Abstract:

In this research, a renewable energy hybrid system (PV-Wind) is modeled to compare different design options based on their economic and technical features. The energy requirements of a RO desalination plant located on the island of Tenerife with a water production capacity of up to 20,000 m³/day will be considered. The system will be connected to the electricity grid.

The HOMER software has been used to produce optimum strategies for renewable energy. The assumptions input into the model were: the technical specifications of the devices, electricity demand of the desalination plant, as well as the solar radiation and the wind speed potentials. Numerous arrangements have been considered by the software. The optimal results have been obtained based on the use of renewable energy. The data used in the study were recorded in Tenerife in the Canary Islands. The experience of this research could be transferred to other Atlantic islands with similar conditions.

Keywords:

Renewable Energy; Desalination; Reverse Osmosis; Canary Islands

1. Introduction

The Canary archipelago is a pioneer in seawater desalination due to its experience in applications with dissimilar technologies. Currently, the Islands have 330 desalination plants, which produce around 214.6 hm³ of fresh water per year [1,2].

In two of the seven main islands that make up the archipelago (Lanzarote and Fuerteventura), desalinated water accounts for 99% and 86%, respectively, of the water used to supply the population and tourism [1,2,3].

The main problem with desalination is the energy required, which is harmful to the atmosphere due to the growing pollution caused by the burning of fossil fuels. The isolated electrical grid of the Canary Islands poses a problem in its optimization, as does the high dependence on imported fuel [3-7].

The use of renewable energies to procure fresh water from seawater for human consumption is beneficial for the environment, since it reduces pollution.

On the island of Tenerife, wind speed and solar radiation are generally high and allow for the optimal use of renewable energy systems (RES) to produce energy. An example of this are the eight solar plants belonging to the "Technological Institute of Renewable Energies" (ITER), with a total of 44.3 MW of installed photovoltaic systems and 65.7 MW of wind energy, installed in different wind farms [8,9].

The groundwater in Tenerife is under threat due to severe overuse. In recent years, desalination from sea water has increased to around 26.64 hm³/year, accounting for 14.0% of freshwater production, and is likely to continue increasing in the medium-term [10].

In this paper, different RES based on wind energy and photovoltaic (PV) systems connected to the electrical grid are modeled in order to assess different designs based on their technical and economic properties. The power needs for a reverse osmosis desalination plant could be guaranteed up to a water production capacity of up to 20,000 m³/day.

The Hybrid Optimization Model for Electrical Renewable (HOMER) [11] has been used to achieve the most optimal designs of RES to supply Reverse Osmosis (RO) systems.

The starting assumptions were: the electrical needs of the RO plant, technical specifications, and the sources of renewable energy (wind speed, solar radiation) on the island. HOMER models the RES with a grid connection, and the RES will always try to deliver the highest power required by the RO plant.

HOMER has been used in numerous studies carried out in many regions of the world, with the objective of finding options to replace part of the conventional energy with RES. Some examples may be found in islands

of the Atlantic Ocean [6,7], in Oceania [12], in Eurasia [13], North American [14,15], Asia [16-22], the Arabian Peninsula [23-27], Southeast Asia [28], the north Pacific Ocean [29] and in Australia [30].

Tenerife was selected for this study due to the rising annual water demands on the island, the high tourism industry, the agricultural operations on the island, the decline of groundwater and the exceptional renewable energy sources on the island.

The main objective of this study is to determine the best renewable energy systems (RES) with connection to the electricity grid to ensure the energy needs of RO plants for the production of fresh water on the island of Tenerife. The research is carried out taking into consideration the best technical-economic configuration. This research can be extrapolated to other regions with similar circumstances of water scarcity and with good sources of renewable energy.

This research is arranged into five sections. Following this introduction is a presentation of Tenerife, its population and the status and production of its water. Section 3 provides the materials and methods that will be used in the study, and defines the principal input variables of the HOMER software. The results and discussions are reported in Section 4. Lastly, Section 5 shows the most significant conclusions of the study.

2. Contextualization of Tenerife Island

The Canary Islands is an archipelago situated on the Atlantic Ocean, in Macaronesia. The archipelago is composed of seven main islands: La Gomera, El Hierro, La Palma, Tenerife, Gran Canaria, Fuerteventura, and Lanzarote (Figure 1). The islands' population is over 2 million. The number of tourists received in the islands in 2022 was in excess of 12 million [26]. The only way to supply this service sector on an island with high water scarcity is by using efficient RO desalination systems [3,4,6,31].

Tenerife is the largest and most inhabited island in the Canary Islands, with around 42.5% of the archipelago's inhabitants. Every single year, more than 5.5 million tourists visit Tenerife, which is why it is considered the most popular island in the Canaries [31].

The largest volume of this tourist population is received in the south of the island, generating a great demand for fresh water, more than 300 liters/day-tourist [32,33]. This water demand is covered in large part by desalinated water.

2.1 Desalination water in Tenerife

Desalination is nothing more than the method of removing salts from brackish or marine water to make it useful for agricultural, industrial or human consumption. In the Canary Islands, desalination provides a significant percentage (19%) of the water supply in many sectors such as agriculture, the tourism industry and the population [3,6,34].

Currently, there are 29 reverse osmosis (RO) seawater desalination plants (EDAM) in Tenerife. The most important plants by water production capacity are shown in Table 1, two of which are located in the south of the island and the other in Santa Cruz de Tenerife, the island's capital. Figure 1 shows the locations of these three desalination plants in Tenerife [10].

Table 1. Fresh water production in three RO seawater desalination plants (EDAM), Tenerife.

RO desalination plant EDAM	Capacity of water production (m^3/day)	Energy consumption (kWh/m^3)
Adeje-Arona	30,000	4.51
Caleta de Adeje	10,000	4.29
Santa Cruz de Tenerife	21,000	4.6

The EDAM with the lowest energy consumption is Caleta de Adeje, due to the improved energy recovery technology used in the desalination process. The RO desalination plant in Adeje-Arona went into operation in 1998, with a total water production capacity of 10,000 m^3/day. Due to the increasing water demand in the region, this water plant's current capacity is 30,000 m^3/day [10]. All these plants supply the demand of the population and tourists.

Figure 1. Map of Tenerife showing the locations of desalination plants, wind farms, meteorological stations and selected locations.

Figure 1 shows the distribution of the wind farms on Tenerife, which are located in those places on the island with the most wind potential, almost all of which are in the south of the island, especially in the region of Granadilla de Abona.

According to the Spanish Wind Observatory [34], on Tenerife wind farms, the preferred wind turbines in both current and new projects are GAMESA, ENERCON, VESTAS and MADE, including the repowering of old wind turbines.

Renewable energy systems such as wind turbines and photovoltaic systems, as well as reverse osmosis desalination, are all mature technologies that can be combined in different arrangements. However, only some desalination plants are currently powered by RES due to the large initial investment required, with no more than 1.0% of the desalination plants on the planet being powered by RES [35,36].

On the island of Tenerife, there is no isolated or connected RES to supply the total energy of a desalination plant, which could reduce the environmental consequences of desalination due to its enormous energy consumption from traditional sources.

All the energy used in the desalination process on the island proceeds directly from the electrical network. That is the reason behind this research, to propose the optimal renewable energy system with network connection.

3. Materials and Methods

After evaluating the state of desalination on the island of Tenerife, identifying the main plants, their production capacities and energy consumption, we decided to consider a maximum production of 20,000 m^3/day for the study, with a maximum energy consumption of 4.50 kWh/m^3 of desalinated water, although this consumption may be lower depending on energy recovery.

An analysis of Figure 1 and the study conducted by the "*Cabildo Insular del Agua de Tenerife"* (Tenerife Water Council) [37] reveal that many desalination plants are located in regions with a high solar and wind potential.

Taking this analysis into consideration, two possible locations for the study were selected, the first in the extreme south of the island, near the Montaña Roja Nature Reserve, and the second in Santa Cruz, the capital of Tenerife (Figure 1). Both locations have a high solar and wind potential and are close to meteorological stations and existing infrastructure (roads, workshops, electrical substations, equipment and supplies, etc.).

3.1. Input variables to HOMER Software

On islands like Tenerife, with high renewable energy resources and water stress, the combination of desalination plants and RES can provide a solution to the large energy consumption of the desalination industry. Combining the desalination and electrical industries requires an optimal design and consistency, and also that it be sustainable.

Taking these objectives into account, we must first propose the selection and sizes of the possible elements of the RES to power the desalination plant. The HOMER software was selected to achieve the most satisfactory design. This software can carry out the simulation, optimization, and sensitivity analyses of the RES (PV-Wind) to determine the energy needs of the desalination plants in question [6]. Figure 2 shows the suggested RES for the simulation. These devices can involve PV modules in combinations of various wind turbines, all connected to the electrical grid.

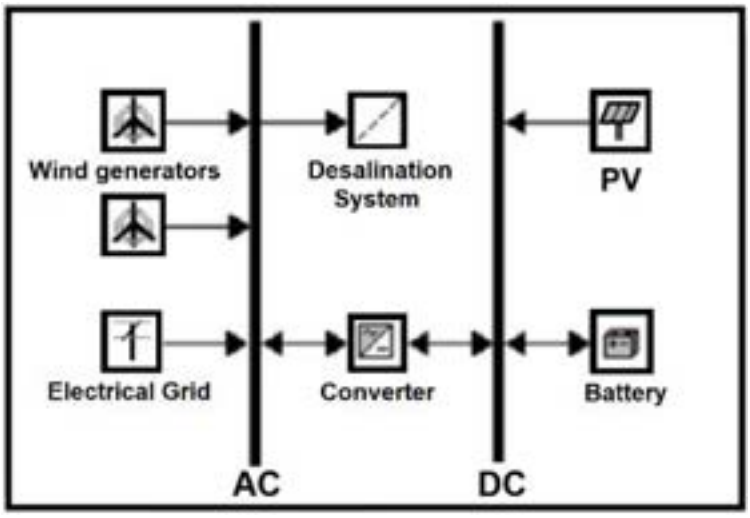

Figure 2. Renewable Energy Systems HOMER model, with electrical grid connection

3.2. Electrical loads

In order to carry out this research it was assumed a desalination plant with a production of 20,000 m^3/day, with a possible energy expenditure of 4.50 kWh/m^3 of desalted water. According to HOMER, the energy consumption of the installation can reach 89,225 kWh/day. The average electricity demand will be 3,719 kW, which may increase to 6,113 kW at peak hours. Figure 3 displays the annual distribution of electrical energy consumed, the average, and the minimum and the maximum consumption per each month.

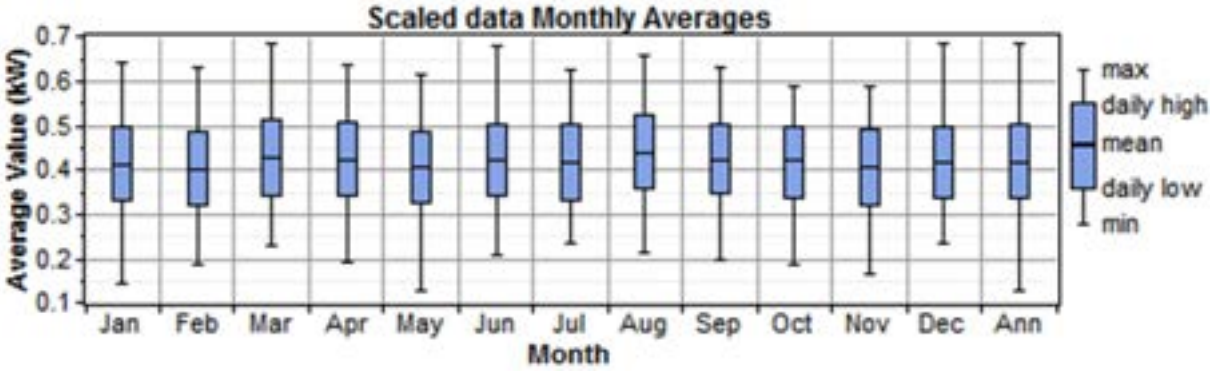

Figure 3. Annual distribution of electrical energy consumed

3.3. Solar radiation

HOMER takes the monthly solar radiation directly from NASA data. Figure 1 shows the meteorological stations used in the study for each location selected, which in this research were the South Airport (*Reina*

Sofía) (C4291) meteorological station for the Montaña Roja Nature Reserve, and the Santa Cruz de Tenerife (C449C) station to study the case in the island's capital. The coordinates used for the study on the island are shown in Table 2.

Table 2. Coordinates of the Meteorological stations

Meteorological stations	**Coordinates** *(Latitude and Longitude)*	**Altitude (m)** *(above sea level)*
South Airport *(Reina Sofía)* **(C429I)**	*Latitude:* 28° 2' 51'' N *Longitude:* 16° 33' 39'' W	64
Santa Cruz de Tenerife **(C449C)**	*Latitude:* 28° 27' 48'' N *Longitude:* 16° 15' 19'' W	35

3.4. Wind speeds

The monthly average wind speeds were taken from the two meteorological stations whose coordinates are shown in Table 2. The first one, located at the Reina Sofia Airport, has a database of more than 35 years and an average annual wind speed of 6.1 m/s. The second is located in Santa Cruz de Tenerife, where the average annual wind speed is 3.0 m/s, according to figures dating back over 85 years. The simulation performed by HOMER uses the Weibull probability density function.

3.5. PV system

When the model of the photovoltaic system is designed, the HOMER software does not take into account the temperature and voltage to which the system is subjected during operation. HOMER assumes that the direct current (DC) output of the PV panel is linearly proportional to the incident radiation [38]. Table 3 shows the cost of the photovoltaic panels used in the research. The photovoltaic panel is assumed to have a useful life of 20 years.

Table 3. Economic data

Components	**Initial capital cost (ICC_{PV})$**	**Replacement cost (RC)$**	**O&M cost ($)**	**Lifetime**
PV panels	7000 ($/kW)	7000 ($/kW)	(0.015)x(ICC_{PV})	20 years
Wind Turbines	1200 ($/kW)	(0.85) x (ICC_{Wind})	(0.025)x(ICC_{Wind})	25 years

3.6. Wind turbine system

Manwell, McGowan and Rogers state in [39] that a standard procedure is used to model wind turbines, assuming that the kinetic energy of the wind turbine is converted to electricity based on a specific power curve. HOMER computes the average wind turbine power (*Pwind*) using the Weibull distribution.

Figure 4 shows the power curves of the wind generators selected for the study, which are manufactured by ENERCON, GAMESA and VESTAS. All these machines were tested in different wind farms on Tenerife. The initial economic data for the wind generators and photovoltaic systems are shown in Table 3.

Table 4 shows the characteristics of the proposed wind turbines, with nominal powers of 800, 850 and 2000 kW.

Table 4. Commercial characteristics of wind generators (*Source:* [40-43]).

Characteristics	**E48**	**E82**	**G52**	**G90**	**V52**	**V80**
Nominal Power (kW).	800	2,000	850	2,000	850	2,000
Hub height (m)	55	78	55	78	55	78
Rotor diameter (m).	48	82	52	90	52	80
Cut-in wind speed (m/s)	3.0	2.0	4.0	3.0	4.0	4.0
Cut-out wind speed (m/s)	25	25	25	21	25	25

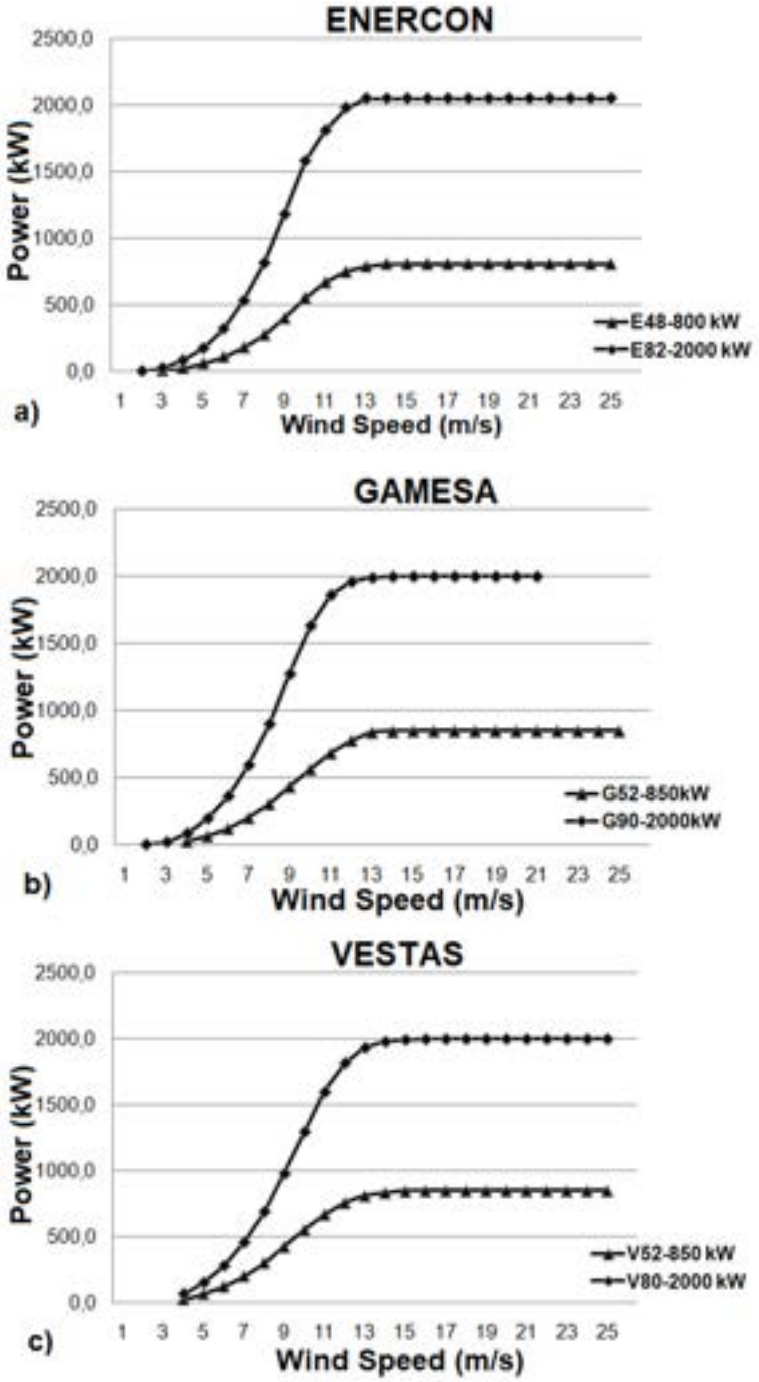

Figure 4. Power curves of the wind generators. a) ENERCON, E48-800 kW and E82-2,0 MW; b) GAMESA, G52-850 kW y G90-2,0 MW; c) VESTAS, V52-850 kW y V80-2,0 MW (Source: [40-43]).

3.7. Economic analysis

Typically, conventional electric systems have a lower initial capital cost than RES, while the cost of operation is higher in thermoelectric plants. In the optimization process, the HOMER software compares the economic characteristics between renewable energy systems and the traditional electrical system to recommend the most economical system [38].

The tools used by HOMER to perform the economic analysis are the “Levelized Cost of Energy” (COE), which calculates the average (cost/kWh) of the electricity produced by the system, and the “Total Net Present Cost” (NPC) ($), which computes the cost to install and operate any system [3,6].

4. Results and discussions

The main problem when designing any RES, whether hybrid or not, is to determine its components and the size of each, which is conditioned by the renewable energy sources in the region where it is installed.

The HOMER software is an excellent tool to use in this situation, since it allows simulating numerous system arrangements. For example, the NPC makes it possible to sort values that are in the viable range and discard those that are unviable.

The results of the technical-economic simulation carried out by HOMER are shown below. The cost of electricity from renewable energy is assumed to be $0.15/kWh; the cost of electricity purchased from the grid is $0.10/kWh; the desalination process is assumed to consume 4.50 kWh/m^3 of desalinated water; and the maximum production capacity of the proposed desalination plant is 20,000 m^3/day.

4.1. Optimization results in Santa Cruz de Tenerife

After modeling the technical-economic aspects with RES based on PV and wind systems from different manufacturers, such as ENERCON, GAMESA and VESTAS, connected to the electrical grid in Santa Cruz de Tenerife to supply energy to a desalination plant, we can state that the optimal energy system to supply energy to a desalination plant in the capital is the grid, with an approximate consumption of 32,666,286 kWh/year and an approximate cost of $3,266,629/year.

This is mainly due to the low wind speeds in the region analyzed, the high costs of photovoltaic systems and the lack of land in the capital to install a solar farm.

4.2. Optimization results in Special Nature Reserve “Montaña Roja”

Tables 5 and 6 show the result of the technical-economic and energy simulation and optimization carried out for the Montaña Roja Nature Reserve area by the HOMER software, using the data set from the Reina Sofía Airport meteorological station. The RES used in this model is the same as that used to model the system in Santa Cruz de Tenerife (PV-wind systems from different manufacturers such as ENERCON, GAMESA and VESTAS connected to the electrical grid).

Table 5. Technical-economic optimization results for the RES (PV-Wind- electrical grid) in the Montaña Roja Nature Reserve.

Turbine Model	No. of Turbines	Initial capital cost ($)	O&M cost ($/year)	Total NPC ($)	COE ($/kWh)
G90	2	4,800,000	1,730,579	26,922,606	0.064
E82	2	4,800,000	1,750,828	27,181,456	0.065
V80	2	4.800.000	1,932,697	29,506,358	0.071

Table 6. Energy optimization results for the RES (PV-Wind- electrical grid) in the Montaña Roja Nature Reserve.

Turbines Model	No. of Turbines	Energy consumption (kWh/year)	Energy purchased (kWh/year)	Energy produced (kWh/year)	Renewable fraction(%)	Energy Sold (kWh/year)	Energy Sold Fraction(%)
G90	2	32,666,340	17,213,290	16,190,625	48.5	737,575	4.5
E82	2	32,666,340	17,555,310	15,941,763	48.0	830,733	5.2
V80	2	32,666,340	18,932,300	14,270,080	43.0	536,040	3.8

Table 5 shows that an initial capital cost of $4,800,000 is considered, which is the same for all possible wind farms connected to the electrical grid. The COE for the different wind turbine models varies between $0.064 and $0.071/kWh, with the system with two G90 wind turbines being the one with the lowest cost/kWh.

The percentage of renewable energy that can be injected into the electrical grid varies between 43.0 and 48.5%, with the system with two G90 wind turbines being the largest producer of renewable energy, followed by the system with two E82 wind turbines (48, 0%). In the latter, up to 5.2% of the total renewable energy produced in a year can be sold.

After analyzing the systems with G90 wind turbines, the energy required for the desalination system totals 32,666,340 kWh/year, of which 15,453,050 kWh/year (47.3%) come from the 4.0 MW wind farm, and the rest (17,213,290 kWh/year) from the electricity grid.

4.3 Polluting gas emissions

Table 7 shows the amounts of polluting gas emissions that can be avoided by wind farms with two G90 wind turbines. This scenario is for the combination with the highest energy production from renewable sources, with a total production of 16,190,625 kWh/year. During the year, only 4.5% of this energy has to be sold to the electricity grid due to excess production, meaning the scenario can be regarded as successful, since 95.5% of the energy is used for desalination (Table 6).

Table 7. Pollutants avoided by the Wind System.

Wind farm	Pollutant	Avoided emissions (kg/year).
2 Turbines (G90)	Carbon dioxide (CO_2)	8,732,130
	Sulfur dioxide (SO_2)	81,390
	Nitrogen oxides (NO_x)	39,710

The RES proposed to supply the maximum possible energy from renewable sources to a desalination plant with a maximum production of 20,000 m^3/day can avoid releasing into the environment 8,732,130 kg/year of CO_2, 81,390 kg/year of SO_2 and 39,710 kg/year of Nitrogen Oxides.

5. Conclusions

The following conclusions can be drawn from the technical-economic analyses conducted for the possible installation of an RES to supply the maximum possible energy from renewable sources to a desalination plant on the island of Tenerife. The places on the island under consideration were the Montaña Roja Nature Reserve and Santa Cruz de Tenerife.

The first technical-economic analysis was carried out for the capital, Santa Cruz de Tenerife, and yielded the finding that an RES cannot be installed in this location to supply energy to a desalination plant due to insufficient wind speed and lack of available land to install a solar farm.

The second technical-economic analysis was carried out for the Montaña Roja Nature Reserve, which has good wind potential. Wind turbines from different manufacturers, such as ENERCON, GAMESA and VESTAS, were analyzed, all of them connected to the electrical grid, which yielded very good results, with the G90 wind turbines being the systems that can inject the greatest amount of energy into the electrical system, with a total of 16,190,625 kWh/year, of which 15,453,050 kWh/year (47.3% the energy required) is used directly in the desalination plant, with the remaining 4.5% being sold to the electricity grid. These RES avoid releasing into the atmosphere 8,732,130 kg/year of CO2, 81,390 kg/year of SO2 and 39,710 kg/year of NOx. The results of this study show that the strategy proposed could be appropriate to be used in similar locations in the Macaronesia region or in other parts of the North Atlantic Ocean.

Acknowledgments

This research has been co-funded by FEDER funds, INTERREGMAC 2014–2020 Programme of the European Union as part of the E5DES project (MAC2/1.1a/309).

Abstract:

The use of low-carbon hydrogen is called to be one of the key vectors for the decarbonization of the energy sector and industry. In that regard, green hydrogen, which is produced through the electrolysis of water using renewable sources of electricity, is the process that offers the most advantages. In order to operate efficiently, water electrolysis technologies require a water source of near-ultrapure quality. To achieve this, a preceding water treatment stage is necessary, and reverse osmosis technology is currently the most widely used. This pressure-driven technology has reached maturity, but it still has certain technological limitations and energy consumption to be considered. This paper presents a comprehensive literature review of water distillation technologies currently available for obtaining the water quality required by green hydrogen electrolyzers. The comparison between mature and innovative water distillation processes showed that membrane distillation is one of the most promising technologies and that it has proved its effectiveness in the desalination sectors, but it has yet to be exploited to produce green hydrogen. This technology uses hydrophobic membranes and can be powered by a low-temperature heat source (between 40 °C and 90 °C), which provides opportunities to use alternative sources of heat, such as solar, geothermal, and even low-quality waste heat. This presents a great opportunity for energy integration with water electrolysis processes, as they generate a low-temperature waste heat flow (around 80 °C) during operation, which is compatible in quality and quantity with membrane distillation process requirements.

Keywords:

Water Distillation; Green Hydrogen; Membrane distillation; Energy Integration.

1. Introduction

It is well-known that the fight against climate change and environmental degradation has intensified in recent years. In that regard, the energy sector has proposed solutions for its decarbonization, with hydrogen (H_2) playing an important role as a possible alternative to the use of fossil fuels [1]. Among the main advantages of the use of H_2 is that it is abundant, non-toxic [2], and has one of the highest energy densities among the well-known fuels [3] (reaching a low heat capacity of 120 MJ/kg [4]). Additionally, H_2 only emits water as a by-product during combustion [2], is much easier to store and transport than electricity [3] and is flexible enough to be used in sectors such as power generation and buildings [5], as well as being a potential solution for the decarbonization of sectors difficult to electrify, such as transport [3].

Although the use of H_2 has increased to a global consumption of almost 90 Mt of H_2 in 2020 [6], there is still no accurate projection of its demand in the years to come. Several authors [3,5,7–10] have taken different base scenarios to make their projections, stating that it will be required from 50 Mt/y of H_2 [10] to 2.3 Gt/y by 2050 [9]. Despite the lack of homogeneity in the projections, a considerable amount of H_2 would be required, and therefore it would be necessary to find a reliable source from which to obtain it.

It should be noted that H_2 is an energy vector, not an energy source, so its veritable contribution to carbon neutrality will depend on how it is produced [1] since it can derive from fossil fuels as from electricity [11]. Therefore, a color-coding system is often used to describe the level of "cleanliness" depending on the type of source and technology used for obtaining the H_2 [4]. The most commonly used colors for H_2 are grey (obtained by steam methane reforming, SMR), blue (obtained by SMR with carbon capture and storage), turquoise (obtained by methane pyrolysis), and green (obtained by water electrolysis) [12].

Almost all types of H_2 mentioned above are considered pollutants to some degree [13] since they are obtained using fossil energies as their primary source. Only the green one is considered a clean source of H_2 [4,14] since the electricity required comes from low-carbon sources such as renewable energy sources (RES) [13]. However, it should be noted that H_2 is currently mainly produced by SMR systems of natural gas (48% of the

total) or using other fossil sources (48%) [2]. This means that only 4% of the total H_2 produced corresponds to green H_2 [15].

Therefore, boosting the production of H_2 through water electrolysis using RES presents great potential to decarbonize the energy sector [3] and could be crucial in addressing the climate crisis [16–18]. In addition, coupling the production of green H_2 with electricity generated from RES (which are considered unstable in terms of generation) is one of the best methods for storing the excess energy from RES, known as power-to-gas storage [2]. Other benefits of green H_2, and its direct relationship with RES, include its compactness, the possibility of being independent of the existing electrical infrastructure, and its attractiveness towards emerging markets [19].

However, it should be noted that the production of green H_2 is still under development, therefore it is currently more expensive than the production methods based on fossil fuels [2]. Nevertheless, it is expected that the use of green H_2 electrolyzers with extended operating hours will enable them to reach competitive costs [20]. Furthermore, due to the many advantages listed above, as well as the fact that the price of RES electricity continues to decrease [16], it is estimated that its production will expand to reach at least 22% of the total H_2 produced in 2050 [2].

The production of green H_2 is defined by two main components: the use of RES and the use of water electrolyzers [19]. The latter are electrochemical devices that separate water molecules (H_2O) into H_2 and oxygen by passing an electric current through them [20]. In order to operate efficiently, water electrolysis technologies require to be fed by a water source of near-ultrapure quality [16]. Consequently, they require a previous water treatment (distillation) stage to protect the electrochemical process. This paper presents a comprehensive literature review of the water distillation technologies currently available for obtaining the water quality required by electrolyzers to produce green H_2, as well as other developing processes that show considerable potential for entering this market.

2. Electrolyzers

Currently, there are several electrolyzer technologies already developed, all of which share the same fundaments: water separation in the electrodes, allowing the transport of ions (H^+ and OH^-) through liquid electrolytes or solid membranes [20]. The two main commercial varieties are alkaline water electrolyzers (AWE) and proton exchange membrane electrolyzers (PEME) [16].

AWE technology has been developed since the 1920s [21], making it the most mature and well-established technology on the market [2]. This technology uses aqueous solutions of KOH or NaOH as electrolytes and typically operates at temperatures between 60 °C and 90 °C [22] and pressures below 30 bar. Its costs are significantly lower than those of other technologies because it does not require the use of expensive catalysts [23] and utilizes simple stainless-steel electrodes [22]. This technology presents a response to sudden changes in power supply in the order of seconds [23], although very abrupt changes can cause soda-like eruptions in the electrolyte [22]. On the other hand, its H_2 purity level is slightly lower than those of other technologies (in the order of 99.95% [19]), due to the use of a relatively permeable separator that can sometimes allow bubbles to pass through [2]. Its feed water quality requirements are slightly more flexible than those of other technologies; however, if impurities are present, they can clog the device and contaminate the electrolyte [22]. Additionally, very low-quality water feed can lead to faster equipment deterioration. Impurities such as Fe, Cr, Cu, Si, AL, and B have the greatest impact on the performance of the system [20].

On the other hand, PEME technology began its history in the early 1950s [16] and is now close to its full technological development [19]. This system features a compact modularity thanks to the membrane-electrode assembly (MEA) concept, which allows easy downsizing [2]. Unlike AWE technology, this system only requires the supply of pure water (no electrolyte is necessary), thus its service life is longer, due to the absence of KOH-induced corrosion [16]. The electrolyte is formed by a solid polymer that allows high conduction of H^+ protons [22]. Its operating temperature is lower than AWE, being able to operate in a range between 50 °C and 80 °C and at pressures below 70 bar [20]. One of its key points is its flexible operation with a fast response time (in the order of milliseconds) [23], which allows it a suitable solution for coupling with RES electricity.

Additionally, the H_2 obtained through PEME presents a high purity, typically around 99.99% [19,24]. This technology, however, has the disadvantage of being more costly than AWE due to the high-cost catalysts [2] and other noble materials, such as Pt or Ir [25], used in the electrolyzer. Furthermore, the precision required for the bipolar dishes due to the MEA system contributes to the increased cost of production [22]. In terms of purity requirements in the water supply, PEME is one of the most demanding technologies as it is quite sensitive to the presence of impurities [22] and this is one of the main reasons for its failure [26]. The components most vulnerable to impurities are the solid membrane, the catalyst, and the porous transport layers [20]. Among the most harmful elements for the system is the presence of Mg_2 and Ca_2, as they generate precipitates on the cathode side [27], which can lead to irreversible damage.

Today, the industry is shifting towards the use of PEME systems due to their compact design, fast response to dynamic changes, and high purity in the generation of H_2 [23,24]. However, AWE systems still have a significant market presence due to their lower cost.

3. Water requirements

3.1. Quality requirements

As can be seen, water electrolysis technologies require a minimum degree of water purity to function properly and avoid damaging their components [26]. However, detailed studies on the required water quality for each type of electrolysis technology are not available [28].

Nevertheless, the industrial standard adopted for this purpose is the ASTM standard specification for Reagent Water [29]. In this sense, it is recommended to use pure water with a minimum quality of type II of the ASTM standard, being preferred type I (ultrapure) for PEME systems [16], as they are more sensitive to impurities. Table 1 summarizes the ASTM water quality types. It can be seen that the purity requirement for electrolyzer feedwater is quite high, considering that commercially sold distilled water typically has a conductivity lower than 10 µS/cm [30].

Table 1. ASTM water quality standard [29].

Parameter	Type I	Type II	Type III	Type IV
Conductivity, min µS/cm (25 °C)	0.056	1	0.25	5
Resistivity, min MΩ-cm (25 °C)	18	1	4	0.2
TOC, max µg/l	50	50	200	No limit
Sodium, max µg/l	1	5	10	50
Silica, max µg/l	3	3	500	No limit
Chloride, max µg/l	1	5	10	50
pH value (25 °C)	-	-	-	5-8

3.2. Quantity requirements

Stoichiometric theory indicates that 9 kg of input water are required for each kg of H_2 produced [20]. In reality, considering the inefficiencies in the electrochemical reaction, this water demand is typically higher, being commonly used an average value of 15 kg of water per kg of H_2 [3,8]. Given the maximum projected H_2 demand of 2.3 Gt/y by 2050 [9], and assuming that all the production relies on generating green H_2, the total direct water consumption for this projected demand would be around 34.5 Gt/y of H_2O [8].

However, it should be noted that this water demand only considers the direct consumption by the electrolysis process; the indirect consumption of the system, which comes from upstream and includes the water consumption for power generation and secondary equipment (mainly water treatment process and cooling water requirements) [3], can be up to 20 times higher than the direct consumption [11]. A maximum value of 126 kg of water per kg of H_2 is currently used for global system estimations [11].

It must be considered that the production of green H_2 will interlock the energy-water-nexus in unpredictable ways given its direct relation [3]. This relationship, together with the significant water demand, has raised doubts about the viability of a green hydrogen-based economy in certain authors [8,31], considering that there are already water shortages (of fresh water), and this demand may pose greater water stress in certain already affected areas [3].

4. Water resource

The world's total water resources are about 1.4 billion km^3 [32], from which 97.5% is sea and ocean saltwater and only 2.5% is fresh water [33]. However, of this total, only 0.27% is accessible for direct use [34], approximately 94500 Gm^3, with the rest being ice and groundwater. Therefore, the projected water requirement for direct electrolyzation feed is relatively small in comparison [3]. Despite this, the idea is not to sum any additional burden to freshwater use, considering that certain areas of the planet already have limited or no access to fresh water supply [8].

It must be taken into account that population growth and increased water demand per capita are among the main factors contributing to the problem of water scarcity. Additionally, it should be noted that the effects of climate change act in synergy with these two factors to increase water stress [35].

The water stress index (WSI) measures the amount of water used relative to the amount of water available [35]. However, it should be noted that the WSI only considers the physical availability of the resource. To gain a more comprehensive understanding of water security, the inclusion of economic and social indices is suggested. In this regard, Gain et al. [36] presented a global water security index (GWSI) that considers criteria such as availability, accessibility, security and quality, and resource management. The results of their analysis indicated that some regions, particularly in the South, are beginning to experience a water safety problem.

Moreover, projected scenarios of water scarcity have been generated, estimating that by 2025, the number of people facing this problem will reach 2.8 billion, and by 2050 it could reach 4 billion [35]. Similarly, the World Water Program estimates that by 2030, only 60% of the world's required water will be available, and according to the OECD, this will drop to 55% by 2050 [32]. These factors have prompted a debate on the need to seek

new sources of fresh water [32]. Given that, in the context of global water distribution, saltwater is the most abundant resource [33], and in light of the other aquatic stressors mentioned above, the possibility of using seawater as a source for obtaining fresh water has been encouraged [37].

Furthermore, in the context of H_2 production, marine environments could be a source of renewable energy for green H_2 [38]. Moreover, recent decades have seen some researchers [1,16,22,26] consider the possibility of generating H_2 through direct electrolysis of seawater. In this sense, efforts have been made to develop electrolyzers, membranes, and catalysts that can operate with seawater without prior purification [26]. However, most studies have come to the same conclusion: a seawater desalination process and subsequent feeding of a classic electrolyzer is much cheaper than a potential direct seawater electrolysis process [1,16,22,26]. This is mainly because the costs of water desalination, which is estimated to be around 0.1 $/kg H_2 in the case of using a reverse osmosis (RO) process [1], are minimal compared to the other costs associated with a classic water electrolysis process, such as the cost of energy consumed [16]. Additionally, the expensive materials needed for direct seawater electrolysis and its technical uncertainties [16], made this technology economically non-attractive [16,26,28].

Therefore, as seawater desalination processes have already reached a level of maturity and are now considered reliable water sources [39], it is recommendable to focus efforts on the technical and economic improvement of these processes [16].

5. Seawater desalination processes

The first desalination technologies date back to World War II and have since been gaining traction around the globe in response to the increasing demand for water [40,41]. As of now, the global desalination capacity is 115 Mm^3/d [42], with 65% of that total capacity located in the Middle East, particularly in the Persian Gulf [32]. The global distribution of different water sources used to supply desalination systems demonstrates that 60% of production uses seawater due to its abundance, while brackish water is the second most used resource, with nearly 21% of the share [43].

There are currently 16876 desalination plants [44] utilizing various technologies to carry out the process. Figure 1 illustrates the global desalination plant distribution. It is evident that RO technology is the most prevalent on the market today, as it consumes less energy than thermal systems and has seen tremendous progress in membrane technology [45] since the 1960s [46]. It is worth noting, however, that in some regions such as the Middle East (which accounts for 47.5% of the overall market [47]), thermal technologies, including multi-stage flash distillation (MSF), are the most widespread [46] and are used in thermal cogeneration.

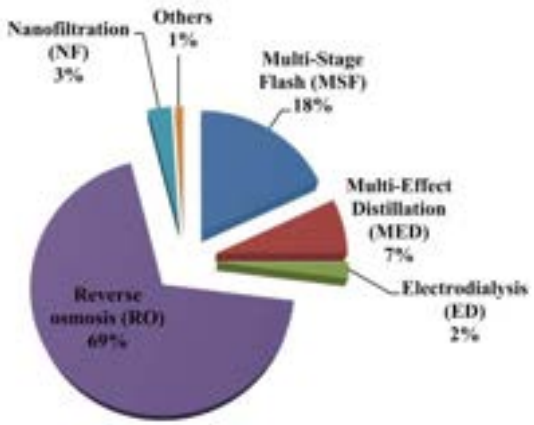

Figure. 1. Worldwide water desalination processes distribution [32].

In general, technologies are currently classified into two major groups: thermal desalination processes and membrane desalination processes [48].

5.1. Thermal desalination processes

In synthesis, thermal desalination processes are phase change techniques [49] that involve heating the feed liquid, under certain temperature and pressure conditions, to create a water vapor that will separate it from the salts and other non-volatile components in the feed stream. This vapor is then condensed to produce a stream of distilled water [50]. The most used thermal desalination processes today include MSF and multi-effect distillation (MED).

As noted above, MSF is based on the principle of boiling seawater (or other feed fluid) at a temperature below its normal boiling point, due to the “flashing effect” [40]. An external heat source, usually steam [41], is required to heat the feed fluid between 90°C and 115 °C [33]. The feed fluid passes through several stages, where the temperature and pressure of each stage decrease compared to the preceding stage [32]. As it passes through

the stages, some of the heated fluid will evaporate due to the stages being at a pressure lower than their vapor pressure. The vapor formed is then condensed on the outer surface of heat exchange tubes where low-temperature salinized water passes [40], and therefore, a distilled condensate could be collected. MSF facilities can consist of 4 to 40 stages [51].

Among thermal desalination technologies, MSF is the most widely used method due to its lower maintenance costs and longer service life [52]. MSF systems, however, face important technological challenges, such as the precipitation of Ca and Mg salts on the tubes of the heat exchanger [53], corrosion [40], and high thermal energy consumption [40,49]. Despite these issues, MSF systems provide good-quality desalinated water [54]. Although the conductivity values of the desalinated product are scarce at the literature level, Deghani et al. [55] demonstrated through experimentation the production of distillate with less than 30 µs/cm from a feed flow with 73 mS/cm.

For its part, MED technology is older than MSF [40] and operates on a similar principle (using a series of vessels at pressures lower than ambient). The main difference between them is that MED generates steam by spraying the feed water in the form of a thin film [40] onto heat exchanger tubes (evaporator), where steam from the previous stage passes [32]. Generally, MED has between 4 to 14 effects [40] and has the advantage of working at temperatures and pressures lower than those of MSF, requiring the heating of salinized water to only 66 °C [51], thus consuming less energy [40]. MED is suitable for small to medium size plants but is subject to corrosion [40] and high maintenance costs due to the utilization of spraying water systems [52]. Their desalinated water quality is comparable to that of MSF, given their similar processes [52].

In general, the operating principle of thermal distillation technologies is simple, but their operating and maintenance costs are high due to the high pressures and temperatures needed to operate them. Moreover, they have low desalination efficiency [56] and require large amounts of energy for the evaporation of water which needs sensitive and latent heat [47], making it difficult to implement them on a large scale [57].

5.2. Membrane desalination processes

Membrane technologies utilize various types of permeable membranes to separate and isolate salts and impurities on one side of the membrane, thereby achieving salt-water separation [56]. The most common membrane processes are RO, nano-filtration (NF), and electrodialysis (ED). The membrane characteristics required for effective separation, such as pore size and mechanical strength, will depend on the type of process.

The RO process is the most widely used membrane technology, and it involves forcing seawater through a semi-permeable membrane (water permeable, but not salt permeable) using a pumping system that requires an electrical supply. The hydraulic pressure applied must be higher than the osmotic pressure, which is related to the concentration of salts in the feed stream [57]. Therefore, the salt concentration directly affects the electrical energy consumption of the system and thus its operating cost (which is one of its main operating costs) [40]. Typically, these systems operate at pressures between 54 bar and 83 bar for seawater desalination [40].

Despite the development of energy-efficient RO systems, as well as energy recovery devices, which have resulted in decreasing the capital and operating costs of the system [16], the increased electrical energy demand to process high salinity solutions remains one of their primary challenges [50]. Additionally, the presence of fouling, defined as the process in which an undesirable material (foulant) adheres to the surface or pores of the membrane [58], is another issue that must be addressed as it can lead to blockage of the membrane and, eventually, complete plugging of the system [40]. Therefore, in order to maintain a constant permeate flow, an increase in the operating pressure will be required, resulting in higher operating costs [59] and reduced process efficiency. This will ultimately impact the overall performance of the process.

For this reason, RO systems typically require a pre-treatment stage, both physically and chemically [16], to ensure their proper operation and to reduce the risks posed to the membrane [57]. However, this also carries environmental risks due to the use of chemicals to control fouling, which could have an adverse impact on the sea [60,61]. For example, the use of coagulants such as ferric salts can cause the coloring of the outlet stream (called red brine) and thus increase the turbidity and reduce the light penetration in the water [62]. In terms of water quality, the distillate produced will depend on the initial quality of the feed stream, the membrane properties, and the operating pressure of the system [52]. However, it has been demonstrated that the quality of desalinated water tends to be lower than that obtained from thermal systems [63], and therefore in many cases a second desalination stage or supplementary process is required.

NF is a pressure-driven process with certain similarities to RO (in fact, its operation is between that of RO and ultrafiltration [64]) but it is capable of operating at lower pressures, higher flow rates, and with lower investment costs [65]. NF has a membrane pore structure that is larger than that of RO, allowing more salts to pass through it [66]. Generally, it has a high rejection rate for divalent ions (around 98%) [64], however, there are certain issues when it comes to the total removal of NaCl in desalination processes [59]. Despite this, some studies [67] have achieved quality results comparable to those of RO when used with salinized water. Ultimately, the choice between NF and other water treatments will depend on the quality requirements, the

quality of the input water, and the capacity required [67]. As is the case with RO, NF also presents problems with fouling control and difficulty in controlling the pore size of the membrane [68].

Another membrane process is the ED, which is an electro-membrane process in which ions are transported from one solution (the feed) to another via a membrane, due to the application of an electrical potential difference [66]. It should be noted that the cost of the process is proportional to the number of salts transported to the membrane, so it is recommended to use it for fluids with a low concentration of solids (between 8 g/L and 10 g/L) [49]. Furthermore, other membrane-based processes, such as microfiltration and ultrafiltration, are not recommended for desalination processes. Nevertheless, these technologies have found a market as a pre-treatment process for RO systems [49].

5.3. Problems of current desalination technologies

As has been seen, the increasing demand for fresh water coupled with its scarcity has led to the use of desalination technologies as one of the main solutions. Although these technologies have already reached a certain level of maturity, they still have challenges to overcome, particularly those related to the discharge of brine [49], high investment costs [56], and high energy consumption [45]. Concerning the latter, it has been noted that desalination processes can consume from 8 to 20 times more energy (thermal or electrical, depending on the process) than conventional surface water treatments [69]. For example, the current consumption of electric energy by desalination processes is 56 TWh, however, it is estimated that by 2040, this consumption would become the second-largest energy-intensive process in the entire water sector with 345 TWh, only surpassed by the water supply energy demand [70]. In addition, high energy consumption is often accompanied by increased greenhouse gas emissions [46]. This is especially true because many desalination systems are still powered by fossil fuels [71]. It is estimated that, overall, 23 kg of CO_2/m^3 of desalinated water are currently being released [63].

Moreover, the technologies mentioned above are designed to be economically viable in large-scale operations (in most cases, the scale is the most influential factor when it comes to capex). For example, in the case of RO, a typical current plant produces 0.1 Mm^3/d of water [72], while commercial electrolyzers do not exceed a power of 10 MW, which is equivalent to the use of approximately 125 m^3/d of water [26]. This illustrates the significant difference in scale between the two processes.

Therefore, it is necessary to find alternative desalination processes with reduced greenhouse gas emissions, lower energy requirements and that can be powered by renewable sources or waste heat [37], in order to sustainably meet the world's growing demand for fresh water and feed water for electrolyzers. In this regard, forward osmosis (FO), reverse electrodialysis (EDR) and membrane distillation (MD) are the principal emerging technologies on the market (the 1% of others, as seen in Figure 1).

FO consumes less energy than RO, since it does not require external hydraulic pressure and has a lower fouling tendency [50]. However, it still poses certain technological challenges in extracting water from the draw solution to regenerate the cyclic process [47]. For its part, EDR works similarly to ED (see section 5.2) but with the added capability of reversing the polarity of its electrodes during specific time intervals, enabling it to minimize fouling and remove deposited materials [47]. However, like ED, its energy consumption depends on the feed concentration, making it more suitable for solutions with low salinity. Finally, MD doesn't require a high electrical consumption and has the potential to be more energy efficient than other processes when valorising waste heat or renewable heat sources, which make it one of the most promising technologies to date for desalination.

5.4. Membrane distillation technology

MD is a non-isothermal membrane process that is based on the generation of a steam phase in a hot solution stream, close to the surface of a membrane [34]. The vapor will be able to pass through the membrane (the hot side of the system) and then condenses onto the cold side of the system, where cold distilled water circulates. This process is made possible by the use of hydrophobic membranes, which allow only the passage of steam, and volatile compounds, while retaining the liquid part in the hot stream (which contains dissolved salts and other non-volatile compounds) [73]. In this way, a permeate (distilled water) can be obtained on the cold side of the system. Figure 2 shows a diagram of a counter-current MD system.

The driving force of MD is the difference in partial vapor pressure between the hot and cold side of the system. This difference is responsible for converting some of the molecules in the supply liquid into vapor [48], thus initiating the mass transfer process described above. MD systems are considered thermal-driven since the partial pressure difference is related to the temperature gradient on the membrane sides [74]. In order for MD to be effective, a temperature difference of at least 20 °C must exist between the two sides of the system [75].

The membrane material and its characteristics are among the most important parameters for the successful operation of MD systems. As the physical barrier between the hot and cold side of the system, its properties will influence the heat and mass transfer. Generally, MD membranes have a pore size between 0.2 μm and 1 μm [76], with a porosity between 65% and 85% [77], a tortuosity regularly assumed to be 2 [78], and a thickness between 0.04 mm and 0.25 mm [79]. Polymers such as PTFE, PP, and PVDF are commonly used for the

fabrication of MD membranes [61], due to their ability to be modulated in terms of intrinsic properties and low surface tension [77].

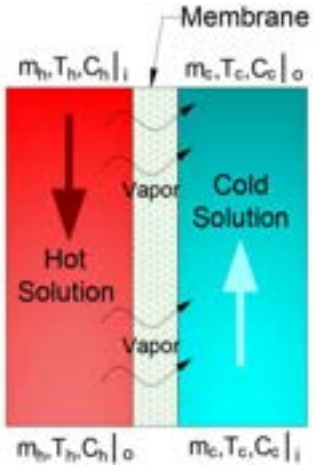

Figure. 2. Diagram of a counter-current MD system.

In addition to the previously mentioned points, MD technology has other advantages. For instance, it is almost insensitive to the initial concentration of the feed stream, which causes problems in other distillation systems [61], and has a high rejection factor, with leads to a theoretically complete separation [80]. Additionally, MD systems are robust, compact, and modular [73], thus reducing investment costs [34].

On the other hand, the main drawbacks of MD technology are its low permeate flow and high energy consumption [50] (cf. 5.4.1). The low permeate flow can be attributed to the air trapped in the membrane, which introduces resistance to the mass transfer [80], with a greater effect than on pressure-driven processes. The high energy consumption is due to MD being a phase change process, which requires a large amount of thermal energy [74], but at a low temperature.

Studies [39,81–84] have shown that distillates produced through MD technology can have electrical conductivities ranging from 2 and 5 µS/cm, with high salt rejection (higher than 99.7%). Furthermore, a second MD distillation stage can improve the purity of the distillate, reaching values near 0.7 µS/cm [81]. It has been found that the quality of the distillate is not affected by the initial operating conditions (temperatures, flows, concentrations) [39,82], due to the membrane, which does not allow for the passage of liquid. However, it is important to note that the operating conditions will influence the time required to achieve low-conductivity distillates since MD technology tends to start its operation producing distillates with high conductivity, which will decrease over time (generally taking a bit less than an hour) [82].

5.4.1. Comparison with other technologies

Table 2 shows a comparison of parameters between the main water desalination technologies used to date and MD technology.

Table 2. Comparison of water desalination technologies.

Parameter	RO	MSF	MED	MD
Electric consumption (kWh/m^3) [63]	3.7 - 8	2.5 - 5	2 - 2.5	0.6 - 1.8
Thermal energy consumption (kWh/m^3) [49]	-	190-390	230-390	100 - 800
Water quality (ppm TDS) [63]	200 - 500	10	10	10
Unit product cost (USD/m^3) [49]	0.52-0.56	0.52-1.75	0.52-1.01	No information
Maximal feed salinity (g/L) [43]	70	180	180	350
Water composition changes tolerance [57]	Very low	Medium - High	High	High
Fouling [57]	High	-	-	Low - Medium
CO_2 emissions (kgCO_2/m^3) [51]	1.75 - 2.79	5.56 -25	4.38 - 17.6	No information

Table 2 reveals that MD technology has several advantages over conventional technologies, and a comparison with the dominant technology in the market, the RO, reveals even more advantages. For example, MD is not limited by a maximum osmotic pressure [85], and the hydrostatic pressure required is much lower than that of RO systems [80], which allows for the use of less resistant materials. Additionally, the membrane required for MD is simpler and has a larger pore size, which reduces the risk of fouling [48], resulting in improved cost recovery [74].

In addition, focused on obtaining adequate water quality to feed water electrolyzers, it can be seen that RO yields the lowest quality among the compared technologies, due to its reliance on the quality of the input water.

Typically, at the industrial level, at least two RO stages are needed to achieve acceptable quality. On the other hand, thermal technologies, MED and MSF, yield better-quality water, albeit with somewhat higher conductivity than with MD [55,82].

Even though the amount of thermal energy needed for MD is much higher than for other systems, there is a critical point to consider: the thermal energy required differs in quality from the thermal systems. Conventional thermal systems require energy sources with temperatures above 90 °C for MSF and at least 70 °C for MED, while MD systems require flexible low-temperature heat, in the 40 °C to 90 °C range [86], making it more economically attractive [63]. Furthermore, the quality of the required heat provides opportunities to use alternative sources of heat, such as solar, wind, geothermal, or even waste heat, making the MD technology more environmentally attractive.

5.4.2. Potential use of waste heat

In this regard, the use of waste heat is versatile due to its various forms (liquid, gaseous or diffuse) and temperatures, which are specific to the industrial process from which they originate [71] and gives it different valorizations. However, its ease of use depends on aspects such as continuity, temperature range, heat transfer modes, and location between source and place of use [87]. Despite these barriers, there is immense potential for this resource to be exploited in various ways [87].

Estimating the existing total waste heat is complicated by the fact that it is difficult to quantify with certainty due to the constant changes in the overall energy mix [88] and changes and variations in the processes that generate this heat. Few studies have sought to quantify the potential of the waste heat field, yet, some estimations indicate that the total waste heat released at a global level would be between 68.2 PWh [87] and 72.7 PWh [88]. It is also estimated that the waste heat could reach 89.4 PWh by 2030 [88].

However, it should be noted that these projected values only reflect the amount of waste heat, not the amount of energy that can be converted into work, known as exergy [87]. Thus, an exergy analysis, taking into account the quality factors, known as the Carnot factor [88], related to the source temperature, is necessary to quantify the true potential of the waste heat that can be used [87]. To this end, it is necessary to recognize different temperature scales at which waste heat occurs. For example, according to the quantification of Forman et al. [87], 20.6% of the waste heat is above 300 °C (high quality), 16% is between 100 °C and 300 °C (medium quality) and the rest is below 100 °C (low quality). By applying the corresponding Carnot factors for each temperature range, and for each sector from which the waste heat originates, the authors obtained a theoretical waste heat potential of 13400 TWh, which is only about 20% of the total waste heat that can be recovered and used.

As can be seen, there is an abundance of waste heat resources that can be recovered and exploited. Moreover, when using this heat source, it is considered that its utilization will not add CO_2 emissions to the balance, as there is no additional fuel needed [71]. However, it is worth noting that it is not entirely free energy (although some studies consider an investment of 0 to simplify the calculations) since its use entails costs related to collection, transportation, processing, and operation, which in some cases may make the use of conventional energy sources more feasible [89]. For this reason, a technical-economic analysis should be carried out in each case of study to ensure the usefulness of the exploitation of this resource.

5.4.3. Potential coupling with hydrogen electrolyzers

The coupling of MD systems and green H_2 generation systems also presents multiple opportunities for exploiting waste heat. The electrochemical reaction of the electrolyzers generates residual heat, due to their inefficiencies [90], which is usually dissipated by a cooling water circuit. The operating temperature of the electrolyzers is typically between 50 °C and 90 °C (depending on the type of electrolyzer) [91,92], which has already been shown to be useful to powered district heating networks when the urban area is close to the electrolization plant [90,93].

Therefore, the heat dissipated by the electrolyzer has a quality that can be used by an MD system, which can be energetically powered by the cooling water of the system. Additionally, the regular configurations of electrolyzers AWE and PEME have certain heat exchangers (for refrigeration) [20] with potentially usable dissipated heat. Some examples are the KOH cooling system in the electrolyzer stack (in AWE systems) or the inter-stage cooling system in the hydrogen compression process.

Some studies have detailed figures on the heat dissipated during the operation of water electrolyzers. Tiktak [90] reported 171 MW of heat dissipated at a temperature of 77 °C while operating at a nominal production rate of 5.25 kg/s of H_2. Similarly, Burrin et al. [91] estimated 0.31 kW of heat at 75 °C during the generation of 18.7 kg/h of H_2. When taking into consideration the equivalence of kg of water required per kg of H_2 (as discussed in Section 3.2), it can be estimated that the electrolysis systems release 604 and 1120 kW/m^3 of required water, respectively. The potential to use this heat in MD systems can be clearly appreciated when compared with the energy demand values presented in Table 2. Despite the potential presented, the MD-green H_2 coupling has not been studied yet, so it is essential to promote these projects to dispel the uncertainties of these systems.

6. Conclusions

The present study conducted a comprehensive literature review of water distillation technologies oriented towards producing hydrogen using water electrolyzers that are powered by renewable electric energy (green H_2). These devices require water of a quality bordering on ultrapure to operate without the risks associated with their electrochemical reaction. Therefore, considering the projections of water requirements for a future green H_2 market, the most viable form of water treatment appears to be seawater desalination.

In this regard, today two large groups of technologies dominate the market: thermal technologies (25%) and membrane technologies, where the main and dominant is RO (69%). However, these technologies still present technical and economic challenges, including high investment costs, high energy consumption (either electrical or thermal), and carbon emissions (linked to the use of fossil fuels).

For this reason, several new technologies are being proposed as potential solutions to these challenges. Among them, membrane distillation technology presents the greatest potential, due to the quality of water it produces, its flexibility with different feed fluids, and its low-quality heat requirement, which opens the possibility of working with renewable heat sources and waste heat. The latter opens the door for the coupling of MD systems with green H_2 generation systems, as there is potential waste heat, in quantity and quality, during the electrochemical reaction on the electrolyzers that could be used to power the MD process. Nevertheless, this technology is still under development, and the study of being coupled with green H_2 generation systems has yet to be conducted, so there remain uncertainties to address.

Abstract:
In this paper a collaborative experience towards the development of a new joint master degree is presented. The design of the curriculum has as main pillars: a) to provide an interdisciplinary view and approach to advanced water treatment solutions, and b) the development of the curriculum is done according to the new challenges for Higher Education in Europe, therefore providing references of good practices with this respect. The experience is worth to be shared as in an immediate future the expected collaboration among Higher Education Institutions in Europe is to increase if an integrated and high quality Higher Education Area is to be developed. The ongoing reviewing/re-structuring process of higher education programmes provides the opportunity to promote new types and levels of learning new technologies and practices in and through pan-European collaboration. The proposal that is motivated by the need for a green approach to water treatment. Like many other industries, water and wastewater treatment plants also face the problem of a staffing shortage. Efficient and productive workers that are skilled in the business are necessary to properly manage water systems. Automation may be a potential solution to this shortage. Not only will it fill in the gaps of needed employment, but it will also put less stress on existing workers. To this aim the Next generation Industrial Control Engineering for Sustainable water system Treatment (NICEST) project is presented in this paper.

Keywords:
Water Engineering, Control Technology, .Higher Education

1. Introduction

There is by now (almost) no doubt that to establish joint collaborative experiences on curriculum design and the establishment of joint degrees in particular is one of the major challenges of the forecasted European Higher Education Area. [6] In particular to work for a joint degree puts on the table existing differences both on academic conception of courses and on established procedures for administrative matters. In fact, Feel Europe!! This could be a possible synthetic way of expressing one of the major characteristics asked for to the newly developed study programmes at European Level. Integration of parts of the curriculum to be offered by leading institutions (therefore taking advantage of acquired expertise) as well as offering the possibility of realising the different cultural experiences both from academic and social points of view.

To overcome these differences is not an easy task. It is the author's opinion that an actual barrier that avoids having a large number of experiences is the lack of knowledge on how to tackle such an interdisciplinary project or, even not knowing what are the problems that the consortium will need to face with.

This communication's aim is to present what the authors experienced as the road taken in order to establish an international joint master degree. It is intended to be a guideline both for the kind of problems that arise on such projects and suggestions for strategies that will help to face them. Different faces of the overall process are presented, highlighting the strategies to follow and the important points to take into account that may be possible source of problems.

Regarding the scope of the study programme, this is motivated by the need for a green approach to water treatment [1]. In fact, the water sector is a key one where digital innovation plays a key role looking forward to the European Green Deal challenge. The Water Sector is at the core of the environmental debate. Water is, quite simply, the most essential natural resource on the planet. Global water challenges affecting water resources, such as climate change, population growth, increasing urbanization and ageing infrastructure, continue to intensify. The European Green Deal is that response. It will drive us forward to climate neutrality by 2050 and at the same time focus on adaptation. The key strategy for the period 2019-2024 is and will be the Twin Transition to a green and digital economy firmly grounded in the objectives of the European Green Deal. No attempt to establish a Green Economy can be successful if it does not involve the water sector in all its facets. Like many other industries, water and wastewater treatment plants also face the problem of a staffing shortage. Efficient and productive workers that are skilled in the business are necessary to properly manage water systems. Automation may be a potential solution to this shortage. Not only will it fill in the gaps of needed employment, but it will also put less stress on existing workers. The ongoing reviewing/re-structuring process of higher education programmes provides the opportunity to promote new types and levels of learning new technologies and practices in and through pan- European collaboration. Currently, there is no programme offered in Europe similar to the one being proposed, nor to modern control systems technology nor with its application to the operation of water systems. The prospective master degree is expected to fulfil the demand for well-qualified personnel required with an enhanced capability for solving many of the water supply problems foreseen in the next 20 years.

On the basis of the two broad issues above, the rest of the paper presents first the rationale; in Section 2.; and innovative and added value of the intended study programme in Section 3.. The rest of the sections are aimed to provide a road-*like* view to help understand as well as to serve as starting point/reference for those that want to undertake a project like this one. Accordingly, Section 4. will present the three general axes to be considered. Those are developed in the corresponding subsections. Additional considerations regarding economic management, student services and transversal issues are reflected in Sections 6., 7. and 8., respectively. The paper end with some conclusions.

2. The topic: NICEST rationale

This study programme is motivated by the need for a green approach to water treatment. In fact, the water sector is a key one where digital innovation plays a key role looking forward to the European Green Deal challenge. The European Green Deal was stated as one of the six ambitions/objectives for Europe described by Ursula von der Leyen in 2019 [1]. The increase in global temperature, the depletion of natural resources and continued biodiversity loss, undermine our security and prosperity. The Water Sector is at the core of the environmental debate [2]. Water is, quite simply, the most essential natural resource on the planet. Global water challenges affecting water resources, such as climate change, population growth, increasing urbanization and ageing infrastructure, continue to intensify. The European Green Deal is that response. It will drive us forward to climate neutrality by 2050 and at the same time focus on adaptation. The key strategy for the period 2019-2024 is and will be the Twin Transition to a green and digital economy firmly grounded in the objectives of the European Green Deal. No attempt to establish a Green Economy can be successful if it does not involve the water sector in all its facets. An important advance towards such progress faithfully reflects the second factor of the Twin Transition: Digitalization.

The problem of diminishing clean fresh-water resources facing Southern Europe and most other parts of the world is very serious. Water is essential for life and is central to both industry and agriculture. The demands on water infrastructure are increasing and have to deal with population growth and climate change. Furthermore, in all Mediterranean and Middle Eastern countries, the scarcity of conventional freshwater resources poses a serious threat to their sustainable socio-economic development. In planning for water uses in various human activities, especially in such arid areas, a primary objective should be sustainable development. This target transcends national boundaries, demanding that society should utilize available water resources in a way that will ensure their availability for generations to come. In addition to political vision, water availability problems need technological know-how for their solution. Moreover, specific efforts are focused on water reclamation and reuse while the recovery of added value products and energy represents a challenging option under the water-energy concept. It is not surprising that both the United Nations and the US National Research Council indicated wastewater reuse as a yet untapped available water source. Water reuse is an integral element of sustainable water management, keeping a viable resource in the natural cycle, and allowing its preservation for future uses, at the same time meeting present supply requirements. According to UNESCO, improved wastewater treatment and increase in water reuse, as called for in Sustainable Development Goals Target 6.3 (Clean Water and Sanitation), will support the global transition to a sustainable circular economy. Hence, a selective approach for wastewater recovery to provide water at specific quality standards for different reuse objectives (industrial, agricultural and even potable) is nowadays desirable and technologically feasible. This ”fit-for-purpose” approach to water reuse could both save water and would reduce production cost and energy

demand by eliminating unnecessary treatment and long-range conveyance, as it typically aims at local reuses, but it requires appropriate plant and control configurations.

All of these issues, and the global challenges that lie ahead of us in the next few decades, mean that Environmental Engineering will rapidly become one of the most important areas of Engineering. Water resources protection, efficient water uses and recycling, air and soil pollution and materials and energy recovery from effluents and wastes are just a few of the problems that need to be tackled in order to assure sustainable growth of the world economy and ecosystem stability. These problems are relevant in both industrialized countries, where solutions are already being found and implemented, albeit not always at the necessary pace, and in developing countries, where interventions according to the state of the art of technology should be concurrent with ongoing development.

Many environmental problems are related to large scale, geographically distributed control system problems: the regional management of water and wastewater resources at basin scale are conceptually and technologically comparable to the management of a regional or national High Voltage Transmission system. The daily management and operation of a large wastewater treatment facility can be compared to a medium-scale industrial process, where optimization and real-time control can contribute to increased productivity and opportunities for water reuse (better effluent quality) and lower costs (mainly energy and process requirements). A similar situation can be found in waste incinerators with recovery of electrical and thermal energy. Unfortunately, this combination of knowledge has seldom crossed the realm of applied research and has never become part of an academic curriculum, except occasionally at taught postgraduate level.

Digital monitoring solutions can help to optimise the management and control of wastewater treatment plants, which may result in higher degrees of energy efficiency as well reductions in chemicals used and carbon or other gas emissions achieving at the same time an effluent of high quality; such an approach is becoming significant considering the variable composition of the influents and the strong effect of environmental conditions to the operation. Nevertheless, the achievement of an effluent of constant quality will allow for its reuse in various applications requiring safe water. Employing such tools, digital process information can be used to simulate possible configurations of a plant for varying design parameters (e.g. inflow conditions) in order to identify the optimal configuration of wastewater management and reuse systems at different scales and to determine the potential for extraction of valuable materials. With regards to data reporting processes, digital solutions can provide valuable input, with regards, for example, to water quality monitoring designed to support the implementation of the Water Framework Directive (WFD). Green innovative technology has been improving the way we treat water so that the environmental footprint left by wastewater treatment plants is smaller and less impactful. With automation and innovation moving forward, we can continue to expand on these ecofriendly technologies to make wastewater treatment greener.

All the previous issues and scenarios, moved us towards the need for the development of a Joint Degree Master Programme entitled Next generation Industrial Control Engineering for Sustainable water system Treatment (NICEST) according to the European Higher Education principles. The objective of this Master Programme is to fill a rapidly developing gap that is emerging for graduates that are trained in key processes and management associated with water supply and reuse. There is great demand for such graduates at the

3. NICEST added value

Innovations in the water domain are fragmented and often experimented at small scales. Thus, there is a need to strengthen the innovation capacity of the water industry. Even a 1% increase in the growth rate of the water industry could create up to 20,000 new Jobs - from Water Reuse in Europe - Relevant guidelines, needs for and barriers to innovation, Publications Office of the European Union: JRC92582).

There is a wide variety of master's degrees in various aspects of environmental engineering outside Europe coming from the USA and with small but developing groups in Asian counties. From a review carried out by this Consortium, as well as from other sources, we can conclude that conventional water treatments are well covered in EU degrees, either from the technology or the management viewpoint. However, there is a real and urgent need for specialised and regular training in newly developed technologies and areas not covered by the current schemes. There are several MSc programmes covering conventional municipal and industrial water treatment. Some of the programmes are aimed at the science and technology of water provision, while others are more focused on the water management systems.

However, curricula analysis demonstrates a clear skills mismatch related to the employers' expectations. The current master-level curricula in water seldom involve Big Data, IoT or other digitalisation approaches or results, and on some occasions, process simulations. The industry is also occupied with further development of conventional solutions. It is important to bridge the historical gap between control engineers and process specialists in order to overcome the many technological and physical challenges in the sector and support the existing EU research and innovation initiatives.

The NICEST scheme offers a unique programme of education in Desalination and Water Treatment Technologies. It addresses the major developing areas of the subject giving the prospective student state of the art knowledge and opportunities to specialise in the major areas of the subject, Desalination, Water Reuse and Wastewater Control Systems. These are key areas of technology and infrastructure in a developing world that will be required to deal with the threats of climate change and help with conflict resolution based on resources. The Master's degree will fulfil the demand for well-qualified personnel required with an enhanced capability for solving many of the water supply problems foreseen in the next 20 years. It will also support these rapidly developing commercial areas of water technology worldwide. Currently, there is no programme offered in Europe similar to the one being proposed.

Because of the approach an also because the water thematic field is at the forefront of the EU and local governments agenda, the project is aligned with European policies:

- supports strengthening the competitiveness of EU water business through talent and innovation in higher education according to the Strategic framework for European cooperation in education and training [6]. It also addresses revitalisation of educational focus towards the growing mismatch between the digital skills water specialists acquire and the demand on the labour market accounting the water digitalisation trend and supporting development towards Digital Single Market.
- focuses on digital technology for teaching and learning, developing digital competences and skills and improving education through better data analysis and foresight meeting the goals of the EU Digital Education Action plan. [8]
- is designed to support the implementation of the European policy agenda for growth, jobs, equity and social inclusion referring to the importance of education and employment. This will transform the teaching and learning of digital skills in a lifelong learning perspective. This will further develop digital skills for the digital economy, e.g. upskilling and reskilling workers and jobseekers, career advice and guidance.

4. Joint Study Programme elements

The road presented arises from an international experience in new Curriculum Development from the perspective of the new challenges for Higher Education in Europe, and with an interdisciplinary approach to content design [3], [7]. One of the factors stressed in the communication is the need for collaborative work among academic and administrative staff. To run an international joint degree implies different procedures than the ones actually running on standard national degrees.

Different faces of the overall process are presented, highlighting the strategies to follow and the important points to take into account that may be possible source of problems:

- Curriculum Structure: topics like the following ones, among others, should be taken into consideration: ECTS adopted as the central concept on the curriculum structure; Mobility designed as an integral part of the curriculum; Integration Actions to let the students know the corresponding local cultures; Teaching and Learning methods are programmed as a mixture of classical (frontal teaching) and modern (read e-learning and web based) methods.
- Curriculum definition management: Adopted roles and procedures: (i) the use of tools for collaborative work is showed to play a central role in the sharing of information and in the development of coordination and communication aspects among partners, (ii) creation of Committees (steering, admission, quality) to tackle the different management aspects and assuring all partners are involved in the different tasks, etc
- Academic, Administrative Procedures and legal aspects: with no doubt different legislations will go into conflict. People coming from academia are not generally aware of all the pinpoints concerning these issues. In addition to put together administrative staff from the different partner members, joint and collaborative work with administrative staff is a must in order to guarantee the success of the experience. The authors are a representative of this collaborative work.

On a broad sense, the idea is to expose on a clear way the implications of this kind of ventures trying to identify the cornerstones of the process in order to assure as much as possible the success of the experience. The sections that follow are organised in such a way that constitute a first step towards a practical guide of the different aspects to be considered. It is a fact that the actual lack of homogeneity among different national legislations and national degrees structure across Europe constitute a continuous source for difficulties and barriers that are to be solved. This situation constitutes an extra reason for a clear as possible guided road to the establishment of an international joint degree.

4.1. Curriculum Structure

The definition of the curriculum should be done from a holistic point of view. It is a usual practice just to put together modules offered at the partner universities in order to generate the global master offer. This usually provides a curriculum with no added value. One of the important points the consortium has to be able to highlight is the added value of the joint degree with respect to the individual courses offered at the partner universities: something that cannot be done by the partners on their own way.

The design of the curriculum is intended to be done on a top-down basis. Starting from the general goals that the consortium is committed to meet and melting down to de details of each one of the integrating modules.

There are some basic questions the consortium has to fix. Even sometimes they seem too basic and obvious it is important to agree on every point from the very beginning. They can by classified on the basis of the aforementioned top-down manner. General Questions at degree level:

- Degree offered (Joint degree, double degree): It should become clear from the very beginning if all partner institutions can award a joint degree (it may depend on local regulations and on each country legal framework) or if double degree awarding is needed. All EHEA countries are supposed to adapt their legal frameworks according to the Bologna process standards prior 2010. To obtain a Joint Degree, a minimum of one semester mobility has to be done to another partner institution (host university/ies).
- Diploma Supplement: Will the Diploma supplement be used? If so the form and content should be agreed.
- What will be the Language of instruction? Use of local languages will introduce the need for deep knowledge of different languages on the students. It is therefore natural to ask for a common language for instruction even local languages are to be introduced in order to help the introduction of local culture settings and to help students
- What will be the mode of study? (full time basis, distance learning based, ...)
- What will be the duration of study? 12 months, 24 months.

These questions can be identified as operational aspects. However, the consortium has also to be able to answer content related questions like: What is the added value of the programme with respect to existing studies? What are the learning outcomes/competences/skills? Professional Qualifications?

With respect to the course structure it is important to think on mobility aspects. What kind of curriculum is desired?

- Will the student we allowed to choose a path from the very beginning? This means the initial hosting institution may not be the same for all the students.
- Will there be the possibility of taking the same modules in more than one institution? This situation will introduce elements of choice based on geographical location more than on educational content. Therefore an unbalanced flow of students may be generated.

Advantage of the local expertise of the partners should be taken and the corresponding specialisations or elective options offered.

At module level, the description suggested from the ECTS User's guide [3] is to be employed. A common module description has to be adopted by all partners in order to facilitate both, coherent information to students as well as transfer of grading and student records information.

4.1.1. Local Constraints

When defining the global structure of the study programme it should be beard in mind that local approvals will be needed from each partner institution (and, in some cases from the local governments). This raises the point that the final structure of the programme should accomplish with local constraints:

- Do all the partners understand and apply the ECTS under the same terms?
- What is the number of elective credits to be offered?
- Is it mandatory to assign a minimum number of credits to the Master Thesis?
- Should the programme assure methodological and/or local culture credits?

The existing local regulations at national level will establish if the awarded degree can be a joint degree or a double degree. For a joint degree it will be needed that all partners be in disposition to award a joint degree.

4.2. Curriculum definition management

4.3. Academic, Administrative Procedures and legal aspects

Admission to the programme is one of the important points the consortium has to agree on. Possibly, each partner institution will have its own procedures and selection criteria. The possible conflicts have to be detected as early as possible. Therefore, each partner has to provide a detailed description of the procedures, required information and documentation the student has to provide as well as the minimum requirements; according to the corresponding national legislation; for a student to access to the degree. Therefore:

- Common standards for admission should be established: mandatory admission requirements. These standards have to accomplish with all institutions requirements. Required documents have to be legalised by at least one of the participating institutions embassies, and the rest should recognise them. It is also advisable that all institutions accept documents officially translated in English or any other agreed language. All these recognitions will make easier the legal procedures that non-EU students will have to follow.
- Common application procedure should be agreed and put in place by the coordinating institution as the consortium secretariat has to be the contact and entering point to the study programme. Note this means that just one application form will be available and that this application form may not be that of any partner
- Joint student selection procedure should be organised by the coordinating institution. The criteria on the basis the applicants will be ranked should be clear and agreed. This will allow to create an applicant scale on the basis of; for example; Accepted / Waiting List / Accept to Waiting List / Cannot Accept

During the entire admission process, staff from the consortium secretariat should be in touch with the candidate and inform him/her on actions to be taken, missing / incomplete documents etc. In addition, dates and timing for application have to be announced. Once the Admission Committee has reached its decision, it is recommended that successful candidates are put in touch with local accommodation offices so that suitable accommodation can be arranged in a timely manner.

Special attention should be put into the troubles some third country students may have in getting the corresponding visas in order to enter to the partner institutions countries. For example, the visa may only be for 6 months. In addition the student may be required to be in their home country to get the visa. This is not a problem for the firs country he/she is to visit. However if the mobility requires the visit to another country this may imply an extra travel. Therefore to be taken in to account in order to minimize foreign student travel.

In case the master is going to deliver a double/multiple degree, every institution will need a certified copy of all admission and registration documents, having to update the academic transcript of all those students that are going to receive the degree issued by their institution (those spending at least one semester).

5. Academic Management

Academic management will be one of the major tasks coordinated by the consortium secretariat and will encompass a sequence of tasks that will follow the life of the student within the programme from its very beginning.

The Consortium's Secretariat will keep the full student record in order to monitor progress, to help the preparation of the Diploma Supplement and other actions requiring the full students' record. On the other hand, host institutions will provide the Secretariat with the corresponding semester qualifications, so that it can update students? academic files. This way the consortium secretariat will be in charge of providing the agreed degree and Diploma Supplement.

As the Consortium's Secretariat is to centralise the student's records, at the end of each semester the marks of each student should be communicated to the Secretariat. For this matter, the definition of the Examination Boards facilitates a communication framework among local institutions and Secretariat. The local Examination Boards will be the local committee that gives validity to the marks obtained by the students during the semester and officially communicates (by using a common agreed form) the results to the Secretariat.

6. Economic Management

As the access point to the programme, the consortium secretariat is the appropriate body to be in charge of the economic management of the consortium. This way the consortium secretariat will receive the agreed fees form the students and distribute them to the partner institutions according to the local costs per enrolled student.

When calculating the registration and administration fees, the consortium has to be sure that the amount will cover official fees at each institution. It is a must that all European students pay the same fee. Third country students' fees may differ.

Different national/local rules concerning fees should be solved at consortium level. This way it is preferable that the student.

In order to avoid problems, it is advisory to establish, on a yearly basis:

- What are the fees to be transferred from the secretariat to the partner universities (by student per semester) depending n the amount of ECTS credits. - Is there any fixed amount devoted to cover administration costs? - Regular meetings of the different meetings are also to be covered. They need to be included into the cost provision. - Publicity and web hosting - Language courses

An interesting option that has also to be considered is the provision of study grants directly from the consortium. If there is the possibility of having sponsors from industry the consortium may consider the possibility of granting some students per year.

7. Student Services

It is important to provide the students with a minimum level of services that guarantee a smooth integration into the local social life as well as facilitate enrolment and development of the lecturing and study activities while the stay in one of the institutions.

The members of the consortium should engage themselves in helping students with incoming procedures such as finding housing and ensure that students will have access to language courses, libraries and canteens as well as to the services of the respective International Offices.

Before any mobility, consortium institutions have to provide legal advice to students, regarding visa requirements to destiny country: how long in advance they have to ask for the visa, required documents, etc. Every European country has its own legislation and requirements, and students needs at least a 6 months stay permit.

In addition it is encouraged to provide a personal faculty advisor, chosen from the teaching staff, which will be assigned to each student. The advisor will help the student for particular needs in the curriculum and in the everyday life. In addition, non academic counselling will be provided by trained counsellors form the student support services

8. Transversal and Good Practice Considerations

The elaboration of joint ventures provides a framework for the application of intercultural integration. Therefore, it is desired for the partners to promote the creation of integrated language programmes and cultural integration. This way the students will undertake other activities for improving their language skills and their knowledge of culture of the host country. Typically these classes will include the written and spoken language and/or the culture and civilization of the host country.

A practical way of helping foreign students integration is to provide them with a manual with information on each university / surrounding, structures, procedures, assistance, language tuition, etc

It is also advisable to have a Master website where all this information can be facilitated.

The implemented procedures should guarantee equal opportunities and rights between male and female. Likewise, it is important to assure easy accessibility to any disabled scholars and students.

9. NICEST Curriculum Structure

The NICEST degree programme aims to provide the student with a thorough knowledge in the field of advanced water treatment and particularly in technologies such as saline water desalination and wastewater treatment and reuse. The programme will comprise different teaching approaches, expertise and research competencies of the participating institutions. It reflects the specific experiences of the involved departments, realises important synergies, and gives preference to the best available and most-up-to-date modules in each field.

The determination of the final academic programme with the detail of the modules to be offered and specific syllabus is one of the purposes of this EMDM project. However, because of the expertise contributed by each partner member, an initial structure of the curriculum has been outlined. It exploits the expertise and international reputation of each one of the consortium partner members, so each partner will contribute to the design of the NICEST curriculum by bringing specific competences and skills corresponding to their area of expertise. In some specific cases, for the benefit of accounting for the best specialists and in favour of a rich consortium, academic collaboration between two institutions is expected during the common first semesters.

The structure of the academic programme is reflected in Figure (1). The overall view shows the two years structure, with the academic semesters and interlaced events such as the integration week, summer school and graduation event.

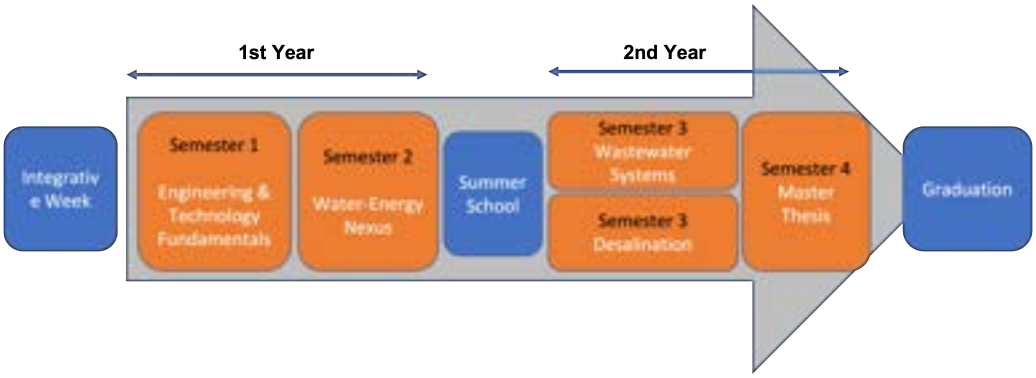

Figure 1: Curriculum degree overview

- Wellcome Integration days: This will provide the first contact of the students with the NICEST Consortium. It is proposed to take place in one place that is not mandatory on the curricular itinerary. This way students will have the possibility can get in touch with the partner and get knowledge about the local facts. The new students will get the opportunity to meet the alumni from the previous cohort who are graduating at the same time.
- Summer School: This will be intended to provide a transition between the fundamental, more generic courses, of the first year to the second year specialisations. It will be organised on a partner institution different from the welcome, integration week. The Summer School will allow for presenting specific topics related to water treatment, also some topics not covered within the study programme (legal issues for example) with the participation of invited guest speakers.
- Graduation event: The graduation ceremony will be organised after the Master's Thesis defence. As previously commented, the idea is to make it coincident, or at least to overlap somehow, with the integration week in order to favour the interaction of recently graduating and newcomers.

Intended structure is:

- Common first year where the basics of Industrial Control, process engineering, sustainability and environmental management, biological processes and aspects related to industrial communication systems and cybersecurity are covered. This first year will be delivered at UAB (Barcelona, Spain) and ULE (Leon, Spain). The second semester will concentrate on what we called the water-energy nexus. This is intended to cover aspects related to energy usage and renewable energies for water treatment. This is a transversal issue that becomes more and more important whatever the water sector we can refer. This second semester will be delivered in Greece with UTH & IHU (Greece) with the research centre CERTH as an associate partner.
- The second year is characterised, at each institution, by the focus on project/specialist work, with courses that reflect the different areas of special expertise of each of the partner institutions. The following specialisation courses are identified at this stage: wastewater treatment UGA & CRA (Romania) and Desalination Engineering ULPGC (Las Palmas, Spain)
- Master project according to the expertise but including co-supervision with an external advisor that complements with needed engineering and technological aspects.

Figure (2) summarises the degree structure and prospective list of modules.

10. Conclusions

In this communication a rough description of the aspects concerned when addressing the conception and design of an international joint degree has been presented. The sections have been structures in order to classify the main points to be addressed and questions to be tackled. The description is by no means far from complete but can be taken as a global picture, therefore a starting point.

Abstract:

This study aims to develop a high-water-yield adsorption desalination system by sorbents screening and lab-scale prototype testing, for future application on board of vessels. For sorbents optimization, silica gel-30%LiCl and vermiculite-45%LiCl composites were developed. The sorption isobars and sorption kinetics were measured and the results contributed to further calculations of SDWP (Specific Daily Water Production). Silica gel-30%LiCl composite was chosen as the optimized one with the highest SDWP. Afterwards, the ad/desorption dynamics of the adsorber made of finned flat-tubes heat exchanger and silica gel-30% LiCl composites were tested in a T-LTJ (thermal large temperature jump) adsorption apparatus. The obtained results were used to calculate the SDWP and optimized cycle time and to evaluate the performances of three system designs (2-reactors, 3-reactors and 4-reactors). The design of 3-reactors was selected, which can reach an SDWP as high as 69 m^3/tonne/day under the condition of $T_{eva/cond}$=20 °C and T_{de}=80 °C.

Keywords:

Adsorption desalination; Silica gel; LiCl; Water uptake; Sorption dynamics.

1. Introduction

Water scarcity was listed as the top 5 global risks in terms of potential impact by the World Economic Forum since 2012 [1]. Desalination has served as the governing technology to provide potable water since the 1980s [2]. Although commercial desalination plants like the multi-stage flash (MSF) are developing rapidly, their drawbacks of high energy consumption and negative environmental impacts [3] lead to the requirement of developing new desalination technologies. Adsorption desalination technology is proposed as a novel desalination method, where the sorbents extract water vapour from the saline water in the sorption process, and such adsorbed water will be released and condensed into potable water in the desorption process. Its dominant advantages are the utilization of renewable and waste heat energy and high-quality produced water [4].

The adsorption desalination technology is still in the early research stage, and the previous research interest lies in verifying the validity of freshwater production [5,6] and proposing advanced system configurations like the 2-evaporator cycle and multistage reactors [7,8]. Despite a large number of sorbents have been fully studied in other adsorption-based systems (adsorption cooling, thermal energy storage, etc.), only limited types of sorbents have been studied. Silica gel and zeolite are the most utilized sorbents for adsorption desalination systems by now, they have good hydrothermal stability, but their cyclic water uptake is lower than chemical sorbents and composite sorbents and the obtained SDWP in the system is generally lower than 15 m^3/tonne/day [9]. Composite sorbents [10] are regarded as the most promising sorbents for their high water uptake amount and tailored sorption properties. However, composite sorbents have not been widely studied for desalination applications. Besides the sorbents, the investigation of the performances in practical systems is also significant. Ad/desorption dynamics are critical to evaluate the operation performance, which is also not so extensively studied in previous publications. Thus, this study developed two types of LiCl-based composite to select the optimized one, whose ad/desorption dynamics in practical desalination systems were experimentally studied, resulting in the development of a high-water-yield system. The optimization of a composite sorbent for desalination purposes is here reported in details from the material development up to the lab-scale testing.

2. Materials synthesis and characterizations

2.1. Materials synthesis

The dry impregnation method was used to develop the silica gel-30%LiCl and vermiculite-45%LiCl composites. Briefly, the dry silica gel (pore size 8.377 nm, particle size 0.5-0.8 mm) or expanded vermiculite (pore size >20 nm, particle size 1.7-2.4 mm) was mixed with LiCl aqueous solution (its volume equals the total pore volume of the matrix and the contained salt mass equals the objective required amount) drop by drop, then composites were obtained after drying in an oven.

2.2. Sorption isobars and sorption kinetics

The sorption isobars of the sorbents were measured by the dynamic vapor sorption (DVS) instrument. The adsorption isobars under 17.21, 23.60 and 42.83 mbar were tested, the results are shown in Figure. 1. It shows that both composites experience multistage sorption process, including physisorption, hydration reaction + deliquescence and solution absorption. A hysteresis loop appears for silica gel-30%LiCl in the full range except for the solution absorption, possibly caused by the capillary phenomenon. No hysteresis loop appears for vermiculite-45%LiCl since its macropores have negligible impacts on the sorption behavior of the LiCl. Generally, the sorption amount increases with the increased vapor pressure or the decreased temperature. Vermiculite-45%LiCl can obtain higher sorption capacity than silica gel-30%LiCl under the same operation condition, owning to its higher salt concentration. The D-A (Dubinin–Astakhov) equation derived from the Polanyi theory was utilized to better describe the equilibrium sorption capacity under various operation conditions:

$$w = w_0 \, e^{-(k \, \Delta F^n)} \qquad [\mathrm{g/g}] \tag{1}$$

where w_0 [g/g] is the maximum sorption capacity, both k [s^{-1}] and n are fitting parameters. ΔF is the free sorption potential and can be calculated by:

$$\Delta F = R \, T \ln\left(\frac{p_{sat}}{p}\right) \qquad [\mathrm{kJ/kg}] \tag{2}$$

The parameters of Eqn.(1) and (2) were summaried in our previous publication [11].

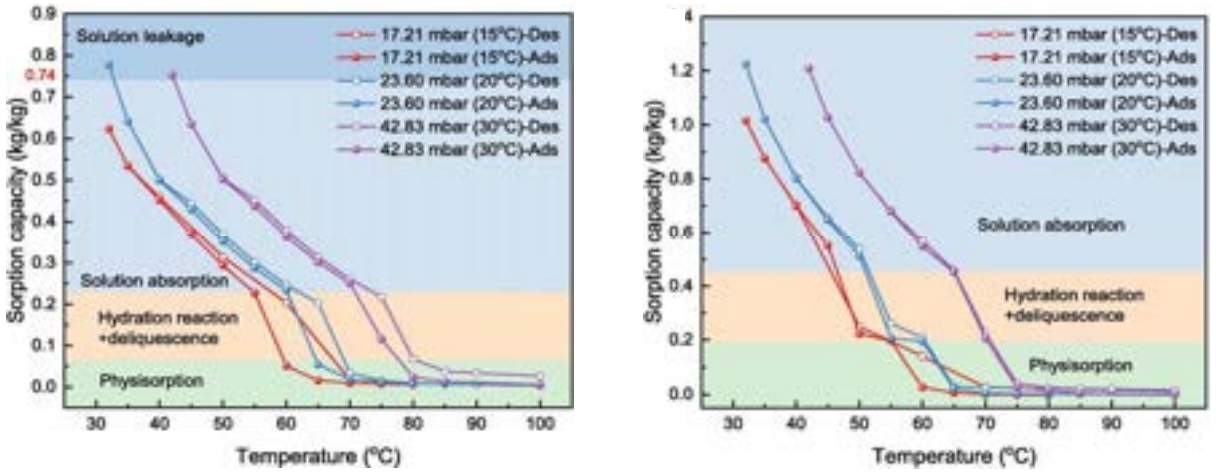

Figure. 1. The sorption isobar curves of (a) silica gel-30%LiCl and (b) vermiculite-45%LiCl composite [11].

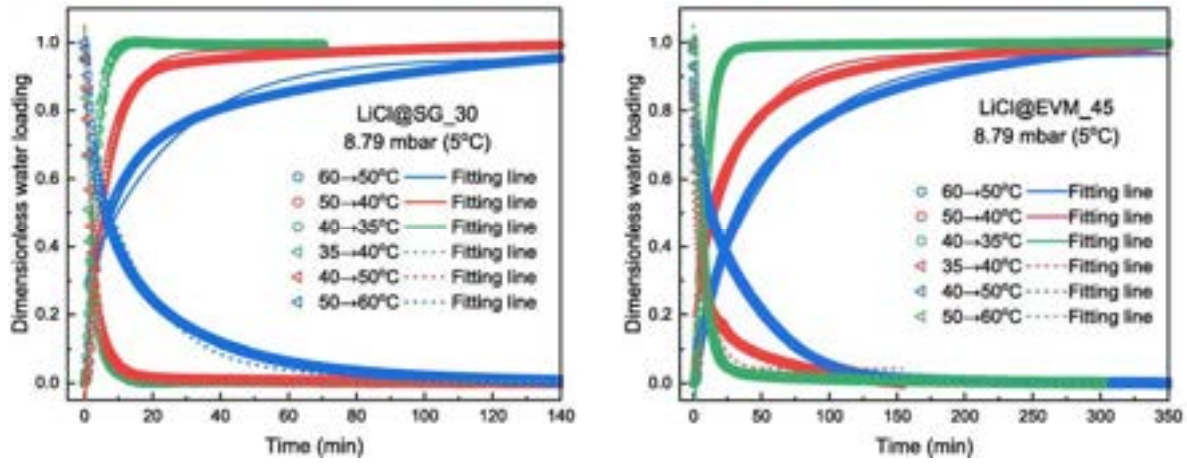
Besides sorption equilibrium, sorption kinetic represents another important aspect to evaluate the achievable sorption properties, and it can be used to calculate the SDWP altogether with sorption equilibrium data. The ad/desorption kinetics at different temperature jump at 8.79, 17.21 and 31.98 mbar were measured by the DVS instrument. Partial results are depicted by Figure. 3. The commonly utilized linear driving force (LDF) model [12] is used to obtain the kinetics coefficient (k) for the evaluation of the sorption/desorption rate:

$$\frac{dw}{dt} = k \, (w_\infty - w) \qquad [\mathrm{g/(g \cdot s)}] \tag{3}$$

In general, the sorption rates of silica gel-30%LiCl and vermiculite-45%LiCl composites are much slower than the ones achieved by pure physical adsorbents commonly used in adsorption machines, such as silica gel and zeolites. This is due to the slower reaction rate of the salt-water hydration reaction as well as to the higher sorption capacity of the composites. Nevertheless, looking at the results reported in Figure. 2, a clear difference can be identified also between composites. Indeed, thanks to the mesoporous structure of the silica gel, the crystal size of the embedded salt is much smaller than the one inside the macropores of the vermiculite. This causes a much faster reaction in silica gel-based composite.

Accordingly, for a lab-scale comparison, the composite embedding LiCl into silica gel was selected to be compared against the reference microporous silica gel, usually applied in adsorption chillers.



(a) (b)

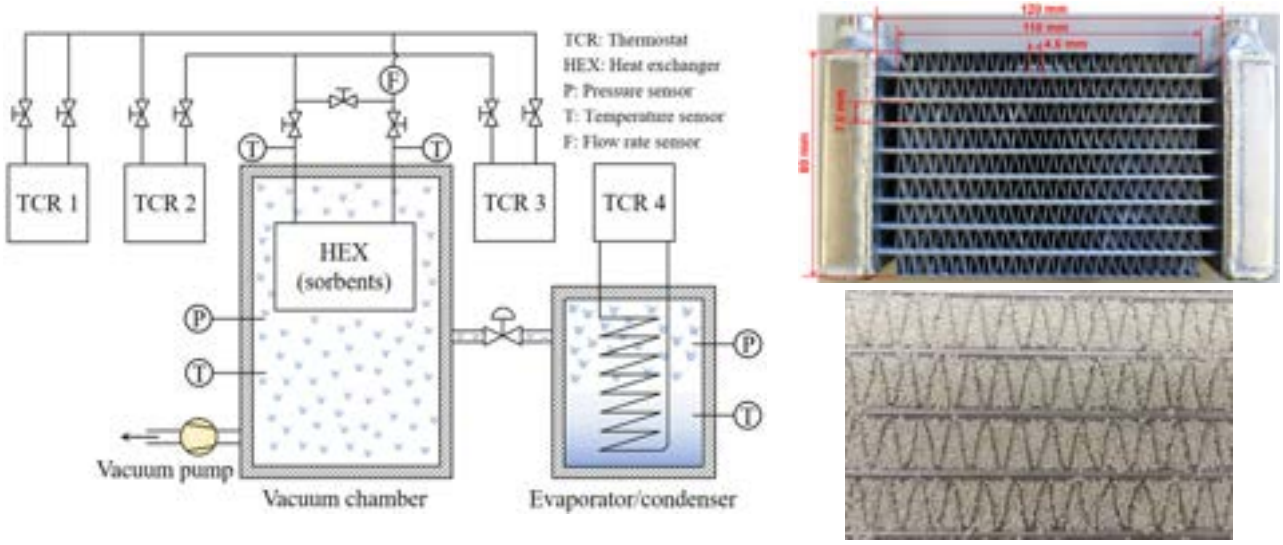
Figure. 3. The ad/desorption kinetics curves of (a) silica gel-30%LiCl and (b) vermiculite-45%LiCl composite [11].

3. Lab-scale adsorption desalination system

3.1. Experimental apparatus and methods

The lab-scale testing was performed aiming at investigating the adsorption kinetic performance of a small-scale adsorber, thus deriving the achievable performance in terms of cooling and desalination capacity.

The applied testing apparatus is reported in the literature as thermal large temperature jump (T-LTJ) (see Figure. 4a). It consists of a vacuum chamber, an evaporator/condenser, four thermostats and a vacuum pump. A finned flat-tubes aluminum heat exchanger (see Figure. 4b) serves as the ad/desorber, and 74.4 g sorbent particles were packed between the fins. Fast temperature jumps/drops are operated by quickly switching the valves after reaching desorption/adsorption equilibrium, aiming to simulate practical adsorption and desorption process.



(a) (b)

Figure. 4. (a) Schematic diagram of the T-LTJ testing system and (b) pictures of the blank heat exchanger and the heat exchanger packed with silica gel-30% LiCl [13].

The testing approach is based on the evaluation of the temperature difference measured at the inlet and the outlet of the adsorber during reference adsorption cycles. Due to the exothermic reaction of the adsorption process, the heat transfer fluid shows a temperature increase at the beginning of the test, due to the high sorption rate, followed by a continuous decreasing caused by the reduction of the sorption rate due to the saturation of the material occurring.

The sorption kinetic rate is then evaluated by analysing the decay (often exponential) of the ΔT measured and deriving typical parameters, such as the characteristic times and the average power, that can be employed to compare different materials and heat exchanger configurations. An uncertainty analysis of the method showed an accuracy in the range between 5% and 8% depending on the operating conditions.

3.2. Experimental results

Following the above introduced description of the methodology,the $\Delta T_{ad/de}$ contributed by the ad/desorption process is calculated by:

$$\Delta T_{ad/de}(t)=\Delta T_{ov}(t)-\Delta T_{bl}(t) \quad (4)$$

where ΔT_{ov} identifies the temperature differences of the inlet and outlet heat transfer fluid of the adsorber under ad/desorption mode, and ΔT_{bl} is this temperature difference of the related blank test, which is needed to depurate the test by the sensible heating and cooling effect of the inert masses (such as the metal of the heat exchanger and the sorbent material thermal capacity).

As demonstrated in previous publications [13], the $\Delta T_{ad/de}$ curves can be well fitted using the exponential function under most operation conditions:

$$\Delta T_{ad/de}(t) = \Delta T_{\infty} + \Delta T_0 \cdot \exp(-\frac{t}{\tau_{ad/de}}) \quad (5)$$

Both adsorption and desorption tests were carried out over the adsorber filled with the composite and the microporous silica gel. For the sake of brevity, only some of the results obtained on the composite sorbent are reported below.

Figure. 5a reports a comparison among different adsorption kinetic curves obtained while testing the composite sorbent, varying the reference desorption temperature. As expected at high temperature the adsorption capacity and thus the measured ΔT is higher, but, overall, the adsorption kinetic is comparable when the reference desorption temperature is varied.

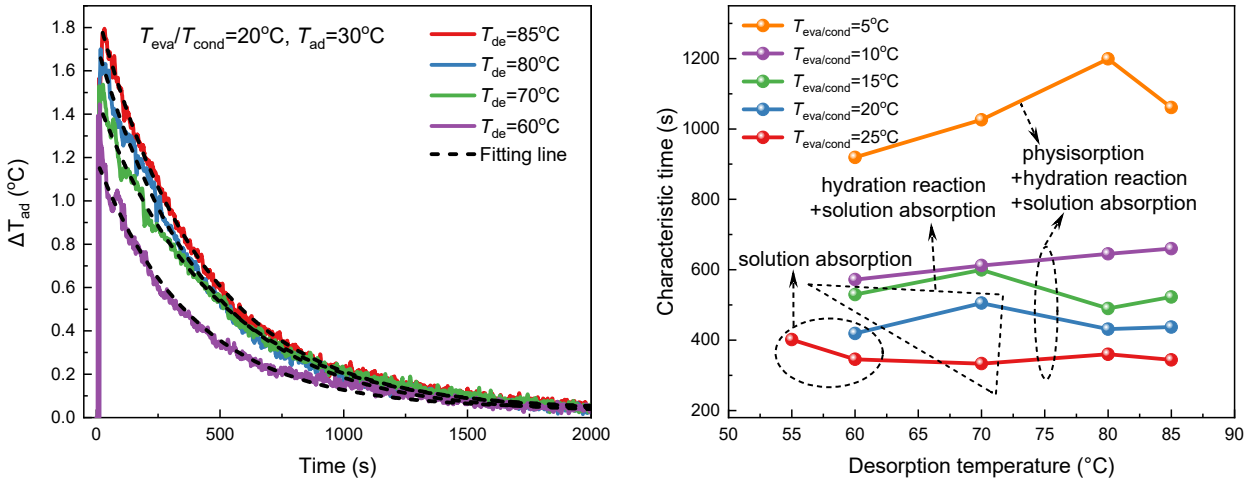


Figure. 6. (a) Comparison of different adsorption runs measured over the composite sorbent and (b) comparison of the achieved characteristic times for all the tests performed [14].

To investigate the effect of the boundary conditions over the kinetic performance, a large set of tests varying different boundaries were performed, and the characteristic times were calculated. Figure. 7b compares the different characteristic times as a function of the reference desorption temperature and evaporation/condensation temperature. As highlighted, the desorption temperature does not play a critical role, while the main difference is obtained by varying the evaporation/condensation temperature. Indeed, the kinetic performance increase by increasing the evaporation/condensation temperature. This can be justified by the higher absolute water vapor pressure inside the testing chamber at higher evaporation/condensation temperature. This reduces the mass transfer resistance across the material packed between the fins of the heat exchanger, thus minimizing the time to reach the equilibrium (i.e. maximizing the kinetics).

Figure. 8a compares the achievable desorption kinetic for two different desorption temperatures, namely, 60 °C and 80 °C, at the same evaporation/condensation temperature, 20 °C. As expected, there is a clear increase in the measured temperature difference passing from 60 °C to 80 °C, due to the higher degree of reaction between water vapor and embedded salt. Similarly, a comparable effect can be highlighted when the evaporation/condensation temperature increases, as reported in Figure. 9b.

Overall, from a direct comparison of adsorption and desorption kinetic performance under similar conditions, usually the desorption run is between 2 and 3 times faster than the adsorption run. This can be ascribed to the

higher pressure gradient occurring between the adsorber and the condenser during the desorption phase, compared to the same existing during the adsorption between evaporator and adsorber, that reduces the mass transfer resistance, thus allowing the vapor leaving the adsorber quickly.

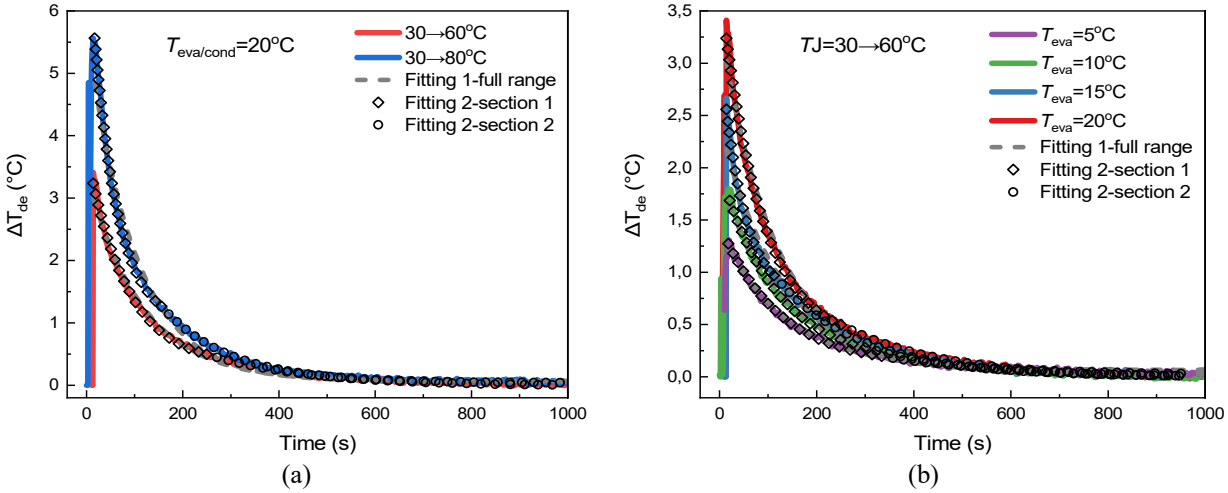

Figure. 10. (a) Effect of the desorption temperature on the sorption kinetic for the composite sorbent and (b) effect of the condensation temperature for the same configuration [14].

3.3. SDWP calculation and preliminary design for a large-scale desalination unit

As already mentioned, one of the most relevant performance indicators to be considered for an adsorption desalination unit is the specific daily water production (SDWP), namely, the volume of desalinated water produced daily per mass of adsorbent material employed, as reported below.

$$SDWP = \frac{86400\left[\frac{s}{day}\right]}{t_{cycle}}(w_{ad} - w_{de})\left[\frac{\frac{m^3}{tonne}}{day}\right] \quad (6)$$

This performance is strongly depending on the adsorption equilibrium difference processed during the cycle (w_{ad}-w_{de}) as well as on the sorption kinetic which is influencing the operating cycle time. Increasing the sorption difference and decreasing the cycle time lead to an overall SDWP enhancement.

Starting from the small-scale testing in the lab, the SDWP for the composite silica-gel/LiCl was calculated for all the conditions tested, as summarized in Table. 1. As it can be highlighted, the SDWP is quite limited at low evaporation/condensation temperatures and it is also almost unaffected under these conditions by the desorption temperature. Differently, as soon as the evaporation/condensation temperature overcomes a certain threshold, i.e. 15 °C, the SDWP increases and shows a relevant difference when the desorption temperature raises from 60 °C and 80 °C. This is justified by the higher amount of water vapor exchanged which does not affect negatively the sorption kinetic.

In general, the composite sorbent can guarantee a SDWP increase in a range from 25% to 50% compared against the standard microporous silica gel, thus confirming the potentiality of reducing the size of adsorption desalination units, which is of utmost importance in mobile applications such as the naval one.

Table. 1. SDWP calculated for all the testing conditions measured at lab scale.

Rererence cycle	$T_{eva/cond}$ 5 °C	$T_{eva/cond}$ 10 °C	$T_{eva/cond}$ 15 °C	$T_{eva/cond}$ 20 °C
$T_{ads/des}$ 30-60 °C	14	25	25	40
$T_{ads/des}$ 30-80 °C	11	24	40	57

The reported calculations were carried out considering a standard 2-adsorbers desalination unit design. Nevertheless, looking at the kinetic testing results, it is clear that, since the desorption process is much faster, it could be reasonable to increase the number of adsorbers, thus being able to re-allocate the adsorption/desorption phases, optimizing the overall performance and exploiting the sorption properties of the material at their maximum level. Preliminary calculations showed that having a 3-adsorbers design can help in further increasing the SDWP in a range from 10% to 15% compared to the 2-adsorbers design.

On this basis, the first large scale setup for testing in the lab is under design, for further investigation before being realized in larger scale for validation on board of a demo vessel.

4. Conclusions

The development of innovative, high efficiency and compact adsorption-based desalination machines requires investigation at materials and components levels. In this paper new innovative composite sorbents were developed and tested both from the equilibrium and kinetic point of view. The most efficient one, based on LiCl embedded inside mesoporous silica gel, was manufactured in large scale and tested in a lab-scale device developed for characterizing sorption kinetic properties under real operating conditions for desalination and cooling applications. A small-scale finned-flat tubes aluminium heat exchanger was used to embed the grains of the composite as well as a reference material (i.e. microporous silica gel). The results demonstrated that the water vapor mass transfer across the adsorber is limiting the kinetic performance, thus affecting the achievable SDWP. Moreover, the desorption kinetic resulted being 2 to 3 times faster than the corresponding adsorption process.

Starting from the obtained results, the estimation of the SDWP of this configuration against the one employing microporous silica gel was carried out, showing a performance increase ranging from 25% up to 50%. Moreover, the possibility of using a 3-adsorbers based adsorption machine resulted the most appropriate one, to manage the difference kinetic performance of adsorption and desorption phases.

This investigation will represent the basis of the design of a lab-scale adsorption desalination machine to be tested in the lab and subsequently on board of a demo vessel.

Solar Energy Drier for Algae with Water Recovery for Island Applications

Eden Mamut[a], Laurențiu Oancea[b] and Marcel Ionescu[c]

[a] *Ovidius University of Constanța, Constanta, Romania, e-mail: emamut@univ-ividius.ro, CA*
[b] *Ovidius University of Constanta, Constanta, Romania, e-mail: loancea@univ-ovidius.ro*
[c] *Europlastic Ltd, Bucharest, Romania, e-mail: marcelionescu2008@yahoo.com*

Abstract:

The paper is presenting the results of the evaluation of a model to address the water-food-energy-ecosystem security nexus on islands from the perspective of structuring circular aquatic bioeconomy loops. The scientific research activities have been based on the achievements made in the ROMANA project on the establishment of a methodology for hierarchical EEA in some geographical control volumes. Specifically, there were taken into consideration two scales as the National economy of Romania and the regional economy of the Constanta County that is part of the Dobrogea Region. Using the results and the validation of the multi-scale approach from ROMANA project, in the present paper, there are presented the results of the possible extrapolation of the method for the case of a country with islands like it is the case of Spain.

Keywords:

Solar Energy Drier, Algae Processing, Water Recovery, Island.

1. Introduction

In the current context of the population growth, degradation of the habitat, the evolution of the accumulation of Green House Gases (GHG) in the atmosphere and trends in the climate change, the situation of the islands and especially of the small islands, is one of the most vulnerable. There are several approaches to address the complexity of the factors that are affecting of mid and long term the socio-economic situation of the islands and the water-food-energy-ecosystem security nexus approach, as [1] demonstrates, is a holistic and well-structured one for their sustainable development.

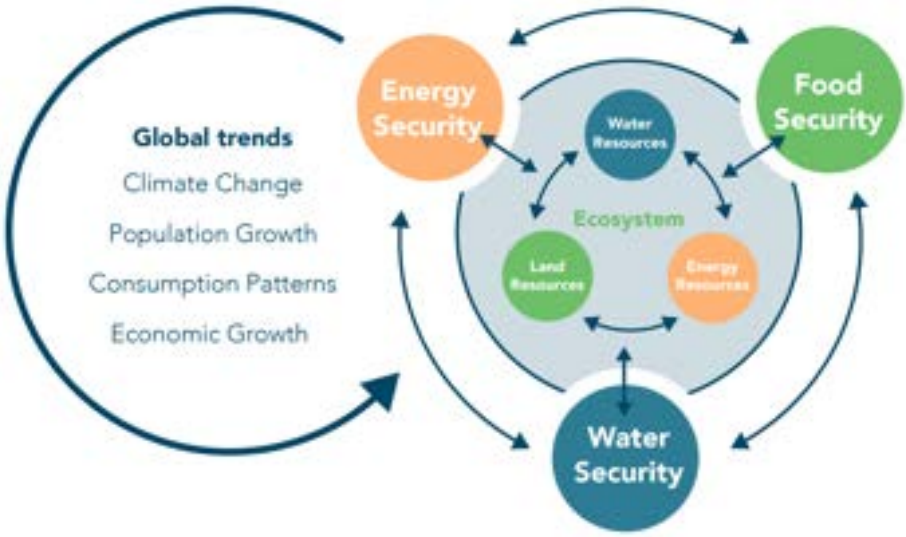

Figure. 1. The interdependences in the Water, Food, Energy and Ecosystem security Nexus [1].

As Austen et al [2] demonstrate, ecosystem valuation must be considered as part of this approach that has to help the achievement of objectives and targets of the environmental policies such as the Good Environmental Status (GES) of the island riparian sea or ocean waters.

As it is mentioned in [3], seaweed and microalgae are responsible of 50% of photosynthesis on Earth and using algae in the Circular Economy concept, the efficiency of solar-to-chemical energy conversion via algal photosynthesis is 4% – 10% compared to 0.5% - 2.2% in land-based farming crops.

In this context, algae harvesting on islands is considered a significant and beneficial activity, particularly if the islands are in areas with abundant algal growth. Algae are photosynthetic organisms that can be found in

marine, freshwater, or terrestrial environments. They play a crucial role in various ecosystems and have numerous applications in industries such as food, pharmaceuticals, cosmetics, and biofuels.

Besides of appropriate selection of algae species and aspects of sustainability and environmental impact, a very important attention must be given to processing and utilization. Once harvested, algae can be processed for various applications. This may involve drying, extraction of specific compounds, or further refinement for specific industries. It's important to have appropriate processing facilities in place to maximize the value and utility of the harvested algae. The economic viability of algae harvesting depends on the costs associated with harvesting, processing, and transportation. Identifying potential markets and customers for the harvested algae products is essential to ensure profitability and sustainability in the long term.

Algae harvesting on islands can provide economic opportunities, promote sustainable practices, and contribute to the local economy. However, it's crucial to balance these activities with the preservation and protection of the island's ecosystems to ensure long-term environmental and economic benefits.

1.1. Humidity content and nutrient value of algae

Algae are considered an extremely heterogeneous group of organisms, very difficult to define. Without being able to consider algae as a single taxon, they could be defined as photosynthetic autotrophic organisms, with a very simply organized vegetative apparatus, called "thal", which can be microscopic, unicellular, or macroscopic, multicellular and which can be found in various habitats, from sufficiently moistened terrestrial ones, to aquatic ones. They are particularly important primary producers for living value chains, the only ones in the seas and oceans, also providing the oxygen necessary for the aquatic life. Macrophytes are also found in continental waters (fresh, salty, or brackish). The estimated net primary production of seaweeds in natural environment by vegetation type is reproduced in figure 2 after [3].

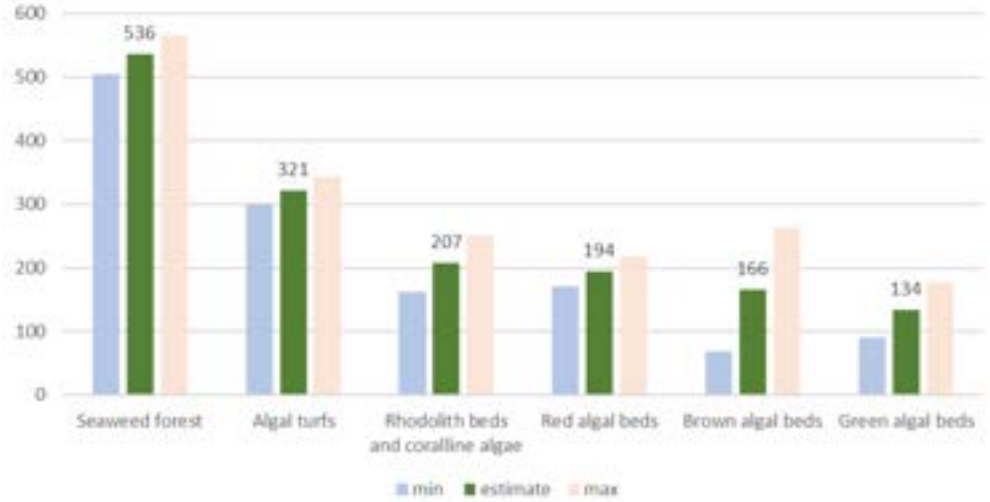

Figure. 2. The net primary production in natural environment by vegetation type, excluding floating algae (in $gC/m^2/year$) [3]

There are three large groups of algae as followings:

- The group of chlorophytes, characterized by the presence of A and B chlorophyll, represents a fundamental phylogenetic line within which the autotrophic terrestrial plants were differential.
- The group of rhodophytes, characterized by the presence of A and D chlorophyll, as well as of phycobilin and especially of phycoerythrin, which gives them the aspect of red colour.
- The group of chomophytes is distinguished by the presence of A and C chlorophyll, along with which there are different types of carotenoid pigments that determine their varied colour as: yellowish, brown – red and red.

As it is mentioned in [4], the total harvested output in the World was reported in 2019 as 34.7 million tonnes of farmed seaweed and 1.1 tonnes of wild-harvested seaweed.

The biochemical composition of seaweed varies depending on the species, geographical space, season, water temperature. Seaweed is valuable for its chemical and biochemical composition having a high content in minerals (magnesium, calcium, phosphorus, potassium, and iodine), micronutrients and carbohydrates. The quality of lipids and proteins is comparable to that of terrestrial plants due to the high content of essential amino acids and the relatively high level of unsaturated fatty acids.

According to Mamut and Ionescu [5], seaweed contains polysaccharides in the range of 30 to 50% of the dry matter content whose structure differs depending on the species. The fraction of soluble fibre is 51 –56% of the total fibres in green and red algae and 67-87% of brown algae. Macrophytes contain considerable amounts of polysaccharides: alginates in brown algae, carrageen, and agar in red algae. In smaller quantities there are xylenes (in red and green algae), ulvans (in green algae) and fucoidans (in brown algae).

Macroalgae extract from the sea an extraordinary wealth of mineral elements. The mineral substance of some macrophytes can reach up to about 36% of the dry matter. Seaweed is a source of iodine and calcium. Only one gram of dried brown seaweed provides 500 to 8 000 µg of iodine, and green and red algae from 100 to 300 µg. Red and green algae, although they have a lower iodine content than brown ones, it is still superior to terrestrial plants. The calcium content in macrophytes accounts for approximately 4 to 7 % of the dry matter.

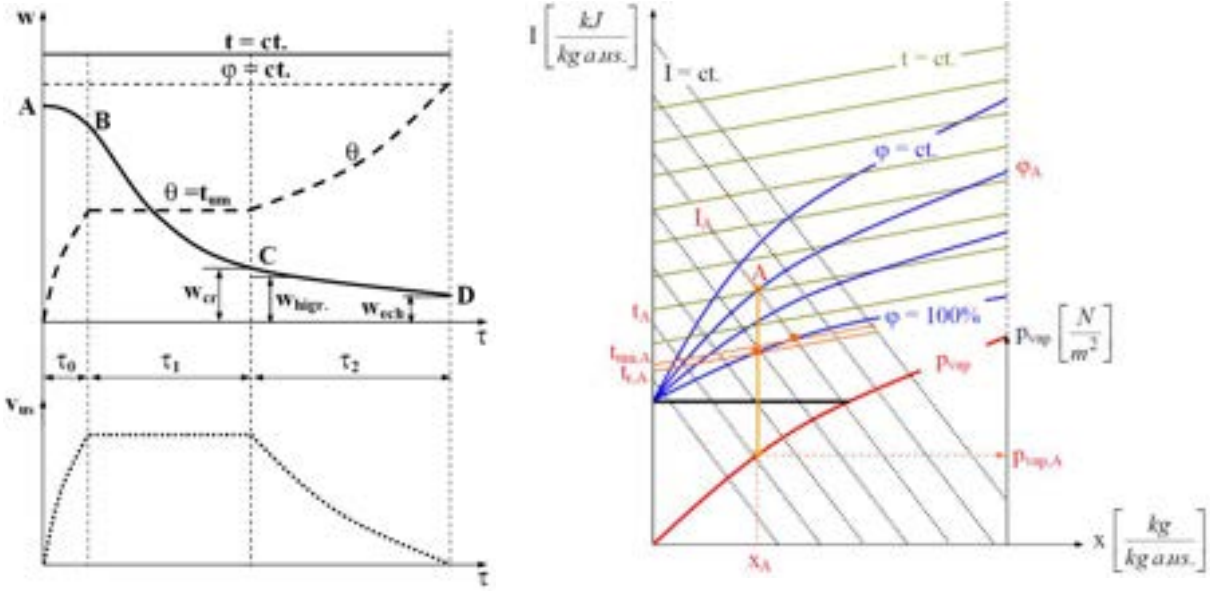
Macrophyte algae are a natural source of vitamins, polyphenols, and carotenoids with antioxidant properties. The extracts from brown algae are distinguished by the high content of fucoxanthin, β-carotene and violaxanthin. In red algae the main carotenoids are α- and β-carotene and their derivatives, zeaxanthin and lutein. The composition of carotenoids in green algae is similar to vegetal: anteraxanthin, zeaxanthin, neoxanthin, β-carotene, lutein and violaxanthin.

The harvested algal biomass is a raw material with high content of humidity and nutrients, which begins to degrade almost immediately after harvesting. For this reason, the algal biomass is requiring a solution for stabilization if it is not processed within a few hours of harvesting. The raw algal biomass can suffer of up to 20% dry matter losses within a week because of biochemical and microbial degradation.

Reducing the moisture content below 15% is a common conservation strategy for lignocellulosic biomass and is likely to be sufficient for the conservation of algal biomass. With few exceptions, drying experiments conducted in various studies were continued until the algae/terrestrial biomass mixtures reached humidity content below 10% at which point they were considered stable. In [6], there are also presented the results of drying temperatures of the algal biomass and the impact on the conservation of the most important components.

1.2. Algae solar drying

In general terms, biomass drying is a preservation technique that involves reducing the moisture content of biomass to prevent microbial growth, degradation, and spoilage during storage. By reducing moisture, the biomass can be stored for longer periods without compromising its quality or value.



A B

Figure. 3. The general process of drying of biomass by using thermal energy: A - Moisture reduction, feedstock temperature evolution and drying speed, B – Drying air humidity evolution during the drying process.

The removal of water from algae can be done with various techniques as: mechanical pressing or centrifugal processing, hot air drying, drum drying, solar drying, microwave drying, as well as freeze drying, spray draying or solvent extraction.

In Figure 3 there are presented the kinetics and main parameters of the hot air-drying process. An alternative of the hot air-drying process is the solar drying process.

Algae solar drying as the process of using solar energy to remove moisture from harvested algae, is an important step in various industries where algae are used, such as biofuel production, animal feed, and food supplements. Solar drying offers an environmentally friendly and cost-effective method for reducing the moisture content of algae.

The classical phases in solar drying of algae are as followings:

- Harvesting: Algae are typically harvested from ponds, tanks, or bioreactors when they have reached the desired growth stage.

- Pre-treatment: Before drying, the harvested algae may undergo pre-treatment processes such as filtration, centrifugation, or dewatering to remove excess water and impurities.
- Drying beds or trays: The algae biomass is spread out in thin layers on drying beds or trays. These surfaces should be designed to maximize exposure to sunlight.
- Solar exposure: The trays or drying beds are placed in an open area where they can receive direct sunlight. The solar energy heats the algae and evaporates the water content.
- Turning and flipping: To ensure uniform drying, the algae biomass needs to be periodically turned or flipped to expose all sides to sunlight. This promotes consistent drying and prevents the growth of moulds or bacteria.
- Protection: During the drying process, it is essential to protect the algae from rain, dust, and contaminants that can degrade the quality of the final product. This can be done by covering the drying beds or trays with a mesh or protective covering.
- Monitoring: The drying process should be regularly monitored to assess the moisture content of the algae and determine when it reaches the desired level of dryness. Moisture meters or visual inspections can be used for this purpose.
- Storage: Once the algae biomass has reached the desired moisture content, it is removed from the drying beds or trays and stored in suitable containers to prevent rehydration.

The drying time will depend on various factors such as the type of algae, thickness of the biomass layer, ambient temperature, humidity, and solar radiation. In the classical installations, the drying process can take several days to weeks, and it may be necessary to cover the drying beds during the night or in unfavourable weather conditions to protect the algae.

Solar drying offers a sustainable and energy-efficient method for algae drying, utilizing readily available solar energy and minimizing the use of fossil fuels or electricity. This method is particularly suitable for regions with abundant sunlight, where it can significantly reduce the energy costs associated with conventional drying methods.

2. Characterization of algae samples

2.1. Algae sampling and characterization

The evaluation of algae drying processes have been developed for the harvested algae from the Black Sea coast. On the basis of the samples collected from the Black Sea shore and from the continental waters, the physico-chemical properties regarding the moisture content were determined, using conventional drying methods: by using as reference the natural drying for 24h and by using an oven and determining the humidity content. Also, the humidity and ash content of the algae were determined using thermogravimetric analysis methods.

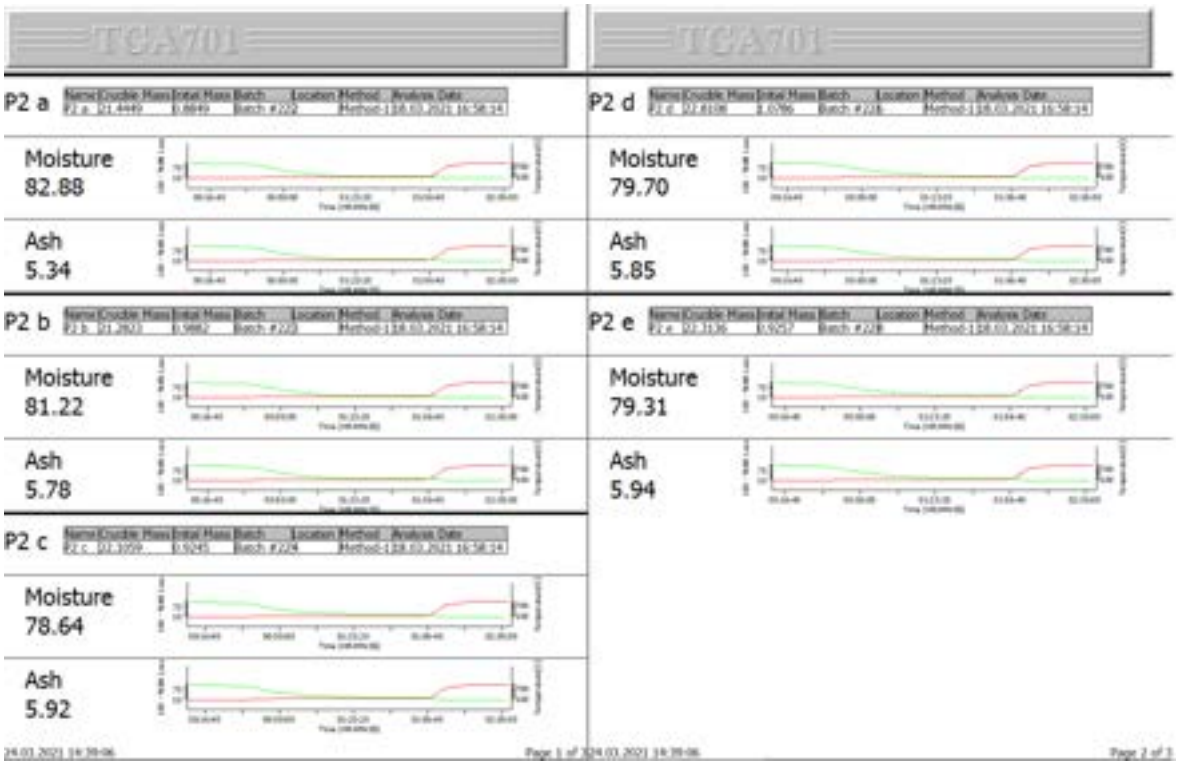


Figure. 4. Water and inorganic matter content of algae samples collected from sea water.

For collected algal samples, the humidity and total solids content have been determined according to ASTM E1756-01 and T412 man-02.

The samples were weighed before being placed in the oven at a temperature of 60°C for 24h. After keeping them 24h in the owen, the samples were weighed, and the difference between the initial and the final mass of each sample is the loss of humidity.

For the samples of algae that were collected from the water and dried naturally for 24h, the average moisture content was 80,35 %. The average content of inorganic substances in water samples of algae was 5,76 %.

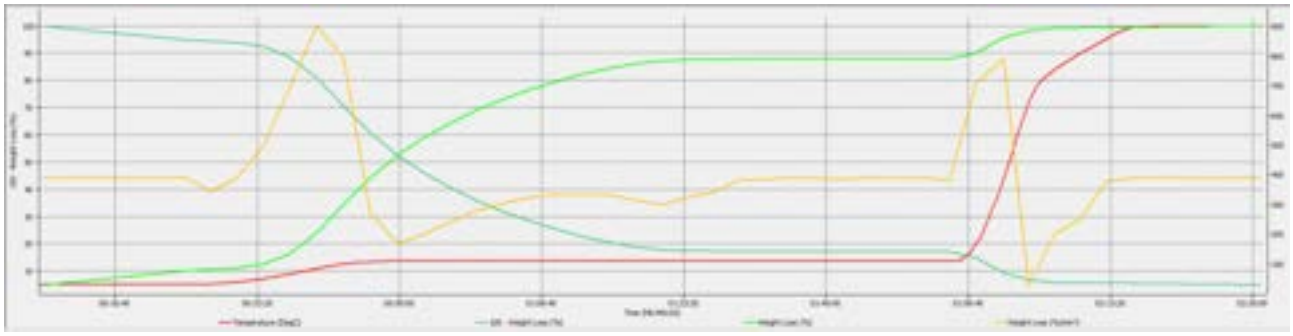

Figure. 5. Graph of the loss of weight in relation to the increase in temperature for algae taken from water.

According to the graph presented in Figure 5, the weight loss was recorded in relation to the increase in temperature. In the temperature range 30 – 45°C the weight loss of the sample was of 7,5%. In the temperature range 45 – 75°C the lost weight of the sample was 15%, and in the temperature range 75 – 90°C, the weight loss of sample was of 23.43%.

For seaweed samples taken from the beach and dried naturally, the average moisture content was 8,34 %. The average content of inorganic matter present in algae samples collected from the beach was 33,05 %.

2.2. Synthesis of the results

As a result of the performed experimental investigations, the dynamics of the weight loss was observed in relation to the increase in temperature.

In the temperature range 30 – 45°C the weight loss of the sample was of 0,98%. In the temperature range 45 – 75°C the weight loss was of 4.05%, and in the temperature range 75 – 90°C, the weight loss of was of 6.2%.

Table 1. Table with the synthesis of the algae sample analyses.

Sample code	Oven Temperature (°C)	Drying period (h)	Initial weight (g)	Final weight (g)	Weight loss (g)	Percentage (%)
P1 a	60	24	5,06	4,62	0,44	8,7
P1 b	60	24	4,96	4,51	0,45	9,1
P1 c	60	24	5	4,67	0,33	6,6
P1 d	60	24	5,07	4,65	0,42	8,29
P1 e	60	24	5,06	4,73	0,33	6,53
P3 a	60	24	5,16	2,46	2,7	52,33
P3 b	60	24	5,14	2,19	2,95	57,4
P3 c	60	24	4,95	2,73	2,22	44,85
P3 d	60	24	5,38	3,13	2,25	41,83
P3 e	60	24	5,04	3,03	2,01	39,89

Following the thermogravimetric analysis of samples collected from water, the following results were obtained:

- the average value of the moisture content of the samples was 5,51 % for the samples of algae collected from the water;
- the average value of the moisture content of the samples was 3,3 % for seaweed samples collected from shore;
- the average value of the total solids content of the samples was 36,43 % for samples of algae collected from the water;
- the average value of the total solids content of the samples was 43,79 % for seaweed samples collected from the shore.

Based on the performed analyses, it was found a weight loss of samples depending on temperature range, as followings:

- in the temperature range 30 to 45 ^{o}C, the weight loss was 0.22%;
- in the temperature range 45 to 75 ^{o}C, the weight loss was 2.55%;
- in the temperature range 75 to 90 ^{o}C, the weight loss was 4.43%.

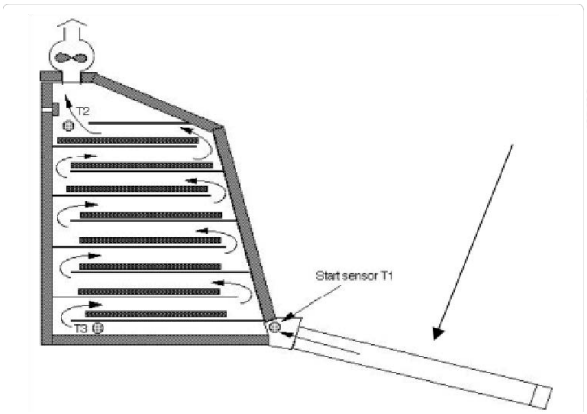
As it may be seen in the table above, depending on temperature range, the following results were obtained:

- in the temperature range 30 to 45 ^{o}C, the weight loss was 0.14%;
- in the temperature range 45 to 75 ^{o}C, the weight loss was 1.3%;
- in the temperature range 75 to 90 ^{o}C, the weight loss was 2.1%.

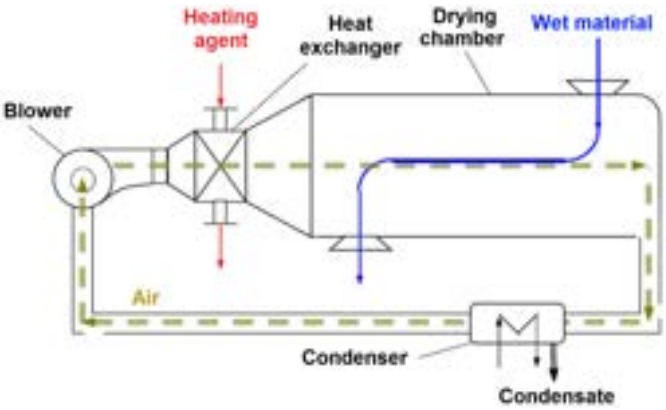
3. Drying equipment

3.1. Reference concepts

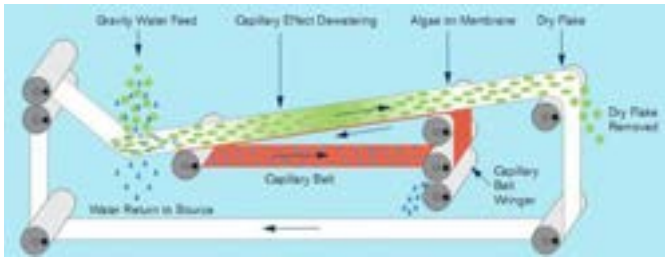
The reference concepts of driers that have been used for the development of the innovative solution are presented in Figure 6. It has been started from the reference concept of solar drier for algae as may be seen in figure 6 A (adapted after [7]). The solar radiation is heating air in the solar collector located in the bottom side and when the drying temperature is reached, the access valve allows the passage of hot air that is flowing over the fixed bed wet biomass absorbing the humidity and evacuating it by natural convection from the one-way evacuation exit located on the top side of the drier.



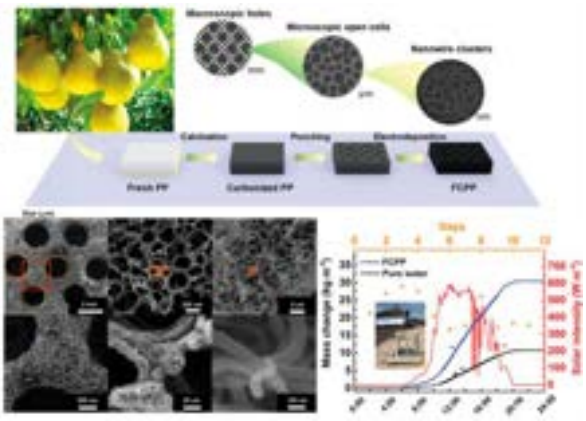
A



B



C



D

Figure. 6. The reference concepts of driers that has been used for the development of the innovative solution of solar algae drier: A – batch solar drier for small quantities of algae (adapted after [7]), B – continuous drying chamber with the recuperation of water condensate, C – drying booster based on a capillary belt (adapted after [8]), D - hierarchically structured nanostructured materials (adapted after [9]).

The solution has been adapted for a continuous drier concept as presented in figure 6 B. It consists of a drying chamber where there is a belt on which from the top side it is fed continuously the wet biomass. The hot air is circulated from the chamber absorbing the humidity of the wet biomass and after drying, the algae is evacuated from the bottom side of the chamber. The high humidity air is recirculated from the condenser and the excess water is recovered as condensate from the bottom side of the graph. The air is further recirculated and reheated before entering in the drying chamber.

To avoid the critical regime (point C in figure 3 A) in the drying process, the innovative concept has been developed by adding a capillary belt as presented in figure 6 C (adapted after [8]). The capillary belt is pressed to the conveyor belt transporting the wet biomass and by the very high hydrophobicity of the capillary material, absorbing the humidity from the bottom and giving a boost to the drying process.

The superhydrophobic material of the capillary belt has been developed as a hierarchically structured nanostructured material like the example presented in figure 6 D (adapted after [9].

3.2. Solar drier concept for continuous processing of wet algae

The concept of the drier has been developed based on a methodology of innovation that started from the definition of the requirements, collection of related information, development of new ideas to address the requirements, co-design of alternative solutions, modelling, testing validation and optimization of the solutions and finally, the selection of the final design by a Multi-Criteria Decision-Making process.

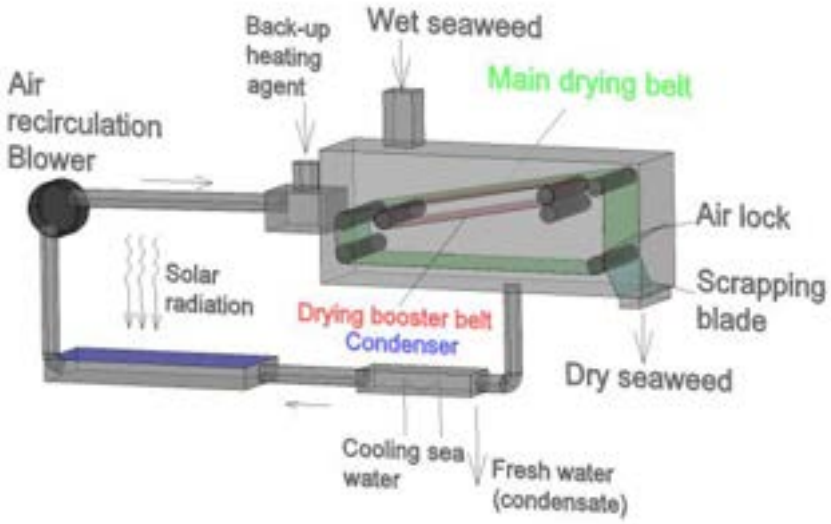


Figure. 7. Innovative concept of drier using solar energy and producing dried seaweed and fresh water.

The solution that has been developed, consists of a continuous belt drier using hot air. The thermal energy is obtained from a solar air collector. The air is circulated in a closed loop that includes a condenser for collecting fresh water resulting from the drying process of algae. As backup thermal energy source, for balancing the intermittence of the solar energy, it has been included a pellet boiler heater.

To avoid the critical drying regime and to improve the efficiency of the drying process, the installation includes a drying booster belt using a fabric that integrates super hydrophilic nanostructured powder for absorbing the humidity from the wet biomass by contact on the bottom side of the main drying conveyor belt.

Therefore, the innovative installation is processing the wet seaweed collected from the sea or the beach, to produce dry algae as a stable, high value concentrate of minerals, vitamins, and other important substances. At the same time, the installation is producing fresh water by the condensation of water vapours from the drying air. As condensing coolant is used the sea water.

The solar energy collectors have been developed by integrating an absorber of solar radiation with a paint integrating Multi Wall Carbon Nanotubes (MWCNT). For the improvement of the convective heat transfer from the absorber to the air stream, a special design architecture has been developed.

4. Hierarchically Multiscale Modelling

The proposed innovative approach is based on the Extended Exergy Accounting - EEA.

The EEA method [10], [11] and [12] is based on the idea that the three Externalities (Labour, Capital and Environmental Cost) can be assigned “equivalent primary exergy values”, under a set of assumptions derived from an exergy budget of the region in which the process is located. EEA is based on a series of assumptions that concern the control volume used for the analysis: since it is necessary to exactly quantify the mass- and energy streams flowing in- and out of a given economic system, the most proper „control volume” to use is at the Country or at the Regional level (like the EU or a sub-regions of Member Countries), where sufficiently disaggregated data are available from reliable sources. Thus, every EEA analysis ought to begin by considering the material, energy and economic balance of the entire Country. Once these global data have been extracted, manipulated and processed, EEA most convenient applications are at intermediate and low (highly disaggregated) levels, down to a single production line. The theory requires that two conversion functionals, the equivalent primary exergy of the unit of monetary circulation, ee_K [J/€], and the equivalent primary exergy of the workhour, ee_L [J/workhour], be calculated at the regional level, and they require the acquisition of two econometric parameters that contain global economic, social and exergetic data [11].

The EEA method begins with the subdivision of the region in which the process is located, in 7 Sectors: Domestic (DO), Extraction (EX), Conversion (CO), Industrial (IN), Transportation (TR), Tertiary (TE) and Agricultural (AG). Each Sector exchanges material and immaterial fluxes with other sectors, with the environment and/or with another conventional -fictitious- system called "Abroad" that accounts for the import/export fluxes. Similarly, every single (material or immaterial) process S taking place in the region exchanges physical fluxes with some of the sectors: all of these fluxes can be converted to extended exergy (i.e., their primary exergetic equivalent) by means of the two above functionals. In particular, EE_{L} is assumed to be originated only in DO, and EE_{K} in TE. Imported commodities are handled through TE.

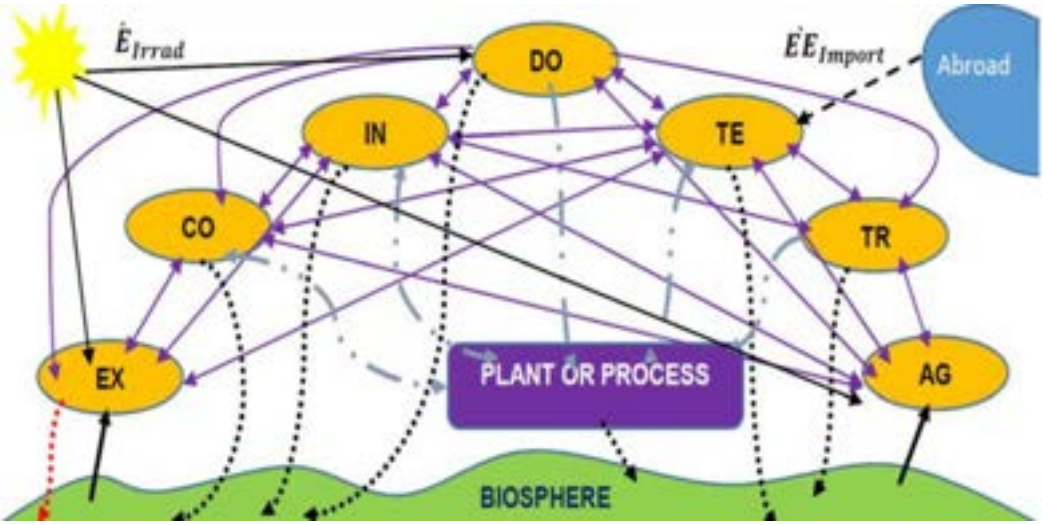

Figure. 8. Structuring the activities in a certain control volume in 7 Sectors: Domestic (DO), Extraction (EX), Conversion (CO), Industrial (IN), Transportation (TR), Tertiary (TE) and Agricultural (AG) (adapted from [12])

Once the above quantities are known, a balance for the EE_j is performed, resulting in a specific extended exergy cost, ee_c [$J_{primary\ exergy}$/unit] that reflects the total amount of primary resources consumed for the production of 1 unit of product X: a genuine exergy cost.

Notice that the EEA method is perfect tool for the assessment of medium- and long range scenarios: since it clearly identifies the contributions from renewable and non-renewable sources, it provides useful quantitative indications about the progress of a process, a technological line, an industrial sector, a Region or a Country along the so-called "transitional path to sustainability".

The calculation of the ee_c requires that highly disaggregated data are available for the Region under analysis. It also requires that updated technical information is available for all feasible technical treatment processes of each pollutant. Additionally, labour and monetary statistics at regional level are necessary to calculate two econometric coefficients, called α and β [7,8] needed for the calculation of ee_K and ee_L. Procedures to calculate these econometric coefficients for a multiscale approach have been validated in the Project ROMANA that is in final phase of implementation at Ovidius University of Constanţa. EEA-based procedures were developed for the integrated evaluation of energy efficiency at Country Level – Romania, county level – Constanţa, and process level for the District Heating System in the Constanţa Municipality.

4.1. Drier scale modelling

For the evaluation of the main energy and commodity flows, at the scale of the drying installation as it is presented in fig. 7, the following values have been calculated:

- required heat for drying,
- absorbed solar radiation energy,
- the resulting flows of water and dry matter the process.

At the drier scale, the conservation equations are as followings:

- specific heat in the convection heat transfer between air and wet biomass

$$q = \alpha\left(t_m - t_f\right) \quad (1)$$

- mass balance equation

$$\dot{m}_1 = \dot{m}_2 + \dot{W} \quad (2)$$

- humidity balance in the drying installation

$$\dot{m}_1 \frac{w_1}{100} + Lx_0 = \dot{m}_2 \frac{w_2}{100} + Lx_2 \quad (3)$$

- thermal balance in the drying process

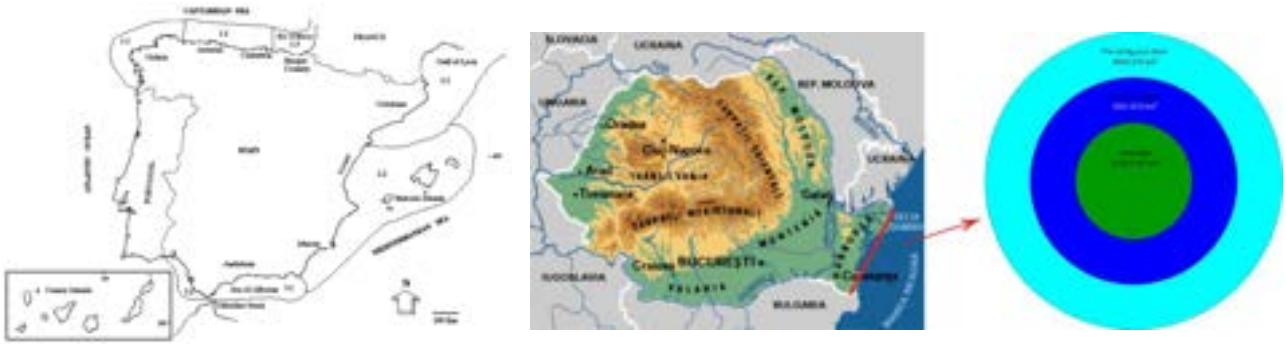
$$q = l(I_2 - I_0) = 1.006(t_1 - t_0) + 1.863x_1(t_1 - t_0) \quad (4)$$

The modelling equations (1) – (4), were written by taking into consideration theoretical conditions, without considering losses from the walls, chemical reactions, and the transportation losses.

The calculated streams of energy and commodities have been integrated in the EEA calculation toolbox.

4.2. Island scale modelling

The scientific research activities that have been developed under ROMANA project, have been concentrated on the establishment of a methodology for hierarchical EEA in some geographical control volumes. Specifically, there were taken into consideration two scales as the National economy of Romania and the regional economy of the Constanta County that is part of the Dobrogea Region. Using the results and the validation of the multi-scale approach from ROMANA project, in the present paper, there are presented the results of the possible extrapolation of the method for the case of a country with islands like it is the case of Spain.



A B

Figure. 8. Equivalent Island model for the yields of algae from the sea waters. A – Regions of Spain that are active in the aquatic bioeconomy [13]. B – Conventional model for structuring a coastal region as an island.

It has to be mentioned that the Dobrogea region has a specific characteristic consisting on the geographical boundaries established by the Lower Danube in the West, Danube Delta in the North and the Black Sea in the East. For this reason, it has been considered the shoreline to the Black Sea and a possible structuring of it as a conventional island shoreline as presented in the fig. 8 B. This offered the possibility to define an equivalent land surface for estimating the specific input of solar energy that could be used for calculating EEA in relation with aquatic bioeconomy inputs. At the same time, offering the possibility to define a reference surface for the associated coastal waters including the equivalent surface of territorial waters and contiguous zone according to the current international laws.

Using the above-mentioned assumption, an equivalent conventional island has been generated and used to apply the EEA method for the evaluation of the relation between the solar energy potential, the aquatic bioeconomy inputs and the outputs in terms of dried seaweed and fresh water, by using the data collected for the Dobrogea region.

5. Experimental results

The estimation of the annual yields of seaweed has been carried out for the conditions in the South-East region of Romania, where the collection season starts in June and ends in October.

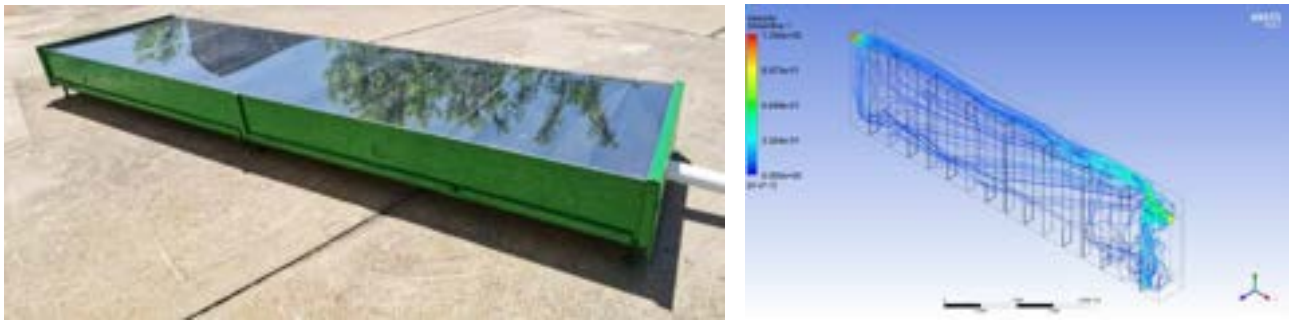
A B

Figure. 9. Collection of the seaweed yields: A – Collection from water; B – Collection from the beach

There is a specialized company that is organized for collecting algae both from the sea shallow waters and from the beaches. The total shoreline is of 180 km and the average annual yield is of 40.000 tonnes.

By comparing the SE region of Romania with other regions, it has to be underlined the importance of the contribution of the Danube River exit to the Black Sea. The high concentration of nutrients transported by the Danube has a major role in supporting the production of algae yields.

The validation of the model of the solar air collector has been done by using a 1:1 physical model that is presented in the Figure 10 A. The solar collector integrates an absorber that was developed using a special paint with MWCNT. The absorption rate of solar radiation that was measured on the experimental prototype was 98.8%.



A B

Figure. 10. Solar air collector validation: A – Experimental validation prototype; B – ANSYS Fluent thermofluidic analysis and optimization model.

An ANSYS Fluent model has been developed for the study of the thermofluidic processes in order to improve the convective heat transfer properties and to define an optimal flow architecture for highest convection heat transfer coefficient.

Considering the annual yield of wet algae collected from water in the range of 40.000 tonnes with an average humidity of 80%, using the model described in paragraph 4.1, it has been calculated the total required heat for the drying process, in the amount of 28.000 MWh/year.

The calculated heat resulted for the estimated final humidity of the dry algae of 10%. The total quantity of dry algae is estimated at 12.000 tonnes.

The by-product obtained from the drying process is fresh water in an amount of 28.000 tonnes/year.

The price for dry algae was estimated at 200 Euro/tonne and the price for fresh water is 2 Euro/tonne.

The total income for the installation has been estimated at 2.4 million Euro for the dry algae and 56.000 Euro for water.

The operational costs included the following items:

- labour costs in an amount of 72.000 Euro
- energy costs (including cost of transport) in an amount of 168.000 Euro
- overheads in an amount of 24.000 Euro

Total operational costs have been estimated at 264.000 Euro.

The investment costs include the following items:

- Solar air collectors – 2.400.000 Euro
- Dryer – 400.000 Euro
- Ancillary equipment and construction works – 280.000 Euro

Total investment cost – 3.080.000 Euro.

Considering a depreciation period of 15 years, with a fix rate of depreciation, it has been obtained a yearly depreciation of 205,333.3 Euro.

From the economic point of view, the investment payback period is of 7.6 years.

But the benefits of exploitation of the seaweed yields are much more complex and include the avoidance of the GHGs that are resulting from the natural decomposition of the biomass. In this respect, it has been developed an EEA model for the evaluation of the energy efficiency in the hierarchical model that has been presented in paragraph 4.

Two configurations were compared: the first one uses a CH_4-fuelled drier, and the second one is the solar drying configuration described above.

The exergy flows of the two processes were analysed first, and the Solar configuration showed a slightly better efficiency: 0.68 vs. 0.66. But the EEA analysis, that includes in the “product cost” the primary exergy flow equivalent to the externalities (Labour and Capital in this case), provided a different picture. Table 2 shows the extended exergy cost ee_c for the two co-products, dry biomass and desalinated water: considering that the exergy cost of Reverse Osmosis desalination is about 0.01 kWh/kg, the process is not a convenient

desalinator. But the primary exergy cost ee_c for the dried biomass is about one third of that of natural gas (3 vs. 15.88 kWh/kg), which makes the biomass very convenient both as a secondary biofuel or as a raw material input for the chemical industry.

Table 2. Extended Exergy Cost ee_c [kWh/kg] of the two co-products.

	Dried biomass	Desalinated water
Natural gas-fired drier	5.61	1.12
Solar drier	5.81	1.16

The calculated quantity of GHG equivalent of CO_2 that is saved in the case the solar drier, is of 4453 tonnes/y. Considering a price per CO_2 certificate of 100 Euro/t the total value of the certificates is 445,300 Euros.

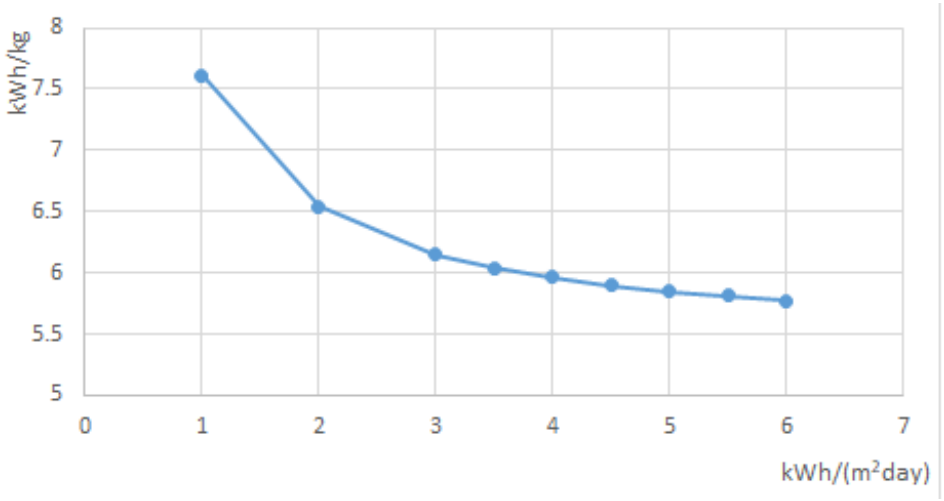


Figure. 11. The impact of solar irradiation of the extended exergy cost of the biomass

In fig. 11, it is presented the influence of the solar irradiation on the extended exergy cost of the dried biomass. It may be seen that the increase of the irradiation is reducing the extended exergy cost based on the reduction of the investment on solar panels.

A similar analysis must be done on the aspects referring to the primary exergy of the dry algae. Depending on the quality of the algae the price is varying between 200 and 1200 Euro/t. In the EEA model that has been used for the present study, the price was used as 200 Euro/tonne.

6. Conclusions

The water-food-energy-ecosystem security nexus approach is a holistic and well-structured model addressing the complexity of the factors that are affecting on mid and long term the socio-economic situation of the islands and for their sustainable development.

The scientific research activities have been presented in the paper were obtained based on the achievements made in the ROMANA project on the establishment of a methodology for hierarchical EEA in some geographical control volumes. Specifically, there were taken into consideration two scales as the National economy of Romania and the regional economy of the Constanta County that is part of the Dobrogea Region. Using the results and the validation of the multi-scale approach from ROMANA project, in the present paper, there are presented the results of the possible extrapolation of the method for the case of a country with islands like it is the case of Spain.

The innovative solution that is presented in the paper is efficient and taking into account only the commercial values for OPEX and CAPEX, the investment payback period is of 7.6 years

But the benefits of exploitation of the seaweed yields are much more complex and include the avoidance of the GHGs that are resulting from the natural decomposition of the biomass. In this respect, at present, there is under development the EEA model for the evaluation of the energy efficiency in the hierarchical model that has been presented in paragraph 4.

Abstract:

The high organic load of the effluent generated in these farms has an important environmental impact, which is amplified in insular or isolated territories. The application of natural treatment systems of wastewater (NTSW) has demonstrated their suitability in these environments, but their design lacks proper characterization and sizing tools for their adequate operation. This work proposes a series of strategies and tools for the design and characterization of NTSW. As an application, an inventory, characterization, sizing, and design is carried out in 9 pig farms with a high environmental impact located on the island of Gran Canaria (Spain). The proposed tools in this work are based on a collection of experimental data over a five-year period of application of NTSW in real farms. This work contributes to facilitate the design and implementation of NTSW in farms located in isolated, island or similar size environments.

Keywords:

Wastewater treatment; natural systems; livestock farms; characterization.

1. Introduction

1.1. Waste generation and characterization overview

Livestock wastes in general, and pig wastes in particular, is made up of a dry part, formed by animal excrement, food remains, bedding, and a liquid part. This mixture is called slurry [1, 2]. Pig slurry is a source of multiple mineral constituents: primary macroelements or nutrients (N, P, K), secondary macroelements (Mg, Ca, Na) and trace elements (Cu, Zn, Mn, Fe, S, B, Mo). The availability of macroelements in slurry for crops is good (N, P) and even comparable to that of mineral fertilizers [3], [4].

The new Spanish legal framework establishing basic rules for the management of intensive and extensive pig farms can be found in Royal Decree 306/2020, of February 11. This Royal Decree (hereinafter referred to as RD306) focuses on environmental issues with respect to the protection of water, soil and air, and on the fight against climate change. Livestock farm effluent with a high organic load has a strong environmental impact that 35 is amplified in island territories.

In turn, slurry may have different properties at any given time due to various factors inherent to production, such as the number of heads, number of sows, piglet, fattening pig. As well as, the form of exploitation, type and management of the farmer, varied diet, cleanliness, the season of the year, emptying of the reception pits and the climate [5– 7].

This is the reason for the interest in developing a characterization tool bases on historical data on the operation of these systems in livestock farms. As indicated by [8, 9], an interesting basic characterization is carried out based on one or several parameters that are easy to determine in situ, leaving other more complex parameters for the laboratory. Likewise, the excessive or unfavourable application of slurry on land can lead to losses of nitrogen and phosphorus by percolation and runoff into surface and subsurface water bodies [8]–[10]. Excess phosphorus and nitrogen in the form of ammonium (NH_4^+), nitrate (NO_3^-) and nitrite (NO_2^-), in waters can accelerate the aging of aquatic ecosystems [11–15]. Ammonia (NH_3) is recognized as one of the most important toxic gases present in swine facilities and has profound effects on pig performance [16] and responds to its toxicity by altering in the barriers and defence mechanisms of the respiratory tract, facilitating the entry of pathogens, and increasing the likelihood of respiratory diseases [17].

Therefore, for a basic characterization of the effluent that allows the sizing of the treatment plant by means of NTSW, the flow rate (Q), chemical oxygen demand (COD), conductivity (EC), total nitrogen (TN) and ammonia (NH_3) are defined.

However, when it comes to dimensioning these systems, there are no tools applicable to agricultural and livestock farms in isolated territories, and they are limited to adaptations based on experience in small communities and rural settlements [29 -30].

1.2. Treatment systems for wastewater

Different slurry treatment systems have been proposed with the aim of reducing the pollutant load so that the treated waste can be reused as fertilizer or safely discharged into the sewage system [18, 19].

Conventional systems involve treating the effluent by means of concentrated physicochemical and biological processes in which the hydraulic retention time (HRT) is relatively short, and a stable operation can be ensured within preestablished and carefully controlled parameters. These have been implemented with varying degrees of success, but numerous problems have been reported, associated especially but not exclusively with the modes of operation and the costs of the system [18, 20–25].

Many pig farms have very tight profit margins and have few human resources due to direct competition with other more suitable production sectors, making on-farm effluent treatment necessary [19, 22, 26 - 27].

Natural treatment systems of wastewater (NTSW) employ effluent storage with a longer HRT which depends on the load applied and the climatic conditions, with the organic matter degraded though the activity of heterotrophic bacteria present in the natural environment. The treatment is carried out by passing the effluent through various types of ponds, artificial wetlands and anaerobic digesters, each of which facilitates a series of natural processes. Such systems have been successfully applied in rural community settings and small settlements with a population equivalent below 1000 [1, 2, 28].

However, when it comes to sizing such systems, there are no tools available for agricultural and livestock farms in isolated territories, with sizing limited to adaptations based on local farmer experience [29 - 30].

1.3. Geographic and primary sector overview

The island of Gran Canaria has a total 136 pig farms, the majority of which are small and family production. However, 10% of these farms account for more than 90% of the census and are industrial farms, in some cases close to environmental protection zones and are shown in Figure 1. For many years, livestock waste has been used as fertilizer in fields or farmland. However, in recent years, the gradual disappearance of these small farms and the increase in intensive livestock farming, the high number of animals per farm and the abandonment of traditional systems have led to a greater fluidity and dilution of the waste generated, thus increasing its volume, but there is not always enough arable land for its correct disposal [30].

Figure 1. Study pig farms in Gran Canaria

According to the applicable Spanish legislation, which establishes basic rules for the management of intensive pig farms, farms can be classified according to their productive capacity, which can be self-consumption farms, reduced farms and industrial farms, a self-consumption farm is considered a farm when it is used for the breeding of animals exclusively for family consumption, with a maximum production per year of 3 fattening pigs and without having a breeding farm; a reduced farm is one that houses a maximum number of 5 breeding animals, being able to keep a number of no more than 25 fattening animals.

This legislation also establishes standards for the management of livestock waste on the farm and the production of manure (theoretical maximum) by livestock unit (LSU). This unit is established for purposes of comparison between livestock species, classifying farms according to this value. By way of example, the corresponding LSU is 0.30 for boars with a waste production of 6.12 m^3/place/year, 0.96 for closed cycle sows with a waste production of 17.75 m^3/place/year, and 0.02 for piglets from 6 to 20 kg with a waste production of

0.41 m^3/place/year. This classification distinguishes between family farms, which may not house more than the equivalent of 5 LSUs, and industrial farms, which are farms with a capacity of up to 120 LSUs.

1.4. Objective

The objective and the novelty of this work is the proposal of a series of strategies and tools for the design and characterization the effluents of NTSW in livestock farms. As an application, an inventory, characterization, and sizing will be carried out for the pig farms with the greatest impact located on the island of Gran Canaria.

2. Materials and Methods

2.1. Model

In this article, the methodology was adapted from that shown and applied [18], in which a study of the water-energy-waste nexus is developed, considering parameters of waste generation, consumption and occupied surface. The integral model is shown in Figure 2, for the evaluation of livestock farms in Gran Canaria, also considering the parameters of greenhouse gas emissions (GHG).

