline{v}|_{\text{avg,LDA}} < 8\,\%$. The maximum values are $|\overline{v}|_{\text{max,CFD}} = 5.13\,\text{m/s}$ and $|\overline{v}|_{\text{max,LDA}} = 4.75\,\text{m/s}$ respectively. Although we set the same volume flow rates in both simulation and measurement, small leakages in the ducting system and non-airtight edges of the diffuser may have contributed to discrepancies between our computed and measured results. In addition to the influence of the inlet duct, the beams inside the diffuser plenum box (see Fig. 2a) cause significant distortions in the flow field. In the centre and near the edge the wake is clearly visible by considerably lower velocities. Since the beams are neglected in the simulation setup, this leads to a significant local deviation. We still consider the computed velocity field to be valid, given the fact, that the beams are neglected. The overall lower average velocity in the measurement is explained by leakages in the measurement setup.

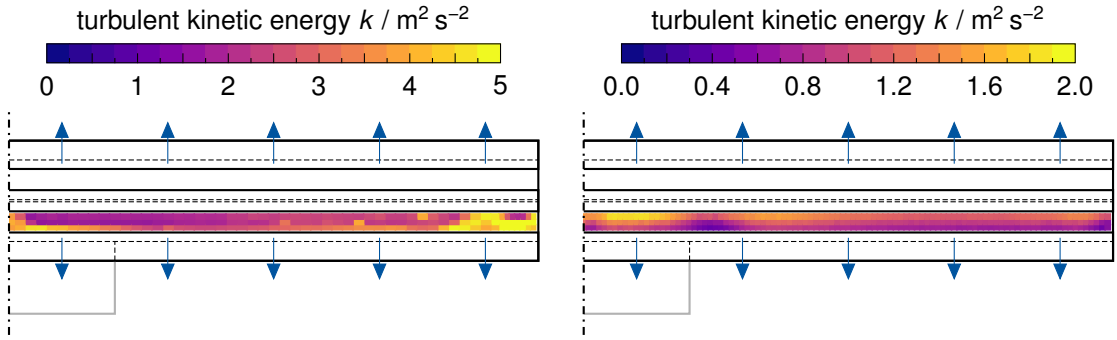
The sampled measured and computed TKE distributions are shown in Figure 7. We observe considerably higher measured levels than in the simulation. Again the wake of the beams is clearly notable, but even in the area between the beams the measured TKE values are approximately doubled. By design the simulation assumes isotropic turbulence ($v_{\text{x}}'^2 = v_{\text{y}}'^2 = v_{\text{z}}'^2$). However, the measurements show a strong anisotropic



(a) Measured flow field

(b) Computed flow field

Figure 6: Velocity field



(a) Measured turbulent kinetic energy

(b) Computed turbulent kinetic energy

Figure 7: Turbulent kinetic energy

behaviour. In our case the variance in z-direction is almost an order of magnitude higher higher than in the other directions ($v_z'^2 \gg v_y'^2 > v_x'^2$). Overall, the measured kinetic energy is higher than in the simulation and the impact of the beam wakes prevent a proper validation of the turbulence.

As an additional metric, we also assess the pressure drop across the diffuser. In Figure 8 the pressure drop Δp is plotted against the volume flow $\dot{V}$. The solid lines indicate the regression model as explained in Section 2.4. and the points represent the individual values. The evaluation shows no significant difference between the measured and simulated pressure drop. Furthermore the regression model shows practically the same slope over the investigated volume flow range. Since the measured and computed pressure drop is practically equal, we only summarise the data sheet and the computed values in Table 3. The data sheet reports a higher pressure drop than measured and computed but also shows a comparable slope. Since the setup used by the manufacturer to assess the pressure drop is unknown, the slightly higher values might be due to other ambient air conditions or differences in the setup. We consider the pressure drop and therefore the wall shear stresses τ_{Wall} to be valid as well, because the pressure drop of our measurement and simulation match (see Fig. 8)

In conclusion, we deem our simulation to be valid in regards to the averaged velocity field and the overall pressure drop across the diffuser. We compute significantly lower turbulence levels. In large parts we account this to the assumption of isotropic turbulence by the $k-\varepsilon$ - model. Another factor might be, that we achieve higher turbulence intensities at the diffuser inlet in our measurements. Since the computation of Curle's model is mainly defined by the wall shear stress instead of the low turbulent kinetic energy in the boundary layer (see eq. 1), we deem it's results sufficiently accurate.

Figure 9 shows the computed flow field on two sections through the whole diffuser which originate at $(x, y, z) = (0, 0, 0)$. The flow exits the diffuser at an angle of $\approx 40°$ and attaches to the ceiling shortly after exit, as can be seen in Figure 9a. The maximum diffuser velocity of $v_D = 6\,\text{m/s}$ occurs in the vicinity of the flaps at $y \approx -15\,\text{mm}$. The velocity field shown in Figure 9b is inhomogeneous, although it is nearly symmetric along the x-axis. The maximum velocity at the outlet plane is lower than the diffuser velocity ($|\overline{v}|_{\text{max},y=0} = 5.24\,\text{m/s} < v_D$), which can be attributed to the larger cross-sectional area available for the flow. By averaging the velocity in the outlet section, we can calculate the relative average velocity, which is roughly constant across all investigated

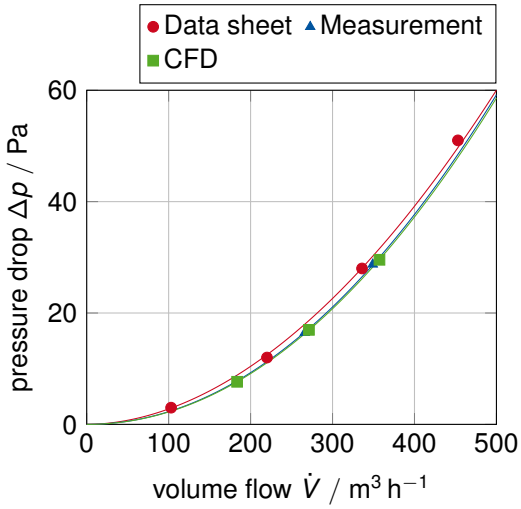


Figure 8: Validation of the pressure drop

Table 3: Overview of Δp_{error} values for the three computed volume flows

volume flow $\dot{V}$ m³/h	$\Delta p_{\xi,x}$ Pa	Δp_{sim} Pa	Δp_{error} %

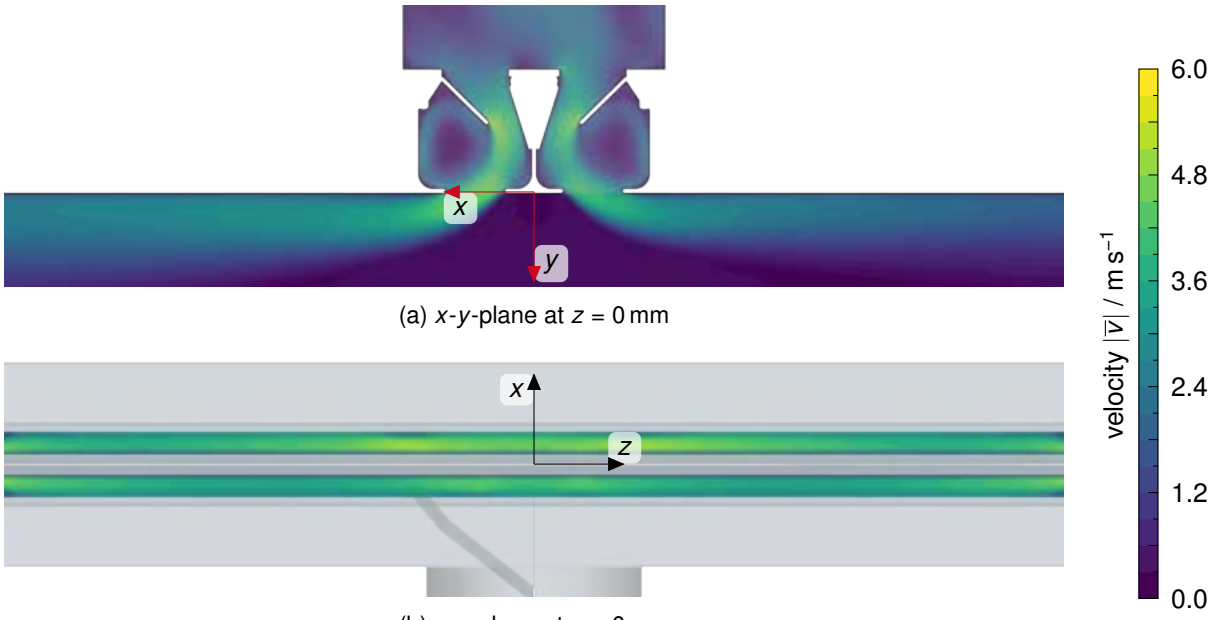
271	18.6	17.0	−9.0
357	31.6	29.6	−6.4



(a) x-y-plane at $z = 0\,\text{mm}$

(b) x-z-plane at $y = 0\,\text{mm}$

Figure 9: Computed velocity field for $v_{\text{D}} = 6\,\text{m/s}$

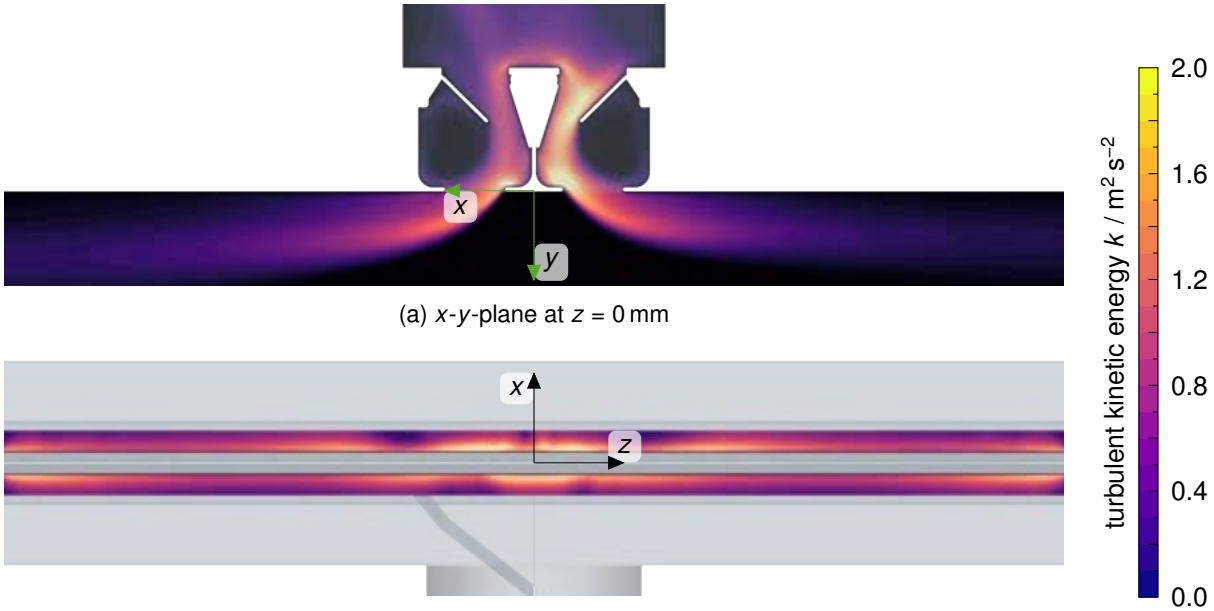
diffuser velocities.

$$\frac{|\overline{v}|_{\text{avg},y=0}}{v_{\text{D}}} = \frac{3.46\,\text{m/s}}{6\,\text{m/s}} = 0.58 \approx \text{const.} \tag{19}$$

Especially in the centre of the diffuser ($-150\,\text{mm} < z < 150\,\text{mm}$) the inflow duct has a great impact on the flow field. The areas where high velocities occur in the upper slot ($x > 0$) are further spread apart ($|z| \uparrow$). We do not observe the same spread distribution in the lower slot ($x < 0$), where multiple areas of roughly equal velocity are located near the centre and near the outer edges.

Figure 10 shows the distribution of the computed turbulent kinetic energy k. Figure 10a depicts a strong imbalance of the TKE between both slots. In the slot near the inflow duct significantly higher levels of turbulence occur. The TKE in the outlet section, shown in Figure 10b, reaches to a maximum of $k_{\text{max},y=0} = 2.11\,\text{m}^2/\text{s}^2$ with its average at $k_{\text{avg},y=0} = 1.06\,\text{m}^2/\text{s}^2$. The overall distribution is also nearly symmetric along the x-axis.

In both slots, the field smoothens towards the edges of the slots. Near the end of the slots ($|z| \gtrsim 470\,\text{mm}$) the influence of the wall becomes more prominent and causes another distortion of the flow field. In particular, we observe a sharp drop in velocity in the outer corners of the slots, which is accompanied by higher values of TKE.



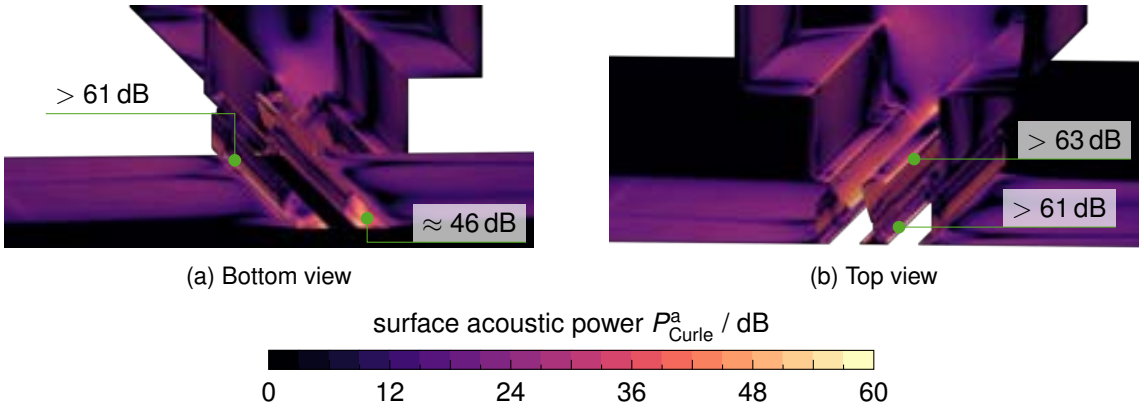
(a) x-y-plane at z = 0 mm

(b) x-z-plane at y = 0 mm

Figure 10: Computed distribution of the turbulent kinetic energy for v_D = 6 m/s

3.2. Broadband noise

In order to identify the regions where high levels are present and therefore identify the most noisy geometric features, we discuss the results of the two broadband noise source models. Figure 11 shows the distribution of the surface acoustic power which was computed with Curle's model. To allow for a better visualisation the model is clipped on a x-y-plane at z = 0 mm. Observing the diffuser from below (see Fig. 11a), different areas of high power levels are visible than from above (see Fig. 11b). The highest power levels are marked in the figures. Due to the dB-scale, it becomes clear that the edges contribute noise that is of several magnitudes stronger than the noise originating from the walls on the short edge (marked with 46 dB).



(a) Bottom view

(b) Top view

Figure 11: Distribution of surface acoustic power according to Curle's model for v_D = 6 m/s

Although Proudman's model depends primarily on the turbulent kinetic energy k, which is not fully valid in the simulations, we still give an impression of the according results in Figure 12. When comparing the distribution of the TKE and P^a_P, the relation becomes obvious. Even if we consider that our model presumably underpredicts the turbulence by a factor of $2-3$, the predicted noise levels according to Proudman's model would be of several magnitudes smaller than the levels predicted by Curle's model. Therefore the contribution of freestream turbulence to the overall noise emissions can be neglected.

Tables 4 and 5 list the integral values for both broadband noise models and all investigated velocities. Across all investigated diffuser velocities the general trends are the same, indicating that the influence of varying flow velocities mainly affects the overall level of emitted sound, rather than the aeroacoustic characteristics of the diffuser itself. Therefore, we again focus only on the medium velocity for a more detailed discussion.

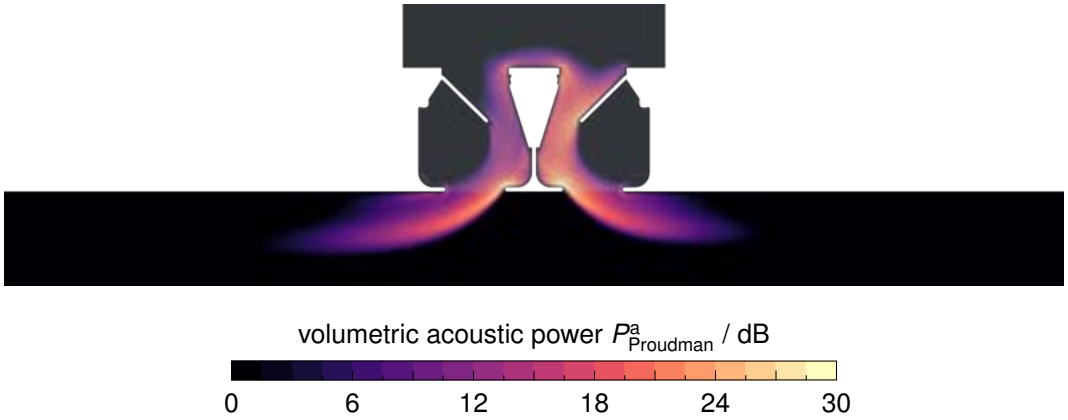


Figure 12: Distribution of volumetric acoustic power according to Proudman's model on a x-y-plane at $z = 0\,\mathrm{mm}$ for $v_D = 6\,\mathrm{m/s}$

Outlet	–65.37	–32.92	–11.02
Room	–68.16	–36.01	–12.63
Total	–58.72	–26.29	–3.79

As we could already observe from the surface distribution (see Fig. 11) the *Flaps* and *Guides* contribute the most to the overall noise emission. Although the *Throttle* also has considerable emissions, it is neglectable compared to the other two surface groups. As already said, the emissions predicted by Proudman's model are neglectable compared to Curle's noise emissions. However we can note, that the increase of $P_{ac,Proudman}$ with rising diffuser velocity is greater than $P_{ac,Curle}$. This aligns with literature ([3, 8, 10]), where the acoustic power is theoretically derived to be dependent on the Mach number $M = \frac{v_D}{c}$.

$$P^{a}_{Curle} \propto M^3 \tag{20}$$

$$P^{a}_{Proudman} \propto M^5 \tag{21}$$

As our results show, the geometric features mainly responsible for acoustic emissions, are the edges in the diffuser plate region. In order to significantly reduce the noise of this particular diffuser, we propose design changes to these edges. Possible alterations may depend on if an edge is of the type of a leading or a trailing edge. Other researches already developed many measures to improve the aeroacoustic behaviour of such edges, which is why we just give a few examples. Gruber et al. [4] and Clark et al. [1] investigated the impact of trailing edge serrations. To improve the behaviour of a leading edge, Hansen et al. [5] added sinusoidal tubercles.

4. Conclusion

In this study, we presented a flow simulation of a two-slot air diffuser to predict areas of high noise emission for three diffuser velocities. By conducting flow measurements with a 3D-LDA system, we successfully validated the flow simulation in regards to velocity field and pressure loss. The computed turbulent kinetic energy is not only lower than measured, but we also observed strong anisotropy in the measured turbulence. However, under the investigated flow conditions, the contribution of freestream turbulence to the noise emission can be neglected. Therefore, the presumably under-predicted TKE does not appear to be relevant to the overall results. This leads us to the conclusion, that our flow model allows an accurate prediction of the most relevant regions responsible for noise emission. The main contributors are edges located in areas of high flow velocity. Both leading and trailing type edges emit noise of roughly equal strength.

There are various measures that can be taken to reduce noise emissions attributed to flow edges, depending on whether the edge being considered is a leading or trailing edge. In further studies these measures can be analysed regarding their influence on the noise emissions.

Abstract:

Energy solutions based in renewable energy sources are needed to overcome fossil fuel crisis due to supply uncertainties, increasing prices and climate changes. Innovative energy solutions for a sustainable and resilient energy system for the cities is required, special attention should also be paid greenhouse gases emissions. Wind energy systems integrated in to building in urban areas are a promising technological alternative. In this work an assessment of wind energy potential in a typical building in Santo Domingo, Dominican Republic was performed. The main idea is establish a methodology to explore how small wind turbines can be integrated in building to contribute to the energy sufficiency in urban areas. For this purpose, was developed a simple but robust framework to provide a city-environment assessment of the wind energy potential considering roof-mounted turbines. An especial distinction was made to capture the effect of the building geometry in the electricity generation using Computational Fluid Dynamic (CFD) modelling and the related in the energy production. The framework is based on seven main steps: (1) site selection, (2) resource prospecting/analysis including CFD, (3) turbine selection, (4) estimation of currently produced energy, (5) Environmental evaluation, (6) Resilience and Economic Analysis, and (7) System Installation. The urban wind energy potential was assessed considering one small two-blade Darrius H-type vertical axis wind turbines on the roofs of a 29 m high-rise buildings, yielding an annual energy production in the best site of about 1030 kWh with a potential CO_2 emission reduction of 0.64 Ton/yr. It was also found that the wind speed decrees significantly downstream the wind flow direction due to the building geometry, this means that the average speed could decrees in about 100% from the site of the wind flow incidence to the opposite, with the consequent impact in the energy generation.

Keywords:

Urban wind energy assessment; Distributed power system; Wind turbine; CFD.

1. Introduction

The world is undergoing an energy transition to limit climate change, the main base of such transition is accelerating the use of clean energy. Several of the United Nations Sustainable Development Goals until 2030 are set in this direction, especially Goal 7, which sets out the challenge of Affordable and Clean Energy for All [1]. For this purpose, it is necessary to reduce the costs of renewable energies and take full advantage of the potential of energy efficiency, digitalization, smart technologies and sustainable solutions for electrification [2]. This paper proposes the use of urban wind energy as one of the alternatives to decouple the necessary economic expansion from the intensive use of fossil fuels. The goal is to promote the idea of providing energy accessibility in a sustainable way for humanity, taking the Dominican Republic (DR) as a case study. In that way, the DR, in the frame of the Paris agreement has the commitment to reduce by 25% the estimated per capita emissions of 3.6 tCO_{2eq} by 2030, with respect to 2010 [3].

Due to the high population density in urban areas, both in emerging and developed countries, tailor-made energy solutions close to the area where demand is generated are required. Globally, consumption in buildings accounts for 30 % of primary energy consumption [4]. With the implementation of energy efficiency measures, savings about 20 – 40 % can be achieved. Small wind turbine (SWT) installations are expected to contribute to the energy transition towards low carbon and high efficiency services in cities [5]. Decentralized generation in urban environments is a possible solution, involving technologies such as solar PV and SWT [6]. In this direction, a full understanding of the renewable resources available in urban environments is needed. Tasneem et al. [7] argued that SWTs can be positioned in or around high-rise buildings, rail tracks, highways, and other

urban sites. The estimated energy of the wind in these places becomes very complicated due to it being aerodynamically irregular and heterogeneous. The obstacles, such as buildings, trees, and others have an influence on wind turbulence [8]. These obstacles significantly reduce the use of the resource through SWTs due to those extract momentum from the wind flow, causing a lower average wind speed [9]. Building shape, height, and separation between itself influence wind flow and direction due to the turbulence and surface roughness produced by them [7]. A proper wind speed assessment, wind selection and installation are the most challenging goals to address. Wind flow around a building is complex, since a separation zone results and vortices generated, however, the main region of interest is where there is an amplification of the flow [10].

For the studies in the urban environment of wind potential the progress of Computational Fluid Dynamic (CFD) scope is a corner stone. CFD can be efficiently integrated in the urban wind energy assessments methods. These studies are in principle dedicated to characterizing air flow through obstacles, such as building and trees in a volume of control. In an urban location the flow is considered as turbulent. In this way should be used the Favre-averaged Navier-Stokes equations with SOLIDWORKS Flow Simulation software to model turbulent flows in the urban environment [11], [12].

A two-equation standard model k-ε is involved in the flow simulations because of its robustness and simplicity, more advanced turbulence models could be employed, however the k-ε model is accurate enough for the purpose of this work. The propose of this study is develop existing methodologies for better prediction of wind behaviour in urban environment and predict the energy potential of small wind turbines in microgeneration.

This research, rather novel in the Caribbean region and especially in the DR, aims to contribute to the characterization of wind in urban environments for the proper assessment of the technology to be used. The wind characteristics and the orography (existing buildings, terrain, etc.) are crucial elements for the deployment of SWT in urban environment. Another expectation of this work is to influence the architecture and urban planning to facilitate the use of the wind resource in the future. This research focuses on the potential of urban building in the DR, Santo Domingo for urban wind energy deployment. One building is studied in detail using CFD analysis in order to achieve the best performance of the wind energy technology.

2. Methodology

The methodology presented in this research have the purpose to perform with adequate precision a characterization of the urban wind energy potential in the Caribbean area, especially in the DR. It is important to highlight the efforts made to combine the current state of the art in the subject and the data available in the context of the region. In the literature consulted, very few studies of urban wind potential in tropical areas have been identified [13], [14]. However, worldwide scale there are many of such studies, important contributions has been made by authors such as AL-Yahyai, Bekele and Rezaeiha [15]–[19]. So far, no consistent research on the potential of urban wind in Caribbean cities has been identified in the consulted literature. In that way, a methodology is proposed to analyse the energy potential of urban wind. This methodology adopts several steps from some existing ones and proposes to incorporate an environmental evaluation and a detailed CFD analysis integrated to Geographic Information Systems (GIS) and on-site measurements. This adding lead to a wider study, taking into account the need to reduce the CO_2 emissions, define best site to install the wind turbine and predict accurately enough the annual electricity generation. The methodology includes seven steps: (1) site selection, (2) resource prospecting/analysis including CFD, (3) turbine selection, (4) estimation of currently produced energy, and (5) Environmental evaluation, (6) Resilience and Economic Analysis, and (7) System Installation as shown synthetically in Figure 1. The last two steps of the methodology are the Resilience and Economic evaluation and the Detailed Engineering of the final project; both are beyond the scope of this work. The step from 1 to 7 presented in Figure 1 are described in the following sections.

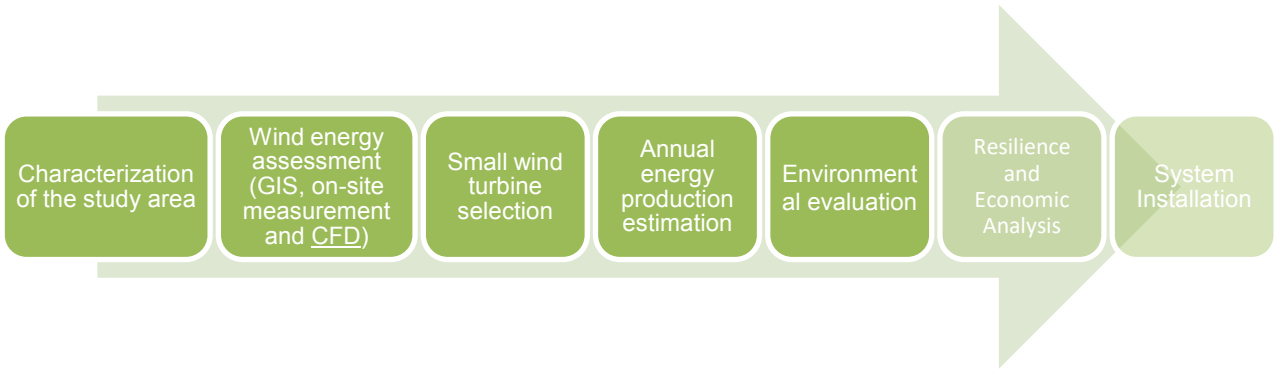

Figure 1. Schematic illustration of the steps of the proposed methodology.

2.1. Characterization of the study area

There is great potential in the use of urban wind for distributed electricity generation in densely populated urban areas [20], [21]. In these environments, small wind turbines (SWTs) can be conceived as building-

integrated from the design phase or installed on rooftops of existing buildings or surrounding areas. Distributed wind energy in cities has the advantage of its proximity to the point of electricity demand, which means reduced costs for high-voltage transmission lines as well as for the necessary devices of such a system [22].

Trees, buildings and other obstacles on the ground influence wind speed and turbulence, especially in sites with low wind speed and high turbulence levels [8]. This significantly reduces the resource utilisation using SWTs, obstacles extract wind flow momentum, resulting in lower average wind speed [9].

In order to identify potentially usable buildings for SWTs siting, parameters such as height, available roof area and structural integrity need to be assessed. A possible method for this purpose was identified in the work performed by Rezaeiha [18]. In this type of research, buildings in cities should identified and classified using GIS databases available on freely accessible websites, such as: [23]. These tools serve as a starting point to stratify buildings that meet the criteria for SWT installation. In this kind of research, in the case of Santo Domingo, buildings considered could be taken from the data base https://skyscraperpage.com/. In the case there is not existing database with information about the buildings an inspection must be carried out.

2.2. Wind energy assessment

In the literature several methods can be found for site-specific urban wind forecasting for energy purposes. The most commonly used methods are: on-site measurement, wind tunnel, numerical weather prediction, Computational Fluid Dynamic (CFD) and analytical methods [18], [24]–[28]. In any case, the main objective is to perform a wind characterization that includes the determination of parameters such as: average speed, direction, turbulence, energy density, etc. In this work, on-site measurements are used to evaluate the urban wind potential in the cities of Santo Domingo and, in DR. A brief description of this method is presented below.

2.2.1 On-site measurement

Wind speed and direction are the main parameters for the characterisation of the urban wind for energy purposes. The reference wind speed is established on the basis of measurements averaged every 10 minutes, according to the International Electrotechnical Commission standard. For the measurement of these parameters, an anemometer installed according to the aforementioned standard at the measurement site is needed [29]. In this study a data set collected from an anemometer installed in representative building in Santo Domingo were used.

Usually, the wind speed and direction are statistically processed and plotted on a polar diagram called a wind rose, where the radial axis indicates the magnitude and frequency of the wind, showing the prevailing wind direction. It can also be displayed in a Cartesian coordinate diagram [21], [30], [31].

The accumulated records of wind parameters allow the construction of probability functions and predict the energy potential. The Weibull, Rayleigh and Lognormal distributions are widely adopted to predict wind speed. The most widely used is the Weibull distribution because of its flexibility and simplicity. However, limitations have been observed in this function for average wind speed lower than 2 m/s or close to zero, in this speed range the density distribution estimation can be very inconsistent [17]. This limitation is not relevant to use this function evaluating the potential for SWT, because typically the cut-out speed of this machines is 2 m/s. In this work, the Rayleigh Distribution, a variant of the Weibull distribution with a form factor equal to 2 is adopted [29]. Weibull distribution $p(v)$ is the probability distribution function used to describe the distribution of wind speeds over time duration. The Weibull probability function is given by Eq. (1):

$$p(v) = \left(\frac{k}{c}\right) * \left(\frac{v}{c}\right)^{k-1} e^{-\left(\frac{v}{c}\right)^{k}}, \quad (1)$$

Where k is the shape factor, a parameter that controls the width of the distribution and c is the scale factor in m/s, this parameter controls the average wind speed and is defined in Eq. (2).

$$c = \frac{V_{avg}}{\sqrt{\pi}}, \quad (2)$$

Where: V_{avg}, is the average wind speed.

The parameters k and c can be estimated by several methods, being the method of maximum likelihood the most commonly used (Karthikeya et al., 2016; Islam et al., 2011).

Another important characteristic of the wind is the Turbulence Intensity (TI), it is defined as the ratio of standard deviation of fluctuating wind velocity to the mean wind speed, and it represents the intensity of wind velocity fluctuation. This index should be calculated at 15 m/s, as it is one of the characteristic parameters included in the classification (classes) of SWTs according to the International Electrotechnical Commission [29]. At presents four SWT classes has been defined, for all classed the turbulence intensity should be 0.18 or less, and for the "S" class, it should be determined according to the referred standard. A turbine should not be exposed to wind turbulence intensity higher than 25 %, so this parameter is essential for determining the installation of small wind turbines [8]. Small wind turbines must be able to respond to frequent urban wind fluctuations and the site and system characteristics [32]. According to the National Renewable Energy

Laboratory (NREL) of the United States, turbulence levels can be categorised as follows: low, if TI have values less than or equal to 10%; moderate, if TI have values between 10% to 25%; and high, if TI have values greater than 25% [33]. The TI calculation is given by Eq. (3).

$$TI = \frac{\sigma}{V_{avg}} \tag{3}$$

Where: σ is the 10-min standard deviation, V_{avg} is 10-min average wind speed.

2.2.2. Computational Fluid Dynamic

Computational Fluid Dynamic (CFD) is a numerical simulation technique to study the behaviour of wind flow in urban locations. This method has become widely used due to advances in number methods and computational resources [34]. The CDF models have the ability to calculate the aerodynamic components with the integration of the Navier-Stokes equations at the periphery of the turbine blades [32]. The CFD is an efficient alternative to characterize the turbulence in the wind in the building. The method has been improved in simplification, calculation model, mesh processing, setting of boundary conditions, equation solver, simulation tools and other aspects [8].

The biggest barrier to the acceptance of CFD results is related to the accuracy of the technique, the costs, and the skill of the user. Verification and valuation is required for the CDF simulation results. Typically, the validation of CFD studies for real urban areas are carried out with field measurement data (Experimental tests) and wind tunnel [13], [28], [32], [34].

According to Mittal et al. [28], the accuracy of the CFD simulation strongly depends on the selection of the turbulence model. The capacity of each turbulence model and its precision for different analysis resolutions are reported in the literature based on the experiences of the researchers. With this method, important findings have been obtained, such as: the recommendation to install small wind turbines 1.4 m above the roof of buildings and if they are horizontal axis wind turbines, that they be installed in the middle of the roof, as well as installing the turbine as high as possible in the windward direction [35].

The proposed methodology for the development building wind turbines projects in an urban environment based on CFD analysis was summarized in the in the Figure 1. This methodology lead to a better estimation and reduced the time, cost and risk of the feasibility studies in the development of such projects.

As mentioned in section 2.1 it is necessary to delimit the project location and the surrounding zone to study the feasibility of the project. It is important to develop a general view aided by the CFD simulation to predict the flow patterns of the wind stream in the urban complex. With the purpose of assess the performance of the small wind turbines on the roof of the building of interest for the CFD simulations. After the site is selected, a standard wind resource assessment is completed, by using statistical and historical field data to estimate the power output of SWTs. The next stage is the CFD-based assessment, which includes four steps: the modelling site assessment, the modelling building-structure study, the modelling SWT study, and the modelling structure-SWT study. In these steps, a CFD model of the site that includes the building and the surrounding areas, is elaborated, as well as a model of the building or structure suitable for CFD analysis. This analysis will allow selecting the type of turbine to install. After the SWTs selection a performance study using CFD analysis should be conducted. The results of this final analysis using the integrated method will define the viability of the project regarding technical performance. In this study is adopted SOLIDWORKS Flow Simulation to evaluate wind behaviour using CFD and applying finite volume analysis [36].

2.3. Selection of small turbines

SWTs are aerodynamic machines, used to convert wind energy into electricity. Electricity production is a function of air density, the sweep area of the turbine blades, and the speed cube [37]. There is a wide variety of designs and types of small wind turbines. Commonly, highly efficient developments are considerably influenced by criteria related to the operation and location of the machine. In the wind turbine industry, there are mainly two designs, horizontal axis wind turbines (HAWTs) and vertical axis wind turbines (VAWTs) [26], [35], [38].

HAWTs are generally installed in areas relatively separated from cities, and with considerable heights above ground level, according to local policies and regulations. These machines must always be oriented with the rotor perpendicular to the wind direction, which makes it unappropriated to be installed in places with frequent changes in wind direction or high turbulence [7], [10].

VAWTs can be classified into two main categories, Darrieus and Savonius rotor. Darrieus VAWTs are usually considered a lift rotor, since the torque is generated by the average lift force. On the other hand, Savonius rotors operate normally by the action of drag force. H-type rotor VAWTs are a combination of lift and drag forces. VAWTs are more used in urban environments because they are less vulnerable to changes in wind directions.

According to the International Electrotechnical Commission (IEC), SWTs are those with a capacity ≤ 50 kW and a rotor swept area ≤ 200 m^2 [29]. Different classifications, according to power, hub height, and swept exist in different countries. In this work we adopt IEC classification.

According to Rezaeiha [18], urban wind energy harvesting systems can be categorized as follow: (i) Stand-alone near building, (ii) Retrofitted to existing building, and (iii) Fully integrated into building architectural form. In this work it is considered appropriate to use a small two-blade Darrieus H-type vertical axis turbine (VAWT). This machine is 1 m in diameter and 5 m in height, with a sweeping area of 5 m^2. This SWTs were selected because a good performance at low speeds and turbulent environments, which is a condition that generally occurs in urban areas.

2.4. Annual energy production estimation

For the estimation of the annual energy production (AEP), the methodology proposed by Rezaeiha [18] is adopted. The equation to estimate the AEP is shown in Eq. (4):

$$AEP = 8760 * \int_0^\infty P\left(V_{avg}; c; k\right) * P(V)dv \quad (4)$$

Where: 8760 are the hours during a year, $P\left(V_{avg}; c; k\right) *$ is the probability of occurrence of a given speed based on the Weibull distribution, and $P\ (V)$ is the power produced by the wind turbine at that speed. The power extracted by the wind turbine is described according to Eq. (5):

$$P(V) = 0.5 * C_P * \rho * A * {V_{avg}}^3 \quad (5)$$

Where: A is rotor area, C_P is the power coefficient of the rotor, V_{avg} is the wind speed and ρ is the air density.

2.5. Environmental evaluation

To evaluate the potential environmental benefit from the installation of the SWTs an assessment of the avoided CO_2 emissions from replacing electricity generation from fossil fuels by electricity from SWTs can be carried out. Fossil fuels prevail in DR electricity sector, according to Guerrero-Liquet: oil (46.27%), natural gas (25.92%) and coal (14.03%), represented 86% of electricity generation in the country. Only 10% of electricity generation is produced from renewable sources, particularly hydropower (6.26%) and wind energy (1.90%) [39]. Is it important to highlight that Oil and coal are the higher CO_2 emitters. With data from the Coordinating Body of the National Interconnected Electrical System (OC-SENI) an estimation of the emission factors for these fuels has been done [40]. It was found that emissions factors expressed in $kgCO_2eq/kWh$ for oil and coal are about 0.75 and 0.98 respectively. On the other hand, according to the Standardized baselines set by the United Nations Framework Convention on Climate Change, the CO_2 emission factor for the SENI in DR applicable to wind and solar power generation project activities is 0.6216 $kgCO_2/kWh$. This standardized baseline will be adopted for calculations in this research [41]. Assuming the SWT electricity generation carbon free, the Avoided Emission (AE) in $kgCO_{2eq}$ can be calculated by multiplying the annual energy production (AEP) in kWh, by Emission Factor (EF) in $kgCO_{2eq}/kWh$, as shown in Eq. (6).

$$AE = AEP * EF \quad (6)$$

3. Case study, results, and discussion

This work has been developed to stablish a methodology to assess the urban wind energy potential in buildings for the Dominican Republic, as a first case study a representative building located in the Technological Institute of Santo Domingo (INTEC) has been taken. The most important findings are presented from a survey campaign carried out at INTEC located in Santo Domingo. Two anemometers were installed for data recording, which are identified with the following nomenclature: Anem1-INTEC and Anem2-INTEC. The Santo Domingo Institute of Technology (INTEC) is a private, non-profit, public service, Dominican higher education institution founded in 1972 by a group of academics committed to the social transformation of the country and the continuous promotion of the quality of education. It is located in the coordinate 18°29'16.81"N, 69°57'45.18"W. A detailed map of the INTEC campus is shown in Figure 2.

The Anem1-INTEC and Anem2-INTEC registered data during the period May-December and June-December 2017 respectively. The sensors were installed in building with 20 m height. A total of 208881 and 152816 records were taken from Anem1-INTEC and Anem2-INTEC, with an availability of 71% and 77% respectively. In 2017 the country was hit by several meteorological adverse events which affected the data collection. Figure 3 a) shows the behaviour of the monthly average wins speed. The mean speed for the periods was about 2.50 m/s at 20 m. At 40 m height the estimated average wind speed using the Hellmann exponential law and the logarithmic wind profile law was 3.05 m/s. The Hellmann exponential is the general methods for estimating wind speeds at higher hub heights from known wind speed at lower heights [30].

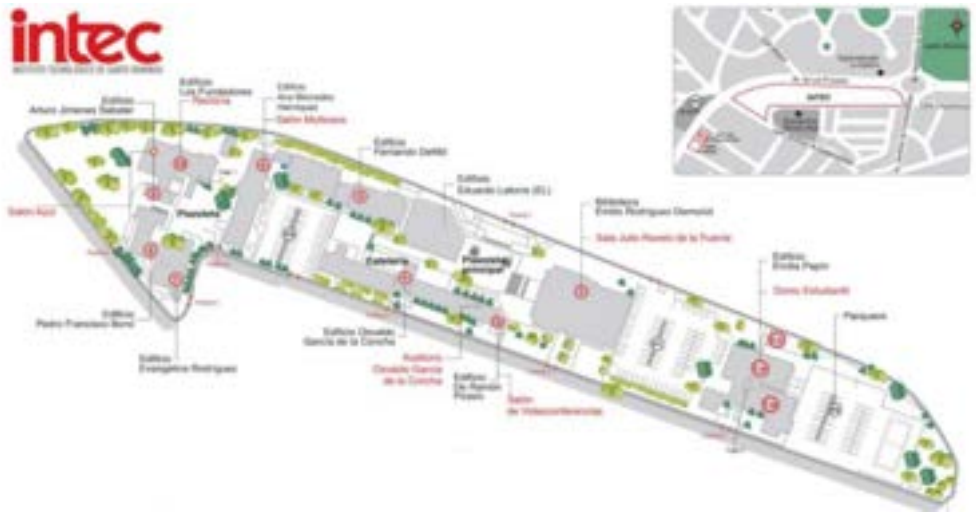

Figure 2. Detailed map of the INTEC campus.

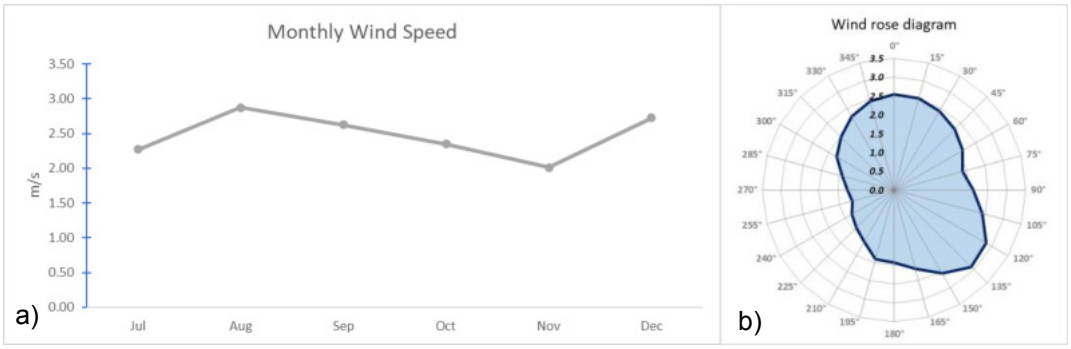

Figure 3. a) Average monthly wind speed, b) Period average wind rose.

Fig. 3b) shows the wind rose for the three sensors during the study period. The predominant wind direction is North-East, with a strong correlation with the data records of the meteorological services for both measurements sites [31]. The predominant wind direction with the highest intensity was registered from 15° respect to North.

Table 1 shows the hourly variation of wind speed (WS) for one day. Table 1 has a colour scale, where red represents unfavourable speeds and green favourable. Note that in the interval from 13:00 to 15:00 the highest energy potential occurs. This is very positive, since the energy consumption associated with air conditioning in this horary is considerable in tropical areas. Note that in Santo Domingo there are average wind speeds higher than 2 m/s during approximately 18h every day.

Table 1. Daily average variation of wind speed.

h	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24
WS	2.00	1.98	1.92	1.91	1.88	1.90	2.06	2.49	2.80	2.90	2.97	3.13	3.21	3.42	3.29	3.07	2.92	2.68	2.54	2.36	2.27	2.14	2.10	2.07

From the minute-by-minute recordings, the average speed was calculated for 10-minute intervals. The most probable speed recorded were 2 m/s, 3 m/s and 4 m/s with probabilities of occurrence of 24.5%, 24% and 17.7% respectively. Figure 4 shows the Weibull distribution for the parameters given in Table 2. For a mean wind speed of 3.05 m/s the corresponding parameters for the Weibull distribution are 3.44 m/s and 2 for the share factor and scale factor, respectively. TI was categorised as moderate, high and low to 63%, 29% and 8%, respectively. This may be mainly associated with the terrain orography, deeming that these measurements were made in a building in an urban environment.

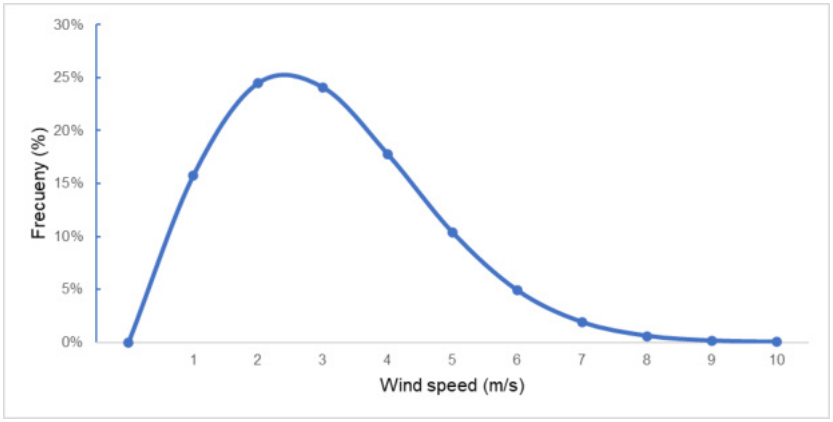

Figure 4. Weibull distribution.

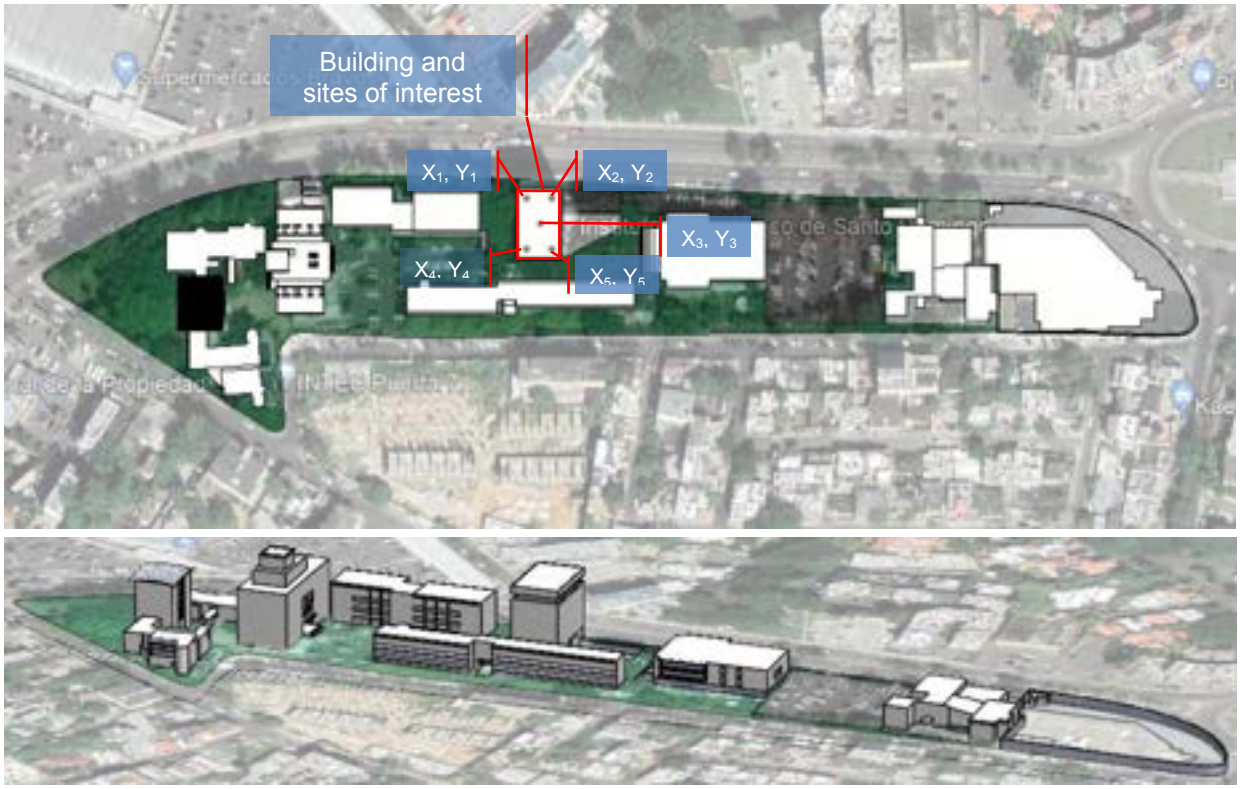

Figure 5. Physical model of the INTEC campus, building and sites of interest.

Table 2 Describes each one of the optimized initial conditions selected which correspond to the CFD simulations performed. The wall condition of 1,000,000 micrometres comes from “Guide to Meteorological Instruments and Methods of Observation”, where it is pointed out that the roughness of the terrain is classified by the class of the terrain. INTEC is surrounded by class 7 terrain, presenting large regular obstacles typical of the suburbs, assigning it a roughness height of 1 m. The decomposition of each velocity parameter is represented at the Table 3.

The configuration of the grid and the determination of the size of the refinement of the mesh states the precision of which the CFD simulation will be performed. For these CFD simulation, a global mesh structured are selected with a manual refinement definition of 249 cells per X, 100 cells per Y and 100 cells per Z. This global mesh refinement exceeds the number of cells assigned in all axis by the highest level of auto refinement with the sole porpoise of ensure precision at the areas of interest. This results in 2,643,484 cells that integrate the meshing of which 78,416 are in contact with solids. Additional to the mesh refinement a control plane tool was employed to increase the density of cells at the areas of interest.

Table 2. Optimized Initial and boundary conditions for the development of CFD simulations.

Analysis type	Fluid Type	Boundary Conditions	Initial and Environment Conditions	Mesh Configuration

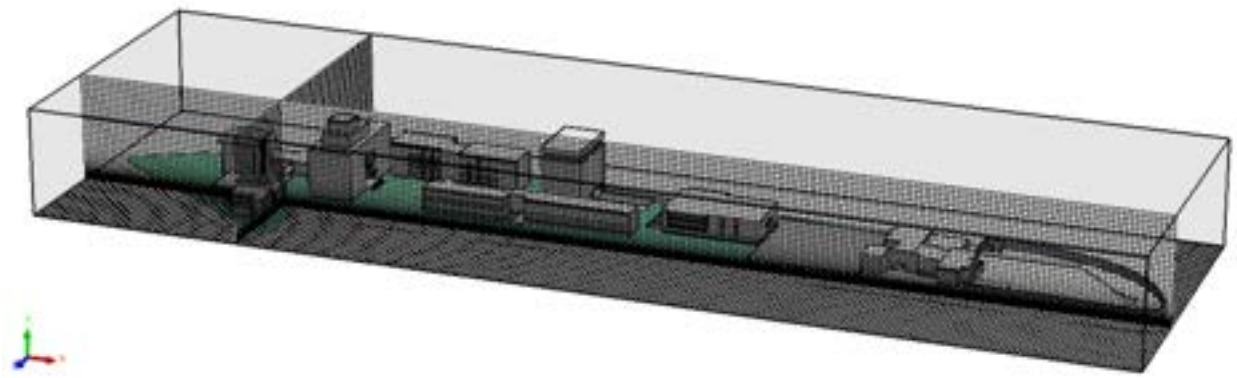

Figure 6. Dimetric view of the INTEC campus in SolidWorks Flow Simulation.

Figure 7 reveals the top view of velocity contour at 3 m/s at 15° of the INTEC was obtained by CFD simulations. Results shows how the wind is distributed across the campus and the high-speed zones over the tall buildings. The image below also reveals the possible positions to locate wind turbines over the EL building. Note in the Figure 7 how different is the wind speed in the different site of interest. From this observation can be deduced that energy generation of a wind turbine can be significantly different depending on the site of installation even over the same roof.

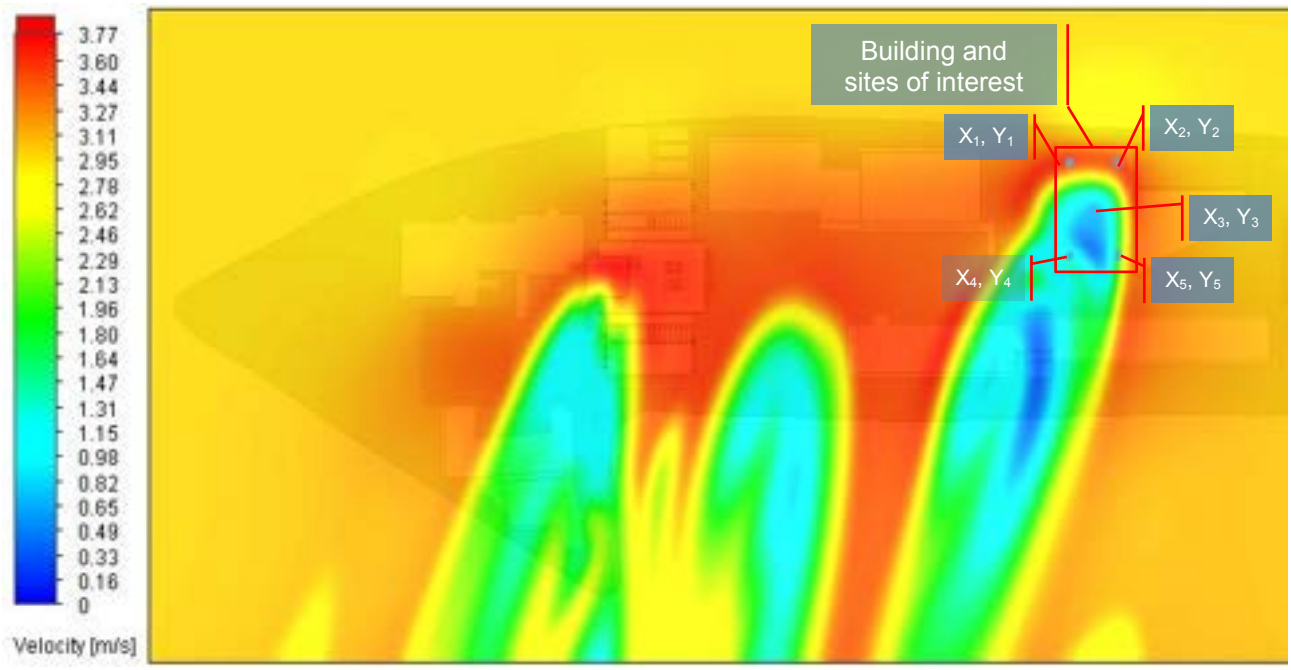

Figure 7. CFD simulation velocity contour at 34 m elevation, 3 m/s free stream flow.

The Table 4 summarise result of measurement analysis regarding the wind speed behaviour based on anemometers measurements collected near the building studied and wind behaviour analysed using CFD analysis.

Table 4. Wind speed information from anemometers and modelling results at sites of interest.

Free stream flow Wind speed (m/s)	Occurrence (hours)	Wind Speed at sites of interest from modelling (m/s)				
		X_1, Y_1	X_2, Y_2	X_3, Y_3	X_4, Y_4	X_5, Y_5
1	1380	1.1	1.1	0.1	0.4	0.3
2	2142	2.3	2.3	0.4	0.9	1.1
3	2106	3.5	3.5	0.6	1.2	1.8
4	1554	4.7	4.6	0.8	1.6	2.5
5	908	5.9	5.8	0.9	1.9	3.3
6	430	7.1	6.9	1.2	1.8	4.9
7	167	8.3	8.0	0.7	1.0	6.9
8	72	9.4	9.2	1.4	3.1	5.1

The Figure 8 shown how the wind speed may differ from one site to another even over the same roof.

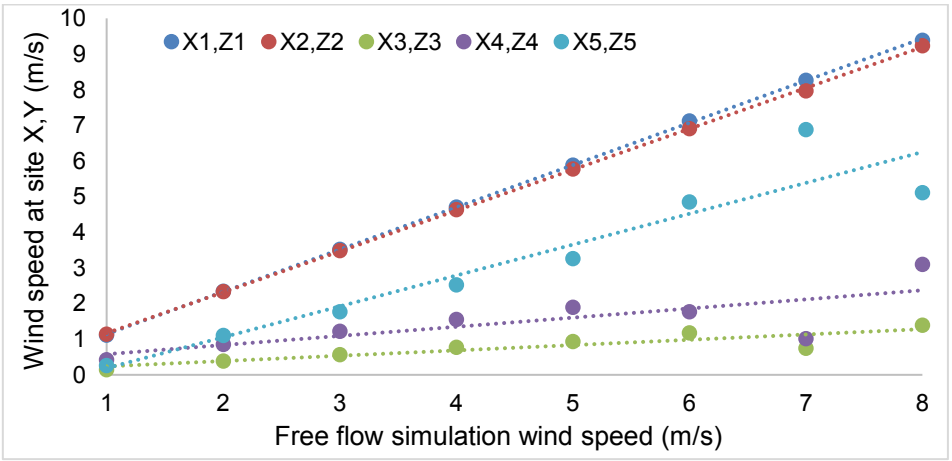

Figure 8. Wind speed at site vs. free flow simulation speed.

Given the wind characteristics described above, VAWT technology was chosen in this study, since this type of turbine have a good performance in urban locations with low wind speeds and high TI [18]. A turbine similar to the one selected by Rezaeiha in the wind potential studies in 12 cities in the Netherlands was selected [18]. The selected turbine is a Darrieus Type-H rotor with a rated power of 2.4 kW at a wind speed of 12.5 m/s and a swept area of 5 m^2. From the power curve of the Darrieus Type-H turbine, the energy produced during the year can be estimated as a function of wind speed regimes. The equation that best fit to the power curve for this machine was estimated using the potential regression method, with a correlation of $R^2 = 0.9944$, the function is given by Eq. (7):

$$y = 1.1501x^{3.0842} \quad (7)$$

Where: y, is the power delivered by the machine in Watt and x, is the wind speed in (m/s).

Table 5 shows the estimated annual power and energy generated for the given speed ranges of a VAWT installed at each sensor position, the energy that could potentially be generated at Anem2-INTEC position. Also, Table 5 shows the estimated annual power and energy generated for the given speed ranges of a VAWT installed at each sensor position, the energy that could potentially be generated at Anem2-INTEC position would be 1030 kWh/year.

Table 5. Power generation based on free stream speed and modelling results at sites of interest.

Speed (m/s)						Ocurr. (h/year)	Power (W)					
Free stream	X_1, Y_1	X_2, Y_2	X_3, Y_3	X_4, Y_4	X_5, Y_5		Free stream	X_1, Y_1	X_2, Y_2	X_3, Y_3	X_4, Y_4	X_5, Y_5
0	0	0	0	0	0	0	0	0	0	0	0	0
1	1.11	1.14	0.14	0.15	0.26	1,380	0	0	0	0	0	0
2	2.34	2.33	0.38	0.86	1.11	2,142	10	16	16	-	-	-
3	3.52	3.48	0.56	1.22	1.77	2,106	34	56	54	-	-	-
4	4.7	4.63	0.77	1.55	2.53	1,554	83	136	130	-	-	20
5	5.88	5.78	0.93	1.89	3.26	908	165	271	257	-	8	44
6	7.08	6.94	1.15	2.39	4.01	430	289	481	453	-	17	83
7	8.27	8.1	1.34	2.81	4.75	167	465	776	729	-	28	140
8	9.46	9.26	1.54	3.22	5.49	72	701	1175	1101	-	43	220

Table 6 shows the estimated annual energy generated for the given speed of a VAWT installed at each sensor position, the energy that could potentially be generated by one unit at X_1,Y_1 position would be 1,030 kWh/year. The avoided emissions CO_2 are also presented in Table 6.

Table 6. Power generation based on free stream speed and modelling results at sites of interest.

Parameters	Generated Energy (W-h/yr)					
	Free stream	X_1, Y_1	X_2, Y_2	X_3, Y_3	X_4, Y_4	X_5, Y_5
Annual energy per VAWT [kWh]	623	1,030	978	0	22	146
Avoided emissions CO_2 [kg/Year]	387	640	608	0	14	91
VAWTs	5	5	5	5	5	5
Total annual energy [kWh]	3,116	5,151	4,891	0	112	731
Total avoided emissions of CO_2 [kg/Year]	1,937	3,202	3,040	0	70	454

The Figure 9 is to illustrate how different can be the energy generation of a wind turbine depending on the site where this is installed even on the same roof. Based on the estimated annual energy production with an emission factor of 0.6216 TonCO_2/MWh, it can be determined that 0.640 tonnes of CO_2 emissions into the atmosphere per year could be avoided per SWT if it is located in the best site.

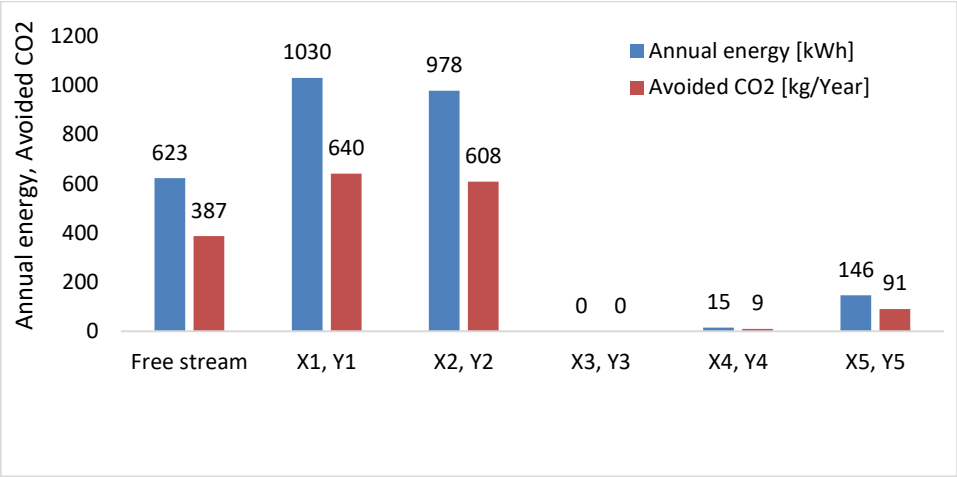

Figure 9. Annual energy generation and Avoided CO_2 emissions at site characterized by the anemometers and by CFD simulations.

4. Conclusions

This research is a starting point for assessing the urban wind potential for electricity generation in urban environment and contribute to the decarbonization of the Dominican Republic energy matrix. The wind generation potential in a typical building located in an urban area from Santo Domingo has been assessed. On-site measurement campaigns conducted at INTEC and simulation result analysis has been used.

The average wind speed in Anem1-INTEC, Anem2-INTEC was about 2.5 m/s respectively, which is considered a relatively low. At 40 m It was estimated an average wind speed of about 3.05 m/s. The prevailing wind direction with the highest intensity was recorded at 15° respect to North. The wind roses have good correlation with freely available GIS databases. Between 13:00h to 15:00h the higher wind intensity occurs.

A methodology was presented to estimate the wind potential in urban buildings taking into account the exact site of the SWT and the building geometry using, and integrated approach based on on-site measurements and CFD analysis. The selected turbine was VAWT Darrieus Type-H, with good performance at low speed and very turbulent environments. The estimated AEP for one turbine in best site was 1030 kWh/yr with a potential CO_2 emission reduction of 640 kg/yr. The site of the turbines even in the same roof is relevant for the energy generation, modelling results shown differences in the estimate energy generation from one corner of the roof to the opposite of 100%.

Future research should quantify 100% of the available potential in buildings with a detailed estimate of the number of buildings and the area available for VAWT installation. In addition, survey studies should be extended both spatially and temporally. Given the geographical position of the DR and its exposure to adverse meteorological events, a resilience and feasibility analysis will be performed for future urban wind potential analysis.

Abstract:

The high concentration of solar light on photovoltaic cells leads to extremely high cell temperatures, leading to decreased cell efficiency. Appropriate cooling techniques need to be integrated to sustain the high rise in temperature and maintain a uniform temperature throughout the photovoltaic cell. This study focuses on the cooling of photovoltaic cells with a confined jet impingement cooling technique. The major objective is to improve cell efficiency using the confined jet impingement technique to avoid hotspots, thermal stress, and current mismatching problem. The channels are created on the backside of the photovoltaic cell such that the coolant strikes the cell at the center and leaves at the four corners of the cell. Water-based ZnO and Ag-ZnO hybrid nanofluids are used as a coolant because of their high thermal conductivity and heat transfer capacity. The results showed better cooling performance and improved cell efficiency of photovoltaic cells with nanofluids compared to water as a coolant. In addition, sufficient temperature uniformity is maintained within PV cells. The effect of the coolant mass flow rate and nanoparticle volume concentration is also studied. Results showed improved cell electrical efficiency at higher coolant mass flow rates and higher nanoparticle volume concentration.

Concentrated photovoltaic; Confined jet impingement; Efficiency; Energy; Nano-fluids

1. Introduction

Solar energy is considered a significant renewable energy source. The annual potential of solar energy is 1,575–49,837 exajoules (EJ), which is 1.8–58 times the estimated future world energy consumption of 860 EJ in 2040 [1,2]. Solar energy can be used by various technologies such as photovoltaic (PV) systems, concentrated PV systems, solar thermal collectors, *etc*. PV systems and solar thermal collectors can be combined to obtain electrical and thermal energy outputs. Photovoltaic thermal (PVT) systems improve solar cell conversion efficiency, expanding solar energy utilization. However, the flat plate PVT system generates heat at low temperatures, which restrains the use of these systems for some high-temperature applications. To overcome such problems, concentrated photovoltaic thermal (CPVT) systems are a better alternative.

Concentrated photovoltaic (CPV) systems utilize optics to concentrate sunlight onto PV cells. Therefore, CPV can replace the expensive PV cells with cheaper concentrator optics to enable harnessing the same amount of solar radiation but with fewer PV receivers. Despite several advantages of a CPV system over flat plates, CPV systems face many challenges. The main challenge is that the high concentration of solar light on photovoltaic cells leads to extremely high cell temperatures, resulting in decreased cell efficiency. A major portion of the available solar energy is converted to thermal energy, leading to problems such as hotspots, current mismatching, and thermal fatigue. It is essential to have a uniform PV cell temperature to avoid current mismatching and thermal stresses. To sustain the high rise in temperature and to maintain a uniform

temperature throughout the photovoltaic cell, appropriate cooling techniques are required to be integrated. Many cooling techniques, such as air-based cooling, liquid immersion, jet impingement, phase change material cooling, heat pipe, micro-channel cooling, and thermoelectric cooling, have been employed, which were reviewed in various literature [3]. Theristis et al. [4] reported that passive cooling is not enough to dissipate heat from the cell under high concentration ratios. Jet impingement is an appropriate cooling method for densely packed PV cells to achieve a uniform cell temperature [5]. Many researchers reviewed unconfined and confined jet impingement cooling systems for PV cells. Recent studies showed that the temperature of the PV cell can be reduced from 1360 °C to 65 °C for a concentration ratio of 1000 suns using confined jet impingement cooling with water at a mass flow rate of 50 g/min [6]. Javidan et al. [7] reported that temperature of the PV module decreased from 63.95 °C to 33.68 °C by using an optical set of parameters for jet impingement cooling. Bahaidarah et al. [8] reported a temperature decrease from 69.7 °C to 36.6 °C using an unconfined jet impingement cooling technique. Zubeer et al. [9] reported that the temperature of an uncooled PV system and a low-concentrated (1-3 suns) PV system was 57.5 °C and 64.1 °C, respectively, which decreased to 36.5 °C with water jet impingement cooling. Barrau et al. [10] studied the performance of hybrid jet impingement micro-channel cooling for densely packed PV cells, and calculated the heat transfer coefficient as a function of pressure drop, and compared the performance of hybrid cooling to micro-channel cooling alone. Markal et al. [11] performed experiments to investigate the effect of impinging air jets on the cooling of PV cells. It was found that the average surface temperature of the PV cell can be decreased by 61.5%, and the output power can be improved by 13.2%. Amanlou et al. [12] studied the effect of air diffuser geometry on the performance of low-concentrated PV systems. Also, the effect of air mass flow rates on concentrated PV cells' performance was studied. It is reported that by increasing the air mass flow rate from 0.0008 to 0.016 kg/s, the electrical, thermal, and overall efficiency of the PV cell was improved by 13.5, 22.75, and 22.41%, respectively. Singh et al. [13] performed numerical modelling and experimental study for performance improvement of PV modules with a hybrid cooling system with a thermoelectric cooler and phase change material. It was reported that TECs provide better cooling than PCMs under similar conditions as panel efficiency increases by 5.73%. It was observed that electrical efficiency shows a maximum increment of 19.4% with hybrid cooling. Sabry et al. [14] studied thermoelectric generator (TEG) cooling on concentrated PV systems. Compared to only a CPV cell on top of a heat sink, the generated power of the CPV/TEG hybrid system increased by 7.4%, 5.8%, and 3% corresponding to using the 30 × 30 mm^2, 40 × 40 mm^2 and the 62 × 62 mm^2 TEG modules, for which the number of junctions is 31, 127 and 49, respectively.

The aim is to design a highly efficient CPVT system with hybrid cooling, such as confined jet impingement and a thermoelectric generator. Although many researchers have worked on the performance of jet impingement cooling of microelectronics, very few studies are reported on confined jet impingement cooling of highly concentrated PV systems. Confined jet impingement cooling provides a better uniform PV cell temperature, eliminating thermal stresses and current mismatching. Most researchers use water as a cooling fluid for jet impingement cooling of PV cells. Nanofluids provide better cooling than water because of their higher thermal conductivity [15]. In this work, the performance improvement of a highly concentrated PV system under confined jet impingement with Ag-ZnO hybrid nanofluids as a coolant is studied. The effect of volume concentration of Ag-ZnO nanoparticles on CPV cell cooling and electrical efficiency is observed. Also, the effect of the mass flow rate of the Ag-ZnO hybrid nanofluid on the performance of confined jet impingement cooling of CPV cell is studied, and the performance of Ag-ZnO hybrid nanofluids is compared with water as a cooling fluid.

2. System description

2.1 System Geometry

The solar cell used in this analysis is a multi-junction solar cell with a reference cell efficiency of 40.3% at a reference temperature of 298 K. The dimension of the solar cell is 10 mm × 10 mm with 0.19 mm thickness. The solar cell is supported by a board structure which consists of a copper structure followed by a ceramic and copper board. The upper copper layer's dimensions are 24 mm × 19.5 mm with 0.25 mm thickness, followed by a 25.5 mm × 21 mm ceramic layer and a 25 mm × 20.5 mm copper layer with 0.32 mm and 0.25 mm thickness, respectively. An aluminium heat sink of 25.5 mm × 21 mm with 4 mm height is placed at the bottom of the structure. An inlet is placed at the center of the heat sink, and four outlets are placed at the four corners. The cooling fluid enters the center of the heat sink and exits through the four outlets at the corner.

(b)

Figure 1. (a) Isometric view of the assembly (b) Solar cell layers and jet impingement channel configuration.

Table 1. Properties of solar cell layers and board structure

Solar cell layer	Thermal conductivity (k) (W/m.K)	Specific heat (C) (J/kg.K)	Density (ρ) (kg/m^3)	Emissivity (ε)
Germanium	60	320	5323	0.9
Copper-1	400	385	8700	0.05
Ceramic	30	900	3900	0.75
Copper-2	202.6	871	2719	0.9

2.2 Governing equations

For solar cell layers:

The heat conduction equation between the layers of the PV cell is as follows:

$$\nabla(k_i \nabla T_i) + q_i = 0 \quad (1)$$

where k_i represents the thermal conductivity of the ith layer.

Internal heat generation term is added for the germanium layer because heat is generated inside the germanium layer due to solar radiation absorption.

The heat generated in the germanium layer is calculated according to the following expression:

$$q_{Ge} = \frac{(1-\eta_{cell}).G.\alpha_{Ge}.A}{V} \quad (2)$$

where *G* is the net concentrated solar irradiation, *α* is the absorptivity of the germanium layer, and *A* and *V* are the surface area and volume of the germanium layer, respectively. η_{cell} is the cell's electrical efficiency.

The net concentrated solar irradiation is a function of the optical efficiency of the solar cell (η_{opt}) and the concentration ratio (CR) of the solar cell.

$$G = I.CR.\eta_{opt} \quad (3)$$

where *I* is the solar irradiation falling on the solar cell.

The electrical efficiency of the solar cell (η_{cell}) is a function of the operating temperature of the solar cell. As the temperature of the solar cell increases, the cell efficiency decreases. The term (1-η_{cell}) represents the portion of absorbed concentrated solar irradiance converted to heat. This heat has to be dissipated or absorbed by the coolants to keep the cell's temperature low. The solar cell's electrical efficiency is expressed in terms of the operating temperature of the cell by the following equation:

$$\eta_{cell} = \eta_{ref} - \beta_{thermal}(T_{cell} - T_{ref}) \quad (4)$$

where cell reference efficiency η_{ref} is taken as 40.3% at reference temperature T_{ref} = 298K and CR = 1000, and $\beta_{thermal}$ is the thermal coefficient and is equal to 0.047%.

For jet impingement:

Continuity equation:

$$\nabla.\left(\rho_f \vec{V}\right) = 0 \quad (5)$$

Momentum equation:

$$\vec{V}.\nabla\left(\rho_f \vec{V}\right) = -\nabla P + \nabla.(\mu_f \nabla \vec{V}) \quad (6)$$

Energy equation:

$$\vec{V}.\nabla\left(\rho_f C_f T\right) = \nabla.(k_f \nabla T) \quad (7)$$

where, ρ, μ and *k* are the density, viscosity, and thermal conductivity of the coolant fluid, respectively. $\vec{V}$ and *P* is the velocity and pressure, respectively.

2.3 Boundary conditions:

The top layer of the concentrated PV system is subjected to mixed convection radiation heat losses boundary conditions. All of the sides of the CPV system are given adiabatic boundary conditions. For the coolant, inlet jets are given uniform temperature and velocity normal to the inlet boundary conditions, and at the outlet, zero-gauge pressure boundary condition was given.

For the top layer of the germanium cell layer and copper layer:

$$-k_{Ge}\frac{\partial T_{Ge}}{\partial z} = q_{rad,Ge\to S} + q_{conv,Ge\to a} \quad (8)$$

$$-k_{cu}\frac{\partial T_{cu}}{\partial z} = q_{rad,cu\to S} + q_{conv,cu\to a} \quad (9)$$

where, $q_{rad,Ge\to S}$ is the radiative heat loss from the Germanium layer to the sky and $q_{conv,Ge\to a}$ is the convective heat loss from the germanium layer to the ambient.

The convective heat loss from the Germanium layer to the ambient can be calculated using the following correlations:

$$q_{conv,Ge\to a} = h_{conv,wind}(T_{Ge} - T_a) \quad (10)$$

$$h_{conv,wind} = 5.82 + 4.07V_{wind} \quad (11)$$

where T_a is the ambient temperature, T_{Ge} is the temperature of the Germanium cell, $h_{conv,wind}$ is the convective heat transfer coefficient, and V_{wind} is the wind velocity.

Radiation heat loss from the germanium layer to the sky can be calculated using the following expression:

$$q_{rad,Ge\to S} = \sigma\epsilon_{Ge}(T_{Ge}^4 - T_s^4) \quad (12)$$

$$T_s = 0.0522T_a^{1.5} \quad (13)$$

where ε_{Ge} is the emissivity of Germanium, T_s is the sky temperature in Kelvin, and T_a is the ambient temperature in Kelvin.

At the interfaces between all layers, thermally coupled boundary conditions are given. At the interface between the germanium layer and copper top layer, the thermally coupled boundary condition is given as follows:

$$-k_{Ge}\nabla T_{Ge} = -k_{cu}\nabla T_{cu} \quad (14)$$

$$T_{Ge} = T_{cu}$$

At the interface between the top copper layer and the ceramic layer:

$$-k_{cu}\nabla T_{cu} = -k_{ce}\nabla T_{ce} \quad (15)$$

$$T_{cu} = T_{ce}$$

At the interface between the ceramic layer and the bottom copper layer:

$$-k_{ce}\nabla T_{ce} = -k_{cu,b}\nabla T_{cu,b} \quad (16)$$

$$T_{ce} = T_{cu,b}$$

At the interface between the bottom copper layer and the heat sink top surface:

$$-k_{cu,b}\nabla T_{cu,b} = -k_{Al}\nabla T_{Al} \quad (17)$$

$$T_{cu,b} = T_{Al}$$

where T_{Ge}, T_{cu}, T_{ce}, $T_{cu,b}$, T_{Al} are the temperatures of the germanium cell layer, top copper layer, ceramic layer, bottom copper layer, and aluminium heat sink, respectively. k_{Ge}, k_{cu}, k_{ce}, $k_{cu,b}$, k_{Al} are the thermal conductivities of the germanium cell layer, top copper layer, ceramic layer, bottom copper layer, and aluminium layer, respectively.

For heat sink inlets and outlets:

At inlet: $V_f = V_{in}$ and T_{in} = 298K

At outlet: gauge pressure P_{out} = 0

All sides of the heat sink wall and the back side are adiabatic.

No slip boundary condition at the fluid-solid interface.

3. Results and discussion

3.1 Validation

The present numerical model is validated with Zahhad et al. [6]. The authors investigated the variation in cell temperature with a mass flow rate of cooling fluid and concentration ratio. The authors studied the variation in thermal stress along the center and diagonal lines of the cell. Zahhad et al. [6] used water as a cooling fluid. Figure 2 shows the variation in the temperature of the Germanium cell with respect to the inlet mass flow rate of the cooling fluid. It is observed that the cell temperature decreases with an increase in the coolant mass flow rate. The configuration with one inlet at the center is better than multiple inlet jets because of the absence of cross-flow. Therefore, the impingement zone develops without restrictions at the target surface of the impinging. A reasonable agreement is found between the present numerical model and the results by Zahhad et al. [6]. An average error of 1.68% and an average temperature difference of 1.33 K is found between the present numerical model and the results by Zahhad et al. [6].