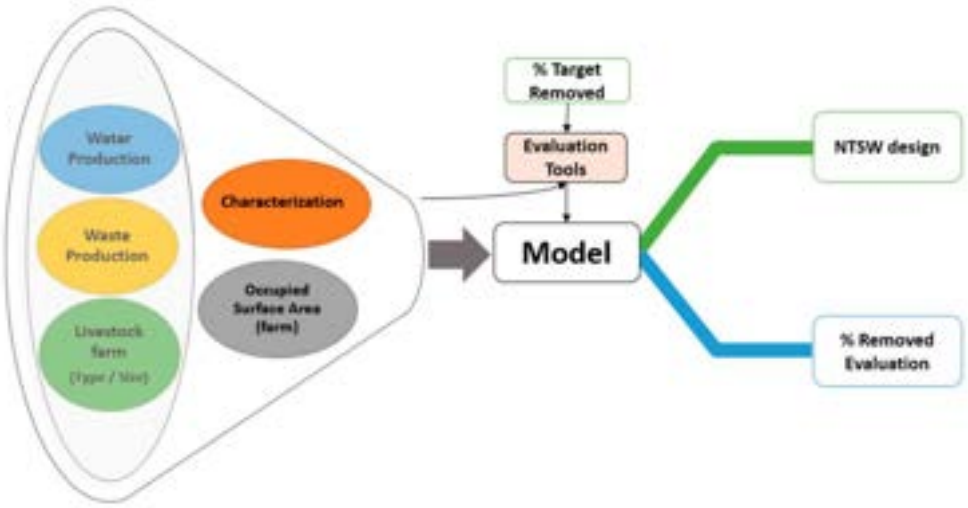

Figure 2. Model

2.2. Waste generation and characterization

Numerous authors have indicated the need to have tools to characterize livestock waste and to monitor parameters that are easy to apply and measure on the farm itself [1, 31–33].

Therefore, the waste generated in each farm was characterized considering the following variables: Q, COD, EC, TN and NH_3 from historical data.

The Q has been characterized by means of the correlation between the effluent flow rate and the number of sows with a correlation coefficient of 0.976 [2]. On the other hand, it was carried out according to Royal Decree 306/2020, of February 11, which includes the manure production (theoretical maximum) by type of livestock. As for COD, the correlation between input COD and Q; with a correlation coefficient of 0.575 [2].

For EC there is no significant correlation between conductivity and Q or COD, but there is a significant correlation with organic matter (Morg). For this reason, Morg was characterized by the correlation between Morg and COD with a correlation coefficient of 0.945 [2]. On the other hand, conductivity was calculated by the correlation between EC and Morg with a correlation coefficient of 0.938 [2].

Finally, the TN generated was characterized by correlation with an r=0.74 [31,34] and the generated NH_3 was characterized by the correlation with a correlation coefficient of 0.91 [31, 34].

Variable	unit	Correlation
Q	m^3/day	$Q=4.425+3.029\times10^{-7}\cdot(No.Sow)^3$
COD	mg/L	$COD=7{,}995.901+360.593\cdot(Q)^2-10.134\cdot(Q)^3$
Morg	mg/L	$Morg=162.505+0.273\cdot(COD)$
EC	dS/m	$EC\ (dS/m)=0.009\cdot(Morg)-8.4\times10^{-7}\cdot(Morg)^2$
TN	mg/L	$TN=83.79\cdot EC^{1.25}$
NH_3	mg/L	$NH_3=39.89\cdot EC^{1.343}$

2.3 Livestock farms.

The 9 selected farms on the island of Gran Canaria have from 15 to 220 sows (3.75 a 55 UGM), the farms total 4,442 animals, representing 94% of the total census on the island [35]. The farms have between 1,180 and 82, 065 m^2 of available land [36].

2.4 Natural Treatment Systems.

For the application of the NTSW, the starting point was the articles [1, 28] which study three livestock farms, one of which is our reference farm [2]. The criteria used for the design were the characteristics of the farms, Q, COD and EC.

2.5 Initial characterization and design of the treatment system.

For the application of the NTSW, the same rotary sieve (50mm) has been applied (and in the case of the digester and ponds plus wetlands, based on the data obtained in these articles, their behavior has been studied according to the needs of the farms studied [1, 2, 28]. The digester is more suited for a high removal of COD 2.33 %/day and ponds plus wetlands system is more suitable for a removal of EC 1.5%/day [2, 28]. To start, set the number of sows of the farm, set a depuration target (measured in COD and EC reduction) and characterize the waste generated, Q, COD, EC, NT, NH_3. A mechanical separation system is applied [21] and we study the behavior it has on the waste. With this final waste, we start to design the digester starting from 1 chamber with the desired volume (22, 10 and 5 m^3) [2, 28], considering the Q of the farm, with a % removal of COD and EC according to the volume of the chamber. As digester data we obtain COD, EC, hydraulic retention time (HRT) and total volume (V_{dig}) and we check if the livestock farm, due to its location and available surface, it is possible and necessary to apply a pond + wetland. For the application of a pond plus wetland we start from the criterion of the location of the farm, considering if it has a nearby population, since this process releases bad odours, and if it is in areas with a high percentage of rainfall and high altitude, being open systems more influenced by climatic conditions (temperature, humidity, rainfall, and evaporation). If it is not possible to design the pond, it is observed whether the results obtained meet the objective. If so, the digester is designed, if not, another chamber is added to the digester and so on.

In terms of its design, it is based on a 15-day HRT, thus setting the maximum volume of the basin (V_{Lag}), a COD removal rate of 1.34 %/day and an EC removal rate of 1.51 %/day [2]. With the results obtained we check if it meets the target. If the COD is high to the target, The volume of the digester would be increased by adding a chamber and so on, if the EC is high to the target we would increase the volume of the pond + wetland. The decision tree is shown in Figure 3, to characterize the natural depuration systems of livestock farms in Gran Canaria.

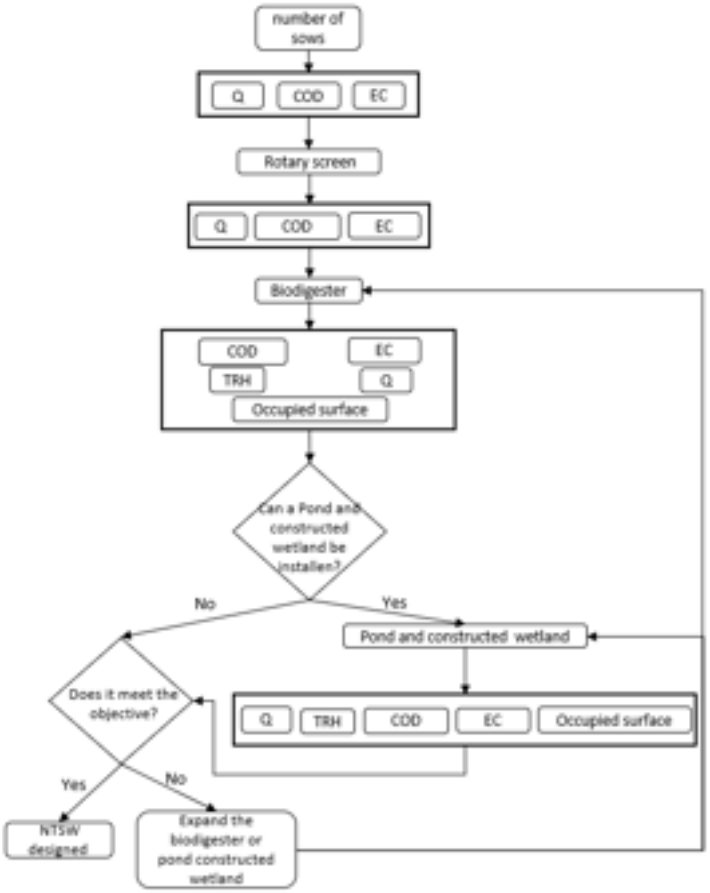

Figure 3. Decision tree.

3. Results and discussion

3.1. Types of farms and waste

This study has focused on 9 farms which, due to their characteristics, type of farm and number of sows, require a treatment system. From the farms studied, the waste generated was characterized, obtaining COD values between 24,078 and 8,049 mg/L, EC between 23 and 16 dS/m and between 2,625 and 1,704 mg/L of NH_3 generated. The selected farms have an available plot between 1,180 and 82,065 m^2, with different soil types and according to the Gran Canaria 2017 management plan could be built on the evaluated soils. By size and type of soil an NTSW can be implemented in the farms. These data are reflected in Table 1.

As mentioned above, to propose a natural depuration treatment system, it is necessary to know the waste generated in each farm, i.e., the slurry Q, COD, EC, TN NH_3.

The slurry flow rate was characterized by two criteria, by correlation and/or by Royal Decree 306/2020, February 11. The choice of one method or the other was based on the type of farm (intensive-confined or semi-confined) and the number of sows. These criteria are since an intensive-confined farm stores more manure than a semi-confined farm. However, intensive-confined farms have been characterized according to the Royal Decree. The reason for this choice is because, although they are industrial farms, the number of sows is lower than the other farms and in the case of using the criterion of number of sows, an error of 62-92% is made, resulting in over-dimensioning the capacity of the NTSW of the farms.

The COD values obtained are in the range between 24,078 and 7,999 mg/L. The mean value is within the range of the observed values of 5,000 and 25,000 mg/L [37], between 28,000 y 13,200 mg/L [38], between 14,200 y 9,400 mg/L [32].

The EC values found are in the range between 16,3 y 23 dS/m. Previous studies have found values, among 13.2 y 33.2 dS/m [31] and from to 9.9 y 25 dS/m [32] hence these results are considered valid.

Table 1. Characterization of farms and livestock wastes

Farm	X	Y	Z	Available area (m^2)	Type of farms	UGM (unit)	Q (m^3/day)	COD (mg/L)	Morg (mg/L)	EC (dS/m)	NT (mg/L)	NH_3N (mg/L)
1	458,08	3,091,56	249.26	18,935	intensive-confined	109.45	7.52	24078.48	6699.93	22.59	4127.14	2625.67

6	440,65	3,096,39	1216.72	10,089	intensive-confined	32.05	1.67	8953.96	2570.94	17.59	3017.58	1875.57
7	457,82	3,085,47	97.72	82,065	intensive-confined	50.95	2.60	10262.17	2928.08	19.15	3356.81	2103.01
8	434,67	3,081,32	202.11	5,931	semiconfined	14.8	0.81	8228.20	2372.80	16.63	2813.02	1739.31
9	445,53	3,097,59	1026.85	35,541	semiconfined	7.27	0.39	8049.96	2324.14	16.38	2761.10	1704.84

Finally, the TN generated was characterized by giving values between 2,746 y 4,347 mg/L and the NH_3 generated between 1,694 y 2,625 mg/L. The results obtained from the calculations performed high values of ammonia, which may affect health and productivity as described by several authors. [39 – 43], It is necessary to adequately manage livestock waste. Table 1 shows the results obtained in this study in the different farms.

3.2 Natural treatment system.

From [2, 28] the characteristics of the farms, where they are located, flow, COD, EC and according to current local legislation sets a maximum discharge target of 1600 mg/L COD and 2500 µS/cm EC the NTSW sizing has been proposed for each farm.

For farm 1, an NTSW consisting of a rotary screen, homogenizer tank and digester has been proposed. In the case of the sieve, it has been designed the same as that of the reference farm, giving a reduction percentage of 45% and an EC reduction percentage of 7.5%. As for the digester, starting with 4 chambers and a chamber

volume of 22 m^3, with a COD reduction percentage of 30%, a necessary volume of 96.82 m^3 and a hydraulic retention time of 13 days was obtained. However, the result of this design did not meet the objective. For this reason, 6 more chambers were added, increasing the COD reduction percentage to 77% and an HRT of 33 days.

In the case of farm 2, the same criteria are used, and the digester is also increased to a HRT of 26 days and a COD reduction percentage of 59.84%. In these two farms it was decided to increase the digester instead of installing a pond and wetlands, like the reference plant, because the digester has a higher percentage of COD reduction than the pond plus wetlands and because the area where these farms are located has low precipitation and therefore does not favour the degradation of organic matter in the pond.

For farms 4, 5, 6, 6, 7, 8 and 9, a NTSW consisting of a rotary screen, homogenizer tank and digester has also been designed. In these cases, the screen is the same for all, but the digester varies in terms of number of chambers, chamber volume and HRT, depending on the effluent conditions. All farms with an average of 25 HRT and an average COD reduction % of 61% meet the discharge criteria. However, farms 5, 6 and 9, due to their location, could be equipped with pond with wetlands. Therefore, for these farms it would be recommended to install a pond and wetland, even if they meet the objective, since this would improve the final discharge conditions. Appendix A shows the results obtained in this study in the different farms.

4. Conclusions

- The characterization of the parameters Q, COD, EC, NT, NH_3
- of the farms studied in Gran Canaria indicates the importance of adequate treatment in the farm itself to minimize the environmental impact that this activity supposes for the environment.
- NTSW are suitable and provide a viable treatment alternative for the livestock waste produced.
- There is no single NTSW model for all pig farms as the type, flow, organic load, location and climatic conditions of each one will dictate the conditions of its design.
- The proposed decision strategy tools for the design of NTSW have proven to be a useful tool for the sizing of the farms considered in the study.

5. Nomenclature

Q	flow rate
COD	chemical oxygen demand
EC	electrical conductivity
TN	total nitrogen
NH3	ammonia
GHG	greenhouse gas emissions
Morg	organic matter
N_o Sow	number of sows
LSU	livestock unit
HRT	hydraulic retention time

Abstract:

Numerous methods are invented to capture the dissipating heat from different sectors, among all, the combination of power generation and fresh water units in the form of integrated systems based on renewable energy has received less attention. In traditional systems, not only was energy wasted to the environment, but fossil fuels caused serious damage to the environment. To overcome this problem, a new solar-biomass driven integrated system is devised in this investigation. Instead of wasting the energy of sCO2 into the environment, a novel system is proposed to increase EUF. Meanwhile, the use of HDH-TVC-RO along with the MED unit increases the amount of freshwater rate. The results indicated that the fresh water rate, GOR, and EUF are 29.36 kg/s, 14.38, and 3.372, respectively. Hence, the total GOR of the devised system is constant with the alteration of input vapor pressure to HDH-TVC; in contrast, the total GOR is increased with the increase of the pressure ratio of compressors. In addition, the behaviour of the EUF is linear in the presence of alteration of both parameters of input vapor pressure parameters to HDH-TVC and the pressure ratio of compressors.

Keywords:

Parabolic trough collector, biomass gasification, SCO2, MED desalination, HDH-TVC-RO.

1. Introduction

Water and power are two essential resources necessary for human survival and the functioning of modern society. Unfortunately, the scarcity of these resources is a growing concern worldwide, particularly in areas with growing populations, increased industrialization, and changing weather patterns. Access to clean and safe drinking water is a fundamental human right, yet many people in developing countries still lack primary access to this resource. Furthermore, power outages and unreliable energy sources can disrupt daily life, especially in countries with limited infrastructure. As the world population grows, there is an urgent need to address these issues and find sustainable solutions to ensure that everyone has access to these vital resources. On the other hand, the production of water and power with fossil fuels has significant environmental impacts that damage the planet. The combustion of fossil fuels releases carbon dioxide and other greenhouse gases into the atmosphere, contributing to global climate change [1]. In addition to climate change, extraction, transportation, and burning of fossil fuels can cause air and water pollution, habitat destruction, and soil degradation. For example, coal-fired power plants produce large amounts of air pollutants such as sulphur dioxide, nitrogen oxides, and particulate matter, contributing to respiratory problems and other health issues[2]. Production of water using fossil fuels can also lead to environmental degradation. Given these negative impacts, there is an urgent need to transition towards cleaner and more sustainable alternatives to produce water and power, such as renewable energy sources such as solar, wind, and biofuels.

Today, the use of Integrated Systems using renewable resources (ISRR) is a very efficient cure to overcome the problems of water and power shortage due to increased efficiency, cost savings, enhanced resilience, reduced environmental impact, and increased flexibility. Over the past decade, several investigations have pivoted the limelight on the all-round usage of the ISRR via proposing various renewable energies such as wind, solar and biofuels (for employing its producing heat) or recommending different thermal-driven

desalination systems (for producing drinking water). Xia et al. [3] proposed a solar-powered supercritical carbon dioxide (sCO_2) cycle for reverse osmosis (RO) desalination. The recommended integrated system includes a sCO_2 power cycle, solar collectors, RO, and LNG subsystem. They employed thermodynamics analysis and maximized the rate of produced drinking water by using a genetic algorithm for parametric optimization. They found an optimal value for the turbine input pressure of the sCO_2 cycle to obtain the maximum exergy efficiency. Under optimal conditions, a proposed ISRR reached the daily exergy efficiency of 4.90% and produced 2537.33 m^3 of drinking water per day. In 2016, Kouta et al. [4] conducted an investigation on ISRR comprised of a solar tower, a sCO_2 subsystem (for power generation), and multiple effect desalination with thermal vapor compression (MED-TVC) (for freshwater production). They compared two sCO2 cycles consisting of regeneration and recompression. ISRR was analysed from thermodynamic and exergoencomic points of view; the result showed that the solar tower generated more than 80% of the total entropy in both configurations, followed by the MED-TVC system, and the sCO_2 subsystem. A case study for different cities in Saudi Arabia was conducted and these results were extracted that the cities of Yanbu, Khabt, and Al-Ghusn achieved the lowest cost, respectively. The Yanbu LCOE was 0.0826 $/kWh and 0.0915 $/kWh for the recompression and regeneration solar cycles at a fraction of 0.5, respectively. Then, Sharan et al. [5] found the optimal feed flow in a cogeneration system consisting of a MED and sCO_2 for the production of electricity and freshwater simultaneously. The results showed that the forward feed is an optimum configuration compared to the parallel/ cross one. Consequently, the forward feed configuration reduced the distilled cost by 2.6% and increased the distilled production by 7.5%. In the same year, Alharbi et al. [6] compared two integrated systems consisting of sCO2 as a power supplier combined with multi-effect desalination coupled with mechanical vapor compression (MED-MVC) and conventional MED. Since the efficiency of the MED system is higher in the forward feed configuration[5], they invented both integrated systems with forward feed configuration. It was generally perceived that the performance of the conventional MED system in universal performance ratio, total water price, and specific power consumption for MED systems was better than that of the MED-MVC system. In 2019, Sharan et al. [7] invented an innovative concept to reduce the cost of distilled water. In this regard, they introduced an ISRR which includes a sCO_2 Brayton cycle that uses its dissipating heat to run a MED system. Concentrating solar power (CSP) plants were responsible for supplying energy to the integrated system. Due to the intermittency of solar radiation, the system included tanks for storing solar energy. Optimization of the storage tank led to reduction of the cost of distilled water by 19% and increase of the capacity of MED system from 46% to 75%. In addition, they compared the MED and RO systems from the point of view thermoeconomic, the comparison revealed that the use of MED can decrease the cost of distillation by 16%. In order to compare the distillation methods in the ISRR systems, Rostamzadeh et al. [8] conducted a cost comparison in two different ISRR systems. They juxtaposed the hybrid HDH-RO system and the solo-RO system, both of them driven by dissipating heat of the wind turbine. The results revealed that the drinking water production using a solo RO unit is cheaper than one using a hybrid HDH-RO desalination unit. Exergic analysis and operation simulations of the concentrated solar-driven power and desalination (CSPD) system are carried out by Wang et al. [9]. They showed that the efficiency of the sCO_2 cycle could be 36.6%, while the distilled water and output power produced by CSPD are 4050.8 t/day and 50.1 MW/day, respectively. In order of thermodynamic metrics, the results pointed out that two highest energy destruction and two minimum exergy efficiency are related to heat exchanger of the desalination system and solar tower receiver. They concluded that the CSPD systems are economically feasible since the system has levelized cost of water (LCOW) of 1.15 $/t and LCOE of 0.059 $/kWh. Since the use of sCO_2 can reduce the cost of solar power generation, Yuan et al. [10] used sCO_2 in the ISRR combined with the MED unit. One of the concerns about the combination of the sCO_2 cycle with the MED unit was the possibility of a decrease in the efficiency of the sCO_2 cycle, which they showed that such a combination does not reduce the efficiency of the sCO_2. They showed in the low split ratio (the ratio of the mass flow rate of the main compressor to the total mass flow rate), approximately less than 0.6, that the amount of freshwater produced decreases with the increase of the split ratio. For values greater than 0.6 the freshwater rate is increased with the increase in the split ratio. In the optimal state, the LCOE is 0.081 $/kWh and the LCOW is 0.81 $/$m^3$. Using the five-effect distillation system, the freshwater results indicated that the rate is 459 m^3/day. Realizing that the heat dissipating from an CSP-sCO_2 can be used for free but with slightly reduced thermal efficiency, Omar et al. [11] invented a new ISRR based on CSP, a CO_2 cycle, and Cascade MED system. The results indicated that four-MED systems can maximize freshwater production, with 57% dissipating heat energy recovery compared to 26% waste heat recovery using a single-MED system. In another study, khanmohammadi et al. [12] proposed an ISRR system consisting of a solar collector, a humidification and dehumidification (HDH) unit. The system is surveyed using environmental simulation and thermodynamic modelling. The results indicated that an increase in the compressor pressure ratio leads to a decrease in COP and freshwater flow. Similarly, freshwater production and exergy efficiency decrease with an increase in the outlet pressure. Although the authors used a solar collector to supply the heat needed for the HDH system, they could use a sCO_2 system to increase the efficiency of the system and supply the energy by using dissipating the heat of the sCO_2 unit.

The use of clean energy to prevent serious damage to the environment is not limited to solar and wind energy. In several scholars, attention has been paid to biomass to supply the heat needed for ISRR

consisting of the sCO_2 cycle. Balafkandeh et al. [13] proposed a biomass-based heating, power, and cooling system configuration consisting of sCO_2.The system was analysed from thermodynamic exergoeconomic viewpoints, in addition an environmental analysis is carried out to evaluate the CO_2 emission of the proposed system. Cao et al. [14] introduced a biomass-fueled integrated cycle to generate adequate power. The invented system includes two Brayton cycles with working fluids of sCO2 and nitrogen. An economic and thermodynamic investigation is performed. To seek the optimum from the exergoeconomic viewpoint, multi-criteria optimization is conducted. The results indicated that the exergetic efficiency reach 43.51% and the power cost leads 19.78 $/GJ in state of optimal point. Finally, in 2023, Hai et al. [15] combined a biomass-fueled SCO2 cycle with a MED desalination system to product power and freshwater simultaneously with the highest efficiency and without harming the environment.

1.1. Scientific Gaps

According to the authors of the above-reviewed works, it can be understated that there are considerable scientific gaps in previous studies dealing with the integration of the sCO_2 cycle with a desalination unit as a bottoming cycle for the production of power and drinking water, simultaneously. Although it has been shown in the above literature that various sources of clean energy including solar, wind and biomass can be used to supply the required heat of the bottoming cycle (e.g., MED unit), each of them has shortage. To date, no one has used the combination of two renewable resources for driving one of the desalination methods. It has been indicated that using the MED unit as the bottoming cycle of the sCO2 system driven by a biofueled heat source is carried out by Hai et al. [15]. However, they did not pay attention to the fact that the fresh water produced by the MED unit has a high temperature compared to the ambient temperature. In this case, by slightly increasing the temperature of the produced water, it can be used as an energy supplier in low-temperature cycles such as HDH unit. Furthermore, it is obvious that the drinking water distillated from a MED unit is more expensive than an HDH unit due to Khalilzadeh and Nezhad [16]reported a high value of 16.16 $/kWh for the cost of fresh water.

1.2. Novelties

Integration of the Rankine cycle with a distillation system can increase the operating pressure of the condenser (in the Rankine cycle), which leads to an increase in the heat-rejection temperature. Still, such a combination reduces the efficiency of the power plant's efficiency[5]. To eliminate the defect of reducing efficiency, it is possible to utilize the sCO_2 Brayton cycle because it has high efficiency compared to the Rankine cycle. On the other hand, the sCO_2 cycle has high-temperature rejection that is suitable for driving an MED system[7]. As mentioned, the biomass-fueled integration of the sCO_2 and MED unit was investigated in 2023. But in the present study, to increase the amount of freshwater production, the freshwater produced by the MED unit, which has a relatively high temperature, was redirected to a new subsystem consisting of HDH-TVC-RO. Solar collectors are used to increase the temperature of the redirected freshwater that drives the HDH-TVC-RO unit. All in all, the primary purpose of this study is multifaceted and is pinched as follows:

- Proposing a novel integrated system using biomass and solar energy as primary sources.
- Using MED, HDH, and RO desalination unit and sCO_2 cycle in the solar biomass-based multigeneration unit.
- investigating a comprehensive study assessing the impacts of vital parameters on the performance of the invented integrated system.

2. Description of the setup

A schematic diagram of the proposed system is shown in Fig. 1. The system consists of five subsystems: gasifier, supercritical CO2 cycle, Multi-effect desalination system, Parabolic Trough Solar and varied pressure humidification-dehumidification system coupled with reverse osmosis. In the gasification process, biomass (68) and environmental air (69) are fed to the gasifier where syngas is produced. Syngas is then fed to the combustion chamber (CC) together with the hot air exiting from the Air pre-heating (76). The high-temperature combustion products (71) are directed to the reactor to supply the energy for the supercritical CO2 cycle, which is used to increase the turbine inlet temperature (TIT) in the S–CO2 cycle (2). The SCO2 power cycle is actually a combination of the Power system and the MED (multi-effect desalination) so that the heat rejected in the gas cooler1 of the S–CO2 system is utilized to run the MED which is used to produce fresh water in the MED system.

Some of the water produced by the MED system increased pressure by the water pump (62). The high-pressure water then takes its initial energy through the PTC (Parabolic Trough Collector) system, and the high-pressure water is converted into steam by the evaporator, which obtains this energy from the exhaust gas. The high-pressure steam (46) by thermal vapor compressor enters a humidification-dehumidification system coupled with reverse osmosis to produce more water.

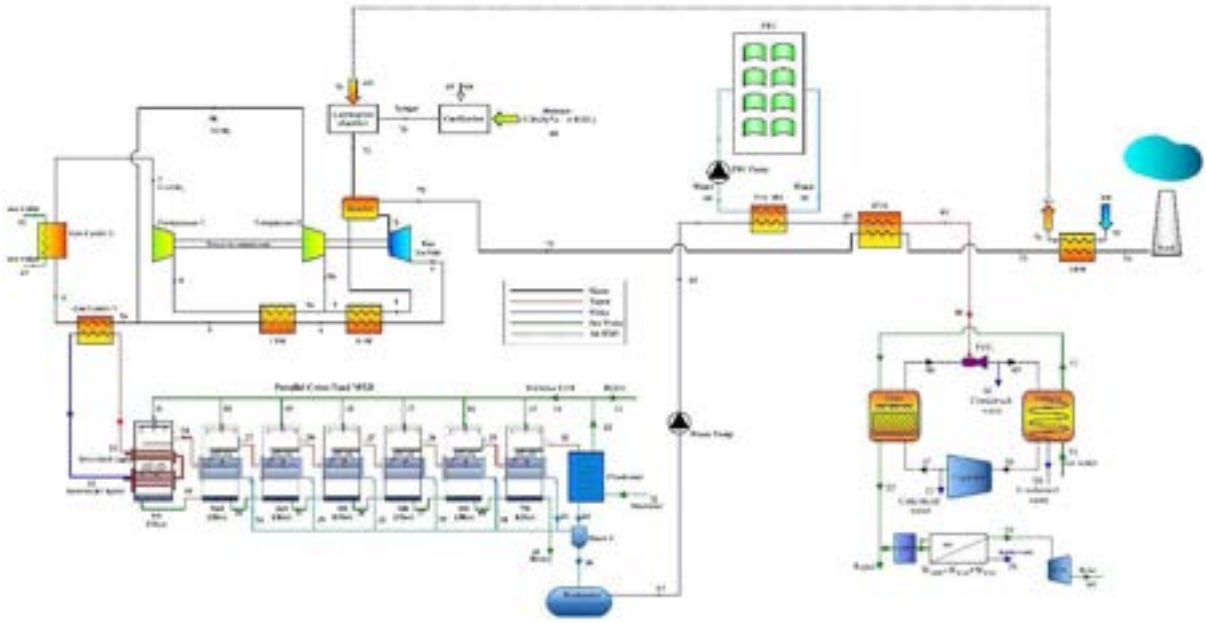

Figure 1: Schematic of the devised solar-biomass-driven power/desalination unit.

3. Materials and Methods

3.1. Thermodynamic assumptions

To analyse the proposed solar-biomass integrated system, below assumptions are developed:

- All Governing equations and thermodynamic process are advanced under steady-state condition.
- The freshwater temperature is assumed as the average temperature of the air in the closed loop of HDH unit.

In addition, other required thermodynamic data for the devised system is illustrated in Table 1.

Table 1: Set of input parameters for thermodynamic simulation of the devised system.

The input data	Unit	Value	Ref.
Ambient temperature	K	298.15	[17]
Ambient press	bar	1.013	[17]
Gasifier and combustion reactions			
Type of biomass feedstock		$Wood\ CH_{1.44}O_{0.66}$	[18]
Biomass flow rate	Kg, s^{-1}	1.115	[19]
Moisture content	%	20	[18]

Number of pressure vessels		42	[28]

3.2. Energy analysis

Conservation equations including energy and mass can be articulated as [29]:

Mass balance Eq.:

$$\sum \dot{m}_{in} - \sum \dot{m}_{out} = 0 \tag{16}$$

Energy balance Eq.:

$$\dot{Q}_{c.v.} - \dot{W}_{c.v.} = \sum (\dot{m}h)_{out} - \sum (\dot{m}h)_{in} \tag{17}$$

Salinity balance Eq.:

$$\sum (\dot{m}S)_{in} - \sum (\dot{m}S)_{out} = 0 \tag{18}$$

The desalination flow ratio (MR) of the HDH unit is expressed as follows [23]:

$$MR = \frac{\dot{m}_{seawater}}{\dot{m}_{dryair}} \tag{19}$$

The effectiveness of humidifier/dehumidifier (ε) is expressed as below [23]:

$$\varepsilon = \frac{\Delta \dot{H}}{\Delta \dot{H}_{max}} \tag{20}$$

The energy, mass and salinity relations for each component of the invented system are showed in Table 2.

Table 2: Mass, Salinity, and Energy balance equations for each component of the proposed system.

Component	Mass and energy balance equations
Reactor	$\dot{Q}_{Rect} = \dot{m}_{71}(h_{71} - h_{72}) = \dot{m}_2(h_2 - h_1)$
Gas Turbine	$\dot{W}_{Gastur} = \dot{m}_2(h_2 - h_3), \quad \eta_{Gastur} = \frac{h_2 - h_3}{h_2 - h_{3S}}$
HTR	$\dot{Q}_{HTR} = \dot{m}_3(h_3 - h_4) = \dot{m}_1(h_9 - h_1)$
LTR	$\dot{Q}_{LTR} = \dot{m}_4(h_4 - h_5) = \dot{m}_8(h_9 - h_8)$
Compressor 1	$\dot{W}_{comp\,1} = \dot{m}_7(h_8 - h_7), \quad \eta_{comp\,1} = \frac{h_7 - h_{8S}}{h_7 - h_8}$
Compressor 2	$\dot{W}_{comp\,2} = (x)\dot{m}_5(h_9 - h_5), \quad \eta_{comp\,2} = \frac{h_5 - h_{9S}}{h_5 - h_9}$
Gas cooler 1	$\dot{Q}_{GC1} = \dot{m}_6(h_5 - h_6) = \dot{m}_{22}(h_{22} - h_{23})$
Gas cooler 2	$\dot{Q}_{GC2} = \dot{m}_6(h_6 - h_7) = \dot{m}_{10}(h_{67} - h_{10})$
Effects	$T_{V,out} = T_{\mathrm{B,out}} = T_{\mathrm{V,in}} - \Delta T_{Eff}$

	$\dot{m}_{\mathrm{SW}} + \dot{m}_{\mathrm{B,in}} = \dot{m}_{V,out} + \dot{m}_{\mathrm{B,out}}$ $\dot{m}_{B,in} S_{\mathrm{B,in}} + \dot{m}_{\mathrm{SW}} S_{\mathrm{SW}} = \dot{m}_{B,out} S_{\mathrm{B,out}}, \quad \dot{m}_{\mathrm{SW}} = \frac{\dot{m}_{14}}{N_{Eff}}$ $\dot{m}_{\mathrm{FW}} h_{\mathrm{FW}} + \dot{m}_{V,out} h_{V,out} + \dot{m}_{\mathrm{B,out}} h_{\mathrm{B,out}} = \dot{m}_{\mathrm{SW}} h_{\mathrm{SW}} + \dot{m}_{V,in} h_{V,in} + \dot{m}_{B,in} h_{\mathrm{B,in}}$
condenser	$\dot{Q}_{Cond} = \dot{m}_{12}(h_{12} - h_{11}) = \dot{m}_{42}(h_{42} - h_{44})$
Mixer	$\dot{m}_{26} h_{26} + \dot{m}_{29} h_{29} + \dot{m}_{32} h_{32} + \dot{m}_{35} h_{35} + \dot{m}_{38} h_{38} + \dot{m}_{41} h_{41} = \dot{m}_{45} h_{45}$
Water Pump	$\dot{W}_{WPump} = \dot{m}_{61}(h_{62} - h_{62}), \quad \eta_{WPump} = \frac{h_{61} - h_{62}}{h_{61} - h_{62S}}$
PTC HX	$\dot{Q}_{PTC,Hex} = \dot{m}_{62}(h_{63} - h_{62}) = \dot{m}_{65}(h_{65} - h_{66})$
Evaporator	$\dot{Q}_{Eva} = \dot{m}_{63}(h_{64} - h_{63}) = \dot{m}_{72}(h_{72} - h_{73})$

High Pressure Pump	$\dot{W}_{hpp} = \dot{m}_{57}(h_{57} - h_{53})$ $\dot{W}_{hpp} = \dot{W}_{exp} + \dot{W}_{ert}, \quad \eta_{pu} = \frac{h_{57s} - h_{53}}{h_{57} - h_{53}}$
Energy recovery turbine	$\dot{W}_{ert} = \dot{m}_{59}(h_{59} - h_{60}), \quad \eta_{ert} = \frac{h_{360} - h_{60}}{h_{60} - h_{60}}$

3.3. Performance Criteria

The net power of the gas turbine is articulated as follows.

$$\dot{W}_{net,GT} = \dot{W}_{Gastur} - \dot{W}_{comp\ 1} - \dot{W}_{comp\ 2} \qquad (31)$$

where, $\dot{W}_{Gastur}$, $\dot{W}_{comp\ 1}$, and $\dot{W}_{comp\ 2}$ are the produced power by gas turbine, Power consumed by compressors 1 and 2. The net output power of the devised system can be written as follows.

$$\dot{W}_{net,total} = \dot{W}_{net,GT} - \dot{W}_{WPump} \qquad (32)$$

The gain output ratio (GOR) of the HDH-TVC-RO unit, MED unit, and the proposed integrated system is expressed as [23]:

$$GOR_{HDH-TVC-RO} = \frac{\dot{m}_{54} + \dot{m}_{55} + \dot{m}_{56} + \dot{m}_{58}}{\dot{m}_{46}} \qquad (35)$$

$$GOR_{MED} = \frac{\dot{m}_{45}}{\dot{m}_{22}} \qquad (35)$$

$$GOR_{total} = \frac{\dot{m}_{45} - \dot{m}_{61}}{\dot{m}_{22}} + \frac{\dot{m}_{54} + \dot{m}_{55} + \dot{m}_{56} + \dot{m}_{58}}{\dot{m}_{46}} \qquad (35)$$

Another important metric in the setup is the Recovery Ratio (RR) which is which is defined as follows for the HDH-TVC-RO unit, the MED unit, and the proposed integrated system [23].

$$RR_{HDH-TVC-RO} = \frac{\dot{m}_{54} + \dot{m}_{55} + \dot{m}_{56} + \dot{m}_{58}}{\dot{m}_{51}} \qquad (36)$$

$$RR_{MED} = \frac{\dot{m}_{45}}{\dot{m}_{11}} \quad (36)$$

$$RR_{total} = \frac{\dot{m}_{45} - \dot{m}_{61} + \dot{m}_{54} + \dot{m}_{55} + \dot{m}_{56} + \dot{m}_{58}}{\dot{m}_{11} + \dot{m}_{51}} \quad (36)$$

Finally, the Energy Utilization Factor (EUF) is defined as [27]:

$$EUF = \frac{\dot{W}_{net,total} + (\dot{m}_{45} - \dot{m}_{61})h_{45,fg} + \dot{m}_{54}h_{54,fg} + \dot{m}_{55}h_{55,fg} + \dot{m}_{56}h_{56,fg} + \dot{m}_{58}h_{58,fg}}{(\ LHV_{biomass} \times \dot{m}_{biomass} + \dot{Q}_{PTC,Hex}\ )} \quad (36)$$

4. Results and discussion

4.1. Model Comparison

In this subsection, a comparison between devised system (shown in Fig. 1) and the five different studies is carried out, and the results are illustrated in Table 3.

In the current research, we explore the utilization of solar energy and biomass gasifier as the primary energy sources, while employing the SCO_2 power cycle for efficient electricity generation. Moreover, we have incorporated multiple units, namely the MED, HDH-TVC, and RO, which collectively yield a substantial amount of freshwater. The proposed cycle exhibits impressive performance, with a power output of 4250 kW and a freshwater production rate of 29.36 kg/s. Notably, the recovery ratio, GOR, and EUF are reported as 23.74%, 14.38, and 3.372, respectively.

Comparatively, our findings demonstrate superior efficiency when contrasted with previous works. Table 3 illustrates that the GOR values and EUF values of prior studies range from 6.3 to 10.2 and from 0.516 to 0.884, respectively, further highlighting the enhanced performance of our present work.

Table 3: Model comparison between the reference system and the devised WT/HDH-MED-MVC system.

Ref.	Similar subsystems	Net output power (kW)	Freshwater rate (kg/s)	Recovery ratio (%)	GOR	EUF
Present study	Solar biomass, SCO2-MED, HDH-TVC-RO	4250	29.36	23.74	14.38	3.372
[8]	HDH-RO	4459	0.59	13.1	-	-
[30]	Solar, MED	419.2	6.8	26.01	8.5	0.884
[31]	SCO2-MED	290960	214.9	-	6.3	0.516
[32]	Biomass, GT, MED	220.4	0.48	-	-	0.55
[33]	Solar, MED-TVC	-	34.72	-	10.2	-

4.1. Basic results

For a base form of the study, the thermodynamic metrics of the devised system are presented in Table 4. The most important metrics include the mass flow rate of biomass, total freshwater distilled from the system, total GOR and EUF.

Table 4: Main thermodynamic metrics evaluated for the devised system.

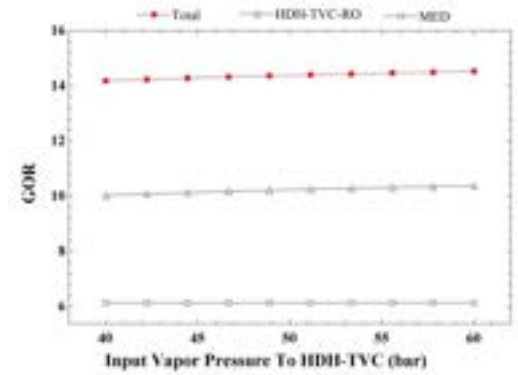
$\dot{m}_{biomass}$	1.155 kg/s
$\dot{W}_{net,total}$	4250 kW
$\dot{m}_{fw,med}$	7.361 kg/s
$\dot{m}_{fw,HDH-TVC-RO}$	24.38 kg/s
$GOR_{HDH-TVC-RO}$	10.23
GOR_{MED}	6.133
GOR_{total}	14.38
RR_{MED}	26.73%
$RR_{HDH-TVC-RO}$	25.36%
RR_{total}	23.74%
EUF	3.372

4.1. Parametric Evaluation

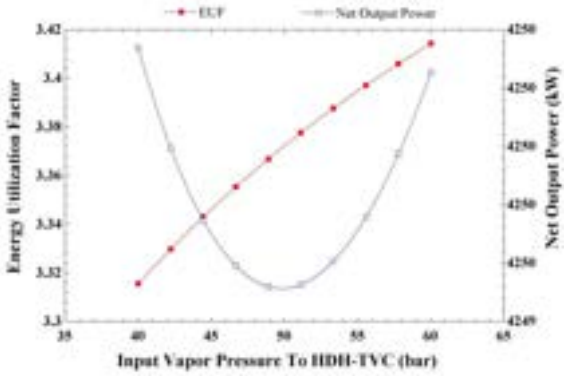
In this section, the impact of the input vapor pressure to HDH-TVC and the compression pressure ratio are investigated on the main impressed performance criteria such as GOR, net output power and EUF for HDH-TVC-RO unit MED unit, and whole invented system.

4.1.1. Impact of the input vapor pressure to HDH-TVC on the system

Fig. 2 shows an alteration of the GOR, net output power, and EUF versus the input vapor pressure to HDH-TVC. As Fig. 2 (a) illustrates, in two subsystems of HDH-TVC-RO and MED, and in the entire system, the GOR is slightly increased with the increase in the input vapor to HDH-TVC. In the entire range of input vapor pressure to HDH-TVC changes from 40 to 60, the GOR value for the HDH-TVC-RO unit is higher than for the MED unit. Fig. 2 (b) shows the net output power as well as EUF versus the input vapor to HDH-TVC. As the input vapor pressure of HDH-TVC increases, the EUF value also increases almost linearly. Accordingly, the EUF value is almost 3.31 in input vapor pressure to HDH-TVC value of 40 and the value EUF increases until it reaches 3.42 at the input vapor pressure to HDH-TVC value of 60. On the other hand, the behaviour of net output power is parabolic in relation to the input vapor pressure to HDH-TVC. In this sense, as the input vapor pressure for HDH-TVC increases to 50, the net output power decreases and then increases.



(a)

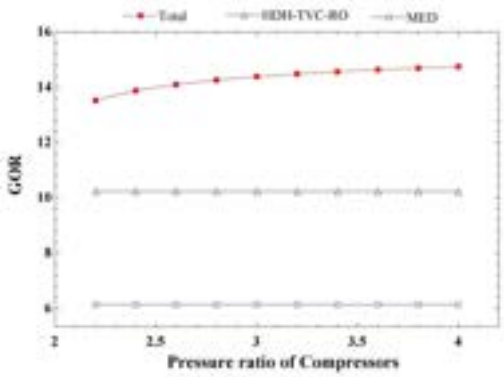


(b)

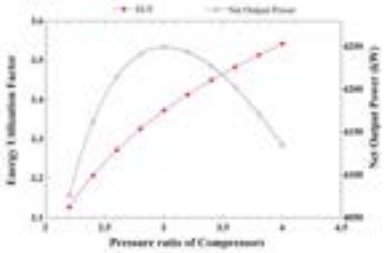
Figure 2: Impact of the input vapor pressure on HDH-TVC on the: (a) GOR, (b) EUF and net output power.

4.1.1. Impact of the pressure ratio of compressors on the system

Fig. 3 displays an alteration of the GOR, net output power, and EUF versus the pressure ratio of the compressors. As Fig. 3 (a) shows, the GOR of the MED subsystem remains almost constant and its value is equal to 6. In HDH-TVC-RO subsystem, the GOR remains constant and its value is equal to 10, similar to what we saw in MED subsystem. It is clear that in general the GOR of the HDH-TVC-RO subsystem is higher than that of the MED subsystem in the entire range of the pressure ratio of compressors. First, the total GOR increases with increasing pressure ratio of compressors. Its value reaches 15 at the pressure ratio of the compressors value of 3.7, then its value remains constant. Fig. 3 (b) shows the net output power as well as EUF versus pressure ratio of the compressors. The effect of pressure ratio changes on EUF is almost linear and the EUF is increased with increase of the pressure ratio of compressors. The EUF increases from 3.1 to 3.55, while the pressure ratio of the compressors varies from 2.2 to 4. The behavior pattern of net output power with the pressure ratio of compressors change is parabolic. The net output power starts from 4050 kW at the pressure ratio of compressors value of 2.2, and the net output power increases until it reaches its maximum (4250 kW) at the pressure ratio of compressors value of 3. Then the net output power decreases until it reaches 4125 kW at a compressor pressure ratio of 4.



(a)



(b)

Figure 3: The impact of pressure ratio of compressors on the: (a) GOR, (b) EUF and net output power.

5. Concluding remarks

An integrated system with renewable resources is a matured solution to tackle the problems arising during the use of fossil fuels. On the other hand, to increase power production, SCO_2 cycles can be used, which have higher efficiency and the ability to drive a MED system. Consequently, in the present study, in addition to using the MED unit, the HDH-TVC-RO unit has also been used in the configuration. In regard to that, the following concluding points can be drawn:

- In the base mode, the fresh water rate, the GOR, and the EUF are 29.36 kg/s, 14.38, 3.372, respectively.
- The GOR of the HDH-TVC-RO unit is 40% higher than that of the MED unit, regardless of the value of input vapor pressure to HDH-TVC and pressure ratio of compressors.
- The total GOR of the developed system is constant and equal to 14.38 by changing vapor pressure to HDH-TVC.
- The total GOR enhances by increasing the pressure ratio of compressors
- The power generation process exhibits an interesting characteristic where an optimal point is reached when the pressure ratio of compressors is set to 3.
- The Energy Utilization Factor (EUF) experiences a notable improvement of 13.5% as the pressure ratio of compressors increases from 2.25 to 4.
- The EUF of the proposed cycle demonstrates a remarkable achievement, being nearly four times higher than that of previous works.

Nomenclature

Symbols		**Subscripts and superscripts**	
GT	Gas turbine	B	Brine
HTR	High Temperature Recuperator	CV	Control volume
LTR	Low Temperature Recuperator	da	dry air
MED	Multi effect desalination	Dhum	dehumidifier
RR	Recovery Ratio	Eff	Effect
EUF	Energy Utilization Factor	en	energy
LHV	Low Heat value $(kJ.kg^{-1})$	F	fuel
RO	Reverse Osmosis	FW	freshwater
HTR	High Temperature Recuperator	Hum	humidifier
LTR	Low Temperature Recuperator	in	inlet

GOR	Gained-Output-Ratio	max	maximum
h	specific enthalpy $(kJ.kg^{-1})$	net	net value
RO	Reverse Osmosis	out	outlet
$\dot{m}$	mass flow rate $(kg.s^{-1})$	pum	pump
N	Number of effects	ert	Energy recovery turbine
P	pressure (bar)	s	constant entropy
S	Salinity $(g.kg^{-1})$	SW	seawater
s	specific entropy $(kJ.kg^{-1}.K^{-1})$	tot	total
T	temperature (K)	v	vapor
TTD	terminal temperature difference(K)	w	work
$\dot{W}$	power (kW)	r	rated
$\dot{Q}$	Heat (kW)	rev	reversible
Greek Symbols		exp	Expander
ω	humidity ratio	hpp	High Pressure Pump
ε	Effectiveness (%)		
η	Efficiency (%)

Abstract:

Over time, the water shortage crisis will have irreparable effects on the lives of many organisms, including humans. As a small contribution to alleviate the problem, the present work presents an innovative cogeneration system based on solar and wind renewable energies for sustainable production of freshwater, power, and wastewater treatment. To produce freshwater and treat wastewater in this system, the integration of a Microbial Desalination Cell with a Humidification-Dehumidification and Reverse Osmosis water desalination unit has been used. These systems obtain the required heat from solar energy to produce freshwater, and when solar radiation is unable to provide this heat, a hydrogen internal combustion engine driven with wind energy is used. Excess heat from the internal combustion engine is fed into the organic Rankine cycle with the working fluid R141B to generate power, to reduce the system waste heat and to increase the efficiency. To check the performance of the proposed system, energy, exergy, exergeoeconomic, and exergoenvironmental (4E) analyses have been carried out. The results of the analysis of the integrated system show that this system can produce 720 kW of electricity and 5.36 m^3/h of freshwater. The energy efficiency of the system is 22.09%, and its overall cost rate and overall environmental impact rate are 540.33 $/h and 17.37 Pts/h, respectively.

Keywords:

Microbial Desalination Cell (MDC); Humidification-Dehumidification (HDH); Hydrogen Internal Combustion Engine (HICE); Solar and wind energy; Cogeneration.

1. Introduction

In today's world, the crisis of freshwater scarcity has become one of the main problems that are exacerbated in many regions of the world due to the continuous reduction of water resources and population growth. According to the World Health Organization statistics [1], only 30,000 m^3 of freshwater worldwide are accessible for human use, and the largest amount of freshwater exists as precipitation and polar ice caps in the North and South Poles, which are difficult to access. Producing freshwater through various methods has been proposed as one of the effective solutions for the optimal management of water resources. One of these methods is the use of cogeneration cycles for producing freshwater, wastewater treatment, and power generation simultaneously. In these systems, it is possible to increase efficiency and benefit from water, energy, and environmental resources.

To increase the efficiency of these systems in freshwater production, the HDH (Humidification-dehumidification) system can be used. In this system, by using air humidification and passing this air through

a cold surface, water humidity can be recovered and fresh water can be produced [2]. Due to the lack of need for external energy sources and simple operation, as well as the benefits of low maintenance and capital costs, HDH has been proposed as an efficient method in freshwater production [3]. In this regard, zubair et al [4]. have investigated that the HDH desalination system integrated with solar evacuated tubes, in various locations, can produce freshwater in the range of 16,430 to 19,445 l with costs ranging from 0.032 to 0.038 US$ per litter. Furthermore, Khoshgoftar Manesh et al [5]. proposed a cycle along with HDH for the production of power, hydrogen, hot water, and freshwater. Their results indicate that the energy and exergy efficiencies, as well as the overall annual cost and environmental impacts of the system, are 23.87%, 28.21%, 0.144 kWh/$, and 0.024 Pts/kWh, respectively. In addition, it is possible to simultaneously generate electrical power, remove salt from water, and treat wastewater using Microbial Desalination Cell (MDC) systems [6]. The features of MDC are perfectly aligned with our goals in freshwater cogeneration cycles, wastewater treatment, and power generation. Furthermore, to prevent energy loss and increase freshwater production, the integration of HDH technology with RO (Reverse Osmosis) is used. By integrating HDH and RO technologies, Ravajiri et al [7]. produced a total of 184.3 m^3/h of freshwater.

There are various methods available for recovering heat used in the freshwater production process. Khoshgoftar Manesh et al [8]. explored a recovering heat process for freshwater production in a proposed system based on an integrated solid oxide fuel cell-gas turbine-organic Rankine cycle-multi effect distillation system. The optimized hybrid system was capable of producing 5000 cubic meters of freshwater per day with five effects on MED-TVC. Various sources such as internal combustion engines, turbines, and solar panels are utilized for heat recovery. However, among them, heat recovery from internal combustion engines is one of the best methods for freshwater production processes, considering the simultaneous production of power and heat as well as the high rate of heat entry into the system by the engines [9]. In addition, various fuels such as gasoline, diesel, and hydrogen can be used in internal combustion engines [10]. The use of hydrogen in these engines results in minimal carbon dioxide emissions and minimizes its pollutants [11]. Furthermore, due to its high atomic energy, the use of hydrogen provides very high efficiency in heat recovery [12]. Nikitin et al [13]. used HICE (Hydrogen Internal Combustion Engine) in a multi-generation system based on solar and wind energy. The dynamic results of HICE have been reported in several different cities, showing an average return ranging from 21.82% to 24.76%.

In cogeneration systems, renewable energies such as solar and wind energy can be utilized. The addition of these renewable energies to cogeneration systems provides numerous benefits for the cycle [14]. One of the greatest benefits of using renewable energies in cogeneration systems is the reduction in production costs [15]. These types of energies are obtained directly from nature, and the costs of fuel, maintenance, and installation of power and heat generation systems from these energies are much lower [16]. Moreover, the use of these energies leads to a reduction in environmental impacts due to the decrease in greenhouse gas emissions [17]. Khoshgoftar Manesh et al [18]. investigated the most important renewable energy-based polygeneration systems for producing fresh water using thermal desalination and membrane processes. The most promising options include the integration of thermal and membrane desalination technologies such as Multi-Stage Flash (MSF), Multi-Effect Distillation (MED), Humidification-Dehumidification (HDH), and Reverse Osmosis (RO). makkeh et al [19]. in another study, investigated a combined system of solar collectors and wind turbines for generating power and freshwater. They reported that this configuration reduces the cost of freshwater production by up to 23%.

Studies indicate that the use of various water desalination methods is essential for mitigating the water scarcity crisis. On the other hand, given the limitations of each water desalination method, integrating different desalination techniques can be effective in improving the efficiency of desalination plants. In this regard, the present work proposes a co-generation system for desalination, power generation, and wastewater treatment based on solar and wind energy. In this system, the scenario of freshwater production is evaluated for the first time by integrating MDC-HDH-RO. Solar energy is utilized to provide the required heat for the system. During possible periods of radiation reduction or at night, an internal combustion engine based on hydrogen produces simultaneous power and heat. Reducing engine losses and recovering its heat is essential for increasing efficiency, and the presence of an Organic Rankine Cycle (ORC) can greatly address this issue. In the end, energy, exergy, economic, and environmental analyses have been utilized in the present study to analyze the efficiency of using such a system from various perspectives. The innovations involved in the present work are as follows:

- Integration of MDC-HDH-RO desalination systems has been utilized for freshwater production.
- A combination of solar and wind energy has been employed to minimize the system's emissions.
- A hydrogen-based internal combustion engine has been utilized to simultaneously generate power and heat.

2. System description

The present work proposes a cogeneration system based on solar and wind energy for freshwater production, power generation, and wastewater treatment in Tehran, Iran. Tehran city is located between 51 degrees 6 minutes to 51 degrees 38 minutes east longitude and 35 degrees 34 minutes to 35 degrees 51 minutes north latitude. The average wind speed and solar radiation in Tehran are 4.5 m/s and 514.05 W/m^2, respectively [20].

To produce freshwater in the current system, MDC-HDH-RO desalination units have been integrated. The saline water is initially introduced into the MDC and desalination using anion exchange membranes (AEM) and cation exchange membranes (CEM) as well as the potential difference between the cells. This process leads to the pre-treatment of wastewater and power generation while producing freshwater. The saline water, after the primary desalination by MDC, enters the Flat Plate Collectors (FPC) and receives the required heat before being directed to the HDH desalination unit for further freshwater production. In HDH, the air is humidified under standard environmental conditions and, as a result of a collision with hot water, heat, and mass transfer occur. Following this, some amount of saline water enters the air as humidity and is transferred to the dehumidifier, where it undergoes mass and heat transfer in the presence of freshwater, resulting in increased production of freshwater. RO integration has been utilized at the outlet of HDH to increase efficiency and further enhance freshwater production.

Because solar energy varies throughout the day and to ensure stable production of fresh water, the use of an internal combustion engine allows for heat recovery in the freshwater production system. To reduce the environmental impact of ICE, hydrogen fuel has been considered for this equipment, which is produced using a PEM electrolyzer.

The power consumption of the PEM electrolyzer is supplied using renewable wind energy. Furthermore, wind turbines are also used to supply the electricity required for RO. The remaining power produced by the wind turbines is injected into the grid.

Finally, to reduce the thermal losses of the studied system, the use of an organic Rankine cycle with R141B as the working fluid has been considered. The proposed system is shown in Fig. 1.

The following assumptions have been made for this system:

- The system has been analyzed in a steady-state condition.
- Changes in potential and kinetic energies are negligible.
- The temperature, pressure, and relative humidity of Tehran city are considered to be 25℃, 1.01 bar, and 30%, respectively.
- Heat losses have been disregarded in all heat exchangers and water desalination units.
- An isentropic efficiency of 85% is considered for the organic turbine and an isentropic efficiency of 80% is considered for the organic pump.
- An isentropic efficiency of 85% is assumed for the RO pump.
- The salinity concentration of the feedwater to the MDC is 35000 mg/l [6].
- Artificial wastewater containing 1000 mg/L of acetate has been used as the feed for the MDC [6].
- The HDH packings are made of polypropylene and have a specific surface area of 320 m^2/m^3 [21].
- Only variations in the air in the x-direction and variations in water in the z-direction have been considered in the HDH desalination process.
- The LTW77 wind turbine model with a capacity of 1 MW has been considered [21].
- The temperature and pressure in the PEM electrolyzer are assumed to be constant at 80 ℃ and 1 bar, respectively [22].
- The air-to-fuel ratio for the internal combustion engine has been considered to be 34.3 [23].
- A 4-cylinder inline internal combustion engine model has been considered.

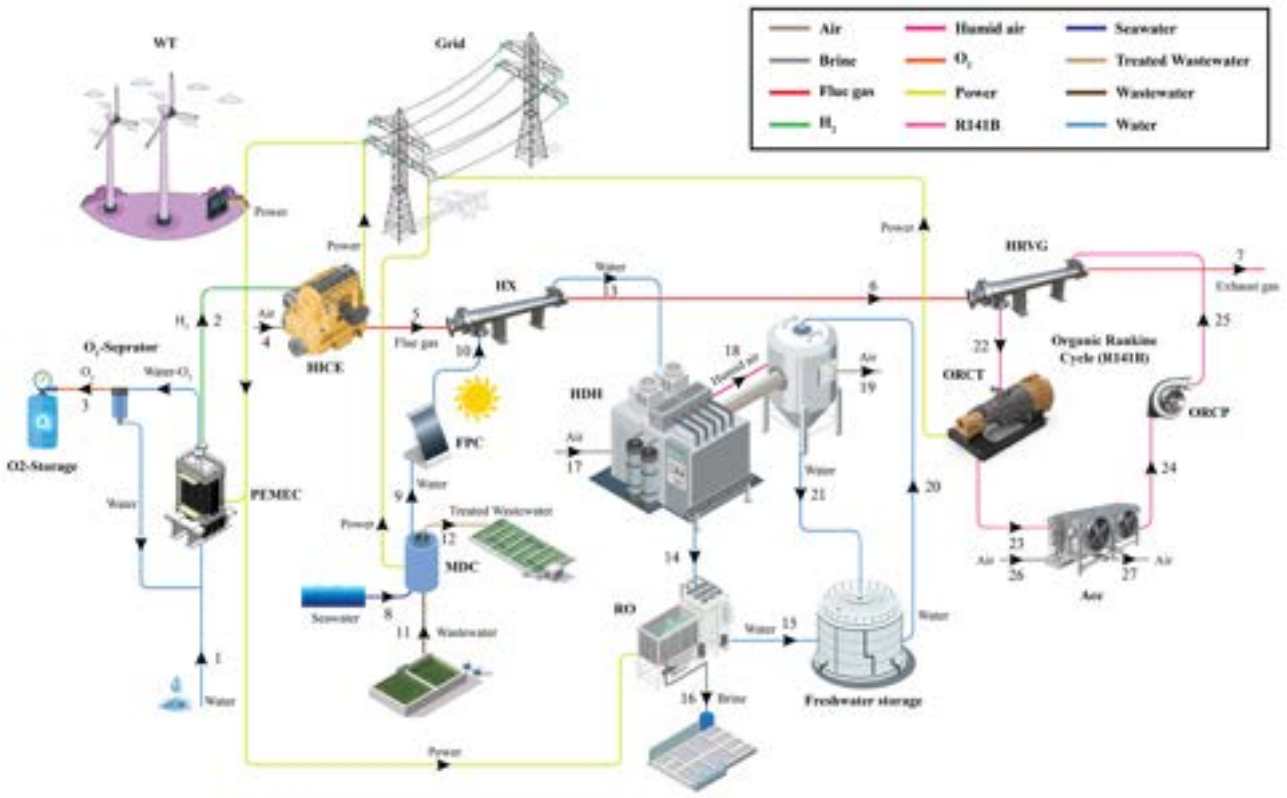

Figure. 1. Schematic of proposed cogeneration for production of desalination, power, and wastewater treatment based on solar and wind energy.

3. Governing equations

The mass and energy balance of equipment is generally calculated using the following equations [24]:

$$\sum_{i=0}^{n} m_{in} - \sum_{i=0}^{n} m_{out} = \left(\frac{dm}{dt}\right)_{system}, \quad (1)$$

$$Q - W + \sum_{i=0}^{n} m_{in}\left(h + \frac{V^2}{2} + gz\right)_{in} - \sum_{i=0}^{n} m_{out}\left(h + \frac{V^2}{2} + gz\right)_{out} = \left(\frac{dE}{dt}\right)_{system}, \quad (2)$$

The concepts of m which means mass flow rate, Q which means heat transfer, and W which means exchanged power is used in the above equation. In Equation 2, the terms within the summation represent the energy flows at the inlet and outlet of the control volume, associated with the energy of the flows. Terms containing V or Z are considered to be zero due to neglecting the kinetic and potential energies. Also, h represents the specific enthalpy. It should be noted that for open systems operating under steady-state conditions, Equations 1 and 2 can be defined in the following form: d/dt=0. However, in many pieces of equipment, it is necessary to create equations to improve their modelling. For example, for flat plate solar collectors, their specific surface area for absorbing solar energy needs to be calculated. Therefore, the heat transfer equations related to this type of equipment should be considered [25]. Moreover, for modelling a PEM electrolyzer, it is necessary to calculate the power consumption by specifying the produced hydrogen flow rate and the potential equations of this electrolyzer [22]. Modelling an RO desalination system requires taking into account the equations related to osmotic and mechanical pressure. Then, the amount of produced freshwater and the pump power consumption of the RO system can be calculated through the recovery ratio [26]. Continuing, for modelling an internal combustion engine based on hydrogen, the amount of recovered heat is calculated by knowing the engine's nominal power [27, 28]. Additionally, to model a wind turbine based on the wind speed of the study area, the equations presented in the references [19, 29] have been used. To model an MDC system, the differential equations presented in the reference [6] have been used. These equations consist of mass balance equations for substrate and microorganisms in the anode compartment, mass balance equations for salt in the desalination compartment, anode compartment, and cathode compartment, in addition to equations for the current generation, which all must be solved simultaneously. The MDC inputs have been obtained from the references [6, 30]. The differential equations for modelling HDH consist of heat and mass transfer equations for water and air in the dehumidifier and humidifier [31]. These equations must also be solved simultaneously.

It is not entirely possible to assess the quality of energy processes in terms of reversibility. Therefore, by adding the concept of exergy to energy analysis, a more comprehensive view of entropy generation and evaluation of

the irreversibility of energy processes can be obtained. Thus, exergy is defined as the useful work capacity and its calculation is relative to a dead reference. The overall exergy balance for all energy systems operating in steady-state can be defined by the following equation [32]:

$$E\ x_Q - E\ x_W + \sum_{i=1}^{n} E\ x_{in} - \sum_{i=1}^{n} E\ x_{out} + E\ x_D = 0, \quad (3)$$

In the above equations, Ex_Q refers to thermal exergy, Ex_W refers to power exergy, and Ex_D refers to the destruction of exergy, which is created as a result of entropy production. The expressions within the summation sign correspond to the flow exergy at the input and output of exergy systems.

Given that the capital payback period and profitability are crucial in system planning, after examining the energy aspects of the system, its economic aspects should also be considered. The economic balance of steady-state energy systems with an exergy approach is defined as follows [33]:

$$C_Q - C_w + \sum_{i=1}^{n} C_{in} \sum_{i=0}^{n} C_{out} + Z_k = 0, \quad (4)$$

In the above equations, C_Q means the heat cost, C_W means the power cost, and Z_k means the equipment purchase rate of the energy system, which is calculated based on references [21, 33].

Life cycle assessment (LCA) is a method for evaluating the environmental pollutants released during the life cycle of a system, from raw material extraction to transportation, construction, and disposal. In the current research, environmental analysis based on LCA, which is defined based on exergy analysis, has been used. Environmental balance is defined for systems operating in a steady state as follows [33]:

$$B_Q - B_w + \sum_{i=1}^{n} B_{in} \sum_{i=0}^{n} B_{out} + Y_k = 0, \quad (5)$$

In the above equations, B_Q means the environmental impact of heat, B_W means the environmental impact of power, and Y_k means the rate of environmental impacts of energy system equipment, which can be calculated using the equations from references [5, 33]. In addition, the constants used in this study are as follows: a 10% interest rate, a maintenance factor of 1.06, a 20-year lifespan for the power plant, 3500 operating hours for FPC, 6000 operating hours for WT, and 8000 operating hours for other equipment [33]. It should be noted that for economic and environmental calculations, the investment cost and equipment weights were obtained from references [5, 21].

4. Results

Table 1 shows the extent of the exergy destruction, costs, destruction costs, environmental impacts, and environmental destruction effects associated with each piece of equipment used in the proposed system. The results of this section indicate that exergy destruction in wind turbines is higher than in other equipment in the system. The reason for this is the higher power production in wind turbines compared to other equipment in the system. After the wind turbine, the internal combustion engine has the highest exergy destruction due to irreversibilities and chemical reactions within it. Regarding the cost destruction, it should be noted that the cost destruction associated with the internal combustion engine is calculated to be higher than other equipment due to the chemical reactions occurring within it. After the internal combustion engine, the PEM electrolyzer has the highest cost destruction. Systems that operate with renewable energy sources (WT, FPC, MDC) have no cost destruction. The results regarding environmental degradation are similar, with the difference that the heat exchanger after the internal combustion engine has the highest environmental degradation.

In Table 2, the results of the 4E analysis of the proposed system are presented. Based on these results, the net power generation, cogeneration exergy efficiency, overall cost rate, and overall environmental impact rate of the system are 0.72 MW, 4.55%, 540.33 $/h, and 17.37 Pts/h, respectively.

Fig. 2 represents the change in humid air temperature inside HDH desalination. In Fig. 2(a), temperature changes in humidification are shown. As expected, the air in contact with warmer saltwater gets hotter. The modelling results also demonstrate these temperature changes with an increase in the length of humidification. In Fig. 2(b) as well, these changes are shown for dehumidification, which operates in reverse. That means the temperature of the humid air decreases in the vicinity of cooler freshwater. These results are also consistent with the modelling.

Fig. 3 shows the absolute humidity change of the air in the HDH desalination. The results of Fig. 3(a) indicate that after the air enters the device, it interacts with salty water and its absolute humidity increases. This result is consistent with the modelling. On the other hand, in Fig. 3(b), in the dehumidification process, water is absorbed from the air, which causes the air to become drier and its absolute humidity to decrease. This process, due to mass transfer with water, leads to the production of freshwater.

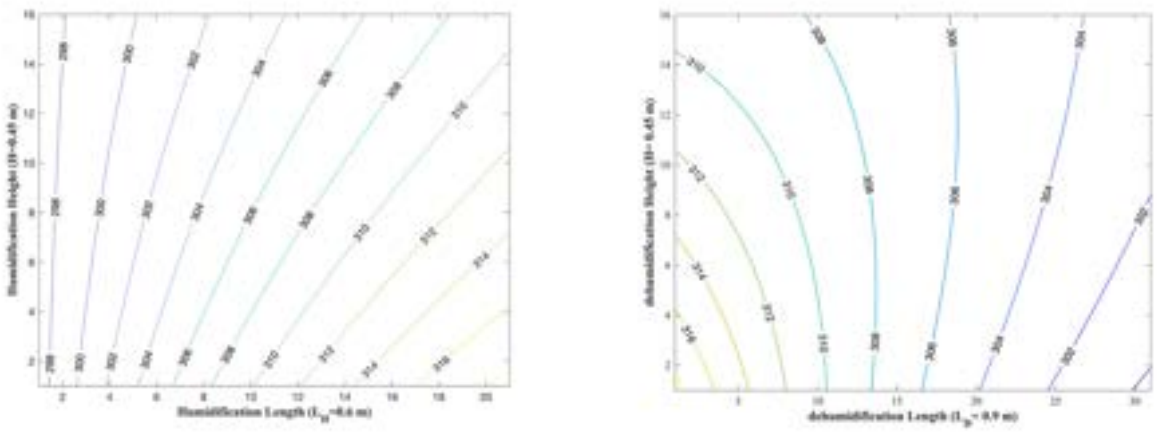
Table 2. Overall results of the analysis.

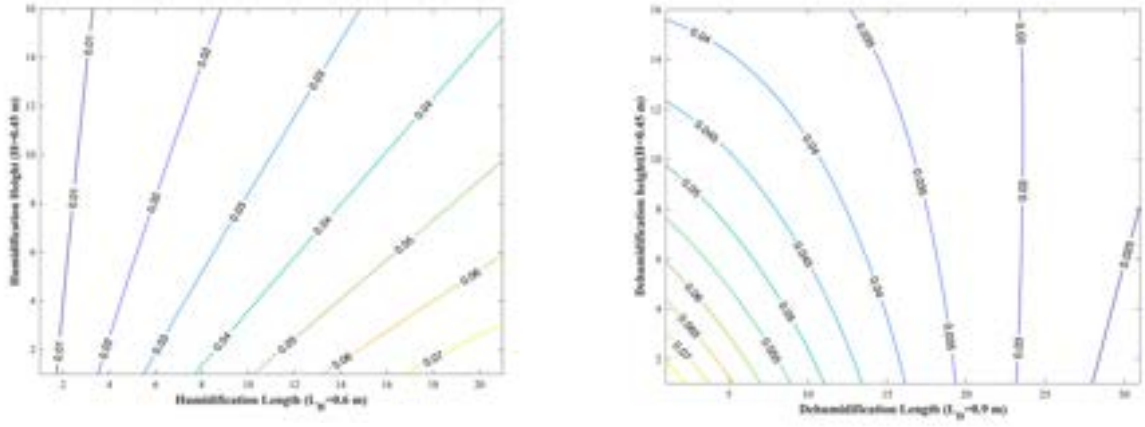
Parameters	value
Net power generation (MW)	0.72
Total freshwater production (m^3/h)	5.36
Cogeneration energy efficiency (%)	22.09
Total exergy destruction (MW)	18.73
Cogeneration exergy efficiency (%)	4.55
Overall cost rate ($/h)	540.33
Overall environmental impact rate (Pts/h)	17.37
Levelized cost of electricity ($/kWh)	0.75
Levelized environmental impact of electricity (Pts/kWh)	0.02
Number of wind turbine	23
Solar field area (m^2)	3000

Fig. 4 shows the change in water temperature in the HDH desalination. In humidification, considering that the incoming water has a higher temperature than the air, it is expected that due to the heat and mass transfer, the temperature of the outlet water is lower. This expectation is consistent with the results of the modelling shown in Fig. 4(a). In this plot, as we move upwards, the water temperature decreases. In dehumidification, conversely, humid air interacts with sweet water and causes the outlet water to become warmer. Therefore, it is expected that the outlet water has a higher temperature than the incoming water. This expectation is consistent with the Fig. 4(b) plot, in a way that as we move upwards in the plot, the water temperature increases.



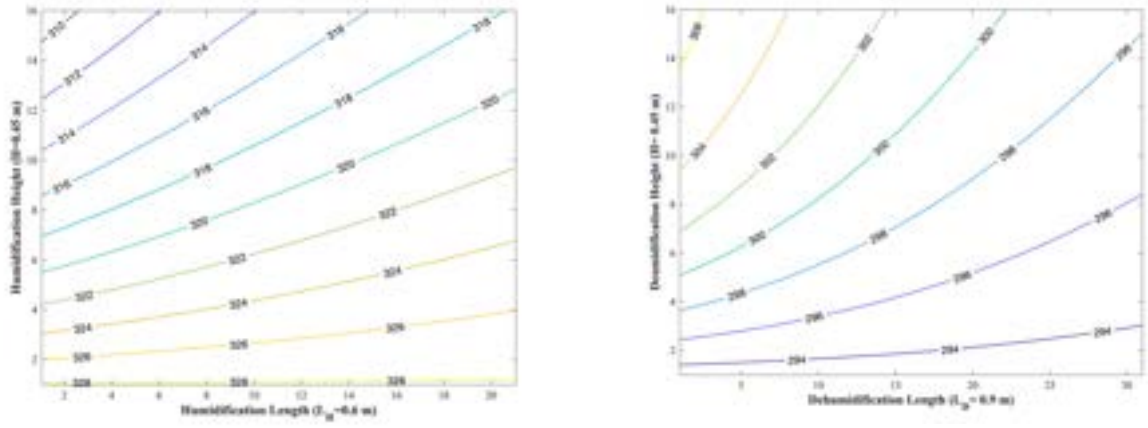
(a) (b)

Figure. 2. Humid air temperature change in HDH Desalination.



(a) (b)

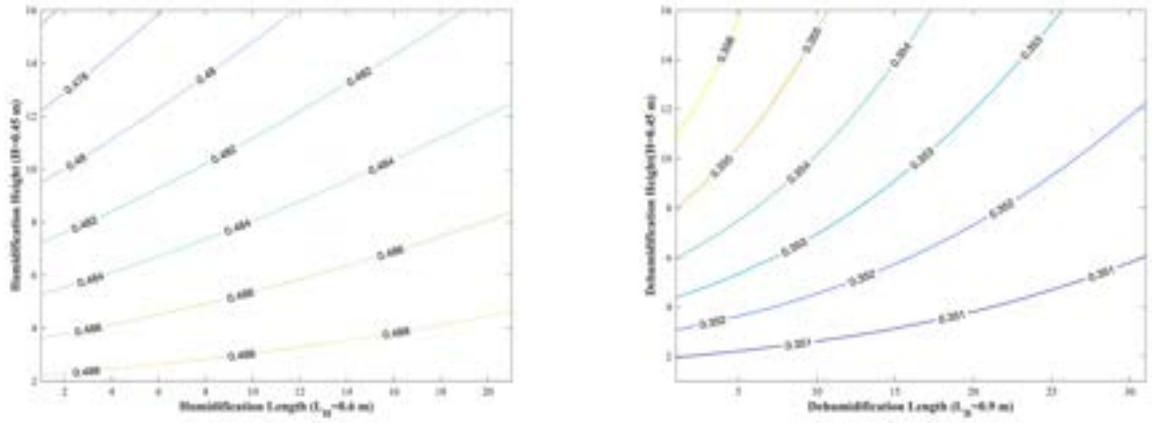
Figure. 3. Absolute humidity change in HDH Desalination.



(a) (b)

Figure. 4. Water temperature change in HDH Desalination.

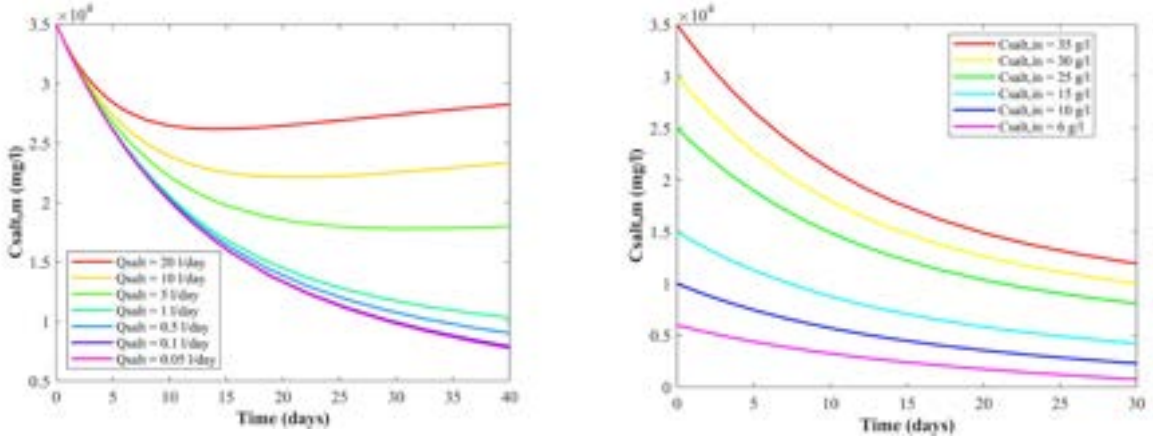
Fig. 5 illustrates the change in water mass flow rate in HDH desalination. In humidification, the water mass flow rate decreases and is added to the ambient air humidity, which its variations are observable. In other words, as we move upwards in plot Fig. 5(a), the water mass flow rate decreases, and the humidity of the ambient air increases. In Fig. 5(b), these changes can be observed conversely for dehumidification.



(a) (b)

Figure. 5. Specific water mass flow rate change in HDH Desalination.

Fig. 6(a) displays the changes in salt concentration over time in the intermediate chamber for different initial salt concentrations. The results indicate that for the initial salt concentration of 35g/l, desalination was achieved by a considerable amount of 65.85%. In Fig. 6(b), the effect of changes in the salt solution flow rates on the variation of salt concentration in the intermediate chamber has been investigated. The results indicate that a higher percentage of desalination can be achieved by decreasing the salt solution flow rates. In other words, desalination has increased from 19.28% at a flow rate of 20 l/day to 77.82% at a flow rate of 0.05 l/day.



(a) (b)

Figure. 6. The salt concentration in the desalination compartment with time for (a) different salt solution flow rates, (b) different initial salt concentrations (when Q_{salt} = 0.1 l/day).

Fig. 7 illustrates that as the growth rate of methanogenic bacteria increases, the current generation decreases and ultimately experiences maximum enhancement when the rate of methanogenic production is equal to zero. Thus, the results confirm that methanogenic bacteria lead to a reduction in the current generation.

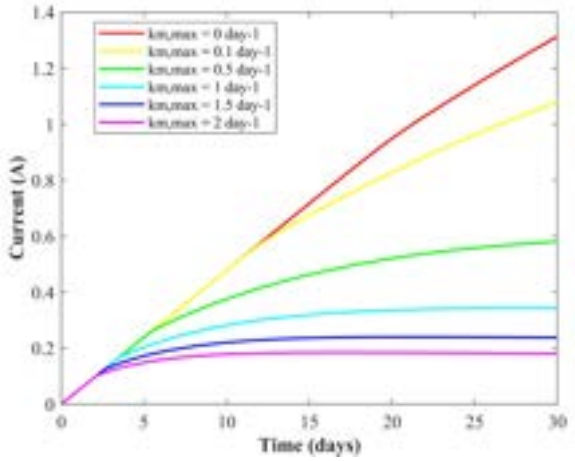


Figure. 7. The relationship between the current production and methanogenic growth rate.

5. Conclusions

The present work presented a cogeneration system for the production of power, freshwater, and wastewater treatment based on solar and wind energy. For freshwater production, the integration of MDC with HDH and RO systems was investigated. The required heat of the complex was combined using FPC and HICE based on solar and wind energy. Energy, exergy, exergeoeconomic, and exergoenvironmental (4E) analyses were used for the integrated system. The overall results obtained indicate that the integrated system can produce 0.72 MW power and 5.36 m^3/h freshwater. Also, the overall cost rate and overall environmental impact rate of the whole system were calculated as 540.33 $/h and 17.37 Pts/h, respectively. A series of other results of the system are as follows:

- In addition to wastewater treatment and power production, the MDC has been able to reduce the concentration of dissolved salt in water by 20 g/kg.
- The RO desalination plant has produced 1.42 kg/s of freshwater using 6 kW of power.
- The highest exergy destruction is related to WT and HICE, respectively.
- The most destructive of costs and destruction of environmental impacts are related to HICE.
- WT has the highest production environmental impacts and the highest investment cost.

In the end, it should be mentioned that the presented system can be used to meet the needs of greenhouses, industrial factories, residential areas, and military barracks. But it is necessary to examine the feasibility of using such a system from various aspects such as safety risk, controllability, etc.

Acknowledgments

This research has been co-funded by ERDF funds, INTERREG MAC 2014-2020 programme, within the E5DES project (MAC2/1.1a/309). No funding sources had any influence on study design, collection, analysis, or interpretation of data, manuscript preparation, or the decision to submit for publication.

Abstract:
Energy technology costs and fuel prices play a critical role in the energy transition towards carbon neutrality. Despite its straightforwardness in comparing standalone technologies, the widely-used levelized cost of energy (LCOE) is not able to estimate the activation condition for low-carbon technologies due to lack of systematic assessment of the complexities in energy systems. In this study, we analyzed the impact of energy cost uncertainties for the deployment of renewables and carbon capture technologies for Switzerland based upon Energyscope, a systematic energy planning platform optimizing both investment and operational strategies for electricity, heat, and mobility. The results show that carbon capture becomes competent to renewable technologies when its cost drops below approximately 70 USD/tCO2. Furthermore, synthetic natural gas (NG) is promising to substitute fossil NG when the import price of the latter rises to above 0.1 USD/kWh level. These discoveries can be helpful for long-term planning, especially in the context of increasing geopolitical concerns on energy supply security.

Energy system, Cost sensitivity, Long-term planning.

1. Introduction

The 2022 United Nations Climate Change Conference (COP27) in Egypt [1] highlights that the global energy crisis, in addition to the impact of climate change, are challenging the efforts to achieve energy security. It calls on the essence of increasing the renewables' share in the energy mix and encourages the continued efforts to phase out fossil fuels. As indicated by [2–4], a radical transformation of the energy sector is mandatory. However, such rapid transition is triggering a series of social-economic concerns, especially in terms of the transition cost, which is commonly regarded as capital-intensive [5–7]. For instance, IEA [7] claims that the investment into clean energy should at least be doubled and triple by 2030 in the announced pledges scenario and the net-zero emission scenario respectively, with respect to 2022 levels (i.e., USD 1.4 trillion).

With the decreasing trends of renewable costs in the last decades, as illustrated in Figure 1, it is likely that renewable costs have already dropped below, or might become competitive to fossil energies, depending on geographical and meteorological conditions (solar irradiation, wind speed etc.). However, it is very difficult to predict the energy costs. On one hand, IRENA [8] emphasizes that most renewable energy technologies benefit from learning-by-doing, thus allowing the decrease of their investment costs at the global scale over time. For instance, the global capacity-weighted average total installed cost of utility-scale solar PV and onshore wind projects in 2021 decreased by 81% and 35% respectively with respect to 2010 values. On the other hand, IEA [7] observed that highly unpredictable exogenous events, such as the Russo-Ukrainian war, may have dramatic consequences on the cost of energy technologies, especially resources, like natural gas (NG) in the case of the Ukrainian conflict. Thus, taking into account learning trends while accounting for uncertainty that may come from exogenous events is key for making plausible decisions in order to achieve energy transition towards carbon neutrality.

Across the current energy research, one common practice is using the Levelized Cost Of Energy (LCOE) [10–12] to compare the energy costs. LCOE is calculated by the ratio of the total cost (investment and operational costs) and total energy output during the lifetime of a technology. By definition, the LCOE metric focuses only on a standalone technology, which is not able to capture the synergies and conflicts occurring between energy technologies among the highly interconnected energy systems. As a result, the conclusion of

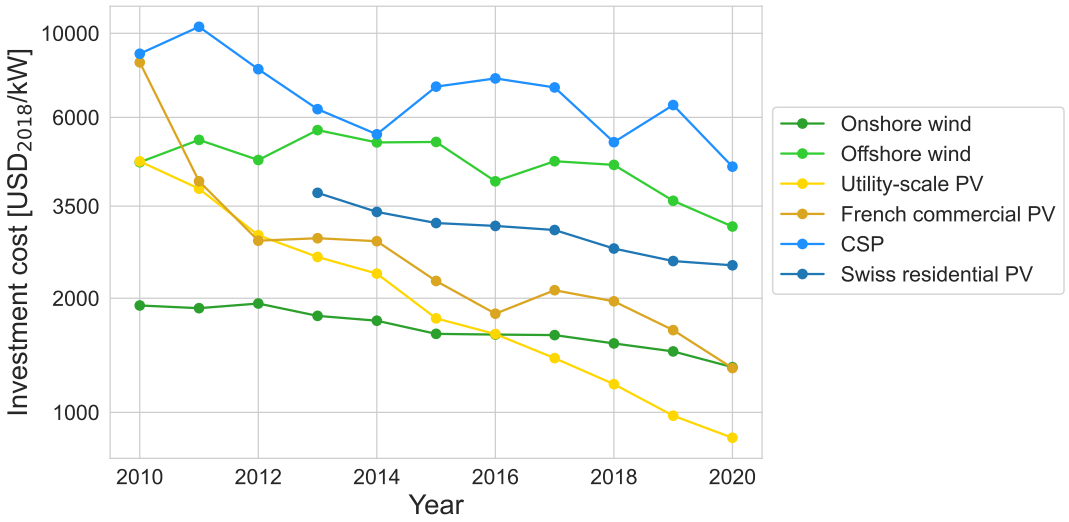

Figure 1: Historical cost trends for the main renewable energy technologies. Data taken from IRENA [9]. The costs are global-averaged data, except for the residential and commercial PV.

”cheap” or ”expensive” based upon simply comparing LCOE may become unreliable in the field of long-term energy planning. For instance, even if the LCOE of a photovoltaic (PV) panel drops below a gas power plant, the system may still keep using the gas, taking into account additional costs for deploying the PV such as the storage (e.g. by battery) and backup technologies. More specifically, Hansen [13] compared the LCOE with Energy System Analysis (ESA) for assessing the cost of integrating an energy technology into an energy system by using the simulation model EnergyPLAN which accounts for systemic perspectives. The results show that the two methods lead to different energy technologies priorities and confirm that the LCOE method lacks to consider crucial systemic dimensions. Ueckerdt et al. [14] proposed a new version of LCOE, namely the Systemic LCOE, that considers both the integration and generation costs. The results show that integration costs may become within the same range as generation costs in the case of high wind shares, thus confirming the possible poor reliability of LCOE without having a systemic view. Consequently, it is important to apply system-level models with a holistic representation of the interactions of energy technologies, to analyze the impact of energy cost variation on the energy transition.

However, the majority of energy models are based upon cost-minimization, or profit maximization assumptions. As emphasized by Trutnevyte [15], costs are a key driver of the energy transition, but there are many others (e.g., social impacts) that may lead to non-rational decision. For instance, the electricity system transition of UK from 1990 to 2014 was not cost-optimized, by a 9-23% deviation according to Trutnevyte [15]. Nevertheless, cost-optimization models such as Energyscope [16] are needed, not for exactly predicting how the future energy system will look like, but as a systemic decision-making tool for generating a series of possible scenarios allowing for uncertainty analysis in order to evaluate potential trade-offs among heterogeneous pathways.

This work aims at unveiling the sensitivity of the future energy system as a function of the of the key energy technologies costs within their uncertainty ranges, while accounting for the interdependence between the different technologies. The sensitivity of the energy system is mainly reflected by the variation of annual energy output (in terms of GWh) for each technology. This paper is organized as below: Section 2 introduces the methodology of our study; Next, some preliminary results are presented and analyzed in Section 3; Finally, we summarize the major novelties of this work and possible future research direction in Section 4.

2. Methodology

2.1. Modelling framework

This research is conducted upon Energyscope, a bottom-up energy system model based on cost-optimization, designed for decision-making in the field of energy transition. It has been originated by Moret [16] as a so-called *snapshot* model. *Snapshots* describe an energy system at a given time mainly in terms of energy technologies installation [MW] and utilization [GWh/year] as well as the investment and operation costs that are associated to these. To generate those results, Energyscope is based on a Mixed-Integer Linear Programming (MILP) optimization problem, that is constituted by a set of energy conversion technologies (including

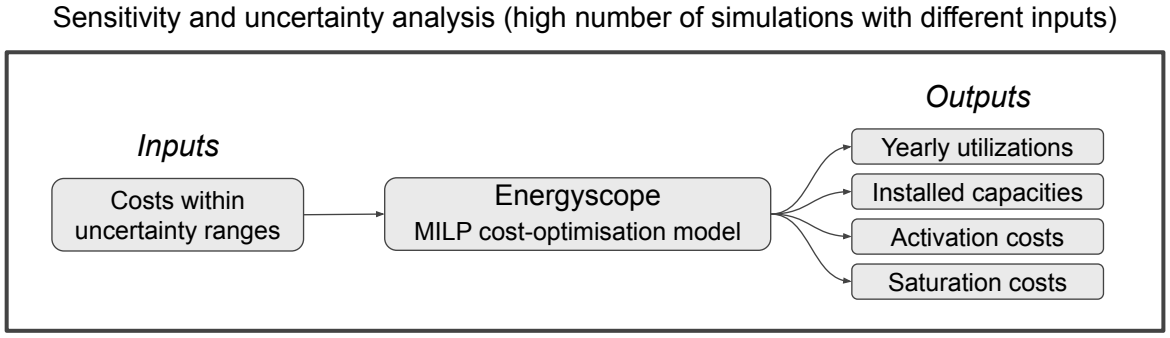

Figure 2: Scheme of the methodology

storage technologies), energy resources as well as the energy end-use demand (EUD). Each energy conversion technology is characterized according to a: 1) reference size [MW], 2) investment cost [USD/kW], 3) maintenance cost [USD/kW/year], 4) Global Warming Potential (GWP), 5) lifetime [year], 6) capacity factor [-], 7) minimum installed capacity [MW] and 8) maximum installed capacity [MW]. This model is working with a monthly granularity in order to account for time-dependent parameters (e.g., EUD, solar irradiation, wind power etc.) that are occurring over a year.

Whereas other energy system models may be proprietary, computationally expensive and only integrating the electricity sector, Energyscope is open-source, has a small computation time (sec) due to its *snapshot* design and both models the electricity, heat and mobility sectors. Its short computation time allows to use this model for sensitivity and uncertainty analysis, which typically requires several thousands of iterations. The modelling of the entire energy system ensures that the interactions between the different energy sectors are taken into account in the results and thus in the decision-making process. The heat sector EUD is further divided between low temperature and high temperature heating needs, whereas the mobility sector EUD is divided between passenger mobility [Mpkm] (itself divided between public and private mobility) and freight mobility [Mtkm] (itself divided between road and rail freight).

The objective function of the MILP optimization problem to minimize is the system total cost, defined by Eq. 1, subject to mass and energy balances, as well as storage behaviours. The optimization variables (written in **bold**), and thus the output of the model, are the energy conversion technologies installed capacities [MW] and yearly productions [GWh/year], the centralised and decentralised heat supply shares, the public and private mobility shares as well as the freight rail and road shares. The complete optimization problem can be found in [16]. We added a modelling of carbon flows [17] by identifying carbon sources, carbon conversion technologies and carbon sinks. This is allowing to model a carbon circular economy within the context of a highly interconnected energy system due to increasing deployment of biomass and carbon capture, use and storage (CCUS) technologies.

$$\min \ \mathbf{C_{tot}} = \sum_{j \in TECH} (\mathbf{C_{inv}}(\mathbf{j}) \cdot \tau(j) + \mathbf{C_{maint}}(\mathbf{j})) + \sum_{i \in RES} \mathbf{C_{op}}(\mathbf{i}) \tag{1}$$

where:

$$\tau(j) = \frac{i_{rate}(1 + i_{rate})^{n(j)}}{(1 + i_{rate})^{n(j)} - 1} \tag{2}$$

$$\mathbf{C_{inv}}(\mathbf{j}) = c_{inv}(j) \cdot \mathbf{F}(\mathbf{j}) \tag{3}$$

$$\mathbf{C_{maint}}(\mathbf{j}) = c_{maint}(j) \cdot \mathbf{F}(\mathbf{j}) \tag{4}$$

$$\mathbf{C_{op}}(\mathbf{i}) = \sum_{t \in T} c_{op}(i, t)\mathbf{F_t}(\mathbf{i}, \mathbf{t})t_{op}(i) \tag{5}$$

The above equations are mainly cost-relevant formulations. More detailed mathematical framework of Energyscope is available in [17, 18]. Next, we define scenarios and vary the model inputs, in order to analyze the corresponding variation of utilization of resources.

2.2. Scenario definition

Two scenarios are defined in this study, namely:

- Scenario (a): State-of-the-art, based upon the Swiss energy system in 2020. This implies all the model parameters and variables, including technology costs, fuel costs, installed capacities, and energy supply, are fixed with the real values in 2020. As the price of natural gas had a significant change before/after the Russia-Ukraine war, we conducted a specific sensitivity analysis on the utilization of natural gas as a function of natural gas cost.
- Scenario (b): Net-zero scenario, based upon the cost projection data (as of 2050) from a variety of sources, such as IEA [5–7] and IRENA [19–21] databases. Built on the future energy system, we perform Monte Carlo simulation in order to explore how robust a net-zero emission system is against cost uncertainty.

Based upon the definition of scenario (b), one interesting topic is to assess the competition between renewables and carbon capture: both are beneficial to realize the climate target, but which condition one might be more widely used compared to the other ? Furthermore, we analyze the simultaneous effects of both carbon capture cost and fuel price on the energy system.

3. Preliminary results

Figure 3 shows the results for scenario (a), illustrating the variation of natural gas utilization as a function of its price. It is observed that NG is not used anymore when the price rises above 90 USD/MWh; when the price drops below 50 USD/MWh (critical point), it begins to be largely used, probably replaced by a massive penetration of wind turbines, as reflected by the green line. In correspondence, the total cost of the energy system becomes almost invariant when NG cost is above the critical point.

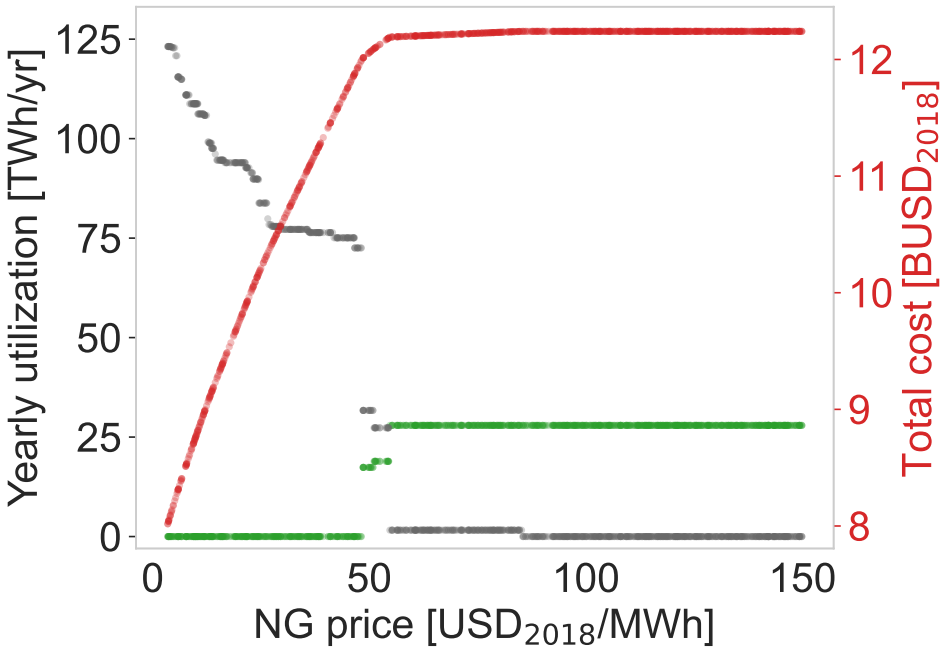

Figure 3: Sensitivity of natural gas consumption (grey dots), wind energy (green dots), and system total cost (red dots) as a function of NG price signal. Other costs are fixed to their 2020 values.

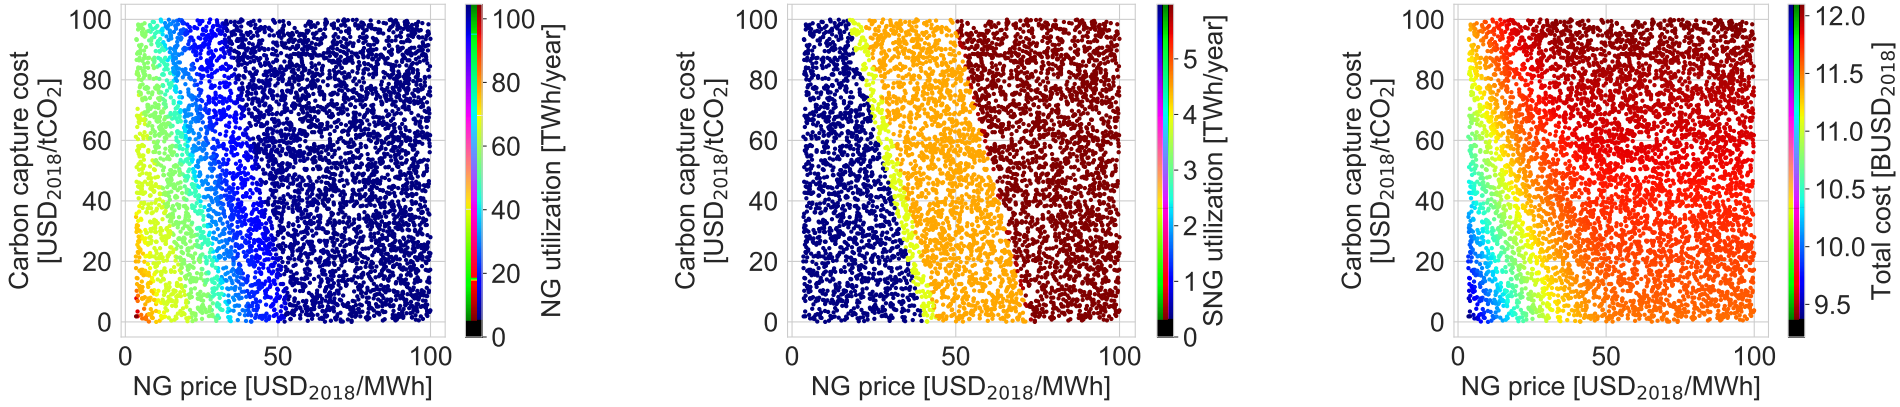
Furthermore, Fig. 4 reflects the impacts of NG price and carbon capture cost on the utilization of NG, Synthetic NG (SNG), and the total cost of the energy system in the net-zero scenario. From Fig. 4 (a), the utilization of natural gas is highly sensitive to the carbon capture cost when NG price remains low. In the most extreme case where the NG price is close to zero, the carbon capture cost has to be surpass 70 USD/tCO2 in order to maintain the NG utilization below 50 TWh/year. When the NG price stays the same as of 2020, i.e., around 30 USD/MWh, a carbon capture cost close to 100 USD/tCO2 can stop the utilization of NG. In practice, these results can be linked to carbon tax and thus conductive to defining effective energy measures.

Figure 4 (b) and (c) serve as supplementary of (a), showing the substitution of NG by SNG and the variation of the total cost of the energy system respectively. When the natural gas cost rises above 45 USD/MWh in the condition of zero carbon capture cost, SNG becomes competitive to NG. A high carbon capture (100 USD/tCO2) cost can even further halve the NG cost for activating SNG facilities. Finally, Fig 4 (c) reflects the corresponding maximal variation of the energy system cost is within $[-10\%, 20\%]$ range assuming the NG price staying the level 2020 and no carbon capture technologies.



(a) NG (b) SNG (c) Total cost

Figure 4: Sensitivity of NG and SNG utilization as well as total cost as a function of both carbon capture cost and NG price. Other costs are fixed to their 2050 value.

4. Conclusion

This study performed sensitivity analyses on the impact of cost on the energy transition, allowing for quantifying the activation cost and saturation cost for different energy technologies and resources. All the results are obtained from a system-level model instead of simply comparing the LCOE, thus improving their plausibility. We believe these results can be easily understood by policy makers and other energy stakeholders, thus contributing to rational decision making, in particular for enacting energy policies.

This paper is dedicated to sharing our research idea. A complete paper with detailed data and more results are in preparation.

Abstract:

Bolivia is a developing country in South America which is slowly starting its energy transition towards more renewable technologies. However, at this moment, Institutions in charge of regulating, operating, and planning the development of the sector are still working with “black box” (or licensed) models, which are costly and less transparent, and are highly dependent on external expertise to formulate national plans. A proper transition will arguably require endogenous know-how and resources to be sustainable, affordable, and sovereign for the country.

In this context, open-source energy models are increasingly used in Bolivia, mostly by academic and non-profit institutions. These are used to study alternative development scenarios, quantify environmental impacts and/or define potential techno-economic requirements.

Previous works have focused on the development of dispatch models that analyse the stability and operation over short-terms and on energy-balance models to study impacts over long-term scenarios. However, while operation and planning aspects are somewhat covered independently, the combination of both is still missing (i.e. high time and spatial resolution and long-term horizon perspectives).

To bridge this gap the PyPSA-Earth model was identified and used to derive a model specific for the Bolivian context using a dedicated workflow. The model is adapted to run and provide country-specific outputs regarding generation capacities, grid expansion and sector-specific demands, which are later compared with historical information to assess its accuracy and capabilities.

Modelling results provide inputs regarding the characteristics of the tool and quantify deviations of its outputs compared to the Bolivian system in 2020. Based on these, it is concluded that the flexibility of the model, combined with its transparent structure, show great potential for implementation.

Keywords:

Energy modelling; Open-source; Bolivia; Energy systems; PyPSA-Earth; Developing countries.

1. Introduction

1.1. General context

Energy modelling has been an extensively researched topic for several decades, particularly in the context of studying energy systems and their components, such as power generation systems, dispatch mechanisms, demand analysis, coverage, and operational capacities at the transmission and distribution levels. Because of this, a diverse range of models can be found in the literature and, depending on the study's focus, models can be classified based in several ways. The paradigm of data utilization, the solving approach, the spatial-scale, and the time-frame studied, among others, are examples of what this classification can be based on [1].

Nevertheless, even among different taxonomies, overarching objectives in energy modelling include enhancing the energy system's characteristics, supporting design and planning efforts, improving the understanding of system components and their interactions, and examining the relationships between various critical aspects. These aspects are mostly related to technology availability, cost reductions, environmental impacts, social factors, and policy implementation [2].

Over time, modelling tools have proliferated and evolved, primarily in industrialized/developed countries, where they were developed to address specific behavioural conditions and technical/operational characteristics. However, these models are subject to significant limitations when applied to developing countries, as they assume high standards of system operation, exhibit inflexibility in the parameters/factors considered, and may

assume data availability, all of which often conflict with the reality of developing countries [3]. Furthermore, these tools were initially developed as closed and proprietary systems by large institutions, which had no obligation or incentive to make their tools publicly available. Consequently, there is a growing need for more open, flexible, transparent, and accessible modelling tools [4].

In the case of Latin America & the Caribbean, a region comprised mostly by developing countries, modelling requirements are driven by the region's characteristics [5]:

- a rapidly increasing energy demand;
- a strong correlation between energy consumption and economic growth;
- highly variable energy intensity consumption;
- increasing energy production costs;
- increasing penetration of non-flexible renewable powerplants;
- large heterogeneity in power systems across neighboring countries;
- the need to achieve universal access;
- improve networks stability at transmission/distribution level;
- dealing with outdated subsidization policies for fossil fuels.

1.2. Previous work and modelling experience in Bolivia

Although the energy sector has a distinct organizational structure in each country, with clearly defined actors and responsibilities, developing economies often lack the resources (technical, human or economic) to invest in their own capabilities. Bolivia is a prime example of this, as outsourced companies and tools have consistently been used for the formulation of planning efforts and strategic documentation [6], specifically for the electric sector [7]. However, due to the nature of the relation between institutions, most of the information provided is provided solely as results generated through black-box models and, reports that don't provide insights into the tools used.

Experience with energy modelling at the institutions in charge of the sector shows a big reliance on licensed tools, such as:

- SDDP (Stochastic Dual Dynamic Programming), a unit commitment hydrothermal dispatch model [8], developed by the company PSR [9];
- PowerFactory, a power system analysis model developed by DIgSILENT [10], used for studying the transmission network, among other uses [11];
- HOMER (Hybrid Optimization of Multiple Energy Resources), a modelling software owned by UL [12], that is used to design and study small hybrid power systems (isolated communities or microgrids) [13].

From a governmental and institutional perspective, outsourcing institutions for the analysis of the power system, with their own licensed modelling tools, can provide some advantages. For instance, that they can provide fast results and simplified information to decision makers, a highly trained technical team and proven experience. However, this practice has its downsides. First, it does not foster the development of local capacities in the institutions that require them, resulting in an overreliance on external know-how. Second, the costs of contracting external personnel, consulting companies, or acquiring licenses for private software are usually high. Third, planning efforts can only cover short to mid-term periods, as long-term scenarios are not flexible enough to be continuously and consistently adapted [14].

To tackle these problems, which aren't unique for the Bolivian case, an array of new open-source modelling tools have started to appear as efforts from various research institutions [4]. These models, which come on a wide array of alternatives, are currently being used to analyse energy systems across the world and seem to be able to answer some relevant questions linked to the design, operation and planning of the sector [15].

Particularly in Bolivia, open-source modelling tools have been started to be used by researchers to develop case studies for the electrical sector with a wide range of approaches: studying the dispatch capabilities of the interconnected electric system (Dispa-SET) [16]; analysing the electrification process based on grid expansion and microgrids for isolated communities (OnSSET - Open Source Spatial Electrification Tool) [17]; analysing energy demands consumption in rural communities (RAMP – Remote Areas Multi energy load Profiles generator) [18]; the optimization of design of microgrids (MicroGridsPy) [19]; or analysing evolution of investments based on policy implementation and sustainable development scenarios in the long-term (OSeMOSYS - Open Source energy MOdelling SYStem) [20].

1.3. PyPSA-Earth

PyPSA-Earth, as many other models, has the general objective of exploring the development of energy systems by considering a set of techno-economic components and optimization functions. However, unlike the studies mentioned before, PyPSA-Earth provides a complementary look of the energy system from the power network perspective by analysing power flows in the system [21]. Additionally, the modelling tool can combine a high spatial resolution representation of the network (missing in OSeMOSYS), optimization functions for expansion of the system (missing in Dispa-SET) and focusing simultaneously on generation and grid components (missing from OnSSET) [22]. Additionally, the model's workflow structure is designed based on the PyPSA-Eur model, an open model dataset for the European region and used for operational and transmission expansion studies [23].

Both PyPSA-Eur and PyPSA-Earth are derived from PyPSA (Python for Power System Analysis), an open-source modelling framework tool designed for simulating and optimizing power systems focusing on the physics of the power flows over multiple periods (typically a full year) and optimizing the total system costs given techno-economic characteristics and constraints of its components [24].

PyPSA's structure considers a representation of power systems based on nodes, which correspond to buses or network elements (generators, loads, and transformers), and edges, which represent transmission lines or cables. The network is described using a linear and nonlinear equations, including Kirchhoff's laws, Ohm's law, and the power flow equations. These equations are used, using numerical optimization techniques such as Newton-Raphson or interior-point methods, to obtain the steady-state operating conditions of the system. PyPSA also includes a range of optimization algorithms for capacity expansion planning, unit commitment, and optimal power flow, which are used to optimize the system's economic and environmental performance under different scenarios and constraints [24].

The PyPSA-Earth model (previously PyPSA meets Africa) has been tested for Africa and a country-specific case, achieving close representations of the system compared to information available on international sources such as the World Bank (networks), Open Street Maps (substations and generation), IRENA (renewable resources) and Our World in Data (energy dispatched), among others [22]. In this sense, although the PyPSA-Earth tool has been proven valuable, its potential for implementation is still to be fully exploited due to its novelty and need for validation in other countries and regions. Because of this, and the fact that no open-source models haven't been used to analyse the Bolivian power network, the opportunity of testing a complementary tool for already existing models and efforts is worth being explored.

1.3. Aim of the paper

While the experiences presented are a good first step in addressing the national necessities for understanding and representing Bolivia's energy sector, the models used must be further developed and validated to ensure they can accurately represent national conditions. This, coupled with a continuous process of exploring new complementary tools, could eventually make the country self-sufficient in terms of know-how and analysis capabilities in the long-term.

One particular gap identified in the existing modelling toolkit developed for Bolivia is the lack of a model that focuses on network representation and expansion. Therefore, the present work aims to address this gap by deriving a country-specific model for Bolivia's power network from PyPSA-Earth, a new open-source modelling tool, and analyse its potential for application, explore requirements for guarantying future work, and identify possibilities for further contribution.

2. Methodology and calculations

Given the open-source characteristics of the model information required for running the model for particular cases is available online, in their github repository and their documentation webpage [25]. Using this information and the current version of the model, the following methodology was applied to derive a model for Bolivia based on PyPSA-Earth:

1. Workflow adaptation: The existing workflow framework for PyPSA-Earth was configured so that scripts and parameters are capable of running a "testing" version of the Bolivian case with its corresponding country-specific conditions.
2. Consistency analysis: In order to assess the accuracy of the model, an optimization scenario is run for the year 2020. This scenario considered variations of relevant parameters such as the number of buses/clusters considered or the time aggregation periods. Results from the optimization process and intermediate stages of the workflow, focused mostly in the representation of networks, generators and energy produced, are later compared with national historical data for the same year.

3. Identification of model's potential and development opportunities: Based on the results obtained in the previous step, a more in-depth analysis is conducted to explore future usage and implementation of the model for the Bolivian case, as well as opportunities for further development of the tool and contribution opportunities to enrich the code.

2.1. Case Study: The Bolivian energy system

Bolivia has undergone significant changes in the development of its energy/electricity system over the years. The Electricity Law of 1994 transferred state-owned companies to the private sector through a process called "capitalization." Prior to this, approximately 70% of electricity came from hydroelectric sources. The law aimed to promote intensive use of natural gas as the primary energy source for electricity generation, as large volumes of Natural Gas (NG) were unused at the time, by establishing a special price for NG used for electricity generation, below international prices [26]. Ever since, low natural gas prices have effectively blocked the development of new hydroelectric and renewable energy in the country, changing the situation so that by 2006, 70% of the generation was generated by NG thermal plants [27].

In 2006, with the arrival of a new left government, the energy policy changed. The electricity sector, along with the hydrocarbon sector, was nationalized, and the National Electricity Company (ENDE) was restructured into a vertically integrated corporation, a "national strategic and corporate public company" [28]. ENDE now has 12 subsidiary companies. ENDE, together with the CNDC (National Committee for Charge Dispatch), as the main coordinator for power dispatch, and AETN (Supervision Authority for Electricity and Nuclear Technology), as the main entity in charge of regulating the electric system, have been stablished as the key institutions that manage the large majority of the electric system in Bolivia [29].

In the last ten years, there have been three notable developments: the creation of the Vice Ministry of Electricity and Alternative Energies (VMEEA), the approval of a Policy on Alternative Energies for the Electricity Sector [30], and the installation of photovoltaic parks and wind farms for larger populations. These, together with newly published documents like the its national development plan (PDES 2021-2025) [31] or the updated NDC (Nationally Determined Contributions) [32], demonstrate the government's willingness to shift the previous paradigm regarding renewable technologies and incorporate them into the electricity sector. In both documents expressed goals are mentioned in which the country should achieve over 75% participation of renewable technologies in its electric system by 2030.

In 2020 Bolivia's National Interconnected System (SIN) recorded a capacity of 3,228.61 MW in its generation mixed and total production of 8,897.3 MWh [33], with conventional thermal plants (NG) being the main contributor with 63.3% of the share, followed by hydroelectric providing 32.3%, and a combination of solar, wind, and biomass power plants for the rest [34]. Currently, the installed capacity in the country is twice the amount required due to large efforts to expand and develop the power generation system to open a potential offer of electric energy to neighboring countries.

Finally, according to the 2020 yearly memoires of the sector's national institutions, Bolivia's power network was composed of high voltage transmission lines operating at 230, 115 and 69 kV, with an accumulated amount of 94 substations and 6340 km of powerlines across the SIN, in 8 of the 9 departments of the country [35]. In the generation aspect, 36 power plants, each with several generation units, are currently being operated [36].

2.2. PyPSA-Earth's Workflow for the Bolivian case

The general structure of PyPSA-Earth is comprised by a workflow with the following main stages: Automated data retrieval from open-source data bases (downloading data for the pre-defined case); data pre-processing and inputs generation (specific data filtering processes used for representative variables); base network generation (inputs are used to create a network model with PyPSA); network optimization for given conditions (solving the desired problem). Following these steps, a post-processing stage is required, in which results have to be explored [37]. While these stages of the workflow can be straightforward, several internal/intermediate processes are considered in each step, amassing to over 20 specific python scripts that deal with each of the tasks required to run the model. The automated handling of these tasks is done with the use of Snakemake, a workflow management tool [38].

Depending on the configuration of the model, what commands are run and their interdependency, rules can be considered or ignored by snakemake. This configuration of the model/simulation is made on an specific file (config.yaml) that works as the main framework definition section, which enables which rules are to be taken into account as well as global parameters considered in the model: number of clusters/buses used to simplify the model, optimizing the network based costs and/or line's volume, emission limits, time resolution and others.

While the PyPSA-Earth model can run easily with a predefined configuration, it is a relatively general model, which needs to be enriched when "zooming" on a particular country. To optimize processing times between runs, a testing-version is set-up considering most of the default configurations, half a year period analysis, 10 clusters to aggregate information of the system and time steps of 8 hours.

After an adaptation process, a running version of the model was achieved for which the case-specific workflow for Bolivia is represented in **Figure. 1.** Additionally, the following changes represent the biggest modifications required to create an operative case for similar countries in the region:

- Specific weather data for South America was considered during the extraction process of online repositories (Copernicus Climate Data Store) [39].
- Landcover data retrieved from the predefined data bundle has been manually replaced by landcover maps for the South America (ProtectedPlanet) [40].
- Offshore wind turbines have not been taken into account in the model to facilitate the execution of the workflow during the creation of renewable availability profiles for offshore wind resources, because of Bolivia's condition as a landlocked country.

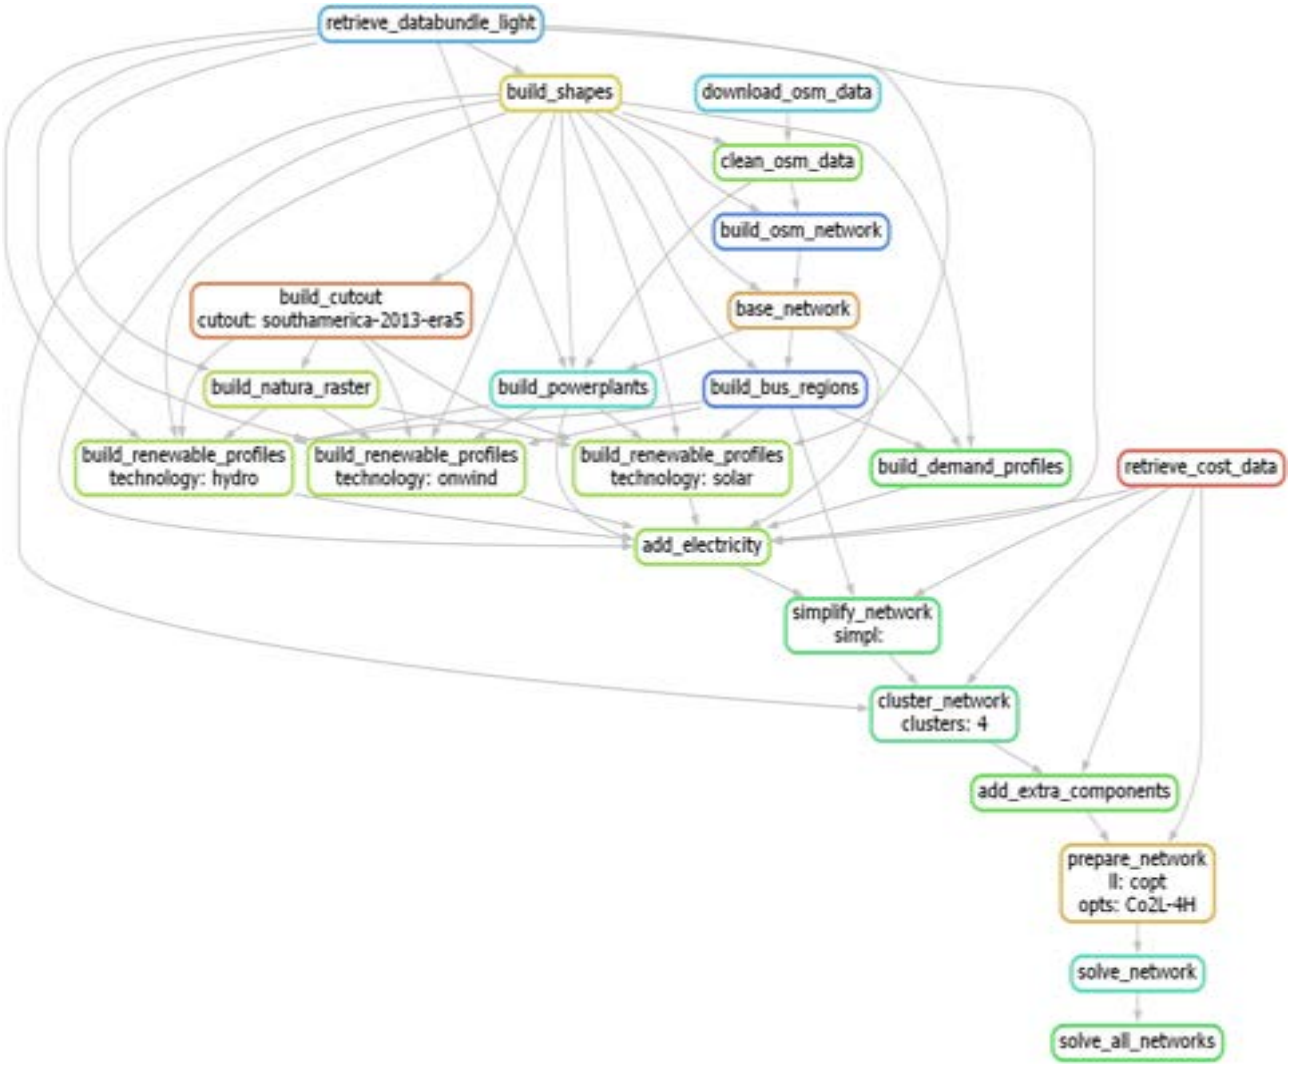

Figure. 1. Case-Specific workflow considered for Bolivia based on PyPSA-Earth.

For the sake of transparency and following the good practice of open-source modelling, a version control of the model can be found on a github repository: https://github.com/carlosfv92/pypsa-earth-BO, where relevant files, details of changes made on scripts and steps taken to run the Bolivian case are available.

2.3. Validation scenarios

Given the characteristics of the model, simulations use a predefined set of data sources to extract bundles of georeferenced information for a given country/region. Information extracted from these sources, combined with some precalculated datasets, allows the workflow to generate the databases required for creating the base network and optimizing its expansion. A list of the most relevant sources and the information they provide is available in **Table.1.**

Table. 1. Relevant data sources for the PyPSA-Earth workflow.

Source	Information extracted
Open Street Maps [41]	Network topology and components
Copernicus Climate Change Service [42]	Climate and weather data
HydroSHEDS [43]	Environmental variables
DRYAD [44]	Economic parameters
Shared Socioeconomic Pathways [45]	Global energy demand projections

After the model is setup for the Bolivian case a validation scenario is considered to study the outputs that can be obtained with the model, taken into account the following characteristics:

- Optimization of the system based on operational costs
- Operation of an entire trial year (2020)
- Time aggregation of 6 hours
- Non existing practical upper limit for emissions
- No restriction regarding the usage of emitting or renewable technologies
- Weather data based on historical information (year 2013)
- Default data sources from online repositories

To have a general grasp of the model's capabilities the analysis on results was focused on three aspects: network representation, powerplants installed capacity and energy demand coverage. For the first case, a major focus is given to how the model recognizes and processes available information regarding substations and transmission lines by modifying clustering values in the configuration and running different cases to compare them to with the existing Bolivian grid. For the second and third case, using a 4-node clustered version of the network, the optimized installed capacities and energy production are revised and compared to the existing operational conditions of the power system.

3. Results and discussion

3.1. Bolivia's transmission network simulation

To compare the capacities of the model to properly represent the Bolivian network in 2020, the model was run with different clustering objectives. Utilizing the plotting functions of networks generated with the PyPSA package and the intermediate results from the workflow, it's possible to explore different states and conditions of the system.

Some examples of what can be analysed are: The base network that the model creates after downloading and filtering default data, which assumes the totality of "usable" data, meaning properly georeferenced, defined and tagged elements (lines, substations and generators); Clustered networks created based on the defined number of buses that are given to simplify the network and the rest of characteristics of the model structure; The optimized network, which results from the final stage of solving the objective function of the system and can include additional or complementary elements in the buses, depending on the technical capacities of the system and their costs.

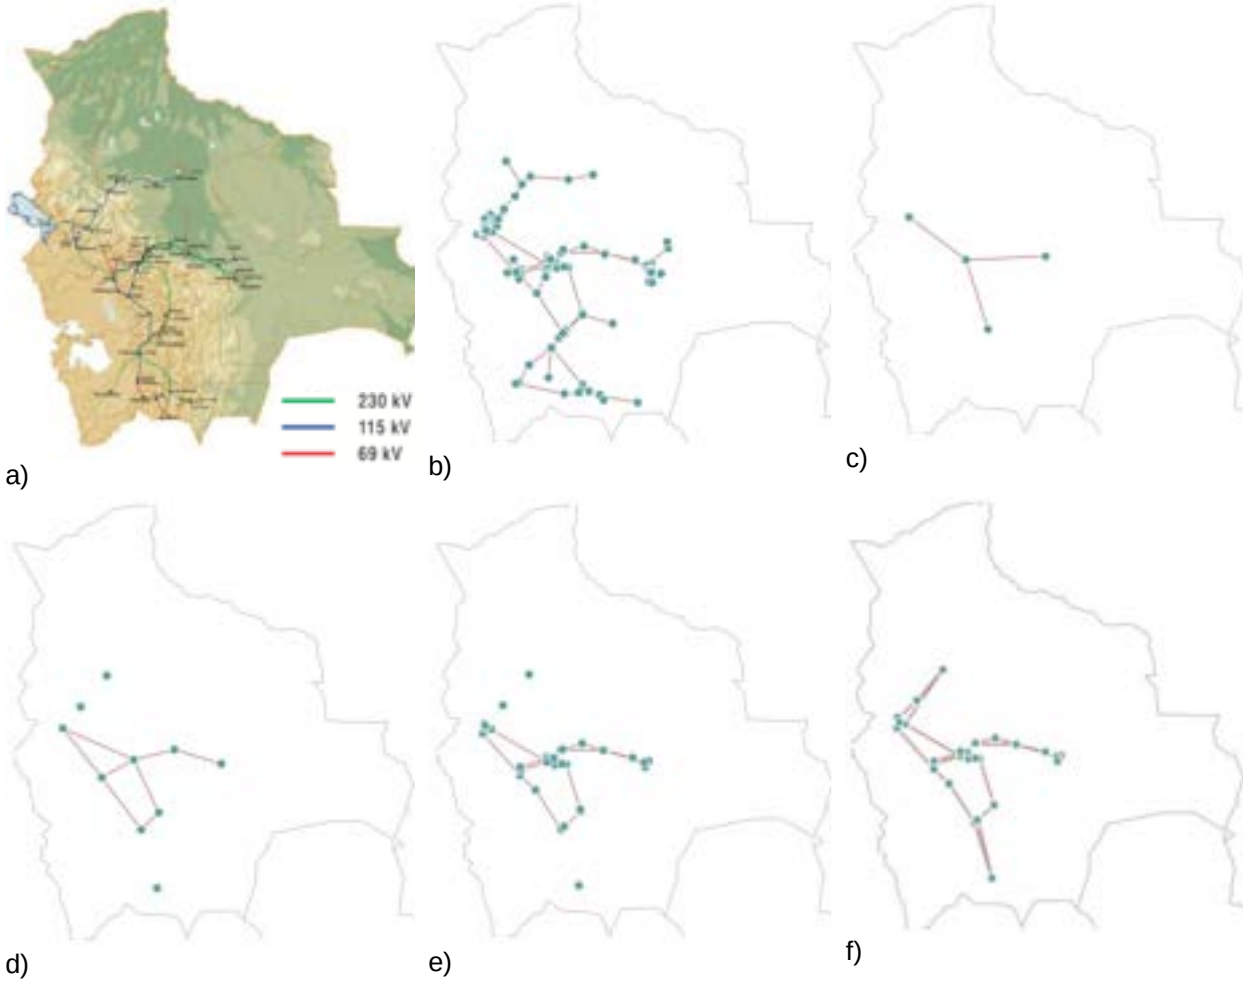

Figure. 2. Network recognition and clustering for Bolivia based on PyPSA-Earth: a) Bolivian transmission network in 2015 according to sectorial development plan *[6]*; b) Representation of the base network and lines pre-simplification and optimization; c) 4-node optimized version of the Bolivian network; d) 10-node optimized version of the Bolivian network; e) 37-node optimized version of the Bolivian network; f) 37-node optimized version of the Bolivian network with forced augmentation of powerlines.

A mix of these different cases, and the way they graphically represent the network, is available in **Figure. 2.** When comparing the real network in 2015 (a) with what is available from online repositories (b), it can be seen that most of the network's elements are considered and most of the relevant characteristics can be found in both cases like the connection rings in the south and central parts of the STI (Backbone Network System), as well as most of its 69, 115 and 230 kV lines. When the model is later clustered and optimized to a four node simplification (c), results are consistent with the 4-zone aggregation that the Bolivian network uses in their planning efforts: the southern area, central area, oriental area and northern area [29]. This representation, even though simplified, provides an overall good understanding of how the energy is used in the country and has already being used in previous studies focused on dispatch to simulate the Bolivian system [16].

After this minimal clustering, increasing numbers of nodes in the system are run (d), however, a limit was found at 37 nodes (e). This limit of nodes representation is derived by the simplification process of the available data into the base network used by PyPSA-Earth before the optimization, which aggregates the system considering only high-voltage components of the system (recognizing only 37 usable points to represent buses).

Because of this same reason, only lines above 30 kV are considered in the analysis, dropping several of the lower voltage lines, which leads to the assumption of several nodes as isolated from the rest of the grid. While this condition might seem problematic, it is important to take into account the scale for which PyPSA-Earth was created (regional and international analysis), therefore high voltage lines were given priority [22]. In this sense, this would represent a great opportunity for future work, given that if the scope/array of lines considered

is modified, this could help study and represent potential integration strategies for isolated communities, which is a major focus according to national policies [32].

Finally, an alternative way to impose the model to consider power flows between nodes can be achieved by forcing the optimization to include a minimum number of interconnections to allow a better representation (f). However, the forced creation of new networks would already represent predefined discrepancies that could affect the rest of the analysis, especially when comparing historical years.

To avoid the creation of isolated nodes and avoid forcing the model to create already existing lines, the 4-nodes representation is used for the rest of the analysis, and, even though this configuration provides a simplified version of the network, it can still be comparable to “existing” conditions.

3.2. Energy demand aggregation and simulated installed capacities

Results from the optimization of the system with the 4-node clustering configuration of the system, show an expected energy demand of 7,558.73 GWh for the entire year, distributing it as shown in **Figure. 3.** These results are in agreement with the total historical energy demand in Bolivia in 2020, according to the Bolivian authorities [29], presenting a discrepancy of 13.5%. Regarding the distribution of energy demands, the representation of the areas in the model is properly encapsulated, showing the same pattern of aggregation of energy consumption in the buses as the one provided in official documentation of the country, with the biggest outlier being the oriental area, having a deviation of 25.2% between the modelled data and the historical values.

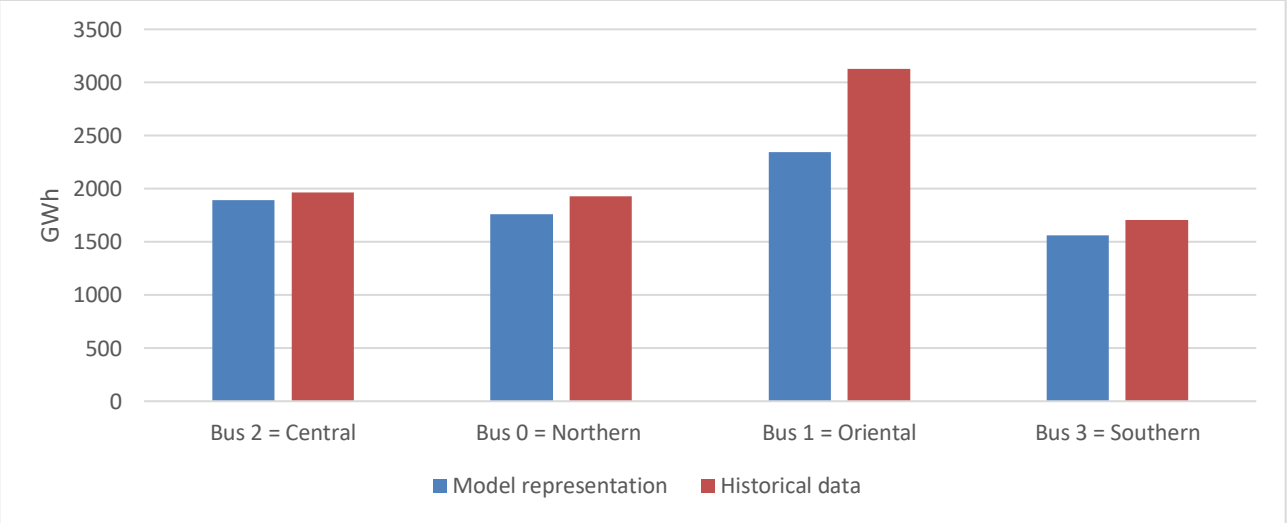

Figure. 3. Comparison of estimated energy demand by node in the model and registered energy demand in Bolivia for the year 2020.

These differences can be explained by the use of aggregated data at a global scale, which assume average growth trends in different scenarios but not at regional or country specific cases [45]. Bolivia in particular, seems a very atypical country due to a large period of sustained economic growth since 2010, where its GDP has had an average yearly value of over 3.5% [46]. This value is significantly larger than what was registered in the rest of the Latin-American region, with and average growth of lower than 2% in the last 10 years [47]. However, making data closer to historical values can be somewhat addressed in the model by adapting some sections in the configuration file. These changes should allow to increase the scaling factor of the referential time series data, by modifying data files used by the model or by including an additional section on the workflow for using country specific trends.

On the other hand, the analysis of installed capacity and its optimization shows structural discrepancies regarding the information used. **Table. 2.** Presents the details of the composition of the available powerplants according to the model and online data sources (Available capacity), the optimized values to cover the 2020 demands (Optimized capacity), as well as the actual data registered for 2020 in Bolivia (Real capacity):

Table. 2. Modelling results for the installed capacities in the Bolivian power system for 2020.

Carrier	Available capacity [MW]	Optimized capacity [MW]	Real capacity (2020) [MW]
OCGT	914.34	1099.40	1029.05
CCGT	-	-	1239.83
Oil	33.99	33.99	31.58
Onwind	25.52	25.52	27.00
Ror	344.00	344.00	-
Res	-	-	734.83
Solar	119.22	119.22	115.07
Biomass	-	-	51.25
Total	1437.07	1622.13	3228.61

Results regarding power generation show that the automated workflow using online data sources underestimates the existing capacities in the model in the year 2020. This is clear when comparing the total Available capacity with the total Real capacity, which is almost twice the value that online data sources take into account. Additionally, other relevant characteristics regarding how technologies are defined in the model can be found, compared to historical information from the national entities:

1) All the NG turbines are considered only as Open Cycle Gas Turbines (OCGT), which is not currently the case, given that several units and centrals are currently operating in the system with Combined Cycles (CCGT);
2) Hydropower in the Bolivian case is mostly composed by small reservoir units (Res), however, all available hydro units are recognized as run-off river powerplants (Ror) in PyPSA-Earth;
3) While not critically significant in terms of capacity, biomass powerplants (Biomass) are not being taken into account in the model, when in reality there is a small installed capacity available.

These discrepancies can be explained by two reasons. The first one being that, for older powerplants, information might not be fully or properly updated in the online data sources like Open Street Maps or PowePlantMatching. This is consistent with the fact that newer plants such as solar or onshore wind (Onwind) are accounted for, while large capacities in the other cases (thermal and hydro) are absent. The second reason would be the lack of proper tagging in the newer centrals, which have been created as expansions from other plants or where several units have been adapted or have grown over time.

Clear examples of these two cases are powerplants with two phases but the same name, like the hydro centrals San Jose 1 & San Jose 2, or the OCGT in Warnes, which were converted into CCGT with additional installed capacities [29]. Both of these issues can be sorted out by considering a country-specific set of data to replace the one generated by the model, however, while this functionality is currently available, there are some mismatching problems that have to be tuned to properly be used.

Finally, when analyzing the optimized capacities proposed by the model to cover power demands in the system, values are quite similar to the historical peak capacity covered in Bolivia, with a value of 1,565,80 MW [34]. This would mean that, while the mix of powerplants used by the model can vary between optimized and historical values, its capacity to optimize the system in order to cover future demands operates properly. The main reason for this variation is that the model does not have the same initial generation (legacy) capacities available in order to operate them, and the current over capacity installed in Bolivia [35], which was enforced mostly due to political reasons rather than technical requirements.

4. Conclusions and future work

Open-source tools are a valuable asset for countries and institutions immersed in energy system modelling. While this topic has been historically worked and developed by private entities and their own private tools, with their current growth, it can be expected that open-source models will eventually be able to replace licensed/black-box software used in energy system modelling.

A key example of this type of tools is PyPSA-Earth, a modelling tool that was developed within an open and transparent framework that allow its developers (and users) to generate simplified representation of the power system network of regions or countries in the world. Some of the novelties of this modelling tool are the integration of georeferenced information into the power flow analysis, the use of predefined online data sources, an optimization approach linked to the operation of the power system and the use of a detailed time resolution.

In this sense, the model was adapted to run the country-specific case of Bolivia for the year 2020 and it outputs were later compared to historical data to assess the capabilities of the model. Results show a high potential for its implementation in the future given that its scope and results are complementary to already developed tools. This would help filling gaps in the modelling requirements and capabilities for a better comprehension of the country's power system.

However, it is also important to address that the work done here is an introductory process to study the capabilities and conditions of the tool in order to assess its applicability in developing countries, with Bolivia being only a case study. Aside of the previous results obtained, several additional, configurations and outputs should also be explored in future work. These aspects are mostly linked to fine tuning of the model in order to allow the change of certain default data files to local-based information in order to improve the capabilities of the tool to represent country-specific cases in a manner closer to reality.

In parallel, particularities of the model's capabilities found in this work should be followed through and developed. For instance, adapting the model to include and focus on additional high voltage lines (voltage levels of 69 and 115 kV for example), would represent a relevant change in the tool and a potential big contribution to the PyPSA-Earth model. Doing this would allow the model to better represent smaller scale systems, as it is not possible to make the assumption that the grids behave or have the same topology as the ones in developed countries

Another example would be to update or further develop the process and adaptations required in the model to use customized data sets of information regarding generators and alternative energy demand projections. Both of these would allow the model to increase the flexibility of PyPSA-Earth by improving its capacities to work in countries with less reliable data in the online sources.

Finally, another potential aspect to exploit in future work would be to develop feedback loop processes between modelling tools developers, users with detailed information and online data providers. This would allow to improve capacities on all fronts at the same time as promoting the open-source philosophy, enhance contribution among researchers and transparency between users of the model and its results.

Acknowledgments

The Belgian cooperation ARES is acknowledged for the financial support for this work, in the framework of the PRD Project: Tailored energy system models for energy planning in Bolivia.

The impact of spatial resolution on optimal renewable energy portfolios

Aina Maimó-Far[a], Victor Homar[a]

[a] Universitat de les Illes Balears, Palma, Spain, aina.maimo@uib.cat, CA

Abstract:

Efforts in the energy planning department are required to achieve the target levels of renewable energy penetration and electricity demand in the European Union. Mean-variance analysis is commonly used to identify the optimal deployment of variable renewable energy sources. By using it, we can determine the most effective ways to increase renewable energy penetration and minimise supply risks through varying spatial and technological deployments. In this study, we investigate the effectiveness of optimising capacities at the scale of climate data grid points, rather than administrative regions, which is a common approach due to data availability and computation costs. We find that a finer description of climate resources and variable renewable energy capacity factors results in a better exploitation of complementarities and offers increased degrees of freedom in optimisation. Our analysis reveals that better describing local conditions results in two advantages over lower resolution approaches: higher average capacity factors and generation combinations with lower covariances. Additionally, we find that higher resolution approaches significantly reduce variability in daily and annual climate frequencies in renewable generation under the optimal scenario. These results highlight the importance of accounting for detailed climate information when identifying optimal renewable deployment scenarios and can provide valuable support for stakeholders and policy makers in making sustainable commitments.

Climate energy assessment model; High-resolution energy modeling; Mean-variance analysis; Renewable energy system planning; Spatial resolution.

1. Introduction

The shift towards low-carbon energy systems is a current and future challenge, with the EU setting goals for decarbonization by 2050 [1]. In turn, each country must establish specific measures to achieve these goals. In Spain, there are multidisciplinary plans in place to mitigate climate change [2] and promote renewable energy [3], which emphasize the need for research and the installation of new renewable energy sources, while also recognizing the challenges associated with integrating them into the electricity system.

Solar photovoltaic (PV) and wind energy are the main variable renewable energy (VRE) sources driving the transition towards a highly renewable future, aiming to cover half of the Spanish energy demand due to their improving technology and decreasing costs [4,5]. Spain has seen a significant increase in the installed capacity (IC) of these sources in recent years, with a 156% increase in PV and a 17% increase in wind IC from the end of 2018 to the end of 2020, compared to only a 1% increase in the previous five years for both technologies [6–8]. By the year 2020, the two sources combined reached a mean penetration level of 30%, and installations are planned to grow even further.

While solar radiation and wind drive the energy generation by PV cells and wind turbines, several factors other than the generation potential are involved in planning these installations, including capital and operation costs. Classical approximations follow atlas-derived average capacity factors to estimate the levelized costs of energy for a given technology and location. However, these factors fail to account for the risk posed by the intermittent nature of the resource and the complementarity between different components of the system. This consideration should not be ignored, as taking advantage of the complementarity of the system is crucial in order to minimize electricity supply risks and meet the demand [9, 10]

To ensure renewable energy systems meet certain requirements, optimization methods are commonly used, but the many factors that can vary from one optimization to another emphasize the importance of configuration in planning renewable energy deployment [11] These factors can include constraints, time span, optimization method, and region. In this article, we apply a common approach to optimize the deployment of VRE sources by simultaneously maximizing the mean and minimizing the variance through modifications to the spatial distribution of IC for each VRE source. This straightforward method helps us identify the scenarios with the lowest variance, which serves as a proxy for supply risk, for a given level of penetration and provides optimal scenarios for multiple penetration levels.

The way generation and demand data are processed and represented is key when applying mean-variance analysis or similar portfolio-based methods. Some studies (e.g. [12, 13]) use regionally aggregated electricity and climatic data in conjunction with portfolio theory to optimize the deployment of VRE across countries or large regions, by using various metrics. However, these results only provide information about optimal deployment for very large areas and do not offer guidance on specific installation locations within those areas. Another approach [14] consists on fixing the total regional IC through an optimization, and then identifying possible deployment locations within each region. This specific allocation of VRE sources uses criteria such as climatic potential and socioeconomic constraints. However, this type of methods could follow initial large-scale distributions that are made under possibly non-representative average conditions.

The process of aggregating different renewable energy generation sites and technologies can lead to a smoothing effect on the generation curve. However, there are alternative approaches to optimization that do not rely on this aggregation, such as using grid-based models or considering existing generation farms as installation points [15, 16]. Despite the more precise description of the system of these methods, they are quite uncommon in the literature [17]. Additionally, obtaining high-resolution data on electricity generation and demand can be challenging, particularly at very high resolutions where the network topology becomes relevant. Nevertheless, the resolution used for optimization is crucial, especially when dealing with highly heterogeneous regions [18, 19].

There is limited research on how different spatial aggregation approaches impact the optimization of renewable energy deployment. Previous studies have looked at a specific form of aggregation, but have not specifically investigated the effects of changes in resolution on the optimal solutions. More extensive research [17] has been done on optimization models, methodologies, and constraints, but there are still no clear answers to the challenges that arise with different levels of resolution.

This article builds upon previous research [20] that investigated the impact of spatial granularity or resolution on renewable energy deployment optimization. However, instead of using administrative regions, this study explores the effects of arbitrary divisions of space on the optimization results, representative of changing resolution. Through a thorough analysis of experiments at varying levels of resolution, we observe the mechanisms that occur as resolution increases and interpret them in relation to the simplifications and underlying drivers of the renewable energy system.

This article is structured as follows: section 2. gives an overview of the methods and data used, section 3. shows and discusses the main results, and finally section 4. summarizes the main conclusions derived from this study.

2. Methods and data

When it comes to implementing renewable energy sources while guaranteeing a stable supply to the network, the challenge can be reduced to a bi-objective optimization problem. This problem involves maximizing the penetration of renewable sources while minimizing the risks of supply failure. To solve this problem, a mean-variance optimization scheme can be used, where the risk is considered as the square root of variance. The resulting set of optimal solutions defines a Pareto front, which represents the minimum variance/risk squared for a fixed mean. In order to optimize renewable energy deployment, the decision variable is the vector of installed capacities of PV and wind at each location, and each location is associated with a specific capacity factor for renewable energy generation. The capacity factor quantifies the percentage of the potential maximum technical production that is actually generated over a period of time. The national demand is also considered, as the primary objective is to determine the optimal generation curve that best matches the demand and its fluctuations, rather than targeting an average specific level of generation.

To optimize the deployment of renewable energy sources, the ratio of national hourly VRE generation to national hourly demand is defined as hourly. However, the model does not constrain the adequacy between generation and demand. This is because the purpose of the mean-variance analysis is to prevent the need to model non-VRE producers that would also contribute to meeting the demand. The mean penetration is then defined as the time average of the hourly penetration series, and risk is defined as its standard deviation. The only constraint set to the capacities is to be non-negative.

We use the e4clim model [21] as our tool, with the consideration of predictable and unpredictable risk [22]. We use ERA5 [23] as the climatic data source, also functioning as out highest resolution grid, and include a nation-wide calibration of generation and demand with electricity data from Red Eléctrica de España (REE). ERA5 has an effective spatial resolution of around 25 km at the latitudes of mainland Spain, with an hourly time step (see Fig. 1a for a reference on the grid and the administrative regions considered). We perform this experiment over a 7-year period with overlapping electricity and climate data, ranging from the years 2014 to 2020. We take the electricity mix at the end of 2020 as a reference, establishing a reference mean penetration of 30%.

We conducted a series of experiments to investigate how the spatial resolution affects the identification of optimal scenarios for renewable energy deployment. Instead of using traditional administrative regions, we created evenly divided artificial regions across the domain, ranging from the full climatic grid resolution to just four total regions. It should be noted that by considering the regions approach, we assume each of them to be homogeneous and capacity to be evenly distributed. We gradually decrease the resolution of the model by aggregating grid points into larger regions (averaging capacity factors and summing installed capacities) and analyze the impact on optimization results. We then compute a Pareto front for each level of resolution. As the resolution of the model increases, so does the ratio of penetration-risk in the system, resulting in steeper Pareto front slopes (Fig. 1b for the fronts using the whole grid and the administrative regions).

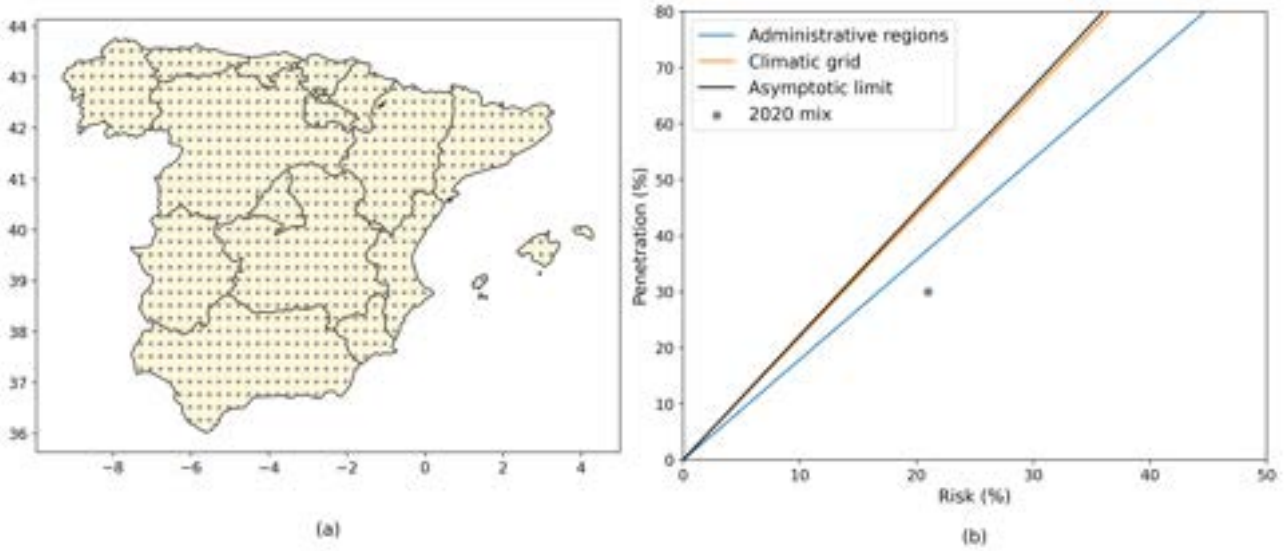

Figure 1: Reference for the administrative regions and full climatic grid approaches in the map (a) and penetration-risk diagram (b). The map (a) shows the full climatic grid over the administrative regions over which they are commonly aggregated. The penetration-risk diagram (b) presents the Pareto fronts for the approaches with administrative regions (blue) and the climatic grid (orange), and for the asymptotic Pareto front (black). The grey dot indicates the location of the 2020 mix.

The Pareto front for each of these experiments is linear in the mean penetration-risk space (fig. 1b). For an arbitrary fixed level of penetration, a minimization of the risk returns the associated capacity distributions for PV and wind. Changing the level of penetration simply introduces a scaling factor to these distributions, which remain the same in relative terms. Therefore, the slope of the Pareto front is constant for each specific resolution, and defines what we call the penetration-risk ratio (PRR).

3. Results and discussion

On a first analysis, we observe that as the resolution of the model increases, there is a corresponding increase in the PRR, with the highest ratio marked by the scenario that uses the full climatic grid. Since the system is powered by climate resources, the extent to which this ratio can increase is limited by the degree to which these resources match the demand. This bounded, increasing behavior indicates the existence of an asymptotic Pareto front, which represents an intrinsic property of the climate driving the system. In this case, ”intrinsic” implies that it is not influenced by the resolution used in the optimization, but it may be affected by the resolution of the climate model used, or the nature of the climate and electricity data that was introduced into the model.

The evolution of the PRR (Fig. 2a) shows a very steep increase at low resolutions, implying that small increments in resolution bring large improvements to the optimization, as the precision in the description of climatic features drastically increases. Once a certain level of resolution is reached, virtually no information is added with increasing resolution because the large climatic modes are already mostly represented, and therefore the PRR practically stabilizes. This implies that the majority of information added at such high resolutions is either redundant, insignificant in relation to the big signals already described, or lacks further resolution from the climatic data. In order to include an analytical dimension that allows us to diagnose the asymptotic behavior of the PRR, we propose a parameterized curve to fit:

$$\mathrm{PRR}(N) = a + \frac{b}{N - c} \tag{1}$$

where N is the number of spatial divisions over the domain, and representative of the resolution, given that the domain remains unchanged. *a*, *b*, and *c* are parameters to be fitted by the known values of PRR and N at varying resolutions. By definition, the asymptotic Pareto front has the largest PRR possible (as $N \to \infty$), which takes the value of $a = 2.22$, and would return lower risk for any level of penetration (or higher penetration for any level of risk) than any other possible configuration with a lower resolution (see Fig. 1a). This value describes the best optimal configuration that could exist under the climate conditions as described by ERA5, but changes in the climatic resolution would not necessarily identify the exact same value.

However, we are not interested only in the asymptotic behavior of the PRR, but in the specific impacts on the optimization of a changing resolution. A first approach is to analyze the total installed capacity for each technology at the 30% penetration level and how they change with resolution (Fig. 2b). At low resolutions, high amounts of capacity are needed to reach a fixed level of penetration, even though they produce higher levels of risk. In a directly opposite behavior to the PRR, the capacity necessary to reach a fixed level of penetration decreases with increasing resolution, reaching a similarly asymptote-like behavior on the lowest necessary capacity to install. This behavior stems from the underlying assumption of homogeneity and even installation that is made in the consideration of regions. Since no additional information is given on the specific locations of installations, it is likely that they fall on suboptimal regions within the area, since the optimization used regional divisions. Through this effect, it is also illustrated that considering low resolution aggregated regions can in turn lead to an overestimation of the necessary capacity by nearly 100%, as the decisions on capacity installation are not accounting for the actual climatic potential.

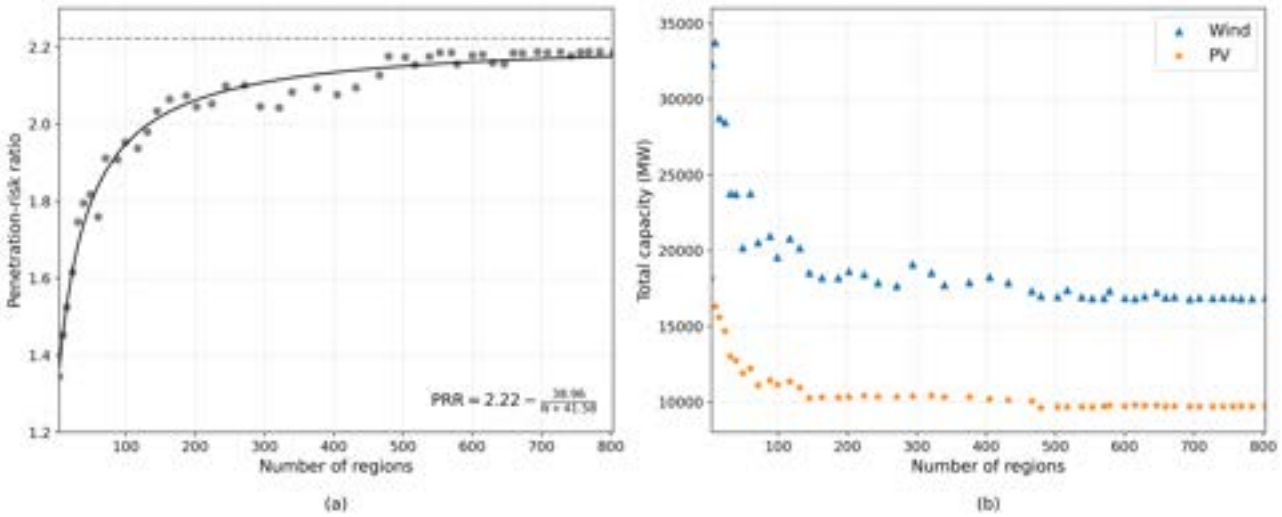

Figure 2: Change with the number of regions of the penetration-risk ratio (a) and total installed capacity per technology at the 30% mean penetration level (b). In (a), the penetration-risk ratio for each number of regions is indicated by a grey dot, the fitting of the points is shown by the solid black line, with the dashed grey line indicating the asymptotic value. The equation for the black line is annotated in the graph, with N the number of regions. For the evolution of capacity (b), the blue triangles indicate the wind capacity, and the orange stars represent the PV installed capacity.

The overestimation of the total installed capacity is an issue that appears in the general vision of the results and that can stem from different causes linked to resolution. In addition to the impacts on total required installed capacity, resolution may also play a role on the spatial distribution of optimal scenarios, which would reveal a significant degrading effect of the regional averaging of the climatic source on the optimization results. An effective method to analyze the spatial dispersion of these distributions is to count the regions with installed capacity exceeding a certain threshold.

Upon analyzing the number of regions with installed capacity exceeding 100 MW at the 30% penetration level, we identify two differentiated behaviors for PV and wind. PV installations (Fig. 3a) are concentrated in a single region across most resolutions, showing no apparent dependence on resolution tendency. This behavior responds to the cyclic nature of PV, which presents little variability across the domain, and is therefore not strongly affected by the averaging process. Indeed, the high covariant component observed in all PV production series within the domain indicates a limited potential for favorable generation complementarities.

The results for wind capacity (Fig. 3b) show a different pattern compared to PV. With increasing resolution, there is a clear tendency for the distribution of installed capacity to spread across a greater number of regions. This suggests that a higher resolution allows for the emergence of more favorable low-covariance combinations

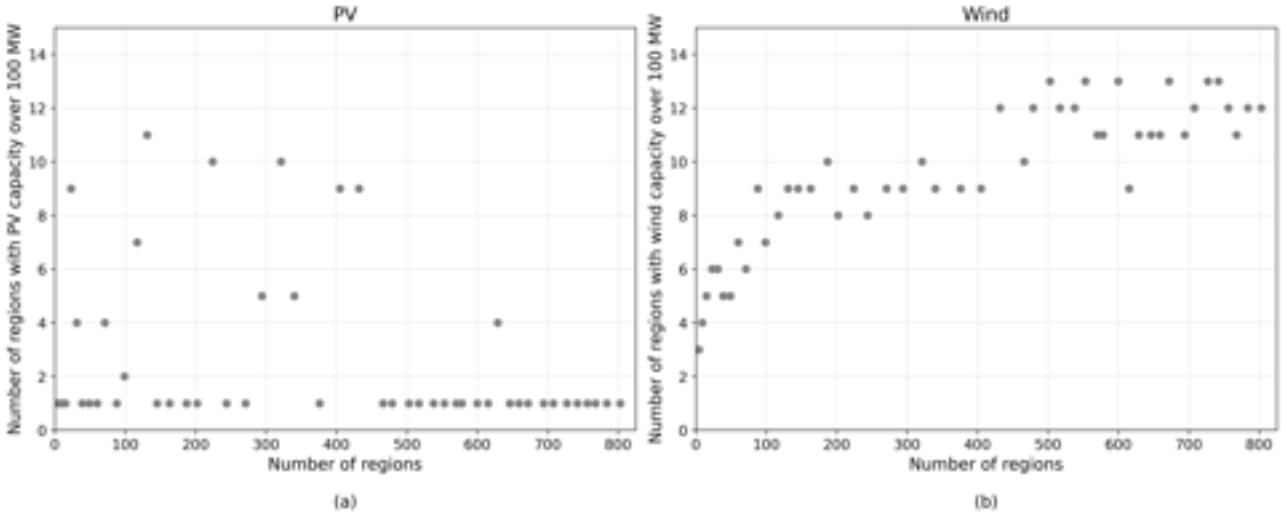

Figure 3: Number of regions exceeding 100MW of installed capacity at a penetration level of 30% at each level of resolution for PV (a) and wind (b).

of wind capacity across different locations. In fact, whereas PV is mostly covariant within the domain, wind resource presents higher variability, and an increased chance for low covariances or even anticovariances to occur is higher. Therefore, using a high enough resolution to capture the potential of favorable low-covariance combinations is key to achieving the maximum actual potential for renewable generation of any given domain.

Thus far, two conclusions that complement the asymptotic PRR results have been drawn. Firstly, the capacity required to achieve a specific level of penetration decreases with resolution, along with the associated risk, due to the better representation of the climatic resource. Secondly, for PV, the capacity tends to be concentrated in a single region, regardless of the modeling resolution, whereas for wind, it spreads across more regions as the resolution increases. These two effects derive from the cyclic quality of PV (following similar patterns all over the domain), and the non-cyclic variable nature of wind.

Therefore, in order to explore the impact of resolution on optimal renewable energy deployment scenarios, the spatial distribution of three resolution levels - low, middle, high - for the 30% penetration target is examined in detail (Fig. 4 a-b, c-d, and e-f, respectively).

The distribution of installed capacity for PV is concentrated in the same region across all three resolution levels, as previously discussed. This suggests that the points that determined the selection of regions in the middle and low resolution scenarios were primarily those located in the region identified by the high resolution scenario. Due to the limited variability of PV, the averaging process does not degrade the results. Additionally, higher resolutions require less capacity in a given region because the optimization more accurately identifies the area with the highest capacity factors and lowest variability, and thus exploits the available climate resources more effectively.

The behavior of wind capacity exhibits two distinct patterns. In the western half of the domain, wind installations behave as PV series in the sense that the entire region follows a similar pattern driven by a substantial influence of sustained strong Atlantic winds. This results in the high resolution wind installations contained within the regions of the middle and low resolution optimal scenarios. On the other side, the eastern half of the domain presents different response. Despite some strong northern winds in the islands and some mountain-influenced winds in the northeast regions, the eastern side of the domain presents very variable patterns, which may not arise at the low and middle resolutions. This is coherent with the more variable Mediterranean climate.

Despite not presenting any installed capacity at the low resolution, the southeastern quadrants of the wind capacity distributions have a region contained in it entering the mix at the middle resolution, and then again presenting zero installed capacity at the high resolution. The capacity allocated at low resolution in the northeast quadrant of the domain, is reallocated differently in the middle and high resolution resulting scenarios. This effect arises from the unique characteristics of each high resolution region being smoothed out when resolution is lowered. The high resolution enables greater detail in the spatial characterization of the climatic resource, allowing previously obscured areas to become visible in the optimal mix. Conversely, areas that were included in the optimal mix at the middle resolution due to the mean, were no longer competitive at the high resolution. The cause behind this is the reduction in region size associated to the increase in resolution. This effect allows high potential areas to stand out without the smoothing effect of the mean, and contrarily considers regions that may stand out only in terms of the mean but that may not contain any smaller areas

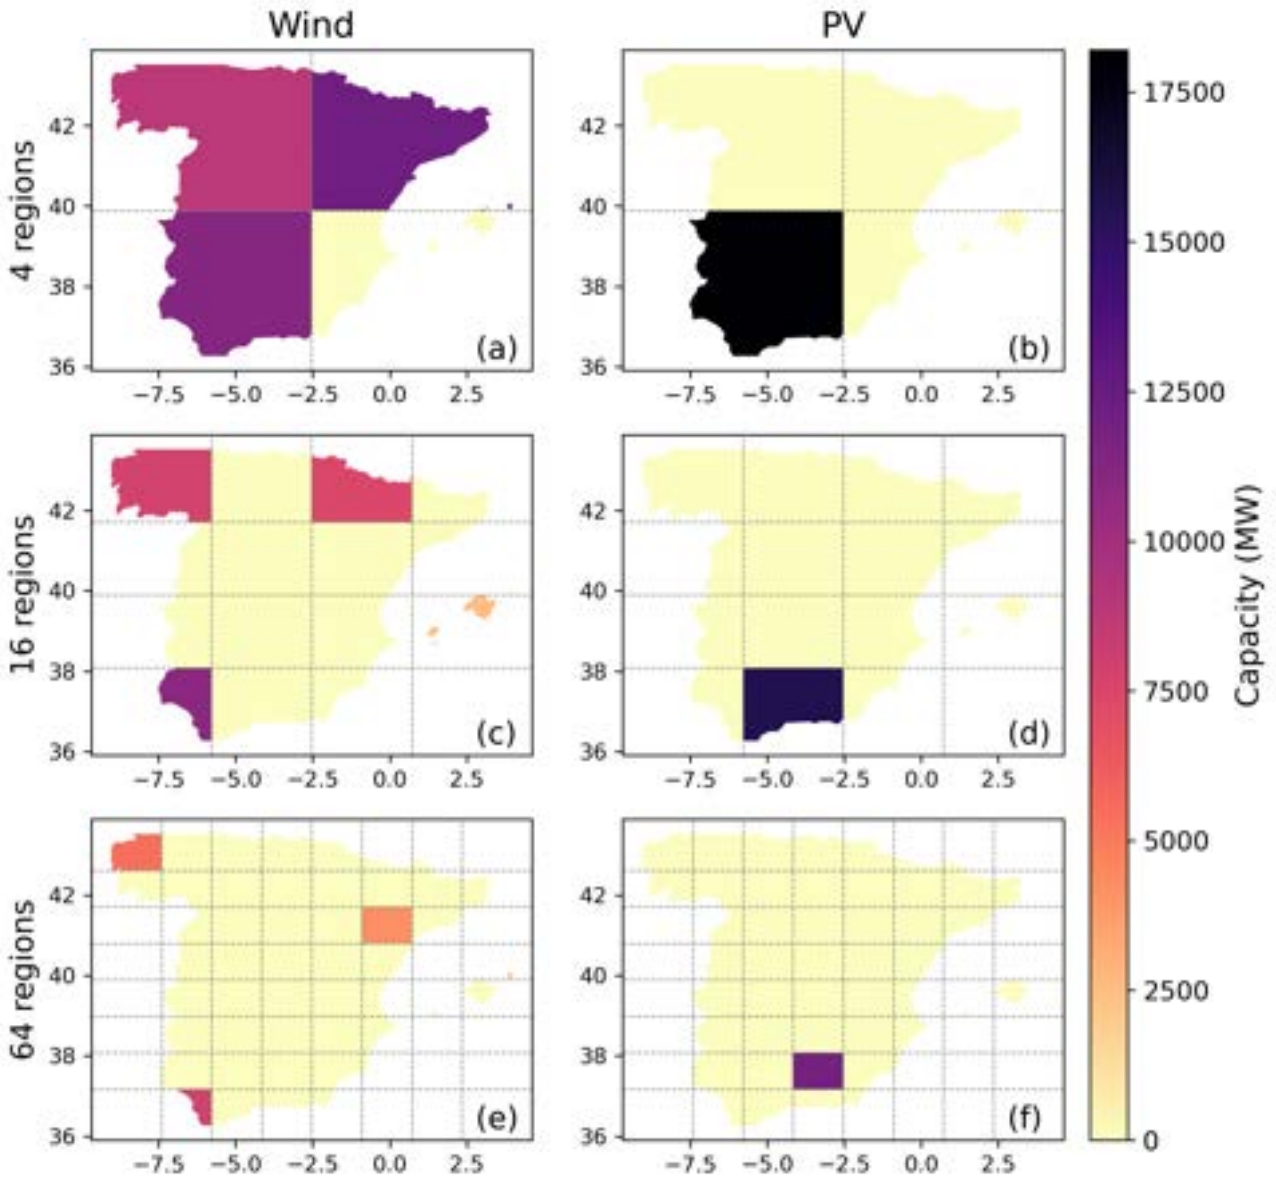

Figure 4: Optimal distribution of installed capacity for wind (a,c,e) and PV (b,d,f) for the configurations with 4 (a, b), 16 (c, d), and 64 (e, f) regions at the 30% penetration level.

of particular potential. This proves key, especially considering that any renewable installation will exploit the corresponding local climatic resource, and not some averaged value.

4. Summary and conclusions

In this article, we determined and analyzed the impacts of resolution on the results of optimization models for VRE deployment. By simple asymptotic reasoning, the absolute limit in penetration-risk ratio for a certain spatio-temporal distribution of climate resource and electricity demand is derived and represented by the asymptotic Pareto front of the system.

The usable resolutions in renewable energy deployment optimization models are primarily bounded by climate data resolution. The intrinsic limit of the attainable penetration-risk ratio can be represented by the asymptotic Pareto front, which provides an estimate of the upper limit in terms of renewable penetration-risk payoff given the available resource. The illustrative example of Spain renders a penetration-risk maximum payoff of 2.22, and therefore the Spanish VRE system should assume a minimum risk threshold of 45% in order to achieve 100% penetration. This front is independent of the resolution used for the optimization, but not necessarily independent of the climate data and its resolution. We find that the frontier reached when using the full climate grid optimization closely approximates the asymptotic behavior of increasing resolution, with minimal differences in penetration and/or risk under 1% at any given level.