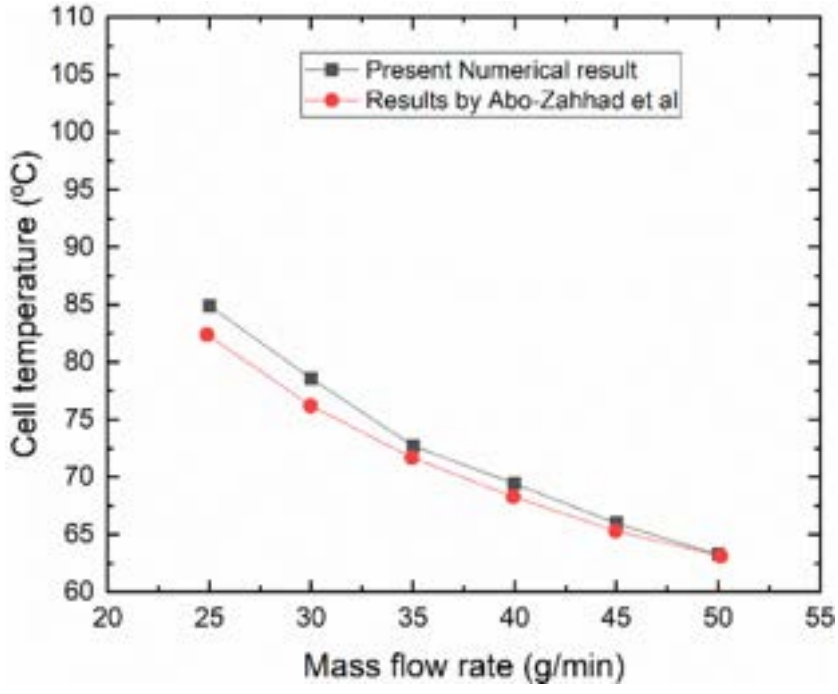

Figure 2. Validation of numerical model with Zahhad et al. [6].

The simulation is further performed for the same configuration with Ag-ZnO hybrid nanofluids as a cooling fluid. The thermophysical properties used for Ag-ZnO hybrid nanofluids are listed below [15] :

Table 2. Thermophysical properties of Ag-ZnO hybrid nanofluids

Volume concentration (%)	Density (kg/m^3)	Specific heat (J/kg-K)	Thermal conductivity ratio (K_{nf}/K_b)	Viscosity (Pa-s)
0.02	1000.932	4186.264	1.08	0.0031
0.04	1001.864	4185.527	1.145	0.0035
0.06	1002.796	4184.791	1.185	0.0042
0.08	1003.728	4184.054	1.25	0.0045
0.10	1004.66	4183.318	1.29	0.0052

Figure 3 shows the cell temperature at varying volume concentrations of Ag-ZnO nanoparticles at a mass flow rate of 25 g/min. The cell temperature decreases with an increase in the volume concentration of nanoparticles. This is because of the enhanced thermophysical properties of nanofluids at a higher volume concentration of nanoparticles. The thermal conductivity of nanofluids increases due to the Brownian motion of nanoparticles. Nanoparticles move through the liquid, and convection is induced due to the Brownian motion of nanoparticles. This leads to an increase in nanofluid thermal conductivity. Also, the ballistic phonon transport of nanoparticles helps increase the thermal conductivity of nanofluids. Due to the increase in the thermal conductivity of nanofluids, the amount of heat transferred from the bottom copper layer to the coolant increases.

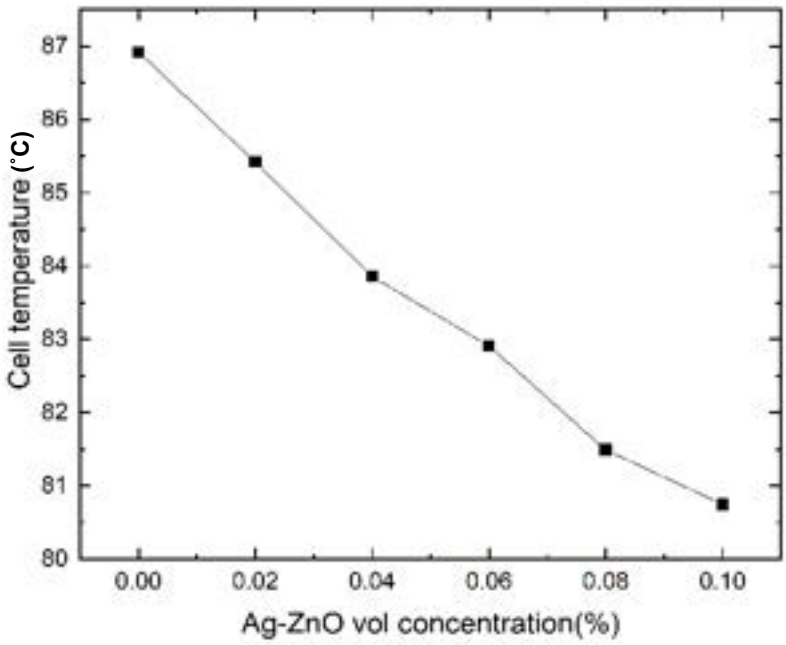

Figure 3. Variation in cell temperature with Ag-ZnO volume concentration.

Figure 4 shows the cell electrical efficiency with a varying volume concentration of Ag-ZnO nanoparticles at a mass flow rate of 25 g/min. It is evident that the electrical efficiency increases with increasing nanoparticle volume concentration. Since the cell temperature decreases with an increasing volume concentration of nanoparticles, the cell's electrical efficiency increases.

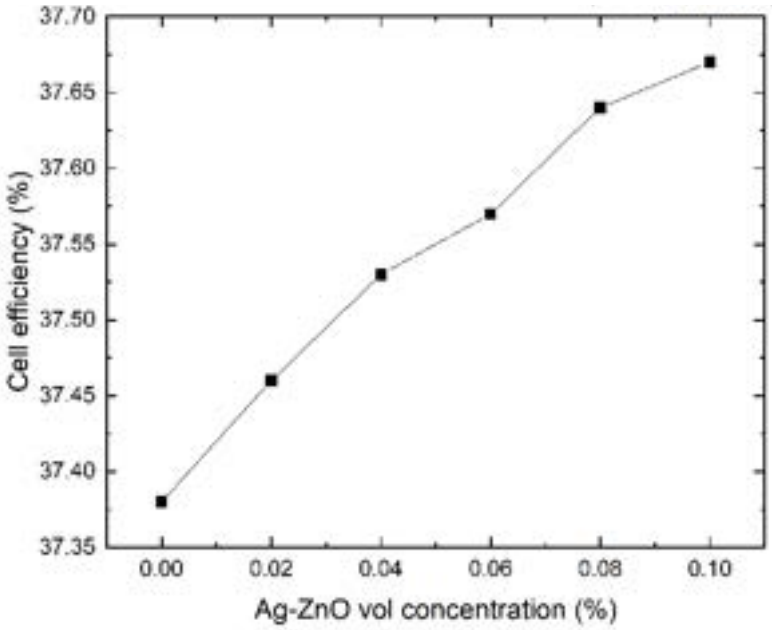

Figure 4. Variation in cell electrical efficiency with Ag-ZnO volume concentration.

Figure 5 shows the effect of the mass flow rate of Ag-ZnO nanofluids at 0.1% volume concentration on the average cell temperature and compares it with water as a coolant. The minimum mass flow rate is 25 g/min to avoid flow boiling. It is observed that Ag-ZnO hybrid nanofluids cool the cell better because of their enhanced thermophysical properties. Therefore, the cell's electrical efficiency will be higher with nanofluids as a cooling fluid.

Although cell temperature decreases at higher coolant mass flow rates, the pressure drop also increases with the increase in the coolant mass flow rate. The net power gained is affected by frictional pressure drops. To use waste heat from highly concentrated PV system applications, the coolant mass flow rate should be low.

Cell temperature variation on the cell surface is also evaluated. It is observed that the maximum temperature difference at the surface of the cell is 2.06 °C for a mass flow rate of 25 g/min at 0.1% volume concentration of Ag-ZnO nanoparticles. It shows that temperature uniformity can be achieved using a confined jet impingement cooling technique on the surface of the PV cell. This will eliminate the problems associated with thermal stresses and current mismatching.

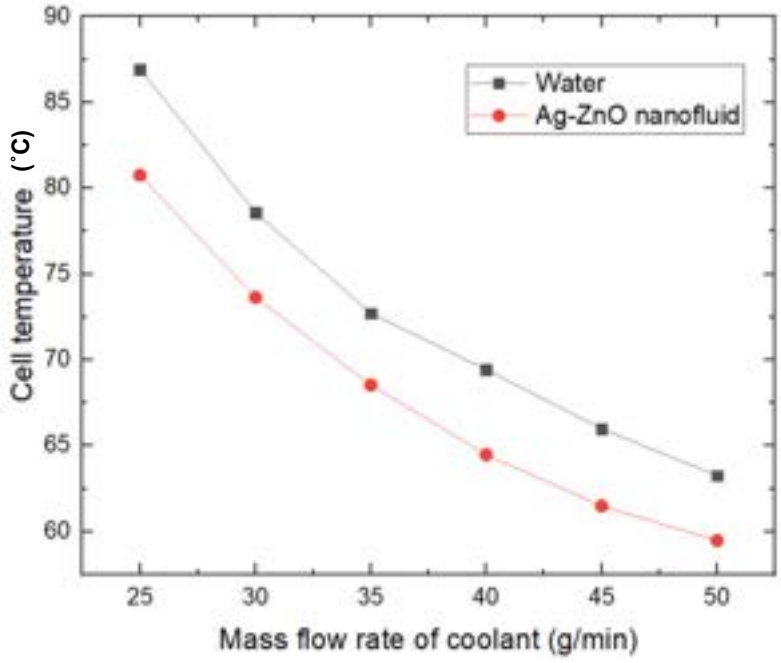

Figure 5. Variation in cell temperature with mass flow rate of coolant.

4. Conclusions

It is found that Ag-ZnO hybrid nanofluids can perform a better cooling of the cell than water because of the enhanced thermophysical properties of nanofluids. The thermal conductivity of nanofluids increases compared to base fluid, which increases heat transfer from the bottom copper layer to the coolant. The higher the nanoparticle volume concentration, the better the cooling effect. Also, nanofluids will increase cell electrical efficiency. It is observed that numerically there is only a slight increase in cell efficiency with nanofluids compared to water. Experiments with the proposed system will be performed in the future. Surely, the cooling of CPV cells and cell electrical efficiency will be improved in experimentation since the effect of Brownian motion and ballistic transport phonon of nanoparticles will be observed in experiments.

Nomenclature

A	area of the solar cell, m^2
CR	concentration ratio
G	concentrated solar irradiance, W/m^2
h	convective heat transfer coefficient, $W/(m^2\ K)$
I	direct normal irradiation, W/m^2
k	thermal conductivity, W/(m K)
L	length, m
$\dot{m}$	mass flow rate of coolant, kg/s
q	heat flux, W/m^2
T	temperature, ˚C
V	volume of solar cell, m^3
v	velocity, m/s
W	width, m

Greek symbols

μ	Viscosity, Pa s
α	absorptivity
$\beta_{thermal}$	solar cell temperature coefficient
Δ	difference
δ	thickness, m
η	efficiency, %
ρ	density, kg/m^3
σ	Stefan-Boltzmann constant, $5.67\times10^{-8}\ W/(m^2\ K^4)$

Subscripts and superscripts

a	ambient
b	base fluid
cell	for cell layer
conv	convection
cu	copper layer

Abstract:

This work proposes a Computational Fluid Dynamics (CFD) model of a cement rotary kiln capable of reproducing some 3D effects which cannot be solved by simpler models. Specifically, flight behaviour and falling position of fuels particles are captured. Furthermore, detailed combustion chemistry (devolatilization, char combustion and moisture evaporation) is solved. The 64-meter-long kiln burns a blend of petcoke and Refuse Derived Fuel (RDF). Both were characterized and their properties introduced in the model. The clinker bed was simplified by fixing a temperature profile, a typical approach in literature. Different air excess numbers (λ) were simulated to assess the impact on flight of particles and combustion profiles. The resulting combustion profiles give a valuable input to simpler models in which a much larger and faster set of simulations can be performed, allowing kiln operators to run several different operational scenarios.

Keywords:

Cement kiln; CFD; Refuse-Derived-Fuel; Combustion.

1. Introduction

Cement production is a major source of environmental pollution due to high energy consumption and pollutant emissions [1-3]. To reduce its impact, studies have focused on using waste-derived fuels and biomass, as well as oxy-fuel and oxy-coal combustion technologies. CFD modelling has been used to investigate the co-combustion of different fuels in cement rotary kiln [1-8].

One study [1] found that annulus fuel feeding results in faster devolatilization and char combustion than central tube fuel feeding. Another study [2] aimed to reduce CO_2 emissions by optimizing the combustion process through co-combusting biomass with pulverized coal and showed that oxy-fuel combustion is promising for cement production and some studies [9-11] about oxy-coal combustion in cement rotary kilns revealed that increased combustion efficiency reduces fuel consumption [11] but may lead to a decrease in the calcination time of cement [10]. Also, the amount of NOx produced increases with increasing oxygen content in the primary air [10, 11].

Waste materials have also been used as alternative fuels in cement rotary kilns, due to the depletion of fossil fuels and an increase in their cost [4]. If thermochemical processes in clinker formation want to be modelled, a mathematical model is necessary to understand and quantify the different processes occurring inside clinker bed, particularly the homogeneous processes taking place in the freeboard of the bed of material being processed [3, 4, 6, 7]. The impact of coating layers on the clinker production process within a rotary kiln burning both coal and Refuse Derived Fuel (RDF) was investigated in one study [7], showing that a thin coating profile increases the gas phase temperature in the kiln (due to the insulation effect) reducing free lime content of the final clinker product. Study carried out in [6] showed that co-combustion of coal and RDF can lead to lower gas and clinker temperatures in the sintering zone, which can affect the clinker properties. Regarding RDF properties, [5] provided a careful characterization of its flight and combustion behaviour, useful for accurate computation of co-combustion with coal.

RETROFEED EU H2020 project main objective is to enable the use of an increasingly variable, bio-based and circular feedstock in process industries (in which a cement production industry is included) through the retrofitting of core equipment and the implementation of an advanced monitoring and control system and providing support to the plant operators by means of a Decision Support System (DSS) covering the

production chain. In this paper, we present the first part of the development of a cement rotary kiln model, comprising careful CFD setup and simulations of a co-firing of petroleum coke (petcoke) and RDF. Results are used to obtain characteristic combustion profiles of both fuels along the kiln, to feed a simpler 1-D model which can provide fast near real time results to the DSS.

2. Materials and methods

Figure 1 shows an overview of the modelled kiln.

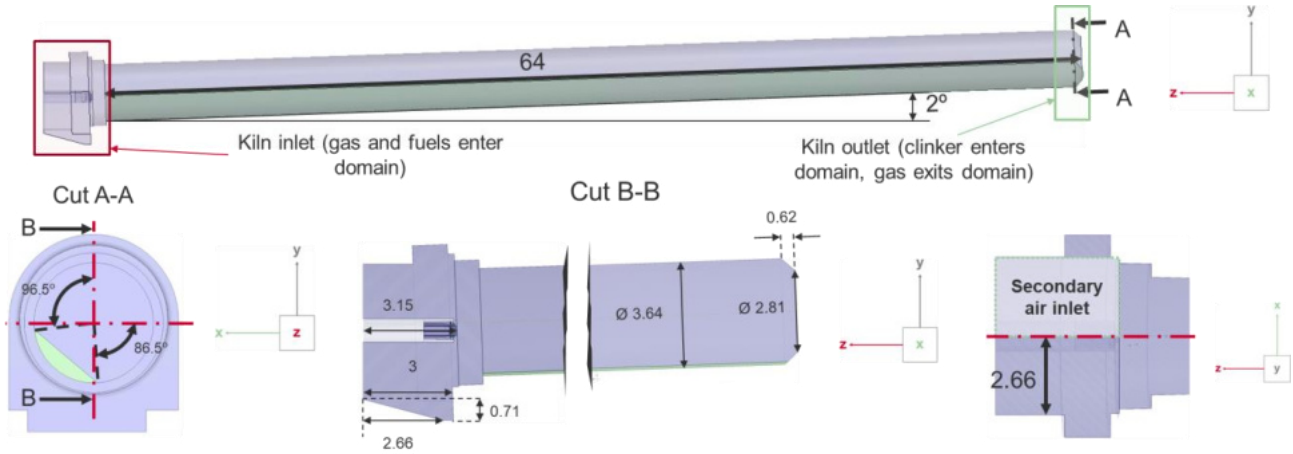

Figure 1. Modelled kiln overview and dimensions. All dimensions in meters. Kiln body is coloured in blue and actually modelled in simulations. Clinker bed is coloured in green, and it is shown only for visualization purposes, since it is not directly modelled in simulations.

2.1. Combustible characterization

In order to properly characterize the employed fuels in the modelled cement kiln, a combination of real measured and literature values was used. Petcoke and RDF are introduced by the burner.

2.1.1. Petcoke

Chemical information about petcoke is gathered in Table 1. For unmeasured values, a literature review was carried out. Properties were selected from the most similar fuel to the actually used. This was assessed by evaluating the Weighted Sum of Errors (WSE) according to Eq. (1), with all the x_i variables in unit basis (for heating values, $x_{i\ real}$ is set to one, given the importance of this term in fuel characterization). The references consulted are: [5, 7, 8, 12, 13, 14, 15, 16, 17].

$$WSE = \sum_{i=1}^{n} \left(\left| \frac{x_{i_{literature}} - x_{i_{real}}}{x_{i_{real}}} \right| \cdot x_{i_{real}} \right) \quad (1)$$

Table 1. Chemical characterisation of employed petcoke.

Parameter		Value	Unit	Source
Ultimate analysis (daf)	Carbon	85.20	%	Measured
	Hydrogen	4.04	%	Measured
	Nitrogen	1.05	%	Measured
	Oxygen	3.12	%	Measured
	Sulfur	6.59	%	Measured
Proximate analysis	Moisture	2.37	%	Measured
	Ash	0.78	%	Measured
	Volatiles	28.8	%	Normalized value of sample 9 from [13]
	Fixed carbon	68.05	%	Normalized value of sample 9 from [13]
LHV		34130	kJ/kg	Measured
Density		1423.5	Kg/m^3	Daqing petcoke from [14]
Specific heat		1000	J/(kg-K)	Average value from [18]

A granulometry analysis was also carried out, which was fitted to a Rosin-Rammler distribution. Results of granulometry are collected in Table 2, and Rosin-Rammler parameters in Table 5.

Table 2. Results from petcoke granulometry.

Diameter range (μm)	Mass fraction in range	Y_d: Mass fraction over diameter range
0.724 - 6.468	0.1	0.9
6.468 - 25.498	0.4	0.5
25.498 - 69.534	0.4	0.1
69.534 - 138.038	0.1	0

2.1.2.Refuse Derived Fuel (RDF)

Before introducing RDF into kiln burner, it passes through a sieve, in which particles with size over 30 mm are removed. After that, metals are also removed from the mix. From the received RDF from different suppliers all along 2020, a statistical analysis was performed to determine the typical share of components in demosite's RDF. Six samples from different suppliers were characterized, shown in Figure 2. It is noticeable the very different nature of each bucket content, confirming the heterogeneous nature of RDF fuels. As for the petcoke, data of RDF coming from demosite analysis is limited and needed to be completed with literature values. Specifically, moisture and ash content, low heating value, as well as elemental composition (ultimate analysis) is available for all the RDF received along 2019 and 2020. RDF received at demosite is divided into five main groups, gathered in Table 3. RDF/CDR is general mix of very different and heterogeneous residues. Plástico e borracha is composed of plastics and undetermined agglomerated particles, having a very high moisture content. Fluff are textiles from different sources. Materiais Impróprios p/Consumo are different residues with a similar aspect to fines as defined by [5]. They are present in demosites silos as a negligible fraction. RDF pellets are present as a low fraction in demosite silos.

From all the suppliers' lorries that arrived at demosite's facilities in 2020, the total quantity of RDF of the different groups described above is gathered in Table 3. The main difference between RDF and petcoke is about the heterogeneity of particles composing it. To properly characterize particles shape and size distribution of RDF is a very challenging task. Together with samples characterization, a literature review was done to fulfil this task. Following [5], it was found that a proper way for defining RDF particles is splitting them into five main groups of particles, namely 3D plastics, 2D foils, paper and cardboard (P&C), textiles and fines (which are unclassifiable particles smaller than ~2mm).

Table 3. RDF types received by demosite in 2020.

RDF type	Sample from Figure 2	Tons received in 2020	Mass fraction over total tons (%)
RDF/CDR	b), d) and g)	26897.4	80.7
Plástico e borracha	e)	902.2	2.7
Fluff	c) and f)	5044.9	15.1
Materiais Impróprios p/Consumo	-	27.3	0.1
RDF pellets	-	443.5	1.3

There is a need to know the quantity of each of the five groups defined by [5] in each of the RDF types from Figure 2, so a proper shape factor and size distribution can be applied to the developed model.

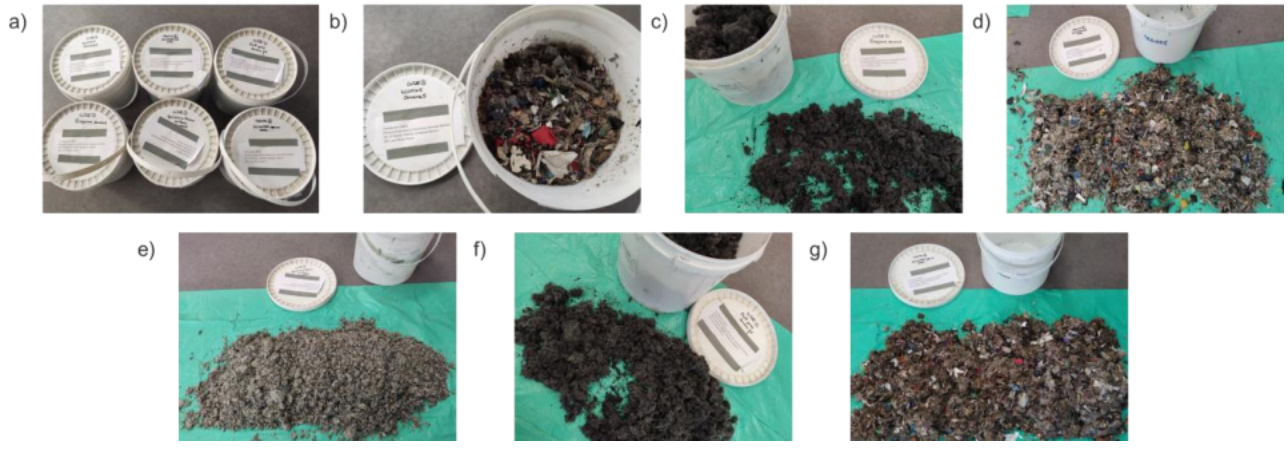

Figure 2. Samples of RDF obtained from different suppliers.

A sieve analysis was carried out for the three main components of RDF mix (RDF/CDR, Plástico e borracha and Fluff), which sum up a 98.6% of the total RDF used in demosite, removing previously particles with a dimension higher than 31.5 mm, which is the procedure followed in demosite. Seven sieves were used, with holes sizes of 100, 63, 45, 31.5, 16, 8 and 3.15 mm. Buckets b), e), d) and g) were sieved. Unfortunately, fluff buckets were not able to be sieved due to continuous sticking and very low density; in this case, size distribution from [5] was used. Results of the size distribution are shown in Table 4. Following the same procedure as for the petcoke, a Rosin-Rammler size distribution was obtained from the above results, obtaining the distribution parameters collected in Table 5 for each sample measured.

Table 4. Size distribution obtained from sieve analysis of RDF.

Sample from Figure 2	Type of RDF	Mass fraction (%) between sizes (mm)[1]			
		31.5-16	16-8	8-3.15	3.15-0
b)	RDF/CDR	66.7	12.4	11.8	9.1
e)	Plástico e borracha	8.4	81.4	6.7	3.5
d)	RDF/CDR	65.1	10.9	14.8	9.2
g)	RDF/CDR	77.3	8.0	8.9	4.8

[1]After removing all >31.5 mm particles and normalizing mass fractions

To properly model the chemical and combustion characteristics of RDF introduced in the developed model, it is still necessary to determine the quantity of each of the five groups given by [5]. Nevertheless, all RDF components were treated as only one, with average values of chemical parameters, due to the high computational cost of computing five different chemical species. A match between the RDF types provided to demosite and those used by [5] was done. By visual inspection, all the six samples were matched to one or various of the types of RDF reported by [5]. These matches are collected in Table 6. Percentages for RDF/CDR are the same as in RDF mixture used by [5], given the visual similarities of both mixtures.

Table 5. Rosin-Rammler distribution parameters of demosite's petcoke and RDF.

Fuel	Sample from Figure 2 (only RDF)	Diameter (μm) $\bar{d}$ (Mean)	Minimum	Maximum	n (size distribution parameter)
RDF	b)	26.0308	3.15	31.5	1.0492
	e)	12.2157	3.15	31.5	2.7679
	d)	25.9332	3.15	31.5	0.9894
	g)	28.0448	3.15	31.5	1.3136

Petcoke	-	34.193	0.724	138.038	0.944

[1]Assumed as textiles. All data coming from [5].

Table 6. Equivalences between RDF used by demosite and the used by [5].

Demosite's RDF type	Sample from Figure 2	RDF component mass fraction (%) following [5]				
		3D plastics	2D foils	P&C	Textiles	Fines
RDF/CDR	b), d), g)	22	24	19	8	27
Plástico e borracha	e)	100[1]	0	0	0	0
Fluff	c), f)	0	0	0	100	0

[1]Despite this sample seemed to be mainly formed of fines particles, they were all agglomerated forming much larger particles that are alike 3D plastics in terms of geometry/shape.

Applying the mass fractions of Table 3 and Table 6, the resulting RDF mixture that was used in the models (only in terms of shape and physical composition; different chemical and combustion parameters are allowed to be introduced) is the shown on the right side of Figure 3. As for the petcoke, a literature review was carried out to obtain the RDF remaining properties that best fitted the ones used by demosite. It was determined that the main parameter for charaterisation of RDF combustion is moisture. Therefore, the following procedure was performed for selecting the RDF chemical properties to introduce in the models:

- A statistical analysis of all the received RDF samples in demosite during 2020 was carried out.
- To avoid abnormal values of moisture which are not representative of a typical RDF mixture, the three quartiles of the moisture content in RDF samples were obtained.

- Three samples of RDF were selected from the whole set: one sample with a slightly lower moisture than the first quartile one; another with a moisture almost equal to the median, and a third with a slightly higher moisture than the third quartile one.

The selected RDF samples chemical properties, as well as density, specific heat and LHV, are collected in Table 7. These will be named as RDF type 1, type 2 and type 3 in the rest of the paper.

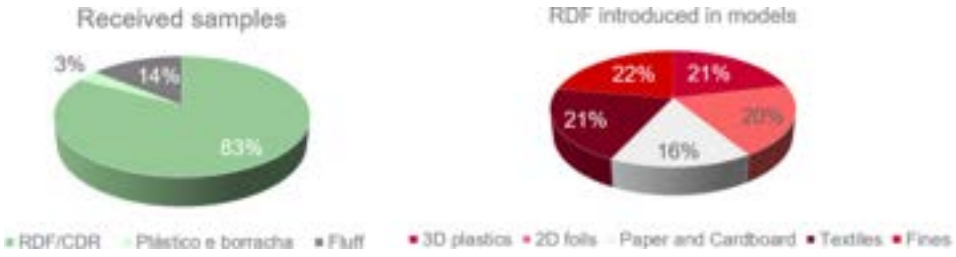

Figure 3. RDF share both in demosite's nomenclature and in reference [5] nomenclature.

Table 7. Chemical characterisation of selected RDF. Ultimate analysis basis: daf.

2.2. Simulation setup

A 3D CFD model was developed to capture the complex behaviour of fuel combustion, specifically its flight behaviour, to obtain burning profiles along its length. Three different mixes of fuels, each with two different air excess numbers (λ) were simulated. Geometry shown in Figure 1 was modelled in Ansys Fluent 2020R1. Clinker phase was not meshed nor directly simulated. Instead, it was set as a moving wall boundary condition with a fixed temperature profile. This approach has been also employed by [3]. Other researchers have used a heat flux boundary condition instead of temperature profile [6]. To avoid the prohibitive computational cost of simulating the whole burner together with the kiln cylinder, simulations of only the burner were performed, to obtain the velocity and turbulence profiles at burner outlet, to be used as boundary conditions of the whole kiln model.

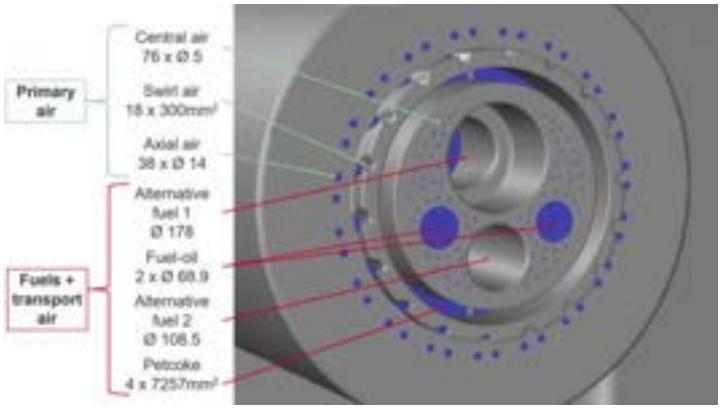

Figure 4. Modelled burner for CFD simulations.

Figure 4 shows the modelled burner. Central air holes were not meshed nor simulated, since they are so small that computational cost of a proper mesh is prohibitive. As the manufacturer of the burner ensures that 1% of flow goes through these holes, that condition was used for the whole kiln simulations. A set of

simulations of the burner alone were performed, to determine the mass flow share for each boundary. In total, five simulations were run, starting with a primary air input of 5 m/s air, and increasing in 5 by 5 steps up to 25 m/s. For all of them, the resulting mass flow share is the one collected in Table 8. Apart from that, it was also checked that, for all cases, the resulting air flow at the swirl outlet has a 0.86/1 relation in terms of tangential/axial flow direction.

Table 8. Mass flow share for each of the three primary air inlets in CFD model.

Boundary	Mass flow share (%)
Axial air inlet	63
Central air inlet	1
Swirl air inlet	36

Since primary air mass flow is fixed in the kiln to 2.83 kg/s, a simulation with the burner model was used to obtain the quantitative values of the k and ε parameters for the turbulence model in axial and swirl inlets, introduced as boundary conditions in the whole kiln model. The results are gathered in Table 9.

Table 9. Turbulence parameters for primary air inlets obtained from simulation with fixed primary air mass flow input.

Boundary	k (m^2/s^2)	ε (m^2/s^3)
Axial air inlet	132.3	896648
Swirl air inlet	243.2	1979220

Table 10 gathers some data about the resulting meshes. A detail of the whole kiln model mesh can be seen in Figure 5. Table 11 shows the type of each boundary of the kiln CFD model.

Table 10. Details of the meshes of CFD models.

Parameter	Burner model	Whole kiln model
Type of cells	Hexahedral	Hybrid polyhedral-hexahedral
Number of cells	2.99 M	2.29 M
Minimum orthogonal quality	0.10	0.27
Maximum aspect ratio	33.45	42.23

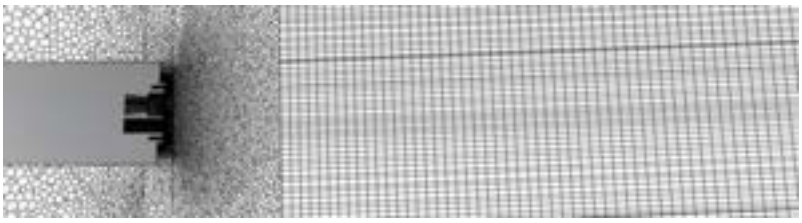

Figure 5. Example of mesh in axial cut plane of whole kiln mesh.

Table 11. Boundary types in CFD kiln model.

Boundary	Name in Figure 4 (only burner inlets)	Boundary
Axial air inlet	Axial air	Mass flow inlet
Central air inlet	Central air	Mass flow inlet
Swirl air inlet	Swirl air	Mass flow inlet
Petcoke inlet	Petcoke	Mass flow inlet
RDF inlet	Alternative fuel 1	Mass flow inlet
Secondary air inlet	-	Mass flow inlet
Outlet	-	Pressure outlet
Burner walls	-	Adiabatic wall
Clinker-gas contact interphase	-	Moving fixed-temperature wall

Details of boundary conditions are gathered in Appendix A: detailed boundary conditions in CFD simulations. Mass, momentum and energy were solved with a Reynolds Averaged Navier Stokes (RANS) approach. Turbulence was solved with the realizable κ–ε model with enhanced wall treatment [19]. Radiation is solved using the Discrete Ordinates model. Chemistry is solved with the species transport model, with one volatiles

species for petcoke and another for RDF. Turbulence-chemistry interaction was solved with the eddy-dissipation model [7]. Particles flight and combustion behaviour were solved with the Discrete Phase Model (DPM) ([3, 6, 7], and similar to the used in [8]). One injection for petcoke and five for RDF were used, with size distribution according to Table 5. Particles devolatilization and char combustion models parameters, as well as water droplet mass transfer model (drying of fuels) and parameters, are collected in Table 22. All values for petcoke and water are obtained from [20], whereas those for RDF come from [5].

Table 12. Combustion modelling parameters for discrete phase model in CFD simulations.

Parameter		Material		
		Petcoke particle	RDF particle	Water droplet
Vaporization temperature (K)		550	550	-
Devolatilization	Model	Single rate		-
	Preexponential factor (s^{-1})	9.59e+04	2.47e+06	-
	Activation energy (J/kgmol)	8.26e+07	1.065e+08	-
Combustion	Model	Kinetics/ diffusion limited		-
	Rate constant	5e-12	5e-12	-
	Preexponential factor (s^{-1})	0.01	0.00204	-
	Activation energy (J/kgmol)	1.05e+08	7.9423e+07	-
Thermolysis	Model	-	-	Single rate
	Preexponential factor (s^{-1})	-	-	5.13e+06
	Activation energy (J/kgmol)	-	-	8.79e+07

3. Results and discussion

One kiln operating point corresponding to typical values was simulated with values shown in Table 13.

Table 13. Common boundary conditions of inlets in CFD simulations.

Parameter	Value	Unit
Primary air flow (divided according to Table 8)	2.83	Kg/s
Petcoke transport air flow	1.17	Kg/s
RDF transport air flow	0.75	Kg/s
Petcoke particles flow	0.61	Kg/s
RDF particles flow (divided according to Figure 3)	1.94	Kg/s
Primary air temperature	49	ºC
Petcoke air and particles temperature	61	ºC
RDF air and particles temperature	34	ºC
Secondary air temperature	916	ºC

Two different excess air numbers were simulated for each RDF type, as shown in Table 14.

As a representative case, some detailed results of temperature and particle flight and reaction behaviour are shown from CFD simulation 1-1. Figure 6 shows the temperature contour of simulation 1-1. As can be seen, temperature increases due to combustion relatively far from burner, unlike traditional petcoke and low-share RDF quantities (such as those reported by [3] and [7]). This is due to the poor combustion quality of RDF, displacing the flame formation downwards. RDF's higher size and ash fraction compared to petcoke can explain this result. It can be also seen that temperature increase starts from the bottom of kiln (i.e., clinker surface), and shows a high peak of temperature in that zone. This is due to the flight of RDF particles (as will be seen in next figures): given their high size (thus, low burning rate) and non-spherical shape, they tend to

fall onto clinker surface instead of being blown away by air. This result is in agreement with the reported by [3, 6, 7]. After the first third of kiln length (~20m), flame profile widens and effectively heats homogeneously the whole domain.

Table 14. Performed CFD simulations boundary conditions.

Simulation	RDF type from Table 7	RDF power share (%)	λ
1-1	1	72.90	1.1
1-2	1	72.90	1.4
2-1	2	61.99	1.1
2-2	2	61.99	1.4
3-1	3	63.25	1.1
3-2	3	63.25	1.4

To explain the above results, Figure 7 shows the particle tracking of each type of particle introduced through the burner up to the half of kiln length. As it can be seen, only petcoke and fines (which are the smallest RDF particles) are blown by air throughout the kiln length. The rest of particles fall onto clinker bed soon, where they start to burn. Though fines are blown by air, they start burning in the same location than the rest of RDF particles. This is due to their low combustion quality (they need very high temperatures to start the reaction) in comparison with petcoke. The burning location of RDF particles explain the peak temperature found at clinker bed surface in Figure 6. These particles flight trajectories of RDF particles also found by [6].

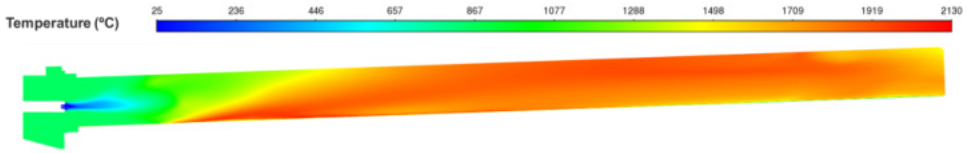

Figure 6. Temperature contours from CFD simulation in a longitudinal plane contour.

To obtain the combustion profiles from the simulations, the CFD domain was split into 64 axial slices, in which the integral of petcoke and RDF volatiles and burnout (char oxidation), as well as water evaporated from particles, was obtained. Results are shown in Figure 8.

Some general comments apply for all the simulations results:

- Petcoke devolatilization and fixed carbon burning show a well-shaped Gauss bell distribution.
- Dried water profiles show two humps. The first coincides with the higher petcoke volatiles and fixed carbon release; the second hump, higher than the first, takes place at around 10 meters, where high temperatures appear near clinker surface.
- Higher air excess show wider distributions, which reflect the higher drag force and flow speed suffered by particles, which tend to spread out their burning locations.
- Very low RDF char is burned in gas phase for all the simulated cases. This results in a burning after falling onto clinker surface, which CFD is unable to capture and has to be taken into account in some way if an accurate modelling is intended, as [3] and [6] affirm.

Something very noticeable is that, for RDF types 1 and 2, burning profiles are very similar regardless the excess air used; on the other hand, RDF type 3 shows large differences in petcoke combustion between the two air excesses simulated, but not on RDF combustion or evaporation. This may be due to the poor resolution of the discretization employed; a higher number of slices may provide less discrepancies between cases. It can be seen that the totality of petcoke combustible matter burns within gas phase in the first 10 meters of the kiln, confirming its very good burning behaviour with respect to RDF. An interesting result is that, in all the cases, RDF power is released earlier in the case with lower air excess, reflecting less drag force and speed of particles.

Another interesting result is that all RDF volatiles are released a bit later than half of the kiln (~40 m). All the RDF char that combusts in gas phase (which is very low in general) also does it mostly in the first 40 meters of the kiln. It can be also seen that, in all the cases, RDF volatiles start to be released earlier and end later in the case with λ=1.4 than in the case with λ=1.1. This may be due to the higher oxygen availability for RDF in the first part of the kiln in the case with λ=1.4, but less gas temperature is achieved (more mass of air is heated), so reaction is slower than in the case with λ=1.1. On the other hand, the opposite happens to RDF

char combustion. It starts later in the case with more excess air. A higher char combustion can be achieved in gas phase when increasing excess air number, particularly in the RDF type 3 case.

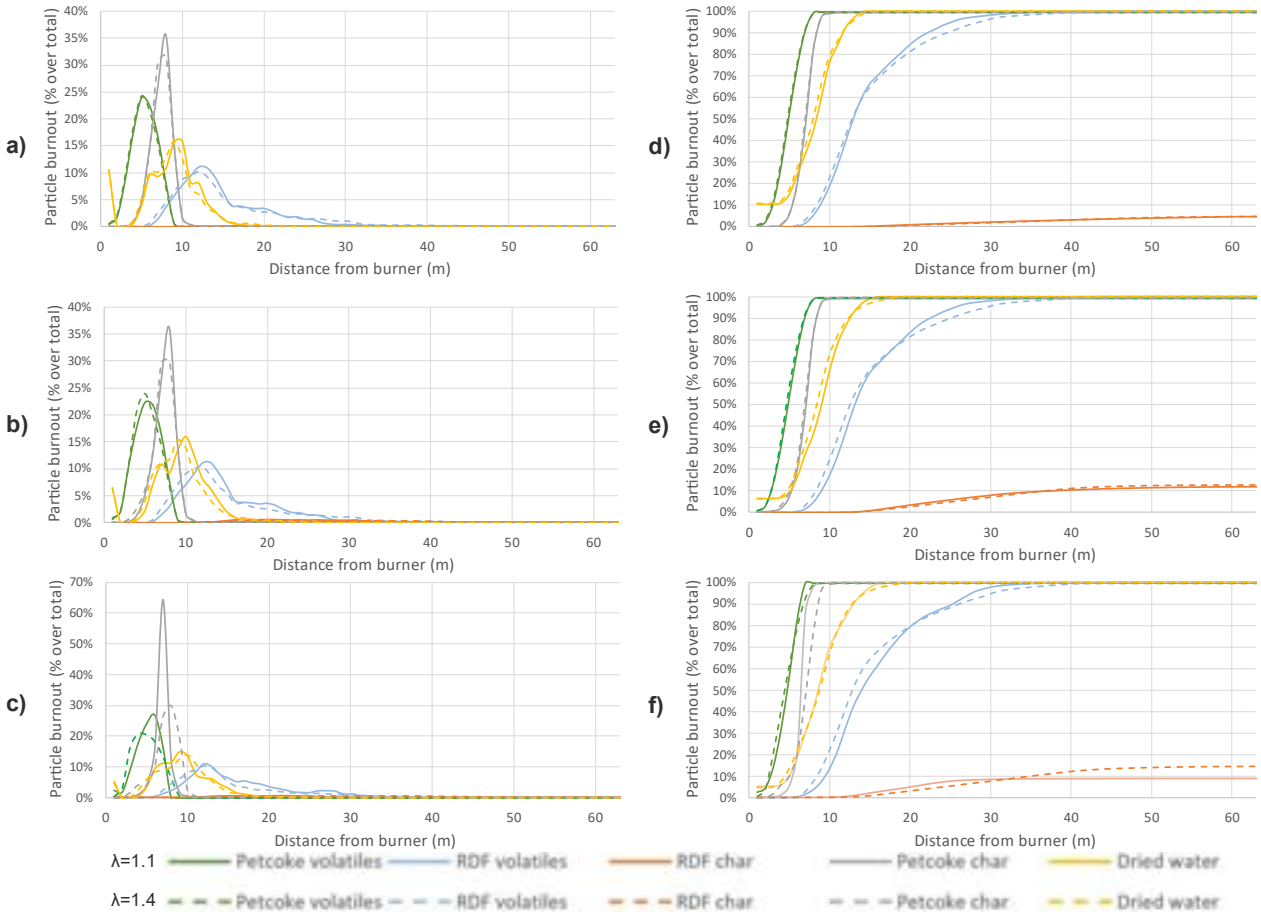

Figure 8. Burning and evaporation profiles from CFD simulations. Left: per slice profile. Right: histogram of profile. a), d) RDF type 1; b), e) RDF type 2; c), f) RDF type 3.

4. Conclusions

From the performed CFD study, some conclusions can be extracted:

- Combustion temperature increases far from the burner due to poor combustion quality of RDF, which displaces the flame formation downwards.
- Temperature increase starts from the bottom of kiln, with a high peak of temperature in that zone due to the flight of RDF particles falling onto clinker surface.
- Only petcoke and smallest RDF particles are blown by air throughout the kiln length, while the rest of particles fall onto clinker bed more or less soon, where they start to burn.
- Petcoke devolatilization and fixed carbon burning show a well-shaped Gauss bell distribution.
- Very low RDF char is burned in gas phase for all the simulated cases, resulting in burning after falling onto clinker surface.
- Burning profiles are very similar for RDF types 1 and 2 regardless of excess air used, while RDF type 3 shows large differences in petcoke combustion between two air excesses simulated.
- All petcoke combustible matter burns within gas phase in the first 10 meters of the kiln, confirming its very good burning behaviour with respect to RDF.
- All RDF volatiles are released a bit later than half of the kiln, and RDF char that combusts in gas phase also does it mostly in the first half of the kiln.
- RDF volatiles start to be released earlier and end later in the case with higher air excess.
- A higher char combustion can be achieved in gas phase when increasing excess air number, particularly in the RDF type 3 case.
- CFD seems to be a useful tool for understanding the combustion behaviour, as well as temperature profiles in the complex processes that take place inside a cement kiln which, in practice, cannot be measured in experiments due to high quantities of dust, kiln rotation and hard temperature conditions. This allows to understand and optimize their functioning.

Abstract:

Plasma gasification is a promising method for the thermochemical conversion of biomass and wastes into high quality syngas with lower tar content and higher energy densities compared to conventional processes. This study aims to optimize a horizontal tubular entrained flow plasma gasification test rig which should produce plasma pyrolysis chars. Therefore, mixing of fuel particles in the plasma zone as indicated by the respective particle temperatures needs to be improved. For that a couple of configurations were investigated by a CFD simulation in Ansys Fluent: First, the plasma torch gas outlet diameter of 1mm was doubled to reduce plasma gas velocities. Then, several vertical fuel particle inlet tubes were integrated at different distances from the plasma torch nozzle (5, 15, 25 and 35mm) to insert fuel particles more directly into the plasma zone. The wider nozzle outlet diameter resulted in higher particle temperatures, lower velocities and better convergence. From the different particle tube configurations, the closest to the plasma inlet, resulted in the highest average particle temperatures, residence times and better distribution in the reactor than the other cases. It was subsequently concluded that the optimal configuration for enhanced particle heating and mixing shall be designed with a 2mm wide diameter and a 49mm long tube that is 5 mm away from the torch outlet.

CFD; Plasma gasification; Entrained flow gasification; Biomass.

1. Introduction

The demand for biomass as a renewable energy source for heat and energy production as well as a source of sustainable carbon for the chemicals and materials industry is expected to increase strongly over the next decades [1]. Therefore, conversion processes are needed which achieve high efficiencies in terms of their feedstock utilization. One approach for the conversion of biomass for the material use of its inherent carbon is gasification. Traditional gasification processes are often autothermal or require the combustion of part of the biomass feedstock to provide the energy required for the gasification and pyrolysis reactions. This leads to a loss of carbon in the form of CO_2 which should be avoided for maximum carbon conversion into syngas. A possible solution is the operation of the gasification process with plasma assistance. In this way, the energy for gasification and pyrolysis reactions is provided through electricity input and higher quality syngas at higher carbon efficiencies can be produced. One type of such gasifier which looks promising based on first process simulations in Aspen Plus is a plasma-assisted entrained flow gasifier for steam gasification of pulverized biomass input [2].

While there has been significant progress on understanding entrained flow gasification of pulverized fuels under conventional gasification conditions [3, 4], plasma gasification under entrained flow conditions has only seen very limited research activity so far. Vishwajeet et al [5] have examined the gasification of sewage sludge in plasma-assisted entrained flow gasification conditions using a nitrogen plasma torch in a vertical drop tube reactor. The focus was placed on achieving a proof of concept. Detailed reaction mechanisms such as, e.g., char burnout behaviour and char reactivity were not studied. As these characteristics are essential for modelling of plasma-assisted entrained flow gasification and, therefore, need to be in place for the simulation-based design of these gasifiers, research into char properties after plasma entrained flow conditions is necessary. For this purpose, the authors have designed a horizontal entrained flow plasma gasification test rig to produce plasma pyrolysis chars for examination in thermogravimetric analysers and characterization. The design of the test rig consists of a horizontal water-cooled tubular reactor with a concentrically positioned DC plasma torch as shown in Figure 1. Pulverized biomass is fed from the top via a ceramic tube into the plasma zone created by the plasma torch. After leaving the plasma zone, the produced char falls onto a solids extraction tool which can be removed from the tubular reactor after the experiments are finished. This makes it possible to study char characteristics of this char created under plasma entrained flow conditions.

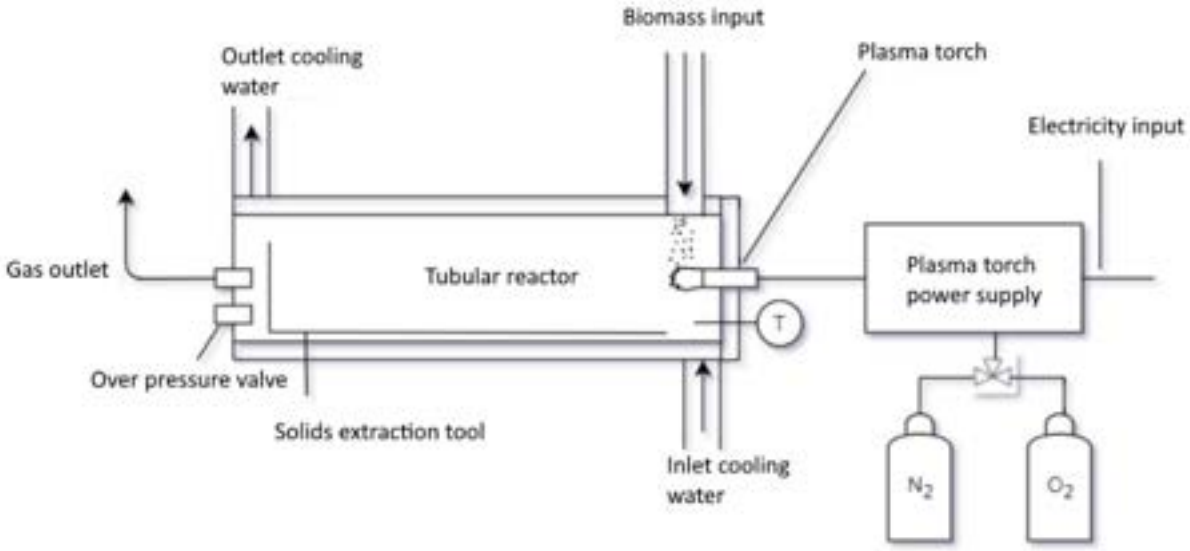

Figure 1. Schematic overview of the tubular plasma gasification test rig for biomass conversion into char under plasma-assisted entrained flow conditions.

In order to produce the highest quality plasma pyrolysis chars, the pulverized fuel needs to mix as well as possible with the plasma zone of the plasma torch resulting in very high heating rates and as high as possible particle temperatures. This leads to two research questions which this research aimed at through computational fluid dynamics simulation of the reactor setup: How can the reactor be modified to improve particle mixing and heating in the plasma zone? At which distance from the plasma inlet should particles be injected to maximize heat transfer to the fuel particles?

Therefore, this research not only helps optimizing the design of the plasma gasification test rig, it also adds to the existing literature on CFD for plasma gasification/pyrolysis because existing CFD research in this area has mainly focussed on fixed bed, downdraft or updraft plasma gasifiers instead of entrained flow reactor setups [6–9].

To answer the research questions, the following cases were simulated in Ansys Fluent:

- Case 0: **1 mm** plasma torch nozzle diameter, free vertical particle drop 40 mm from torch outlet
- Case 1: **2 mm** plasma torch nozzle diameter, free vertical particle drop 40 mm from torch outlet
- Case 2: 2 mm plasma torch nozzle diameter, vertical particle inlet tube **5 mm** from plasma torch outlet
- Case 3: 2 mm plasma torch nozzle diameter, vertical particle inlet tube **15 mm** from torch outlet
- Case 4: 2 mm plasma torch nozzle diameter, vertical particle inlet tube **25 mm** from torch outlet
- Case 5: 2 mm plasma torch nozzle diameter, vertical particle inlet tube **35 mm** from torch outlet

Section 2 presents an overview of the methodology behind the simulations for these cases. Section 3 details how the geometry for the model was generated and presents the mesh independence study. Section 4 goes into detail on the simulation results for the different cases by presenting the results and discussing them. Section 5 finishes with the conclusion and outlook into future research opportunities.

2. CFD modelling methodology

The CFD simulation of the reactor was performed using Ansys Fluent. The CFD model simulates the plasma gas, in this case air, as a single high temperature fluid neglecting species created by the plasma through ionization, dissociation, etc. The pulverized biomass particles, in this case torrefied wood particles, are simulated with the help of a discrete phase model with the Eulerian-Lagrangian approach [10]. Ionization and dissociation of air in the single fluid model is covered with the help of adjusted plasma air properties. Chemical reactions involving the torrefied wood particles have been neglected as the major focus of the created model is on assessing the mixing behaviour and heat transfer between the hot plasma gas zone and the particles.

2.1. Air plasma properties

The adjusted plasma air properties are retrieved from curve fits calculated by Gupta et al. [11] for a temperature range of 1,000-30,000 K. The study considers 11 species while neglecting real-gas interactions and radiation effects. The plasma torch manual [12] specifies the power range as well as the temperatures of the arc plasma. At an operating temperature of $T_P = \sim 17 \cdot 10^3\ K$, the gas composition varies drastically from undissociated air. Table 1 compares the mole fractions of species at temperatures lower than 1,000 K, 5,000 K and 17,000 K.

Table 1. Mole (X) and mass (w) fractions of air components at atmospheric pressure for different temperatures, adapted from [13].

		N_2	O_2	N	O	N^+	O^+	e^-
Temperature /K	M /g/mol	28.01	32.00	14.01	16.00	14.01	16.00	5.49e-4
<1,000	X	0.78	0.21					
	w	0.76	0.23					
5,000	X			0.23	0.08	0.29	0.08	0.03
	w			0.34	0.14	0.43	0.10	1.63e-6
17,000	X			0.09	0.03	0.35	0.09	0.45
	w			0.16	0.06	0.61	0.17	3.07e-5

As the mole fractions were read off a logarithmic diagram provided by Selle [13], the values remain somewhat inaccurate. This realization arose when later computing the ionization degree using three different equations from [14]:

$$\alpha_i = \frac{1-X_A}{1+X_A} = \frac{X_{A+}}{1-X_{A+}} = \frac{X_{e-}}{1-X_{e-}} \tag{1}$$

where x_A, x_{A+} and x_{e-} denote the molar fraction of (dissociated) neutral species, ionized species and electrons, respectively. This yields $\alpha_i \in [77\%, 83\%]$ and thus a maximum deviation of 5.9%, which was accepted for further calculations.

In the material dialogue box in Ansys Fluent, properties can be adapted in many ways: Aside from the defined gas models (ideal gas, real gas, kinetic theory...), there are user-defined options as well. To transfer the curves from Gupta et al. [11] to Fluent, two of those were tried out; the first being the piecewise polynomial and the second the user defined function (UDF). The UDF option resulted in a much less stable simulation, forcing the authors to go for the piecewise polynomial option for specific heat capacity, thermal conductivity, and viscosity. Since Gupta et al. [11] provide no graph for the density, it had to be computed.

2.2. Model choice and assumptions

As the pressure-based solver is more suited for thermochemical conversion (e.g., combustion, …) cases and offers many advantages over the density-based solver, it was chosen and combined with the energy and discrete phase models for all simulations of the plasma entrained flow gasification test rig. The flow was assumed to be steady while particles are unsteady by default. The model has also only been tested using inert wood particles, which by definition do not exchange mass with the gas and follow the laws of inert heating and cooling [15]. Since this mass exchange is the main source of energy and momentum transfer, the study deals with a one-way coupling case and so, no interaction with continuous phase was needed. Instead, the Discrete Random Walk Model was activated for all cases because it produces much more realistic tracks. As the turbulence at the wall boundary are of less interest, the k-ω-model and its related SST-models were excluded for this study. Instead, the standard k-ϵ-model was selected, for it is better at modelling the bulk phase than the former and simpler than the latter. This model choice is also supported by Bobzin et al. [16], who examine an argon arc plasma spray using Ansys-CFX and classify it as a "valid alternative". There, the k-ω-model yields fairly different profiles of the arc plasma than all other investigated models. As a simplification, radiation effects are not considered as the focus of this simulation is mainly on the mixing behaviour of fuel particles and plasma zone as indicated by particle temperatures.

2.3. Boundary conditions

This section explains which boundary conditions as well as particle variables were set for the simulations. An overview of all values can be found in Table 2, Table 3, and Table 4.

2.3.1. Inlet

To determine the mass flow rate, the energy equation (2) was applied to the plasma torch represented as an electric heater and subsequent nozzle as depicted in Figure 2:

$$\frac{d}{dt}(U + K + \phi) = \sum_j \dot{m}_j \left(h_j + k_j + \phi_j\right) + \sum_j \dot{Q}_j + \dot{W}_V + \dot{W}_S \tag{2}$$

where the upper case variables U, K and ϕ denote the internal, kinetic and potential energy, respectively, while the equivalent lower case letters signify their specific forms for the different components j. h_j represents the specific enthalpy of component j. Furthermore $\dot{m}$ stands for the mass flow rate, $\dot{Q}$ for the heat flux and $\dot{W}_V + \dot{W}_S$ (volume change and shaft work) for the technical work.

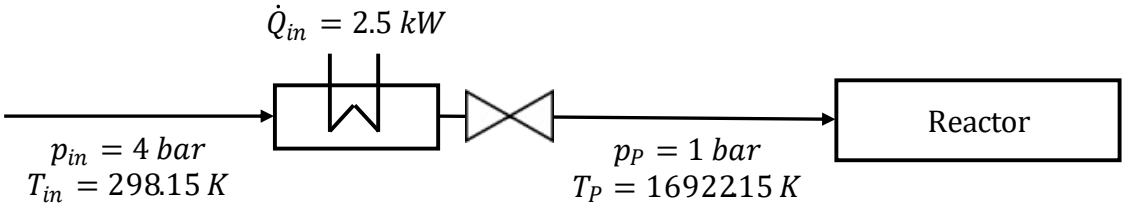

Figure 2. Simplified representation of plasma torch as thermodynamic process leading to plasma inlet: Temperature T and pressure p before (in) and after (P) power input $\dot{Q}_{in}$.

The subscripts in and P denote the states at the inlet of the heater and the outlet of the plasma torch, respectively. Compressed air enters at an operating pressure of $p_{in} = 4\,bar$ [12] and an assumed temperature of $T_{in} = 300K$. It then flows isobarically through the plasma torch that is connected to a power supply and is expanded after the plasma torch, which is illustrated as a nozzle in Figure 2. Through this abrupt (ideally isentropic) expansion, the pressure is reduced back to atmospheric pressure ($p_P \approx 1bar$). According to the torch manual [12], the plasma zone is expected to enter the reactor at a core temperature of $T_P = 16922.15K$. For the incoming specific enthalpy, Bernoulli's equation for compressible ideal gases was used without the kinetic term ($h_{in} = c_p \cdot T_{in} + p/p(T_{in})$) [17, 18] while the outgoing specific enthalpy h_P was taken from [11] for $T_P = 16922.15K$. The energy equation was then solved for the velocity at the outlet of the nozzle. To characterize the flow conditions, some dimensionless numbers were calculated: Reynolds number (Re), turbulence intensity (TI) and Mach number (Ma).

As the standard configuration of the plasma torch uses a very small outlet diameter of 1 mm which results in very high outlet velocities with Mach numbers >0.5, it was decided to modify plasma torch nozzle diameter from 1 mm (= case 0) to 2 mm (= case 1, reference case). For this reference case, plasma temperature increases slightly while Mach number and plasma gas velocity drastically decrease (see Table 2).

Table 2. Calculated plasma inlet conditions for varied plasma inlet diameters. For general boundary conditions and torrefied wood properties please refer to Table 3 and Table 4 respectively.

Case	0 (Smaller diameter)	1 (Reference)
d_P /[mm]	1.00	2.00
T_P /[K]	16922.15	17193.74
v_P /[m/s]	3561.33	917.65
$\dot{m}$ /[kg/s]	1.60E-2	1.60E-2
Ma /[-]	0.58	0.15
Re /[-]	7.53E+5	3.18E+5
TI /[%]	2.95	3.28

2.3.2. Gas outlet

As the gas outlet at the end of the reactor is a pressure outlet where internal and atmospheric pressures can be assumed to be roughly equal, the gauge pressure was set to zero and the backflow temperature to 360 K, which was the mass weighted average of total temperature at the outlet from an initial simulation. By also using the mass weighted average of velocity in z-direction at the outlet, the turbulence intensity was determined. The outlet variables are listed in Table 3 and were used for all cases.

2.3.3. Reactor wall

The wall thickness of the reactor's stainless steel wall was set to 2.5 mm [19] with a heat generation rate $\dot{Q}_{gen}$ of 0 W/m3. Since shell conduction treats the boundary as a thin wall [20] and disables the wall material specification, which is important for heat transfer phenomena, it was deactivated. It was assumed that the heat transfer rate from the cooling water to the reactor wall is much greater than that of air inside the reactor to the reactor wall. Thus, it was assumed that the wall temperature is constant at 293.15 K. The wall boundary conditions are summarized in Table 3.

Table 3. General boundary conditions.

	Plasma inlet	Particle inlet		Outlet		Reactor wall
d_P /[mm]	2.00	5.00	d_{out} /[mm]	26.00	d_{wall} /[mm]	25.00
T_P /[K]	17193.74	298.15	$T_{Backflow}$ /[K]	358.43	T_{wall} /[K]	293.15
$\dot{m}$ /[kg/s]	1.60E-2	2.34E-1	p_{gauge} /[Pa]	0	$\dot{Q}_{gen}$ /[W/m^3]	0
TI /[%]	3.28	2.50	TI /[%]	2.49	Shell cond.	no

2.3.4. Particle injections

The simulated torrefied wood particles have a density of $\rho = 700kg/m^3$, a lower heating value of $LHV = 19.855MJ/kg$ and a specific heat capacity of $C_p = 2310J/kgK$ based on previous lab analysis. The mass flow rate of the torrefied wood particles was determined by specifying that the plasma power should make up 50% of the lower heating value input of the wood particles. This is typically the maximum required plasma power input to operate under pure allothermal plasma gasification conditions for comparable feedstocks [2]. Based on this assumption, the mass flow of wood particles were calculated resulting in the values indicated in Table 3. The wood particles were assumed to have a particle size distribution as shown in Table 4.

Table 4. Torrefied wood injection settings for Discrete Random Walk Model.

Inert Wood Particles					
d_{min}	/[m]	9E-5	T_{BM}	/[K]	298.15
d_{max}	/[m]	1.1E-4	v_{BM}	/[m/s]	10.31
d_{mean}	/[m]	1E-4			

3. Geometry and mesh generation

The first step of the CFD simulation of the plasma entrained flow gasification test rig was to create a geometry and mesh which is mesh independent for an acceptable level of deviation from the benchmark mesh. The target was to accept a maximum deviation from the benchmark mesh of 10%. A lower deviation level is not required because the simulations serve the purpose of informing the optimization of the experimental set-up. Maximum accuracy is not necessary for this purpose.

3.1. Mesh

The reactor design as shown in Figure 1 was recreated using SpaceClaim. The first step was to simplify the constructed plasma-jet-tube configuration down to what is essential for Fluent calculations, so the cooling jacket, the tubular viewing window and all external components were neglected. Running the first few simulations showed that the posterior section of the 1.5 m long reactor had no influence on results and was hence cut off to reduce computational time.

To generate the mesh, several tubular bodies of influence (BoI) were defined for each section of the tube: Starting from the smallest grid cell size x_{min} at the plasma inlet, the mesh was gradually coarsened along the tube as demonstrated in Figure 3. Since the chosen mesh type is poly-hexcore, the octree meshing algorithm had to be taken into account when conducting the sensitivity study, so that they do not get set arbitrarily during meshing. Therefore, the target cell size x of each refinement level had to fulfil the relation:

$$x = x_{min} \cdot 2^t \tag{3}$$

where x_{min} denotes the smallest cell length (in this case: at the plasma zone refinement), and t the number of transition layers from x_{min} to x_{max}. The plasma zone's BoI includes the sharpest part of the plasma zone and is supported by a face of influence with the same cell size at the inlet boundary.

The starting point for x_{min} was inspired by Wilhelm [21], where a mesh refinement of 10 cells per diameter was used. The following relation has proven to be sufficiently accurate in his case:

$$d_c = \sqrt{\frac{A(d_c)}{A(d_i)}} \cdot d_i \tag{4}$$

For an inlet diameter of $d_i = 1mm$ and a cell diameter of $d_c = d_i/10$, the resulting minimum cell size was 0.1mm (case C). From there on, the other cell sizes were derived. Then x_{min} along with its other cell sizes were reduced to create the different cases for the mesh independence study as shown in Table 5.

3.2. Mesh independence study

After performing the simulations for the mesh independence study using the mesh parameters as detailed in the previous section, the velocity magnitude and total temperature were evaluated along the reactor length for each refinement level and compared to the most detailed reference case A. This yields the discrepancies plotted in Figure 4 along the significant part of reactor.

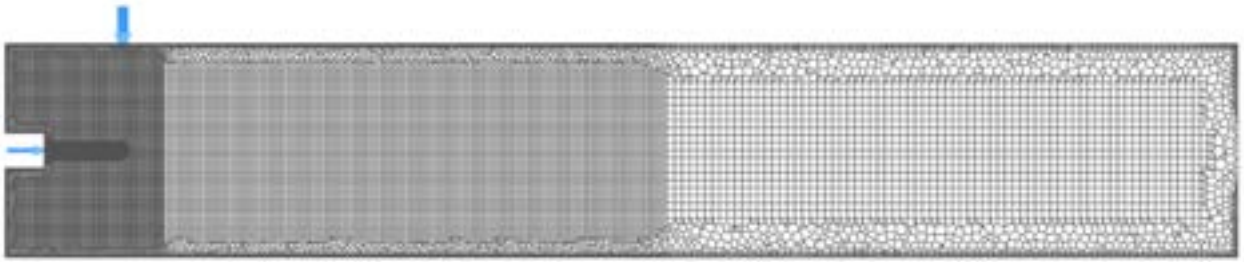

Figure 3. Poly-Hexcore mesh of reactor tube (coarsened to xmin = 0.12mm for visibility).

Table 5. Mesh independence study: Cell lengths x /[mm] for each body of influence of transition layer t.

BoI t	Plasma zone 0	Anterior 3	Middle 4	Posterior 5	Total cells
A	0.06	0.48	0.96	1.92	9,772,469
B	0.08	0.64	1.28	2.56	4,301,751
C	0.10	0.80	1.60	3.20	2,274,814
D	0.12	0.96	1.92	3.84	1,370,240

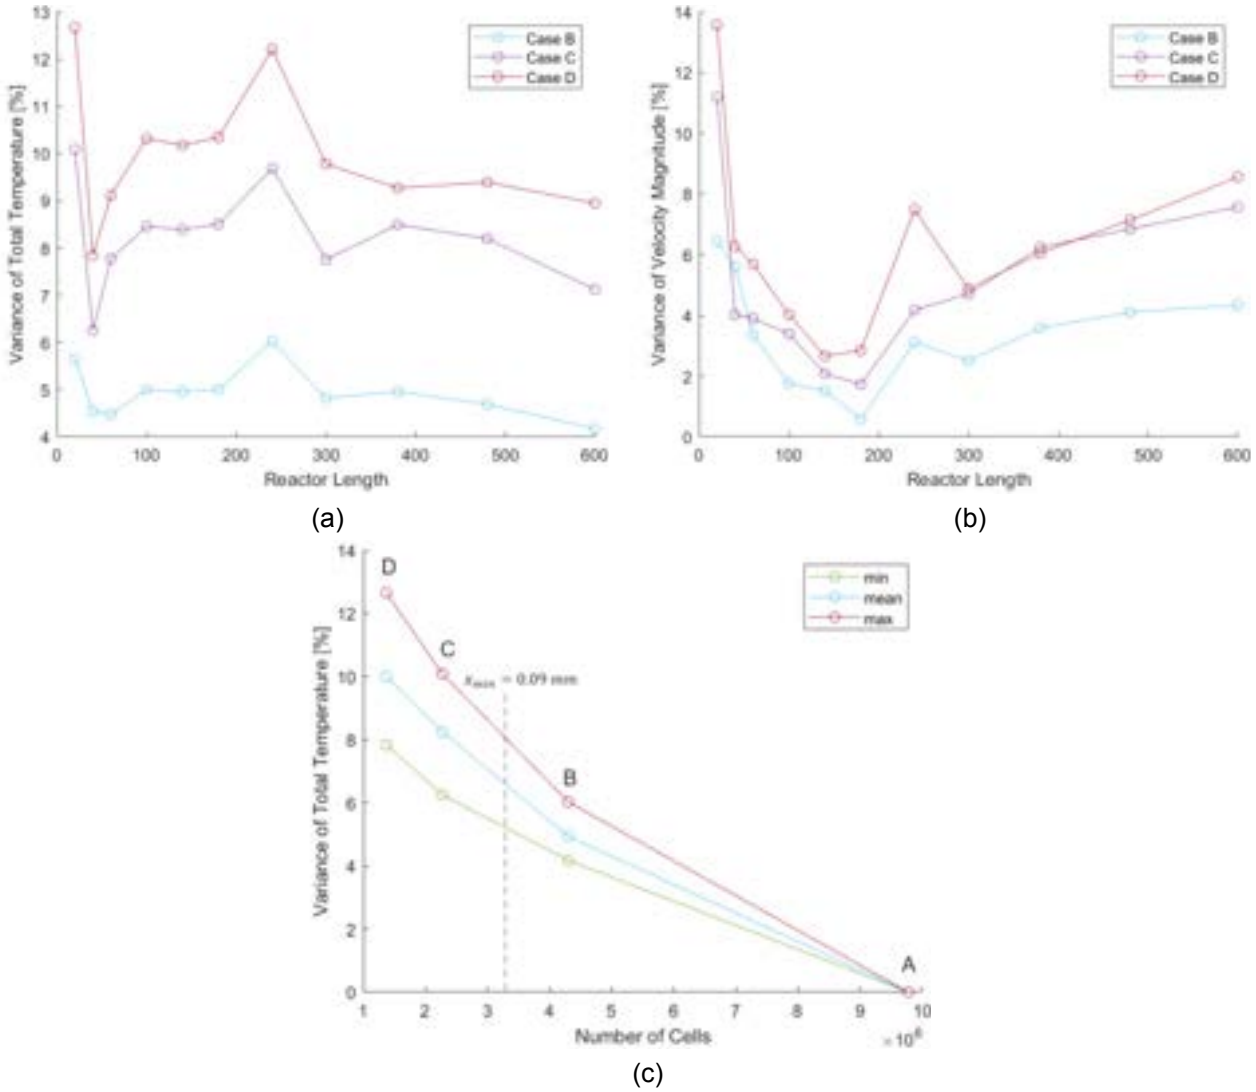

Figure 4. Mesh independence study for mesh cases A, B, C and D. (a) Total temperature error along the reactor length in mm for cases B, C and D relative to case A. (b) Velocity magnitude error along the reactor length in mm for cases B, C and D relative to case A. (c) Mean, minimum and maximum error of velocity magnitude along the reactor length as a function of the number of cells for meshes A, B, C and D.

Due to the high inlet velocity of the plasma gas and the sharp temperature gradients, one can see the highest variance at the inlet (20 mm from reactor inlet) and another peak in the middle. A possible explanation for the peak in the middle could be that the solution seems to start at the boundaries and spreads throughout the reactor with more iterations. As mass-weighted variables have not been tracked at each measurement point during the simulation, the properties at this position of the reactor might not have plateaued yet. Supporting this explanation is the fact that this peak is farther away from the outlet of the reactor's mesh (630 mm from reactor inlet) where the cell size is larger, so the converged solution is reached quicker. Also, the mass imbalance is comparatively higher at this position.

Because the velocity magnitude shows higher variability than the temperature, it has been chosen as the determining factor for the final mesh size; its minimum, maximum and mean values are plotted against the cell number in Figure 4 (c). Weighing computation expenses against solution accuracy led to the decision, that a refinement level of $x_{min} = 0.09\,mm$ should suffice to keep the maximum deviation from mesh A below 10%.

Based on this mesh independence study, a slightly modified final mesh B' was created using the mesh B as the basis. This resulted in the mesh data as shown in Table 6 and made it possible to reduce the required number of cells by ~28% compared to mesh B.

Table 6. Modified mesh refinements: Cell lengths x /[mm] for each body of influence of transition layer t.

BoI t	Plasma zone 0	Anterior 3	Middle 4	Posterior 5	Total cells /[%]
B	0.08	0.64	1.28	2.56	100
B'	0.09	0.72	1.44	2.88	71.80

4. Results and discussion

4.1. Cases overview

The first two cases, case 0 and case 1, which were assessed, only vary geometrically in terms of the outlet diameter of the plasma torch nozzle as shown in Table 2.

The other cases focus on the way in which the biomass particles are introduced to the plasma zone. Case 1, and also case 0, assume a simple opening at the top of the reactor's tube through which biomass particles can be sent into the reactor. To examine the direct effect of plasma on biomass particles, the particle inlet was brought closer to the plasma zone with the help of a vertical particle inlet tube, which was integrated at different distances from the plasma torch outlet for the cases 2 to 5. The job of the vertical particle inlet tube was to guide the biomass particles as close to the plasma zone as possible. Assuming the tube is made from high-temperature resistant ceramic material, its length l_{tube} was determined, so that it does not meet temperatures exceeding 1500 K. To obtain the plasma zone's temperature profile, the particle inlet was defined as a wall and its mass flow rate, turbulence intensity as well as hydraulic diameter were set to 0, so that the flow is not affected by cold incoming air. The injected particles were also defined as massless. The distance of the vertical particle inlet tubes from the plasma torch outlet was then varied along the 1500 K isotherm. The resulting inlet tube positions for the cases 2 to 5 and case 1 as the reference are listed in Table 7.

Table 7. Geometry parameters for varied particle inlet tube lengths l_{tube} and distance of the particle inlet tube from the plasma torch outlet s_{tube}. All remaining parameters are based on Table 3 and Table 4.

Cases		1 (reference)	2	3	4	5
l_{tube}	/[mm]	0.00	49.00	46.50	44.50	42.50
s_{tube}	/[mm]	40.00	5.00	15.00	25.00	35.00
$d_{part,in}$	/[mm]	5.00	5.00	5.00	5.00	5.00

4.2. Cases 0-1: Results of plasma torch outlet diameter variation

The main results for cases 0 and 1 consisting of average particle temperatures and respective residuals are presented in Figure 5.

Figure 5 (a) shows the average temperature of all particles in a selected time interval for both cases. In case 1, the plasma gas flows in at a velocity of $v_1 = 917.65 m/s$ and a temperature of $T_1 = 17193.74 K$ compared to $v_0 = 3561.33 m/s$ and $T_0 = 16922.15 K$ in the reference case. The conservation of energy explains this increase in temperature, which compensates the reduction in the kinetic term because of the lower plasma gas velocity. Consequently, particles reach average temperatures up to 2.1x higher in case 1 compared to case 0 ($T_{max,0} = 986.534 K$ and $T_{max,1} = 2092.61 K$). They also remain hotter as indicated by higher volume-averaged temperatures ($T_{V,0} = 513.64 K$ and $T_{V,1} = 703.45 K$). Therefore, case 1 performs better than case 0 at achieving a good mixing between biomass particles and the hot plasma gases in the plasma zone.

The residuals also indicate that convergence for case 0 is worse than convergence for case 1. Due to the increased mass flow rate and thereby also velocity gradient at the inlet, the solution does not converge as smoothly for case 0. Despite the enlargement of the plasma zone and anterior bodies of influence and using a finer mesh than the initial one (0.08 mm), the continuity remains above 10^{-3} for case 0 as shown in Figure 5 (b). Furthermore, the volume-averaged velocity oscillates around $v_{V,0} \approx 0.7m/s \pm 0.03m/s$ while temperature stagnates at $T_{V,0} \approx 520K$. This behaviour could be explained by one of three potential causes; the first one being the mesh, the second one under relaxation factors and the third being the complexity of the flow:

1. The mesh might still not be sufficiently fine in some areas of the reactor. The higher inlet velocity also leads to increased velocities in other parts of the reactor.
2. Under-relaxation factors (URFs) were varied differently for both cases, which could justify this behaviour.
3. Because of the complexity of the flow, a unique solution might simply not exist. As the solution of the flow is steady, it is very likely to have more than one solution for the same boundary conditions. This would justify why properties oscillate periodically between two possible states.

As case 1 performed better in terms of both the average particle temperatures, as a proxy of the quality of mixing between particles and plasma zone, and convergence, the worse convergence of case 0 was not further studied. Instead, it was decided, as already indicated in section 2.3.1 due to the lower plasma gas velocities, to continue with case 1 as the base case for the further improvement of the reactor.

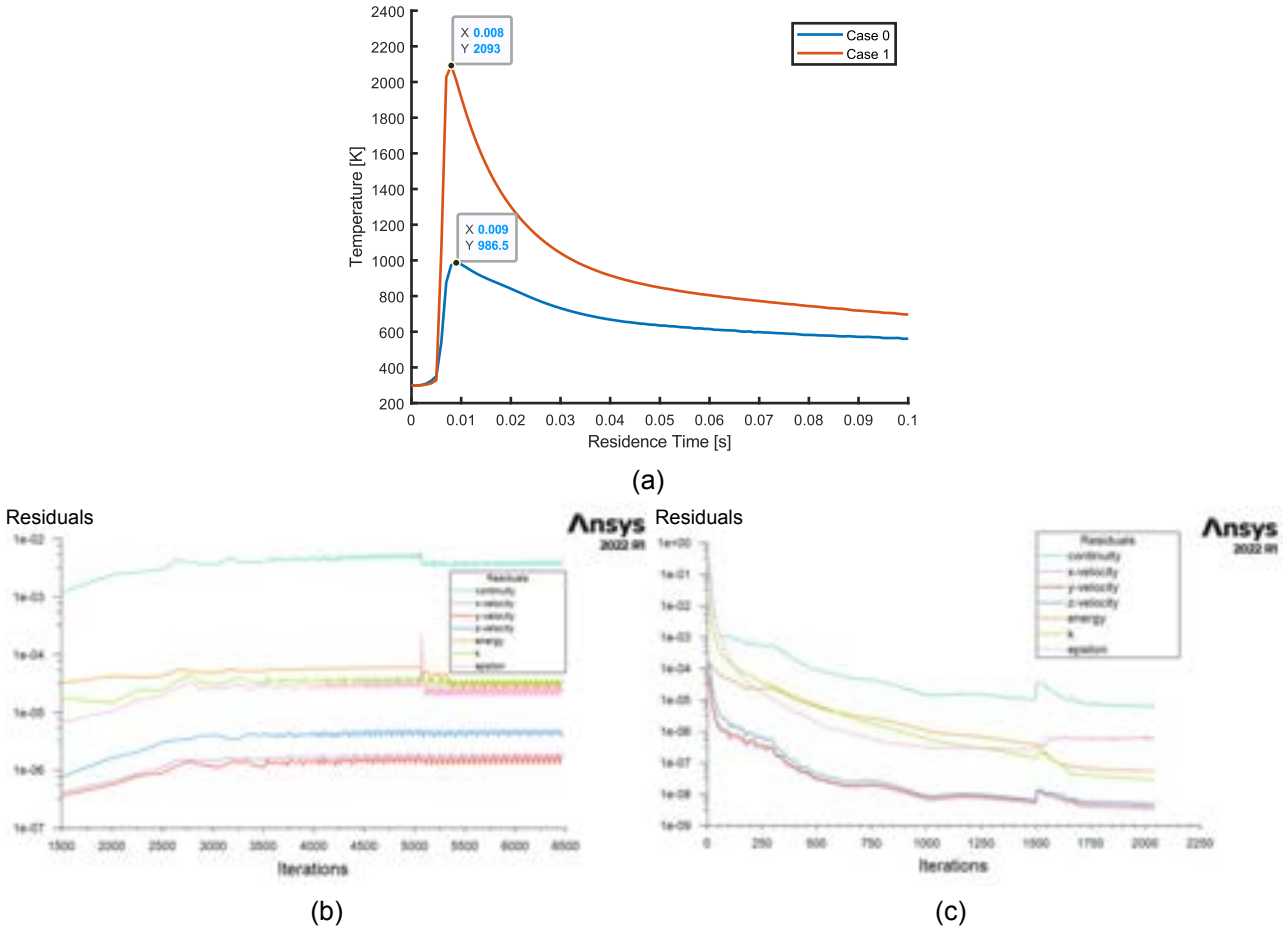

Figure 5. Comparison of residuals and average particle temperatures of cases 0 and 1. (a) Average particle temperatures over residence time for cases 0 and 1. (b) Residuals of case 0. (c) Residuals of case 1.