Both PV and wind technologies exhibit similar patterns in terms of the total installed capacity, and with in-

creases in penetration, the necessary capacity decreases while also lowering the risk, as a result of more accurate descriptions of the real climatic reality. However, they show different behaviors when the actual distributions of capacity are considered. PV tends to have all its capacity concentrated in one region. By its nature, PV follows a similar pattern over the whole domain (i.e., the predictable daily and seasonal cycles), which implies that the potential benefits of combining different installation location are small. Contrarily, wind presents a more varying nature over the territory, which in turn favors instances where combining wind resources is beneficial to the overall system. As a result of this changing quality, wind capacity distribution varies with the changing resolution due to some high-potential areas being averaged out across regions, as well as some regions having better averaged values than their individual components. However, in areas with strong sustained wind patterns, wind capacity follows a similar behavior to PV.

The use of higher resolution data can prevent overestimations of necessary capacity. The usage of the highest possible resolution helps identify the synergies between different locations for installation. In turn, these synergies allow for smaller amounts of installed capacity to reach high penetration levels. Lower resolution approaches limit the possible combinations and the precision of their components, which presents a reduced representation of reality that is detrimental both in terms of return and in terms of necessary capacity.

Abstract:

In this paper, we propose a multi-RREH (Remote Renewable Energy Hub) based optimization framework. This framework allows a valorization of CO2 using carbon capture technologies. This valorization is grounded on the idea that CO2 gathered from the atmosphere or post combustion can be combined with hydrogen to produce synthetic methane. The hydrogen is obtained from water electrolysis using renewable energy (RE). Such renewable energy is generated in RREHs, which are locations where RE is cheap and abundant (e.g., solar PV in the Sahara Desert, or wind in Greenland). We instantiate our framework on a case study focusing on Belgium and 2 RREHs, and we conduct a techno-economic analysis. This analysis highlights, among others, the interest of capturing CO2 via Post Combustion Carbon Capture (PCCC) rather than only through Direct Air Capture (DAC) for methane synthesis in RREH. By doing so, a notable reduction of 9.2% is observed in the total cost of the system under our reference scenario. In addition, we use our framework to derive a carbon price threshold above which carbon capture technologies may start playing a pivotal role in the decarbonation process of our industries. For example, this price threshold may give relevant information for calibrating the EU Emission Trading System so as to trigger the emergence of the multi-RREH.

1. Introduction

While the whole world is engaged in a process to decrease greenhouse gas emissions, capturing CO2 appears more and more as a crucial element to limit global warming. Once it is captured, CO2 may be either stored (CCS - Carbon Capture and Storage), either valorized (CCU - Carbon Capture and Utilisation), for instance through synthetic methane generation. In this article, we focus on CCU, where CO2 is seen as a required ingredient in the process of generating synthetic methane, together with *green* hydrogen, i.e. hydrogen obtained from renewable energy-based electrolysis.

In this paper, we build on top of the Remote Renewable Energy Hub (RREH) approach [3] to propose a multi-hub, multi CO2 sources approach. CO2 is captured using both Post-Combustion Carbon Capture (PCCC) and Direct Air Capture (DAC) technologies. Hydrogen is produced from electrolysis using renewable energy in a RREH which is particularly well-suited for producing cheap and abundant renewable energy (e.g., solar energy in the Sahara desert, or wind energy in Greenland). The RREH concept also relies on the following idea: some locations show large amount of energy consumption while not having lots of renewable energy resources (e.g., Europe). On the opposite, some places have abundant renewable energy while having almost no energy demand. In its original formulation, the RREH concept suggests to use DAC technologies to feed the CO2 demand at the RREH. In this paper, we include PCCC technologies as an alternative to DAC technologies: in addition or replacement to being captured in the atmosphere, CO2 emitted in energy intensive locations may be transported to the RREHs to be combined with green hydrogen for producing neutral synthetic methane.

We propose a methodology for assessing the technico-economic feasibility of exporting CO2 into RREH where synthetic CO2-neutral methane would be generated using locally produced green H2. We formalise an optimisation problem where CO2 sources are in ”competition” to provide CO2 to the methanation units in the RREHs. This methodology is based on a linear program modelling of Belgium energy system, including gas and electricity demand, and main CO2 emitters. We rely on previously published approaches to develop our approach Berger et al. [3], and, in particular, we use the GBOML language Miftari et al. [17] to model the energy system and to optimize it.

Our methodology is evaluated in the Belgian context: we consider Belgian CO2 emissions and Belgian gas and electricity demand. CO2 may be captured using Post Combustion Carbon Capture (PCCC) in Belgium or DAC in RREH locations. CO2 neutral synthetic methane will be produced in a remote energy hub from where it would be shipped back to serve the Belgian gas demand. We derive a CO2 emission cost in order to have a neutral emission system. We also determine a value of lost load (*i.e.* a price associated with a lack of energy service) in order to serve the energy demand at all times. Several scenarios are studied with different prices of CO2 emissions, allocation or not of unserved energy and forcing of a given RREH.

2. Related Work

This work is mainly related with the following topics that may play an important role in the deep decarbonation of our societies: (i) global grid approaches, (ii) power-to-X technologies, multi-energy systems and and energy hub approaches, and (iii) CO2 quotas markets.

Global Grid (GG) approaches [7], [25], sometimes referred to as Global Energy Interconnection approaches [16], are related with the idea of harvesting renewable energy from abundant and potentially remote renewable energy fields to feed the electricity demand in high demand centres. These approaches have mainly been oriented towards solutions using the electricity vector to repatriate energy from energy hubs, and have received a growing interest starting from the DESERTEC concept [23] that focuses on Sahara solar energy resources from the Sahara desert to serve the European electricity demand. More recently, wind from Northern Europe and Greenland has also been identified as a promising resource to be valued within the GG context [21]. Resource and demand configurations combining several types of resources as well as demand time zones show better results [25].

Multi-energy systems approaches [19, 20] exploit the benefits of integrating energy demand and generation, as well as infrastructure. Power-to-X technologies, in particular power-to-CH4 technologies using hydrolysis and renewable energy for producing H2 [15], offer a CO2 neutral solution to serve gas demand, but also a way to store vast quantities of energy issues from renewable sources [5]. Recently, Berger et al. have proposed a modeling framework [3] for assessing the techno-economics viability of carbon-neutral synthetic fuel production from renewable electricity in remote areas where high-quality renewable resources are abundant. Let us mention that the idea of energy hubs was preexisting the work of Berger et al. [14, 18, 22], however the contribution of Berger et al. is the introduction of remote energy production, far from the demand. Our contribution is in line with the latter.

As this work aims to enhance the value of CO2, it is closely linked to the European Union Emissions Trading System (EU ETS). The EU ETS system, which is described on the European Commission's website [1] and in [6], is a 'cap and trade' program. The system sets a cap on the total amount of certain greenhouse gases (GHG) that can be emitted by the facilities covered by the ETS. Within the cap, facilities are given emissions allowances, which can be traded with one another. The total number of allowances available is limited to ensure that they have value, and the cap is gradually reduced over time to lower total emissions. If a facility fails to cover its emissions fully, it faces substantial fines. Conversely, if a facility reduces its emissions, it can either retain the surplus allowance for future use or sell it to another facility that has not succeeded in covering its own emissions. This trading mechanism aims to reduce GHG emissions as soon as it becomes the most cost-effective solution and encourage investments in low GHG emissions solutions.

3. CO2 Valorisation in a Multi-Remote Renewable Energy Hubs Approach

The Remote Renewable Energy Hub concept was first introduced in [3] where the authors proposed a hub for synthesizing CH4 based on hydrogen and CO2 captured from the air thanks to a methanation unit. This concept has emerged within the context of global grid [7] and multi-energy systems approaches. These approaches aim at optimising the generation and utilisation of renewable energy (RE) by both (i) looking for abundant and cheap RE fields, (ii) taking advantage of daily/seasonal complementary of RE, as well as (iii) using power-to-gas technologies for better addressing RE generation fluctuations and meet e-fuels demand to act as a substitute for molecules derived nowadays from fossil fuels.

In the original article [3], the methanation unit was supplied with CO2 by a Direct Air Capture unit, and the energy demand was fulfilled by a single RREH located in Algeria. However, in this paper, we propose to investigate the feasibility of valorizing CO2 captured through Post Combustion Capture techniques at the energy demand center (EDC). Additionally, we deviate from the original paper by introducing a multi-RREH approach, wherein the EDC serves as a CO2 provider to a set of multiple RREHs, denoted as $RREH_1, \dots, RREH_h$. Each hub $RREH_i (1 \leq i \leq h)$ has its unique characteristics, such as renewable energy type, potential, distance from the EDC, and means of CO2 transport from the EDC, which can affect its competitiveness.

In order to illustrate the concepts discussed above, we have developed a model for a multi-RREH system

[1] https://climate.ec.europa.eu/eu-action/eu-emissions-trading-system-eu-ets_en

based on the following assumptions: (i) the EDC is Belgium, encompassing its gas and electricity demands as well as its CO2 emissions, (ii) there are two RREHs: one situated in the Sahara desert with access to solar and wind resources, and another in Greenland benefiting from the high-quality wind fields in the region. A detailed schematic of the resulting system is shown in Fig. 1. Similar to [3], we employed the GBOML language [17], a recently developed language tailored for energy system optimization (refer to section 4. for more information), to model the system.

We note that the GBOML model code with two RREHs and one EDC system is available online[2] and can be easily extended to add additional RREHs and EDCs.

4. Modelling

This section provides insight into the optimization framework that underlies the multi-energy system model proposed in this work. The GBOML language introduced in [17], a recently developed language dedicated to modeling graph-based optimization of multi-energy systems, is utilized to build this model. The optimization problem can be viewed as optimization on graphs, where a multi-energy system is considered as a set of nodes $\mathcal{N}$ that contribute to the (linear) objective and local constraints, and hyperedges $\mathcal{E}$ are used to model the constraints between nodes, such as those between RREHs and the EDC in our context.

The formalism employed in this work follows that introduced in [3]. The entire system is defined by sets of nodes $\mathcal{N}$ and hyperedges $\mathcal{E}$. The optimization horizon is denoted by T, with time-steps indexed by $t \in \mathcal{T}$, where $\mathcal{T} = \{1, \dots, T\}$.

A node $n \in \mathcal{N}$ is defined by internal X^n and external Z^n variables, where internal variables describe the specific characteristics of the unit, such as the nominal power capacity installed in the asset. Equality constraints $h_i(X^n, Z^n, t) = 0$ with $i \in \mathcal{I}$ and inequality constraints $g_j(X^n, Z^n, t) \leq 0$ with $j \in \mathcal{J}$, are employed for each $t \in \mathcal{T}$ to model operational constraints.

Each node n has an associated cost function $F^n(X^n, Z^n) = \sum_{t=1}^{T} f^n(X^n, Z^n, t)$ that typically represents the capital expenditure and operational expenditure, i.e., CAPEX and OPEX, respectively.

Finally, equality and inequality constraints on hyperedges can be defined as $H^e(Z^e) = 0$ and $G^e(Z^e) \leq 0$ with $e \in \mathcal{E}$ to model the laws of conservation and caps on given commodities.

One can read this type of problem as:

$$\begin{aligned} \min \quad & \sum_{n=1}^{N} F^n(X^n, Z^n) \\ \text{s.t.} \quad & h_i(X^n, Z^n, t) = 0, \forall n \in \mathcal{N}, \forall t \in \mathcal{T}, \forall i \in \mathcal{I} \\ & g_j(X^n, Z^n, t) \leq 0, \forall n \in \mathcal{N}, \forall t \in \mathcal{T}, \forall j \in \mathcal{J} \\ & H^e(Z^e) = 0, \forall e \in \mathcal{E} \\ & G^e(Z^e) \leq 0, \forall e \in \mathcal{E}. \end{aligned} \tag{1}$$

The main assumptions underlying our model are the following:

- Centralised planning and operation: In this framework, a single entity is responsible for making all investment and operation decisions.
- Perfect forecast and knowledge: It is assumed that the demand curves, as well as weather time series, are available and known *in advance* for the entire optimisation horizon, i.e., $\forall t \in \{1, \dots, T\}$.
- Permanence of investment decisions: Investment decisions result in the sizing of installation capacities at the beginning of the time horizon. Capacities remain fixed throughout the entire optimisation period, i.e., $\forall t \in \{1, \dots, T\}$.
- Linear modelling of technologies: All technologies and their interactions are modelled using linear equations within this framework.
- Spatial aggregation: The energy demands and generation at each node are represented by single points. The topology of the embedded network required to serve this demand locally is not modelled in this approach. This can be viewed as an extension of the copper plate modelling approach used in electrical power systems.

In our problem, all cost functions and constraints are affine transformation of the inputs. More details on the constraints of each technology can be found in [2], [3]. Additionnaly, the local objective function corresponding

[2] https://gitlab.uliege.be/smart_grids/public/gboml/-/tree/master/examples

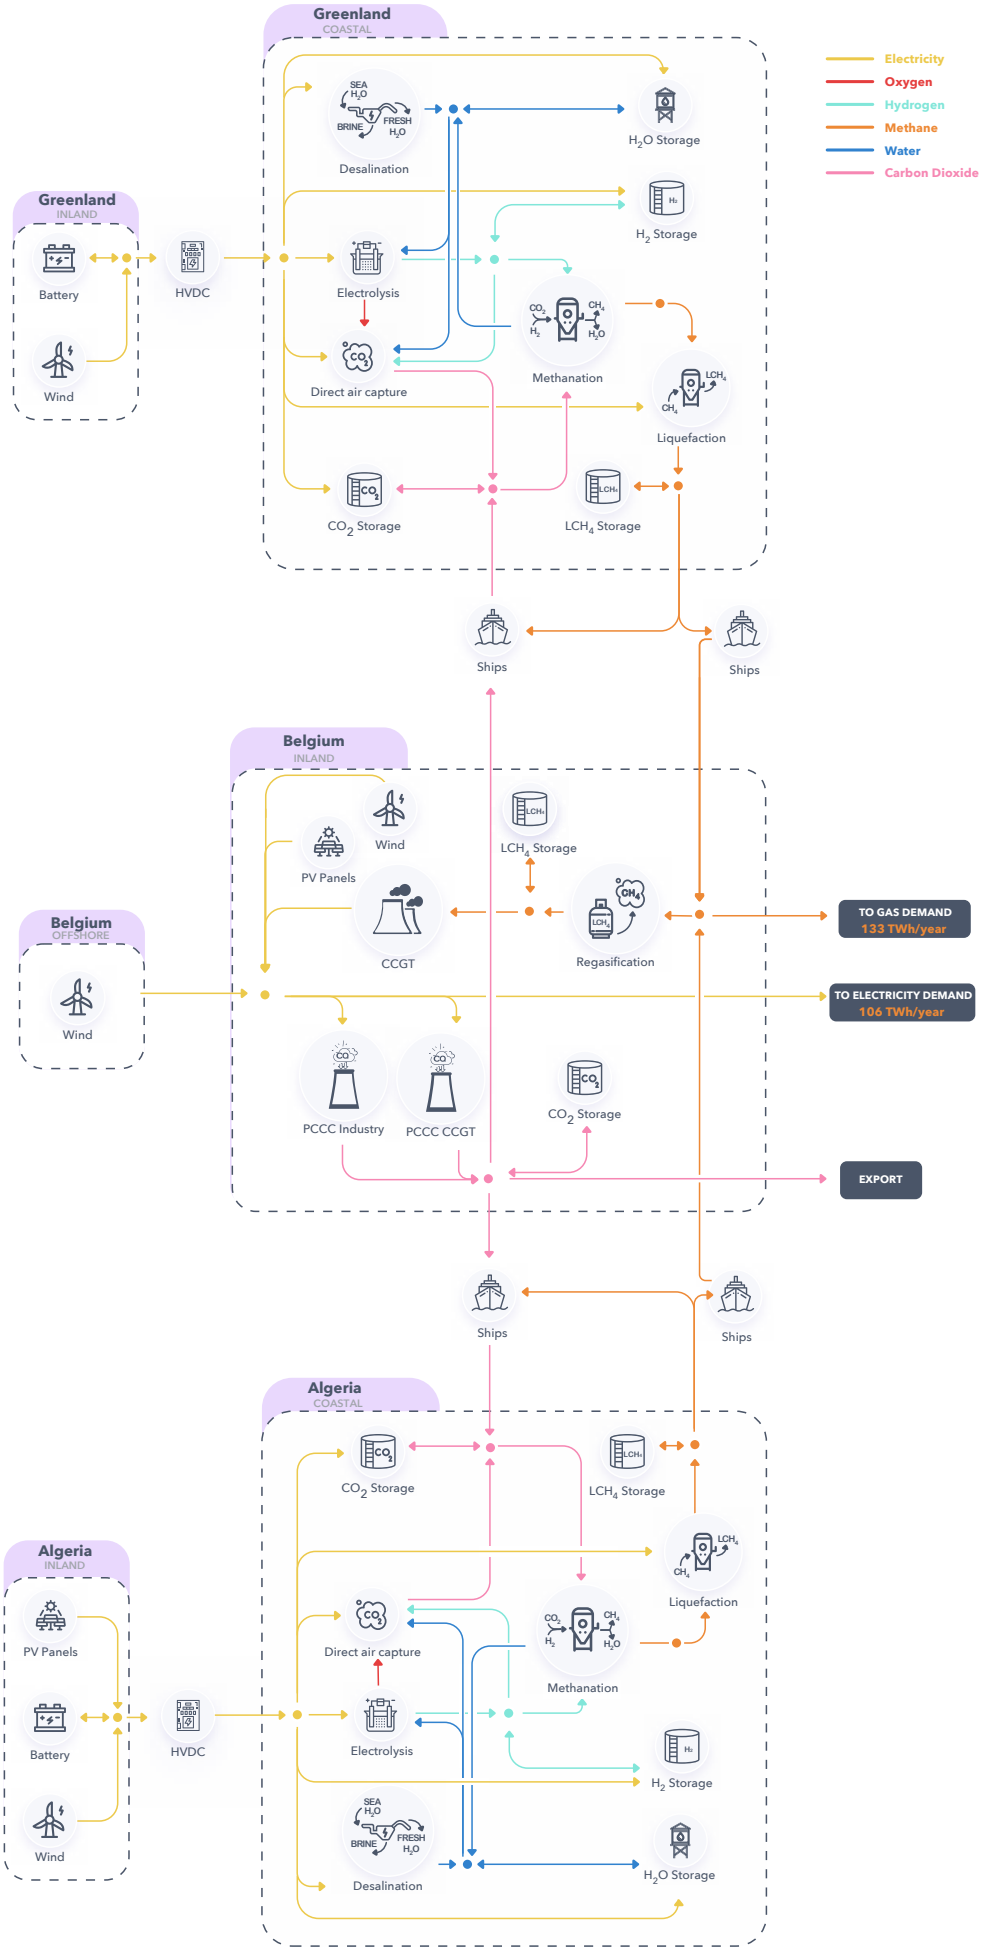

Figure 1: A schematic illustration of the remote energy hub. CO2 being captured, it may be used to synthesize fuel either locally either in a remote energy hub where renewable energy may be cheaper and more abundant.

to the CAPEX is modelled with a uniform weighted average cost of capital (WACC) of 7% for each technology. Thus, the CAPEX is computed using the following formula:

$$\zeta^n = \text{CAPEX}_n \times \frac{\text{w}}{(1-(1+\text{w})^{-\text{L}_n})} \tag{2}$$

with L_n the lifetime of technology n and w the WACC. Hence, ζ^n represents the annualised cost of investing in technology n.

Moreover, a cap on the net CO2 emissions (*i.e.* release in minus captured from the atmosphere) is added to the model. This latter is defined as

$$\sum_{t\in\mathcal{T}}(\sum_{a\in\mathcal{A}} q^a_{co2,t} - \sum_{c\in\mathcal{C}} q^c_{co2,t}) \leq \kappa_{co2}\nu \tag{3}$$

with $\mathcal{A}$ and $\mathcal{C}$ representing the sets of technologies that release CO2 into the atmosphere and those that capture CO2 directly from the atmosphere, respectively, κ_{co2} represents the CO2 cap in kilotons per year, and ν represents the number of years covered by the optimization horizon. The shadow price, or marginal cost, which is the dual variable associated with (3) allows for the derivation of a CO2 cost in €/t. A detailed explanation of dual variables as marginal costs in linear programming can be found in [4, Chapter 4].

5. Case Study: Belgium

This case study is focused on Belgium with two remote renewable energy hubs: one located in Algeria and another one located in Greenland. We will analyse the techno-economic feasibilty of the system while responding to an energy demand composed only of electricity and gas in Belgium.

5.1. Data

The data cover 2 years: 2015 and 2016. It is used to characterize energy demand as well as load factors for renewable energy sources.

Renewable generation profiles

In order to determine the generation profiles of variable energy sources in Belgium we use the data from the transmission system operator (TSO) of Belgium [11]. The profiles for the RREH located in Algeria are extracted with the same methodology as in [3]. For the RREH situated in Greenland, the profiles of renewable energy are extracted thanks to the MAR model [12] and given a power curve for an offsore wind turbine MHI Vestas Offshore V164-9.5MW.

Energy consumption

The energy consumption data is collected for two energy vectors: gas ([13]) and electricity ([10]) with the same methodology as in [2]. In Fig. 2, the data corresponding to the two years is represented, where the signal is daily aggregated. In some cases, gas usage is shifted towards electricity needs, as described in [2, section 4.2.2]. This shift is due to the use of heat pumps, which can help decarbonize heating in Europe. For both energy vectors, industrial and heating demands are taken into account.

The peak power demand is equal to 60.13 GWh/h for both gas and electricity. The energy demand for electricity ranges from 6.42 to 20.29 GWh/h, while that for gas ranges from 5.51 to 39.84 GWh/h. The total energy demand is on average 106.45 TWh/year and 132.65 TWh/year for electricity and gas, respectively.

5.2. Model Configuration

Our model consists of three main components (see Fig. 1): the energy demand center located in Belgium and two Remote Renewable Energy Hubs (RREHs) situated in Algeria and Greenland. The RREH in Algeria is modeled as described in [3] with the same techno-economic parameters. The distinction is made with the inclusion of the CO2 connection between Belgium and Algeria. The RREH in Greenland is similarly modeled, with the exception of the removal of the photovoltaic potential and the modification of the high-voltage direct current (HVDC) line to a length of 100 km rather than 1000 km.

The transportation of CO2 is achieved through the use of boats, which have a CAPEX of 5M€/kt, a lifespan of 40 years, and an average daily energy consumption of 0.0150 GWh/day. CO2 transport data was obtained from [1]. The loading and traveling time for these boats are assumed identical to those for liquefied methane carriers [3], *i.e.* 24 and 116 hours, respectively. In order to fill the tank of CO2 carriers with fuel (liquefied methane), these tanks are loaded when unloading the CO2 at the RREH. Indeed, at the RREH, synthetic CH4 is available without having undergone any additional transport-related losses. Except for the storage facilities, liquefaction of CO2 has been excluded from the model. Sideways analyses have confirmed that this assumption has a negligible impact on the optimal objective.

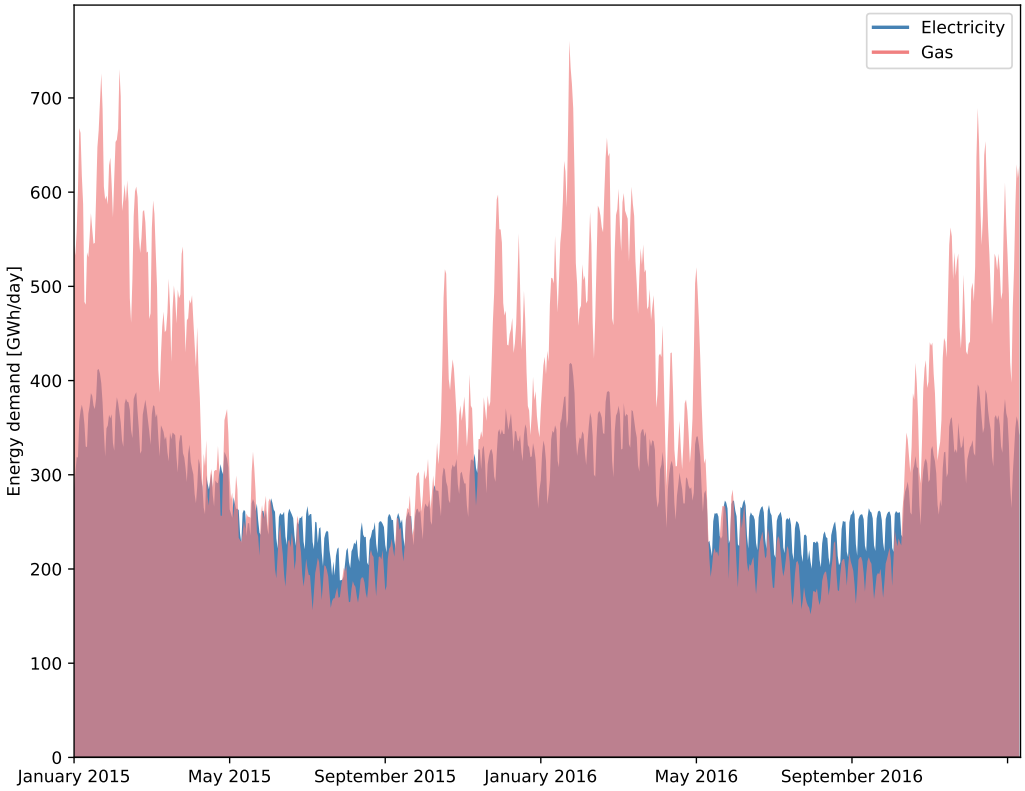

Figure 2: Daily aggregated profiles of electricity and natural gas demand covering the years 2015 and 2016 spanned by the optimisation.

Belgium is modeled with an electricity and gas demand as depicted in Fig. 2, with various means of production, including wind power, solar power, and a combined cycle gas turbine. The solar potential is limited to 40GW. The wind potential is equal to 8.4 GW and 8 GW for onshore and offshore capacities, respectively. The techno-economic parameters of each technology deployed in Belgium follow those in [2].

We have also added a CO2 source that is equivalent to 40Mt CO2/year, which corresponds to the energy sectors and industrial processes greenhouse gases in Belgium in 2019 [8, Table 4.1.1 (pp. 165- 166)]. We assume that we can install post-carbon capture technologies (PCCC) in these sectors.

In terms of carbon capture technologies, the model has access to direct air capture installed at the RREHs, as well as a PCCC in Belgium on the 40Mt of CO2 per year and a PCCC installation on the CCGT.

As stated in [2], the cost of PCCC is 3150M€/kt/h of CAPEX. The variable operating and maintenance costs (VOM and FOM) have been neglected in this analysis. However, a demand of $0.4125 GWh_{el}/kt_{CO2}$ of electricity is required. The expected lifetime is assumed to be 20 years.

Similarly, according to [3], the cost of DAC is equal to 4801.4 M€/kt/h of CAPEX. Similar to PCCC, VOM and FOM are ignored. The operational requirements for DAC are $0.1091 GWh_{el}/kt_{CO2}$ of electricity, $0.0438 kt_{H2}/kt_{CO2}$ of di-hydrogen, and $5.0 kt_{H20}/kt_{CO2}$ of water. The expected lifetime is assumed to be 30 years.

5.3. Results

In this section, we explore several scenari. We describe the variables that are used to differentiate the scenari

1. Cost or Cap on CO2: either a cap is set of 0 t/year or a price at 80€/t or 0€/t
2. Cost of energy not served (ENS): either energy not served is not allowed or a penalty of 3000€/MWh is imposed for each unit of unproduced energy.
3. Forcing or not the use of a given RREH.

Scenario	Cap on CO2 (kt)	Cost of CO2 (M€/kt)	ENS	Cost ENS (€/MWh)	Objective (M€)
1	0.0	0.0	No	-	83742.61
2	0.0	0.0	Yes	3.0	80778.02
3	No	0.08	Yes	3.0	78872.94
4	No	0.0	Yes	3.0	76323.94
5	0.0	0.0	No	-	111209.95

Table 1: Scenari parameters.

The results are generated with 5 scenari:

Scenario 1: This scenario seeks to avoid energy scarcity, whatever the cost. Therefore, no ENS is allowed. In addition, a hard constraint is set on CO2 emissions: a cap on CO2 is set.

Scenario 2: This scenario follows the same assumptions as scenario 1 except that it leverages the constraint on energy not served. The cost associated to electricity not served is equal to 3000€/MWh, which is a standard value in the electricity context [24].

Scenario 3: This scenario leverages the constraint on CO2 emissions, and does not force the avoidance of energy not served but is penalized by 3000€/MWh not served. A penalty is associated with any CO2 emission in the atmosphere in the form of a fee equal to 80€/MWh - a value that reflects the current price of CO2 in the EU-ETS trading system [9].

Scenario 4: This scenario follows the same assumptions as scenario 3, with the difference that the cost of CO2 is equal to 0€/MWh. The aim is to showcase the system's configuration in the absence of any considerations for CO2 emissions.

Scenario 5: This scenario follows the same assumptions as scenario 1, with the difference that the only available RREH is in Greenland.

These scenari summarized in Table 1 vary in their degree of constraint. Scenario 1 is the most restrictive, with a cap on CO2 emissions and no allowance for energy not served. Scenario 2 allows for energy not served, while scenarios 3 and 4 remove the cap and replace it with CO2 prices of 80€ and 0€ per ton, respectively. Finally, scenario 5 requires the use of the RREH in Greenland, with parameters identical to those of scenario 1.

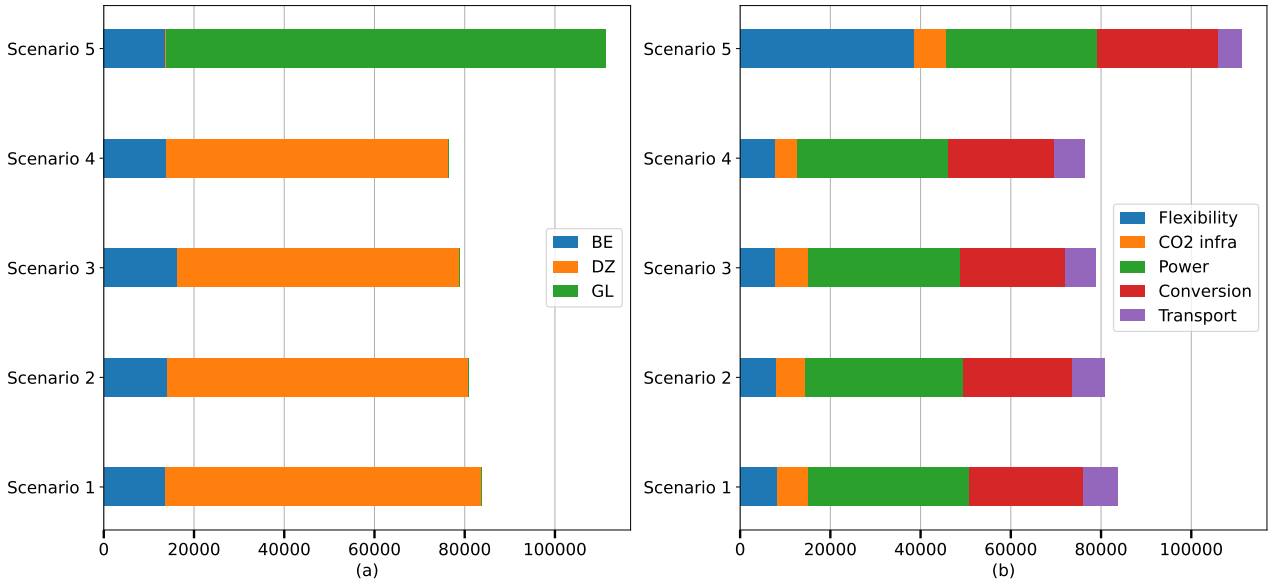

Figure 3: (a): Breakdown of costs per scenario and per cluster (Belgium (BE), Algeria (DZ), and Greenland (GL)). (b): Breakdown of costs per scenario per asset function. Flexibility covers storage capacities, CO2 Infra covers CO2 capture, storage, and transport, Power covers means of electricity production, Conversion covers all assets that convert one commodity into another and Transport HVDC lines and CH4 carriers.

5.4. Analyses and Discussion

In this section, we introduce and discuss the results in detail. We choose to present a cross-scenario analysis in the light of key indicators and statistics extracted from the model.

Total cost.

The results indicate that the costs associated with enabling the hub in Algeria are substantially lower than those in Greenland, as depicted in Fig. 3 (a) where nothing is built in the Greenland hub from scenarios 1 to 4, despite it being available for use. This disparity in costs can be attributed to the over-dimensioning of flexibility assets, particularly the storage capacities, as illustrated in Fig. 3 (b). This is mainly explained to electricity generated solely through wind available in Greenland, whereas both solar and wind electricity are obtainable in Algeria. This implies that the flexibility assets have to take the lead in maintaining a minimum of electricity delivery required in the electrolysis power plant.

Furthermore, a reduction in total costs is observed in the first four scenarios with respect to the objective. This is explained with the order on the scenari based on their degree of constraint with scenario 1 being the most constrained and scenario 4 being the least.

Power installation capacities.

All power capacities installations are displayed in Table 2.

The potential in Belgium of solar energy is never reached while for both wind offshore and onshore the potential is reached in all scenari.

From scenario 1 to scenario 2, the only difference being the allowance of ENS, there is an increase in the installation of controllable energy production assets. Indeed, there is a shift in capacity from CCGT to solar energy in Belgium between the first scenario and the second.

Comparing scenario 1 and 5, solar energy in Belgium is more expensive than importing CH4 from the RREH in Algeria. Importing from Greenland is more expensive and leads to an increase in power capacity installation in Belgium for solar, but it does not reach the maximum potential.

Another interesting comparison can be made with the work of [3], where the capacity installation in the hub for the reference scenario is 4.3GW of solar and 4.4GW of wind. In our case, the reference scenario 1 displays 100.51GW and 103.62GW, respectively. The power installation capacity is multiplied by approximately 23 while providing, on average, 282TWh/year of gas (HHV) to serve the gas demand and part of the electricity demand in Belgium, which is 28.2 times the gas production in the original paper.

Scenario	Wind onshore BE	Wind offshore BE	Solar BE	CCGT BE	Wind GL	Wind DZ	Solar DZ
1	8.40	8.00	10.56	22.69	0.00	103.62	100.51
2	8.40	8.00	15.35	17.95	0.00	98.43	95.47
3	8.40	8.00	14.95	17.83	0.00	93.32	90.32
4	8.40	8.00	14.72	17.82	0.00	93.28	90.28
5	8.40	8.00	17.48	19.58	129.43	0.00	0.00

Table 2: Total Power installation in GW per scenario.

CO2 installations (transport, capture).

In Table 3, the capacities of the CO2 capture units and the installations of transport capacity per scenario are displayed. Each time PCCC is activated, we recall that capturing CO2 is the only means to create gas in our system, and thus a minimum installation is required to support the demand. On the other hand, the DAC is only activated when a CO2 cap is set. PCCC has an efficiency of CO2 capture set to 90%, which means that a direct air capture technology asset is necessary to recover the remaining 10% of emissions in the atmosphere. This leads to a direct consequence, which is that when the DAC is available, the capacity of transport decreases because CO2 is locally available in the hub. However, the cost of CO2 capture by PCCC added to transport of CO2 is cheaper than the cost of DAC in the RREH. The only way to put PCCC out of business would be to have a distance between the hub and the energy demand center so long that the transport cost would increase too much.

Due to the higher concentration of CO2 in manufacturing smoke compared to the air, PCCC will likely always be cheaper than DAC, even with significant improvements in the DAC process. As a result, the operational costs associated with the energy required for PCCC will be lower than those of DAC.

Cost of CO2 derived and Cap of CO2.

From the first, second, and fifth scenarios, we are able to derive a shadow price thanks to the CO2 cap constraint. These correspond to approximately 162.77€/tCO2 for the first and second scenarios and 235.65€/tCO2

Scenario	PCCC	PCCC CCGT	DAC DZ	DAC GL	Carrier DZ	Carrier GL
1	4.11	2.62	1.30	0.00	8.030	0.000
2	4.11	2.07	1.47	0.00	7.142	0.000
3	4.11	1.80	0.00	0.00	9.694	0.000
4	3.76	2.06	0.00	0.00	9.701	0.000
5	4.11	2.40	0.00	1.35	0.000	7.564

Table 3: Capacity, in kt/h, of CO2 capture technology and transport by hub and per scenario.

for the fifth scenario. This shows that given the system considered, i.e., Belgium and RREHs, putting a price of CO2 equal to 162.77€ would avoid these emissions in the atmosphere and activate the export of CO2 to Norway for storage purposes. In scenario 3, where a price of 80€/tCO2 is set, there is a net balance in the atmosphere of approximately 15Mt/year. In scenario 4, where no price is fixed, there is a net balance in the atmosphere which is equivalent to 16Mt/year.

We would like to emphasize that the CO2 cap in our model only considers the emissions from the industrial and energy sectors, which are fully modeled. It does not account for a part of the emissions resulting from the gas demand served. Of this demand, 32% is attributed to industrial needs, which are included in the statistics of the 40 Mt of CO2 emitted per year (see subsection 5.2.), while the remaining 68% is due to heating and is not covered by our cap. This heating gas demand translates to approximately 12.3 Mt of CO2 emitted per year.

Cost of CH4 derived

To estimate the cost of CH4 production, we first subtract from the optimal objective function the cost of the means of electricity production in Belgium (PV, on/off shore wind, CCGT), the cost of unserved energy (when applicable), and the cost related to export of CO2 for sequestration. All of these costs are substracted because they do not refer directly to the cost of producing synthetic methane. Then, we divide the obtained cost by the total energy content (HHV) in CH4 produced at the output of the regasification power plant in Belgium.

These methane costs, listed in Table 4, are compared to the price of 147.9€/MWh of methane (HHV) obtained by [3]. Our scenarios achieve a lower cost for gas production (except for Greenland). This demonstrates that PCCC, which uses smoke with a high concentration of CO2 combined with transport, is more cost-effective than having only access to a DAC unit, as previously mentioned.

In our system, no fossil gas is available for import to Belgium; only synthetic gas produced from CO2 capture is used. If fossil gas were still available for import, our model would seek to minimize costs and import as much cheap gas as possible while staying within our carbon budget.

Scenario	1	2	3	4	5
[€/MWh]	136.00	137.19	133.89	129.27	192.00

Table 4: Estimation of methane price by retrieving the costs of power installations in Belgium, costs of unserved energy, and costs of exporting CO2 for storage purposes.

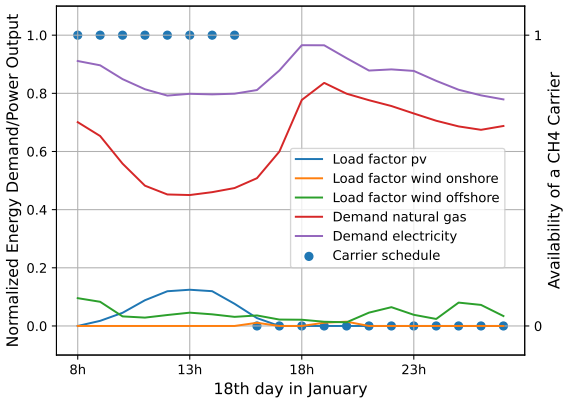

Figure 4: Evening of January 18th leading to the maximum shadow price associated with the hard constraint on energy not served in scenarios 1 and 5.

ENS cost discussion

The cost of unserved energy is a fixed parameter in scenarios 2, 3, and 4, but not in scenarios 1 and 5. Instead, a hard constraint is imposed to ensure that electricity demand is always met, resulting in a shadow price associated with the constraint. The maximum shadow price values for scenarios 1 and 5 are 913,640€/MWh and 1,075,913€/MWh, respectively. This is attributed to the peak in electricity and gas demand observed on January 18th at 18:00 (as shown in Figure 4), where renewable energy load factors were low. Thus, all energy demand had to be supplied by the Combined Cycle Gas Turbine (CCGT) and gas resources.

6. Conclusion

In this work, we present our framework of multi remote energy hubs with capture of CO2 enabled in an energy demand center and its valorization by synthesizing methane in remote renewable energy hubs. We demonstrate the feasibility of serving the energy demand at the horizon 2050 of an entire country with only renewable energy and gas power plant fueled by synthetic methane while decarbonizing the energy and industry sectors on a case study implying Belgium as energy demand center and two RREHs: Greenland and Algeria. Our reference scenario exhibits a gas price of 136.0€/MWh instead of 149.7€/MWh in [3] where only direct air capture was available in the RREH in order to feed CO2 into the methanation process. This shows the potential of Post Combustion Carbon Capture installations in the context of remote renewable energy hubs supply chains. We also derive a cost of CO2 of 163€ per ton in order to avoid any emission in the industrial and energy sector in Belgium. Finally, our model effectively captures the ”competition” between different RREHs and is able to select exactly in which investments should be prioritized. In our simulations, the investments were made only for the RREH located in Algeria. In this respect, it would be interesting to study further how the different devices structuring the RREH in Greenland should be modified to become competitive with the RREH located in Algeria. This could be done for example by modifying the wind turbines selected for the Greenland hub so that they can operate with higher nominal wind speeds and higher cut-off speeds in order to better exploit the strong winds in this area.

7. Acknowledgements

The authors would like to thank Jocelyn Mbenoun for the templates and the useful conversations about energy, as well as Bardhyl Miftari and Guillaume Derval for their useful help with shadow pricing. The authors extend also their thanks to Julien Confetti for his precious help in the elaboration of script for generating the multi-hub picture. This research is supported by the public service of the Belgium federal government (SPF Économie, P.M.E., Classes moyennes et Energie) within the framework of the DRIVER project. Victor Dachet was supported by the Walloon region (Service Public de Wallonie Recherche, Belgium) under grant n°2010235 – ARIAC by digitalwallonia4.ai.

Abstract:
The success of the energy transition in the building sector depends not only on the technical feasibility but also on the economic viability of energy modernization measures. Subsidy programs for building owners and energy prices exert a strong influence on this economic viability and thus on the spread of low-emission building energy systems. Against this background, this study presents a bi-level optimization approach to determine cost-efficient subsidy strategies. At the upper stage, the government aims to reduce subsidies to reach CO_2 targets. At the lower stage, individual building models optimize their total costs by modernizing the heat conversion technology or insulating the building shell. To achieve solvability, the lower model is implemented into the upper model as a discrete set, resulting in a single-stage problem. The model determines the minimal subsidy rates that make the purchase of the technologies and measures worthwhile for the building owner, depending on a CO_2 target aimed by the government. Results show that the introduction of subsidy programs has a considerable steering effect on emission savings. The targeted promotion of low-emission heat supply technologies, such as HPs, with up to 40 % subsidy quota in combination with subsidies for insulation measures contributes significantly to their installation in existing buildings and thus to the achievement of climate protection goals, if the future expansion of renewable energies in the electricity mix is taken into account. With the current costs and emission factors of pellet, the promotion of pellet heating can further contribute to strong emission savings.

1. Introduction

The European Union is committed to decreasing greenhouse gas emissions by a minimum of 55 % by 2030 and achieving climate neutrality by 2050 [1]. These ambitious targets necessitate significant efforts across all energy consumption sectors. As the building sector is accountable for 36 % of European greenhouse emissions [2], it plays a crucial role in achieving emission reductions. The European Commission has reported that 75 % of the European building stock is energy inefficient [3], highlighting the necessity for energy retrofitting. To lower building-related emissions, the European Union intends to double the current retrofit rate, which is currently less than 1 % per year. In practice, the decision of building owners to renovate their buildings is primarily driven by economic considerations. The installation of building envelope insulation or the utilization of low-emission heating technologies entail significant capital expenditures and may not be economically viable in every case. To overcome these financial barriers and promote retrofits, various policy instruments have been developed. According to Vedung [4], there are three general types of policy instruments: regulations, economic means, and information dissemination. Regulations establish energy efficiency standards and partially limit the choice of heating technology in the building sector. Subsidy programs, on the other hand, affect the economic viability of low-emission energy systems. Information flow is critical to educating building owners about sensible renovation measures. Among these policy instruments, Ruparathna et al. [5] identify financial incentives as essential means to encourage the energy retrofitting of bRegulationsuildings. Among these, direct capital grants for retrofit works are the most common financial incentives in Europe [5].

1.1. Subsidy programs in optimization models

In recent years, numerous research papers have incorporated subsidy programs into models for designing and optimizing energy systems for individual residential buildings to quantify their effects. Asadi et al. [6] formulate a multi-objective optimization model that optimizes renovation decisions for discrete insulation measures and

the installation of solar thermal collectors. The Mixed-Integer Linear Program (MILP) minimizes investment costs, taking into account investment grants, while maximizing energy savings. Ashouri et al. [7] present a MILP for the design optimization of a building energy system. The authors model a large portfolio of heat conversion technologies, plants for renewable energy production and different thermal and electrical storage types. The target function minimizes total costs, including investment grants and feed-in tariffs, and a penalty term punishing thermal comfort violations. The works of Harb et al. [8], Renaldi et al. [9], and Schütz et al. [10] show further examples of the integration of incentives in MILPs for building energy system design optimization. All three models minimize the total costs of the building owner but differ in the portfolio of modernization strategies considered and incentive schemes. Harb et al. [8] focus on CHP systems and feed-in tariffs for CHP electricity. Renaldi et al. [9] consider hybrid systems with HP and implement remunerations for heat generated by HP. Schütz et al. [10] integrate all building-relevant German subsidies in their MILP, including investment grants for single measures, subsidies for reaching efficiency standards, as well as feed-in tariffs for PV and CHP electricity. All models demonstrate that subsidies effect the economic viability of modernization measures and thus the investment decision. While most of the models simplify the conditions of the subsidy programs and omit the constraints under which support is granted, Schütz et al. [10] integrate a significant portion of the funding measures available in Germany along with their restrictions into the model.

1.2. Optimization models for the improvement of subsidy programs

While building owners aim to minimize total costs through modernization, funding agencies aim to enhance the energy performance of buildings while minimizing the costs of subsidies. The goal of the funding agency is to allocate subsidies effectively to individual buildings, providing incentives to undertake energy-efficient retrofitting and achieve emission savings. Different research papers attempt to formulate optimization models to model the relationship between the funding agency and energy systems with the goal to improve subsidy programs from the perspective of a funding agency. Liu et al. [11] present an optimization model for multi-energy systems on an urban scale. The model is formulated as a Stackelberg competition, commonly used in game theory. In this case, the state as funding agency aims to minimize total subsidies while meeting an emission reduction target or achieving a share of renewable energy. The upper level perspective is modeled as a mixed-integer linear program (MILP) with binary variables determining the minimum size of plants required for subsidies. Subsidies include investment grants and remuneration for renewable energy production. At the lower level, a city determines how to meet its energy demand at the lowest possible total annual cost (TAC). The lower problem is modeled as a linear program (LP) with plant size and operation as continuous decision variables. Both perspectives result in a bi-level optimization problem (BiOP). In order to solve the BiOP, Liu et al. reformulate the original problem. Since the lower problem is modeled with continuous variables and linear inequalities, it is continuously differentiable, and the Karush-Kuhn-Tucker (KKT) conditions can be applied to include the lower problem in the upper problem. By reformulating the resulting non-linear terms through discretization of variables and the use of the Big-M method, Liu et al. are able to reformulate the BiOP into a single-stage MILP. Martelli et al. [12] introduce a model to determine optimal incentives and CO_2 prices to achieve emission reduction targets for a multi-energy systems on a district scale. The upper problem of the BiOP minimizes incentives for produced renewable heat and electricity while maximizing the income from CO_2 prices. The overall budget and emissions are constrained, and the costs for the lower problem must not exceed a maximum value. The lower level problem minimizes the TAC to cover the energy demand of the district. Technology choices on the lower level are implemented with binary variables resulting in a MILP. As the problem is not continuously differentiable, a problem reformulation by means of the KKT conditions is not possible, and the problem is solved with a gradient-free direct search algorithm (Particle-Generating Set-Complex Algorithm) which was developed by the authors and is not open source available. Prada et al. [13] determine the influences of investment grants in Italy by formulating a BiOP. Both levels are solved separately for different investment grants, and the solution of both problems is compared. At the upper level, the funding agency aims to minimize the primary energy demand of the building stock and its own investment, resulting in a multi-objective target function. The lower level model minimizes the primary energy demand and the TAC. By comparing variations, the originally formulated problem is not necessarily solved to optimality. Another example of solving a BiOP to determine optimized subsidy programs in energy science is the work of Zhou et al. [14] . The model minimizes subsidies for renewable electricity production on the upper level while achieving a minimum share of renewables in a electricity production system. The lower level minimizes the total cost of the portfolio and is modeled as a graphical flow problem with nodes for producers as well as consumers and with discrete technology choices resulting in a MILP. The authors solve the BiOP by a combination of a modified CPA on the lower level and a heuristic approach on the upper level.

1.3. Rationale of the work

The aforementioned approaches demonstrate the potential of subsidy programs to influence investment decisions and present various models for determining optimized subsidies. The studies utilize BiOPs to optimize investment grants and remunerations for renewable energy production. To ensure solvability, the BiOPs are ei-

ther reformulated into a single-level problem if possible or solved using heuristics at the upper level. The BiOPs presented in the studies focus on connected urban and multi-energy systems. Prada et al.'s BiOP [13] takes the single building perspective into account but is not solved to optimality. Therefore, the following aspects have been identified as research gaps based on the findings of the literature review:

- How can subsidies be optimally allocated from the perspective of a funding agency to reduce building stock emissions, while considering individual investment decisions at the level of single residential buildings?

The formulation of a BiOP based on the literature presented shows promise. However, compared to previous works on multi-energy systems, the consideration of building stocks requires the inclusion of multiple entities in the lower-level problem. It is not sufficient to assume, as in Liu et al. [11], that every technology is chosen at the lower level resulting in a linear programming problem. As a result, the main contribution of this work is to address this challenge by:

1. Formulating a BiOP to determine the minimum subsidies required for individual modernization measures to achieve an emission reduction target.
2. Integrating the perspectives of multiple building owners into the BiOP for optimized subsidy allocation.
3. Reformulating the BiOP as a single-level optimization problem and presenting an approach to solve it using deterministic optimization methods.

The paper is organized as follows: The second section describes the methodology and model formulation and illustrates the use of the German single-family-house building stock as a case study as well as the input data used. The third section analyzes the results, and the fourth section constitute the conclusion.

2. Methodology

To determine optimized subsidy schemes, a BiOP is utilized in this study. At the lower level, individual building entities aim to minimize their costs, while on the upper level, a funding agency aims to encourage energy-efficient modernizations by disbursing subsidies to achieve an emission reduction target. The method employed in this paper is designed for this two-stage approach. Subsection 2.1. outlines the model used on the lower level, while Subsection 2.2. formulates the BiOP. In Subsection 2.3., the application of the method is presented through a case study of the German residential single-family house building stock, including the necessary input data. Figure 1 gives an overview about the methodology in this paper.

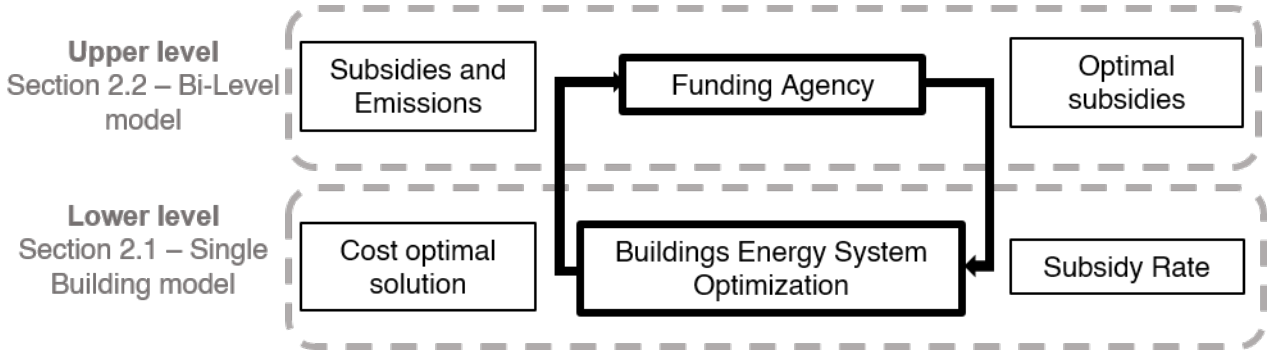

Figure 1: Overview over the Bi-Level approach with the funding agency on upper level and individual buildings on lower level

2.1. Single Building model

At the lower level, we use a mixed-integer linear programming (MILP) design optimization model developed by Schütz et al [10]. The model's detailed features can be found in Schütz et al. [10]. We present only the main features and adaptations of the model for this work. The model selects the optimal energy system in terms of total annualized costs considering available system technologies and insulation measures. The paper considers gas boilers (GAS), electrical air-source heat pumps (HP) with electrical heaters (EH) as backup heaters, and pellet boilers (PEL) as heat generators. Photovoltaic collectors (PV) and solar thermal collectors (STC) are available as solar energy harvesting options. Additionally, batteries (BAT) and thermal energy storages (TES) are included as possible energy storage options. In addition, we consider the insulation of the building's outer wall (WALL), roof (ROOF), ground floor (FLORR) and window replacement (WIN) as possible measures.

The optimization program offers two retrofit scenarios, retrofit and advanced retrofit, to reduce the building's energy demand. As the model's input were updated compared to the original version of Schütz et al., section 2.3.2. describes the updated input data. To reduce computing time and to consider extreme days, we implement a k-MILP clustering [15] algorithm to represent the annual profiles of weather data, domestic hot water (DHW), and electricity demand through eight weighted type days complemented by two extreme days. The target function minimizes the total annualized costs (TAC) for the building owner, which are calculated based on the VDI 2067 [16] standard. The cost function includes annualized investments (c^{inv}), demand costs (c^{dem}), and revenues from the sale of surplus electricity ($r^{el,sell}$) or subsidies (r^{sub}).

$$\min(c^{inv} + c^{dem} - r^{el,sell} - r^{sub}) \tag{1}$$

If the observation period exceeds the service life of a system, the residual value is calculated based on a replacement investment. The investment is comprised of acquisition costs for the system technology and renovation costs for building envelope measures. Demand costs and profits from surplus electricity fed into the grid are annualised using a dynamic factor and annuity factor. Binary variables x are utilised to map system selection, and to bound the nominal heat output Q^{nom}_{dev} of a heat generator *dev* with its minimum and maximum size.

$$\dot{Q}^{nom}_{dev} \leq \dot{Q}^{nom}_{max,dev} \cdot x_{dev} \quad \text{and} \quad \dot{Q}^{nom}_{dev} \geq \dot{Q}^{nom}_{min,dev} \cdot x_{dev} \tag{2}$$

For the PV and STC systems, the integer variable z specifies how many modules are installed on the roof. The area of all installed solar modules must not exceed the maximum roof area A^{roof}_{max}.

$$\sum_{sol \in \{STC,PV\}} z_{sol} \cdot A_{sol} \leq A^{roof}_{max} \tag{3}$$

For the building envelope components, the decision variable $x^{retrofit}$ represents whether the component is retrofitted and to which retrofit level. The retrofit levels considered are standard (strd), retrofit (retrofit) and advanced retrofit (adv). The *strd* level is associated with no costs and each component of the building envelope has to select one level.

$$\sum_{i \in \{strd,retrofit,adv\}} x^{retrofit}_{shell,i} = 1, \forall \text{ shell in Building Shell} \tag{4}$$

The heat demand is calculated according to DIN EN 12831 [17] and includes the heat required for room heating and DHW production. The DHW demand is considered by time series as a fixed input parameter, while the space heating demand is computed based on the building envelope renovation and the difference between indoor and outdoor temperatures. The resulting heat demand must be provided at each time step. Further details on the modeling of heat generators and technical devices can be found in Schütz et al [10] . This study focuses on the impact of investment subsidies for individual retrofit measures. Under the German subsidy scheme for individual measures, a percentage of the investment costs is subsidized for the installation of HP, PEL, PV, STC, BAT, or for retrofitting components of the building shell to a maximum heat transfer coefficient U^{max} (WALL: 0.2 $\frac{W}{mK}$, WIN: 0.95 $\frac{W}{mK}$, ROOF: 0.14 $\frac{W}{mK}$, FLOOR: 0.25 $\frac{W}{mK}$).

2.2. Bi-Level model

To determine optimized subsidy schemes for modernization measures, a model is described which includes the objectives and goals of the funding agency as well as the funding recipients. Between the funding agency and the funding recipient exists a dynamic behaviour and their decision making process is intertwined. Within the studies of game theory in economics, this market situation is known as the Stackelberg Competition. The game consists of a leader and a group of follower. The leader makes an action which can be observed by all followers. After that, the followers react with an action best suited for their needs. With regard to the optimization of federal subsidy funding, the state takes the position as leader who decides about subsidy shares for different renovation measurements and building owners are the followers who use the provided subsidy share to minimize their total annualized costs.

As an assumption, the funding agency aims to minimize its use of paid subsidy funds and thus its costs. At the same time, a CO_2 goal is defined for the considered building stock and the funding agency has to provide at least as much subsidy funds as needed to achieve the CO_2 goal.

The decision variables of the funding agency are the funding shares provided for a device or a building shell modernization measure and are denoted with ϕ^{inv}. The individual buildings decide for their best investment strategy with the variables c^{inv}(y) which derives from the solution of the lower problem (LowP). In addition, the variable *em*(*y*) obtained from the LowP is the amount of CO_2 emitted, which must not exceed the parameter em^{lim}.

This results in the following form of the upper problem (UppP):

$$\begin{aligned} \mathit{UppP}: \quad & \min \quad \phi^{inv} \cdot c^{inv}(y) \\ & \text{s.t.} \\ & \qquad em(y) \quad \leq \quad em^{lim} \\ & \qquad\quad y \quad \in \quad \text{argmin}(\mathit{LowP}(\phi)) \end{aligned} \tag{5}$$

In the above formulation, the decision variables of the UppP and LowP are multiplied and thus constitute a non-linearity. To avoid this non-linear terms, the linearization following the approach of Liu et al. [11] is applied. For this purpose, the variable ϕ^{inv} is mapped as a discrete interval *KX* with a step length *KM* and the binary variable δ_k and the continuous auxiliary variable CX_k are introduced. The equations describing the linearization are displayed in equations 6a - 6e.

$$\sum_{k \in KX} \delta_k \leq 1 \tag{6a}$$

$$CX_k \leq \delta_k \cdot M \quad , \forall k \in KX \tag{6b}$$

$$c^{inv} - CX_k \leq (1 - \delta_k) \cdot M \quad , \forall k \in KX \tag{6c}$$

$$CX_k \leq c^{inv} \quad , \forall k \in KX \tag{6d}$$

$$\phi^{inv}_{min} + (\phi^{inv}_{max} - \phi^{inv}_{min})/KM \sum_{k \in KX} k \cdot \delta_k = \phi^{inv} \tag{6e}$$

Using equation 6e, the auxiliary variable δ_k can be translated back to the original variable ϕ^{inv}. The UppP of the BiOP can be represented using only linear terms and can be stated as follows:

$$\begin{aligned} \mathit{UppP}: \quad & \min \quad \phi^{inv}_{min} \cdot c^{inv} + (\phi^{inv}_{max} - \phi^{inv}_{min})/KM \sum_{k \in KX} CX_k \\ & \text{s.t.} \\ & \qquad\qquad em(y) \quad \leq \quad em^{lim} \\ & \qquad \text{Equations (6a)} \quad - \quad \text{(6e)} \\ & \qquad\qquad\quad y \quad \in \quad \text{argmin}(\mathit{LowP}(\phi)) \end{aligned} \tag{7}$$

As there are still binary variables present in this model, a reformulation of the BiOP to a single-stage optimization program using the KKT condition is not possible. Instead, the solution space of the LowP is discretized and included in the UppP to formulate the optimization problem as a single-level model.
The result of a single-building optimization can be roughly divided into energetic renovation measures of the building envelope, which improve the heating load of the building, and technology for heat generation, which covers the heating load. Three levels are considered as renovation measures for the building components WALL, WIN, ROOF and FLOOR. The heating load can be covered either by GAS, HP with back up EH or PEL. Furthermore, the roof can be used for PV or STC. As a simplification, the roof area is divided into the discrete steps no usage, half usage, or full usage. Within the cases of full usage PV, a further distinction is made between the possibility to buy BAT or not. For the discretization of the solution space, all combinations between the components are calculated and stored. The single building model is then reformulated making use of the discrete combinations. A binary variable λ_i for each possible combination *i* indicates whether the combination *i* is chosen as the optimal solution. Using the TAC_i and the investment c^{inv}_i of the combination *i*, the optimization program of the single building model can thus be represented as follows.

$$\begin{aligned} \mathit{LowP}: \quad & \min \quad \sum_{i \in \mathcal{K}} \lambda_i (TAC_i - c^{inv}_i \cdot \phi^{inv}) \\ & \text{s.t.} \\ & \qquad \sum_{i \in \mathcal{K}} \lambda_i \quad = \quad 1 \\ & \qquad\quad \phi^{inv} \quad \in \quad \text{argmin}(\mathit{UppP}(\lambda_i)) \end{aligned} \tag{8}$$

We use the following approach to resolve the bi-level structure of the BiOP: If only the constraints of the LowP are included in the UppP, the optimizer selects a package of measures, thereby minimizing the funding agency's objective function. However, the selected package of measures is not necessarily the preferred solution for the single building. To reflect this, equations are added using the Big M method to ensure that the selected measures are also optimal for the single building with the current solution of the UppP. Assuming that

a combination i_1 from the set of combinations $\mathcal{K}$ can be considered as the optimal set of measures. Then the total cost minus the subsidies of combination i_1 must be less than or equal to the total cost minus the subsidies of any other possible combination i_2 in $\mathcal{K}$. Generalizing this constraint for any i_1, i_2 in $\mathcal{K}$ yields:

$$TAC_{i_1} - c_{i_1}^{inv} \cdot \phi^{inv} - (1 - \lambda_{i_1})M \quad \leq \quad TAC_{i_2} - c_{i_2}^{inv} \cdot \phi^{inv} \quad , \forall i_1, i_2 \in \mathcal{K} \tag{9}$$

From equation 9 follows that λ_{i_1} can only take the value 1 if no other combination $i_2 \in \mathcal{K}$ exists for which there is a lower cost under the current solution ϕ^{inv}. Although equation 9 ensures that the optimal package of measures is selected for the individual building, this formulation of constraints is not efficient. Since the set $\mathcal{K}$ is iterated over twice, the number of constraints is quadratic to the possible combinations in $\mathcal{K}$ leading to high computation time to generate the constraints of the optimization model. To counteract this, we use a Cutting Plane Algorithm (CPA) and systematically add only the constraints that restrict the solution space. The optimization problem is first initialized without equation 9 and a branch-and-bound algorithm (B&B) is started. If an admissible solution is found, the combination i for which λ_i takes the value 1 is determined. If another combination $j \in \mathcal{K}$ exists for which the total cost is lower than with i, the specific constraint is added, by which the current solution i is no longer admissible. The flow of the CPA is outlined in algorithm 1.