4.3. Cases 1-5: Results of variation of particle inlet tube's position

The intention behind varying the tube position is to find the configuration where particles reach the highest temperatures and maintain them for the longest period. Figure 6 shows the average particle temperatures plotted over the residence time. For each case, the mean value of all temperatures in a specified time interval were evaluated using Matlab and then plotted with the other cases. Figure 7 compares particle temperatures and their tracks for the different cases. The graphs of the two figures clearly indicate that cases 2 and 3 perform better in terms of maximum (average) temperature compared to the other cases which do not exceed 2200K. This is essentially a consequence of the extreme temperatures particles come in contact with in the core

plasma zone, which reach up to 15,000K and 7,500K, respectively. The higher deflection angle of the plasma zone might also improve the particle heating, as higher temperatures are shifted downwards towards the particle tracks and thus heat them longer. High collision velocities also cause particles to be distributed better in cases 2 compared to other cases. As previously established by Gupta et al. [11], the higher thermal conductivity at such temperatures is higher and therefore particle heating is improved even more significantly as shown in Figure 6 (a). The delayed peak in case 1 is due to the fact that particles have to travel longer from the top of the reactor before hitting the flame – while the residence time only starts counting in cases 2 to 5 when the particles exit the ceramic tube close to the plasma zone. The slight bump in cases 4 and 5 may be a consequence of high turbulence in that time interval, which could be deduced from the particle tracks. But it may also be a consequence of incomplete convergence.

When looking at the long-term particle temperatures in Figure 6 (b), case 5 surpasses the other cases, even if only slightly. Looking at the particle path lines, it gets clear that this is because particles fly back into the plasma region and are thereby reheated. However, particles in all cases do not maintain a high temperature after the sharp decline down from the peak. This goes back to the relatively low overall temperature of the gasifier. It shows that the particles are quenched rather fast upon leaving the plasma zone reaching temperatures <1000K within <<0.1s in all cases. This is beneficial for the production of plasma pyrolysis char as fast quenching would be helpful in preserving the change of the char properties caused by the plasma zone.

Based on Figure 6 and Figure 7, case 2 looks the most promising. It achieves both a very high peak temperature, indicating a good mixing of particles with the plasma zone, as well as comparatively fast quenching of the particle temperature after the plasma zone.

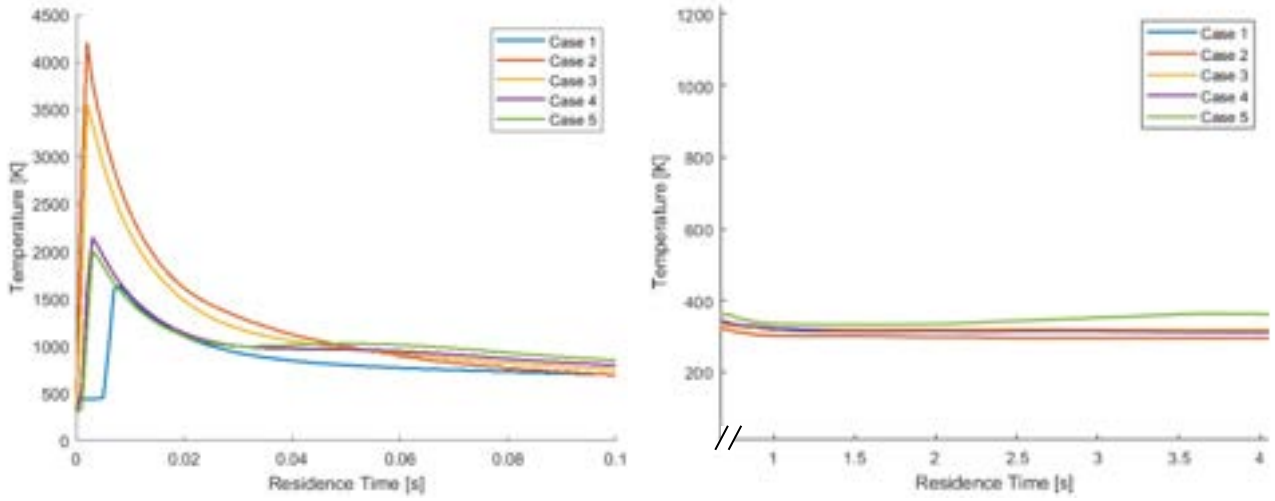

Figure 6. Average particle temperature distribution over residence time for cases 1-5. (a) Average particle temperature peaks during first 0.1 seconds of residence time. (b) Long-term average particle temperatures.

Based on the residuals for cases 2 to 5 in Figure 8 and those of case 1 in Figure 5, the convergence of cases 2, 4 and 5 are far less stable than cases 1 and 3. One reason is the change and increase in the plasma zone upon integration of the plasma tubes (cases 2-5). This means that the plasma zone BoI does not only need to be angled but enlarged as well. For case 2 the instability could be easily explained by the fact that the collision velocities of particles and plasma gas are significantly higher than in all other cases as the particle inlet tube in this case is closest to the plasma torch outlet. Even after modifying the plasma zone BoI in case 2, the residuals still oscillate, but around 10^{-4} to 10^{-3} instead of 10^{-2} before modification. The gradual decrease in the residuals around 2000 iterations (Figure 8 (a)) is a consequence of reduced under relaxation factors, which were improving the solution until approximately 2700 iterations.

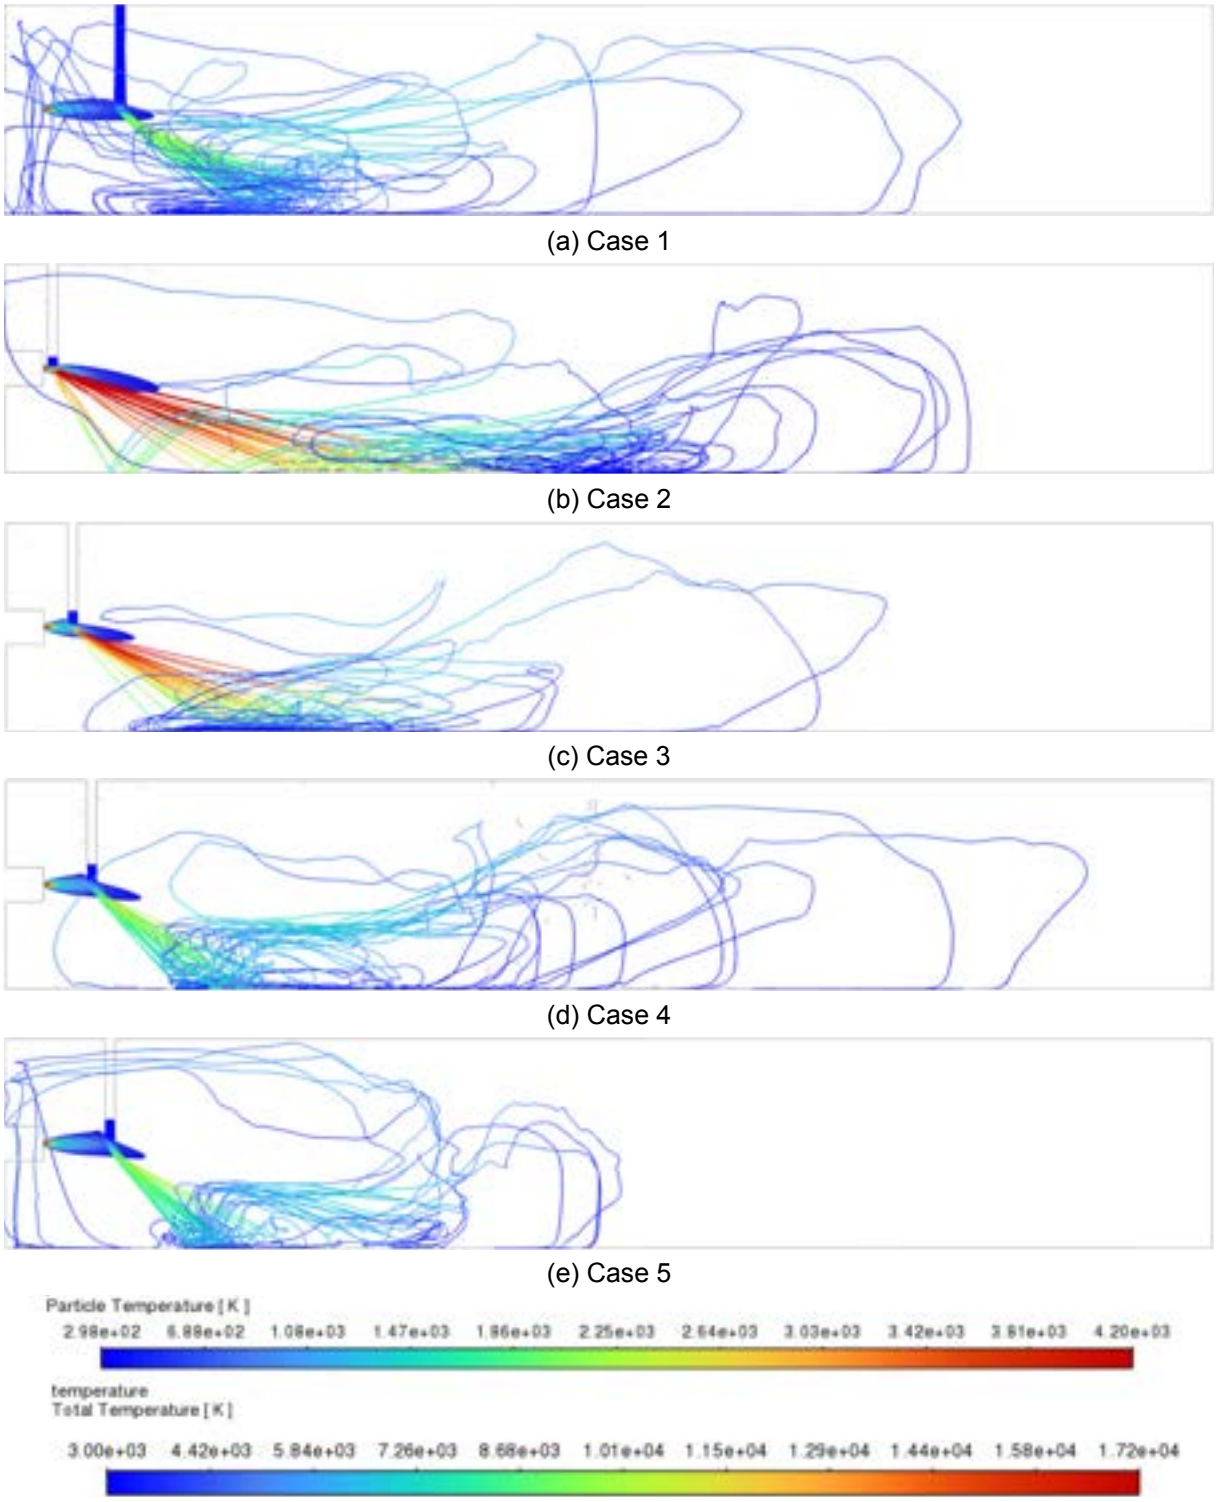

Figure 7. DC arc plasma zone temperature and (inert) torrefied wood particle streamlines coloured based on temperature for cases 1 to 5.

Same applies for cases 4 and 5, where volume-average-temperature and velocity are oscillating periodically around the same range that is computed by case 1. It is only in case 3 where both physical and numerical properties stagnate as shown in Figure 8 (b). Although the same case and data file was used for interpolation at the beginning, this case is far better converging than all three other cases.

However, since all cases oscillate periodically around 10^{-4} to 10^{-3}, the change in solution should not be significant. For example, in case 4: $v_{V,4} \approx 0.7m/s \pm 0.05m/s$ and $T_{V,4} \approx 700K \pm 5K$. The aim of these cases anyway is to reveal the trend of the best tube position for particle mixing and heating, which would not be heavily affected by oscillations at such a comparatively small magnitude. As long as the physical phenomena make sense, which they do in all of those cases, the result should be valid.

5. Conclusion

This work has investigated the flow characteristics of a DC air plasma torch in a horizontal tube reactor and investigated different optimization options to improve the interaction of biomass particles with the plasma zone. Plasma gas properties were modelled by integrating the adjusted plasma air properties provided by Gupta et al. [11]. Simplifying assumptions were made to ensure the feasibility of the CFD model – among others, neglecting chemical reactions, assuming a single fluid model and ignoring heat exchange by radiation. The different optimization options which were assessed focused on the one side on changing the plasma torch's outlet nozzle diameter to adjust plasma gas velocities and on the other side the integration of vertical biomass particle inlet tubes to better guide the fuel particles directly into the plasma zone (at distances 5, 15, 25 and 35 mm from the torch outlet along the isotherm of 1500 K). It can be concluded that the wider diameter offers not only better convergence, but much higher particle temperatures as well. From all conducted cases, the closest tube to the plasma inlet (case 2) leads to the highest particle temperatures. Cases 4 and 5 do not seem to offer a significant advantage over case 1 without a tube. All cases exhibit comparatively fast quenching (<<0.1s) of the particle temperatures after the plasma zone, which is beneficial for producing plasma pyrolysis char for further experimental analysis. In addition, all cases (except for case 5) show the same long-term cooling behaviour. The deciding factor for the best configuration to enhance particle heating is therefore only highest average temperatures, which was demonstrated in case 2 followed by case 3.

The created CFD simulation model is a good starting point for further research into modelling of plasma-assisted entrained flow gasification. In subsequent models, it would make sense to look into the option of changing the single fluid model to a more sophisticated plasma representation also accounting for dissociated and ionized, highly reactive species. For this, it would also be beneficial to integrate chemical reactions into the model as well as radiative heat transfer to better simulate the processes happening in the high temperature zones. In this regard, a combination with other existing CFD models for conventional entrained flow gasification such as the model developed by DeYoung [10] will be a suitable next step. In addition, experimental data will be necessary to inform the modelling and create kinetic models for the simulation of these plasma gasification processes. Experimental results from the modelled test rig can also be used to validate the simulative results.

Abstract:
The objective of the work was to improve convective heat transfer intensity in the polymer pipes, e.g., made of high-density polyethylene or cross-linked polyethylene, by applying and optimizing internal pipe surface modifications in the form of small helical ribs. These helical ribs act as turbulence promoters and additionally induce angular velocity in the flowing medium, increasing the flow path length. Such pipes with the modified inner surface may be applied in the vertical and horizontal ground heat exchangers, which are one of the most expensive elements of ground-source heat pump systems. Improving heat transfer intensity between ground and working fluid in pipes may reduce the required number or length of boreholes and, therefore, decrease the overall installation costs of the heat pump system. This will allow more heat delivery to the working fluid per one running meter of the borehole. However, due to the increased turbulence in pipes with the modified internal surface, the pressure losses will also increase, which will increase the power consumed by the pump. Therefore, finding the balance between heat transfer gains and pumping losses is necessary. This paper further numerically analyzes previously selected modifications with rectangular and equilateral triangular cross-sections. Factors such as the height of ribs (vortex generators) and helix pitch were studied in terms of pressure drop and convective heat transfer intensity. Optimal geometrical parameters of ribs were found. Compared to the smooth pipes, optimized pipes with rectangular turbulators had Nusselt numbers 47-58% higher for the considered Reynolds number range, while pipes with triangular turbulators 21-42%. However, optimized pipes also had 92-126% and 31-39% higher pressure drops for rectangular and triangular turbulators, respectively, than the smooth pipe in the same Reynolds number range.

Convective heat transfer intensification; Ground heat exchanger; Numerical simulations; Internal surface modification; Polymer pipe.

1. Introduction

Recently, the share of renewable energy sources in total power and heat generation significantly increases as society focuses more and more on ecological and renewable energy sources. This is due to high greenhouse gas emissions by conventional power and heat sources, an increase in global warming, and high prices of fossil fuels. Renewable energy sources have been replacing fossil fuels-based power sources for years. The current social pressure and political decisions are speeding up this trend. In the European Union, the power sector must quickly adapt to the assumed emission targets by replacing coal-fired power plants, heating plants, and combined heat and power plants with new gas/hydrogen turbines, nuclear reactors, and renewable energy sources. However, in order to achieve the very ambitious climate neutrality targets established by the European Union, it is necessary to dynamically develop technologies allowing more efficient utilization of renewable power and heat sources. This should be done on a macro-scale (i.e., on the level of the power generation system) and on a micro-scale (i.e., on the local level by power and heat consumers). One of the solutions which can be applied on the micro-scale level is the application of heat pumps for space heating and domestic hot water production. Among them, ground-source heat pumps are characterized by the highest efficiency. Therefore, such heat pumps should especially be promoted.

Ground-source heat pumps are used to transfer the heat from the ground to the buildings. Their investment costs are usually higher than in the case of air-to-air or air-to-water heat pumps, but the exploitation costs are lower as they have a higher average coefficient of performance than other types of heat pumps. They work in

combination with the ground heat exchangers, one of the system's most expensive elements. The pipes for ground heat exchangers are usually made of polymers, e.g., high-density polyethylene (HDPE) or cross-linked polyethylene (PEX). One of the ways to decrease the overall cost of the ground-source heat pumps might be by increasing heat transfer intensity in the ground heat exchangers. This operation may reduce the required number or length of boreholes and, therefore, the system installation's overall costs. The higher effectiveness of ground heat exchangers can be achieved, e.g., by increasing the heat transfer rates inside pipes due to the introduction of modifications in the form of small helical ribs or fins on the internal surface of the pipes used in the ground heat exchanger. The purpose of the modifications on the pipe's internal surface is to increase the intensity of heat transfer between the soil and the working medium flowing through the pipe. The modifications act as turbulence promoters, increase flow turbulisation, force the formation of angular velocity in the flowing medium, and increase the flow path length. This will allow more heat delivery to the working fluid per one running meter of the borehole. However, due to the increased turbulence, the pressure losses will also rise in polymer pipes with internal surface modifications. That will increase power consumption by the pump, which circulates the working medium in the lower heat source. Therefore, the modifications allowing for the highest heat transfer intensity increase at the lowest pressure drop should be designed.

The studies on increasing heat pump systems efficiency were focused, among others, on improving the efficiency of the thermodynamic heat pump cycle itself [1], improving control systems and optimizing the heat pump system configuration and operation [2,3], or using hybrid heat pumps systems in combination with other systems [4-6]. There are only a few efforts to increase the heat transfer efficiency in the ground heat exchangers applied in the heat pump systems. The factors affecting vertical ground heat exchanger efficiency were summarised in [7]. The working fluid mass flow rate, thermal properties of the pipe material, thermal properties of the grout material and soil, soil density and moisture level in the ground, the geological structure of the earth crust in implementation location, groundwater presence, borehole diameter and depth, inlet and outlet pipe diameters, and the pipes' configuration (e.g., coaxial, single/double U-tube, spiral-tube, and multi-tube) are the ground heat exchanger parameters which have the greatest impacts on the efficiency of ground-source heat pump systems. Some of these parameters are related to the ground heat exchanger location and ground parameters. Therefore, the engineers have no influence on them. But there is a group of factors, e.g., the level of flow turbulization in the pipe, which may be modified and optimized to improve heat transfer rates in the ground heat exchanger.

The internal surface modifications, e.g., in the form of grooved, riffled, or corrugated surfaces, in pipes made of metals, were studied numerically and experimentally in many works [8-10]. However, this problem was not investigated thoroughly in the case of polymer pipes. There are only a few papers in which this problem was undertaken. The pressure drop in polyethylene (PE) pipes with internal micro-fins was numerically investigated in [11]. But the simulations were carried out for only one shape of internal micro-fins, and for pipe configurations and sections typical for vertical ground heat exchangers, i.e., entrance, U-turn, and downward sections, were considered. Łapka and Wachnicki [12] recently simulated fluid flow and heat transfer in PEX pipes with internal helical turbulence promoters in the configurations typical for ground heat exchangers. The internal pipe modifications were in the form of rectangles, trapezoids, triangles, and semicircles. They calculated the dependencies between the shape of the internal embossment and the Nusselt number (Nu) and pressure drop in relation to the smooth pipe.

This short state-of-the-art shows that there is a lack of knowledge related to the heat transfer intensity and pressure drop in the polymer pipes with internal modifications. Moreover, the polymer pipes' properties and manufacturing methods are significantly different from pipes made of metals. This means that the knowledge about heat transfer intensification in metal pipes cannot be directly applied in the case of plastic pipes. Therefore, this problem is further analyzed in this paper. Previous studies in [12] showed that heat transfer intensity in polymer pipes might be significantly improved, i.e., in the Reynolds number (Re) range of 3000-8000, depending on the shape of modification, the Nu rose up to 25% in relation to the smooth pipe. But the penalty was a significant increase in the pressure drop, which also depended on the modification shape. Among the studied shapes, Łapka and Wachnicki [12] choose the triangular vortex generators as having the most promising pressure drop and heat transfer characteristics. The second shape selected in this paper was rectangular due to its possible manufacturing easiness. However, Łapka and Wachnicki [12] emphasized that before considering these shapes in practical applications, they have to be optimized in terms of pressured drop and heat transfer intensity, i.e., by finding their optimal geometrical parameters. Therefore, the optimization problem of polymer pipes' internal modifications is undertaken in this paper.

The paper is organized as follows. At first, considered internal modifications of the polymer pipes are presented. Then, the simulation methodology is described. Next, selected shapes of turbulence promoters and the way of their optimization are described. After that, the results of the simulations are shown and discussed in terms of Nu and pressure drop characteristics, and then the work is concluded.

2. Considered pipe models and initial studies

In the previous work [12], six internal modifications were tested, i.e., their influence on the heat transfer intensity and pressure drop were evaluated in the Re range of 3000-8000 and in reference to the smooth pipe. The

considered pipes had an outer diameter of 32 mm. The minimum wall thickness was 2.9 mm, so the inner diameter of the reference smooth pipe and also the base of the modification was 26.2 mm. The internal surface modifications were based on extruding certain shapes along the helix. In [12], this helix had a pitch of 300 mm. The considered geometries are shown in Fig. 1. For all cases, the embossings were 1.4 mm high. The first case had modification prepared by embossing a rectangle 2.8 mm wide (Fig. 1a). The second one had the shape of a trapezoid with arms at an angle of 15° and the distance between the arms centers of 2.8 mm (Fig. 1b). In the third, the vortex generators were equilateral triangles (Fig. 1c). In the fourth, the vortex generators were semicircles with a radius of 1.4 mm (Fig. 1d). In the fifth and sixth (Fig. 1e and f), the turbulators had the shape of rectangular triangles with an angle at the base of 60°, and with the right angle located on the left- and right-hand side, respectively. Moreover, the reference pipe with a smooth surface was also prepared to obtain reference results.

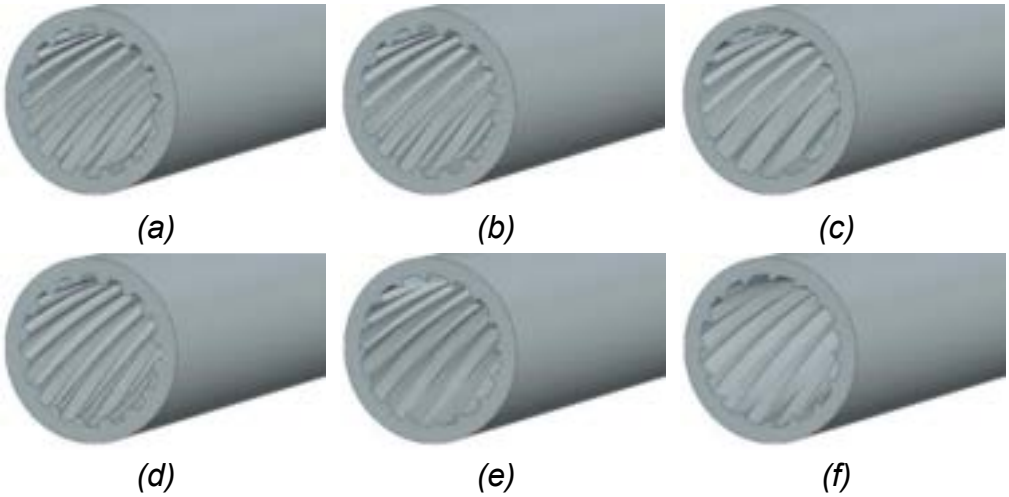

Figure 1. Shapes of turbulence promoters: a) rectangular, b) trapezoidal, c) equilateral triangle, d) semicircular, e) rectangular triangle with a right angle on the left-hand side, f) rectangular triangle with a right angle on the right-hand side.

The simulations conducted in [12] showed that triangular vortex generators had the most promising pressure drop and heat transfer characteristics. They had the lowest pressure drop increase compared to the reference pipe, i.e., they attained a pressure drop 95-125% higher than the reference pipe. The convective heat transfer was most intense for pipes with vortex generators in the shape of equilateral triangles. Moreover, the pipe with rectangle embossing performed well in terms of heat transfer intensity. In the whole considered Re range, these two types of modifications, i.e., equilateral triangle and rectangle, attained c.a. 21-23% higher Nu in relation to the smooth pipe. However, the pipe with rectangle modification had the most significant pressure drop increase, i.e., 170-190% in reference to the smooth pipe. Despite this, considering the results obtained in [12], and also manufacturing limitations, i.e., that modifications in the form of a right triangle might be difficult to manufacture and that the rectangular vortex promoters seem to be the easiest to manufacture, the optimization in terms of heat transfer and fluid flow characteristics was carried out for the embossing having shapes of a rectangle (Figure 1a) and equilateral triangle (Figure 1c). It is expected that further optimization of these geometries might significantly improve their heat transfer efficiency and reduce the pressure drop.

3. Optimization strategy

The vortex generators' optimization process was based on parameterizing some of their geometrical features (i.e., dimensions). The parameters for the optimization process were chosen so that it was possible to obtain great changes in the heat transfer and pressure drop characteristics in the pipe. The goal was to capture geometric features that can most significantly affect the pipes' heat transfer and fluid flow performances. For both selected models, the influence of the pitch of the helix was investigated. This parameter can potentially greatly impact variations in the pressure drop and heat transfer characteristics in the flow. In the base geometries, the pitch of the helix was set to 300 mm [12]. In this paper, additional calculations have been carried out for the pitch values of 150, 450, and 600 mm. The second examined parameter was the size of the turbulators, which was defined as their height. The turbulators were properly scaled to maintain the turbulence shape itself. The basic height of the vortex generators was 1.4 mm [12]. The current calculations have been performed for the following embossing heights: 0.6, 1, and 1.8 mm. Based on the optimization of these two parameters, pipe internal modifications that will potentially achieve the best heat transfer and pressure drop performances were selected. When creating optimized geometries, other geometrical parameters, e.g., the number of turbulators on the perimeter and the width of the embossing, were left unchanged. It was assessed that their influence is not as significant as the influence of helix pitch and embossing height.

4. Simulation methodology

4.1. Discretisation

The computational meshes were generated for the optimized models presented in Figures 1a and b. Due to the necessity for the correct prediction of convective heat transfer at the pipe's internal wall, very fine meshes in the wall region had to be generated. The goal was to create as structured meshes as possible. Therefore, the sweep method available in the software ANSYS Meshing was used for this purpose, together with significant mesh refining to the wall. The length of the division along the axis was 1 mm. Additionally, the mesh size at the pipe walls was set to 0.00005 m to keep $y+$ as low as possible for the whole considered Re range. These allowed for keeping the same meshes at the inlet and outlet from the computational domain (necessary due to the periodic flow assumption in the first phase of the solution) and obtaining a satisfactorily dense mesh close to the wall. The generated meshes consisted mainly of very good quality hexahedral elements. For a few geometries, triangular prism elements were also generated. An exemplary mesh for a pipe with a rectangular turbulator with a height of 1 mm is shown in Figure 2, while the parameters of the generated meshes are presented in Tables 1 and 2 for pipes with rectangular and triangular vortex generators, respectively.

The meshes' qualities shown in Tables 1 and 2 were within acceptable ranges. However, to obtain these parameters' values, the models with modified internal surfaces had to have a very large number of elements due to the necessity to resolve near-wall regions accurately (see fine mesh at pipe boundaries in Figure 2). Moreover, the aspect ratio was very high to keep a suitable value of $y+$ at the wall, i.e., the k-ω shear stress transport (SST) turbulence model was applied in numerical simulations and required $y+$ to close or be below 4-5.

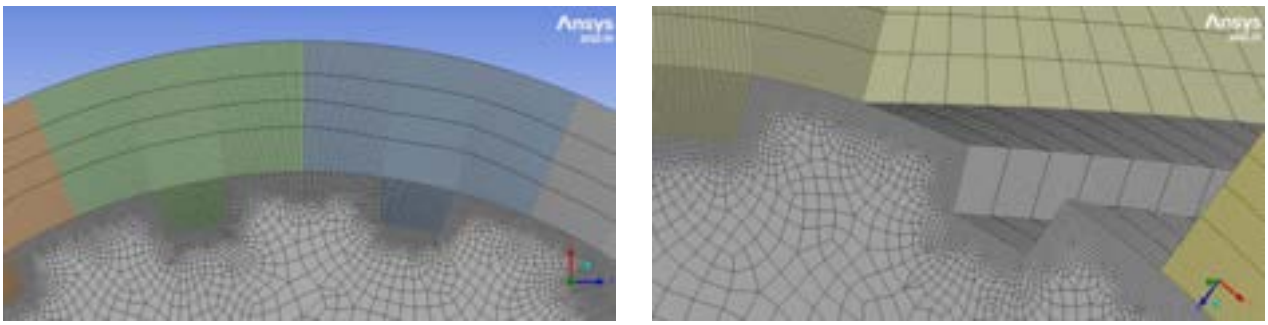

Figure 2. An exemplary mesh for a pipe with rectangular turbulators with a height of 1 mm.

Table 1. Parameters of meshes for pipes with rectangular turbulators.

Turbulator geometry	Number of elements	Max skewness	Max aspect ratio
Height = 0.6 mm	26 633 700	0.86	86.1
Height = 1.0 mm	32 958 900	0.86	84.7
Height = 1.4 mm (base pipe)	91 407 600	0.74	316.59
Height = 1.8 mm	52 866 000	0.86	76.7
Pitch = 150 mm	28 716 300	0.89	95.5
Pitch = 300 mm (base pipe)	91 407 600	0.74	316.59
Pitch = 450 mm	27 999 000	0.89	97.7
Pitch = 600 mm	30 336 360	0.87	240.4

Table 2. Parameters of meshes for pipes with triangular turbulators.

Turbulator geometry	Number of elements for single	Max skewness	Max aspect ratio
Height = 0.6 mm	26 028 900	0.89	285.7
Height = 1.0 mm	27 901 800	0.86	229.2
Height = 1.4 mm (base pipe)	117 933 300	0.74	198.51
Height = 1.8 mm	33 593 400	0.90	181.8
Pitch = 150 mm	28 716 300	0.89	204.9
Pitch = 300 mm (base pipe)	117 933 300	0.74	198.51
Pitch = 450 mm	19 101 600	0.88	230.6
Pitch = 600 mm	17 353 600	0.90	250.5

Compared to the calculations made in [12], the computational grids are characterized by much higher values of the aspect ratio parameter because longer pipes were simulated (0.3 m in [12] vs. 0.9 and 1.2 m in this work) to ensure thermally and hydrodynamically fully developed flow in the rear part of the pipe. This positively

affects the accuracy of calculations and mapping changes in thermal and flow parameters along the pipe axis (i.e., the fully developed flow was obtained). On the other hand, skewness has slightly increased. But elements with poorer skewness are mainly located in the solid region. Only the energy equation that accounts for heat conduction in solid elements is solved there, which solution is immune to poorer quality elements. In the fluid region, the maximum skewness never exceeds 0.72 in pipes with rectangular vortex generators and 0.81 with triangular vortex generators. The *y*+ values also slightly increased compared to the results from [12], ranging from 1 to 2 for the maximal considered Re of 8000. However, the SST *k*-ω model allows accurate calculations for *y*+ up to 4-5.

4.2. Solution strategy

In the beginning, it was necessary to consider the stabilization of the thermal boundary layer in the pipe. This was required to find heat transfer rates for fully developed flow in the rear part of the pipes, in which the calculation results were averaged. Therefore, it was necessary to determine the optimal length of the tested pipe sections. It turned out that very good results were obtained for a pipe with a length of 0.9 m for 150, 300, and 450 mm pitches and 1.2 m for a pitch of 600 mm. The results for averaging were picked from the pipe section of length between 0.8 and 0.9 m.

Performed initial verification for the model of smooth pipe using Nu number correlations showed that the differences between correlations and numerical results were in the range of 3-5% for considered Re values. This analysis proves the good accuracy of the developed model. Moreover, mesh sensitivity analyses were performed for the smooth pipe and selected pipes with ribs, i.e., refined meshes were generated with smaller elements close to the walls. For refined grids, the *y*+ was below 1. These simulations' results were compared with those obtained for meshes used in this paper. The relative differences in calculated Nu numbers between current and fine meshes were below 1%, which showed the grid size independence of the developed model. The model validation was not performed at the current state, but the experimental studies are ongoing.

The solution strategy was divided into two phases. In the first phase, the periodic fluid flow problem in pipes without heat transfer was considered to find hydrodynamically fully developed velocity and turbulence fields in the computational domains. The fluid flow in the pipes was solved using the *k*-ω SST turbulence model implemented in the commercial engineering software ANSYS Fluent. In the second phase, the energy equation was only solved based on the fluid velocity and turbulence fields in the pipes obtained in the previous phase, but the problem was not further assumed periodic. In this phase, the momentum and turbulence equations were not solved. This strategy allowed for simulations of short repeatable segments of the pipes. The heat transfer problem in the pipes was solved based on the hydrodynamically fully developed flow and turbulence fields. As fluid flow and heat transfer equations were decoupled (i.e., fluid properties were assumed temperature-independent), the applied solution strategy did not influence the accuracy of the results. But it significantly speeded up the simulations and reduced the required length of pipe necessary to be simulated to obtain developed flow and thermal profiles.

Table 3. Properties of PEX and 24% wt. ethylene glycol solution.

Property	PEX	Ethylene glycol solution
Density (kg/m^3)	940	1049.56
Specific heat (J/kg/K)	2302.3	3852.09
Thermal conductivity (W/m/K)	0.46	0.258
Dynamic viscosity (kg/m/s)	-	0.00387

Table 4. The hydraulic diameters, cross-sectional areas, and mass flow rates of the working medium for assumed pipes geometries.

Turbulator geometry	Hydraulic diameter (m·10^3)	Cross-sectional area (m^2·10^4)	Mass flow rate (kg/s)		
			Reynolds number		
			3000	5500	8000
Smooth pipe	26.20	5.350	0.233	0.427	0.622
Rectangular height 0.6 mm	22.09	5.179	0.265	0.487	0.708
Rectangular height 1.0 mm	19.91	5.048	0.287	0.527	0.767
Rectangular height 1.4 mm	16.63	4.929	0.336	0.616	0.896
Rectangular height 1.8 mm	14.41	4.640	0.365	0.669	0.974
Triangular height 0.6 mm	22.97	5.358	0.264	0.484	0.705
Triangular height 1.0 mm	21.08	5.299	0.285	0.523	0.760
Triangular height 1.4 mm	19.35	5.212	0.306	0.559	0.814
Triangular height 1.8 mm	18.61	5.096	0.325	0.596	0.868

4.3. Material properties

The pipes were assumed to be made of PEX, while the working medium was 24% wt. aqueous solution of ethylene glycol. Their properties assumed in the simulations are given in Table 3.

4.4. Boundary conditions

In the first phase of the calculations, a periodic boundary condition at the inlet and outlet from the pipe with a given mass flow rate was applied (see Table 4, which contains mass flow rates for different Re, hydraulic diameters, and cross-sectional areas of pipes). In each case, the hydraulic diameter-based Re values were assumed to be the same and equal to 3000, 5500, and 8000. These values corresponded to smooth pipe glycol velocities of 0.335, 0.614, and 0.893 m/s, respectively. However, differences in the values of hydraulic diameters caused the mass flow to vary for each pipe with different vortex generator shapes, as shown in Table 4. In the case of variable helix pitch, mass flow rates were the same for each helix pitch and corresponded to the values for the respective pipes with a height of the turbulators equal to 1.4 mm. In the case of the variable height of the turbulator, mass flow rates varied, as shown in Table 4. In the second phase of the calculations, the fixed glycol temperature of 275.15 K was set at the pipe's inlet and 323.15 K at the external pipe surface. The rest of the surfaces were assumed to be adiabatic. The pipe outer wall temperature was significantly higher than the usual ground temperature, i.e., 281.15 K. However, this boundary condition allowed for obtaining a measurable working fluid temperature increase along the pipe section. The results were read from the pipe section of length between 0.8 and 0.9 m. Obtaining larger temperature increases in the pipe also eliminated the impact of possible numerical errors.

5. Results

5.1. Parametric simulations

In [12], the results of pressure drops and temperature increase in the pipe, heat flux density on the pipe wall, and average Nu were presented. However, to determine the effectiveness of the tested pipes, it is enough to look at the pressure drops and Nu values. In order to show the performances of the modeled pipes, these parameters are shown relative to the smooth pipe in Figures 3 and 4.

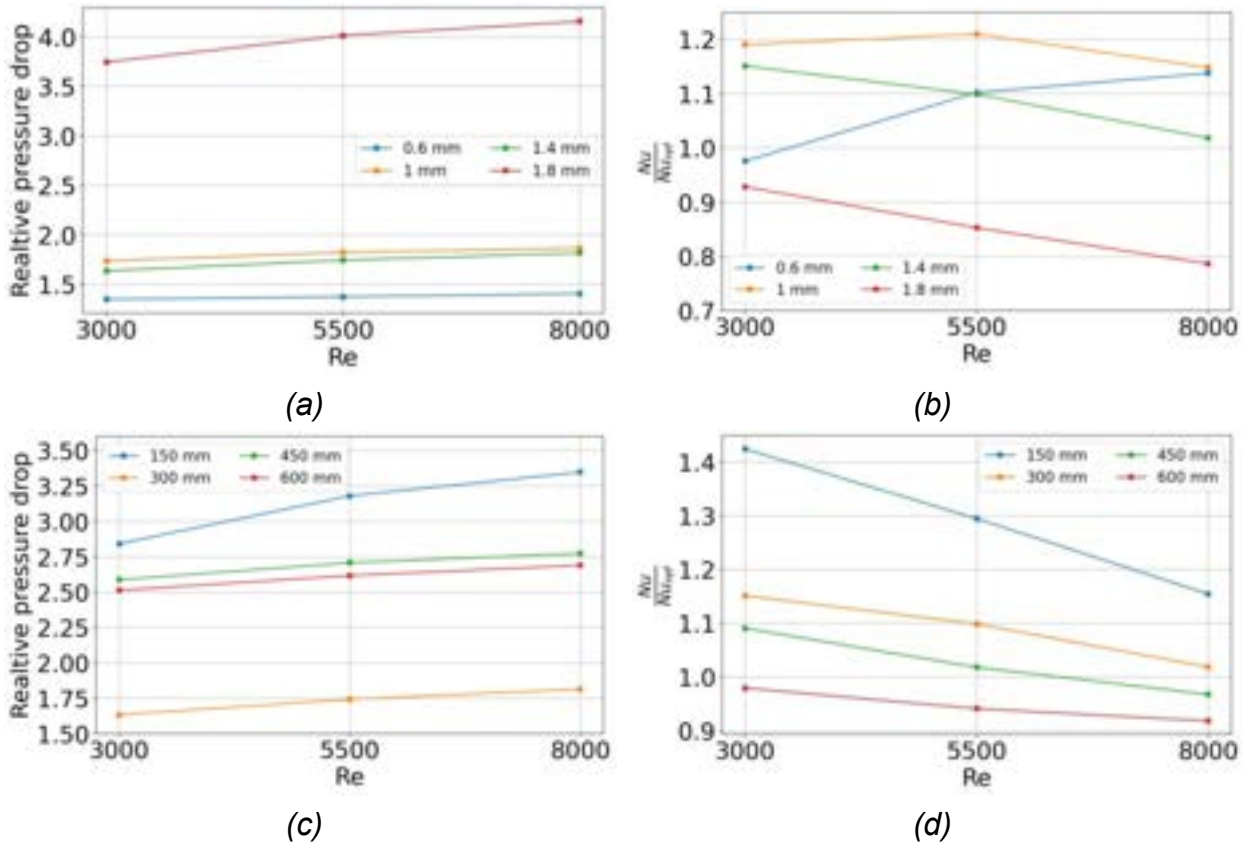

Figure 3. Parametrization analysis results for the model with rectangular turbulators: a) pressure drop depending on turbulator height, b) Nu depending on turbulator height, c) pressure drop depending on the pitch of the helix, d) Nu depending on the pitch of the helix.