Algorithm 1 CPA for iterative restricting the solution space

        end for
    end if
end if
```

Since the funding agency wants to achieve a CO_2 target for a stock consisting of different buildings, the set $\mathcal{B}$ is defined which includes the different building types. Using the discretization of the single building optimization presented in equations 10, the CPA presented in algorithm 1 and considering a building stock defined by the set $\mathcal{B}$, the BiOP can be reformulated as a single stage MILP by the following equations 10.

$$\begin{aligned}
\min \quad & \sum_{b \in \mathcal{B}} \Big(\sum_{i \in \mathcal{K}_b} (\phi_{min}^{inv} \cdot \lambda_{i,b} \cdot c_{i,b}^{inv}) + (\phi_{max}^{inv} - \phi_{min}^{inv}) / KM \sum_{k \in KX} CX_{k,b} \Big) & & & \\
\text{s.t.} \quad & & & & \\
& \sum_{i \in \mathcal{K}_b} \lambda_{i,b} & = & 1 & , \forall b \in \mathcal{B} \\
& \sum_{b \in \mathcal{B}} \Big(\sum_{i \in \mathcal{K}_b} \lambda_{i,b} \cdot em_{i,b} \Big) & \leq & em^{lim} & \\
& \sum_{k \in KX} \delta_{k,b} & \leq & 1 & , \forall b \in \mathcal{B} \\
& CX_{k,b} - \delta_{k,b} \cdot M & \leq & 0 & , \forall k \in KX, b \in \mathcal{B} \\
& \sum_{i \in \mathcal{K}_b} \lambda_{i,b} \cdot c_{i,b}^{inv} - CX_{k,b} - (1 - \delta_{k,b}) \cdot M & \leq & 0 & , \forall k \in KX, b \in \mathcal{B} \\
& CX_{k,b} - \sum_{i \in \mathcal{K}_b} \lambda_{i,b} \cdot c_{i,b}^{inv} & \leq & 0 & , \forall k \in KX, b \in \mathcal{B} \\
& \lambda_{i,b}, \delta_{k,b} & \in & \{0,1\} & , \forall i \in \mathcal{K}_b, k \in KX, b \in \mathcal{B}
\end{aligned} \tag{10}$$

2.3. Application at case study

2.3.1. Building stock data

The focus of this study is on the residential single-family house stock in Germany. The European TABULA [18] project provides 12 archetypes that classify the German residential building stock based on the building's energetic quality, with each archetype representing a specific age class of buildings. Since buildings constructed after 2001 are assumed to already have good energy performance, they are not included in this study. To achieve comparability, all buildings are assumed to have a heated net floor area of 150 m^2 and three occupants per household. The building geometry is parameterized based on the TABULA database, using relation

factors between net floor area and buildings shell components similar to Lauster et al [19]. Potsdam is chosen as the location to represent a typical moderate German climate.

2.3.2. Inputs on building level

Different technical and economical inputs as well as time series data are necessary inputs on single building level: Typical modernization measures and heat transfer coefficients for the different archetypes originate from the TABULA typology [18]. Technical device efficiencies are obtained from manufacturer data, while the HP's behavior is modeled according to DIN V 18599 [20]. Emission factors of the energy sources originate from [21] and [22]. General economic parameters are based on the past 10-year development and are presented in Table A.2. Energy prices are scenario dependend and explained in section 1. Investment costs for building shell retrofitting are obtained from IWU [23] and include fixed and area-related costs. Installation costs for heating technologies are sourced from BDEW [24], while costs for PV and STC are from the online construction database Sirados [25]. Device investment costs are derived from market research and include fixed and power-related (for heating technologies) or area-related (for PV and STC) costs. Operation and maintenance costs are presented as percentages of component costs. Hourly time series data for outdoor temperature and solar radiation are obtained from the German Meteorological Service (DWD) [26] to account for the interaction with the outdoor climate. Load profiles for domestic hot water and electricity demands are generated using the RichardsonPy [27] tool and serve as hourly input data. These inputs are summarized in Appendix A.

2.3.3. Scenarios

Two scenarios are considered to estimate the impact of future changes in energy prices and emission factors. The transition to renewable energy sources is expected to change the electricity mix, leading to fluctuations in electricity prices and emission factors. Additionally, the pellet market is affected by demand changes and the use of wood in other sectors. Therefore, scenario A represents the current market situation in Germany, while scenario B considers prognosed energy prices and emission factors for the year 2030 [28]. For scenario A, the emission factors for 2021 are based on current data, while for scenario B, the emission factor for electricity is expected to decrease according to the German climate targets for the energy sector. A linear regression model is used to extrapolate an emission factor for electricity from the grid in 2030. The emission factor for pellets in scenario A is based on sustainable forestry practices in Germany [21]. However, Röder et al. [29] found that the production conditions highly influence the emission factor of pellets. To account for possible increased demand effects and non-sustainable forestry practices, scenario B assumes an emission factor of 100 $\frac{g_{CO_2}}{kWh}$ for pellets. Table 1 summarizes the assumptions for both scenarios.
Pehnt et al. [30] propose a system of emission classes to rate buildings based on their maximum CO_2 emissions relative to their living space. These classes range from A+++ for buildings emitting less than -10 $\frac{kg_{CO_2}}{m^2}$ to H for those emitting more than 60 $\frac{kg_{CO_2}}{m^2}$. To incentivize PV electricity feed-in, the system offers an emission credit that can result in negative emissions. In this study, we adopt Pehnt et al.'s emission classes and investigate the minimum required subsidies to attain classes A to C in average over all buildings. Therefore, the area-related climate targets are multiplied by the living space and the numbers of buildings in the considered building stock. Table 1 shows the resulting emissions targets A,B and C, which are the same for both scenarios.

Table 1: Energy prices Emissions factors in different scenarios

		Scenario A	**Scenario B**
Energy prices in $\frac{EUR}{kWh}$	Electricity	0.400	0.327
	El. HP	0.350	0.246
	Pellet	0.104	0.110
	Gas	0.120	0.125
Emission factors in $\frac{g_{CO_2}}{kWh}$	Electricity	420	164
	Pellet	36	100
	Gas	202	202
Emission targets in Mil. t_{CO_2}	A	6.9	6.9
	B	16.6	16.6
	C	27.6	27.6

3. Results

The optimized subsidy strategy yields different outcomes based on the desired climate target of the funding agency. Figure 2 (a) summarizes the optimized subsidy shares for individual measures for the emission targets A, B, and C for both scenarios A and B. In addition to the subsidy rates, an analysis of the investments indicates

the effects of the subsidy schemes. Therefore, Fig. 2 (b) shows the annualized investment costs per emission target and scenario divided into a bar for plant technology and a bar for shell measures.

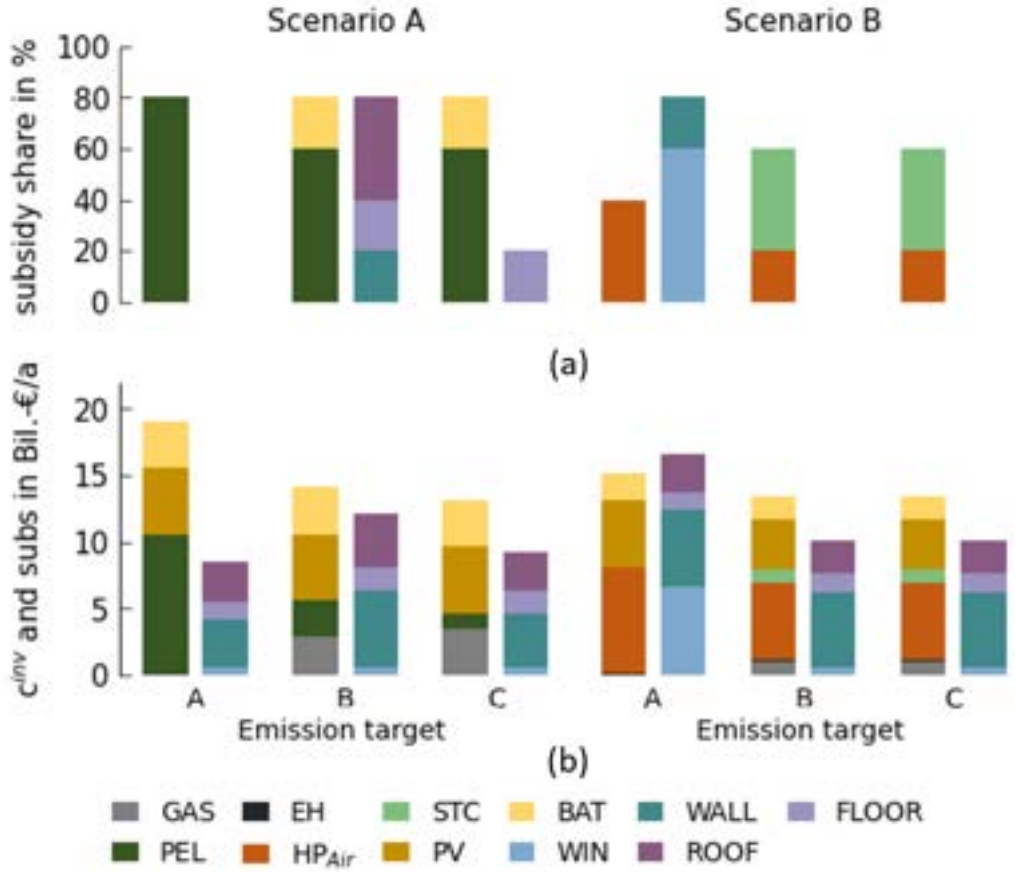

Figure 2: Investment costs for plant technology (left bar) and insulation measures (right bar) for different emission targets and scenarios

In the case of emission target A and parameters of scenario A, the unique subsidized technology is PEL with an investment grant of 80 %. Under this funding rate, all building entities install PELs as their heat conversion technology, making the investment in PELs the highest cost position for emission target A in scenario A. Pellets are nearly climate neutral and given the emission factors of scenario A, lead to a significant CO_2 reduction. Compared to the heat generation by HP, pellet heat supply is cheaper, given the price assumptions of scenario A. Moreover, due to the higher emissions factor of the current German electricity mix, the heat supply by pellet leads to lower emissions per kWh than an alternative supply by HP. Besides the investment in PEL, Fig. 2 shows high investments in PV and BAT systems. Installing PV and BAT is advantageous in all buildings due to the high electricity prices, resulting in cost savings in electricity supply by the means of PV and BAT. Therefore, no subsidies for PVs and BAT are required. The investment in PELs leads to a decrease in emissions even without any subsidies for shell modernization measures due to the low pellet emission factor. Even without incentives, measures on the roof and ground floor are chosen in old buildings as they come with comparatively low investment costs. In old buildings with poor insulation standards, the insulation of the outer wall is favorable under the high energy prices of scenario A even without subsidy. Newer buildings refrain from modernizing the building shell. However, the results of high penetration of PELs should be considered with regard to demand effects and the associated increases in the pellet price and emission factor, as shown in scenario B (see section 1). In scenario B, the optimal solution is to promote HPs with a 40 % investment grant, while also providing subsidies for window replacement (60 % share) and wall insulation measures (20 % share). The differences to scenario A can be explained by the lower electricity prices and emission factors and the increased pellet emission factor making the HP the best option in terms of CO_2 avoidance costs. Figure 2 shows high investments in HPs and PVs in this scenario. Electrification of the energy system of each building achieves the emission target for emission target A. Investments in PV's and BAT reduce costs from the building owner's point of view. To reach the ambitious emission target, investments in the insulation of the building shell are necessary as Fig. 2 demonstrates. As wall insulation is highly effective in heating demand reduction, it should be promoted to retrofit old building ages with poor insulation standards. As window replacement is

expensive in relation to energy and cost savings, its implementation must be promoted with subsidies of 60 %. The results show that the subsidies for the building shell lead to modernization in older buildings with poor insulation standards, while buildings with higher insulation standards refrain from renovation measures.

Optimization results for emission target B show similarities with regard to the subsidised technologies but differ in subsidy shares and promoted renovation measures. In scenario A, the investment in PELs should be promoted with a 60 % investment grant. Compared to emission target A, Fig. 2 demonstrates that the total investment in PELs for emission target B is only a quarter of the investment in PELs for emission target A. The PEL subsidy share of 60 % leads to PELs only being used in modern buildings, where the outer wall is not retrofitted after the optimization. These modern buildings initially have a better insulation standard than older buildings. In buildings with retrofitted outer wall, the investment in a GAS is preferred to the choice of a PEL due to the low investment costs in combination with only slightly higher demand related costs. PVs and BAT are again, like in all scenarios, chosen even without subsidies and lead to high emissions savings. Instead of stimulating the investment in low-emission heat conversion technologies on a large scale, the energetic modernization of the outer wall, the ground floor and the roof is promoted for emission target B in scenario A. The increased subsidies lead to higher investments in insulation measures, especially for the insulation of outer walls and the roof. Scenario B shows a different subsidy strategy for emission target B compared to emission target A: HPs are promoted with a 20 % investment grant and STC with a 40 % investment grant. This subsidy scheme leads to HPs being installed in all buildings except for old buildings with a low insulation standard, where they operate with lower efficiency than in better insulated buildings. The reduction of the investment in HPs amounts to 25 %. In older buildings with low insulation standards, GAS are installed. STC supports the heat supply in buildings with GAS, where they can achieve relevant emission savings.

For emission target C in scenario A, the results show an optimized subsidy share of 60 % for PEL and 20 % for FLOOR. In this scenario, the PEL only supplies older buildings with poor insulation standard, that do not modernize the outer wall. The investments in PELs, therefore, decrease by more than half compared to the results for emission target B. The lower share of PELs is replaced by GAS, resulting in lower investment costs but higher emissions. The investments in PVs and BAT are the same as for emission target B. A subsidy share of 20 % for floor measures ensures that all buildings undertake a floor modernization. The subsidy strategy and investments for emission target C in scenario B are exactly the same as for emission target B. No feasible solution seems to lie between emission target C and B.

Examining the amount of subsidies disbursed and the consequent emission avoidance cost can provide insights into the efficient utilization of subsidy funds. Figure 3 illustrates the total annualized subsidies and the CO_2 avoidance costs for emission targets A, B, and C under both scenarios A and B. It is apparent that the

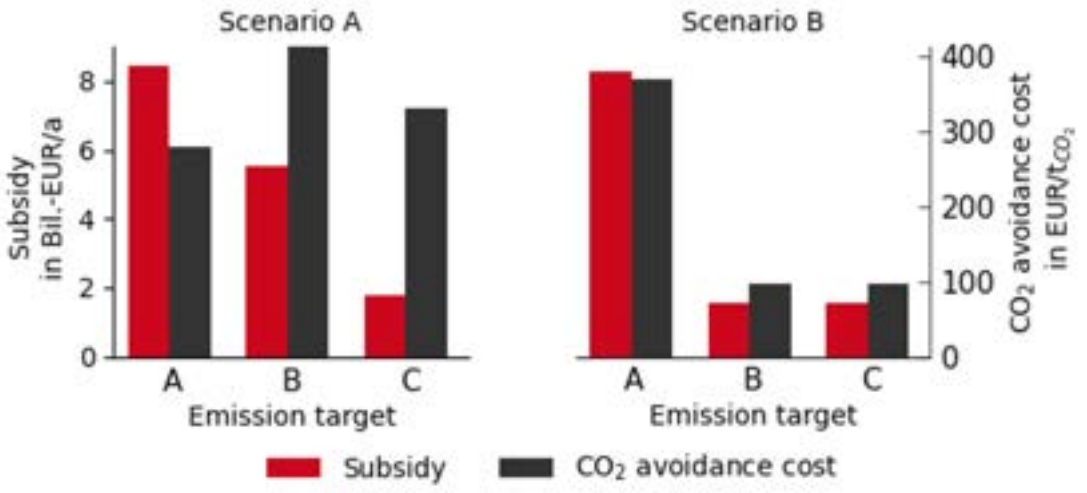

Figure 3: Total amount of annualized subsidies and emissions for different emission targets and scenarios

required subsidies increase significantly with more ambitious climate objectives. In scenario A, complete decarbonization of the building stock is achieved for emission target A, even if the climate target permits higher emissions. The low emission factor of pellets in combination with an emission credit for electricity fed into the grid, results in a balance of approximately zero emissions for the building stock. Compared to emission targets B and C, the CO_2 avoidance cost for target A are comparatively low due to the high emission savings. For emission target B, the building stock's emissions rise to 16.3 million tons of CO_2 per year, while subsidies

decrease by 30 %. When aiming for emission target C, the emissions increase by one-third compared to class B, while the costs decrease by two-thirds, leading to lower CO_2 avoidance costs. Lower climate targets are found to be more cost-effective in terms of emission savings. In scenario B, the emission targets B and C are achieved with significantly lower CO_2 avoidance costs than in scenario A. The use of heat pumps in combination with lower emission factors of electricity leads to cost-efficient emission reductions. In the region between the emission targets C and B, only one optimal solution prevails over all others and leads to the same subsidy strategy. The inference that ambitious objectives necessitate significant subsidies can also be drawn from the results of scenario B.

4. Conclusion

This study introduces a BiOP for the optimal allocation of subsidies to achieve emission targets in a building stock. The method is applied to the residential single-family house building stock of Germany. Results show that an optimized strategy depends on aimed emission targets, energy prices, and emission factors of energy sources. If sustainable forestry can supply pellets with low emission factors, the best strategy is to promote PELs with high subsidy shares of up to 80 %. In combination with PV systems PELs can contribute to the decarbonization of the building stock. As the investment in PELs and the associated investment grant is comparatively expensive, the optimized subsidy strategy for less ambitious climate targets provides lower subsidy shares for PEL and additional subsidies for insulation measures for outer wall and floor insulation amounting to 20 %. If the electricity mix improves as aimed by the government and predicted by recent forecasts, the subsidy of HPs will be optimal in terms of minimized subsidy cost for emission reduction. High emission reductions must be promoted with a subsidy share of 40 % for HPs and accompanied by the promotion of window replacement with 60 % and outer wall insulation with 20 %. For lower emission targets, the promotion of insulation measures is not necessary. A subsidy rate of 20 % for HPs and 40 % for STCs which are combined with GAS achieves significant emission savings. With the progressive expansion of renewable energies in the electricity mix, funding agencies are advised to promote the electrification of heat supply through HP. These incentives should be accompanied by incentives for building insulation in poorly insulated old buildings.

The method presented allows a detailed technical examination of the investment decision of different building entities and proposes an approach for reformulating a bi-level problem with a lower-level MILP. The consideration of MILP at both levels of the bi-level problem and the application to a stock of individual buildings, each with its own decisions, is a novelty in the literature. The optimization program presented supports the decision-making process for subsidizing various energy-related measures and can facilitate the decision-making process of a funding strategy. When reformulating the problem into a one-stage problem, the solution space had to be discretized. This discretization could lead to inaccuracies in the problem solution. In addition, a very simple approach to mapping the building stock is used in this work. For the demonstration of the methodology, this seems justified. Future work should attempt to achieve a more accurate spatially resolved mapping and map the current state of modernization in buildings. A temporal resolution of the refurbishment process as well as the inclusion of limited resources such as investment budgets or craftsmen's capacities can be achieved by the method. Demand effects, which could lead to rising energy prices, can only be taken into account by the method through parameter variations.

Abstract:

The world crusade to close the electrification gap is coming to an end in most regions of the world. In recent years the research in the area has concentrated on the development of planning methods to minimise the cost of implementation. Although successful, the lack of focus on the complex dynamics that govern electricity demand lead to over/under-sizing of technical solutions resulting in waste of resources and missed developing opportunities. In this sense, this paper aims to propose an electricity demand model for rural communities in Bolivia, based on an open-source bottom-up stochastic tool for load profile computation. The "energy sufficiency" concept is used to ensure that people's basic needs for energy are met in all the analysed cases. Information from various sources, such as on-site surveys, databases and national reports were used to characterise the main geographical areas in Bolivia and the relative specific categories of users. Specific load curves generated with the model were used as inputs in a micro-grid sizing tool and the results were compared with an approach using a demand analysis in less detail. Main results show that the model obtained is capable of generating stochastic demand curves for single or multiple rural communities according to contextual particularities. Notably, the geographic location and the socio-economic characteristics have a significant impact in the peak loads and the total demand. Considering small industries as an income generating activity can increase in the peak load by about 45%, consequently, there is an economic impact when investing in the solution.

Keywords:

Rural electrification, developing countries, energy sufficiency, energy demand

1. Introduction

The global effort to close the electrification gap has made significant progress in recent years moved by the Sustainable Development Goal 7 [1]. However, much of the research in this area has focused on minimizing the cost of implementation, often at the expense of considering the complex dynamics that govern electricity demand in rural communities [2]. This narrow focus has led to the implementation of technical solutions that are either oversized or undersized, leading to resource wastage and missed opportunities for development. [3, 4]. Therefore, it is crucial to develop planning methods that consider the specific contextual factors influencing electricity demand in rural communities [5]. This approach ensures that technical solutions are adequately sized and effectively meet the basic energy needs of the population [6]. In order to achieve this, the selection of the optimal electricity supply strategy and the capacity of the local generation and storage system heavily rely on the anticipated electricity usage. This demand is determined by both the shape and height of the hourly load curve, as well as the overall energy consumption, as evidenced in [7].

According to the literature, there is a wide range of energy modelling tools with different scopes and capabilities to support energy planning at different scales. However, it is clear that there are still challenges related to the demand side, that need to be addressed [8]. Energy System models have demonstrated limited representativity of societal transformations such as behaviour of actors, transformation dynamics on time and heterogeneity across and within societies, that could potentially have impacts in the demand side [9, 10]. Regarding to demand estimation tools, [11] concludes that deterministic models for energy demand estimation are simpler to comprehend and use, but the results they generate are inflexible and have limited information. Conversely, stochastic methods require more resources and complex mathematical models but offer a more precise understanding of demand scenarios. In [12], the authors incorporated high-resolution demand estimation to an energy planning process, however, there is still room to improve the level of detail in the estimation in sectors such as productive activities.

Although there is no universally recognized definition for energy access, the literature frequently uses the term to describe a scenario in which individuals have access to modern energy sources and affordable end-use technologies [13, 14]. It is worth noting that while facilitating access to improved energy carriers is essential, it alone is inadequate for achieving broad-based poverty reduction and promoting socioeconomic development [14]. In this regard, recent studies have examined the impact of incorporating energy sufficiency scenarios in the context of electricity demand in Bolivia to estimate the amount of energy rural communities might need [15]. The current research aims to contribute to this effort by calibrating a bottom-up stochastic tool that can effectively capture the distinctive characteristics of the electricity demand in a developing country context.

2. Methodology

This section outlines the methodology employed to achieve the proposed objective. The approach encompasses four primary stages, as illustrated in Figure 1. In the first stage, an analysis was conducted on the database containing historical electricity consumption per household situated in rural areas where the rural communities already possess access to electricity. Through this analysis, significant variables that affect residential electricity consumption and typical monthly aggregate consumption ranges for each region were identified.

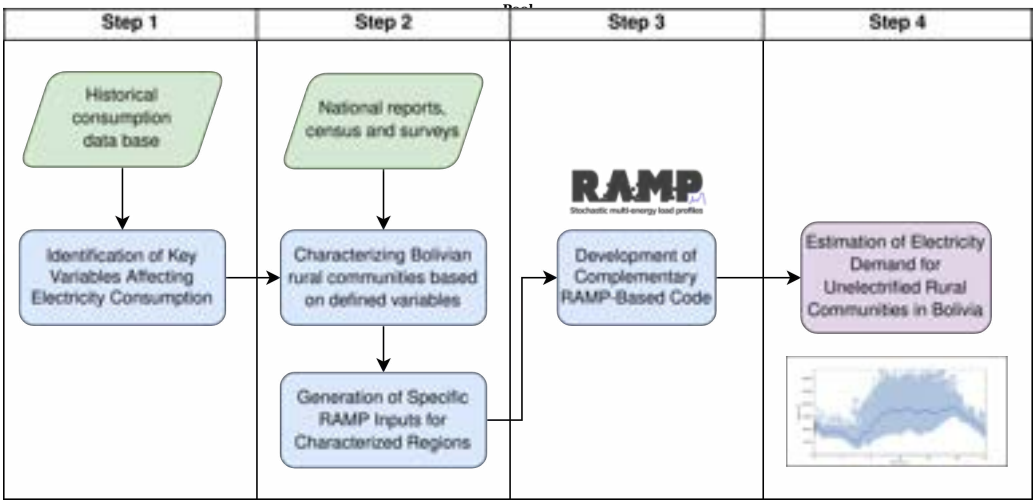

Figure 1: Flowchart of the four-step methodology

The second stage involved developing tailored inputs for the RAMP model for the region under study. This was achieved by considering the different sectors of energy consumers in the rural communities. The inputs for the RAMP model were created using the data obtained from in site surveys from previous studies, which were then cross-checked and replicated closely with the monthly aggregate consumption data acquired in the preceding stage. National reports and standards were employed to construct the RAMP inputs for the remaining sectors.

The third stage focuses on the development of a tool for village load formulation based on RAMP model, to utilize the tailored inputs created in the previous stage to generate stochastic load curves that are appropriate for specific scenarios. The model is designed to incorporate the most critical variables identified in the first stage. In the final stage of the study, the model is employed to generate load curves for rural communities in developing countries based on different established scenarios. These scenarios involve communities with different characteristics, thereby providing insights into how demand varies across diverse contexts.

2.1. A bottom-up stochastic tool for estimation of energy demand: RAMP

The RAMP tool is a stochastic model that operates from the bottom-up and is capable of generating load curves based on user behavior. It is a valuable tool for exploring the demand of remote communities and as an initial step towards sizing appropriate energy systems. The tool is built upon three layers: users, user types, and appliances. The top layer involves defining various User types (such as households, commercial activities, public offices, hospitals, etc.) based on the modeller's discretion. The level of detail for each User type can vary depending on the available information, for example, households can be divided into income classes or building types for greater precision. The second layer involves determining the number of individual Users associated with each User type, while the third layer focuses on the Appliances owned by each User. This three-layer structure enables independent modeling of the behavior of each Appliance and the creation of a unique load profile for each individual User within a given User type. Aggregating all independent User profiles generates a total load profile that is different for each model run, replicating the unpredictability of

users' behavior and producing a range of daily profiles. Further information about the model can be found [16]. In order to approach the reality of a community or region as accurately as possible, it is essential to conduct a detailed characterization of its users. This is particularly important when studying the electricity demand of communities that have yet to gain access to electricity, and it represents a significant challenge.

3. Case of study

3.1. The Bolivian Context

Bolivia, a South American nation, is yet to achieve complete electrification coverage across its entire territory. However, universal access to electricity has been set as a national target to be achieved by 2025. As of 2018, the country had registered a national electricity coverage of 93 %, with 99% of urban areas and 80% of rural areas covered [17]. According to a previous study, rural communities with fewer than 50 households were mainly low-income and might not generate enough demand to make micro-grids economically feasible. Furthermore, the dispersed nature of some of these communities complicates the installation of a local grid [18].

3.2. Main regions of geographic importance

The rural communities in Bolivia are distributed throughout the country's three geographic regions: lowlands, valleys, and highlands. The National Agricultural Compendium [19] describes the characteristics of these regions. The lowlands span over an area of 670,000 km2 and exhibit a diverse mixture of land uses, tenure systems, and actors ranging from indigenous peoples to small-scale farmers and agro-businesses. The valleys are situated between 1800 and 3000 meters above the sea level and are known for their narrow valleys, rough terrain, and moderate climate. The highlands are defined as regions situated at an altitude exceeding 3000 meters above sea level, primarily located in the western part of the country, and inhabited by numerous remote indigenous communities. Agriculture is a significant activity in all three regions, with temperature, precipitation, and altitude serving as fundamental factors in determining the productive potential and production systems. It is noteworthy that cultural disparities exist among these regions, which could potentially impact individuals' attitudes and practices towards electricity consumption.

3.3. Rural community structure

The structure of the rural communities in Bolivia has been previously defined in [15], which comprises a residential consumption sector (RS), a community services sector (CS) and an income generating activities sector (IGA).

The Electricity Authority's 2020 Statistical Yearbook [20] indicates that the residential sector represents the largest portion of national electricity demand (both in the National Interconnected System and in the Isolated Systems), accounting for 43.56% of the total. This is followed by the industrial sector at 22.2%, the general category at 18.8%, mining at 6.4%, and public lighting and other sectors at 9%. The 2016 National Demographic and Health Survey in Bolivia [21] reveals the prevalence of various electrical appliances in households across different regions of the country that are notably different. Community services aim to provide education, health services, and clean water to the population, and common infrastructure for this purpose includes hospitals, schools, drinking water supply systems, and sports facilities.

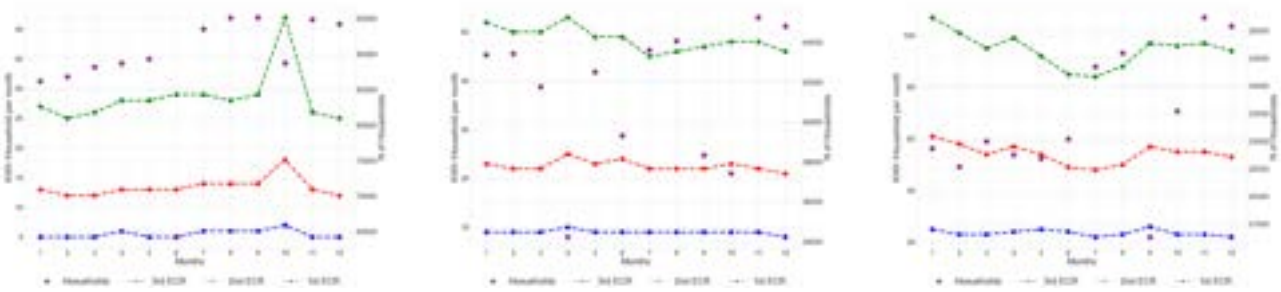
Income-generating activities (IGA) in Bolivian rural areas are primarily agricultural and livestock-based, with 78% of the employed population working in this sector [22]. However, non-agricultural activities also contribute to the income of rural households, with 22% of the population engaged in manufacturing, sales and repairs, and construction. Livestock activities are important sources for improving the income of rural households, with more than 12% of rural household income coming from livestock activity and derived products. Agricultural production has low productivity and generally faces low prices in the market, but self-consumption of agricultural products provides food security for rural households [23, 24]. Different types of irrigation are used for agricultural activities, and the transformation of agricultural products is an important form of economic diversification in rural communities. Non-agricultural IGA's vary by region, reflecting the characteristics of local idiosyncrasy. Energy needs for IGA should not be neglected, as access to electricity can impact rural economies, with the transformation processes of agricultural products representing an opportunity for growth and diversification.

4. Results and discussion

The results obtained from the characterization of rural communities and their energy consumer groups, which were incorporated into the design of the tool, are presented in this section. Subsequently, the analysis of the demand profiles generated with the model is presented.

4.1. Generation of tailored inputs for RAMP

The findings of the initial phase of the investigation reveal the impact of certain variables on electric power consumption in rural communities that are connected to the main grid. The analysis of the database was



(a) Highlands (b) Valleys (c) Lowlands

Figure 2: Quartiles of electricity consumption of electrified households in rural areas.

initially developed by filtering the data of consumers in rural areas, classified in the three defined regions. A correlation analysis was performed using variables such as percentage of poverty, geographic location, proximity to roads, among others, corresponding to the municipality to which these residential consumers belong. The results of this analysis show that the variables of impact on electricity consumption at a residential level are: the geographic location or altitude and the household income.

To characterize and generate taylored inputs for RAMP, a range of information sources were utilized, including site surveys, national reports, and databases. Site surveys conducted specifically for the purpose of generating RAMP inputs for previous studies [25–27] were used as a point of reference, conducted in rural communities such as El Espino, La Brecha, El Sena, and Raqaypampa, located in distinct geographical regions across the country. Additionally, the 2012 Census national database [28] was employed, with demographic data projected through 2025. To determine the variables with the most significant impact on energy consumption at the national level, the electricity consumption database from [29] was utilized to validate variables that influence electricity consumption.

4.1.1. Residential sector

The 2016 National Demographic and Health Survey in Bolivia [21] reveals the prevalence of various electrical appliances in households across different regions of the country. Radios, televisions, and cellphones are the most commonly used appliances in both low and high poverty municipalities, which are predominantly rural communities. Refrigerators are more commonly used in low poverty regions of the lowlands compared to the highlands, where temperatures are lower. Radios are more frequently used than TVs in high poverty regions. Access to modern appliances is limited in high poverty regions [30]. Although different types of family composition have been recorded among the communities, the average number of persons per household in rural areas of Bolivia is 3.1, according to the 2016-2017 Household Survey [31].

To gain an overview of residential electrical consumption, it was possible to perform an statistical of the monthly electricity consumption ranges that represent general behavior over the course of a year, using the mentioned data base from [29]. This was achieved by computing the median of all percentile threshold values for each month. By identifying the most representative consumption ranges in this way, as showed in figure 2, it is possible to use them to characterize the electrical consumption patterns of low, middle, and high-income households in all three regions under consideration.

Figure 2 highlights the significant regional disparities in electricity consumption. The harsh living conditions in the highlands result in the lowest consumption rates. Conversely, the valleys have much higher electricity usage than the highlands, typically consuming twice as much across all consumption ranges. However, it is in the lowlands that the most substantial impact on overall electricity consumption is present, with values almost twice as high as those of the valleys. The reason behind this effect relies on tend to use appliances to improve the comfort due to high temperatures. Moreover, the use and energy consumption of refrigerators are also influenced by these temperatures, as demonstrated in [32, 33].

The findings of the study highlight the importance of taking into account the unique characteristics of different regions when modeling electricity usage in rural communities. By doing so, it becomes possible to more accurately capture the diverse needs and behaviors of households across the country. However, it was found that the difference in consumption between households was mainly driven by one appliance, namely refrigerators. Therefore, the study focused on only two categories of residential users, high-consumption and low-consumption, based on their overall electricity usage. The RAMP appliance configuration used in the study was designed to adequately represent these behaviors, which were consistent with the results of on-site surveys. This approach can help researchers and policymakers make informed decisions about energy planning

and management in rural communities, taking into account the specific characteristics and needs of different regions.

4.1.2. Community Services Sector

To deliver community services, appropriate infrastructures are needed including hospitals, schools, drinking water supply systems, sport facilities, public lighting and churches. government-mandated norms and standards for the community sector are uniform across the country, and as a result, altitude don't have any effect on the composition and characteristics of the energy users of this sector. This means that the list of appliances and the usage patterns associated with each service will remain unchanged. The only variation across different regions considered is in the behaviours of thermal appliances, which is determined by the average temperature of the targeted area.

Therefore, the selection of various types of facilities took place using specific criteria for different services. The criteria assumed for this methodology are described in the following sections for each type of facility considered and summarized in Table 1a.

Table 1: Criteria for the allocation of a) community services infrastructure and b) IGAs in rural communities according the population size of the communities

(a)

Infrastructure	Criteria
1 Health post	if 500-1000 inhab.
1 Health center	if more than 1000 inhab.
1 Public lighting post	per every 10 HH
1 Sport field	if more than 500 inhab.
1 Church	if more than 500 inhab.
1 Water supply system	per every 100 HH
1 School A	if less than 100 inhab.
1 School B	if 100-500 inhab.
1 School C	if more than 500 inhab.

(b)

Activity	HL	VA	LL
1 Irrigation system	30HH	22HH	18HH
1 Transformation activity	200HH	200HH	200HH
1 Grocery store	25HH	25HH	30HH
1 Restaurant	30HH	30HH	30HH
1 Workshop	80HH	70HH	60HH
1 Entertainment center	100HH	80HH	60HH

4.1.2.1 Health facilities

For this infrastructure, the "National Norm for the Characterization of Primary Health Care Facilities" [34] sets guidelines and standards for its availability in rural areas, including infrastructure and equipment requirements. For communities with a population between 500 and 1000, a "health post" is mandated, while for those with between 1000 and 10,000 inhabitants, a "health centre" with the capacity for hospitalization is required. If a community has fewer than 500 residents, it must be within a two-hour driving distance from both low and high-capacity healthcare facilities. The equipment ownership data per facility type was collected from the norm as well.

4.1.2.2 Educational facilities

With regards to education, three types of schools have been identified as the most common in rural areas, based on community size. Type A schools are small multi-level establishments located in the smallest and most remote communities with a population of less than 100 people. Type B schools have a larger number of classrooms and offer a range of instruction from primary to secondary education, with double-shift operation for communities with a population between 100 and 500. Type C schools are well-equipped educational institutions that can accommodate a greater number of students, typically in larger villages near cities or major roads when the population exceeds 500 [34]. Access to educational facilities remains a significant challenge for those living in rural areas. For example, education coverage still stands at 73-83% in the lowlands, indicating that significant improvements are still possible despite recent progress [34].

4.1.2.3 Drinking water supply systems

The type and characteristics of drinking water systems are influenced by the availability of water resources and the terrain in which the community is located. However, a standard water supply system has been chosen for each type of community in this study [35], as the modeling of these systems is not the primary focus. Future research could aim on doing a more in-depth characterization of water supply systems, as they are crucial for the health and well-being of rural communities, as emphasized by the Sustainable Development Goal 6 (SDG 6).

4.1.2.4 Public lighting and other community services

The presence of streetlights in rural communities is guided by the standards set forth in a document published by the energy ministry [35], which provides guidelines for the implementation of energy access projects. Accordingly, the guideline states that a streetlight must be installed for every 10 households in a community.

In recent years, the availability of sports facilities in rural communities has increased due to government health policies, as the Supreme Decree No. 1868 of the 2014 testifies [36]. As a result, in this work is considered that communities with a certain number of inhabitants will have this kind of community services.

4.1.3. Income Generating Activities

Income generating activities are defined as responsible for income increase or productivity growth. Neglecting the energy needs of IGA increases the risk of energy marginalization in rural communities, leading to greater energy inequality and a significant underestimation of the communities' total energy needs [37]. This sector is divided into agricultural and non-agricultural activities. Non-agricultural activities include grocery stores, restaurants, workshops, and entertainment businesses , while agricultural activities encompass irrigation systems and the processing of agricultural products.

As already done for the other two sectors, it is fundamental to explore how the three drivers influence the modelling of IGAs. Naturally, agricultural activities are substantially influenced by altitude as it serves as a crucial determinant for the viable sustenance of various plant and animal species [38]. Consequently, irrigation and transformation activities are affected.

Non-agricultural IGAs are reflect the local idiosyncrasies of each region. For instance, certain areas in the lowlands, like the Beni region, have a higher concentration of recreational and food businesses [39]. Taking into account these regional variations is crucial for modelling, but it can also be a complex task due to the limited availability of this type of data. For this reason, the empirical formulas presented in Table 1b are an estimation that aims at capturing the frequency of appearance of these businesses, based on [39], [40], [41].

The level of UBN in a community determines the composition of its energy sectors. As already mentioned, based on a specified level of poverty, the selection of IGA energy users follows the rules outlined in 2. Consequently, each community IGA user will be included in the community structure only if a certain UBN threshold is met.

In the other hand, the number of IGA users is influenced by specific regional criteria, but the overall number is also considered proportional to the total population, which is calculated using an empirical formula. For example, in the highlands, there is one grocery store for every 25 households, while in the lowlands, there is one grocery store for every 30 households. The criteria assumed for this methodology are explained in the following sections for each type of IGA considered and summarized in Table 1b.

4.1.4. Irrigation systems

In rural areas, there are various types of irrigation systems, some of which require electricity while others do not. Most of the irrigation relies on flood-gravity techniques, which cover around 97% of the irrigated land. However, there has been an increasing adoption of modern irrigation methods such as sprinkler or drip irrigation, which account for the remaining portion. Based on the "Irrigation Development National Plan" [42], the majority of requested irrigation projects in rural areas are of micro or small typologies. To simplify the analysis, it is assumed that rural villages are more likely to have small or micro systems that include an electric pump and a drip irrigation system. It is also assumed that each system can cover up to ten acres of cultivated land.

The total number of irrigation systems is determined by a function of the population, taking into account the number of households and the region they belong to. This correlation is derived from a simple analysis of irrigation system databases, specifically by studying the distribution of irrigation systems across Bolivia [43]. The variation in the number of irrigation systems aims to reflect differences in climatic conditions and rainfall volume, as well as the significance of the agribusiness industry in the region. However, as the primary focus of this study is not on modelling these systems, and due to the potential complexity of such task, it is suggested that future research could explore deeper into characterizing these systems.

4.1.5. Transformation activities

Agricultural product transformation can boost economic growth, diversifying the source of income while increasing the electricity consumption due to the need of processing equipment and machinery [44]. Among governmental and non-governmental support programs, the provision of equipment is often included to support the processing. However even after access to electricity, the thriving of processing products remains challenging.

In this context, one processing activity has been selected for each region and will only be introduced once the energy sufficiency status is achieved. Extensive analysis, based on [38], was conducted to select relevant

processing activities for each region and for the national context. Therefore, Quinoa processing was selected for the highlands, cereal processing for the lowlands, and a small-scale dairy industry for the valleys.

The seasonal behaviour of quinoa and cereals must be taken into account for these processing activities, and therefore these activities are only modelled during the harvest period, which typically spans from July to October [38]. Additionally, to determine the number of processing units, it was decided to introduce one unit for every 200 households, based on [44], with the exception of the milk dairy industry, which has a fixed assumed number of one unit. The details of all users defined and characterized for each zone, the appliances associated with each of them and their use characteristics can be found in the repository `https://github.com/CIE-UMSS/RAMP_Bolivia.git`

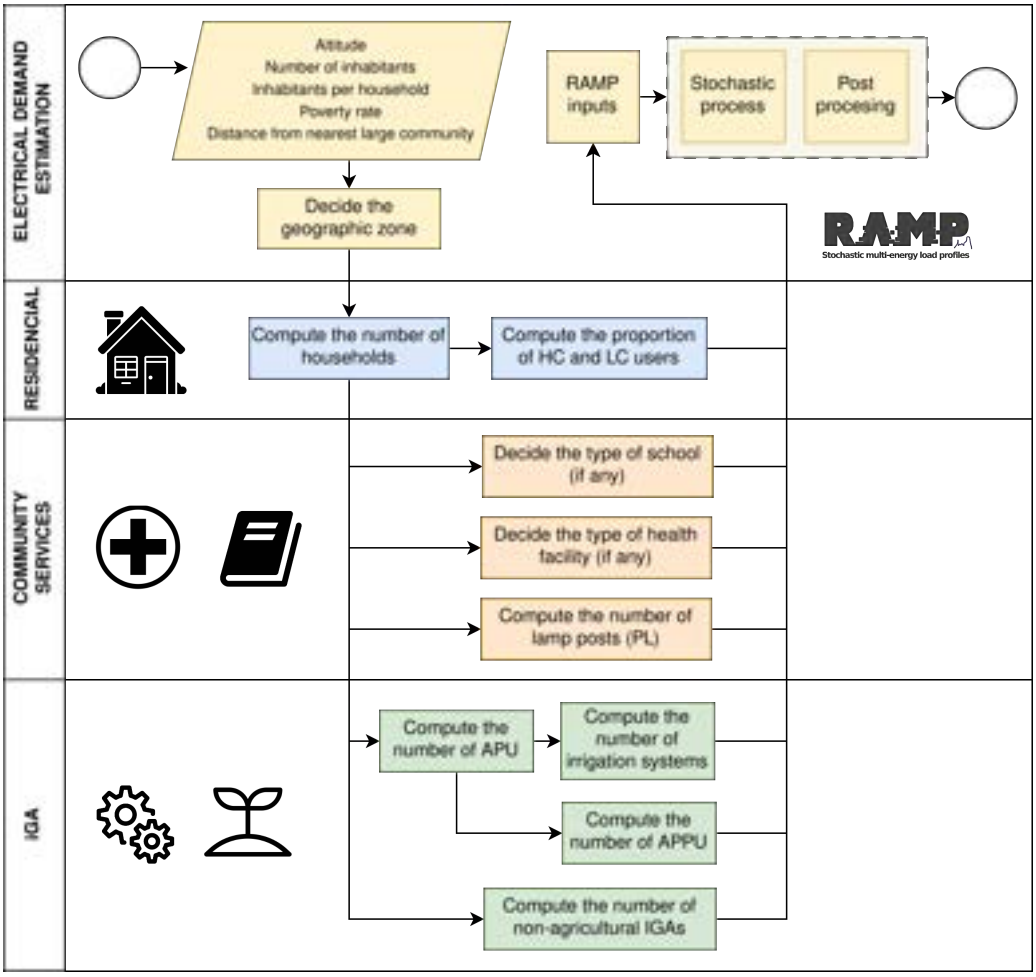


Figure 3: RAMP inputs creation per community

4.2. Estimation of Electricity Demand for Unelectrified Rural Communities in Bolivia

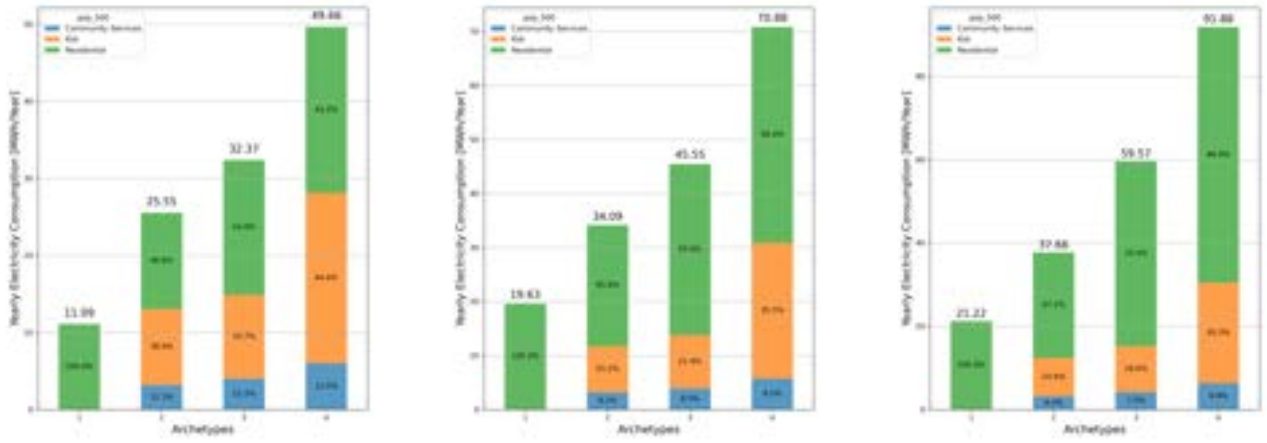
The model, which is based on RAMP, enables the generation of load curves for remote communities situated within Bolivian territory. The inputs for the model include community size, altitude (which determines the region in which the community is located), the proportion of high and low consumption (defined by the UBN), the average number of people of a family. A summary of how the complementary model works to calculate energy demand based on the mentioned data is shown in figure 3

The electricity demand for a year was simulated for four different scenarios in each region. The characteristics provided by the complementary model for these scenarios, in the form of RAMP inputs, can be seen in the Table 2, which represent four different states that theoretically improve living conditions since the percentage of poverty decreases and the availability of community services is greater. Likewise, economic diversification improves. The four archetypes where simulated for a community of 500 inhabitants in each one of the three important regions.

Figure 4 illustrates the computed annual electricity demand for each scenario. The aggregate demand and the participation of each sector within it can be observed. Notably, annual aggregate demand is higher in the lowlands and decreases at lower altitudes. This is partly due to the behavior of residential demand, described in section 4.1.1., and to the predominance of this sector's demand in overall demand. On the other hand,

Table 2: Four scenarios considered for each community size.

N°	Poverty (%)	Community Services	Agricultural IGA's	Non-agricultural IGA's
1	96	No community Services	No irrigation or transformation	No commerce
2	90	Public lighting + water supply system	No irrigation or transformation	Grocery stores + restaurants
3	70	Public lighting + water supply system + school	Irrigation	Grocery stores + restaurants
4	53	Public lighting + water supply system + school + hospital + other community services	Irrigation + transformation	Grocery stores + restaurants + workshops + entertainment business



(a) Highlands (b) Valleys (c) Lowlands

Figure 4: Simulated yearly demand for rural communities of 500 inhabitants in the highlands, valleys and lowlands of Bolivia

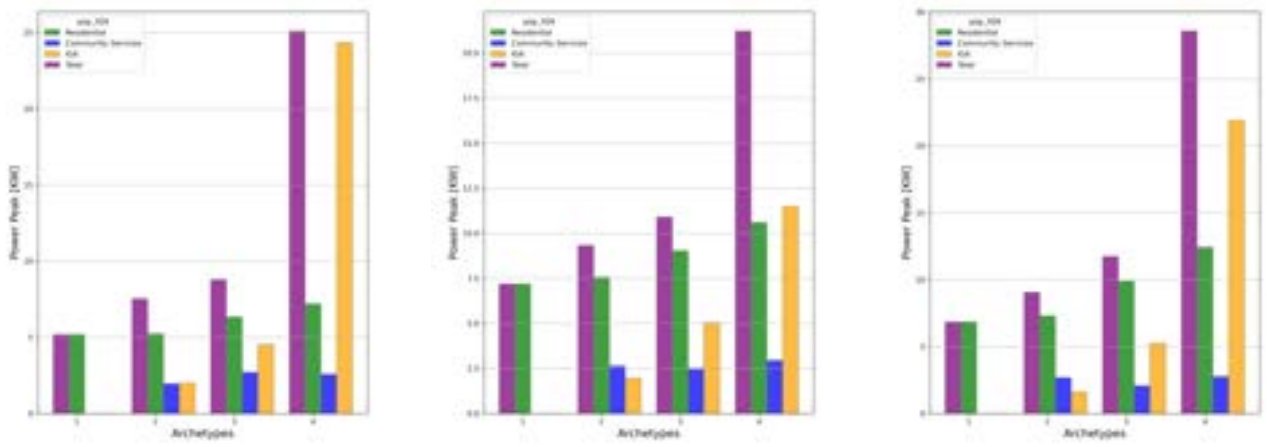
it can be observed that the share of IGAs in the aggregate consumption of the highlands reaches a higher share because the production and transformation processes of typical products of these regions tend to be more costly in terms of energy consumption. The demand corresponding to the community services sector experiences a slight increase from region to region due to the thermal appliances owned by users within this group.

Analyzing the peak loads showed in Figure 5, it can be observed that in the lowlands, the peak load reaches about 28KW as opposed to the lowlands, where it reaches around 25KW. However, the main contribution in both cases is made by the activities related to the transformation of products. Again, in the case of the IGAs in the highlands, the contribution to the peak is higher due to the complexity of the equipment required in the processes selected for the region.

Figure 6 shows an example of a load curve generated for a community in the lowlands using RAMP. It is possible to appreciate the stochasticity with which the 365 daily profiles (one year) are generated, from which an average daily load curve is computed. The peak load range is observed between 12 noon and 6 p.m. in this case.

5. Conclusion

The estimation of electricity demand in remote communities is a crucial yet challenging task for energy planning. This study aimed to calibrate a bottom-up stochastic tool to generate load curves for rural communities in Bolivia. Although previous research has recognized the need to improve demand analysis processes, they



(a) Highlands (b) Valleys (c) Lowlands

Figure 5: Simulated peak loads for rural communities of 500 inhabitants in the highlands, valleys and lowlands of Bolivia

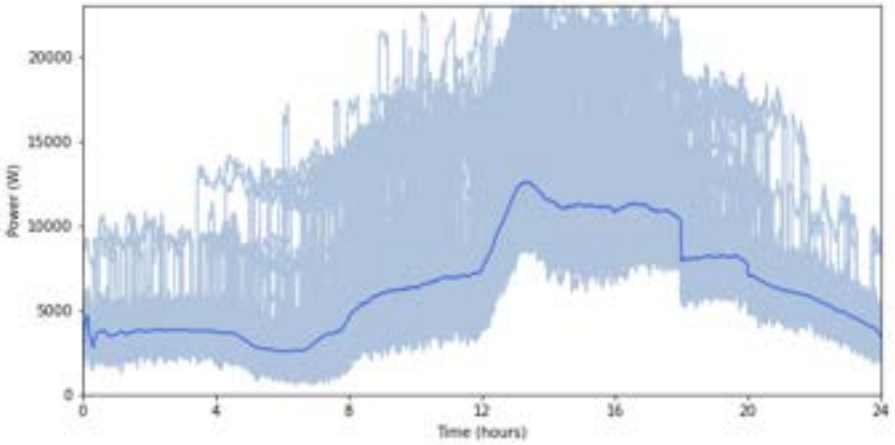


Figure 6: Average load curve computed with RAMP for a community with a population of 500 people in the LL, with scenario 4 characteristics (according Table 2)

have rarely considered energy use related to income-generating activities. Additionally, demand phenomena are strongly linked to contextual factors, requiring careful calibration and adjustment processes. However, the RAMP tool proved to be a powerful tool in capturing specific features of the zones under study to formulate adequate load curves. The biggest challenge remains obtaining accurate calibration information.

Exploring energy demand across consumer sectors and rural communities can provide useful insights for energy planning towards universal access. The proposed model enables the calculation of rural communities' demand using critical characteristics such as size, poverty rate and altitude. The study successfully simulated demand for rural communities from various regions of Bolivia, capturing the particular characteristics that highlight the main differences between the regions in terms of peak loads and aggregated demand. This study emphasized the high impact of geographical location on energy use and the electricity needs for productive uses, which depend on regional potential. Future work includes improving the model for serial computation of the demands of multiple rural communities.

Abstract:
To achieve the climate goals, the European Union needs to increase the renovation rate of buildings from 1 to 3 %. In owner-occupied buildings, financial incentives for renovation are motivated by energy cost savings. However, 30 % of all Europeans live in rented property, where conflicting stakeholder interests arise. Landlords are responsible for renovation decisions on the building envelope and the energy system as well as the corresponding investments. Tenants, for their part, face rising rents as investments are apportioned and only slightly benefit from falling utility costs. Literature calls this conflict the landlord-tenant dilemma. However, existing publications lack a precise quantification of the conflict, and little is known about the effects on technology choices and the heat transition. To address this gap, we incorporate the different perspectives of landlords and tenants in a model-based approach for optimized technology choice in form of a mixed-integer linear program. We compare optimal individual technology choices against the total cost optimum for renovations decisions. Additionally, we examine how changes in the regulatory framework affect the landlord's technology choice. Thereby, we consider the regulatory framework of Germany because of a comparatively low home ownership rate of 49 %. On this basis, we assess the technology choice of different stakeholders in terms of its impact on costs and emissions. Our study reveals that total costs and emissions are up to 29 % and 143 % higher for landlords deciding for rented houses compared to owner-occupied properties. Current approaches to solve the dilemma, such as tenant electricity and an energy-differentiated reference rent, could lead to the replacement of technical equipment and favor the development towards a climate-friendly energy system. However, the renovation of the building envelope is only partly considered in decisions of landlords, and operating costs are completely disregarded. As a result, tenants are the most burdened within the transition to a climate-neutral building stock.

Keywords:
Landlord-tenant dilemma; Renovation; Multi family houses; Optimization; MILP; Emissions; Costs.

1. Introduction

The building sector is responsible for 36 % of the greenhouse gas emissions in the European Union (EU) [1]. To achieve the set climate goals, e.g., a climate-neutral building stock by 2050, an increase of the renovation rate of buildings is required. While the European Commission is aiming for an increase in the renovation rate from an average of 1 % to 2 % [2], recent studies assume a minimum renovation rate of 3 % necessary to achieve the climate targets [3]. In addition to the renovation of the building envelope, a transformation of the building energy system is needed to defossilize the heating sector.

This transformation involves considerable costs for renovation measures, and the question of who pays for the heat transition arises. Especially in rented property, where 30 % of all Europeans live [4], conflicting stakeholder interests and the challenge of an appropriate cost distribution between the landlord (owner) and the tenant (user) arises. Landlords are responsible for the renovation decisions on the building envelope and the energy system, as well as the corresponding investment, but will not benefit from future energy cost savings. On the other side, tenants face raising rents and often only slightly decreased energy costs. This causes the so-called *landlord-tenant dilemma*, which involves two major challenges concerning the landlord's decisions:

1. Missing incentives to invest in renovation measures
2. No interest in renovation decisions that lower operating costs for tenants

Based on these issues, a third problem arises:

3. Lack of emission reductions and incentive to reach the climate targets

To achieve the climate targets, it is therefore essential to resolve these challenges. This means incentivizing investment decisions by landlords that simultaneously contribute to a favorable solution for tenants and, furthermore, do not contradict the climate goals.

In comparison with other EU countries, Germany has the largest rental share in the residential building stock of 51 % [4]. In regard to the *landlord-tenant dilemma*, Germany has introduced a retrofitting fee (RF). This fee is supposed to refinance the investments in renovation measures by allocating a proportion of the investment to the tenants. However, the RF leads to further problems, as its determination is only cost-based and the profitability depends strongly on the development of market rents [5]. In addition, the cost-based calculation results in an increase in base rents (rent without energy costs) for which tenants are not necessarily compensated with reduced energy costs [6].

As a further step, Germany has introduced the Tenant Electricity (TEL) Act in practice, which is intended to simplify the sale of self-generated electricity from landlords to tenants. In addition, literature proposes different approaches to resolve this dilemma. A promising solution is an energy differentiated (ED) local reference rent (LRR) [6–8]. According to the German Civil Code (BGB) landlords in Germany have the right to increase the rent up to the LRR, irrespective of any renovation decision. Taking into account energy related attributes of buildings within an ED LRR could lead to renovation decisions that actually reduce energy demand and green house gas emissions and therefore, simultaneously costs.

Although this approach seems promising, most publications focus on qualitative studies on the *landlord-tenant dilemma* and its solutions and lack precise quantification of it. Therefore, little is known about the associated technology choices of landlords and the consequences for tenants. This further implies, literature has not yet investigated the specific impact of the dilemma on the heat transition. To address this gap, we develop a model-based approach in from of a mixed-integer linear program (MILP) to perform a holistic investigation of the conflict and the possible solutions by TEL and an ED LRR.

The developed optimization model is based on an existing MILP, that includes renovation measures of the building envelope and the building energy system [9]. As Germany is the country with the highest share of rented property in Europe, we extend the model by the respective legal framework of Germany for this study. Additionally, we incorporate the different perspectives of the stakeholders and compare individual technology choices with the total cost optimum and emissions of an owner-occupied building. With this framework, we close the current research gap by answering the following questions:

- How does the building owner's renovation decision differ between owner-occupied and rented buildings based on current regulations?
- Do TEL or an ED LRR solve the dilemma?
- What is the impact of the *landlord-tenant dilemma* on the heat transition?

2. State of the art

2.1. Landlord-tenant dilemma in literature

The *landlord-tenant dilemma* has been studied in various research disciplines, whereby economic, legal, and social science as well as engineering approaches can be identified. Table 1 provides an overview of the different research disciplines and their consideration of relevant aspects related to the *landlord-tenant dilemma*. The evaluation reveals three relevant aspects - building calculation, rental law and other legal framework. With regard to the building calculation, the literature overview denotes whether the studies consider renovations of the building envelope and the building energy system and the studies' level of detail in the building modeling. The area of rental law focuses on whether rent payments and the RF or the LRR and therein specifically ED features are considered. Furthermore, the overview lists whether requirements from the Building Energy Act (GEG), subsidies, CO_2 price allocation, feed-in tariffs and TEL are taken into account.

Studies from economics [7, 8, 10, 11] and legal science [6, 12, 13] focus on the current rental law and neglect a precise building calculation. The analyses from social science mostly show a detailed consideration of the stakeholder's willingness to pay and some individual aspects of rental law, but strong simplifications in other aspects [14–17]. Engineering approaches represent actual refurbishment options on the building envelope and building energy systems with varying degrees of accuracy in building modeling [18–20]. However, these models widely disregard the applicable rental law. In addition, all considered publications only occasionally address aspects of other related legal frameworks (e.g., GEG or CO_2 price allocation).

This literature review demonstrates that scientific publications so far mostly focuses on individual topics instead of combining all relevant aspects related to the *landlord-tenant dilemma*. For instance, Braeuer et al. [19] examine TEL in terms of its profitability for the landlord, but neglect rental payments. Henger et al. [5, 8] and Mellwig et al. [11] extensively address the rental law and further combine it with subsidies, but disregard

a specific examination of the building and some regulations (e.g. GEG and TEL). Since these topics are interdependent we close this gap by developing a comprehensive optimization model taking into account all mentioned aspects within this study.

2.2. Solutions to the landlord-tenant dilemma

In 2017, the TEL Act came into force in Germany with the aim of creating incentives for landlords to invest in systems for the self-generation of electricity. Moreover, the reviewed literature proposes a variety of further possible ways to resolve the *landlord-tenant dilemma* (see Tab. 2). The most frequently referenced solutions in literature are an adjustment of the current RF, an ED LRR, and the so-called one-third model.

For an adjusted RF, literature suggests an RF that is no longer solely dependent on the cost, but rather on energy savings. The aim is to prevent landlords from benefiting from increasing the costs of renovations. The ED LRR aims for a similar goal. A higher LRR for climate-friendly energy systems is intended to create incentives for renovation decisions that are favorable for all stakeholders and the climate targets. The one-third model was first presented by Mellwig et al. [11]. The model states that the costs of an energy-efficient renovation should be equally allocated between landlords, tenants, and the state.

Among the suggested solutions ED LRR is the only proposed solution that already has a legal basis in the context of the rental law in Germany. Moreover, current political efforts with a law to reform the rent index law indicate that LRRs will play a central role in the future. However, in the reviewed literature, ED LRRs have not been quantitatively addressed yet. Therefore, we contribute to literature by applying the developed optimization model to address the question on whether or not an ED LRR represents a possible solution to the *landlord-tenant dilemma*. Also, very few have examined the impact of TEL on the landlord's renovation decision [19]. Therefore, we combine both solutions to show their effects and dependencies.

Table 2: Overview of presented solutions for the landlord-tenant dilemma

Approach	Source
Adjustment of the retrofitting fee (RF)	[7], [8], [10], [13], [12], [17]
Energy differentiated local reference rent (ED LRR)	[7], [8], [6]
One-third model	[11], [8], [12], [17]
Energy and climate fund model	[5], [8]
Separate surcharge on cold rent	[6], [12]
Differentiation of subsidies by landlord type	[17]
Obligation to renovate	[17]

3. Method

3.1. Optimization framework

We extend an existing MILP for design and operational optimization of residential buildings. For a complete documentation of the initial model, we refer to Schütz [21]. Figure 1 presents all aspects of the extended MILP.

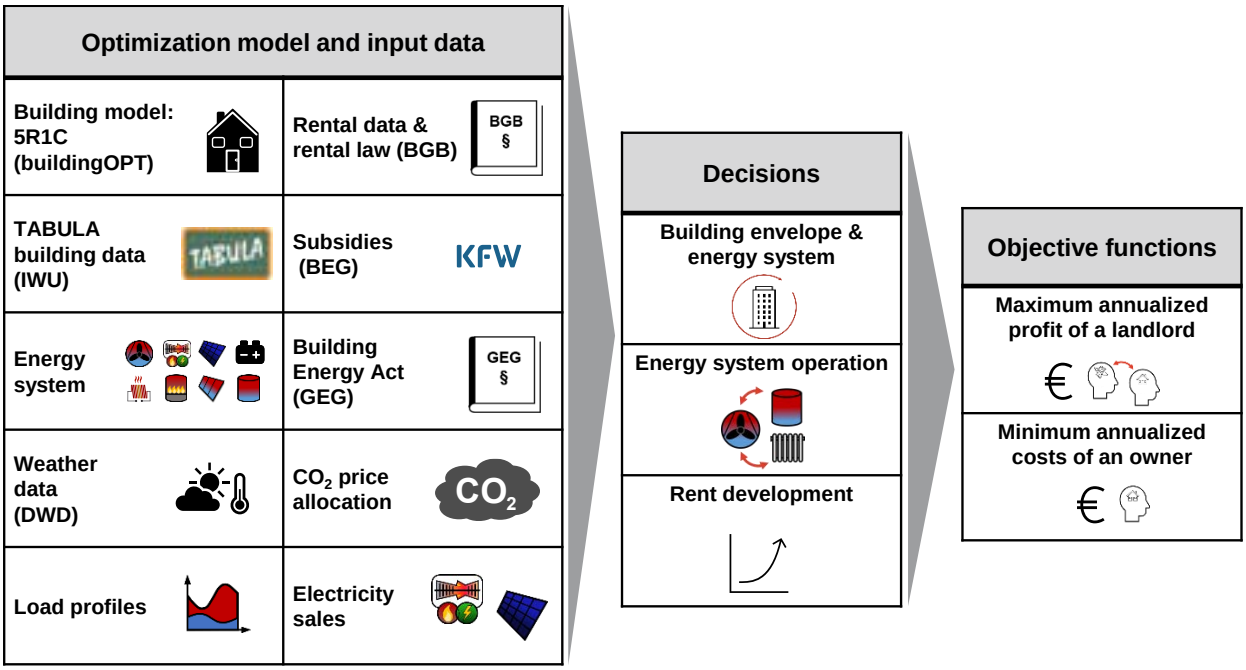

Figure 1: Overview of the optimization model and its decisions and objectives.

3.1.1. Objective functions

The objective of the model is to find a cost-optimal technology choice at the beginning of a specified time period from different perspectives. The annuity serves as economic metric [22]. Table 3 illustrates the relevant financial contributions for the respective stakeholders. Costs are marked with a minus sign (-), revenues with a plus sign (+) and no consequences with an empty field ( ). Investments, installation costs and subsidies are incurred at the beginning of the period under consideration. Maintenance costs, consumption costs, emission costs, metering costs, feed-in revenues, rental payments and TEL payments are incurred annually. A price-dynamic present value factor is determined to reflect price changes, except for rental payments. For the latter the cost for tenants for each year (y) are obtained by multiplying variable specific rental payments c_y^{rent} with the living area (A) and discounting it to the starting point by q. The annualized rental payments $c_{\text{ann}}^{\text{rent}}$ are then determined by applying the capital recovery factor (CRF) to the sum of yearly rent payments over the considered time period T (1).

$$c_{\text{ann}}^{\text{rent}} = \left(\sum_{y \in (1,\ldots,N)} \frac{c_y^{\text{rent}} \cdot 12 \cdot \text{A}}{q^y} \right) \cdot \text{CRF} \tag{1}$$

Feed-in/ self-consumption surcharges	+	+	
Subsidies	+	+	
Rent		+	-
TEL*		(+)	(-)

*only if TEL is applied

3.1.2. Decision variables

As a result of the optimization, the model decides on the cost-optimal combination of the building envelope and the energy system design and operation. Thereby, we consider various renovation measures, which can be combined in any way. For the facade, the roof and the windows four levels with increasing insulation standard can be selected independently. Regarding the energy system we consider boilers (BOI), combined heat and power engines (CHP), air source heat pumps (HP), electric heaters (EH), solar thermal collectors (STC), photovoltaics (PV), thermal energy storages (TES) and batteries (BAT). In case of optimized costs in a landlord-tenant relation, the MILP also determines how the rent can be increased according to regulations. For the rent development, the two rent increase mechanisms LRR and RF are available (see subsubsection 3.1.3.).

3.1.3. Optimization model and input data

Building and energy system

The building and energy system models are provided by the existing MILP. The thermal behavior of the building is described by a 5R1C model based on DIN EN ISO 13790 [23]. The 5R1C model summarizes the entire building into one thermal capacity and five thermal resistances. The whole building is modeled as one thermal zone with central heating. Building data for the initial building standard is taken from TABULA typologies [24]. To determine the size of the initial energy system, the standard heating load according to DIN EN 12831-1 is used with with a set indoor temperature of 20 °C.

To derive the external influences due to ambient heat and solar irradiation, local weather data from the Germany's National Meteorological Service are applied [25]. In this work, hourly resolved ambient temperatures and solar irradiances for average years are used. The method of Richardson et al. serves as a basis for the definition of electricity demand profiles [26]. Profiles for domestic hot water are retrieved by combining the presence profiles according to Richardson et al. with the domestic hot water profiles according to Beausoleil-Morrison [27]. In each case, the load profiles take into account that the peak demand grows degressively with the number of households, since a temporal distribution of the loads takes place.

Regulations and economic boundary conditions

With regard to the rental law, we implement regulations for rent increase, specifically the allowed rent increase mechanisms for the LRR according to § 558 BGB and for the RF according to § 559 BGB. The combination of both mechanisms is integrated based on a German Federal Court of Justice ruling [28]. For both mechanisms, we only consider existing tenants, as more extensive regulations apply to new tenants (e.g., rent control - see § 556d BGB). The RF allows the costs of renovation measures to be passed on to the tenant in the amount of 8 % of the investment. The LRR, which is determined every two years, is specified in rent indices and reflects the rent for comparable residential spaces. The landlord may increase the rent in accordance with the housing characteristics in particular location, size, type, features and quality.

The review of current literature reveals an ED LRR as one promising solution for the *landlord-tenant-dilemma*. To evaluate the impact, we implement an LRR with ED and without ED. The ED LRR in this work is based on the final energy demand for heating and domestic hot water as defined for the building energy pass (§§ 79-88 GEG). Other types of energy differentiation are possible and used in practice [29,30]. However, the final energy demand must be determined after renovation measures and allows for a standardized comparison of buildings. The binary variable x_{lev} indicates which LRR level (lev) has to be applied based on the achieved final energy demand $Q^{\text{fin}}_{\text{tot}}$ (4). Thereby, each energy quality level has a maximum final energy demand Q^{fin}_{lev} and only one energy level can be chosen (4). The corresponding LRR c^{lrr}_{y} is selected from the available LRRs $c^{\text{lrr}}_{y,lev}$ (3). The variable x^{switch}_{y} indicates whether the LRR is applied in the respective year if the RF was previously used. The switch is only possible once since the RF becomes part of the newly determined rent (5).

$$Q^{\text{fin}}_{\text{tot}} \leq \sum_{lev \in L} Q^{\text{fin}}_{lev} \cdot x_{lev} \tag{2}$$

$$c^{\text{lrr}}_{y} = \sum_{lev \in L} c^{\text{lrr}}_{y,lev} \cdot x_{lev} \quad \forall\, y \in (1, ..., T) \tag{3}$$

$$\sum_{lev \in L} x_{lev} \leq 1 \tag{4}$$

$$x^{\text{switch}}_{y} \leq x^{\text{switch}}_{y+1} \quad \forall\, y \in (1, ..., T-1) \tag{5}$$

For the allowed combination of the LRR and the RF, we distinguish whether a switch from the RF to the LRR has occurred using the big-M method with the binary x^{switch}_{y}. If the RF is applied, the base rent is the rent of the previous year c^{rent}_{0} (year 0 before the start of the period under consideration) or the initial LRR of the unrenovated state $c^{\text{lrr,init}}_{1,lev}$ and the RF is charged on top (6). Alternatively, the rent can be increased according to the LRR of the refurbished condition (7). The calculation of the RF c^{rf} is based on 8 % of the investment minus received subsidies.

$$c_y^{\text{rent}} \leq c^{\text{rf}} + max(c_0^{\text{rent}}, c_{1,lev}^{\text{lrr,init}}) + M \cdot x_y^{\text{switch}} \quad \forall\, y \in (1, ..., T) \tag{6}$$

$$c_y^{\text{rent}} \leq x_y^{\text{lrr}} + M \cdot (1 - x_y^{\text{switch}}) \quad \forall\, y \in (1, ..., T) \tag{7}$$

For both rent increase mechanisms, independent capping limits must be respected. The capping limit for the LRR consists of a maximum percentage rent increase within three years (§ 558 Art. 3 BGB). The capping percentage $c_{\text{limit}}^{\text{lrr}}$ depends on the local housing market (8). The capping limit of the RF consists of an absolute rent increase value per m^2 (§ 559 Art. 3a BGB). The capping limit $c_{\text{limit}}^{\text{rf}}$ is dependent on the rent before the application of the RF (9) and is constrained by (10). By (11) and (12) we take into account the independence of both capping limits.

$$c_{\text{limit}}^{\text{lrr}} = \begin{cases} 0.15 & \text{if} \quad \text{tense market} \\ 0.20 & \text{if} \quad \text{no tense market} \end{cases} \tag{8}$$

$$c_{\text{limit}}^{\text{rf}} = \begin{cases} 2\ \frac{€}{\text{m}^2} & \text{if} \quad max(c_0^{\text{rent}}, c_{1,lev}^{\text{lrr,init}}) \leq 7\ \frac{€}{\text{m}^2} \\ 3\ \frac{€}{\text{m}^2} & \text{if} \quad max(c_0^{\text{rent}}, c_{1,lev}^{\text{lrr,init}}) > 7\ \frac{€}{\text{m}^2} \end{cases} \tag{9}$$

$$c^{\text{rf}} \leq c_{\text{limit}}^{\text{rf}} \tag{10}$$

$$c_y^{\text{rent}} \leq c^{\text{rf}} + c_{\text{limit}}^{\text{lrr}} \cdot c_{y-3}^{\text{rent}} + M \cdot x_y^{\text{switch}} \quad \forall\, y \in (1, ..., T) \tag{11}$$

$$c_y^{\text{rent}} \leq c_{\text{limit}}^{\text{lrr}} \cdot c_{y-3}^{\text{rent}} + M \cdot (1 - x_y^{\text{switch}}) \quad \forall\, y \in (1, ..., T) \tag{12}$$

For the modeling of the basic structure of the subsidies, we refer to the original model [21]. In this study, some new regulations are added and existing parameters are changed according to current standards. Thereby, we take into account current subsidies for efficient buildings from BEG in form of single measures and the overall building efficiency. The BEG single measures, among other measures, subsidizes the installation of HPs, STCs, TESs and the insulation of the facade, the roof and the windows. Regarding the overall building efficiency, BEG subsidizes the achievement of certain efficiency house levels based on specified values for the annual primary energy demand and the specific transmission heat loss. Further, GEG prescribes U-values for the facade, the roof and windows that must be achieved as a minimum in the case of renovations (§ 48 GEG). Alternatively, limit values for the annual primary energy demand and the specific transmission heat loss after renovation must be met (§ 50 GEG).

Since 2023 the CO_2 costs of fossil energy solutions are split between landlord and tenant based on a distribution scheme considering the specific emissions [31]. The higher the CO_2 emissions relative to the heated living space, the higher the landlord's share of the costs.

Owners can profit from the feed-in and the self-consumption of PV and CHP power. According to the Renewable Energy Sources Act (EEG), PV feed-in is remunerated for 20 years (§ 25 Art. 1 EEG) depending on the installed capacity (§ 48 Art. 2 EEG). CHP feed-in is regulated by the CHP Act (KWKG) and remunerated for 30,000 full load hours (§ 8 Art. 1 KWKG) depending on the installed capacity (§ 7 Art. 1 KWKG). The CHP remuneration includes the average price for base-load electricity (CHP-index) [32] in addition to the federal surcharges. For the self-consumption of PV power, we consider the option of a TEL between landlord and tenant. In this case, the German Energy Act (EnWG) states that the landlord acts as the electricity supplier for the tenant with a price cap of 90 % of the respective basic supply tariff (§ 42a Art. 4 EnWG). In addition, the federal tenant electricity surcharge is granted (§ 48a EEG). The CHP self-consumption is remunerated regardless of a tenant electricity contract (§ 7 Art.2/3 KWKG).

3.2. Use case

We apply the developed model for two typical multi family houses (MFHs) according to TABULA. Table 4 presents the specifications for both buildings, which mainly differ in the construction age and thus also in their energetic quality (e.g., heat demand and building envelope). The energy system of the initial building consist of a gas BOI with low efficiency (82 %) based on data from TABULA. Since Hamburg is considered a good example in Germany for the implementation of an ED LRR as described in 3.1.2., we choose Hamburg as the location for our study [33]. Here, LRR levels are determined by dividing the final energy demand into five levels (0-4). MFH D (MFH H) is classified into level 0 for a final energy demand above 167.7 kWh/m^2 (84.3 kWh/m^2) and in the highest level 4 for final energy demands below 121.0 kWh/m^2 (48.5 kWh/m^2). This results in an LRR dependent on the energetic level between 7.06 and 9.88 €/m^2 (6.30 and 10.30 €/m^2). Table 5 provides information about energy tariffs and assumptions about revenues from feed-in electricity. General economic parameters, e.g., for energy prices developments, and prices for all considered technologies are listed in the appendix A. For improved solving times, we apply a k-medoid clustering after Domínguez-Muñoz et al. [34] and solve the problem for four representative days with a MIP gap of 0.5 %.

Table 4: Use case: MFH D and MFH H from TABULA

	MFH D	MFH H
Construction period	1949-1957	1984-1994
Living area	575 m^2	707 m^2
Apartments	9	10
Annual heat demand	210 kWh/m^2	115 kWh/m^2
Nominal heat load	61 kW	43 kW

	MFH D	MFH H
BOI	74,2 kW	52,0 kW
TES	45,6 kWh	56,1 kWh
Facade (F)	1,2 W/(m^2K)	0,6 W/(m^2K)
Roof (R)	1,6 W/(m^2K)	0,4 W/(m^2K)
Window (W)	3,0 W/(m^2K)	3,0 W/(m^2K)

Table 5: Energy prices from the end of 2022 (Scenario 1) and predictions for 2030 (Scenario 2) [35] (left). Assumptions for feed-in of CHP and PV electricity (right).

Prices		Scenario 1	Scenario 2	Unit
Gas price		0.2004	0.125	€/kWh

CHP self-consume	0.015 - 0.08*	€/kWh
PV feed-in	0.082-0.109*	€/kWh
PV self-consume	0.0167-0.0267*	€/kWh

*dependent on the installed power

4. Results

4.1. Effects of the landlord-tenant dilemma

In a first step, we analyze how the renovation decision of the building owner differs between owner-occupied and rented buildings. Therefore, we first consider the use case without any of the suggested solutions to the *landlord-tenant dilemma* (ED LRR or TEL). Figure 2 compares total annual costs and emissions of the initial state with the owner-occupied building and a landlord-tenant relation for MFH D (left) and MFH H (right). For comparability, only the costs that correspond to the owner-occupied building are shown (see Tab. 3), hence rent payments, although they are considered in the landlord's decision, are not illustrated. It becomes obvious that for both buildings the landlord's decision is worse than the decision in an owner-occupied building in terms of costs and emissions. For MFH D for example, the owner of an owner-occupied building chooses a HP in combination with an EH and a PV. Further, the decision leads to an increased insulation of the roof (R), which lowers the total energy demand by around 16.7 % compared to the initial state. In contrast, the landlord of a rented property chooses a hybrid system consisting of a BOI, a HP and an EH. Compared to the owner-occupied building this is not only more expensive when comparing total costs (+29 %) over the considered lifetime, but also causes higher emissions (+123 %). Instead of a hybrid system, the landlord of MFH H only chooses a BOI, which leads to increased costs (+22 %) and high emissions (+143 %) compared to the respective owner-occupied building.

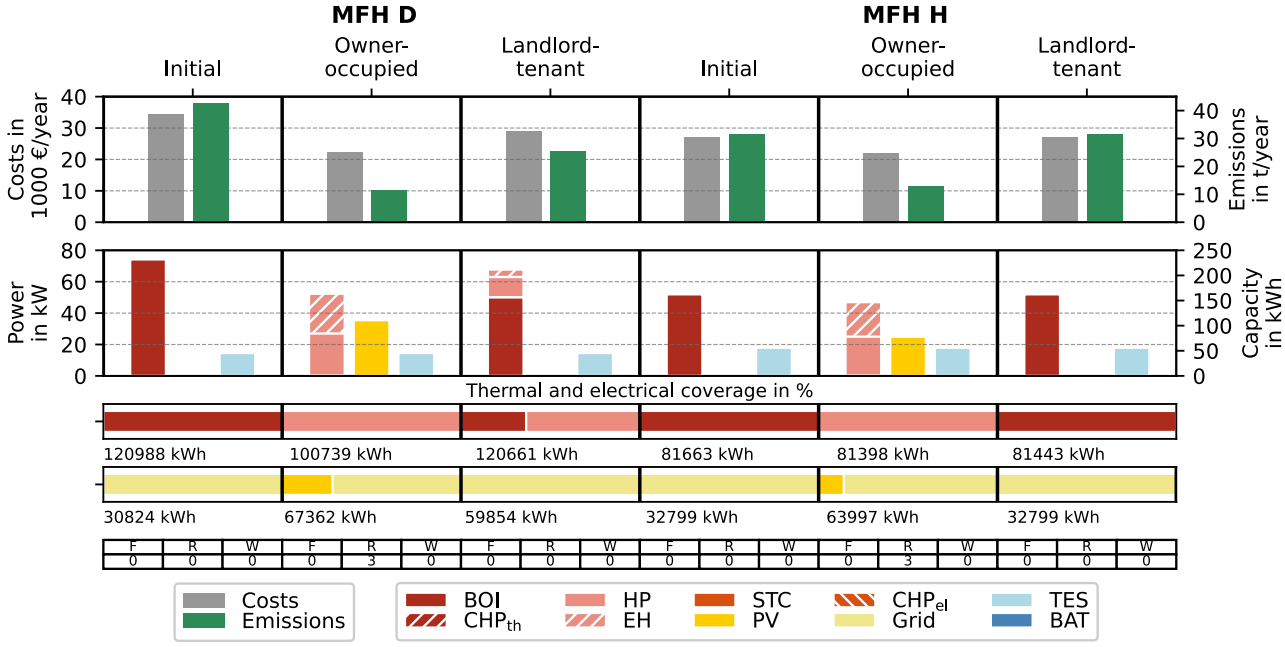

Figure 2: Renovation decisions for owner-occupied and rental buildings within price scenario 1.

Regarding the *landlord-tenant dilemma*, it can be concluded that although the landlord decides to replace the energy system, the favorable renovation of the roof is omitted for both considered use cases. This illustrates that there is no incentive for a landlord to invest in the building envelope and thus to decrease the energy demand (problem 1). Moreover, our results show that for both buildings the landlord decides on an energy system, which is not optimal in terms of total annual costs and emissions compared to the total cost optimum of an owner-occupied building (problem 2 and 3).

4.2. Solutions to the landlord-tenant dilemma

Based on the depiction of the *landlord-tenant dilemma*, we examine solutions proposed in the literature and, in some cases, already used in practice. Figure 3 shows the effect of an ED LRR without the application of TEL for two pricing scenarios for 2022 and 2030 (1 and 2). We find that in all scenarios with ED (w ED) compared to the scenarios without ED (w/o ED) an electrification of the energy system takes places by choosing an EH and/or an HP instead of a BOI or a CHP. This leads to decreased emissions, ranging from savings of only 1.6 % for MFH D to 51.9 % for MFH H in price scenario 1 (2022). Besides the different energy systems, in case of MFH H, the landlord also decides to renovate the roof to the highest energetic standard.

In terms of costs, the results show differences in revenues for the landlord and costs for the tenants compared to the respective initial status. Because of the ED, landlords can increase the rent more if a lower final energy demand is achieved. Thus, in scenarios with ED the landlord decides on renovation measures that lead to the highest level of energetic quality (level 4), enabling the highest rent increase. This results in higher revenues for the landlord, as well as higher cost for tenants, since the rent increase is not compensated for by lower energy costs, within all scenarios. Within price scenario 2 (2030), we can observe the highest increase in revenues for MFH D (+100.8 %) and in costs for MFH H (+54.3 %).

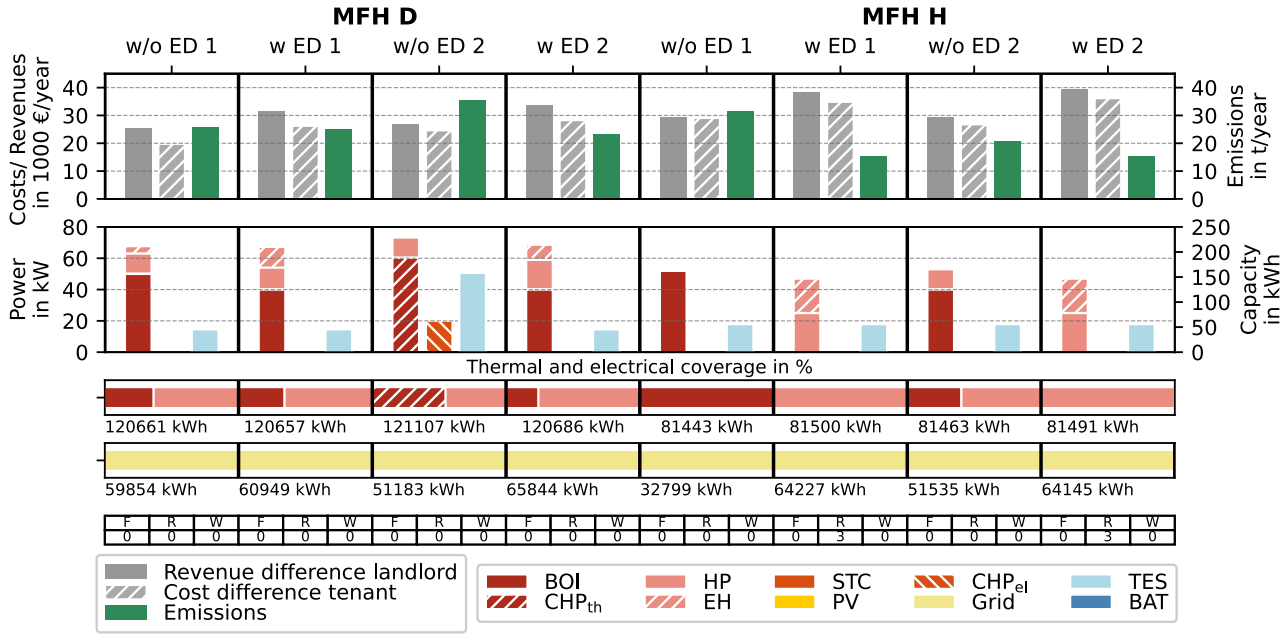

Figure 3: Renovation decisions in a landlord-tenant relation without (w/o) and with (w) ED LRR for price scenarios 1 and 2 (without TEL).

Regarding the *landlord-tenant dilemma* we see a slight reduction in the severity of the first problem of missing incentives for investments of the landlord, e.g., partly renovation of the roof of MFH H. In addition, the landlord invests in climate-friendly technologies (problem 3). However, due to high electrification combined with only minor measures on the building envelope, this could lead to an overload in the power grid during peak loads in the future. Referring to the second level of the dilemma, the tenant is burdened with significantly higher costs. Thus we can even observe an intensification of the second problem.

Finally, Fig. 4 presents the combination of ED LRR with TEL. In contrast to Fig. 3, the results reveal that TEL leads to the investment in PV in all considered scenarios. However, in the scenarios without ED (w/o ED) the owner's decision leads to mainly fossil based technologies for the remaining energy system. The energy system of MFH D, besides a small HP, mainly consists of a CHP as the landlord is able to sell the produced electricity to the tenants. In the case of MFH H, the landlord solely chooses a BOI. Although all scenarios have a PV, compared to the results without TEL that leads to higher emissions of up to 40.8 % for MFH D in price scenario 1 (2022).

Combining TEL with ED LRR, again a defossilization of the energy system takes place. Compared to Fig. 3 the emissions in the scenarios with ED are only higher for MFH D in price scenario 2 (+3.1 %). For all other

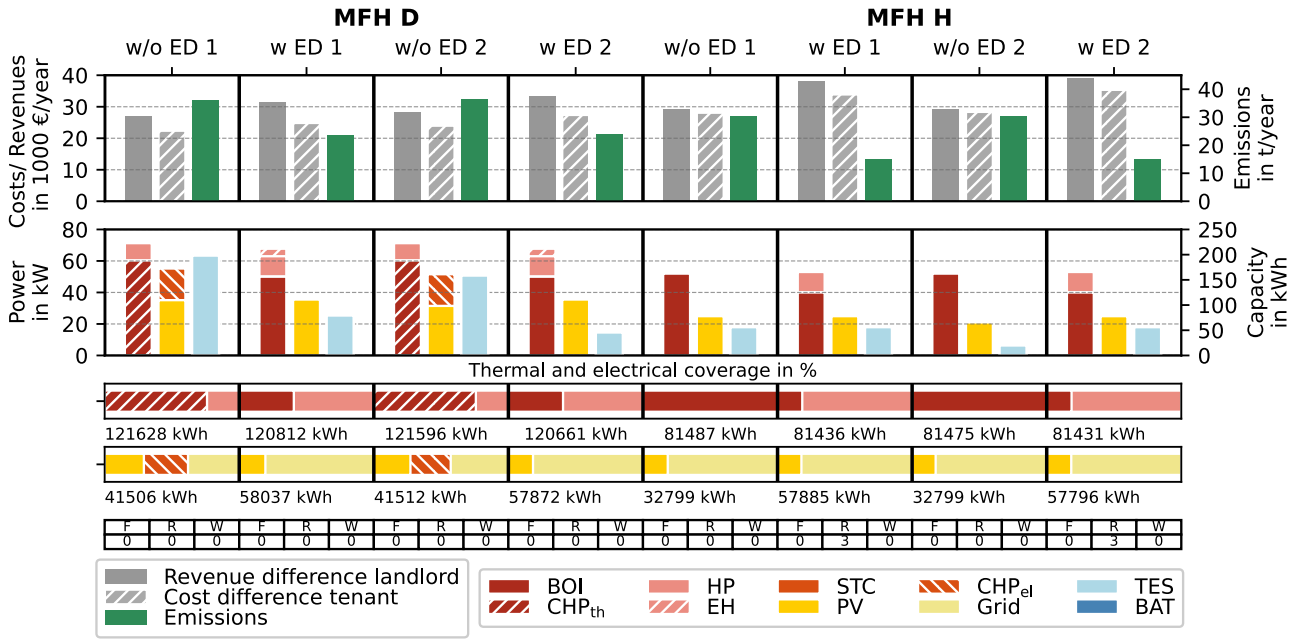

Figure 4: Renovation decisions in a landlord-tenant relation without (w/o) and with (w) ED LRR for price scenarios 1 and 2 (with TEL).

scenarios the combination of both solutions leads to favorable results in terms of emissions (up to 5.6 % for MFH D in price scenario 1) compared to the single approach of ED LRR. In terms of cost allocation, revenues for the landlord and costs for tenants are again significantly increased under the combined approach compared to the initial state. However, in comparison with the exclusive application of energy differentiated LRR, the landlord's revenues and the tenant's costs are slightly reduced (up to 0.3 % and 1.5 %).

Regarding the *landlord-tenant dilemma*, we find that TEL incentivizes the investment of landlords in PV. On the other hand, for the heating system, TEL rather favors CHP than a HP, which is consistent with the findings of Braeuer et al. [19]. In combination with the ED LRR, the decision of the landlord is again favorable for a more climate-friendly solution, adressing the first and the third problem of the dilemma. However, the second level of the conflict is only marginally improved, since the ED only considers the final energy demand, not the operating costs.

5. Discussion

In the optimization framework, we assume that the operation of the energy system is always optimal as we have a perfect foresight, allowing e.g., load shifts. That means that we likely underestimate operational costs in the MILP. This is particularly relevant for the operation of the HP in the owner-occupied building (see subsection 4.1.). Since the operation of the HP is highly dependent on the outdoor temperature and covers the entire heat demand within the considered period (see Fig. 2). This could mean that in practice the results are closer to each other and the second level of the landlord-tenant dilemma might be slightly less severe than presented. On the other hand, within the landlord-tenant relation, tenants are the ones burdened with operating costs. This means an underestimation of the operational cost, could also intensify the second level of the *landlord-tenant-dilemma*. Besides the operation of the energy system, in practice the heating behavior of the tenants might look different, too. For now, all apartments are assumed to be heated to 20 °C. Future studies should consider user behavior and related effects such as rebound and prebound effects as this could have a great impact on the results [36].

6. Conclusion

We extended a MILP for renovation decisions on the energy system and the building envelope to analyze the *landlord-tenant dilemma*. The dilemma consists of two levels. First, the landlord's missing incentives to invest in renovation measures, and second, increasing costs for tenants due to the landlord's decisions. To examine these two levels, we integrated the different perspectives and cost shares of landlords and tenants into the model and the objective function. The extension included the regulatory framework from Germany, in particular the rental law, but also, for example, the allocation of emission costs between landlords and tenants. Based on this, we implemented TEL and an ED LRR as possible solutions to the conflict. As a use case we chose two comparable typical buildings from the German city Hamburg with different construction ages.

The analysis without any of the proposed solutions confirmed both levels of the dilemma. The results showed

that for rented buildings the landlord's decisions are unfavorable in terms of total costs (29 %) and emissions (143 %) compared to an owner-occupied building. The application of TEL pushed investments in PV, but on the other hand, also led to a more fossil based heating system. In case of ED LRRs, we observed greater incentives of the landlord to invest in climate-friendly technology and, in some cases, in an advanced roof insulation. However, for both solutions, alone and combined, the *landlord-tenant dilemma* was only partially resolved for the first level. With regard to the second level, we found increasing costs for the tenants compared to the initial state for all considered scenarios. Thus, we deduce that the concept of ED LRRs needs to be extended and should not only be limited to the final energy demand.

In order to transfer these results further, additional building types and influences of different boundary conditions (e.g. location, price developments) should be investigated in the future. Furthermore, the operation of the energy system and user behavior should be modeled more precisely.

Appendix A Economical assumptions

Table A.1: General economical parameters and price developments [35]

General parameters		**Price development**	**Scenario 1**	**Scenario 2**
Observation period	20	Yearly el. price change	0.969	0.981
Interest rate	0.035	Yearly gas price change	0.960	0.992
Yearly inflation	1.02	Yearly CO_2 price change	1.08	1.02

Table A.2: Economical parameters for devices from manufacturer sheets and [37]

Device	**Power/ Capacity**	**Investment Costs**	**Installation Cost**	**OM Cost**
BOI	15 - 240 kW	2,158 - 13,516 €	5,000 €	3 %
HP	6 - 27 kW	7,800 - 18,315 €	1,530 €	2.5 %
CHP	2.5 - 293 kW	15,293 - 199,363 €	5,800 €	5 %
STC	continuous	245.22 €/m^2	6,500 €	1.5 %
PV	continuous	900 €/kWp	250 €/kWp	1 %
TES	0,116 - 7.3 m^3	756 - 6,973 €	500 €	0 %
BAT	5.5 - 66.24 kWh	7,638 - 47,785 €	2,500 €	0 %
EH	continuous	245 + 19 €/kW	2,000 €	0 %
Fasade	4 insulation levels	2.8484 €/(cm)	98.1968 €	0 %
Window	4 u-value levels	-226.8908 €/(W/m^2K)	736.18 €	0 %
Roof	4 insulation levels	4.1645 €/(cm)	105.5533 €	0 %

Abstract:

The penetration of renewable energies in island environments poses a series of challenges such as stability, demand response and guarantee of supply, among others. Throughout this work, a study methodology will be presented based on the current conditions of electricity demand in the Canary Islands and their electricity production system to mitigate the emission of greenhouse gases and improve the penetration of renewable energies in island electricity systems. Based on the initial data, a tool will be proposed that optimizes the energy production system through combustion technology (non-renewable) and combines it with the production of energy through renewables that meet expectations both in dynamic response, safety, scaling and integration with renewable energy systems, in terms of efficiency and power. Resulting in a series of cases, under different operating conditions, providing different scenarios and an expansion of up to 36.78% of the renewable installed capacity in the Canary Islands (70% in Gran Canaria) with a reduction of 65.13% of tCO_{2eq} and a reduction in fuel consumption of 71.45%.

1. Introduction

1.1. Energetic overview.

All abound in the need for decarbonization [1], [2][3], [4][5], [6][7], in the need to increase the penetration of renewable energies, in the need for a broader vision of the management of our resources with better management of our technologies. The Canary electricity systems face challenges of environmental, economic, and social sustainability, largely dependent on imported fossil fuels for electricity generation [8]–[10]; this leads to an increase in the cost of electricity and CO_2 emissions; a reduction can be made using more renewable energy sources [11]–[13]. The penetration of renewable energies is in the phase of being the great challenge to become a half reality [14]–[16]. With the passage of time, environmental awareness has increased, this has driven the mobilization of island governments (promoting wind farms, and encouraging the installation of solar panels, etc.) and the mobilization of the end user of energy, with the installation of solar panels, use of electric vehicles, etc. [17]–[19]. This reality faces another not so beneficial environmentally in the production of energy and the age of the existing power generation equipment in the Canary Islands, with more than 30 years, as well as the type of fuel, Fuel Oil, Diesel, and Diesel Oil, and ignoring Natural Gas [20] [21][22]. For this study, energy data have been available until 2020, in this last year it is observed that the primary energy consumption of 3,541,855 toe (-27.49%) and 2,504,547 toe (-31.85%) of final energy, is not representative, that is why this article will refer to the data at a general level to the year 2019, last reference year before the COVID-19 pandemic [23].

It is about finding a balance between type of combustion energy production technologies, types of fuels, renewables and demand behavior that take us to the most optimal point of energy production to meet demand. That is, to produce energy through renewable energies, to make it as much as possible by optimizing and expanding all renewable systems, and for the production of energy through combustion technologies, that this is the lowest possible, with the lowest possible GHG emission, and with the least number of tons of fuel consumed possible and trying to make the fuel used the least polluting. We establish a tool that relates all these variables to us and inspect the situation with different hypotheses.

1.2. GHG emissions overview

In relation to the emission of GHGs due to electricity generation, they are mainly due to the gases formed in combustion, so that, for these purposes, CO_2 and NO_2 emissions are considered. The emission factors provided by "Red Eléctrica de España" use the GWP (Global Warming Potential) value included in the IPCC Fifth Assessment Report (AR5) and shown in [24][25]**Table 1**.

Table 1. Emissions according to generation technologies in Spain.

Technology	CO_2 emissions *(tCO_2/MWh)*	NO_2 emissions *(tCO_2/MWh)*	*Non-peninsular territories system Greenhouse gas emissions ($tCO_{2\text{-}eq}/MWh$)*	Peninsular territories system Greenhouse gas emissions *($tCO_{2\text{-}eq}/MWh$)*
Combined cycle (diesel)	0.60	0.00	0.60	-
Combined cycle (natural gas)	0.41	0.00	0.41	0.37
Diesel (diesel, fuel oil)	0.65	0.03	0.68	-
Steam turbine (fuel oil)	0.90	0.00	0.90	0.77
Steam turbine (coal)	-	-	-	0.95
Steam turbine (nuclear)	-	-	-	0.00
Gas turbine (diesel)	1.12	0.00	1.12	-
Gas turbine (natural gas)	0.84	0.00	0.84	-
Solar-Photovoltaic	0.00	0.00	0.00	0.00
Wind	0.00	0.00	0.00	0.00

In the Spanish electricity systems of the island territories (Canary Islands and Balearic Islands) these CO_2 emission factors are basically the same as those used to determine the remuneration for costs of emission rights of generation groups and which is included in national legislation in Royal Decree 738/2015, which regulates the activity of electricity production and the procedure for dispatch in the electricity systems of the non-peninsular territories. Emissions per electricity consumption, in 2019, are 0.331 $kgCO_{2\text{-}eq}$./kWh Final Energy and 2.368 $kgCO_{2\text{-}eq}$./kWh Primary Energy for the peninsular system, and 0.776 $kgCO_{2\text{-}eq}$./kWh Final Energy and 2.994 $kgCO_{2\text{-}eq}$./kWh Primary Energy in insular systems (IDAE, 2016). In the Canary Islands, the mix of conventional technologies makes the average emission of 0.694 $tCO_{2\text{-}eq}$./MWh, by comparison for 2019, the average emission of Spain was 0.190 $tCO_{2\text{-}eq}$./MWh.

2. Energy situation in the Canary Islands in 2019.

2.1. Energy and environmental values.

The participation of the different sources and technologies in the coverage of electricity demand in terms of gross energy in the Canary Islands in 2019, by island and technology is shown in **Appendix A.** Note that the penetration of renewables is 15.9%.

In 2019 the Canary Islands had an installed capacity of 3,320.03MW, of which 623.67MW are renewable sources and 2,696.36MW are non-renewable sources. The installed power is shown in **Appendix B**.

Fuel consumption for electricity generation in the Canary Islands in 2019 was 1,702,166.0 MT (57.6% fuel oil, 41.2% diesel oil and 1.2% diesel-oil). By technologies, the steam units consumed 595,170 mt of fuel oil and 515 mt of diesel, the diesel units 384,935 mt of fuel oil and 18,826 mt of diesel and 21,259 mt of diesel-oil, the gas turbine units 12,995 mt of diesel and the combined cycle units 294,378 mt of diesel, all of which are substitute fuels as the design fuel in these units was natural gas. Fuel consumption and GHG emissions for 2019 are shown in **Appendix C** and are represented in the following graphs.

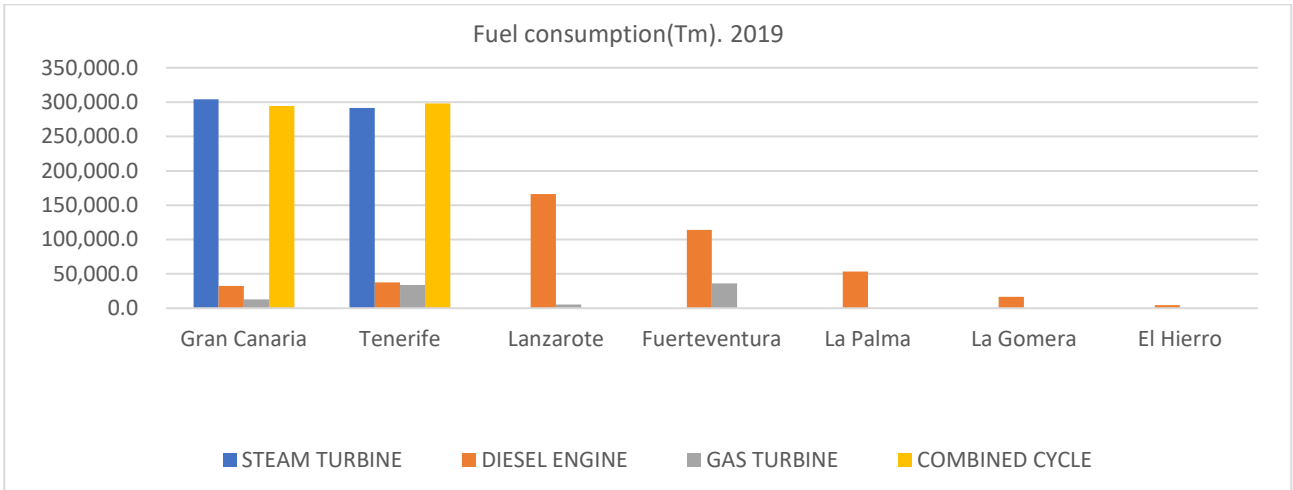

Figure1. Fuel consumption by islands and technology in the Canary Islands. Source: Canary Islands Energy Yearbook 2019.

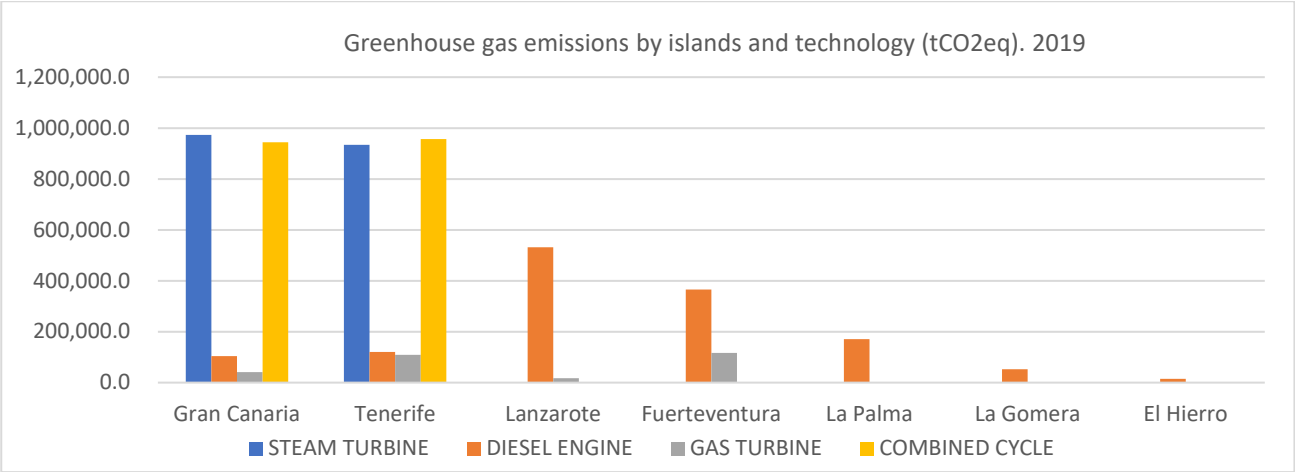

Figure2. Greenhouse gas emissions by islands and technology in the Canary Islands. Source: Canary Islands Energy Yearbook 2019.

As for emissions, for 2019 in the Canary Islands it was 5,454,911 $tCO_{2\text{-eq}}$. Of these, 99.7% was CO_2, 0.1% CH_4 and 0.2% NO_2. As for the emission factor ($tCO_{2\text{-eq}}$./MWh) calculated based on the energy produced, the results are shown in **Appendix D,** differentiated by islands and power equipment. It is worth mentioning the high emission factor of gas turbines and the fall of this factor in El Hierro due to renewable energies.

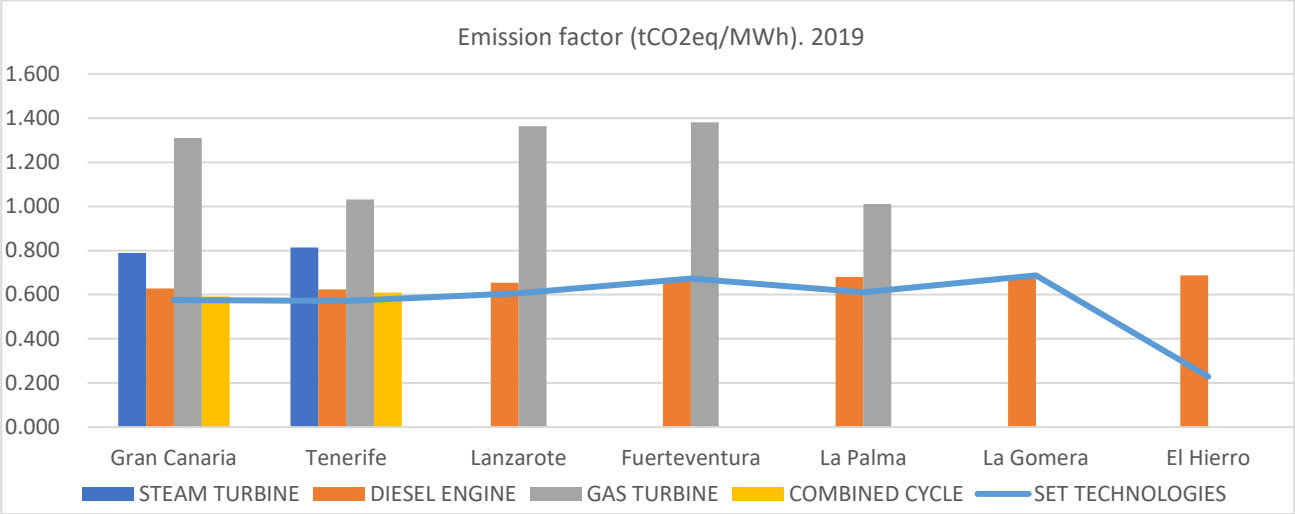

Figure3. Emission factor by islands and technology in the Canary Islands. Source: Canary Islands Energy Yearbook 2019.

The lowest emission factor is that of combined cycle power plants (0.601 $tCO_{2\text{-eq}}$./MWh) and diesel engines (0.656 $tCO_{2\text{-eq}}$./MWh). An overall emission factor for the Canary Islands, including renewable production, is estimated at 0.584 $tCO_{2\text{-eq}}$./MWh. **Table 2** shows the date and time of highest demand by islands in 2019.

Table 2. Demand peaks. Source: Canary Islands Energy Yearbook 2019.

Island	date	hour	MW
Gran Canaria	02/10/2019	20:58	537.00
Tenerife	02/10/2019	20:21	576.00
Lanzarote	31/12/2019	19:06	139.00
Fuerteventura	17/08/2019	20:53	113.00
La Palma	19/08/2019	21:36	43.00
La Gomera	17/08/2019	21:59	12.10
El Hierro	20/08/2019	21:27	8.10

Specifically, in Gran Canaria, the moment of greatest demand was on October 2, 2019 (20:58h,) with emissions of 0.631 $tCO_{2\text{-eq}}$ MWh-1 and a peak of 537.0 MW (**Figure 4**). The demand curve is very similar to the rest of the days except for small fluctuations produced by particular cases. In turn, the different groups are programmed to meet that demand curve. That is why it is necessary to carry out a good programming for a correct functioning of the network. It is also worth emphasizing the difficulty of predicting the curve correctly, and the validity of the data obtained to provide the necessary power and specifically in systems based on renewable energies (wind and solar) existing on the island.

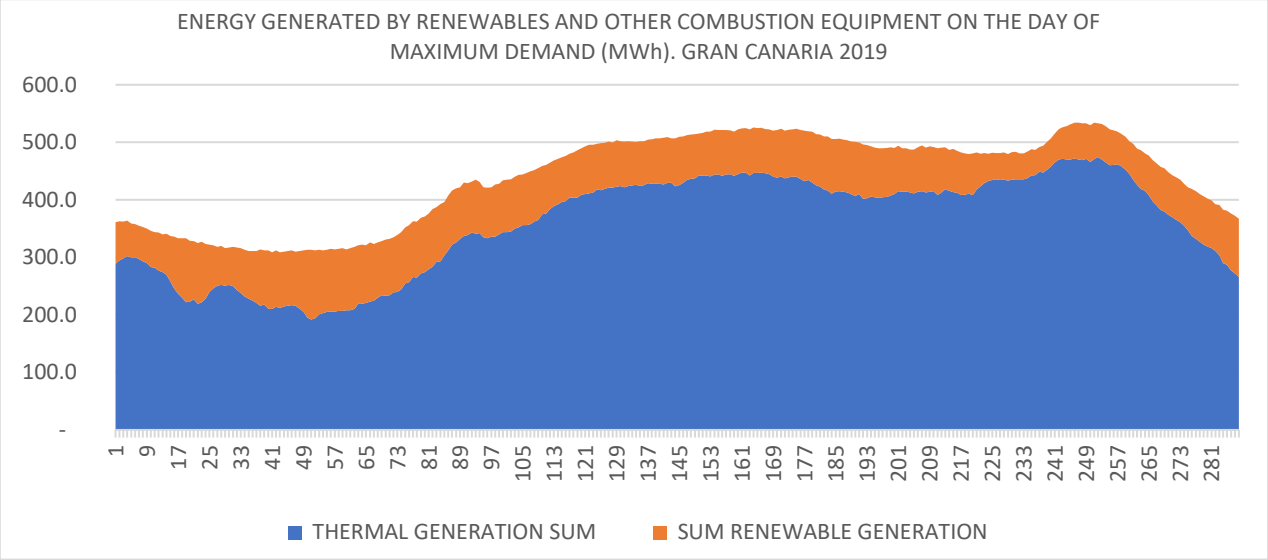

Figure 4. Demand curve Gran Canaria. Peak demand 2019. Thermal and renewable generation. Source: Canary Islands Energy Yearbook 2019.

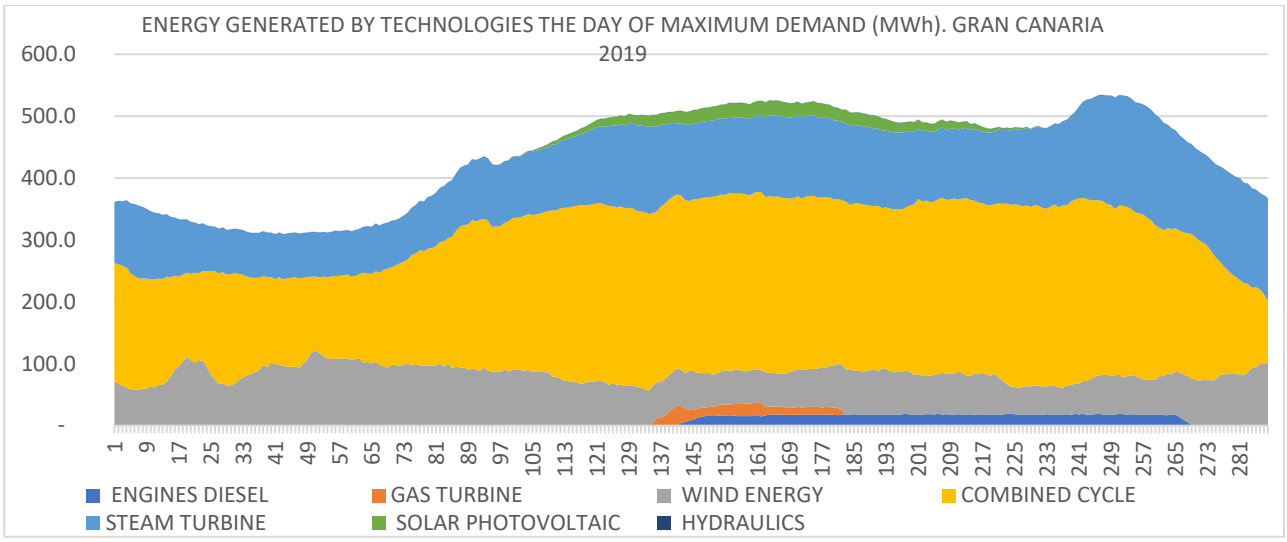

Figure 5. Demand curve Gran Canaria. Peak demand 2019. Generation differentiating technologies. Source: Canary Islands Energy Yearbook 2019.

For the peak demand day, the steam turbine and combined cycle groups contribute 33.35% and 51.28% of the electricity to the grid, leaving the Diesel and gas turbine groups for the tips and being the contribution of renewables (wind) of 11.83% (**Figure 5**).

2.2. Penetration values of renewable energies in the Canary Islands.

The data collected start from 2004, in that year, the Canary Islands had 138.22 MW installed and for Gran Canaria 75.85 MW. In this time horizon, with an average annual growth of 8%, two specific years stand out where there were very significant increases in installed capacity compared to the previous year, years 2008 and 2018, in the case of Gran Canaria, the technology that drove the development of the sector was wind generation. It is observed how the penetration of renewable energies has been slow during the years studied. As indicated above, the penetration of renewables in 2019 was 15.9%.

3. Material and methods. Non-renewable production system alternatives based on the expansion of the penetration of renewables and optimization of existing equipment.

3.1. Tool.

A tool is proposed that helps to regulate and optimize the energy production equipment and describes the different existing combinations in achieving an energy production that meets the demand, all this optimizing fuel consumption, reducing GHG emissions, increasing the penetration of renewables and reducing the CO_2

emission factor, (tCO_{2eq}/MWh). The following list has been defined that covers all the possibilities of operation of energy production equipment in the Canary Islands. With this ratio it is possible to obtain, for the different operating conditions, the power produced, GHG emissions, fuel consumption, etc.

$$E=\{[ax\alpha1+a´x(1-\alpha1)]xA+[bx\alpha2+b´x(1-\alpha2)]xB+[cx\alpha3+c´x(1-\alpha3)]xC+[dx\alpha4+d´x(1-\alpha4)]xD\}x(1+\beta)$$

where:

Table 3. Definition of parameters.

Technologies				Definition of parameters.
Steam turbine	Engines diesel	Gas turbine	Combined cycle	
a´	*b´*	*c´*	*d´*	Studied value of this technology running on 100% usual fuel
a	*b*	*c*	*d*	Studied value of this technology running on 100% natural gas
α1	*α2*	*α3*	*α4*	% use of natural gas in this technology
A	*B*	*C*	*D*	% of operation of this technology
Renewable		*β*		% contributed from this technology calculated on the total contributed by the rest of technologies not including renewables.
		R		% contributed from this technology calculated on the total contributed by all technologies, including renewables.

A variation of this expression, also interesting since it is a function of the percentage of penetration of renewables in the system (R), is:

$$E=\{[ax\alpha1+a´x(1-\alpha1)]xA+[bx\alpha2+b´x(1-\alpha2)]xB+[cx\alpha3+c´x(1-\alpha3)]xC+[dx\alpha4+d´x(1-\alpha4)]xD\}/(1-R)$$

The indicator "CO_2 *GREEN"* has also been defined. This indicator evaluates the status or situation of the objective " $tCO_{2\text{-eq}}$ *ZERO*", the cancellation to 100% of the $tCO_{2\text{-eq}}$. In short, it is the amount of $tCO_{2\text{-eq}}$ that has stopped being emitted into the atmosphere in the energy production process per person. This percentage increase in the *$tCO_{2\text{-eq}}$/inhabitant* that are no longer emitted, causes environmental damage to decrease in the same proportion, as well as damage to people's health.

3.2. Starting values 2019.

For this we start from the base that in 2019 as indicated we have in the Canary Islands the following indices:

Greenhouse gas emissions 5.454.911,00 tCO_{2eq}, Emission factor 0,584tCO_{2eq}/MWh and Fuel consumption estimation 1.702.166,00 Tn.

3.3. Procedure.

With this relationship we establish several hypotheses with the aim of reducing emissions, fuel consumption, and increasing the penetration of renewables. Applying the relationship established for the existing situation in 2019 for Gran Canaria, we obtain:

Fuel consumption =a´xA+b´xB+c´xC+d´xD = 643.814,00 Ton

Energy production ={a´xA+b´xB+c´xC+d´xD}x(1+β) = {a´xA+b´xB+c´xC+d´xD}/(1-R) = 3.581.933,00 MWh

Greenhouse gas emissions =a´xA+b´xB+c´xC+d´xD = 2.063.911,00 tCO2eq

It has been contemplated that there is no Natural Gas in 2019 in Gran Canaria and the respective data have been entered:

Table 4. Data for the situation in Gran Canaria 2019

	Steam turbine		Engines diesel		Gas turbine		Combined cycle	
	a´	*a*	*b*	*b´*	*c*	*c´*	*d*	*d´*
Fuel consumption estimation (Tn)	604.618,4	528.898,2	144.308,2	144.308,2	619.815,9	479.656,8	745.377,9	576.825,5
Energy Produced (MWh)	2.452.800	2.452.800	735.840	735.840	1.519.422	1.519.422	4.044.754	4.044.754
Greenhouse gas emissions (tCO2eq)	1.936.141	1.421.637	462.166	462.166	1.989.295	1.648.313	2.392.330	1.982.216
	α1	*A*	*α2*	*B*	*α3*	*C*	*α4*	*D*
Gran Canaria 2019	0,00%	50,24%	0,00%	22,50%	0,00%	2,09%	0,00%	39,49%

Being β= 18.29% and R= 15.46% for energy production.

3.4. Proposal of hypotheses of operation of equipment preserving the current type of fuel.

3.4.1. HYPOTHESIS 1: Reordering power plants with historical annual maximums. Penetration of renewables: 15.9%.

In this hypothesis, we proceed to work with the least polluting equipment in the different production centers of the islands, bringing them to a production ceiling marked by the maximum annual historical productions. The

historical annual maximums of combined cycle plants (3,418,748MWh) and diesel engines (2,390,736.2MWh) which are the least polluting have been studied, proportionally rearranging the rest of the equipment. Preserving the penetration of renewables (1,480,634MWh, 15.9%). This results in an overall emission factor of 0.563 $tCO_{2\text{-}eq}$/MWh.

Table 5. Hypothesis 1.

Technology	Energy Produced (*MWh*)	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (*Tn*)
Steam turbine	2.045.977,0	1.641.421,5	0,802	512.582,8
Diesel engine	2.390.736,2	1.562.556,1	0,654	488.206,3
Combined cycle	3.418.748,0	2.052.294,4	0,600	639.433,0
Renewable (15,9%)	1.480.634,0	-	-	-
Total	9.336.095,2	5.256.271,9	0,563	1.640.222,1

3.4.2. HYPOTHESIS 2: Rearrangement of power plants working exclusively with the least polluting. Penetration of renewables: 15.9%.

In this hypothesis, we proceed to continue working with the least polluting equipment in the different production centers of the islands, but we work exclusively with them, ignoring the rest of the equipment. All this entails producing 5,428,740.4MWh in the combined cycle plants and 2,426,720.8MWh diesel engines, which are the least polluting, leaving the rest of the equipment in disuse or as reserves. Preserving the penetration of renewables (1,480,634MWh, 15.9%). All this results in an overall emission factor of 0.519 $tCO_{2\text{-}eq}$/MWh.

Table 6. Hypothesis 2.

Technology	Energy Produced (*MWh*)	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (*Tn*)
Diesel engine	2.426.720,8	1.585.013,5	0,653	495.218,0
Combined cycle	5.428.740,4	3.259.874,3	0,600	1.015.678,5
Renewable (15,9%)	1.480.634,0	-	-	-
Total	9.336.095,2	4.844.887,8	0,519	1.510.896,4

3.4.3. HYPOTHESIS 3: Reorganization of power plants working exclusively with the least polluting, but incorporating the Chira-Soria project. Penetration of renewables: 29.5%-36.8%.

In this hypothesis, we proceed to continue working with the least polluting equipment in the different production centers of the islands, but we work exclusively with them, ignoring the rest of the equipment. The Chira-Soria power plant is incorporated. With this addition, a global penetration in renewables in Gran Canaria is expected between 51% and 70%.

If we estimate 51% in Gran Canaria **(HYPOTHESIS 3a),** which affects the overall figure of penetration of renewables in the Canary Islands, rising to 29.1%. All this entails producing 4,307,822.1MWh in the combined cycle plants and 2,310,552.60MWh diesel engines, which are the least polluting, leaving the rest of the equipment in disuse or as reserves. The penetration of renewables would be (2,717,720.5MWh, 29.1%). This results in an overall emission factor of 0.440 $tCO_{2\text{-}eq}$/MWh.

Table 7. Hypothesis 3a.

Technology	Energy Produced (*MWh*)	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (*Tn*)
Diesel engine	2.310.552,6	1.512.050,4	0,654	472.435,9
Combined cycle	4.307.822,1	2.596.890,5	0,603	809.112,7
Renewable (29,1%)	2.717.720,5	-	-	-
Total	9.336.095,2	4.108.940,9	0,440	1.281.548,5

If we estimate 70% in Gran Canaria **(HYPOTHESIS 3b),** which affects the overall figure of penetration of renewables in the Canary Islands, rising to 36.8%. All this entails producing 3,658,707.6 in the combined cycle plants and 2,243,280.5MWh diesel engines, which are the least polluting, leaving the rest of the equipment in disuse or as reserves. The penetration of renewables would be (3,434,107.1MWh, 36.8%). This yields an overall emission factor of 0.394 $tCO_{2\text{-}eq}$/MWh.

Table 8. Hypothesis 3b.

Technology	Energy Produced (*MWh*)	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (*Tn*)
Diesel engine	2.243.280,5	1.469.798,2	0,655	459.242,9
Combined cycle	3.658.707,6	2.212.962,0	0,605	689.492,2
Renewable (36,8%)	3.434.107,1	-	-	-
Total	9.336.095,2	3.682.760,2	0,394	1.148.735,1

3.4.4. Summary of these 5 hypothesis:

The following is a summary of the improvements produced by these 4 variants of hypothesis:

Table 9. Summary and comparison of the hypotheses planted

Hypothesis	% Renewable penetration	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (Tn)	% improvement	Green CO_2 (tCO_{2eq}/inhabitant year)
2019	15,86%	5.454.911	0,58	1.702.166	-	2,50
1	15,86%	5.256.271	0.56	1.640.222	-3,8%	2,41
2	15,86%	4.844.887	0.52	1.510.896	-12,6%	2,22
3a	29,11%	4.108.940	0.44	1.281.548	-32,8%	1,89
3b	36,78%	3.682.760	0.39	1.148.735	-48,1%	1,69

Logically, we improve the green CO_2 index by incorporating more renewables and stop producing CO_2. It is worth mentioning the significant improvement with the entry of the Chira-Soria project. If we compare green CO_2 between islands and by hypothesis we obtain:

Table 10. Island Green CO_2 (tCO_{2eq}/inhabitant year)

Hypothesis	Gran Canaria	Tenerife	Lanzarote	Fuerteventura	La Palma	La Gomera	El Hierro	Canarias
2019	2,42	2,28	3,52	4,02	2,06	2,42	1,25	2,50
1	2,34	2,21	3,46	3,51	2,06	2,42	1,25	2,41
2	2,11	1,98	3,46	3,51	2,06	2,42	1,25	2,22
3a	1,25	1,98	3,46	3,51	2,06	2,42	1,25	1,89
3b	0,75	1,98	3,46	3,51	2,06	2,42	1,25	1,69

We can see that the worst situation is in terms of Green CO_2 is on the island of Lanzarote and Fuerteventura and the best in El Hierro. Gran Canaria approaches El Hierro from the 3rd hypothesis and Tenerife in the 4th hypothesis, like the rest of the islands.

3.5. Proposal of hypotheses of operation of equipment changing the type of current fuel.

We continue with more Hypotheses, but now we make a variant on the previous Hypotheses. This variant consists of the modification of the fuel. As far as possible and allowed the equipment will move to use Natural Gas.

Natural gas produces CO_2 emissions 40-50% lower than those of coal and 25-30% lower than those of fuel oil. As for NOx, the nature of the gas (its combustion takes place in the gas phase) allows to achieve a more perfect mixture with the combustion air which leads to complete and more efficient combustion, with less excess air. Methane, which is the main component of natural gas, is a more potent cause of the greenhouse effect than CO_2, although methane molecules have a shorter lifetime in the atmosphere than CO_2. De according to independent studies, direct losses of natural gas during extraction, transport and distribution worldwide, they have been estimated at 1% of the total gas transported, the CO_2 emission in the combustion of Natural Gas is 58 $kgCO_2/GJ$ compared to that of Fuel Oil or Diesel which is 79 $kgCO_2/GJ$ and 70 $kgCO_2/GJ$ respectively. On the other hand, we have that the calorific value of natural gas is higher than that of the other fuels usually used in the Canary Islands.

Table 11. Calorific power.

Fuel type	Higher calorific power (Kcal/Kg)	Lower calorific power (Kcal/Kg)
Fuel	10.430,00	9.850,00
Diesel	9.265,00	8.713,00
Diesel oil	10.790,00	10.140,00
Natural gas	12.474,00	11.259,00

All this makes the convenience of using Natural Gas double since we need to burn less fuel to produce the same electricity and less CO2 is generated by electricity produced. The distribution of fuel for the current situation (starting situation) where all equipment except diesel engines switch to Natural Gas is as shown in **Appendix E** as well as the new emission distribution ($tCO_{2\text{-}eq}$) expected for this new situation. As a result of the change of fuel we managed to reduce emissions of polluting gases by 16.17%, from 5,454,911.4 tCO2-eq to 4,573,053,30 $tCO_{2\text{-}eq}$ and reduced fuel consumption by 13.44%, from 1,702,166.00 tons to 1,473,468.48 tons. The new emission factor is 0,490 tCO_{2eq}/MWh.

3.5.1. NG-HYPOTHESIS 1: Rearrangement of power plants with historical annual maximums. Penetration of renewables: 15.9%.

As already indicated above, in this hypothesis we proceed to work with the least polluting equipment in the different production centers of the islands, bringing them to a production ceiling marked by the maximum annual historical productions. The historical annual maximums of combined cycle plants (3,418,748MWh) and diesel engines (2,390,736.2MWh) which are the least polluting have been studied, proportionally rearranging

the rest of the equipment. Preserving the penetration of renewables (1,480,634MWh, 15.9%). With all this we obtain a global emission factor of 0.563 $tCO_{2\text{-}eq}$/MWh to 0.479 $tCO_{2\text{-}eq}$/MWh.

Table 12. NG-Hypothesis 1.

Technology	Energy Produced (*MWh*)	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (*Tn*)
Steam turbine	2.045.977,0	1.205.228,3	0,589	448.391,4
Diesel engine	2.390.736,2	1.562.554,0	0,654	488.206,3
Combined cycle	3.418.748,0	1.700.472,5	0,497	494.837,9
Renewable (15,9%)	1.480.634,0	-	-	-
Total	9.336.095,2	4.468.254,7	0,479	1.431.435,6

3.5.2. NG-HYPOTHESIS 2: Rearrangement of power plants working exclusively with the least polluting. Penetration of renewables: 15.9%.

In this hypothesis, we proceed to continue working with the least polluting equipment in the different production centers of the islands, but we work exclusively with them, ignoring the rest of the equipment. All this entails producing 5,428,740.4MWh in the combined cycle plants and 2,426,720.8MWh diesel engines, which are the least polluting, leaving the rest of the equipment in disuse or as reserves. Preserving the penetration of renewables (1,480,634MWh, 15.9%). With all this, we went from a global emission factor of 0.519 tCO2-eq/MWh to 0.459 $tCO_{2\text{-}eq}$/MWh.

Table 13. NG-Hypothesis 2.

Technology	Energy Produced (*MWh*)	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (*Tn*)
Diesel engine	2.426.720,8	1.585.011,2	0,653	495.218,.0
Combined cycle	5.428.740,4	2.701.038,7	0,498	786.002,9
Renewable (15,9%)	1.480.634,0	-	-	-
Total	9.336.095,2	4.286.049,9	0,459	1.281.220,9

3.5.3. NG-HYPOTHESIS 3: Reorganization of power plants working exclusively with the least polluting but incorporating the Chira-Soria project. Penetration of renewables: 29.5%-36.78%.

In this hypothesis, we proceed to continue working with the least polluting equipment in the different production centers of the islands, but we work exclusively with them, ignoring the rest of the equipment.

The Chira-Soria power plant is incorporated. With this addition, a global penetration in renewables in Gran Canaria is expected between 51% and 70%.

If we estimate 51% in Gran Canaria **(GN-HYPOTHESIS 3a),** which affects the overall figure of penetration of renewables in the Canary Islands, rising to 29.1%. All this entails producing 4,307,822.1MWh in the combined cycle plants and 2,310,552.60MWh diesel engines, which are the least polluting, leaving the rest of the equipment in disuse or as reserves. The penetration of renewables would be (2,717,720.5MWh, 29.1%). With all this, we went from an overall emission factor of 0.440 $tCO_{2\text{-}eq}$/MWh to 0.392 $tCO_{2\text{-}eq}$/MWh.

Table 14. NG-Hypothesis 3a.

Technology	Energy Produced (*MWh*)	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (*Tn*)
Diesel engine	2.310.552,6	1.512.048,9	0,654	472.435,9
Combined cycle	4.307.822,1	2.151.709,3	0,499	626.147,9
Renewable (29,1%)	1.480.634,0	-	-	-
Total	9.336.095,2	3.663.758,3	0,392	1.098.583,8

If we estimate 70% in Gran Canaria **(NG-HYPOTHESIS 3b),** which affects the overall figure of penetration of renewables in the Canary Islands, rising to 36.8%. All this entails producing 3,658,707.6 in the combined cycle plants and 2,243,280.5MWh diesel engines, which are the least polluting, leaving the rest of the equipment in disuse or as reserves. The penetration of renewables would be (3,434,107.1MWh, 36.8%). With all this, we went from an overall emission factor of 0.394 $tCO_{2\text{-}eq}$/MWh to 0.354 $tCO_{2\text{-}eq}$/MWh.

Table 15. NG-Hypothesis 3b.

Technology	Energy Produced (*MWh*)	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (*Tn*)
Diesel engine	2.243.280,5	1.469.797,0	0,655	459.242,9
Combined cycle	3.658.707,6	1.833.597,1	0,501	533.577,2
Renewable (36,78%)	3.434.107,1	-	-	-
Total	9.336.095,2	3.303.394,1	0,354	992.820,1

3.5.4. Summary hypothesis, production with teams working with natural gas:

As a summary of these 4 new hypotheses, a summary of the improvements produced by these 4 variants of hypotheses is shown below:

Table 16. Summary and comparison of the hypotheses planted

Hypothesis	% Renewable penetration	Greenhouse gas emissions (tCO_{2eq})	Emission factor (tCO_{2eq}/MWh)	Fuel consumption estimation (Tn)	% improvement	Green CO_2 (tCO_{2eq}/inhabitant year)
2019	15,86%	5.454.911	0,58	1.702.166	-	2,50
NG 2019	15,86%	4.573.053	0,49	1.473.468,48	-	2,10
NG-1	15,86%	4.468.254	0,48	1.431.435,58	-2,3%	2,05
NG-2	15,86%	4.286.049	0,46	1.281.220,92	-6,7%	1,97
NG-3a	29,11%	3.663.758	0,39	1.098.583,77	-24,8%	1,68
NG-3b	36,78%	3.303.394	0,35	992.820,10	-38,4%	1,52

Logically, the trend shown of improvements without the incorporation of Natural Gas increases with the incorporation of this fuel. We improve the green CO_2 index by incorporating more renewables and stop producing CO_2. It is worth noting the significant improvement with the entry of the project Chira-Soria. If we compare the green CO_2 between islands and by hypothesis we obtain:

Table 17. Island Green CO_2 (tCO_{2eq}/inhabitant year)

Hypothesis	Gran Canaria	Tenerife	Lanzarote	Fuerteventura	La Palma	La Gomera	El Hierro	Canarias
2019	2,42	2,28	3,52	4,02	2,06	2,42	1,25	2,50
NG 2019	1,92	1,81	3,50	3,85	2,06	2,42	1,25	2,10
NG-1	1,89	1,78	3,46	3,51	2,06	2,42	1,25	2,05
NG-2	1,79	1,68	3,46	3,51	2,06	2,42	1,25	1,97
NG-3a	1,06	1,68	3,46	3,51	2,06	2,42	1,25	1,68
NG-3b	0,63	1,68	3,46	3,51	2,06	2,42	1,25	1,52

We can see that the worst situation is still in terms of Green CO_2 that of the island of Lanzarote and Fuerteventura and the best in El Hierro. Gran Canaria approaches the Iron and improves from the GN-Hypothesis 3ª and Tenerife in the 4th Hypothesis, like the rest of the islands.

3.6. Results.

As a summary of the results we have:

Hypothesis 2: this approach is what offers immediate results at the lowest cost. As indicated in its approach, it consists of working exclusively with the least polluting equipment in the different production centers of the islands, combined cycle and Diesel engines. We subject this equipment to greater mechanical stress, but bearable with good maintenance according to its use. The most affected would be the combined cycles of Gran Canaria and Tenerife that their use would be 67.83% and 67.10%, and the Diesel Engines of Fuerteventura and Lanzarote that their use would be 67.35% and 55.57%. The rest of the equipment would have a use of less than 45%. With all this we lower total GHG emissions ($tCO_{2e}q$) by 12.59% and fuel consumption (Ton) by 12.66% and the economic and temporary cost is practically zero.

Execution Time: Immediate; Economic cost: Minimum; Decrease in total GHG emissions (tCO2eq):12.59%; Decrease in fuel consumption (Ton):12.66%; Renewable penetration: 15.86%.

NG Hypothesis 2: this second approach described in the GN. hypothesis2, consists of working exclusively with the least polluting equipment in the different production centers of the islands, combined cycle and Diesel engines, but we also change the fuel used in the combined cycle, going from diesel to natural gas.

We subject these teams to a mechanical stress like that of the previous hypothesis, although it is somewhat lower in the combined cycle. As a result, we obtain:

Execution Time: Average; Economic cost: medium; Decrease in total GHG emissions (tCO2eq):2 2.08%; Decrease in fuel consumption (Ton):1 8.91%; Renewable penetration: 15.86%.

Hypothesis 3a: third approach for our objective is the one described in hypothesis3a, to work exclusively with the least polluting equipment in the different production centers of the islands, combined cycle and Diesel engines, with their usual fuel, but we also incorporate the Chira-Soria project that incorporates the Chira-Soria plant and that foresees a penetration in renewables overall in Gran Canaria between 51% and 70%. In this hypothesis, 51% was estimated in Gran Canaria (the minimum expectation of this project), which affects the overall figure of penetration of renewables in the Canary Islands, rising to 29.1 1%.

Execution Time: Medium-High; Economic cost: medium-high; Decrease in total GHG emissions (tCO2eq):3 2.76%; Decrease in fuel consumption (Ton): 32.82%; Renewable penetration: 29.11%.

NG Hypothesis 3a: a fourth approach to our objective is that described in the GN. hypothesis3a, to work exclusively with the least polluting equipment in the different production centers of the islands, combined cycle and Diesel engines, changing the fuel of the combined cycle to natural gas, but we also incorporate the Chira-

Soria project that incorporates the Chira-Soria plant with a penetration in renewables global in Gran Canaria between 51% in Gran Canaria (the minimum expectation of this project), which affects the overall figure of penetration of renewables in the Canary Islands, rising to 29.1 1%.

Execution Time: Medium-High; Economic cost: medium-high; Reduction of total GHG emissions (tCO2eq): 48.89%; Decrease in fuel consumption (Ton):54.94%; Renewable penetration: 29.11%.

NG Hypothesis 3b: a fifth approach and the most optimal of all for our objective is the one described in the GN. hypothesis3b, working exclusively with the least polluting equipment in the different production centers of the islands, combined cycle and diesel engines, changing the fuel of the combined cycle to natural gas, but we also incorporate the Chira-Soria project that incorporates the Chira-Soria plant with a penetration in renewables global in Gran Canaria between 70% in Gran Canaria (the maximum expectation of this project), which affects the global figure of penetration of renewables in the Canary Islands, rising to 36.78%.

Execution Time: Medium-High; Economic cost: medium-high; Reduction of total GHG emissions (tCO2eq):65.13%; Decrease in fuel consumption (Ton): 71.45%; Renewable penetration: 36.78%.

3.7. Conclusions.

There are several measures that can be taken because of the result of this study through the tool proposed to achieve our environmental objective. All these measures to be taken depend in turn on several factors:

Economic factor: The measures to be taken can be very expensive with a satisfactory result or less expensive and obtain to a lesser degree a satisfactory result. Although not always the investment is directly proportional in a linear way to the result.

Temporal factor: If we take into account this factor, we can find several situations ranging from the immediacy of the actions to be taken or the other extreme that is to go to several years of delay in achieving completion of that action, and of course all intermediate situations are also valid.

The results will improve as these two factors grow, that is, we have more time and more investment.

Abstract:

As emerging countries work to balance the energy trilemma and provide secure, affordable, and environmentally sustainable energy, the link between energy, water and food and the rising demands for all are stressing the supply resource. The Republic of Ecuador is withinside the method of improvement a residential, industries and commercial demand plan which ends up in an supply call for increase, with a populace of 17.08 million population for 2018, it affords an strength boom of about 7.13% annual common until 2027, this means that our mounted strength supply should be capable of deliver all of the demand for and its annual increase, it is miles because of this that during our research we are able to examine the incorporation of recent and proposed plant life deliberate to fulfil the call for of the residential, commercial and industries in tiers that the country is planning to make bigger way to the renewable energy withinside the efficient energy matrix, withinside the equal manner the export of energy to neighbouring international locations Colombia and Peru is proposed. However, to reap this incredible alternate we pose numerous hypotheses that describe the hypothetical demand of residential, industries and commercial call for and in addition to the development of recent renewable technology plant life. Traditional and unconventional taking gain of renewable sources in abundance which include capacity water strength, wind strength, sun strength amongst others to generate electric supply and because of the modern-day state of affairs, deepen a public and private funding settlement to reap our objective, on this manner, pleasing our biggest hypothetical cases, we are able to be capable of deliver all of the energy needs for the year 2035, making sure a strong interconnected country wide grid with its enough reserve potential and making sure that each one the residential call for is included plus the projected commercial and industry call for pleasing the big emblematic projects, that the sizable majority will directly generate new jobs, financial boom and we are able to develop as a global industrialized nation.

Keywords:

Energy planning; Electric power; Renewable energies; Ecuadorian energy matrix.

1. Introduction

This paper reviews the current state of the Ecuadorian Electric Sector, defining its structure, production, energy consumption and the legal framework on which the future expansion of the Generation System through private investment is based, as well as the concession model of certain awarded projects to the present date. The Generation planning in the Ecuadorian Electric System is based on different programs at the state level such as the Electricity Master Plan (2018-2027) [1] and the National Energy Efficiency Plan, its general objectives being to increase the generation capacity of electrical energy in an efficient and clean manner with the environment, which the Ministry of Energy and Non-Renewable Natural Resources has called 'The change of the energy matrix'.

1.1. Electricity sector main actors

The Ecuadorian electricity sector is made up of legal entities dedicated to the activities of generation, self-generation, transmission, distribution and commercialization, public lighting, import and export of electrical energy, as well as natural or legal persons who are considered consumers or end users [2, p. 20-21].

1.1.1 Generation.

Generation and/or Self-generation activities in the country are carried out by public and private companies, which must pass certain requirements to be authorized by the competent authority. Generating companies

are those that have permission for the economic operation of one or more plants and deliver their production to one or more points of the National Transmission System, Distribution System, or isolated points. Self-generating companies are those dedicated to an industrial or commercial activity, whose electricity generation is used to supply their demand, and if applicable, the surplus can be made available to the sector. In 2019 there were 129 generation plants, of which 77 correspond to public companies and 52 plants to private companies. Now, the Electric Corporation of Ecuador Public Company maintains the largest amount of electricity production. Of the national installed generation capacity of 7,320 MW by 2020, 86% corresponds to CELEC EP, that is, 6,366.2 MW, which is distributed as follows: 27 Power Plants that correspond to 90% of the thermal park, 14 Hydroelectric Power Plants with 89% and an installed capacity of 4,498.73 MW and finally a wind power plant with 9% of a capacity of 16.5 MW.

1.1.2 Transmission.

CELEC EP - Transelectric Business Unit oversees the planning, operation, maintenance, and expansion activities of the National Transmission System, based on the energy policies established by the Ministry of Energy and Non-Renewable Natural Resources (MEM).

1.1.3 Commercial and Distribution units.

The distribution and commercialization of electrical energy is carried out by state companies corresponding to eleven (11) Business Units of the National Electricity Corporation Public Company, additionally there are nine (9) companies established as public limited companies, which act according to current regulations. The energy consumption of the distribution companies in 2019 can be seen in Figure 1.

1.1.4 International links

The Ecuadorian Electric System currently has two International Interconnections of a legal nature, one with Colombia through a 230 kV link, and another with Peru through charge block transfers.

1.2. Structure of the electricity sector

Figure 2 shows the interrelation of the actors in the electricity sector with the other control agencies. The Ecuadorian electricity sector is made up of a governing body that is the MEM, which through the Vice-Ministry of Electricity and Renewable Energy, is the entity responsible for meeting the country's electricity energy needs, through the formulation of the pertinent regulations, development plans and sectoral policies for the efficient use of its resources.

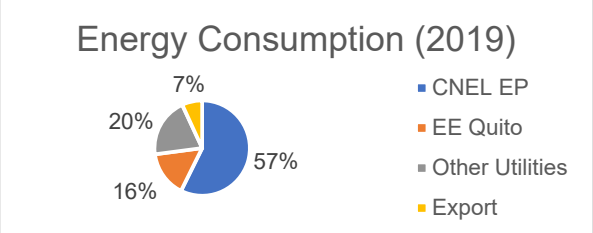

Figure 1 Energy consumption 2019 [1]

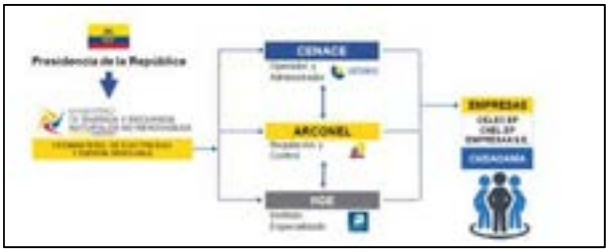

Figure 2. Structure of the Ecuadorian electricity system [1].

The National Electricity Operator (CENACE) is a strategic technical body attached to the MEM, which will act as technical operator of the National Transmission System (NTS) and is the commercial administrator of the energy block transactions, and responsible for the continuous supply of electricity at the lowest possible cost, preserving the global efficiency of the sector [2].

Executive Decree 1036 issued by the Presidency of the Republic of Ecuador established the merger of the Mining Regulation and Control Agency (ARCON), the Hydrocarbons Regulation and Control Agency (ARCH) and the Electricity Regulation and Control Agency (ARCONEL) [3] into one single entity called: Agency for the Regulation and Control of Energy and Non-Renewable Natural Resources (ARC) since July 1, 2020. By provision of the Organic Law of 'Public Electricity Service' (PES), it corresponds to ARCONEL, in its legal nature (Art. 14) regulate and control the activities related to the public electric power service and the general public lighting service, safeguarding the interests of the consumer or end-users, having among its attributions the issuance of the regulations to which the electric companies; CENACE and consumers or end users; whether these are public or private, observing the energy efficiency policies, for which they are obliged to provide the information that is required, the same that are previously approved and issued by its Board of Directors.

The Geological and Energy Research Institute (IIGE), created by Executive Decree No. 399 of May 15, 2018, through the merger of two institutes focused on research into energy efficiency, renewable energy, geology, mining, and metallurgy. With the creation of the IIGE, scientific research regarding earth sciences is strengthened, which will improve institutional capacities by generating a specialized human and technical resource, with greater scope for scientific work, technological development, and local innovation.

Electricity Corporation of Ecuador (CELEC EP) is a public company, dependent on the MEM, which was born in 2009 after the nationalization and unification of various companies in the sector. Its objective is the generation and transmission of Electric Power. National Electricity Corporation (CNEL EP) is a public company established in 2008, to provide public services of distribution and commercialization of electrical energy.

1.3. Energy production

According to the CENACE [2], in 2019 the Gross Energy produced in 2019 was 27,733.96 GWh. By origin, around 88.39% (24,513.99 GWh) was obtained from hydraulic sources, 10.14% (2,811.52 GWh) from thermal sources, and 1.45% (402.62 GWh) from renewable generation, and the remaining 0.02% (5.83 GWh) to international interconnections, as shown in Figure 3. The energy produced [2] from hydraulic sources has increased from 71.6% in 2017 to 88.39% in 2019. The Renewables gross production is distributed in 62% for Biomass, 20% Wind, 10% for Biogas and 8% for Photovoltaic Generation, as shown in Figure 4.

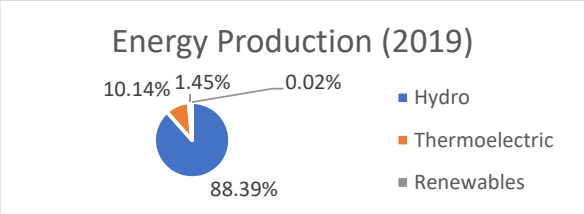

Figure 3. Energy Production by source in year 2019

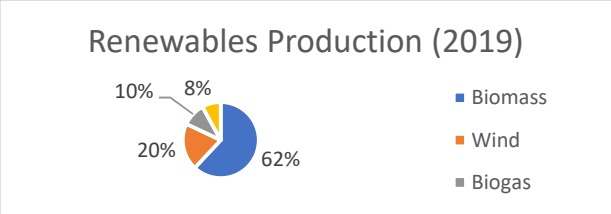

Figure 4. Renewables production in year 2019

1.4. Energy demand

The growth in energy demand in 2019 reached 8.12% compared to 2018. Table 1 includes a monthly comparative table of the energy demands of the Ecuadorian electricity sector between 2018 and 2019.

Table 1. Energy demand (GWh) 2018 and 2019 [2]

Month	2018	2019	Percent change %
January	2,064.02	2,096.56	1.58
February	1,764.59	1,946.52	10.31
March	1,970.88	2,150.00	9.09
April	1,970.93	2,117.26	7.42
May	1,999.55	2,162.90	8.17
June	1,838.77	2,000.16	8.78
July	1,862.94	2,042.18	9.62
August	1,867.16	2,034.04	8.94
September	1,845.81	1.974,23	6.96
October	1,891.27	2,040.53	7.89
November	1,870.50	2,059.80	10.12
December	1,947.52	2,129.05	9.32
Total	22,893.94	24,753.23	8.12

The per capita consumption of electricity in 2017 was 1,157.99 kWh/inhabitant, according to the National Institute of Statistics and Censuses of Ecuador.

1.5. Private Investment Opportunities

The legal framework where the opportunity for private investment in the electricity sector is based are:

- Concession Contracts (Art. 25 et seq. PES and 18 et seq. of its regulations) through MEM public selection processes.
- Projects under the Public-Private Association modality are delegated Management Contracts (PES incentives for public-private associations).
- Associative capacity of public companies to fulfil their business goals and objectives. Any type of association, strategic alliances, mixed economy companies with public or private sectors at the national or international level or within the popular and solidarity economy sector. (Art. 35 and following of the Organic Law of Public Companies).

In December 2020, through a public selection process for the concession to the private electricity generation, the renewable projects Villlonaco II and III wind farms and El Aromo photovoltaic systems (PV), with an installed capacity of 110 MW, and 200 MW, respectively, were awarded to the Spanish companies Consortium Cobra Zero-E Villonaco and Solarpackteam. These awards involve the design, construction, operation, and maintenance of new power generation projects located in the provinces of Loja (wind) and Manabí (PV).

This research contains a number of preliminary research questions that have not been previously explored in detail, and that do not have definitive answers regarding the impact that generation projects would have on the Ecuadorian electricity sector, (i) what will Ecuador's energy planning be like and the income of the different generation projects to satisfy the energy demand during the period from 2020 to 2035?, (ii) what will be the energy production supplied by the renewable blocks in the Ecuadorian Electric System during the period from 2020 to 2035?, (iii) what will be the best scenario to satisfy the energy demand in the period 2020 to 2035?, (iv) will it be possible to supply the demand for electrical energy without having Cardenillo and Santiago hydroelectric projects?

2. Methodology

2.1. Data availability

In this chapter we will review the technical information available by the control agencies of the Ecuadorian electricity sector such as MEM, CENACE and ARC, which will serve as input data for our modelling in the Long Emissions Analysis Platform (LEAP).

For the operational data, the CENACE 2019 Annual Report was used, for the forecast load and generation projection, the Electricity Master Plan 2018-2027 issued by the MEM was used, for certain specific data the System Data (SISDAT) Database was used, and the Annual and Multiannual Statistics of the Ecuadorian Electricity Sector 2018, Resolution ARCONEL – 069/16.

2.2. Historic production

The historical production for the year 2019 of the generation plants of the Ecuadorian Electric System was obtained from the CENACE Annual Report 2019, specifically in annex 2.3 (Net production by generation company [GWh] 2019). As shown in Table 2.

Within the report issued by CENACE, the power plants or generation units whose historical production in 2019 is zero have not been considered. This situation occurs because the effective capacity in hydroelectric generation that Ecuador currently has increased considerably in recent years, causing the lower capacity thermal plants to not be required in daily dispatches, other plants do not have the authorization of the governing bodies to participate in the Ecuadorian electricity sector, even though these plants are currently operational, additionally there is another group of plants that are intervened by the Ecuadorian state, whose equipment and components are deteriorating due to lack of operation and maintenance. Table 3 shows a summary of the companies with the drawbacks.

2.3. Energy Capacity

The energy capacity of the power plants and/or generation units was obtained by means of the Statistical Information Reports of the Ecuadorian Electricity Sector available in the SISDAT database of ARC as shown in Table 4.

It was considered that the reports are of high quality and contain the fundamental information of the Ecuadorian Electric System, this information will be useful for our modelling in the LEAP software in the ‘Exogenous Production’ section.

Table3. Companies with problems in their legalization

Company	Nominal Power [MW]	Fuel

Electroquil	180	Diesel Gas Turbine
Intervisa Trade	105	Diesel Gas Turbine
Ulysseas	30	Naphtha

In accordance with the provisions of the Electricity Master Plan, the expansion of generation will be carried out with the following objective: Guarantee the supply of electricity in Ecuador through the optimal expansion of the electric power generation stage, in the short, medium and long term, with criteria of efficiency, sustainability, quality, continuity and security; promoting the use of renewable energy resources, in an area of sufficiency, energy sovereignty, social and environmental responsibility; considering technical, economic, financial and administrative aspects.

Table 5 details the Electricity Generation projects that are under construction, Table 6 details the Electric Power Generation projects with Enabling Titles. Table 7 details the hydroelectric projects with more than 500 MW that have a final study and design, and Table 8 presents the summary of the generation projects for the case of the productive matrix that are additional to the Base case, detailing the most probable date of commercial operation, the name of the generation project, the company or institution in charge, the current state (construction, studies, etc.), if the project is financed with public or private funds, the type of technology (hydroelectric, thermoelectric, Non-Conventional Renewable Energies, among others), the nominal power (MW), and the estimated average annual energy (GWh/year).

2.4 Generators factors of maximum availability

Resolution No. ARCONEL-069/16, in its literal 4, defines the referential availability factors:

> "*…the referential availability factors are detailed by type of technology of the generating plants, which will serve for the comparison of the monthly average availability factor; and, for the liquidation of the fixed charge or annuity*."

These Values are presented in Table 9. The referential maximum availability values indicated by the resolution do not consider the Generation systems with renewables, for this reason due to the availability of their primary energies such as wind and solar energy, in our modelling we will enter the value of 100%. for this type of technology.

2.5. Other considerations

Within this study, the following special aspects must be considered, referring to the generation projects that will enter in the following years:

- The Paute-Cardenillo Hydroelectric Project is the last project to be built for the development of the Paute River Complex and will work jointly with Sopladora, Mazar and Molino. It will have an installed capacity of

596 MW. The referential investment of the project has a cost of USD 1.3 billion and will be awarded to the private company that will be responsible for the design, construction, implementation, administration, operation, and maintenance of the project.

- The Santiago hydroelectric project is in the southeaster region of Ecuador, it is located on the river of the same name within the Amazon hydrographic region, in the Tiwintza, Limón Indanza and Santiago de Méndez cantons, in the province of Morona Santiago, it will have an installed capacity of 3,600 MW. Due to its size, it will be executed in phases. This project will also be concessioned to a private company.
- The renewable blocks corresponding to technologies such as hydroelectric, wind, solar and biomass are projects that will be in different sectors of the country, and that will be concessioned to private companies according to the structured legal framework.
- The Chespi, Chontal, Tortugo and Tigre Hydroelectric Generation projects with a total capacity of 943 MW have the following investment time: Chespi (48 months, USD 793 million), Chontal (60 months, USD 435 million), Tortugo (50 months, USD 471 million) and Tigre (54 months, USD 215 million) are considered in our modelling.

Additionally, for the analysis of the demand, it is necessary to consider the hypotheses raised in the Master Plan, where the industrial city of Posorja is considered and from 2030 it will be a normal scenario of demand growth, the needs are projected for 12,000 GWh energy and 3,000 MW power.

Within the operational planning of the electrical system, there must be a rolling reserve that can act in the event of possible dynamic scenarios or sudden increases in demand, according to what is established by the Master Plan, this reserve is around 20% in the Ecuadorian Electrical System. Which considers the technical reserve, the primary frequency regulation, and the secondary frequency regulation.

Additionally, the cold reserve must be considered, unlike the rolling reserve, this is not available immediately. The cold reserve is the part of the non-rolling reserve (hydraulic or thermal) that can come into service and reach its available power in a time of no more than 15 minutes, which are within a merit list, to cover the deficit of generation reserve caused by various contingencies that occur in the system.

The cold reserve amount will be determined based on a reliability study, while in the case of the NTG it has been technically determined. The maximum value of the cold reserve according to the dispatch and operation procedures (of CENACE) must be equal to the generation unit with the highest power dispatched, thus preventing way the probable loss of the largest generation of the system.

3. Results

This section details the results to carry out the modelling of our Ecuadorian Electric System, for which we use the LEAP program [4], obtaining an analysis of the planning of electric power generation systems. The planning of electrical power systems represents a great economic development, for this reason it is necessary to define strategies for its expansion in the medium and long term, within this scenario the forecasted load plays an important role, for this reason we will follow the approaches determined in the Master Plan. The analysis carried out exclusively involves the expansion of generation and its attention to the scheduled demand, the expansion of the Transmission and Distribution Systems that require additional investments is not being considered, although the power losses did were considered.

The Hypotheses that we will present below are those found in the Master Plan where three study hypotheses are proposed that generated seven projection scenarios in LEAP, of which six were inherited from a trend scenario of energy demand. The study hypotheses will allow the construction of scenarios that will manage to articulate the policy of productive development, energy efficiency and basic industries (Master Plan). To make a projection from 2020 to 2035, the possible trends in the short, medium, and long term were entered with the aim of being able to determine the energy needs in the stages of generation and transmission of Electric Power. From 2030 to 2035, a normal increase in demand growth has been considered; needs of 12,000 GWh and 3,000 MW are projected. To enter the data of the demand 2030 to 2035 in the LEAP program in the base scenario we must create a folder in the Demands branch that we will call 2030 loads where an ‘energy-intensive technologies" will be created, when selecting the reference case, we locate the variable ‘Final Energy Intensity’. In this scenario, it contemplates what is the upward growth trend of users of industrial, commercial, and residential consumption. An average annual growth of 5.44% is estimated from 2018 to 2027, reaching 33,840 GWh in 2027 (Master Plan chapter 3 Electricity Demand, page 84) considering the average annual growth of 2.43% in users, reaching 6.48 million of users in 2027.

Hypothesis 1 corresponds to the projection baseline, which considers the trend growth of electricity demand; it incorporates econometric models, analysis of previous periods and analytical schemes. Hypothesis 2 results from incorporating into the projection baseline Hypothesis No. 1, the singular loads of the industrial group, which are linked to mining, cement, steel, oil, transportation, among others; energy efficiency projects, the load of the agricultural and agro-industrial community of Ecuador and to the Connection of the NTG with the Interconnected Petroleum Electric System (SEIP), with the purpose of optimizing the use of energy resources in an integral way (Master Plan, Chapter 3 page 92). The singular loads correspond to the electrical demand of industries that are expected to grow or expand. The singular loads were classified as:

singular loads in operation and projected. The data for each classification can be found in the Electricity Master Plan in Chapter 3, page 94. Due to its importance, in the projection of electricity demand, the incorporation of new technologies that are commercialized in the future were considered, the incorporation of which foresees significant electricity requirements. These projects are the Quito (capital city) Metro, the Cuenca (third city) Tram, electromobility (mass transportation) and the entry of electric vehicles. (Master Plan Chapter 3 page 95). For the hypothesis No. 3, in addition to all mentioned in hypothesis 2, the incorporation of the demand corresponding to Basic Industries, thereby obtaining the power and energy requirements of the electrical system in all functional stages, this scenario is what is called the Productive Matrix Case for the elaboration of the expansion studies of generation and transmission. (PME Chapter 3 page 96).

The Master Plan proposes the construction of two emblematic hydroelectric projects Cardellino and Santiago with an installed capacity of 596 MW and 3,600 MW, respectively. The decision of how to include the Central Santiago to the NTG is complex because within the planning there are many important variables that are currently not clearly defined regarding the concession, adjudication, construction timeline, operating stages and in how many years would be the most beneficial for its commissioning and operation, for this reason five additional scenarios inherited from hypothesis 3 are proposed.

Scenario 1 where the Renewable Blocks and the Hydroelectric Plants made up of Chespi, Chontal, Tortugo and Tigre are included to the NTG, but the contribution of Santiago and Cardenillo is not considered. Scenario 2 corresponds to the inclusion of Cardenillo (2026), does not consider the contribution of Santiago. Scenario 3 which includes Santiago with a power of 3,600MW in the following possible phases of operation: (i) phase 1: 1,800 MW (2026) and phase 2: 1,800 MW (2030); (ii) phase 1: 2,400 MW (2026) and phase 2: 1,200 MW (2030); and phase 1: 1,200 MW (2026), phase 2: 1,200 MW (2028) and Phase 3: 1,200 MW (2030).

This section shows the results of the LEAP simulations regarding the demand and energy generated by the power plants modelled in each of the scenarios proposed with their respective hypotheses. This Section is organized as follows: Section 3.2 corresponds to the demand results for each of the hypotheses of the proposed scenarios. In Section 3.3 is the energy planning of the system for each of the proposed scenarios.

3.1 Demand

The demand for electricity is presented with a growth of 5.44% for the period from 2020 to 2035, confirming an entry of singular loads projected in operation from 2020 to 2035, the entry of the transportation load corresponding to transportation in year 2020, the export of energy is maintained in the same current terms, the development of the industrial city of Posorja from 2023 and from 2030 the demand increases by 12,000 GWh. The demand results for hypothesis (number 3) are shown in Figures 5 (graph) and 6 (tabular), respectively.

Figure 5. Graph - demand results for Hypothesis 3

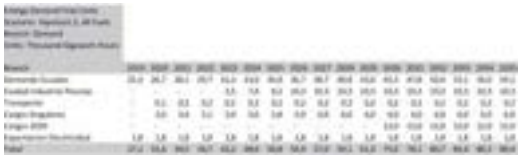

Figure 6. Tabular - demand results for Hypothesis 3

For Hypothesis 2, the demand presents a growth of 5.44% for the period between 2020 and 2035, transport charges and singular charges are considered from the year 2020, we maintain electricity exports and energy requirements from of 2030. The results obtained are shown below in Figures 7 and 8. For Hypothesis 1, demand presents a growth of 5.44% for the period from 2020 to 2035, we maintain electricity exports and energy requirements from 2030. The results obtained are shown below in Figures 9 and 10.

3.2. Generation

3.2.1. Hypothesis 1

For Hypothesis 1, in the final year of the analysis, 2035, there is a generated energy of 75,058 GWh and an estimated demand of 72,896 GWh. The maximum installed generation capacity is given in the year 2028 with 11,605 MW. In Figure 11 we observe the energy supplied by the generation plants.

3.2.2. Hypothesis 2

For Hypothesis 2 in the year 2035 there is an energy of 81,442 GWh and an estimated demand of 79,096 GWh. The maximum installed generation capacity occurs in the year 2028 with 11,605 MW. In Figure 12 we observed the energy supplied by the generation plants.

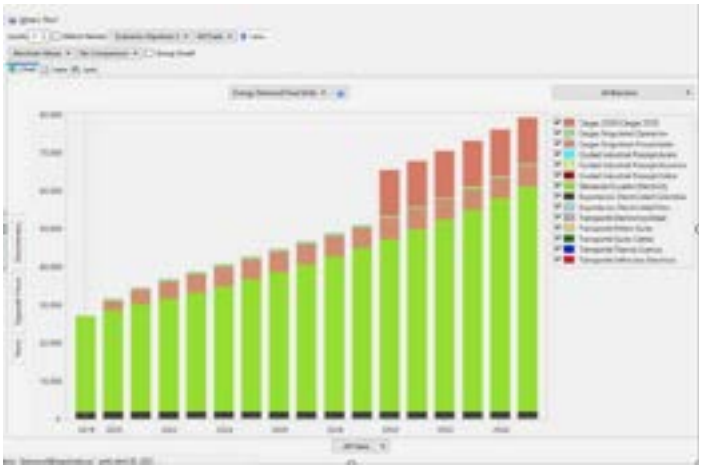

Figure 7. Graph - demand results for Hypothesis 2

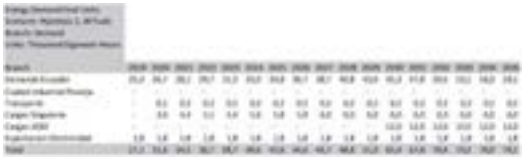

Figure 8. Tabular - demand results for Hypothesis 2

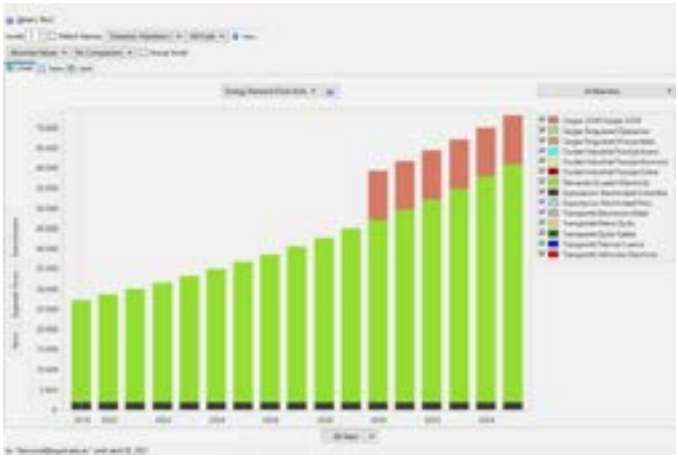

Figure 9. Graph - demand results for Hypothesis 1

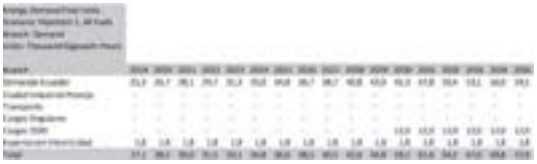

Figure 10. Tabular - demand results for Hypothesis 1

3.2.3. Hypothesis 3

For Hypothesis 3 in the year 2035 there is a generated energy of 89,320 GWh and an estimated demand of 89,380 GWh. The maximum installed generation capacity is given in the year 2028 with 11,605 MW. In Figure 13 we observed the energy supplied by the generation plants.

3.2.4. Hypothesis 3 – Cardenillo

For Hypothesis 3 and entry of the Cardenillo Power Plant in 2026, in 2035 there is a generated energy of 91,690.4 GWh, an estimated demand of 89,380 GWh and an installed capacity of 11,261 MW. The maximum installed generation capacity occurs in the year 2028 with 12,201 MW. In Figure 14 we observed the energy supplied by the generation plants.

3.2.5. Hypothesis 3 – Santiago A

For Hypothesis 3 and the entry of the Santiago Power Plant in 2026 with 1,800 MW, there is an installed capacity in the system of 13,601 MW. When the second phase of 1,800 MW enters in 2030, there is the capacity maximum installed in the system of 15,801 MW., and in the year 2035 we have a generated energy of 92,031 GWh and an estimated demand of 89,380 GWh. In Figure 15 we observed the energy supplied by the generation plants.

3.2.6. Hypothesis 3 – Santiago B

For Hypothesis 3 and entry of the Santiago Power Plant in the year 2026 with 2,400 MW., there is an installed capacity in the system of 13,661 MW., when entering the second phase of 1,200 MW in the year 2030, there is the maximum capacity in the system of 15,801 MW., and in the year 2035 we have a generated energy of 92,031 GWh and an estimated demand of 89,380 GWh. In Figure 16 we observed the energy supplied by the generation plants.

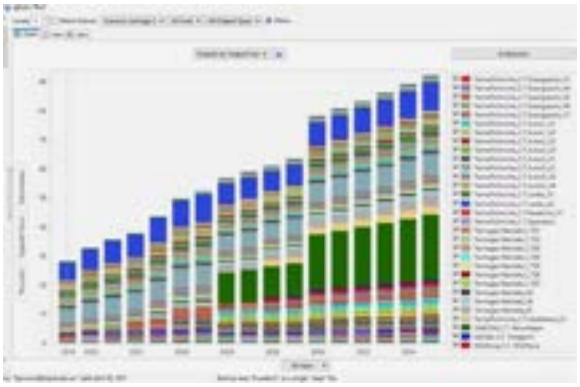

Figure 16. Energy supplied by the Generation Plants - Santiago B

3.2.7. Hypothesis 3 – Santiago C

For Hypothesis 3 and the entry of the Santiago Power Plant in 2026 with 1,200 MW, there is an installed capacity in the system of 12,461 MW. When the second phase of 1,200 MW enters in 2028, we have an installed capacity of 14,601 MW., and when entering the final phase of 1,200 MW in the year 2030, we have the maximum capacity in the system of 15,801 MW., in the year 2035 we have a generated energy of 92,031 GWh and an estimated demand of 89,380 GWh. In Figure 17 we observed the energy supplied by the generation plants. Regarding renewables, we can see the importance of this group, Figures 18 shows where we see its growth from the projects awarded recently, which would be the beginning of a group of projects that will be fundamentally for the energy development of the country contributing additionally to minimizing CO_2 emissions.

4. Discussion

Although in this paper the authors has carried out a systematic and brief review of what corresponds to the Ecuadorian Electric Sector reviewing its regulations and energy planning for the period 2020-2035, we have to indicate that the results of the simulations for each scenario indicate how the generation will be distributed over time, although we guarantee that the different loads are attended in all the periods analysed, there will always be maintenance, contingencies and other internal and external eventualities to which one must be prepared, as the success of continuing to have generation that meets our demand, as well as possible energy exports to neighbouring countries depends exclusively on the continuation of the energy policies carried out by the current National Government.

There will be many criteria that differ specifically with the inputs of specific generation, with the way in which the expansion of the system is proposed, energy policies, cost of energy, etc., but there is a point in which all the technicians and officials of the In the electricity sector we converge, attention to demand and avoid energy rationing in the near future, we must maintain this perspective, for years we have seen how the electricity sector has not had the continuity that is required and the results are in history and as in a previous era, there was a severe impact on the electricity supply. Additionally, we could optimize the income of new projects by applying non-traditional methods for their study where costs have their own decision scenario. The updating of the data as well as the useful life of the equipment proposes a vision of reengineering and replacement of generators that due to useful life must be replaced in the future.

5. Conclusion

The analysis of the demand and the energy planning of the generation was carried out in different scenarios, for this reason the values proposed in the available technical information were used, it is necessary over time to be able to guarantee that the hypotheses proposed for the demand can be met or adjustments must be made that lead to a rescheduling in relation to long-term energy projects. The Santiago hydroelectric project becomes essential for the country's energy development. It has been shown that the National Electric Power System would not be able to supply the demand for electricity when the industrial city of Posorja is under development.