In the first step, the pipes with rectangular turbulators were taken into account. Figure 3a shows that the size of the turbulators has a significant impact on the values of the obtained pressure drops. Generally, the larger

the turbulator, the greater the pressure drop. It can be seen that for turbulators with a height of 1.8 mm, the pressure drop is very large and is over 250-300% of the value for a smooth pipe. Thus, heights in the range of 0.6-1.4 mm, which are characterized by much lower pressure drop increase than the height of 1.8 mm, have the potential to improve the performance of the rectangular turbulators. For a height of 0.6 mm, the increase of the pressure drop is about 35-40%, while for 1 mm and 1.4 mm, the pressure drop rises by 60-80%. Figure 3b also shows that very large turbulators do not improve convective heat transfer. Pipes with heights of 0.6 mm and 1.4 mm achieve very different results depending on the Re. Pipes with vortex generators of a height of 1 mm turned out to be the best, characterized by an increase of the Nu in the range of 15-21% in the entire range of Re. Considering the pitch of the helix, it can be seen in Figure 3c that a pitch of 150 mm gives by far the greatest pressure drop, up to 230% more than for the smooth pipe. The pipe with a helix pitch of 300 mm turned out to be the best, which had the smallest increase in the pressure drop in the range of 60-85%. However, the results of the intensity of convective heat transfer indicate that the model with the smallest pitch of the helix gives the best results. It records an increase in the Nu by 15.5-43% compared to the smooth pipe. The model with a pitch of 300 mm already gives an increase of only 2-15%. The other two pipes perform worse both in terms of pressure drop and intensity of convective heat transfer than the base case. Based on these results, an optimized pipe was proposed. Its turbulators height is assumed to be 1 mm, and the pitch of the helix of 150 mm is selected.

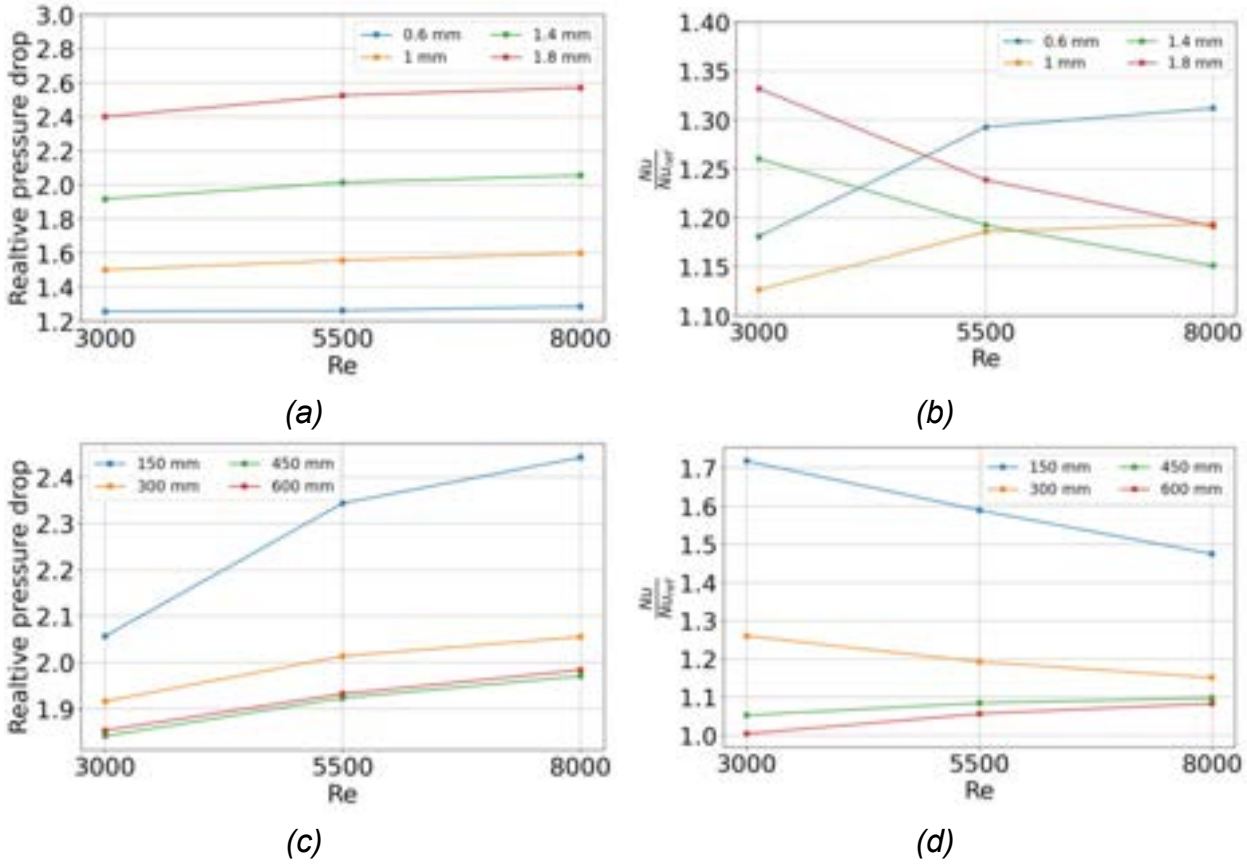

Figure 4. Parametrization analysis results for the model with triangular turbulators: a) pressure drop depending on turbulator height, b) Nu depending on turbulator height, c) pressure drop depending on the pitch of the helix, d) Nu depending on the pitch of the helix.

In the second step, the pipes with triangular turbulators were considered. Again, the increase in the size of the turbulators causes an increase in the pressure drop (Figure 4a), but this time the relationship is much more clear and linear. Of course, the best results are obtained for the pipe with 0.6 mm high turbulators, for which the increase is only 23%. For a height of 1 mm, it is already 50-60% depending on Re value. The thermal performance of all pipes is similar. The increase in the Nu is in the range of 12-33%. Larger turbulators (i.e., 1.4 and 1.8 mm) show better properties at lower Re numbers, while smaller turbulators (i.e., 0.6 and 1.0 mm) are more effective at higher Re. Considering the pitch of the helix, again, the pitch of 150 mm gives the greatest increase in pressure drop of 105-143% (Figure 4c) and the greatest increase in the Nu of 47-72% (Figure 4d). For other pipes, the increase in the pressure drop is significantly lower and amounts to 83-105%. But the increase in the Nu is also much smaller for these pipes and is in the range of 1-26%. Based on these results, the selected optimal pipe with triangular turbulators has a turbulators height of 0.6 mm and a helix pitch of 150 mm.

5.2. Optimized models

In this section, proposed optimized pipes are investigated. Information on computational meshes for optimized pipes is presented in Table 5, while mass flow rates for different Re, hydraulic diameters, and cross-sectional areas of these pipes are presented in Table 6.

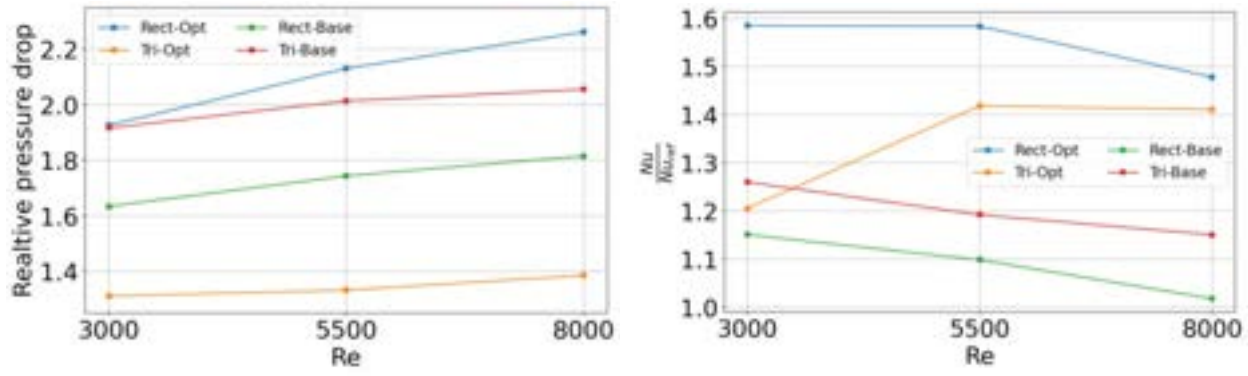
Table 5. Parameters of meshes for optimized pipes.

Turbulator geometry	Number of elements	Max skewness	Max aspect ratio
Rectangular	24 056 100	0.86	277.58
Triangular	37 247 400	0.79	119.80

Table 6. The hydraulic diameters, cross-sectional areas, and mass flow rates of the working medium for optimized models.

Turbulator geometry	Hydraulic diameter ($m \cdot 10^3$)	Cross-sectional area ($m^2 \cdot 10^4$)	Mass flow rate (kg/s)		
			Reynolds number		
			3000	5500	8000
Rectangular	19.04	5.155	0.307	0.562	0.818
Triangular	22.97	5.358	0.264	0.484	0.705

The results obtained for the optimized pipes were compared with the base pipes calculated, among others, in [12]. Relative pressure drops and Nu were again compared in Figure 6.



(a) *(b)*

Figure 5. Results for optimized models: a) pressure drop and b) Nu for different values of Re (Rect-Base – base pipe with rectangular turbulators, Rect-Opt – optimized pipe with rectangular turbulators, Tri-Base – base pipe with rectangular triangular, Tri-Opt – optimized pipe with rectangular triangular).

The optimized pipes have much better convective heat transfer performances. The increase in the Nu for the optimized pipe with rectangular turbulators is 47-58%, while for the pipe with triangular turbulators is 21-42%. For non-optimized pipes (base geometries), it was 2-15% and 15-26%, respectively. The average increments of the Nu for optimized pipes relative to the smooth ones are several times greater in both cases. The situation is different in the case of pressure drops, and the optimized model with rectangular turbulators has higher pressure drops. Optimized triangular turbulators are much better in this regard. For the pipe with triangular turbulators, a lower pressure drop was recorded for the considered Re range than for the base pipe, i.e., the relative pressure drop varied in the 31-39% range. For the optimized pipes with rectangular turbulators, the increase in pressure drop is 92-126%.

It should be noted that in these simulations, the Re was in the same range for all cases. This resulted in significantly higher glycol mass flow rates in modified pipes than the smooth ones, as modified pipes had lower cross-sectional area and lower hydraulic dimeters than the smooth pipe. For optimized pipes, the mass flow rates were higher, c.a. 32 and 13% for rectangular and triangular vortex promoters, respectively. Applying the same mass flow rates of the working medium in the smooth and modified pipes will result in a much lower pressure drop increase than shown in this work, while Nu will still be significantly higher. This shows that the practical implementation of pipes with turbulence promoters in ground heat exchangers may be profitable.

6. Conclusions

This paper presents numerical optimization of the geometry of turbulence promoters in polymeric-made pipes in terms of heat transfer and fluid flow performances. Two rib shapes, i.e., rectangular and triangular, were

selected based on the previous studies [12] as the most promising. Two geometrical parameters, i.e., vortex generators' height and pitch of the helix along which the ribs were extruded, were selected as variable parameters.

In the first step, a series of simulations were conducted for four ribs heights and four helix pitches. The results of these simulations allowed for finding the pressure drop and Nu characteristics for each pipe with internal surface modifications for Re in the range of 3000-8000. The results were analyzed, and optimal turbulators parameters were proposed based on that. For both rectangular and triangular vortex generators, their optimal height was selected to be 1 and 0.6 mm, respectively, while the pitch of the helix in both cases was chosen to be 150 mm.

In the second step, optimal turbulators' performances were compared to the initial (base) geometries. The optimized pipes have much better convective heat transfer performances. The increase in the Nu for the optimized pipe with rectangular vortex generators was 47-58% regarding the smooth pipe, while for the pipe with triangular modifications, it was 21-42%. These values, on average, are several times higher than for the initial turbulence promoters' geometries. However, for rectangular modifications, the pressure drops were higher than for base pipes and were in the range of 92-126%. Optimized triangular turbulators are much better in this regard. The triangular vortex promoters attained pressure drops in the 31-39% range, which was lower than for the base case.

In the performed analyses, the Re was in the same range for all simulated cases. This resulted in significantly higher glycol mass flow rates in modified pipes than the smooth ones. Applying the same mass flow rates of the working medium in the smooth and modified pipes will result in a much lower pressure drop increase than shown in this work for the fixed Re range, while Nu will still be significantly higher. This shows that the practical implementation of pipes with turbulence promoters in ground heat exchangers might be profitable.

Abstract:

The depletion of fossil fuels and increased greenhouse gas emissions are crucial factors forcing innovation in various branches of industry and life. In the 21st-century air conditioning is becoming a necessity in terms of well-being and health. Therefore, adsorption cooling technology constitutes a very promising alternative to energy-consuming and environmentally hazardous vapour compression chillers. The main challenge in the wider popularization of adsorption technology is the intensification of heat and mass transfer within the adsorption bed. Therefore, the paper presents different sorption reactor concepts aimed at solving the aforementioned issue. The main parameters influencing heat and mass transfer for each of the analyzed cases are calculated using the computational fluid dynamics code adapted to capture the specific phenomenon occurring in the adsorption bed. The developed numerical model is validated against the experimental data collected on the test stand dedicated to experimental research of innovative adsorption beds operating in various conditions. The results of numerical modelling with the use of the developed coupled CFD & DEM model concerning the adsorbent particles movement and variation in relative temperature of the adsorbent within the fluidization process are presented in the paper. The research allowed to define the design parameters of the adsorption bed that allow intensifying the heat and mass transfer in the adsorption reactor and, in consequence, significantly contribute to the development and popularization of the adsorption cooling technology.

Adsorption chiller; CFD & DEM coupling; Computational fluid dynamics; Discrete element modelling; Fluidization; Heat and mass transfer.

1. Introduction

1.1. Innovation for a sustainable future

The depletion of fossil fuels and the urgent need to reduce greenhouse gas emissions have forced various industries to innovate and develop sustainable alternatives. The major development activities are carried out in energy [1], transportation [2], agriculture [3], and construction industry [4] among which the energy industry is one of the largest contributors to greenhouse gas emissions and climate change. To reduce emissions, the industry has shifted toward renewable energy sources such as solar, wind, and geothermal power. In addition, innovations in energy storage technologies such as batteries and hydrogen fuel cells are also helping to make renewable energy more viable. According to the roadmap presented by the International Renewable Energy Agency [1], renewable energy technologies could provide 90% of the world's electricity by 2050, reducing greenhouse gas emissions by 60%. In addition, cooling systems are responsible for up to 26% of electricity consumption depending on the country [5], with more than 40% of energy consumption in the residential and service sector [6]. This leads directly to the occurrence of peak demand for electricity during the summer period

when the capacity of the power system is the lowest. Such a situation may result in local power deficits or even blackouts, examples of which have already appeared many times. Therefore, the energy industry has been exploring alternative and sustainable energy sources such as solar energy or wind energy but attempts have also been made to waste heat utilization. One of the technologies allowing to effectively utilize the low-grade waste heat for chill generation, seawater desalination or long-term heat storage is the adsorption technology.

1.2. Advantages and disadvantages of adsorption technology

Adsorption technology involves using solid adsorbents to capture and store or transform energy. The process involves the adsorption of a gas or vapour onto a solid surface, which releases heat energy. Several types of adsorbents can be used in adsorption technology, such as zeolites, activated carbons, and metal-organic frameworks (MOFs). Each type of adsorbent has unique properties that make it suitable for specific applications. Metal and carbon nanotube additives to adsorbent are capable to improve its thermal diffusivity and subsequently the overall performance of the process [9]. One of the advantages of adsorption technology is its ability to use low-grade waste heat sources, which are typically not viable for other heat recovery technologies. The recent interest in adsorption cooling technology results from the following benefits of adsorption chillers in comparison to conventional vapour-compression systems:

- powered with a renewable or waste heat source of temperature as low as 50°C [10], which directly leads to a reduction in CO_2 emissions and pollution [11],
- environmentally friendly due to the absence of hazardous and environmentally harmful refrigerants [12],
- capable to desalinate seawater [13],
- almost zero electricity consumption [14],
- no moving parts resulting in high reliability [15],
- quiet due to the absence of compressors and no vibration [16],
- simple control & maintenance [16].

But the widespread application of adsorption chillers is limited by the following shortcomings of adsorption cooling technology:

- low coefficient of performance [17],
- large weight & volume [15],
- intermittent cooling [18],
- high initial procurement cost [18],
- exploitation under vacuum conditions [19].

1.3. Adsorption chiller work cycle

The adsorption process in the chiller is used to transfer heat and produce cooling, with the refrigerant being adsorbed onto the surface of a solid adsorbent material [20]. The work cycle of an adsorption chiller typically involves several subsequent stages, including adsorption, refrigerant transfer, desorption, and refrigerant condensation.

1.3.1. Adsorption

In the adsorption stage, the adsorbent material is exposed to the refrigerant vapour and the refrigerant molecules are adsorbed onto the surface of the adsorbent. The adsorption process is driven by a heat source, which raises the temperature of the adsorbent and facilitates the adsorption of the refrigerant.

1.3.2. Refrigerant Transfer

Once the refrigerant is adsorbed onto the adsorbent material, the next stage of the cycle is the transfer of the refrigerant. This involves the movement of the refrigerant vapour from the adsorber to the evaporator.

1.3.3. Desorption

In the desorption stage, the temperature of the adsorbent is lowered. This causes the refrigerant molecules to be released from the surface of the adsorbent and return to the vapour phase. The desorption stage is the key to the cooling process as it releases the heat that was previously absorbed during the adsorption stage.

1.3.4. Refrigerant Condensation

The final stage of the work cycle is the condensation of the refrigerant vapour back into a liquid. This stage involves the use of a condenser, which is typically cooled using a cooling medium such as water. As the refrigerant vapour flows through the condenser, it gives up its heat to the cooling medium and condenses into a liquid, ready to repeat the cycle.

1.3.5. Thermodynamic cycle

The sorption reactor operates between the condenser/evaporator pressure and the minimum/maximum adsorbate concentration levels. The Clapeyron diagram depicted in Figure 1 illustrates the four ideal thermodynamic stages occurring in the bed i.e., isosteric preheating (1–2), isobaric desorption (2–3), isosteric precooling (3–4), and isobaric adsorption (4–1).

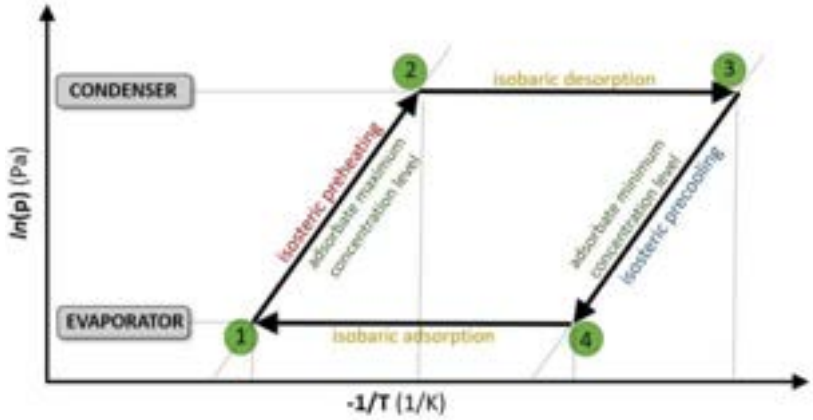

Figure 1. Clapeyron diagram of a basic adsorption chiller work cycle

1.4. Adsorption chiller construction

The operation of an adsorption chiller typically involves a closed-loop system, which includes an evaporator, an adsorber, a condenser, and a desorber as shown in Figure 2a. The refrigerant absorbs heat and evaporates in the evaporator, while it is adsorbed onto the surface of the adsorbent material in the adsorber. The refrigerant is cooled and condenses back into a liquid in the condenser and the desorber is where the refrigerant is desorbed from the adsorbent material, releasing the heat that was previously absorbed. Typically, the adsorber and desorber are combined into one sorption reactor to simplify the system and reduce its overall cost (Figure 2b). Moreover, at least two sorption reactors operating interchangeably are commonly used to assure constant delivery of cool (Figure 2c). The operation of an adsorption chiller is controlled with valves linking the above-mentioned parts of the system. Researchers have also proposed more sophisticated concepts: combined heating and cooling adsorption chiller [21], three-bed adsorption chiller [22] or re-heat two-stage adsorption chiller [23].

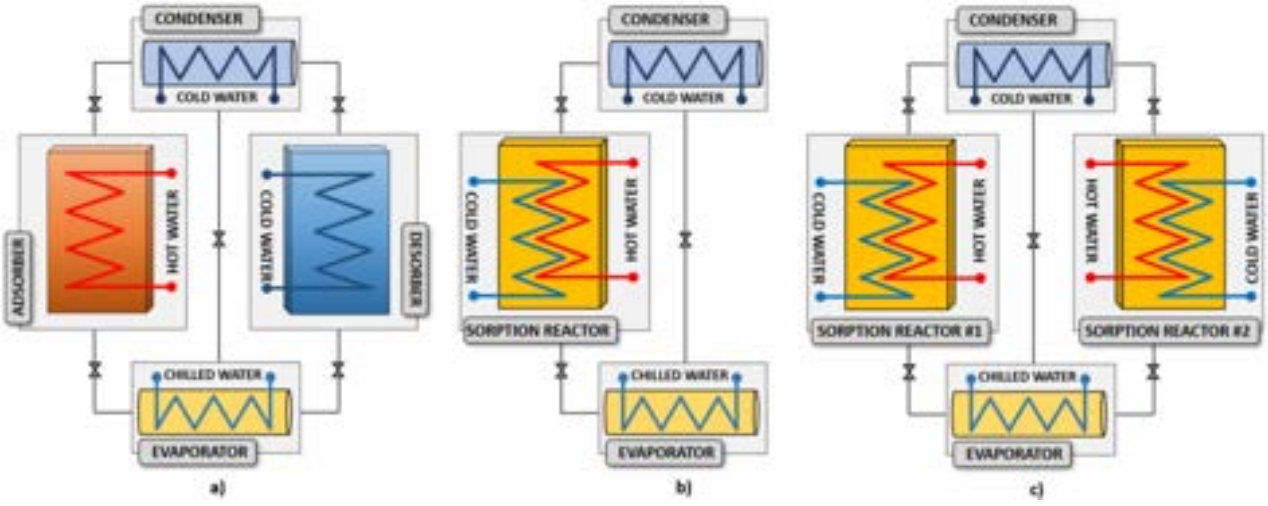

Figure 2. The schematic diagram of the adsorption chiller construction: a) basic concept, b) adsorber and desorber combined into a sorption reactor, c) two sorption reactors operating interchangeably.

1.5. Previous research

The effect of cooling temperature on the performance of a solar adsorption chiller with enhanced mass transfer was investigated in [24]. The authors proposed a new enhanced mass transfer mode with two condensers and a micro vacuum pump for decreasing the desorption pressure. The refrigerant vapour was condensed before being pumped into the receiver, which increased the density of the refrigerant and improved the mass flow

rate with the same pressure and working speed of the pump. The performance of the solar adsorption cooling system with the enhanced model was evaluated and compared with three different cooling temperatures. The results showed that reducing the cooling temperature can greatly improve the coefficient of performance (COP) under the mode of enhanced mass transfer.

The integrated adsorption-absorption system driven by transient heat sources for cooling and desalination was investigated in [25] and [26]. In the first case, the system operated with a relatively low exergy efficiency in the absorption cycle of up to 15.33%. The adsorption bottoming cycle successfully utilised the heat from the absorption subsystem at a relatively higher exergy efficiency of up to 42.69%. The execution of a transient heat source of sinusoidal waveform enhanced the water production by up to 30% and the cooling of absorption and adsorption subsystems by 24% and 15%, respectively. The performance of innovative combined absorption and adsorption cooling systems employing the same evaporating and condensing units was theoretically investigated in [26]. The performance of the proposed system was compared with a separated absorption and adsorption cooling system, combined absorption and adsorption cooling system employing the parallel operation mode, a conventional single-stage adsorption cooling cycle, and other integrated systems available in the literature.

Triply periodic minimal surface structures have been implemented in adsorber/desorber to improve the performance of adsorption cooling systems in [27]. The use of metal triply periodic minimal surface-based structures considerably increased the effective thermal conductivity of the porous media/metal composite due to its large surface area to porous media volume. A fully three-dimensional computational fluid dynamics model was constructed using ANSYS Fluent in the above-mentioned research. This research methodology was also applied in [28].

An experimental and analytical study on the application of adsorber plate heat exchangers in thermally driven chillers was carried out in [29]. The authors investigated the effect of both heat and mass transfer characteristic lengths of two different adsorber plate heat exchangers for application in an adsorption chiller on the adsorption and desorption kinetics. It turned out that the adsorption kinetics is mainly influenced by the mass transfer characteristic lengths, while the desorption kinetics is dominated by the heat transfer characteristic lengths of the adsorbent domain.

Apart from computational fluid dynamics, the artificial intelligence approach is also commonly used in the analysis of adsorption systems. Heat and mass transfer prediction in fluidized beds of cooling and desalination systems was researched in [30]. The developed model allowed the study of input parameters' effect on the outputs and optimize the operating strategy of the bed. Also, the cost of manufacturing adsorption chillers is described in the scientific literature [31] - at a maximum Coefficient of Performance of 1 and maximum Specific Cooling Power of 300 W/kg, the specific selling price of a Silica gel adsorption chiller is €1018 per kW of cooling power.

The effectiveness of adsorption technology in waste heat utilization has been proved in numerous research papers e.g. [32]. The authors conducted experimental and theoretical analyses on the effects of temperature, dew point, and the flow velocity of high-temperature moist air on the regeneration rate in the adsorption heat pump systems.

1.6. Motivation and novelty

Despite the presented numerous research activities aiming to improve the adsorption cooling technology, further research and development are needed to optimize it and make it more cost-effective for commercial applications. Therefore, this paper aims to propose the novel concept of using computational fluid dynamics (CFD) coupled with discrete element modelling (DEM) to analyse the benefits of using fluidization to improve heat and mass transfer within the adsorption bed. Such an approach has never been used before and reveals great potential for further improvement in optimizing the construction of adsorption reactors with numerical methods. It will deliver new knowledge, especially concerning the adsorbate velocity field within the sorption reactor at the operating conditions (absolute pressure below 3 kPa) and it will allow to design the reactor and control the process in a way that maximizes the heat and mass transfer within the whole volume of the adsorbent material.

2. Methods and research objects

As the heat and mass transfer in the sorption reactor are the main factors influencing the overall performance of the adsorption chiller, several design concepts of the reactor were analysed within the carried-out research. They are described in the following paragraphs with the newest concept of fluidized sorption reactor being the main focus of attention.

2.1. Honeycomb sorption reactor

The concept of a honeycomb sorption reactor depicted in Figure 3 was presented in detail in [33]. It contributed to the increased heat transfer surface area and simultaneously assured a compact and lightweight design of the chiller. The computational fluid dynamics analysis performed with the use of the developed endothermic desorption model incorporated into the ANSYS Fluent software allowed defining of the optimal design of the

investigated type of heat exchanger and its correlation with basic factors influencing the performance of the sorption reactor and its dimensions such as the gradient of heating/cooling water temperature, logarithmic mean temperature difference, heat exchanger mass to sorbent ratio, effective mass factor, heat transfer surface to sorbent mass ratio and solid volume fraction. Moreover, the spatial temperature distribution in the reactor as well as the influence of construction material on the above-mentioned factors were defined.

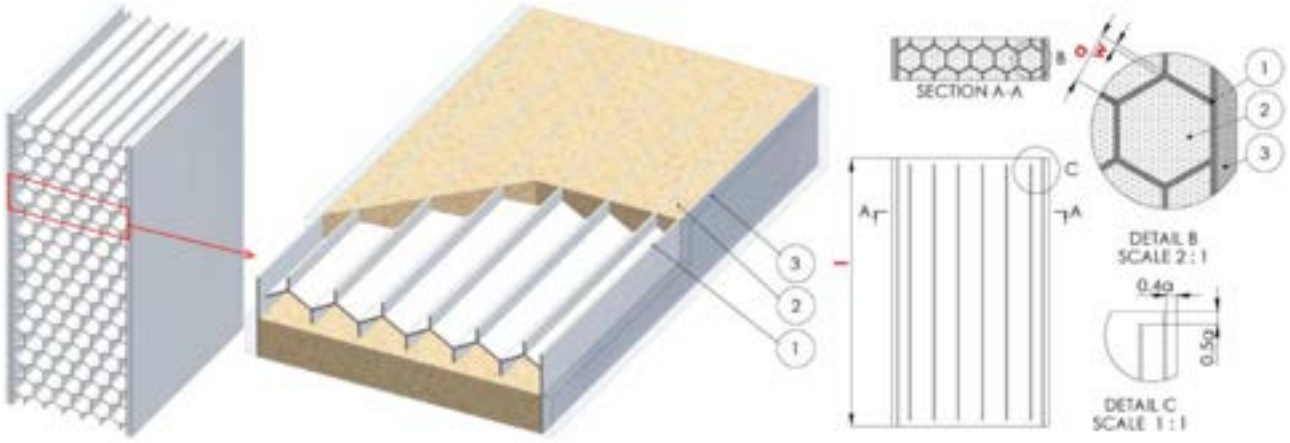

Figure 3. Concept of a honeycomb sorption bed [33], 1 – metal heat exchanger, 2 - sorbent, 3 – heating/cooling water collector

The commercial ANSYS Fluent tool dedicated to computational fluid dynamics was used in this research. However, it does not allow for sufficient consideration of the aspects related to heat and mass exchange during sorption processes. Therefore, the User-Defined Functions (UDF) capability was used to create the model of sorption processes, as it is necessary to take into account fluctuations in the local intensity of heat production or consumption during the exothermic adsorption or endothermic desorption process, respectively. The above-mentioned intensity of heat production or consumption in the sorption reactor depends directly on the local temperature of the sorbent. The mathematical dependence of the sorption intensity and the sorbent temperature was determined as a polynomial function of coefficients defined and validated during previous studies concerning heat transfer in the sorption beds [34].

2.2. Multi-disc sorption reactor

The innovative construction of a multi-disc sorption reactor depicted in Figure 4 was investigated and presented in detail in [35]. In contrast to the commonly applied designs, in a multi-disc reactor, the sorbent is placed in separate disc-shaped packets, and the cooling/heating water washes the packets of sorbet from the outside transferring heat. The adsorbate vapour flows through the fixing net into the sorbent packets penetrating them. The fixing net holds the granular sorbent inside the disc-shaped packets.

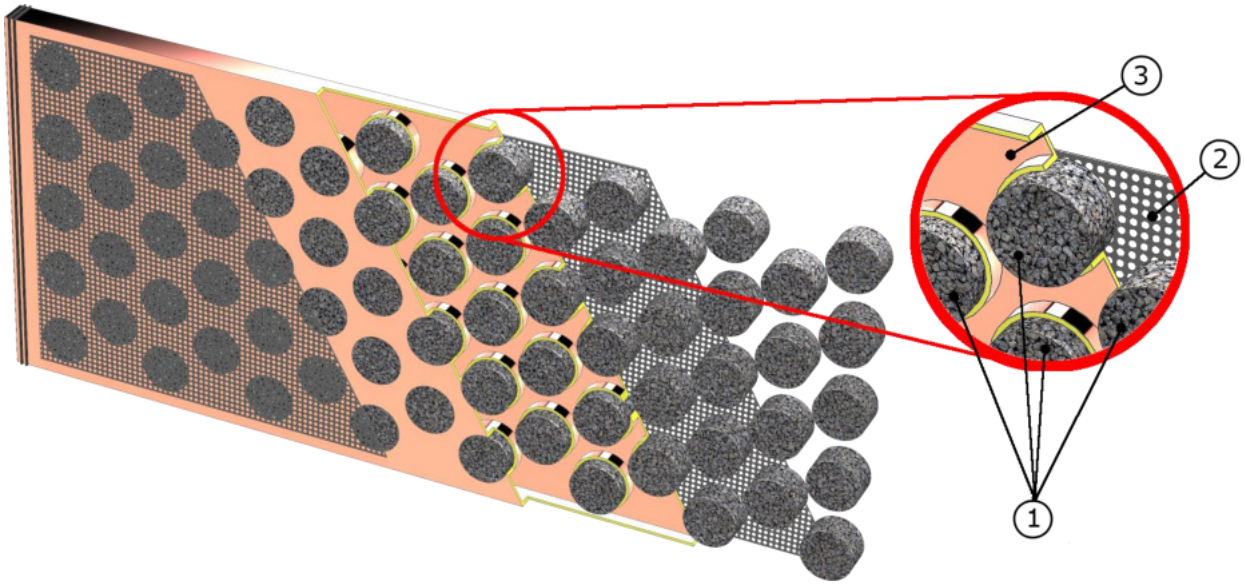

Figure 4. Section view of the investigated multi-disc sorption bed [35]: 1 - disc-shaped sorbent packets; 2 - fixing net; 3 - the main body of the sorption reactor

The proposed construction allowed to place the sorption reactor e.g. in the ceiling of the building or integrating it with solar panels to directly supply the reactor with the necessary heat. Such a solution allows to significantly expand the potential installation sites of the adsorption chillers and thus reduces the need to save a large space for the installation of the adsorption chiller – it is one of the main disadvantages of these devices. Another advantage of the proposed solution is its potential for scalability by adjusting the number of sorbent discs to the expected cooling capacity of the adsorption chiller or the possibility of installing two or more multi-disc sorption reactors with sorbent packages one above another with the space between them being a vapour collector [35].

2.3. Disc-shaped fluidized sorption reactor

The low coefficient of performance of the conventional fixed-bed adsorption chillers is one of their main disadvantages. It results from the low heat transfer in the sorbent beds. One of the well-known methods, allowing to improve the heat transfer coefficient between the porous material and the immersed heating surface is fluidization [36]. Therefore, based on the best practices and numerical models developed and validated within the research concerning honeycomb sorption reactor and multi-disc sorption reactor, the novel concept of a disc-shaped fluidized sorption reactor has been proposed to maximize the coefficient of performance of the adsorption chiller.

2.3.1. Experimental test stand

The experimental test stand was adapted to investigate the operation of the disc-shaped fluidized reactor and to deliver experimental data necessary to validate the developed numerical model of the sorption reactor described in paragraph 2.3.2. Coupled CFD & DEM.

The schematic diagram and the photograph of the experimental test stand are depicted in Figure 5. The test stand consists of a bottom tank operating as an evaporator and an upper tank equipped with an interchangeable sorption reactor. Both tanks are connected to the vacum pump and to each other via valves controlled individually by the data acquisition and control unit. Both tanks are equipped with electrical heating and an additional inlet/outlet to be supplied with liquid medium (water) for cooling or heating. Moreover, mass sensors, absolute and relative pressure sensors and temperature sensors are installed in both tanks. A detailed description of the experimental test stand is provided in [37].

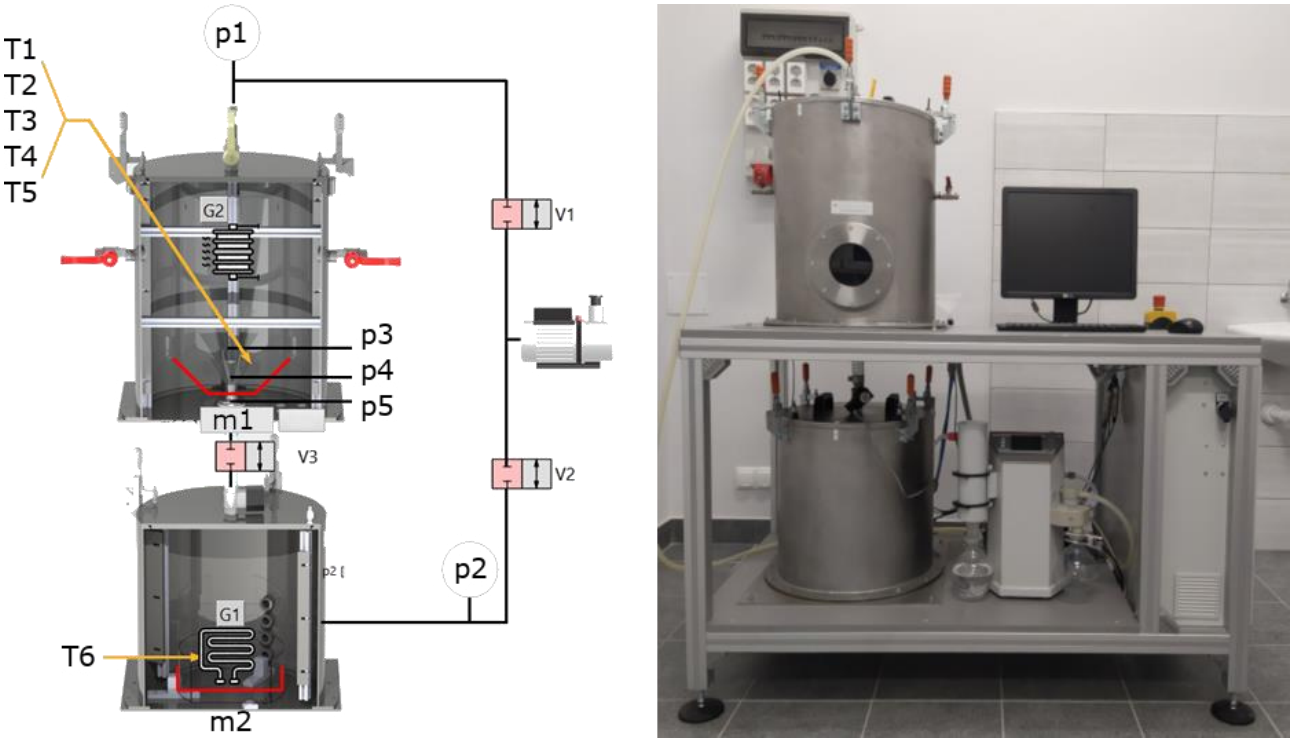

Figure 5. Experimental test stand: schematic diagram (left) and photograph (right)

The top tank can be equipped with different types of sorption reactors and for the purpose of the research the investigated disc-shaped fluidized reactor depicted in Figure 6 was installed in the test stand. The diameter of the reactor was 30 mm and the height of the adsorbent material bed was 30 mm at steady state. The spherical silica gel of 500 μm diameter and bulk density equal to 780 kg/m^3 was used as the adsorbent. The initial pressure in the top tank was 1500 Pa and 2500 Pa in the bottom tank resulting in the initial pressure difference of 1000 Pa. This pressure difference was the driving force of the fluidization process in the sorption reactor. The fluidization lasted until the equilibrium of pressure in both tanks which was 20 seconds.