If we want to maintain Ecuador's electricity trade balance as an Electricity exporting country, we must continue with the energy investment plans currently issued by the MERNNR, otherwise we will once again need imports from the existing binational electrical interconnections with Colombia and Peru.

The production of renewables in the Ecuadorian Electric System will have a substantial increase from 2023 with the concession of the EL Aromo and Villonaco projects (II and III).

Once the analysis of the different scenarios of the phases in which the Santiago hydroelectric project could be put into operation, it can be concluded that the best option is to divide it into three phases of 1,200 MW each and that revenues should be in 2026, 2028 and 2030 respectively. In this way, it could be supplied without the projection of the most critical demand raised by the MEM.

Abstract:
The global call for an environmentally friendly, sustainable and reliable distributed energy community is gaining traction nowadays, pushing the scientific community to explore novel multi-energy system layouts for highly decarbonised design. The complexity of highly integrated systems resides in selecting the components optimal capacities and establishing the demands for electricity, cooling and heating. While traditional fossil-based centralised distribution is not affected by intermittencies of renewables, highly decarbonized decentralised energy communities need to cope with the variability – in the short and long term – of renewables and the end-users demands. The scientific community addresses this problem by integrating various energy storage technologies in the energy community, but the selection of the most suitable technology and the related optimal capacity requires advanced optimisation tools capable of simulating years of the system operations, including stochastics factors that affect prices, costs and carbon taxes and regulations. The authors developed over the last five years the DECAPLAN™ Digital Platform capable of solving master-planning and optimal dispatch strategy problems. DECAPLAN™ includes hybrid heuristic/deterministic algorithms, based on a Genetic/MINLP solver, for establishing the optimal energy community design in respect of financial indicators, such as NPV, ROI and CO2 per year. In the paper, the authors present a real case in the Mediterranean Tropic region, showing a sensitivity analysis of the effect of environmental policies on the whole system design. Results in terms of energy community optimal component selection and optimal dispatch strategy are presented together with a sensitivity analysis on the effect of fuel and CO2 tax prices variability over the next decade.

Decarbonization, Master-Planning, DECAPLAN™, Distributed Energy Community, Optimization

1. Introduction

Scientists are calling for an energy transition [1] which must confront the limitations of reality , and specifically address the inadequate infrastructures that currently exist. The electricity sector is the primary focus of this transition, as evidenced by the significant increase in the installation of electric renewables over the past two decades [2], which has largely been achieved through a centralized approach that involves connecting new renewable energy power plants to the grid. While this has reduced the Primary Energy Factor of the Power Grid, it has also placed additional stress on the grid due to the influx of new energy production [3]. To address the balancing issues that result from the mismatch between energy demand and production, storage facilities have been included, but their limited size and high costs have impacted the grid's operation [3, 4, 5]. In light of this, it is necessary to consider the energy balance at the national level as the sum of smaller-scale energy balances, highlighting the crucial role of local Distributed Energy Communities (DECs) [16] in achieving a more balanced and sustainable energy mix [7, 8, 9]. By reducing changes and stress on the grid infrastructure, local energy communities can focus on local emission factors linked to energy mixes [10], leading to a decentralized search for renewable energy plants and the establishment of Renewable Energy Communities codified in the EU Directive REDII. Additionally, incentive schemes supporting Self-Consumption aim to provide community members with shared added value in terms of environmental and financial impacts throughout the energy chain [12, 13].

Solar PV and Solar Collectors on the roof, hot water storage, electric batteries in the basement are the most used tools made available to the citizens to participate to this new entity. Beside them, innovative technologies are taking place such hydrogen energy systems. Similarly, centralized approach for assisting the Grid is taking place first even with the limitations in size and impact due to the high costs. Later, small scale hydrogen energy

systems are seeing interest thanks to devices like the reversible fuel cells offering the production and utilization of hydrogen as a service for the buildings and in cooperation with other sectors like the mobility.

The integration of DECs in the existing infrastructure is a challenge faced by the scientific community in the last decade and affects the large scale DECs development due to some limitation such as the Capital Investment Cost, the Intermittency and variability of the renewable energy resources, the limited capacity related to the site-specific conditions and also on the technical challenge of integrating DECs into the existing grid. Indeed, to accommodate the DECs power generation it could be required to upgrade the grid infrastructure and may involve significant regulatory and policy changes.

Furthermore, in order to answer the call for higher decarbonization DECs, the integration of multi-energy highly integrated systems allows for drastically reduction in CO2 emissions but not necessarily in a easy-to-implement techno-economic manner. Accordingly, the selection of the most suitable technology and the related optimal capacity requires advanced optimisation tools capable of simulating years of the system operations, including stochastics factors that affect prices, costs and carbon taxes and regulations. The authors developed DECAPLAN™ digital platform capable of solving master-planning and optimal dispatch strategy problems. DECAPLAN™ includes hybrid heuristic/deterministic algorithms, based on a Genetic/MINLP solver, for establishing the optimal DEC design in respect of financial & environmental indicators, such as NPV, ROI and CO2 emitted per year. In the paper, the authors present a real case in the Mediterranean Tropic region, showing results in terms of energy community optimal component selection and optimal dispatch strategy, together with a comparative analysis on the achievable Operating Cost (OPEX) savings and CO2 emission reductions related to DEC configuration complexity.

2. Technical Background

The role of citizens regarding energy consumption and production has progressively changed during the last years. From passive energy consumers, they have become “prosumers” or active energy consumers because they both consume and produce energy, mainly through the installation of photovoltaic (PV) panels on their rooftops [14]. Renewable Distributed Energy Communities (DEC) can be defined as a group of prosumers composed of diverse users (e.g. individual households, municipal bodies, private businesses etc.) who share power plants for the generation and self-consumption of electricity, cooling and heating from renewable energy sources [15]. The diffusion of Renewable DECs produces benefits in terms of sustainability, costs and safety [16, 17] because DECs show:

- Localized generation of highly decarbonized electricity, cooling and heating, concurrently reducing CO_2 emissions, fuel poverty and energy losses during distribution.
- reduced grid fees and energy costs;
- flexibility of the energy usage due to the integrations of energy storage technologies for allowing peak shaving operations at DECs level.

DECs are also characterized by social innovation because they reinforce support between citizens and encourage their participation towards climate neutrality and energy transition through a democratic control over energy investments [18].

2.1. Existing Distributed Energy Community and the reference case

Renewable Distributed Energy Communities are progressively spreading in Europe, mainly in Germany, Denmark and Netherlands [18]. Italy is still characterized by a much lower number of active communities, equal to around 20 [19, 20].

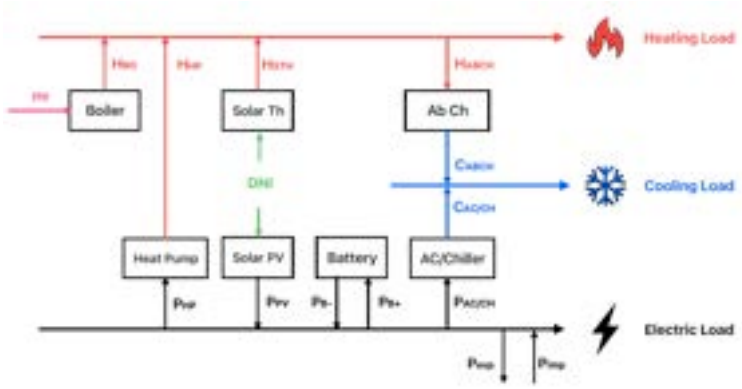

Figure 1. Schematic representation of the Renewable DEC of this study

According to literature [18 - 21], solar technologies are the most common used in Renewable DECs. Indeed, solar panels and solar collectors allows for quick and easy-to-customize installations suitable for rooftops of different buildings such as households, public buildings, and farms. Another important characteristic of existing energy communities is in the local production and consumption of energy, combined - when possible - with a variety of end-user uses of energy with the aim to match demand and generation, minimizing energy import/export from/to the power grid.

In this paper, the authors model and investigate the environmental and economic viability of different configurations of a Renewable DEC located in the Mediterranean Tropic region (latitude of around 37° 35' 59.9784"), where solar availability is relatively huge. The Renewable DEC is made up taking the main features of a real DECs and the overall demands of heat, domestic hot water, electricity, and cooling into consideration. The DEC account for a real municipality of around 350-400 inhabitants

The load demands of electricity, heating and cooling have been evaluated by considering that the DEC serves different types of users. Indeed, specific load profiles for different destination of usage have been combined, and mainly are related to:

- a shopping center with a supermarket, a coffee bar and a chemist's.
- a sport club.
- a town hall.
- 200 households

The authors present different DEC configurations (case studies A1 – E5), based on the DEC layout given in figure 1, varying the equipment technology and related installed capacity for supplying the end-users needs.

The DEC layout modelled by the authors and adopted for running the simulations is depicted in figure 1 together with the equipment providing for the generation and consumption of the required end user demands in terms electricity, heating and cooling. Indeed, the system has been modelled in buses as described below:

- Electricity Bus: Solar PV (P_{PV}), Battery Discharge (P_{B-}) and Power imported from the grid (P_{imp}) are the positive contribution for the positive terms for the electric load generation, while Heat Pump (P_{HP}), Battery Charge (P_{B+}), Air-condition/Chiller System ($P_{AC/CH}$) and power exported to the grid (P_{exp}) are negative ones.
- Heat Bus: Natural Gas fed Boiler (H_{BO}), Heat Pump (H_{HP}) and Solar Thermal Collector (H_{STH}) are contributing to the satisfaction of the Heat Load demand (H_{Load}), while Absorption Chiller (H_{ABCH}) is reducing the H_{Load} generation, for supplying the Cooling Load (C_{Load}).
- Cooling Bus: the C_{Load} is supplied by AC/Chiller ($C_{AC/CH}$) and by the Absorption Chiller (C_{ABCH}) cooling generation equipment.

The DEC can import and export electricity from or to the grid in case of lack or excess of production from the installed plants in the community, as shown in Figure 1.

2.2. The sensitive Parameters characterizing DECs

As mentioned in Paragraph 2, DEC can serve different kinds of end-consumers and related needs. Accordingly, the load demands of electricity, domestic hot water, cooling, and heat of the community are obtained by combining each of the load demands related to the various end-users in the DEC. Indeed, each consumer has specific load demands [22], which vary on the basis of the time period of the day and of the week (e.g. working days and holidays), the month of the year and the season. Other factors impacting on the load curves are [23, 24]:

- building size and architecture, looking at gross floor area (GFA) (m^2) and volumetric extension (m^3);
- building energy class and the related energy efficiency policies for planning;
- differentiation between regions and countries in terms of climate (e.g. DNI, ambient temperature, relative humidity), economic conditions and Technology Level (e.g. developed countries have a lower number of people per household).

In previous scientific works, the authors presented a deep analysis of the load demands from industrial [25, 26], commercial and domestic users [27-29]. In this study, the total demand of the DEC is evaluated by taking both the in-situ analyses performed in previous works and the available data referred to European municipalities located at the same latitudes of the DEC [25-29] into consideration.

Figure 2 shows - the normalized electricity load profiles of a typical winter working day related to the different users for being part of the proposed DEC. The type of user determines different trends: the shopping centre shows a practical constant load during the day, both the sports club and the households have the load peak during the evening, while the town hall shows his peak in the morning.

The DEC is modelled according to available data of real municipalities in the Mediterranean tropic region in terms of number, floor area and volumetric extension of households, buildings and facilities [30, 31].

The generation side is evaluated considering the values of temperature and solar irradiance at the latitudes of the DEC [32, 33]. An optimization of the design of the community structure is executed grouping diverse types of users with the aim of matching demand and generation curves, reducing energy export to the external grid.

The assumptions and the DEC architectural features are presented to perform the analysis to evaluate the load demands (electricity, cooling, and heating) of the DEC, it is important to understand how the boundary conditions (namely temperature and DNI) and the buildings/infrastructure configuration influences the heat/cold gain of the system and as well the electrical consumption. Indeed, based on the general specific daily load profile given in section 2, in the specific case scenario the DEC serves four diverse types of users, namely households, a shopping centre, a sports centre and a town hall, supplying electricity, domestic hot water, heat and cooling. According to the proposed case study located in the Mediterranean area, the authors have summarized in Table 1 the main characteristics of the community's buildings, while in Table A.2 shows the number of families with the number of family members living in the community.

The yearly temperature and DNI distribution for the given location, have been retrieved by MARRA-2 Data base. The yearly curves for the different load demands and different type of user are evaluated thanks to DECAPLAN™ Digital Platform by finetuning the parameters on the basis of the data derived from literature [34], that account for the variability of the demands supply during the day, week and month. As an example, the aggregated load demands of electricity, cooling and heating for a typical week during the winter (January) and during the summer (July) have been presented in figure 3 by the authors.

Table 1. DEC Buildings Architectural Characteristic

Type of building	Floor surface [m^2]	Volumetric extension [m^3]
Real estate district	13,590 – 13,600	40,770 – 40,780
Shopping centre	820 – 830	2,900 – 2,910
Sports centre	710 – 720	2,140 – 2,150
Town hall	230 - 240	700 - 710

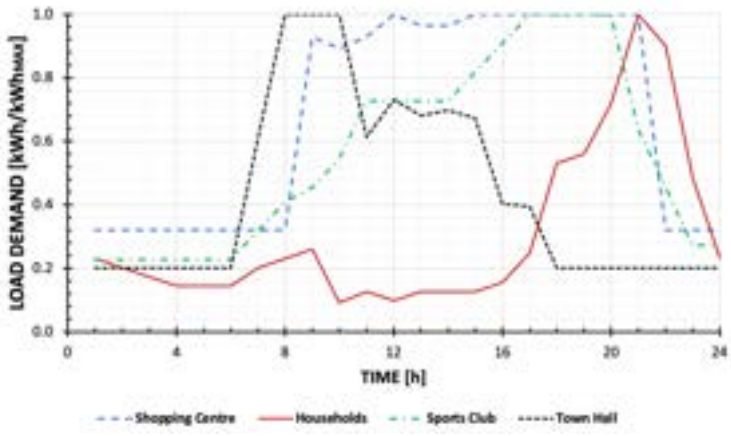

Figure 2. Electricity Load Demands for different DEC user during a typical winter working

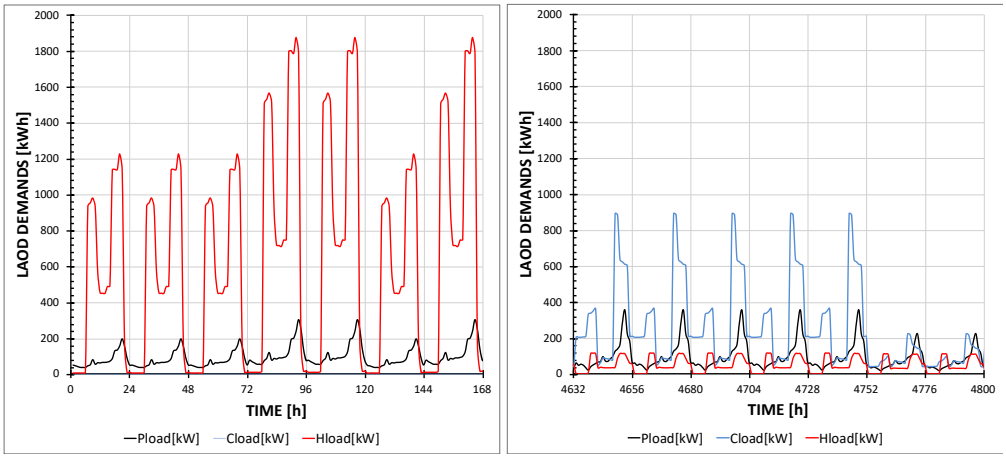

Figure *3.* Typical Load Demands Profile during winter (left) and summer (right) for reference case study.

3. Materials and Methods

In this section, the methods used for data collection, modeling and analysis are described. The DECAPLAN™ digital platform [34-37] is proprietary software of MEDS Venture Global Pte Ltd start-up company spin-off of Nanyang Technological University. The DECAPLAN™ Digital Platform has been developed by the authors over the last five years for designing power plants, microgrids, and industrial and building estates characterised by high energy mix by establishing the best plant arrangement and choosing among database (DB) the most suitable commercially available components. The DECAPLAN™ allows for concurrently optimising the best multi-energy plant design and operation by solving the energy dispatch (unit commitment) problem for given electricity, cooling and heating demands. In this paper, the optimal solution is addressed to minimise the primary energy consumption and the greenhouse pollutant emissions (CO_2) by minimizing them at the same time. The mathematical formulation of the DECAPLAN™ objective function enables the digital platform to search for the best solutions taking the Operational Expenses (OPEX), the Localized Cost of Electricity (LCOE), the Return of the Investment (ROI), and other parameters into consideration. More details on the modelling approach and the optimisation strategy are given in the next section. The proposed system layout includes several DEC components such as Solar PV, Solar Cooling, Heat Pumps, Chillers, Energy Storage Technologies (namely battery in the specific DEC) and others as well as their part-load off-design maps for optimized asset management.

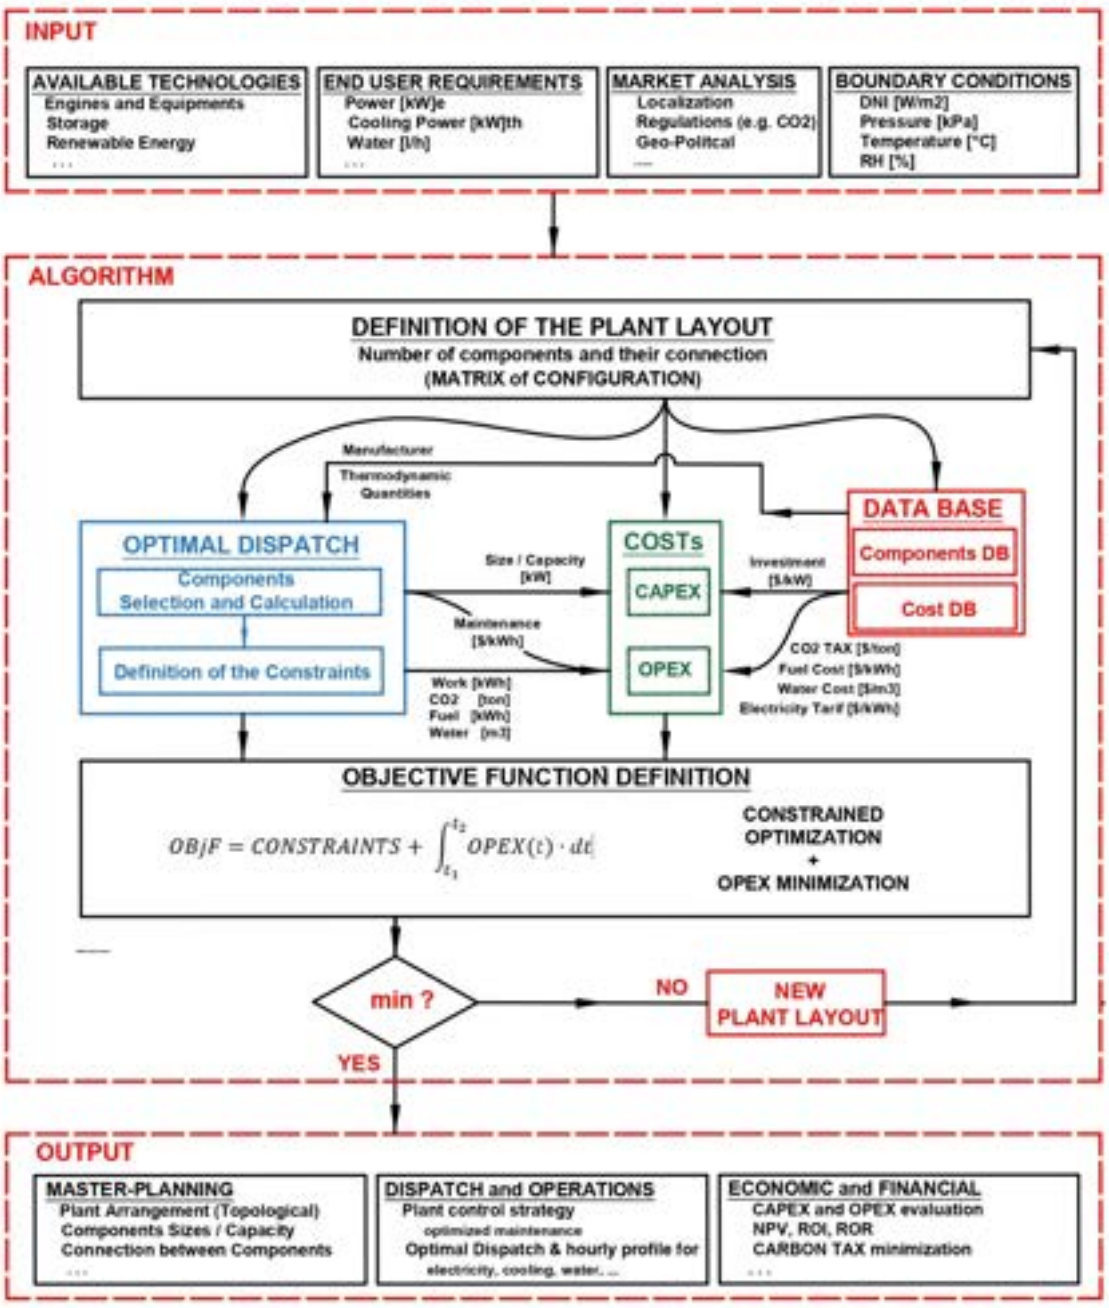

Figure 4. The functional block diagram of DECAPLAN™ digital platform

Details on the mathematical formulation for the Master Planning (MP) and the Optimal Dispatch Planning (ODP) are discussed by the authors in [36, 37], while for purposes of this work the functional scheme with the description of the main features of the DECAPLAN™ digital platform is summarized below. The simulation tool for the DEC system was developed using a modular approach at the component level. To set up the DEC simulator, steady-state 0-D component models were adopted as per the method proposed by the DECAPLAN™ digital platform algorithm. The DECAPLAN™ includes various solvers such as quadratic programming, mixed-integer linear programming (MILP), and mixed-integer non-linear programming (MINLP).

Research has shown that the mixed-integer quadratic programming technique used by the DECAPLAN™ digital platform is robust and efficient, as demonstrated by comparisons with a hybrid heuristic algorithm based on GA and PSO solvers [36, 37] and other mathematical approaches [35 - 37]. Additionally, the use of stochastic algorithms has been found to potentially lead to suboptimal results in master-planning problems [65-67]. Figure 4 provides a complementary block diagram to understand the optimization process flow that the end-users need to perform, specifically the optimal dispatch block diagram DECAPLAN™.

The algorithm consists of three parts: the *input layer*, where conditions such as temperature, DNI, and precipitation profiles, as well as plant demands and costs, are inputted; the *optimal dispatch layer*, where the algorithm matches and connects components, ensuring that conservation equations are not violated; and the *output layer*, where the optimal dispatch strategy for the power plant and its associated costs are presented. Additionally, the algorithm uses a modular approach to simulate power systems and incorporates a database of component performance maps to evaluate costs, degradation, and maintenance. Accordingly, the authors have developed ad-hoc thermal components for the specific scientific work, including solar cooling, heat pumps and thermal solar.

3.1 DEC Main Component Modelling

Solar PV: is modelled by adopting lumped performance features. The scheme of the PV model is presented in figure 6-A. The generated power PPV is calculated as (eq.1):

$$P_{PV} = DNI \cdot S_{PV} \cdot \eta_{PV} \quad (1)$$

Where DNI, SPV and η_{PV} are the direct normal irradiance (DNI), the solar PV surface and the solar PV efficiency. The η_{PV} in the actual conditions is established by the adoption of normalized maps developed by the authors that relates the solar PV reference efficiency, the DNI and PV cell temperature (typically referring to the panel type and to the manufacturer testing conditions) to the actual DNI and cell temperature T. The lower the cell temperature, the higher the efficiency. Typically, DB provides 0 °C as the minimum value. Accordingly, η_{PV} is expressed functionally by (eq.2):

$$f\left(\frac{\eta_{PV}}{\eta_{PV_R}}, \frac{DNI}{DNI_R}, \frac{T}{T_R}\right) = 0 \quad (2)$$

Solar Thermal Collector: is modelled similarly to the Solar PV module, but as the output useful quantity is the Heat Power (H_{STH}) defined in (eq.3), where η_{STH} is the STC efficiency, evaluated in similarities with the procedure of eq.2.

$$H_{STH} = DNI \cdot S_{STH} \cdot \eta_{STH} \quad (3)$$

Heat Pumps: the characteristic equation allowing for evaluating the useful effect H_{HP} is given in (eq.4), and the details of the modelling approach are given in [35, 37], as well as per the absorption chiller and vapour compression chiller details. Off-design curves are also discussed in [35,37]

$$H_{HP} = COP_{HP} \cdot P_{HP} \quad (4)$$

Chillers Systems: the AC/Chiller system and the absorption chiller equations are summarized in (eq.5) and (eq.6), and the full model details can be found in [37]

$$C_{ABCH} = COP_{ABCH} \cdot H_{ABCH} \quad (5)$$

$$C_{ACCH} = COP_{ACCH} \cdot P_{ACCH} \quad (6)$$

Fuel Boiler: the model allows for evaluating the useful effect H_{BO} (eq.7) based on the routine described in [37] for evaluating the complete combustion details of the process together with exhaust gas composition, carbon emitted.

$$H_{BO} = m_{fBO} \cdot \eta_{BO} \cdot LHV_f \quad (7)$$

Battery: the entire description of the model is described by the authors in [37], the main equation required for solving the ODP is given in (eq.8), where the battery energy capacity at the time-step *t+1* is evaluated as

function of the optimized control strategy of the battery and the capacity at the time-step *t.* For ensuring the energy conservation equation during the whole period of the battery operation, an equality constraint is introduced (eq.9).

$$E_{BATT}(t+1) = E_{BATT}(t) + P_{B+} \cdot \Delta t - P_{B-} \cdot \Delta t \quad (8)$$

$$E_{BATT}(t = t_{START}) = E_{BATT}(t = t_{END}) \quad (9)$$

3.2 Environmental Techno-Economic Indicators

The overall CO2 emissions are evaluated by taking into consideration the specific emission factors of the different energy generation processes, in the specific case from the import of the electricity from the national grid and from the combustion process in the fuel fed boiler. At DEC level the production of electricity from RES and export to the national grid could be expressed as a negative/avoidance of CO2 emitted and included in the evaluation. For accounting this term, that can or not included in the Scenario evaluation, the authors have adopted a (δ = 0 or δ =1) variable in the formulation. According to the above, the CO2 emissions per year are expressed by (eq.10

$$CO_2 = \sum_{t=1}^{8760} (Pimp - \delta \cdot Pexp) \cdot \Delta t \cdot f_{CO2_{grid}} + mf \cdot \Delta t \cdot f_{CO2_{fuel}} \quad (10)$$

The overall operating cost O_{PEX} is evaluated as the sum of the running costs (e.g. cost of the electricity imported and fuel), maintenance cost, renting cost of the surface where installing DEC equipment and by the carbon tax, expressed by (eq.11). Accordingly, the overall OPEX, fully described in [35,37] is sinthetically expressed by (eq.12):

$$O_{CO2_{TAX}} = CO_2 \cdot TAX_{CO2} \quad (11)$$

$$O_{PEX} = O_{RUN} + O_{MAIN} + O_{RENT} + O_{CO2_{TAX}} \quad (12)$$

3.3 Power Constraints, Objective Function and Optimization Strategy

The solution of ODP consists of two main steps such as the minimisation or maximisation of the objective function (*ObF*) and satisfying of the equality constraints, namely electricity and cooling power flow (electricity and cooling bus load demands). From a numerical perspective, the adopted solver is based on simultaneous solutions; this means that concurrent to the equality constraints satisfaction, the *ObF* is also optimised. In the current work, the *ObF* to be maximised has been set to be the linear combination of the OPEX and CO2 emissions reduction of the k-th scenario, versus the OPEX and CO2 emissions of the reference case (REF) NPV, expressed by (eq.13).

$$ObF - Search\ MAX\ of:\ CF_k + \Delta CO2 = \left(OPEX_{REF} - OPEX_{k_{th}}\right) + \left(CO2_{REF} - CO2_{k_{th}}\right) \quad (13)$$

The satisfaction of the energy flows (operational constraints) for the economic dispatch on the electric bus is expressed by (eq.14), on cooling bus by (eq.15) and on heating bus by (eq.16).

$$P_{Load} \cdot \Delta t = P_{imp} \cdot \Delta t + P_{pv} \cdot \Delta t + P_B^- \cdot \Delta t - P_B^+ \cdot \Delta t - P_{exp} \cdot \Delta t - P_{ACCH} \cdot \Delta t - P_{HP} \cdot \Delta t \quad (14)$$

$$C_{Load} \cdot \Delta t = C_{ACCH} \cdot \Delta t + C_{ABCH} \cdot \Delta t \quad (15)$$

$$H_{Load} \cdot \Delta t = H_{HP} \cdot \Delta t + H_{BO} \cdot \Delta t + H_{STH} \cdot \Delta t - H_{ABCH} \cdot \Delta t \quad (16)$$

The formulation of the optimisation problem has been fully described by the objective function and constraints structure definition. In the next section, the test case and the analysis of the results are presented.

4. CASE STUDIES

The schematic representation of the Renewable DEC presented by the authors in figure 2 allows to generate multiple case studies in respect of the components included in the DEC layout and of the capacity. Furthermore, the different case studies can also be contextualized in different energy policy scenarios where Incentives, Carbon Certificates and Financial Rewards for CO2 avoidance and power generation in the DEC can be taken into consideration. According to the above, the authors have explored five DEC configurations (Layout) A, B, C, D and E, and for each of the configuration varied the number of Solar PV (0, 250, 500 and 1000), according to the maximum allowable gross floor area available for the PV installation. For the configuration C, the authors have selected the maximum number of Solar Thermal Collector of 500 unit. The matrix of the configuration generated and optimized by DECAPLAN™ Digital Platform is given in Table 3. Looking at the number in Table 2, since some of the equipment such as Heat Pumps, NG fed Boilers AC/Chiller unit splitter are specific of each unit of each building, the authors have assumed that if the component exist (N = 1) while if not (N = 0).

Table 2. Case Studies – DEC Configuration Matrix

CASE STUDIES	A1 - REF	A2	A3	A4	B1	B2	B3	B4	C1	C2	C3	C4	D1	D2	D3	D4	E1	E2	E3	E4

Table 3. Case Studies – DEC Assumption for the Optimization

Parameter	Value	Unit of Measure
Fuel (Price, LHV)	(1.00, 50.0)	(Euro/kg, MJ/kg)
Electricity tariff (Buy/Sell)	Refer to Figure A.3	Euro/kWh
PV (Peak Capacity, Surface, Efficiency)	(550, 2.584,21.1)	(Wp, m^2, %)
STH (Surface, Efficiency)	(2.0, 40.0)	(m^2, %)
COP (HP, VCCH, ABCH)	(2.6, 5.5, 0.7)	(-)
*Battery (*RTE, SOC_M, SOC_m*)*	(93, 95, 5)	(%)
Carbon Tax	80.0	Euro/Ton
DEC Emission Factor	0.212	$kgCO_2$/kWh electric
Natural gas Emission Factor	0.192	$kgCO_2$/kWh fuel

For the battery component instead, it is assumed that it can serve the entire DEC and so introduced with the nominal capacity, expressed in kWh.

On top of these 20 case studies (A1 – E4), the authors have also investigated three policy scenario related to the qualifications in terms of CO2 carbon credit and financial gain of selling the excess of electricity generated by the DEC to the National grid. The results of the scenario analysis will be deeply presented in the result section, by differentiating the colours of the candle stick bars charts. Accordingly, the three scenarios are considering that the yearly exported electricity (kWh exp):

- Scenario 1 (Blue): allow CO2 Certificate Recognition and exported electricity is reward.
- Scenario 2 (Red): NOT allow CO2 Certificate Recognition and exported electricity is reward.
- Scenario 3 (Green): NOT allow CO2 Certificate Recognition and exported electricity is NOT reward.

Price of electricity bought and sold are 230 and 70 euro/MWh.

4.1 Assumptions

According to the DEC building specifications given in section 2, to the ambient condition given by MARRA Database, and to the yearly load profiles for electricity, cooling and hearting shown in figure 3, the main assumptions required for the calculations have been presented in table 3. Indeed, main components specification such as nominal capacity, surface of each module, efficiency, and performance indexes such the Coefficient of Performance (COP) are fundamental parameters to perform the optimization process thanks to DECAPLAN™ Digital Platform.

To perform the environmental techno-economic analysis, prices of electricity (sell and buy) and cost of the carbon tax are also needed. Accordingly, since it has been considered power can be imported (Pimp) and exported (Pexp) from and to the National grid, buy & sell prices are 230 and 70 euro/MWh, respectively. Furthermore, to assess the overall yearly production of pollutant emissions in terms of Ton of CO2/year from the DEC, the emission factors of the system and associated to the combustion of the natural gas into fuel fed boilers have also been included in the optimization and thus included in table 3.

Once boundary conditions and assumptions have been set, the authors have been able to run the optimization and the scenario analysis above-mentioned thanks to DECAPLAN™ Digital Platform. Accordingly, results of the optimization together with discussion and consideration are given in section 5.

5. RESULTS & DISCUSSION

In this section, the authors present the results of the environmental techno-economic optimisation carried out by the DECAPLAN™ Digital Platform, taking the different DEC configuration and scenarios into considering. The case study A1 (order number 1) is the reference case study and represent the scenario in which all the electricity is imported from the national grid, all the cooling load is satisfied by the generation of air conditioning from individual unit splitters and the heat load is supplied by the heat power generated through the Heat Pump. In this configuration, the yearly CO2 emitted by the DEC is of 732 Ton/year and the overall OPEX are of about 540,000 euro/year. These two numbers are very important because they become the benchmark/baseline to

compare all the other case studies and scenarios. Looking at the same DEC configuration A4 equipped with 1000 Solar PV modules, it can be observed by the charts given in figures 5 and 6, that for the scenario 1, where the amount of kWh exported to the grid is accounted in the overall CO2 emission per year, the year CO2 emissions drop of 21% to 575 Ton/year and the yearly OPEX decreases of 22% to 420,000 euro/year. This trend is justified by the fact that the integration of the solely Solar PV in the DEC configuration does not modify the load allocation of the other loads, such as cooling and heating. When A4 configuration is instead compared among the three scenario 1, 2 and 3, it can be clearly be observed that cCO2 credit mechanism of the scenario 1, does not allow in case 2 and 3 to achieve the same CO2 emissions reduction. Indeed, in case 2 (and equivalently in case 3) the maximum CO2 reduction is of 57 Ton/year, corresponding to about -9% CO2 emission reduction. On the OPEX side instead, scenario 2 shows 427,000 euro/year and scenario 3 shows 452,000 euro/year. The evaluation of the scenario B4, where the generation from the NG fed Boiler is swap with the Heat Pump system, shows an interesting trend among CO2 and OPEX. Indeed, given the marginal cost of the electricity from the grid and of the fuel and the different emissions factors, the solution B4 reduces the CO2 emissions of 65% leading to a yearly emitted value of only 254 Ton/year, with a corresponding OPEX of 460,000 euro/year, that is anyway a saving of 14.8% in the OPEX of the DEC. The introduction of 500 Solar Thermal Collector for the generation of heating and cooling in case C4, keep the reduction of the CO2 emissions practically unchanged, up to 66%, corresponding to an absolute value of 249 Ton/year, and reduces the OPEX of 15.0%, leading to a yearly OPEX of 457,000 euro. The scenarios D4 and E4 are characterized of the introduction of 2000 kWh and 20000 kWh battery capacity in the DEC. In the case of the smaller battery, D4, the CO2 emission reduction is of 64.5%, while the OPEX reduction is of up to 28%, corresponding to a yearly operating cost of 385,600 euro. In case of the large battery instead, E4, the CO2 emissions reduction is 64.0 %, while the OPEX reduction is up to 33.2%, corresponding to a 359,000 euro/year DEC operating cost. The reason behind the massive reduction on the OPEX due to the integration of the battery in the design of the DEC is because it allows to perform the peak shaving procedure and allow to reduce the dependency of the DEC from the National Grid. On the CO2 emissions perspective instead, the fact that each charging/discharging operation is characterized by a loss (round trip efficiency) leads to increase the demand of electricity (energy) in the DEC and consequently to a marginal increase of the CO2 emitted, in comparison between the case without battery. It is worthy of note, that the reduction is anyway very considerable and for sure – the OPEX cost massive reduction will justify the solution. An important consideration related to the introduction of the battery system into the layout are related to the fact that the exported power – in the case of 20000 kWh capacity – is almost zero along the entire year. This is an important consideration since grid complexity and regulation would rather prefer the DEC to be independent from the grid to ensure stability on the frequency of the electricity generated by the DEC system.

Indeed, by comparing the charts given in figures 7 and 8, that represents configurations D4 and E4, it is possible to observe how the capacity of the battery influences different aspects. The red chart representing the power imported from the National grid allows to understand how the dependency from the Nation Grid is much lower in case E4. Looking at the summer period, the DEC is fully independent from the National Grid and furthermore, the electric work exported to the grid is practically zero for the entire year. On the battery duty cycle operations, the grey chart in figures 7 and 8, it can be observed that the case D4 equipped with the smaller capacity, the battery system is adopted in day-to-day operations, accounting for supplying the DEC in case of intermittency of RES in the short term. When the capacity of the battery increases up to 20000 kWh, the storage solution become and interesting tool for planning long term operations, for ensuring flexibility and grid independence of the DEC system.

6. CONLCUSIONS

The paper investigated the promising topic of Renewable Distributed Energy Communities and their role in achieving environmental techno-economic alternatives in the pathway towards decarbonization. The concurrent requirements from the DEC users of electricity, cooling and heating make the design of optimal DEC a complex process, since multitude of variables are involved in the optimization process. The authors have developed a digital platform – DECAPLAN™- that can solve Master-Planning and Optimal Dispatch Problems of highly integrated DEC. Thanks to the modular approach proposed and to the optimization algorithm the authors have ranked the best DEC configurations in terms of potential in CO2 emissions and OPEX reduction. It has been demonstrated that an optimal designed DEC with Solar PV, Heat Pumps and Solar Thermal Collectors is capable to reduce of up to 65.1% the CO2 emissions yearly, when compared to the case in which all the assets are generated via fossil fuel sources (boilers and import from national grid). Indeed, the CO2 Emissions drop from 732.6 Ton/year to just 249.5 Ton/year, reducing the environmental impact of the DEC and reducing the cost associated to the carbon tax (savings of almost 40,000 euro per year of CO2 Tax). The maximum saving from the OPEX perspective – instead – takes place when the DEC is equipped with a large capacity electrochemical energy storage system, with capacity ranging between 2,000 and 20,000 kWh). Indeed, the CO2 reduction comparted to reference case is still very high – with 64% reduction, corresponding to 259.4 Ton/year, but the OPEX drop from 537,000 euro/year to about 385,000 euro/year, that leads to about 28.2% savings yearly, in the case of the 2,000 kWh battery. The authors decided to consider at the day of today the smaller battery as the most easy-to-implement solution for DEC since a much larger battery of 20,000 kWh would also imply to account for thermal management problems and surely much higher CAPEX. It is worth of note, that the larger energy storage capacity simulated in the paper as an electrochemical energy storage system, could also be simulated by alternative storage solutions and plant configurations, based on Hydrogen solutions.

For concluding, the authors have not considered the impact of the CAPEX in the optimal design of the system and for sure it will be the next brick the authors will integrated in the analysis for fully understanding and assessing the environmental techno-economic viability of DEC, in the holistic perspective, accounting for the entire lifetime of the DEC.

Abstract:

Accelerating the green energy transition is of great importance in fighting global climate change. Currently, the Danish island Aero utilizes a large amount of fossil fuel-based energy resources in the electricity, heating, and transport sectors. In line with the holistic green transition initiatives in Denmark and the holistic goal of the fossil-fuel free Danish energy sector by 2050, this study aims to find a feasible solution for the island to be fully sustainable relying solely on renewable energy sources, operating in island mode. To that end, different approaches are investigated including the electrification of the transport sector, installing energy storage systems, increasing renewable energy production capacities, energy production planning, and demand side management. Using linear programming, a hybrid scenario combining these energy approaches is developed and an hourly optimization is conducted to balance the island's energy production and demand. The proposed hybrid scenario is compared to the island's current energy system operation (base scenario) via a techno-economic approach, where dimensioning of the technologies is evaluated and the overall system cost is projected. The results showed that the hybrid scenario achieves higher renewable energy contribution (100%) and lower system cost (1625.9 DKK/month/person) compared to that of the base scenario (55.77% and 1689.6 DKK/month/person respectively). In connection to the hybrid scenario, a sensitivity analysis is carried out to investigate the impact of specific modifications to the hybrid scenario on the system's technical and economic performance. The results showed that installing an additional ferry is the most beneficial approach to improve the hybrid scenario's performance.

1. Background and motivation

To mitigate climate change and global warming, Denmark has set an ambitious goal to phase out fossil fuels and achieve CO_2 neutrality by 2050 [1]. Complying with the holistic goal of this fossil-fuel free Danish energy sector, Danish island Aero aims to be CO_2 neutral and self-sufficient in renewable energy by 2025 [2]. Aero has long been stepping towards green energy transition and the CO_2 emissions have been reduced by 38% in the period from the year 2008-2019. However, the current energy systems in Aero still rely on a large amount of fossil fuel-based energy resources in the three main sectors, i.e. the electricity, heating, and transport sectors.

Aero has already equipped wind turbines and PVs for green electricity production, the transport and heating sectors are responsible for the major CO_2 emissions on Aero. This is largely due to the use of fossil fuel-based cars and buses for transportation as well as oil burners for individual heating. To make it sustainable, the transport sector will be completely electrified by substituting fossil fuel-based vehicles with electric vehicles, and the oil burner will be replaced by district heating and electric water heating. However, these measures will lead to an increase in electricity demand. In addition, Aero aims to operate in island mode in the future without importing or exporting electricity, which poses a big challenge for the energy balance between supply and production. To address this issue, the current Aero energy systems need upgrades to be fully sustainable relying solely on renewable energy sources and operating in island mode.

`

Possible solutions for the energy system upgrading encompass electricity generation expansion and electricity storage. In this paper, several different green energy technologies suitable for the conditions of the island have been selected. However, there are remaining questions to be answered in order to find the most feasible solution for a green energy system operation for the island of Aero:

- What is the optimal capacity of the energy system?
- How to optimally operate the energy systems to balance energy production and supply?

The multi-energy systems characterize energy systems on Aero as an energy hub where energy production, storage and usage by end-users are involved. Many studies in the literature apply mathematical optimization to find the optimal design and operation of energy systems.

Pazouki et al. [3] investigated the optimal planning and scheduling of an energy hub consisting of CHP, boiler, wind turbine, and electric and thermal energy storage systems. They formulated a mixed-integer linear programming (MILP) strategy for optimizing the energy hub under different season scenarios and analyzed the functionality of each subsystem in the energy hub in terms of delivering electricity and heat demand. Wang et al. [4] developed the energy hub model consisting of PV, CHP, boiler, HP, battery, and thermal energy storage systems. The proposed MILP optimization achieves a significant reduction of energy cost and CO_2 emissions as compared to the system without optimization. Some other similar works on the mathematical modeling and optimization of multi-energy systems can be found in [5]–[7]. An optimization study was done before for the Danish island of Bornholm, where the energy system was simulated both on an hourly basis and then from second to second [8]. Apart from optimizing energy system operation, some studies also apply mathematical optimization to optimize the capacity of different kinds of production [9]–[11].

The objective of the paper is to achieve self-sufficiency in renewable energy and operate in island mode on Aero by 2025. In this regard, this paper proposed a hybrid scenario devising a roadmap for upgrading the current energy system. The proposed hybrid scenario combines different approaches ranging from the electrification of the transport sector, installing energy storage systems, increasing renewable energy production capacities, energy production planning, to demand-side management. Furthermore, a mathematical optimization model for hour-to-hour balancing energy supply and demand is developed to find the optimal capacities for renewable energy production units and optimal dispatching schedules for various energy systems.

The rest of the paper is structured as follows: Section 2 describes the methodology and formulation of the optimization problem. Section 3 presents and discusses the optimization results for different scenarios. Lastly, the conclusions and contributions of the work are highlighted in Section 4.

2. Methodology and problem formulation

In this section, we present the formulation of the hourly optimization problem for a one-year simulation, which is applied to the energy system on Aero to find the most feasible solution for a green energy system operation by 2025. The mathematical models of the energy system associated with their operational constraints are described first, followed by objective functions for different scenarios and collected data for simulation. The energy system models described below contain both current existing energy systems and perspective energy systems to be installed in the hybrid scenario. The selection of the perspective energy systems relies on the preliminary study carried out in [12].

2.1. Model constraints

Energy balance

The balance between electricity production and demand is constrained in Eq.(1). Likewise, the balance between heating production and demand is constrained in Eq.(2),

$$P_{T,EL}^{t} = D_{T,EL}^{t}\,, \forall t \tag{1}$$

$$P_{T,H}^{t} = D_{T,H}^{t}\,, \forall t \tag{2}$$

2.1.1. Electricity sector

Interconnection to the main grid

The electricity interconnection to the island today has a limited capacity of 100 MW. This constraint only applied to the current energy systems while the future energy systems operating in island mode will not involve the use of the interconnection.

$$-I_C \le I^t \le I_C\,, \forall t \tag{3}$$

Where the value I^t is positive during import, and negative during export.

Wind turbine

$$0 \le P_W^t \le P_{Wmax}^t \cdot F_W\,, \forall t \tag{4}$$

$$1 \le F_W \tag{5}$$

`

Where F_W is the scaling factor of the current wind capacity, allowing optimize wind turbine capacity suitable for the future energy system.

Photovoltaics (PV)

$$0 \leq P_{PV}^t \leq P_{PVmax}^t \cdot F_{PV}\,, \forall t \quad (6)$$

$$1 \leq F_{PV} \quad (7)$$

Where $F_{PV}$is the scaling factor of the current PV capacity, allowing optimize PV capacity.

Organic Rankine cycle (ORC)

The ORC has a certain capacity for heat and power, which are constrained in Eq.(8) and Eq.(9) respectively. Eq.(10) defines the maximum ratio between power and heat production.

$$0 \leq P_{ORCEl}^t \leq P_{ORCElmax}\,, \forall t \quad (8)$$

$$0 \leq P_{ORCH}^t \leq P_{ORCHmax}\,, \forall t \quad (9)$$

$$P_{ORCEl}^t \leq P_{ORCH}^t \cdot ORC\eta_{El/H}\,, \forall t \quad (10)$$

Biogas

Biogas turbine is the potential energy generation system to be installed, which makes use of biomass on Aero to produce electricity. Additionally, this requires installing a biogas plant that converts biomass to biogas first. In Eq.(11), the model is constrained so the model only uses the manure available on the island, and thus emissions in connection with the transport of biomass from outside the island are also avoided.

$$\frac{\sum_{n=1}^{8760} P_{Bio}^t}{\eta_{Bio}} \leq C_{Bio}\,, \forall t \quad (11)$$

$$0 \leq P_{Bio}^t \leq C_{Bio,C}\,, \forall t \quad (12)$$

The space heating, electric water heating and refrigerator described below are demand response unit that integrates consumers into the electricity system.

Space heating

An air-to-water heat pump is used for space heating. Eq.(13) is the model for indoor temperature dynamics, while Eq. (14) represents the constraint of the electric power of the heat pump. Eq. (15) is the indoor temperature constraint.

$$\theta_i^{t+1} = \theta_i^t - \frac{1}{C \cdot R}\left(\theta_i^t - \theta_0^t + R \cdot D_{Sp}^t \cdot COP^t\right), \forall t \quad (13)$$

$$0 \leq D_{Sp}^t \leq D_{Sp,C}\,, \forall t \quad (14)$$

$$\theta_{i,min}^t \leq \theta_i^t \leq \theta_{i,max}^t\,, \forall t \quad (15)$$

Electric water heating

Similarly, Eq.(13) is the model of water temperature in the tank.

$$\theta_{EWH}^{t+1} = \theta^t + \frac{1}{C}(-\alpha(\theta_{EWH}^t - \theta_i^t) - v^t + COP^t \cdot D_{EWH}^t), \forall t \quad (16)$$

$$0 \leq D_{EWH}^t \leq D_{EWH,C}\,, \forall t \quad (17)$$

$$\theta_{EWH,min}^t \leq \theta_{EWH}^t \leq \theta_{EWH,max}^t\,, \forall t \quad (18)$$

Refrigerator

The electricity is used in the refrigerator of each household to main favorable temperatures for food storage. The temperature inside the refrigerator has to satisfy the constraints in Eq.(19) and Eq.(21). The maximum electrical power of the refrigerator is constrained in Eq (20).

$$\theta_{ref}^{t+1} = \epsilon \cdot \theta_{ref}^t + (1-\epsilon)\left(\theta_i^t - R \cdot D_{ref}^t \cdot \eta\right), where\ \epsilon = e^{-\frac{\Delta t}{R \cdot C}},\ \forall t \quad (19)$$

$$0 \leq D_{ref}^t \leq D_{ref,C}\,, \forall t \quad (20)$$

$$\theta_{ref,min}^t \leq \theta_{ref}^t \leq \theta_{ref,max}^t\,, \forall t \quad (21)$$

There is no electricity storage available on Aero currently, the potential electricity storage considered are Li-ion battery, high temperature thermal storage and hydrogen storage. As the constraints are similar for the three storage systems, here only the constraints for Li-ion battery storage are elaborated in detail.

Li-ion battery storage

In a battery, the state of charge (SOC) must be kept consistent with the in- and outputs, which is constrained in Eq.(22). The charge and discharge are constrained in Eq.(25) and Eq.(26) to ensure the battery does not charge or discharge too quickly. In Eq.(23) the SOC is constrained between 0 and the maximum value.

`

Constraint in Eq.(24) is to ensure the SOC at the first hour of the year and last hour of the year is consistent, enabling running the storage for multiple years.

$$SOC_b^{t+1} = SOC_b^t + Ch_b^t - Dis_b^t, \forall t \quad (22)$$

$$0 \leq SOC_b^t \leq SOC_{b,C}, \forall t \quad (23)$$

$$SOC_b^1 = SOC_b^{8760} \quad (24)$$

$$0 \leq Ch_b^t \leq Ch_{b,C}, \forall t \quad (25)$$

$$0 \leq Dis_b^t \leq Dis_{b,C}, \forall t \quad (26)$$

High-temperature thermal storage

High temperature thermal storage (HTTS) belongs to both the electricity and heating sectors. It is charged with electricity, which is used to heat rocks or minerals to very high temperatures, as high as 600 °C. The heat is then used to generate steam, which runs through a turbine to produce electricity and heat.

$$SOC_{HTTS}^{t+1} = SOC_{HTTS}^t + Ch_{HTTS}^t - Dis_{HTTS}^t, \forall t \quad (27)$$

$$0 \leq SOC_{HTTS}^t \leq SOC_{HTTS,C}, \forall t \quad (28)$$

$$SOC_{HTTS}^1 = SOC_{HTTS}^{8760} \quad (29)$$

$$0 \leq Ch_{HTTS}^t \leq Ch_{HTTS,C}, \forall t \quad (30)$$

$$0 \leq Dis_{HTTS}^t \leq Dis_{HTTS,C}, \forall t \quad (31)$$

Hydrogen storage

Hydrogen storage consists of three parts, an electrolyzer, a hydrogen tank and a fuel cell. The surplus electricity production can be stored in the form of hydrogen via electrolyzing water. The stored hydrogen can be used to produce electricity in need through fuel cells.

$$SOC_{Hyd}^{t+1} = SOC_{Hyd}^t + D_{Elec}^t \cdot \eta_{Elec} - D_{FC}^t, \forall t \quad (32)$$

$$0 \leq SOC_{Hyd}^t \leq SOC_{Hyd,C}, \forall t \quad (33)$$

$$0 \leq D_{Elec}^t \leq D_{Elec,C}, \forall t \quad (34)$$

$$0 \leq D_{FC}^t \leq D_{FC,C}, \forall t \quad (35)$$

$$SOC_{Hyd}^1 = SOC_{Hyd}^{8760} \quad (36)$$

$$D_{FC}^t = P_{FC}^t / \eta_{FC}, \forall t \quad (37)$$

2.1.2. Heating sector

On Aero, approximately a third of the households are heated with individual heating, while the rest are heated with district heating.

Solar collector

Solar collectors are very similar to wind turbines and PVs in that they are limited by the solar flux and the installed capacity. However, for solar collectors, the amount of installed capacity cannot be changed, as there are already a lot of solar collectors on Aero.

$$0 \leq P_{SC}^t \leq P_{SC,C}^t, \forall t \quad (38)$$

Straw boiler

$$0 \leq P_{DHB}^t \leq P_{DHB,C}^t, \forall t \quad (39)$$

District heating heat pump

$$0 \leq P_{DHHP}^t \leq P_{DHHP,C}^t, \forall t \quad (40)$$

$$D_{DHHP}^t \cdot COP_{DHHP}^t = P_{DHHP,}^t, \forall t \quad (41)$$

Seasonal heat storage

Aero currently equips a pit thermal storage for seasonal heat storage. The pit storage is a water reservoir and it uses a heat pump to discharge the heat. The maximum state of charge ($SOC_{SS,C}$) of the seasonal heat storage is 6.638 MWh.

$$SOC_{SS}^{t+1} = SOC_{SS}^t + Ch_{SS}^t - Dis_{SS}^t - H_L, \forall t \quad (42)$$

$$0 \leq SOC_{SS}^t \leq SOC_{SS,C}, \forall t \quad (43)$$

$$SOC_{SS}^1 = SOC_{SS}^{8760} \quad (44)$$

`

$$0 \leq Ch_{SS}^{t} \leq Ch_{SS,C}\ , \forall t \quad (45)$$

$$0 \leq Dis_{SS}^{t} \leq Dis_{SS,C}\ , \forall t \quad (46)$$

2.1.3. Transport sector

Passenger electric vehicles and electric buses are not installed in Aero currently, while E-ferry is already running. They all serve as electric batteries with specific charging and discharging patterns.

Passenger electric vehicles

The specific electric car "Renoult Zoe" is used, which has a 53 kWh battery and a 400 km driving distance. All cars are assumed to be in use every morning at 7 am, when people go to work, and ready for charging again from 5 pm when they get home, until the next morning. It is assumed that 20% of cars drive 5 km twice every day and the owners have a charging box at home, with a capacity of 11 kW.

$$SOC_{AllEV}^{t+1} = SOC_{AllEV}^{t} + D_{AllEV}^{t} - Dis_{AllEV}^{t}, \forall t \quad (47)$$

$$0 \leq D_{AllEV}^{t} \leq D_{AllEV,C}\ , \forall t \quad (48)$$

$$0 \leq SOC_{AllEV}^{t} \leq SOC_{AllEV,C}\ , \forall t \quad (49)$$

Buses

Two public buses on Aero run the same route but from mirrored starting points. Each route takes approximately one hour and there is time for the buses to charge for 5 minutes after the completion of each route. The buses can charge completely during the night.

$$SOC_{bus}^{t+1} = SOC_{bus}^{t} + D_{bus}^{t} - Dis_{bus}^{t}, \forall t \quad (50)$$

$$0 \leq D_{bus}^{t} \leq D_{bus,C}\ , \forall t \quad (51)$$

$$0 \leq SOC_{bus}^{t} \leq SOC_{bus,C}\ , \forall t \quad (52)$$

Electric ferry (E-ferry)

The ferry starts at 6 in the morning, makes six round trips per day, and has 32 mins in Aeroskoebing between trips to charge if needed, returning to Aeroskoebing at midnight. The e-ferry has a large battery of 4.3 MWh. The charger in Aeroskoebing has a capacity of 4.2667 MW.

$$SOC_{EF}^{t+1} = SOC_{EF}^{t} + D_{EF}^{t} - Dis_{EF}^{t}, \forall t \quad (53)$$

$$0 \leq D_{EF}^{t} \leq D_{EF,C}\ , \forall t \quad (54)$$

$$0 \leq SOC_{EF}^{t} \leq SOC_{EF,C}\ , \forall t \quad (55)$$

2.2. Objective functions

This section details objective functions for various scenarios investigated in this paper. Overall, the objective functions are the same targeting minimizing the cost, enabling comparison of different scenarios. But they are subject to different constraints in accordance with the considered technologies for a specific scenario.

Business as usual (BAU) scenario

In order to compare the proposed hybrid scenario with the current energy systems on Aero, a business as usual (BAU) scenario was created resembling the current system, which will be the reference scenario for performance evaluation. The objective function of the BAU scenario is to minimize the costs consisting of variable costs, fixed operational costs and investment costs.

$$minimize \sum_{n=1}^{N} (C_V^n \cdot U^n) + \sum_{n=1}^{N} (C_I^n + C_F^n) \cdot C^n$$

$$s.t.\ Eq.(1-4), (6), (8-10), (13-21), (38-46), (53-55)$$

Where *n* denotes different technology, the variable costs (C_V^n) for each technology are multiplied by the use (U^n) of that technology. The fixed operational costs (C_F^n) and investment costs (C_I^n) for each technology are multiplied by the capacity (C^n) of that technology.

Hybrid scenario

As compared to BAU scenario, hybrid scenario has expanded wind turbines and PVs capacity, installed biogas turbines, electrified all buses and personal vehicles, eliminate the use of cable for connection to the mainland grid, added new energy storage systems including Li-ion battery storage, high temperature thermal storage and hydrogen storage. The objective function of hybrid scenario is to minimize the costs as well, which is the same as that of BAU scenario.

`

$$minimize \sum_{n=1}^{N}(C_V^n \cdot U^n) + \sum_{n=1}^{N}(C_I^n + C_F^n) \cdot C^n$$

$$s.t.\ Eq.(1-2),(4-55)$$

Furthermore, extensions of the hybrid scenario were also investigated to see how the system changes under different conditions. Among them, the second ferry, exporting surplus electricity, and PtL technology are investigated.

Hybrid+2Ferry scenario

Currently, Aero has several ferry routes to the mainland and other islands, but there is only one electric ferry available between Soeby and Fynshavn. Therefore, it is interesting to investigate the possibility of replacing more of them with e-ferries. In hybrid+2Ferry scenario, the objective function is still minimizing the costs, subject to the same constraints in hybrid scenario, except that additional constraints for the second ferry are added.

Hybrid+Export scenario

Though Aero aims to operate energy systems in island mode, it is still worth investigating the potential economic benefits of selling surplus renewable electricity production to the mainland grid. In hybrid+Export scenario, the objective function is the same as that of the hybrid scenario, and the constraint for interconnection is included, allowing the export of electricity.

Hybrid+PtL scenario

The hybrid scenario does not consider green fuels for heavy transport since it is not yet the goal for the municipality by 2025. In continuation of this, complete sustainability is the aim for 2030, where elements like heavy transport must be considered through the Power-to-Liquid process. Hybrid+PtL share the same objective function as that of the hybrid scenario, but is subject to additional constraints for jet fuel and methanol production as shown in Eq. (56-63):

$$D_{FT}^t \cdot \eta_{FT} = P_{FT}^t\ ,\ \forall t \tag{56}$$

$$\sum_{t=1}^{T} P_{FT}^t = D_{jet}^{Annual} \tag{57}$$

$$0 \le P_{FT}^t \le P_{FT}^{max},\ \forall t \tag{58}$$

$$0 \le P_{FT}^{max} \tag{59}$$

$$D_{MeOH}^t \cdot \eta_{MeOH} = P_{MeOH}^t,\ \forall t \tag{60}$$

$$\sum_{t=1}^{T} P_{MeOH}^t = D_{MeOH}^{Annual} \tag{61}$$

$$0 \le P_{MeOH}^t \le P_{MeOH}^{max},\ \forall t \tag{62}$$

$$0 \le P_{MeOH}^{max} \tag{63}$$

2.3. Data collection and implementation

To perform optimization, some essential data needs to be collected apart from the data for technology size and operating limitations. These data are outdoor temperature, solar irradiance, wind data profile, the electricity spot price, electricity demand and heating demand. One-year data (in the year 2018) is collected in a resolution of an hour. Note that the hourly electricity demand and heating demand for Aero cannot be found specifically. Hence, the electricity demand was estimated by scaling down the total electricity demand for Denmark to fit the size of Aero, and the heating demand was estimated by scaling down the total heating demand for Odense to fit the size of Aero. Figure 1 illustrates the derived electricity and heating demand.

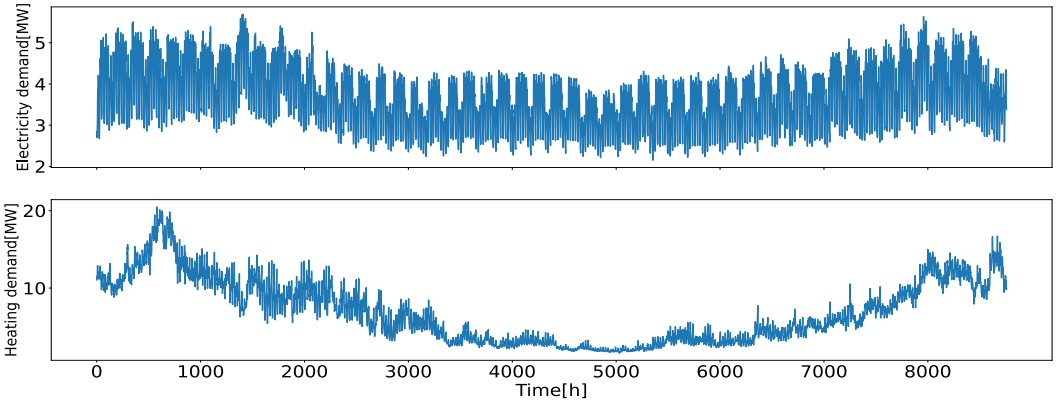

Figure. 1. Electricity and heating demand for Aero.

`

The optimization was implemented in Matlab [13] using the package Yalmip [14], and the optimization problem was solved using “Linprog” solver for linear programming.

The expected outcomes of the optimization are the optimal capacity for existing PV and wind turbine expansion, the optimal capacity of the potential energy units, and the optimal dispatching schedule for each energy system involved.

3. Results and discussions

In this section, the optimization results of different scenarios are presented. Table 1 summarizes the main capacities of different energy systems in the investigated scenarios. As shown in the BAU scenario, the current wind turbine and PV capacities are 12 MW and 1.232 MW, respectively, while their capacities increase in the other four scenarios due to the increasing electricity demand. To better visualize the energy flows from the production side to the storage and end-user side, the corresponding Sankey diagram for each scenario is provided and discussed.

Table 1. Capacity overview of different scenarios

Capacity	Unit	BAU	Hybrid	Hybrid+2Ferry	Hybrid+Export	Hybrid+PtL
Interconnection (Import/Export)	[MWh]	11273/16305	/	/	Export: 519814.8	/
Wind capacity	[MW]	12	15.8	18.7	153.2	37.1
Wind production	[MWh]	38499	28568.4	30771.1	386351.0	115051.1
PV capacity	[MW]	1.232	15.4	18.9	164.0	34.7
PV production	[MWh]	1642.9	13813.4	16228.6	178797.1	39673.5
Li-ion capacity	[MWh]	/	4.4	5.6	0.28	0.20
HTTS capacity	[MWh]	/	0	0	0	0
Hydrogen capacity	[MWh]	/	0	0.45	0	0
Biogas turbine	[MW]	/	3.9	4.1	4.3	4.5
Jet fuel production capacity	[MW]	/	/	/	/	2.22
Methanol Production capacity	[MW]	/	/	/	/	5.99

3.1. BAU scenario

As shown in Figure 2, the current energy systems in Aero consume a large amount of fossil fuels for personal vehicles and household heating. The heating sector in Aero consists of around 1/3 individual heating and 2/3 district heating. The straw boiler, solar collector, ORC unit and seasonal storage supply a lot of district heating. District heating is close to using 100% renewable energy sources, depending on whether the electricity consumed in the heat pump comes from renewable energy sources or the mainland grid.

In BAU scenario, the importing and exporting of electricity happen frequently throughout the year to secure an hour-to-hour balancing of electricity demand and production. The total exporting electricity is higher than the total importing electricity, indicating there are many situations of having excess renewable electricity production, which necessity electricity storage for flexibility.

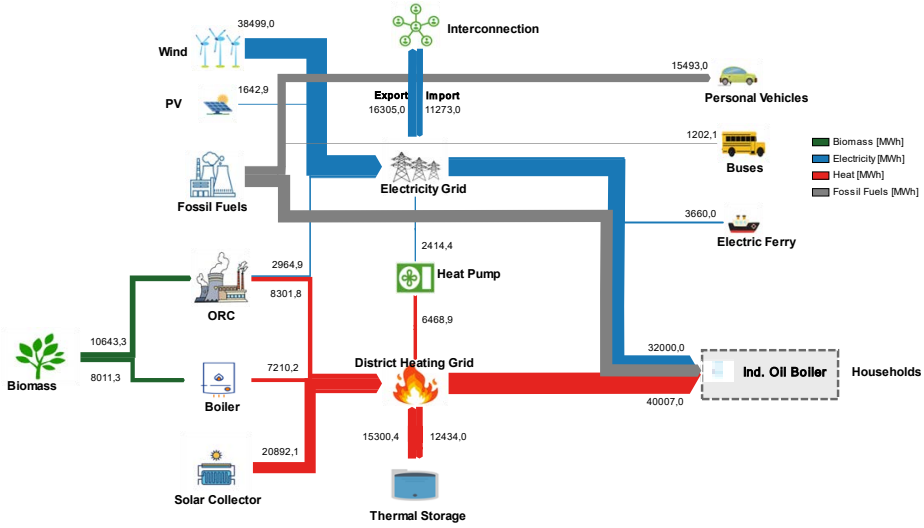

Figure. 2. Energy flows in BAU scenario.

`

3.2. Hybrid scenario

Figure 2 illustrates the energy flow in hybrid scenario. As compared to BAU scenario, the interconnection is no longer available in hybrid scenario. The wind turbine capacity increases slightly, while the PV capacity increases more than 10 times. Hybrid scenario recommends installing a biogas turbine with a capacity of 3.9 MW. Concerning storage, a 4.4 MW Li-ion battery is included while the HTTS and hydrogen storage are not used. To run primarily on RES and storage, a very large amount of storage is needed for long periods when production is needed. However, this can be done far more easily with controllable production, in this case, the biogas turbine. This is far better since the storage of biogas or manure is far easier than storing hydrogen or electricity in a battery.

The demand for vehicles and individual heating is lower in hybrid scenario than that of BAU scenario. This is because the efficiencies of combustion engines and boilers used in BAU scenario are much lower than electric motors and heat pumps used in hybrid scenario, resulting in larger fuel demand.

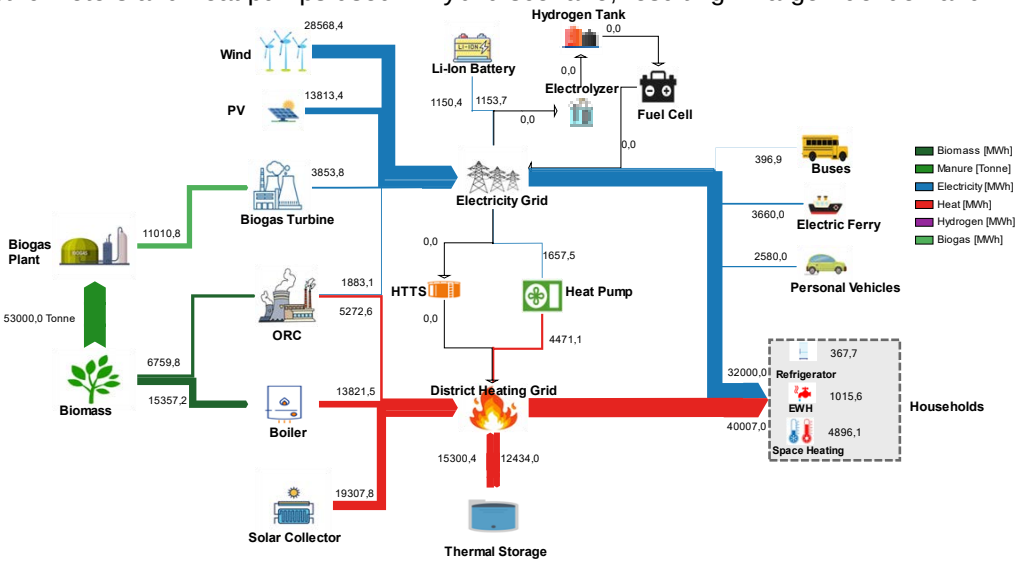

Figure. 3. Energy flows in hybrid scenario.

3.3. Hybrid+2Ferry scenario

The energy flow in the scenario with an additional e-ferry is seen in Figure 4, and the capacities can be seen in Table 1. The new ferry requires some extra electricity demand, leading to an increase in the capacity and production from renewable energy sources (RES) as compared to hybrid scenario. Furthermore, this increased demand also means that more long-term storage is suddenly needed, which means that hydrogen storage is included in a small capacity (0.45MWh). It is the only scenario that hydrogen storage is used among the investigated five scenarios and the Li-ion storage capacity also increases slightly compared to hybrid scenario. The barely used hydrogen storage in most scenarios is due to the high investment and operational cost, which is economically cost-ineffective.

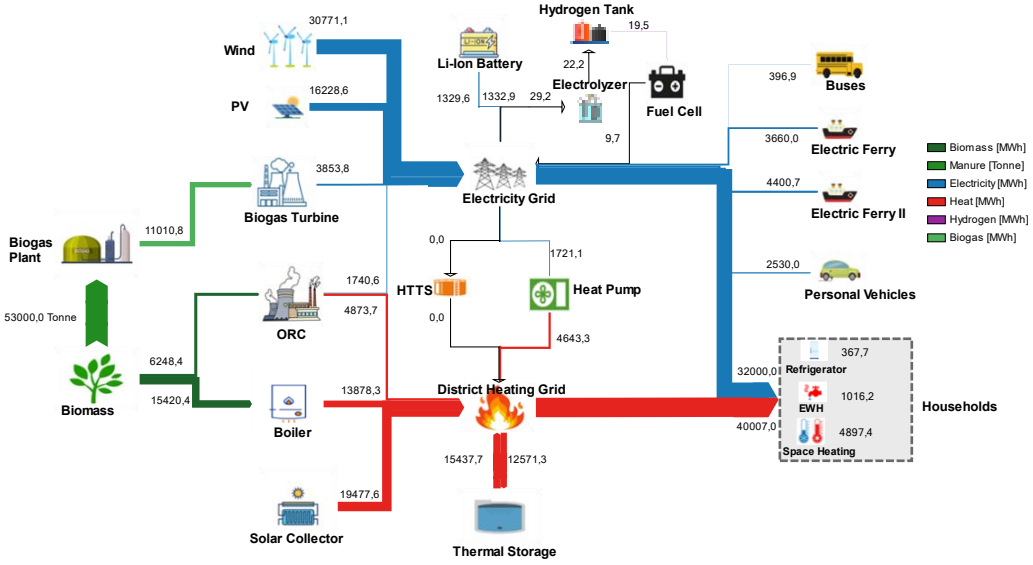

Figure. 4. Energy flows in hybrid+2Ferry scenario.

`

3.4. Hybrid+Export scenario

It is clear from Table 1 and Figure 5 that allowing exporting surplus electricity changes the system significantly, and that making money from selling excess production to the grid is very much possible for most of the hours of the year. The RES capacities can be extremely high because production can be exported, and they can cover most of the demand. However there are still hours without wind or sun, therefore the battery, ORC unit and biogas turbine are necessary. The battery storage is used less than in other scenarios as the system prioritizes selling the surplus electricity for profits, resulting in a very small battery capacity (0.28MWh).

Hybrid+export scenario seems good as it benefits from selling electricity, but the model is based on current electricity prices. In the future, there will be an increasing amount of RES in the Danish system, which will most likely decrease the possibilities for profits from selling it. Furthermore, Aero is a small island with attractive nature and vacation homes, which creates a lot of resistance to building objects that damage the view, it is, therefore, infeasible to build that much wind turbine and PV capacity.

The hybrid+Export does not comply with the goal of island mode operation on Aero by 2025. But in the case that the demand on the island is met and there is still potential to produce a lot of green electricity, it would be ideal to export this electricity. In this way, the national main grid will benefit from the green electricity that would otherwise have been lost.

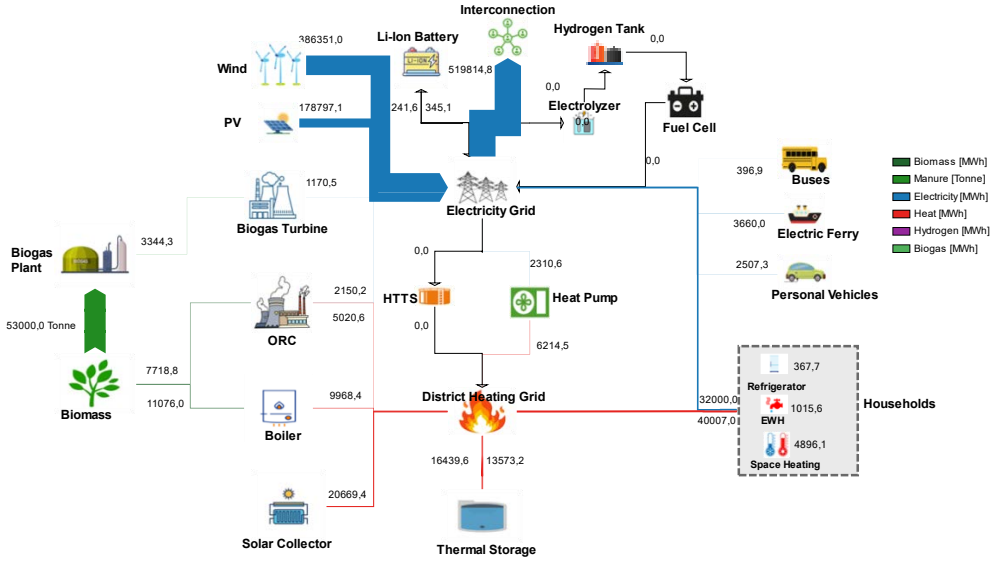

Figure. 5. Energy flows in hybrid+Export scenario.

3.5. Hybrid+PtL scenario

As shown in Figure 6 and Table 1, involving Power to Liquid in the system changes the system considerably as compared to hybrid scenario, though the changes are not as significant as hybrid+Export scenario. Since the efficiency of PtL process is low, the demand for electricity increases substantially. The RES production needs to fit the high demand. Therefore, a huge capacity of RES is needed in this scenario.

Hybrid+PtL scenario has no HTTS, no hydrogen storage, and a small Li-ion battery storage (0.2MWh), indicating the RES capacities in this scenario are almost fully utilized by end-users. This is because the PtL can almost always use the produced electricity. The PtL capacities are also relatively large. The results show that the PtL is not only an extra demand but is very useful for balancing the system.

3.6. Techno-economic evaluations

To quantitatively evaluate the technical feasibility and economic benefits of each scenario before real implementation in practice, the two key performance indicators (KPIs) are calculated and presented in Table 2. The metric of renewability is defined in Eq. (64), which reflects the share of renewable energy production over the total energy input for the island. It is assumed that the imported electricity is 100% based on fossil fuels. For Hybrid, Hybrid+2Ferry, Hybrid+Export, and Hybrid+PtL scenarios, the term "$I_{Imp} + P_{fossil}$" is zero, resulting in 100% renewability. However, only 55.77% of energy demand is supplied by renewable energy sources for the BAU scenario, which justifies applying a hybrid scenario to realize self-sufficiency in renewable energy.

$$Renewability\ \% \ = \ 1 - \frac{I_{Imp}+P_{Fossil}}{I_{Imp}+P_{Fossil}+P_{Wind}+P_{Bio}+P_{PV}+P_{ORCel}+P_{ORCheat}+P_{Boiler}+P_{SC}} \quad (64)$$

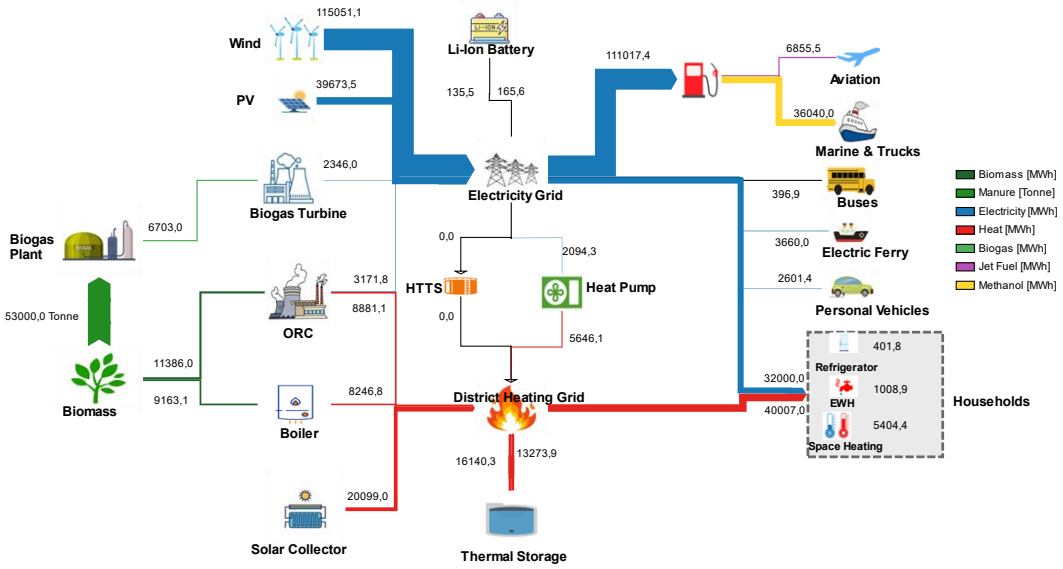

Figure. 6. Energy flows in hybrid+PtL scenario.

The total cost is calculated based on the annualized investment costs considering its lifetime, variable costs, and fixed operational costs. Then, the individual cost [DKK/month/person] is calculated and presented in the table, corresponding to what each citizen on Aero must pay to run the system.

As shown in Table 2, the lowest cost is achieved in the hybrid scenario, while hybrid+PtL exhibits the highest cost due to the expensive Power-to-Liquid unit. Therefore, the hybrid scenario is the final recommended scenario for the energy system upgrade roadmap for Aero by 2025 considering both technical feasibility and economic benefits.

Figure 7 shows the cost breakdown for each system. It can be seen that infrastructure cost accounts for the major part of total cost in all investigated scenarios except for the hybrid+Export scenario, where cost by renewable energy production predominates. This is because hybrid+Export scenario encourages selling electricity to the mainland grid for earnings, resulting in higher RES production and high cost for RES facility expansion. Note that infrastructure is an aggregate item consisting of several elements such as expenses for electric vehicles, buses, ferry, individual heating, and demand response units.

The results show that installing an additional ferry is the most beneficial approach to improve the hybrid scenario's performance among hybrid+2Ferry, hybrid+Export, and Hybrid+PtL scenarios. Even though hybrid+Export results in less cost, it is not advised as it violates the goal of island mode operation.

Table 2. Summary of the KPIs for different scenarios

KPIs	Unit	BAU	Hybrid	Hybrid+2Ferry	Hybrid+Export	Hybrid+PtL
Renewability	[%]	55.77	100	100	100	100
Cost	[DKK/month/person]	1689.6	1625.9	2035.6	1680.3	2430.3

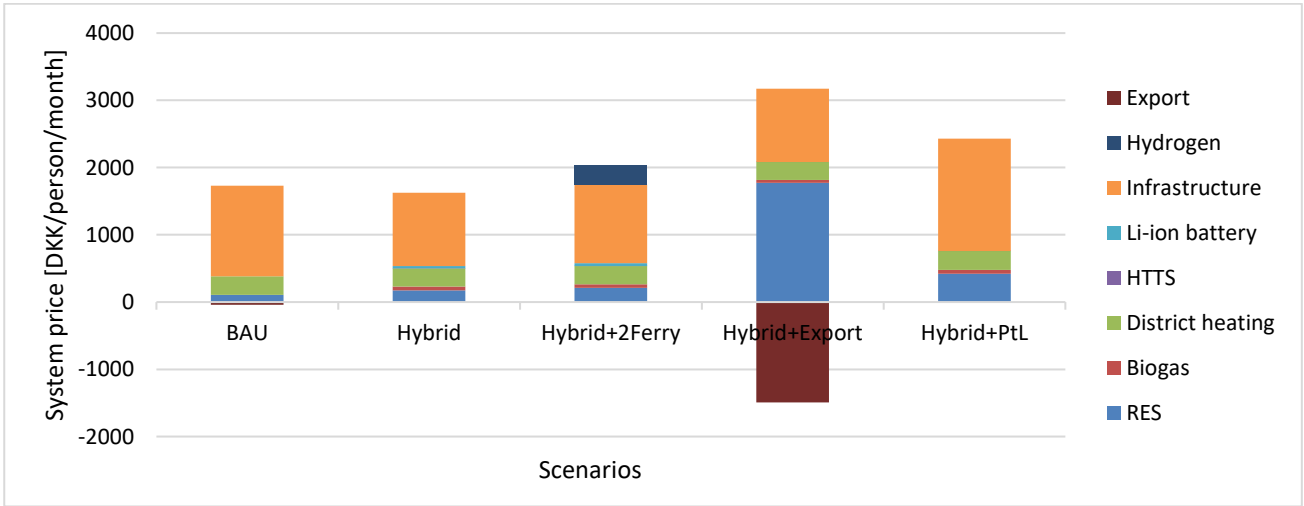

Figure. 7. Cost breakdown for all scenarios

`

4. Conclusion

This paper aims to find a feasible solution for a Danish island Aero to be fully sustainable relying solely on renewable energy sources and operating in island mode by 2025. To that end, a hybrid scenario, as a combination of different technologies including electrification of the transport sector, installing energy storage systems, expanding renewable energy production capacities, energy production planning, and demand-side management, is proposed. A linear programming optimization problem is formulated in accordance with the hybrid scenario to optimize the energy system capacity and energy system operation.

The proposed hybrid scenario performance is analysed and compared to a business-as-usual (BAU) scenario, where the energy system remains unchanged but the energy system operation is optimized. A techno-economic approach is used to quantitatively evaluate the system's performance in terms of renewability and costs. The hybrid scenario yields 100% renewability and 1625.9 DKK/month/person, while the BAU scenario achieves 55.77% renewability with a higher cost of 1689.6 DKK/month/person. Thus, the established hybrid scenario should be seen as an achievable green energy system for the island in 2025, with various options for development. Among them, extensions of the hybrid scenario by including the second ferry, exporting excess electricity, and installing Power-to-Liquid units are investigated and compared, the results show that including the second ferry is the most beneficial approach to improve the hybrid scenario's performance, with a cost of 2035.6 DKK/month/person.

Nomenclature

P	energy production, MW
D	energy demand, MW
I	interconnection to the main grid, MW
F	scaling factor, -
SOC	state of charge, -
COP	coefficient of performance, -
ORC	the Organic Rankine Cycle unit
C	thermal capacitance, J/K
R	thermal resistance, K/W
v	hot water consumption, MW
Ch	charge power, MW
Dis	discharge power, MW

Greek symbols

η	efficiency, -
θ	temperature, °C

Subscripts and superscripts

t	number of hours during a year
i	indoor air
W	wind turbine
C	maximum capacity
PV	photovoltaics
Sp	space heating
EWH	electric water heating
ref	refrigerator

`

$ORCEL$	electricity output of the Organic Rankine Cycle
$ORCH$	heat output of the Organic Rankine Cycle
Bio	biogas turbine
b	li-ion battery
$HTTS$	high temperature thermal storage
Hyd	hydrogen storage
FC	fuel cell
$Elec$	electricity demand of the electrolyzer
SC	solar collector
DHB	district heating straw boiler
$DHHP$	district heating heat pump
SS	seasonal heat storage
EF	electric ferry

Abstract:
Energy modeling has been playing a crucial role in defining solutions for effective energy planning. Bottom-up energy system planning models, namely those models characterized by high technological detail, typically present exogenous techno-economic parameters which rely on data gathered by the user, from specific costs to efficiencies. However, poor to no attention has been given to the date to the financial parameters of energy models, which are often assumed and barely justified (e.g., “discount rate equal to 10%”, full stop). Still, model outputs are drastically sensitive to variations of finance-related parameters and must provide the financing structure that a decision-maker should implement for funding the advised energy planning strategies. This results particularly crucial for mini-grid sizing in sub-Saharan African countries, where the challenge of the energy transition entails the construction of massive new capacities to improve energy access rates and tiers of service, demanding an enhanced collaboration between private and public sectors. The case study, applied on an off-grid mini-grid in Mozambique, proposes a comparison between scenarios with increasing financial detail and a possible conceptualization of the hard link between detailed financial modelling and a bottom-up energy model for mini-grid optimization. Different financing schemes are modelled and their impact on the energy modelling outputs assessed. Project finance hence emerges as a useful approach that could upgrade the financing structure of domestic power projects in African countries. This may lead to many benefits: more sustainable and affordable interest rates where corporate finance is missing, improved risk management, diversified funding mix, and facilitated financial support from international institutions.

Keywords:
Mini grid; energy planning; financing schemes; access to energy; Mozambique; project finance.

1. Introduction

The electrification of rural areas in developing countries is a critical challenge for achieving sustainable development goal 7 (SDG7) of United Nations’ Agenda 2030 [1], aimed to assure access to electricity and to clean fuels and technologies for all by 2030. Despite the significant progress that has been made in recent years, with global access to electricity rising from 83% in 2010 to 91% in 2020, still the 80% of world’s people without access to electricity lived in rural areas in 2020 [2]. This results in limiting the ability to develop local economies and reducing their chances of improving living standards. On the one hand, new technological solutions for decentralized generation such as mini-grids are increasing their viability for last-mile electrification [3], providing high standards of service for densely populated rural areas [4]. The use of such solutions grew significantly between 2010 and 2019: the number of people with access to decentralized solutions, including solar home systems and mini-grids, more than tripled, rising from 12 million in 2010 to 39 million in 2019 [2]. Alongside this, a large community of energy modellers specifically focused on the optimal sizing of decentralized solutions has raised in the last decade, bringing to several models and approaches for their effective planning [5,6]. On the other hand, new business models [7] and financing schemes [8] are emerging, evidencing the need of private sector involvement for fostering off-grid electrification. According to several scholars [5,9] and international organisations [10–12], the profitability and the attractiveness of investment in mini-grid solutions still remains one of the key barriers for their definitive market upscaling in developing countries, characterised by limited resource, governance and infrastructure. Moreover, as sub-section 1.3 will detail, there is an increasing interest, both at academic research and at international institutions levels, to understand to which extent assumptions on financial parameters affect the ouput of energy modelling scenarios. In fact, these parameters are crucial to provide the financing structure that a public or private decision-maker should implement for funding the advised energy planning strategies.

This paper proposes a modelling exercise able to test the suitability of different financing structures for triggering virtuous financing markets for mini grids in Mozambique. The methodology adopted will advance a possible conceptualization of the hard link between financing structures and a bottom-up energy model for

mini-grid sizing, thus assessing the impact of financial parameters on the energy modelling outputs. The first introductory sub-sections of the work have the scope of framing the problem of mini-grid financing in relation to mini-grid sizing. First, the state-of-art of mini-grid financing in Africa is briefly investigated, providing references and a non-exhaustive overview of the trends of the sector. Existing financing structures are hence introduced into the discussion. Second, sub-section 1.2 is devoted to summarising the state-of-art of energy modelling for mini-grid sizing in African contexts. The research gap is then identified in sub-section 1.3, where claims from recent literature are reported to push for the increase of financial detail in energy modelling research. The rest of the paper is structured as follows: section 2 details the modelling methodology adopted, inclusive of energy and financial modelling; section 3 draws the case study of Ndoro village in the Caia district of Sofala Province Mozambique; results are then discussed critically in section 4; finally; section 5 concludes the work providing outlooks derived from the exercise.

1.1. Financing mini grids in Africa

Even though mini-grids already represent a least-cost option for delivering high tiers of energy services in many contexts [4], the existing mini-grid sector in sub-Saharan Africa (SSA) is characterized by early-stage market fragmentation, lack of competition, high transaction costs, perceived investment risks, and high cost of capital. According to a market report by the Mini-grids Partnership [13], in 2020 a total of 5544 mini-grid projects have been mapped as installed and operative among Asia (60% of the total), SSA (39%), Island nations (1%) and Latin America (0.4%). Of these, more than 60% were powered by solar or solar-hybrid energy, the 21% exclusively by hydropower, the 11% by fossil-fuels and the remaining by biomass, wind, or other energy sources. Despite the very reduced current market, the suitability of mini-grid solutions towards universal access to electricity has been reproved by the International Energy Agency (IEA) in the Sustainable Africa Scenario (SAS) of the last Africa Energy Outlook [11]. In this scenario, aimed to give access to electricity to 90 million people in Africa each year on average from 2022 to 2030, the 32% of the new connections are established via renewable mini-grids and the 21% via renewable stand-alone systems. The Outlook shows how mini-grid systems could constitute a profitable business for small private companies in small and isolated communities, which would remain out of electrification policies planned by the national grid operators. However, according to Williams et al. [9], there are three main financial challenges for their definitive market upscaling: revenue insecurity, due to the capital-intensive nature of electrification investments and to the associated high costs of unincentivized energy tariffs, unaffordability to consumers, related to the spread inability to pay, and reduced access to finance, due to the poor local investment climate mostly associated to perceived risks.

The immaturity of the mini-grid market in Africa is reflected by the typical structure of financing of these systems. Traditional financing of power projects, including plans for off-grid electrification, usually sees the participation of the national government, through its national energy ministry or agency, as the major funder. The main source of the investment usually comes from the governmental development budget or from aided borrowing by multilateral and bilateral development agencies. In the current situation, the participation of the private sector is therefore very limited: it is involved at the stages of construction and first running of the power plant, but the property (and the associated risk of investment) is still owned by a national public utility, in most of the cases. In general, two types of financing can be employed in the mini-grid market for structuring a new investment:

Table 1. Types of financing in the African mini-grid market.

Type of financing	Description
Debt	Debt financing consists in the mini-grid developer borrowing capital from lenders such as banks, privates, or other financial institutions to fund the project. Debt must then be repaid at an agreed cost, called return on debt or interest rate, and within a certain time horizon, called maturity of debt. Debt repayment is generally independent from the performance and prioritary to equity repayment. As Smith summarises in his book [14], debt lenders that currently invest in African countries markets can be grouped into: private commercial lenders (domestic or international), foreign countries, African state-owned firms, multilateral commercial banks, and export-import banks. However, debt financing remains widely untapped in the mini-grid market due to its low attractiveness and bankability. As a result, rates of return on debt are still high: locally sourced debt often reaches interest rates up to 20% in SSA [9], but for the mini-grid market this figure can increase up to 30% for countries such as Sudan and Somalia [15].

Equity	Financing by equity means that the mini-grid developer invests his own capital available (i.e., the residual cash flows from existing assets) into a new asset, namely the mini-grid infrastructure. Equity can also be supported by project promoters such as local banks who, in case of attractive projects, can enter the investment as shareholders. Equity is therefore derived from the company's shareholders' capital, which will be repayed according to a rate of return on investment called return on equity. Apart from private capitals, equity investors in mini-grids market in developing countries are mainly development finance institutions (DFIs) and impact investors [13]. It is worth mentioning that the return on private equity is usually high since it embeds several upfront uncertainties on the success of the investment, especially for high-risk projects such as mini grids in developing countries. For this reason, it is usually supported in blended finance with grants.

Grant financing can support both equity and debt. Donors (international institutions, regional development banks, governments through national cooperation agencies, private foundations, etc.) provide grants in highly concessional forms, meaning to null (donation) or negligible rate of return. This is the most common type of funding for the mini-grid sector in SSA and can subsidize the investment in various ways: reducing the upfront capital requirements, ensuring revenues and limiting their volatility, and reducing the interest owned to the debt provider [16], in case of blended commercial lending. Currently, two types of grants are adopted in mini-grid financing structures [13]: upfront grants (usually blended with equity from the developer or shareholders) and result-based financing grants (a type of public-private partnership including a commercial lender as third party between a public institution and private developer).

Finally, it is relevant to highlight that the technical solution chosen for a local electrification plan strongly influences the cost of capital and the possible financing structure. As Agutu et al. [15] argued, mini grid solutions represent a infrastructure-based system and imply a high initial investment. Their strong dependence on the local regulatory framework and on the political setting of the country makes them perceived as riskier with respect to stand-alone systems, thus requiring longer maturities and higher return rates and costs of capitals. Moreover, the specific components that constitute a mini grid system (i.e., PV panels, diesel generators, battery banks, hydropower turbines, wind turbines, etc.) have very diverse cost structures [17]: renewable energy technologies imply high initial investment cost, whereas fossil fuels-powered technologies will have greater operation and maintenance costs. As this study will reprove, the least-cost sizing of the mini-grid is relevantly affected by the cost structure of its components and especially by how the associated investment and operating costs will be paid back (i.e., by the financing structure chosen).

1.2. Energy modelling for off-grid planning

Energy modelling has proved, over the last 20 years, to be growing in relevance on providing evidence based and scientifically solid insights for energy strategy formulation [18]. Thanks to energy modelling it is possible to develop energy scenarios, assess the potential impact of the penetration of technologies in the market and identify optimal strategies to achieve energy related goals. However, as Debnath et al. highlighted in 2018 [19], the entirety of the existing energy system models originated in developed countries, and for this reason, some key issues that affect the developing world's energy systems are not considered in such models. Among such issues, the author's identifies lack of reliable data, and the issue of access to energy, urging for more attention dedicated to modelling suppressed demand and the socio-political feedbacks of developing countries.

Especially when it comes to mini-grid sizing and off-grid energy planning, a more specific set of challenges exists [5], the main reason for that being that off-grid energy system are not purely a technological challenge, but above all a social challenge, as the main goal of developing off-grid systems for access to energy is to trigger local development [20], which is complex phenomenon to include into modelling frameworks [21]. A set of specific models has been developed along the years for supporting off-grid energy planning [22], and can be classified into two categories: i) Off-Grid Strategy Selection Models, and ii) Off-Grid System Sizing Models. As for the second category of models, Akbas et al. [22] categorise them into models aiming to provide: optimal system configuration and unit sizing, optimal power dispatch strategy, and optimal network design. The present study specifically addresses the first two issues, involving the selection of types of energy resources and least-cost sizing of mini grid system components, which become crucial when considering costs and impacts of a project for rural electrification. Optimal power dispatch will come together with system configuration since the optimization will be run on the hourly availability of resources.

1.3. Research gap and article's scope

Recent literature has been highlighting how energy models must be tailored to the african specific context [19,23], specifically highlighting the diffused disregard of the cost of capitals for financing energy access

options in the energy modelling discipline [5,15,24,25]. This absence brings to a general neglection of the impacts of financial parameters on the outputs of energy modelling exercises and eventually devaluates the research evidence that may outcome to support policy and decision makers. A contribution by Lonergan et al. [26] critically reviewed how the cost of capital is accounted in existing energy system models and found that, even though most existing models still rely on own assumptions and on expert elicitation for selecting an exogenous cost of capital, the literature trend is directing towards academic reference values, project data and financial data. This encouraging trend suggests that the energy modelling community is becoming more and more aware of the impact of the cost of capital to the model results. The International Energy Agency (IEA) is also moving in this sense: a "cost of capital observatory"[1] has been launched in 2022 to collect and update data on the cost of capital of renewable energy projects, with a specific focus on some developing countries. This work has the scope of complementing the existing literature providing a simple approach to expand the hard link between energy and financial modelling on the local scale. A new hybrid modelling methodology is hence proposed to reflect the financing structures of a mini grid investment.

2. Modelling methodology

2.1. Financial modelling approach

The financial modelling approach adopted in this work introduces some essential features of financial analysis for pushing beyond the traditional approach present in energy modelling. The modelling of the cost of capital is here presented to substitute the discount rate with the Weighted Average Cost of Capital (WACC). From this parameter, scenarios on the financing structures of the investments are produced.

2.1.1 Weighted Average Cost of Capital (WACC) and Leverage (L)

This parameter represents the cost of capital invested in the project averaged on its financing structure and can be intended as the minimum return over which the investment becomes profitable, given a certain structure. It must hence be minimized as much as possible. It is here defined as in Steffen [27] formulation:

$$WACC = R_D * (1 - t) * \frac{D}{D+E} + R_E * \frac{E}{D+E} \quad (1)$$

Where the following definitions and units of measure hold:

D	Total level of debt	[kUSD]
E	Total level of equity	[kUSD]
R_D	Cost of debt (i.e., the interest rate)	[-]
R_E	Cost of equity (i.e., the return required by the equity shareholders)	[-]
t	Corporate tax deduction (debt is assumed as tax deducible)	[-]

Two complementary definitions follow in Eq. (2) and Eq. (3). To this work, the total asset value of the investment is defined as the sum of debt and equity invested in the project:

$$V = D + E \quad (2)$$

An additional parameter to be introduced is the Leverage ratio, also known as the debt-to-equity ratio. This parameter gives a proxy of the risk perceived by investors, or viceversa as the attractiveness of the investment to external debtors.

$$L = D/E \quad (3)$$

The Leverage ratio varies between 0 (the project is fully financed by equity) and +∞ (the project is fully financed by debt). According to the definitions provided in Eq. (2) and Eq. (3), Eq. (1) can be reformulated as a function of the Leverage ratio, thus bringing to Eq. (4):

$$\begin{cases} \frac{D}{D+E} = \frac{1}{1+\frac{E}{D}} = \frac{1}{1+\frac{1}{L}} = \frac{L}{1+L} \\ \frac{E}{D+E} = \frac{1}{1+\frac{D}{E}} = \frac{1}{1+L} \end{cases}$$

[1] https://www.iea.org/data-and-statistics/data-tools/cost-of-capital-observatory

$$WACC = R_D * (1-t) * \frac{L}{1+L} + R_E * \frac{1}{1+L} \quad (4)$$

$$WACC = f(L)$$

Eq. (4) represents the Weighted Average Cost of Capital as a function of the Leverage ratio (or debt-to-equity ratio), varying between 0 and 1. This explicit formulation allows to represent R_D, R_E and t as parameters, while L will be kept as the only variable of the financial model. It is worth noticing that being the leverage L in a [0; +∞) domain, WACC varies depending on the parameters above mentioned, and can be qualitatively depicted as in **Figure 1**.

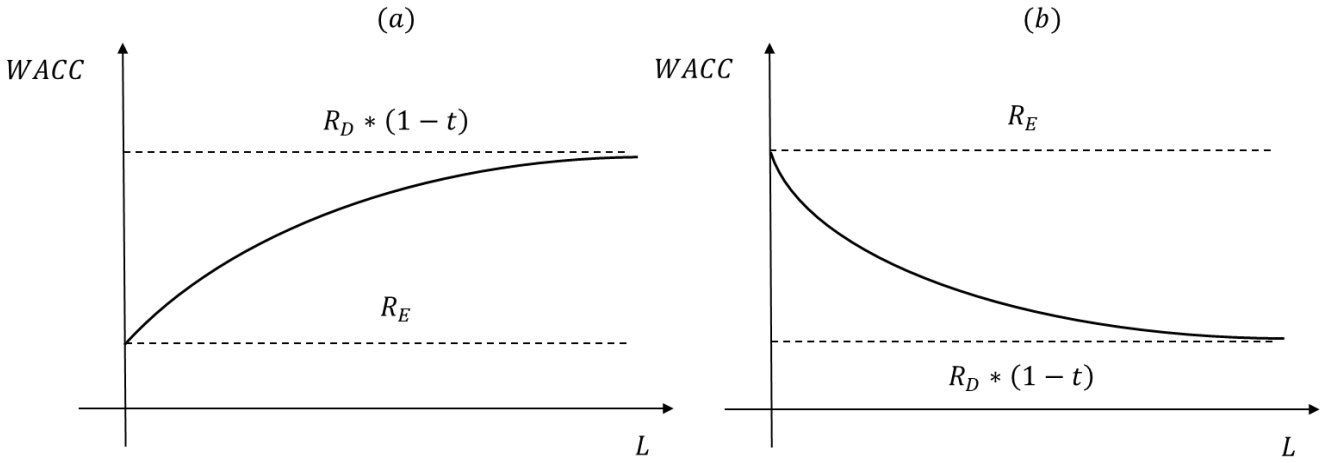

Figure 1. WACC as function of the leverage, for different values of return on equity and return on debt. In (a), the return on debt discounted of taxes is higher than the return on equity, and the WACC. The opposite works for (b).

In general, the higher the equity E is invested in a project, the less risk is perceived by new lenders and the more the cost of borrowing external capitals can reduce over the time, pushing for an increase of D. Consequently, as the above graphs reflect, the WACC can be minimized by:

(a) maximizing the level of equity E (i.e., minimizing L) in the case that the rate of return on debt (R_D) discounted of taxes (t) results greater than the rate of return on equity (R_E); or
(b) maximizing the level of debt D (i.e., maximizing L) in the case that the rate of return on equity (R_E) results greater than the rate of return on debt (R_D) discounted of taxes (t).

In the case of this study, the WACC will be minimized according to the scenario of interest, referring to configuration (a) or (b). Finally, it is worth mentioning that the figures of R_D and R_E strongly depend on the financing structure adopted for the project. As will be advanced in the following sections, a structure built with a project finance approach can help in maximizing the leverage while keeping the return on debt low, if the solidity of future cash flows is assumed [28].

2.1.2 Scenario setting

Three scenarios are here considered, stemming from the ones proposed by Agutu et al. [15]. As already mentioned, the leverage is generally high in SSA power projects, but the return rates on debt are still high, thus bringing to high costs of capital if borrowed through debt. The scenario setting must hence start from the consideration that, in the current mini grid sector in SSA, the most common condition is represented by the rate of return on debt (R_D) discounted of taxes (t) resulting greater than the rate of return on equity (R_E).

The first scenario represents a common *status-quo* situation for the mini grid sector, in which the whole costs are assumed to be covered by public funded equity (i.e., granted at very low rate of return). However, this situation hinders the participation of private lenders or shareholders and does not therefore contribute to develop the sector market, for the reasons already mentioned. For this, a second scenario is introduced, called *increasing private participation* scenario. In this scenario, the shifting from a 20% to a 100% debt-financed mini grid is represented, while keeping the rates of return fixed to the current condition. Finally, the third scenario foresees a *public intervention* in which the regulator intervenes to substantially increase the corporate tax discount (t) and to produce a rate of return on debt (R_D) discounted of taxes (t) lower than the return on equity (R_E). Sensitivity analyses, corresponding to different financing structures, will be performed to understand the impact of these parameters on the modelling outputs.

2.1.3 Assumptions

It is worth mentioning that the financial modelling approach above introduced entails two main assumptions that are far from being negligible in the context of this study. These are:

(i) the source of financing for the investment will provide 100% of the investment on due time, disregarding the upstream sources and markets, and

(ii) the investment will be paid back in its entirety, with assured revenues over the lifetime of the project.

2.2. Energy modelling approach

The open-source energy modelling approach applied in this work emulates the one adopted by Stevanato et al. [29]. It couples an open-source bottom-up energy planning model, MicrogridsPy [30], with an open-source stochastic load demand generator, RAMP [31].

MicrogridsPy is a two-stage linear stochastic mini-grid optimization software developed in python (pyomo) by several authors in the years (original version in 2019 by Balderrama et al. [30]; multi-energy system optimization by Stevanato et al. [32]; multi-year capacity expansion, or MicrogridsPy-MYCE, by Stevanato et al. [29]; last published version in Stevanato et al. [33]). MicrogridsPy requires as inputs: the load demand with hourly resolution, the time series of the variable renewable energy sources with the same time resolution of the demand, and other parameters of techno-economic and financial nature. Both the inputs and the outputs are meant to be user-friendly, being written in intuitive excel sheets. The most advanced version of MicrogridsPy (2.0, March 2023, published at [33]) allows the user to:

- choose the objective function of MicrogridspPy between economic ones (minimum Net Present Cost or non-actualized Operation Costs) or environmental ones (minimum CO2 emissions), or a weighted combination of the two (multi-objective optimization),
- implement stochastic optimization,
- implement multi-year evolving load demand and multi-step capacity expansion,
- account for possible future connection to the main national grid,
- account for existing capacity already installed (brownfield optimization),
- deal with data paucity issues by mean of built-in load archetypes for rural users and endogenous calculation of renewable energy sources production from NASA-Power database.

The code, available in GitHub [34] and in constant updating, is open-source under the EUPL v1.1 license and needs an external solver for the model resolution. The compatibility of MicrogridsPy with a stochastic load profile generator such as RAMP (Remote-Areas Multi-energy systems load Profiles, [31]) has been already tested in existing literature [29,35]: the coupling of the two models provides a powerful energy planning tool to account for stochasticity both on input and design sides of the problem, thus producing more robust modelling results. According to the financial modelling approach introduced in the previous section, some input parameters as well as structural equations of MicrogridsPy have been modified to realise the hard linking with the financial modelling and run the scenarios introduced. The updated code is available in a new branch of MicrogridsPy 2.0 [36]. The user is now allowed to insert the input parameters of **Table 2** in the "Model_data.dat" file.

Table 2. New input parameters to MicrogridsPy.

Parameter and default value	Comment
`param: WACC_Calculation := 1;`	`# 1 to select Weighted Average Cost of Capital calculation, 0 otherwise`
`param: cost_of_debt := 0.11;`	`# Cost of debt, i.e., rate of return on loaned debt capital`
`param: cost_of_equity := 0.12;`	`# Cost of equity, i.e., rate of return on equity capital from shareholders`
`param: tax := 0.02;`	`# Corporate tax to be discounted from loaned debt`
`param: equity_share := 0.10;`	`# Total level of equity as a share of the total investment cost [-]`
`param: debt_share := 0.90;`	`# Total level of debt as a share of the total investment cost [-]`
`param: Discount_Rate := 0.02;`	`# Generic discount rate to be applied if WACC_Calculation is not selected`

The parameters are hence used in a pre-processing function that computes the leverage and the WACC as in Eq. (4). Moreover, all the functions including any actualization of costs have been updated to use WACC instead of Discount_Rate, including the Levelized Cost of Electricity (LCOE). Above all, the objective function will be the minimization of the Net Present Cost (NPC), now defined as:

$$NPC = \sum_{y}^{N} \frac{Inv_y + Fix_y + Var_y - Salvage}{(1+WACC)^y} \quad (5)$$

3. Case study: Ndoro village

3.1. Mozambique off-grid energy context

According to the World Bank [37], Mozambique is among the top 20 access-deficit countries (7th in the world), with 22 million people lacking access to electricity in 2020. This share, corresponding to the 38% of the national population, is mostly located in rural areas under extreme poverty caused by lack of electricity, income, education, and healthcare [38]. Mini-grids are not a new phenomenon in the country: since almost more than 25 years, the public services have owned and operated off-grid diesel generators for remote villages [39,40]. Off-grid electrification via renewable-based or hybrid mini-grids is increasing in the region but at insufficient pace to meet economic and demographic growth [16, 18], because of several barriers that are being investigated in disciplinary literature and reports. Among these, Baruah and Coleman [42] indentify economic and financial barriers such as: high cost of capital from local banks (i.e., associated to high interest rates), short maturity of lending, underdeveloped microfinance options, reduced attractiveness for foreign capitals, and no national-led incentives to mobilize low-cost finance to private-sector led off-grid projects. As Soares et al. [43] proved in their recent investigation, private sector stakeholders in the mini-grid sector of Mozambique consider economic factors as the most limiting ones for the enabling of the national market. Particularly, the authors highlight how the five economic factors, including general economic stability, cost of investment, and positive economic environment, are mostly equally important, according to the stakeholders interviewed.

3.2. Materials

3.2.1 Ndoro village

The village of Ndoro is situated in the Administrative Post of Ndoro, in the Caia district of Sofala Province, at the geographical coordinates of 34°56'35.6"E 18°6'59.5"S, located 62 kilometers away from the nearest national electrical network. This distance has resulted in a lack of access to electricity for over 19,161 residents of the Ndoro community. The current village's energy sources are primarily dependent on diesel generators, solar panels, wood, dung, charcoal, waste, candles, kerosene, portable electric torches, and batteries (see **Table 3**). Due to the dispersed population of the village, it is difficult to plan and execute initiatives for installing a mini grid. The absence of electricity has resulted in numerous difficulties for the community, including limited access to education and healthcare, lack of communication facilities, and decreased economic opportunities. The community's reliance on traditional sources of energy has also contributed to environmental degradation and pose health hazards. Efforts to address this problem and bring sustainable electricity to Ndoro are underway, including the installation of solar home systems However, due to the challenges posed by the village's reduced economic opportunities and geographical location, these initiatives lack extensive planning and resources. Nonetheless, providing reliable and sustainable energy to the people of Ndoro remains crucial for their overall development and wellbeing.

Table 3. General information of Ndoro village

Location (lat., lon.)	Lat. - 18°6'59.5"S Lon. - 34°56'35.6"E; 62 km from Caia district, Sofala province, where the nearest national electricity grid is located
Population	19’161
Number of users interviewed	69
Social services	Hospitals, Schools, Church, Police office, Administrative post
Productive activities	Bars, Tents, Barbershops, Tailor workshop, Mills
Sources/devices used	Lighting – candles, kerosene, portable electric torches, and small lithium batteries Heating and cooking – wood, dung, residues, and charcoal

During the site visits, between 2019 and 2020, it was possible to collect data from households, public institutions, and commercial infrastructures, reaching an overall of 69 potential users. The local energy needs were investigated in two ways: first, through the field visit, which allowed for the observation of the village's actual condition; and second, through meetings with focus groups involving institutions and the local leadership. This second step allowed to define tailored scenarios of demand evolution, too. During the on-field visit, it was also possible to assess the viability of local renewable energy sources for generating electricity. The solar energy resource is unbounded, and its huge potential is freely available with few topological constraints. Relevant hydropower resource is absent. The load demand estimated from the data collected and the correspondent scenarios have been organized in a shared Zenodo repository, accessible at [44]. The following sub-section aims to detail the inputs that are provided to the model.

3.2.2 Model definition

Energy resource assessment

First, the potential of each energy source available in Ndoro has been evaluated. As for fossil fuels, the on-field visit confirmed the availability of diesel in the local market to supply diesel generators, provided by local sellers at a roughly constant price of 1.1 USD per litre. As for renewable energy assessment, the built-in feature for renewable energy assessment of MicrogridsPy 2.0 has been adopted to build the hourly resolution time series to provide as input. The solar resource potential found was characterized by annual average global horizontal irradiation of about 1712.72 kWh/m^2, with daily average of 400 Wh/m^2 and peaks of almost 1000 Wh/m^2. The potential of wind was evaluated at 23 m of height from the soil with the peak values over 14 m/s, and the yearly average wind speed of 4.055 m/s, in which is considered too low for efficient power generation.

Load demand definition

Even tough the current situation of Ndoro is far from being energy intensive, growth scenarios contained in [44] detail the perspective provided by local focus groups. High growth scenario has been chosen for the scope of this analysis, due to the willingness of investigating financing structures for a >100 kW of peak power capacity mini grid. In fact, this represents the most suitable case for a commercial-alike study. The output of RAMP software is depicted in **Figure 2**, showing the estimated evolution of Ndoro yearly load duration curves along the modelling horizon (2022-2041).

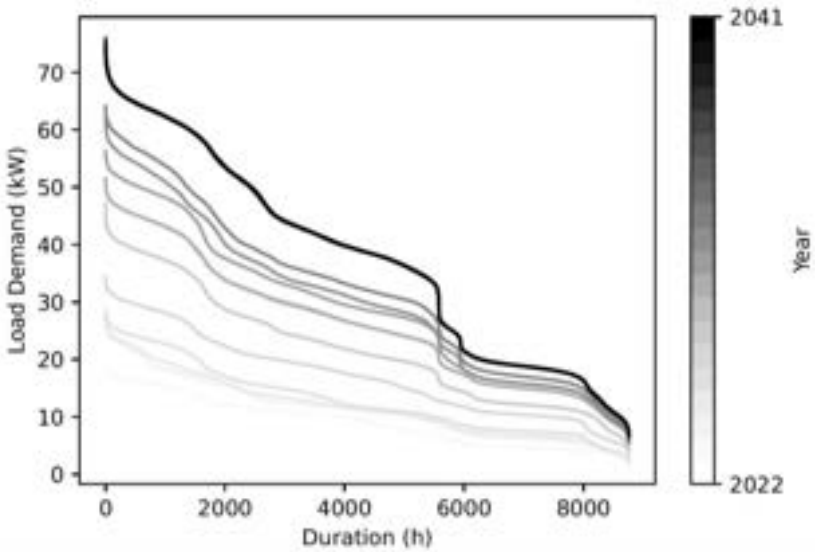

Figure 2. Estimated load duration curve evolution in Ndoro village.

Technology selection and techno-economic parameters

The model considers the possible technologies that could be employed for the construction of a 3rd generation hybrid mini grid [10]: solar PV panels, wind turbines, diesel generators and lithium-ion batteries. The techno-economic parameters for the definition of these technologies are available at [45].

Financial parameters and financing structures

The sensitivity analysis has been conducted on the parameters that characterize the scenarios drawed according to the rationale previously introduced. The combinations of these parameters correspond to a specific financing structure. Values for Mozambique market have been taken and adapted to the case study from the publication by Agutu et al. [15]. A summary and critical description of the financing structures are proposed in **Table 4**.

Table 4. Summary of financing structures associated to the scenarios considered.

Scenario	Description	R_D	R_E	t	D [%]	E [%]	WACC
Status quo	The scenario represents the business-as-usual case, characterised by total absence of private capital participation. The resulting WACC is low, due to the low rate of return required by public funding.	0.26	0.13	0.02	0	100	0.13

Increasing private participation	The scenario represents an increasing of private capital participation from a partially public funded to a non-funded mini grid. However, since the market is assumed to be static, the rates of return are fixed to the status quo boundaries, and the overall WACC increases as D increases. The return on equity in this scenario is slightly increasing with respect to the status quo, due to the participation of private shareholders in the equity market, too.	0.26	0.17	0.02	20	80	0.187
					40	60	0.204
					60	40	0.221
					80	20	0.238
					100	0	0.255
Public intervention	The scenario shows how a substantial increase of t, consisting in a massive public incentivizing scheme, brings to a $(1-t)*R_D$ lower than R_E. This changes the slope of the WACC curve (see Figure 1.) and makes the increase of D functional to the reduction of the WACC, thus pushing for the participation of the private sector.	0.26	0.17	0.4	20	80	0.167
					40	60	0.164
					60	40	0.162
					80	20	0.159

4. Results and discussion

The extent of impact of the financing structure is assessed observing the modelling outputs of the mini grid, i.e., the values taken by the decision variables of the model. The comparison of the results makes sense at scenario level and broader considerations can be made to provide an outlook for the research.

Table 5. Summary of results associated to the scenarios considered.

Scenario	WACC	PV [kW]	Diesel genset [kW]	Battery bank [kWh]	LCOE [USD/kWh]	NPC [kUSD]
Status quo	0.130	83.42	41.94	138.49	0.271	330.201
Increasing private participation	0.187	48.96	41.94	54.62	0.313	247.892
	0.204	38.3	60.21	12.91	0.321	227.569
	0.221	32.45	70.85	0.08	0.328	209.055
	0.238	28.98	74.17	0.05	0.335	192.876
	0.255	26.01	74.25	0.03	0.341	178.748
Public intervention	0.167	64.75	74.31	107.08	0.299	273.146
	0.164	65.93	46.79	107.42	0.297	277.203
	0.162	66.77	46.68	107.67	0.296	279.968
	0.159	68.55	46.6	111.97	0.294	284.196

In the *status quo* scenario the WACC has been taken at a value of 0.13 from [15], considering 100% equity financing sourced from public fund. As already debated in different literature, this scenario is not advisable since it excludes the participation of private capitals. However, the relatively low WACC provides high PV and battery bank capacity, corresponding to the greater NPC of all the scenarios.

As for the *increasing private participation* scenario, the resulting installed capacities are depicted in Figure 3. The five values of WACC considered correspond to a variation of the debt share from 20% to 100%. It is already evident from the depicted results how the PV technology, as well as the LCOEs, benefit from lower discount rates, in this case related to the lower debt shares. It is worth mentioning that the proposed configuration cannot raise debt penetration, being the return on debt still too high compared to the return on equity. Conversely, the *public intervention* scenario shows how in the case of a massive incentivizing intervention (t) by the regulator, the increase of debt share D can reduce the WACC. In this case, the modelling outputs are much less sensitive due to the reduced range of variation of the WACC.

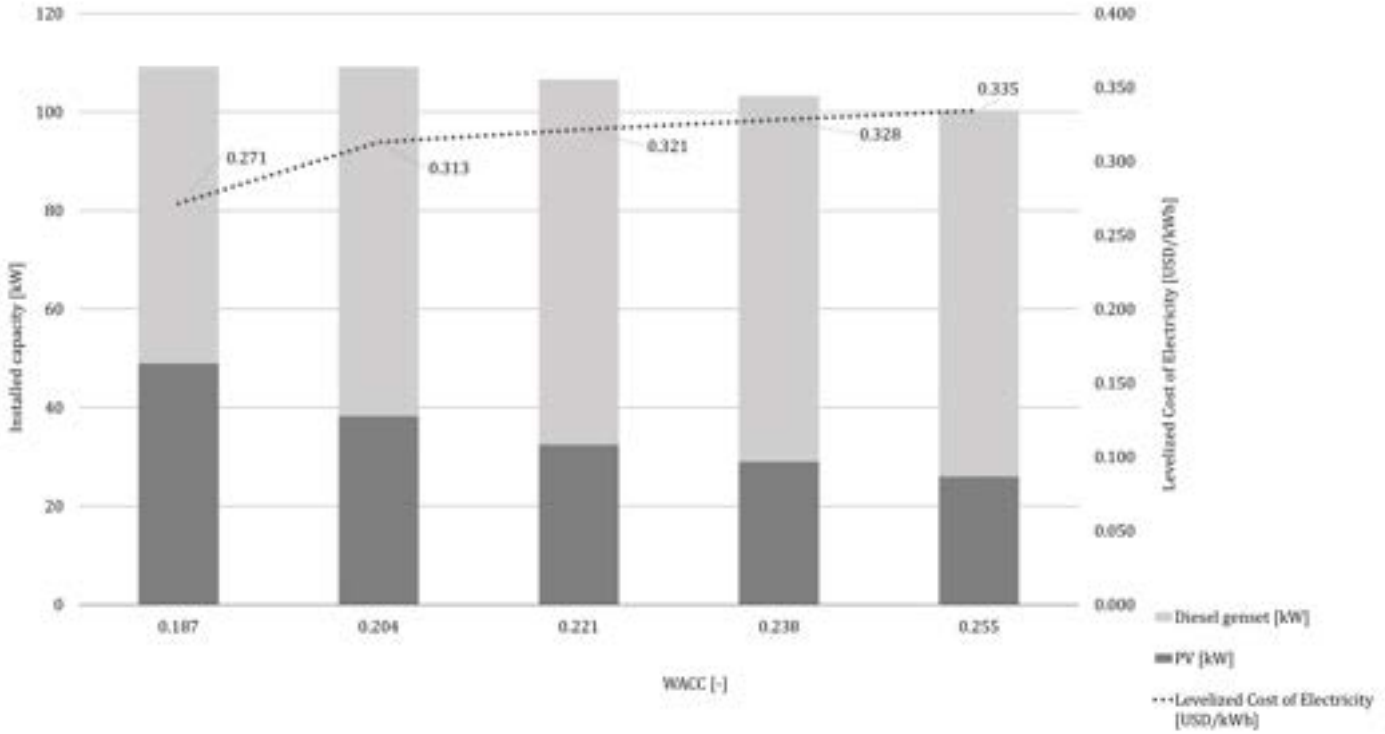

Figure 3. Capacities and LCOE as function of WACC in the *Increasing private participation* scenario.

All the above results are derived from scenarios with current rates of return, which are provenly inefficient and unattractive from a market perspective. The *public intervention* scenario moves in the sense of changing the slope of the WACC as function of the leverage L by varying the (1 – t) factor, i.e., switching from configuration (a) to (b) in **Figure 1**. On the one hand, this proves that, from the regulator perspective and to the goal of enhancing private participation, it would be more efficient to facilitate through a tax discount rather than through equity public funding. On the other hand, such a massive incentivizing intervention (correspondent to 40% of sourced debt) is far from being possibly realised in Mozambique.

5. Conclusion

The study conducted and the results proposed have some limitations to highlight. The limitations are strictly related to the assumptions already commented; for instance, the willingness to accept and wilingness to pay for the service have been assumed, granting that the capitals invested will be paid back. However, as Dibaba et al. [46] highlight, the effective financial sustainability of an off-grid solution cannot neglect the business model that interfaces with the users. Moreover, the financial modelling approach adopted in this study has disregarded the technolgy-specific rates of return, though national and scenario-related values for the costs of capitals have been taken. Out of the results obtained and referring to **Figure 1**, a massive public intervention would be needed to reach an efficient mini grid market in which the increase of the leverage L produces lower WACCs and higher penetration of renewables. The installation of renewables, characterised by lower variable costs and higher initial investment costs, is in fact favoured by lower WACCs in the actualization procedure. Another option to produce this effect is to directly tackle the rates of return and reduce R_D. To this scope, new financial approaches can be introduced. Project finance has been pointed out as a possible tool to upgrade the financing structure of domestic power projects in developing countries [28] and maximise the leverage while diversifying the sources. Such an approach could help in sourcing from climate finance, too, as suggested by Rai et al. [47], thus merging advantages of multiple investment streams while reducing the rates of return. In the case of mini grid financing, project finance is still almost unexplored and could be adopted for financing portfolios of several mini grids, able to ensure more solid cash flows and to mitigate the risk perceived by investors [13]. From the modelling perspective, this requires a more detailed representation of the cash flows and, possibly, a net present value-oriented optimization, able to account for the payback maturity and conditions of the different sources of financing.

Abstract:

Renewables are becoming more and more important due to the ambitious decarbonization targets. In this scenario, the improved integration of hydropower can play a crucial role thanks to its programmable operation, which is a valuable feature. In some countries it is a primary alternative to fossil resources, for example Italy, where hydro currently covers roughly half of the renewable power generation. Hydropower flexibility poses considerable modelling challenges due to the scarce availability of data. This work aims at addressing this research gap, by analysing the impact of hydropower details on energy system models. Using open-source information, a detailed dataset of Italian hydroelectric programmable plants (pumped hydro and reservoirs) is created. For each plant, storage capacity, geographical location, and nominal power are available. The multi-annual historical operational data are exploited to derive a precipitation inflow timeseries for each electricity market bidding zone, which is then distributed on power plants aggregated by administrative region. This new set of data is applied to a multi-node, multi-sector, and multi-vector energy system model, which optimises the design and operation of a carbon-neutral Italian energy system, looking at a 2050 framework with assigned energy vectors demand. Results are compared to those of a fixed-hydropower operation case, thus being able to assess how the modelled flexibility impacts the optimal solution. The analysis favours an improved understanding of future energy systems, helping to shape properly integrated systems with a great amount of non-programmable sources.

Hydropower; Energy dispatch; Integration; Energy system modelling.

1. Introduction

The focus on decarbonization has been increasing steadily over the years, permeating every aspect of society. Within the energy sector, this trend has spurred the growing importance of renewable energy sources (RES), stimulated by ever-more ambitious targets. This demanding path is pushing each technology to find new ways to improve efficiency and economic viability. The European Union has exemplified this trend through initiatives such as FitFor55 [1] and REPowerEU [2], which provide substantial public funds to improve investments and enhance the energy security of the region.

Such initiatives offer an exceptional opportunity for EU countries to gain greater control over their energy supply, thus enhancing their economic stability and security. This could help to mitigate the impact of global energy market fluctuations, which is particularly important for countries with high dependence on imported energy sources. For instance, Italy suffered significant economic consequences in 2022 as a result of its heavy reliance on gas and oil imports. Renewable energy sources, on the other hand, offer countries the necessary autonomy. This is particularly true when the manufacturing of RES-based technologies is not reliant on critical materials, which may otherwise hinder the achievement of climate targets.

Within this framework, hydroelectric power generation is a crucial asset, since it is a clean energy source that does not require the use of rare or strategical elements for its construction. In addition, unlike solar and wind sources, its operations can be programmed to fit the needs of the grid. Accordingly, its smart integration can lead to an important reduction of CO_2 emissions and to a better design of the energy system reducing the duty of other storage options.

Even if the flexibility of hydropower is relevant for realistic analyses, its accurate integration in Energy System Models (ESMs) is often challenging. This can be attributed to the absence of a unified dataset that lists all

hydroelectric plants and their corresponding rated power and storage capacity. Hydropower modelling in ESMs typically relies on the Joint Research Center (JRC) database [3], which provides data on hydroelectric power generation at a plant-specific level and is continuously updated over the years. However, numerous plants are not included in the database, and energy capacity data of reservoir systems are often unavailable. Looking at a country or continental scale, the available hydroelectric power and energy capacities result considerably underestimated. This data deficiency is common also to Italy, and it is also compounded by the difficulty in obtaining precipitation inflow profiles for each hydroelectric plant. As a result, aggregated data are often utilized, leading to higher levels of uncertainty in the results.

This work aims at addressing this research gap, by analysing the impact of hydropower flexibility on carbon-neutral integrated energy systems, focusing on the case of Italy. Using open-source information, a detailed dataset of Italian hydroelectric programmable plants (pumped hydro and reservoirs) is developed. This provides the storage capacity, geographical location, and nominal power of each plant, as well as the inflow time series by region (NUTS-2 areas). Such database is exploited to investigate the impact of hydropower operation in the Italian energy system using OMNI-ES, a multi-node, multi-sector, and multi-vector ESM, which optimizes the total annual cost, under the constraint of net-zero CO_2 emissions for a target year with assigned demand of energy vectors. To conclude, results are compared to a case with fixed hydropower operation based on historical hydroelectric power generation profiles. The structure of this work is the following: Section 2 describes the methodology developed for the gathering and elaboration of the required data. The model used is presented in Section 3, where also the scenario description and the assumption for the simulation are presented. The main results are then shown and discussed in Section 3, and finally, the key conclusions are summed up in Section 4.

2. Methods and data

This section introduces the methodological approach of the analysis. This includes the development of the Italian hydropower database (Section 2.1), the description of the OMNI-ES model (Section 2.2), the design of the assessed scenario (Section 2.3), and the modelling of hydroelectric plants (Section 2.4).

2.1. Hydro power generation and storage data in Italy

Hydroelectric power plants can be divided into three main technologies: run-of-river (RoR), hydro water reservoir (HWR), and pumped hydro storage (PHS). The first takes water from the flow of the rivers to generate electricity, thus representing a non-programmable source. HWR plants, instead, use dams to create basins that enable long-term energy storage. PHS is analogous, but it offers the possibility to pump water back to the upstream basin, allowing for cyclic operation. Accordingly, HWR and PHS guarantee dispatchable electricity, and their operation can be optimised according to the need of the grid.

To investigate the role of HWR and PHS in decarbonised scenarios, this work develops a detailed database of the existing plants in Italy. Hydroelectric power generation has historically been a relevant source of energy in Italy due to the country's favourable natural conditions. However, the construction of dams in almost all the suitable locations has already taken place, leaving limited scope for new installations. Consequently, hydroelectricity is expected to have lower relevance in the Italian energy system in future scenarios compared to solar photovoltaic and onshore wind [4], which feature a significantly larger potential of capacity expansion [5]. Although hydroelectric power generation faces limited opportunities for expansion, it could still provide a crucial contribution to the energy system, offering the opportunity to perform long-term storage (from weekly and monthly to seasonal) avoiding investments for new installations and reducing the risk of curtailment of solar and wind electricity. The existing databases of the national transmission system operator (TSO) [6] and ENTSO-E [7] are characterised by a poor spatial resolution, as data are aggregated either at national or bidding zone level. However, recent studies have shown that in systems where renewables dominate, grid dispatchability cannot be guaranteed, thus requiring a higher level of spatial resolution to incorporate possible congestion limits [5,8]. In addition, the available open-source databases lack information on the energy storage capacity of HWR and PHS plants. To fill these gaps, this works develops a comprehensive dataset of Italian HWR and PHS systems, providing the energy capacity and location of each plant.

The analysis starts from the JRC hydropower database [3], which provides reliable data for what concerns the plants name and power capacity. However, only few of them feature the information about the energy capacity, and the comparison with the number of plants provided by the Italian TSO *Terna SpA* [6] shows that a significant number of plants is absent in the JRC database. Specifically, the TSO reports a total of over 4000 plants, whereas the JRC database lists approximately 300 plants. As a result, the JRC database underestimates the national power capacity of hydro by over 20% (19.4 GW_e compared to 24.7 GW_e). Accordingly, a dedicated and detailed search has been carried out to complete the list of plants and to retrieve the energy capacity. The analysis relies on freely accessible sources, largely derived from the websites of plant owners and of the Italian Ministry of infrastructures and transport [9]. In particular, the latter provides the volume of the basins. In the cases for which the storage capacity (C) is absent, it is evaluated as:

$$C = \eta \cdot C_{water} \cdot H \quad (1)$$

where η is the turbine efficiency, assumed equal to 87% considering a reference value for a plant featuring a Pelton turbine. Such assumption is in many cases conservative, as it is applied also to plants where the more efficient Francis turbines are installed. The water capacity of the basin is expressed by C_{water}, while H represents the head (in m) from the dam to the turbine where the conversion into electricity occurs. In the cases for which the plant head is not explicitly provided, it is estimated from topological data.

Values at the plant level are then aggregated to have a regional detail, in order to comply with the resolution of the ESM (see Section 2.2). The final values are represented in Figure 1, and are used as input to the model to define the maximum capacity of each region.

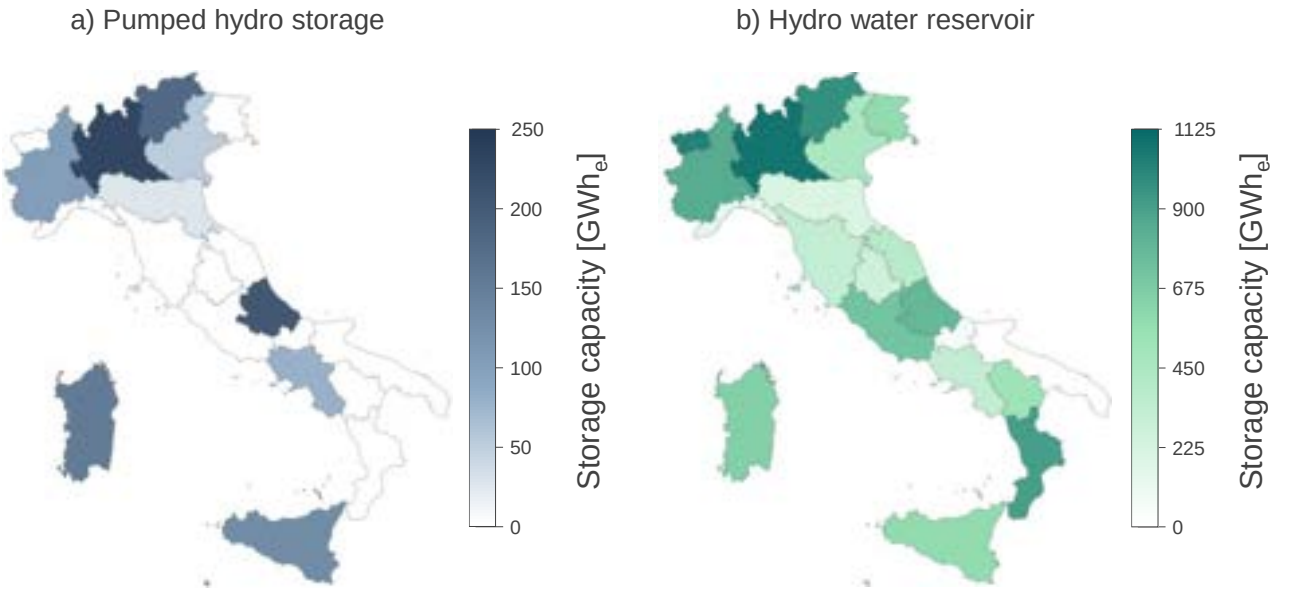

Figure 1. Energy storage capacity by region for (a) pumped hydro storage and (b) hydro water reservoir plants.

After having defined the capacities for each region, the water inflow is computed. This depends on the precipitations occurred in the watershed connected to each plant. However, detailed inflow data at a plant level are unavailable, and it is difficult to link a specific dam to the precipitation in the upstream portion of the watershed over a specific time period. Accordingly, the analysis considers the aggregate inflow by region.

The time series of the aggregate filling rate of HWR and PHS plants provided by ENTSO-E [7] is the starting point to derive the precipitation inflow. In particular, data represent the weekly-resolved estimation of the stored energy value (SEV) aggregated by bidding zone. The inflow time series is computed as:

$$Inflow_i = SEV_{i+1} - SEV_i + \sum_{j=1}^{168} (E_{HWR,j} + E_{PHS_{gen},j} - E_{PHS_{cons},j}) \quad (2)$$

where $E_{HWR,j}$, $E_{PHS_{gen},j}$, and $E_{PHS_{cons},j}$ are respectively the energy generated by reservoirs plants, the one generated by pumped storage plants, and the pumping consumption of pumped storage plants. Profiles of these quantities are available from ENTSO-E with an hourly resolution [10], so they are summed over each week of the year to be consistent with the SEV data. The *i* subscripts indicate the weeks in the year while the *j* ones represent the hours. To be consistent with the TSO inputs, a change in the ENTSO-E profiles is required. Indeed, since in the TSO data HWR are higher in terms of capacity, a compensation regarding the overall energy generated by them is needed not to underestimate the inflow. Consequently, the ENTSO-E profiles are scaled to match the overall generation by bidding zone provided by the TSO. The difference between the two data providers is due to different classification criteria regarding the type of hydropower plants. These are classified according to the time in which the overhead basin is filled by water stream. Specifically, the TSO sets as threshold between RoR and HWR a filling time of 2 hours, while ENTSO-E considers a value of 24 hours.

The resulting profiles represent what is assumed to be the charging or discharging of the bidding zone basins due to only the natural contributions (i.e., precipitations, evaporation, icing). As an example, Figure 2 shows the inflow profiles of two bidding zones (i.e., Centre-North and Sardinia). The inflow profiles clearly show that the distinct bidding zones feature seasonally different precipitation profiles. This is especially noticeable comparing northern and southern regions, where the basins are used as seasonal water storage to compensate the absence of rain during summer. Figure 2 also shows how, depending on the season, the inflow may also feature negative ones. These may result from evaporation and ice formation, or may be due

to maintenance of dams, which can require to empty the whole basin. Another reason may be the minimal vital flow that each river must provide and that, in the case it is regulated artificially, must be preserved through the spilling of water from reservoirs, especially in periods where no precipitations occur and the power plants are turned off. These data also show how in some regions (e.g., Sardinia) precipitations are extremely concentrated in time, highlighting importance of artificial basins for the river flow regulation.

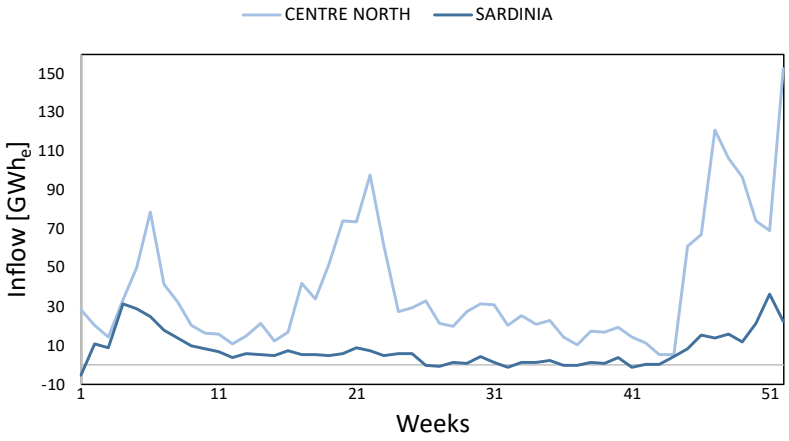

Figure 2. Inflow profiles of the Centre-North and Sardinia bidding zones.

The obtained inflow profiles must be distributed over the two different technologies (i.e., HWR and PHS) and over the regions that constitute each bidding zone. This is attained by dividing the inflow proportionally to the regional energy capacity of HWR and PHS plants (as previously derived). This is equivalent to assuming that plants with larger capacity benefit from a proportionately greater share of the bidding zone inflow.

2.2. Model description

The Italian energy system is modelled with the OMNI-ES model described in Ref. [5]. Considering a target year (2050 in this work), the model optimizes the national energy system by minimizing the total annual cost (including both capital and operational expenditures), covering all end-use sectors (residential and services, industry, road mobility, aviation, and navigation) and considering capacity expansion for all the included technologies adopting a brownfield approach. OMNI-ES is based on a multi-node formulation with a regional (NUTS-2) resolution and solves the energy balances on an hourly basis, adopting a perfect foresight approach. As

Figure **3** shows, the model encompasses a multiplicity of energy vectors (electricity, methane, hydrogen, liquid fuels – fossil, biogenic, or hydrogen-based) and the related transport networks, enabling the possibility to exploit the existing gas grid to deliver a blend of methane and hydrogen. In addition, OMNI-ES tracks the CO_2 flows considering carbon sources, sinks, and uses, in order to introduce a net-zero emission constraint.

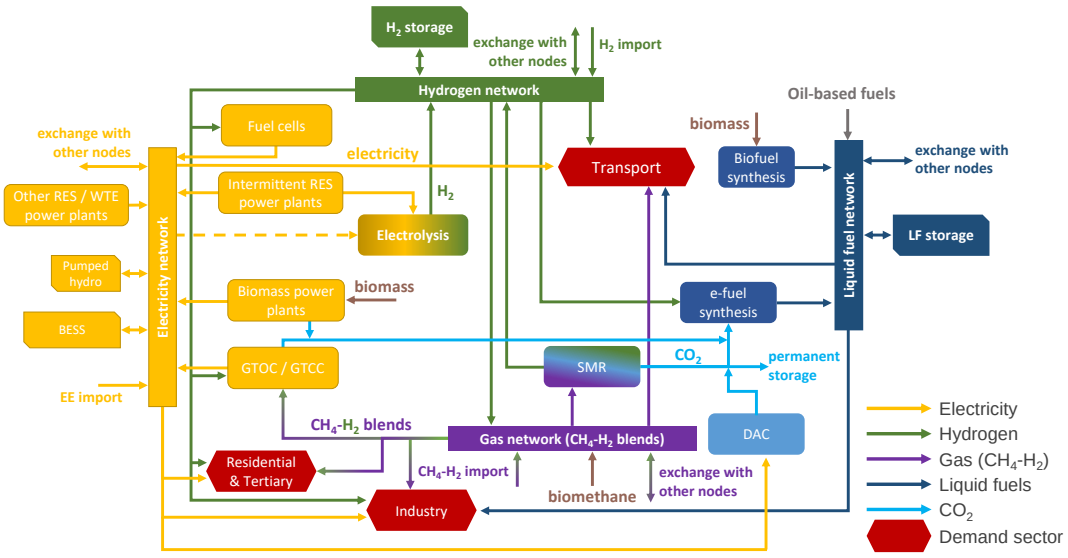

Figure 3. Schematised structure of the OMNI-ES model: nodal balances of energy vectors and CO_2 [5].

2.3. Scenario definition

This work applies the OMNI-ES model to investigate the role of hydroelectricity in a long-term scenario for Italy, considering 2050 as target year and enforcing the achievement of economy-wide carbon neutrality.

OMNI-ES requires as exogenous input the demand quantity and hourly profiles of each energy vector. Specifically, the analysis considers the evolution of all end-use sectors towards the adoption of decarbonized options. The resulting sectorial energy vector demand is summarized in Figure 4, considering the share by energy vector and the total annual demand by sector. The underlying assumptions are briefly presented in the remainder of this section, while a detailed discussion may be found in Ref. [5].

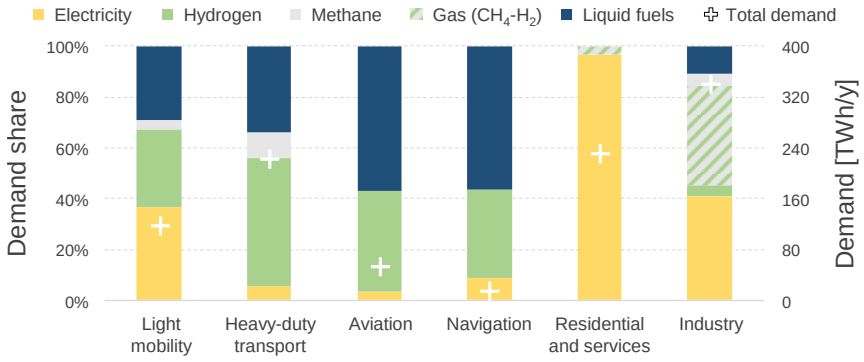

Figure 4. Demand of energy vectors by sector: shares on energy basis (left axis) and annual quantity (right axis).

The electric load encompasses the projection of the conventional consumers demand based on population and gross domestic product (GDP) growth and increased electrification in households, as assumed by the transmission system operators [11], and the additional demand from the electrification of building heating, transport, and industrial heat generation. The gas demand is assumed to be satisfied with a CH_4-H_2 blend with unconstrained hydrogen fraction, and takes into account the projected consumers demand as defined by the transmission system operator [11], a residual use of gas systems for heating of buildings, and high-temperature industrial heat generation. Pure hydrogen uses encompass applications in the transport sector and in industry, while liquid fuels are used in transport, considering the possibility to exploit carbon-neutral fuels in internal combustion engines, aviation, and navigation, and industry as chemical feedstocks.

In the heating sector, 75% of the thermal demand is assumed to be covered via electric heat pumps, 15% via district heating, 5% via gas absorption heat pumps, and 5% via biomass boilers. Cooling introduces an additional electricity demand, defined accounting for thermal comfort needs. The corresponding hourly-resolved profiles for each technology are determined following the methodology presented in Refs. [12–14].

Demand shares in transport are defined on the basis of recent long-term estimations for the sector [15,16]. The stock share assumptions for road transport (reported in Table 1) consider a massive presence of battery electric vehicles (BEVs) in light mobility, while hydrogen-powered fuel cell electric vehicles (FCEVs) and internal combustion engine vehicles (ICEVs) fed with liquid fuels (LF) are more relevant in heavy transport. The analysis also maintains the current reliance of part of road transport on pure CH_4, with use of either natural gas or biomethane. For aviation and navigation, demand shares are assigned considering the national consumption as reported in Figure 4, taking into account both passenger and freight transport.

Table 1. Road transport stock share assumptions.

Category	ICEV-LF	ICEV-CH_4	BEV	FCEV
Passenger cars	10%	-	75%	15%
Light-duty vehicles	20%	5%	50%	25%
Heavy-duty vehicles	20%	10%	10%	60%
Buses	15%	-	50%	35%

The industrial demand of energy vectors is built from historical consumptions [17], considering the adoption of decarbonized technologies. In particular, the analysis assumes the complete electrification of low-temperature (< 100 °C) process heat generation (excluding the systems already based on biomass, geothermal, and solar energy), while medium- and high-temperature (> 100 °C) heat generation based on oil derivatives and solid

fuels is considered to be converted to gas boilers fed by a CH_4-H_2 blend with hydrogen fraction up to 100%. Regarding the chemical industry, all fossil-based feedstocks are assumed to be converted to carbon-neutral options. This involves the replacement of natural gas in ammonia and methanol production with hydrogen, and the substitution of naphtha in high-value chemicals (HVC) and BTX (benzene, toluene, and xylenes) with carbon-neutral methanol [18]. Primary steelmaking is assumed to switch to Direct Reduction of Iron ore (DRI) and Electric Arc Furnaces (EAF), considering that, as DRI feed, half of the production relies on methane and half on hydrogen. The implementation of carbon capture and storage (CCS) is imposed for the methane-based production. Carbon capture and permanent sequestration is considered also in cement production.

The potentials for renewable energy sources are determined based on Ref. [5]. The solar photovoltaic potential is estimated to 405 GW_e, considering both rooftop- and ground-based plants, while the available wind speed and the geomorphological features of the territory limit the onshore wind potential to 224 GW_e. Considering areas with suitable wind intensity and seabed morphology for piled foundations [19], the offshore wind potential is set to 9.5 GW_e. For thermoelectric power generation, the analysis considers the revamping of combined-cycle gas turbines (CCGTs) and open-cycle gas turbines (OCGTs) with the installation of high-efficiency devices fuelled by CH_4-H_2 blend, as well as the phase out of oil- and coal-based plants. The maximum capacity of CCGTs and OCGTs is set 50% higher than current values (resulting in 83 GW_e for CCGTs and 5 GW_e for OCGTs), as revamping generally involves larger machinery. The biomass-based power generation potential is assumed equal to today's installed capacity (4 GW_e), as biomass availability is the main constraints for its exploitation. In accordance with national strategies, the operation of Waste-to-Energy (WtE) plants is kept unvaried (the installed capacity is currently 1 GW_e) [20]. As most available areas have already been exploited, only a slight increase of geothermal (+10%, reaching 1 GW_e) and run-of-river (+20%, reaching 7 GW_e) capacity is considered. For the same reason, the installed capacity of HWR and PHS is assumed unvaried (see Section 2 for the discussion on the current status of hydroelectric power generation).

Regarding domestic sources, the upper boundary for domestic gas production is set to the 2019 value, equal to 47 TWh_{LHV}/y, taking into account both onshore and offshore wells [21]. A biomass availability of 52 TWh_{LHV}/y is determined considering waste and residual solid biomass exclusively [22], while a biomethane production potential of 55 TWh_{LHV}/y is estimated considering the upgrading of biogas produced from livestock residues and biodegradable waste [22,23]. Finally, an annual storage capacity of 20 Mt_{CO2}/y is assumed as upper boundary for permanent CO_2 sequestration, corresponding to the lower boundary of the range indicated in the national long-term strategy [4].

2.4. Modelling of hydroelectric power generation

Based on the description provided, the aim is to analyze the impact of flexible hydropower operation on the national energy system in long-term scenarios with high levels of renewable energy penetration. To this end, two scenarios are investigated. The first does not enable hydropower flexibility of reservoir plants, assigning the operation of HWR plants based on historical generation profiles. The second scenario differs from the previous one in the way in which the reservoir plants are modelled. Here, the model selects the optimal plant operation, according to the equation:

$$Q_{HWR}^{r,t+1} = Q_{HWR}^{r,t} + \tilde{q}_{inflow,HWR}^{r,t} - \frac{q_{\mathrm{otp},HWR}^{r,t}}{\tilde{\eta}} \tag{3}$$

where, referring to the generic region r and time step t, $Q_{HWR}^{r,t}$ is the energy storage content of HWR plants, $\tilde{q}_{inflow,HWR}^{n,t}$ is the inflow as determined in Section 2.1, and $q_{\mathrm{otp},HWR}^{r,t}$ is the output power generation of HWR plants. Specifically, the inflow $\tilde{q}_{inflow,HWR}^{n,t}$ is an exogenous input data, while the storage content $Q_{HWR}^{r,t}$ and the power output $q_{\mathrm{otp},HWR}^{r,t}$ are model variables endogenously optimised.

The database developed in Section 2.1 provides the hourly profiles of natural inflow and the available storage capacity of HWR plants, which bounds the storage content in each region. To provide a realistic assessment, the initial level of the basins is imposed equal to the historical one at the first hour of the year. The level at the end of the year is instead imposed to be greater than or equal than the minimum value between the initial storage content and the historical end-of-year level. For this analysis the reference year, from which the historical data are derived, is the 2019. The choice is made to be consistent with the data used in Ref. [5], which considered 2019 as reference weather year. In addition, 2019 represents an average year for what concerns precipitations and basins filling levels. To conclude, the operation of pumped hydro storage plants is optimised in both scenarios, and run-of-river plants are modelled with assigned profiles equal to the historical ones, assuming a 20% capacity increase to account for new installations.

3. Results and discussion

Given the model description, the main assumptions, and the input data, the analysis compares the cost-optimal energy system configuration in a scenario with assigned HWR plant operation based on historical profiles (considered as reference) and in one with optimised flexible HWR operation.

Figure 5 shows the HWR duration curve comparison between the flexible and the assigned operation scenarios. The curve of the reference scenario features a smoother trend, as hydroelectricity has traditionally provided base load generation. When enabling flexible operation, HWR plants exhibit a peaking behavior, as the operating hours do not cover the whole year and the profile is shifted towards higher power values.

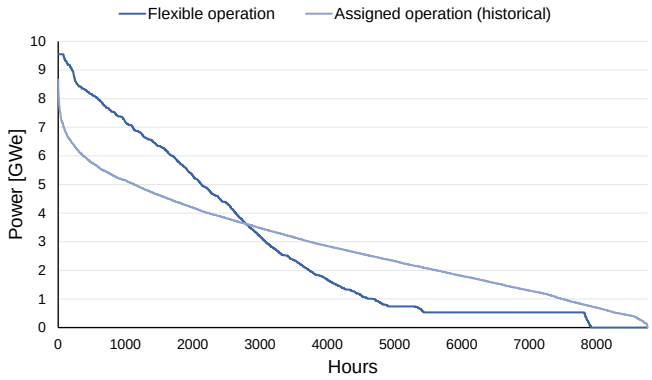

Figure 5. Duration curves of hydropower reservoir (HWR) plants in the flexible and in the reference scenarios.

Figure 6 shows the comparison of the storage energy value by bidding zone in both scenarios, following the geographical division of 2019. Specifically, the curve of the reference case is derived from historical data from ENTSO-E for the year 2019. In contrast, the flexible scenario aggregates results from individual regions across the bidding zones.

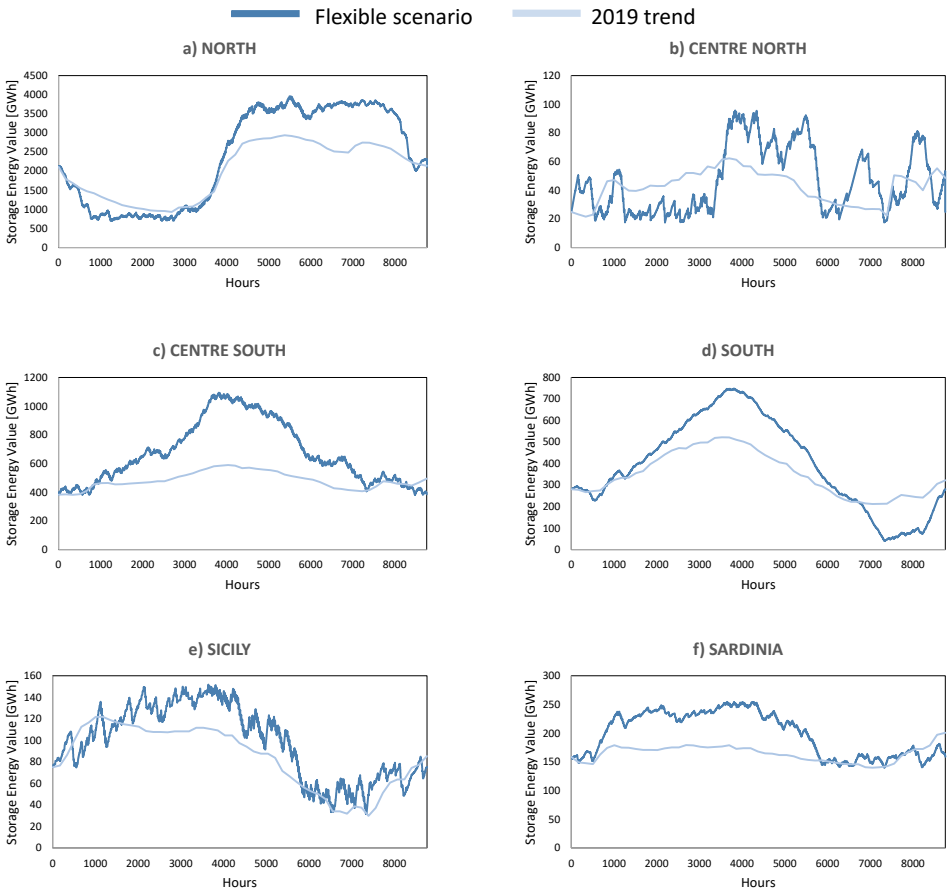

Figure 6. SEV comparison between the flexible scenario output and the 2019 profiles, for the aggregation of HWR and PHS basins in each bidding zone.

The model is allowed to vary between the maximum capacity of the basins, determined by the analysis illustrated in Section 2, and a minimum storage content, set equal to the historical minimum basin level. In some bidding zones (e.g., Sicily) the difference between the two lines is less marked, showing that using the assigned historical profiles does not represent a great difference, as HWR power generation is mostly driven by the availability of inflow. Instead, the curves are more distinct in bidding zones (e.g., Centre-South) resulting in a higher amount of energy stored during summer to be then discharged in autumn when photovoltaic generation is lower. Results reveal that the North bidding zone, which represents nearly 65% of the national value in terms of capacity, exhibits a trend similar to the historical one. However, it features a more pronounced seasonality, reaching differences of the energy stored during summer in the order of 1000 GWh_e.

These results show how hydroelectric basins operation can be assimilated to storage systems and that HWR detailed modelling can lead to a different optimal system configuration. In this regard, Table 2 shows the variation of the installed capacities of the most relevant technologies between the two scenarios. The introduction of HWR flexibility significantly impacts on the installation of battery energy storage systems (BESS), which feature a sensibly lower capacity in the flexible scenario. This is due to the possibility to exploit existing assets (i.e., hydroelectric plants) as storage systems, reducing the need for new installations that would represents an extra cost for the system. Indeed, the optimised use of HWR replaces BESS role in balancing short-term oscillations of renewable power generation. The availability of investment-free storage options enables a larger deployment of solar photovoltaic, which is the RES power generation technology with the lowest lower levelized cost of electricity, while the wind capacity undergoes a corresponding decrease. To avoid curtailment, the system relies on a larger hydrogen storage capacity, which is also used to compensate the greater seasonal unbalances that result from the additional PV installations. Gas turbine-based power generation capacity decreases by 22 %, as the flexible operation of HWR plants guarantees dispatchable electricity to assist the grid in hours where non-programmable sources are not available.

Table 2. Installation of main technologies.

Technologies	Reference scenario	Flexible scenario	Variation
Solar photovoltaic [GW_e]	311	338	+8%
Wind [GW_e]	130	127	-2%
Gas turbine-based power generation [GW_e]	17	15	-13%
Battery energy storage [GWh_e]	106	81	-24%
H_2 storage [GWh_{LHV}]	944	1212	+28%

Figure 7 focuses on the integration between PV and hydro reservoirs in the flexible operation scenario. The black line represents the cumulative duration curve of these two technologies, while stacked columns represent the share of HWR (in light blue) and photovoltaic (yellow) on the generated power in each hour. The figure shows a complementarity relation between solar PV and HWR, as the latter is used when solar radiation is scarce or not available. Indeed, the share of hydro reservoir generation starts to appear only at low power, increasing significantly in the right part of the chart.

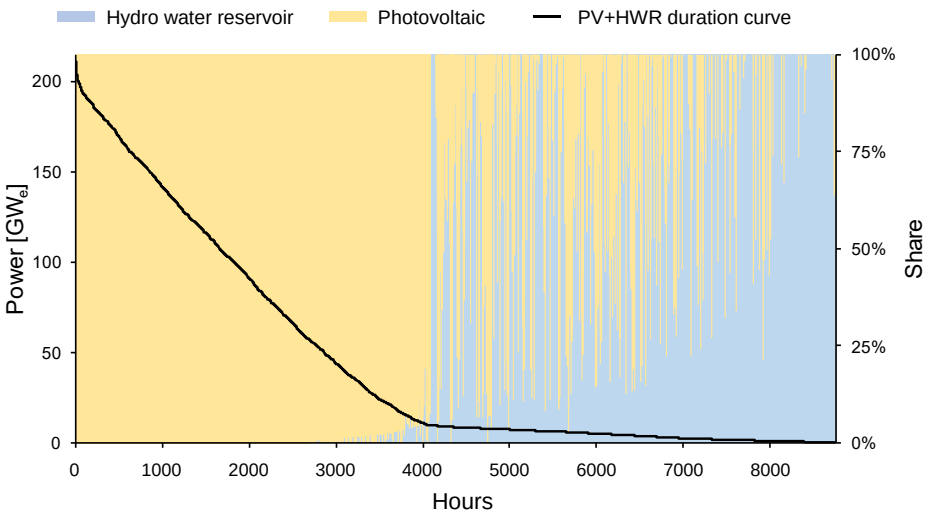

Figure 7. Cumulative PV and HWR duration curve (left axis) and hourly share on generated power (right axis).

Such behavior is also evident in Figure 8, which highlights that hydro reservoirs are adopted to compensate for the lack of PV generation during nighttime or low-solar-radiation days. The operation of the two systems features a strong daily pattern, with HWR covering the load in the early morning and late afternoon and PV taking over the central hours of the day. Consistent with the trend highlighted in Figure 5, HWR plants often operate at peak power. A certain degree of seasonal complementarity is also observed, as HWR generation in the central hours of the day intensifies in periods with low availability of solar radiation, such as the end of January, November, and December. Figure 8 also provides insights on the effect that the optimised management of hydroelectric systems has on reducing the need for BESS capacity, with the former compensating short-term renewable generation deficits.

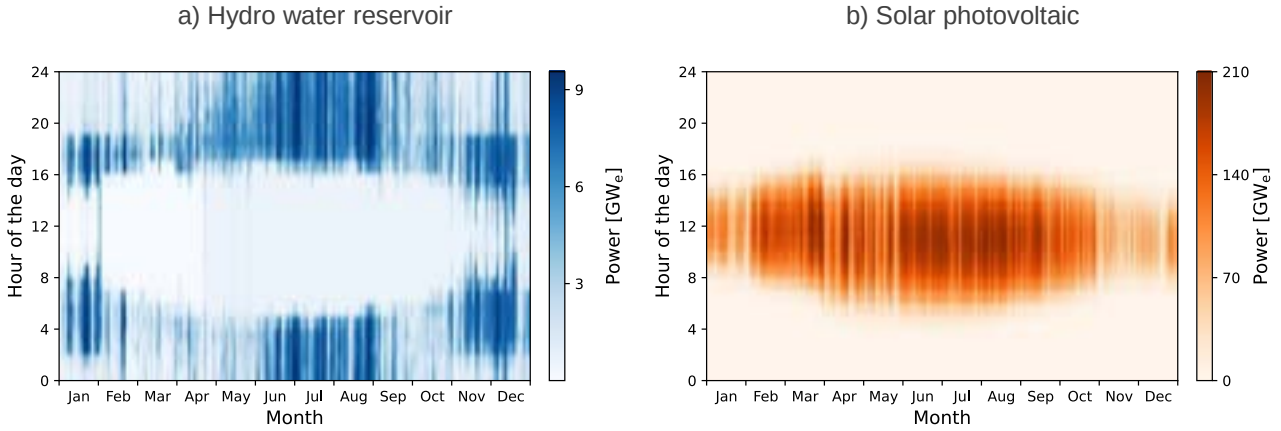

Figure 8. Hourly-resolved power generation profiles of hydro water reservoir (a) and solar photovoltaic (b).

4. Conclusions

The study presented in this work investigated the impact of hydropower flexibility on the Italian energy system, by introducing detailed hydropower data in a multi-node, multi-sector, and multi-vector energy system model. A comprehensive dataset of the programmable hydroelectric plants (pumped hydro and reservoirs) in Italy was created using open-source information. Compared to the available hydropower data sources, the developed dataset includes a complete list of plants, providing the nominal power and the energy storage capacity, which is typically unavailable in both national and European databases. Data have been aggregated to the regional level (NUTS-2) to compute the natural inflow profiles of HWR and PHS systems. The OMNI-ES energy system model was adopted to investigate the role of hydropower in economy-wide carbon-neutral scenarios. Adopting a perfect-foresight approach, the model application compared a flexible HWR operation scenario with optimised management of HWR plants, and an assigned operation scenario with HWR generation profiles based on historical data. The year 2019 was considered as reference for all the time series, while sensitivity analyses on the impact of the weather year are left to future assessments.

Results show that hydropower operation shifts from baseload to peak generation, thus acting as compensation of the intermittent generation of non-programmable sources. Accordingly, the system avoids the installation of additional flexibility elements, such as battery energy storage and gas turbine-based power generation, which feature a 24% and 13% capacity reduction compared to the assigned-operation scenario, respectively. Correspondingly, the optimised hydropower operation enables the deployment of additional solar photovoltaic capacity (+ 8%), leveraging its LCOE. Overall, the system is positively impacted by the possibility to perform both short-term and seasonal storage exploiting already existing assets, improving the integration of intermittent renewable sources in the energy system. Further developments of the work will involve the assessment of the impact of the reference climate year, considering different historical time series characterised by higher or lower precipitation. The effect of climate change will also be addressed, investigating the change of hydropower resources caused by global warming.

Abstract:
Energy system models are indispensable tools for energy planning and decision making. They identify the most cost-effective way of delivering energy to the final consumer. No one tool that addresses all the energy system-related issues. Every model has its own strengths and limitations and serves a different purpose. This paper aims to compare the capabilities of two different model formulations to model both the hydro scheduling and the short-term dispatch problems in hydro-dominated power systems. On the one hand, SDDP, a commercial model for hydrothermal generation scheduling with a representation of the transmission network, has been used by the Bolivian system operator for dispatch simulations. Conversely, Dispa-SET, an open-source unit commitment and economic dispatch model with mid-term hydrothermal coordination capability, has been used previously in several Bolivian case studies. In this paper, both models were applied to the same input dataset of the Bolivian electric system considering probabilistic results for 43 weather years from 1984 to 2021. SDDP optimizes the system under all weather years, while Dispa-SET optimises under one full year, for which 43 runs were made. The results show that SDDP generation, reservoir level and spillage fall into the ranges of Dispa-SET results. Some differences that are present mainly lie in the conceptualization of the methods of both models. SDDP prioritizes the dispatch of hydro units, while Dispa-SET, with a higher temporal and technical resolution, maximizes the use of non-dispatchable units such as variable renewables and run-of-river.

Keywords:
Dispa-SET Bolivia; Energy system modelling; SDDP; Hydro scheduling.

1. Introduction

The Paris Agreement and Sustainable Development Goals (SDGs) are crucial global frameworks addressing environmental and development challenges, requiring changes in every country. The Paris Agreement commits countries to achieve net-zero greenhouse-gas emissions by the middle of the century, while the SDGs consist of 17 SDGs and 169 targets for Prosperity, People, Planet, Peace, and Partnership [1]. SDG7 aims to ”Ensure access to affordable, reliable, sustainable and modern energy for all” [2]. For this, renewable generation expansion is critical in helping to mitigate global warming. These agreements have significant implications for national development plans for developed and developing countries [3]. Bolivia’s Nationally Determined Contribution (NDC) [4], consistent with the Paris Agreement, presents climate goals and actions aligned with emission reduction and adaptation to the impacts of climate change. Bolivia aims to achieve a transition in electricity generation towards renewable energy and targets 79 % renewable energy consumption and 50 % of renewable installed capacity by 2030. Bolivia’s alternative energy goal by 2030 is to reach 19 % energy consumption from Biomass, Solar, Wind and Geothermal energy, contributing to SDGs 7,8,12, and 13.

Energy models are essential analytical tools that can support SDG goals by analyzing potential energy project impacts [5]. Energy models’ quantitative analysis supports much of academic research and energy policy-making [6]. There is a wide variety of models, each with its unique blend of paradigms, techniques and solutions. Each model’s extensive range of choices makes it unlikely that a single model could incorporate them all at once [7]. While most models’ source code is not available for public access or modification, open-source models allow users to access and modify the model code. According to Pfenninger [6], open-access models improve the quality of science, allow more effective collaboration across the science-policy boundary, increase productivity through collaborative burden sharing and allow profound relevance to societal debates. In Energy models, when solving the hydrothermal scheduling problem (HTSP) in a system with a large share of hydro generation, such as Bolivia, water inflows play an essential role in the decision-making process. The scheduling of generators must consider various future possibilities, and if a cascade system exists, water

availability is influenced by decisions made in upstream reservoirs. These issues complicate the HTSP, and when an optimization model is designed for it, the decision variables that must be considered include the turbined water used for generation, storage, and spillage [8].

The models of interest for this study are a Stochastic dual dynamic programming model (SDDP) and a Mixed-Integer Linear Programming model (MILP), both bottom-up and dynamic energy models. The Brazilian engineering company PSR has used SDDP algorithm in its software bearing the same name, which has been applied in operations studies in more than 30 countries, including Bolivia. On the other hand, the Dispa-SET model, which uses the MILP algorithm, is an open-source model that has been applied in previous research in different countries, including Bolivia. Both models analyze the components and interconnections between different energy sectors, allowing the comparison of the impact of different technologies on the energy system and finding the best future alternative [9]. They can also find optimal solutions for energy systems under predefined constraints [10]. SDDP and Dispa-SET models have been used in previous research for hydro-thermal scheduling. For example, Gjerden et al. [11] applied SDDP for the Norwegian hydropower system, with 500 hydropower modules applying a stochastical time resolution of one week, showing that the statistical properties of the inflow model significantly impacts the model performance and that the accuracy of SDDP-based models are dependent on the number of inflow series. In [12] the soft-linking between two models was done, where Dispa-SET is used for mid-term hydrothermal coordination, optimal unit commitment and power dispatch over the whole African continent. In this article, the water-energy nexus was analyzed, whose indicators reveal that the water stress induced by power generation activities is problematic in some power pools. Zarate et al. [13] modelled the Bolivian power system on Dispa-SET, focusing on hydropower to assess the effects of different rainfall years on the ability of hydropower to generate and store electricity in the Bolivian electric system.

In this paper, these two energy models are compared, applied to the Bolivian electric system for the year 2026, where renewable energy projects are planned to be implemented. The paper is structured as follows: Section 2 provides an overview of the Bolivian case study; Section 3 describes the methodology that was followed for the model mapping and the simulation configuration; Section 4 presents the modelling results and comparison between the two models; Section 5 concludes.

2. Case study - The Bolivian energy system

The Bolivian electric system consists of the National Interconnected System (SIN) and the Isolated System, which provide electricity to main cities and remote places, respectively. This study focuses on the SIN, which is divided into four zones: North (La Paz and Beni), Oriental(Santa Cruz), Central(Oruro and Cochabamba) and South (Potosí, Chuquisaca and Tarija) (Fig.1). In 2021, SIN energy production was 9628.93 GWh, 33.24% from hydro, 62.31% from thermal (mainly gas), 3.52% from solar PV and 0.93% from wind power plants. [14]

Figure 1: The Bolivian National Interconnected System zones: North (La Paz and Beni), Oriental(Santa Cruz), Central(Oruro and Cochabamba) and South(Potosí, Chuquisaca and Tarija), with the new transmission lines scheduled to be implemented by 2026 [15].