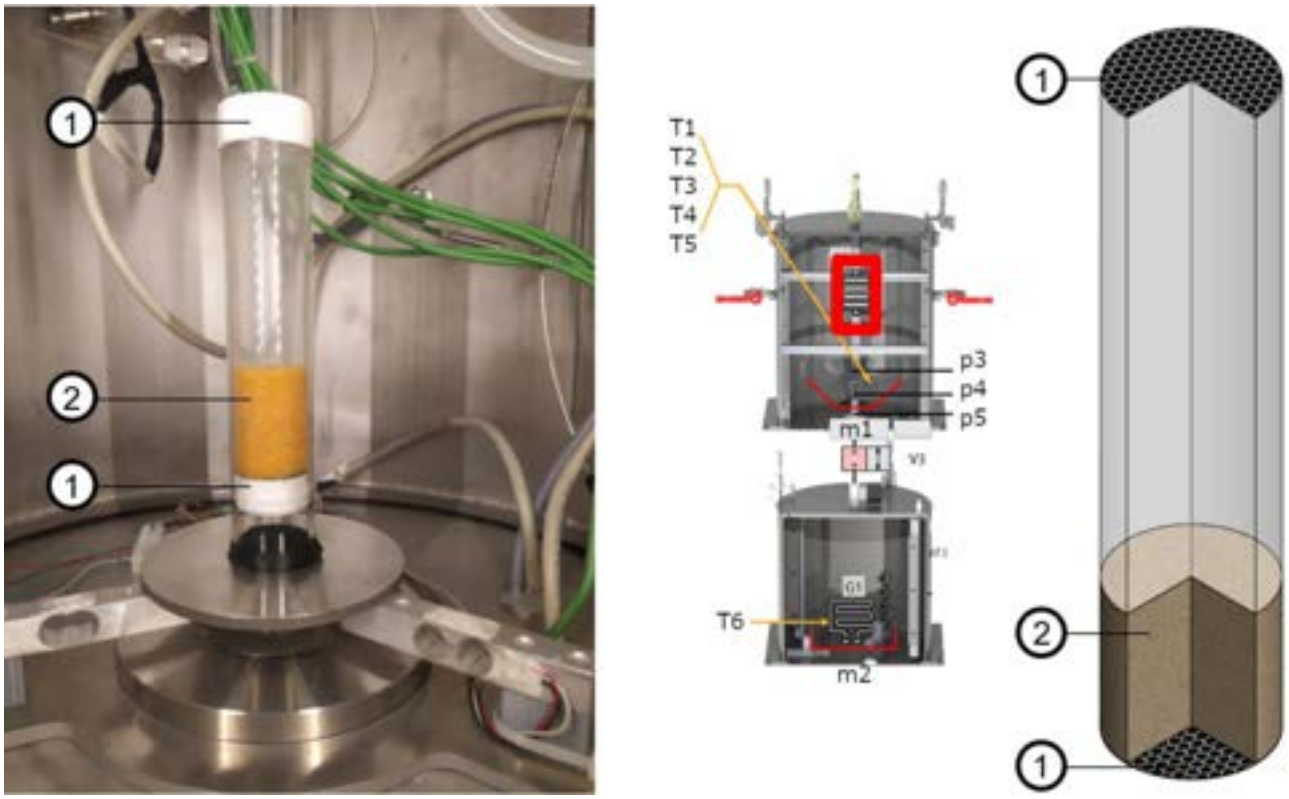

Figure 6. Disc-shaped fluidized sorption reactor: 1 – fixing net, 2 – silica gel

2.3.2. Coupled CFD & DEM

The detailed numerical analysis of the disc-shaped fluidized reactor is a challenging task due to the lack of suitable models. Therefore, the carried-out research aimed to develop a comprehensive model coupling the computational fluid dynamics code with the discrete element method. Such an approach is a promising alternative for modelling granular-fluid systems, expanding the range of coupled particle-fluid processes that can be managed with numerical simulations. Two-way coupling, in which the fluid flow affects the particle movement and the particle flow influences the continuous phase behaviour was applied within the research. Complex phenomena such as heat and mass transfer in a fluidized reactor can be handled with such configured tools after further expanding their standard capabilities with an adsorption/desorption model.

Therefore, the numerical research was divided into two stages: (1) adsorbent particles movement and heat transfer with wall-particle and particle-particle interactions, and (2) additional analysis with a user-defined function capable to take the heat and mass transfer resulting from the sorption processes into account. The results resented below are obtained within the first stage of the research.

The developed model was validated using the data registered on the experimental test stand presented in paragraph 2.3.1.

3. Results

The results of numerical modelling with the use of the developed coupled CFD & DEM model concerning the adsorbent particles movement and variation in relative temperature of the adsorbent within the fluidization process lasting 20 seconds are presented in Figure 7 for time step equal 1 s. The initial pressure difference equal to 1 kPa between the bottom tank (evaporator) and the upper tank induced the flow of the adsorbate (water vapour) directed towards the upper tank. Within the first second of the process, all the adsorbent particles were fluidized by the flow and approx. 40% of the total number of particles were suspended in the upper part of the reactor. The upper fixing net indicated in Figure 6 with the number (1) prevented the particles from being pushed out of the sorption reactor. These particles were suspended there until the ninth second of the process – at that time the pressure difference between the tanks was reduced, which induced a decrease in the adsorbate flow velocity. Therefore, the particles suspended in the upper part of the reactor began to move towards the bottom of the reactor where they were effectively fluidized and the heat transfer was intensified. This process lasted until the sixteenth second when the fluidization stopped due to the decrease of the flow velocity below the fluidization velocity. It can be seen that the heat transfer between the sixteenth and the twentieth second significantly decreased and occurred mostly only in the 10% of the particles located at the very bottom of the disc-shaped fluidized sorption reactor.

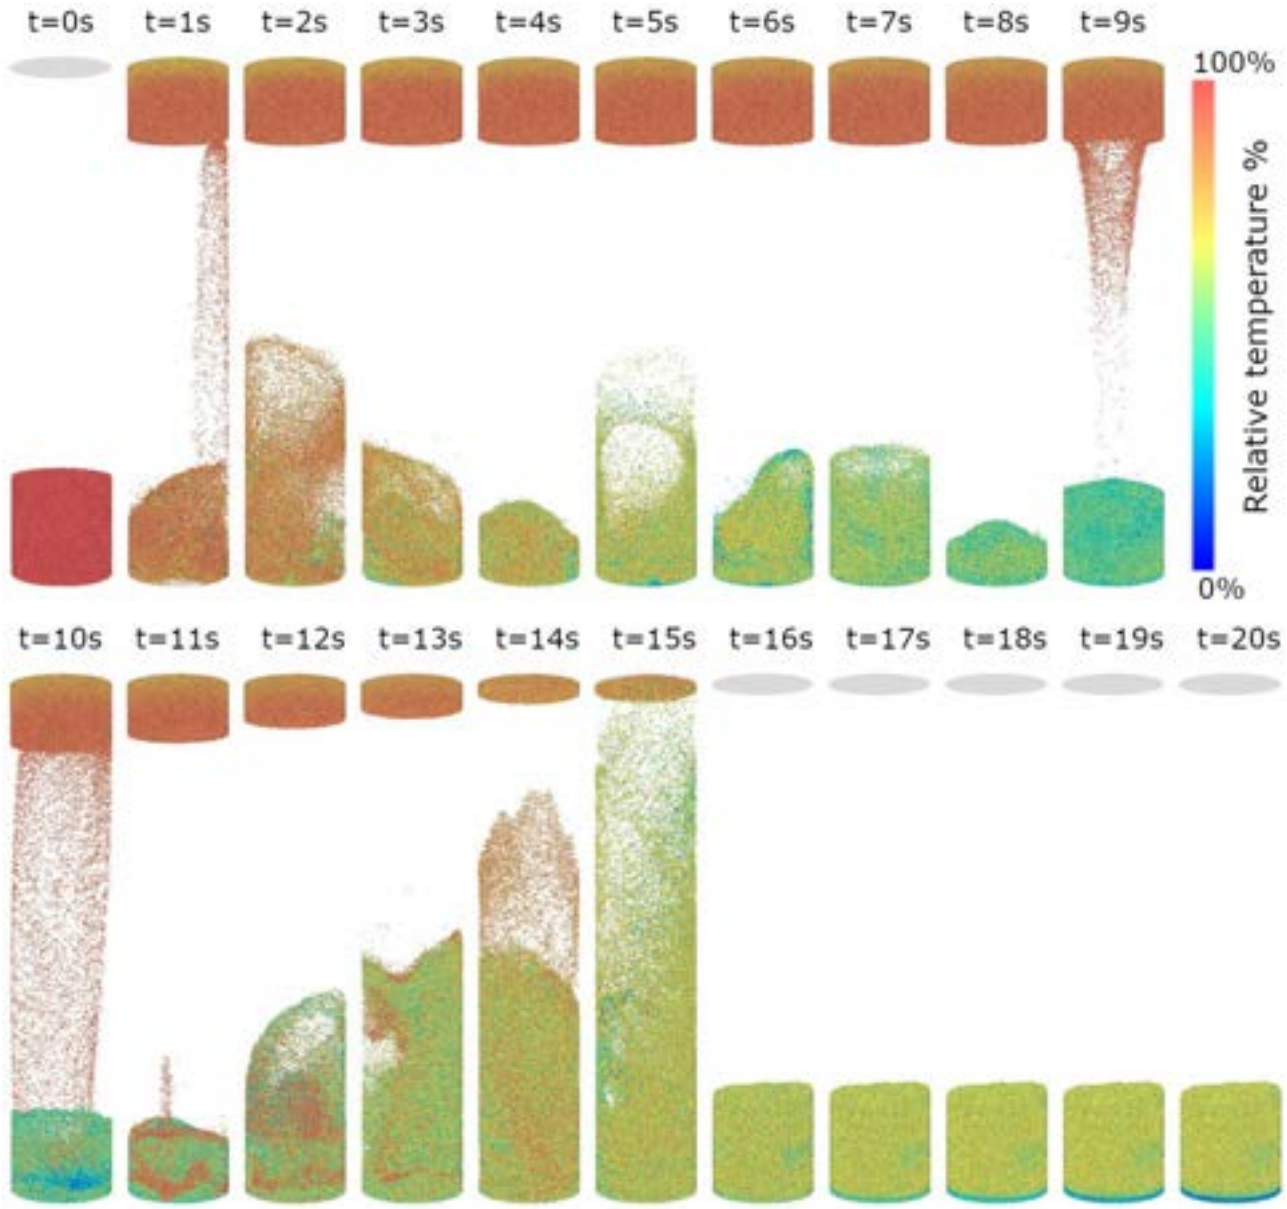

Figure 7. Adsorbent particles movement and variation in relative temperature of the adsorbent within the disc-shaped fluidized reactor for consecutive time steps.

4. Conclusions

The paper presents three concepts of sorption reactors dedicated to adsorption chillers with a special focus on the novel disc-shaped fluidized reactor. All the reactors are analysed with numerical methods. The new approach of coupled computational fluid dynamics and discrete element modelling was applied in the numerical analysis of the disc-shaped fluidized sorption reactor.

The developed numerical model was validated using the data obtained on the experimental test stand.

The results indicate that the coupled CFD & DEM modelling approach is a powerful and cost-effective research tool capable of effectively analysing complicated physical phenomena occurring in the proposed concept of a disc-shaped fluidized reactor. Such an approach has never been used before and reveals great potential for further improvement in optimizing the construction of adsorption reactors with numerical methods.

Further research is needed to extend the model with a user-defined function capable to take the heat and mass transfer resulting from the sorption processes into account. Moreover, the optimal pressure difference inducing the adsorbate flow has to be defined to intensify the heat and mass transfer within the process. The above-mentioned issues will be investigated and presented in the forthcoming papers.

Abstract

Utilization of spray ejector condenser in order to carry out direct-contact condensation of vapour with inert gas (CO_2) on a spray of subcooled liquid integrated with separator (to make pure CO_2) has been proposed for the task of condensation and CO_2 separation in the negative CO_2 emission gas power plant. Condensation and separation has a significant impact on the thermodynamic efficiency of the entire negative CO_2 emission gas power plant cycle. The study presents the accomplished analysis using the numerical model of cyclone separator cases with varying spray ejector condenser outlet conditions. The model incorporates the continuity and momentum equations to describe the phenomenon of separation. Here, transient, turbulent and three-dimensional separator is numerically modelled based on a control volume method in Fluent. The Reynolds Stress Model is also derived from Reynolds Averaged Navier-Stokes's solution. This model is adopted to numerically simulate turbulent flow in separators. In addition, the mixture model is applied for simulation of turbulent swirl two-phase flow in gas-liquid separator. To obtain a numerical model and optimize the purification of CO_2, firstly, different length of cone of cyclone separator should be investigated. Then, the numerical simulation on different value of volume fraction of two phase flow is conducted, and by applying 10% up to 20% of volume fraction for water liquid, the model is derived. Results show that as the liquid volume fraction decreases, the separation efficiency improves. The most optimal separation efficiency of 90.7% is achieved when the liquid volume fraction is at 10%. In addition, Increasing the length of the cone results in both higher efficiency and pressure drop. Specifically, when the length of the cone is increased from 128 mm to 528 mm, the efficiency and pressure drop increases by 4.2% and 194.14 (pa), respectively.

1. Introduction

Carbon dioxide is deemed to be a major contributor to global warming [1]. Given the substantial effect of CO_2 on climate change, various methods have been devised in recent years to manage carbon emissions, including CO_2 capture [2] and storage [3]. Generating electricity with negative CO_2 emissions is achievable through a new concept that involves oxy-combustion in a wet combustion chamber, followed by separation of water and CO_2 through a compact spray ejector condenser (SEC), and finally compression of the separated CO_2. The developed cycle of a negative CO_2 emission power plant includes some devices, out of which, spray ejector condenser as well as separator plays an indispensable role to make pure CO_2. Figure 1 depicts the process flow diagram (PFD) of the negative CO_2 emission gas power plant [4, 5]. As it can be seen in Fig.1b, separation unit consists of SEC and cyclone separator. The main task of SEC is to condense the water vapour from the exhaust gases while maintaining a compact system structure, so that it has two inlets (for suction fluid and motive fluid) and one outlet. At the SEC outlet, the water liquid and CO_2 are expected to enter the cyclone separator for purification of CO_2.

Cyclones are widely utilized in industries including mineral, chemical, environmental and petroleum engineering for separating gas from solids or liquids [6, 7]. The performance of a cyclone separator is influenced by various factors including its structure geometry and operational parameters [8]. Studies have also been investigated on the impact of a cone that is extended with a vertical tube on the efficiency of a cyclone separator [9, 10]. The effects of cone and cylinder length on separation efficiency and pressure drop have been investigated by Brar et al. [11] and Prasanna et al. [12].

In this paper, the SEC and cyclone separator are considered a novel separation process to purify CO2, which has not been extensively studied in previous literature. Therefore, a tangential-flow CO_2-water separator was designed to obtain the desired high-purity CO_2 flow for the Negative CO_2 Emission Gas Power Plant (nCO_2PP) [13]. To obtain a numerical model and optimize the performance of separator, firstly, the effect of cone size could be defined. Then, a suitable value of liquid volume fraction depending on conditions of spray ejector condenser can be obtained using separation efficiency, so that the numerical simulation on different value of volume fraction of water liquid is conducted, and by applying 10% up to 20% of volume fraction for water liquid, the model is derived.

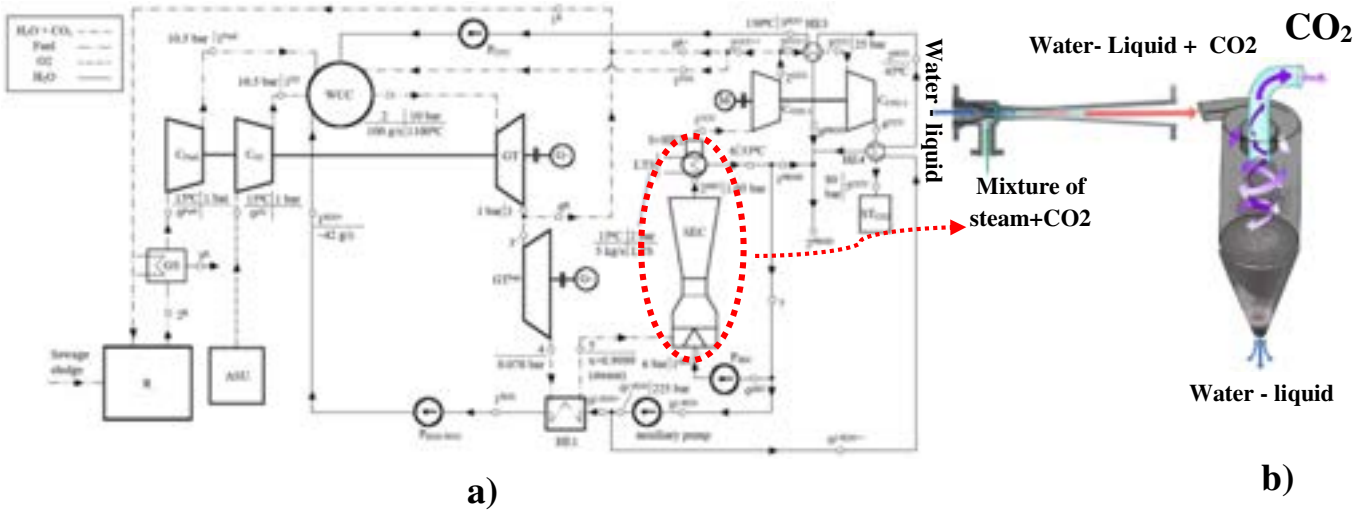

Figure. 1. a) Negative CO_2 emission gas power plant process flow diagram (PFD), b) Capturing CO_2 part consist of spray ejector condenser (SEC) and cyclone separator [4, 5]

2. Modeling

The effectiveness of a cyclone separator is influenced by various factors, and optimal separation efficiency and reduced pressure loss can only be achieved when the dimensions of its components are suited to the purpose. The tangential inlet type is widely adopted in industries and is considered mature with a simple structure typically consisting of a cylinder and cone section. Figure 2a shows the geometry of a three-dimensional tangential inlet cyclone separator. CO2-Water mixture enters the separator with high velocity in a tangential direction and rotates rapidly in the annular space between the exhaust pipe and cylinder. Under the influence of centrifugal force, the water droplets in the mixture are hurled to the wall and then fall down along the wall due to the gravity and momentum of the mixture. Afterward, they are discharged through the underflow outlet. The purified CO2 travels upward through the center and discharges through the exhaust pipe. The dimensions of three-dimensional tangential single inlet cyclone separator have been indicated in Fig 2b and table 1.

2.1. Governing equations

In this study, we applied the mixture model, also known as the algebraic slip model, a simplified version of the Euler-Euler approach. This model is appropriate for bubbly, droplet, or particle-laden flows where the volume fraction of the dispersed phase is high enough (>10%), to ensure pronounced inter-particle collision. The mixture model allows fluid phases to flow at different velocities and permits fluid phases to penetrate each other, and enables the exchange of mass, momentum, and energy between fluid phases. The mixture model has also been used in CFD simulations of turbulent swirl two-phase flow in gas-liquid cyclone separators.

However, the calculation for the continuous and dispersed fluid phases is performed through the following methods: The Reynolds-averaged Navier-Stokes, continuity, and momentum equations are used to solve for the continuous phase.

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho u_i)}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial (\rho u_i)}{\partial t} + \frac{\partial \left(\rho u_i u_j\right)}{\partial x_j} = \frac{\partial P}{\partial x} + \frac{\partial}{\partial x}\left(\mu \frac{\partial^2 u_i}{\partial x_j^2} + \frac{\partial^2 u_j}{\partial x_i^2} - \frac{2}{3}\delta_{ij}\frac{\partial u_k}{\partial x_k} + \frac{\partial}{\partial x_j}\right)\left(-\rho\overline{u_I u_J}\right) \tag{2}$$

$$\left(-\rho\overline{u_I u_J}\right) = \mu_t\left(\frac{\partial^2 u_i}{\partial x_j^2} + \frac{\partial^2 u_j}{\partial x_i^2}\right) - \frac{2}{3}\left(\rho k + \mu_t \frac{\partial u_k}{\partial x_k}\right)\delta_{ij} \tag{3}$$

The equation for the continuity of the mixture can be calculated as:

$$\frac{\partial (\rho_m)}{\partial t} + \frac{\partial (\rho_m u_m)}{\partial x_i} = 0 \tag{4}$$

Mixture momentum:

$$\frac{\partial (\rho_m u_{mi})}{\partial t} + \frac{\partial \left(\rho_m u_{mi} u_{mj}\right)}{\partial x_i} = \frac{\partial P}{\partial x_i} + \frac{\partial}{\partial x_j}\mu_m\left(\frac{\partial u_{mi}}{\partial x_j} + \frac{\partial u_{mj}}{\partial x_j}\right) + \rho g_i + \frac{\partial}{\partial x_i}\left(\sum_{q=1}^{n} \alpha_q \rho_q u_{dr,qi} u_{dr,qj}\right) \tag{5}$$

Where u_m is the mass-averaged velocity, ρ_m is the mixture density and μ_m is the viscosity of the mixture.

$$U_m = \frac{\sum_{q=1}^{n} \alpha_q \rho_q u_q}{\rho_m}\ ,\ \rho_m = \sum_{q=1}^{n} \alpha_q \rho_q\ ,\ \mu_m = \sum_{q=1}^{n} \alpha_q \mu_q \tag{6}$$

Where $u_{dr,q}$ represents the drift velocity for secondary, calculated as $u_{dr,q} = u_q - u_m$.

In the RSM with a time step of 0.001 (s), the equation for transport is formulated as follows.

$$\frac{\partial}{\partial t}\left(\rho\overline{u_i' u_j'}\right) + \frac{\partial}{\partial x_k}\left(\rho u_k \overline{u_i' u_j'}\right) = D_{ij} + P_{ij} + \Pi_{ij} + \varepsilon_{ij} + S \tag{7}$$

where the two terms on the left side represent the local time derivative of stress and the convective transport term, respectively. The five terms on the right side are:

The stress diffusion term: $D_{ij} = -\frac{\partial}{\partial x_k}\left[\rho\overline{u_i' u_j' u_k'} + \overline{(P' u_j')}\delta_{ik} + \overline{(P' u_i')}\delta_{jk} - \mu\left(\frac{\partial}{\partial x_k}\overline{u_i' u_j'}\right)\right]$ (8)

the shear production term: $P_{ij} = -\rho\left[\overline{u_i' u_k'}\frac{\partial u_j}{\partial x_k} + \overline{u_j' u_k'}\frac{\partial u_i}{\partial x_k}\right]$ (9)

The pressure-strain term: $\Pi_{ij} = \overline{p\left(\frac{\partial u_i'}{\partial x_j} + \frac{\partial u_j'}{\partial x_i}\right)}$ (10)

The dissipation term: $\varepsilon_{ij} = -2\mu\overline{\frac{\partial u_i'}{\partial x_k}\frac{\partial u_j'}{\partial x_k}}$ (11)

and the source term: S (12)

2.2. Numerical simulation and boundary conditions

As it mentioned the CO_2-water multiphase flow in the cyclone separator was accurately modeled using the multiphase mixture model in ANSYS Fluent 2021 R1. This was deemed necessary as the CO_2 and water phases are expected to have a strong interaction within the swirling environment of the cyclone separator. In the interpenetrating continuum, CO_2 was the primary (continuous) phase and water was the secondary (dispersed) phase and surface tension was considered. The SIMPLE algorithm was applied to establish the coupling between the pressure and velocity in the continuity and momentum equations. PRESTO scheme was considered for its superior performance in estimating high-speed swirling flows and flows in curved domains. The momentum, volume fraction, and kinetic energy equations were discretized using the QUICK method, which provides more accurate results for rotational swirling flows compared to first- and second-order schemes due to its higher-order discretization. The first-order discretization can result in higher error and unreliable results [14]. The boundary conditions are presented in Table 2.

Table 2. Boundary conditions

Boundary	Types
Inlet	Velocity inlet
Outlets	Outflow
Wall	No Slip wall

3. Evaluation of numerical model

The ANSYS Fluent 2021 R1 was used to evaluate the flow pattern of the studied cyclone separator. As a preliminary parameter, the separation efficiency was calculated, which was defined as follows:

$$\eta = \left(\frac{\dot{m}_{liquid\ at\ inlet} - \dot{m}_{liquid\ at\ gas\ outlet}}{\dot{m}_{liquid\ at\ inlet}}\right) \times 100 \tag{13}$$

Where $\dot{m}$ is the mass flow rate.

3.1 Grid Independence

The geometry and mesh of the cyclone separator created in Gambit 2.4.6 are shown in Fig. 3. To ensure accuracy in calculations, all edges were meshed in the created model. Following that, all the faces and volumes were meshed. For the purpose of meshing, the Tet/Hybrid elements and TGrid type were employed to create cells appropriate for the geometry involved in computational fluid dynamics (CFD) simulations. A high-quality mesh was crucial to avoid errors caused by numerical diffusion. Thus, mesh-independent solutions for the cyclone separator were verified using different grids. So, to examine the independence of the results from the grid size, the variation of tangential velocity and separation efficiency versus different nodes is shown in Fig 4. As it can be seen, the results of 40574 and 80974 grids are different from other grids (120654 and 160214). Even though the 120654 and 160214 consequences are approximately the same, in order to lower computational cost, the 120654 nodes have been opted.

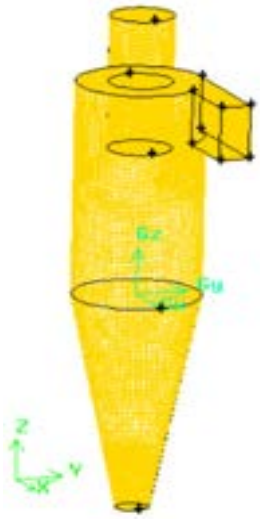

Figure. 3. Meshing of cyclone separator

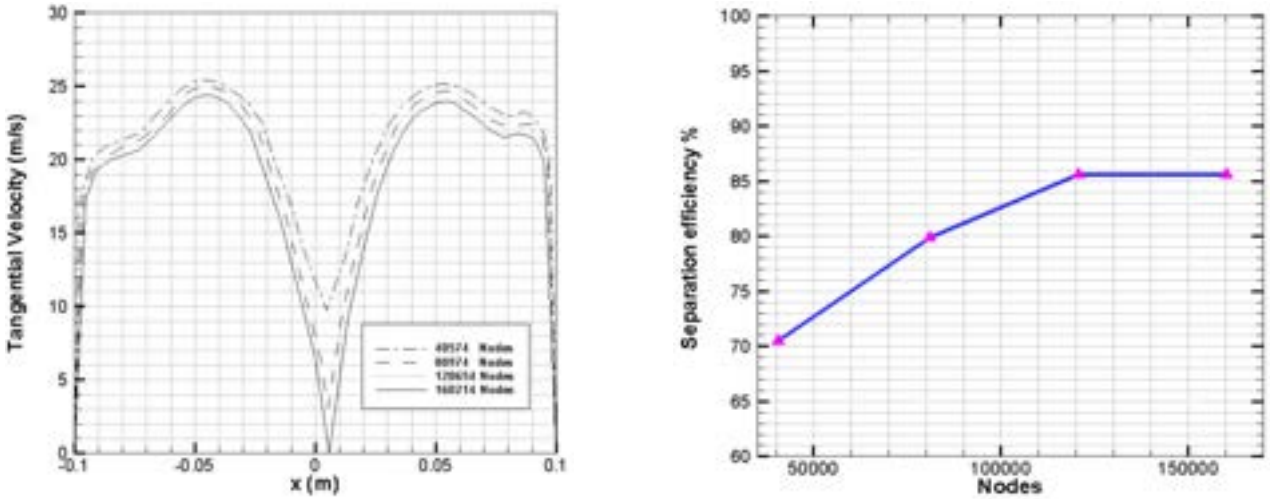

a) **b)**

Figure. 4. Grid independency for a) Tangential velocity and b) separation efficiency of single inlet cyclone at 2.8 ($\frac{kg}{s}$) when volume fraction of water is 10%

3.2 Model Validation

Figure 5. shows predicted variation of the Pressure drop, tangential velocity and separation efficiency in comparison to the results of Wang et al [15]. In their physical experiment, air was fed into the inlet of the cyclone, and its flow rate was monitored using a flowmeter. The velocity of both phases was set at 20 m/s. The outlet tube was open to the atmosphere and the gas pressure at the top of the vortex finder was maintained at 1 atm. The volume fraction of the second phase was 10%. The measurement of velocity and pressure in the gas field was performed using a five-hole probe, which comprised an adjustable frame and five pressure transducers. The voltage signals generated by the five pressure transducers on the five-hole probe were amplified after being placed in the gas flow field. The amplified voltage signals were collected by a data acquisition system equipped with a

microprocessor and a personal computer. As it can be seen in Fig 5. good agreement was achieved between the experimental and the numerical results data taken from the studies by Wang et al.

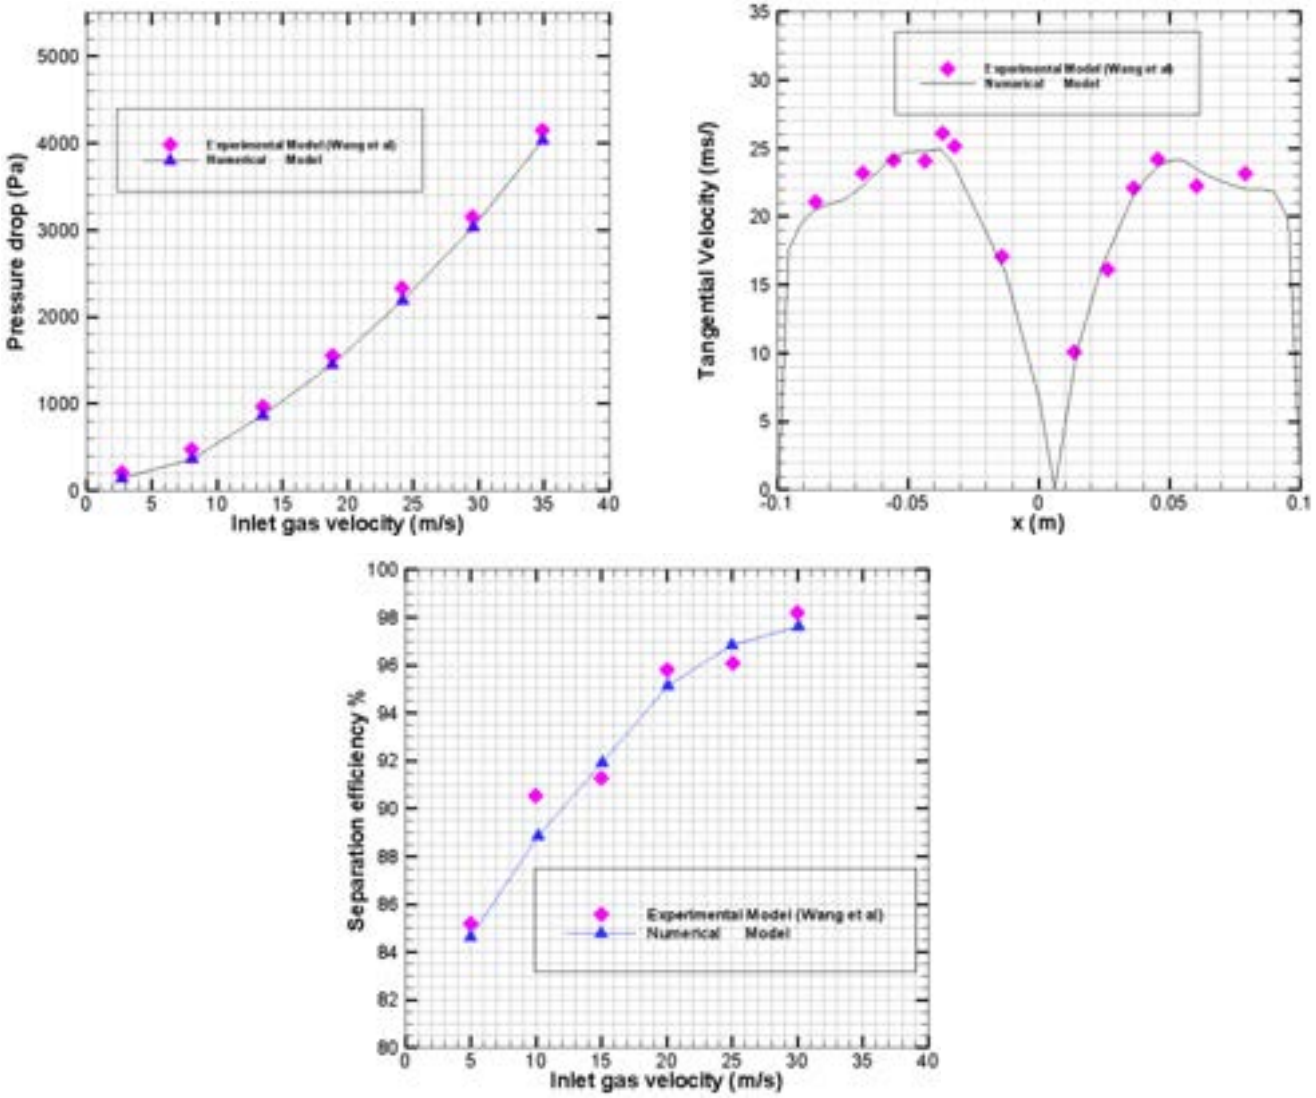

Figure. 5. Pressure drop, tangential velocity and separation efficiency comparison of experimental model (Wang et al) and current simulation

4. Results and discussion

4.1 Effect of cone size

The design and operation of a cyclone separator is crucial in determining the efficiency of particle separation in various industrial applications. One of the design parameters that affects the performance of the cyclone separator is the size of cone. Figure 6 depicts geometry and mesh of cyclones with different cone length. In this section, the effect of cone size (at constant total length of cyclone: 638 (mm)) on the efficiency and pressure drop of a cyclone

separator has been examined (Table.3). The results indicate that while the efficiency of the cyclone increases with a longer cone, there is also a corresponding increase in pressure drop

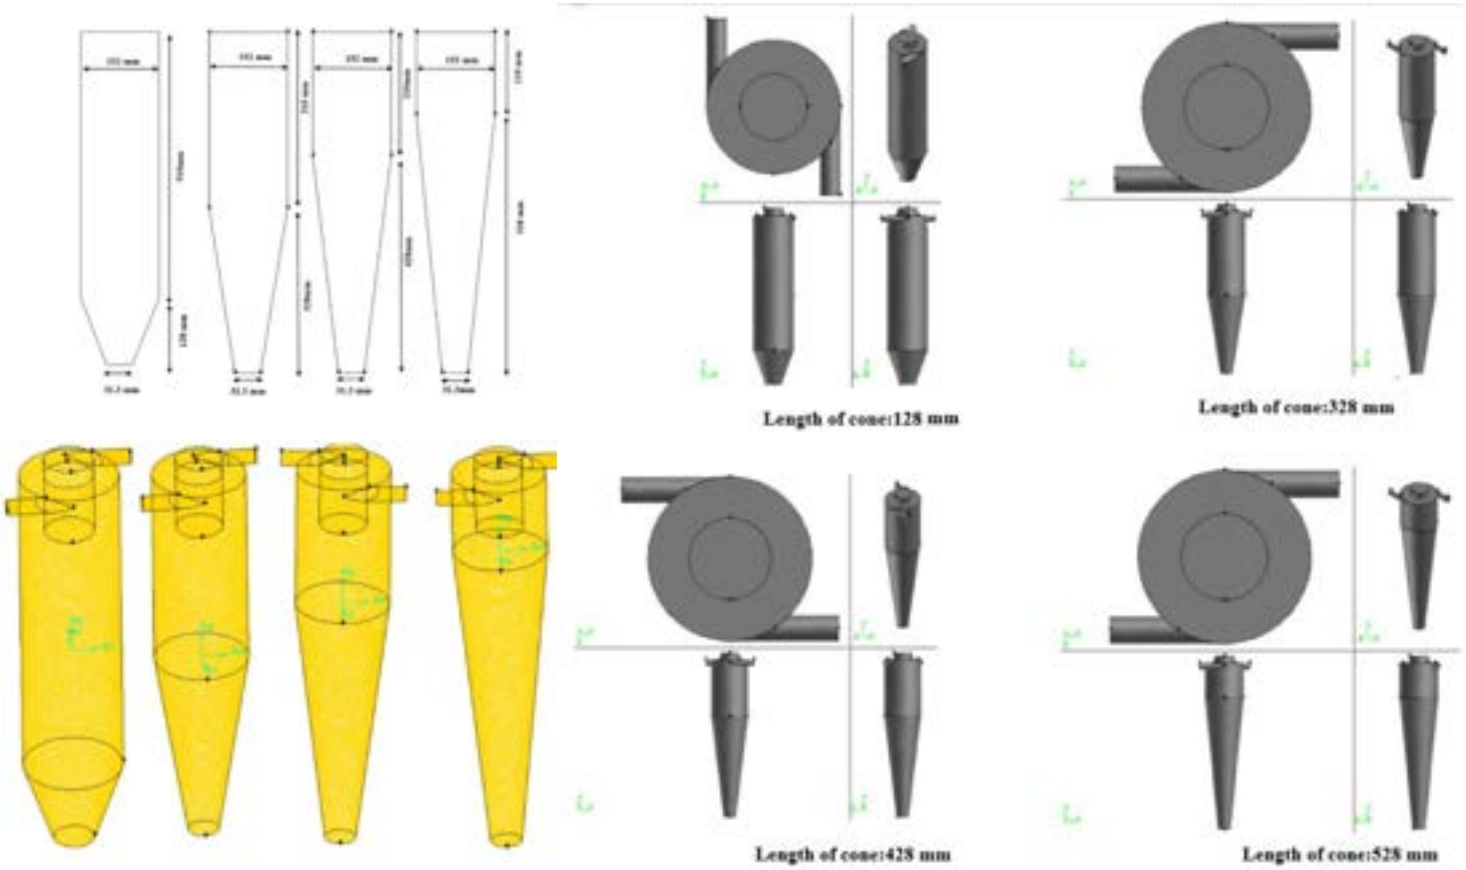

Figure.6. Geometry and mesh of cyclones with different cone length

Table 3. Mass flow rate of liquid phase at the inlet and gas outlet for different length of cone at 10% of liquid volume fraction and diameter of water droplet : 10 (μm)

Length of Cone (mm)	$\dot{m}_{liquid\ at\ inlet}$ (kg/s)	$\dot{m}_{liquid\ at\ gas\ outlet}$ (kg/s)	Efficiency %	Pressure drop (Pa)
128	0.43527386	0.14555562	66.5 %	514.62
328	0.43527386	0.136807	68.6 %	556.62
428	0.43527386	0.13143237	69.8 %	622.66
528	0.43527386	0.12750024	70.7 %	706.76

4.2 Efficiency of cyclone separator depending on SEC outlet conditions

When a saturated vapour contacts subcooled drops with a size larger than the critical value, the condensation occurs. Following our previous analytical model [16, 17], it is assumed that the inlet properties of the fluids are

supplied at a state denoted as "inlet" in Figure 7. To calculate the suction mass (m_g) and pressure at the beginning of the mixing zone, knowledge of the equations resulting from the flow in the inlet zone is required.

$$m_g = u_{gin}\rho_g A_{gin} = u_{g0}\rho_g(A_0 - A_l) \tag{14}$$

From Bernoulli equation:

$$p_{g,in} + \frac{1}{2}\cdot \rho_{g,0}u_{g,in}^2 = p_{g,0} + \frac{1}{2}\cdot \rho_{g,0}u_{g,0}^2 + \Delta p_{loss,1} \tag{15}$$

The suction pressure ($p_{g,1}$) generated by the liquid jet mixing with gases can be calculated by balancing the momentum between the pre-mixing section and the entrance to the mixing section, which corresponds to states 0 and 1.

$$p_{g,0}A_{g,0} + m_g u_{g,0} + p_l A_l + m_l u_l = p_{g,1}A_1 + (m_g + m_l)u_l \tag{16}$$

To obtain the values in state 2, the conservation equations for mass, energy, and momentum were applied simultaneously for the adiabatic process. When a non-condensable gas (CO_2) is present in the condensation space, it is necessary to analyse both heat and mass transfer. Based on the equations used in our previous analytical study [16, 17], condensation of vapour on subcooled droplet stream, heat balance of droplet stream and balance of mass and heat for vapour-gas mixture have been considered.