The Bolivian electric plan 2025 [16], proposes expanding the electrical infrastructure and gradually incorporating the Isolated System into the SIN. The plan targets 70 % hydroelectric generation and 4 % alternative energy generation [16]. The plan includes the incorporation of Miguillas power plant with two generation units, Umapalca with 83 MW and Palillada with 116 MW, both located in La Paz; Ivirizu power plant with two generation units, Sehuencas with 194 MW and Juntas with 89 MW of installed power located in Cochabamba, and Condor with 1,4 MW in Potosi. The renewable generation projects to 2025 consider the incorporation of 2 wind farms, La Ventolera, with 23 MW of power, located in Tarija, and Warnes-2, with 20 MW of power, located in Santa Cruz [16] [15]. The total installed capacity in 2022 was 3495 MW, and it is planned to increase to 4036 MW with the hydroelectric and renewable energy projects for 2025. Figure 2 shows the current installed capacity for each zone (2022) and the projected installed capacity for 2025 by zone, with new additions mostly in the form of hydro, VRE and biomass. The existing VRE installed capacity is 29.4% in 2022 and is expected to grow to 38.8% by 2026. The new VRES projects are mainly in the form of hydro and wind.

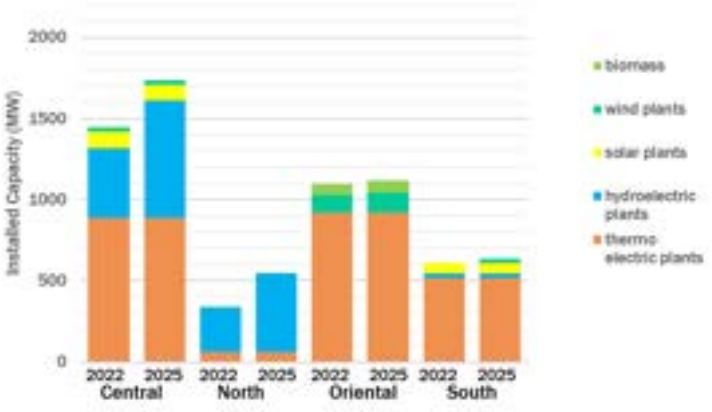

Figure 2: Current (2022) and projected (2025) total installed capacity (MW) by zone. New additions are mostly in the form of hydro, VRE and biomass.

The expansion of the electrical transmission infrastructure between the neighbouring zones by 2026 includes [17] [15].:

- A new transmission line between Central and Oriental zone with the Carrasco-Brechas line of 500 KV, which in the future will be part of the exporting lines to neighboruring countries.
- A new transmission line of 230 KV between Central and North zone with Santivañez-Miguillas line
- A new line between the Central and South zone with 230 KV in the line Mizque-Sucre.

3. Methodology

The work presented in this paper is a continuation of previous Dispa-SET studies for the Bolivian energy system [18] [19], with the novelty of probabilistic analysis of results. The input data for Dispa-SET was obtained from the Bolivian electric system of SDDP software, which is used by CNDC (Comité Nacional de despacho de carga) and ENDE Corporation, to ensure consistency and compare simulation results for 2026 after incorporating new generation and transmission infrastructure.

3.1. Stochastic dual dynamic programming model

SDDP model is used to optimize the expected value of a benefit function or a cost function over a given planning horizon involving weeks or months stages [20]. The optimization problem in this model is solved using dynamic programming, and the solution is used to update a set of dual variables [**?**]. SDDP breaks down the multistage nonlinear problem into a series of stage linear problems (assuming that the overall problem is convex). The dual variables are then used to formulate and solve a linear programming problem that generates a new set of feasible solutions. Rougé et.al. [20] says: " The basic idea behind SDDP is to approximate the convex benefit-to-go function by Benders cuts, mathematical objects that can be thought of as hyperplanes. The algorithm then simulates reservoir operation decisions by using these hyperplanes approximating the true benefit-to-go functions".

SDDP software is a hydrothermal dispatch model with a detailed representation of the transmission network. SDDP considers hydro plants operations, thermal plant modelling, spot markets, supply contracts, hydrological uncertainty, transmission network, and load variations to find the least-cost operating policy of a proposed

hydro system. The main outputs from SDDP are hydro and thermal generation, thermal operation costs, energy interchange, fuel consumption, deficit risks and energy not supplied, short-run marginal costs and marginal capacity benefits.

3.2. Mixed-Integer linear programming model

Dispa-SET, a deterministic dynamic programming algorithm, is an open-source unit commitment and economic dispatch (UCED) model, developed within the Joint Research Centre of the EU Commission. It is a multi-sectoral energy model that represents the short-term operation of large-scale power systems with a high level of detail to assess the flexibility needs of systems with a high share of VRES, solving the UCED problem. Dispa-SET is expressed as a Mixed-Integer-Linear-Program (MILP), written in python and solved in GAMS. The model's objective function is to minimize the total operational system cost [21].

Dispa-SET includes a Mid-Term Scheduling (MTS) module, a relaxed formulation of the core hydro thermal MILP formulation, executed in the pre-processing phase, enabling fast and efficient pre-allocation of the State of charge (SOC) of all storage units present in the system. Since Dispa-SET simulations are performed for a whole year with a time step of one hour, the problem dimensions are not computationally tractable if the optimization is done at once [12]. Therefore, in the unit commitment and power dispatch module (UCM), the problem is split into smaller optimization problems that are run recursively throughout the year. The initial values of the optimization for any given day are the final values of the optimization of the previous day. A look-ahead period is included and then discarded to avoid issues linked to the end of the optimization period. This optimal hydro allocation is particularly relevant in systems with a high share of hydro dams and pumped hydro reservoirs [12]. Results from MTS are used as guidance curves of the reservoir levels, which are then used as minimum level constraints in the UCM module.

3.3. Comparison between model capabilities

Both Dispa-SET and SDDP are dynamic, partial equilibrium, hydro scheduling models. The summary of modelling features between SDDP and Dispa-SET is shown in Table 1. Dispa-SET is a model that needs accurate input data that can be run in parallel on several historical weather years. The results from such analysis can be statistically processed and presented in a probabilistic format. SDDP is a stochastic model that needs a significant amount of historical data to calibrate the inputs, considering uncertainties of parameters. Dispa-SET is an open-source model, while SDDP is a commercial model. Dispa-SET has a higher temporal and technical resolution than SDDP, taking into account the variability and uncertainty of renewable energy sources, as well as the demand variability and network congestion.

Table 1: Comparison between SDDP and Dispaset models

	SDDP	Dispa-SET
Type	Stochastic	Deterministic/Probabilistic
Open Source	X	✓
Therm	Mid-term	Mid-term
Geographical area	National/Regional	Regional/National/Continental
Optimization	Dynamic LP	Dynamic MILP/LP
hydro scheduling	✓	✓
Unit Commitment and Power Dispatch	Limited	Full
Resolution	5 blocks/week	hourly/15 min
Equilibrium	Partial	Partial
Multisectorial	Gas/hydrogen/electricity/water	Any
Renewables representation	5 blocks/week	Per hour/ 15 min
Reserves	predefined	co-optimization
Network	DC Power flow	NTC/DC Power flow
Curtailment	X	✓
Shed Load	✓	✓

The inflow modules of the two models are different. The deterministic model (Dispa-SET) tries all possible historical inflows individually. SDDP, on the other hand, uses a stochastic inflow model (periodic auto-regressive model) that, based on the available historical data, generates synthetic inflows (mapping the unknown future with an unlimited amount of possible inflows) in an attempt to match the inflow profile of the historical data [22].

3.4. Model mapping

In this study, SDDP and Dispa-SET models were applied to the same input dataset of the Bolivian electric system to evaluate it for the year 2026 with the new infrastructure projects. Figure 3 presents the link between

SDDP and Dispa-SET models. In the inputs section, the parameters from SDDP are shown next to the equivalent parameters of Dispa-SET, for which conversion scripts written in python were used to have an automatic input data mapping. SDDP does the simulations of the system operation considering weekly stages with five demand blocks (Peak, Semi Peak, Intermediate, Medium and Low). To use the SDDP database for Dispa-SET, the weekly time step resolution was converted to an hourly resolution based on the five hourly demand blocks (Fig. 4) approved by AETN (Autoridad de Fiscalización y Control Social de Electricidad) [23].

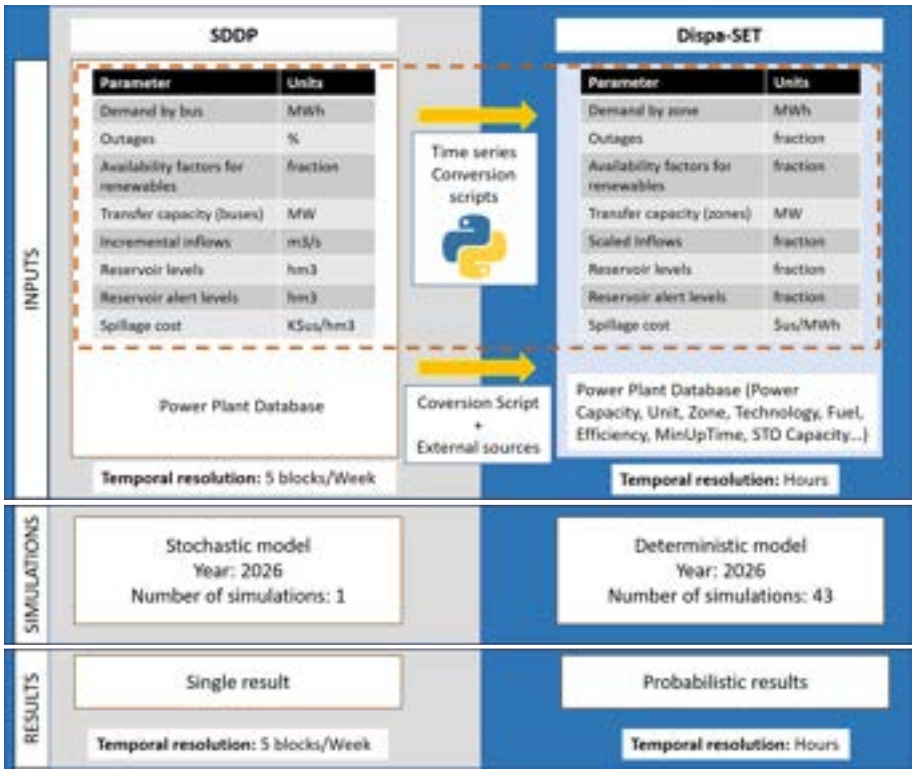

Figure 3: Link of SDDP databases to Dispa-SET for the input data and differences in the simulation configuration and results

Three types of data mapping were done:

- 1-1: Direct mapping of power plant data.
- 1-N: Time series mapping from five blocks per week to an hourly resolution, for parameters such as Outages and Availability factor.
- N-1: Time series mapping from five blocks per week to an hourly resolution, where the parameters described by bus in the SDDP database, such as demand and transfer capacity, were grouped by zone for Dispa-SET.

For Power Plant Database, besides the information from SDDP, external sources of information were needed for the operational parameters of generation units.

Figure 4: Hourly demand blocks approved by AETN, which show in which hours and days of a week each demand block is present [23].

Most Bolivian hydropower plants are part of a cascade system, where downstream water availability relies on

the usage of the unit upstream. Though weekly mean incremental inflow data is available, approximations of inflows and outflows for each unit are required. Three hydro inflow approximation hypotheses were conducted:

- The first one summing the inflows of the unit above plus the external inflows to each unit.
- The second approximation was applied for units that do not have generation capacity but gather or provide flows, using an approximation function to obtain its outflow and spillage.
- The third approximation was applied to Corani, the largest hydro dam, with 2958 storage hours. For this unit, the outflows were considered as the average of the total yearly inflows, considering that Corani has an almost constant generation during the year.

Approximations for each unit's historical weather years (1979 to 2021) were computed, and a statistical analysis was done with the expected generation of the computed inflows. For some units, the variation range between the weather years is particularly high, for example, Sehuencas, with an absolute difference of 1.335 TWh between the lowest and highest values. The approximation was compared to the generation plus spillage of SDDP data for the year 2026. Figure 5 shows that SDDP generation for each hydro unit fits into the range of the expected generation of the Dispa-SET model, proving the hydro inflow approximation hypothesis above-mentioned.

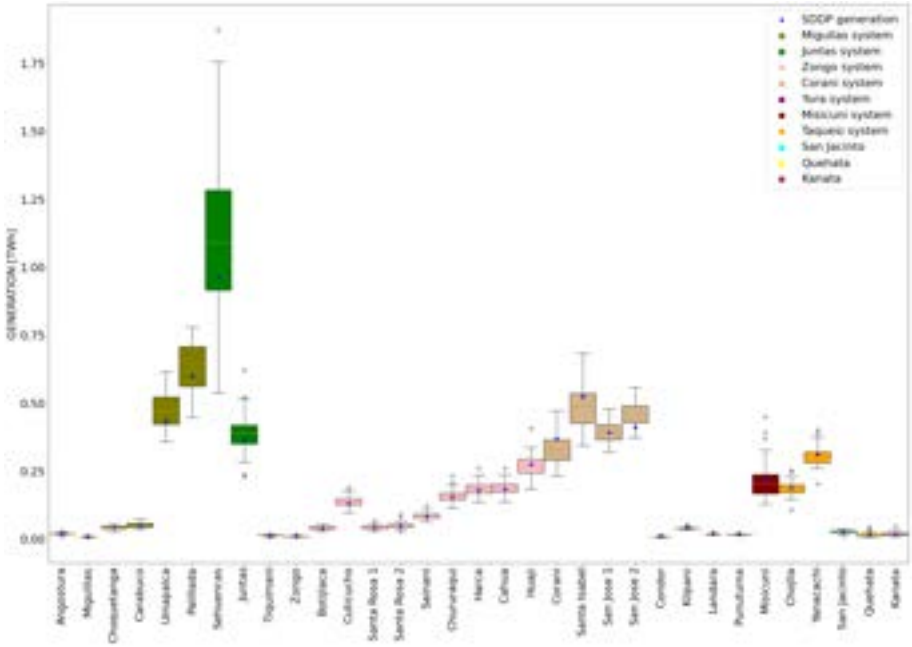

Figure 5: Comparison of SDDP and Dispa-SET generation based on inflows

Bolivia's SDDP simulation begins on the 1st of April, while Dispa-SET's starts on the 1st of January. Various parameters were influenced by the distinction in starting dates, particularly reservoir levels, alert levels, and initial reservoir volumes. Reservoir levels were derived from SDDP runs in Dispa-SET, and the initial reservoir volume inputted in SDDP simulations was adjusted the 1st of April in Dispa-SET.

3.4.1. Reservoir level constraints

The goal of the unit commitment problem is to minimize the total power, transportation system operational cost. The objective function of Dispa-SET is therefore, to minimize the total generation cost over the optimization period (Eq. (1)). In this study, the model has been expanded by the following constraints: Reservoir Alert Level and Spillage cost by unit, as proposed in Eq. (2), where the total system cost is defined as the sum of different cost items such as fixed, variable, ramping, start-up and shut-down, shed load, and the Cost of "storage Alert Level" and "Cost of Spillage" that have been added. In this equation, "i" stands for a subset of simulated hours for one iteration.

$$\underset{i \in I}{\text{minimize}} \left\{ SystemCostRollingHorizon = \sum_{i} SystemCost_i + StorageLevelViolationCosts_i \right\} \quad (1)$$

$$
\begin{aligned}
SystemCost_i = {} & FixedCost_i \cdot TimeStep + StartUpShutDownCosts_i \cdot TimeStep \\
& + VariableCost_i \cdot TimeStep + RampingCost_i \cdot TimeStep + CurtailmentCosts_i \cdot TimeStep \\
& + TransmissionCosts_i \cdot TimeStep + EnergyNotServedCosts_i \cdot TimeStep \\
& + CostStorageAlert_i \cdot LL_StorageAlert \cdot TimeStep + CostSpillage_i \cdot Spillage \\
& + CurtailedPower_i \cdot CostCurtailment \cdot TimeStep
\end{aligned} \tag{2}
$$

The constraint Cost of Storage Alert prevents the reservoir level to go below Storage Alert Level, which will only be violated to avoid power rationing and is set to the equal 1,1* Marginal Cost of the most expensive unit in the system, as in proposed in (3), where ”s” is the set of all storage units (with reservoir).

$$
\begin{aligned}
& StorageCapacity_s \cdot Nunits_s \cdot min\left(StorageAlertLevel_{s,i}, AvailabilityFactor_{s,i}\right) \\
& \qquad \leq StorageLevel_{s,i} + LL\_StorageAlert_{s,i}
\end{aligned} \tag{3}
$$

3.5. Simulation configuration

To consider different future possibilities based on water availability, 43 simulations were run in Dispa-SET. Each simulation reflected the inflows from a different historical weather year (1979-2021). During the historical weather years, 1984 was the wettest year, and 2016 was the driest (Fig 6). In Dispa-SET, all units are considered individually for each hydro plant to be observed in the results. The constraint ”Reservoir Alert Level” is considered in both models for particular hydro dams such as Corani, Miguillas, Angostura, Zongo, San Jacinto and Misicuni.

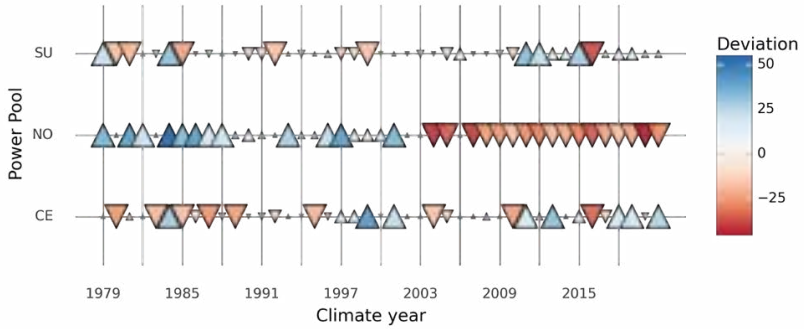

Figure 6: Annual variability (percentage deviation from the mean) of inflows in the 43 climate years. The size of the triangles indicates the inter-annual variability, the direction highlights the increase or decrease compared to the mean, and the colour indicates the intra-annual variability.

From a computational point of view, the variability of the inflows (from 1979 to 2021) directly impacts the simulation times. The simulation time was ranged from 2 hours up to 25 hours for the year 2001, which is the year with excessively high inflows that might not be historically accurate.

4. Results and Discussion

This section presents the expected configuration of the Bolivian electric system for the year 2026. All new VRES and hydro projects are included.

4.1. Energy mix

Figure 7 shows the share of renewable generation for 2026 from all the simulations ordered from the highest to the lowest share of renewable generation. Bolivian electricity production from renewable energy is expected to range between 45.9 % and 65.2 % in 2026. The share of renewable energy in Bolivia in the Stochastic model is 59%, which fits in the range of Dispa-SET share. The North zone is expected to have the highest share of renewable generation with 98 % due to the new hydro projects planned to be installed in this zone. The Central zone is expected to share between 60.3 % to 79 % of renewable energy. Oriental and South zones are expected to still rely more on natural gas to produce electricity than renewable energy. Despite the connections between zones, Bolivia is expected to still depend on natural gas to generate electricity.

In the Bolivian electric plan 2025, VRE was planned to reach 74 % of the total production. From the probabilistic results of the MILP model, it can be seen that with the addition of new power plants, VRE could reach between

45.9% and 65.2 % of the total generation, where biomass is excluded, whereas, in SDDP the VRE share represent 59%.

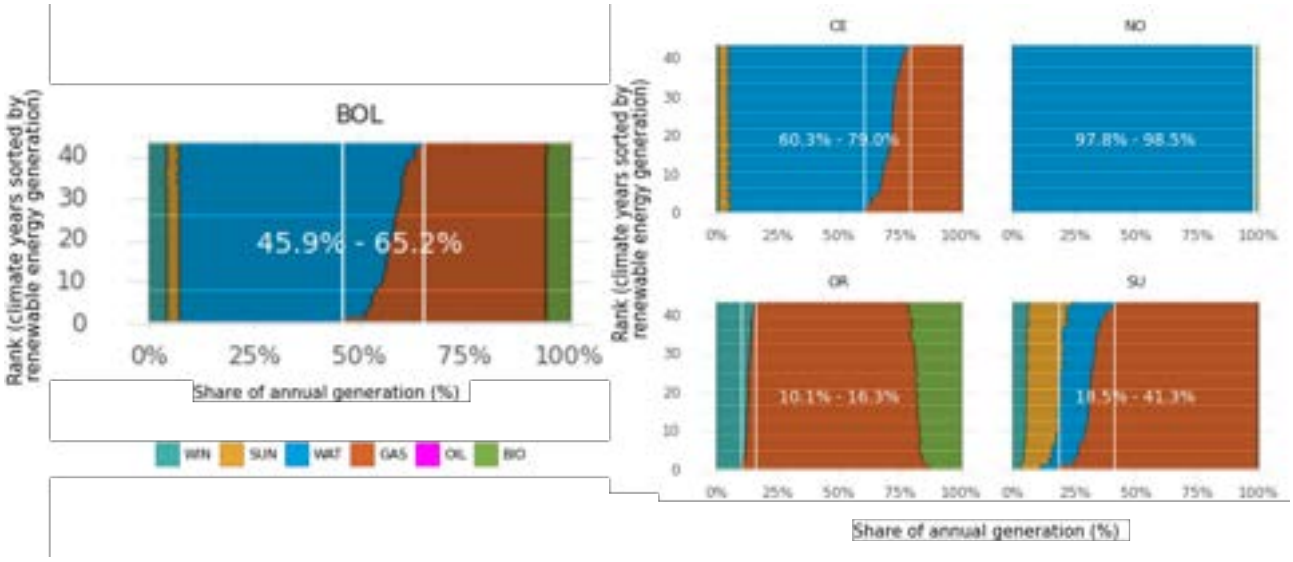

Figure 7: Generation mix and renewables share for the considered climate years of Bolivia and by zone for 2026 from the 43 simulations results, ordered by the share of renewable generation. White lines indicate minimum and maximum shares of renewable generation.

The difference in the total hydro generation between SDDP and Dispa-SET (an average weather year) is 5 %, the Central zone has a difference of 0.1%, the North zone has a difference of 11%, and the South zone has a difference of 7 %. The hydro units with the highest impact on the total generation are Sehuencas, Palillada and Santa Isabel, with a share of 14.5%, 10.6% and 9.3% of the total generation, respectively.

4.2. Power dispatch

The year 2026 power dispatch was analyzed per zone using inflows closest to the average weather year (Fig 8). Bolivia experiences dry months from May to October when the electric system relies on thermo-electric units. During the wet season (December to April), North and Central zones primarily utilize hydroelectric plants. In the dry season, the Central zone uses gas and hydro plants, exporting energy throughout the year to the North, Oriental, and South zones. Conversely, the North zone imports energy during the dry season but exports during the wet season due to hydroelectric production. Oriental and South zones import energy during the wet season but generate electricity from natural gas in the dry season. While the Oriental zone can export its gas-generated production, the South zone still needs to import energy. In all zones, the grid is stable, and there is no congestion in the transmission lines. As for the reservoir levels, they are filled during the wet season.

4.3. Reservoir Levels and generation

The largest Bolivian hydro dams in the Central zone are Corani (with 2958 storage hours), Misicuni (with 2779 storage hours), Miguillas (that will be implemented by 2026 with 1072 storage hours), Angostura (with 525 storage hours), Sehuencas (a new power plant with 257 storage hours); and in the South zone is San Jacinto (with 730 storage hours).

The variation in water supply affects these units' generation, reservoir level and spillage. Simulations results for all these units are presented in Fig. (9), where the black line is the median of the results of all the historical data, the regions with darker colour show that 20% of the results are in that range. The lighter colour shows that 100% of the results are in that range. From the inflows plots, it can be seen that for some years, the inflows are extremely high compared to the median, which indicates the long simulation time, which for some years took up to 25 hours.

The Reservoir levels were compared between the two models. SDDP reservoir level results are plotted as a grey dashed line. The reservoir alert level was included as a solid red line. The inflows are higher during the wet season, and reservoir levels do not go below the reservoir alert level. Sehuencas hydroelectric plant does not have an alert level, but its reservoir level follows a similar tendency to SDDP results. Angostura hydroelectric plant has an alert level and a defined volume for the 1st of April (green cross). For this unit, the reservoir level of SDDP is higher than the median of Dispa-SET in the dry season. However, it's still in the range of the results

of Dispa-SET. The reservoir level of Miguillas hydroelectric plant follows a similar tendency to SDDP. Corani reservoir level in SDDP simulation goes up from 0,3 to 0,54 the last week of December. However, given the available inflows, this would not happen, so for this unit, Dispa-SET results are more reliable.

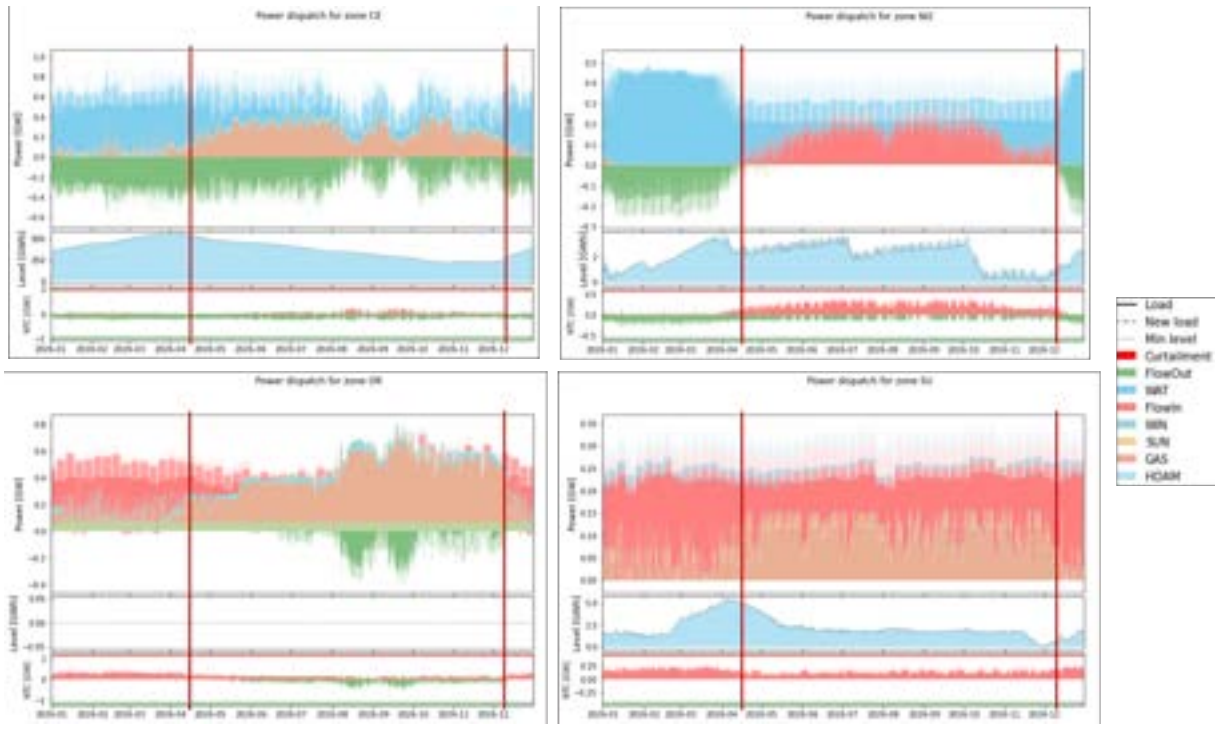

Figure 8: Power dispatch by zone for 2026 based on an average year (2003). The red vertical lines show the limits for the dry season, from April to December

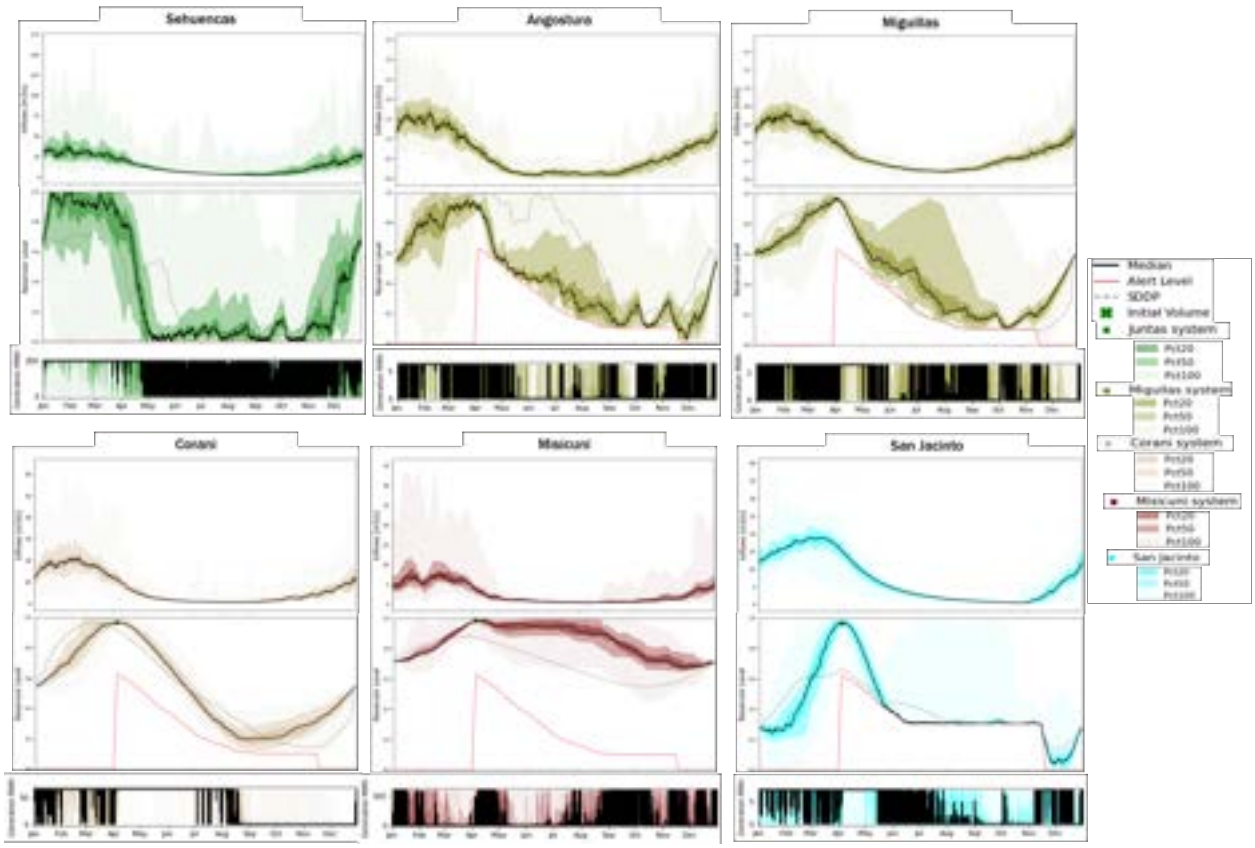

Figure 9: Inflows, Generation and Reservoir Levels from the 43 runs for the biggest hydro dams of Bolivia.

The maximum generation variation range between the weather years was found for Sehuencas, with an absolute difference of 0.941 TWh between the lowest and highest generation (for years 2020 and 1985, respectively). The difference in SDDP generation related to the weather years is 44% compared to the lowest value, 5.7% compared to the median, and 53% compared to the highest value.

4.4. Spillage

Spillage results for both models were compared (Fig.10). Dispa-SET's range of spillage for 43 years is shown in a boxplot for each unit, while blue dots represent SDDP's spillage results. The spillage results from SDDP fit into the range of the results obtained in Dispa-SET. The units Kanata, Zongo, Tiquimani, Kilpani and Punutuma in Dispa-SET do not have any spillage for any year, while in SDDP, there is some spillage. The variation range between the weather years is exceptionally high for Sehuencas, with an absolute difference of 0.54 TWh between the lowest and highest values. The difference in Sehuencas' SDDP spillage related to the weather years is 100% compared to the lowest value, 15.6% compared to the median and 260% compared to the highest value.

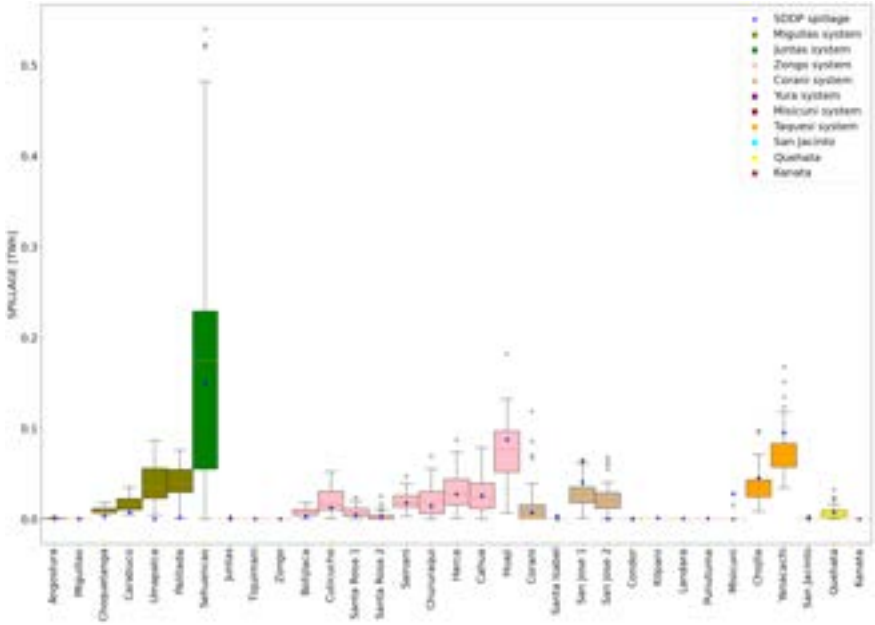

Figure 10: Spillage comparison for 2026 from SDDP (blue dots) and Dispaset (boxplot)

4.5. Water value

The expected marginal value of water, referred as storage shadow price, expresses the opportunity cost of water [24]. Figure 11 shows the Storage Shadow price for the main hydroelectric dams for a wet year (1984), a dry year (2016) and an average year (2003). The storage shadow price, dependent on the water value, is higher in the dry season than in the wet season. For the wet year, the Corani storage shadow price reaches 1500 from September to December, while in the dry year, the price reaches that value one month earlier. Comparing this with the reservoir level (9), the median reaches the lowest level in September. For San Jacinto, the shadow price is higher in December when the reservoir level reaches a lower value. In general, for the dry year, a high shadow price is present during more hours than the wet and average year since water availability is lower.

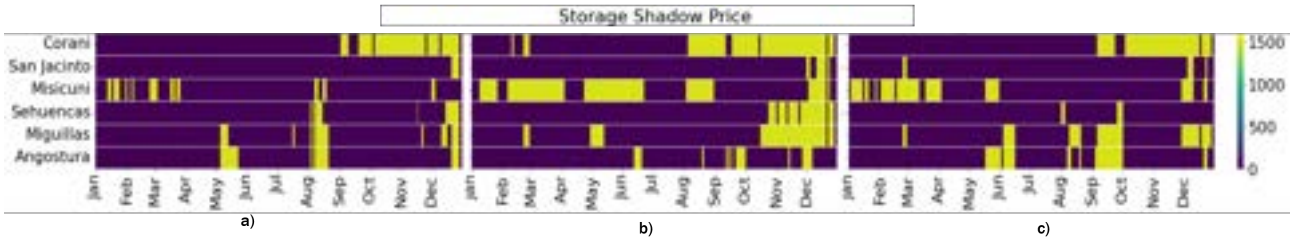

Figure 11: Storage shadow price for the main hydro dams a) for a wet year (1984) b) for a dry year (2016) c) for an average year (2003)

5. Conclusions

The article compares the results obtained by two model formulations, SDDP and MILP, applying the same input data and constraints to analyze the Bolivian electric system to 2026. In the MILP formulation, 43 simulations were done to obtain probabilistic results since the Bolivian electric system is highly dependent on hydropower, and its generation varies during the year and year by year. These results were then compared with SDDP. The novelty of this work is the probabilistic way to show the likelihood of certain events happening, such as the distribution of the State of charge (SOC) for each hydro dam, dispatch of each hydro unit, spillage and generation distribution.

The automatic input data mapping from SDDP to the MILP model was successfully implemented. For the inflows of hydroelectric power plants in a cascade system, an approximation was made for each unit for all the historical weather years. We show that SDDP values are within the MILP model range. Furthermore, in the objective function of the MILP model, constraints have been added for the reservoir level (reservoir level alert) and the spillage cost.

Simulation results indicate that the two models' power generation is in the same range. The maximum variation ranges between the weather years are found for the Sehuencas hydropower plant, which is the unit that has the highest impact on the power system, comprising 14.5% of the total generation. The maximum generation variation between the weather years for Sehuencas is 44% compared to the lowest generation value, 5.7% compared to the median and 53% compared to the highest generation.

The reservoir levels obtained in the probabilistic results follow a similar tendency to the reservoir levels of SDDP, except for some minor deviations, especially in small units with low storage hours. Spillage from SDDP falls between Dispa-SET ranges. Sehuencas power plant has the maximum spillage variation ranges between the weather years. The difference in Sehuencas' SDDP spillage related to the weather years is 100% compared to the lowest spillage value, 15.6% compared to the median and 260% compared to the highest spillage value.

The MILP and SDDP formulations can be used as complementary models for decision-making on the Bolivian electric system operation, taking advantage of their strengths and compensating for their limitations. SDDP has a greater detail in the representation of the electric network, and it takes into account uncertainties of the input parameters. Incontrast, the MILP formulation has a higher time resolution that can provide a more detailed and accurate resolution for renewable energy and has probabilistic results that provide statistical analysis. Low-resolution models, like SDDP, may exhibit deviations from more detailed modelling, especially for renewable systems, not considering the dependency of VRE on weather conditions that vary throughout the day. On the other hand, high-resolution models capture the system's dynamic due to the change in weather conditions.

Abstract:
Energy is vital to reduce poverty and improve social and economic development. For more than a century, modern economies have based their growth on fossil fuels, which has led to global warming, environmental pollution, and social problems. In accordance with the Paris Agreement (2015), governments have committed to evaluating their energy systems to seek appropriate solutions to support their decarbonization and keep global warming well below 2^{o}C. In order to achieve this objective, developing countries are making considerable efforts, among which is considered a shift to the use of renewable energy sources to satisfy their growing demand. Despite the current development and planning for the sector, there is room for improvement within the long-term planning and evaluation of energy systems. This paper analyses the difference between fossil-based and renewable-based growth in terms of economics, technical and environmental effects in Bolivia. To do so, all the country's energy sectors, including electricity, heat, and mobility, are covered and optimized through the open-source energy system modeling framework EnergyScope. Results showed a sustainable energy scenario in 2035, which accounted for 66% of renewable share and 44.64 €/t$CO_{2\text{-eq.}}$ related to a compensation value for the difference with the business-as-usual scenario based on future government plans. This work demonstrated that a Bolivian energy system with a high share of renewable resources is possible, leading to energy sovereignty addressing climate change.

Keywords:
Bolivia, Sustainable growth, Renewable energy, Energy system modeling, Energy development.

1. Introduction

Poverty reduction, industrial activities, and improvement of education and healthcare services are strongly related to the energy a society can consume. Nonetheless, the availability of energy supply is not the only objective, but also to achieve sustainability to maintain an ecological balance, social equity, and economic vitality [1]. The use of fossil fuels has led to global concern about the emissions of greenhouse gases (GHG). Therefore, one hundred and ninety countries have pledged to the Paris Climate Agreement to limit the global average temperature increase to 1.5℃ or well below 2℃ and have established clear goals to be fulfilled by the years 2030 and 2050 [2]. Decarbonization exploits pressure on all nations globally, but even more low and middle-income countries, which in most cases, have planned to rely on fossil fuels to achieve development [3]. Although Bolivia possesses a relatively low contribution to global GHG emissions (0.21% of the total 48.6 GtonCO_2eq registered in 2021) [4], it was the 43th country with the highest emissions per capita in 2021 (9.6 tonCO_2eq/person) [5]. Thus, Bolivia has signed the agreement and is putting significant efforts to meet the commitment and also become a primary net exporter of electricity in South America [6].
According to the information provided by the Ministry of Hydrocarbons and Energy (MHE), Bolivia's total primary energy supply (TPES) in 2021 was 202.9 TWh, based mostly on fossil fuels (80.7% and 11.9% of the energy coming from fossil gas (FG) and oil, respectively). From this value, 58% corresponded to gas export (117.4 TWh) [7]. Related to other sources, such as biomass, hydro, solar, and wind energy, reached 7.4%. Similarly, the power sector has relied heavily on fossil gas for the last two decades. The Bolivian power grid is divided into the National Interconnected System (SIN) and the Isolated Systems (SAs). For instance, the country's total installed electricity generation capacity was 3.72 GW for 2021, of which 71.03% comes from thermoelectric power plants, 20.36% from hydropower plants, and 8.60% from other renewable sources such as wind energy and photovoltaic systems [6]. Moreover, fossil fuel-based electricity generation is subsidized by approximately 46.63 €/MWh for diesel [8], and 3.95 €/MWh for FG (Supreme Decree No. 29510) [9]. In this context, the government has established policy guidelines, including universal electricity access, reducing the consumption of petroleum derivatives, and increasing renewable energy use for electricity generation [10].

Nevertheless, most of Bolivia's energy objectives and projections are based on 2007 statistics and extend until 2030. Recent expansion plans for the sector are described in the Patriotic Agenda for 2025 [11] and the update of the Intended Nationally Determined Contribution (INDC) [2]. For instance, the Electrical Plan of the Plurinational State of Bolivia (PEEBOL2025) presented by the MHE stipulated the installation of 183 MW of renewable energy by 2025 [12], and the Alternative Energy Development Plan (PDEABOL2025) included a simple estimation of the renewable energy potential of the country [13]. Recent projections from the National Electricity Company (ENDE) indicate that 74% of the newly installed and existing capacity will be hydropower (Hydro dam and hydro run-of-river), 4% other renewable, 12% combined cycle plants, and 10% thermal power plants. Nonetheless, only the SIN is accounted for in these forecasts. So, electrification plans for rural communities that cannot be included in the SIN are also required [12].
Furthermore, Bolivia aims to become an electricity exporter to neighboring nations. With the new large hydropower capacity inclusion, the electricity exports could account for up to 21% of total electricity exports in South America [14]. Besides the estimated hydroelectric potential of 39.86 GW related to the watercourses of the large rivers that surround Pando, Beni, and the strip that goes from the Yungas of La Paz in the north of the country to Tarija in the south, Bolivia holds a high RE potential, which is distributed throughout its territory. Thus, the country has a high solar energy potential due to its position south of the equator line and high altitude above sea level (higher than the international solar radiation average). Practically, 97% of all the national territory is suitable for solar energy, and the remaining 3% have been identified as areas of dense cloudiness located to the east of the Andes region [15]. According to Bolivia's Atlas of global solar radiation, the existing solar radiation in the country's lowlands (Santa Cruz, Beni, Pando, and north of La Paz) reaches a maximum of 5.1 kWh/m^2/day. At the same time, in the sector of the valleys (Cochabamba, Chuquisaca, and Tarija), this value can vary between 5.1 and 6.7 kWh/m^2/day and in the Altiplano (La Paz, Oruro, and Potosí), the radiation is between 6.7 and 9.5 kWh/m^2/day [16]. The most robust wind resource is located in the southern and western regions of the department of Santa Cruz, in the southwestern sector of the department of Potosí, in a strip to the west and south of La Paz and Cochabamba [17]. Furthermore, twenty-one potential geothermal resources have been detected in the country's western mountain range, eastern mountain range, and Altiplano, near the departments of Potosí, Oruro, and La Paz [15]. Significant biomass resources are available in the country, likewise. For instance, forest biomass such as firewood and logs can be extracted in the Amazon region principally. In 2005, Bolivia possessed a wood stock of 317 million m^3 in its forested area. It was estimated that the sustainable production capacity of the Bolivian forest was 20 million m^3 of wood stock per year [15, 18]. Due to the country's unique natural circumstances, Bolivia produces various agricultural products. According to the agricultural census conducted by the National Institute of Statistics, the six most important crops grown in Bolivia are sugarcane, soy, sorghum, corn, rice, and sunflower, with the Department of Santa Cruz being the primary producer [19]. Morató et al. estimated that approximately 3.7 Mton/year of sustainable biomass on a dry basis is available in Santa Cruz [20]. Even though agricultural and forest residues are abundant in Bolivia, they are not utilized as a low-cost energy source to increase the proportion of renewable energy in the energy mix and reduce fossil fuel consumption.
The Bolivian energy sector is the second largest contributor to the country's GHG emissions (After agriculture, forestry, and other land uses). Although the country lacks rigorous emissions reduction targets, the INDC, presented by the authorities to United Nations Framework Convention on Climate Change (UNFCCC), projected a decrease in GHG emissions from 0.41 tonCO_2eq/MWh in 2015 to 0.04 tonCO_2eq/MWh in 2030 in the country's power sector [2, 21]. Additionally, the Global Climate Risk Index (IGRC) of 2021 ranked Bolivia as the most affected and the tenth most vulnerable country in the world [2]. This highlights Bolivia's need for strategic energy policies and carbon reduction goals to protect its most vulnerable communities and rich biodiversity. Thus, the energy system will allow renewable energy (RE) to be competitive, cope with subsidies, and deal with the absence of negative GHG emission pricing. Therefore, the focus of this study is to model a fully sustainable transition for Bolivia across all energy sectors and assess the feasibility of such a transition in terms of economics, technical and environmental effects to help shape future Bolivian society's energy behavior and reach the objectives for a long-term sustainable energy system with low-carbon emissions. The remainder of the paper is structured as follows. Section 2 describes the methods of the EnergyScope model. Section 3 presents the current Bolivian energy system and information about resources, demand, and technologies. Section 4 provides results by sector for each scenario. These results and main limitations are discussed in Section 5. The main conclusions are summarised in Section 6, then recommendations for future works are made.

2. Methods

The present research relies on *EnergyScope TD*, a bottom-up linear programming modeling framework for the long-term planning of energy systems, including a high share of RE and representing the heating, mobility, and electricity sectors equally [22]. It has already been applied to develop energy transition scenarios for European countries such as Switzerland [22, 23], Belgium [24], Italy [25], as well as Uganda [26]. Given demands in the different sectors and resources, the model identifies a design and an hourly operation optimisation of

the conversion technologies to minimize the overall system cost, considering a constraint on greenhouse gas emissions. The main input data of EnergyScope TD are founded on three elements: resources, technologies (energy conversion, storage and infrastructure), and demand, as depicted in Fig. 1. Furthermore, it involves typical days (TD) to reduce the computational time (around one minute on a personal laptop) while keeping a simple and straightforward formulation. The reconstruction method by Gabrielli et al. enables consideration of seasonal phenomena [27]. In this application, twelve TDs have been used, which was shown to be a good trade-off between accuracy and computation time [24]. Moreover, the version utilized is the one that corresponds to Limpens' thesis [26]. Even though the original model accounted already for more than 100 options for technologies, resources and demands, an adaptation was required for the present study. The main additions were:

- Resources: Liquefied petroleum gas (LPG).
- Demand: Heat demand for cooking.
- End-use categories: Cooking and mobility freight air.
- Technologies: Open cycle gas turbine (OCGT), diesel genset, biomass combustion power plant, syngas combustion power plant, firewood stove, LPG stove, FG stove, oil stove, electric stove, aircraft, biomass fermentation to bioethanol, esterification to biodiesel, diesel engine, LPG burner and gasoline bus.

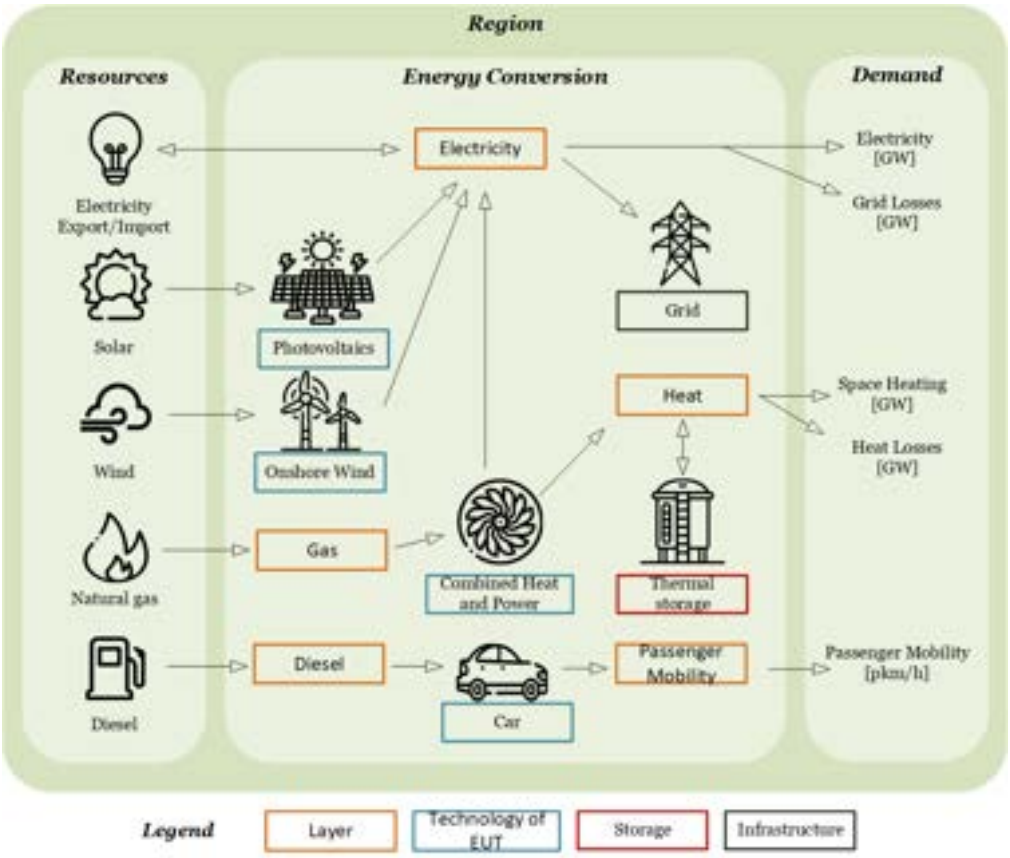

Figure 1: Conceptual representation of an energy system: Resources are converted by technologies to supply end-use type (EUT) demands related to electricity, mobility, and heating. Layers, such as *Electricity and Heat*, require to be balanced in each period. This figure is inspired from [22].

3. Case study: Bolivia

This section presents an overview of the Bolivian energy system based on the last national energy balance presented by the Ministry of Hydrocarbures and Energy (MHE) for the year 2021 [28,29], and the main techno-economic information to perform the optimisation for the year 2035.

3.1. Demonstration for the year 2021

Primary energy consumption in Bolivia for the year 2021 reached 94.28 TWh, with an approximate population of 11.84 million inhabitants [30]. Regarding sources, fossil fuels (FG, diesel, gasoline, LPG, and light fuel oil (LFO)) represented 87.0% of the country's final energy demand. In this context, the participation of renewable

energy sources was limited to less than 14% of the total: wet and woody biomass with 9.1%, hydropower with 3.4%, and others (solar and wind) with a proportion of 0.5%. This data was assembled and summarized in a Sankey diagram, Fig. 2.

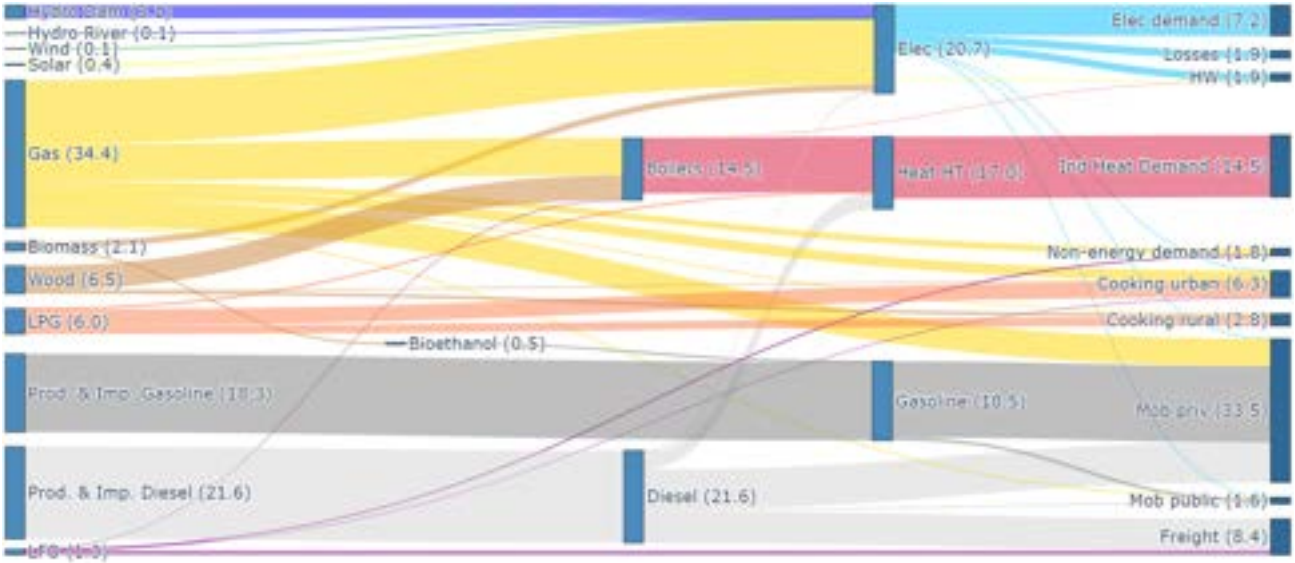

Figure 2: Energy flows of the modeled Bolivian energy system for 2021 (Units: TWh). The left side integrates all the resources while the right side retrieves the final energy consumption. The conversion technologies are in between. Energy exports are not represented. Abbreviations: mobility (mob), private (priv), electricity (Elec), liquefied petroleum gas (LPG), light fuel oil (LFO), industrial (Ind), domestic hot water (HW), low temperature (LT), high temperature (HT), importation (Imp), production (Prod).

As shown in Fig. 2, the present landscape of energy utilization in Bolivia could be divided into electricity, transport, and heat. The electricity generation was mainly covered by gas turbines (open-cycle and combined-cycle technologies), which represented around 59.7% of the total amount, followed by hydropower (29.7%), biomass (4.2%), photovoltaic (3.2%), diesel gensets (2.1%), and wind (1.1%) [6, 29]. The mobility sector was split into public transport with diesel, gasoline, gas buses, and electric aerial tramways. On the other hand, private transport comprised light vehicles fueled by gasoline, diesel, fossil gas, and electricity [31, 32]. Trucks contributed the most to freight transportation. Still, there were also rail, boat, and air transport options. Heat use was subdivided into three major demands: cooking, domestic hot water (HW), high-temperature heat (HT) from industrial processes such as manufacturing (foods and beverages, textiles, no metallic, and metallic), cement production, mining, and quarrying [31]. Residential and commercial cooking demand in Bolivia was mainly based on LPG (approximately 73.6%), followed by fossil gas (23.2%), woody biomass (2.5%), electric (0.4%), and LFO stoves (0.3%). A division between cooking in rural and urban areas was made, as the gas network does not cover the entire country. Likewise, the industry also relied on FG [28]. Overall, the EnergyScope TD model accurately portrayed the final energy consumption (FEC) of the Bolivian energy sector and its associated GHG emissions for the year 2021. The assessment of the present state of the system revealed 94.19 TWh/y in terms of primary energy consumption, differing only 0.1% from the country's energy balance [28]. Similarly, regarding CO_2 emissions related to the energy sector and waste, the model calculated 24.51 $MtCO_{2\text{-eq.}}$/y whereas CAIT country greenhouse gas emissions reported 23.17 $MtCO_{2\text{-eq.}}$/y [4, 33, 34].

3.2. Scenario in 2035

Due to a vast array of modern technologies and a rapid expansion of the economy, the energy system of Bolivia may undergo significant changes. So, this section presents the resources and technology potentials and forecast demands for Bolivia in 2035, a period that allows for substantial transformations yet close enough to know the available technologies at that time.

3.2.1. Energy resources

The resources available for the Bolivian energy system could be divided into fossil and renewable.

3.2.1.1 Fossil resources

Bolivia holds FG reserves (2 729, 1 009, and 1 485 TWh of proven, probable and possible reserves in 2018) [29]. Furthermore, the economy of the country relies to a great extent on fiscal revenues and tax collection from FG exports. In 2021, nearly 72% of its total FG production was exported (75.45 and 48.22 TWh of FG to Brazil and Argentina, respectively). Those accounted for 20.5% of Bolivia's total exports (around 1 924

M€) [35]. Nonetheless, oil extraction is limited (14.09, 89.00, and 220.25 TWh of crude oil, natural gasoline, and condensate proven reserves in 2018, respectively) [29]. Consequently, the government has to import diesel, gasoline, and other oil-based products. Since 2001, Bolivia has subsidized those fuels in the energy sector, intending to pass on affordable prices (46.63, 53.48, 35.45, 3.95 €/MWh related to diesel, gasoline, LFO and FG subsidized prices, respectively) [36]. For comparison, the prices used in this article correspond to the ones without the subsidy (Table 1). Moreover, the estimated prices of fossil fuels for the horizon of 2035 in Bolivia are based on the projection of the U.S. Energy Information Administration (EIA), expressed in the reference case of the Annual Energy Outlook 2022 (153.91, 163.21, 139.10, 15.03, 33.27 €/MWh for diesel, gasoline, LFO, FG, and LPG, respectively) [37].

3.2.1.2 Renewable resources

Renewable energies are essential to the energy transition; consequently, their deployment is crucial. Real weather data and scaled inflows were used to model solar, wind, and hydro resources to account for temporal variations in availability. For each hour, average capacity factors for wind and solar were computed using the open-source Renewables Ninja database [38–40]. For hydropower plants, hourly water inflows were used. The Electric Load Dispatch Committee (CNDC) supplied these hydrological data; values are publicly available in [41]. The biomass and waste yearly resources could be summarized as follows: 17.81 TWh of wet biomass from agricultural residues [42], 5.2 TWh of wet biomass from the 2010 approximated value of organic municipal solid waste [30, 43], 4.5 TWh of wet biomass used to generate electricity in 2021 [29], 5.7 TWh of wet biomass used to reach the maximum volume mentioned in the agreement by the government and the bioethanol producers until 2025 [44], 1.2 TWh of wet biomass from elephant grass of the two future biomass power plants planned by the government [45] and 28.6 TWh of wet biomass from the three future biodiesel production facilities planned to be built until 2025 [46]. Unfortunately, no information about woody biomass resources such as forest residues has been reported. So, only firewood for cooking was considered in this article, accounting for the sustainable production of wood as a limit [18]. The potential geothermal estimates were determined according to Gawell et al. [47], besides the planned Laguna Colorada geothermal power plant, which is currently a pilot plant [48]. Table 1 summarizes the resource potential described previously.

Table 1: Energy resources and their potential.

	Sources	TPES in 2021 (TWh)	Availability (TWh/y)	Price in 2021 (€/MWh)	References
Fossil fuels	Gasoline	18.54	(no limit)	124.12	[29]
	Diesel	21.72		111.31	
	LFO	1.07		85.12	
	FG	34.43		10.66	
	LPG	6.03		21.58	
Biomass	Woody	0.78	150	16.98	[18, 29]
	Wet	2.07	63	10.32	[29, 30, 42–46]

3.2.2. Energy demand

The Latin American Energy Organization (OLADE) published a report offering future energy projections of the Andean zone. Those numerical values included the yearly FEC by fuel based on future expansion plans of the energy sector, energy balances, and gross domestic product (GDP) growth of Bolivia, Colombia, Ecuador, Perú, and Venezuela until 2050 [49]. The yearly end-use demand (EUD) was estimated and used as an input parameter in the model based on this final energy demand. Besides, cooling demand was not specified due to the lack of information on the consumption of residential, commercial, and industrial subsectors. Nonetheless, as in other developing countries, refrigeration, food conservation, and air conditioning (AC) requirements in Bolivia are usually covered by electricity [50]. Therefore, it is already included in electricity demand. For instance, AC is seldom used in the households of the Altiplano and the valley regions. On the other hand, electric fans and AC systems utilizing liquid refrigerants are commonly employed in the country's lowlands urban areas. These can account for up to 40% of the total energy demand in an urban household in Santa Cruz during a hot summer day [51, 52]. Moreover, commercial and home refrigerators and other complex industrial systems in the country usually comprise electric compressors [50]. Table 2 illustrates the differences between the end-use demand in 2021 and 2035.

Table 2: Comparison of energy end-use demand for 2021 and 2035. Abbreviations: temperature (Temp.), passenger (pass.), tons(t).

		Units	2021	2035	Δ	References
End-use demand	Electricity	(TWh)	7.2	10.1	+2.9	[28, 49]
	Heat High-Temp. [a]	(TWh)	14.5	19.9	+5.4	
	Heat Low-Temp. [a]	(TWh)	1.8	2.5	+0.7	
	Cooking [a]	(TWh)	5.1	6.9	+1.8	
	Mobility pass. [a]	(Gpass.-km)	73.7	101.0	+27.3	
	Freight [a]	(Gt-km)	15.5	21.2	+5.7	
	Non-energy [a]	(TWh)	1.8	2.4	+0.6	

[a] In [49], the FEC is provided instead of the EUD; hence own calculations were performed to estimate these values.

The forecast given in Table 2 shows an increase in all types of demands of around +37%. Electricity increase was the most important (+42%). The increase in energy demand was related to the projected economic growth of the country at an average annual GDP growth of 2.7% since 2024 [49] and the population growth with an average rate of 1.33% for the 2020-2040 period [53]. In addition to yearly demands, an hourly time series is used to dispatch the variable demand over the year. Thus, the electricity demand series was obtained from CNDC [54], and the mobility demand was adapted from [55].

3.2.3. Energy technologies

The technologies utilized in this study can be divided into three categories: conversion, storage, and network. Conversion refers to transforming one energy carrier into another with conversion efficiency. Storage devices can store energy over time, characterized by input/output efficiency and losses. Lastly, networks permit the transport of certain energy carriers across the nation, such as the gas or electrical grid. The networks are characterized by transmission losses. In this case, the one for the electricity grid is set at its historical value of 17.2% [28, 29]. Future technologies were based on local commercial availability [51, 53], government plans, and trends in Bolivia, so hydrogen-based, carbon-capture, heat pumps, and seasonal storage technologies were not considered. Table 3 shows different technologies' installed capacity and potential.

4. Results

In the following section, the model was applied to prospect the energy system at the horizon of 2035. The data used were listed in Section 3.2. First, the Business As Usual (BAU) projected scenario based on the future power plants [12] and biodiesel production facilities [61], planned by the government until 2025 was presented 4.1.). Then, a renewable-based scenario was proposed and compared to the BAU one (see 4.2.).

4.1. Business As Usual (BAU) case

The Business As Usual case was based on the characterization of the Bolivian energy system without GHG constraints, leading to a scenario without considering major changes in consumption trends or policies that alter the behavior of the system components. Hence, a minimum capacity for power plants, the technologies for producing biodiesel and bioethanol, and the share between the different mobility technologies were maintained.

4.1.1. Major trends in energy consumption

Optimisation results stated a FEC of 142.08 TWh per year, representing an increase of 50.8% compared to the year 2021. Figure 3 illustrates the energy balance over the year 2035 from primary to final energy consumed for this solution. As can be seen, the system still relied heavily on FG (around 42.9% of the total demand), which was consistent with the regional policies of extraction, production, and use of this resource. Furthermore, the national reserves were sufficient to supply the mentioned demand besides the significant growth and the export volumes of the current contracts (Approximately 2 619.1 TWh of total gas demand from 2021 to 2035). Related to renewable resources, there was a massive increment of biomass to produce biodiesel and bioethanol in this scenario according to the government plans. Regarding GHG emissions, the system produced 25.74 $MtCO_{2\text{-eq.}}$ (around 1.81 $tCO_{2\text{-eq.}}$ per capita), during its yearly operation, which represented a 5.0% increase compared to the system of 2021, and 66% smaller than the Belgian cost optimum BAU scenario for 2035 [24].

4.1.2. Power sector

Electricity generation was dominated by hydro dam power plants (6.24 TWh), followed by combined cycle gas turbines (3.34 TWh), Photovoltaic plants (PV) (1.75 TWh), geothermal plants (0.80 TWh), wind turbines (0.61 TWh), hydroelectric run-of-river power units (0.30 TWh), open cycle gas turbines (0.27 TWh), and bioenergy steam turbines (0.51 TWh). Aside from the planned power plants established in PEEBOL2025, only one

Table 3: Installed capacity of technologies and their potential.

	Technology	Capacity in 2021	Initial capacity in 2035	Max. Potential	References
Electricity generation ($GW_{elec.}$)	Combined cycle gas turbine	1.05	1.05	(no limit)	[6]
	Open cycle gas turbine	1.06	1.06

	LFO aircraft	2.1	2.1		
Storage (TWh)	Battery of electric vehicles	0.01	0.01	(no limit)	[29]

energy technology represented a cost-effective solution and experienced an increment. PV installed capacity rose from 0.18 GW to 0.88 GW.

4.1.3. Heat sector

Heating demands (HW, HT, and cooking) were projected to increase from 21.40 TWh in 2021 to 29.32 TWh in 2035. Regarding HT demand, gas-based heating remained nearly the sole technology (Almost 99.9% of total demand). HW demand was provided by gas boilers (with 99.2%) and solar thermal (around 0.8%). The latter's share was based on the current installation ratio of these technologies in Bolivia (500 systems/y), according to Noël [59] and Fernandez [52]. Finally, the cooking demand was covered by FG (68.4%), electric (16.2%), and LPG stoves (15.4%) in the urban areas and by FG (81.7%) and LPG (18.3%) in rural areas. Moreover, biomass and kerosene stoves were reduced from the solution, covering only 0.1 MWh of the cooking demand. The share of the different fuels used for cooking was projected based on the information presented by the National Statistics Institute of Bolivia (INE) in 2021 [62].

4.1.4. Transport sector

The final energy demand for public and private passenger transportation was based on FG (42.5%), gasoline (34.1%), diesel (20.9%), and electricity (2.4%). Moreover, electric tramways for public transport showed an

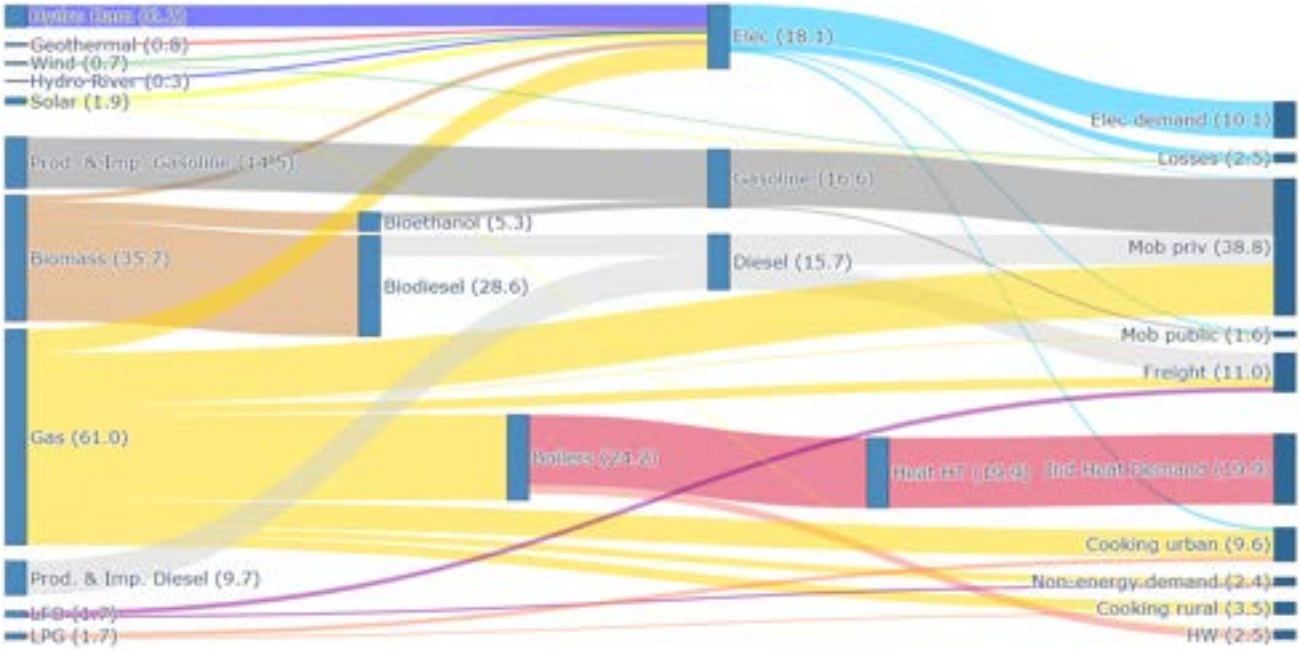

Figure 3: Energy flows of the modeled Bolivian energy system for 2035 BAU scenario (Units: TWh). The left side integrates all the resources while the right side retrieves the final energy consumption. The conversion technologies are in between. Energy exports are not represented. Abbreviations: mobility (mob), private (priv), electricity (Elec), liquefied petroleum gas (LPG), light fuel oil (LFO), industrial (Ind), domestic hot water (HW), low temperature (LT), high temperature (HT), importation (Imp), production (Prod).

increase. Those technologies resulted in an installed capacity of 0.81 GW. On the other hand, fossil fuels technologies (FG, diesel, and LFO) almost completely covered freight transport demand (63.2%, 23.0%, and 13.8% of diesel vehicles, FG vehicles, and aircrafts, respectively). Furthermore, freight share was 85.0% of transportation by road, 13.8% of transportation by air, 1.1% of transportation by rail, and 0.1% of transportation by boat. Even though the demand for liquid fossil fuels was considerable, approximately 12.7% of all gasoline and 38.3% of all diesel were produced from biofuels such as bioethanol and biodiesel.

4.2. Renewable energy (RE) case

In this scenario, the system was simulated considering the minimum GHG constraint that allowed finding a feasible optimisation solution, determining whether total growth based on renewable resources was achievable, and seeking a low carbon emission case.

4.2.1. Major trends in energy consumption

In contrast to the BAU scenario, the system depended on biomass as the principal primary energy source (40.5 TWh and nearly 29.5% of TPES). Nonetheless, biofuel production remained the same due to a lack of information on the maximum production limit. For instance, the government created a program in 2022 to promote oil production of oil species such as African palm, jatropha, macororó, and soybean (Supreme Decree No.4764). Those energy crops are expected to be farmed, reaching an approximate production of 638 344 m^3/y of biodiesel [63]. Moreover, an agreement with local ethanol producers has established a maximum purchase of 380 000 m^3/y of bioethanol by 2025, an amount which will be used as blended fuel with gasoline (Law No. 303/2017-2018) [44]. As shown in Figure 4, FG was still present but reduced (around 78.7 % less than the BAU scenario). Regarding CO_2 emissions, the system produced 12.50 $MtCO_{2\text{-eq.}}$/y, representing a 49% of decrement compared to the 2021 case.

4.2.2. Power sector

Electricity generation was dominated by PV (25.03 TWh), followed by wind turbines (15.75 TWh), hydro dam power plants (6.54 TWh), geothermal plants (2.38 TWh), bioenergy steam turbines (1.93 TWh), and hydroelectric run-of-river power units (0.31 TWh), and limited production of combined cycle and open cycle gas turbines (2.66 MWh). In terms of total installed capacity, PV arrays reached 12.70 GW, wind power 4.98 GW, bioenergy steam turbines 0.65 GW, and geothermal plants 0.30 GW.

4.2.3. Heat sector

The energy supply for the heat sector was extensively electrified. To illustrate, HT demand was based on direct-electric heating (around 77% of total demand), followed by gas boilers (23%). Also, the HW demand

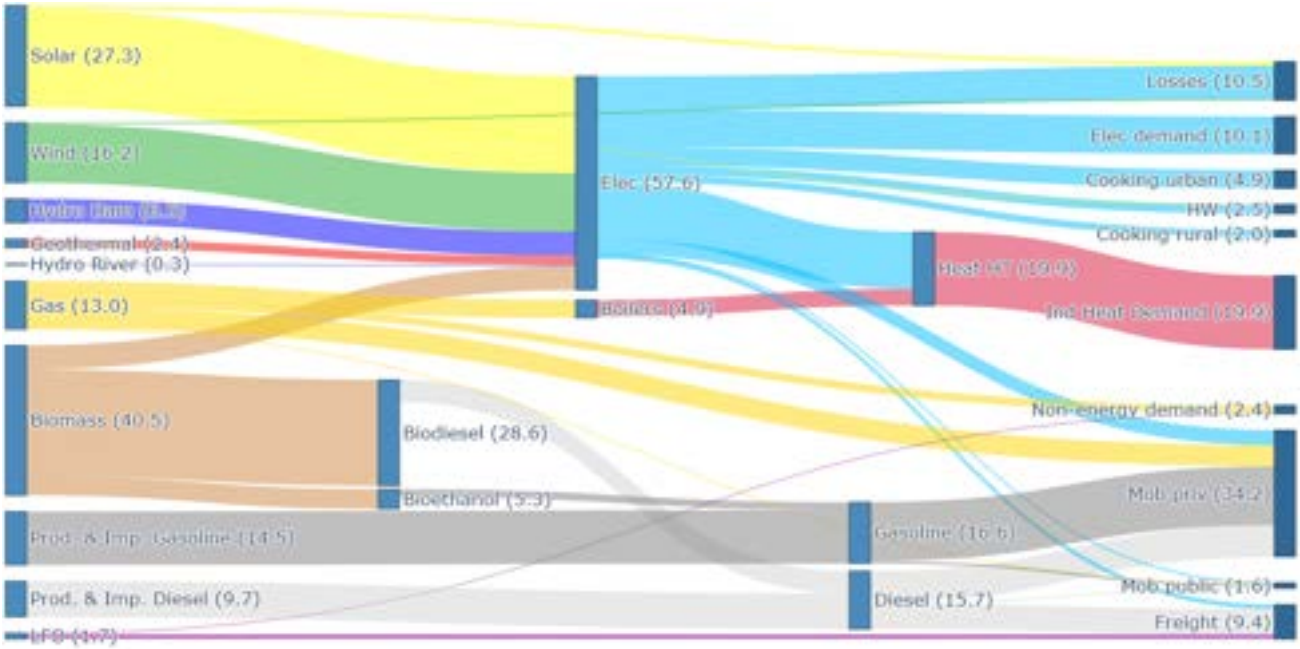

Figure 4: Energy flows of the modeled Bolivian energy system for 2035 RE scenario (Units: TWh). The left side integrates all the resources while the right side retrieves the final energy consumption. The conversion technologies are in between. Energy exports are not represented. Abbreviations: mobility (mob), private (priv), electricity (Elec), liquefied petroleum gas (LPG), light fuel oil (LFO), industrial (Ind), domestic hot water (HW), low temperature (LT), high temperature (HT), importation (Imp), production (Prod).

was provided by electric heating (99.2%), and the rest corresponded to solar thermal (around 0.8%). Finally, the cooking demand was almost completely covered by electricity in urban and rural areas.

4.2.4. Transport sector

Regarding the transport sector, there was a limited electrification share. The mobility demand for public and private passenger transportation was covered by gasoline (34.1%), electricity (27.4%), diesel (20.9%), and FG technologies (17.6%). Similar to the BAU scenario, electric tramways ended up with an installed capacity of 0.81 GW. The demand for freight transportation was covered by diesel-based vehicles (63.2%), electric trucks (23.0%), and aircraft (13.8%). The share between rail, boat, road, and aviation freight transport remained the same as the BAU scenario.

5. Discussion

This section highlights key insights and trends from the preceding sections. Finally, the limitations of the work were enumerated.

5.1. Comparison of scenarios

In 2035, according to the BAU scenario results, the Bolivian energy system is still fossil-based, with traditional fuels accounting for 62% of the TPES. Most of the primary energy goes to mobility (51.4 TWh), whereas heating and industrial processes are the second sector (24.2 TWh), electricity the third one (18.1 TWh), and cooking the last one (13.0 TWh). In contrast, the RE scenario is only 28% fossil-fuel dependent on the TPES. Moreover, the electricity sector represents 56.5 TWh in terms of primary energy due to the high electrification of the scenario, followed by the mobility sector with 45.1 TWh, heating and industrial processes with 22.7 TWh, and cooking with 6.9 MWh. Regarding the system's annualized total cost, the BAU scenario shows a lower value than the RE scenario (6 925 and 7 516 M€ per year for BAU and RE scenarios, respectively). Nonetheless, the RE solution reduces 49% of GHG emissions from 2021 (51% fewer emissions than the BAU scenario), which is equivalent to 44.64 €/$tCO_{2\text{-eq.}}$ of compensation. Moreover, it is essential to highlight that the mobility sector is a main constraint to the system transition, as the majority of the vehicles throughout the 14 years of analysis remain in the system due to the permissive laws and regulations in Bolivia. Nearly 8% of the total vehicle fleet in 2021 was composed of vehicles manufactured in 1885 or below, according to INE [62]. Moreover, the importation of new vehicles is still under the Euro II emissions standard [64].

5.2. Limits of the study

The energy system optimisation model was intended for developed economies with well-established networks and accounting for all users with electricity access. Moreover, more studies are required to confirm the dispatchability of various resources, such as agricultural and industrial residues, municipal solid waste, biofuels, or power for cooking. Furthermore, decentralized energy systems like microgrids, a significant component of Bolivia's power sector, should be accounted for. Additionally, a model for cooling demand could be determined and evaluated to estimate this consumption and associated technologies. Also, a more thorough market analysis is required to evaluate the costs of the existing technologies, their evolution, and the introduction of others. Energy policies could be evaluated especially for the transport sector and account for an increase in the share of public mobility. Finally, this study does not address the socioeconomic effects of the transition based on fossil fuels or renewable energy.

6. Conclusions

The Bolivian energy system is going to experience a transition from a fossil fuel-based supply to one with a high share of renewable resources to fulfill the commitment of the Paris Agreement and future governmental plans. Nowadays, the country is going through strong population and economic growth, which is reflected in future energy demand projections. In this context, the energy system was assessed utilizing the EnergyScope TD framework in order to gain a comprehensive understanding of its reality. The adapted version of the model for Bolivia is freely available at [65].

The case study consistency was verified by applying the energy system optimisation for the national energy balance of 2021, showing a high similarity between the reported and simulated values. Furthermore, the highest energy demand in the mentioned year was related to the transport sector, mainly supplied by gasoline (18.5 TWh), diesel (17.2 TWh), and fossil gas (6.7 TWh). This is followed by heat demand for industries, agriculture, and mining, mostly based on FG (8.7 TWh). Electricity demand was covered principally by FG (14.9 TWh), and finally, cooking demand was based on LPG (5.8 TWh), FG (2.5 TWh), and wood (0.8 TWh). The latter was more used in rural populations.

A projection of the energy system by 2035 allowed to identify difficulties and opportunities. With the current subsidies for fossil fuels, the system would economically prefer to experience growth based on fossil energies. For this reason, a optimisation was carried out including future plans, fuel prices, and technologies costs from the government's point of view. The latter scenario being called the business-as-usual scenario. It represents a share of 32% renewable sources related to the final energy consumption and a 5% rise of greenhouse gas emissions compared to the 2021 case. Furthermore, this scenario could not meet the emissions target of the INDC (0.18 ton$CO_{2,eq}$/MWh).

On the other hand, a sustainable scenario with a constraint in greenhouse gases emissions to reach a low-carbon system showed a renewable resources share of 66%. Although this latter was a bit more expensive, it showed a 49% decrement of CO_2 emissions during its operation from the base case, which is also equal to 44.64 €/t$CO_{2\text{-eq.}}$ of compensation. This growth driven by renewable energy required the electrification of heat and transportation systems, as well as enhancing renewable electricity generation using solar, wind, biomass, and geothermal technologies. Finally, this work has demonstrated that a Bolivian energy system with a high share of renewable resources could meet a significant increase in energy demand for all sectors at every hour throughout the year. Yet, to achieve this change, national policies must set ambitious goals for the transportation and heat sectors. Future studies should consider the pathway to assess the complete transition of the system, including more policy scenarios for different sectors.
Moreover, an improvement of the technical resolution is required, assessing the potential of microgrid systems such as PV-battery systems necessary to generate electricity, especially in remote areas, and addressing the extension of the electricity and gas network around the country.

Abstract:

Carnot battery is considered one of the most promising technologies for large-scale electricity storage. Among the available configurations, the so-called Integrated Energy Storage System (I-ESS) developed by the University of Padova research group allows the use of components of unused gas turbine power generation units for storage purposes. In particular, during low-demand hours, the electricity generated in surplus by, e.g., wind and solar, is used in an electric heater to heat up the air sucked by a fan. When air passes through the tank composed of a packed bed of solid material, it heats the bed itself. Therefore, excess electricity is stored as sensible heat in the storage material. Air then leaves the tank and is released into the atmosphere. During peak demand hours, the heat stored in the packed bed is extracted and converted again into electricity using a modified gas turbine in which the combustion chamber is bypassed and replaced by the storage tank. Having established that the I-ESS configuration can compete with the other large-scale storage technologies, the focus of this work is on the I-ESS off-design performance during the discharge phase. An investigation that still lacks in the literature. To predict the behaviour of the plant in part-load, the characteristic curves of the turbine and the compressor are implemented into the mathematical model of the I-ESS. In this way, the influence of key parameters such as pressure ratio, turbine inlet temperature, and generated power is analysed for the different state of discharge of the tank. The parameter that most affects the discharge time is the temperature of the tank. In fact, for a temperature of 1200 K, the total discharge time is up to 35 h. The discharge efficiency reaches 25.3%.

Renewable Energy, Thermal Energy Storage, Off-design, Part-load analysis, Carnot battery.

1. Introduction

Reducing CO_2 emissions from human activities is one of the most urgent challenges in our society, and the electricity sector is one of the most impactful in terms of greenhouse gas emissions. For this reason, the production of power from renewable energy sources (RES) is of crucial importance to boost the sector decarbonisation. However, variability and unpredictability, the distinctive traits of renewables such as wind and solar, are pushing the need to develop and install energy storage units (ES) to avoid mismatch between electricity supply and demand. Various ES technologies have been developed over the years, each with its features in terms of power, capacity, response time, etc. Due to these differences, ES technologies can be classified according to their role in grid regulation, the way adopted to store the electricity, the amount of storable energy, etc.

Among large-scale technologies, electrochemical (flow batteries, FBs) and mechanical storage (pumped hydro storage (PHS) and compressed air energy storage (CAES)) are considered mature and commercially available solutions. However, FBs suffer from a short lifespan, whereas PHS and CAES are subjected to stringent geographical constraints. In addition, CAES needs a fossil fuel stream, whereas PHS requires an almost constant water flow rate. Furthermore, the vast exploitation of suitable PHS installation sites (especially in Europe and the United States), coupled with the drawbacks mentioned above, limits the further spread of this mature technology.

In fact, in recent years, due to the need for new types of grid-scale ES, researchers have begun to look at *thermomechanical* storage. Among these technologies, there are liquid air energy storage (LAES) systems and the so-called *Carnot batteries* (CBs). The latter is one of the most promising solutions in the field of large-scale electricity storage, as underlined by both Vecchi et al. [1] and Lampasi et al. [2]. The general working principle of a CB is as follows: during the charge, electricity is converted into heat and stored as thermal energy. When power is requested from the grid, thermal energy is converted back into electricity and delivered to the grid.

Several types of CB have been studied over the years (i) using sensible and latent thermal energy storage (TES), (ii) performing the charge by direct electric heating, heat pumps and low-temperature waste heat, and (iii) discharging the system by means of different thermodynamic cycles such as the Rankine, Brayton-Joule, and Kalina cycles [3]. Despite the proposals, the most studied CB plant arrangement is the one named Pumped Thermal Energy Storage (PTES).

PTES is characterised by a high energy density, low self-discharge rate, no geographical limitations, and a small installation footprint. It is based on a high temperature heat pump cycle, which converts the off-peak electricity into thermal energy and stores it inside two man-made thermally isolated tanks (usually called 'thermal energy storage' (TES)): one hot (storing temperature from 500°C to 1000°C) and one cold (storing temperature ranging from -150°C to -70°C). During high-demand hours, the system is discharged. In this phase, a thermal engine cycle is adopted to convert stored thermal energy into electricity. The working fluid is a gaseous medium, air, or argon, while electricity is stored as sensible heat using inexpensive and solid materials such as concrete, gravel, or other common minerals [4–6]. In addition, PTES allows the use of components from existing out-of-market fossil-based thermal power plants.

The latter is the motivation that led the authors of this work to develop the Integrated Energy Storage System (I-ESS): a storage unit that can be embedded in unused or currently being decommissioned fossil-based power plants, as well as at the same installation site for wind and solar plants [7, 8].

Briefly, the plant stores electricity as sensible heat in a high-temperature artificial tank consisting of a packed bed. The I-ESS plant is an open cycle that adopts air as a working fluid in both the charging and delivery modes. The charging scheme consists of a high-temperature tank, a fan, an electric heater, an electric motor, and a heat exchanger, while the delivery unit is made up of a compressor, a turbine, an electric motor/generator and the same high-temperature tank. In practise, the power train is a gas turbine in which the high-temperature tank replaces the combustion chamber.

Compared to PHS and CAES, I-ESS does not suffer from geographical constraints and does not require a stable water flow, such as PHS, or a natural gas stream such as CAES. Unlike FBs, the I-ESS plant is characterised by a longer cycle life, whereas, compared to PTES, the I-ESS layout features a lower complexity. Despite the previously conducted studies demonstrated the feasibility of the I-ESS plant (see, e.g., [7, 8]), and its ability to be coupled with a variable renewable-based facility to smooth its variable production (see, e.g., [9]), it is necessary to investigate the off-design behaviour of the system during the discharge phase. This is a critical phase due to the need for fast matching the grid requirements; a fact that forces the I-ESS plant to operate in off-design conditions.

To this end, the mathematical model of the I-ESS is improved by implementing the performance maps of the turbomachines and a tailor-made control strategy in order to make the mathematical model able to predict the off-design behaviour of the I-ESS during the discharge. To investigate only the discharge phase, the starting point of the TES tank is an isothermal condition.

The rest of the work is organised as follows. Section 2. describes the I-ESS layout, while Section 3. presents the off-design mathematical model of the I-ESS storage unit. Section 4. summarises the most interesting outcomes of the numerical investigation, while Section 5. states the conclusions.

2. Integrated Electricity Storage System (I-ESS)

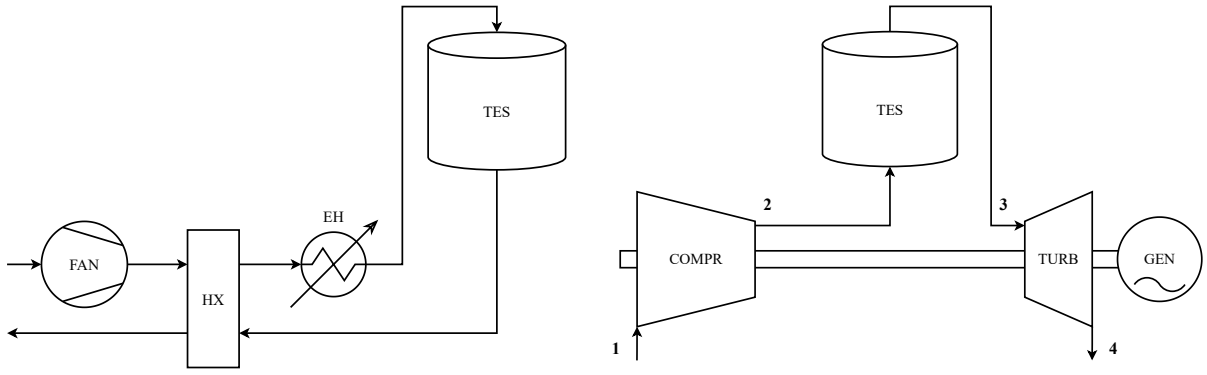
The storage plant investigated in this work is based on the configuration developed and tested by Benato et al. [7, 8]. The arrangement is named Integrated Energy Storage System; a thermomechanical unit for storing electricity in the for of sensible heat that allows the use of components of existing unused or in-decommissioning fossil power plants. In this way, the system provides flexibility to the grid without installing additional capacity.

The layout of the plant is sketched in Figure 1.

During charge, a fan guarantees the circulation of air in the storage charging circuit. Air is the heat transfer fluid. After being sucked by the fan, the air is preheated in a heat exchanger (HX) using the energy content of the air leaving the storage tank and then heated up by a resistive electric heater (EH). Hot air leaving the electric heater is at a high temperature and enters the TES tank. Air heats the solid material that constitutes the thermal energy storage tank. Therefore, electricity is stored as sensible heat because of an increase in the temperature of the storage material. The power input during the charging phase is in the fan and in the electric heater. The adoption of an EH allows the air temperature to be maintained at the input of the packed bed at a fixed value independently of the other operating conditions.

Note that in a PTES system, the storage inlet temperature is an independent variable only if the compressor's inlet conditions are constant. This is guaranteed by a heat exchanger; a component that is the source of high losses.

The discharge cycle is based on the Brayton-Joule thermodynamic cycle. In terms of components, the discharge arrangement is a gas turbine, where thermal storage replaces the combustion chamber or an air bot-



(a) *Charge phase* (b) *Discharge phase*

Figure 1: Layout of the I-ESS system in (a) charge and (b) discharge modes.

toming cycle in which the heat exchanger is replaced with the TES tank.

The air under ambient conditions is sucked and compressed by a compressor. Then it is heated in high-temperature TES. Consequently, the temperature of the material that makes up the TES decreases with increasing of the discharge time. Finally, the hot air expands through a turbine and returns to the atmosphere. The mechanical power generated by the turbine is converted into electricity through the electric generator. In this way, excess electricity generated by renewable sources and not requested by the grid is stored as sensible heat and then reinjected into the grid when required.

In the I-ESS configuration, the compressor and the turbine can be radial and axial turbomachines depending on the plant nameplate power. In this case, the devices are axial turbomachines that work at a constant rotational speed.

Although the layout of both working conditions is shown in Figure 1, only the discharge phase is investigated. The reason for this choice is as follows. In previous studies, it was shown that, despite poor efficiency, the investment costs of I-ESS are really competitive with other ES technologies [7]. Furthermore, a proper selection of the type and shape of solid storage material allows the plant to reduce costs, as well as design a storage facility that can store a different amount of energy in the same volume [8]. A feature that intrinsically guarantees the scalability of the plant based on the needs of the network. However, an in-depth analysis of plant behaviour under off-design conditions is still lacking. To fully understand the potential of the proposed storage system and develop custom management strategies, the decrease in turbomachine efficiency under part-load conditions must be taken into account. For these reasons, this work is focused on off-design modelling of the I-ESS system with an in-depth description of the compressor and the turbine through the use of performance maps.

3. The I-ESS off-design numerical model

During the delivery phase, the thermal reservoir temperature profile changes continuously. This means that the turbine inlet temperature (TIT), which is the driving parameter in calculating the equilibrium point of the system, also changes continuously. This fact leads to two important consequences. On the one hand, unlike a conventional power plant, the I-ESS never works under design conditions. Therefore, it is important to build an ad hoc mathematical model to describe its off-design behaviour. However, the system operates in a continuous transient state. Therefore, the steady-state working point does not exist.

In the already available I-ESS mathematical model, only the thermal reservoir one is dynamic, whereas the rest of the components, as well as the control strategy, are treated with a steady-state approach. This means that the model is built on the hypothesis that the time constant of the thermal phenomena is higher than the time constant of the mechanical one. With this approach, a pseudo-steady-state equilibrium point is computed at each time step.

Obviously, this way of modelling the turbomachinies is widely adopted and guarantees to describe in an appropriate manner the behaviour of the system, especially if the simulation time involves the entire year. However, to predict the step response and the start-up/shut-down of the storage unit, a proper dynamic model of the whole system must be built, but this is beyond the objectives of this work because it is focused on the discharge arrangement.

The system consists of two axial turbomachines and a packed-bed thermal reservoir. The power regulation of the plant takes place by managing the angle of the variable inlet guide vanes (VIGV) at the compressor inlet, while the rotational speed of the shaft remains constant. The model is built in a Matlab environment, while the

thermophysical properties of both air and storage material are taken from the *NIST* databases.

3.1. The I-ESS off-design model

3.1.1. The air compressor model

Turbomachines are modelled with a zero-dimensional approach. In fact, the behaviour of both the compressor and the turbine is described through their performance maps. Standard maps are taken from the database of commercial software [10] and then scaled according to the design point. The working point, which is characterised by a certain combination of pressure ratio (pr), mass flow rate ($\dot{m}$) and isentropic efficiency (η_{is}), is expressed as a function of rotational speed (N) and auxiliary coordinate β (see Equation 1).

$$\{pr, \dot{m}, \eta_{is}\}_c = f(\beta_c, N_c) \tag{1}$$

Due to the maps' interpolation, these values can be derived. Then, providing as input the inlet pressure and temperature, it is possible to compute the outlet conditions using Equation 2 and Equation 3.

$$p_2 = p_1 \cdot pr_c \tag{2}$$

$$T_2 = T_1 \cdot \left(1 + \frac{1}{\eta_{is,c}} \cdot \left(pr_c^{\frac{\gamma-1}{\gamma}} - 1\right)\right) \tag{3}$$

During off-design operating conditions, the I-ESS management system varies the VIGV angle (α_{IGV}) to keep the rotational speed constant. The laws that describe the modification of the compressor working point as a function of α_{IGV} are as follows.

$$a_{VIGV} = \frac{\partial \dot{m}\,[\%]}{\partial VIGV\,[^\circ]} \tag{4}$$

$$b_{VIGV} = \frac{\partial (pr_c - 1)\,[\%]}{\partial VIGV\,[^\circ]} \tag{5}$$

$$c_{VIGV} = \frac{\partial \eta_{is}\,[\%]}{\partial VIGV\,[^\circ]} \tag{6}$$

The values of the coefficients a, b, and c are set equal to 1, 1 and 0.01 as suggested in Ref. [11]. The positive values of α_{IGV} correspond to the closure of the variable inlet guide vanes. In contrast, negative values mean an opening of the VIGV compared to the design position ($\alpha_{IGV,des} = 0$).

3.1.2. The turbine model

The turbine is also modelled using standard maps scaled according to the design values of the pressure ratio and the corrected mass flow. As given for the compressor, the values of the mass flow rate, the pressure ratio and the isentropic efficiency are expressed as a function of the rotational speed and the auxiliary coordinate β (Equation 7).

$$\{pr, \dot{m}, \eta_{is}\}_t = f(\beta_t, N_t) \tag{7}$$

The turbine geometry is fixed, and there are no variable inlet guide vanes. The outlet temperature and pressure are calculated as given in Equation 8 and Equation 9.

$$p_4 = \frac{p_3}{pr_t} \tag{8}$$

$$T_4 = T_3 \cdot \left(1 - \eta_{is,t}\left(1 - \left(\frac{1}{pr_t}\right)^{\frac{\gamma-1}{\gamma}}\right)\right) \tag{9}$$

3.1.3. The thermal energy storage with packed bed mathematical model

The thermal energy storage tank is the key component of the I-ESS plant because it allows the storage of electrical energy in the form of sensible heat.

Several models can be found in the literature for the description of the thermal reservoir [12] but, in this case, the TES-PD model developed by Benato et al. [13] is adopted. The TES-PD model is a 1D model in which

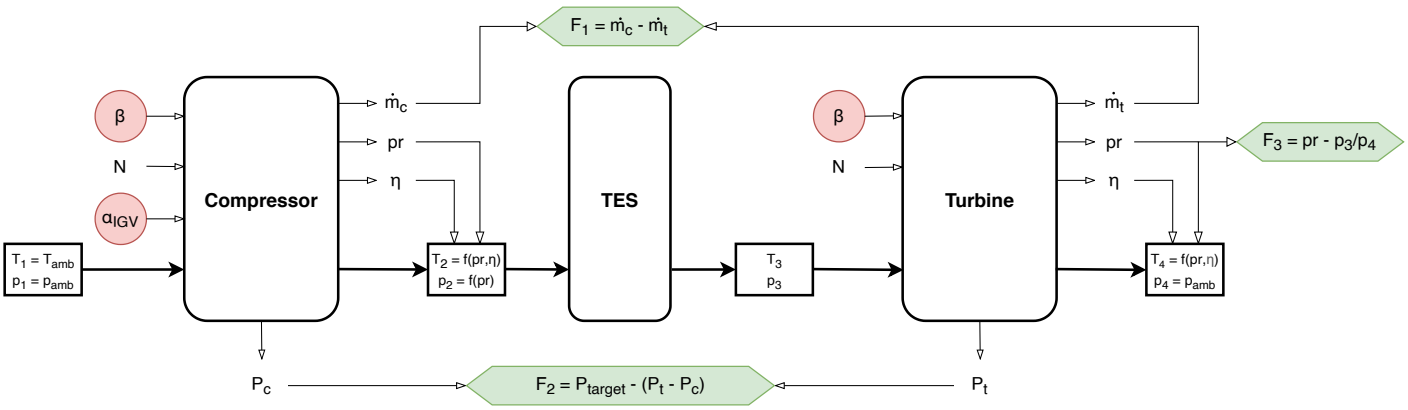


Figure 2: Scheme of the calculation for the matching procedure. The matching variables are highlighted in red, while the functions are highlighted in green.

the tank is discretised into *n* layers characterised by the same dimension. The influence of the number of discretisations on both the computation time and the accuracy in the calculation of the temperature profile has been thoroughly investigated in Ref. [13]. One of the peculiarities of the model is its ability to take into account the variability of the thermophysical properties of both the solid material that makes up the packed bed and the heat transfer fluid (air). For more details, the interested reader can refer to [13].

3.2. Components matching

The I-ESS model calculates pseudo-steady-state points, where the turbomachines are supposed to instantaneously adapt to the thermal behaviour of the reservoir. This means that for each time step, the power and the mass balance are fulfilled.

In this scenario, finding the equilibrium point of the system requires solving a system of non-linear equations of dimension three [14]. The procedure is based on the gradient-based `fsolve` algorithm available in the *Matlab* suite. It employs a variant of the Powell method (trust-region algorithm [15]). In Equation 10, δx is the vector that contains step changes of the matching variables, J is the Jacobian matrix, and F is the vector with errors. The matching variables are β_{compr}, α_{IGV} and β_{turb}, while the errors come from the check of the turbine pressure ratio, the mass continuity, and the power balance, as shown in Figure 2.

$$J \cdot \delta x = -F \tag{10}$$

At each iteration k, the new variables are calculated as $x_k = x_{k-1} + \delta x$. The system is solved when $F = 0$. The final values of β_{compr}, α_{IGV}, and β_{turb} are those that meet the equations of mass and power balance and give a net power equal to that set as input.

3.3. The I-ESS model setup

Being the aim of the work to study the off-design behaviour of the I-ESS system during the discharge process to improve the accuracy of the plant behaviour prediction, the design parameter of the system must be defined. To evaluate in future work the advantages in terms of accuracy of using compressors' and turbines' maps instead of simplified models, the I-ESS design parameters are the same as those in the work presented in Ref. [9].

In particular, the thermal storage volume is equal to 250 m^3, while its height is 6.6 m. The packed bed is made up of spheres of aluminium oxide (Al_2O_3). The density, void fraction, and diameter of the spheres are summarised in Table 1.

The design power of the power train is set at 0.8 MW, while the compressor pressure ratio and the polytropic efficiency of both turbomachines are set at 8.5 and 0.85, respectively.

Based on the design characteristics of the gas turbine used to build the I-ESS power train, the thermal reservoir design temperature, which is equal to the turbine inlet temperature, is set at 1200 K while the air mass flow during discharge is 4.42 $kg \cdot s^{-1}$.

The turbomachines have an axial arrangement. Therefore, for the compressor and the turbine, an axial map is selected from the commercial software database. Subsequently, the selected maps are scaled according to the design values. Note that this is common practise in the case of a lack of information on the performance maps of the machines considered [16].

To properly study the delivery phase, the discharge investigation is carried out starting from a TES tank under

Geometry	packed-bed	
Material	Al_2O_3 (allumina)	
Shape	spheres	
TES volume	250	m^3
TES height	6.6	m
Al_2O_3 density	3990	$kg\,m^{-3}$
Void fraction	0.4	$-$
Spheres diameter	50	mm

Table 1: Design characteristics of the TES.

isothermal conditions (1200 K).

4. Results and discussion

After model validation (see, [7, 8]), a preliminary investigation is conducted with the aim of finding the technical minimum of the system. As said, for simplicity, the reservoir starts in an isothermal condition.

At the beginning of the discharge phase, the I-ESS-deliverable power is set to the nameplate one. However, in the progress of the discharge, the temperature of the packed bed decreases and, consequently, the turbine inlet temperature. Therefore, the I-ESS management system is not able to maintain both the power and the rotation speed at the design value. Then, since the control strategy is devoted to maintaining a constant rotational speed, the power delivered to the grid is reduced with the decrease in the state of charge of the TES (see Figure 3). The power reduction continues until the system can no longer provide power by maintaining a constant rotational speed. This condition corresponds to a power equal to about 40% of the design one. Taking into account the safety margin, the I-ESS technical minimum is set equal to 50% of the gas turbine nameplate power.

The analysis of the discharge phase from the full charge to the technical minimum reveals that, as the TIT changes, the equilibrium point of the system also changes. Therefore, to maintain the rotational speed constant, the angle of the VIGVs must be continuously adjusted (Figure 3). The initial value of α_{IGV}, when the VIGVs are in the design condition, is $\alpha_{IGV} = 0$. Initially, to maintain the rated power, the VIGVs have to slightly open to counterbalance the decrease in the TIT. Then, when the power is scaled, α_{IGV} suddenly increases to a positive value (Figure 4).

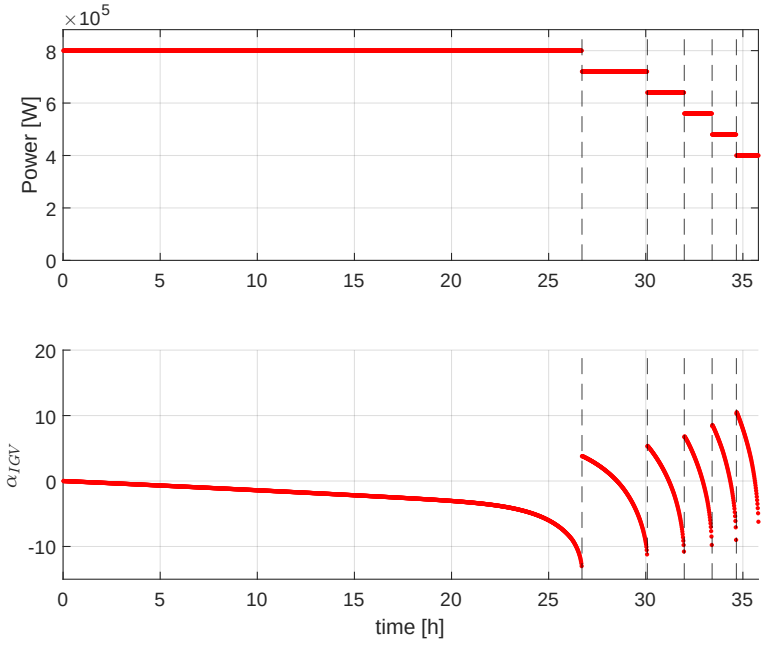

Figure 3: Power trend and α_{IGV} trend over time.

As said, during the delivery phase, the temperature of the packed bed decreases. Figure 5 shows the temperature trend of some layers over time. It is interesting to note that the temperature of the first layers quickly drops to 600 K, which is the compressor outlet temperature. The first layer is slightly heated after some time

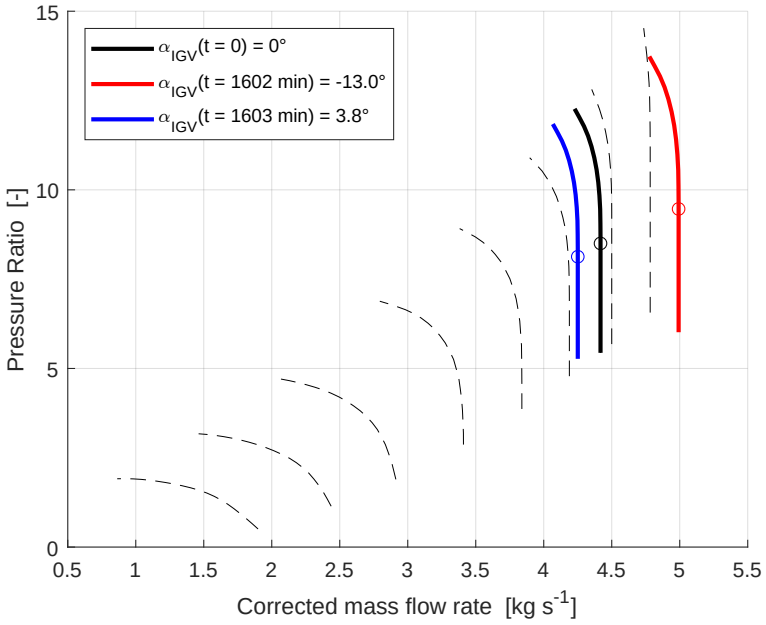

Figure 4: Shift of the speedline according to α_{IGV}.

step, and this is due to an increase in the compressor pressure ratio related to the regulation of α_{IGV}.

The discontinuities in the temperature trend come from the step regulation of the net power, as shown in Figure 3. The graph in Figure 5 also shows the trend of TIT over time. The TIT follows the trend of the last layers of the reservoir.

Figure 6 shows the thermodynamic cycle at both the beginning and the end of the discharge. Note that, at the end of discharge, both $\eta_{is,c}$ and *TIT* are lower compared to the design point.

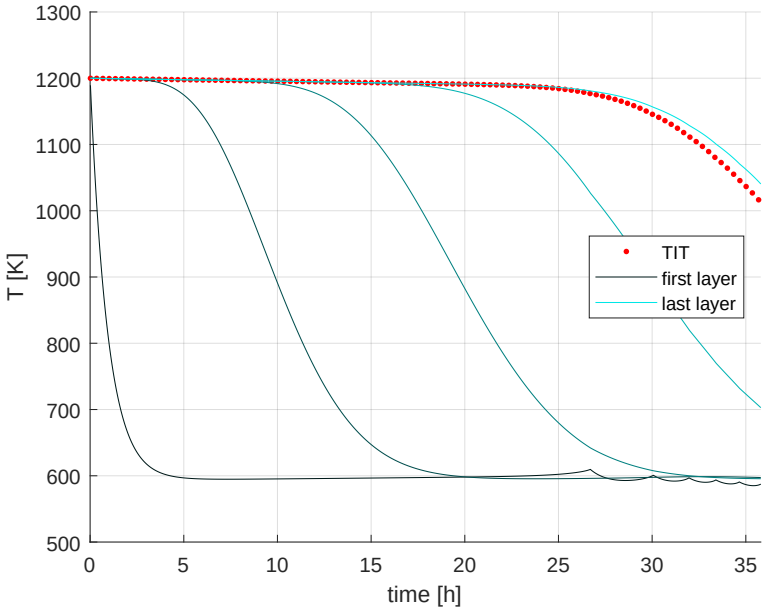

Figure 5: Temperature trend of some sample layers and TIT trend over time.

The choice of the number of layers for the discretisation of the packed bed influences the accuracy of describing the thermofluid dynamics of the reservoir [13]. However, the focus of this work is to study the performance of the whole system, rather than the thermal storage itself. Therefore, a sensitivity analysis is performed to evaluate the effect of the number of layers (*n*) on the accuracy of the model.

The turbine inlet temperature is selected as a key parameter as the driving variable in the calculation of the thermodynamic cycle. The analysis revealed that, varying *n* from 30 to 160 with a step of 30, the standard deviation in the TIT calculation at the end of discharge is approximately 0.02%. For this reason, a number of 60 layers is chosen as a good compromise between computational speed and accuracy.

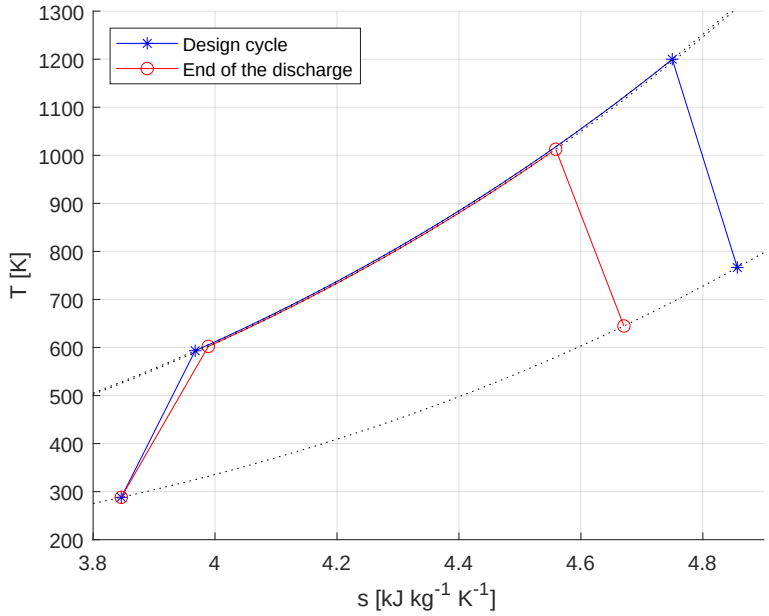

Figure 6: Thermodynamic cycle at the design point and at the end of the discharge.

After this preliminary investigation devoted to the definition of the technical minimum and the number of layers in which storage needs to be discretised, it is interesting to study the total discharge time and the discharge time at nameplate power by varying by the tank temperature, the design power and the power step size.

Figure 7 shows the influence of design parameters on the total discharge time and the discharge duration at the nameplate power.

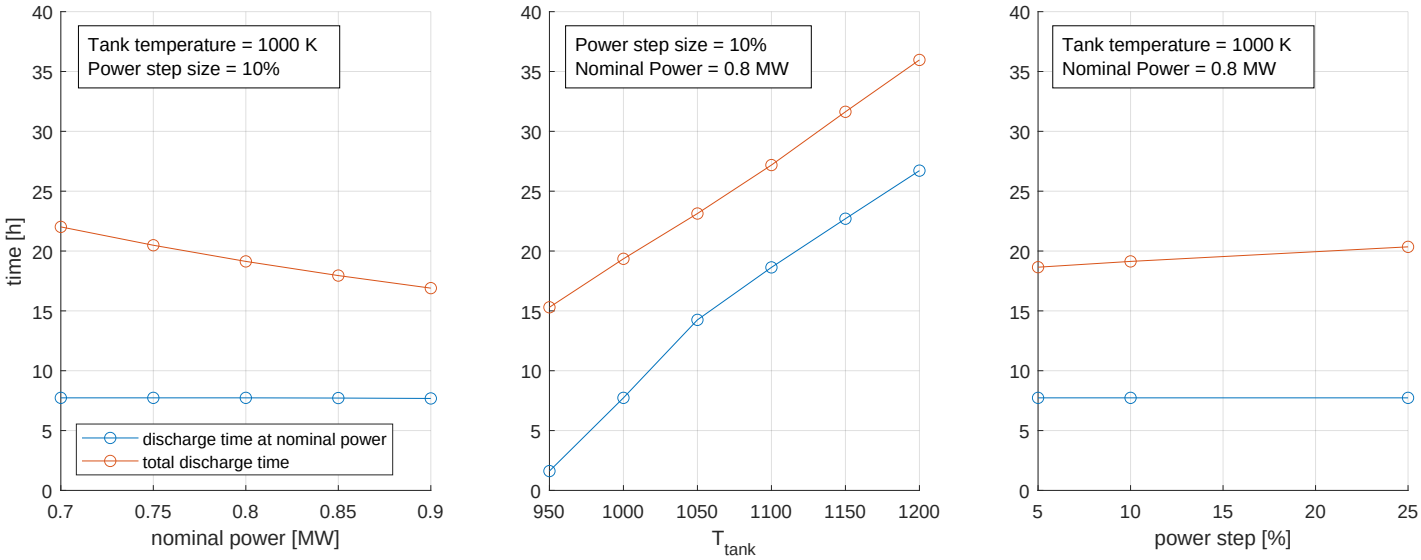

Figure 7: Influence of design parameters on the total discharge time and the discharge duration at nameplate power.

The discharge time at nameplate power is strongly influenced by the reservoir temperature: the higher the temperature, the longer the time for which the system can deliver the nameplate power.

The nameplate power and the power step size do not affect discharge duration. Furthermore, the total discharge time increases rapidly if the storage temperature increases, while it increases only slightly with the power step size. However, the total discharge time decreases if the nominal power is high.

It is also interesting to analyse the maximum thermal energy that can be stored in the tank. With the hypothesis of heating the tank from ambient temperature (293 K) to 1200 K, the maximum storable thermal energy is 201.6 MWh_{th}.

Taking into account the full discharge, the maximum exploitable energy can be calculated as:

$$E_{th,discharge} = M \cdot \frac{1}{n} \cdot \sum_{j=1:n} \left(\int c_p(T) \cdot dT \right) \tag{11}$$

where n is the number of layers, M is the mass of the solid and c_p is the specific heat of the solid.

Given the technical minimum fixed at 50%, the maximum exploitable thermal energy is 106.1 MWh_{th}, which results in 26.9 MWh_{el}.

Note that, for the hypothesis of the investigation performed, the charge phase is not modelled. Therefore, the Round-Trip Efficiency (RTE) cannot be defined on the basis of the selected starting state of charge.

Hovewer, considering the TES isothermal (not reachable condition) at a temperature of 1200 K, the efficiency of the discharge phase can be computed as

$$\eta_{discarge} = \frac{E_{el,discharge}}{E_{th,discharge}} \tag{12}$$

and resulted equal to 25.3%.

5. Conclusions

The off-design performance of an Integrated Electricity Storage System (I-ESS) has been analysed in this study. To this end, a proper off-design model of the plant has been built. The model takes into account the part-load behaviour of the turbomachines with a zero-dimensional approach using performance maps. Although it includes a dynamic description of the Thermal Energy Storage, the model of the system calculates pseudo-steady-state points. In this way, the behaviour of the plant during a complete discharge can be studied, starting from an isothermal reservoir. The results show that the temperature of the reservoir is the parameter that affects primarily the performance of the plant in the delivery mode.

With an increase in tank temperature, both the total discharge time and the nameplate power discharge time increase. In contrast, as the design power is increased, the total duration of the discharge decreases. In addition, the power step size has a smaller influence on these parameters.

The results also show that the number of layers for TES discretisation is not as relevant for the calculation of the performance of the whole system. Therefore, this parameter can be kept to the minimum possible to speed up the computation time without significantly affecting the model accuracy. The efficiency of the delivery phase, for the selected working conditions, is equal to 25.3%. Future developments will involve the implementation of off-design characteristics of the fan, electric heater, and heat exchanger in the charging model. In this way, the round-trip efficiency can be defined and computed as well as the thermodynamic and economic performance of the full operation of the system. After that, the dynamic behaviour can be analysed and tailor-made management strategies developed based on grid needs.

Abstract:

In recent years, when the energy demand has increased day by day, the continuity of energy has become an important issue as well as the need to meet the demand from nature-friendly technologies. Thermochemical Heat Storage (THS) systems are among the important approaches that help the continuous and efficient use of renewable energy resources with its high energy storage density and long storage times. Researches on composite structures consisting of sorbent salt and porous matrix couple among storage materials are noteworthy for the development of sorption materials and thus the heat storage system. Composite sorbents were prepared by impregnating sorbent salt ($CaCl_2$ and $MgCl_2$ etc.) as single and mixture into two different matrix materials, anodic Aluminium oxide (AAO) template and pumice (P), is carried out in this study. The cyclical heat storage behaviours of the obtained composite structures were investigated with the laboratory scale thermochemical heat exchanger prototype system. The aim of this study is that the effect of host matrices with different pore diameters one of whose is produced in the laboratory and other is natural on the thermochemical heat storage capability. Moreover, different sorbent salts which are impregnated into these pores on the heat storage capability is also compared with the help of prototype system.

Keywords:

Thermal Energy Storage (TES), AAO templates, Pumice, Composite Material, Salt-impregnation.

1. Introduction

The visible and tangible negative effects caused by the use of fossil fuels shows that we are facing a global climate crisis. Due to the intermittent nature of renewable energy sources, a great majority of the energy demand today is still met by fossil fuels [1]. While this situation reveals the importance of storage for the efficient use of the energy, it is also critical to improve these systems in order to meet the energy demand of the increasing population with environmentally friendly and sustainable technologies [2,3]. Thermal Energy Storage (TES), one of the energy storage approaches, has important application areas such as the efficient use of intermittent solar energy and the recovery of low-grade industrial waste heat released directly into the atmosphere [4,5]. There are three types of TES systems such as sensible, latent and thermochemical heat storage [3,6]. Thermochemical Heat Storage (THS) systems, in which heat is stored and released as a result of the reversible sorption-desorption process, are remarkable for their long storage times and high energy storage density [7,8]. In sorption heat storage systems, heat is stored as a result of physical changes in the storage medium. During the charging (desorption) process, hot dry air (eg, waste heat, heat emitted from solar collectors) is passed through the storage material to remove absorbed water. As a result of the endothermic reaction, heat is stored by the material as potential energy. During the discharge (sorption) process, water vapour absorption occurs by passing humid air through the storage material and the stored heat is released. As long as the storage material is not in contact with humid air, heat is stored with almost no loss [9,10]. For storage systems with low thermal losses and high energy storage capacity, mass and heat transfer are expected to be high as well as the material maintaining thermal, physical and cyclic stability [8]. Therefore, the development of storage mediums is very important for the improvement of these systems.

In recent years, composite materials obtained by impregnated sorbent salt into a porous host matrix are among the prominent sorption materials [6,11]. In the literature, many porous matrices with different pore diameters and surface areas are used as a structural support for sorbent salts such as zeolite [12], silica gel [13], activated carbon [14], attapulgite [15], wakkanai siliceous shale (WSS) [4], vermiculite [16], etc. The porous matrix helps to maintain the physical stability of the material during repetitive cycles while also improving mass and heat transfer [17]. In recent studies for the development of sorption materials, in addition to natural rocks, new generation porous materials such as MWCNT [18], MOF [19], AAO [20], silicone foam [21], concrete [22], which are synthesized in the laboratory, are also preferred as host matrix.

Sorbent salts, the main absorbing component that stores heat, are notable for their high energy storage densities [2]. The existence of problems such as deliquescence and agglomeration that make the use of sorbent salts difficult is stabilized by the porous host matrix [23]. In the literature, many sorbent salts such as $CaCl_2$, LiCl, $LiNO_3$, $MgCl_2$, $SrBr_2$, $SrCl_2$, LiBr, $MgSO_4$, K_2CO_3 are used for sorption heat storage with host matrix [2]. Also salt mixtures are impregnated into porous matrices in order to improve their water uptake capacity and operate at relatively low regeneration temperatures [6,15]. Different porous matrix/salt pairs are investigated to develop systems with high energy storage capacity and cyclic stability [24]. Nejhad et al. [22], the cyclic heat storage capacities of the composite sorbents they synthesized with 3 different porous matrices (aerated porous concrete, vermiculite, zeolite) were investigated with a laboratory scale fixed-bed open THS prototype system. Accordingly, energy storage densities of 196-175, 180-163, and 251-114 kWh/m^3 were obtained, respectively, for APC-$CaCl_2$, vermiculite-$CaCl_2$ and zeolite-$CaCl_2$ composites at low regeneration temperature (85-95 °C). Mehrebadi et al. [25] investigated the composite sorbents prepared with two porous (pumice, expanded clay) matrix and different sorbent salts ($Al_2(SO_4)_3$, $MgSO_4$, $CaCl_2$, $MgCl_2$, $SrCl_2$) using a laboratory scale filled bed reactor. According to the results, $SrCl_2$ has the highest energy storage density (29 kWh/m^3 for expanded clay and 7.3 kWh/m^3 for pumice) and the study points out that pumice has cyclic stability. Yilmaz et al. [26], used anodic Aluminium oxide (AAO) templates produced with two step anodization method in the laboratory as porous host matrix for four different sorbent salts and their mixtures. The energy storage densities obtained for AAO-LiCl and AAO-CaCl2 composites as a result of DSC analysis are 242.2 and 220.8 kJ/kg, respectively.

In this study, anodic aluminium oxide (AAO) templates and pumice (P) used as porous host matrix. Composite materials were prepared by impregnating mono and mixed sorbent salts ($CaCl_2$, $MgCl_2$) into host materials. AAO templates with pore size controlled by electrochemical process parameters were produced in the laboratory with a two-step anodization process. The aim of the study is to compare the behavior of sorbent salts impregnated into different host matrices. For this purpose, the cyclical energy storage density (E_d) of the obtained composite materials were investigated with the laboratory scale thermochemical heat exchanger prototype system.

2. Materials and Method

In this study, anodic Aluminium oxide produced by anodization from 99.99% pure aluminium and pumice, a natural rock, were used as host material in order to be able to absorbed sorbent salts. AAO templates were obtained by applying two-step anodization method to high purity (99.99%) aluminium plates. Aluminium plates were immersed in an isopropyl alcohol at 35-40 °C in an ultrasonic bath for 10 minutes prior to anodization and then they etched in an etching solution containing $CuSO_4$, H_3PO_4 and HNO_3 at 85 °C for 2 minutes. Following these processes, two-step anodization process was started. Aluminium plates were anodized in a 0.6 M oxalic acid solution at 10 °C at 40 V for 30 minutes during both the first and second step anodization process. AAO with regular pore structure were obtained at the end of second anodization step. AAO samples obtained via the two-step anodization method were immersed in 0.1 M NaOH solution for 15 minutes in order to enlarge the existing pore diameter prior to salt impregnation. Then the moisture in the pores was evaporated by keeping it in an oven at 110 °C for 24 hours. The similar procedure was also applied to pumice to be completely dehumidified and ready for salt impregnation. The dried AAO and pumice templates were filled with two mono salts and their mixtures.

In order to be able to obtain composite structure, matrix materials (AAO and Pumice) completely were immersed into saturated mono and mixed salts and they were hold at 10 Psi and 30 ^oC under vacuum for 48 h. This aimed to fill existing pores with salt solution via capillary action. Dry sample weights before and after salt impregnation are given in Table 1. The amount of impregnated salt in pumice was measured by taking the sample weight before and after the salt impregnation. The amount of salt absorbed per unit area for AAO samples was calculated empirically by dividing the amounts of salt impregnated into each sample by the total surface area as in our previous study [26].

Table 1. Dry sample weights before and after salt impregnation.

Impregnated salt and ratios	Sample weight before salt impregnation (g)	Sample weight after salt impregnation (g)
Matrix: AAO		
$CaCl_2$	0.157	0.278
$MgCl_2$	0.149	0.349
$CaCl_2$ + $MgCl_2$ (1:1)	0.133	0.219
Matrix: Pumice		
$CaCl_2$	16.12	42.29
$MgCl_2$	16.24	40.72
$CaCl_2$ + $MgCl_2$ (1:1)	17.01	43.03

2.1. Characterization

Microstructures of both AAO and pumice, acting as a matrix, before and after salt impregnation were investigated with Zeiss brand Sigma 300 model FESEM. Theoretical thermal energy storage capacities of the composites were characterized using a Differential Scanning Calorimetry (DSC). Analyses were performed with a TA Instruments Q2000 model DSC instrument in the temperature range of 30-140 °C, according to BS EN ISO 11357-4 standards. In addition, composite materials were characterized by a laboratory-scale prototype. Figure 1 shows the prototype system consisting of a humidifier, heater, cabinet and fan.

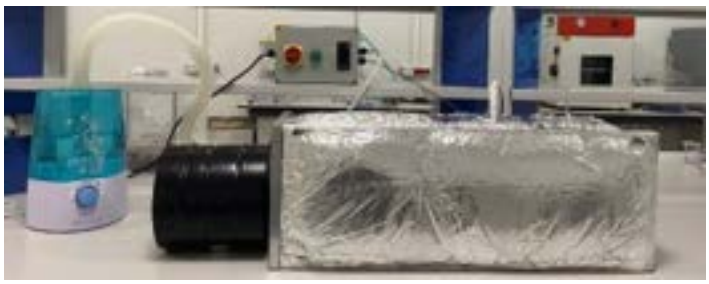

Figure 1. Thermochemical heat exchanger prototype.

In the prototype system, experiments were carried out as three consecutive discharge-charge cycles and the cyclic behaviour of composites were investigated. During discharge process, the air was humidified and blown through the cabin with help of a fan. The humid air was passed through across the composite material. Water vapour was absorbed by the composite and heat released during this time. During charging process, air was heated to 80-85 °C with the help of an electric heater and hot dry air passed across the composite material. Meanwhile, moisture inside the composite was removed and heat stored.

3. Results and Conclusions

In this study, the results show that the average pore diameter of AAO film was about 85±5 nm as shown in Figure 2(a). The pores were regular and high ordered. Figure 2(b) shows a cross-sectional view of the AAO template.

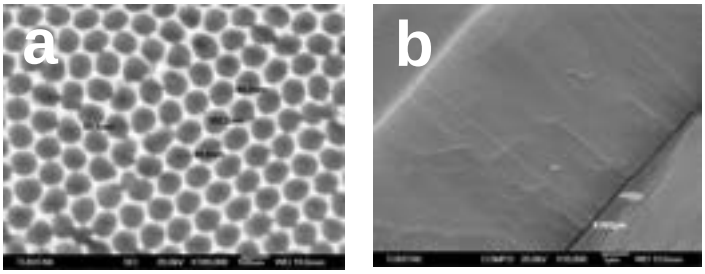

Figure 2. FESEM image from top: a) and cross-section b) of AAO template

The average thickness of the nanotubes is approximately 8µm. The increase of the lengths of the nanotubes depends on the increase of the anodization period. The lengths of the nanotubes are directly proportional to the duration of second step of the two step anodizing. The images of pumice, used as matrix material, before and after salt impregnation are given in figure 3.

Figure 3. Images of pumice: a) before salt impregnation, b) $CaCl_2$ impregnated, c) $MgCl_2$ impregnated and d) mixed sorbent salts impregnated.

Figure 4 shows the FE-SEM images obtained after salt impregnation of both matrix materials: (a) AAO-based composite structure following salt impregnation, (b) pumice before salt-impregnation, and (c) pumice-based composite structure following salt impregnation. SEM images show that the pores of both matrix materials could be filled with sorbent salts.

Energy storage density (Ed), is one of the important parameters for evaluating the suitability of any material for THS application. In this regard, after synthesizing composites structures of salt impregnated, Ed of these materials were evaluated through characterization methods. For the DSC analysis, synthesized materials were kept in a moist environment (RH=90%) over 48 hours to ensure that they are saturated with water. Later on the fully hydrated materials were placed within DSC device. For evaluating the Ed, total energy consumption for moisture desorption (until the material reaches anhydrous state) was calculated. Within the DSC studies, the specific heat capacity (Cp) is determined with the Equation (1). In the Equation ΔQ and ΔT represents the variation of heat supplied to the material and the variation of the applied desorption temperature with the time, while m shows the mass of the sample by integrating the area under the desorption heat–Cp curve.

$$Cp= \Delta Q/(m.\Delta T) \quad (1)$$

Theoretically, total energy consumption for moisture desorption in charging could be considered equal to the thermal energy generated in discharging process for the same amount of moisture adsorption. Consequently, energy density of the material could be obtained by calculating the ratio of desorption energy consumption to the weight of the sample [26]. As shown Table 2, the highest theoretical Ed value was obtained for $MgCl_2$ impregnated into both pumice and AAO. On the other hand, $CaCl_2$ has also the lowest E_d value for both host matrices.

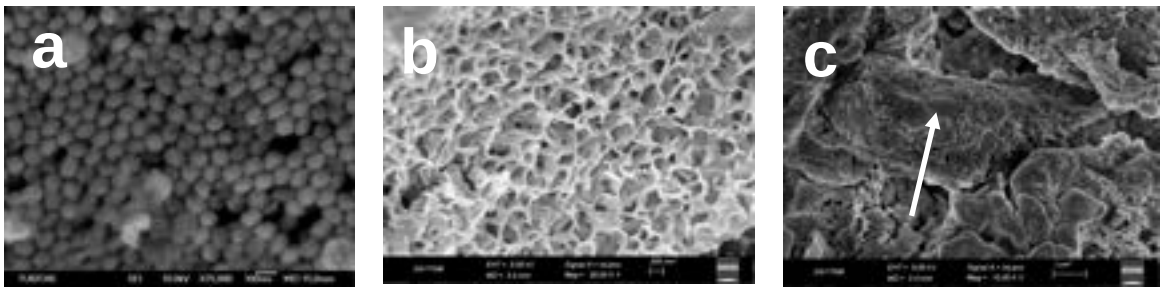

Figure 4. FESEM images of a) AAO after salt impregnation, b) pumice before salt impregnation and c) pumice after salt impregnation

Table 2. E_d values calculated as a result of DSC.

Samples	E_d (kJ/kg)
AAO-$CaCl_2$	161.68
AAO-$MgCl_2$	836.19
AAO-$CaCl_2$+ $MgCl_2$	795.12
P-$CaCl_2$	1255.83
P-$MgCl_2$	1700.39
P-$CaCl_2$+ $MgCl_2$	1657.41

The heat storage capacities of the composite structures, whose theoretical energy storage capabilities were determined with DSC, were also measured with the laboratory scale thermochemical heat exchanger prototype system. The experiments were carried out as three consecutive discharge-charge cycles for each composite and the cyclic heat storage capabilities of the composite sorbents were obtained. Figure 5 (a) and (b) shows the outlet air temperature (T) changes for AAO and pumice composite materials over three discharge cycles, respectively. The input air temperature was measured 18-20°C as it was affected by the fluctuating room temperature during the experiment. Due to the high absorption rate, temperature rise was observed at the beginning of each cycle in all composites.

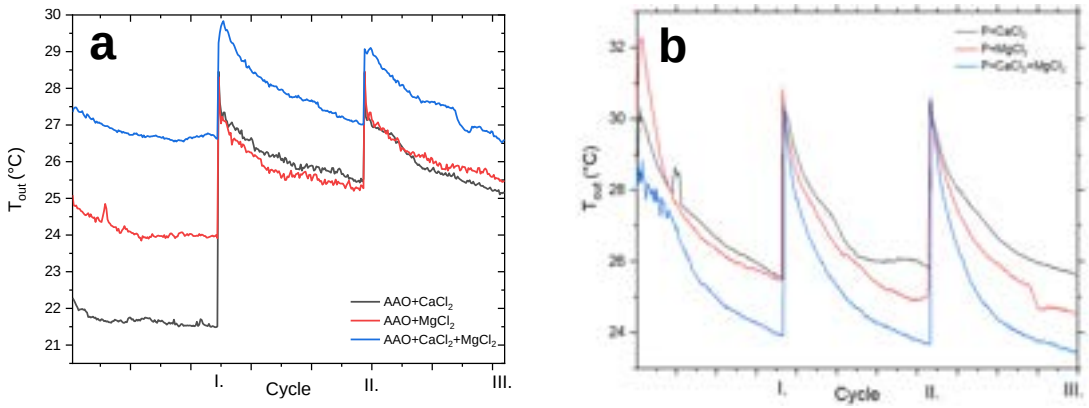

Figure 5. Output temperature changes of (a) AAO matrix composites, (b) pumice matrix composites

The heat output rate (out) values of all composite materials during the discharge process are shown in Figure 6. The heat output rate can be determined based on the enthalpy changes before and after the sorption material (Eq. 2), as well as the mass flow rate (discharge) in the discharge phase, the specific heat (Cp) at constant pressure and the difference between input and output temperatures of the system [22].

$$\dot{Q}_{\text{out}} = \dot{m}_{discharge} C_p (T_{\text{out}} - T_{in}) \qquad (2)$$

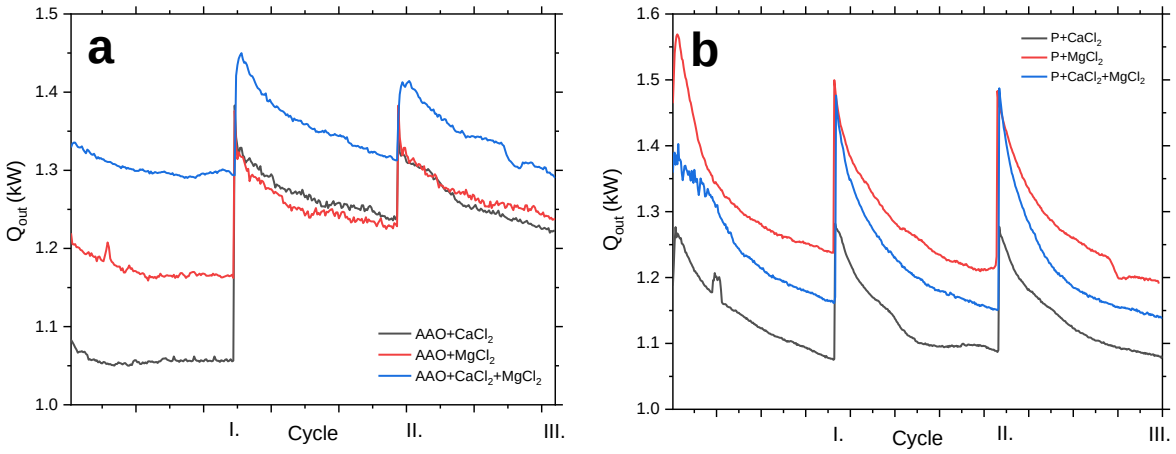

Figure 6. Heat output rate values of six composite materials over three discharge cycles: a) AAO matrix composites and b) pumice matrix composites .

It is seen that the average output heat flow rates for AA0-$MgCl_2$:$CaCl_2$ are 1.29, 1.37 and 1.35 kW for all three cycles, respectively. Just as at the output temperature, the heat flow rates for the mixed salt impregnated

sample exhibit also stable behaviour in all three cycles. On the other hand, while the heat flow rate for the AAO-$MgCl_2$ sample is average 1.18 kW in the first cycle, this value reaches the order of 1.28 and 1.29 kW in the second and third cycles, respectively. It is seen that these values for Pumice-$MgCl_2$:$CaCl_2$ are on average 1.25, 1.24 and 1.24 kW. Especially in the first cycle, the sample with the lowest heat flow rate was the AAO-$CaCl_2$ and pumice-$CaCl_2$ samples with 1.06 kW and 1.16 kW, respectively. On the other hand, the reason for the increase in the output heat flow rate of the AAO-$MgCl_2$ and AAO-$CaCl_2$ composites, especially in the 2nd and 3rd cycle, might have been due to the increase of ΔT in the repeated cycles.

The energy storage densities of the system were calculated by the ratio of the total energy output value to the volume of the composite material for the discharge phase to be obtained by integrating the equation (2) over the discharge period [22].The cyclic energy density (Ed) values of the discharge phases of the six composite materials are given in Table 3.

Table 3. *Cyclic energy density (E_d) values of six composite materials over three discharge cycles.*

Matrix	Impregnated salt	Cycle	E_d (kWh/m^3)	Matrix	Impregnated salt	Cycle	E_d (kWh/m^3)
AAO	$CaCl_2$	1	180	Pumice	$CaCl_2$	1	411
		2	92			2	328
		3	70			3	269
	$MgCl_2$	1	131		$MgCl_2$	1	658
		2	99			2	485
		3	88			3	518
	$CaCl_2$ + $MgCl_2$ (1:1)	1	160		$CaCl_2$ + $MgCl_2$ (1:1)	1	597
		2	144			2	469
		3	135			3	418

As can be seen, the highest energy density values were obtained in the mixed salt in AAO matrices and in $MgCl_2$ impregnated samples for pumice matrices throughout all cycles. Accordingly, while the highest energy density value was obtained for the AAO-$MgCl_2$:$CaCl_2$ composite in the first cycle, the highest value was obtained for the pumice-$MgCl_2$ composite in the similar cycle. Ed values of all composite samples obtained using the thermochemical heat exchanger prototype test setup are different from the values calculated as a result of DSC analysis. This result shows that, theoretically, the statement that the total energy absorbed by the material during desorption is equal to the energy it can produce during sorption is not entirely true.

Within this study, mono and mixed salt impregnated AAO and pumice based composite samples were synthesized and characterized for thermochemical heat storage applications. The results obtained are given below:

- In the prototype test setup, the highest Ed value was obtained in the pumice-$MgCl_2$ composite with 658 kWh/m^3.

- As a result of the measurements in the thermochemical heat exchanger prototype, AAO-$MgCl_2$:$CaCl_2$ composite had a high exit temperature in all three cycles and exhibited a high stable performance during repeated cycles compared to AAO-$CaCl_2$ and AAO-$MgCl_2$.

- Similar stable behaviour for all three cycles was also obtained in pumice-$MgCl_2$ composite.

- The fact that the Ed values obtained for AAO-$MgCl_2$:$CaCl_2$ in every three cycles are close to each other, unlike the AAO-$CaCl_{l2}$ and AAO-$MgCl_2$ composites, is an indication that the AAO-$MgCl_2$:$CaCl_2$ composite has cyclic stability, and this is promising for the efficient use of THS systems. Similarly, pumice-$MgCl_2$ is preferable in the efficient use of THS systems.

Abstract:
Thermal energy storage (TES) is a key issue in efficient energy system applications, especially in the context of renewable energies. In this respect, phase change materials (PCM) have attracted interest as an active solution for efficient energy management, particularly in the building sector. This paper presents a modeling of a thermal battery based on PCM in the case of solar systems assisted by heat pump (SAHP). The storage tank allows to store the heat produced via unglazed solar panels (Batisol®) and represents the heat source of the heat pump. The heat pump can supply the heating and domestic hot water (DHW) needs of a building. The storage consists of a block of PCM contained between two plates of heat transfer fluid (HTF). A 2D model is used to describe the behaviour of the PCM and a 1D model is preferred for the HTF plates. The objective of the study is to dynamically simulate the thermal behaviour of this storage for different hot inlet temperature profiles: step, trapezoidal functions and profile of the temperature at the outlet of the thermal panels for a winter and summer period of 8 days. This 2D model would be useful to validate a simpler model for optimisation of the operational parameters of the system.

Keywords:
Thermal energy storage, Phase change material, Solar system assisted heat pump, Domestic hot water, Low-temperature heating.

1. Introduction

In order to limit temperature rise, it is important to reduce the environmental impact of energy production and consumption. According to the International Energy Agency [1], the building sector is considered to be one of the largest energy end-use sectors in the world. The growing demand for energy is increasing the pressure on the environment. One of the main challenges to reduce the environmental impact of buildings is therefore to replace fossil fuels with renewable resources. Thermal energy storage (TES) has been particularly studied in recent years as it is essential to compensate for the intermittency of renewable energies, by correcting the mismatch between energy supply and demand [2]. Moreover, TES are increasingly used to meet the heating and cooling needs of buildings. There are three types of TES: sensible, latent and thermochemical [2]. Phase Change Materials (PCM) are materials that can store large amounts of thermal energy in the form of latent heat of fusion when they change from a solid to a liquid state for example at a specific phase change temperature or temperature range if the PCM is not a pure compound. This phase transition process is reversible, allowing thermal energy to be stored and released at relatively constant temperatures. Compared to sensible heat storage materials, PCM offer several significant advantages, like a higher heat storage density at small temperature ranges [3]. PCM can store between 5 and 14 times more thermal energy per unit volume than sensible heat storage materials [4]. As a result, the use of PCM can help to reduce the size of heat storage systems, making them more suitable for residential applications. Thermochemical storage is more interesting in terms of storage density. However, this technology is less mature than that with PCM.

Solar systems assisted by heat pump (SAHP) can provide an efficient and environmentally friendly heating

and cooling solution for residential and commercial buildings. The role of a heat pump in the heating system is to increase the thermal energy from a lower temperature level to a higher temperature level [5]. Moreover, the use of PCM heat storage between the solar facade and the heat pump can improve the overall performance of the SAHP. Several studies have been conducted to assess the benefits of using PCM in SAHP [6–9]. Firstly, the solar energy stored in the PCM unit can be used as a heat source for the evaporator in the heat pump. As a result, the temperature of the evaporator is almost constant and the heat pump can operate under more stable conditions. This leads to a better Coefficient of Performance (COP) for the heat pump.

Depending on the type of application at the output of the heat pump (heating, cooling), the temperature levels are not the same and therefore the PCM used changes [6]. Four temperature ranges have been listed by Du *et al.* [6]: low (-20 to 5 °C), medium-low (5 to 40 °C), medium (40 to 80 °C) and high (80 to 200 °C) temperatures. For a heating or domestic hot water applications, the medium temperature level is considered since the buffer tank temperature setpoint is usually expected at 60 °C. Many studies have been carried out on such systems [6, 8–10]. However, as each storage is different (size, design and PCM used in particular), it is important to model its thermal behaviour correctly in order to explore the optimal operating parameters later.

The objective of this paper is to dynamically simulate a TES based on PCM integrated on SAHP. In a first part, the methodology and the case study will be presented. Then, several operating scenarios will be investigated in the results section. The profile of the hot temperature entering in the thermal battery will be a step, then a trapezoidal function, and finally this of the outler temperature of thermal panels in winter and summer periods using measured climatic conditions as boundaries. Finally, last part will conclude.

2. Material and Methods

This section is divided in three parts. Firstly, the global system is described, composed by solar thermal panels, PCM battery and heat pump. In next steps, the models of the different components of the system are defined. Dynamic models are based on the conservation of mass and energy equations.

2.1. Definition of the system

The studied system is composed of solar panels, a TES based on PCM, and a heat pump, as illustrated in Fig. 1. The system is divided in three circuits. The first, connecting the solar facade to the buffer tank, is made up of glycol. The second circuit, connecting the thermal battery to the heat pump, is composed of water. An air heater is integrated in parallel with the solar storage to supply heat to the heat pump when the temperature of the thermal battery is not high enough. The last circuit, also made of water, connects the PCM battery for heating and domestic hot water (DHW) to the heat pump.

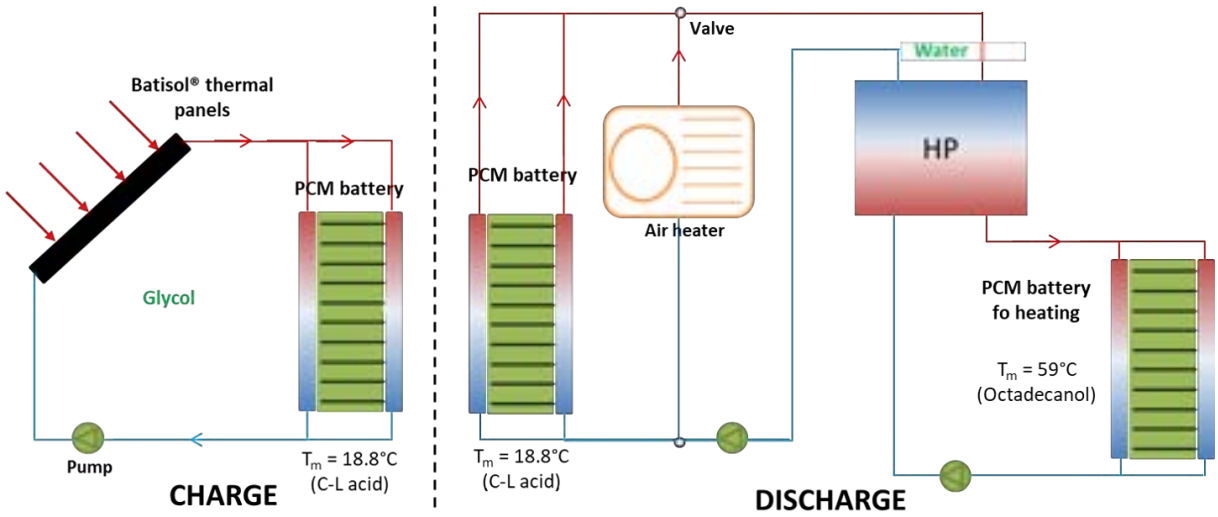

Figure 1: Global diagram of the solar assisted heat pump with thermal battery based on PCM.

The solar facade is composed of unglazed thermal panels (Batisol®) [11, 12], developed by Nobatek/INEF 4 [13]. The dimensions of the PCM-based storage are 0.4 m x 0.4 m x 0.4 m (Fig. 2a). The heat pump can produce both low temperature heating and DHW for a building application. The same thermal battery is used for the DHW and buffer tanks. Only the PCM changes between the two batteries, to match the desired temperature level. For the buffer tank, a mixture of 61.5% capric acid and 38.5% lauric acid (C-L acid) is used. Its melting temperature is 291.95 K. For the heating PCM battery, octadecanol is prefered. Indeed, its melting temperature is 332.46. The thermophysical properties of these materials are depicted in Table 1.

Table 1: Thermophysical properties of C-L acid [14] and octadecanol.

Name	Value for C-L acid	Value for octadecanol	Unit
T_m	291.95	332.46	K
L	$140.8 \cdot 10^3$	$208.45 \cdot 10^3$	J/kg
ρ_{PCM}	897.5	850	kg/m^3
$c_{p,l}$	1970	1750	$J/kg/K$
$c_{p,s}$	2240	2150	$J/kg/K$
λ_s	0.143	0.301	$W/m/K$
λ_l	0.139	0.205	$W/m/K$

2.2. Model of the Batisol® panels

The model of the thermal solar facade was described previously by Bouzouidja *et al.* [15]. From the time-varying input parameters, taken from a weather file, and the operating parameters, the temperature at the panel outlet is determined [15]:

$$T_{out,sol} = \frac{T_{in,sol} \cdot \dot{m} \cdot c_{p,H} + \alpha \cdot A_{sol} \cdot (0.5 \cdot T_{in,sol} - T_{ext}) + G_{sol} \cdot A_{sol} \cdot \gamma}{\dot{m} \cdot c_{p,H} - 0.5 \cdot \alpha \cdot A_{sol}} \tag{1}$$

Where $T_{in,sol}$ and T_{ext} are the temperatures at the entrance to the solar facade and outside (K), A_{sol} the surface of the solar facade (m^2), G_{sol} the solar flux (W/m^2), $\dot{m}$ the low rate of the Heat Transfer Fluid (HTF) circulating in the thermal panels (kg/s) and $c_{p,H}$ the specific heat capacity of the hot fluid (glycol) ($J/(kg \cdot K)$). The coefficients α and γ have been determined experimentally (γ = 0.63). The first one depends on the wind speed:

$$\alpha = -(7.84 + 3 \cdot v_{wind}) \tag{2}$$

2.3. Model of the thermal energy storage based on phase change material

In order to model the behaviour of latent heat storage, the following simplifying assumptions have been made:

- Natural convection is neglected. Only conduction is considered,
- No supercooling or superheating,
- Incompressible and Newtonian HTF,
- Kinetic and potential energy variations are neglected,
- Isothermal phase change (Octadecanol is a pure body so this assumption is correct. Since C-L acid is a mixture, the phase change temperature range is between 291.65 and 292.25 K [16]. As the melting temperature of this PCM is considered to be 291.95 K, the uncertainty of this assumption is +/- 2%),
- Density variation of PCM neglected during the phase change,
- Thermophysical properties are independent of temperature, but different for liquid and solid phases,
- The storage walls are assumed to be perfectly insulated (adiabatic boundary conditions) (Fig. 2b).

The shape of the thermal battery and its operation are described schematically in Fig. 2. The PCM is placed between two plates where the HTF circulates. Thus, a symmetry plane is visible in the middle of the battery. During the charging step, hot fluid is injected into the two plates. During the discharging step, cold fluid is injected. As a result, the charging and discharging steps are carried out separately. The plates where circulates the HTF are modelled in one dimension, a plug flow being assumed. The PCM part located between two plates is modelled in 2D because the heat diffusion operates in axial and longitudinal directions.

Fins are added to the plates to increase the contact area between the PCM and the HTF. To account for the fins, the effective conductivity of the PCM is expressed as:

$$\lambda_{eff} = a \cdot \lambda_{PCM} + (1 - a) \cdot \lambda_{fin} = a \cdot (\lambda_s + f_l \cdot (\lambda_l - \lambda_s)) + (1 - a) \cdot \lambda_{fin} \tag{3}$$

Where a is the proportion of PCM in the volume under consideration ($-$), λ_{PCM}, λ_s, λ_l et λ_{fin} are respectively the thermal conductivities of the PCM, the solid and liquid phases of the PCM and the fins ($W/m/K$), and f_l the liquid fraction of the PCM ($-$).

The enthalpy, the temperature and the liquid fraction of the PCM (according to x and y), and the temperature of the hot HTF (according to y) are determined with 4 to 11.

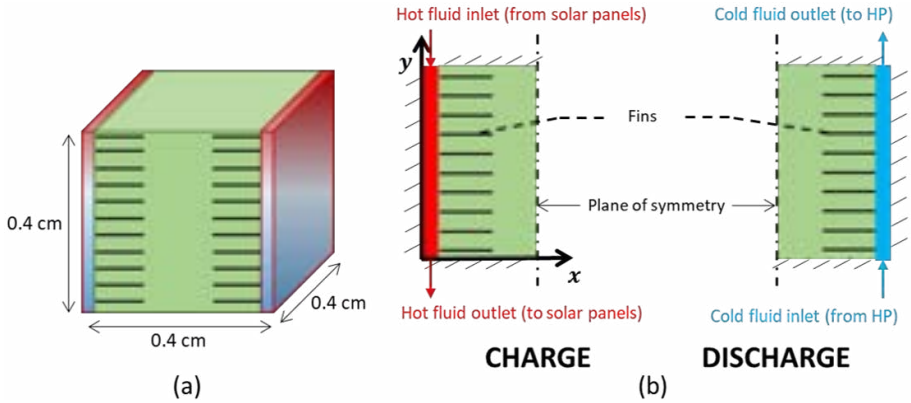

Figure 2: Diagram of the dimensions of the PCM-based thermal battery (a), and diagram of the PCM-based thermal battery with two plates for the charging and discharging steps (b).

- **Exchanges between the HTF (hot or cold) and the PCM:**

  For hot fluid:

$$\rho_H \cdot V \cdot c_{p,H} \frac{\partial T_H}{\partial t} - \dot{m}_H \cdot c_{p,H} \cdot \frac{\partial T_H}{\partial y} \cdot P = h_H \cdot A \cdot (T_H - T_{PCM}) + \lambda_H \cdot V \cdot \frac{\partial^2 T_H}{\partial y^2} \tag{4}$$

  For cold fluid:

$$\rho_C \cdot V \cdot c_{p,C} \frac{\partial T_C}{\partial t} + \dot{m}_C \cdot c_{p,C} \cdot \frac{\partial T_C}{\partial y} \cdot P = h_C \cdot A \cdot (T_C - T_{PCM}) + \lambda_C \cdot V \cdot \frac{\partial^2 T_C}{\partial y^2} \tag{5}$$

- **Exchanges in the PCM:**

$$\frac{\partial H_{PCM}}{\partial t} = \frac{\partial \lambda_{eff}}{\partial x} \cdot \frac{\partial T_{PCM}}{\partial x} + \frac{\partial \lambda_{eff}}{\partial y} \cdot \frac{\partial T_{PCM}}{\partial y} + \lambda_{eff} \cdot \frac{\partial^2 T_{PCM}}{\partial x^2} + \lambda_{eff} \cdot \frac{\partial^2 T_{PCM}}{\partial y^2} \tag{6}$$

$$H_{PCM}(T_{PCM}) = f_l \cdot H_l + (1 - f_l) \cdot H_s = \rho_{PCM} \cdot ((c_{p,s} + f_l \cdot (c_{p,l} - c_{p,s})) \cdot T_{PCM} + L \cdot f_l - f_l \cdot (c_{p,s} + f_l \cdot (c_{p,l} - c_{p,s})) \cdot T_m) \tag{7}$$

$$f_l = \begin{cases} 0 & for\ H_{PCM} < H_s \\ \frac{H_{PCM} - H_s}{H_l - H_s} & \\ 1 & for\ H_{PCM} > H_l \end{cases} \tag{8}$$

- **Boundary conditions for the PCM in contact with hot (during charging step) or cold (during discharging step) HTF:**

  For hot fluid (for x = 0 and 0.4 m):

$$h_H \cdot (T_H - T_{PCM}) = -\lambda_{eff} \frac{\partial T_{PCM}}{\partial x}\ for\ x = 0\ m \quad and \quad h_H \cdot (T_H - T_{PCM}) = \lambda_{eff} \frac{\partial T_{PCM}}{\partial x}\ for\ x = 0.4\ m \tag{9}$$

  For cold fluid (for x = 0 and 0.4 m):

$$h_C \cdot (T_C - T_{PCM}) = -\lambda_{eff} \frac{\partial T_{PCM}}{\partial x}\ for\ x = 0\ m \quad and \quad h_C \cdot (T_C - T_{PCM}) = \lambda_{eff} \frac{\partial T_{PCM}}{\partial x}\ for\ x = 0.4\ m \tag{10}$$

- **Boundary conditions for the PCM in contact with the outside (adiabatic conditions):**

$$\lambda_{eff} \frac{\partial T_{PCM}}{\partial y} = 0\ for\ y = 0\ and\ 0.4\ m \tag{11}$$

- **Initial conditions:** All temperatures are fixed at 283.15 K. The enthalpy of the PCM is determined by 7 at 283.15 K. The liquid fraction is considered equal to 0.

Where h_H and h_C are the convective exchange coefficients of the hot and cold fluid respectively ($W/m^2/K$), T_H, T_C, T_{PCM} and T_m are the hot and cold temperature, the temperature of the PCM and the melting temperature of the PCM, L the latent heat (J/kg), ρ_{MCP} the PCM density (kg/m^3), $c_{p,l}$ and $c_{p,s}$ are the specific heat capacity of the liquid and solid phases respectively ($J/kg/K$), P the exchange perimeter (m), A the exchange area (m^2) and V the volume of the representative element considered (m^3). The convective exchange coefficients are determined from the Nusselt number, assuming that the wall thickness of the plate is very thin and therefore negligible.

The boundary conditions of the thermal battery depend on the configuration studied. Four scenarios have been investigated. Firstly, the profile of hot temperature entering the thermal battery follows a step. In a second stage, it is a trapezoidal function. Finally, the battery based on PCM is connected to the Batisol® panels and two periods of 8 days are simulated: winter (from January 1 to 8) and summer (from July 1 to 8). In the latter two cases, the profile of the outlet temperature of the solar panels is used as input to the PCM:

$$T_H(x, y = 0.4, t) = T_{out,sol} \tag{12}$$

2.4. Resolution of the differential algebraic equations and software used

The software used to model the system is OpenModelica v1.18.0. The Modelica library (v3.2.3) is considered. The spatial discretisation is performed manually while the temporal discretisation is performed via the DASSL integrator available on OpenModelica. The tolerance used in the DASSL integrator is 10^{-6}. For the PCM-battery model, equations are discretised using an explicit second-order discretisation scheme with finite differences. For the boundary conditions (9 to 11), second-order decentred schemes are used.

3. Results and Discussion

This section is divided into three parts. The first one aims at studying the behaviour of PCM-based TES for a hot inlet temperature profile following a ramp (case 1). The second part investigates the behaviour of the system under trapezoidal loads (case 2). Finally, the battery is connected to the Batisol® solar facade and an 8-day simulation is performed for two periods of the year: from 1 to 8 January (winter, case 3) and from 1 to 8 July (summer, case 4). The hot HTF temperatures investigated at the buffer tank inlet are shown in Fig. 3. The colours red, green, blue and yellow refer to cases 1, 2, 3 and 4 respectively. For the next figures, the coordinates (x = y = 0 m) are placed at the bottom left of the PCM in Fig. 2.

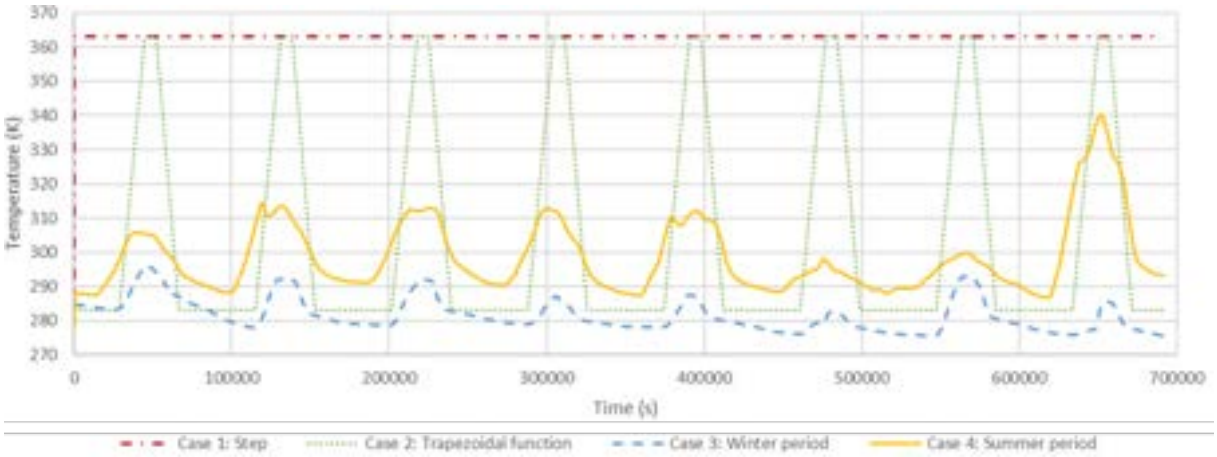

Figure 3: Four hot temperatures profiles considered at the input of the PCM-based TES battery.

The simulation times are relatively fast for simulating 8 days ($6.912 \cdot 10^{-5}$ s) on a standard laptop (processor: 12th Gen Intel®Core(TM) i7-12700H 2.69 GHz and RAM: 32 Go). They amount to 30 s and 2 min for cases 1 and 2 respectively. When the weather file is used and the Batisol® thermal panel model is added, the simulation times are slightly longer but remain below 5 min.

3.1. Profile of the hot inlet temperature following a step

For the case 1, the input temperature profile follows a ramp from 283.15 to 363.15 K in the first second of the simulation. The evolution of the liquid fraction and the temperature of the PCM in the tank are studied in Fig. 4 over time for the first slice of PCM in contact with the hot plate (for x = 0 m), according to the vertical. The colours purple, green and red refer to the high (y = 0.4 m), middle (y = 0.2 m) and low (y = 0 m) parts of the PCM respectively. Solid lines are used for the temperature and dashed lines are preferred for the liquid fraction. The same marking and colour code will be used in the following sections. Initially, the PCM is in the solid state

(f_l = 0) at 283.15 K. Its temperature increases until it reaches the melting temperature (291.95 K) at 18.2 s for y = 18 (in purple), the top of the PCM in contact with the hot plate. This temperature is reached at 20.8 s for the middle of the PCM (in green), and 23.2 s for the bottom of the PCM (in red). From these times onwards, the temperature of the PCM remains constant while the liquid fraction increases until it reaches unity, indicating that all the PCM has changed from the solid to the liquid state. This event occurs at 78.0, 82.1 and 87.5 s for the top, middle and bottom of the PCM respectively. From then on, the liquid fraction remains constant and the temperature of the PCM gradually increases, while approaching the temperature of the hot HTF.

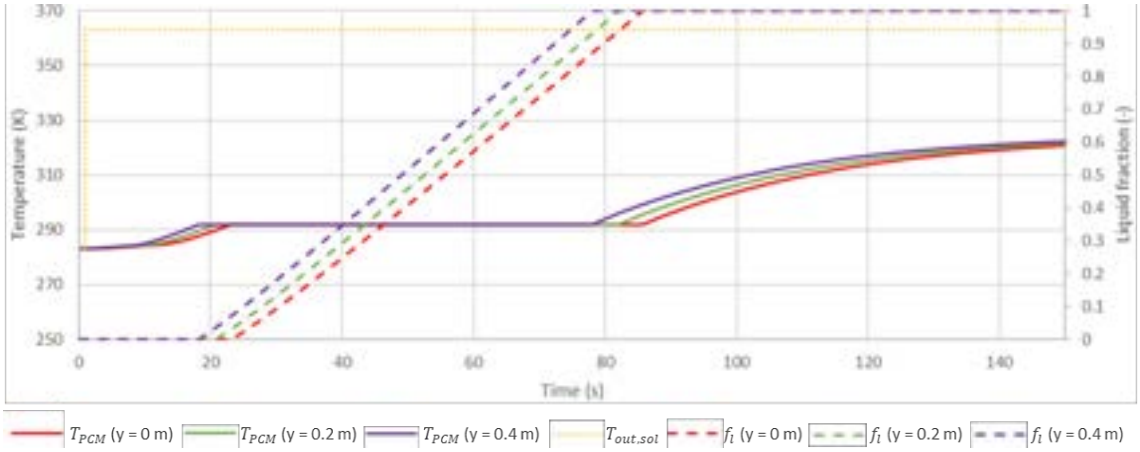

Figure 4: Case 1: Temperature and liquid fraction evolution for the first PCM layer in contact with the hot plate (x = 0 m) and for y = 0, 0.2 and 0.4 m.

The evolution of these two variables has also been studied for different values of x in Fig. 5. As the battery is symmetrical, only the coordinates at x = 0 (in red), 0.06 (in yellow) and 0.2 m (in green) are presented for the sake of clarity. In this case, the profiles are clearly different. The phase change from solid to liquid state is clearly visible for the first layer in contact with the hot plate. For x = 0.06 m, the temperature evolves linearly without reaching the melting temperature. As a result, the liquid fraction remains constant and equal to zero. For the PCM in the middle of the battery (x = 0.2 m), the temperature remains almost constant (283.15 K), indicating that the heat has not reached the core of the battery in 150 s.

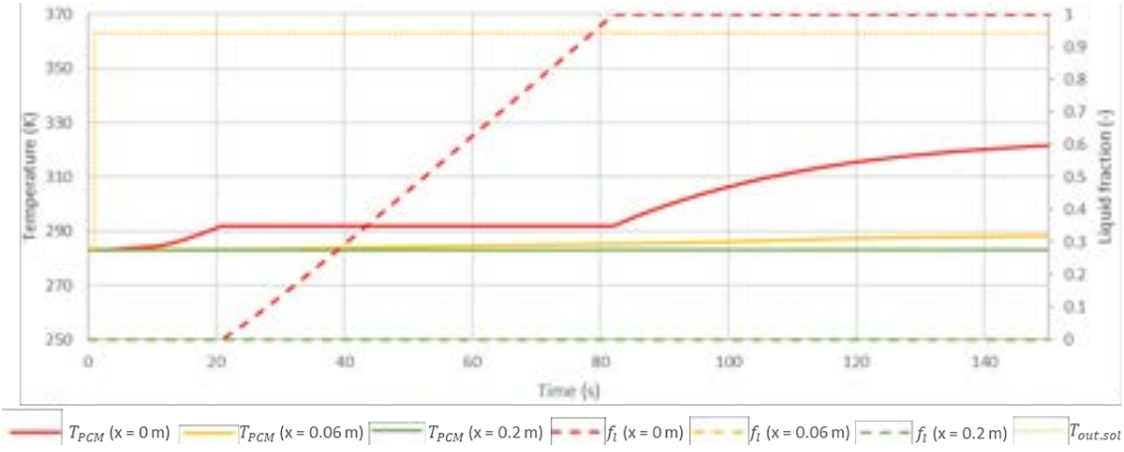

Figure 5: Case 1: Temperature and liquid fraction evolution in the longitudinal direction (for x = 0, 0.06 and 0.2 m) for the PCM layer in the middle (y = 0.2 m).

Figures 4 and 5 show the interest of considering a 2D model for PCM tank, according to longitudinal (x) and vertical (y) directions, since the temperatures in the PCM are different in both directions.

3.2. Profile of the hot inlet temperature following a trapezoidal function

Before studying the thermal behaviour of the storage connected to the solar facade, a trapezoidal function is used to simulate the evolution of the hot temperature at the battery inlet (Fig. 3). The period of this function is decomposed on 28800 s of width, 16200 s of rising , 7200 s of width, 14400 s of falling, for a total period of 86400 s. The temperature and liquid fraction are studied as before, for the first slice in contact with the hot

plate (for x = 0 m) (Fig. 6), and the slice in the middle of the PCM (for y = 0.2 m) (Fig. 7). The same evolution as for the ramping test is observed. In a first step, the temperature of the PCM increases until it reaches the melting temperature of the PCM (at 30634 s) (Fig. 6a). Then the liquid fraction increases until it reaches unity (Fig. 6b). At this point (31049 s), the temperature of the PCM increases again (Fig. 6a). The temperature of the PCM follows the temperature of the hot HTF at the battery inlet, with an average difference of less than 6%. In order to store as much heat as possible and not send it to the solar circuit, it can be interesting to stop the charging step when the temperature of the PCM becomes higher than that of the hot coolant. Figure 6 shows that this moment occurs at 52200 s.

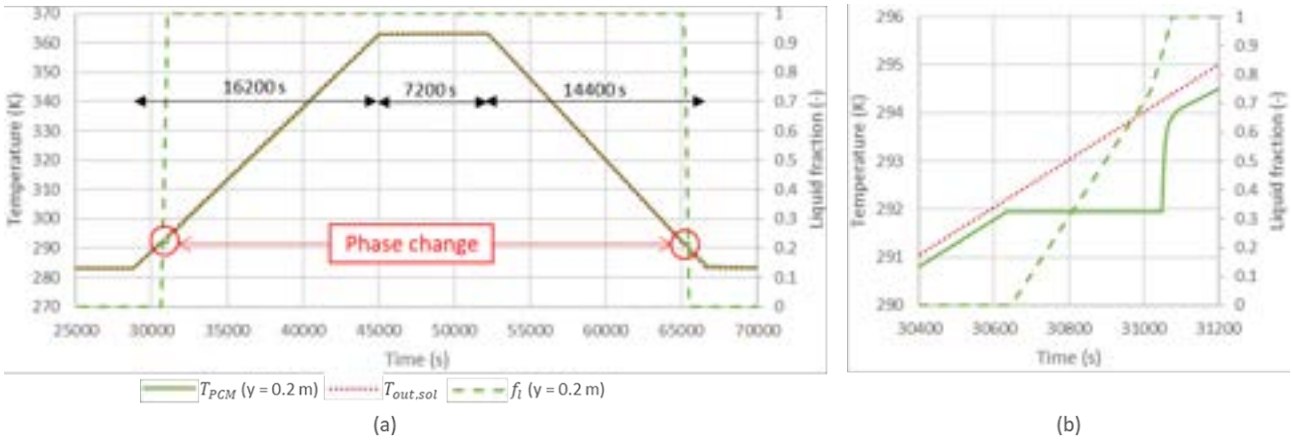

Figure 6: Case 2: Temperature and liquid fraction evolution for the first PCM layer in contact with the hot plate (x = 0 m) and for y = 0.2 m (a), focus on the phase change between 30634 and 31049 s (b).

Figure 7a shows the evolution of the temperature and liquid fraction of the PCM in the longitudinal direction (x = 0, 0.06 and 0.2 m) for the PCM layer at y = 0.2 m. The difference in temperature is clearly visible for the three curves. The further the PCM is from the hot plates, the lower its temperature and the longer the phase change takes. The heat propagation is thus clearly visible along the PCM. The core of the PCM (x = 0.2 m in green) takes the longest time to melt, but also to solidify as the hot inlet temperature decreases. The change from liquid to solid state is thus much longer (13 times longer) than for the PCM layers closer to the hot plate. For the yellow curve (x = 0.06 m), after the phase change, slight instabilities are visible in the PCM temperature. This must be due to the discretisation step and/or the discretisation scheme, whose order should be increased to be more accurate, and/or the DASSL integrator whose tolerance must be increased. The phase change step is significantly larger for x = 0.2 m. This is because the heat propagates from layer to layer. During the phase change of a PCM layer, all the energy required to achieve the phase change is absorbed. Therefore, for the liquid fraction of the layer x = 0.2 m to fluctuate, the liquid fractions of the previous layers must already have reached an equilibrium (solid or liquid state). This is illustrated in Fig. 7b, which shows a zoom of the transition from solid to liquid state (between 31000 and 35000 s) for the layers x = 0 (in red), 0.02 (in purple), 0.04 (in blue) and 0.06 m (in yellow). It can be seen that the liquid fraction of the next layer increases when the liquid fraction of the layer under consideration has reached 1. As a result, even if the melting temperature of the PCM has been reached for a PCM layer, it is necessary to wait until the change of state has taken place in the layers closer to the hot plates before the phase change begins in the PCM layer.

3.3. Profile of the hot inlet temperature following the outlet temperature of the Batisol® panels

When the PCM-based storage is connected to the Batisol® thermal panels, the temperature of the inlet hot HTF is calculated by 1. The surface area of the thermal panels is 25.5 m^2 (5 m wide by 5.1 m long). The surface area consists of 16 panels with 24 channels. Meteorological data from Cholet (next to Nantes) in 2021, in the northwest of France, are used. Figure 8 presents the evolution of the solar power and the outdoor temperature for the 2 periods (winter and summer) considered. The solar power amounts to 112 W/m^2 over the 8 winter days considered, whereas over the summer period considered this value is 2.5 times higher. The average outdoor temperature is 280 K and in summer 291.83 K. These two periods were chosen to represent different types of days, with more or less sunshine and wind, cold or hot outside temperatures (Fig. 8). In addition, 8-day periods were considered in order to determine the capacity of the battery to store heat during renewable energy intermittencies and day/night alternations.

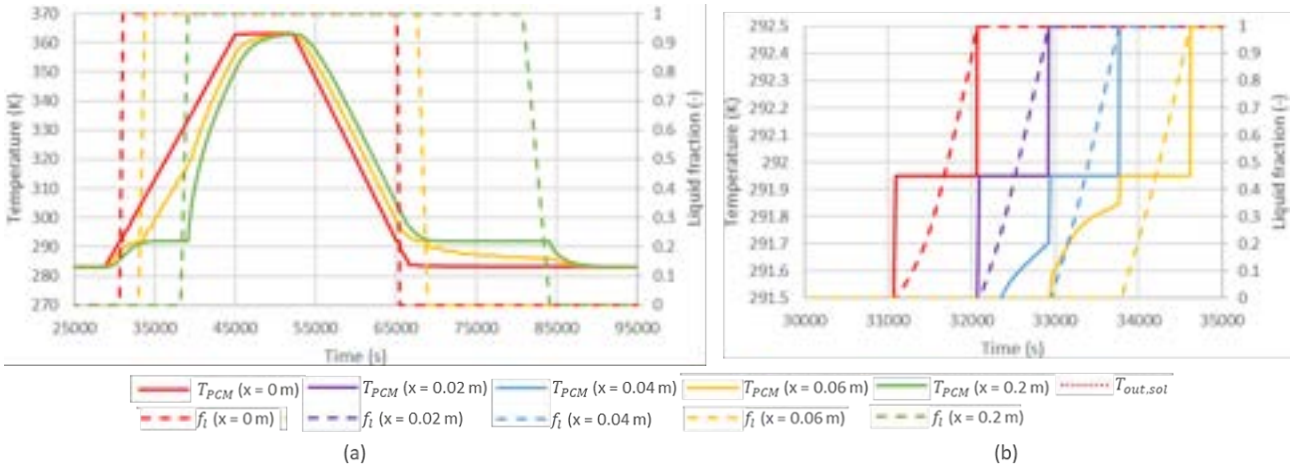

Figure 7: Case 2: Temperature and liquid fraction evolution in the longitudinal direction (for x = 0, 0.06 and 0.2 m) for the PCM layer in the middle (y = 0.2 m) (a), focus on the phase change of the first four PCM layer (from x = 0 to 0.06 m) (b).

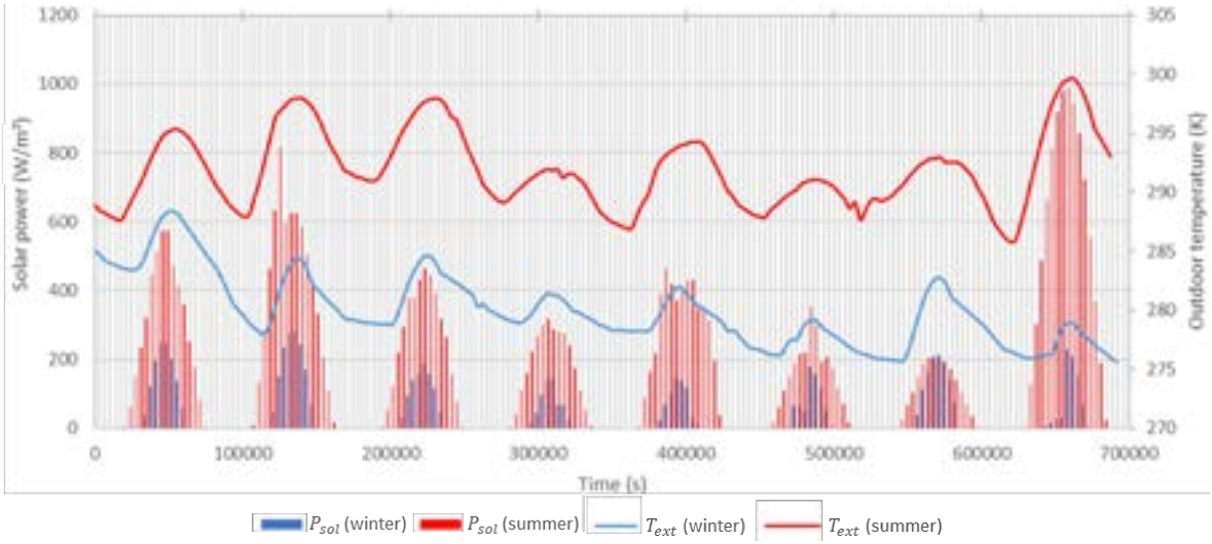

Figure 8: Cases 3 and 4: Evolution of solar power and outdoor temperature over the 8 days studied in winter and summer.

3.3.1. Winter period

The winter period chosen to simulate the behaviour of the PCM battery is from January 1 at 0am to January 8 at 23pm. In order to simplify the understanding of the graphs over longer periods (8 days), only the temperature and liquid fraction of the middle cell (y = 0.2 m) of the layer in contact with the hot plate (x = 0 m) are considered in Fig. 9. Over the 8 days simulated, the temperature at the exit of the solar facade is only higher than the melting temperature of the PCM on four days (Fig. 3). The PCM temperature exceeds the melting temperature only on January 1, 2, 3 and 7, as shown in Fig. 9. Indeed, the liquid fraction remains zero except between 11.15am and 4.5pm on January 1st, between 12.4pm and 16pm on January 2, between 14pm and 15.15pm on January 3, between and 13pm and 15.5pm on January 7. On other days, the PCM never reaches the melting temperature. Nevertheless, heat is stored in the solid state, as with sensible TES but with low efficiency. Fig. 9 shows that it is important to choose a material with a melting temperature that is not too high in order to take advantage of the phase change. If the melting temperature was 298.15 K (291.95 K for C-L acid), the PCM would not have changed state during the winter period under consideration. As a result, the use of PCM-based storage would not be interesting.

The temperature of the PCM in contact with the hot plate is almost as high as that of the hot HTF at the inlet, with an average difference of 0.3% over the 8 days. Figure 10a shows the evolution of the temperature and liquid fraction for the PCM layer at y = 0.2 m and for x = 0 (in red), 0.06 (in yellow) and 0.2 m (in green). As seen earlier, the temperatures are lower and lower from the outside of the PCM towards the inside. Indeed,

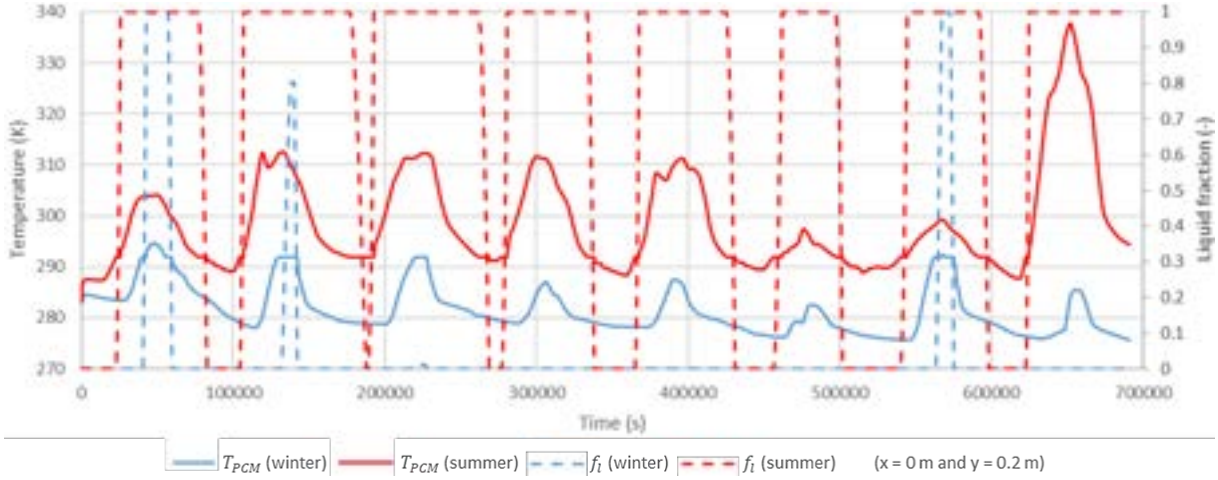

Figure 9: Cases 3 and 4: Temperature and liquid fraction evolution for the first PCM layer in contact with the hot plate (x = 0 m) and for y = 0.2 m.

the green curves show that the PCM has not changed state in the middle of the thermal battery. Furthermore, Fig. 10 shows the heat propagation along the PCM, with lower temperatures at the ends of the PCM, after the hot temperature at the inlet is decreased (after 60000 s). In general, the heat propagates well in the PCM, since the temperature differences between the different layers of PCM in the hot HTF are less than 0.8%. The instabilities visible at x = 0 and 0.06 m are due to the slight change in temperature at the outlet of the thermal panels (red dotted line in Fig. 10a), which of course depends on the weather conditions. These instabilities appear at the extremities of the PCM close to the hot plates (such as at x = 0 and 0.06 m) but not at the centre of the PCM (at x = 0.2 m). As seen previously, the liquid fraction of the x = 0.2 m layer remains zero while the melting temperature has been reached (291.95 K at 53100 s). This is due to the liquid fractions of the layers closer to the hot plate, which have not all reached unity. The output temperature of the solar panels decreases from 47483 s onwards, and consequently the energy supplied to the PCM. As a result, the middle layer (x = 0.2 m) has not received enough energy to make its phase change. Figure 10b is a zoom of the phase change (solid to liquid) in Fig. 10a. Before a layer changes phase, it is necessary that the liquid fraction of the previous layer has reached unity. Figure 10b shows this clearly, with the increase from 0 to 1 in the liquid fraction at x = 0 m (38900 to 40440 s), then that at x = 0.02 s (40440 to 42747 s), then that at x = 0.04 m (42747 to 44826 s) and finally that at x = 0.06 m (44826 to 47470 s).

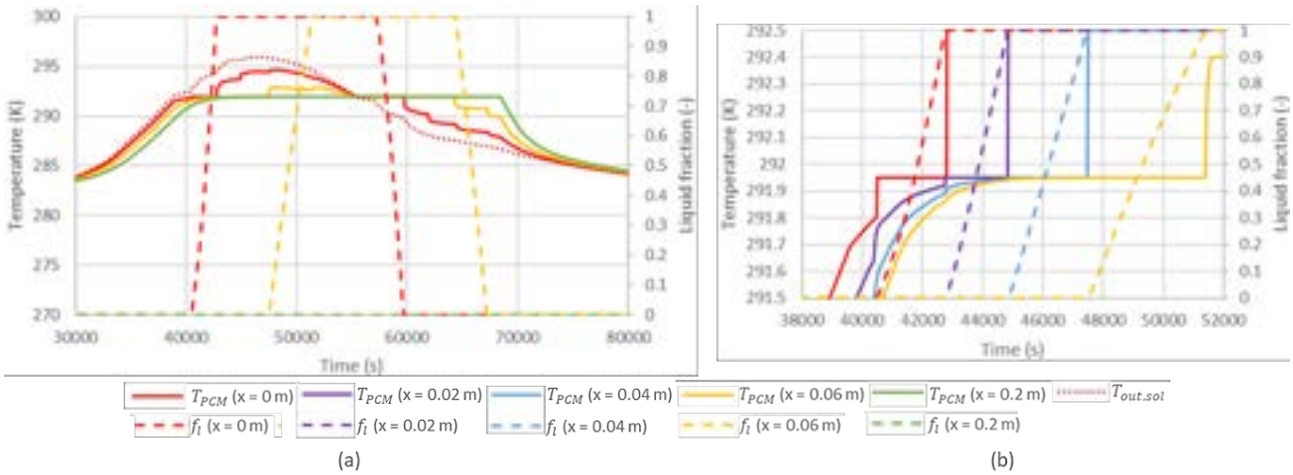

Figure 10: Case 3: Temperature and liquid fraction evolution in the longitudinal direction (for x = 0, 0.06 and 0.2 m) for the PCM layer in the middle (y = 0.2 m) (a), focus on the phase change of the first four PCM layer (from x = 0 to 0.06 m) (b).

3.3.2. Summer period

The summer period chosen to simulate the behaviour of the PCM battery is from July 1 at 0am to January 8 at 23pm. The temperature and liquid fraction at x = 0 m and y = 0.2 m are shown in the same figure as the winter period (Fig. 9). The temperature of the hot HTF at the storage inlet is significantly higher than during the winter

period (up to 340 K vs 296 K as illustrated in Fig. 3). The differences between the maximum temperatures expected by the hot fluid at the outlet of the thermal panels range from 2% (January 7 and July 7) to 16% (January 8 and July 8). On average the temperatures are 8% higher in summer. As a result, the behaviour of the PCM is also different between winter and summer periods, with phase changes occurring less often in winter. The advantage of using PCM in summer is therefore much greater, since it is possible to limit the size of the battery thanks to the change in the state of the material, unlike the use of sensible storage. Even on less sunny days such as July 6, when the temperature of the hot HTF does not exceed 297 K, there is enough heat to allow the PCM to change state. The PCM remains in a liquid state longer than in winter, between 7am and midnight on average over the 8 days considered.

As for the winter period, the difference between the temperature of the PCM in contact with the plate and that of the hot HTF is small (0.5% difference on average over the 8 days). Figure 11a shows the evolution of the temperature and liquid fraction for the PCM layer at y = 0.2 m and for x = 0. (in red), 0.06 (in yellow) and 0.2 m (in green). The temperature differences from the outside to the inside of the PCM are also clearly visible. From 16.4pm onwards, the temperature of the PCM in the core of the battery is higher than that of the PCM in contact with the hot plate. It would therefore be interesting to stop the charging step and start the discharging step by switching the hot (solar system) and cold (heat pump) inputs. The same instabilities as for winter period appear in Fig. 11a for the same reasons (small fluctuations of the temperature at the outlet of the thermal panels due to climatic conditions). The phase change zoom of the first four layers is illustrated in Fig. 11b (for x = 0 (in red), 0.02 (in purple), 0.04 (in blue) and 0.06 m (in yellow)).

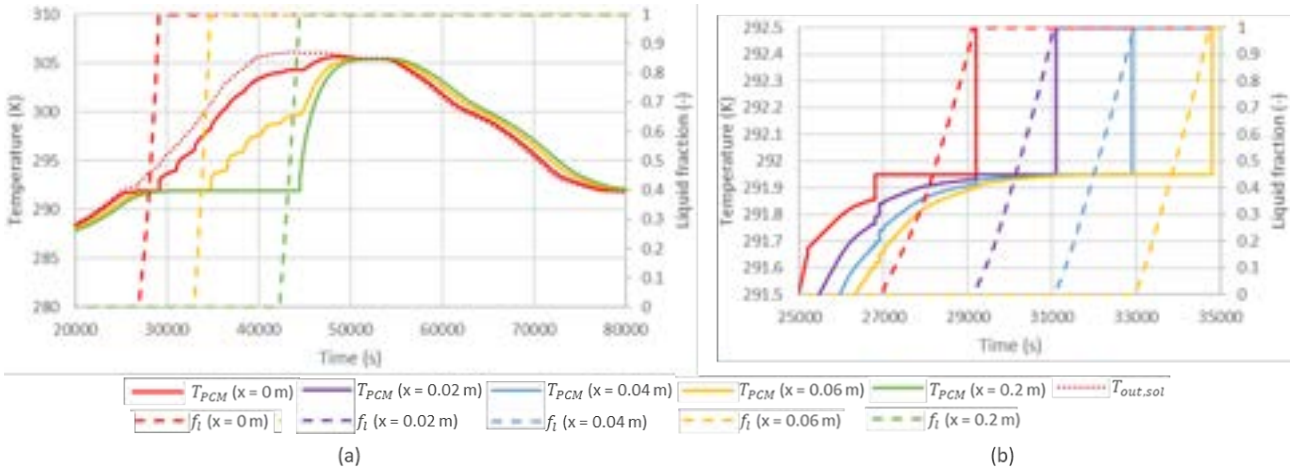

Figure 11: Case 4: Temperature and liquid fraction evolution in the longitudinal direction (for x = 0, 0.06 and 0.2 m) for the PCM layer in the middle (y = 0.2 m) (a), focus on the phase change of the first four PCM layers (from x = 0 to 0.06 m) (b).

The energy stored by the thermal battery for the two periods considered (winter and summer) is given in Table 2. During the winter period under consideration, the average stored energy is 164 Wh per day. In summer, this value is 6 times higher. The sunniest days (January 1st in winter and July 8 in summer) store 5 to 7.5 times more energy than the days less suitable for thermal collectors (January 6 and July 6). On average, the PCM battery can store 2.6 kWh/m^3 per day of energy in winter and 6.6 kWh/m^3 for January 1st. In summer this value reaches 15.1 kWh/m^3 per day on average and 29.3 kWh/m^3 for July 8. The benefit of PCM is clearly visible in summer, with almost 6 times more energy stored by the battery than in winter, partly due to the more frequent phase changes.

Table 2: Energy stored in the thermal battery per day (Wh).

Period	Minimal value	Maximal value	Mean
Winter	56 (January 6)	423 (January 1st)	164
Summer	385 (July 6)	1877 (July 8)	964

4. Conclusion

A dynamic model of a SAHP based on the use of thermal panels (Batisol®) and a latent heat storage was presented. This system aims to provide the heating and domestic hot water needs of a building. The TES is

composed of a PCM contained between two plates where HTF circulate. During the charging step, the hot HTF is fed by the thermal panels. During the discharging step, the direction of the fluid is reversed and the cold HTF is fed by the heat pump.

The thermal behaviour of the PCM tank is studied for four different profiles of the charging temperature: ramping, trapezoidal functions, temperature at the outlet of the thermal panels in winter (from January 1 to 8) and in summer (from July 1 to 8). The simulations carried out in OpenModelica showed the behaviour of the PCM during the phase change. The developed model showed the importance of choosing a PCM with a melting temperature range suitable for the studied application. In winter, only the sunniest days allows the PCM to melt while in summer the phase change occurs every day. On average, this thermal battery can store 6.6 and 15.1 kWh/m^3 per day of energy in winter and summer respectively.

The simulations showed that the 2D model of the system is necessary to take into account the horizontal and vertical temperature variations in the battery. This model will be further validated with experimental data. It will also allow the development and the validation of a simpler model. The final goal will be to optimise the SAHP system on its operational parameters with the simpler model.

Abstract:

This paper explores various combinations of electric heat pumps (EHPs), hydrogen boilers (HBs), electric boilers (EBs), hydrogen absorption heat pumps (AHPs) and energy storage technologies (electric and thermal) to assess their potential for matching heating and cooling demand at low cost and with low carbon footprint. Thermodynamic and component-costing models of various heating and cooling technologies are integrated into a whole-energy system cost optimisation model to determine cost-effective configurations of heating and cooling systems that minimise the overall investment and operation cost for both the system and the end-user. Case studies presented in the paper focus on two archetypal systems that differ in terms of heating and cooling demand and availability profiles of solar and wind generation. The proposed approach quantifies how the cost-efficient portfolios of low-carbon heating and cooling solutions are driven by the characteristics of the system such as share of variable renewables or heating and cooling demand. Modelling results suggest that capacity choices for heating and cooling technologies will vary significantly depending on system properties. More specifically, air-to-air EHPs, with their cost and efficiency advantages over air-to-water EHPs, could make a significant contribution to low-carbon heat supply as well as cooling, although their contribution may be constrained by the compatibility with existing heating systems. They are found to be a useful supplementary source of space heating that is able to displace between 20 and 33 GW_{th} of capacity of other heating technologies compared to the case where they do not contribute to space heating.

1. Introduction

An increasing number of countries and regions worldwide have committed to net-zero carbon emission targets, including the United Kingdom (UK) [1] and the European Union (EU) [2], who aim to reach net-zero by 2050. Reaching this target will require widespread decarbonisation across all sectors of the economy [3], including the residential energy sector, which accounts for over one-third of global carbon emissions [4].

A large portion of carbon emissions from the residential sector can be attributed to heating, which is predominantly supplied by natural gas boilers in many countries. In the UK for example, gas boilers account for more than 85 % of domestic heat supply [5]. The main low-carbon alternatives are electrically-driven vapour-compression heat pumps, which have seen a large market growth in recent years [6]. Electric heat pumps (EHPs) do however depend on a decarbonised electricity supply to realise their emission reduction potential [7]. Alternatives are hydrogen boilers (HBs) [8] or hydrogen-fired absorption heat pumps (AHPs) [9], which require a supply of low-carbon hydrogen, or solar-thermal heating systems, which typically require a backup heating system.

In addition to space heating and hot water, provision of space cooling is becoming increasingly relevant. It already constitutes a significant share of energy demand in warmer climates, with the demand also increasing in moderate climate countries, such as in central Europe, as the average temperatures increase and extreme heat waves become more frequent [10]. Over the last decade, energy demand for space cooling increased more than twice as fast as the overall energy demand in buildings. Higher temperatures caused by climate

change [11], coupled with increasing incomes and growing populations, are driving rapid growth in residential cooling, with the share of households with air conditioning increasing globally from 25% in 2010 to 35% in 2021 and estimated to increase further to 45% by 2030 [12]. As reported in [13], some 2 to 4 billion people could be exposed to heat stress due to lack of effective indoor cooling, giving rise to multiple risk factors for heat-related illnesses [14].

It is also recognised that access to effective cooling (and heating) does not need to come at the expense of the environment if it is pursued through clean technologies. Residential cooling can account for a large share of peak electricity demand in critical periods of the year [15], potentially causing outages or requiring costly upgrades to energy infrastructure. These could be mitigated by demand response strategies, integration of energy storage assets and other sector coupling based solutions. IEA's Net Zero Emissions by 2050 Scenario [16] sets three space cooling-related goals: (i) 20% of existing buildings and all new buildings net zero by 2030, (ii) cooling set-point moderated in the range of 24-25°C, and (iii) average efficiency of new cooling devices increased by at least 50% by 2030.

EHPs come in various types and with various heat-source and sink fluids [17]. Space cooling has been traditionally provided by conventional electrically driven air-conditioning units [18], which are mostly able to only pump heat in one direction (i.e., to be only used for cooling). However, air-conditioning units are fundamentally air-to-air (AA) EHPs, and recently, almost all new commercially available AA EHPs are designed to be reversible [19]. This means that they can be used to provide both space heating and cooling, depending on the given weather. Naturally, however, air-to-air heat pumps cannot provide hot water.

At the same time, space heating can also be provided by air-to-water (AW) EHPs, which use water as the heat sink fluid. In this case, the heat is transferred to air using radiators. The advantage of AW EHPs is that they can also provide domestic hot water (which is often required at a temperature close to that required by modern radiators) [20], but unlike AA EHPs, they cannot be used to provide space cooling directly (additional equipment like ducts would be required in that case).

Large-scale electrification of heating and cooling will significantly increase national electricity demands. Moreover, it will increase seasonal differences in load, as heating and cooling demands are primarily driven by the ambient temperature. Therefore, it is expected that, in cold countries, electricity load in winter will be significantly higher, especially during peak hours. Similarly, hot countries are expected to have high electricity loads in the summer. In the UK context, Quiggin and Buswell [21] predicted an increase in peak electricity demand of 55 GW as a result of heating electrification, while Hoseinpoori et al. [22] expect that the peak demand may increase by up to 170% by 2050. It has been shown that energy storage, both at household-level and whole-energy system level, alongside other means of flexibility can help reduce necessary investments in low-carbon power generation capacity and therefore deliver decarbonisation objectives at a lower cost [23].

At the household level, energy storage typically comes in the form of thermal energy storage via hot water tanks or other sensible heat options, or more advanced approaches via thermochemical storage, phase change materials, building thermal inertia or molecular storage, which offers potential for inter-seasonal storage with extremely low energy losses [24,25]. In the case of storage integration to EHP, such storage could be in the form of thermal energy (to achieve higher seasonal COP due to the night-day temperature lift fluctuations) or electric energy, enabling demand response capabilities and withdrawal of electricity during off peak periods. In both cases, the strategy is to decouple heat demand of the household and electricity demand of the heat pump, thus allowing households to shift their demand to off-peak hours to level the electricity demand profile [20]. At the whole-system level, a distinction is typically made between short-term and long-term energy storage. Short-term storage is valuable for quick load balancing and grid stability [26], while long-term storage can provide large quantities of dispatchable generation for multiple hours or even days. The conventional large-scale energy storage technology is pumped-hydro storage, but further development potential is limited. Instead, novel storage technologies such as compressed-air energy storage [27], hydrogen storage [28] or large-scale batteries [29] show promise for application in future decarbonised energy systems.

This paper aims to provide a quantitative framework for identifying cost-optimal portfolios of heating and cooling technologies, including electrically driven technologies (i.e., AW EHPs and reversible AA EHPs) and hydrogen-driven technologies (HBs and AHPs) that can provide heating and cooling. Cost-optimisation is carried out from the whole-system cost perspective, including investment and operation cost of energy production, storage and end-use technologies. Heating demand is hereby distinguished between space heating, space cooling and domestic hot water demand. One of the main novelties of this specific work is the fact that, for the first time, the two types of EHPs (AW and AA) are included in the energy system optimisation framework, allowing the investigation of energy-system implications, and discussing transition cost trade-offs between different technological options in the context of simultaneously decarbonising residential heating and cooling. Additionally, the impact of long-duration energy storage is also explored as a means to reduce the impact of heat electrification on the electricity system.

The methodology used to identify energy-system implications of different heating technologies and the description of the techno-economic models is provided in Section 2. Energy-system results are provided in Section 3 and Conclusions are provided in Section 4.

2. Method

This section presents the key features of the energy system model that is applied to identifying cost-efficient portfolios of low-carbon heating and cooling technologies. This is followed by the description of the techno-economic models of heating and cooling technologies that have been used in the energy system model. The section concludes with the summary of key assumptions and scenarios used in the analysis.

2.1. Energy system model with decarbonised heating and cooling

The model presented in this section represents an upgraded version of the energy system model presented in [30]. This model optimises the total investment and operation cost of a carbon-constrained energy system, including electricity and hydrogen production and storage technologies, as well as the key techno-economic features of end-use heating and cooling technologies. The objective of the model is to minimise the overall cost of delivering electricity, heat, and cooling to end-consumers. Some features of the model that are not central for this paper have been omitted from the formulation due to space constraints.

Key extensions to the energy system model, when compared to [30], include: a) explicit consideration of investment decisions into end-use technologies for cooling; b) adding AA EHP to the portfolio of end-use heating and cooling technologies that the model can invest in; and c) distinguishing between heat demand for space heating (SH) and for hot water (HW), as well as between heat outputs from various technology to supply these two heat demands.

2.1.1. Objective function

The model minimises the total system cost, which contains terms associated with: a) investment in electricity generation and storage and the associated operation cost (φ_{el}), b) investment in hydrogen production and storage with associated operation cost including, if relevant, hydrogen import cost ($\varphi_{\mathrm{H_2}}$), and c) investment cost in end-use technologies for low-carbon heating and cooling ($\varphi_{\mathrm{heat-cool}}$):

$$\min z = \varphi_{\mathrm{el}} + \varphi_{\mathrm{H_2}} + \varphi_{\mathrm{heat-cool}} \tag{1}$$

Terms representing the electricity sector and hydrogen sector costs are formulated in the same way as in [30]. The electricity cost includes investment cost of generation assets and battery energy storage systems (BESS) as well as generators' operating cost, while the hydrogen sector cost includes the investment and operation costs of electrolysers, methane reformers and hydrogen storage, as well as the cost of hydrogen imports. This ensures that the cost of supplying electricity and hydrogen to low-carbon heating and cooling systems are not fixed input parameters into the calculation, but rather endogenously integrated into the cost-minimisation model by explicitly representing all investment and operation cost categories associated with electricity and hydrogen supply.

The investment cost of end-use heating and cooling technologies $\varphi_{\mathrm{heat-cool}}$ includes the cost of investment into heating and cooling assets, which is the product of the capacity decision variable μ and per unit cost π for AW EHP, AA EHP, EB, HB, AHP and TES assets:

$$\varphi_{\mathrm{heat-cool}} = \pi^{\mathrm{AW}}\mu^{\mathrm{AW}} + \pi^{\mathrm{AA}}\mu^{\mathrm{AA}} + \pi^{\mathrm{EB}}\mu^{\mathrm{EB}} + \pi^{\mathrm{HB}}\mu^{\mathrm{HB}} + \pi^{\mathrm{AHP}}\mu^{\mathrm{AHP}} + \pi^{\mathrm{TES}}\mu^{\mathrm{TES}} \tag{2}$$

Note that the operating cost of low-carbon heating and cooling technologies is implicitly considered through electricity and hydrogen balance equations.

2.1.2. Energy balance constraints

The balance constraint for power supply and demand stipulates that in each time interval t the total electricity supply, which consists of the total electricity generation (p^{gen}) plus net electrical storage output ($p^{\mathrm{bs}}_{\mathrm{dch}} - p^{\mathrm{bs}}_{\mathrm{ch}}$), needs to match total demand across various categories, which include electrified heating (p^{AW}_t, p^{AA}_t and p^{EB}_t) but also other non-heat segments such as baseline system demand, appliance and EV demand (d^{el}_k), and electricity demand for operating methane reformers and electrolysers, which is expressed as the product of their hydrogen output ξ and specific electricity consumption L^{el}:

$$\sum_{g=1}^{G} p^{\mathrm{gen}}_{g,t} + \sum_{s=1}^{S}\left(p^{\mathrm{bs}}_{\mathrm{dch},s,t} - p^{\mathrm{bs}}_{\mathrm{ch},s,t}\right) = \sum_{k=1}^{K} d^{\mathrm{el}}_{k,t} + p^{\mathrm{AW}}_t + p^{\mathrm{AA}}_t + p^{\mathrm{EB}}_t + \sum_{r=1}^{R} L^{\mathrm{el}}_r \xi^{\mathrm{ref}}_{r,t} + \sum_{e=1}^{E} L^{\mathrm{el}}_e \xi^{\mathrm{elH2}}_{e,t} \tag{3}$$

Hydrogen balance constraint (4) ensures that the total hydrogen supply from electrolysers (ξ^{elH2}), reformers (ξ^{ref}) and imports (ξ^{imp}) matches the total demand for each t, including non-heat demand for hydrogen (Ξ^{ext}), demand from HBs and AHPs (ξ^{HB} and ξ^{AHP}), consumption of hydrogen power generators (ξ^{gen}) and net hydrogen storage operation ($\xi^{\mathrm{hs}}_{\mathrm{ch}} - \xi^{\mathrm{hs}}_{\mathrm{dch}}$):

$$\sum_{r=1}^{R} \xi^{\mathrm{ref}}_{r,t} + \sum_{e=1}^{E} \xi^{\mathrm{elH2}}_{e,t} + \sum_{i=1}^{I} \xi^{\mathrm{imp}}_{i,t} = \sum_{u=1}^{U}\left(\xi^{\mathrm{hs}}_{\mathrm{ch},u,t} - \xi^{\mathrm{hs}}_{\mathrm{dch},u,t}\right) + \xi^{\mathrm{HB}}_t + \xi^{\mathrm{AHP}}_t + \xi^{\mathrm{gen}}_t + \Xi^{\mathrm{ext}}_t \tag{4}$$

2.1.3. Energy production and storage constraints

The model also includes standard constraints for conventional and variable renewable generation, which are omitted here to avoid repetition. These constraints include limits on allowed new capacity of generation technologies, unit commitment and output constraints, operating cost constraints including no-load cost, variable cost and start-up cost, annual output limits and dynamic constraints (ramping, start-up, reserve, response and inertia). This part of model formulation is described in more detail in [35]. In a similar way, standard constraints on hydrogen production and storage are implemented as presented in [36].

2.1.4. Constraints on end-use heating and cooling technologies

End-use heat balance is represented separately for space heating and hot water (given that some technologies, such as AA EHP, can only provide one of those). The space heating constraint (5) ensures that the net space heating output of all technologies, expressed as the product of either hydrogen or electricity consumption and the relevant COP or efficiency coefficient η, or in case of TES as net discharging, meets the SH demand X^{sh}:

$$p_t^{\mathrm{AW,sh}}\eta_t^{\mathrm{AW}} + p_t^{\mathrm{AA,sh}}\eta_t^{\mathrm{AA,sh}} + p_t^{\mathrm{EB,sh}} + \xi_t^{\mathrm{HB,sh}}\eta^{\mathrm{HB}} + \xi_t^{\mathrm{AHP,sh}}\eta_t^{\mathrm{AHP}} + h_{\mathrm{dch},t}^{\mathrm{TES,sh}} - h_{\mathrm{ch},t}^{\mathrm{TES,sh}} = X_t^{\mathrm{sh}} \quad (5)$$

Expression (6) does the same for hot water demand X^{hw}; note that this constraint does not include any contribution from AA EHP, as it was assumed that they cannot be used to supply hot water.

$$p_t^{\mathrm{AW,hw}}\eta_t^{\mathrm{AW}} + p_t^{\mathrm{EB,hw}} + \xi_t^{\mathrm{HB,hw}}\eta^{\mathrm{HB}} + \xi_t^{\mathrm{AHP,hw}}\eta_t^{\mathrm{AHP}} + h_{\mathrm{dch},t}^{\mathrm{TES,hw}} - h_{\mathrm{ch},t}^{\mathrm{TES,hw}} = X_t^{\mathrm{hw}} \quad (6)$$

Finally, cooling demand balance is very straightforward as it assumes only AA EHPs can meet residential cooling demand X^{cl} (note that cooling COP for AA EHPs, $\eta^{\mathrm{AA,cl}}$, may be different from heating COP $\eta^{\mathrm{AA,sh}}$):

$$p_t^{\mathrm{AA,cl}}\eta_t^{\mathrm{AA,cl}} = X_t^{\mathrm{cl}} \quad (7)$$

Upper bounds on heating and cooling technology outputs limit their total output (which is the sum of space heating, hot water and cooling outputs, as applicable to different technologies) to the level of their installed heating capacity μ, which is ensured through constraints (8)-(10). Note that all heat technology capacities μ are expressed as heat output rates, except AA EHPs, where the capacity is expressed in terms of cooling output. Also note that the COP values for AA EHPs are differentiated between space heating and cooling, while for all other technologies the same COP applied for all types of heat output.

$$\left(p_t^{\mathrm{AW,sh}} + p_t^{\mathrm{AW,hw}}\right)\eta_t^{\mathrm{AW}} \le \mu^{\mathrm{AW}}, \qquad \frac{p_t^{\mathrm{AA,sh}}\eta_t^{\mathrm{AA,sh}}}{W_{\mathrm{HC}}^{\mathrm{AA}}} + p_t^{\mathrm{AA,cl}}\eta_t^{\mathrm{AA,cl}} \le \mu^{\mathrm{AA}}, \qquad p_t^{\mathrm{EB,sh}} + p_t^{\mathrm{EB,hw}} \le \mu^{\mathrm{EB}} \quad (8)$$

$$\left(\xi_t^{\mathrm{HB,sh}} + \xi_t^{\mathrm{HB,hw}}\right)\eta^{\mathrm{HB}} \le \mu^{\mathrm{HB}}, \qquad \left(\xi_t^{\mathrm{AHP,sh}} + \xi_t^{\mathrm{AHP,hw}}\right)\eta_t^{\mathrm{AHP}} \le \mu^{\mathrm{AHP}} \quad (9)$$

$$h_{\mathrm{dch},t}^{\mathrm{TES,sh}} + h_{\mathrm{dch},t}^{\mathrm{TES,hw}} \le \mu^{\mathrm{TES}}, \qquad h_{\mathrm{ch},t}^{\mathrm{TES,sh}} + h_{\mathrm{ch},t}^{\mathrm{TES,hw}} \le \mu^{\mathrm{TES}} \quad (10)$$

Coefficient $W_{\mathrm{HC}}^{\mathrm{AA}}$ in (8) denotes the ratio between heating and cooling capacity for AA EHPs, which in this study was assumed to be equal to 1.2.

Given that AA EHPs can provide space heating through hot air rather than hot water, it was assumed that they cannot produce excess heat output to be stored in TES, but rather to only meet a proportion of instantaneous heat demand. This is ensured through constraint (11):

$$p_t^{\mathrm{AA,sh}}\eta_t^{\mathrm{AA,sh}} \le X_t^{\mathrm{sh}} \quad (11)$$

TES balance and energy limit constraints are implemented using expressions (12) and (13), where q^{TES} is the State-of-Charge (SOC) of TES, τ is its duration, $\eta_{\mathrm{ch}}^{\mathrm{TES}}$ and $\eta_{\mathrm{dch}}^{\mathrm{TES}}$ are charging and discharging efficiencies, respectively, $\alpha_{\mathrm{loss}}^{\mathrm{TES}}$ is the hourly loss rate, and Δ is the duration of the unit time interval:

$$q_t^{\mathrm{TES}} = q_{t-1}^{\mathrm{TES}}\left(1 - \alpha_{\mathrm{loss}}^{\mathrm{TES}}\Delta\right) + \Delta\left[\eta_{\mathrm{ch}}^{\mathrm{TES}}\left(h_{\mathrm{ch},t}^{\mathrm{TES,sh}} + h_{\mathrm{ch},t}^{\mathrm{TES,hw}}\right) - \frac{1}{\eta_{\mathrm{dch}}^{\mathrm{TES}}}\left(h_{\mathrm{dch},t}^{\mathrm{TES,sh}} + h_{\mathrm{dch},t}^{\mathrm{TES,hw}}\right)\right] \quad (12)$$

$$q_t^{\mathrm{TES}} \le \mu^{\mathrm{TES}}\tau^{\mathrm{TES}} \quad (13)$$

2.1.5. System-wide constraints

Total carbon emissions in the energy system result from the operation of thermal generators and methane reformers. An annual system-wide carbon emission target is implemented as in [30], while the system reliability constraints are also included in the model as in [35].

2.2. Techno-economic models of end-use heating and cooling technologies

In this work, detailed techno-economic models of AW EHPs, AW AHPs, EBs and HBs previously developed by the authors in Refs [17] and [30] are used to estimate the cost of heating and cooling technologies as a function of size and their performance as a function of the outside temperature. In addition to these, comprehensive data has been now collected to also properly model AA EHPs. The characteristics of these technologies are integrated

within the energy system model so that key technology attributes are adequately represented, allowing for an informed comparison of heating and cooling options from an energy system perspective.

EHPs in households are mainly made of four components: a condenser, an expansion valve, an evaporator and an electricity-driven compressor. The process involves heat being absorbed from a certain heat source, transferred to a working fluid (often referred to as refrigerant) in the evaporator. This is followed by the compression of the vapour working fluid, the temperature and pressure of which are raised during this process until it is condensed. Heat is then transferred to a heat sink fluid, which is used to satisfy the heat demand. The working fluid is lastly passed through an expansion valve, a process which reduces its temperature and pressure, and the cycle is then repeated. AHPs, like EHPs, involve a condenser, an expansion valve and an evaporator. The only difference is that the electricity-driven compressor is replaced by an absorption cycle, meaning that the main source of energy in an AHP is heat.

For all technology models, steady-state operation of components and negligible heat and pressure losses in heat exchangers and pipes are assumed. Both performance and cost estimates are validated using data obtained from UK manufacturers in the case of EHPs, where for AHPs the performance was validated against relevant previous studies. A simplified thermodynamic model was used to estimate the performance of the HB, while an efficiency of 100% was assumed for the EB. Unlike in previous work [30], EHPs are now separated in AW EHPs, which can provide space heating and hot water (but not space cooling), and AA EHPs, which can provide space heating and space cooling (but not hot water). It should be mentioned that an AW EHP could also provide cooling assuming ductwork and other equipment is installed, but this option is not common in residential applications and is not considered in this study.

Heat pump performance is often measured by the coefficient of performance (COP), which is a measure of the ratio between heat output and energy input. For EHPs, energy input is in the form of electricity $\dot{W}_{\mathrm{in}}$, while for hydrogen-driven AHPs, it in the form of heat $\dot{Q}_{\mathrm{in}}$ coming from a hydrogen boiler. Similarly, boiler efficiency is the ratio of heat output to energy input, where the latter is in the form of electricity for EBs and hydrogen fuel $\dot{Q}_{\mathrm{fuel}}$ for HBs. Technology performance is described by Eqs. (14)-(17):

$$COP_{\mathrm{EHP}} = \frac{\dot{Q}_{\mathrm{EHP}}}{\dot{W}_{\mathrm{in}}} \tag{14}$$

$$COP_{\mathrm{AHP}} = \frac{\dot{Q}_{\mathrm{AHP}}}{\dot{Q}_{\mathrm{in}}} \tag{15}$$

$$\eta_{\mathrm{EB}} = \frac{\dot{Q}_{\mathrm{EB}}}{\dot{W}_{\mathrm{in}}} \tag{16}$$

$$\eta_{\mathrm{HB}} = \frac{\dot{Q}_{\mathrm{HB}}}{\dot{Q}_{\mathrm{fuel}}} \tag{17}$$

The specific price of heating and cooling technologies is shown as a function of heat output at nominal operating conditions in Figure 1. The prices for AW EHP, AHP, EB and HB are estimated using the validated component-costing models and manufacturer data as in Ref. [30]. For AA EHPs, data has been collected for more than 75 currently commercially available units and a best-fit line based on power regression is generated. Installation costs are not included in Figure 1, but are set to be equal to £2,200 for all investigated HPs and £1,400 for all investigated boilers. All prices include VAT (20%).

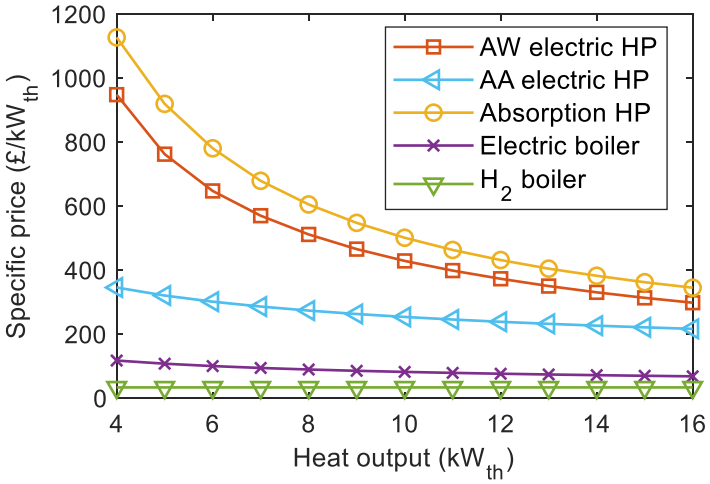

Figure 1. Specific price of heating and cooling technologies as a function of heat output at nominal operating conditions. Prices include VAT.

Heat pump COP is plotted as a function of outside air temperature for different HP types in Figure 2. For the AW EHP and AHP options, the hot-water delivery temperature is assumed to be equal to 55 °C, while the performance curves for heating and cooling of the AA EHP assume an indoor target air temperature of 21°C. The efficiencies of EB and HB are also shown for comparison purposes.

It is interesting to note the significantly lower cost and higher performance of AA EHPs when compared to AW EHPs. The cost difference is attributed to the need for additional components when installing AW EHPs, as well as the larger surface area required to transfer low-temperature heat to radiators and then to air. However, AA heat pumps have the disadvantage of requiring a separate system for hot water, while they may be often accompanied with noise and air-movement issues which may impact end-users and require careful consideration.

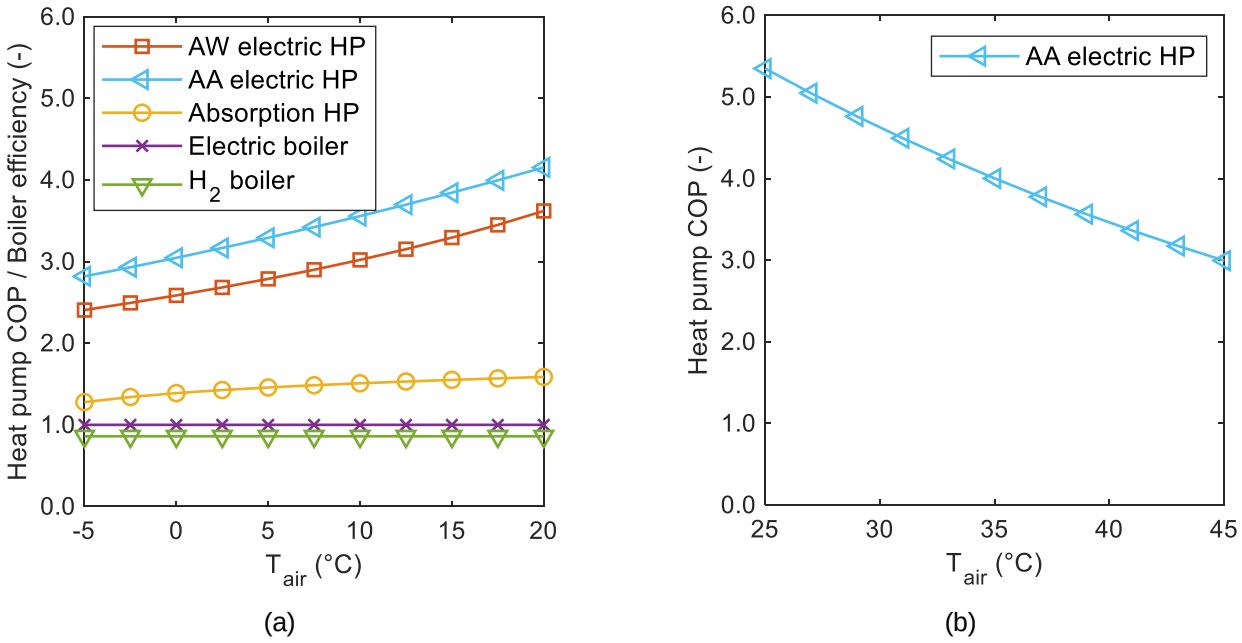

Figure 2. Heat pump COP or boiler efficiency as a function of outside air temperature for (a) heating; and (b) cooling. For heating using AW electric HP or absorption HP, a hot-water delivery temperature of 55 °C is assumed. For heating and cooling using AA electric HP, an indoor target air temperature of 21 °C is assumed.

2.3. Key assumptions and system scenarios

This section discusses the key features of energy system scenarios used in the study and assumptions on the demand for end-use heating and cooling.

2.3.1. Archetypal energy systems

One of the main objectives of the paper is to study the impact of system characteristics on cost-efficient portfolios of low-carbon heating and cooling technologies. To that end, two archetypal energy systems are assumed in the study, North and South, similarly to the approach in [30]. Size of both systems has been chosen to approximately correspond to the size of the UK electricity system, with an annual demand of 400 TWh_{el}. The two archetypal systems have the following key distinctive features:

1. North system represents a simplified version of the UK energy system, characterised by cooler climate conditions, which has a much higher residential heating demand (142 TWh_{th} for SH and 43 TWh_{th} for HW) than the South system (30 TWh_{th} for SH and 21 TWh_{th} for HW), which is broadly modelled to resemble a southern European country. Peak heat demand was also much higher in the North than in the South, as illustrated in the heat Load Duration Curves (LDCs) for the two systems in Figure 3. At the same time the energy demand for cooling energy was assumed to be about 10 times higher in the South (203 TWh_{th}) than in the North (19 TWh_{th}). LDCs for cooling demand are also shown in Figure 3.
2. Availability profiles for renewable generation are assumed to be different between the two systems, with the wind utilisation factor in the North significantly higher than in the South (58% vs. 35%), and the solar PV utilisation factor in the North much lower than in the South (11% vs. 24%). As a result, the nominal Levelised Cost of Electricity (LCOE) of wind and PV in the North was £43/MWh_{el} and £56/MWh_{el}, respectively, while in the South the same LCOEs were £39/MWh_{el} and £25/MWh_{el}.

In each case study the model cost-optimised the supply of low-carbon heating and cooling to 15.7 million residential customers by investing in end-use technologies including AW EHPs, AA EHPs, AHPs, EBs, HBs and TES. Any electricity or hydrogen demand for residential heating was subject to optimisation by the model, depending on investment choices for end-use technologies. Additionally, it was also assumed the system

needs to supply a hydrogen demand of 97.5 TWh annually to meet the hydrogen requirements outside the residential heating sector, such as in the industrial and transport sectors.

In all studies both systems are cost-optimised with the objective to achieve net zero carbon emissions. The model can meet this target by investing in a range of production technologies (both zero-carbon and positive-carbon) as well as in carbon offsets in the form of electricity generation using Bioenergy with Carbon Capture and Storage (BECCS). In all cases the energy system is modelled in hourly resolution as a single node system, i.e., ignoring the transmission, interconnection or distribution networks.

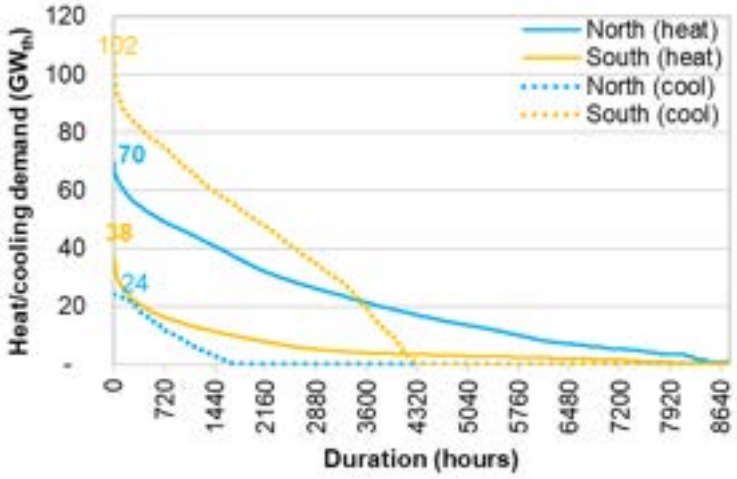

Figure 3. Load duration curves (LDCs) for hourly heat and cooling demand in North and South systems.

The assumed price of natural gas for power generation and H_2 production was £21.8/MWh, while hydrogen import was also assumed to be available (in addition to production) at the price of £100/MWh. District heat networks or industrial heat demand were not included in the scope of this analysis.

2.3.2. Space heating and hot water demand modelling

Household-level heating and cooling technologies are optimised for a typical UK household, which was identified by applying a k-means clustering method to the Cambridge Housing Model [31] data set, which contains detailed information on the UK building stock. The data set only provides annual values for space heating and domestic hot water demand, however, hourly demand values are required as model inputs. For space heating, the methodology of Watson et al. [32] is used to disaggregate the demand. The daily space heating demand is determined from a correlation with the daily mean ambient temperature. It is then distributed to the individual hours using the daily profile for the coldest range presented by Watson et al. [32], as it was deemed to be the most representative of pure space heating demand. For domestic hot water, the daily hot water flowrate profile of Herrando et al. [33] is applied. The flowrate is then converted into an energy demand by assuming a hot water delivery temperature of 55 °C and a monthly-varying cold water mains temperature according to [34].

UK-representative space heating and hot water demand profiles were used in the North archetypal system, as well as representative cooling demand profiles for the UK. In the South system, all heating demand was scaled down according to temperature fluctuations that are representative for Greece, while at the same time cooling demand was scaled upward in the same way. Daily average values for COP for various heating and cooling technologies for the North and South annual temperature profiles (obtained based on Figure 2) are shown in Figure 4. As expected, due to generally lower temperatures, the North system is characterised by higher COP values for cooling but lower COPs for heating. There is also a noticeable COP advantage when using AA EHPs to provide space heating rather than AW EHPs, although as discussed elsewhere in the paper using AA EHPs for space heating may not be practical, especially in colder climates.

The assumed costs of low-carbon heat options were based on the analysis presented in the previous section and on typical asset sizes, as follows (note that these figures include both the component costs from Figure 1 and the relevant installation cost):

- AA EHP: £578/kW_{th}
- AW EHP: £300/kW_{th}
- AHP: £638/kW_{th}
- EB: £139/kW_{th}
- HB: £98/kW_{th}
- TES: £75/kWh_{th}

In addition to the upfront investment cost, it was also assumed that all assets require an annual maintenance cost in the amount of £35/kW_{th}/yr for all HP and boiler technologies, and £20/kW_{th}/yr for TES. Asset lifetime

was assumed to be 20 years for AA EHPs, AW EHPs and AHPs and 15 years for EBs, HBs and TES. A 5% interest rate has been assumed for all heating technologies to convert overnight cost into annualised values required by the model. The assumed duration of TES (the ratio between energy capacity and heat charge and discharge rate) was 3 hours.

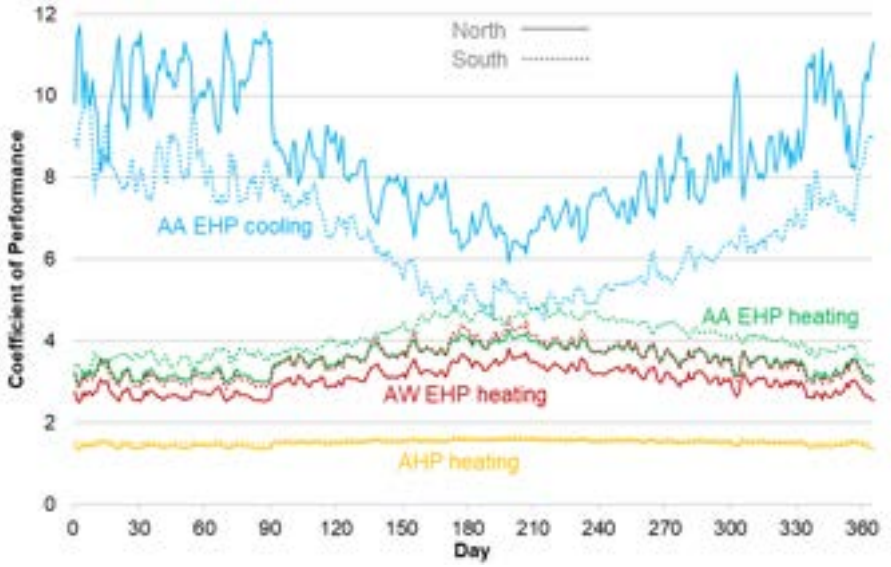

Figure 4. Values of Coefficient of Performance for various heating and cooling technologies in North and South systems.

2.3.3. Case studies

Main case studies run for both the North and South archetypal energy systems with a net-zero caron target include:

- Unlimited: no limits to provision of space heating (SH) from AA EHPs
- No SH from AA EHPs: no SH allowed from AA EHPs
- AA SH 30%: share of AA EHPs in SH limited to 30%
- AA SH 20%: share of AA EHPs in SH limited to 20%
- AA SH 10%: share of AA EHPs in SH limited to 10%

The main purpose of these studies is to explore the potential contribution of various heating technologies, and in particular AA EHPs, to space heating under different assumptions and constraints. The reason for this is that although AA EHPs could potentially offer a competitive alternative to AW EHPs with high COP values for heating, there are several practical barriers for their widespread deployment in countries such as the UK. These include space constraints, multiple room installations, difficult integration with existing heating systems and radiators etc. For that reason, AA EHPs are often seen as a possible top-up source of space heating rather than a bulk source of heat, and the range of case studies listed above is an attempt to explore how various levels of contribution of AA EHPs to space heating affect the overall portfolio of end-use heating technologies.

In addition to the case studies above, another set of modelling runs was carried out to study the impact of peakiness of heat demand, where the heat profiles used in this study were replaced with peakier heat demand profiles used in [30], in order to assess the impact of the shape of the heat profile on the cost-efficient portfolio of heating technologies. For illustration, heating profiles used in the main case studies had a peak per household of around 4.5 kW_{th}, which is lower than the peak of 7 kW_{th} that was used in the previous study. Case studies with higher peak heat demand were only carried out for the two extreme cases, i.e., “Unlimited” and “No SH from AA EHPs”.

The final set of studies assumed that the system also had an option to invest in very low-cost long-duration energy storage (LDES). The aim of these studies was to test whether installing LDES in the electricity system could help with managing the seasonality of heating and cooling demand. The LDES case studies were also run only for the “Unlimited” and “No SH from AA EHPs” scenarios. The cost of LDES in these studies was assumed at the level of 100% (£6.5/kWh) and 50% (£3.2/kWh) of the cheapest LDES option identified in [37], which was a 120-hour underground Compressed Air Energy Storage (CAES).

3. Results

This section discusses the results of various case studies aimed at establishing cost-efficient portfolios of low-carbon heating and cooling technologies across different system conditions and scenarios. More specifically, the case studies presented here focus on the following aspects:

- Impact of system geography, reflected in the volumes of heating and cooling demand and in the availability profiles of wind and solar PV generation;
- Impact of availability of AA EHPs for space heating;
- Impact of availability of low-cost long-duration electricity storage (LDES);
- Impact of heat demand profile, i.e., the level of peak demand for space heating.

Key modelling results presented in this section focus on the cost-optimal capacity mix of low-carbon heating and cooling technologies and the annual volumes of supplied heat and cooling from different technologies.

3.1. Cost-efficient portfolios of end-use heating and cooling technologies in baseline scenarios

Results for the cost-optimal compositions of heating and cooling portfolios across the main case studies for the North and South systems are shown in Figure 5. Not surprisingly, a significant volume of AA EHP capacity is added across all case studies as it represents the only option to supply cooling demand. This capacity is at least 24 GW_{th} in the North and 104 GW_{th} in the South system. In the "Unlimited" scenarios in the North the model adds even more AA EHPs than the minimum required for cooling, around 43 GW_{th}, as it represents a more cost-efficient option than installing AW EHPs. Such high capacity is sufficient to cover almost the entire space heat demand in the "Unlimited" scenarios for the North and South systems. Given that AA EHPs cannot provide hot water, a relatively small volume of AW EHPs and TES (as well as some HBs in the North) is installed to ensure that hot water demand is met.

In the other extreme, where AA EHPs are not used to provide any space heating, the heat demand is met through a mix of AW EHPs (49 GW_{th} in the North, 13 GW_{th} in the South), EBs (3 GW_{th} and 15 GW_{th}), HBs (10 GW_{th} and 5 GW_{th}) and TES (8 GW_{th} and 6 GW_{th}). Due to their higher investment cost, AW EHPs are installed to operate as baseload heat source, meeting most of the heat requirements, while boilers and TES are used as peak heat sources. AHPs are not chosen as part of the cost-optimal portfolio in any case studies due to their high assumed investment cost.

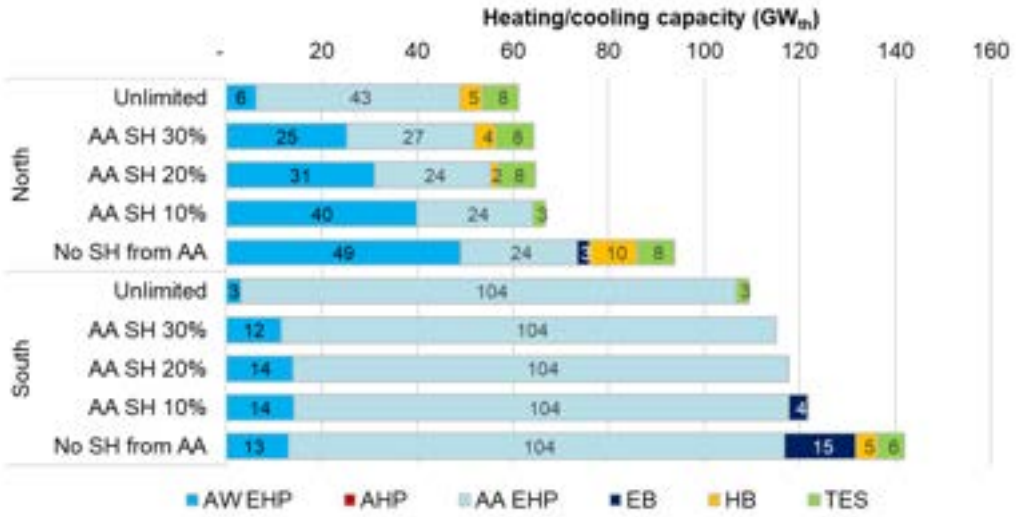

Figure 5. Cost-optimal capacities of low-carbon heating and cooling technologies for various scenarios in North and South systems.

In case studies where AA EHPs were allowed to contribute between 10% and 30% of the annual space heating demand, the model installed a significantly higher capacity of AW EHPs than in the "Unlimited" scenarios, but lower than in the opposite extreme without contribution of AA EHPs to SH, as it was now possible to use AA EHPs as a peaking technology instead of boilers or TES. In the North system, reducing the target contribution of AA EHPs to heat supply also reduced their capacity to 24 GW_{th}, the minimum needed to meet cooling load.

Finally, it needs to be noted that the case studies with low-cost LDES available for investment in the electricity system did not yield any change in system investment decisions including the investment in end-use heating and cooling technologies. In other words, even at a low cost the model did not decide to invest in LDES, resulting in the same investment decisions as in the case studies without LDES.

3.2. Share of various technologies in heating and cooling supply in baseline scenarios

Figure 6 shows the split of annual supply of space heating (SH), hot water (HW) and cooling between different technologies. Supply of cooling is very straightforward as it was assumed that only one technology (AA EHPs) can meet cooling demand.

In both North and South systems most of the HW demand is supplied using AW EHPs, which is the most efficient technology for converting electricity into heat for HW supply (note that AA EHPs were not assumed to be able to supply HW). In scenarios with no SH from AA EHPs there is some supply of HW from EBs and HBs, although their share in HW supply is well below 10%.

The mix of SH supply on the other hand varies significantly across different scenarios. In the "Unlimited" scenarios the contribution to of AA EHPs to space heating is between 93% (South) and 96% (North), while the remainder is supplied by AW EHPs. As the share of AA EHPs in SH supply is gradually constrained to 30%, 20%, 10% and 0% of total SH demand, the share of AW EHPs expectedly increases to make up for the shortfall, as does the installed AW EHP capacity (see Figure 5). When the share of AA EHPs in SH supply drops to zero, some of the SH is also supplied from boiler technologies (mostly from EBs), at the level of 2% in the North and 17% in the South. Higher share of EBs in heat supply in the South can be explained by the availability of low-cost electricity from solar PV in the South, allowing for inexpensive supply of electricity to EBs.

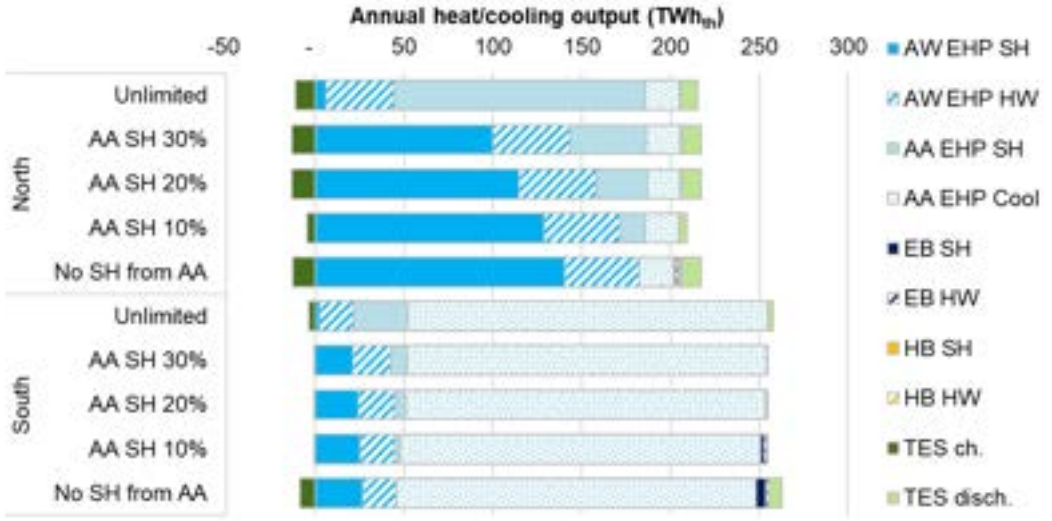

Figure 6. Annual output of low-carbon heating and cooling technologies for various scenarios in North and South systems.

In all North scenarios and the 0% scenario in the South there is also a visible contribution of TES to total SH and HW supply, at the level of up to 6% of total heat in the North and 14% in the South. Note, however, that due to cycle losses associated with charging and discharging TES, it effectively represents a net heat demand.

3.3. Impact of heat demand profiles

Sensitivity studies with higher peak heat demand resulted in cost-optimal portfolios of end-use technologies shown in Figure 7. Higher peak heat demand did not affect the technology portfolio in the "Unlimited" scenario in the South, while in the North the capacity of AA EHPs increases by 9 GW$_{th}$ as it is used to contribute to meeting the higher peaks in heating demand.

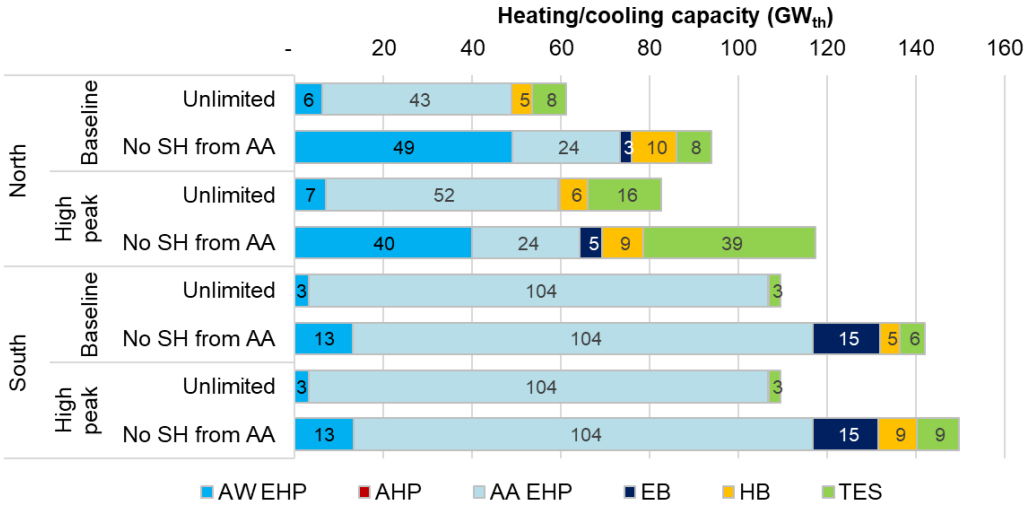

Figure 7. Cost-optimal capacities of low-carbon heating and cooling technologies for various peak heat demand scenarios in North and South systems.

In the scenarios with the AA EHP share in SH supply constrained to 0% there are more notable differences in the cost-optimal technology portfolios. In the South system, where the SH demand is several times lower than in the North, the main change is that the higher peak requires a slightly higher capacity of HBs (9 vs. 5 GW_{th}) and TES (9 vs. 6 GW_{th}) than in the baseline studies, while the capacities of other technologies remain the same.

In the North system, however, the SH peak demand is much higher and therefore the composition of end-use heating technologies changes to a much greater extent. Peakier demand makes AW EHPs slightly less economically attractive due to their cost structure (high investment cost but relatively low operation cost), so their capacity reduces from 49 to 40 GW_{th}. At the same time, higher peaks make technologies such as boilers (with lower investment cost but higher operating cost) more attractive, so their total capacity increases from 13 to 14 GW. Nevertheless, the greatest change is observed in the capacity of TES, which increases from 8 to 39 GW_{th}. This indicates that TES is the preferred end-use option to meet high peak demand through discharging heat, while being recharged during off-peak periods using the heat produced by AW EHPs.

4. Conclusion

This paper formulated an approach for making cost-optimal selection of low-carbon heating and cooling technologies from the system perspective, looking at two archetypal systems, North and South, with different heating and cooling demand characteristics as well as different availability profiles for variable renewables. The modelling included various boiler technologies, thermal energy storage and heat pumps, including a distinction between two types of EHPs (Air-to-Water and Air-to-Air), into the energy system optimisation framework.

Case studies presented in the paper show that a cost-optimal portfolio of end-use heating and cooling options will greatly depend on the characteristics of the system where they are deployed, both in terms of typical heating and cooling demand patterns, but also with respect to the availability of low-cost variable renewable generation. The results suggest that AA EHPs, with their cost and efficiency advantages over AW EHPs, could make a significant contribution to the future low-carbon heat supply in addition to cooling, although their share of heat supply may be constrained by several factors such as compatibility with incumbent heating systems or the need for multiple unit installations. Nevertheless, they could be used as an efficient top-up source of space heating in addition to AW EHPs, displacing some of the need for electric or hydrogen boilers, as well as thermal energy storage.

Note that the presented approach considers the aggregate heating/cooling sector, and therefore does not suggest an appropriate mix of technologies for an individual household. Given the variety of heat requirements across different customers and the diversity of heat demand, different households would install different portfolios of technologies depending on their specific circumstances, including their individual heat demand patterns, willingness to adopt new low-carbon technologies, and the household income profile. Future work in this area will focus on the effects of diversity and extreme weather on capacity requirements for low-carbon heating and cooling technologies, where higher peaks during extreme weather conditions may require more peaking capacity.

Abstract:
Packed beds are essential components for future utility-scale long duration energy storage, such as A-CAES and Carnot batteries, and are expected to operate under a large variety of operating conditions. The operating behaviour can be visualised compactly within Ragone plots, which show the extractable energy over a range of discharge powers. They can additionally demonstrate the effect of different operational limits. Ragone plots are a well-known framework within electrochemical energy storage, but have not been applied to packed bed thermal energy storage. In this work, Ragone plots of packed beds are developed, to quantify off-design behaviour and the energy-power trade-off. For this purpose, a one-dimensional, two-phase, transient, Schumann-style model for a non-pressurized packed bed is implemented in the modelling language Modelica. It is charged up to a nominal thermal energy of 100 MWh and subsequently discharged with two different discharge regimes, namely a constant mass flow discharge or a constant heat tranfer rate discharge. The shape of the obtained Ragone plots is characterised by limited self-discharge and little decline in available energy at high constant mass flow discharges. The enforcement of the mass flow limit and imperfect heat transfer dynamics lead to a residual thermal energy within the storage, which can be extracted at lower heat transfer rates. Analogies to electrochemical energy storage are drawn, where polarisation causes a conceptually similar residual energy.

1. Introduction

In this paper, a packed bed thermal energy storage (TES) is studied and characterised within the Ragone plot framework and analogies between electrochemical energy storage are demonstrated. This is important since packed beds are considered strong contenders for TES components in future long-duration energy storage, such as Carnot batteries [1], compressed air energy storage (CAES) [2] and in the decarbonisation of industrial heat [3], due to their favourable characteristics. These characteristics include excellent heat transfer, low material costs, a low environmental impact, a high operational temperature range and high output temperature levels, due to thermal stratification. The study of packed beds has attracted considerable research attention, especially their modelling [4, 5], parametric optimisation [6] and performance aspects [7].

The Ragone plot shows the available energy as a function of discharge power and thus characterises the inherent energy-power trade-off of energy storage [8]. It is a very fundamental relation and can be construed as a “common language” of energy storage [9]. The characterisation of packed beds within this framework therefore enables the direct comparison with different energy storage technologies, across their respective fields.

The Ragone plot was first introduced by David Ragone in 1968 [10], and over the following years established itself a concept in the field of electrochemical energy storage, e.g. batteries and supercapacitors. They have recently also been applied in the field of TES (and associated technologies). Latent heat TES has been characterised with Ragone plots by [11–13]. Of these, Woods et. al. [12] presents a comprehensive Ragone plot analysis of different phase change materials. Here, the energy-power trade-off in a finite volume is shown, whereby heat transfer is improved at the cost of energy capacity. The publication lays the foundation for Ragone plot characterisation of TES as standalone components. The thermal energy is extracted at different constant heat transfer rates $\dot{q}$, as the thermal equivalent to electric power.

Christen [9] characterised pumped thermal energy storage (PTES) with both latent and sensible TES via Ragone plots. Here the TES is not characterised directly, but as a component within electric energy storage.

The analysis employs endoreversible thermodynamics [14] (perfect heat engine with irreversible heat transfer) to estimate the electric power delivered. Further, a lumped-model approach is used, which means there is no spatial temperature variation. This implies perfect mixing within the sensible TES, where the output temperature decays during the entire discharge process. In contrast, in a thermally stratified packed bed, a high, nearly constant output temperature can be held over the first part of a discharge until thermal front has migrated towards the outlet. A packed bed therefore lies somewhere between mixed sensible and latent TES in terms of maintaining high output temperatures, which is beneficial in a thermodynamic power cycle.

The contribution of this paper is to conduct the first analysis of packed beds within the Ragone plot framework, as this has not been attempted before. For this, a state-of-the-art packed bed model is used. Analogies between packed bed TES and electrochemical energy storage discharge modes are developed, to effectively translate the Ragone plot framework. An assessment of off-design performance of packed beds follows, both in the context of pure thermal energy storage and as a thermal reservoir for a power cycle. The remainder of the paper is structured as follows: Section 2 describes the methodology of the Ragone plot and the employed packed bed model. Section 3 shows the obtained results and highlights key findings. Section 4 summarises the results and derives the conclusion from the presented analysis.

2. Methodology

2.1. The Ragone plot framework and discharge regimes

A Ragone plot essentially is a collection of energy-power value pairs from full discharges of any kind of energy storage. These value pairs form a Ragone curve or energy-power (E-P) curve. Ragone curves are often presented as specific values, based on storage mass (gravimetric energy and power density) or on storage volume (volumetric energy and power density) However, absolute values are also used, depending on what makes most sense in the given context.

Christen and Carlen [8] have expressed the Ragone curve as stemming from constant-power (CP) discharges, where a constant power P can be applied to an fully charged energy storage for a finite time t_{end} until an internal operating limit terminates the discharge. This results in the following E-P relation:

$$E(P) = P \cdot t_{\text{end}}(P) \tag{1}$$

However, the electrochemical ES community routinely characterises batteries with constant-current (CC) discharges. This does not result in an unambiguous energy-power point, because the power varies in the course of this type of discharge. In these cases, the E-P value pair for a constant current I is obtained by averaging the power over the discharge time, resulting in

$$E(I) = P_{\text{ave}}(I) \cdot t_{\text{end}}(I) \tag{2}$$

These two fundamental discharge regimes found in batteries (CC/CP) have direct equivalents in packed bed TES, which are all shown together for illustration purposes in Fig. 1. All subfigures show the potential variable of the energy storage (voltage U for the lithium-ion battery and the specific enthalpy difference Δh of the fluid at inlet and outlet for the packed bed) and the flow variable (current I for the lithium-ion battery and mass flow rate $\dot{m}$ for the packed bed) over the course of the discharge time.

Fig. 1 a) and b) are the respective constant flow discharge regimes. In a CC-discharge of a lithium-ion-battery in a), the output voltage decays until the discharge is terminated by reaching the predefined operating limit U_{min}. The output power $P(t) = U(t) \cdot I$ also decays. Analogously, in Fig. 1 b) Δh decays during the constant mass flow discharge (referred to as “CF”-discharge hereafter), until termination at T_{min}. Here the potential variable and flow variable multiplied result in a decaying heat transfer rate $\dot{q}(t) = \Delta h(t) \cdot \dot{m}$ delivered to the application. The Ragone plot from a CF-discharge of a packed bed can thus be expressed as:

$$E(\dot{m}) = \dot{q}_{\text{ave}}(\dot{m}) \cdot t_{\text{end}}(\dot{m}) \tag{3}$$

To compensate the decaying voltage in lithium-ion batteries, the current can be increased during the discharge to deliver a constant power, see Fig. 1 c). The packed bed equivalent is increasing the mass flow to compensate the decaying Δh and deliver a constant heat transfer rate $\dot{q}$, referred to as a “CQ”-discharge hereafter. The CP and CQ discharge regimes have a higher control effort, but are necessary if load-following must be achieved [9]. Here, the discharge can be terminated by reaching a potential variable limit (i.e. U_{min} or T_{min}) or by reaching a flow variable limit, here I_{max} or $\dot{m}_{\text{max}}$. The Ragone plot derived from multiple CQ-discharges become simply:

$$E(\dot{q}) = \dot{q} \cdot t_{\text{end}}(\dot{q}) \tag{4}$$

It must be noted, that in [12], the constant heat transfer rate for the latent heat TES Ragone plots is realised by adjusting the inlet temperature instead of the mass flow. We consider an increase in mass flow better suited for

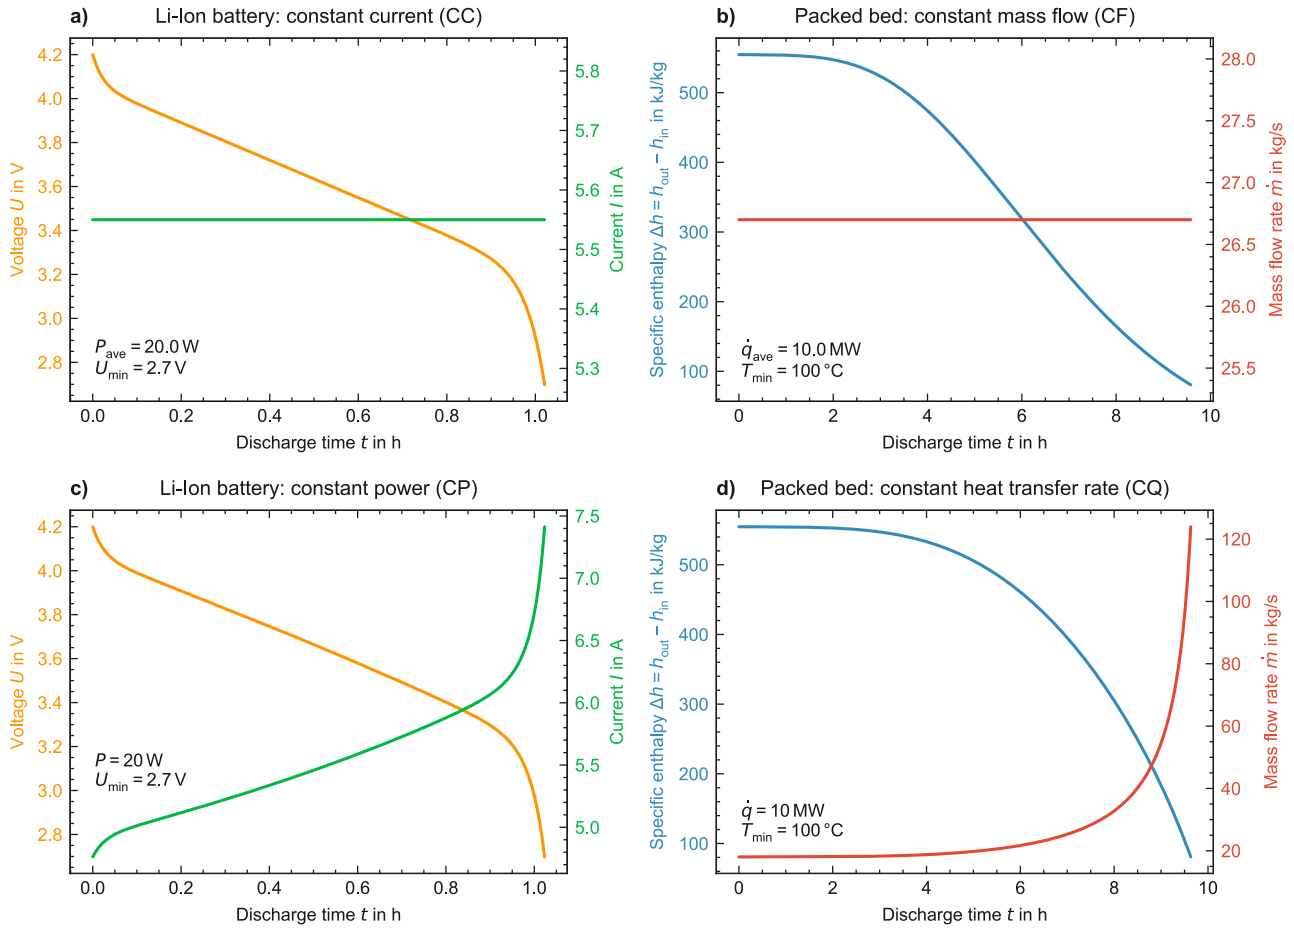

Figure 1: Equivalent discharge regimes for electrochemical ES, represented here by a lithium-ion battery, in a) and c) and packed bed TES in b) and d).

this analysis. The adjustment of the inlet temperature premises another heat source/sink apart from the TES itself, which is deemed impractical. In the course of this analysis, a representative packed bed will be studied under both CF and CQ discharge regimes.

2.2. Packed bed sizing

The packed bed is sized for a nominal energy capacity $E_{\text{nom}} = 100\,\text{MWh}$ in a top-down design approach, with inlet temperatures assumed at $T_{\text{in}} = T_{\text{max}}$ of 550 °C during charge and 20 °C = $T_{\text{amb}} = T_{\text{min}}$ for discharge. The packed bed is considered a non-pressurised rock-air system. The amount of rock mass m_s needed is calculated from [6] as follows:

$$E_{\text{nom}} = \frac{m_{\text{s}}}{\beta} \cdot c_{\text{p,s}} \cdot (T_{\text{max}} - T_{\text{min}}) \tag{5}$$

The packed bed is oversized by a factor $\beta = 1.5$ to prevent energy and exergy lost by exiting hot air, in accordance to results from Cardenas et. al. [6]. The basic geometry, namely radius r and height H is calculated via (6) and (7), for an aspect ratio of $\alpha = 0.7$ [6].

$$r = \left(\frac{m_{\text{s}}}{2\pi \cdot \alpha \cdot \rho_{\text{s}} \cdot (1 - \epsilon)} \right)^{1/3} \tag{6}$$

$$H = 2 \cdot r \cdot \alpha \tag{7}$$

The nominal discharge time is set at $t_{\text{nom}} = 10$ hours. From this, the nominal mass flow $\dot{m}_{\text{nom}}$ can be calculated via the following simplified relation:

$$\dot{m}_{\text{nom}} = \frac{E_{\text{nom}}}{t_{\text{nom}} \cdot \overline{c_{\text{p,f}}} \cdot \overline{\Delta T}} = \frac{E_{\text{nom}}}{t_{\text{nom}} \cdot \dfrac{c_{\text{p,f}}(T_{\text{max}}) + c_{\text{p,f}}(T_{\text{min}})}{2} \cdot \dfrac{(T_{\text{max}} - T_{\text{min}})}{2}} \tag{8}$$

The according specific mass flow G_{nom} is:

$$G_{\text{nom}} = \frac{\dot{m}_{\text{nom}}}{2\pi \cdot r^2} \tag{9}$$

The key design parameters of the packed bed are summarised in Table 1, where the values are colour-coded according to their degree of freedom in the design process. The design process chronology is from the top to bottom of the table.

Table 1: Overview over packed bed design parameters, colour-coded according to their degree of freedom in the design process. With = high degree of freedom, = limited degree of freedom and = resulting value.

Design parameter	Unit	Value	Source
E_{nom}	MWh	100	
T_{min}	°C	20	
T_{max}	°C	550	[4]
solid specific heat capacity $c_{\text{p,s}}$	J/kgK	960	[15]
solid density ρ_{s}	kg/m^3	2560	[15]
rock mass m_{s}	t	1061.3	
aspect ratio α	-	0.7	[6]
oversize factor β	-	1.5	[6]
porosity ϵ	-	0.40	[4]
rock diameter d	m	0.02	[4]
radius r	m	5.40	
height r	m	10.80	
cross section A	m^2	91.47	
t_{nom}	h	10	
nominal mass flow $\dot{m}_{\text{nom}}$	kg/s	36.33	
nominal specific mass flow G_{nom}	kg/sm^2	0.3972	

The wall is composed of three layers, adopted from [16]: an internal tube, an insulation layer and an outer steel vessel. Their respective parameters are listed in Table 2.

Table 2: Wall composition of packed bed

Design parameter	Unit	Tube	Insulation	Steel vessel
thickness r	m	$0.001 \cdot 2r$	$0.05 \cdot 2r$	$0.001 \cdot 2r$
thermal conductivity k	W/mK	0.12	0.15	20

2.3. Packed bed model description and validation

The Ragone plot analysis is conducted on the basis of a dynamic physical model of the packed bed, according to current standard modelling practise. The model is a transient, two-phase, Schumann-style model, widely used in the study of packed beds. The model is governed by mass conservation and by an separate energy balance for solid and fluid respectively, linked through the convective heat transfer between fluid and solid. The model further considers axial conduction through the solid and losses from fluid to ambient. The equations are taken from [4]. For the fluid phase this is:

$$\epsilon\, \rho_{\text{f}}\, c_{\text{p,f}}(T_{\text{f}})\, A\, \frac{\partial T_{\text{f}}}{\partial t} = h_{\text{V}}\, A\, (T_{\text{s}} - T_{\text{f}}) + c_{\text{p,f}}(T_{\text{f}})\, G\, A\, \frac{\partial T_{\text{f}}}{\partial x} + U_{\text{wall}}\, 2\, \pi\, r\, (T_{\text{amb}} - T_{\text{f}}) \tag{10}$$

with the volumetric heat transfer coefficient h_{V} from the correlation of Coutier and Faber [15] and the overall loss coefficient through the wall U_{wall}. U_{wall} is calculated as conduction through a multi-layered cylinder wall [19] with no thermal capacitance of the wall. The convection at the inner wall is from [20], while the convection at the outer wall is considered as free convection near a vertical surface [18]. For the solid phase the energy conservation equation is:

$$(1 - \epsilon)\, \rho_{\text{s}}\, c_{\text{p,s}}\, \frac{\partial T_{\text{s}}}{\partial t} = h_{\text{V}}\, (T_{\text{s}} - T_{\text{f}}) + k_{\text{bed}}\, \frac{\partial^2 T_{\text{s}}}{\partial x^2} \tag{11}$$

with the axial thermal conductivity of packed bed k_{bed}. This is evaluated according to the model of Zehner, Bauer and Schlünder [18]. The two-phase formulation is important to capture transient effects, i.e. when fluid

and solid are not in thermal equilibrium [17]. The energy E contained in the packed bed is determined via the temperature of the solid [4] and is given in (12). The pressure loss in the packed bed is calculated via the Ergun equation [18].

$$E = \int_0^H \rho_s \, c_{p,s} \, A \, (T_s(x) - T_{amb}) \, dx \tag{12}$$

2.3.1. Implementation

The numerical model is implemented in the acausal, multi-physics modelling language Modelica and solved within the open source modelling environment OpenModelica. As OpenModelica cannot solve partial differential equations (PDE), a finite volume discretisation is applied to (10) and (11) to form a set of coupled ordinary differential equations (ODE), where each control volume is governed by an ODE. The discretisation scheme and structure of the layer-based equations are adopted from [17]. The temperature-dependent thermodynamic properties of air are calculated at every point in time with the integrated "ReferenceAir" medium model contained in the Media library. This is a real gas model for dry air in the range of 130 K to 2000 K, based on Helmholtz equations of state.

2.3.2. Validation

The packed bed model is validated with the experimental data of Meier et. al. [21], further described by Hänchen et. al. [4], by scaling the model to the geometric dimensions specified. The result is shown in Fig. 2. The model shows good thermal agreement, but overestimates pressure losses by approx. 10 %, which is a known effect of the Ergun equation for randomly packed, spherical rock beds [22]. However, the equation is standard practise [18] and agreement is deemed satisfactory for the scope of this work.

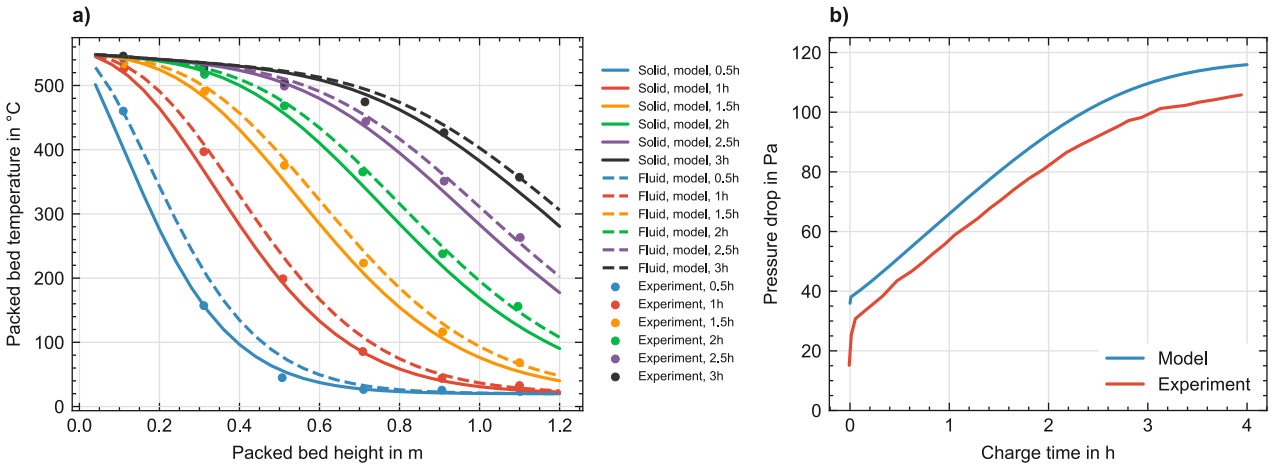

Figure 2: Validation of a) thermocline behaviour and b) pressure drop of the packed bed model with U_{wall} = 0.678 W/m²K at 523 K and a bypass flow of 15 % reported in [4]. Comparison with experimental data from [21]. The model is discretised into 30 layers.

2.4. Consideration of auxiliary components

In a non-pressurised packed bed, airflow is driven by an auxiliary fan/blower and the pressure drop Δp incurred through the bed must be compensated [6]. This must be considered in the Ragone plot analysis, because high mass flows result in higher pressure drops. Additionally, because the mass flow will be varied between discharges in the CF regime and during the course of a discharge in the CQ regime, a reasonable $\dot{m}_{max}$ must be determined. Whether the auxiliary is considered a fan or a blower depends on the pressure ratio, but the distinction is not clear-cut in literature [23]. For simplification purposes, we only refer to "fan" from this point onward.

The required auxiliary fan power is expressed as [24]:

$$P_{aux} = \frac{\dot{V} \cdot \Delta p}{\eta_{fan}} \tag{13}$$

with η_{fan} assumed at 80 % [24] for all operating points. This is a simplification, as the fan will operate in unsteady, off-design conditions. Even in a constant mass flow CF charge/discharge, the pressure loss to be compensated varies in the course of the charge/discharge, as the thermodynamic properties of the fluid inside

the packed bed change. This is also confirmed experimentally in Fig 2 b). The off-design behaviour of fans can be characterised with performance maps, which are usually determined experimentally and are specific to a fan type and geometry. However, with variable speed drives, satisfactory efficiencies can be achieved over a large range of mass flows, respective volume flows [24]. Therefore the consideration with a single efficiency is considerd sufficient and analysis with detailed performance maps is not deemed expedient.

Up to a pressure ratio of 1.3, air can be assumed as a incompressible medium [25], and therefore P_{aux} is calculated with the volume flow at inlet in 13. This is often viewed as the limit between fans and compressors [25]. This limit adopted here as the maximum allowable fan pressure ratio and higher pressure losses are a priori deemed impractical. From this condition, a maximum mass flow $\dot{m}_{max}$ can be iteratively determined from simulation runs, resulting in $\dot{m}_{max} = 158\,\mathrm{kg/s}$ or $4.3 \cdot \dot{m}_{nom}$. The maximum specific mass flow is thus $G_{max} = 1.727\,\mathrm{kg/sm^2}$.

3. Results and Discussion

3.1. Ragone plots from CF-discharge

In a first step, Ragone plots are developed from multiple constant mass flow (CF) discharges, as specified in Section 2.1. The packed bed is fully charged to nominal energy, then subsequently immediately discharged until the cut-off temperature is reached. This is repeated multiple times, starting from a mass flow of $0.1 \cdot \dot{m}_{nom}$ up to $\dot{m}_{max} = 4.3 \cdot \dot{m}_{nom}$. The result is shown in Fig. 3 a) for a cut-off temperature of $T_{min} = 20\,^{\circ}\mathrm{C}$ and in b) for $T_{min} = 100\,^{\circ}\mathrm{C}$.

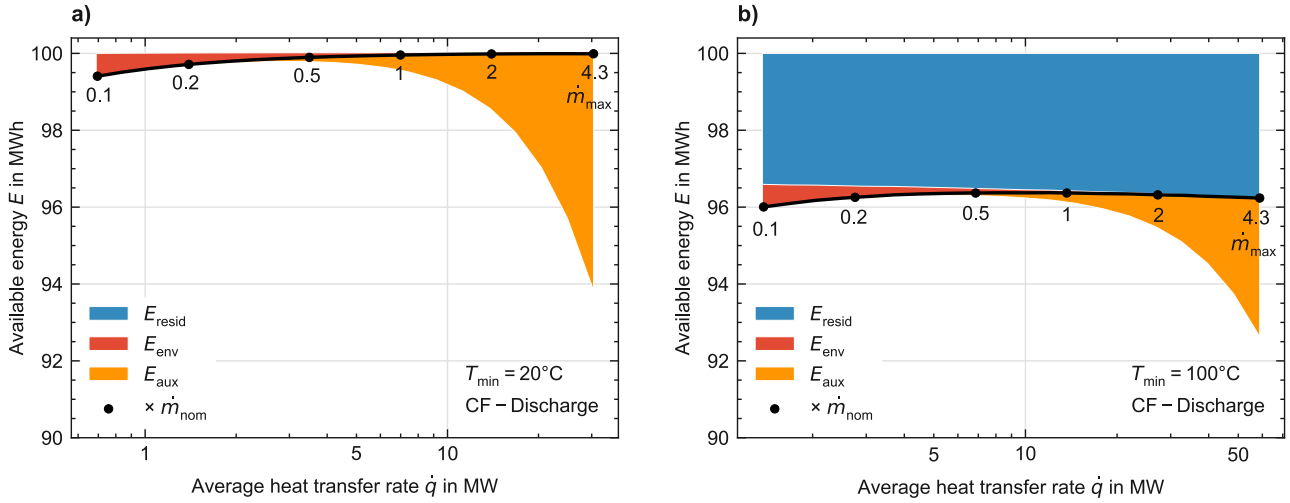

Figure 3: Ragone plots from multiple CF-discharges.

The Ragone curves (in black) show the available thermal energy over the average heat transfer rate. Certain mass flows are demarcated by dots; these are multiples of the nominal mass flow (conceptually similar to the C-rate in lithium-ion batteries). Classically, the Ragone curve is shown without any other descriptive elements. In this case, a novel visualisation is implemented to demonstrate how the Ragone curves are composed. The area above the curve (thermal energy that cannot be extracted) is color-coded, where red equals energy lost to environment and blue is residual energy in the storage. Further included is the electric energy required by the auxiliary fan to achieve the respective mass flows (yellow). This is not subtracted from the Ragone curve, because it does not lessen the available thermal energy, but is included for reference. It rises sharply for higher mass flows.

The Ragone curves confirm known packed-bed qualities. Thermal energy can be contained well, even for long discharge durations at low mass flows, signalled by low losses to the environment. Additionally, higher mass flows don't negatively impact available thermal energy to the extent that, e.g. high currents limit available energy in Li-Ion batteries. The forced convective heat transfer is still very good at high mass flows. Because of these characteristics, the shape of the Ragone curve in the CF-discharge regime is relatively flat. It is important to note that thermal front degradation does not show itself in Fig. 3, because the energy content remains the same and the bed is oversized to the extent that the thermal front degradation does not reach the outlet in the discharge durations considered.

The location of the Ragone curve on the E-Q plane is largely determined by the cut-off temperature. In Fig. 3 a), no thermal energy remains in the packed bed, whereas in Fig. 3 b) the higher cut-off temperature moves the entire Ragone curve downward, resulting in residual thermal energy. This is shown in Fig. 4, for multiple

different T_{min}. The residual energy and energy lost to the environment are not included here for visual clarity, only the auxiliary energy.

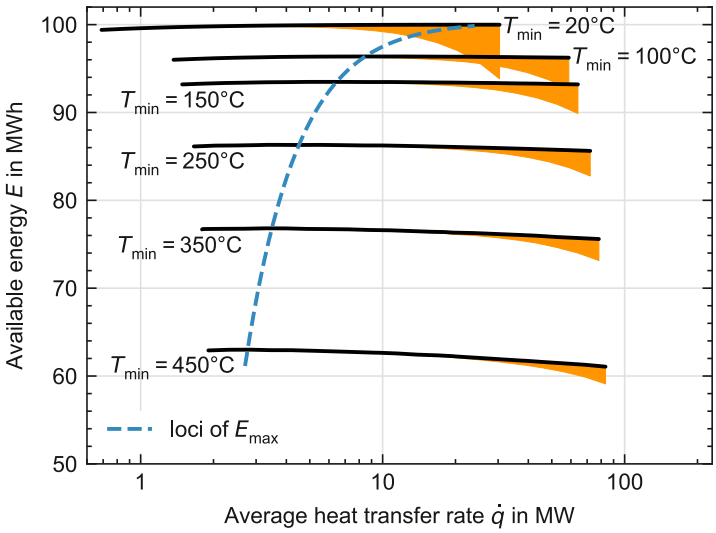

Figure 4: Ragone plots with varying cut-off temperature limits T_{min}.

One thing that becomes clear in Fig. 4, is that there is no single unique assignment between $\dot{q}_{ave}$ and $\dot{m}$. Depending on T_{min} and the resulting discharge end time, a specific $\dot{m}$ might result in different $\dot{q}_{ave}$. Secondly, one can observe a slight decrease in available energy at higher $\dot{q}_{ave}$. This can be attributed to an effect that is equivalent to polarisation in lithium-ion batteries. Polarisation is when charge transfer from and into the electrode cannot keep up with high current demands, resulting in overpotentials [26]. These lead to a premature termination of discharge and cause a residual energy that can only be extracted at lower currents. In the packed bed, imperfect heat transfer dynamics at high mass flow rates results in a temperature difference between fluid and solid. At the end of the discharge, the solid still has a higher temperature, but the fluid outlet temperature is lower and triggers the discharge cut-off. This effect is shown in Fig.5. It shows the temperature difference ΔT between solid and fluid, plotted over the specific mass flow G for several different lower cut-off temperatures.

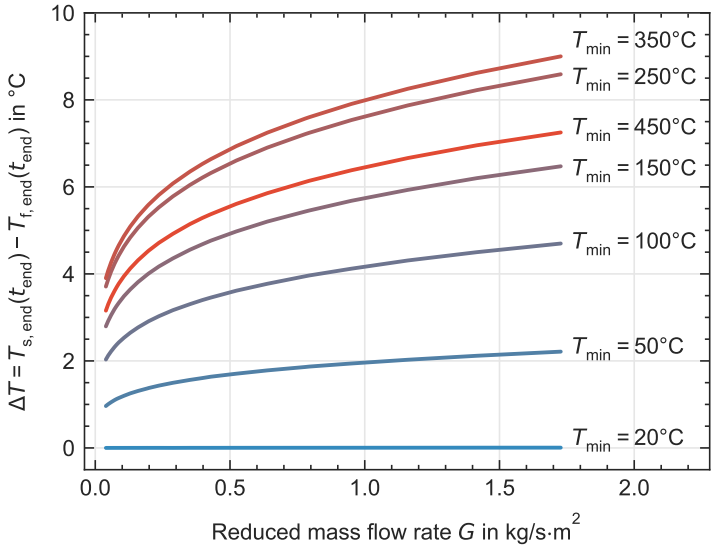

Figure 5: Temperature difference $\Delta T(t_{end})$ between solid and fluid at the end of discharge for different T_{min}.

From Fig.5 it can be seen that higher mass flows generally result in higher ΔT and thus higher "polarisation". But ΔT is also dependent on T_{min}. The temperature difference is highest within the thermocline, and stopping the discharge as the steepest point of the thermocline exits, results in highest ΔT (here at $T_{min} = 350\,°C$). This in turn leads to the highest amount of residual energy due to heat transfer limitations.

3.2. Ragone plots from CQ-discharge

In the second part of the analysis, Ragone plots constant heat transfer rate (CQ) discharges are developed, presented here in Fig. 6. As in Section 3.1., the packed bed is fully charged and immediately discharge until termination by either reaching the predefined maximum mass flow $\dot{m}_{\mathrm{max}}$ or the cut-off temperature T_{min}. This is repeated for multiple heat transfer rates, with the E-Q value pairs forming the Ragone curve. In 6 a), the

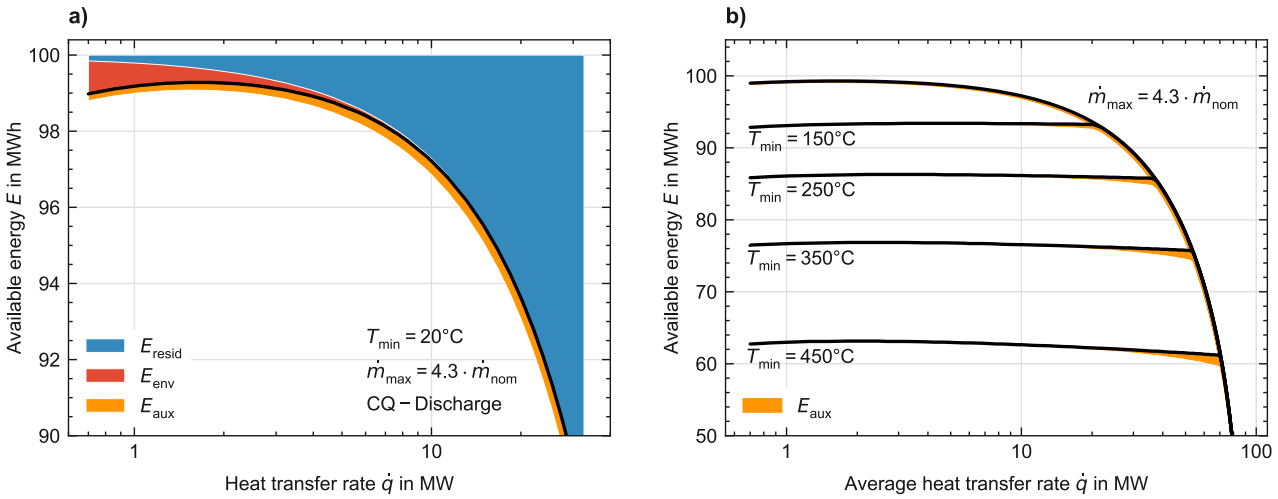

Figure 6: CQ-Ragone plots, curve composition in a) and variation of T_{min}.

Ragone plot for $T_{\mathrm{min}} = 20\,^{\circ}\mathrm{C}$ shows a very different curve, than its CF-counterpart in Fig. 3 a). Here, the minimum temperature cut-off does not come into play, because the Ragone curve (in black) is limited by the maximum mass flow $\dot{m}_{\mathrm{max}}$ in every discharge. As shown in Section 2.1., the mass flow is increases towards the end of the discharge, to compensate the decaying output. In this case, $\dot{m}_{\mathrm{max}}$ is always reached before $T_{\mathrm{min}} = 20\,^{\circ}\mathrm{C}$. This cut-off leaves a residual energy (blue) within the storage that can only be extracted at lower heat transfer rates, even in the case of $T_{\mathrm{min}} = 20\,^{\circ}\mathrm{C}$. The auxiliary energy needed is more evenly distributed, because the fan only operates at high mass flow rates at the end of the discharge.

Figure 6 b) shows the Ragone curves for different lower temperature limits T_{min}. Here, for higher T_{min} limits, the Ragone curves are each composed of two distinct sections, a relatively flat temperature-limited section and a mass-flow-limited section, where the available energy drops quickly. The mass flow limit forms an outer enveloping curve for all the Ragone curves.

It must be noted, that the available energy reaches a limit of 0 at $\dot{q}_{max}$. This is not shown in Fig. 6 b) as it is not considered an actual practical operating point and the axes are identical to the CF-discharge in Fig. 3 b) for comparison purposes. At this point $E \to 0$, $\dot{q}$ is only applied for infinitesimally short discharge duration, and the maximum mass flow limit $\dot{m}_{max}$ is immediately enforced.

3.3. Packed bed as a thermal reservoir for a power cycle

The Ragone plots presented in Section 3.2. and 3.1. show only available energy and do not differentiate between exergy and anergy. This energy-based analysis is valid, as packed beds can be utilised purely in a thermal energy storage context, e.g. in the recuperation of waste heat, that is used to preheat fluid streams at a later point. If desired, energy quality (i.e. exergy) demands can be encoded in these Ragone plots, by setting a certain T_{min}, but this is a quite roundabout way.

Alternatively, a simple way to evaluate the packed bed as a thermal reservoir for a power cycle is to apply a Carnot efficiency $\eta_{\mathrm{carnot}} = 1 - T_{\mathrm{out}}/T_{\mathrm{amb}}$ to the output, which has been employed by [9]. This is a theoretical analysis, as there is no consideration of control regimes or any other irreversibilities apart from those included in the packed bed model, but it is a quick and convenient manner in which to produce electric energy over power Ragone plots, based on a specific TES. Fig. 7 a) shows the result of such an analysis, where the output power P is kept constant, until the storage is unable to deliver it and the discharge is terminated. Unlike the analysis in Section 3.1. and 3.2., the maximum mass flow is set as $\dot{m}_{max} = 1.5\dot{m}_{nom}$ because the achievable mass flow variations are more limited in a power cycle.

Here, also $E(P_{\mathrm{max}}) \to 0$, which Christen [9] generally asserted for sensible heat storage. However, the shape of the Ragone curve is bulged outwards towards higher E and P values, instead of inwards like the mixed sensible TES [9]. The thermal stratification and good heat transfer of the packed bed enable a higher Carnot efficiency over a longer part of discharge. This Ragone plot can easily be compared to the E-P relation of other electric storage technologies, regardless of their functional principle. This is demonstrated in Fig. 7 b), where

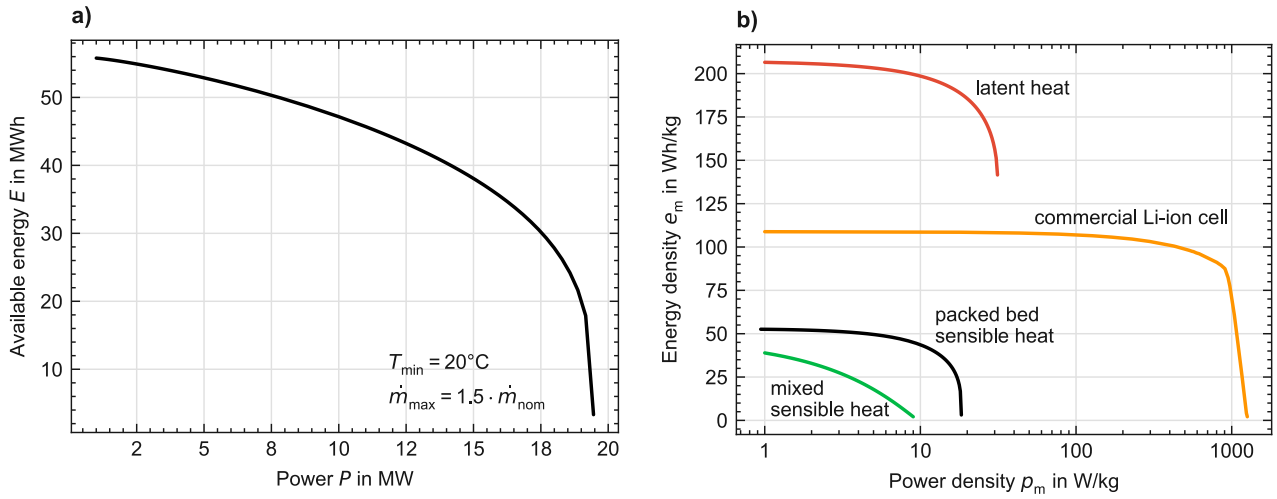

Figure 7: a) Ragone plot from CP-discharge of the 100 MWh packed bed via a Carnot engine. b) Gravimetric Ragone plot of the packed bed-based PTES and comparison to mixed sensible and latent heat PTES from [9], in addition to a commercial Li-ion battery cell.

the specific-value Ragone curves of perfectly mixed sensible and latent heat PTES from [9] are included for comparison purposes, in addition to a commercial Li-ion battery cell. It should be noted that the specific-value Ragone curve of a full Li-ion system with periphery would have lower specific values. The Ragone curve shape of the packed bed PTES underlines its characteristics, as it shares both the property of mixed sensible heat, where $E(P_{max}) \rightarrow 0$, but also the convex Ragone curve shape of latent heat. As a storage technology, packed bed-based PTES have relatively low gravimetric energy and power densities.

3.4. Comments on cyclic stability

Packed bed behaviour is known to reach quasi-stationary cyclic temperature profiles in charge-discharge cycles of constant duration [7]. This is achieved after a certain number of cycles (5-20 cycles is the range typically found in literature). In the packed bed analysed here, the cyclic stability is reached after ten cycles, as shown in Fig. 8. Packed bed analyses are often conducted on the basis of these quasi-stationary temperature pro-

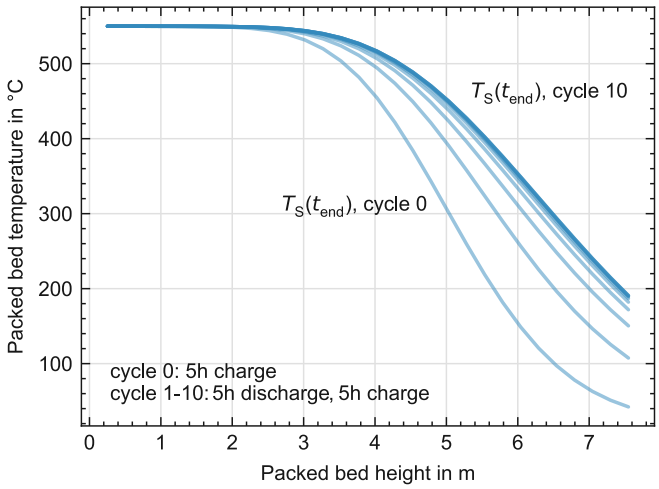

Figure 8: Cyclic stability in the packed bed temperature profile: Final temperature $T_s(t_{end})$ after charge.

files [4, 5, 7], however in case of Ragone plots, we have not integrated this into the analysis. Several issues arise when applying the cycle stability logic into the Ragone framework. Firstly, the stable temperature profile is different for every cycle length [7], introducing an additional level of variability. Secondly, the energy in the packed bed after reaching cyclic thermal stability will differ from the nominal energy. In Fig. 8 it is approx. 25 % higher than E_{nom}. Additionally, the losses incurred along the way by the multiple cycles cannot be cleanly integrated into a subsequent Ragone plot analysis. Cyclic analysis makes sense in a cyclical load regime, e.g. storage for concentrated solar power. However in a thermal load-following paradigm or variable discharge

waste heat output, cyclic operation will not be given in any case. And while the Ragone plot also does not cover all possible load scenarios, its benefit lies in the formulation of a consistent scenario [9] and the comparability to other storage technologies.

4. Conclusions

The presented analysis aimed to evaluate packed bed TES within the Ragone plot framework and draw analogies to the field of electrochemical energy storage. An exemplary 100 MW packed bed model was sized and simulated under different discharge regimes. The main conclusions are derived as follows:

- Two discharge regimes are identified for packed beds, namely CF (constant mass flow) and CQ (constant heat transfer rate), which have direct counterparts (CC and CP) in the field of electrochemical energy storage.
- The energy-power trade-off of packed beds, quantified here with Ragone plots, is low and the analysed packed bed shows good performance over a large range of discharge demands.
- Imperfect heat transfer dynamics cause a residual energy in packed beds, that is conceptually equivalent to polarisation in electrochemical energy storage.
- The Ragone plot framework is well-defined, simple-to-use scenario, that is well-suited for off-design characterisation of TES. This can be done both within the function as pure thermal energy storage and as a thermal reservoir for a power cycle. The obtained results can be compared directly and quantitatively with any other energy storage technology.

Integration of Salt Cavern Hydrogen Storage in a 100% Renewable Energy Supply Scenario

Francesco Piovesan[a,b], Ali Akbar Eftekhari[b]

[a] *University of Padova, Padova, Italy, francesco.piove@gmail.com*
[b] *Technical University of Denmark, Lyngby, Denmark, aliak@dtu.dk*

Abstract:
We address two critical environmental and technical problems for the integration of subsurface salt cavern hydrogen storage with 100% renewable electricity. First, the storage/production rate of hydrogen must match the unpredictable pattern of renewable electricity supply and (more predictable) demand for electricity by creating and strategically locating enough salt caverns. Secondly, creating and maintaining so many salt caverns requires large volumes of fresh/seawater. We develop two static and dynamic models for Denmark as a successful case of wind power development, considering the surplus energy and demand forecasts. The static model predicts the minimum amount of hydrogen needed for balancing the average annual supply and demand of electricity and fresh water necessary for the construction of required salt caverns. The model considers all the round-trip exergy losses of electricity-H2-electricity in the electrolyzers, fuel cells, compressors, and pipelines. The dynamic model considers the variable supply from wind farms and user demand over time; We also include the effect of the inertia of the electrolyzers, fuel cells, and compressors, and technical constraints, e.g. salt cavern pressure and pipeline flow capacity, to design sufficient storage sites that can dynamically balance the fluctuating supply of renewables and variable user demand. The static model predicts a realistic volume of salt caverns for storing the surplus green hydrogen; however, in the absence of small-scale storage solutions (batteries), we show that the number of required caverns and injection/production wells become unrealistically high, with high energy demand and cost for maintenance water treatment.

1. Introduction

The unprecedented consequences of climate change caused by greenhouse gases emissions and the geopolitical circumstances have increased investments on renewable energy production to limit the environmental impact while maintaining the energy security. The increasing penetration of intermittent renewable energy sources, i.e., wind and solar, in the energy production mix stresses the necessity of finding storage solutions to cope with their intrinsic intermittency and unpredictability. In a fully renewable scenario, it is necessary to evaluate which are the most convenient and relevant solutions for storage. Here, we address these concerns focusing on the salt cavern storage of green hydrogen integrated in the electricity supply of Denmark. Different solutions for energy storage exist (Figure 1), with different storage capacity and power rating (i.e. energy charge and discharge per unit time). Many of these technologies are already available commercially, while some others are in lower Technology Readiness Level (TRL).

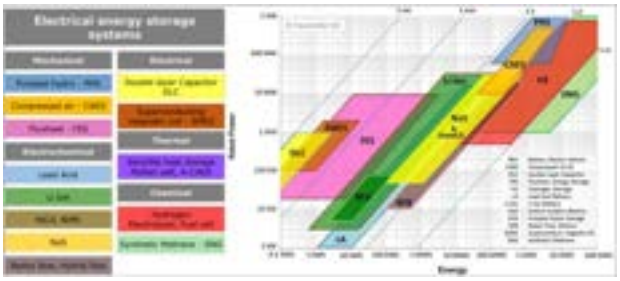

Figure 1: Classification of electrical energy storage systems according to energy form (a); Comparison of rated power, energy content and discharge time of different EES technologies (b), own representation based on (International Eletrotechnical Commission (IEC), 2011).

Electrochemical technologies cover the majority (over 85% as 2016 new installation data) of the new energy

storage solutions, with the Li-Ion technology being the predominant one. Research and development is focused on increasing the number of charge cycles (i.e. the number of times the battery can charge and discharge), reducing production costs and tackling the recycling problem. Different technologies are available, e.g., NaS (Sodium Sulphur), $NaNiCl_2$ (Sodium Nickel Chloride), Pb-Acid (Lead-Acid), Li-Ion (Lithium Ions), Ni-MH (Nickel metal hybrid), Ni-Cd (Nickel-Cadmium), and flow batteries, all with a general common issue of not presenting sufficiently high energy densities to be considered for large storage systems. Second type of technologies is Thermal Energy Storage (TES). All TES technologies are based on the usage of thermal energy as mechanism of storing energy [5]: **MSTES** (Molten Salt thermal energy storage) is the most used TES technology; it has good heat transfer properties and relatively low cost; drawback is the usage of corrosive salts and the necessity of maintaining a minimum temperature value to avoid the solidification of the salts. **PCM** (Latent-phase change material) is based on the latent heat stored by phase change material; as TCS this technology is still in a development stage. **TCS** (Thermochemical storage) where heat or cold is stored by means of different chemical reactants; as PCM, it is in a development stage. **SHS** (Sensible Heat storage) is another possibility to store energy through sensible heat storage; this storage can be done through the usage of solid materials (like sand, concrete or similar materials [4]) or liquid materials (most common used is water, fundamental in the solar thermal systems [11]). TES technologies are mainly in development stage so they do not represent at the moment a suitable solution for our purpose. The most exploited large-scale technologies for energy storage are based on storage of energy through gravity (for hydro) and pressure (for CAES) [4] [8]. These technologies allow high long-term energy storage capacities but present major drawbacks as high investment costs (for civil constructions), high environmental impact (especially hydro), not widely available conditions for their construction and high inertia of the system (charge-discharge process) compared to electrochemical or electrical storage technologies. Electrical storage technologies, like SMES (superconduction magnetic energy storage), Capacitors and Supercapacitors, allow high power densities and really fast charge/discharge times (as well as response times) but they have low energy density so they are not useful for large-scale energy storage purposes. Here, we focus on green hydrogen that has a higher energy density compared to TES and CAES, and can be stored in much larger scales in the safe subsurface salt caverns. The technology is mature, but the current research is generally focused on the capacity and safety of storage. Consequently, the production rate that is critical to the integration of hydrogen storage in the energy networks, has not received considerable attention specially on its technical aspects. We will, therefore, focus on the dynamic behaviour of salt cavern storage and production of hydrogen in the Danish future electricity network to further investigate the technical obstacles of integrating salt caverns in a realistic safe and resilient energy supply and demand scenario.

2. Materials and Methods

The base of this project is the analysis of salt caverns hydrogen storage solutions to permit the switch to a completely renewable energy-based society. To cover the entire energy demand curve with only resources like wind or solar it is necessary to consider a storage solution that is able to cope with the intermittency and unpredictability of the renewable supply. The analysed storage solution is artificial subsurface salt caverns: the calculations have started with an estimation of the amount of hydrogen that must be produced to cover the demand. Once completed, it has been possible to calculate the required salt caverns volume that had to be artificially created.
This type of static analysis has been carried out considering initially a simplified model. In this model a limited number of cities and storage locations has been considered and their positioning and connections have been manually evaluated. This method will be explained in the dedicated section 3.1.. The consequences of the functioning of the system in terms of behaviour over time, with a set of defined assumptions, will be instead analyzed in the second dedicated paragraph 3.3.. The case study related to Danish 2050's wind production and demand projections starts with the simplified model case.

3. Case Study

3.1. Simplified Model

In order to proceed in the study and evaluation of the simplified model it has been necessary to make few assumptions:

1. No limits on number and dimension of wind farms that can be installed in the North Sea: this hypothesis doesn't differ excessively from the actual conditions present in the North Sea.
2. Analysis starts from the demand and goes backwards, considering all the efficiencies of the components of the energy system, to the necessary production to cover it.
3. Electrolyzers are considered to be modular so the efficiency is evaluated as approximately independent from the size of the plant.

4. It is considered possible to place caverns for storage on the entire area of the simplified map (even though some more limited regions are considered to proceed with the modelling process).
5. All industries have been able to convert their production lines and processes to the usage of hydrogen instead of methane: this hypothesis is used to pursue the simplified analysis but the conversion of the industrial lines to hydrogen could be an issue that has to be addressed.
6. Injection and extraction points are considered placed in the center of the respective regions and it is supposed to have one cavern for each city of the model.

Before defining all the scenarios it is necessary to design a simplified map for the calculations (sm stands for simplified map), which is here reported (Figure 2).

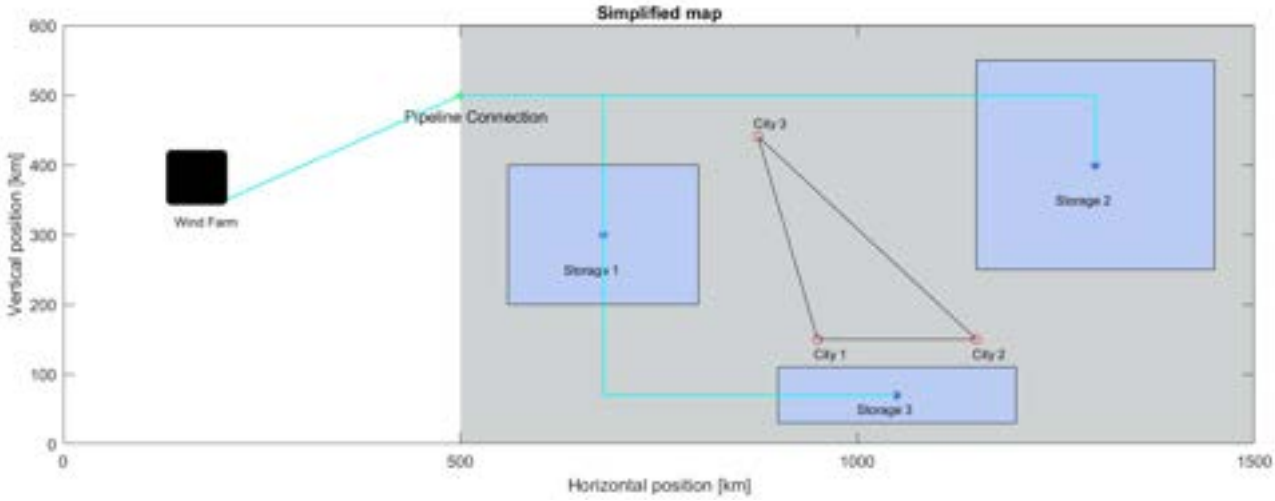

Figure 2: Map for the simplified model with pipeline connections

In this map three cities have been reported, considering a subdivision of the peak power requested into 50%, 30% and 20% respectively for cities 2, 3 and 1. The storage sites 1, 2 and 3 are respectively dedicated to cities 3, 2 and 1. Under the hypothesis of having in 30 years four times the wind power capacity and 1.5 times the power demand by users, through the Danish data of the last 10 years the future trends of production and consumption have been evaluated for each city (Figure 3) and overall (Figure 4).

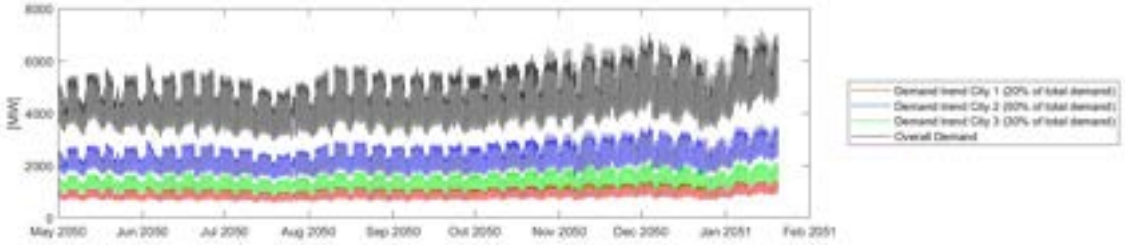

Figure 3: Projection of demand trend for each city and overall in 30 years based on Danish past electricity supply and demand data

We have assumed one offshore wind farm that covers all the electricity production. Moreover, we have defined a hydrogen island where we have the convergence of the power produced by the wind farm, the electrical transformers and the hydrogen production and storage. It is important to note two characteristics of this island:

- Average Sea Depth: North Sea has an average depth of 90 m with maximum depth of 700 m so it has been considered a value of 200 m for the analysis. [1]
- From the 20 GW 70% H_2 case (page 51 of [12]) we have obtained a set of reference dimensions for the artificial island.

With a temporal resolution of 1 hour, a 9-months time frame considered and an overall shortage (calculated as the difference between the overall demand and the wind farm production per each unit of time) in terms

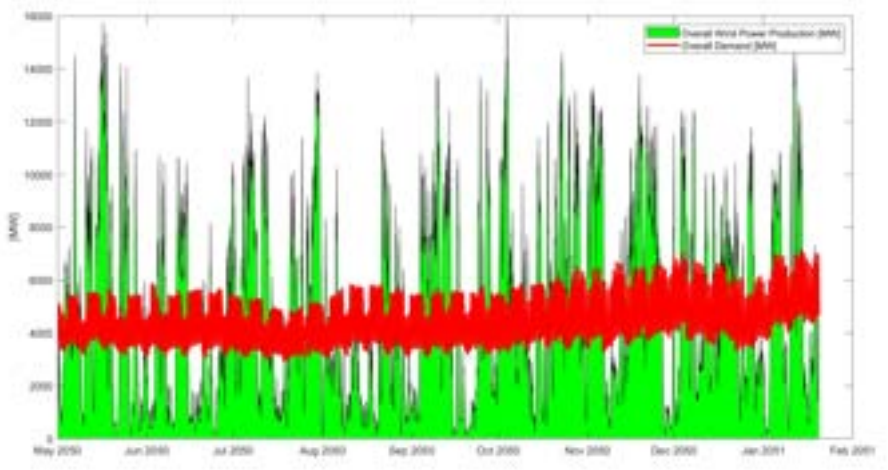

Figure 4: Projection of overall demand and wind production trend in 30 years based on Denmark's supply and demand data in 2020

of power it has been possible to integrate over time to obtain the energy shortage and divide per each city obtaining:

- $E_{shortage,city1} = 6.97 \times 10^4$ MWh
- $E_{shortage,city2} = 1.74 \times 10^5$ MWh
- $E_{shortage,city3} = 1.05 \times 10^5$ MWh

We then calculate the surplus that has to be extracted and stored to cover these shortages.

3.2. Analysis and Results

3.2.1. Fraction of surplus energy needed

With the efficiency ranges of fuel cells and electrolyzers (see Table 1 and Table 2), we calculate and obtain the energy required surplus to cover the average shortages, presented in this paragraph. The conversion efficiency to hydrogen and back to electricity are considered in our calculations.

Table 1: Overview of main electrolyzers technologies efficiencies [13]

Technologies	Minimum Efficiency [%]	Maximum Efficiency [%]
Alkaline	51	65.3
PEM	55.5	72.4

Table 2: Overview of main Fuel Cells technologies efficiencies [3]

Technologies	Electrolyte	$T_{operating,min}[K]$	$T_{operating,max}[K]$	$\eta_{electrical,min}[\%]$	$\eta_{electrical,max}[\%]$
AFC	Aq. KOH	333.15	393.15	60	60
DMFC	PEM	303.15	363.15	80	80
MCFC	Molten Li2CO3 and K2CO3	873.15	923.15	45	47
PAFC	Phosphoric Acid	433.15	473.15	40	40
PEMFC	PEM	333.15	363.15	53	58
SOFC	Yttrium stabilized zirconia	1073.15	1273.15	35	43

Considering these efficiencies permits to understand the amount of energy that has to be taken from the surplus to cover this shortage of electricity and quantify the energy losses. The quantities for all cities are reported in Table 3, while a bar chart has been used to evaluate the requirements for each city based on the electrolyzers-FC technologies considered (Figure 5). These values may change quite significantly with the chosen conversion technology, from average values in the order of $10^5 MWh$ for maximum efficiency factors to values in the order of $10^6 MWh$ for the minimum efficiency factors.

Table 3: Average energy [MWh] that has to be used from surplus to cover the shortage for all cities considering the minimum and maximum efficiencies for each fuel cell technology (columns) and electrolyzers (rows)

	AMC		DMFC		MCFC		PAFC		PEMFC		SOFC	
Alkaline	$1.14*10^6$	$8.90*10^4$	$8.55*10^4$	$6.68*10^4$	$1.52*10^6$	$1.13*10^6$	$1.71*10^6$	$1.34*10^6$	$1.29*10^6$	$9.21*10^4$	$1.95*10^6$	$1.24*10^6$
PEM	$1.05*10^6$	$8.03*10^4$	$7.85*10^4$	$6.02*10^4$	$1.40*10^6$	$1.03*10^6$	$1.57*10^6$	$1.20*10^6$	$1.19*10^6$	$8.30*10^4$	$1.80*10^6$	$1.12*10^6$

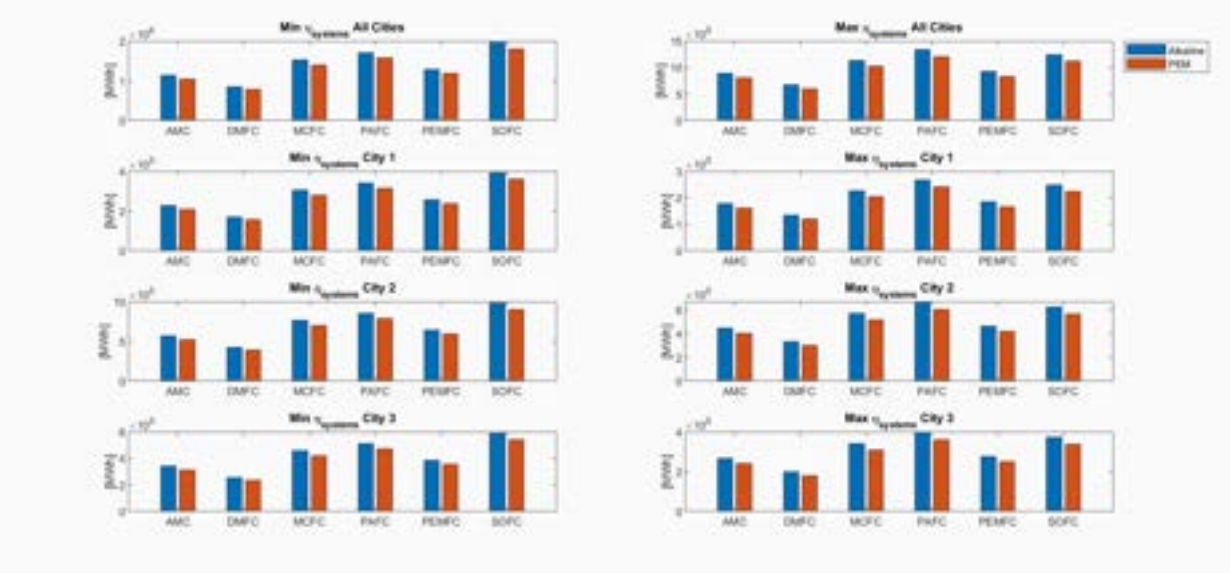

Figure 5: Visual representation of energy requirements from surplus considering minimum and maximum efficiencies of each system for all the cities and for each city taken singularly

After estimating the energy that has to be stored and the fraction of energy surplus that has to used to address the energy shortage, we define two scenarios. The first one is based on production of hydrogen in a dedicated offshore island and then sent to the coast to the storage sites. The second possibility is energy transmission through electrical cables, meaning that hydrogen storage and conversion is done offshore and the onshore storage is done with hydrogen produced locally.

3.2.2. Evaluated Scenarios: Hydrogen Island and local production

In this scenario it is considered that hydrogen is produced and transmitted to onshore storage sites through the usage of pipelines. In both this scenario and the following electrical one there is the presence of offshore storage site, used as first storage location. This storage site can be considered as a solution also to avoid the construction of onshore storage sites but the costs for the construction are higher offshore than onshore. Considering the presence of an offshore wind farm at a distance of 300 km from the coast in east direction, we evaluate: the production and storage of hydrogen offshore, the transmission of it through pipeline, and the conversion to electricity onshore through the usage of fuel cells. Previously (3.2.1.) the calculations of the energy shortages and the storage (energy and hydrogen) have been presented. Now we also include the energy required for the compression for storage, the compression for transmission and the volume of the necessary artificial salt caverns. The production of hydrogen is carried out in a designated artificial hydrogen island which should be placed at maximum 5 km from the wind farm. Moreover, its position has to be chosen considering aspects like the positioning of salt caverns and the pipeline design, as presented in Figure 2.

To evaluate the dimensions of the necessary salt caverns and, at the same time, the effect on hydrogen density and the geothermal gradient, we developed an iterative function. This permitted to calculate the dimensions (height and diameter), average temperature and average density starting from the the cavern roof depth, an initial estimate of the cavern bottom depth, storage pressure, mass of hydrogen to be stored, an equation of state for hydrogen density, and the height-diameter ratio of the cavern. The cavern roof depth and the pressure, considered to be the maximum pressure, have been taken from the set of values (cavern roof depth, maximum and minimum storage pressures) cited in [9]. The results for the first city, in terms of height and diameter of the caverns, are reported in Table 6.

In order to evaluate the amount of freshwater needed to build the salt cavern the construction process of the horizontal caverns HA-4 and HA-5 in Huai"an (China) has been taken as reference [6]. For these caverns the

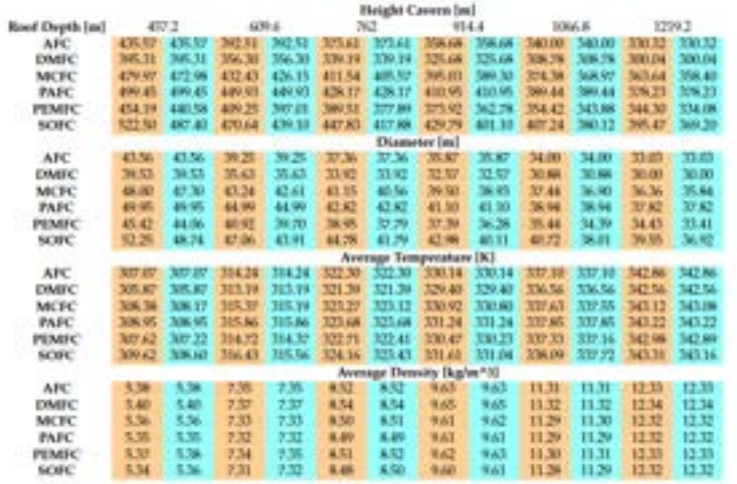

Figure 6: Results for city 1 in terms of Height and Diameter of caverns, average temperature and density of hydrogen; the orange colour refers to the minimum efficiency of FC technologies, the light blue refers to the maximum

characteristics are presented in the Table 4.

Table 4: HA-4 and HA-5 cavern and building process characteristics (Huai"an, China) [6]

Cavern	**HA-4**	**HA-5**
Volume Cavern [m^3]	52000	121000
Volume Freshwater Needed [m^3]	3329000	3690000
Volume Cavern/Volume Freshwater needed	64.02	30.50
Concentration Brine [kg_{salt}/m^3]	300	

From the volume ratio of cavern to freshwater needed for salt cavern construction, we calculated the volume of freshwater needed considering the minimum and the maximum values of this ratio and the minimum and maximum efficiencies of the FC technologies. The amount of freshwater needed in all cases (maximum and minimum efficiency for FC technologies, maximum and minimum volume ratio cavern - volume freshwater) is not negligible and has to be taken into account in terms of environmental impact and economic costs to treat and transport the salty brine after dissolving the subsurface salt. Lastly, it has been evaluated the pressure drops of the hydrogen pipelines necessary to cover the energy demand for each city. Based on a defined set of assumptions the pressure drops have been calculated and presented in Table 5. The values of the pressure

Table 5: Pressure drops in [*bar*] per each pipeline (column, first for city 1, second for city 2 and third for city 3), considering all the FC technologies (rows) with their minimum and maximum values of efficiencies

	Min η_{FC}			**Max** η_{FC}		
AFC	305.00	282.74	759.39	234.07	295.03	654.65
DMFC	375.93	442.55	903.41	361.74	381.08	890.32
MCFC	191.51	221.27	536.81	241.16	270.44	602.28
PAFC	156.04	245.86	549.90	156.04	233.57	445.16
PEMFC	255.35	282.74	680.83	198.60	295.03	615.37
SOFC	163.14	233.57	405.88	177.32	295.03	628.46

drops make necessary the presence of intermediate pumping stations to increase the pressure and guarantee the arrival of the hydrogen to the storage sites.
The second possible solution is the transmission of energy through the usage of electrical lines and having the production of hydrogen directly on the storage sites. In this scenario there is no hydrogen transmission through pipelines: hydrogen is produced on the hydrogen island and stored offshore in a dedicated site for the purpose of converting to electricity when the windmills are down. Hydrogen is also produced onshore with surplus of energy sent with electrical interconnection between the hydrogen island and the shore. The possible presence of offshore storage would permit to reduce the number of storage sites onshore and to increase the social acceptance of the hydrogen storage on the first place. As for the other scenario, the analysis has been carried out from the storage site while acknowledging that it is necessary to consider also the efficiency of electrical

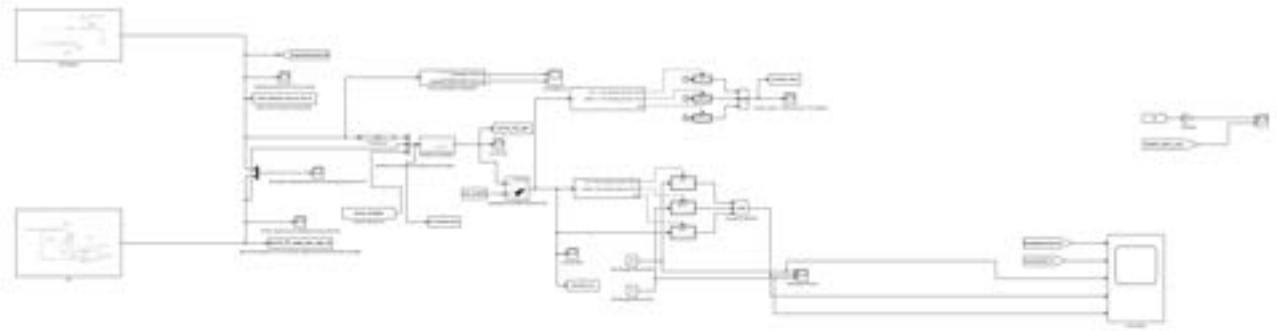

Figure 7: Simulink Dynamic Model

transmission from sites to cities.
The process for the calculation of the dimensions of the artificial caverns is the same as the previous scenario, the main difference is related to the addition of electrical components (with their efficiencies) between the hydrogen island and the onshore storage sites. The elements that have to be considered are inverters (DC-AC), transformers (AC-AC) and transmission lines (in DC or AC).

3.3. Dynamic Model

In section 3.1., the hydrogen storage requirements have been analyzed and calculated considering a static approach, serving two purposes: first, the overall shortage of energy caused by the mismatch of the wind production and the user demand curves. Secondly the percentage of the surplus needed to cover that shortage through the production and storage of hydrogen. The latter point has been carried out taking into account constant values of the efficiencies of the components of the system and ignoring the dynamic behaviour of the system. Here, we consider the functioning and the consequences of the behaviour of the system components over time, under a defined set of assumptions, that includes:

1. The system is considered to be isolated thus no interconnections with other countries or grids are considered.
2. We projected the increase of the wind power installed and the increase of user demand with an expected enhancement of 50% of the current demand and a nominal wind power installed equal to 5 times the currently installed power with respect to the data considered (2017-2019).
3. Dynamic behaviour for electrolyzers, fuel cells (start up and ramp up time) and compressors (time to reach predefined pressure specifications) are considered.
4. The model used for the description of the storage behaviour is 0-D (zero-dimensional or bulk model).

a Matlab script and a Simulink model have been developed to calculate the impact of inertia of system components and the constrained injected and extracted mass flow rates and fixed volumes of storage sites on the security of energy supply for a dynamic demand. We also use the script to estimate the required number of caverns for a balanced supply and demand of electricity in Denmark.

Figure 7 shows the Simulink model developed to solve this problem, implementing specific subsystems (with relative control systems) for fuel cells, electrolyzers and compressors necessary to manage the system and allowing it to be able to follow the demand and production trends (Figure 8). Here the electrolyzers system (with its control system) is briefly presented. For the fuel cell system the function principle is similar.

3.4. Electrolyzers system

Electrolyzers functioning (as molar flow rate of hydrogen produced [mol/s]) is related, following the Faraday's law (Equation 1), to the number of cells n_{cells}, to the current flowing through I_{Ez}, Faraday's parameter F, and Faraday's efficiency η_F (calculated with Equation 2). [10]

$$\dot{n_{H_2}} = \frac{n_c I_{Ez}}{2F}\eta_F \tag{1}$$

$$\eta_F = 96.5 \exp\left(\frac{0.09}{I_{Ez}} - \frac{75.5}{I_{Ez}^2}\right) \tag{2}$$

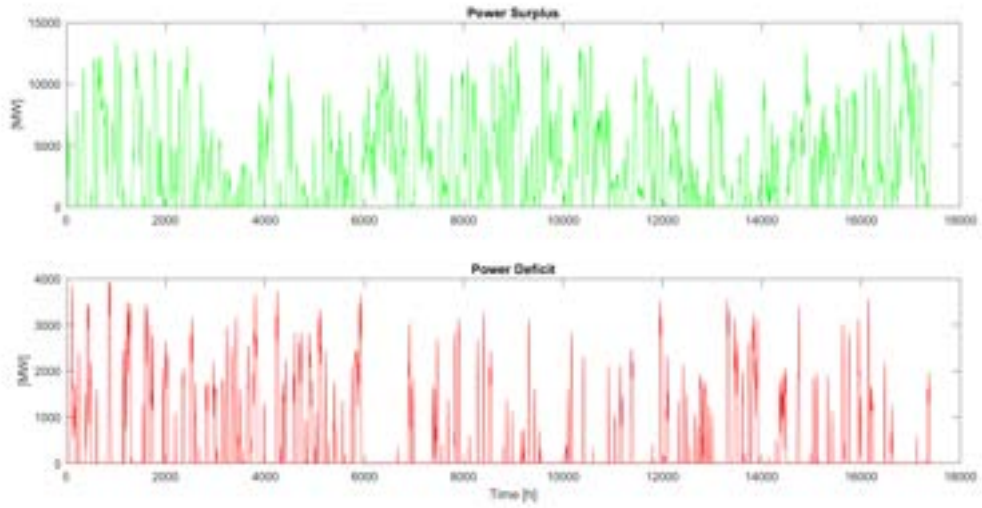

Figure 8: Power surplus and deficit of the system (expressed in [MW])

In the analysis, a simplified version of electrolizer efficiency is considered, that is independent of the above parameters and the outlet pressure. Instead, we consider the behaviour over time of the electrolyzers in terms of start-up time (supposing a hot start-up) and ramp-up time, which are respectively defined as the time interval between the electrical connection and the beginning of the hydrogen production and the time interval necessary to reach the nominal power output from the end of start-up process.
These two parameters have been considered as part of the main simulation and have been obtained from data of products available on the market, like the electrolyzer Plug EX-425D [2]. They have been fixed at these values (even though they have been modified to see their impact on the simulation):

- $\Delta t_{Start-Up} = 10s$
- $\Delta t_{Ramp-Up} = 30s$

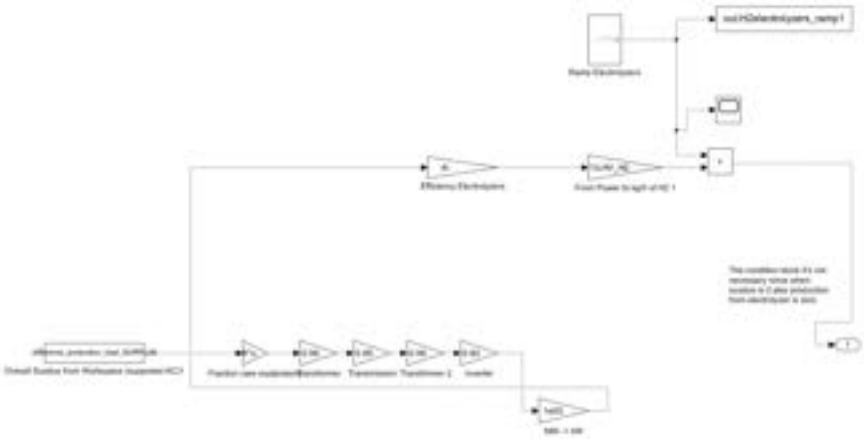

Figure 9: Simulink electrolyzer simplified model

These parameters have been added to Simulink as presented in Figure 9. It has been considered a constant value of efficiency and then converted the value of energy consumed by electrolyzers to the amount of hydrogen produced. Considering the start-up and ramp-up times, we obtain the produced hydrogen mass flow rate over time (Figure 10). This mass flow rate has been then used in the zero-dimensional storage model to evaluate the amount of hydrogen stored and withdrawn over time. It is important to highlight that not the entire overproduction is converted into hydrogen to reduce the number of electrolyzers required. For this purpose a value of 30% of the surplus production has been considered and also varied to evaluate the impact of this parameter on the system.

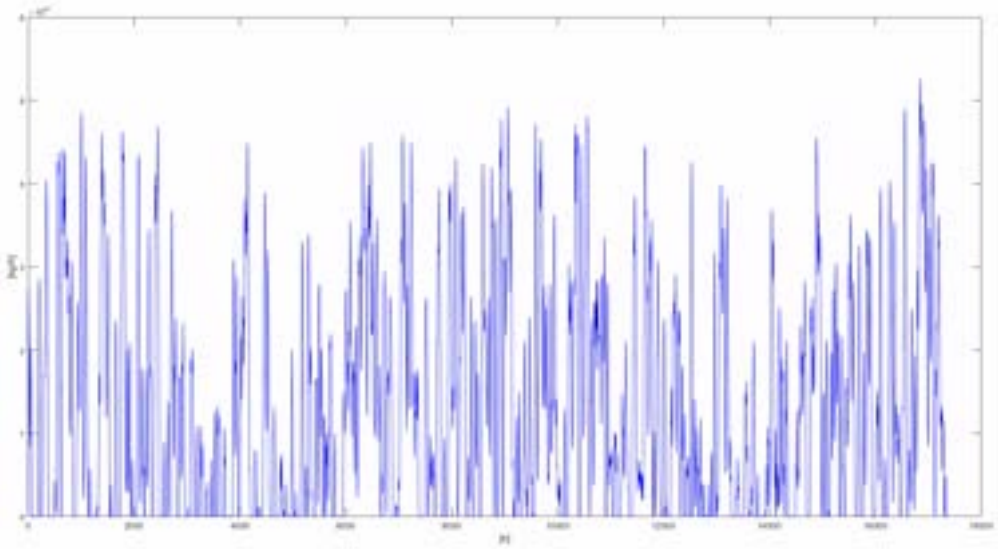

Figure 10: Electrolyzers hydrogen mass flow production rate (reference conditions)

3.5. Parameters of the simulation

The following parameters are the reference ones of the simulation :

- $fraction_{surplus}$ = 0.3 $\Rightarrow$ fraction of the wind surplus power that is used to power the electrolyzers;
- $percentage_{fillingstorage}$ = 0.8 $\Rightarrow$ initial percentage of storage filling;
- $T_{H_2} = 300K \Rightarrow$ fixed temperature for the analysis;
- $\Delta t_{Start-up,El} = 10s \Rightarrow$ start-up time for electrolyzers;
- $\Delta t_{Ramp-up,El} = 30s \Rightarrow$ ramp-up time for electrolyzers;
- $\Delta t_{Start-up,FC} = 10s \Rightarrow$ start-up time for FC;
- $\Delta t_{Ramp-up,FC} = 15min = 900s \Rightarrow$ ramp-up time for FC;
- $V_{simulation,firstattempt} = 6.49 \times 10^8 m^3 \Rightarrow$ first attempt value for simulation storage volume (placed equal to the volume of storage in first case of minimum efficiency in the static model multiplied by 10^3);
- $\Delta p_{\%,Max,FC} = 10\% \Rightarrow$ maximum percentage pressure drop admitted for storage-FC pipelines;
- $d_{pipe,FC} = 18cm = 0.18m \Rightarrow$ diameter extraction well and storage-FC pipeline connection (considered a typical value for natural gas underground storage wells diameter [7])
- $\Delta p_{\%,Max,El} = 5\% \Rightarrow$ maximum percentage pressure drop admitted for electrolyzers-storage pipelines;

the simulation has returned the results presented in Table 6:

Table 6: Simulation results with reference values of simulation parameters

	FC	Electrolyzers
λ	0.01	0.01
$v_{H_2}\,[m/s]$	59.5	49.3
Re_{H_2}	1.19×10^6	9.87×10^5
$\dot{m}_{H_2,SinglePipe}\,[kg/s]$	6.64	4.87
$\dot{m}_{H_2,SinglePipe}\,[kg/h]$	2.4×10^4	1.75×10^4
n_{wells}	18	3
$V_{Storage}[m^3]$	1×10^9	

These parameters have been iteratively modified to evaluate their impact on the simulation and possible solutions to the related issues.

4. Discussions of Results

4.1. Simplified Model

From the results of the simplified model we can clearly observe the impact of the chosen fuel cell - electrolyzers technologies on the required storage volume, even without considering the dynamic behaviour of unit operations. This choice directly affects, considering the range of efficiencies of the system, the amount of energy that has to be extracted (by electrolyzers) from the power surplus and the amount of energy that has to be actually stored in the form of hydrogen in the storage sites. This latter aspect is essential since it influences the dimensions of the underground artificial storage site in height and diameter, modifying the amount of freshwater (and, therefore, the environmental and economical impact) required for the construction process. These values can range, depending on roof depth, FC technology and cavern-freshwater volume ratio between $6.5 \times 10^6 - 7.2 \times 10^7 m^3$ for city 1, $1.6 \times 10^7 - 1.8 \times 10^8 m^3$ for city 2, and $9.7 \times 10^6 - 1.1 \times 10^8 m^3$ for city 3. These values are around 1% to 10% of annual Danish freshwater consumption.
Moreover, as it has been possible to highlight with the two scenarios, design choices in terms of storage placement and energy transmission can affect the cavern design and the system behaviour. System that can range from an offshore solution with main storage solution build under the seabed and electrical energy converted and transmitted from the hydrogen island to hydrogen production carried out in this dedicated artificial island, transmitted to land via pipelines and stored locally underground ready to be employed by the fuel cells system.

In the simplified model we ignored the inertia of the components of the system, e.g., fuel cells, electrolyzers, and compressors. Using the dynamic model, through running simulations for a 2 years time frame (with 1 hour resolution), we analysed the impact of the dynamic behaviour of each unit on the overall energy supply and demand. All these components have been implemented in a Simulink model, each one considering their fundamental working parameters and control systems. For the electrolyzers we included the start-up and ramp-up time intervals in the model and its blocks. Similarly it has been done for the fuel cells, applying the same parameters and blocks in the model. Concerning the compressor, based on its pressure-time dependency curve, a simplified control system has been implemented. Lastly, for the overall system, different control systems has been added. This Simulink model has been then exploited, as other functions that have been developed, inside a Matlab script with the aim of evaluating the storage volume, the number of electrolyzers and fuel cells wells and the mass flow rates through them respecting the pressure drop constraints and other model assumptions. This script has been iteratively modified changing the value of the main parameters of the system elements to visualize their impact on the overall system.

4.2. Dynamic Model

From the results of the dynamic model it is possible to analyse the sensitivity of the supply/demand system to the parameters that define the dynamic behaviour of its individual units. The first noticeable result is the storage volume difference between the static simplified model and the dynamic one: in the first case, the values obtained in the simulation are in the order of $10^6 m^3$, which can be covered by a few small to average-sized caverns (depending on the chosen FC-electrolyzers technologies considered and the characteristics of the cavern such as the roof depth). However, for the dynamic model we obtained required storage volumes in the order of $10^9 m^3$, e.g., around 1000 relatively large salt caverns. This 3 orders of magnitude difference between the two cases are related to physical constraints (mass flow rates of the pipelines and the following of the production and consumption curves), cavern pressure limits (i.e., $2.23 \times 10^6 - 7.09 \times 10^6 Pa$) and the start up times of the elements of the system (that do not allow the perfect following neither the production nor the consumption curves).
Moreover, choosing a fuel cell or electrolyzer technology with a high start-up time causes a system failure in following respectively the demand (in terms of shortage) and the production surplus curves (results not shown). This issue can be solved by developing or choosing components with lower start-up time or with predictive approaches to the system control, through which the components are activated earlier in time considering the predictions of production and demand. Components with high ramp-up times, instead, do not allow to fully exploit the potential of the power surplus (electrolyzers) or be able to supply the power needed by user in time: this problem may be solved with different approaches such as developing faster technologies, installing a higher number of these components to counterbalance the effect (but with additional investment costs and overdimensioning the system) or adding fast technologies (such as electrochemical storage) in parallel to mitigate this issue.
We also considered the fraction of surplus electricity to be converted into hydrogen and the initial storage filling percentage. The first aspect is important since considering higher fractions allows to increase the production of hydrogen thus being a possible mitigating solution for electrolyzers with high start-up and ramp-up time intervals. Higher fraction though results in higher number of components, higher mass flow rates and therefore an increase of the size of the system with consequent increase of complexity and costs. Moreover, it does not allow the electricity network to be integrated in a larger European network by exporting the surplus to other

countries or regions with a high demand. Lastly, the initial storage filling percentage, also known as the cussion gas, is significant in the starting of the system since low initial level do not allow to have a sufficient buffer to follow the user demand; for this reason it is necessary to consider the initial filling as part of the installation procedure.

5. Conclusions

The large-scale storage of hydrogen in salt caverns, although a mature technology and relatively safe to implement, presents some important issues that have to be resolved. Firstly, the volume necessary to support even a simple 3-cities system is extremely high; it is challenging to find energy and water resources for the construction of around 1000 caverns and to find environmentally friendly and less energy-intensive solution to clean up and dispose off the construction and maintenance brine. Secondly, a large volume of cushion gas is required to start up the caverns such that it can reach a minimum required pressure for producing hydrogen from the caverns. This requires a large amount of surplus energy that might not be available. Thirdly, the high start up time of the fuel cells makes the use of hydrogen as the only grid balancing solution almost impossible. It is therefore necessary to address the immediate shortages of electricity in the network by other solutions, e.g., the aforementioned parallel electrochemical battery systems, or use reliable predictive models to deal with the not perfect following of the surplus and shortage curve by the components of the system. Finally, we would like to encourage the researchers in the field of subsurface hydrogen storage to dedicate more time and resources to investigating the production rate of hydrogen from the storage sites such as salt caverns, aquifers, and depleted reservoirs. The safe storage, although a necessary condition, is not sufficient to integrate the subsurface hydrogen storage in the energy supply and demand.

Abstract:
One of the keys to the current energy and ecological transition is the development of electrical energy storage. This demand has motivated the development of alternative technologies that overcome some of the shortcomings of the storage systems used until now. Among these, Carnot battery has experienced a rapid development in the last decade. Its principle is to store electrical energy in the form of heat and restore it with a heat engine. This technology has several advantages: a long life span, the possibility to increase easily its storage capacity, and the use of small environmental footprint materials. Current research tends to show the lack of competitiveness of classical Carnot batteries architectures compared to other technologies due to their relatively low roundtrip electric efficiency. It is therefore necessary to investigate the integration of heat streams in order to increase their attractiveness. A large part of the industrial energy consumption is used for thermal purpose. It is estimated that a large part of this energy is then lost as waste heat. The aim of this paper is to provide economic key performance indicators concerning the potential of a Carnot battery integrating waste heat recovery in a given industry. The key performance indicators provided are based on the temperature level of the waste heat, the energy rates consumed and dissipated by the industry, the type of primary energy used and the electricity pricing. This paper shows that electricity pricing is the key to this technology development. High price variability and negative purchase prices are factors leading to a potentially interesting profitability of this system. The primary energy ratio is the second most important parameter influencing the results. As an illustrative example: an industry with a recoverable waste heat at 100 °C, a gas consumption three times higher than the electricity consumption, and a ratio of the minimum (positive) purchase price of electricity to the maximum sale price equal to 50% can expect a maximum reduction in its electricity bill of 25%. This maximum reduction rises to 50% if the the gas consumption is seven times higher than electricity consumption or if the electricity price ratio is 27%.

1. Introduction

1.1. Context

The main challenge to massively develop renewable energy is the electrical storage. Among the different possible technologies, the Carnot Battery (CB) is more and more developed. This concept uses a Heat Pump (HP) to convert excess renewable electricity into thermal energy . The thermal energy is stored until there is a peak of electrical consumption, a Heat Engine (HE) can re-convert this thermal energy into electricity. In its stand-alone layout, this technology presents a low roundtrip efficiency. However, its potential to integrate heat fluxes makes it profitable in various cases (Thermally Integrated Carnot Battery). In the most common configuration, the heat pump can work with a low temperature difference between the waste heat temperature and the thermal energy storage temperature. This leads to high Coefficient Of Performance (COP) and therefore high roundtrip efficiencies [1, 2]. Waste heat represent a huge waste, especially in the industry sector. 42% of the waste heat is lost at temperatures below 100 °C and 20% between 100 °C and 299 °C [3]. The integration of Carnot batteries in the industry is promising since it makes an efficient use of waste heat and it allows to store electricity (increase of renewable energy self-consumption).

1.2. State of the art

Few papers discuss the potential of Carnot batteries based on mappings. Some papers refer to specific case studies and are listed in [4]. The first attempt to characterize the performance of such a system in a wide range of operating conditions is performed in [5] through a constant efficiency model. In this paper, the roundtrip efficiency of a Thermally Integrated Carnot Battery is plotted for different waste heat temperatures and ambient temperatures. It allows to identify which cases are interesting (high waste heat temperature, low

glide of the sensible storage and low ambient temperatures). Also, it was shown that the efficiency is improved in zones where the compactness (and the use of the waste heat) of the system is low. This conclusion has been discussed in several papers [1, 4, 6]. [4] proposed an enlarged mapping with a larger range of working temperatures. A zone where the three Key Performance Indicators (waste heat use, roundtrip efficiency and compactness) are not competing has been found. To the best authors' knowledge, no literature focus on the waste heat constraints in the industrial sector which can significantly affect the Carnot battery potential.

1.3. Aim of this paper

The main question that an industry could ask about the installation of a Carnot battery to valorize its waste heat is the profitability. A precise calculation of the benefit can not be obtained without a detailed study of the case. The aim of this paper is to give the absolute maximum values that could be reached in terms of benefit of such a system for a given industry. The Key Performance Indicators (KPIs) provided are determined according to global parameters allowing to easily characterize an industry (primary energy ratio, electricity pricing and waste heat temperature mainly) without an in-depth study. The results provided are voluntarily very optimistic so that a mismatch between the industry's expectations and these results indicates a clear incompatibility. In this case, the installation of a Carnot battery integrating waste heat recovery is not justified and this possibility can be dismissed without further study. The case of favorable results for the industry studied will automatically lead to a further study of the solution integrating the time constraints that such a system implies to determine the real benefit that can be brought. The compatibility of the industry's expectations with the results of this study is therefore a necessary but not sufficient condition for the profitability of the system.

2. Methodology

2.1. Assumptions

2.1.1. Conservatism principle

Since the aim of this paper is to provide the necessary conditions for the further study of the potential integration of the system, it is important not to exclude any case. To this end, all the assumptions made in this study are deliberately very optimistic. In particular, the cycles studied as well as the exchangers are considered as perfect. Since this study ignores the temporality for the purpose of convenience, the coordination of the waste production with the electricity costs is considered ideal in order to favor advantageous results. The limitations in terms of electrical power exchanged with the grid is largely overestimated. No limitation are put on the thermal storage volume. Also, the investment cost of the system is neglected. This is a very conservative assumption since this cost is directly linked to the nominal power of the system and its storage volume. On the other hand, the evaluation of the benefits in terms of cost reduction of the electrical substation is not considered. In view of the previous hypothesis, it is considered that neglecting this element will not put in default the conservatism required in this study.

2.1.2. Restriction on industry studies

Since the problem is treated ignoring temporal constraints and for the clarity of the methodology, some limitations must be set on the industries studied. The studied industry is taken as a whole and a single CB is matched as appropriate as possible. This CB has only one storage whose nominal temperature is fixed and greater than the maximum waste heat temperature considered. This consideration implies that an additional cold storage is not considered. It is assumed for each process (or sub-process) a nominal waste temperature invariable over time. The ambient temperature is fixed at $20^\circ C$. The waste heat is entirely dedicated to the CB. No district heating or recovery of this heat to reintegrate it into the process is considered. The waste heat not used by the CB is lost. The waste heat rejected by the heat engine of the CB is also lost.

The availability of Renewable Energy Sources (RES) internal to the industry, whose production is not always self-consumed, is a special case that requires a specific methodology. This case is treated in Section 3.6..

2.1.3. Limit values of the studied system

Based on the literature and in order not to exclude any case according to the principle of conservatism, the following values are used as limit values of the studied system:

- The unavoidable irreversibilities of a real system lead to the consideration of an efficiency g with respect to the ideal cycles. This value is often estimated [5] between 0.4 and 0.5 so in this study, $g = 0.5$.
- According to [7], the waste heat of the industry not directly recovered on-site is below 200 °C excepted for the iron and steel industry (200-400 °C, 700-900 °C) and the glass industry (500-600 °C). Waste heat temperature $T_w \in [T_{amb}, 200]^\circ C$ is considered for this study. This choice is justified in Section 3.5..
- The highest temperature cycle (Brayton) that can be applied to a CB is in the order of 1200 °C [1, 2]. This value (used in (22)) is considered as the limit reached in the system.

2.2. Carnot battery description

The purpose of this section is to describe the Carnot battery as it is considered in the following development. The goal is to define the most generic architecture in order not to exclude any case and to make assumptions that allow to respect the conservatism principle announced in the previous section. Two approaches are considered in the description of the cycles used: a machine working with a Carnot cycle and one working with a Lorenz cycle. This allows to cover entirely the existing and future Carnot batteries.

2.2.1. Generic architecture

Figure 1 represents the architecture of a CB as general as possible when it integrates waste heat recovery. An amount of used waste heat $Q_{w,used}$ extracted from the available waste heat Q_w such that

$$Q_{w,used} = Q_w \frac{\Delta_{T_w}}{T_{w,in} - T_{amb}} \tag{1}$$

corresponds to a quantity of heat stored according to the COP of the heat pump considered:

$$Q_{sto} = Q_{w,used} \frac{1}{1 - \frac{1}{COP\ g}} \tag{2}$$

The electrical energy W_{HP} stored by the CB is determined by

$$W_{HP} = Q_{sto} - Q_{w,used} \tag{3}$$

The stratification of the storage and its thermal insulation are considered perfect so that the amount of thermal energy recovered from this storage is equal to the stored amount Q_{sto}. This thermal energy is used to feed the heat engine and to extract the electrical energy W_{HE} according to

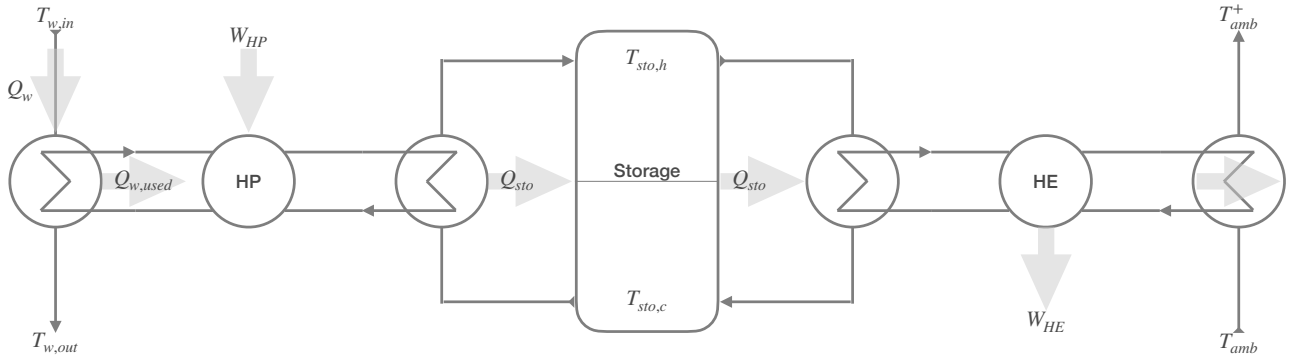

Figure 1: Generic architecture of a Carnot battery integrating waste het recovery

2.2.2. CB with Carnot cycles

Cycles based on Carnot HP and HE are mainly used in CBs. These ideal cycles are represented by their T-S diagram in Fig.2 and Fig.3 respectively. The performance of these cycles is determined by the system temperature levels also shown in the diagrams. For the HP, the COP is expressed by

$$COP_{Carnot} = \frac{T_{sto,h}}{T_{sto,h} - T_{w,out}} = \frac{T_{w,in} + lift_{HP}}{lift_{HP} + \Delta_{T_w}} \tag{5}$$

The COP can be maximized by minimizing Δ_{T_w}. However, according to (1), this will decrease $Q_{w,used}$ and thus the maximum stored energy. This value is therefore kept as a parameter in the study. Concerning the HE, its performance η is expressed by

$$\eta_{Carnot} = 1 - \frac{T^+_{amb}}{T_{sto,c}} = 1 - \frac{T^+_{amb}}{T_{w,in} + lift_{HP} - \Delta_{T_{sto}}} \tag{6}$$

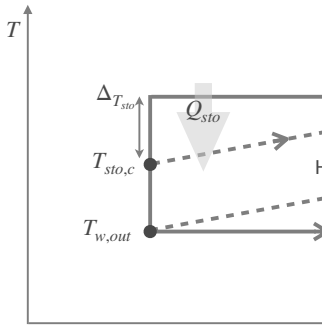

Figure 2: Ideal HP based by the characterizing temp sented in T-S diagram

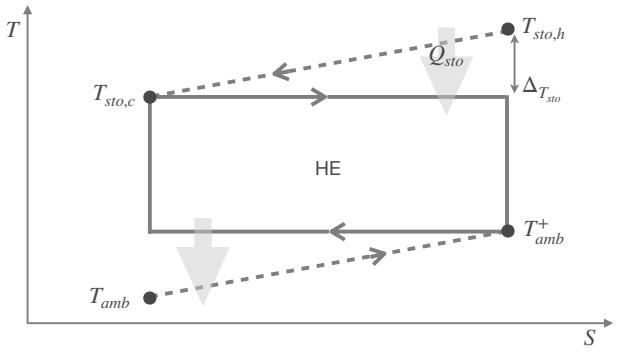

Figure 3: Ideal HE based on Carnot cycle limited by the characterizing temperatures of the CB represented in T-S diagram

2.2.3. CB with Lorenz cycles

Lorenz cycles [8] are based on heat exchanger at variable temperatures when Carnot cycles are isothermal. The implementation of these cycles requires zeotropic working fluids, super or trans-critical cycles, or a serial assembly of multiple HP and EH. This type of cycle is less implemented in CB than the Carnot cycle. However, with identical temperature glides, it theoretically gives better performance and several projects are currently developing this type of system. In order to remain conservative and to cover a maximum of possibilities, these two types of cycles will be used to obtain results according to the implementation of a CB working with Carnot or Lorenz cycles. Figures 4 and 5 represent the two Lorenz ideal cycles as well as the system temperatures in T-S diagrams. The COP and η are expressed by

$$COP_{Lorenz} = \frac{T_{sto,h} + T_{sto,c}}{T_{sto,h} + T_{sto,c} - T_{w,in} - T_{w,out}} = \frac{2T_{w,in} + 2lift_{HP} - \Delta_{T_{sto}}}{2lift_{HP} + \Delta_{T_w} - \Delta_{T_{sto}}} \tag{7}$$

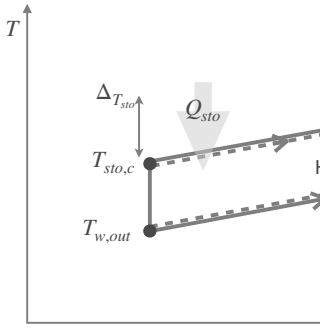

Figure 4: Ideal HP basec by the characterizing temp sented in T-S diagram

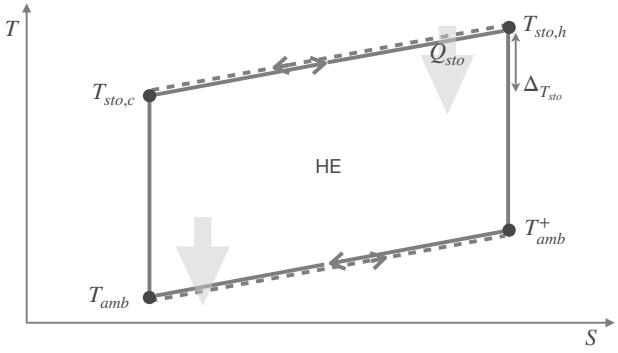

Figure 5: Ideal HE based on Lorenz cycle limited by the characterizing temperatures of the CB represented in T-S diagram

2.3. Industry description

The purpose of this section is to provide a generic description of energy flows in an industry so that it can be adapted to any industry. The characteristics of the industry allowing further development will also be identified.

2.3.1. Characteristic period

Temporal considerations of energy flows in industry would involve complex modeling to obtain results. Since the purpose of this study is to provide a first approach, these considerations are ignored. The different energy flows are integrated over a characteristic period $\Delta t(0 \rightarrow T_f)$.

This period is to be chosen on a case by case basis. Ideally, it should cover a duty cycle representative of the industry. This period also corresponds to a cycle on the storage, so it would seem judicious that it is of the

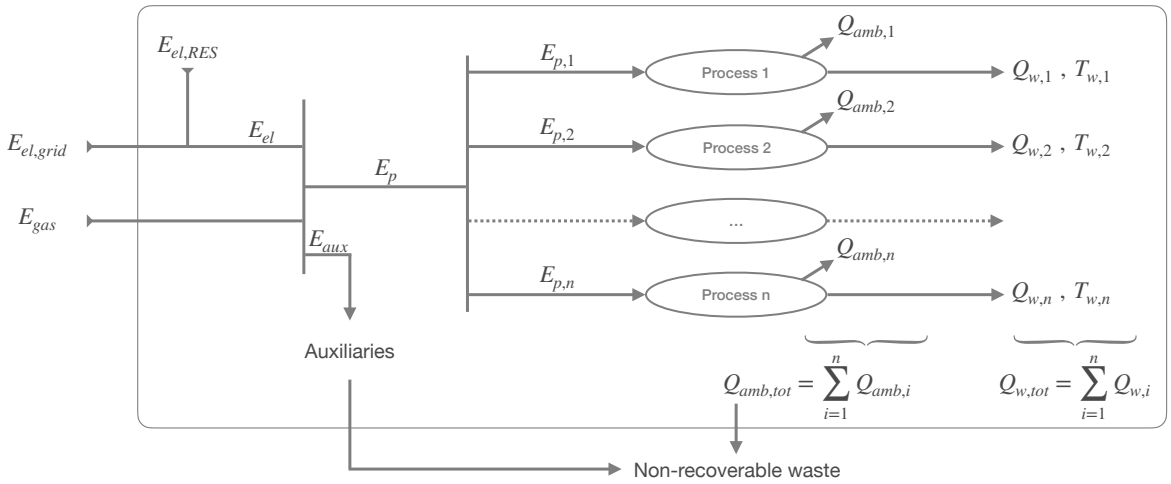

Figure 6: Generic representation of energy fluxes distribution in an industry integrated on the characteristic period Δt

2.3.3. Distribution of primary energy

A first useful characteristic of the industry is its primary energy allocation E_{gas}/E_{el}. In the case of fully self-consumed RES, E_{el} should be taken as the sum of RES electricity production and imported electricity $E_{el,grid}$ (Fig.6).

2.3.4. Waste heat temperatures

The processes are ranked from 1 to i such that $T_{w,1} > T_{w,2} > ... > T_{w,n}$. According to [7], this ranks in most cases the amount of waste heat such that $Q_{w,1} < Q_{w,2} < ... < Q_{w,n}$ but it is not a necessary condition.

2.3.5. Electricity pricing

Considering the variable cost C of electricity over the period Δt, different electricity pricing are identified:

- (A) $C_{buy} = C_{sell} = C \in \mathbb{R}_0^+ \ , \ \forall t \ \in [0, T_f]$
- (B) $C_{buy} = C_{sell} = C \in \mathbb{R}^+ \ , \ \forall t \ \in [0, T_f]$
- (C) $C_{buy} \in \mathbb{R}_0^+ \ , \ \forall t \ ; \ C_{sell} \in \mathbb{R}^+ \ , \ \forall t \ ; \ with \ C_{buy} \geq C_{sell} \ , \ \forall t \ \in [0, T_f]$
- (D) $C_{buy} \in \mathbb{R} \ , \ \forall t \ ; \ C_{sell} \in \mathbb{R}^+ \ , \ \forall t \ ; \ with \ C_{buy} < C_{sell} \ iff \ C_{sell} = 0 \ , \ \forall t \ \in [0, T_f]$

By these definitions: $(A) \subseteq (B) \subseteq (D)$ and $(A) \subseteq (C) \subseteq (D)$. An industry included in several electricity pricing as defined will be characterized by the most restrictive.

An electricity cost ratio C_{min}/C_{max} used as a parameter in the study is determined for each electricity pricing with for (A) and (B):

$$C_{min} = \min_{\forall t}(C) \text{ and } C_{max} = \max_{\forall t}(C) \tag{9}$$

By definition, the ratio is strictly greater than zero for (A) and equal to zero for (B). For (C) and (D), the ratio is determined with:

$$C_{min} = \min_{\forall t}(C_{buy}) \text{ and } C_{max} = \max_{\forall t}(C_{sell}) \tag{10}$$

By definition, the ratio is strictly greater than zero for (C) and less or equal to zero for (D).

This definition of the electricity cost ratio for (C) and (D) cannot be applied in the special case $\max_{\forall t}(C_{sell}) = 0$. It is therefore necessary to defined two sub-categories ((C*) and (D*)) of electricity pricing for which a special treatment is applied with a definition of the electricity cost ratio given by

$$\frac{C_{min}}{C_{max}} = \frac{\min_{\forall t}(C_{buy})}{\max_{\forall t}(C_{buy})} \tag{11}$$

Using strictly the limits of the electricity cost for determined C_{min} and C_{max} ensures conservatism. A more moderate choice of these values can lead to more restrictive results but closer to reality. These values are used to define the price for the entire selling and buying period. If the limits used represent only a very short period compared to Δt, the results will be so optimistic that they will no longer be useful. A good practice rule would be to choose a limit if it represents at least 5% of the period Δt.

2.4. Recoverable waste heat

The quantity of waste heat Q_w available for the HP is an important parameter to characterize the industry. With the usability factor u representing the proportion of primary energy converting in available waste heat, it is defined by

$$Q_w = u(E_{gas} + E_{el}) \tag{12}$$

In an ideal configuration, $u = 1$. This will never be the case in reality. u is bounded by a value $u_{s,max}$, with the subscript s refers to the selected $T_{w,s}$. It is defined by

$$u_{s,max} = (1 - \frac{E_{aux}}{E_{gas} + E_{el}}) \sum_{i=1}^{s} (\frac{E_{p,i}}{E_p}(1 - \frac{Q_{amb,i}}{E_{p,i}})) \tag{13}$$

The purpose of this section is to describe in more detail the expression of $u_{s,max}$.

2.4.1. Auxiliary consumptions

In the frequent case where all the incoming energy of the industry is not dedicated to the processes on which waste recovery is possible, it is necessary to deduct these auxiliary consumptions from the primary energy transformed into usable waste heat. This consumption is included in the factor $(1 - \frac{E_{aux}}{E_{gas}+E_{el}})$.

2.4.2. $T_{w,s}$ selection

Since it is assumed that there is only one CB and one storage, the temperature of the waste heat exploited $T_{w,s}$ must be unique and chosen between the $T_{w,i}$ temperatures. In the case $T_{w,s} > T_{w,n}$, part of the processes are excluded from the waste heat recovery system. This reduces the amount of energy exploitable by the factor $(\sum_{i=1}^{s} \frac{E_{p,i}}{E_p})$.

However, the choice of $T_{w,s}$ higher than $T_{w,n}$ has the advantage of increasing the performance of the system. At the time of the exploitation of the results, it is necessary to test various couples $[T_{w,s}; u_{s,max}]$ in order to select the optimum for the considered industry. The selected $T_{w,s}$ corresponds to the temperature $T_{w,in}$ of Section 2.2..

2.4.3. Processes ambient losses

In any process, not all of the primary energy $E_{p,i}$ used can be converted into usable waste heat. Unavoidable losses $Q_{amb,i}$ are rejected throughout the process ($Q_{w,i} = E_{p,i} - Q_{amb,i}$), which completes the previously developed factor:

$$\sum_{i=1}^{s} (\frac{E_{p,i}}{E_p}(1 - \frac{Q_{amb,i}}{E_{p,i}})) \tag{14}$$

In the case where $Q_{amb,i}$ is too difficult to evaluate for each process, a value $Q_{amb,tot}$ can be estimated for all the processes so that this factor is replaced by

$$(1 - \frac{Q_{amb,tot}}{E_p}) \sum_{i=1}^{s} \frac{E_{p,i}}{E_p} \tag{15}$$

2.4.4. Direct measurement of the available waste heat

The determination of the above factors can be complex. In some cases, it is easier to measure the quantity of waste heat directly after the processes. In this case, (13) becomes

$$u_{s,max} = \frac{\sum_{i=1}^{s} m_i c_{p,i} (T_{w,i} - T_{amb})}{E_{gas} + E_{el}} \tag{16}$$

with m_i the mass flow rate of the waste heat constituent for the process i integrated over Δt and the corresponding specific heat $c_{p,i}$. It is necessary to note that if waste heat constituents can condense in the considered temperatures, it is necessary to take into account the latent energy.

2.5. Calculation of the economic gains generated by the CB

Based on the assumptions, equations and values previously introduced, it is possible to calculate the maximum economic gain brought by the installation of a CB integrating waste heat recovery. The evaluation of this gain is directly linked to the considered electricity pricing and will be evaluated differently for each case. Since the aim is to determine the maximum profitability of the system, the waste heat will always be considered as available when the prices are the most favorable.

The purpose of these gain expressions is to highlight the terms characterizing an industry: C_{min}/C_{max}, u and E_{gas}/E_{el}. These latter two terms are expressed on the basis of (1-4,12) by W_{HP}/E_{el} and W_{HE}/E_{el} such as

$$\frac{W_{HP}}{E_{el}} = u(\frac{E_{gas}}{E_{el}} + 1) \frac{\Delta_{T_w}}{T_w - T_{amb}} \frac{1}{COPg - 1} \tag{17}$$

$$\frac{W_{HE}}{E_{el}} = u(\frac{E_{gas}}{E_{el}} + 1) \frac{\Delta_{T_w}}{T_w - T_{amb}} \frac{COP\eta g^2}{COPg - 1} \tag{18}$$

2.5.1. (A) and (C) electricity pricing

For electricity pricing (A) and (C), the maximum gain can be defined as the reduction in the electricity bill. The most favorable conditions are a purchase (W_{HP}) of electricity at C_{min} and a resale (W_{HE}) of electricity at C_{max}. To ensure maximum gain, the electricity consumed is hypothetically purchased at C_{min}.

$$gain_{(A,C)} = \frac{W_{HE} C_{max} - W_{HP} C_{min}}{E_{el} C_{min}} = \frac{W_{HE}}{E_{el}} (\frac{C_{min}}{C_{max}})^{-1} - \frac{W_{HP}}{E_{el}} \tag{19}$$

2.5.2. (B) and (D) electricity pricing

For electricity pricing (B) and (D), the previous gain formulation cannot be used since C_{min} is less than or equal to zero. The maximum payoff must therefore be evaluated as the maximum net profit generated by the installation of the system. Stored electricity is always bought and sold at the most favorable prices. The gain must be normalized in order to express a usable value in the results.

$$gain_{(B,D)} = W_{HE} C_{max} - W_{HP} C_{min} \quad \rightarrow \quad \frac{gain_{(B,D)}}{E_{el} C_{max}} = \frac{W_{HE}}{E_{el}} - \frac{W_{HP}}{E_{el}} \frac{C_{min}}{C_{max}} \tag{20}$$

2.5.3. (C*) and (D*) electricity pricing

For electricity pricing (C*) and (D*), it is never interesting to sell electricity back to the grid. Electricity restitution (W_{HE}) must only be used to cover the electricity consumption of the industry E_{el}. In the formula, the cost of electricity applied to W_{HE} must therefore be the same as applied to E_{el}. In order to express the maximum gain, C_{max} is used. This formula expresses the gain as the maximum reduction of the electricity bill.

$$gain_{(C^*,D^*)} = \frac{W_{HE} C_{max} - W_{HP} C_{min}}{E_{el} C_{max}} = \frac{W_{HE}}{E_{el}} - \frac{W_{HP}}{E_{el}} \frac{C_{min}}{C_{max}} \quad \text{with } W_{HE} \leq E_{el} \tag{21}$$

2.5.4. Choice of system parameters

In accordance with the principle of conservatism, for each point $[T_w, E_{gas}/E_{el}, C_{min}/C_{max}]$ the choice of the system parameters $(\Delta_{T_w}, \Delta_{T_{sto}}, lift_{HP})$ as described in the Section 2.2.1. is determined by the following optimization problem:

$$\begin{aligned} & \max(gain) \\ s.t. \quad & 0 \leq \tfrac{W_{HP}}{E_{el}} \leq 1 \quad , 0 \leq \Delta_{T_w} \leq T_w - T_{amb} \\ & 0 \leq \tfrac{W_{HE}}{E_{el}} \leq 2 \quad , 0 < \Delta_{T_{sto}} \leq T_{sto,h} - T_{amb} \\ & 0 \leq \tfrac{Q_{sto}}{E_{el}} \quad , 0 < lift_{HP} \leq 1473K - T_w \; [K] \end{aligned} \tag{22}$$

It is assumed that the consumption of electricity by the CB must be in the order of the industry's electricity consumption. The value of 1 is deliberately optimistic in order to remain conservative. Considering the electricity restituted by the CB distributed between the consumption of the industry and the grid, the value of 2 is chosen with the same considerations. For the electricity pricing (C*) and (D*), the constraint $W_{HE}/E_{el} \leq 1$ is added. In the case where Carnot cycles are considered, $\Delta_{T_{sto}} = 0$ (Section 2.2.2.).

3. Results and discussions

Results are determined with T_w=100 °C as an example and for discussions. Complementary results are shown in Appendix A, with waste heat temperatures covering the whole range considered.

Figures 7, 9 and 11 show the results for a CB based on Carnot cycles. Figures 8, 10 and 12 show the results for a CB based on Lorenz cycles. These results correspond to the gain as defined by (19), (20) and (21).

It is important to note that the results (Fig.11 and 12) for electricity pricing (B) and (D) express the maximum net benefit normalized by E_{el} and C_{max} and not the maximum reduction in electricity bill. The scale applied is therefore different.

All results are obtained with u = 1 and are expressed as a function of E_{el}. In order to apply u, it is necessary to multiply the results obtained by its value. In the case of a self-consumed RES electric production, the results must be expressed as a function of $E_{el,grid}$ and are therefore to be multiplied by $E_{el}/E_{el,grid} = 1+(E_{el,RES}/E_{el,grid})$.

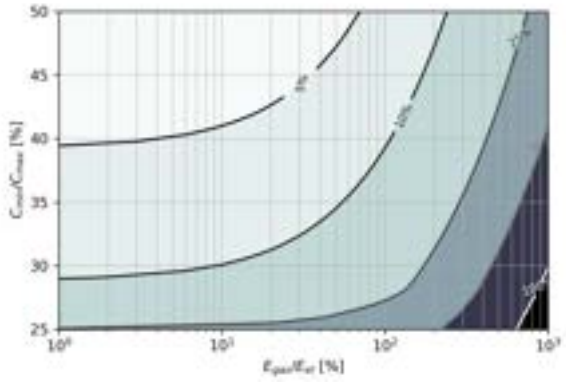

Figure 7: Maximum gain for electricity pricing (A) and (C) with CB based on Carnot cycles (T_w=100 °C)

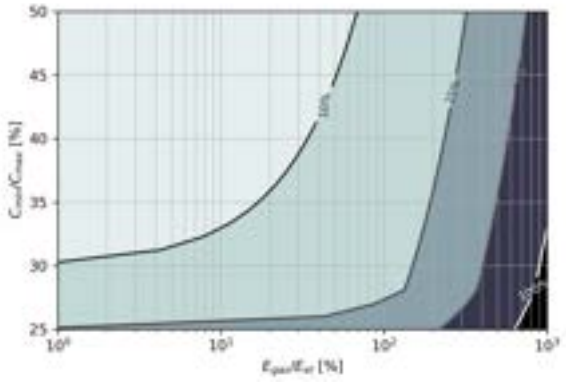

Figure 8: Maximum gain for electricity pricing (A) and (C) with CB based on Lorenz cycles (T_w=100 °C)

Based on the results obtained for 100 °C (representative of the other T_w trends), some preliminary observations are made. Calculations based on the Lorenz formulations always give similar or better results than those based on the Carnot formulations. A clear superiority of the Lorenz cycles is visible from an electricity cost ratio higher than 30%. However, the differences are small compared to the assumptions. It is necessary not to jump to conclusions. Moreover, in practice, the application of Lorenz cycles is more expensive and more complex to implement. [9]. It is interesting to note that the optimum glides $\Delta_{T_{sto}}$ for Lorenz cycles are close to the maximum of the allowed values, while they are at zero for Carnot cycles. This gives an important advantage to Lorenz cycles in real considerations. Increasing waste temperatures promotes good results. Also, the results improve with the increasing of gas proportion and/or the decreasing of electricity cost ratio.

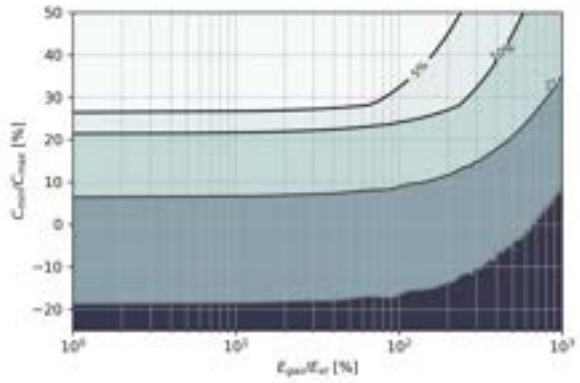

Figure 9: Maximum gain for electricity pricing (C*) and (D*) with CB based on Carnot cycles (T_w=100°C)

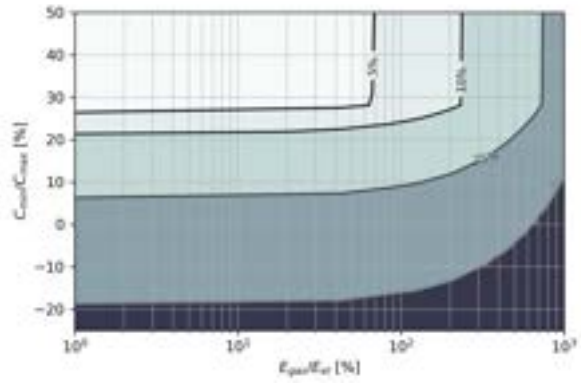

Figure 10: Maximum gain for electricity pricing (C*) and (D*) with CB based on Lorenz cycles (T_w=100°C)

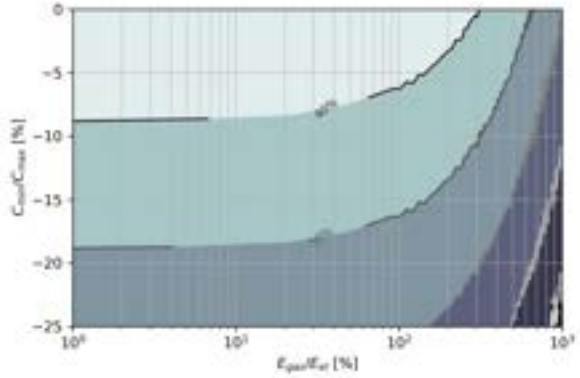

Figure 11: Maximum gain for electricity pricing (B) and (D) with CB based on Carnot cycles (T_w=100°C)

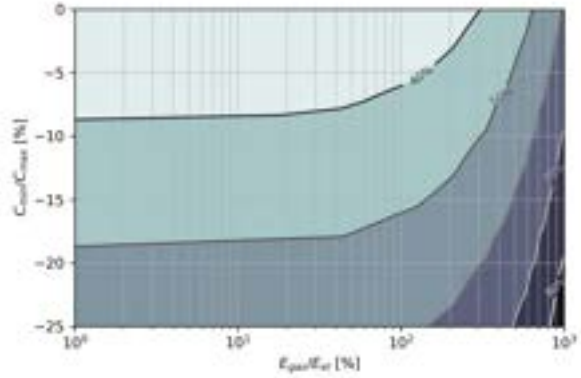

Figure 12: Maximum gain for electricity pricing (B) and (D) with CB based on Lorenz cycles (T_w=100°C)

3.1. Impact of the electricity pricing

For (A) and (C), a realistic case is an electricity cost ratios above 35%. In the case of E_{gas}/E_{el}=1, the gain is 10% for T_w=100°C. These results are weak compared to the hypotheses. Moreover, in some industries, the cost of electricity is still constant. The results for T_w at 50 and 200°C are respectively 5% and 25%. (C*) must tend towards (D*) to be in the same order, i.e. a purchase cost less than or equal to zero.

Cases (B) and (D) seem more interesting. In general, a purchase cost less than or equal to zero seems to be a necessary condition for profitability. Considering the investment of the system, the conservative assumptions and the fact that u = 1 for these results, a gain of 10% seems to be the minimum to find interest in the system. A more variable electricity pricing will therefore be the key to this technology.

3.2. Impact of the gas consumption

Increasing gas consumption increases gains. It is obvious that the objectives in terms of reducing emissions of greenhouse gases lead to avoid this solution. It is therefore an additional argument for an adapted electricity pricing.

In the case of a gas-intensive industry, the system can be interesting. First of all, it allows to reduce the electricity bill and to use the RES more advantageously. In a second time, its decarbonization will make the system less efficient. However, since this transformation of the industry will be done over the next 30 years and that the life cycle of a CB is of the same order, it is interesting to consider that the installation of the system will already put in place heat recovery devices that will be later used for other purposes.

3.3. Discussion on the restriction of the industries studied

The industry studied is considered to be entirely operated by a single CB and storage (Section 2.1.2.). It is possible to remove this assumption by dividing the processes by groups and linking each group to a CB and a storage (so different T_w). It is necessary to adapt the corresponding i indices in 13 and repeat the methodology

several times. The gains can then be summed up. This method, if not applied sparingly, has the disadvantage of further distorting the results of reality by neglecting the investment cost of several systems instead of one.

An ambient temperature different from 20 °C has a significant impact on the results (a lower T_{amb} improves the gains and vice versa). This is one of the reasons why the characteristic period must be chosen carefully. It is always possible to do once the methodology for a winter case and once the methodology for a summer case and then average the results. The results for different T_{amb} are available in the Appendix A.

Finally, [5] demonstrates that considering only batteries with hot storage remains conservative.

3.4. Waste heat used

From Fig.13 and Appendix A, it appears that the maximum recoverable waste heat fraction is below 50% in realistic cases for electricity pricing (A), (C) and (C*). For (B), (D) and (D*) this fraction can rise to between 60 and 70% for restricted areas of application. Thermal Integrated Carnot Battery is therefore not a dedicated waste heat recovery technology (it makes use of it but with constraints).

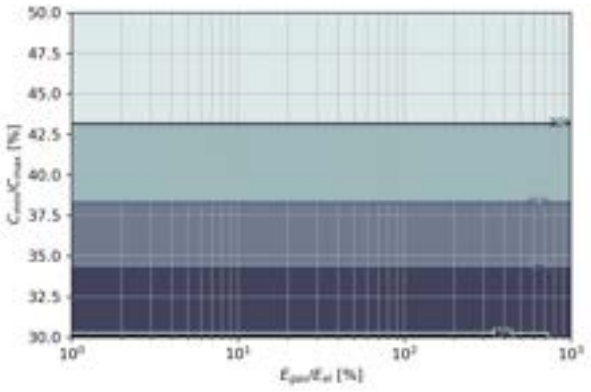

Figure 13: Waste heat used $Q_{w,used}/Q_w$ to obtain the maximum gain for electricity pricing (A) and (C) with CB based on Carnot cycles (T_w=100 °C)

3.5. Optimized use of Thermal Integrated Carnot Batteries

Another application for Thermal Integrated Carnot Battery is the integration of district heating. This solution has an interesting potential of profitability [10]. It could be possible to combine the two systems to increase the potential benefits. In this case, the methodology of this paper can no longer be used as is. It is possible to include the consumption of the district heating network in the ambient losses ($Q_{amb,i}$ for (14) or $Q_{amb,tot}$ for (15)) . In this case, the results give lower gains to which must be added the economic gains due to the district heating network.

The waste heat temperatures considered in this paper are based on a study [7] considering that higher temperatures waste heat are used to feed the lower temperature processes. In most sectors, waste heat above 200 °C is used for this purpose. The iron and steel industry and the glass industry are special cases. The waste heat temperatures, although very high, are not converted because the majority of the processes require an even higher temperature. The recovery of this waste is however not considered because its quality allows a much more interesting balance with other technologies [1]. Graphs in Appendix A show the limits of the considered system, for high temperatures, in terms of energy efficiency.

3.6. Non-self-consumed RES

The case of non-self-consumed RES are directly related to time constraints. Despite the assumptions made, it is not possible to express the gain for all electricity pricing:

- (D*) is used instead of (C*) with $\frac{C_{min}}{C_{max}} = 0$
- (D*) can be used as is
- (D) is used instead of (B) with $\frac{C_{min}}{C_{max}} = 0$
- (D) can be used as is

For the transformations in (B) and (D), a strong assumption must be made: non-self-consuming production occurs only when the network is saturated and imposes $C_{sell} = 0$. In all these cases, the term $E_{el,RES}$ of the correction $1 + (E_{el,RES}/E_{el,grid})$ factor must be evaluated as the sum of the RES production (self-consumed

or not). For (A) and (C), it is not possible to conclude. In any case, if the energy of the non-self-consumed RES is small compared to the self-consumed RES, these steps can be neglected given the advantageous assumptions on which the gain calculations are based.

4. Conclusions and perspectives

The objective of this paper was to determine Key Performance Indicators concerning the potential of Carnot battery integrating waste heat recovery in Industry. A generic definition of the Carnot Battery was determined according to Carnot and Lorenz. Industry was also described generically. The necessary assumptions were made to cover as wide a range as possible. The different parameters of the system were then determined. On the one hand for the industry with simple to define values: ratio of primary energy used, ratio of minimum and maximum electricity costs, temperatures of available waste heat, and electricity pricing type. On the other hand, the Carnot Battery parameters are optimized to give the most optimistic results. For each combination of industry parameters, a maximum gain is calculated, which is the main result of this work. Throughout, conservative assumptions are applied so that the results are as robust as possible.

Industries using at least as much electricity as gas and for which the ratio of the minimum (positive) purchase price to the maximum selling prices is over 50% cannot expect significant benefits from using Carnot batteries integrating waste heat recovery. Intermediate results are also defined and discussed leading to the following conclusions:

- Electricity pricing with high variability and negative purchase prices will be the key to this technology.
- The application of Lorenz cycles can theoretically significantly increase the benefits of the system compared to Carnot cycles in the least favorable cases.
- The system is more efficient for gas-intensive industries. It can be a gateway to low temperature waste heat recovery.
- The amount of waste heat recovered remains low in all cases. It is used for the benefit of the system, but Thermal Integrated Carnot Battery is not a dedicated waste heat recovery technology
- The introduction of other heat streams (District Heating) can contribute to the sustainability of the system.
- It is difficult to conclude in the case of a Renewable Energy Sources not entirely self-consumed without strong assumptions. Further study will often be required.

An interesting perspective will be to test several cases and to position them on the graphs. This will allow to determine more precisely which industries are unsuitable for the system and which ones would deserve a more advanced study. On the other hand, it would be interesting to realize a more complex model integrating temporal considerations, investment prices and a Carnot Battery defined according to considerations closer to reality. Describing this model on the basis of the same parameters as those of this paper will allow the second more advanced study. Finally, the confrontation of the results with other storage systems as well as with a model integrating more widely the use and the management of heat flows would be of great interest.

Appendix A Additional mappings

Although reduced to a minimum, the number of parameters in this study only allows to propose mapping for illustration purposes. In order to provide to the reader the specific KPIs adapted to his case of interest, all the results for the considered ranges can be found at: `https://hdl.handle.net/2268/302631`

Thermodynamic and economic analysis of a Carnot battery with a two-zone water tank as thermal energy storage

Abstract:

In the process of energy transition, the share of renewable energy sources is increasing. This leads to strong fluctuations in power generation. To balance supply and demand, energy storage is required. Carnot batteries could be a promising storage technology to solve this problem. These batteries convert electrical energy into thermal energy through an electrical resistance heater or a heat pump and stores this energy for a period of time. Later, the thermal energy is converted back into electrical energy through a heat engine.

A Carnot battery with a two-zone tank and water as a storage medium was investigated. This type of storage allows storage temperatures above 100 °C under atmospheric conditions. The system studied here applies a storage temperature of 115 °C. Charging is realized with a CO_2 heat pump, while discharging uses a heat engine with an organic fluid. This Carnot battery was implemented and simulated in EBSILON® *Professional*. The supplied electrical power was 18 MW and the maximum outlet temperature was 150 °C. Derived from the day-ahead market [1], a charging and discharging time of 4 h was applied. To identify the most promising concept for practical applications, the round trip efficiency, levelized cost of electricity (LCOE), and technology readiness level (TRL) of the different Carnot battery configurations were compared. In addition, a simplified sensitivity analysis was performed to assess the influence of the uncertainties of the economic parameters on the LCOE. Furthermore, the change in the LCOE with a variation in the charging and discharging duration was investigated.

The advantage of a CO_2 heat pump is that applications with high input power have already been implemented, which leads to an estimated TRL of at least 6. By contrast, heat pumps for temperatures above 100 °C utilizing screw or piston compressors are only available for lower power applications.

Keywords:

Carnot Battery, CO_2 Heat Pump, Organic Rankine Cycle, Water Storage Tank.

1. Introduction

Electricity generation from renewable energy is subject to fluctuations due to weather conditions. To ensure a secure power supply with an increasing share of renewable energy, energy storage systems are needed to temporarily store electrical energy, and thus compensate for fluctuations. Pumped thermal electricity storages, known as a Carnot battery (CB), is a promising technology in this respect. A CB is a system that converts electrical energy into thermal energy through an electrical resistance heater or a heat pump and stores this energy for a period of time. Later, the thermal energy is converted back into electrical energy through a heat engine. CBs have been studied in different configurations involving supercritical, transcritical, and subcritical processes [2]. Comprehensive overviews of CBs can be found in [2, 3]. For storing thermal energy, sensible, latent, or thermo-chemical energy storage systems are available. A sensible energy storage system consists of a single storage tank with a thermocline (stratified storage) or two tanks, where the storage medium is pumped from one tank into the other.

An overview of the research literature is given below. This study focuses on configurations in which CO_2 transcritical processes are used. Several authors dealing with CBs have considered transcritical processes predominantly using CO_2 [4–11] as a working fluid. Energy storage on the hot side is often realized in tanks with hot water [4,7,8,10]. This allows a temperature glide between the storage medium (water) and the working fluid. On the cold side, either an ice storage tank [4, 7] or the environment [10, 11] are considered as storage units.

Mercangöz et al. [9] described a transcritical charging and discharging process using CO_2 as a working fluid. The concept included two storage units, one of which stored thermal energy at higher temperatures in water

tanks at a maximum temperature of 123 °C and the other stored energy in an ice storage tank at a temperature of -5 °C. Because of the irreversibilities that occur in the process, the ice storage is supplemented by an additional circuit during the charging process to dissipate losses to the environment. With a nominal turbine power of 1 MW (η_{turbine} = 86 %, $\eta_{\text{compressor}}$ = 81.5 %, η_{expander} = 80 %, and η_{pump} = 80 %) for a pilot project and a nominal turbine power of 50 MW (η_{turbine} = 91 %, $\eta_{\text{compressor}}$ = 89 %, η_{expander} = 88 %, and η_{pump} = 86 %) for a commercial plant, round trip efficiencies of 51 % and 65 %, respectively, were achieved.

Morandin [4, 5], starting from the base case, optimized the transcritical CO_2 charging and discharging process. The base case included, on the hot side, a sensible energy storage system using water as a storage medium, with several tanks storing energy at different temperatures, and, on the cold side, an ice storage system consisting of two tanks. The ice storage tank contained a salt mixture to lower the freezing point to -21.2 °C. An air fan was also integrated into the charging and discharging process to release the resulting irreversibilities to the environment in the form of heat. By optimizing the base case with eight water tanks and a maximum discharge temperature of 177 °C, a round trip efficiency of 60 % was achieved. By adding an internal heat exchanger in the charging and discharging process to the base case configuration, the round trip efficiency was increased to 62 %. The expansion of the working fluid occurs in the two phase/wet steam area, which is associated with technological problems. To prevent these problems, a throttle can be used instead of the expander, which in turn leads to a drop in round trip efficiency.

Another study on CB was presented by Kim et al. [8], based on Morandin and Mercangöz [4, 9]. Nevertheless, in the study by Kim et al. [8] the concept involved isothermal compression/expansion using a liquid expander and a water injection to cool the working fluid during the charging process and to heat it during the discharging process, respectively. At a maximum pressure of 160 bar and a maximum charging temperature of 150 °C, and under high isentropic efficiencies ($\eta_{\text{compressor,charging}}$ = 90 %, $\eta_{\text{expander,charging}}$ = 85 %, $\eta_{\text{compressor,discharging}}$ = 0.85 %, $\eta_{\text{expander,discharging}}$ = 90%) an overall efficiency of 74.5 % was obtained.

Steinmann et al. [7] studied a CB that consisted of transcritical CO_2 cycles and two storage units at different temperatures. The first storage unit was a pressurized water storage tank with a temperature up to 160 °C. The other one was an ice storage unit with a temperature of 0 °C. With an isentropic compressor and turbine efficiency between 80 % and 90, % the round trip efficiency was about 45 %.

Baik et al. [10] investigated CBs with a transcritical CO_2 process involving two-tank liquid systems, each on the hot and cold side. The tanks on the cold side used the environment with a temperature of 20 °C as a heat source and heat sink, respectively. These storage tanks were operated with water. Compared to the concepts in [4, 5, 7], a throttle was integrated into the charging process instead of an expander. The maximum storage temperature was 120 °C and isentropic efficiencies of 85 % were assumed for the: compressor, turbine, and pump. The round trip efficiency was studied as a function of the lower storage temperature of the two-tank system on the hot side, which varied between 25 and 70 °C. Under these conditions, round trip efficiencies ranged from 14.7 % to 29.1 %, with the maximum reached at the lower storage temperature of 40 °C on the hot side.

Koen et al. [11] analyzed the transcritical process by testing different working fluids, such as CO_2, R1234yf, R1234ze(e), R1234ze(z), R152A, R161, R13I1, and ammonia, and different storage media such as water,Therminol D12, and Therminol 66. The concept included a compressor and an expander for both charging and discharging processes. A storage unit was implemented on the hot side, designed as a two-tank system. A low-temperature storage tank was dispensed, with and thus, a heat exchanger used the environment as the second storage unit. Under optimal operation conditions with polytropic component efficiencies of 90 %, round trip efficiencies between 50.5 % and 57.6 % were obtained. The best result was achieved using the working fluid R13I1 at a maximal storage temperature of 206 °C.

The described concepts generally use the round trip efficiency to evaluate their configurations. In this study, besides the round trip efficiency, the levelized cost of electricity (LCOE) and the technology readiness level (TRL) were determined to answer the following questions:

With which CBs could a system be realized in a timely manner?

Which efficiencies are achieved and what are the resulting LCOEs of the investigated CBs?

How does reducing the pinch point of the heat exchangers affect the round trip efficiency, purchased equipment cost, and LCOE?

The study focuses on various CB concepts based on the transcritical charging process with CO_2 as a working fluid. Using CO_2, an appropriate compressor at an outlet temperature greater than 100 °C, allows the implementation of a heat pump at a larger scale [12, 13]. So far, it is only possible to implement heat pumps in the kW range with positive displacement machines, using a high compressor discharge temperature [14]. A two-zone storage tank is used as a thermal energy storage (TES). This type of storage consists of an upper and a lower chamber, which are separated from each other by a partition wall. These chambers are filled with water

at different temperatures and are connected by pipes. The water in the upper chamber exerts pressure on the lower chamber. This allows the storage of water in the lower chamber in a pressureless state at temperatures $> 100\,^{\circ}\mathrm{C}$. Compared to pressure-loaded tanks with water, the two-zone storage tank is a safer and cheaper option [15]. In combination with the two-zone storage tank, the working fluid (CO_2) is suitable for the transcritical charging process. This mode of operation has the advantage that the CO_2 approximates the course of the temperature glide of the storage medium (water) in the two-zone storage tank. One way to discharge the TES is to use a heat engine, which is also operated with the same working fluid (CO_2) in transcritical mode. Alternatively, subcritical processes with different organic working fluids can be considered as these subcritical processes are already used in practice, (e.g., in geothermal plants) [16].

2. Design and Simulation of the Carnot Battery

The CB consists of a transcritical charging process and a sensible thermal energy storage (TES). The discharge of the TES is either transcritical or subcritical. The schemes of the charging and discharging subprocesses are shown in Fig. 1 a) and b), respectively. The subprocesses are described below.

Charging Process

Excess electrical energy is used to compress the working fluid to a supercritical pressure (HP1-HP2). After transferring the heat to the TES (HP2-HP3), the working fluid is further cooled in the regenerative heat exchanger (HP3-HP4) until the liquid state is reached. Then, the working fluid is first expanded in a liquid expander to a nearly saturated liquid (HP4-HP5) before it is further expanded in the throttle to the evaporating pressure (HP5-HP6). The working fluid evaporates in the heat exchanger (HP6-HP7) by the heat supply from a river and is further heated in the regenerative heat exchanger (HP7-HP1).

Discharging Process

The liquid working fluid is compressed in the pump to a high-pressure level (HE1-HE2). Heat is then transferred to the fluid in the heat exchanger (HE2-HE3), using the two-zone energy storage. In a transcritical process, the fluid is heated with a phase change during temperature decrease, whereas in a subcritical process, the fluid undergoes a phase change at a constant temperature and evaporation also takes place. Then, the working fluid is expanded in the turbine (HE3-HE4), which drives the generator. To close the cycle, the working fluid is condensed in the heat exchanger (HE4-HE1) by releasing the heat to a river and reaches the initial state (HE1).

For the discharging process, a heat engine in transcritical operation mode with the same working fluid (CO_2) as in the charging process was compared with heat engines in subcritical operation mode, using the following working fluids:

- R600a (isobutane), R134a, and R245fa as these fluids are already used in geothermal power plants [16].
- R1233zd(E), as this working fluid is already used in CB laboratory setups [17, 18].
- R1234yf, discussed as replacement fluid for R134a [19].
- R290 (propane), which is used in refrigeration and heat pump systems [20].

2.1. Modeling and Simulation

The modeling and steady-state calculation of the Carnot battery were performed in EBSILON® *Professional* [21]. For this purpose, the components (e.g., the turbine, heat exchanger, and others) are placed on the graphical surface and connected by lines. The line between the components corresponds to electrical, mechanical, or physical lines through which fluids flow. At a point of the physical line, a starting value and the fluid must be defined. With further measuring points, which are to be placed on the corresponding lines, further operating points in the system can be defined. The component 'controller' allows changing an actual value until the setpoint is reached. These controllers are used to determine the mass flow in the subprocesses. For implementing different working fluids, substance databases such as Refprop [22] are available.

The charging process is supplied with 18 MW of electrical power, which is needed to operate the compressor and the two pumps for pumping the river water and the hot water from the two-zone storage. According to [12], the upper pressure and temperature level in HP2 is a maximum of 140 bar and 150 °C, respectively. The maximum storage temperature in ST1 is 115 °C and is based on the already implemented two-zone storage [15]. The heat losses in the two-zone storage tank are neglected in this work. To evaporate the CO_2 in the heat exchanger from HP6-HP7, water is taken from the environment at 10 °C and 1 bar (state: w1), which is reduced by 5 K (state: w3).The temperature in HP6 is determined by specifying a terminal temperature difference or a pinch point in the heat exchanger. This, in turn, results in the evaporation pressure and thus the pressure HP6 and HP7. The same pinch point is specified in all heat exchangers. Pressure losses are also neglected in the process. Isentropic, mechanical, and electrical efficiencies of the components are specified

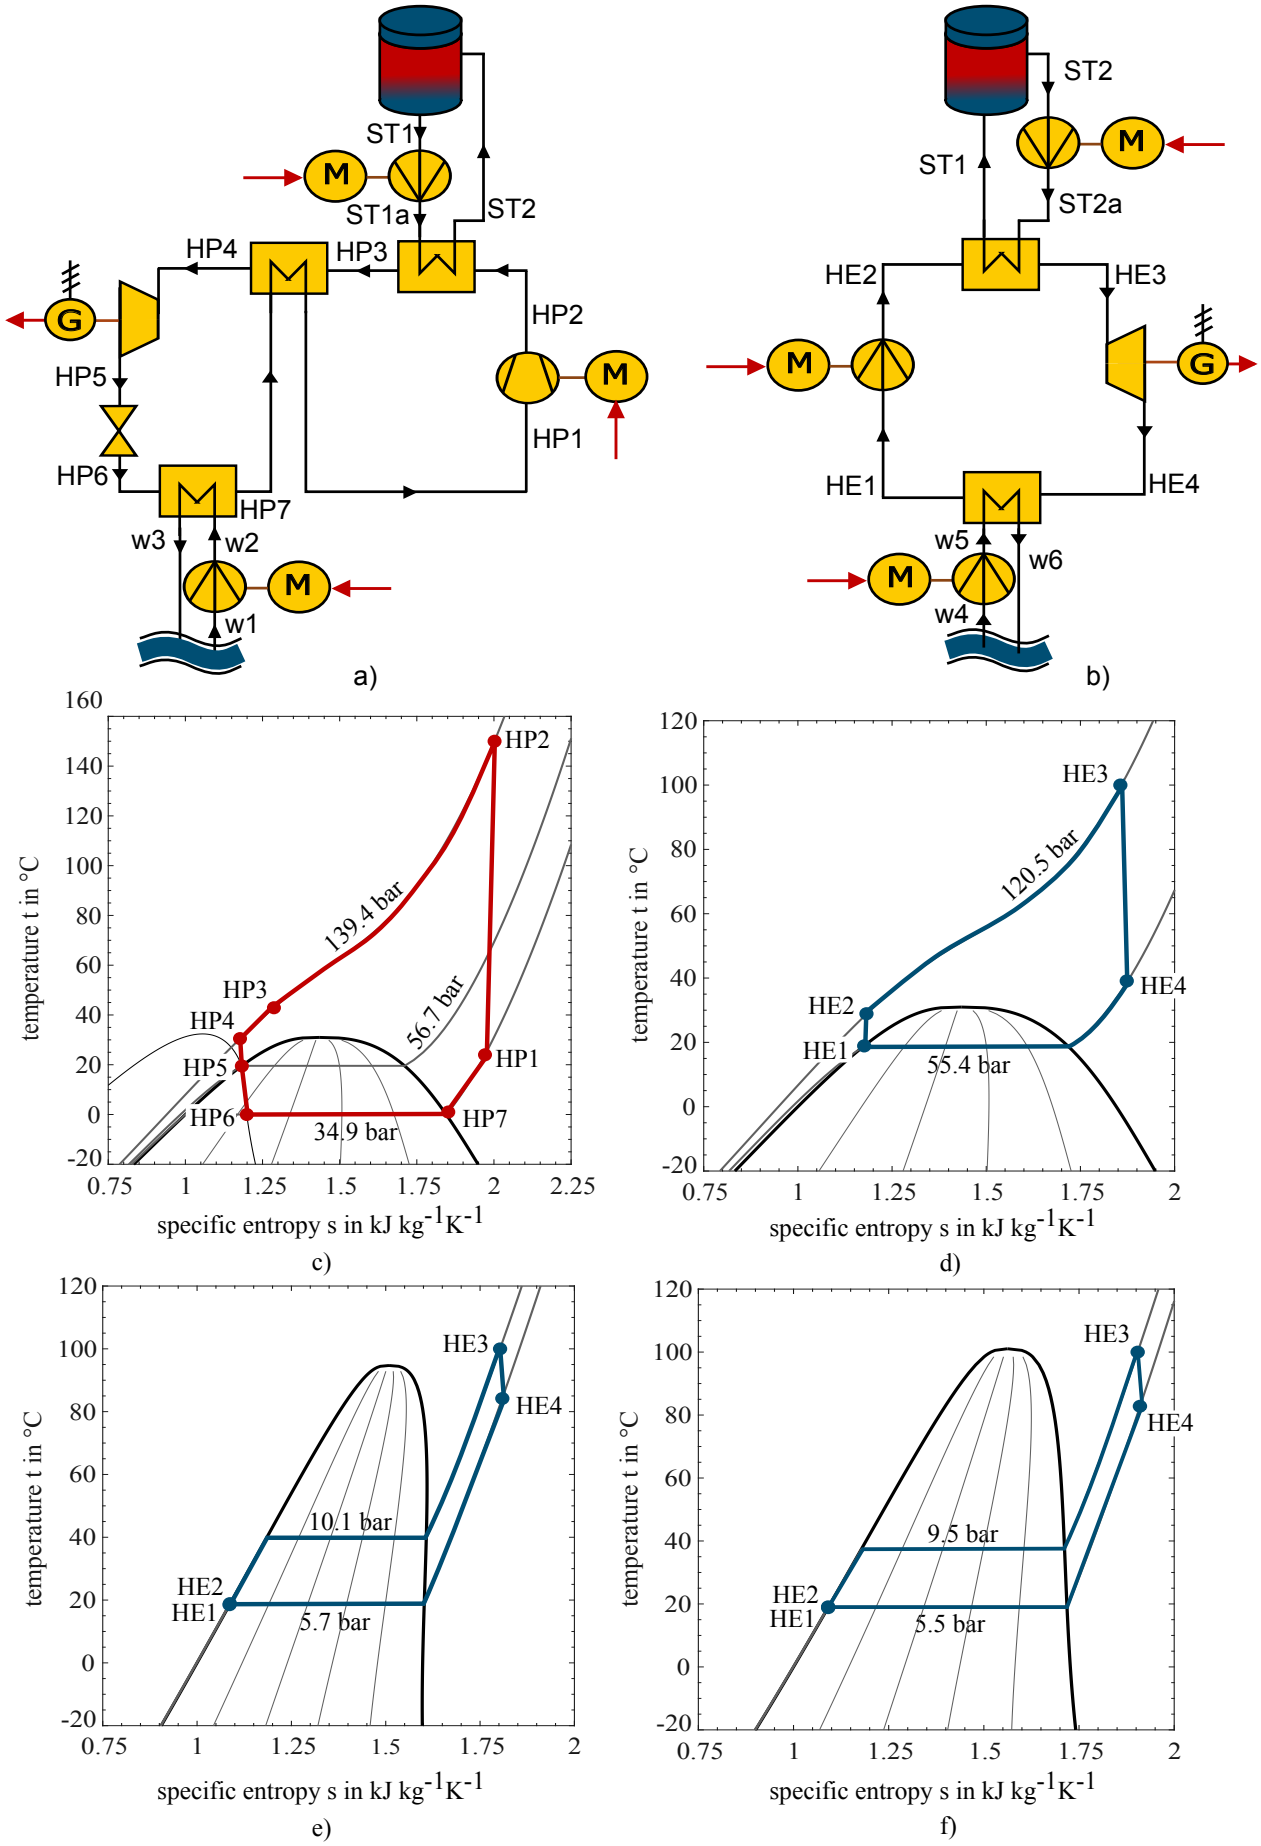

Figure 1: Scheme of the a) charging cycle and b) discharging cycle; t,s diagram of c) charging with CO_2; d) discharging with CO_2; e) discharging with R1234yf and f) discharging with R134a [22].

(see Table A.1). These values are the same for all concepts. As a condition, the lower storage temperature T_{ST1} is defined in such a way that the CO_2 is liquid in state HP4.

2.1.1. Results of the Simulations

Tables 1 and 2 present an overview of the simulation results for the different configurations when two different pinch points are specified. Under a pinch point of 5 K, the transcritical CO_2 discharge process (Configuration 1) achieves the highest round trip efficiency (21.9 %), whereas the other configurations with ORC fluids vary between 9.6 % and 13.7 %. In general, a decrease in pinch point leads to an increase in round trip efficiency. This may be because, the evaporation pressure in the discharge process can be increased and the condensation pressure in the discharge process can be decreased. The overall process of Configuration 1 thus increases in efficiency from 21.92 % to 33.48 %. A greater increase in round trip efficiencies is achieved with Configurations 2-6 (see Figure 2) compared with the pinch point of 5 K. The lower pinch point allows the lower storage temperature T_{ST1} to be increased, which has a positive effect on the heat engine. However, the lower storage temperature is limited upward, otherwise, the state of aggregation before the liquid expander in the heat pump is gaseous. Figure 2 shows the temperature curves of the fluids in the heat exchangers between HP2 and HP3 and between HE2 and HE3, assuming different pinch points. With a reduction of pinch point, the cost of the purchased equipment increases because of the need for a larger heat exchanger area. Considering the LCOE, the financial cost at the expense of efficiency is examined as well. In the following, the working fluids R1233zd(E) and R245fa are not considered for the economic analysis because of the low round trip efficiencies and the low pressure ratios obtained in the discharge process.

3. Economic Analysis

This subchapter describes the methods used for calculating the purchased equipment costs (PECs) as well as the levelized cost of electricity (LCOE).

3.1. Equipment Cost