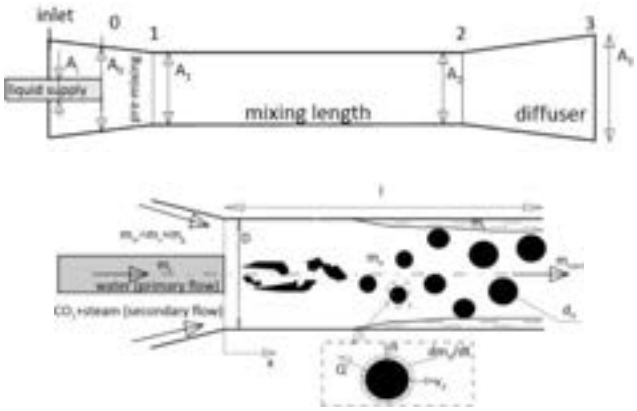

Figure. 7. Schematic of the spray ejector of condenser [16, 17]

4.2.1 Effect of volume fraction

As mentioned above, spray ejector condenser and cyclone separator have been used as a separation section of a negative CO_2 emission power plant in regard to making pure CO_2. Two choking phenomena exist in the ejector performance: one in the primary flow through the nozzle and the other in the entrained or suction flow (due to acceleration of the entrained flow from a stagnant state at the suction port to a supersonic flow in the mixing chamber). In addition, a jet coming out of the nozzle dissipates and breaks up into various-sized drops. The liquid stream breaks into droplets under the influence of waves formed on the surface of the stream due to instability. These waves cause a loss of stability and the formation of primary droplets. Secondary droplet breakup occurs under the influence of aerodynamic forces. Primary droplets are deformed and broken up by aerodynamic drag forces and surface tension forces.

So, according to aforementioned effects, volume fraction of water liquid will be different. This section presents the accomplished analysis using the numerical model of cyclone separator cases with varying SEC outlet conditions. To this end, 10%, 15% and 20% of volume fraction of water liquid have been considered. Figure 8 indicates the contour of volume fraction of water liquid for dual inlet cyclone at 2.8 ($\frac{kg}{s}$) inlet mass flow rate for 10%, 15% and 20% feed stream liquid volume fraction.

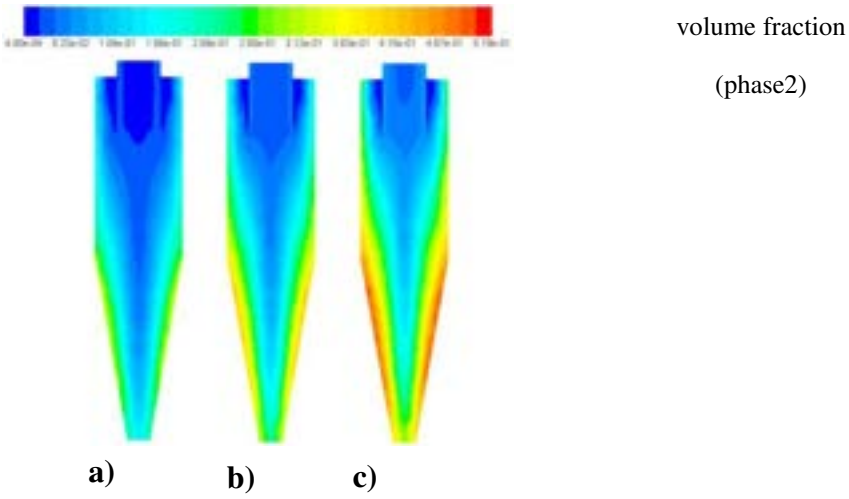

Figure. 8. The contours volume of liquid fraction for 2.8 ($\frac{kg}{s}$) inlet mass flow rate, at feed stream liquid volume fraction a) 10%, b) 15 % and c) 20%

To assess the impact of liquid volume fraction on the internal configuration separation performance, the separation efficiency was computed at various volume fractions using Equation 13, and the results were compared. The separation efficiencies, inlet and outlet liquid mass flow rates ($\dot{m}$) at the considered three liquid volume fractions are shown in Table 4. As seen in the table, separation efficiency increases with decreasing liquid volume fraction, so that the maximum separation efficiency has been obtained at 10% of liquid volume fraction and its value is 90.7%.

Table 4. Separation efficiency of dual inlet cyclone at different volume fraction of water liquid when diameter of water droplet is 10^{-5}

Liquid Volume Fraction	$\dot{m}_{liquid\ at\ inlet}$ (kg/s)	$\dot{m}_{liquid\ at\ gas\ outlet}$ (kg/s)	Separation efficiency, $\eta\%$
10 %	2.74649	0.254949	90.7 %
15 %	4.1197319	0.43964297	89.33 %
20 %	5.4929759	0.68230528	87.58 %

5. Conclusion

A numerical simulation was conducted to optimize the performance of a tangential-flow vanes CO_2-water separator design in Negative CO_2 Emission Power Plant (NCO_2PP) in regard to producing high-purity CO_2, using a transient RSM turbulent model and a three-dimensional model.

The key findings are summarized as follows:

- Increasing the cone length leads to elevated efficiency and pressure drop.
- The cone length is extended from 128 mm to 528 mm, the efficiency and pressure drop increase by 4.2% and 194.14 pa, respectively.
- Separation efficiency improves as the liquid volume fraction decreases, with the highest efficiency of 90.7% achieved at a liquid volume fraction of 10%.

For future research, the proposed model will be experimentally tested using single and multi-nozzle configurations to generate the motive fluid jets. Additionally, electro hydrodynamic (EHD) effects can be used to enhance heat transfer in direct contact condensation in spray ejector condensers. EHD is a process that involves the interaction between electric fields and fluid flow. In direct contact condensation, EHD can be used to create an electrostatic field that enhances the droplet size distribution, which leads to improved heat transfer. One way to implement EHD in spray ejector condensers is to use a corona discharge to create an electric field that attracts the charged droplets towards the condenser surface. This increases the surface area available for heat transfer and also increases the mass transfer rate between the droplets and the condenser surface. Another way to use EHD in spray ejector condensers is to apply a voltage to the ejector nozzle. This can cause the liquid droplets to break up into smaller droplets, which increases the surface area available for heat transfer and also enhances the mass transfer rate. So, it is aimed to impose EHD in spray ejector condenser which results in significant improvements in heat transfer efficiency and can also reduce the overall size of the condenser. Moreover, a quadruple inlet cyclone separator will be used to purify CO_2.

Abstract:
Hydrodynamics cavitation has the potential to significantly improve the efficiency and effectiveness of a wide range of industrial processes, including water treatment, chemical reactions, food processing, and biomass pretreatment. Cavitation can be used to replace traditional processing methods that are more energy-intensive or use harmful chemicals, which can help to increase the sustainability of industrial processes. Overall, using cavitation for process intensification can help improve efficiency, sustainability, and circularity in industry. One of the most used device that is easy to integrate with the production line is the cavitating Venturi reactor. In the present work, influence of the key geometric parameters such as the height and length of Venturi throat are evaluated to find the optimum reaction conditions enhancing cavitating treatment intensity and minimizing the pressure drop. The analysis has been conducted by varying the ratio of the throat section to the inlet section, keeping constant the cavitation number, to have cavitation dependent only on the geometry. A series of multiphase simulations have been performed using an open-source solver (OpenFOAM) that implements the Zwart-Gerber-Belamri cavitation model. The adopted modelling approach was the VOF (volume of fluid) mixture type coupled with the URANS (Unsteady Reynolds Averaged Navier Stokes) method, in which a komegaSST turbulence model has been applied. An FFT analysis was conducted to evaluate the cavitation regime. It was observed that by increasing the throat diameter, the frequency of the re-entrant jet mechanism decreases while the cavitation region extends. Finally the impact of pressure drop in various geometries was evaluated and compared with the CEP (cavitation efficiency parameter), a term developed to properly evaluate the efficiency of the cavitation phenomenon.

Keywords:
CFD, multiphase, cavitation, process intensification , energy saving.

1. Introduction

Hydrodynamic cavitation has gained a strong interest in recent years for its unique features, versatility, and effectiveness in many fields. Among them, it is possible to mention waste wastewater treatment and biofuel production [1]. In wastewater treatment, hydrodynamic cavitation represents a useful help to achieve high standards of depuration. Generally speaking, standard wastewater treatments aim to reduce the concentration of certain pollutants. Biological treatments are widely used, but they are not completely effective on constituents persistent to biodegradation, which undergo only minor structural changes in absence of additional treatments [2]. Moreover, the widespread diffusion of high-environment impact industrial processes, that produce new kinds of pollutants, has accentuated this fact [3]. So, in the context of wastewater treatments, there is a necessity to apply specific processes able to reduce the presence of these pollutants. In this sense, cavitation can be considered a very promising option, eventually coupled with advanced techniques (such as Advanced Oxidation Processes, AOP). Indeed, the so high values of pressure (up to a GigaPascal range) and temperature (in the order of 10 000 K) are suited for all the mechanisms of degradation of biological and chemical compounds [2]. In the hydrodynamic cavitation phenomenon applied to wastewater treatment, all consequences deriving from bubbles collapse are employed [4]: thermal, mechanical and chemical effects. The thermal effects include temperature gradient and temperature rise rate, which are beneficial to damage the structure of pathogens and to assist other removal mechanisms. The intensive mechanical effect breaks the outer structures of pathogens, inactivating them. The chemical effects are determined by the breaking of water molecules, leading to the formation of strongly oxidising radicals: hydroxyl OH and hydrogen peroxide -OH 2, which are highly effective on persistent pollutants. The real effectiveness of hydrodynamic cavitation on various species of water pollutants depends on the operating parameters and specific design of cavitating reactors [1], [3], [4]. Moreover, the combined use of hydrodynamic cavitation with other advanced oxidation processes has been proposed [3], [[5]. Regarding biofuels, hydrodynamic cavitation can be employed to enhance the production of biodiesel and bioethanol. In particular, bioethanol production is based on the availability of a

sugar matrix, that could derive from sugar/starch crops (1st generation bioethanol) or lignocellulosic plants (2nd generation). The latter has gained particular attention because it does not need dedicated crops. This process relies on some pretreatments aiming to change the supramolecular structure of biomass in which the cellulose, lignin and hemicellulose are closely interconnected to finally release free sugars making them available for the next transformation (fermentation, distillation, refining) [6], [7]. In this regard, hydrodynamic cavitation can be used as a pre-treatment for delignification, effectively and with energy savings compared to traditional technologies. Results obtained in several tests indicate that pre-treatment with hydrodynamic cavitation leads to excellent ethanol production yields and a high degree of ethanol purity [8] For extensive industrial uses, hydrodynamic cavitation (HC), produced by accelerated flow, is well suited [9].When compared to other generation techniques like optic, acoustic, and particle, HC has the benefits of good scalability, simplicity of manufacture, and a promising treatment outcome. The geometric design of the cavitating device has a significant impact on cavitation intensity like operating pressure, flow rate, etc. Numerous devices have been investigated as cavitating reactor for process intensification, including orifices, venturi, vortex diodes, etc. Even so, there are still gaps in the knowledge of cavitating flow through these devices, particularly the cavitating venturi, despite its simplicity and widespread use. The design methods for a cavitating reactor currently used are mostly empirical and have no optimization criteria that can increase the yield of the process to which cavitation is applied. Another gap in the literature is the lack of an unambiguous term for evaluating the efficiency of a cavitating device. Various methods, based on experiments, for assessing cavitation intensity have been proposed, for example, Dastane et al. [11] estimated the efficiency of the cavitation process by introducing a parameter called Cavitational Efficacy Ratio (CER), the ratio between pressure generated after cavity collapse and pressure losses. The collapse pressure reflects the greatest quantity of energy that a cavity can release when collapsing. Wu et al. [10] developed a formulation for the energy released during the cavitation phenomenon to quantify its intensity. Other works attempt to give a formulation for cavitation efficiency however for engineering purposes they are very complex and difficult to use on an industrial scale. From the aforementioned literature, it is clear that stronger cavitation causes higher effects on process intensification. This connection is straightforward and natural. In this paper, various key parameters are analyzed to evaluate which one is the best in terms of optimization of cavitation performance and pressure loss minimization. To evaluate the impact of the geometry, 2D axisymmetric simulations taken from the literature have been used. Next, a cavitation model based on the Rayleight-Plesset equations developed by Zwar-Belamri-Gerber [16] and a modification for turbulent viscosity proposed by Delgosha [19] was implemented in a multiphase solver available in OpenFOAM software. After validating the model on a literature test case taken from Stutz-Reboud [12], sensitivity analysis was performed on the cavitating device.

2. Numerical Model

To simulate the phenomenon of cavitation, an unsteady solver of the OpenFOAM has been adopted. The solver was modified appropriately to increase the accuracy of the results. The chosen solver is designed to simulate the phenomenon of cavitation for an incompressible, isothermal, and immiscible fluid. It adopts a VOF mixtures (Volume of fluid) approach with an interface capturing method proposed by Hirt and Nichols [14]in which a single set of governing equations is defined for the two liquid-vapour phases. The Reynolds-averaged Navier stokes equations in their unsteady formulation for Newtonian fluids have been considered, than the conservative equations of mass, momentum, and the transport equation for the volume fraction α, used to solve the interface between liquid and vapour, can be written as:

$$\frac{\partial \rho_m}{\partial t} + \nabla \cdot (\rho_m \mathbf{U}) = 0 \tag{1}$$

$$\frac{\partial (\rho_m U)}{\partial t} + \nabla \cdot (\rho_m \mathbf{U}\mathbf{U}) = -\nabla P + \nabla \cdot [\mu_{eff}(\nabla \mathbf{U} + (\nabla \mathbf{U})^T)] + f_\sigma + \rho_m g \tag{2}$$

$$\frac{\partial \alpha_v}{\partial t} + \nabla \cdot \mathbf{U} + \nabla \cdot [\mathbf{U}\mathbf{c}\alpha_v(1-\alpha_v)] = S_\alpha \tag{3}$$

Where μ_{eff} represents the sum of molecular viscosity and turbulent viscosity, S_α The term due to the amount of evaporation and condensation rates, f_σ is the surface tension force acting at the liquid-vapour interface while the third LHS term of the transport equation of volume fraction is called as artificial compression term, which is not zero only at the interface. This contribution is important because using a VOF approach with a purely convective α equation would lead to numerical diffusion and thus in a non-conservative interface. The generic fluid property is instead calculated as a weighted average over the volume fraction of the individual properties

of the two liquid-vapour phases. For the fluid was considered Newtonian although someone to be treated may exhibit different behavior because a general treatment has been conducted. The specific response of cavitating fluids, whether it leads to a suppression or enhancement of non-Newtonian behavior, depends on the rheological properties of the fluid, such as its viscosity, elasticity, yield stress, and the specific conditions of the cavitation process, including pressure, flow velocity, and geometry. The properties of the individual phases were calculated using REFPROP software and were considered constant, as in most of the work in the literature:

$$\phi_m = (1 - \alpha_v)\phi_l + \phi_v\alpha_v \tag{4}$$

To model the phase change effects due to the cavitation phenomenon, the Zwart-Gerber- Belamri (ZGB) [16] model based on the Rayleigh-Plesset equations has been implemented: it describes the behaviour of the single cavitation bubble in space and time. By simplifying the terms due to surface tension, the second-order derivatives, liquid viscosity, and non-condensable gas, the relationship between the change in the bubble radius and the pressure become:

$$\frac{dR}{dt} = \sqrt{\frac{2(P_v - P)}{3\rho_l}} \tag{5}$$

From this equation it is possible to express the evaporation and condensation rates and derive the source terms to be included in the transport equation [3]. Considering spherical bubbles of radius R_B , with a density per cell equal to n, it is possible to write:

$$\alpha_v = n(\frac{4}{3}\pi(R_B)^3) \tag{6}$$

From here, combining equations 6 and 5, after some mathematical steps it is possible to derive the formulation of the sink terms of evaporation and condensation proposed by [16]:

$$\dot{S}_\alpha = \begin{cases} F_v \frac{3r_{nuc}(1-\alpha_v)\rho_v}{R_B}\sqrt{\frac{2}{3}\frac{P_{sat}-P}{\rho_l}} & \text{if } P < P_{sat} \\ F_{\text{cond}} \frac{3r_v\alpha_v}{R_B}\sqrt{\frac{2}{3}\frac{P-P_{sat}}{\rho_l}} & \text{if } P > P_{sat} \end{cases} \tag{7}$$

where $r_{nuc} = 5x10^{-4}$ is the nucleation site volume fraction, $R_B = 10^{-6}[m]$ nucleation site radius and $F_v = 50$, $F_{cond} = 0.01$ empirical calibration constants. These model parameters were set as proposed by ZBG. For turbulence modelling, a k-omega SST (Shear Stress Transport) was proposed by Menter [17]. As suggested by the work of Chebli, Delgosha et Al. [13] modification for turbulent viscosity was added in order to simulate unsteady behaviour of cavitating flow [Equation 8,9]. The model uses two transport equations: one for the turbulent kinetic energy k and another for the specific dissipation rate of turbulent kinetic energy omega. The k equation accounts for the production and dissipation of turbulence, while the omega equation accounts for the transport and destruction of turbulence. The SST model uses a blending function for a smooth transition between a near wall low-Reynolds number model and a far field high-Reynolds number model. Other turbulence models, such as the Reynolds Stress Model or the Large Eddy Simulation, may also be appropriate for certain cavitation applications.

$$\mu_t = f(\rho)a_1\frac{k}{\max(a_1\omega, b_1F_{23}\mathbf{S})} \tag{8}$$

$$f(\rho) = \frac{\rho_v + \alpha_l^n(\rho_l - \rho_v)}{\rho_v + \alpha_l(\rho_l - \rho_v)} \tag{9}$$

A wall-resolved approach was chosen for the wall boundary layer. For this reason, the grid was built to have a Y^+ less than 5, as is usually done in the literature. Regarding unsteady cavitation flows, it has been observed in the literature that standard turbulence models cannot correctly predict the oscillatory behaviour of the flow. The turbulent viscosity is a key parameter in turbulence models that describes the rate at which turbulent energy is dissipated into heat. In cavitating flows, the presence of vapour bubbles can cause significant changes in the

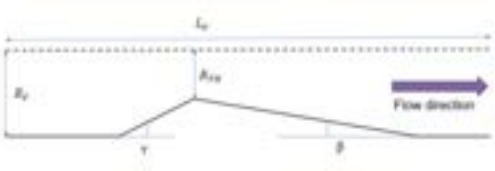

Figure 1: schematic view of nozzle geometry where L_V = 340mm is the lenght of entire domain, R_{TH} and L_{TH} = 10mm are the radius and lenght of the throath, R_V = 50mm radius of the channel and γ = 22.5°- β = 6° are the convergent and divergent angle.

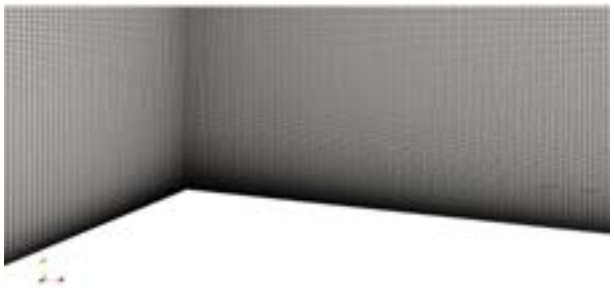

Figure 2: View of 2D axisymmetric computational mesh in which the grid thickening in the near-wall and cavitation region can be observed.

turbulent viscosity due to the highly compressible nature of the vapour phase. As is reported in the literature turbulent viscosity is overestimated in the cavitation region, since most turbulent models are not sensitive to phase change. This causes an inhibition of the phenomenon of cavitating bubble cluster shedding that affects the correct numerical prediction. For this reason, a correcting function [eq 9] developed by Delgosha [19], a modification to standard turbulence models that aims to account for the effects of cavitation on the turbulent viscosity, was implemented. The value of n is fixed to 10 as suggested by Delgosha et al. [19]

3. Geometry and numerical setup

For sensitivity analysis on the influence of throat cross-section on the phenomenon of cavitation, a Venturi-type reactor studied by Long et al. [15] was taken as a test case. The chosen geometry is shown in [Figure 1]. To prevent the length of the throat from having an impact in the simulations, we decided to remove it and use a sharp edge. As pointed out by the work of Ulla et al. [18] , the absence of the throat section, increases cavitation length. The domain for the simulation was realized by an axisymmetric structured 2D mesh shown in the figure 2 , consisting of about 100k hexahedral elements. In the regions near the wall, the mesh was refined and a wall resolved approach was adopted. For numerical simulations, 4 geometries were chosen in which the convergent and divergent ramp angles were kept constant and the throat height was varied: 5-10-15-20 mm. Boundary conditions represent a crucial aspect for simulations of cavitation phenomena since the development of the cavitation generates numerous pressure oscillations that spread within the channel, both upstream and downstream. For this reason to avoid pressure fluctuations and possible spurious solutions, two stitches were added, one downstream and one upstream of the venturi nozzle. The following boundary condition is used: an imposed velocity at the inlet equal to 0.89 m/s (in agreement with experimental data where the reference flow rate was imposed equal to 1.74 L/s), a static pressure set at the outlet equal to 200k Pa that was selected to reproduce the pressure value at the inlet measured from experimental data. One of the most widely used dimensionless parameters to study cavitation phenomena is the cavitation number, which takes into account the pressure drop in the fluid and the kinetic energy of the fluid, which are the two main factors that influence the behaviour of cavitation, and is defined as:

$$\sigma = \frac{P_{out} - P_{sat}}{\frac{1}{2}\rho U_{TH}^2} \tag{10}$$

where P_{out} represents the pressure imposed at the outlet, P_{sat} the fluid saturation pressure calculated at a temperature of 19°, U_{TH} the average velocity in the throat section. To evaluate the effects of throat diameter on the development of the cavitation region, which is a useful effect for process intensification, and to study the

Table 1: list of numerical models and schemes

behaviour of pressure drop, 4 geometries were created. For the generation of the geometries, the convergent and divergent ramp angles were kept constant, while for the boundary conditions, both the outlet pressure and the throat velocity were kept constant by varying the inlet velocity to obtain the same cavitation number value (shown in table 2). A second-order numerical schemes for both time and other variables has been used, and in addition, the PIMPLE algorithm was used for solving governing equations, while the MULES algorithm (semi-implicit and second order in time) was used to ensure that the volume fraction (alpha) remains between strict bounds of 0 and 1. Regarding computational settings, we chose a time step $TS = 10^{-7}[s]$ to ensure a $CFL < 0.7$.

4. Result

4.1. Re-entrant jet mechanism

the unsteady phenomena governing cavitation are mainly two:

- Shock front mechanism in which a shock front is formed in a certain region of the cavitation zone and moving upstream causes vapour condensation.
- Re-entrant jet mechanism is a pressure driven mechanism in which a vortex causes the detachment of a cavitating cluster that is carried downstream by the flow.

For all simulations, we observe that only the re-entrant jet mechanism is present. To investigate the influence of geometry in terms of re-entrant jet mechanism and shedding frequency, virtual probes are located on the axis in the control section near the inlet. In figures 3 and 4 show the dynamics of the re-entrant jet mechanism and the pressure signal obtained from the simulation of the Venturi device having a throat diameter of 10 mm. From point A to point E the cavitation zone grows until the re-entrant jet is created and cavitating cell detachment occurs. Subsequently attached sheet cavity decrease until disappears (point H). Starting from here we have three pressure spikes related to points (G to I), where the cavity breakoff takes place. This is the first cycle of the cavity shedding mechanism. After that, at point (L) the appearance of a new cavitating region, marking the beginning of the secondary cycle with pressure peaks less intense than in the first cycle happens. Once the cavity that was generated in the first cycle collapses the shedding phenomenon ends (Q) and the pressure values return to those of state A.

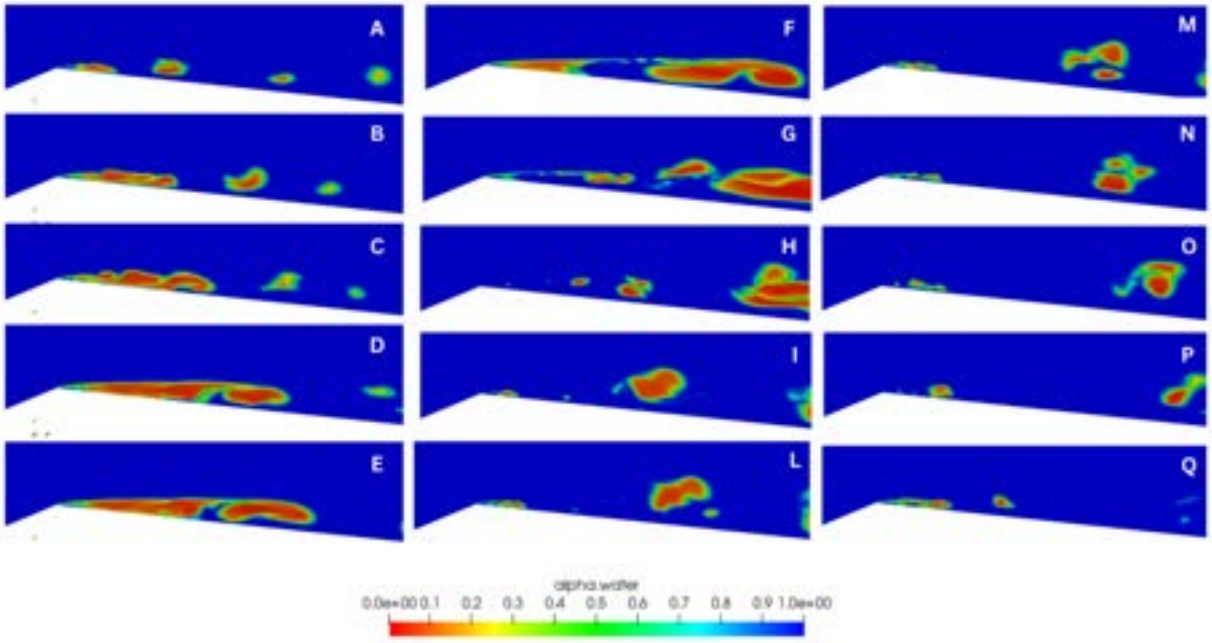

Figure 3: Re-entrant jet cycles in a Venturi device with D_{TH} = 10mm. From point A to H the first cycle of the re-entrant jet mechanism, characterized by an extended cavitation region, is shown. From I to L can be notices the second cycle in which the extension of cavity is smaller that the first.

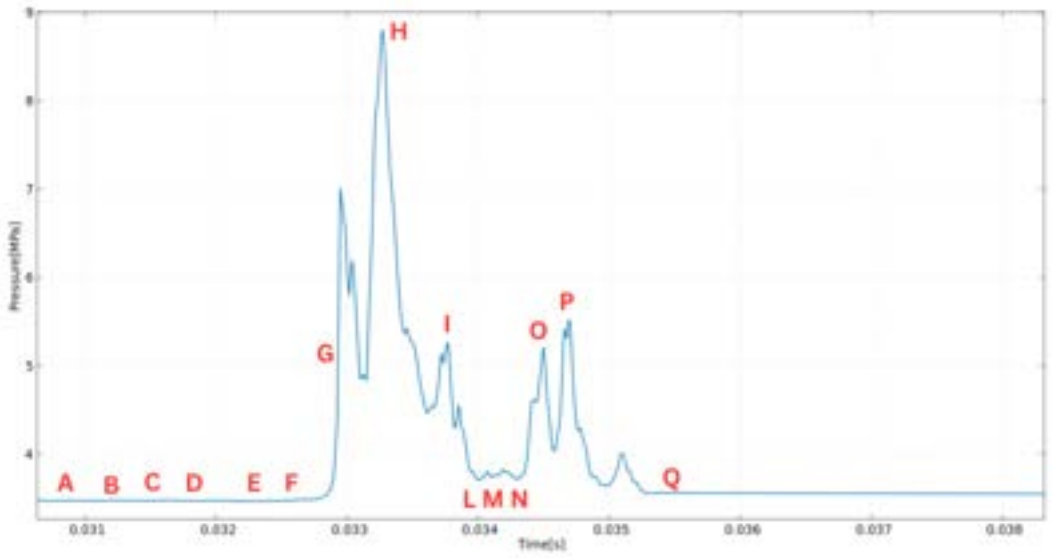

Figure 4: Pressure behaviour calculated at the inlet section in a Venturi device with D_{TH} = 10mm

Using the FFT fast Fourier transform 5, it was possible to analyze the characteristic frequencies of the re-entrant jet phenomenon of the four simulated geometries. At smaller throat cross sections, the frequency of the system increases while the pressure peaks associated with the breakoff of the cavities decrease. As reported in a later section, this behaviour is associated with the formation of a cavities in the first shedding cycle. Downstream of the throat, the pressure recovery is more gradual for larger diameters, this causes the life of the cavitating cells to increase (the collapse position is moved downstream), this lead to dwindle of frequency. The oscillation period increases. Geometries with larger throat cross sections showed higher oscillation, both in terms of frequency and flow rate. This is something to investigate as it could be an undesirable effect for the system in which the cavitating device will be installed.

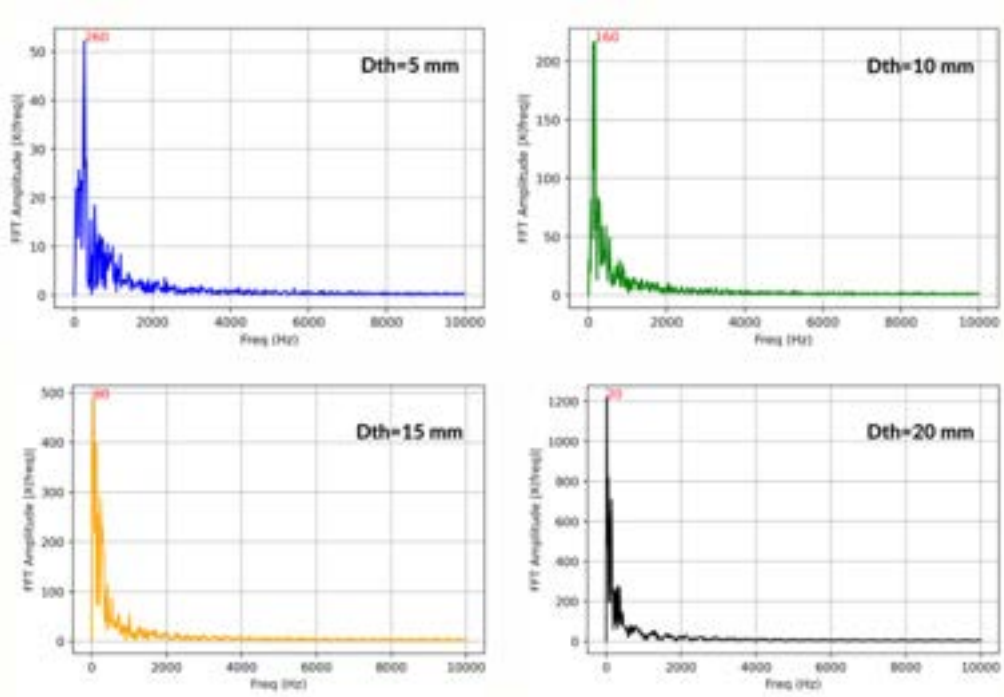

Figure 5: Result from FFT analysis, the number in red represents the frequency of the system .

4.2. Evaluation of overall cavitation efficiency

From the simulations obtained, it was possible to calculate parameters related to cavitation efficiency (length of cavitation, the value of volume fraction at certain stations and amplitude of the cavitating region) and parameters related to pressure drop with which an optimized geometry could be chosen. For this purpose, it has been developed a term called cavitation efficiency parameter (CEP) for evaluating cavitation efficiency that takes into account the average volume occupied by cavities:

$$CEP = \frac{\sum_{i=0}^{n}[V_i \alpha_{Vi}]}{\pi D_{in} \frac{D_{TH}^2}{4}} \tag{11}$$

where V_i is the volume of i-th cell , α_{Vi} is the value of vapour volume fraction in the i-th cell, n is the number of cells, while D_{TH} is the throat diameter. The ratio represents a weighted average over the volume fraction of the cavitating volume and a cylinder having diameter equal to D_{TH} and height equal to the channel's diameter D_{in}. To calculate CEP a python code that takes as input the results obtained from the simulations and returns the value of CEP was developed. This parameter is very fast and simple to be obtained and can be easily integrated into the design process of the cavitating device. Then the value of pressure losses over the entire nozzle was calculated, defined as:

$$K = \frac{\Delta P}{\frac{1}{2}\rho U_{TH}^2} \tag{12}$$

where ΔP is the difference between total pressure at the inlet and outlet while U_{TH} is the throat velocity. These two parameters were used to compare the various simulations and estimate the influence of the throat section on the cavitation process. Time average Volume fraction fields are shown in figure 6 for the four geometries. It can be seen that as the diameter increases, the cavitation region becomes larger. The lengths of the average cavitating region for the various geometries are given in Table 3 while the plot of K and CEP are shown in fig. 7. From the results obtained, it can be seen that at the same cavitation number both losses and CEP have a favourable trend for larger diameters. The best configuration seems to be that for DTH = 20mm in which the cavitation volume increases while the losses decrease as the main flow has less blocking effect due to the cavitating region.

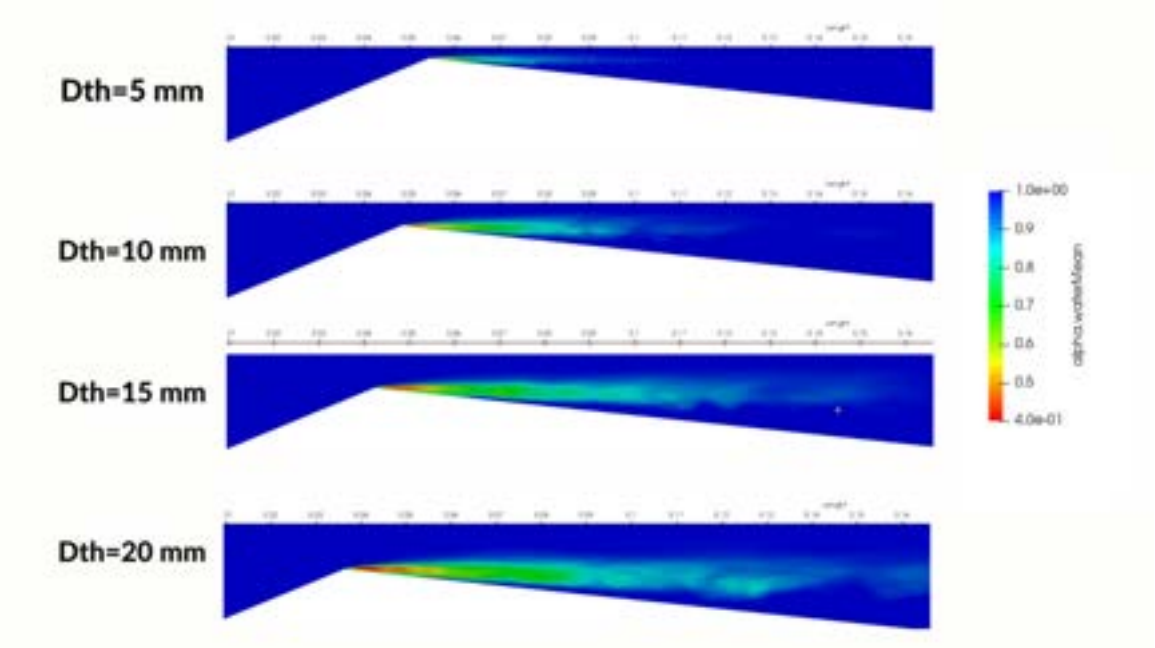

Figure 6: Time average liquid volume fraction for simulated geometry.

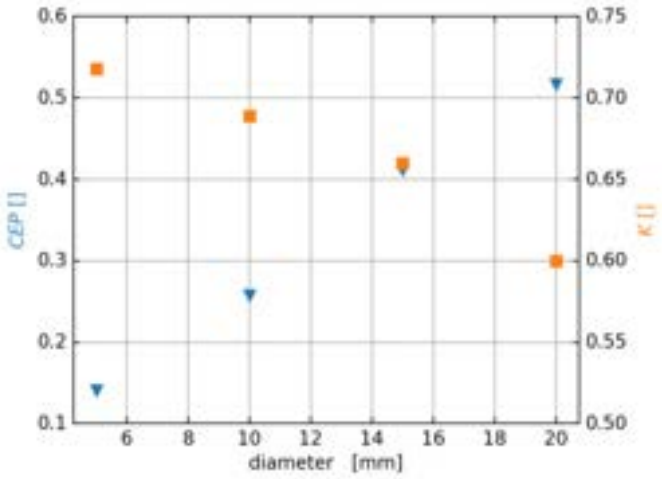

Figure 7: The graph shows the trend of K losses and CEP as a function of throat diameter.

4.3. Effect of throat length in cavitating flow dynamics

This section analyzes the differences in terms of the dynamics of the cavitation phenomenon between a sharp-edged geometry and a geometry in which there is a throat section of length L_{TH}. It has been decided to consider the geometry with D_{TH} = 10mm and L_{TH} = 10mm. Once the simulations were finished, it was possible to evaluate the differences between the two geometries using the FFT and calculating both the K losses and the cavitating efficiency parameter. The presence of the throat region causes the emergence of a quasi-stable sheet cavity region, which causes a clear decrease in the oscillation period. In terms of frequency, we have a reduction from 160 Hz for the sharp-edged to 40 Hz for the geometry in which the throat region is present. While the amplitude related to the pressure spike remains almost the same (Figure 9). Regarding the velocity field, the presence of two recirculation zones located at the beginning of the throat section and at the beginning of the diverging ramp is observed in figure 10. The instabilities that are generated at the sheet cavity interface, tend to energize the flow in the second recirculation zone. This results in an inhibition of the cavitation phenomenon which is therefore less intense than having a sharp-edged throat. The performance for process intensification values of CEP = 0.17 while the losses give a value of K = 0.58. Compared with the values found for the sharp-edged geometry, it is observed that CEP decreases given the smaller extent of the cavitation region. Pressure losses, directly related to the extent of the cavitation region where the largest contributions of pressure degradation are shown, also decreasing from 0.689 to 0.58.