In addition to its efficiency, the cost of a CB is also important. For a first estimation of component costs, the Turton method [23] was used. With this method, the PECs are calculated on the basis of cost functions, which result from predefined factors and characteristic size parameters, such as the power or heat exchanger area.The estimation of the PEC of the generators' was based on the six-tenths rule [24]. The reference values were obtained from the cost of the generator by Balli et al. [25]. The PEC of the throttle was negligible compared to the other components. A detailed description for estimating PEC is available at [26]. For calculating the PEC

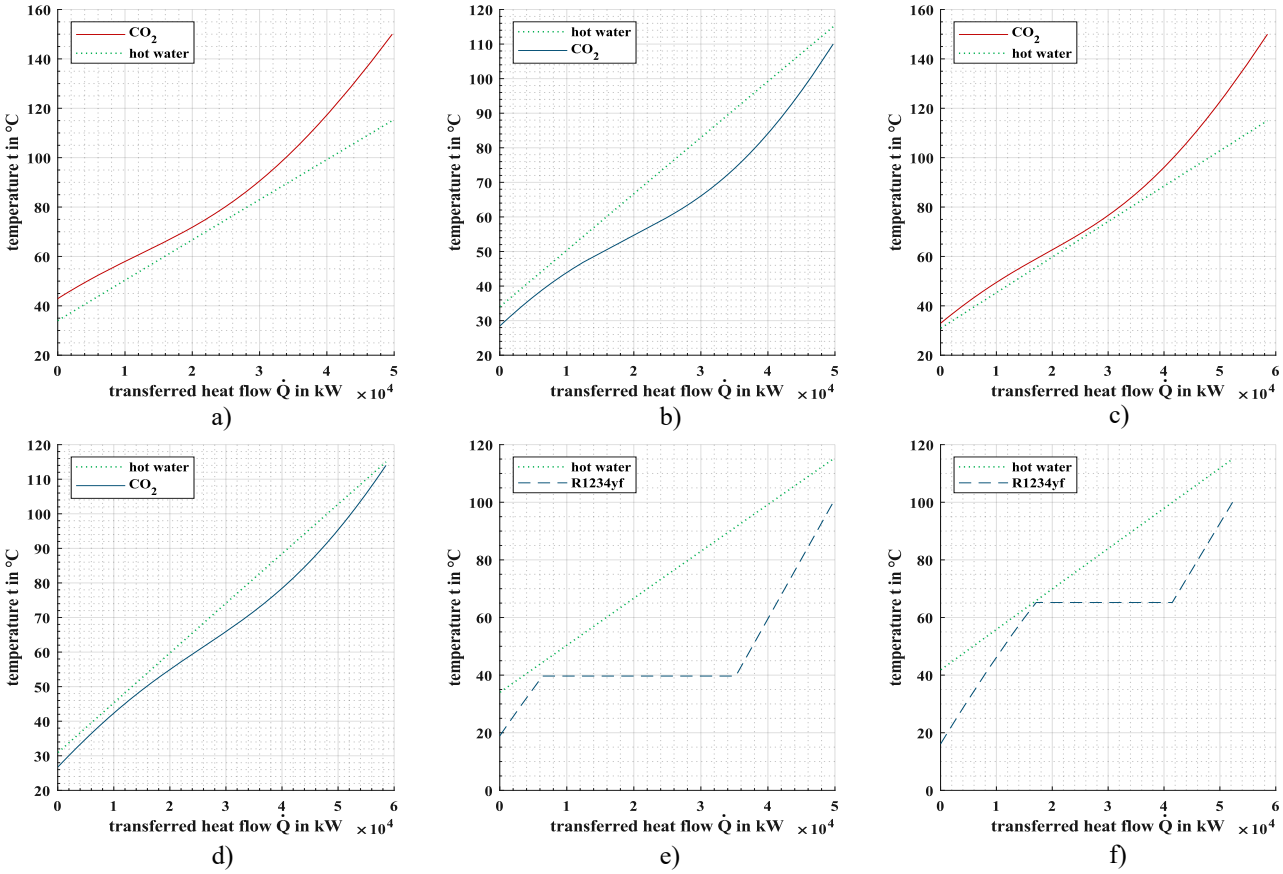

Figure 2: t,Q diagram of a) Configuration 1 in the heat exchanger (HP2-HP3) with pinch point= 5 K; b) Configuration 1 in the heat exchanger (HE2-HE3) with pinch point= 5 K; c) Configuration 1 in the heat exchanger (HP2-HP3) with pinch point= 1 K; d) Configuration 1 in the heat exchanger (HE2-HE3) with pinch point= 5 K; e) Configuration 6 in the heat exchanger (HE2-HE3) with pinch point= 5 K; f) Configuration 6 in the heat exchanger (HE2-HE3) with pinch point= 1 K for illustration of the curve between the fluids.

of the two-zone storage tank, an average value of 550 €/m^3 [15] was applied. The PECs are based on specific reference years. Hence, it is necessary to update costs by considering the price development, inflation, and other factors, with the aid of the cost index Chemical Engineering Plant Cost Index (CEPCI). For the selected reference year (2021), the CEPCI was 708 [27]. The official exchange rate of the European Commission [28] was applied for converting other currencies into euros.

3.2. Levelized Cost of Electricity

For comparing the CB configurations, LCOE was calculated according to [29]. The LCOE is composed of the economic expenditure of the system during its lifetime and the total amount of electricity generated. Taking into account the purchase cost of the supplied electrical energy $c_{\mathrm{el,in}}$, the LCOE can be calculated according to the following equation:

$$LCOE = \frac{I + \sum_{t=1}^{n} \frac{A_t}{(1+i)^t}}{\sum_{t=1}^{n} \frac{En_{t,\mathrm{el}}}{(1+i)^t}} + \frac{c_{\mathrm{el}}}{\eta_{\mathrm{rt}}}. \tag{1}$$

The time period is set to n = 25 years. The aim is to operate the CB 365 days a year with a uniform charging and dicharging time of $\Delta\tau$ = 4 h. This results in the annually produced amount of electricity $En_{t,\mathrm{el}}$ with $En_{t,\mathrm{el}} = 365 \cdot \Delta\tau \cdot P_{\mathrm{out}}$. The investment costs I include not only the PECs, but also take into account other costs (e.g., for pipes, measuring devices and installation) [30]. To determine the investment costs I, the total PECs are multiplied by the Lang factor (F_{Lang} = 4.74) [30]. The annual operation and maintenance costs A_t are determined using a constant factor F_{op} = 0.015. This factor (F_{op}) is multiplied by the total investment costs.The purchase cost $c_{\mathrm{el,in}}$ of the supplied electrical power during charging is determined using the day-ahead market for Germany and Austria of the European Energy Exchange. Application of the approach of Dietrich [31] to the reference year 2021 results in a purchase cost of $c_{\mathrm{el,in}}$ = 6.64 € cents/(kWh)$^{-1}$ [32]. The debt interest rate i is estimated from the program 'Renewable Energies Standard' [33] of the credit bank KfW. This program is

finances renewable energy systems such as battery storage and power-to-X systems and enables debt capital financing of 100 %. A debt interest rate of i = 3.49 % [34] was selected for the program at a maximum fixed interest period of 20 years. Because the period of time is 25 years in this study, we assumed that the interest rate remains fixed and does not change over the additional 5 years. No adjustments for inflation were made.

3.3. Results of the Economic Analysis

Table 3 gives an overview of the total PEC and LCOE of the different configurations for a uniform charging and discharging time of 4 h at a pinch point of 5 K in all heat exchangers. The total PEC of the subcritical processes of Configurations 1-3,5,6 averages $12.209 \cdot 10^6$ €. Configuration 1, based on the CO_2 HE, has PECs about 3 million euro higher than others. Despite, Configuration 1 has the lowest LCOE (123 €cents $(kWh)^{-1}$). The other configurations are in the range of 183-214 €cents $(kWh)^{-1}$ because of their poor round trip efficiency. With the decrease in pinch point, component costs for Configuration 1 increased by almost 57 %, whereas the other configurations became on average 20 % more expensive (see Table 4). A higher LCOE for Configuration 1 was obtained. This is mainly due to the increased costs for the heat exchangers, resulting from the reduced temperature differences within them in the heat engine, from the hot TES to the discharging process. For the other configurations, a reduction in pinch point had a positive effect on LCOE, which was reduced by 50 % on average. Tables 5 and 6 show that the LCOEs were further reduced with a uniform charging and discharging time of 5 and 6 h, respectively. The two-zone storage system should be larger, but this additional cost does not affect the total PEC or the LCOE as much. In addition, Fig. 3 compares the shares of the PECs of the different components for Configuration 1 (CO_2) and for Configuration 6 (R1234yf) with different pinch points. The subprocesses of charging, storage, and discharging are presented in different colors. For all variants, the compressor (including the motor) is the most cost-intensive component, but with a lower pinch point, the cost proportion of the heat exchangers increases. The distributions of the PECs of the other configurations are similar to Configuration 6.

Table 3: PEC and LCOE with a pinch point of 5 K in heat exchangers during uniform charging and discharging for 4 h.

Configuration	1	2	3	5	6
PEC [10^6 €]	15.387	12.152	12.213	12.236	12.233
LCOE [€cents $(kWh)^{-1}$]	123	214	192	195	183

Table 4: PEC and LCOE with a pinch point of 1 K in heat exchangers during uniform charging and discharging for 4 h.

Configuration	1	2	3	5	6
PEC [10^6 €]	24.118	14.670	14.683	14.712	14.751
LCOE [€cents $(kWh)^{-1}$]	128	105	96	96	95

Table 5: LCOE with a pinch point of 5 K in heat exchangers during uniform charging and discharging for 5 h with $c_{el,in}$ = 6.8 € cents $(kWh)^{-1}$

Configuration	1	2	3	5	6
PEC [10^6 €]	15.685	12.449	12.512	12.535	12.532
LCOE €cents $(kWh)^{-1}$	106	187	168	170	160

Table 6: LCOE with a pinch point of 5 K in heat exchangers during uniform charging and discharging for 6 h with $c_{el,in}$ = 7 € cents $(kWh)^{-1}$

Configuration	1	2	3	5	6
PEC [10^6 €]	15.984	12.747	12.810	12.833	12.830
LCOE [€cents $(kWh)^{-1}$]	95	169	152	154	145

3.4. Sensitivity Analysis of the LCOE

A sensitivity analysis was performed to identify the parameters with the most substantial effects on the LCOE. Table 7 lists the parameters and the corresponding results of the sensitivity analysis. The results of one configuration are shown in this work, because they are comparable to those of the other configurations. Only the absolute values differed among configurations. The fluctuation of the purchase costs exerted the greatest influence on the LCOE. The lower and upper limits of the purchase costs corresponded to 2020 and 2022, respectively. With a relative deviation of around 18.7 %, investment costs also have a major influence on the LCOE. Fluctuations between 6 and 10 percent occur with different period of time and debt interest rate. Due

to the large uncertainties in LCOE, these configurations are not suitable to evaluate economic viability. In this work, LCOE is applied to compare the different configurations.

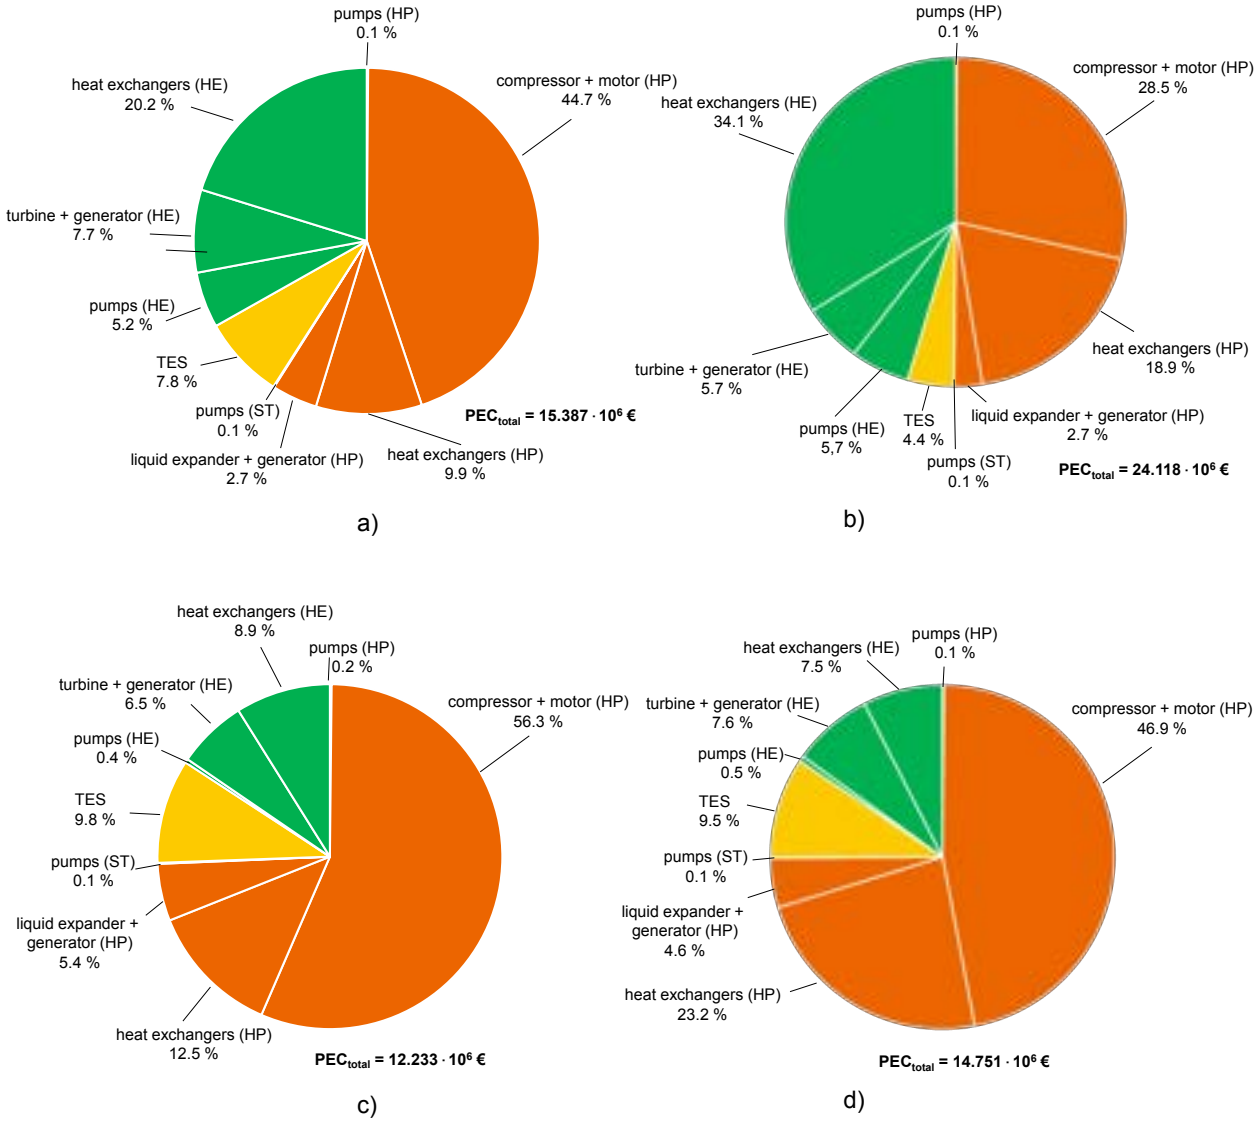

Figure 3: PEC distribution for configuration 1 a) with a pinch point of 5 K, b) with a pinch point of 1 K and for configuration 6 a) with a pinch point of 5 K and b) with a pinch point of 1 K.

Table 7: Sensitivity analysis of the LCOE for configuration 1 with a pinch point of 5 K

Parameter	**Value**	**Variation of LCOE**
Investment costs I	$0.7 \cdot I_{\text{base case}}$	-18.68 %
(base case: $72.935 \cdot 10^6$ €)	$1.3 \cdot I_{\text{base case}}$	+18.68 %
Factor for operational costs F_{op}	1 %	-5.14 %
(base case: 1.5 %)	2 %	+5.14 %
Period of time n	20 years	+9.95 %
(base case: 25 years)	30 years	-6.48 %
Debt interest rate i	2.39 % [34]	-7.20 %
(base case: 3.49%)	4.69 % [34]	+8.38 %
Purchase cost of electricity $c_{\text{el,in}}$	1.82 €cents $(\text{kWh})^{-1}$	-16.21 %
(base case: 6.64 €cents $(\text{kWh})^{-1}$)	16.31 €cents $(\text{kWh})^{-1}$	+32.54 %

4. Technology Readiness Level

The technology readiness level (TRL) scale of the European Commission [35] is a method used to assess the maturity and readiness of a technology or concept. The TRL scale ranges from 1 to 9, with 1 being the

Table 8: TRL scale [35]

Phase	TRL level	Condition
Research	1	Basic principles observed
	2	Technology concept formulated
	3	Experimental proof of concept
Development	4	Technology validated in lab
	5	Technology validated in relevant environment
	6	Technology pilot demonstrated in relevant environment
Deployment	7	System prototype demonstration in operational environment
	8	System complete and qualified
	9	Actual system proven in operational environment

lowest level of technological maturity and 9 being the highest. In the following section, the TRL is applied to the subprocesses.

4.1. Evaluation of the Subprocesses

CO_2 heat pump
CO_2 heat pumps using positive displacement machines and throttle for expanding CO_2 are already offered on the market. However, these are limited in their capacities [14]. A configuration similar to the concept in this study was developed and successfully implemented in the form of a test rig by MAN Energy Solutions [12, 13]. The necessary components are also offered by this company. Instead of a displacement machine a barrel compressor is used, enabling a higher capacity. As a result, the subprocess is classified as TRL6. Since there is not evidence yet of a prototype in a relevant operational environment, a TRL of 7 is not achieved.

Two-zone storage
This storage system is assigned a TRL of 8 because it is already being used in various facilities [15], but is not yet in mass production.

CO_2 heat engine
The CO_2 discharging process has been studied experimentally [36]. Therefore, a TRL of at least 3 is achieved. One manufacturer offers a commercial system [37] based on a supercritical process and with high temperature heat supply. In our study, a lower heat supply temperature of 115 °C is used. Consequently, the subprocess is assessed as TRL = 5, and still needs further testing and development under operational conditions to achieve a TRL of 6.

ORC with R600a
In Grünwald, Germany [16], an ORC process with isobutane as the working fluid is already used to generate electricity. An electrical output of 4.3 MW is achieved at a geothermal spring inlet temperature of 135 °C,. Consequently, the subprocess achieves a TRL of 8.

ORC with R134a
A geothermal power plant using the working fluid R134a is in operation. The power plant is able to generate 5.5 MW of electrical power using a geothermal spring with an inlet temperature of 118 °C [16]. Therefore, the HE is assigned a TRL of 8.

ORC with R290
Propane is widely used as a working fluid in refrigeration systems [20]. So far, only one research group [38] is known to use propane in their transcritical process for geothermal power generation. Hence, the subprocess results in a TRL of 5.

ORC with R1234yf
R1234yf was developed as a replacement for R134a. ORC with this working fluid has been investigated and verified through numerical simulations, achieving a TRL of 3. However, a prototype or experimental investigation has not yet been developed or conducted, which is necessary to achieve a TRL of 4 [19].

4.2. Evaluation of the Overall Process

The TRL of the overall processes is determined by the lowest TRL resulting from the subprocesses. Configurations 2 with R600a and 3 with R134a reach the highest TRL level with 6. The lowest TRL level is reached by configuration 6 with R1234yf.

5. Discussion

Under the assumption of a pinch point of 5 K, the investigated configurations achieved round trip efficiencies between 9 % and 22 % and LCOEs between 123 and 214 €cents $(kWh)^{-1}$, with Configuration 1 using CO_2 in

the heat engine process achieving the best results. Reducing the pinch point demonstrated that configurations using subcritical processes result in better round trip efficiencies and substantially lower LCOEs. Compared to Configuration 1 with CO_2 in the discharge process, increasing efficiency by 11.5 % results in a higher LCOE because in the greater heat transfer surface area between the hot water and CO_2 during the discharge. This results in high component costs. Configurations 2 and 3 with R600a and R134a, respectively, achieved the highest overall TRL and therefore enable prompt implementation. The ORC fluid R134 achieved better results compared to isobutane. However, because of its high global warming potential (GWP), this fluid may be excluded from ORC processes in the future by the European Union.

Although Configuration 1 with a pinch point of 5 K showed the highest round trip efficiency, the lowest LCOE, and an overall TRL of 5, this combination with the environment as a heat reservoir is unsuitable because if the ambient temperature increases, the evaporating pressure and temperature in the heat engine approach the critical point of CO_2, leading to technical problems. One possibility is the combination of an ice storage with an intermediate circuit. However, in this case, a heat exchanger must be integrated into the process to dissipate the heat generated by irreversibilities from the system to the environment. Nevertheless, indirect ice storage adds further costs and irreversibility.

CBs based on transcritical CO_2 cycles showed a substantially higher round trip efficiency in some studies [4, 7–9, 11]. The reason for this is primarily due to the utilization of different CBs. First, the CBs use a second storage tank at a low temperature, integrated directly into the subprocesses, either with ice slurry storage [9] or ice storage [7]. Because of the high pressure of the working fluid (CO_2), ice storage is not feasible [13]. Ice slurry storage tanks are uncommon [39], resulting in a lower TRL level. Higher round trip efficiencies also result for pressurized tanks with water at high storage temperatures, as shown in previous publication [4]. Moreover, multiple high-temperature storage tanks are employed to improve the temperature glide between CO_2 and the storage medium (water). This necessitates the use of multiple heat exchangers, which substantially increase the complexity of the system.

Furthermore, unlike the approach taken in this study, many publications do not account for losses in the motors and generators, and rely solely on machine for the expansion process during charging, which could make the system unfeasible from a technical point of view.

Another improvement in round trip efficiency is achieved through supercritical discharge processes and ORC fluids as working fluids [11]. However, this requires higher storage temperatures and the use of alternative storage media in case the storage medium exceeds 160 °C. Furthermore, an appropriate compressor that can achieve high temperatures is needed for the charging process. Consequently, a low TRL is expected.

Under simplified assumptions, such as the absence of storage heat and pressure losses, the actual forward and return efficiencies of the system are expected to be lower than those predicted by the configurations.

6. Conclusion and Outlook

In this study, CBs based on a transcritical CO_2 charging process with an electrical power input of 18 MW were numerically modeled and simulated stationarily, using the Ebsilon software. A two-zone storage tank with water as a storage medium at a maximum temperature of 115 °C was used. For the discharge, a transcritical CO_2 process and subcritical processes with different organic working fluids were investigated and compared to each other on the basis of round trip efficiency, LCOE, and TRL. With a pinch point of 5 K, Configuration 1 (transcritical CO_2 HE) resulted in the highest round trip efficiency and the lowest LCOE. Despite an overall TRL of 5, this configuration is unsuitable for implementation because the operating points of the evaporator in the HE approach the critical point as the ambient temperature increases, which could lead to technical problems. The other configurations resulted in very low round trip efficiencies, leading to a high LCOE. By reducing the pinch point in the heat exchangers, the efficiencies can be increased, which has a positive effect on the LCOE. Among the subcritical processes, the working fluid R1234yf (Configuration 6) could be an alternative. However, this variant was classified with the lowest TRL level. Similar round trip efficiencies and LCOE at a higher TRL level were achieved with the ORC fluid R134a (Configuration 3). However, the refrigerant R134a has a high global warming potential and is already banned in the automotive sector [40]. The same TRL level was achieved with R600a (Configuration 2), which has the highest LCOE due to its poorer round trip efficiency. The economic values were estimated under considerable uncertainties, as the sensitivity analysis on LCOE showed. Detailed information on component costs and a full financing calculation are required for an economic evaluation of the configurations, as well as the specifications of an accurate plant design, such as the isentropic efficiency of the turbine, compressor, and pumps. With a uniform charging and discharging time of 4 h, the LCOEs are very high, but can be reduced if the charging and discharging duration increases. Because Configuration 1 is excluded as a possible option in this study, replacing the environment as a storage unit with ice could be considered in further investigations to obtain an overview of the possible round trip efficiency, LCOE, and TRL compared to the configurations studied here.

Appendix A

Table A.1: Component parameters used in Ebsilon

Parameter	Symbol	Value	Unit
Isentropic efficiency compressor	$\eta_{is,compressor}$	85	%
Isentropic efficiency liquid expander	$\eta_{is,expander}$	85	%
Isentropic efficiency pumps	$\eta_{is,pump}$	80	%
Isentropic efficiency turbine	$\eta_{is,turbine}$	85	%

Abstract:

Today lithium-ion stands out among the various battery technologies in vehicle applications thanks to their good energy density, low self-discharge and the absence of the memory effect. Nevertheless, lithium-ion batteries pose many challenges such as driving range, lifespan, safety issues and also the charging time which is still significant

In order to reduce the charging time, it is necessary to inject a very high current into the battery which may drastically raise its temperature and thus reduce its lifespan. Today, in most cases, the battery pack of an electric vehicle is cooled through flat cooling plates, mounted either by the lateral or the bottom surfaces. These cooling plates can also be used to warm up the battery in cold weather. But during the fast charge, this configuration poses some problems and can be not efficient enough to cool or heat the batteries.

In this study, a battery module is thermally managed not only by the bottom cooling plate but also by a second cooling plate placed on the busbars. According to simulations and experimental tests regarding one case study, this configuration makes it possible to not only cool the module more quickly by reducing the thermal time constant by 47% but also reduces the battery maximum pick temperature reached with a conventional cooling system by 6°C. It stands out that the top cooling plate acts like a thermal bridge which unifies the temperature inside the battery module and thus support the equal ageing process of the batteries.

Keywords:

Electric vehicle, batteries, thermal management, cooling plate, thermal gradient, lifespan

1. Introduction

The battery pack is the only and main source of energy of an electric car, and to be able to replace an internal combustion engine vehicle, several technical challenges exist that engineers and specialists must face, in order to both increase the autonomy and lifespan while reducing the charging time. Lithium-ion batteries (LIBs) have gradually evolved from a variety of technologies due to their low self-discharge rate, high energy density and lack of memory effect, this type of batteries has revolutionized the energy storage technology and enabled the mobile revolution [1]. Li-ion batteries are available in different shapes and configurations, including cylindrical, prismatic and pouch cells. Temperature is one of the key limiting factors for battery pack performance and lifetime. Temperature heterogeneity inside LIBs causes different electrochemical reaction rates within the cells. This can lead to uneven current density distributions, local State of Charge (SoC) differences and local ageing differences, which may not only accelerate the global ageing, but also reduce the accessible energy of the battery. Temperature rise and spatial temperature gradient minimization inside the cell is among the main thermal challenges during fast charge [2]. Thermal Management Systems (TMS) are employed in majority of vehicles to counter these challenges [3]. A 5°C variation in temperature can reduce the battery pack's capacity by

1.5–2% [4], and its power capabilities by 10% [5]**.** To improve cooling capability of LIBs, various researchers have incorporated different cooling techniques. Nowadays, liquid cooling, air cooling and phase change material are widely adopted for battery thermal management. Depending on the technical requirements and cost, battery pack manufacturers can use one or several cooling methods. The TMS can be classified into active cooling and passive cooling.

Active cooling consumes extra energy for pumps and fans powering but still more efficient than passive cooling[6]. The active liquid cooling can also be classified into direct-contact and indirect contact. For indirect contact, the liquid is a combination of water and ethylene glycol to avoid liquid freezing at low temperatures inside the cooling plates, while for direct contact, the liquid must be dielectric to avoid any short-circuits. Recently, the direct-contact liquid cooling method has gained increased attention due to its high cooling efficiency [7]. The battery thermal management serves to monitor, control and maintain the optimum operating temperature conditions of a battery. The items that are considered in designing the cooling plate are: (a) the cooling plate should maintain the temperature of batteries at the manufacturer's recommended temperature during normal operation, (b) the cooling plate should dissipate maximum possible heat from the batteries in case of thermal runaway, (c) the coolant pressure drop inside the cooling plate should be minimized, and (d) the size and weight of the TMS should be minimized [8].

Although the above research has achieved remarkable results in battery thermal management, some challenging questions remain: (a) there is little previous literature on battery inner thermal gradient minimization based on both experimental tests and simulations, (b) so far, little work has investigated the benefits of cooling and heating the batteries by putting a cooling plate on top of the battery module, and its role in the battery thermal management.

The aim of this study is to better manage the battery temperature by reducing not only the pick maximum temperature but also the inner thermal gradient, by adding a cooling plate on top of the battery module. The objectives of the present work are as follow:

-perform different experimental tests on a battery module managed thermally in the first case by a bottom cooling plate and then by a top and bottom cooling plates
-compare the results of both technologies in term of thermal management
-build a model and do the calibration using the data acquired during the experimental tests
-use the model to investigate other scenarios in extreme conditions (current and temperature), and of course assess the role of top cooling plate in the battery temperature variation. The last sections conclude and give perspectives on the research topic

2. Electrothermal modelling of Li-ion batteries

2.1. Battery module model

The battery module consists of 12 prismatic cells connected with busbars to form a 3p4s battery module as represented in the Fig. 1(a). To model the battery module, a fine modeling of its constituents is necessary, by modeling the cells in Fig. 1(b) and also the busbars. Fig.1(c) shows the cover detached from the casing and also the Jelly roll (JR) which represents the heart of the cell and the main part of the battery.

In this section the proposed model is established. With the current, the initial temperature, and the environment temperature as inputs, the model can predict the internal temperature distribution and the state of charge of the battery. The battery module model consists of three sub models, a thermal model, an electrical model based on Electrical Circuit Network ECN and a heat generation model.

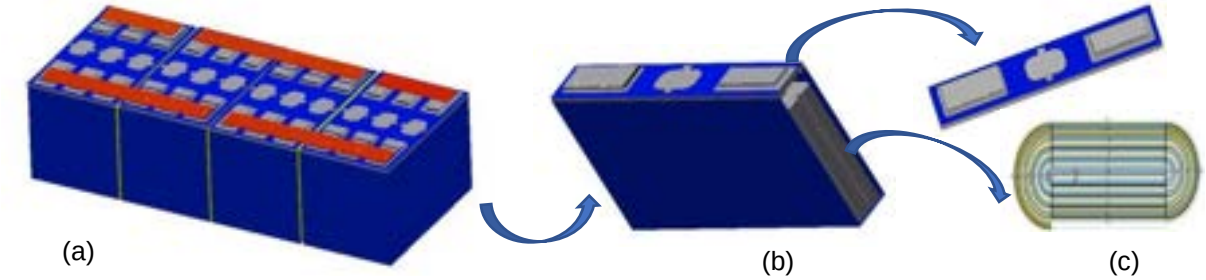

Figure. 1. Structure of the studied system: a) battery module, b) battery cell, c) Cover detached from the casing and JR inside the battery cell

One of the most critical steps for developing battery prognostics solutions is to establish a battery model which enables the auto-maker to simulate battery behavior and interpret battery issues in a form that can be understood by users and designers [9].
Different methods from the electrical, thermal, mechanical and electrochemistry perspectives have been used to establish different battery models, and the dynamic behaviors of the battery regarding different charging/discharging rates and temperatures have been investigated. Among the various battery models, electro-thermal modeling is commonly used to study the relationship between the current and the temperature of battery. The battery electro-thermal model couples the electrical and thermal models closely. The initial inputs of the electrical model are the discharge current, the SOC level and the temperature. The inputs of the electrical model generates heat for the thermal model, this last provides a temperature output signal. Then this temperature signal is fed back to the electrical model, since the new temperature affects the electrical parameters such as the internal resistance.

Generally, the heat generation of the battery Q_{gen} during charge and discharge contains two parts: reversible and irreversible heats, and it can be expressed by Eq. (1). The entropy change is responsible for the reversible heat Q_{rev} which can be expressed by Eq. (2), and the irreversible Q_{irr} heat the heat generated by ohmic resistance is expressed by Eq. (3)

$$Q_{gen} = Q_{irr} + Q_{rev} \tag{1}$$

$$Q_{rev} = I\, T_b \frac{dOCV}{d\, T_b} \tag{2}$$

$$Q_{irr} = I^2 R \tag{3}$$

In order to avoid the accumulation of heat at the level of the cell, this heat is often exchanged with the neighboring elements of the cell by conduction Q_{cond}, or dissipated by different TMS by convection Q_{dis}. The two modes of heat exchange are detailed in the two equations below Eq. (4) and Eq. (5) respectively

$$Q_{cond} = \frac{(T_{neigh} - T_B)}{R_{th}} \tag{4}$$

$$Q_{dis} = h_{conv}(\, T_{env} - T_B) \tag{5}$$

The battery temperature is affected by various heat transfer paths. To reduce the battery temperature, part of the heat generated has to be dissipated to the external environment in order to avoid the heat accumulation and thus reduce the temperature raise [10].

2.1.1. Battery cell model

The research object is a commercial 67 Ah prismatic battery cell. The battery cell specifications are tabulated in table 1.

Table 1. Specifications of the battery cell

Specification	$Value$
Cathode material	NMC
Anode material	Graphite
Nominal capacity	67Ah
Cut off voltages	2.8-4.2V
Dimensions	150mm 30mm 100mm
Thermal conductivities	40-2.5-40 W/m.K
Thermal capacity	1200 J/Kg.K

The battery cell is a complex system since it consists of several elements such as JRs, a casing, a cover and electrical insulating films. To finely model the cell, the JRs and the casing are modeled in order to be able to represent the thermal behavior of the battery by having a temperature response at each point of the cell whether at inside or outside. The JR and the casing modeling approaches are now described.

2.1.1.1 JR modeling

The challenge is to be able to visualize and quantify the temperature gradients within the cell, while having a model that can be simulated in seconds so that it can be embedded on an electric vehicle. Considering the complex geometry of the JR, it was necessary to design a mesh which makes it possible to represent all the heat exchanges in all directions inside the cell. To successfully reproduce the thermal behaviour of the JR, it is essential to provide a reliable mesh able to represent as good as possible the heat exchanges within the JR, and good assessment of the cell inner thermal gradient. The proposed model consists of meshing the JR in thickness as well as in height. The particularity of this mesh compared to what could be found in literature, is that it takes into account the orthoradial direction which shows that the heat can be exchanged between the meshes by going around the windings. The Fig. 2 shows the proposed mesh by considering the three directions, axial (according to the height of the JR), radial (normal to the winding), orthoradial (parallel to the winding).

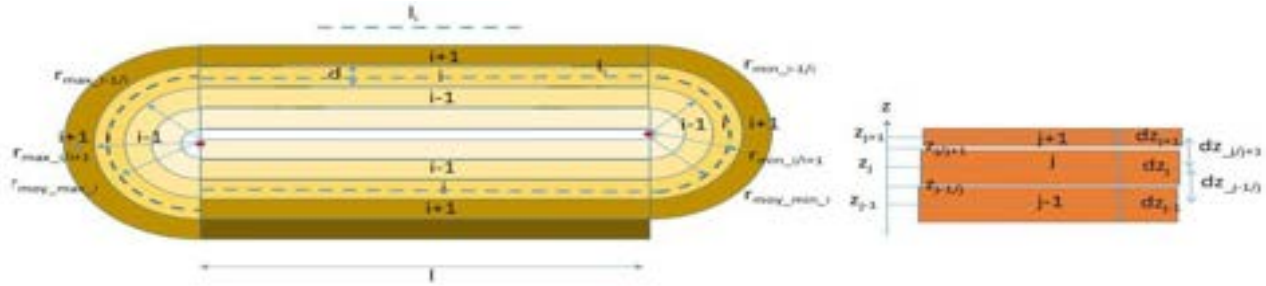

Figure. 2. The proposed mesh of the JR

The JR is obtained by wrapping the electrodes around a hollow space. Each turn is qualified as an elementary layer which is made of different sub layers. Each elementary sub layer has its own thermal conductivity and capacity, its own thickness as well as its own density. All these essential data for the thermal model are taken from literature in absence of having been able to obtain them from the supplier. The JR model is well detailed in [11] with all the equations that represent the physics at the JR level.

To summarize, the heat generated by a mesh i,j can be calculated according to the following equation:

$$\dot{Q}_{i,j} = R_{30s\,i,j} I^2{}_{i,j} + I_{i,j} T_{i,j} \frac{\partial OCV_{i,j}}{\partial T_{i,j}} \tag{6}$$

2.1.1.2 Casing modeling

To get a full model of the cell, the JR have to be linked to the other elements of the cell that surround it, starting with the casing which acts as a thermal bridge between the JR and the external environment. In order to visualize the thermal gradient on the casing, the latter is meshed in height, and each mesh j of the casing is connected with a mesh imax,j of the JR. Since the casing is made of aluminium, its specific characteristics are known.

2.1.1.3 Busbar modeling

The busbar modeling strategy consists of breaking down the busbar into meshes and assign to each mesh the following Fourier equation:

$$m_{BBi} C_{BB} \frac{dT_{BBi}}{dt} = Q_{generated} + Q_{dissipated} + Q_{exchanged\ by\ conduction} \tag{7}$$

where m_{BBi} is the mass of a mesh i,j of a busbar, C_{BB}, $Busbar$ specific heat capacity, and $Q_{generated}$ represents the heat generated mostly by Joule effect according to eq. (8) ,

$$Q_{generated} = \frac{\rho\, l_{BBi}}{S_{BB}} * I^2 \tag{8}$$

$Q_{dissipated}$, denotes the heat dissipated either by natural or forced convection, and $Q_{exchanged\ by\ conduction}$ represents the heat that could be exchanged between the busbar and the upper part of the tab and also with the neighbouring meshes of the busbar. The fig. 3 shows the meshed busbar. The heat exchange by radiation was neglected in this paper.

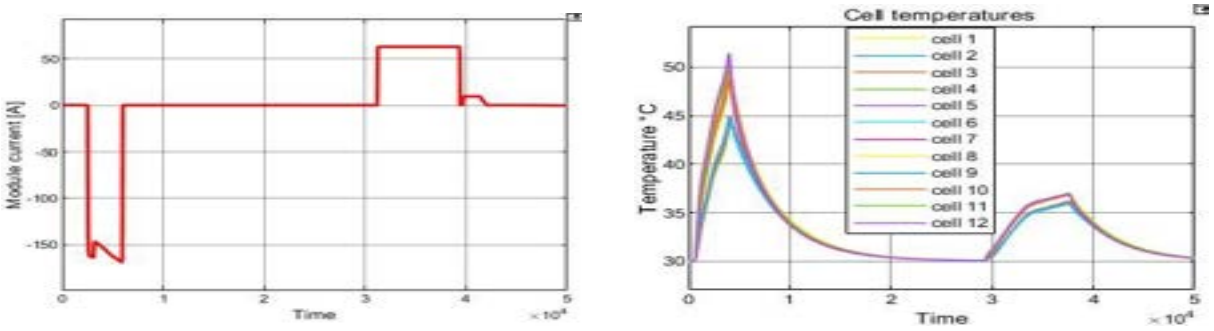
Figure. 3. The meshed busbar connecting six cells

2.1.1.4 Battery module model

Once the battery cell model is well obtained, it is duplicated 12 times to form the 3p4s module model, thus the module is made of 4 blocks of 3 cells each. The cells of the same block are coupled thermally through the busbars as well as through the meshes of their casings. Once the block is built, it is duplicated four times by assuming that the cells are identical, and they have all the same characteristics. Then the four blocks are coupled thermally together through busbars to form what we call a 3p4s battery module.

Figure 4(b) shows the temperature responses of the 12 cells for the current profile represented in the Fig. 4(a). This current profile was chosen to represent both charge and discharge scenarios, and also investigate the electrical resistance variation as function of SoC.

The hypothesis are not detailed for this part, because the goal is to show that the model allows to have the temperature responses of the twelve cells for a given current profile, the assumptions will be detailed in the part dedicated to (results and comparison).



(a) (b)

Figure. 4. Simulation results after building the model: a) Input current, b) cells temperatures

2.2. Model calibration

Before starting the calibration of the module model, some assumptions have been considered.

2.2.1. Assumptions

The following assumptions have been made for model calibration

-the cells inside a module are all identical

-the presence of thermal spacers between the blocks means that the only thermal path between the block of cells becomes the busbars

-the electrical resistances between the busbars and the tabs are considered null.

-the temperatures of the air in the climatic chamber and of the liquid circulating inside the plates are constant throughout the test.

-the initial and boundary conditions of the model are supposed to be suitable to the experiment conditions

(a) (b) (c)

Figure.5. Battery module thermal management: a) module without any cooling plate, b) module with bottom cooling plate, c) module with top and bottom cooling plates

2.2.2. Battery module without any cooling plate

In order to calibrate the model detailed above, some electrothermal tests have been carried out on the 3p4s module. The first tests have been carried out on the module without any cooling plate as shown in the Fig. 5(a), and the goal is to reproduce correctly the thermal and electrical responses of the twelve cells. At first the battery module has been put in a climate chamber. So, the first parameter to be determined was the heat exchange coefficient h_{conv}. The second parameter was the contact electrical resistances between the electrical load and the battery module terminals. These contact electrical resistances can play a very important role in the thermal behavior of the batteries, especially when the contact is bad.

2.2.3. Battery module with a top and bottom cooling plate

The same electrothermal tests have been carried out, first on the battery module coupled to a bottom cooling plate (first case see the Fig. 5(b)) and then on the battery module coupled to the top and bottom cooling plates (second case as shown by the Fig. 5(c)).

Once the data acquisition is done through thermocouples, the goal was to assess the benefits of adding the cooling plates and then compare the technologies in term of efficiency in thermal management of the batteries. At the model level the only parameters that had to be determined in order to reproduce the thermal responses of the cells were: (a) the thermal resistances between the bottom cooling plate and the bottom surfaces of the cells for the first case and (b) the thermal resistance between the top cooling plate and the busbars for the second case.

3. Measurement setup and test procedures

A dedicated test stand has been developed to assess the efficiency of the cooling system extended with a cooling plate through the upper surface on which the connection electrodes are installed. All experimental tests were performed for the same battery module at the same, strictly controlled conditions. Each time, preconditioning procedure was preceded to reach the same initial state of charge and state of health of the tested battery module before tests. The test stand consists of the Li-Ion battery module, the thermal management system, charging/discharging system and a control and acquisition system.

3.1. Tested battery module

For the evaluation of the cooling improvements, the high-power battery module has been selected. The battery module was made of 12 Li-Ion prismatic cells connected in the 3s4p setup. Technical parameters of the cells were listed in subsection 2.1.

3.2. Thermal Management system and thermal test procedure

The thermal management system consists of two water cooling plates, water chiller and thermal chamber. As shown in Fig. 6, the battery module was placed in the thermal chamber. The bottom dedicated cooling plate was connected in parallel with top cooling plate and supplied from the chiller CW-6100AN. The inlet temperature of purified water was control by the chiller. Cooling plates were integrated with battery module through 3 mm thick thermal pad.

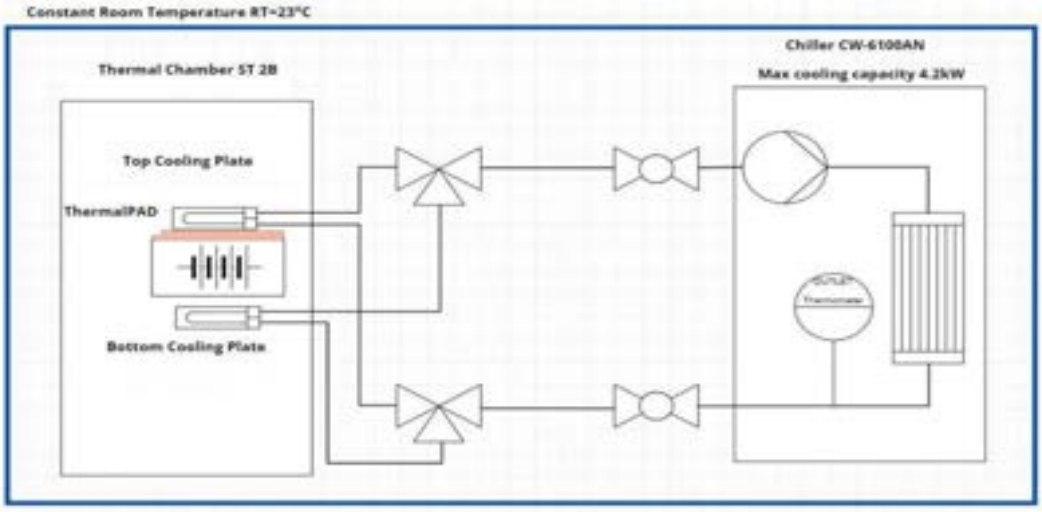


Figure. 6. The diagram of the thermal management system

4. Experimental results

4.1. Charging battery module

The thermal response of the battery module was measured during charge test, where coolant temperature was set at T_C = 20 ºC and ambient temperature was T_A = 25 ºC. The thermal response of battery module with only bottom cooling plate during the charge test is shown in Fig. 7. The temperature of a bottom cooling plate was measured by sensor labeled as T_{cp} which was placed between battery module and cooling plate. Temperature inside climate chamber was recorded by two sensors TA and TA1. Time constant for this process equals to τ = 5700s. Maximum temperatures were recorded on terminals of tested module. The temperature 49.6°C was recorded by sensor 37. The highest temperature recorded inside battery module exceeded 43°C (sensor 19, sensor 20, sensor 21) and it was recorded during highest charge current I_{CHA} = 190A. On the other hand, the lowest temperature was recorded on side walls of battery module, and it did not exceed 37°C (sensor 43, sensor 45, sensor 41 and sensor 40).

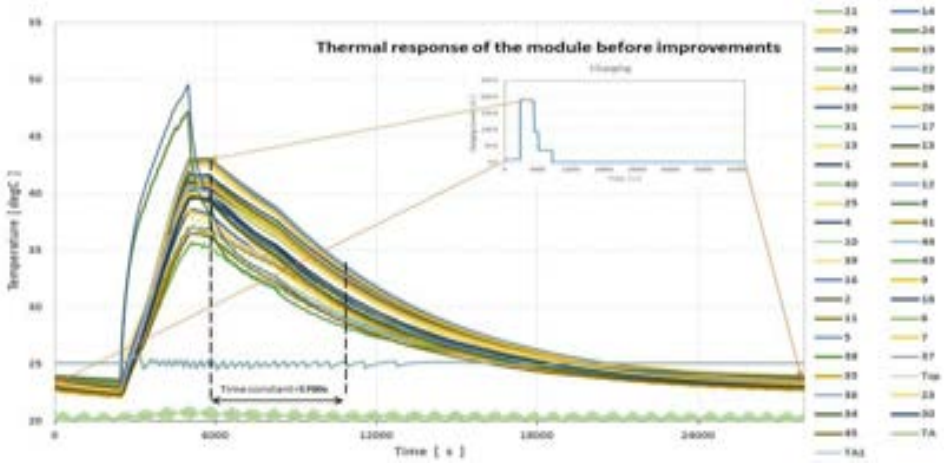

Figure. 7. Thermal response of battery module with bottom cooling plate during charge process, where T_A = 25 ºC, T_C =20 ºC

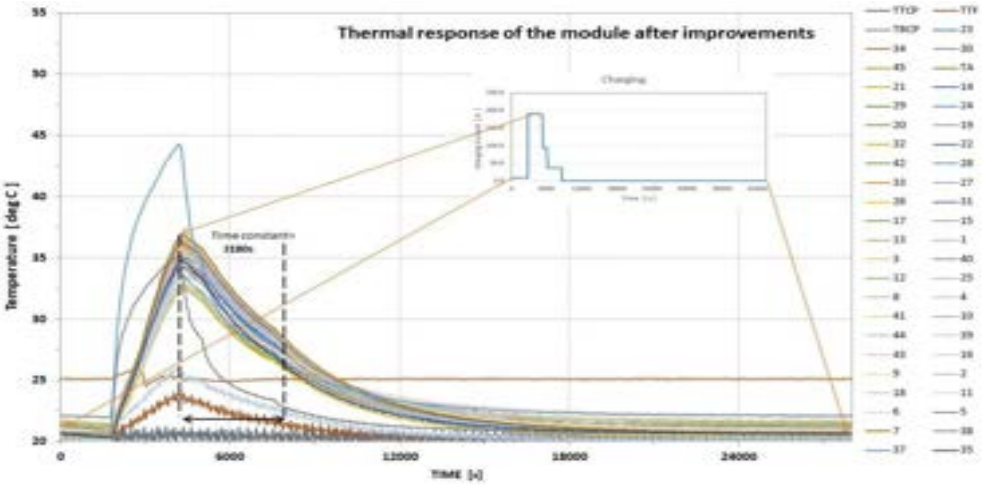

Figure. 8. Thermal response of battery module with top and bottom cooling plate during charge process, where T_A = 25 ºC, T_C =20 ºC

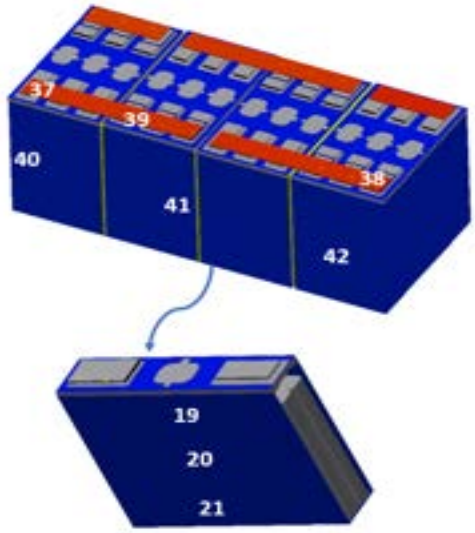
Additional top cooling plate caused drop of maximum temperature measured on terminals to 44°C (sensor 37) and 35°C (sensor 38) as shown in Fig. 8, and also the drop in the average temperature of battery module. Highest temperature recorded by sensors placed inside the battery module (e.g. sensor 19, sensor 20, sensor 21) was 37°C and it was lower by 6°C in comparison to the test with only one cooling plate. Temperature on the side walls of battery module did not exceed 33°C. Cooling time constant was decreased by 44% from τ = 5700s to τ = 3180s. Another advantage of adding the top cooling plate is clearly visible with a smaller temperature discrepancy inside the battery module from

7°C to 3.5°C. Therefore, the aging process of batteries inside the battery module can be easily controlled. Average relative improvement rate equals to 21%. The highest improvement (37%) was recorded for sensor 38 placed on one of terminals. Average relative improvement inside the battery module was around 19%.

The thermocouples described above are shown in the figure bellow.



Sensor position		Sensor number
Module external busbar connection	Negative side	37
	Positive side	38
Module busbar cell connection	4th cell from module negative side	39
Module side plate	HV connector side (module negative side)	40
	HV connector side (module middle side)	41
	HV connector side (module positive side)	42
	Non-HV connector side (module negative side)	43
	Non-HV connector side(module middle side)	44
	Non-HV connector side (module positive side)	45

Sensor position		Sensor number
Cell casing greatest surface	Upper of surface	19
	Middle of surface	20
	Bottom of surface	21

Figure 9. Layout of the temperature sensors

4.2. Discharging battery module

After charging tests, the discharge test was conducted with T_A = 25°C and T_C = 30°C. In Fig. 10, thermal response of battery module with only bottom cooling plate during the investigation is given. The same test was conducted once again for battery module equipped with bottom and top cooling plates. Thermal behavior of the module is shown in Fig. 11. Differences in C-rate profile caused longer time constant for cooling process which was equaled to τ = 7260s. For this case study, the time constant was decreased by 55% in the tests with two cooling plates. Maximum temperatures before and after adding the top cooling plate (45°C and 43°C) were recorded on terminals of battery module. Maximum recorded temperature after improvement inside the battery module dropped by 2°C, but on the other hand the temperature inside the module was more uniform in a test with top and bottom cooling plates. At t = 6000 s, the temperature difference measured inside the battery module and on external walls dropped by half from 5°C to 2.5°C. It stands out that the average relative improvement rate was 31%.

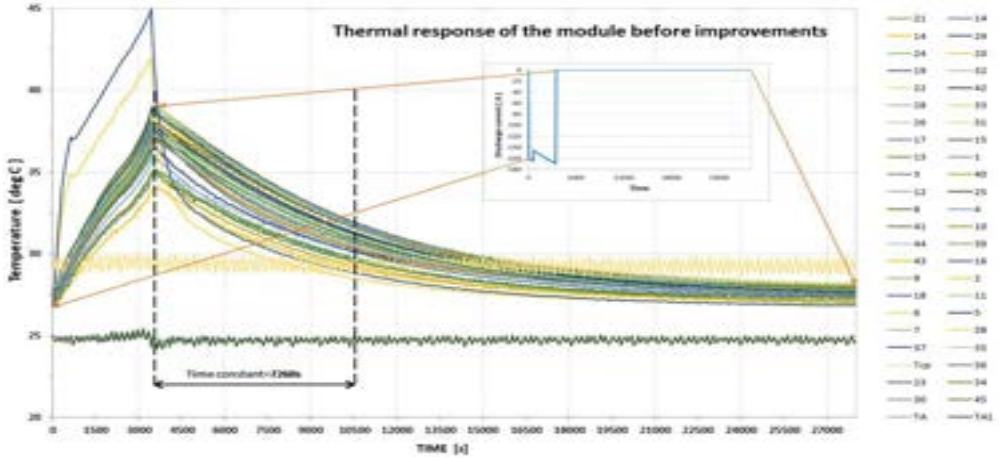


Figure. 10. Thermal response of battery module with bottom cooling plate during discharge process, where T_A = 25 ºC, T_C =30 ºC

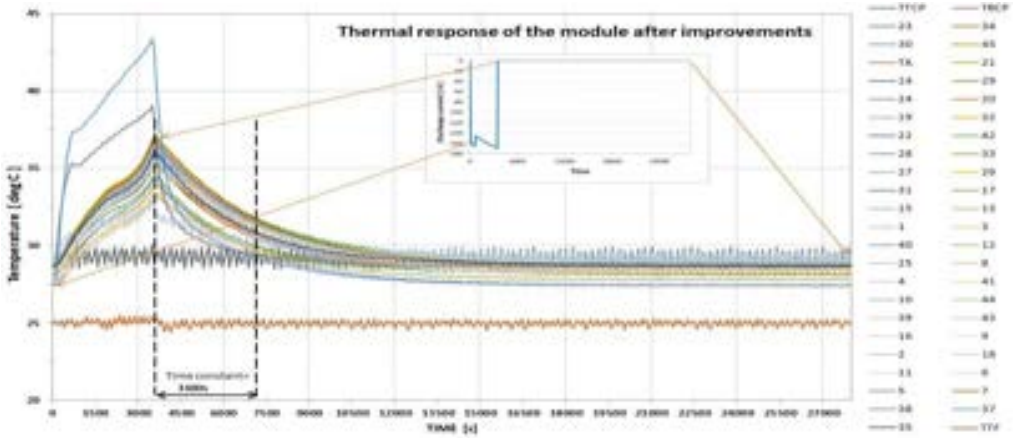

Figure. 11. Thermal response of battery module with top and bottom cooling plate during discharge process, where T_A = 25 ºC, T_C =30 ºC

5.Results comparison

Different electrothermal tests have been carried out to validate the battery module model. In this paper for the sake of brevity, only one test will be discussed.

In this test, the current profile used to validate the model is shown in Fig. 12(a). The advantage of this current profile is that it allows to scan the entire SoC range in order to check the lookup-tables of the electrical resistances of the batteries during charge and discharge as well as that of the OCV, this current profile also permits to assess the effect of the current amplitude on the thermal and electrical responses of the batteries.

The experimental test conditions have been taken into consideration and some simplifying assumptions and boundary conditions have been set in order to simulate the model and compare the obtained signals with those of the experiment:

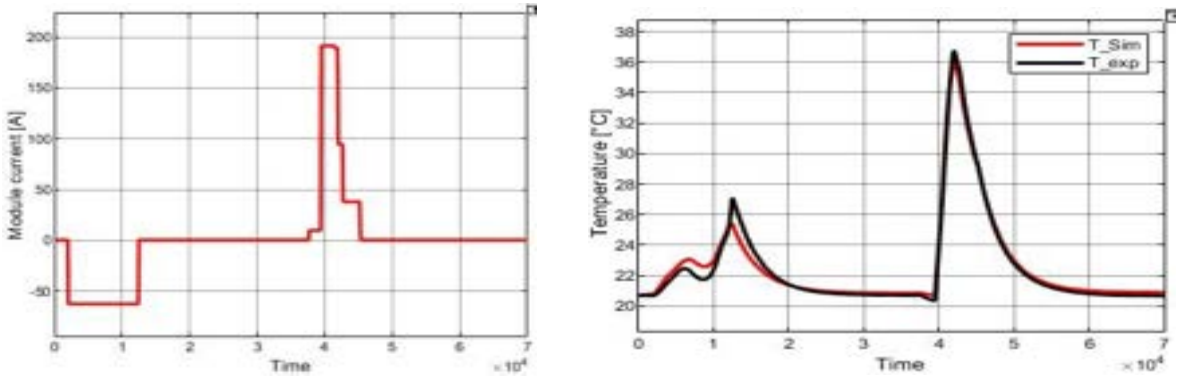
-the module is cooled with the top and bottom cooling plates

-the air temperature is set at 25°C and coolant temperature at 20°C

-the initial temperature is set at 20.7°C

-one cell of the module is targeted to do the comparison between the model and the experiment, and the considered thermocouple is fixed at the center of the great surface of this battery

The Fig. 12(b) shows the temperature response of the model in red compared to the temperature given by the thermocouple in black.



(a) (b)

Figure.12. Model validation results: a) Input current, b) cell temperature

In this section a comparison between the three configurations presented in the Fig. 5 has been done in order to assess the benefits of adding the cooling plates regarding the battery module thermal management. According to the Fig.13, the third configuration (module with top and bottom cooling plates) represented by the blue color is the most efficient in term of thermal management, and it's the

best way of extracting and dissipating the calories generated by the battery during charge and discharge. As a consequence, the maximum pick temperature is reduced compared to the configuration represented by the black curve where the module is cooled only by the bottom cooling plate. Also, one can note that the time constant is shortened which proves the efficiency of this configuration.

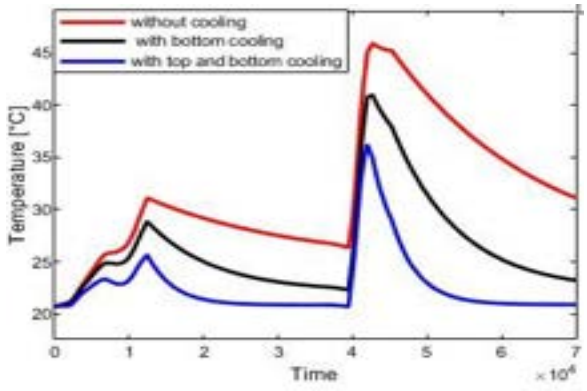


Figure. 13. Thermal management system performance

6.Conclusion

In this study, a methodology of battery module modelling is proposed, by taking into account the battery cells, the busbars and also the thermal spacers between the battery cells. A qualitative study is done on a battery module by investigating the benefit of adding the top cooling plate in the overall battery module thermal management. According to simulations and experiments regarding one case study, the configuration with top and bottom cooling plates makes it possible to not only cool the module more quickly by reducing the thermal time constant by 47% but also reduces the battery maximum pick temperature reached with a conventional cooling system by 6°C. Different electrothermal tests have been carried out to validate the battery module model with different scenarios in term of air/coolant temperatures and current profiles in (charge and discharge). It stands out that the model has a good reproducibility, and the error is always below the thermocouple's uncertainty. It stands out also that it gets easier and more efficient to extract calories from the batteries by adding the top cooling plate.

In this paper, only the prismatic cells are concerned, but the methodology can be applied on different battery types and for different battery module topologies.

Abstract:
The basic technological principle of a Carnot Battery is to transform electricity into heat, store the heat and transform the heat back into electricity and/or heat. This technology has been developed more and more in the last years. This study considers the integration of a 10 kW Carnot battery in a district heating in a building with photovoltaic panels. It allows to provide both thermal and electrical peaks shaving. Few prototypes exist up to now and a clear methodology to size a Carnot battery properly does not exist. This paper tries to draw guidelines based on a state of the art, simulation models and lessons learnt from experimental campaigns. The idea is to help engineers to develop Carnot battery which are cheap, robust and efficient.

Keywords:
Carnot battery, electrical energy storage, district heating, heat pump, Rankine cycle, Thermal Energy Storage.

1. Introduction

1.1. Context

The share of electricity production needs to increase sharply in the next decades to decrease the impact of humans on the environment. However, there is a significant mismatch between renewable energy production and consumption. This means that electrical energy storages will play a very important role in the future. A recent alternative technology has therefore been studied for several years: the Carnot battery [1-4].

1.2. Carnot battery

The principle of a Carnot battery is rather simple: a heating cycle converts electricity into thermal energy, to store it and to use a power cycle to convert it back to electrical energy when needed. Different configurations are possible to achieve a Carnot battery (CB): the considered technology in this paper is a heat pump (HP) combined with a Rankine cycle (RC) [1-4]. This technology is interesting because it relies on massively produced components (low-cost), it allows the integration of heat flux trough the low operating temperatures and one single machine can replace the combination of the HP et RC (reversible HP/RC) [5-8].

1.3 Thermal integration

Typically, the power-to-power ratio (P2P), defined as the electrical energy output (discharge) divided by the electrical energy input (charge) is below 60% for classical CB. This is the reason why it can be helpful to valorize heat fluxes in the system to improve its performance. There are two different options to integrate heat into a CB. On the one hand, the hot storage configuration uses a heating system (heat pump in this example) to increase the waste heat temperature. This allows the power cycle (RC in this example) to increase its performance by working with a higher temperature difference. On the other hand, the cold storage configuration stores thermal energy at temperatures lower than the ambient (through a vapor cycle in this example). Once again, it allows the power cycle to work efficiently with a higher temperature difference.

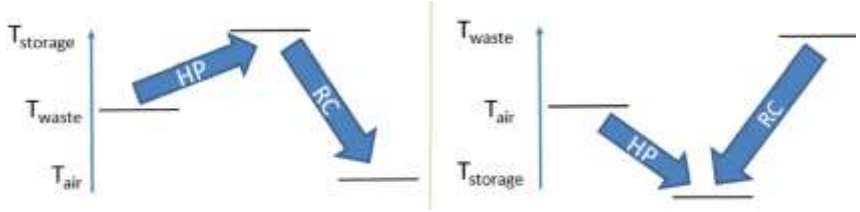

Figure. 1. Hot storage configuration versus cold storage configuration [4].

1.4 District heating

The coupling of a Carnot battery, using a hot water tank as thermal energy storage, with a district heating (DH) is promising. Figure 2 depicts an illustrative theoretical example of the system. First, it can shave the DH thermal consumption of the building (Fig. 2) through a direct use of the stored hot water. Secondly, the excess renewable production converts thermal energy from the DH in a hot water tank at higher temperature (Fig. 2). When the electrical power consumption of the building exceeds the renewable production, the CB (Rankine Cycle - RC) can convert the thermal energy into electricity to cover the electrical peak (Fig. 2).

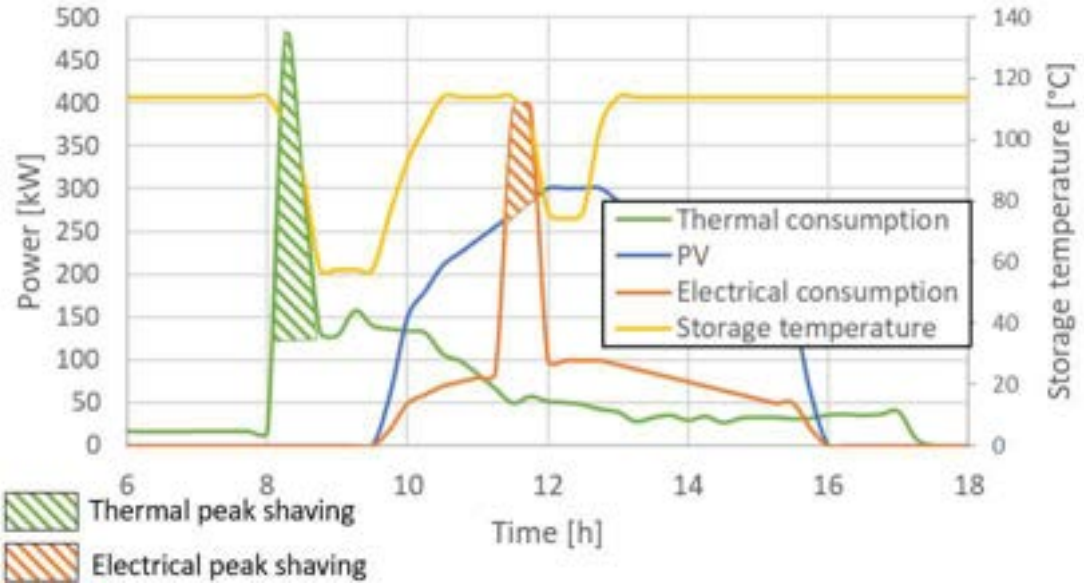

Figure. 2. Coupling of a Carnot battery using a hot water tank with a district heating

Few papers discuss the integration of such a CB with a DH. In 2019, some authors [9] show the interest of the system compared to electro-chemical batteries. To the author best knowledge, [10] is the only paper discussing the design of a CB using a reversible HP/RC system. The authors show the interest of having one single machine to decrease the investments (reversible volumetric machine and reversible heat exchangers). Several fluids have been considered and the optimal fluid is selected (R1233ZD) [11]. Also, the trade-off in the glide of the storage (difference between high and cold temperature) is highlighted: a high glide leads to low roundtrip efficiency while a low glide leads to a bulky hot water tank (and related high investments) [11].

1.5 Aim of the paper

This paper is only focusing on Rankine based Carnot batteries. After a short introduction, the methodology of optimal and robust sizing is exposed. The case study is described: the integration of a Carnot battery in a district heating system. Following this, the optimal design is presented. The objective is to propose a machine which is robust, optimized and cheap. Finally, a discussion analyses the results and provides guidelines for future machines.

2. Methodology

2.1. Case study

The case study is the thermodynamics laboratory of the ULiège (Belgium). Typical annual energy consumption from the DH is 344 MWh, the electrical production from PV is 568 kWh and the electrical consumption of the building is 105 MWh. The DH operates typically between 65°C and 75°C with morning peak up to 470 kW (15 mins – see Figure 2). According to Uliège data, the electrical consumption presents very high peaks (up to 200 kW) for short periods of time (few minutes), the electricity price is assumed to be 0.3 eur/kWh (buy) and 0.1 (sell) and the cost of the thermal heat from district heating is 0.07 eur/kWh.

2.2. Method

As this section will show, there is a large number of possible configurations to design a CB integrated in a given case study. For this reason, it is helpful to have guidelines to select which one should be the most profitable before performing detailed simulations. It is also possible to simulate all the configurations but this is time consuming and usually this step can be simplified thanks to some guidelines (Figure 3).

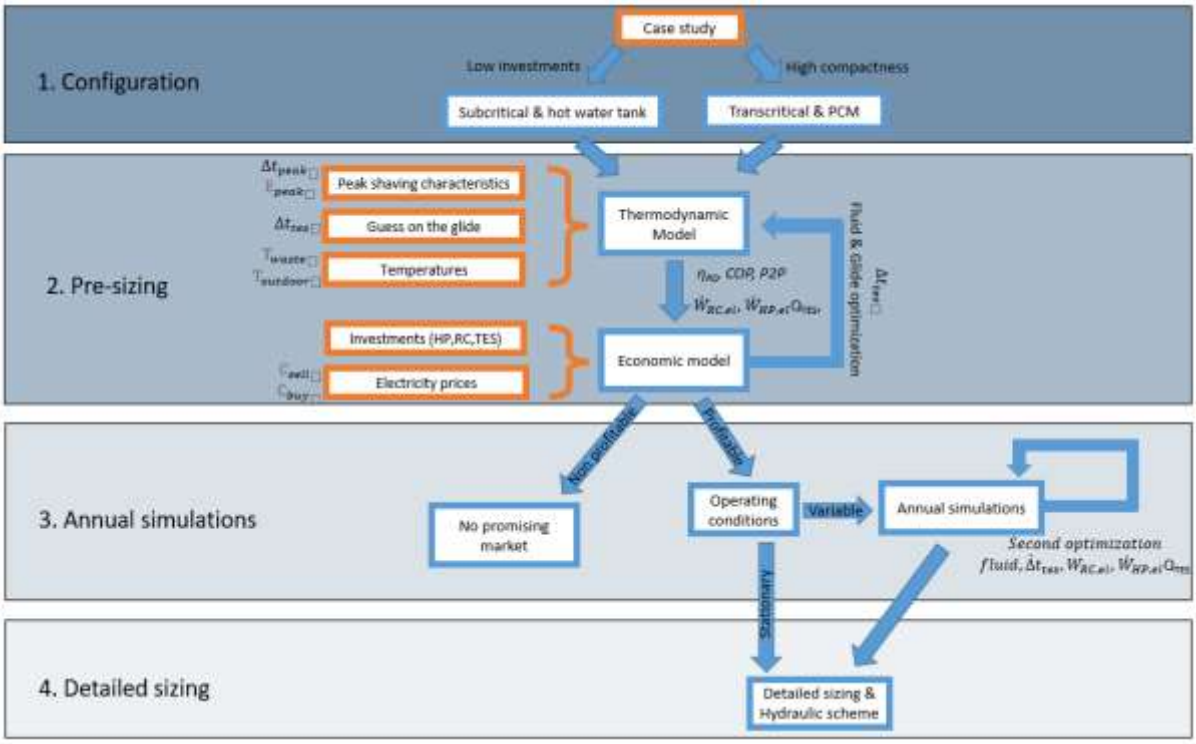

Figure. 3. Flowchart to perform the sizing of a Carnot battery based on a Rankine cycle.

2.2.1. Configuration: Selection of the configuration based on the case study

Depending on the system, constraints could be different from one application to the other.

Classically, the configuration for Rankine based Carnot battery uses a hot configuration (see section 1.3) with a subcritical thermodynamic cycle and a hot water tank. If the application presents temperature close to 0°C, then the cold configuration seems promising [10]. If no heat flux is integrated, if the heat flux allows a high temperature glide (>50 K) or if a high compactness is required, a transcritical cycle is more suitable. If an application requires a low glide, a rather low power density and a high energy density, PCM could be profitable.

Table 1. Selection of the configuration

Configuration	*Hot* Higher efficiency [11]	*Cold* Optimal for ice storage
Thermodynamic cycle	*Sub-critical* Cheap	*Transcritical* Optimal for high glides (>50 K)
Thermal energy storage	Hot water tank Low cost	PCM Optimal for low glides

2.2.2. Pre-sizing: Sizing based on the nominal conditions (temperature, power and capacity)

The main parameter to optimize is the glide of the thermal energy storage. The high thermal energy storage temperature should be optimized in order to obtain a compromise between high revenues (low glide – high power-to-power ratio) and low investments (high glide - compact storage). In the nominal point, the low temperature of the thermal energy storage should be slightly above the highest temperature of the thermal flux (waste heat or district heating) [10,11]. To start the design procedure, let's assume a guess glide (e.g. 25 K). This value will be optimized a posteriori.

Boundary conditions of the case study needs to be known (outdoor temperature, electricity price – buy (C_{buy}) and sell (C_{sell}), energy production from renewable, electrical consumption of the building and other thermal fluxes (E_{heat})). Also, the peak consumptions (thermal and/or electrical), which have to be shaved, should be identified in terms of power and duration. A decent approximation is to consider that the power of the RC $\left(\dot{W}_{RC,el}\right)$ should be able to cover the difference of power between the electrical peak consumption and the base load consumption. Another approximation that can be done at this step is to consider the same power for the HP and for the RC. This allows to get comparable discharge/charge durations. Based on the nominal conditions and the a priori chosen glide, it is possible to evaluate the efficiency of the Rankine cycle

and the COP of the HP. In some cases (high glides, low waste heat temperature) the COP can be very low and therefore an electrical resistance could be more profitable. Based on the RC efficiency and the COP of the HP, it is possible to identify the power-to-power ratio with a constant efficiency model [11]. An open source Matlab model using Coolprop with documentation is available [12]. The thermal energy storage should be able to store energy to cover the peak duration (Δt_{peak}). If the peak shaving is related to the thermal consumption, the capacity of the thermal energy storage (Q_{TES}) is straightforward. If the aim is to perform electrical peak shaving, the capacity of the storage can simply be computed as Eq. 1. At this step, it is important to check if the energy of the thermal flux (waste heat or district heating) is sufficient.

$$Q_{TES} = \frac{\Delta t_{peak} \dot{W}_{RC,el}}{\eta_{RC}} \quad (1)$$

This calculation allows to compute the HP power, the RC power and the storage capacity for a given glide. The yearly benefits (Eq. 2) are expressed as the gains from electricity production of the RC (E_{RC}) and from the eventual sub-sizing of the electrical or thermal and electrical substations ($fees_{red}$) minus the cost (electricity consumed by the HP (E_{HP}) and eventual cost of the thermal flux - E_{heat}).

$$Benef_{yearly} = E_{RC} + C_{buy} - E_{HP} - C_{sell} + fees_{red}(\dot{W}) - (E_{heat}.C_{heat}) \quad (2)$$

The investment can be estimated through literature for the RC [13], the HP [14] and the thermal energy storage [15]. Therefore, it is possible now to simulate a wide range of glide to optimize a chosen economic indicator (Pay-Back Period, Return On Investments…). At this point, if the system does not produce benefits, the integration of a Carnot battery for the application could be of lower interest (too low-price variability, too low temperature of waste heat…). Iterations on the TES glide and the working fluid [11] are necessary to obtain the final design.

2.2.3 Annual Simulations: perform yearly simulations /off design model/control

If the working conditions of the system are similar every day of the year, this step could be skipped. If not, yearly simulations should be performed for a more detailed performance evaluation. Optimally, a dynamic model should be developed. However, since this is time consuming, a steady-state model can be used in a first approach. An optimal control strategy is mandatory in order to optimize the performance and the profitability of the system. At this step, it is possible to optimize in a more accurate way the glide, the RC and HP powers and the storage capacity.

2.2.4 Detailed sizing

The power of both heat pump and RC, the glide and the capacity of the storage are defined. The selection and sizing of heat pump components are classical and manufacturers can provide accurate performance data. Generally thermostatic expansion valves are preferred because of their low cost but, in some cases, electronic expansion valves can be used (highly variable operating conditions). For the Rankine cycle, a reference book presents the process of sizing and selection for the components [17]. This paper will therefore not focus on these aspects which are already well documented. However, some specific comments can be highlighted for Carnot batteries.

If HP and RC conditions are similar, it is interesting to consider the mutualization of some components. Sometimes, only heat exchangers are shared between the HP and the RC [7,8,10] but it is also possible to use the same volumetric machine to act as a compressor and as an expander [16]. High efficiencies of the compressor and expander are crucial to obtain promising performance [6]. In this configuration it is important to control actively the circulating charge of working fluid in the system in order to obtain a high robustness and optimized performance [8]. Also, in the case of volumetric machines, the oil circulation must be ensured through a dedicated oil loop or through an optimal sizing of the piping in order to ensure sufficient speed of working fluid to entrain the oil [6]. Finally, it is possible to keep the working fluid flow direction identical in HP and RC (classical configuration) or to invert the direction of the working fluid (inverted configuration). Few comparisons exist between both systems and more information can be found in [6].

3. Results and discussion

The case study is described in section 2.1. The methodology from section 2.2 is applied to the case study to illustrate the design flowchart.

3.1. Configuration

The first step is to choose a given configuration. Because of the absence of compactness constraints, a classical sub-critical cycle with a hot water tank is chosen according to Table 1.

3.2. Pre-sizing

According to section 2.1, electrical peaks appear for a very short fraction of the time. However, thermal consumption peaks occur every morning during 15 mins. Therefore, the sizing of the machine is performed according to the thermal discharge mode. It would make less sense to size a Carnot battery to shave the electrical peak if it is only used less than 1% of the year.

From there, knowing the daily thermal consumption peak power (≈400 kW) and its duration, the capacity of the hot water tank is calculated (100 kWth). The temperature spread of the district heating is from 63°C to 77°C. Knowing this and temperature levels, the hot water tank volume can be deduced (6.1 m^3). The HP is sized in order to get a full refilling of the thermal energy storage in one hour and a half (this value comes from the PV profiles and electrical consumption of the building). Therefore, the condenser power of the HP is 80 kW. Based on the temperature levels and power aforementioned, the sizing model can be run [12]. Since the working conditions of HP and RC are similar, a reversible HP/RC system is considered. The given design values are summarized in Table 2.

Table 2. Sizing of the components

Mode	Charge - HP	Discharge - RC
Electrical power [kW]	10.7	5.6
Condenser power [kW]	82.5	94.6
Evaporator power [kW]	67.3	100
Cold temperature [°C]	62	20
Hot temperature [°C]	76	70
Scroll efficiency [%]	69.5	61.8
COP/eta [-]	7.69	5.5
Optimal volume ratio [-]	1.68	3.04
Evaporator pressure [bar]	3.34	4.05
Condenser pressure [bar]	6.02	1.18
Condenser flow (sf) [l/s]	1.4	2.6
Evaporator flow (sf) [l/s]	3.2	2.99
Working fluid mass flow rate [kg/s]	0.422	0.449
COP/eta with rv optim [-]	1%	11%

3.3. Annual simulations

Simulations of the systems have extensively been described in a former paper [18]. It confirms that the pre-sizing is economically interesting.

Results, presented in table 3, show the Carnot battery expected performance when working in each possible operating mode: the HP runs to charge the storage for about 1967 hours during a year of operation, producing about 97509 kWh of thermal energy at the expense of 19672 kWh of renewable electricity surplus, working with an average COP of almost 5; over an operating year, 65133 kWh of thermal energy is reconverted into 5331 kWh of electricity, by the Carnot battery working in RC mode for about 1296 hours, with an average efficiency of 7.92 %; eventually, for a total of 290 hours per year, the Carnot battery works in pure thermal discharge mode to cover the early morning thermal demand peaks (peak shaving), for a total amount of 18036 kWh of thermal energy.

The economic convenience of adding the Carnot battery to the integrated system is evaluated in terms of pay-back (PB) period, which is obtain dividing the Carnot battery investment cost by its annual economic benefit: the investment cost includes the HP/RC cost (a specific cost of 2000 €/kW has been considered [4]) and the TES cost [15]. The economic benefit represents the differential gain between two scenarios, namely with and without the Carnot battery intervention, that is the sum of positive and negative contributions (represented as revenues and expenses in figure 4): the positive ones are due to the DH substation downsizing (lower DH substation investment costs), the thermal demand covered by the Carnot battery instead of been provided by the DH, and the RC production both for selling and self-consumption; while the additional negative contributions include the reversible HP/RC and storage levelized investment costs, and the HP electricity consumption both from photovoltaic (PV) surplus and grid purchase. As a result, the PB period is assessed to be slightly more than 6 years, which is acceptable considering 30 years as typical lifetime period for these systems.

Table 3. Annual results

Mode	Charge - HP	Discharge - RC	Thermal discharge
Average COP/efficiency [-]	4.957	0.0792	-
Electrical energy [kWh]	19672	5331	-
Thermal energy [kWh]	97509	65133	18036
Running hours [h]	1967	1296	290
Pay-Back Period [years]		6.12	

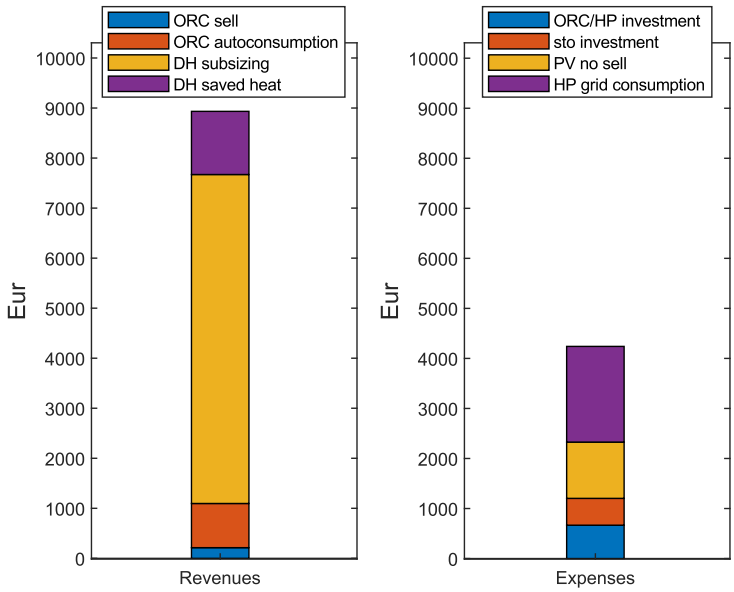

Figure. 4. Carnot Battery annual revenues and expenses

3.4. Detailed sizing in the case of the described case study

Unfortunately, it was not possible to find a suitable volumetric machine that can work properly in HP and RC mode. The proposed solution is to use three machines in parallel (table 4). Two scroll compressors ensure the compression for the HP (see Fig. 5) while three scrolls can be used for the RC (higher volumetric flow rate). The scrolls are run at constant speed. The glide of the RC is optimized to a value of 8 K for the RC. The last line of the table refers to the loss of efficiency related to the inadapted volume ratio of the volumetric machine compared to the optimal one. It would have been better to work with a machine able to vary its volume ratio actively to optimize the performance (no products were found in this operating conditions). A centrifugal pump is chosen because volumetric pumps are less robust and needs a higher degree of sub-cooling [6]. The heat exchangers are sized to reach a low pinch-point (2 K) since it significantly impacts the global performance. Also, the pressure drop on the refrigerant side is limited to 50 mbars. The expansion valve of the heat pump is electronically controlled. The liquid receiver volume is 10 liters, in order to adapt the charge depending on the operating mode.

Table 4. Description of the components

Component	Parameter	Value
Volumetric machines	Swept volume [cm3]	121
	Volume ratio	1.7
	Shaft speed [RPM]	6000
Pump	Volumetric flowrate [l/s]	0.5
	Shaft speed [RPM]	3000
LP heat exchanger	Area [m2]	15.2
	Number of plates [-]	120
HP heat exchanger	Area [m2]	17.8
	Number of plates [-]	140
Hot water tank	Volume [m3]	7
	Thermal isolation thickness (PU) [mm]	125

The layout of the system is presented in figure 5. The idea is to control the refrigerant charge through the valves. In HP mode, VLR and VEV are open while VPP is closed. In RC mode, VPP is open while VLR and VEV are closed. VEV can be opened for a short period in case there is not a sufficient charge in RC mode.

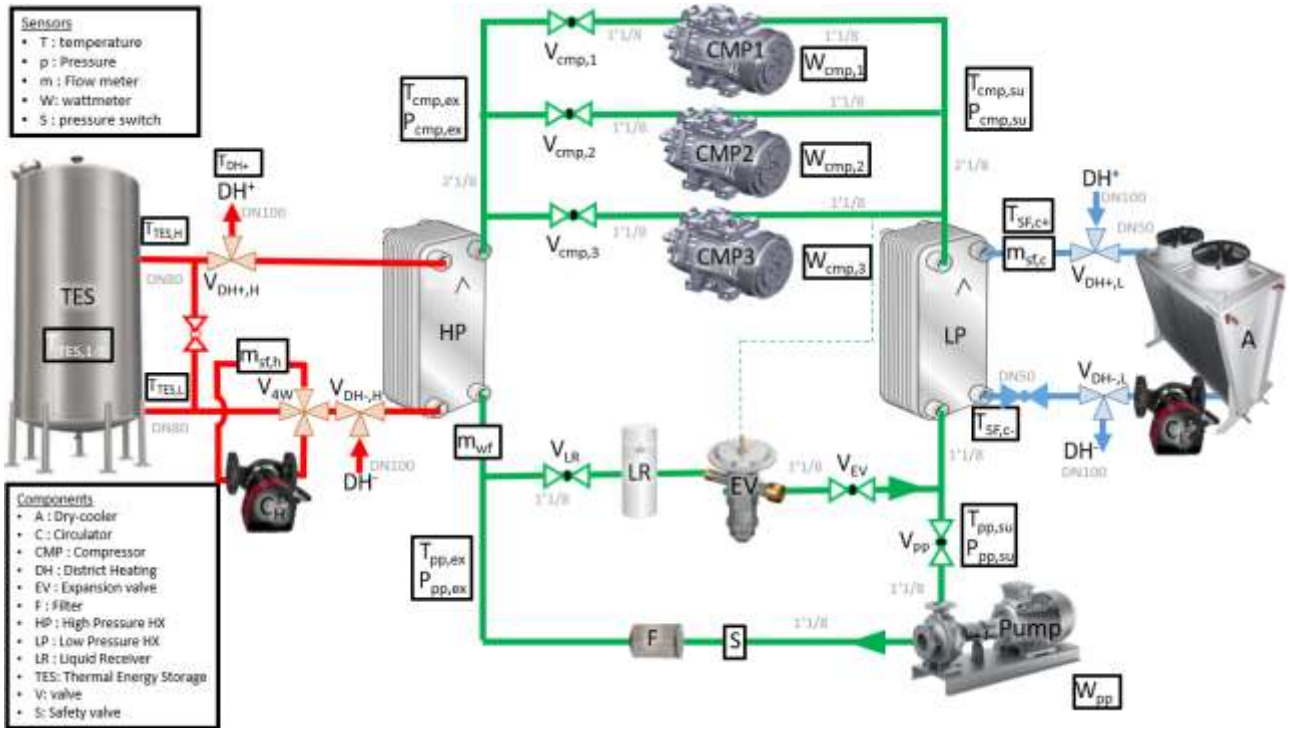

Figure. 5. Hydraulic scheme of the Carnot battery integration

In figure 5, DH- refers to the exhaust piping of the district heating (cold) while DH+ is the supply piping of the district heating (hot). In thermal discharge, the hot water circulator (CH) sends cold water from the district heating (DH-) to the hot water tank while hot water from the tank is sent to the hot part of the district heating (DH+). The other components are not used in this mode. In HP mode, the evaporator (LP heat exchanger) takes the heat from the dry-cooler or from the DH. Then, hot water is produced in the condenser (HP heat exchanger) and sent to the top of the hot water tank. In RC mode, the district heating is not used. The evaporator (HP heat exchanger) receives hot water from the top part of the thermal energy storage. The condenser dissipates its heat through the dry-cooler.

Conclusion

The design of a Carnot battery is a complex task (there are a lot of layouts, technologies and operating parameter to choose and optimize). This paper proposes a simplified approach to choose among the possible configurations and to size the components. The idea is, based on the state of the art and on experimental results, to ensure an optimal design with realistic hypothesis. An illustrative case is presented with a 10 kWe machine integrated to a district heating. The next step is to test the machine and to analyze the experimental results.

Abstract:

A liquid air energy storage is a novel technology receiving substantial interest for balancing the supply and demand of energy because of its high energy density and not being geographically constrained. The main challenge of the liquid air energy storage system demonstrated so far is its low round-trip efficiency. Internal heat recovery, using hot and cold thermal energy storages, increases the round-trip efficiency of the liquid air energy storage. High temperature thermal energy storages are widely studied for different applications. However, the poor performance of the cold thermal energy storage is currently a bottleneck to achieve cost-effectiveness of the liquid air energy storage system. That is due to the very low temperatures and the large temperature span of the cold energy storage. In this paper, two types of cold thermal energy storages, a packed-bed sensible storage and a latent heat storage with cryogenic phase change materials, were applied to a stand-alone liquid air energy storage system. A one-dimensional transient numerical model was developed to analyse the storage systems. The round-trip efficiency, liquid air yield, and expansion work of the liquid air energy storage system were evaluated considering both storage options. The results indicate that the latent heat packed bed storage configuration has higher round-trip efficiency (41 %), liquid yield (58.1 %), and power output (42 MW) than those of the configurations with sensible heat storage. However, there are some sensible materials, like quartzite rocks that, with the same volume of the packed bed, perform as well as cryogenic phase change materials due to their high densities.

Keywords:

Cold thermal energy storage; Latent heat storage; Liquid air energy storage; Packed bed rock thermal energy storage; Phase change materials; Sensible heat storage.

1. Introduction

Large-scale energy storage systems are promising options to mitigate the variability of renewable energy sources and to balance the energy supply and demand [1,2]. Liquid air energy storage (LAES) is a novel technology that has recently gained increasing attention. The LAES system is not geographically restricted and requires much less storage volume than those of the more mature technologies – in the order of 700 times less than that of compressed air energy storage [3,4]. The LAES system comprises three processes: 1) charging process – excess electricity (e.g. from wind and/or solar energy) is used to drive a liquefaction process, 2) storing process – liquid air is stored in cryogenic tanks at nearly ambient pressure, and 3) discharging process – the liquid air is pressurized, regasified and expanded in turbines producing electricity. At present, the LAES technology is at an industrial demonstration level. The main challenge that the LAES system confronts is its low round-trip efficiency, the ratio of the electricity generated during the discharging process to the electricity consumed during the charging process, in comparison to other energy storage systems such as a compressed air energy storage [5]. The round-trip efficiency of the LAES system can be improved by introducing hot and cold thermal energy storages, which allow for the internal recuperation of

hot and cold fluid streams. However, the designs of the heat exchangers and thermal energy storages present some challenges – specifically with respect to the cold thermal energy storage system. So far, various studies have been conducted on High-Grade Cold Energy Storage (HGCS). Broadly speaking, HGCS can be divided into three types: storage using fluids (methanol and propane) [6], using packed beds (such as rock and pebbles) [7], and using phase change material (PCM) [8]. So far, various research studies on LAES systems have been done specifically focused on cold storage systems with different designs, and a majority of those consider packed bed rock storage systems.

Wang et al. [9] applied a dynamic model to analyse the performance of a standalone LAES system by using sensible heat packed bed rock storage for both the cold and hot energy storages, achieving a round-trip efficiency of 43 %. She et al. [4] studied an LAES system with a two fluids system for the cold energy storages and thermal oil for hot energy storage and attained a round-trip efficiency of 53 %. Ryu et al. [10] analysed a LAES system based on the Linde-Hampson refrigeration cycle using a combination of sensible and latent heat packed bed storage systems as the cold energy storage unit. A round-trip efficiency of 60.6 % was obtained. In this case the required temperature for liquefying air could be provided continually during the phase change of the PCM. Tafone et al. [11] investigated a cold thermal energy storage for the LAES system by using a cryogenic PCM. It was found that by using cryogenic PCM as the storage medium, the temperature at the outlet of the packed bed is limited by the melting point of PCM and therefore, the temperature of the heat transfer fluid at the inlet of cold box is lower than the case with sensible heat particles which reduces the compressor power requirement.

Bashiri Mousavi et al. [12] studied a packed bed with three layers of different PCM as a cold storage system of the LAES system and reached a round-trip efficiency of 42.5 % when the system has reached equilibrium. They designed the packed bed's tank with the PCM with lowest melting point located at the bottom of the tank and the PCM with highest melting point placed at the top of the tank. Sciacovelli et al. [13] used a modular packed bed system filled with quartzite rocks. They validated their numerical model with experimental of the LAES pilot plant available at the University of Birmingham, UK. They also investigated the effect of charging and discharging pressure on the round-trip efficiency of the LAES system. It was observed that there is an optimum value for charging pressure that results in the maximum round-trip efficiency (50 % under nominal conditions). Guo et al. [14] developed a dynamic model to analyse the packed bed as the cold energy storage in the LAES system. Granite was used as the storage material and the results suggested that because of both the intermittent period between charging and discharging cycles and the cold energy loss, the round-trip efficiency is 16.8% lower than that of the ideal system in quasi-steady state. Tafone et al. [15] developed a performance map for the LAES system. They investigated the effect of various parameters including turbomachinery isentropic efficiency, storage pressure of liquefied air in the tank, efficiency of hot and cold energy storage, charging and discharging pressure, and the ratio of recirculation mass flow rate. It was observed that increasing the liquid air tank pressure enhances the heat capacity of the recirculation fluid. In turn, this increases the efficiency of the cold box unit, and, as a result, the system's performance becomes independent of the charging pressure.

Wang et al. [16] applied a two tanks system with pressurized propane as the heat transfer fluid for cold energy storage in the LAES system and obtained an electrical round-trip efficiency of 50 % as well as a combined heat and electricity efficiency of up to 81%, using the excess heat available in the hot energy storage system as the heat source. Hüttermann and Span [17] studied nine different storage materials in a packed bed for the cold energy storage unit of the LAES system. The results demonstrated that the system with lead has the maximum efficiency of the packed bed cold storage among other materials due to its lower variation of specific heat capacity over the temperature span than that of the other storage particles. Peng et al. [18] developed a model to investigate the performance of an LAES with sensible heat packed bed (using rocks as the particles) as the cold energy storage. They found that the round-trip efficiency of LAES system is affected by the inlet temperature of cold box, charge and discharge pressure. A maximum round-trip efficiency of 62 % is reachable for optimal conditions for the LAES system.

Storage systems with two working fluids have the disadvantage of using working fluids that are usually flammable [9] and the necessity and using four tanks, increasing the complexity for industrial applications.[9] In this context, a packed bed energy storage system with sensible or latent heat particles is a promising technology for cold storage systems for industrial LAES systems. This technology can relatively easy be integrated into the LAES system and covers the entire temperature range of the cold storage in a single tank. In addition, because of large latent heat of PCMs, PCM based storage has a high energy density, which makes it suitable as a storage medium.

The objective of this paper is to identify the optimum storage medium for cold storage packed bed system in stand-alone LAES systems. Three different materials were investigated: quartz and silicon dioxide as sensible materials and an alcohol-based fluid as latent heat PCM. The materials are used in the form of particles placed in a tank. A thermodynamic model of the LAES system integrated with a 1-dimensional transient numerical model of the packed bed system was developed. The round-trip efficiency, liquid yield, and turbine output are compared for the three different cold thermal energy storage units for the LAES system. There is only a single previous study available in the open literature comparing sensible and latent

heat materials for packed bed cold storage for LAES applications [11]. However, in Ref. [11] different storage materials for the packed bed cold storage were evaluated solely in terms of storage performance. In contrast, the current paper presents, for the first time, an analysis of the effects of different storage materials for the packed bed cold storage on the LAES performance. Such analysis will be useful both for industry and academia for the future development of cold energy storage units for LAES systems.

In the following, section 2 discusses the methods. Section 3 presents and discusses the results obtained from numerical simulations, while section 4 summarizes the conclusions of the work.

2. Methods

2.1 System description

Figure 1 shows a schematic diagram of a liquid air energy storage system (LAES) with two tank hot and packed bed cold energy storages. The proposed system consists of a charging cycle and discharging cycle. The charging cycle consists of multi-stage compressors, air-oil heat exchangers with the thermal oil VP1, a cold-box, a cryo-turbine, a gas-liquid separator, and a liquid air tank. The discharging cycle consists of a cryo-pump, an evaporator, air-oil heat exchangers, and multi-stage turbines. In order to utilize the cold energy, a cold packed bed storage is located between the charging and discharging cycles. Packed bed storage improves the cycle efficiency by exchanging heat between the charging and discharging processes. When the electricity price is low, the air is compressed through multi-stage compressors. Initially, the cold packed bed storage transfers cold energy to the compressed air, causing the temperature of point A7 to decrease to a cryogenic temperature (A8) inside the cold box. After the cooling process, compressed air is expanded to ambient pressure through a cryo-turbine and separated into liquid (A_Liq) and gaseous forms (A10). At peak hours (during a discharge process), liquid air is evaporated while the cold energy is stored in the packed bed cold storage. Gaseous air is heated in the thermal oil heat exchangers and expanded through air turbines to generate electricity.

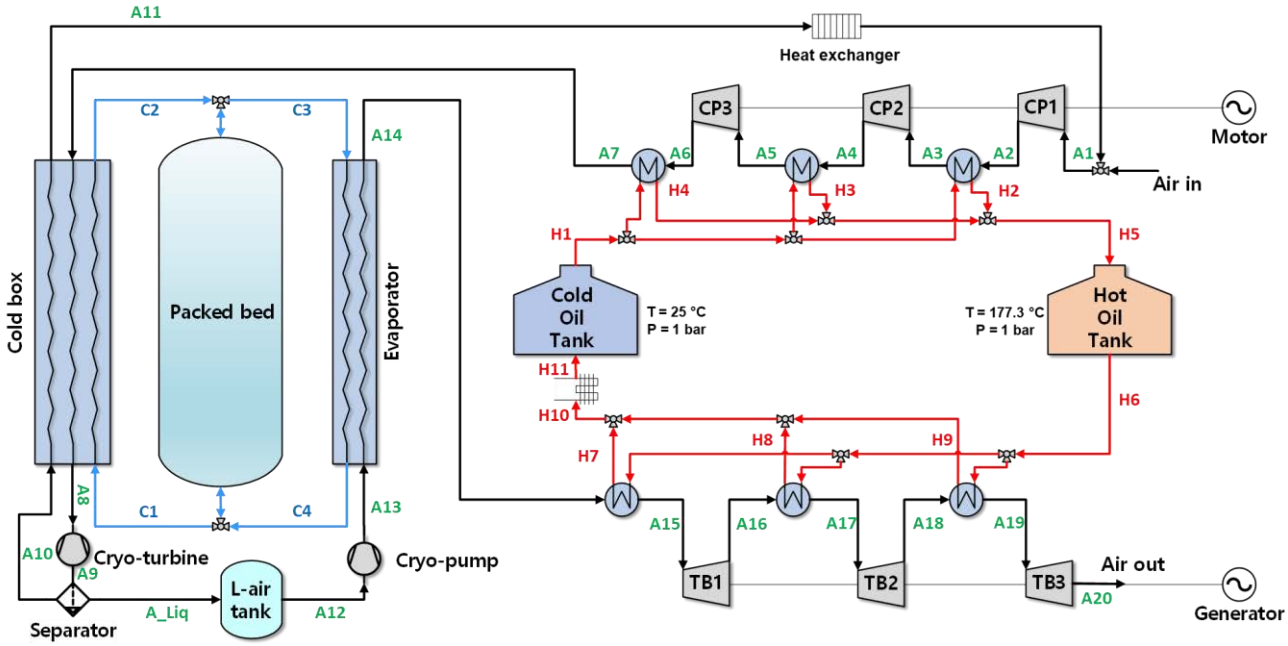

Figure. 1. *Schematic diagram of liquid air energy storage system with cold packed bed storage (CP and TB stand for compressor and turbine, respectively).*

The input parameters of the system are presented in Table 2. The design charging cycle power input (96 MWe), hot thermal energy storage capacity (800 MWh_{th}) and volume (9000 m^3), cold thermal energy storage systems' volume (15000 m^3), and charging time (8 hrs) were fixed for the analysis. The design discharging cycle power output is calculated based on the available liquid yield during charging cycle and discharge duration of 8 hrs. In order to achieve 96 MW of power input for the LAES charging cycle, 17 MPa was selected as the fitting charging pressure. It is worth to note that the LAES system is designed as a large-scale electricity storage system, which require a large volume of the packed bed storage for cold thermal energy as well as a large volume of tanks for the hot thermal energy.

Due to manufacturing constraints of packed bed systems, the diameter of the tank must not exceed 6 m, and the recommended H/D ratio for packed bed systems based on literature is 2 [19,20]. Based on these considerations, the packed bed's height and inner diameter were set to 12 m and 6 m, respectively. In order to achieve the total storage capacity needed for the system, a series of packed beds in a parallel

configuration was used. In total 44 packed bed tanks are needed, which means that the input of the packed bed system (C2 during LAES charging and C4 during LAES discharging) was divided among 44 packed bed tanks. Similarly, the outlet streams of the packed bed tanks were collected, leading to the desired outlet flow of the packed bed system (C1 during LAES charging and C3 during LAES discharging). In order to avoid the use of multiple cold energy storage tanks, it may be a possibility to use one or a few underground packed bed storage tanks [21], however, in this case the LAES system will not be geographically unconstrained, which is one of the major advantages of the LAES technology.

Table. 2. *Input parameters for the system modelling.*

Parameter	$Value$
Particle diameter	0.02 m
Ambient temperature	293 K
Ambient pressure	101 KPa
Charging pressure	17 MPa
Packed bed initial temperature	101.47 K
Pinch points:	
Air-Oil heat exchangers	5 K
Cold box	2 K
Evaporator	2 K
Turbomachinery isentropic efficiency [9]:	
Compressors	89 %
Cryo-turbines	90 %
Cryo-pump	80 %
Gas turbines	75 %

2.2 Component thermodynamic model

In order to simulate the proposed system, the mathematical modelling of the components is implemented into the MATLAB environment. The specific enthalpy change is modelled by the isentropic efficiency model. The compressor power input, $\dot{W}_C$, and the gas turbine power, $\dot{W}_T$, are calculated as follows:

$$\dot{W}_C = \dot{m}(h_{out} - h_{in}) = \dot{m}(h_{out.is} - h_{in})/\eta_{CP} \quad (1)$$

$$\dot{W}_T = \dot{m}(h_{in} - h_{out}) = \eta_{TB} \times \dot{m}(h_{in} - h_{out.is}) \quad (2)$$

where $\dot{m}$ is mass flow rate, h is specific enthalpy, and η is the isentropic efficiency of each component.

Heat exchangers are modelled with basic heat balance equations. The heat exchangers are assumed to be counter-flow heat exchangers and a pinch point limitation is applied.

$$\dot{Q}_{hot} = \dot{m}_{hot}(h_{H_{in}} - h_{H_{out}}) \quad (3)$$

$$h_{C_{out}} = h_{C_{in}} + \frac{\dot{Q}_{hot}}{\dot{m}_{cold}} \quad (4)$$

Pinch point: $min(T_{hot} - T_{cold}) = 5K$ (5)

where $\dot{Q}$ represents the heat transfer rate, h_H and h_C are specific enthalpy of the hot side and cold side, respectively. Subscripts in and out represent the inlet and outlet stream.

The multi-stream cold box is the most important component in the proposed system because the liquid air yield and round-trip efficiency are directly affected by its performance. Compressed air is cooled down to cryogenic temperature by compressed cold air from cold packed bed storage. For simplifying the multi-stream heat exchanger's calculation, it is assumed that there is no heat transfer between cold side fluids. Also, the outlet temperatures of the fluids on the cold side are imposed. The heat transfer rate of the hot side fluid and objective pinch point temperature are calculated as follows:

$$\dot{Q}_{hot} = \dot{m}_{hot}\left(h_{H_{in}} - h_{H_{out}}\right) = \dot{Q}_{pacekd\ bed} + \dot{Q}_{recycle} \quad (6)$$

Pinch point: $min\left(min\left(T_H - T_{packed\ bed}\right), min\left(T_H - T_{recycle\ air}\right)\right) = 5K$ (7)

where $\dot{Q}$ represents heat transfer rate, and T_{fluid} is the temperature of each fluid.

As the modelling is transient, and the mean liquid yield is calculated as follows:

$$Y = \frac{1}{t_{ch}} \int_0^{t_{ch}} y.\, dt \quad (8)$$

The round-trip efficiency is defined as the ratio of the total electricity generation in the discharging process to the power consumption in the charging process:

$$\eta_{RTE} = \frac{W_{discharging}}{W_{charging}} = \frac{\int_0^{t_{dis}} \dot{W}_T - \dot{W}_{CRP} dt}{\int_0^{t_{ch}} \dot{W}_C - \dot{W}_{CTB} dt} \quad (9)$$

where the subscripts CRP and CTB represents the cryo-pump and cryo-turbine, respectively.

2.3 Packed bed modelling

For calculating the heat transfer performance of packed bed storage, the energy balance equation is used. The energy equation for fluid and solid particles presents in Eq. (10) and Eq. (11), respectively. The packed bed storage is considered a 1D cylindrical tank and radial distribution of temperature based on Eq. (12) is considered inside the particles.

The following assumptions were made:

1. The distribution of velocity in the entire packed bed tank is constant and uniform. This assumption is valid for systems with $D/d_p > 30$ [22].
2. The heat transfer mechanism between the heat transfer fluid and particles are convection and conduction. Radiation is neglected.
3. The porosity is uniform along the packed bed tank.
4. The particles are of the same size and spherical shape.
5. The heat loss of the tank to the ambient is considered.

$$\varepsilon \rho_f c_{p.f} \left(\frac{\partial T_f}{\partial t} + u_f \frac{\partial T_f}{\partial z} \right) = \varepsilon k_f \frac{\partial^2 T_f}{\partial z^2} + \frac{6(1-\varepsilon)}{d_p} h_{fp} \left(T_s - T_f \right) + h_w \left(T_w - T_f \right) \quad (10)$$

$$(1-\varepsilon) \rho_s c_{p.s} \frac{\partial T_s}{\partial t} = (1-\varepsilon) k_s \frac{\partial^2 T_s}{\partial z^2} + \frac{6(1-\varepsilon)}{d_p} h_{fp} \left(T_f - T_s \right) \quad (11)$$

$$\rho_p c_{p.p} \frac{\partial T_p}{\partial t} = k_p \left(\frac{\partial^2 T_p}{\partial r^2} + \frac{1}{r} \frac{\partial T_p}{\partial r} \right) \quad (12)$$

where ε is the porosity of the packed bed, ρ is density, c_p is the specific heat of fluid, k is thermal conductivity, d_p is the particle diameter, h_{fp} is the heat transfer coefficient of fluid to solid, h_w is the heat transfer coefficient of heat loss to the ambient, and T is temperature. Subscripts f, p, and s are fluid, particle, and solid, respectively.

In order to model the thermophysical properties of the PCM, an effective heat capacity method is used [23]. The latent heat is represented as a sensible heat spread over a finite temperature difference. Thus, the specific heat of PCM is defined among three phases, namely solid, solid-liquid transition, and liquid phases:

$$c_{p.p} = \begin{cases} c_{p.s} & T_p < T_{m1} \\ \frac{c_{p.s} + c_{p.f}}{2} + \frac{L_H}{Tm2 - Tm1} & T_{m1} < T_p < T_{m2} \\ c_{p.f} & T_p > T_{m2} \end{cases} \quad (13)$$

$$k_{p.p} = \begin{cases} k_{p.s} & T_p < T_{m1} \\ \frac{k_{p.s} + k_{p.f}}{2} & T_{m1} < T_p < T_{m2} \\ k_{p.f} & T_p > T_{m2} \end{cases} \quad (14)$$

where T_{m1} and T_{m2} represent the solidification and melting temperatures of the PCM during the solid-liquid transition, and L_H is the latent heat. For updating the air properties which are temperature dependant, the REFPROP library [24] is used and applied to the model.

In order to solve the energy balance equation, boundary conditions and initial conditions are specified for the fluid and solid:

$$T_f(z=0) = T_{in}; \quad \frac{\partial T_f}{\partial z}(z=H) = 0 \quad (15)$$

$$T_s(z=0) = T_{in}; \frac{\partial T_s}{\partial z}(z=H) = 0 \quad (16)$$

$$T_f(t=0) = T_{in}; T_s(t=0) = T_o \quad (17)$$

$$\frac{\partial T_p}{\partial r}(r=0) = 0; \quad T_p\left(r = \frac{R}{2}\right) = T_s \quad (18)$$

where T_{in} is the packed bed inlet temperature, T_o is the initial temperature, and T_s is the solid temperature. Figure 2 depicts a schematic view of a packed bed filled with particles.

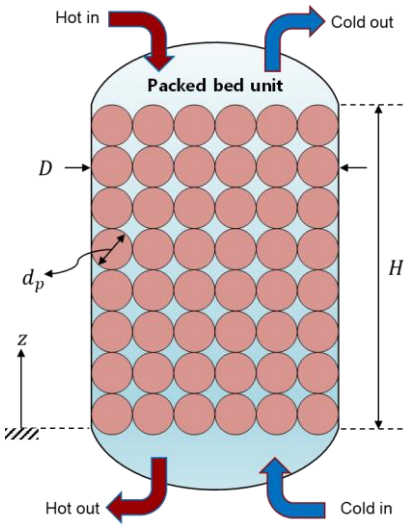

Figure. 2. *Schematic view of 1D packed bed with geometry indicators.*

In order to apply heat transfer between the fluid and solid, an empirical correlation is applied. For the Nusselt number, the following correlation is used [25]:

$$Nu = \frac{h_{fp} d_p}{k_f} = 2 + 1.1 Pr^{\frac{1}{3}} Re_p^{0.6};\ Pr = \frac{k_f c_{p,f}}{\mu_f};\ Re_p = \frac{\rho_f d_p \varepsilon u_f}{\mu_f} \tag{19}$$

For calculating the porosity of the bed, Eq. (20) is used. [25]

$$\varepsilon = 0.375 + 0.17 \frac{d_p}{D} + 0.39 \left(\frac{d_p}{D}\right)^2 \tag{20}$$

The heat loss to the ambient is calculated based on the overall heat transfer coefficient from the inner to the outer wall, see Eq. (21). The inner convection heat transfer coefficient is defined according to Beek [26], see Eq. (22).

$$\frac{1}{U_w} = \frac{1}{h_i} + \frac{D}{2} \sum_{j=1}^{m} \frac{1}{k_j} ln \left(\frac{d_{j+1}}{d_j}\right) \tag{21}$$

$$h_i = \frac{k_f}{d_p} \left[\left(0.203 Pr^{\frac{1}{3}} Re_p^{\frac{1}{3}}\right) + \left(0.220 Pr^{0.4} Re_p^{0.8}\right) \right] \tag{22}$$

where h_i is the inner convection heat transfer coefficient, Re is Reynolds number, and Pr is the Prandtl number.

The governing equations are solved by the MATLAB software [27] using finite difference method and the implicit method. The first-order upwind scheme is used to discretize the temporal and advective term, while the second-order central differencing is used to discretize the diffusion term. The overall calculation method is illustrated in Figure 3.

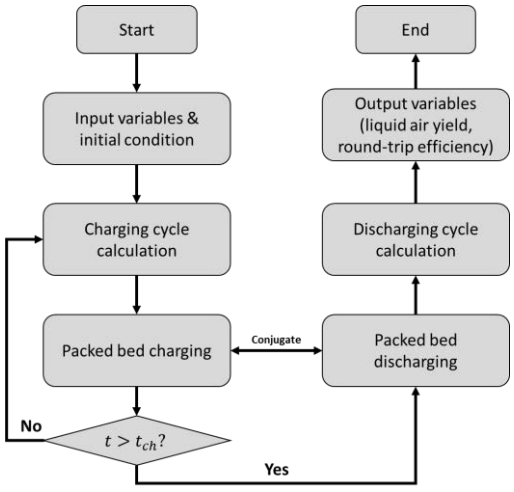

Figure. 3. *Overall calculation method of the LAES system.*

Table 2 represents the thermophysical properties of the quartz rocks [3] besides, the cryogenic PCM which is an alcohol-based fluid [11]. The thermophysical properties of silicon dioxide (SiO_2) are calculated based on correlations as a function of the particles' temperature proposed by Wang et al. [9] and Sciacovelli et al. [13].

3. Results and discussion

In this section, first, the validation of the packed bed model is presented. Then the optimum value for discharging pressure is found based on a sensitivity analysis. Afterwards, the different particle materials are compared in terms of LAES round-trip efficiency, liquid air yield, and gas turbine power.

3.1 Model validation

The developed model for the packed bed is validated by comparing the results with experimental data from a study by Li et al. [28] who analysed a packed bed system with microencapsulation of molten salt as phase change material. The packed bed in their study had a height of 0.26 m and a diameter of 0.26 m. The particle diameter was 0.034 m. The authors considered both the axial and radial temperature distribution along the bed's tank by applying thermocouples at various locations of the tank. When validating results of the 1D model developed in this work, the mean value of the radial temperature distribution at each axial location of the experimental data is considered. Figure 4 presents a comparison of the model results with the experimental data showing PCM particle temperature profiles over time for different axial locations. It is found that the maximum mean absolute percentage error is smaller than 2 %, suggesting that the current model provides reasonable results.

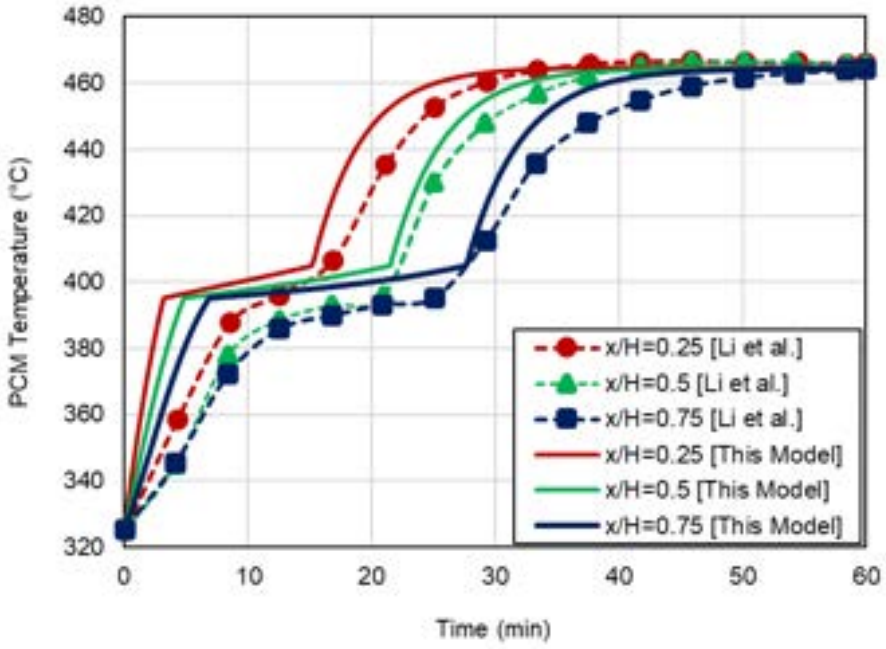

Figure. 4. *Validation of packed bed model.*

The validation of the LAES thermodynamic model is done by comparing the current model results with experimental results presented by Sciacovelli et al. [13], see Table 3. The experimental setup of the Sciacovelli et al. [13] research study only contains the LAES discharging cycle. The mass flow rate of air is

1.8 kg/s in that setup. The results presented in Table 3 indicate that the thermodynamic models developed in the current work provide reasonable results.

Table. 3. *The results of current model compared to the results from [13].*

Parameter	Results of the current model	Results of Ref. [13]	Deviation
Turbines' power	277.77 kW	277.85 kW	0.38 %
Cryo-pump's power	29.79 kW	30.01 kW	0.73 %

3.2 Optimal discharging pressure

Two important parameters of LAES systems that have a significant influence on their overall performance are the charging and discharging pressures. In this paper the charging pressure was defined and kept constant, while it is required to evaluate the optimum value of the discharging pressure. Figure 5 presents the LAES round-trip efficiency, cryo-pump power consumption, turbine power output, and net power output of the discharging cycle versus the discharging pressure varying from 10 MPa to 25 MPa. The results indicate that the round-trip efficiency increases with the increase of discharging pressure. However, the more dominant effect of the increase in discharging pressure is on the cryo-pump power consumption, which is increasing sharply with increasing discharging pressure. According to Figure 5, the additional gain in round-trip efficiency is small for discharging pressures exceeding 18 MPa. Thus, the discharging pressure is set to 20 MPa (purple band in Figure 5), resulting in a round-trip efficiency of 41 %, cryo-pump power consumption of 2.6 MW, turbine power output 42 MW, and hence a net power output of 39.4 MW.

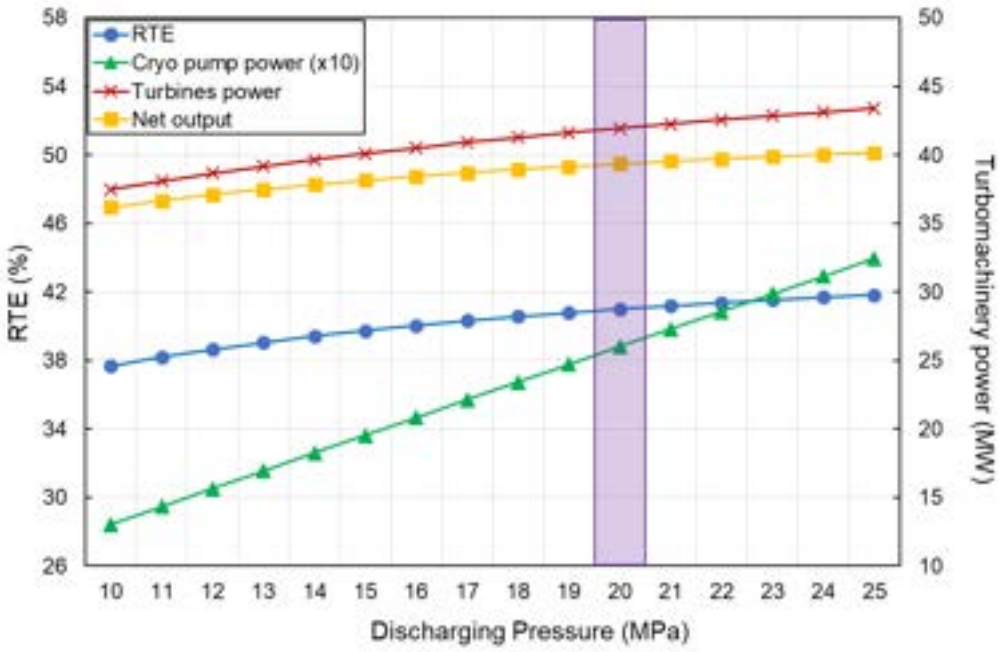

Figure. 5. *LAES round-trip efficiency, cryo-pump power consumption, turbine power output, and net power output of the discharging cycle versus the discharging pressure.*

3.3 Performance of LAES system with different particles in the packed bed

Figure 6 presents a comparison of the LAES round-trip efficiency, mean liquid air yield, and turbine power output for packed bed systems with the three different particles for the cold energy storage. The results suggest that the SiO2 particle results in the poorest performance, while the PCM and quartz particles attain very similar performances.

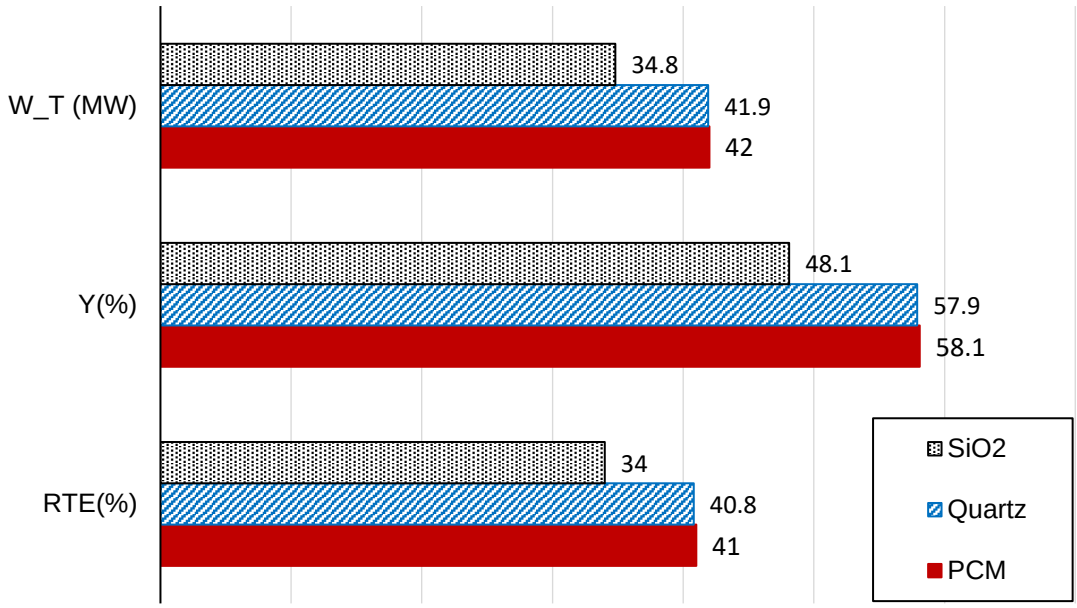

Figure. 6. *Round-trip efficiency (RTE), mean liquid air yield (Y), and output power of the turbines ($\dot{W}_T$) for the three different particle types.*

In order to understand the effects of the particle materials, Figure 7 presents the heat transfer fluid temperature at the outlet of the packed bed (point C1 in Figure 1) versus time for the three different particle materials. The outlet temperature of the air starts to increase after 66 minutes, 128 minutes and 161 minutes for the SiO2, PCM and quartz, respectively. The temperature of point C1 directly affects on the temperature of point A8, the parameter, which have a significant influence on the liquid air yield, the round-trip efficiency and the output power of the turbines. A lower temperature in point A8 results in a higher liquid air yield. The poor performance of SiO2 particles is because of the rapid increase in temperature of C1 (Figure 7), due to unfavourable thermophysical properties of SiO2 in terms of specific heat capacity and density in comparison with PCM and quartz. In contrast, the increase of air temperature over time for the cases of PCM and quartz is controlled in a better way and as a result, these two systems present better performance due to a lower temperature at the inlet of cold box. The phase change phenomenon of PCM is noticeable in the temperature range around the PCM melting point (155 K to 158 K), where the air temperature remains constant for the rest of the charging time. It can be observed that the outlet temperature (C1) does not exceed the melting point of PCM since there are still some particles in the solid state. The reason why the quartz particle achieves similar performance as that of the PCM, although it is not a phase change material, is that quartz particle keeps the air temperature equal to the packed bed's initial charging temperature for a longer time duration than does the PCM. This is because the density of quartz particles is more than 3 times higher than that of the PCM considered for the analysis. As the volume of the packed bed and the porosity are the same for all 3 particle materials, the higher particle density results in a higher particle mass. Therefore, the storage mass of the quartz system is more than 3 times than that of the PCM for the same volume of the packed bed system.

The behaviour of liquid yield over time for the three particle materials is presented in Figure 8. Similar to the temperature in point C1, the liquid yield is constant while the PCM changes phase, reaching a steady state of 0.467 after 354 min. The maximum value of the liquid yield (slightly above 0.7) is attained for the longest duration for the quartz particles because the temperature in point C1 is kept at the minimum value for the longest duration for this material. The liquid yield starts to decrease from the maximum value after 199 min, 160 min and 87 min for the quartz, PCM and SiO2, respectively.

4. Conclusions

In this paper a comparative analysis of sensible heat and latent heat packed bed cold energy storages for LAES systems was presented. The investigated particles are quartz and silicon dioxide representing sensible heat storage materials and an alcohol-based fluid representing a latent heat phase change material. A thermodynamic model of the LAES system integrated with a 1-dimensional transient numerical model of the packed bed system was developed. The particles were compared in terms of the LAES round-trip efficiency, mean liquid yield, and output power of the turbines. The results suggest that the optimum value for discharging pressure of the system is 20 MPa. Among the analysed particle materials, the PCM and quartz achieve the highest round-trip efficiency for the LAES system, 41 % and 40.8 %, respectively. The round-trip efficiency of the silicon dioxide is lower, 34 %, due to unfavourable thermophysical properties. The reason why the quartz particle achieves similar performance as that of the PCM, although it is not a phase change material, is that quartz particle keeps the air temperature at the cold storage outlet equal to the packed bed's initial charging temperature for a longer time duration than does the PCM. This is because the density of quartz particles is more than 3 times higher than that of the PCM considered for the analysis, resulting in a greater mass of the cold storage based on quartz. In general, the choice between PCM particles and quartz particles for a LAES cold storage system depends on factors such as the required energy density, the desired charging and discharging rates, the available space and weight limits, and the cost of the materials. These aspects will be investigated in future work.

Acknowledgment

The research presented in this paper was partly developed within the project “Sustainable large-scale energy storage in Egypt” (Project no. 21-M13-DTU), funded by the Ministry of Foreign Affairs of Denmark and administrated by Danida Fellowship Centre. In addition, the research was partly funded by a Korea Agency for Infrastructure Technology Advancement (KAIA) grant provided by the Ministry of Land, Infrastructure and Transport (Grant RS-2022-00143652). The financial support is gratefully acknowledged.

Abstract:

Adiabatic compressed air energy storage (A-CAES) is a promising storage technology to face the challenges of high shares of renewable energies in an energy system by storing electric energy for periods of several hours up to weeks. In order to reduce the investment costs and increase the flexibility of the storage system, the so called KompEx LTA-CAES® was developed by Fraunhofer UMSICHT. This new A-CAES concept is using a combination of reversibly operable turbo- and piston machines (KompEx machines). Doing so, these modules can achieve wide CAS pressure ranges (corresponding to high exergy densities) and thus can be combined with any compressed air storage volume. To realize efficient and stable operation despite a wide pressure range, a suitable control strategy of both KompEx machines is required. This paper investigates the introduced A-CAES system by a dynamic simulation, focusing on the interaction and synergy between the reversibly operable turbo- and piston machines. Results indicate that the roundtrip efficiency of this system is expected to be at the low end (55,5%) of literature values for A-CAES (52–66% for low-temperature A-CAES), which is relatively high compared to published A-CAES systems considering similar pressure ranges.

1. Introduction

A-CAES systems have the potential to play an important role in realizing a sustainable energy supply infrastructure based on renewable energy. The general interest in A-CAES is illustrated by many R&D activities all over the world in recent years. Nevertheless, the economically viable implementation of A-CAES plants is a great challenge under political and economic conditions in most countries at the present time – and probably also in near future.

This paper gives an overview of published thermodynamically investigated A-CAES concepts. Furthermore, a new low-temperature A-CAES concept developed by Fraunhofer UMSICHT called »KompEx LTA-CAES® modular« is presented (Section 3), which aims to overcome current barriers regarding the economic realization of A-CAES. Special features are the modular design and the use of reversibly operable turbo- and piston machines (KompEx machines).

2. State of the art

Although the individual components of many A-CAES concepts are commercially available, A-CAES systems are still almost exclusively in the R&D phase due to economic barriers. For this purpose, several demonstration plants have been built worldwide [1–4]. The first commercial adiabatic CAES plant was commissioned in Goderich (Ontario, USA) in 2019 [5], and others are currently under construction in China [6]. Nevertheless, A-CAES are still mainly studied on a theoretical level, which is illustrated by a large number of thermodynamic studies published in the last decades. This section briefly introduces the general function and typical classification of A-CAES systems and gives an overview of published layouts.

2.1. Functional principle of adiabatic CAES

The basic principle and the main components of adiabatic CAES are shown in Figure 1. During the charging process, ambient air is compressed by electrically driven compressors (C). The heated compressed air is cooled and stored in a compressed air storage volume (CAS), while the thermal energy is temporarily stored in a separate thermal energy storage (TES). During discharging, the stored compressed air is released from the CAS, heated via the TES and expanded in expanders (E) to generate electricity via generators.

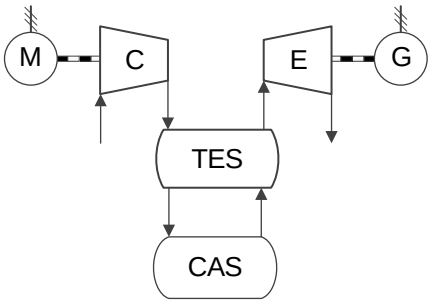

Figure 1. General block diagram of A-CAES (based on [7]).

The plant layout design, suitable technologies and the resulting operating behaviour of A-CAES systems are crucially dependent on the addressed storage temperature. Therefore, the following section gives an overview of general plant layouts and their special characteristics.

2.2. Classification of A-CAES

According to the importance of the process temperature, A-CAES can be divided into three different process types [8]:

- High temperature processes (HT) with temperatures above 400 °C
- Medium-temperature processes (MT) with temperatures between 200 °C and 400 °C
- Low-temperature processes (LT) with temperatures below 200 °C

The process temperature is essentially determined by the number of the used compression stages and heat management. In HT processes, ambient air is compressed via one or two stages, which leads to high process temperatures at corresponding final pressures. In LT processes, multi-staged compressors with intercooling are used, resulting in lower process temperatures. Higher process temperatures are leading to generally higher cycle efficiencies (Figure 2) but also to higher investment costs, since special thermally resilient components are required. Furthermore, the start-up times are limited to 10–15 minutes due to the high thermal stresses in the components [48]. A-CAES systems with lower process temperatures, in contrast, are technically easier to design (e. g. a simple storage medium such as water can be used), resulting in lower investment costs. Furthermore, lower thermal stresses are allowing faster start-up times (down to < 5 min.) and thus the participation in certain electricity markets like the ancillary service.
In contrast to a Carnot cycle process, the maximum process temperature has only a minor influence on the cycle efficiency of A-CAES systems (Figure *2*). The illustrated efficiency range (solid lines) is based on a simple equation introduced by Kreid [9], where fixed design values for relevant main components like efficiency of motor and generator, compressor and expander as well as pressure and thermal losses are taken into account. The efficiency range illustrated in Figure *2* is resulting by assuming a turbomachine efficiency between 70 and 85 %. The plotted data points are representing electrical cycle efficiencies of adiabatic plant layouts calculated in thermodynamical studies (Table A.1). The decreasing efficiency for lower storage temperatures is resulting from proportionally higher thermal losses at constant temperature gradients [10].

2.3. Key parameters of published A-CAES concepts

Published A-CAES concepts are varying widely regarding the design of compression/expansion stages, thermal storage and compressed air storage as well as implemented control strategies. To highlight the special features of the developed KompEx LTA-CAES®, the following section briefly provides an overview of typical plant layouts and key performance indicators of published A-CAES concepts.

Storage temperature and used thermal storage media

The storage temperature of the thermal energy storage of A-CAES plants is dependent on the final CAS pressure as well as on the design and heat management of the compression train. Depending on the process type, water, thermal oils or rockfills are most commonly used as thermal storage media (Table A.1).

Cycle efficiency

The plant efficiencies calculated in published A-CAES studies are showing a logarithmic dependency on the storage temperature (trend line in Figure *2*) and mostly a reasonable agreement with the predicted efficiency range according to Kreid [9]. The two upper outliers ([11, 12]) can be explained by the comparatively high design efficiencies of the compression and expansion machines of 88 to 92 % assumed in each of these papers. In comparison, the calculation of the upper cycle efficiency according to Kreid [9] is based on a maximum efficiency assumption of 85 %.

Several thermodynamic studies [13–19] are calculating A-CAES cycle efficiencies which are – in some cases significantly – below the cycle efficiency range according to Kreid [9] (Figure *2*). A closer look at the

corresponding plant layouts shows that in these the CAS volumes are operated within a relatively wide pressure range (Table A.1). As a result, the compressors are increasingly operated outside their optimum. Furthermore, the corresponding plant layouts are using throttle valves to ensure a constant inlet pressure in the expansion machines during the discharging process. This measure is leading to an optimum operation of the expanders at the cost of high losses of the usable potential energy stored in the CAS. These losses are rising with larger operating pressure differences of the CAS. The two negative effects described are leading to relatively low cycle efficiencies.

The developed KompEx LTA-CAES® addresses a relatively wide CAS pressure range but nevertheless reaches a comparatively higher electrical efficiency of 55.53 % (point 14 in Figure 2). This is obtained by the special constellation of the compressors/expanders and the implemented control strategy of the plant layout, which will be discussed later.

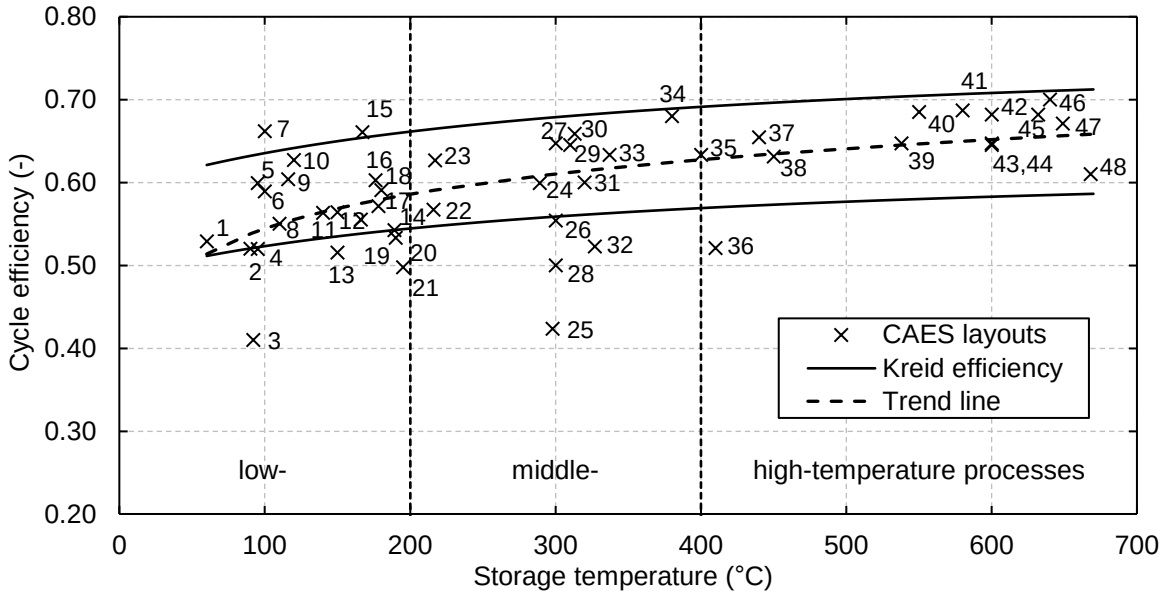

Figure 2. Predicted CAES cycle efficiencies according to [9] and calculated by published A-CAES studies depending on storage temperature (based on [8]); see Table A.1 for the literature allocation of the CAES layout data points.

Charging and discharging power

The designed installed charging/discharging capacity of investigated system layouts usually is depending on the addressed application. The focus of past studies is mostly on huge central applications. This usually includes storage systems that are used for the temporal shifting of large amounts of energy with high electrical power (> 20 MW_{el}, Table A.1). These systems usually operate at the medium and high-voltage level and can provide grid services such as minute reserves. In contrast, decentralized storage concepts are characterized by lower charging/discharging powers and energy storage volumes. They are usually located near the consumer and are suitable to compensate generation and consumption peaks or to backup island grids. Both centralized and decentralized storage applications are considered promising, especially when coupled with fluctuating renewable energies like wind turbines or photovoltaic plants. [20, 21]

CAS technology and exergy density

The amount of energy to be stored as well as geographical conditions have a decisive influence on the choice of a suitable CAS technology. In studies on centralized A-CAES concepts, underground salt caverns are generally used to store the compressed air (Table A.1), since they have low specific investment costs (€/m³) when storing large amounts of energy. The maximum pressure and the realizable pressure difference of salt caverns are strongly dependent on their geological characteristics. In corresponding studies, the salt caverns are commonly operated with pressure differences of less than 40 bar.

In the field of decentralized applications, storage capacities below 20 MW_{el} are usually required. Due to the strong geographical dependency and the high specific investment costs of salt caverns when storing smaller energy quantities, they are unsuitable in this case. Therefore, artificial CAS technologies with smaller storage volumes, e. g. in the form of steel tubes, steel cylinders or steel spheres are more appropriate in decentralized applications (Table A.1) [20]. In contrast to underground salt caverns, the maximum storage pressure and the realizable operating pressure difference for these CAS systems are much higher. Thus, significantly higher exergy densities can be achieved, which is of great importance for the economic operation of artificial CAS technologies as they have relatively high specific investment costs.

As an example: When charging the CAS isothermally at 15 °C, a pressure range of 80–100 bar results in an exergy density of about 2.5 kWh/m³, while a pressure range of 60–100 bar results in about 5 kWh/m³ [23].

3. KompEx LTA-CAES®

This section describes the new A-CAES concept which has been developed within the joint project »KompEx LTA-CAES® modular - Development of a modular low-temperature compressed air energy storage system with reversibly operable machines (KompEx)« funded by the German Federal Ministry for Economic Affairs and Climate Action [22]. The goal was to overcome existing barriers regarding the economic realization of adiabatic CAES based on four novel approaches. (1) A modular design to reduce unit costs through possible serial production. (2) Low storage temperatures to enable short start-up times and thus participation in profitable electricity markets. (3) To reduce investment costs, reversibly operable machine sets (KompEx machines) for compressed air are being developed. (4) By combining turbo- and piston machines, wide pressure ranges within the CAS can be realized, enabling an economical use of various CAS technologies, and thus reducing the geographical dependency from salt caverns.

3.1. Plant Layout

Figure 3 is showing the simplified block diagram of a KompEx module. Ambient air is compressed to a certain intermediate pressure via an intercooled multistage radial turbomachine ($TM_{1\text{-}n}$) driven by a motor-generator (MG). The Intercooling is carried out via plate heat exchangers ($HX_{1\text{-}n}$). The occurring thermal energy is stored by a two-tank liquid thermal energy storage – referred as low-pressure thermal energy storage ($LP\text{-}TES_{hot/cold}$) in the following. Depending on the current operating state (charging/discharging), the heat storage medium (water) is transported between the two tanks via a pump through the heat exchangers. The process section consisting of motor generator, radial turbomachine, heat exchanger and LP-TES is referred as low-pressure process (LP-process) in the following.

After the LP-process, high-pressure piston machines ($PM_{1\text{-}n}$) – each consisting of 2 individually operable cylinders – are compressing the low-pressure air to the pressure level of the CAS, which varies with the filling level. Each of the piston machines has its own motor-generator to switch single machines on and off during the charging or discharging process, which is important for the implemented process control strategy (Section 3.3). Due to the higher pressure ratios and thus higher outlet temperatures of the piston machines, the respective occurring thermal energy is stored via a high-pressure thermal energy storage (HP-TES) in the form of an indirect-flow concrete storage. Using two separated TES systems is resulting to a higher exergetic efficiency of the overall process. A trim cooler (TC) connected downstream of the HP-TES is ensuring low inlet temperatures to the CAS in order to reduce the required storage volume. The section consisting of piston machines including the motor-generators, HP-TES and trim cooler corresponds to the high-pressure process (HP-process) of the KompEx LTA-CAES®.

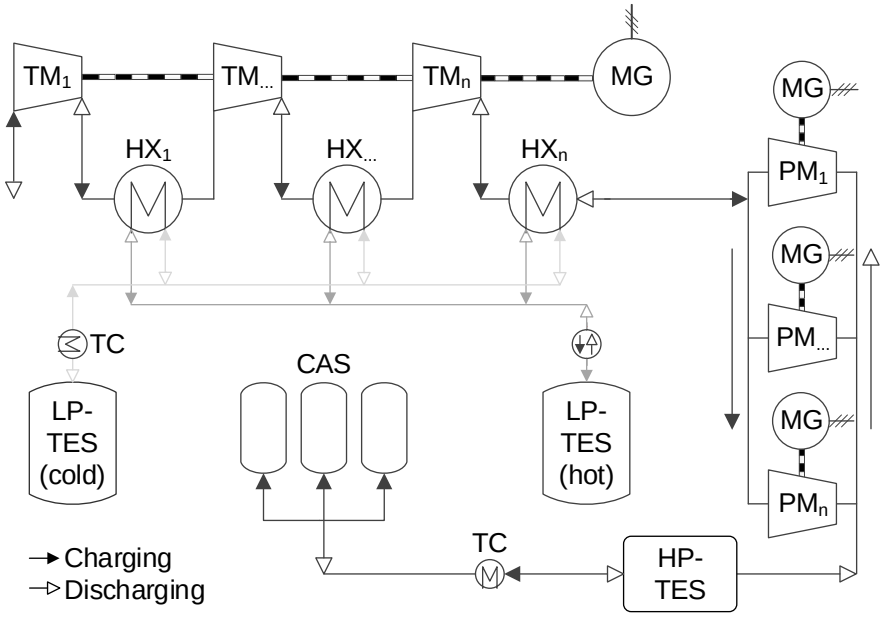

Figure 3. Simplified block diagram of the KompEx LTA-CAES® module [23].

During the discharging process, the compressed air is flowing through the same components in the reverse direction. The compressed air is heated via the respective TES system and then expanded in the KompEx machines to generate electricity in the motor-generators. By using the reversibly operable KompEx machines, a complete machinery train including expanders, heat exchangers and pipes can be omitted resulting in

reduced investment costs. Furthermore, the synergetic use of turbo- and piston machines enables an efficient operation of wide pressure ranges and thus the option of using artificial CAS technologies in addition to salt caverns. Finally, the described KompEx layout represents one module. In order to achieve higher storage capacities, several modules can be interconnected. This provides greater flexibility in terms of suitable storage applications and the potential to reduce costs by series production.

3.2. Design parameters

The design parameters of the investigated KompEx LTA-CAES® module were developed within the KompEx project (Table 1). The use of reversibly operable turbo- and piston machines in A-CAES systems leads to some special design constraints compared to concepts with separate compressors and expanders. Since the compression and expansion of the compressed air in the KompEx system are performed by the same machines, the respective design volume flows and thus the charging and discharging power are linked. This also applies to the design efficiency of the compression and expansion mode of the KompEx machines. Optimizing the KompEx machines for one of the two operating modes has a direct influence on the efficiency of the other one. Consequently, a compromise design of the KompEx machines is required. As a result, lower nominal efficiencies can be expected compared to separated state-of-the-art turbo- and piston machines. The listed nominal efficiencies (Table 1) of both machine types for each operation mode were calculated by detailed CFD simulations within the KompEx project [22]. Furthermore, the KompEx layout is specially designed for decentralized storage applications. Therefore, the CAS volume is operated within a wide pressure range to achieve high exergy densities and thus to reduce the investment costs of the CAS volume.

Table 1. Design parameters of the investigated KompEx LTA-CAES® module [23].

Design parameter	Value	Unit
Nominal electrical Power of charging	2	MW_{el}
Nominal electrical Power of discharging	1	MW_{el}
Pol. nominal efficiency in compression mode of TM	82	%
Is. nominal efficiency in expansion mode of TM	85	%
Pol. nominal efficiency in compression mode of PM	76	%
Is. nominal efficiency in expansion mode of PM	80	%
CAS volume	1.304	m^3
CAS pressure range	40–100	bar
Number of turbomachines	3	-
Number of piston machines	11	-

3.3. Control strategy

There are many different possible applications for energy storages. Examples include trading on spot markets, providing ancillary services, increasing power generation from fluctuating renewable energies and supplying electricity in off-grid regions. In some cases, a combination of different applications is also possible. Depending on the storage application, different regulatory and technical requirements must be fulfilled by the storage system. In particular, participation in ancillary services is associated with strong restrictions. The frequency restoration reserve relevant for CAES systems, for example, is requiring a constant power input and output over a defined period with a maximum deviation of 5 % [24, 25].

The KompEx LTA-CAES® is designed to cover a wide range of the mentioned applications. Therefore, a control strategy was implemented to provide constant charging and discharging power, which is necessary due to the strongly varying storage pressure. For this purpose, the turbomachine stages are designed with variable diffusor guide vanes, which enables a wide operating range of the entire turbomachinery train. In addition, single cylinders of the piston machines can be switched on and off during operation to adjust the pressure between turbo- and piston machines (Section 4.1). Furthermore, the valve on the pressure side of the piston machines can be adjusted during discharging process, which enables a less fluctuating controlling in contrast to the charging process.

3.4. Dynamic model

The investigation of the KompEx LTA-CAES® is carried out with a dynamic plant model developed in Modelica/Dymola considering real property data of humid air. The operation behaviour of the KompEx machines is modelled via black box models with implemented polynomial surface functions. In these, the efficiencies and pressure ratios of each compressor/expander stage are determined as a function of the volume flow and the respective actuating value (guide vane angle in the turbomachines; valve position in the piston machines). To consider thermal losses to the environment, the heat exchanger, ND-TES, HD-TES, CAS and piston machines are modelled diabatically. The dynamic behaviour of the heat exchangers and the HD-TES are considered by two-dimensional discretized models (finite volume method). Detailed information

regarding the dynamic model, the implemented KompEx surface functions and equations of each component can be found in [23]. The operating schedule of the simulated A-CAES is predefined via a time series in the form of the electrical charging and discharging power. The actual plant power is compared with the predefined power by means of a PID controller and adjusted accordingly via the control variables implemented in the turbo and piston machines.

4. Results and discussion

The introduced KompEx plant layout was investigated in detail regarding dynamic interactions, partial load and cycling behaviour as well as occurring exergetic losses. In this paper, the focus is only on the control strategy and interaction between the turbo- and piston machines. More detailed investigations can be found in [23].

4.1. Reference storage cycle

The dynamic curves of relevant process parameters presented in the following are based on the dynamic system simulation of a full storage cycle at nominal load operation and steady state. The system is considered to be steady state when the stored exergy in the CAS and TES after a full cycle is equal to that of the previous cycle within a deviation of ±1.0 %.

The charging and discharging process is taking about eight hours, the storage process is set up to four hours. During charging process the storage pressure in the CAS rises continuously to the maximum pressure of 100 bar, drops slightly during storage process due to thermal losses to the environment and decreases to the minimum storage pressure of 40 bar during discharging (Figure 4, diagram top left). The electrical power consumption and generation is kept practically constant (diagram top right) during the charging and discharging process via the mass flow rate (diagram bottom left), which is adjusted by the implemented control systems (diagram top right). This is necessary since the total pressure ratio and thus power of the turbo- and piston machines varies at constant mass flow rate. The exergetic charging and discharging efficiency is strongly dependent on the current operating point resp. storage pressure (diagram bottom right). This illustrates that a dynamic process simulation is crucial for a realistic representation and evaluation of the overall system. The characteristic behaviour of the illustrated process variables is primarily resulting from the interaction of the turbo- and piston machines and the implemented system control, which are described in detail in the following section.

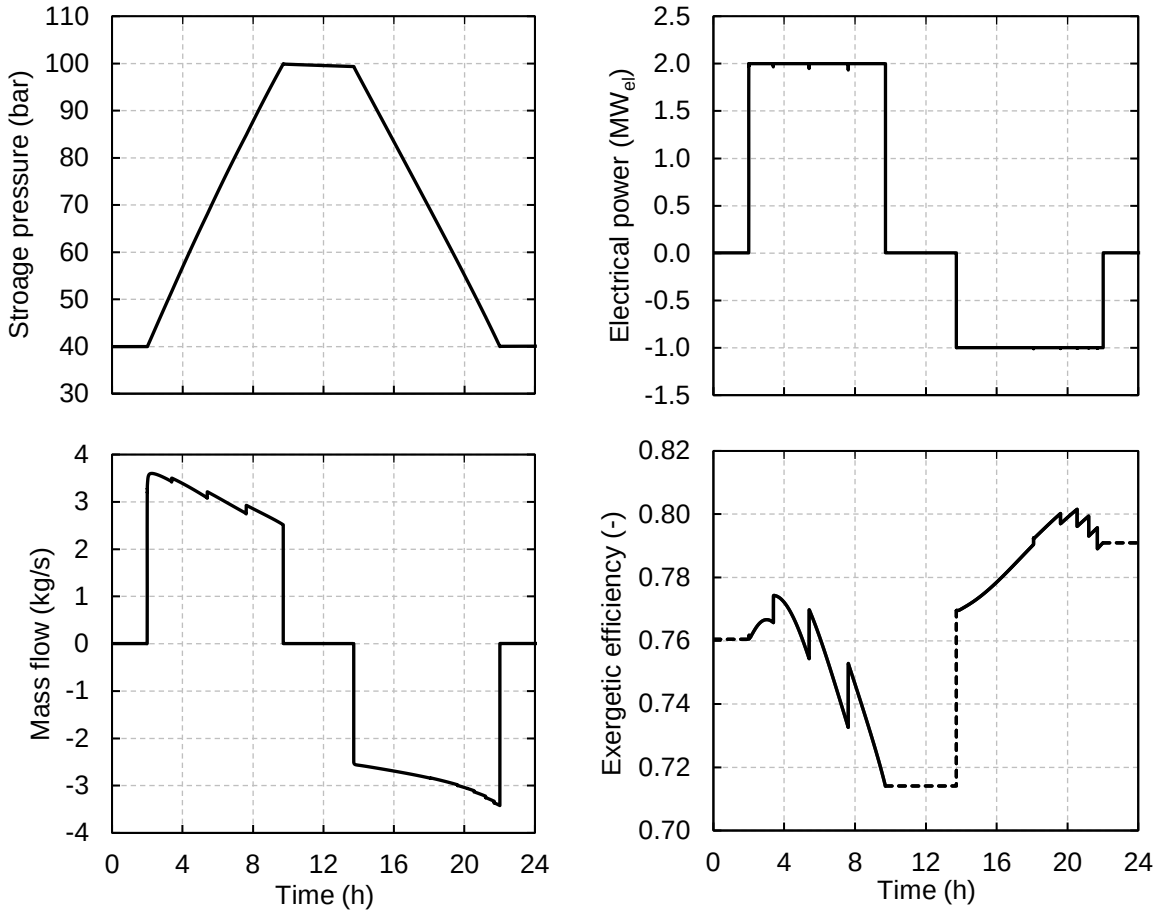

Figure 4. Storage pressure, electrical charging and discharging power, mass flow and charging and discharging efficiency of the reference storage cycle [23].

4.2. Interaction of the turbo- and piston machines

This section describes the control strategy and interaction of the turbo- and piston machines during a full charging process. The dynamic process behaviour of adiabatic CAES is essentially determined by the transient behaviour of the CAS. Therefore, the process parameters regarding the charging process are plotted as a function of the storage pressure (Figure 5). The pressure ratio (increasing from 3.58 to 8.88) and thus electrical power consumption of the piston machines is rising from 0.81 to 1.12 MW_{el} (diagram top left) due to the increasing storage pressure. This power increase is compensated by adjusting the mass flow via the variable guide vanes of the turbomachines reducing its power consumption (diagram top right).

The varying mass flow caused by the control system is resulting in a continuously varying operating point of the turbo- and piston machines, which is illustrated by the intermediate pressure (pressure between turbo- and piston machines) fluctuating during the charging process (Figure 5, diagram bottom left). The peaks observed in the shown diagrams are caused by the shutdown of single piston cylinders during the charging process, which is controlled by a discrete control loop. The reduction of the mass flow to provide a constant overall power consumption leads to an increased pressure ratio of the piston machines according to its implemented characteristic surface function. As a result, the pressure ratio of the three-stage turbomachine and thus the intermediate pressure decreases continuously. In order to ensure both machine types are operating efficiently and within their operation range, a piston cylinder is switched off at a specified minimum intermediate pressure of 11 bar (diagram bottom right). This causes an abrupt drop in the mass flow and thus in the electrical power consumption of the piston machinery train. The control system integrated in the turbomachinery train compensates this power drop by adjusting the guide vane angles of each stage resulting in an increased mass flow and power consumption. Due to the described abrupt interactions, both machine types are reaching a new operation point with a raised intermediate pressure. Further charging of the KompEx LTA-CAES® again causes the intermediate pressure to decrease until the next piston cylinder is switched off.

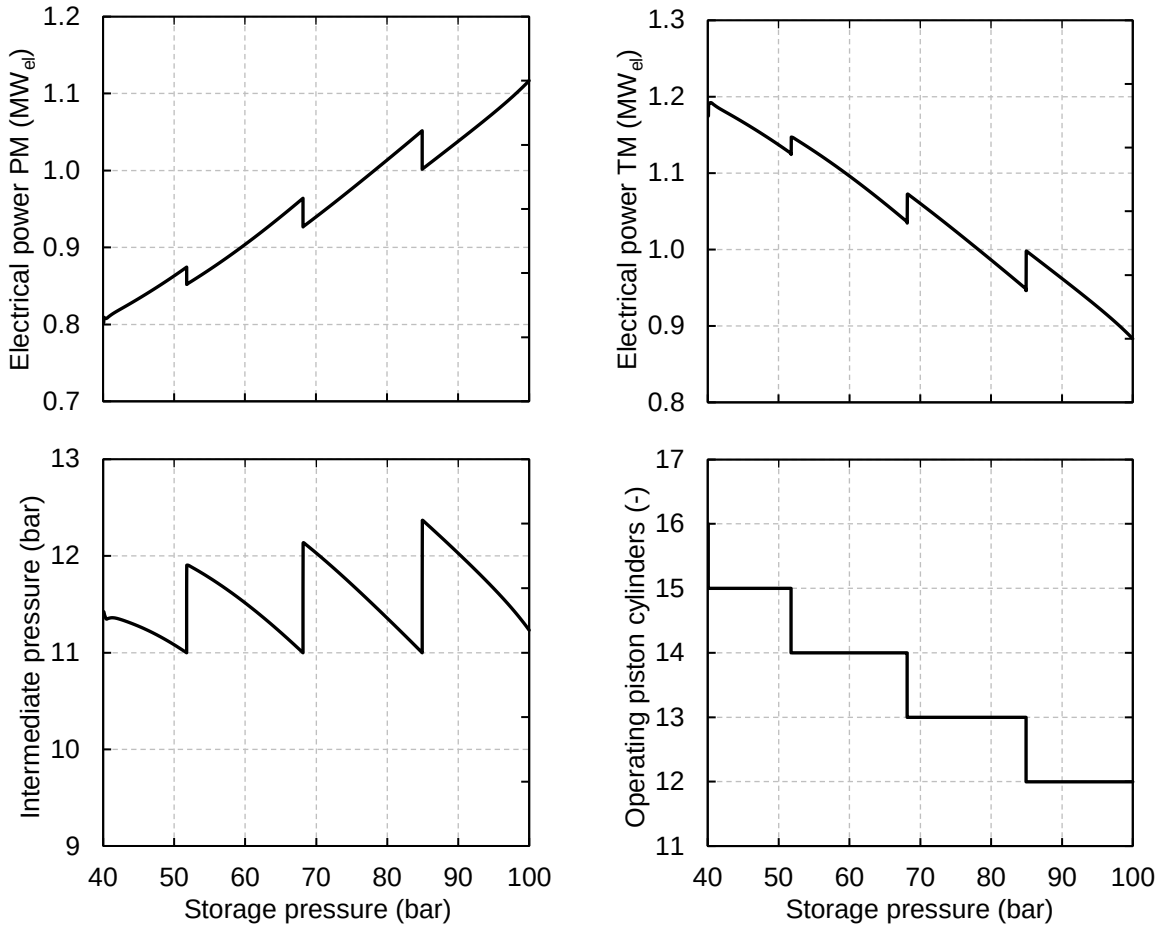

Figure 5. Electrical power of turbo- and piston machines, intermediate pressure and number of operating piston cylinders as function of the storage pressure for the reference storage cycle [23].

4.3. Part load behaviour

An important aspect that is often neglected in the literature investigating on A-CAES concepts using isochoric CAS is the influence of the varying CAS pressure range on the part load ability when a constant charging and discharging power shall be provided. To illustrate the described relationship, Figure 6 is showing a complete charging process (40 to 100 bar) with minimum and maximum power consumption of the KompEx system drawn in the efficiency map of the three-stage turbomachinery. Its operation limits are the limiting factor for the minimal operable power load of the overall system. The normalized efficiency and volume flow rate of 1.0 correspond to the respective design values.

During the charging process and thus rising storage pressure, the volume flow rate is reduced by the control system to realize a constant electrical power consumption of the overall system (Figure 4). Therefore, the volume flow rate must be reduced by up to 30 % via the outlet guide vanes of the turbomachine stages when charging with maximal power load. This implies that a great share of the part load ability of the turbomachinery – dependent on the operating CAS pressure difference – is consumed to provide a constant power consumption. Thus, the minimum electrical power consumption (62 % of nominal load) of the overall system is limited by the maximum applied storage pressure (100 bar in this case). Consequently, reducing the upper storage pressure leads to a better part load ability of the A-CAES system but also to a reduction of the exergy density.

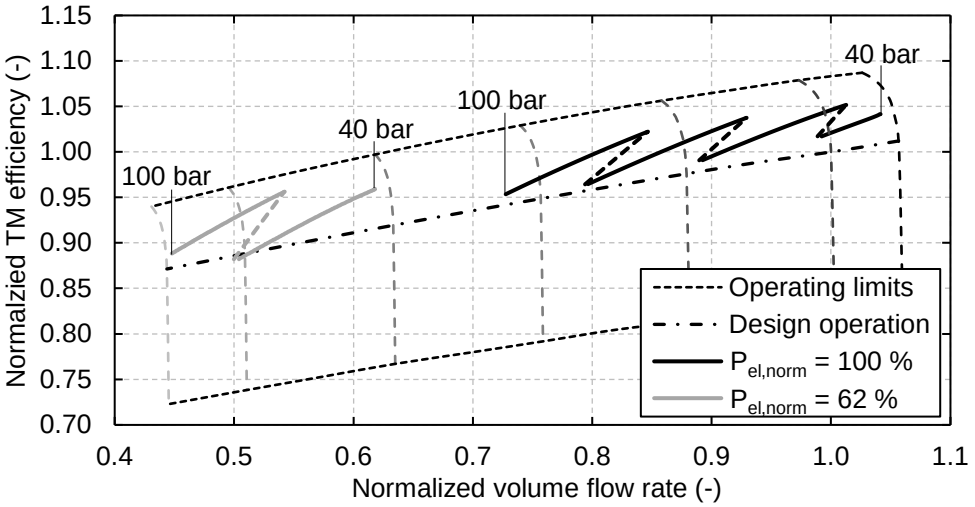

Figure 6. Efficiency map in the compression mode of the three-stage turbomachine and operating curve of the KompEx LTA-CAES® during charging process at minimum (62 % of nominal load) and maximum (100 % of nominal load) power consumption.

5. Conclusion

The introduced KompEx LTA-CAES® is able to efficiently realize wide CAS pressure ranges by the synergized use of turbo- and piston machines and appropriate control systems. Concretely, this is done by continuously varying the guide vanes of the turbomachines and a discrete control system to switch off single piston cylinders during the charging process. This offers an advantage compared to traditional A-CAES concepts using only turbomachines, especially when considering decentralized storage applications where artificial CAS technologies instead of salt caverns are usually suitable. For these applications, a high exergy density can have a decisive influence on the investment costs of the CAS volume and thus on the profitability of the overall system.

The strong fluctuations of process parameters during charging process (Figure 5) could be reduced by using piston cylinders with smaller swept volumes. Besides to the mass flow variation, the fluctuating intermediate pressure in particular is resulting to an operation of both machine types apart their design values. In order to realize a constant intermediate pressure and avoid discrete process fluctuations, a continuous control unit in the piston machinery train could be used, e. g. by implementing a variable speed control. This would lead to a more precise control and thus more efficient operation of the turbo and piston machines.

The operation behaviour of the reversibly operable turbo- and piston machines considered in this paper are derived from detailed CFD simulations within the KompEx project. In order to validate the respective data points, a test facility of the reversibly operable turbomachine is currently under construction.

[1] The calculation of the cycle efficiency in thermodynamic studies is often not uniform. Many studies are only calculating the thermal efficiency resp. are neglecting mechanical and electrical losses. For a better comparability, the thermal efficiency in the marked sources is converted to the electrical cycle efficiency by assuming an electrical conversion efficiency of 0.96 for the charging and discharging process. In the respective sources, the charging and discharging power are also converted to electrical powers using the same factor.

Abstract:

This paper presents an optimal control strategy for an industrial heat pump with thermal energy storage (TES) in a brewery. The objective of the study is to investigate the potential benefits of load shifting using the TES and the impact of the fluctuations of electricity price, solar radiation and carbon intensity of the grid on the system operating costs and CO_2 emissions. The study is conducted using a simulation model, and the results show that by utilizing the TES, the operating costs and CO_2 emissions of the heat pump can be reduced significantly. The optimal operation of the heat pump is found to be highly dependent on the electricity price and the efficiency of the heat pump. Furthermore, the study shows that cost-optimal operation leads to a reduction in CO_2 emissions and vice versa. The study highlights the potential benefits of implementing such an optimal control strategy in industrial settings, where energy demands are high and subject to electricity price fluctuations. However, accurately predicting parameters such as electricity price, solar radiation, and energy demand is crucial for the optimal control strategy to be effective. Implementing a predictive model that can accurately predict these parameters is necessary to exploit the potential of the optimal control strategy.

Keywords:

thermal energy storage, industrial heat pump, solar energy, heat recovery, energy efficiency, load shifting

1. Introduction

The transition from fossil fuels to renewable energy sources in the power sector presents a significant opportunity for the electrification of industry and the implementation of Power-to-Heat technologies, which would yield substantial environmental benefits. High Temperature Heat Pumps (HTHP) are capable of supplying heat up to 150 °C with high energy efficiency by upgrading industrial waste heat [1]. However, with the share of renewables in electricity production increasing, there is an emerging imbalance between energy production and consumption, necessitating new grid management approaches.

Thermal energy storage (TES) can play a vital role in enhancing grid flexibility by providing a means to balance the intermittent nature of renewable energy sources. TES systems enable excess thermal energy to be stored during times of high availability and used later during periods of low availability, such as during peak demand hours [2]. While TES have already been used for industrial waste heat recovery [3], the use of this technology may be key to help integrate HTHP and electrify industrial process heat.

While the combination of heat pumps and thermal energy storages to offer demand flexibility for domestic and district heating systems has been investigated in several papers [4]–[8], the industrial application is generally overlooked [9].

The objective of this study is to assess the capacity of an industrial heat pump system, when integrated with TES, to lower CO_2 emissions and operating expenses by optimizing its operating schedule. Additionally, this study examines the potential benefits of varying the system size, considering investment expenses, and conducts a sensitivity analysis of the parameters that mostly impact the results.

1.1 Case study

A brewery in Faxe, Denmark, previously described by Hansen et al.[10] is used as the case study throughout this work to evaluate the potential savings from the implementation of optimal heat pump operation. This industrial facility has an indirect heat recovery system that recovers heat from high-temperature processes and stores it in a 375 m^3 (V_{tank}) to later distribute it to various processes. The external heating is supplied by a

natural gas boiler through a pressurized hot water loop with a forward temperature of 145 °C. The cooling system currently rejects heat to the ambient through cooling towers. Additionally, the brewery installed a 12 MW ($P_{\mathrm{PV,nom}}$) photovoltaic (PV) park to reduce its electricity consumption.

As a measure to reduce the consumption of natural gas and contribute to its carbon neutrality goals, the facility will install a 1.2 MW ($Q_{\mathrm{HP,max}}$) heat pump to upgrade the heat from the condensers of the refrigeration system to deliver it to the heat recovery tank. This heat pump is the focus of this study. The heat source of the heat pump is stable throughout the year and the heat recovery tank offers an opportunity to optimize its operation.

A schematic representation of the system to be studied is given in Figure 1:

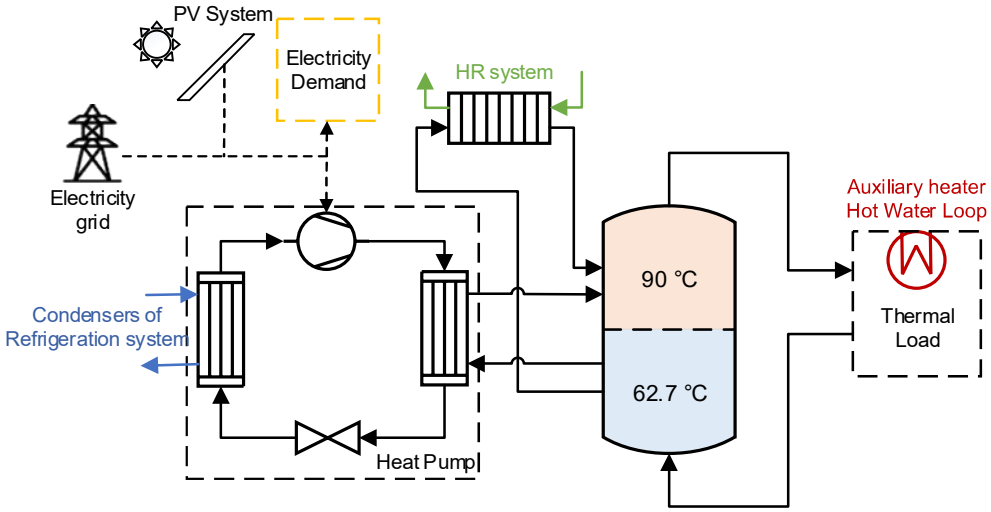

Figure 1:Schematic of the studied heat pump and TES system

Hourly data from the process demand ($Q_{\mathrm{Load},t}$), heat recovery system ($Q_{\mathrm{HR},t}$) and electricity consumption ($P_{\mathrm{load},t}$) is given by the brewery in order to calculate the potential savings from the optimal HP operation.

2. Methods

Hourly-based Time-series data of the electricity prices, carbon emission intensity and solar radiation, in combination with the thermal load, heat recovery and electricity consumption of the facility are used to optimize the operation of the heat pump delivering heat to the heat recovery tank. The optimization is performed in Python using Pyomo [11].

The study compares the CO_2-optimal and cost-optimal strategies with a base-case scenario that assumes no smart control. Additionally, an investigation is included to determine the optimal tank and heat pump size and to highlight the importance of thermal energy storage (TES) in the proper integration of the heat pump.

2.1. Preliminary calculations

In every case, the Coefficient of Performance (COP) of the heat pump is considered constant. It is calculated considering a fixed source temperature (T_{source}), which corresponds to the temperature of the condensers of the refrigeration system; fixed sink inlet ($T_{\mathrm{sink,in}}$) and outlet ($T_{\mathrm{sink,out}}$) temperatures corresponding to the temperatures in the tank; and a fixed Lorenz efficiency (η_{Lor}).

$$\mathrm{COP} = \eta_{\mathrm{Lor}} \cdot \frac{T_{\mathrm{sink,out}} - T_{\mathrm{sink,in}}}{T_{\mathrm{source}} \cdot \ln \frac{T_{\mathrm{sink,out}}}{T_{\mathrm{sink,in}}}} \quad (1)$$

The capacity of the tank ($E_{\mathrm{tank,max}}$) is also fixed for the entirety of the simulation. It is calculated as:

$$E_{\mathrm{tank,max}} = V_{\mathrm{tank}} \cdot \rho \cdot c_p \cdot \left(T_{\mathrm{sink,out}} - T_{\mathrm{sink,in}}\right) \quad (2)$$

The output from the PV system ($P_{\mathrm{PV},t}$) is calculated from the dataset representing a “Design Reference Year” on horizontal solar radiation ($G_{h,t}$) from the Danish Meteorological Institute [12] and the incidence angle (θ_t), dependant on the hour, day of the year, location, and tilt of the panels.

$$P_{\mathrm{PV},t} = P_{\mathrm{PV,nom}} \cdot \frac{G_{h,t}}{G_{\mathrm{STC}}} \cdot \cos(\theta_t) \quad (3)$$

2.2. Model description

The calculation of the annual cost and carbon emissions is based on the energy balance on the tank for every timestep (t) as well as the balance on the electricity used and the electricity generated from the PV panels.

In this study, the tank is considered a perfectly stratified tank, with two distinct temperature levels ($T_{\text{sink,in}}$ and $T_{\text{sink,out}}$) without mixing or ambient losses. The energy on the tank on the following timestep ($E_{\text{tank},t+1}$) is calculated using Eq. (4) from the current energy level ($E_{\text{tank},t}$), the heat recovered ($Q_{\text{HR},t}$), the energy output of the HP ($Q_{\text{HP,max}} \cdot x_t$) and the thermal demand ($Q_{\text{Load},t}$).

$$E_{\text{tank},t+1} = \begin{cases} 0 & if \quad E_{\text{tank},t} + Q_{\text{HR},t} + Q_{\text{HP,max}} \cdot x_t - Q_{\text{Load},t} < 0 \\ E_{\text{tank},t} + Q_{\text{HR},t} + Q_{\text{HP,max}} \cdot x_t - Q_{\text{Load},t} & if \quad 0 < E_{\text{tank},t} + Q_{\text{HR},t} + Q_{\text{HP,max}} \cdot x_t - Q_{\text{Load},t} < E_{\text{tank,max}} \\ E_{\text{tank,max}} & if \quad E_{\text{tank,max}} < E_{\text{tank},t} + Q_{\text{HR},t} + Q_{\text{HP,max}} \cdot x_t - Q_{\text{Load,t}} \end{cases} \tag{4}$$

Therefore, the energy from the heat recovery system to be curtailed ($Q_{\text{curt},t}$) and the energy that must be supplied to the load using the auxiliary boiler ($Q_{\text{boiler},t}$) are also calculated using Eq. (5) and Eq. (6):

$$Q_{\text{curt},t} = \begin{cases} 0 & if \quad E_{\text{tank},t} + Q_{\text{HR},t} + Q_{\text{HP,max}} \cdot x_t - Q_{\text{Load},t} < E_{\text{tank,max}} \\ E_{\text{tank,max}} - E_{\text{tank,t}} + Q_{\text{HR},t} + Q_{\text{HP,max}} \cdot x_t - Q_{\text{Load},t} & if \quad E_{\text{tank},t} + Q_{\text{HR},t} + Q_{\text{HP,max}} \cdot x_t - Q_{\text{Load},t} > E_{\text{tank,max}} \end{cases} \tag{5}$$

$$Q_{boiler,t} = \begin{cases} 0 & if \quad E_{\text{tank},t} + Q_{\text{HR},t} + Q_{\text{HP,max}} \cdot x_t > Q_{\text{Load},t} \\ Q_{\text{Load},t} - E_{\text{tank,t}} + Q_{\text{HR},t} + Q_{HP,\text{max}} \cdot x_t & if \quad E_{\text{tank},t} + Q_{\text{HR},t} + Q_{\text{HP,max}} \cdot x_t < Q_{\text{Load},t} \end{cases} \tag{6}$$

Finally, the operational costs and CO_2 emissions can be calculated. The price of electricity ($p_{\text{elec},t}$) and natural gas ($p_{\text{gas},t}$) in Denmark are found in Energinet [13] and the corresponding taxes as of 2021 are applied ($p_{\text{elec,taxes}}$). The data on the carbon intensity (CI_{elec}) is taken from ElectricityMaps database [14], and for the combustion of natural gas (CI_{gas}), a value of 200.8 g/kWh is considered [15].

The costs and emissions related to the combustion of natural gas are calculated using Eq. (7) and Eq. (8) respectively:

$$\text{Cost}_{\text{gas}} = \frac{1}{\eta_{\text{boiler}}} \cdot \sum_{t=0}^{t=n} Q_{\text{boiler},t} \cdot p_{\text{gas},t} \tag{7}$$

$$\text{CO}_{2\text{gas}} = \frac{\text{CI}_{\text{gas}}}{\eta_{\text{boiler}}} \cdot \sum_{t=0}^{t=n} Q_{\text{boiler},t} \tag{8}$$

For the electricity, the production from the PV panels is considered. The cost and emissions from the purchased electricity is calculated using Eq. (9) and Eq. (10) respectively:

$$Cost_{\text{elec}} = \sum_{t=0}^{t=n} \begin{cases} \left(p_{\text{elec},t} + p_{\text{elec,taxes}}\right) \cdot \left(\frac{Q_{\text{HP,max}} \cdot x_t}{COP} + P_{\text{load},t} - P_{PV,t}\right) & if \quad \frac{Q_{\text{HP,max}} \cdot x_t}{COP} + P_{\text{load},t} > P_{\text{PV},t} \\ p_{\text{elec},t} \cdot \left(\frac{Q_{HP,\text{max}} \cdot x_t}{COP} + P_{\text{load},t} - P_{PV,t}\right) & if \quad \frac{Q_{\text{HP,max}} \cdot x_t}{COP} + P_{\text{load},t} < P_{\text{PV},t} \end{cases} \tag{9}$$

$$CO_{2\text{elec}} = \sum_{t=0}^{t=n} \begin{cases} CI_{\text{elec},t} \cdot \left(\frac{Q_{\text{HP,max}} \cdot x_t}{COP} + P_{\text{load},t} - P_{\text{PV},t}\right) & if \quad \frac{Q_{\text{HP,max}} \cdot x_t}{COP} + P_{\text{load},t} > P_{\text{PV},t} \\ 0 & if \quad \frac{Q_{\text{HP,max}} \cdot x_t}{COP} + P_{\text{load},t} < P_{\text{PV},t} \end{cases} \tag{10}$$

2.3. Heat Pump operation

2.3.1. Base case operation

The basic control strategy of the heat pump does not consider fluctuations on electricity price or CO_2 emission intensity, nor the power produced by the PV system. In this case, the operation of the heat pump is solely regulated by the energy level stored in the tank.

When the state of charge of the tank ($E_{\text{tank},t}$ / $E_{\text{tank,max}}$) is below 50 %, the HP is working at its maximum capacity ($x_t = 1$). As the energy level in the tank approaches the 50 % threshold, the power output of the HP is proportionally reduced. In order to avoid curtailing energy from the HR system, the HP is deactivated ($x_t = 0$) when the tank level reaches 80 % of its maximum capacity. To avoid curtailment of energy from the heat recovery system, the HP is turned off when the level on the tank is at 80 % of its maximum capacity. This straightforward control strategy is intended to prevent energy wastage while maximizing the use of the heat pump. The control of the HP as function of the energy level on the tank can be shown in Figure 2:

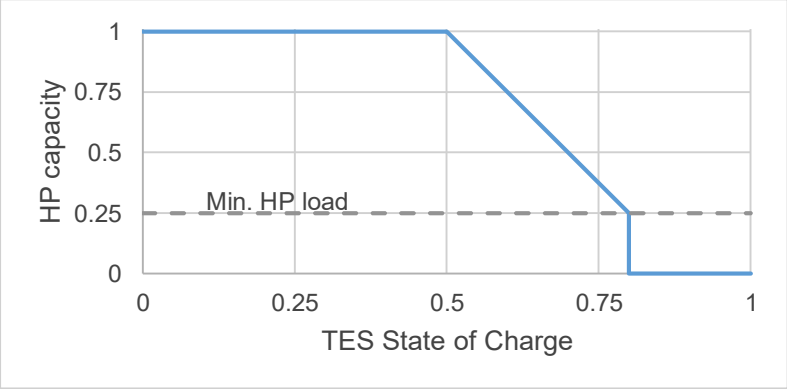

Figure 2: HP control strategy for the base case

2.3.2. CO_2 and cost-optimal heat pump operation

In contrast to the previous section, the CO_2 and the cost-optimal operation strategies consider the fluctuations on the electricity price or carbon intensity as well as the fluctuation of the power output of the PV panels. The model described previously is implemented in Pyomo, with the capacity of the HP at each timestep (x_t) as the optimization variable.

Two distinct optimizations are performed with two different objective functions: a cost-optimal operation ($\text{Cost}_{\text{gas}} + \text{Cost}_{\text{elec}}$) and a CO_2-optimal operation ($\text{CO}_{2_{\text{gas}}} + \text{CO}_{2_{\text{elec}}}$).

Additional constraints are included to limit the maximum ramp-up ($x_{\text{ramp-up}}$) and ramp-down ($x_{\text{ramp-down}}$) of the heat pump capacity between consecutive timesteps.

2.4. Uncertainty and sensitivity analysis

Throughout this analysis, certain parameter values have been assumed, and while some of these assumptions are reasonable, others, especially those related to the efficiency of the heat pump, are subject to significant uncertainty.

To investigate the robustness of the study's conclusions under different scenarios and to put the potential benefits of the optimal operation schedule into perspective relative to other sources of uncertainty, an uncertainty analysis is conducted. Table 1 shows the parameters that will be investigated.

Table 1: Parameters and uncertainties used in the analysis

Parameter	Mean value	Type of deviation	Deviation
T_{source}	15 °C	Uniform, absolute	3 K
$T_{\text{sink,in}}$	62.7 °C	Uniform, absolute	1 K
$T_{\text{sink,out}}$	90 °C	Uniform, absolute	1 K
η_{Lor}	50 %	Normal, absolute	5 %
η_{Boiler}	95 %	Normal, absolute	5 %
$x_{\text{min.load}}$	25 %	Uniform, absolute	5 %
$x_{\text{ramp-up}}$	90 %	Uniform, absolute	10 %
$x_{\text{ramp-down}}$	90 %	Uniform, absolute	10 %

The parameters related to the efficiency of the HP have high uncertainty. The value of 50 % is reasonable approach to the calculation of the efficiency of the HP and is taken from a recent market overview [1]. The other parameters including the ramp-up, ramp-down and minimum load are taken from the technology catalogue [16].

The values for the temperatures and the efficiency of the boiler are given by the brewery. For these parameters, less conservative approach to its uncertainty has been taken.

Among the possible techniques, the Monte Carlo analysis is chosen for the present study [17]. This method is chosen for its usefulness not only for uncertainty but for the sensitivity analysis by linear regression techniques. After defining the parameters and their uncertainties, a sampling number of *N*=2000 is defined, and a sampling matrix is generated by means of Latin hypercube sampling. Finally, *N* number of simulations are performed using this matrix, and the results are retrieved to analyse their uncertainties.

A sensitivity analysis is also performed for the economic savings and CO_2 reduction when using a cost-optimal operation schedule. For the sensitivity analysis on the model, the Standardized Regression Coefficient (SRC) method is used. The SRC method provides a measure of the sensitivity of the model output to each input parameter. It does this by quantifying the magnitude and direction of the effect of each input parameter on the output, while controlling for the effects of the other input parameters. This method quantifies the sensitivity of the results on input parameters by constructing a linear model based on the outputs from the Monte Carlo simulation [18].

2.5. Optimal heat pump and tank size

The optimized operation schedule of the HP may result in an improved business case for the HP and TES system. To explore this further, this work includes a small investigation on the investment costs of the system and compares the optimal sizing of the HP and TES to the base case operation.

The investment cost ($\mathrm{Cost}_{\mathrm{inv,tank}}$ and $\mathrm{Cost}_{\mathrm{inv,HP}}$) functions are found in the Technology Catalogue from the Danish Energy Agency [16]:

$$\mathrm{Cost}_{\mathrm{inv,tank}} = 7450 \cdot {V_{\mathrm{tank}}}^{0.53} \tag{11}$$

$$\mathrm{Cost}_{\mathrm{inv,HP}} = 0.73 \cdot Q_{\mathrm{HP,max}} \tag{12}$$

The investment cost is annualized by annualization factor considering a discount rate of *i*=5% and a lifetime of LT_{HP}=25 years and LT_{tank}=40 years.

$$\mathrm{Cost} = Cost_{\mathrm{inv}} \cdot i \frac{(1+i)^{\mathrm{LT}}}{(1+i)^{\mathrm{LT}} - 1} + \mathrm{Cost}_{op} \tag{13}$$

Note that, in this part of the analysis, an uncertainty analysis is not performed, as such an optimization would have been much more time-consuming and computationally demanding. The average values of the parameters presented in Table 1 are used.

3. Results

3.1. Energy use

The annual thermal energy demand of the facility is 16,815 MWh, with 8,587 MWh provided by the heat recovery system. The amount of heat delivered by the HP and the boiler, however, differ for every case. Table 2 shows the annual thermal energy use in the facility in all of the three cases:

Table 2: Results on heat use

	Base case operation	Cost-optimal operation	CO_2-optimal operation
Heat Pump	8,017.5 ± 0.2 MWh	8,166.4 ± 0.2 MWh	8,107 ± 4 MWh
Boiler	210.1 ± 0.2 MWh	61.3 ± 0.2 MWh	119 ± 4 MWh
Heat Recovery	8,587.3 MWh	8,587.3 MWh	8,587.3 MWh
Curtailment	0 MWh	0 MWh	0 MWh
Total load	16,815.0 MWh	16,815.0 MWh	16,815.0 MWh

In every case, the entirety of the energy from the HR system is utilized, and the curtailment of energy is avoided. From the three scenarios, the cost-optimal operation avoids utilizing the boiler as much as possible, even more than the CO_2-optimal operation. This implies that, with a sufficiently low HP efficiency and a very unfavourable electricity mix, the natural gas boiler is in fact avoiding CO_2 emissions. There is, however, a high degree of uncertainty in this aspect, and this strategy seems to be the most sensitive to the uncertainties of the inputs.

As for the electricity use, the electricity demand of the brewery before considering the HP is 28,063 MWh and the solar panels produce 8,074 MWh annually. Table 3 shows the main results on the electricity use on the three cases:

Table 3: Results on electricity use

	Base case operation	Cost-optimal operation	CO_2-optimal operation
Elec. Purchase	24,110 ± 12 MWh	24,120 ± 12 MWh	24,097 ± 10 MWh
Elec. Sold	1,283 ± 1 MWh	1,241 ± 1 MWh	1,241 ± 1 MWh
HP consumption	2,839 ± 13 MWh	2,891 ± 13 MWh	2,867 ± 12 MWh
PV production	8,074.4 MWh	8,074.4 MWh	8,074.4 MWh
Demand (without HP)	28,061.7 MWh	28,061.7 MWh	28,061.7 MWh

In both cost and CO_2 optimal operation schedules, the selling electricity from the PV power is avoided compared to the base case operation. The uncertainties in the results, especially in the electricity consumption of the HP, seem to be larger than the uncertainties presented in Table 2.

It is important to note that the electricity consumption of the heat pump, and therefore the focus of this optimization represents only between 9.1 and 9.3 % of the total electricity demand.

3.2. Potential for cost and CO_2 emission reduction

While the difference in annual energy consumption is not substantial, the cost and emissions reduction achieved through smart operation of the system is, given that the HP only represents a fraction of the energy consumption of the brewery, quite significant. Specifically, the total operation cost including natural gas and purchased electricity is 2,934,900 ± 1,500 € in the base case, but it is reduced to 2,901,700 ± 1,400 € and 2,918,800 ± 1,500 € in the cost- and CO_2-optimal cases, respectively. Additionally, the annual CO_2 emissions are 7,021 ± 3 kgCO_2eq. in the base case and are reduced to 6,964 ± 3 kgCO_2eq. and 6,922 ± 3 kgCO_2eq. in the cost- and CO_2-optimal cases, respectively.

The potential for reduction of costs and emissions is shown in Figure 3:

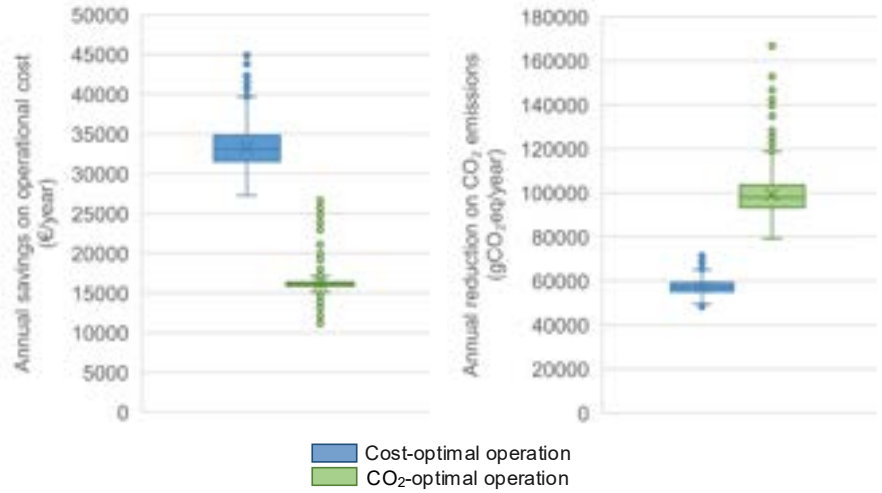

Figure 3: Potential for cost and emission reduction using a cost-optimal and CO_2-optimal HP operation

The average cost reduction is 33,286 ± 108 €/year and 16,148 ± 38 €/year for the cost- and CO_2-optimal operation, respectively. Similarly, the reduction in CO_2 emissions is 57.27 ± 0.13 kgCO_2eq. and 99.19 ± 0.38 kgCO_2eq. for cost- and CO_2-optimal operation, respectively. These results show that the cost-optimal smart operation of the heat pump not only would imply economic savings but also reduce CO_2 emissions and vice versa, as the CO_2-optimal operation would imply a reduction in the operational cost.

3.3. Sensitivity analysis

The sensitivity of the results shown in Figure 3 on the input parameters from Table 1 is measured using SCR method. The Standardized Regression Coefficients for each input with respect to each of the four model outputs are shown in Table 4:

Table 4: SRC of the input parameters for each of the outputs

	Cost reduction (Cost-optimal)	Cost reduction (CO_2-optimal)	Emissions reduction (Cost-optimal)	Emissions reduction (CO_2-optimal)
T_{source}	-0.126	-0.041	-0.106	-0.120
$T_{\text{sink,in}}$	-0.031	-0.070	-0.097	-0.041

$T_{\text{sink,out}}$	0.067	0.084	0.128	0.071
η_{Lor}	-0.947	-0.368	-0.798	-0.930
η_{Boiler}	0.217	-0.130	-0.564	-0.119
$x_{\text{min.load}}$	-0.140	-0.043	-0.117	-0.109
$x_{\text{ramp-up}}$	-0.001	0.002	-0.003	-0.007
$x_{\text{ramp-down}}$	-0.006	-0.005	-0.004	-0.013
R^2	0.981	0.165	0.985	0.900

The linear fit is good for the cost and emissions reduction on the cost-optimal operation case and for the reduction in emissions for the CO_2-optimal case, having a coefficient of determination (R^2) of 0.981, 0.985 and 0.900 respectively. On the other hand, a linear model cannot describe the variance of the reduction in cost on the CO_2-optimal case, with an R^2 that is 0.165, a value way below the acceptable threshold [19]. In this case, the SRC method does not capture all the interactions between the inputs and the non-linear behaviour of the system. Therefore, some sources of uncertainty may remain unaccounted for. It is possible that this uncertainty can be attributed to the non-linear relationship between the electricity price and the CO_2 intensity of the grid, which may not be fully captured by the linear model used in this study.

The Lorenz efficiency of the HP is in any case the main source of uncertainty. A negative, high SRC value indicates that an increase in the Lorenz efficiency will decrease the savings relative to the basic operation. This is an expected outcome, since the COP improvement will decrease the costs and CO_2 emissions, the absolute difference in the savings is diminished.

3.4. Optimal heat pump and tank size

The reduction of operational cost derived from the use of the TES for load-shifting affects the business case of the HP and the TES. The optimal size of the HP and TES system using an optimized operation schedule differs from the optimal size using the base case operation. Figure 4 shows the annualized costs (from Eq. 13) for different configurations of HP and TES for both the base-case and the cost-optimal operation:

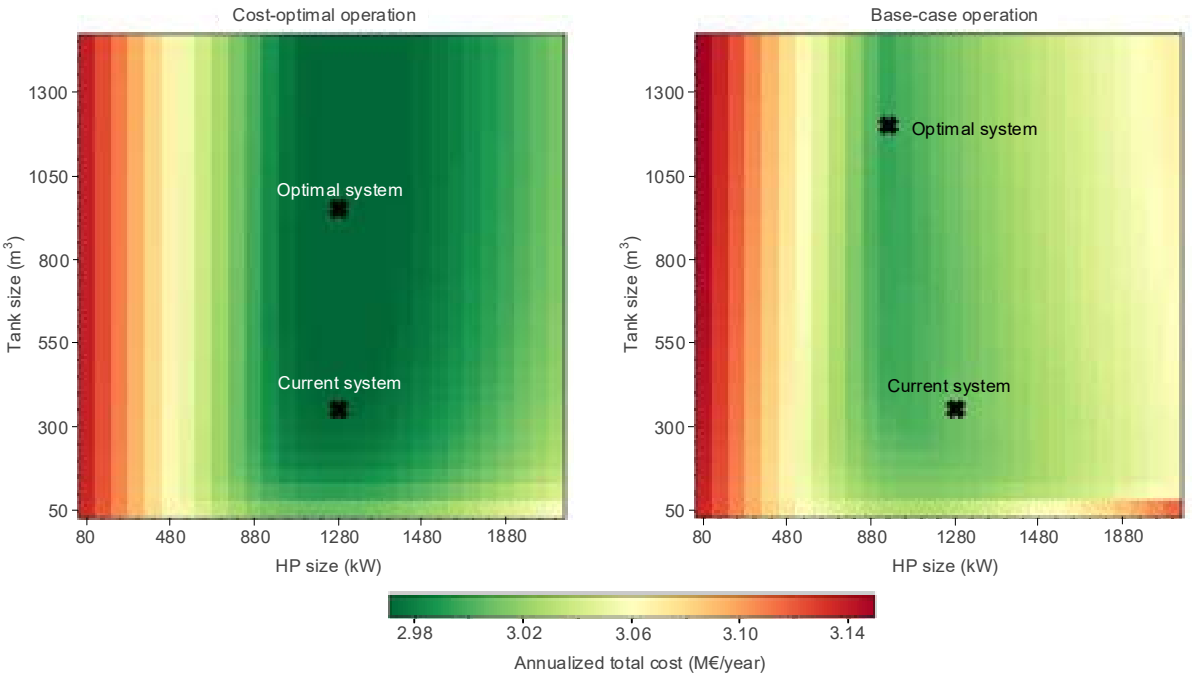

Figure 4: Annualized total costs of different HP and TES sizes using cost-optimal and base-case operation schedules

The optimal size of the system is a 960 kW HP with a 1,200 m^3 tank for the base case and a 1,280 kW HP with a 950 m^3 tank for the case with an optimized operation schedule.

As shown, the optimal size of the system is dependant on the operation strategy used. When the optimized operation is implemented, the HP size can be much larger, completely avoiding any combustion of natural gas

and being able to supply more heat during the hours with high solar output or low electricity prices. Additionally, the tank size much smaller, as its operation is optimized to take advantage of the entirety of its capacity.

Note that, due to space constraints, the current TES system installed in the brewery is largely undersized. With the current HP system projected, an additional 375 m^3 of storage capacity (doubling the size of the current tank) would reduce the annual operation costs of the facility by 8,300 € for the base case and 12,300 € for the cost-optimal case.

4. Discussion

The results show a big potential for savings with the smart operation of the Heat Pump. These reductions on cost and emission, however, do not necessarily come from a reduction on the energy use (as shown in Table 1 and Table 2) but from an optimal scheduling of the HP.

To visualize this effect, the consumption of electricity for three normal days of operation is shown in Figure 5 for the cost-optimal schedule. Note that, in this figure, the electricity has been normalized to the electricity demand of the brewery and does not represent absolute values.

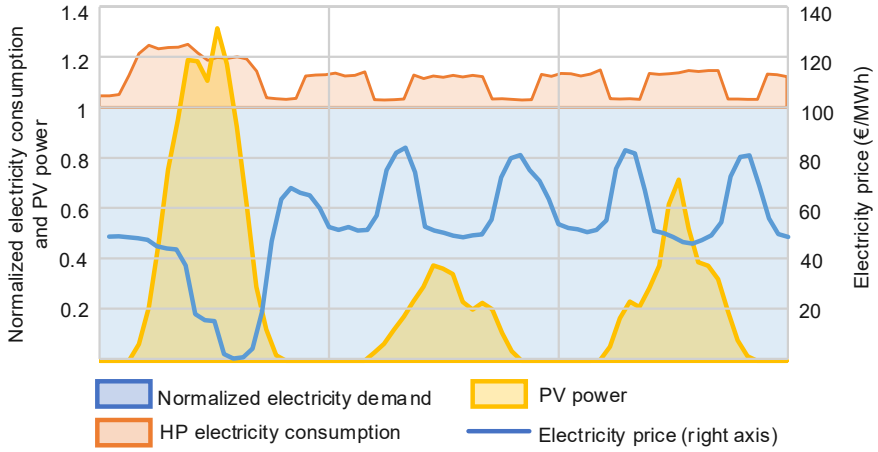

Figure 5: Normalized electricity consumption and electricity price for the Cost-optimal operation schedule for three days of operation

The electricity consumption of the HP represents, at most, less than 30 % of the rest of the brewery's electricity demand. This relatively small flexibility, however, is exploited in order to avoid an excess on the PV power production to be sold to the grid. It is also noticeable that, during the hours with peak electricity price (right axis in Figure 5), the HP is working at minimum load when possible.

A similar behaviour can be observed in the CO_2-optimal schedule. Figure 6 shows the electricity consumption in the CO_2-optimal case during the same three days of operation:

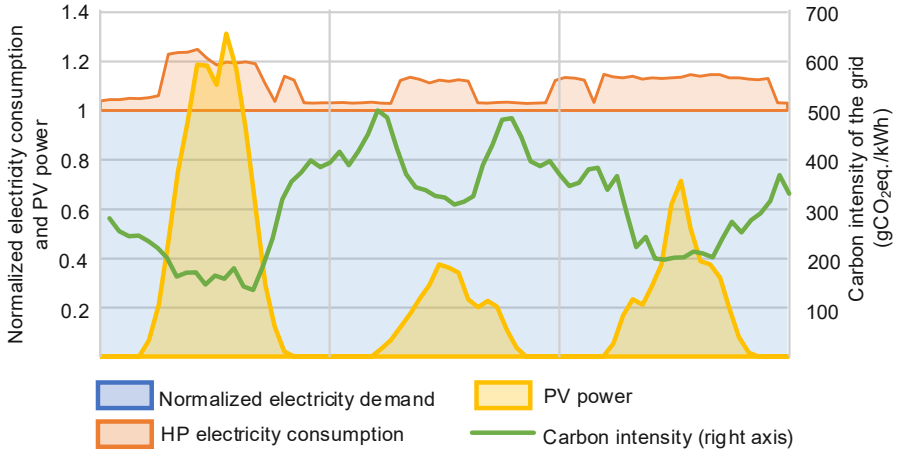

Figure 6: Normalized electricity consumption and carbon intensity of the grid for the CO_2-optimal operation schedule for three days of operation

In this case, the electricity from the PV park is used as much as possible, and the fluctuations in the carbon intensity of the grid also affect the operation of the HP. During high carbon intensity hours, the HP is working at minimum load.

The effects observed in Figure 5 and Figure 6 are, as shown in the results from Figure 3, not exclusive. The electricity cost is closely related to the electricity mix and therefore its carbon intensity. As the most carbon-intense are also the most expensive energy sources, the cost-optimal schedule is also reducing CO_2 emissions.

4.1. Heat pump operation

As shown in Figure 5 and Figure 6, both the fluctuations of the energy price or carbon intensity and the generation from the PV park increase the impact of the optimal HP operation. Figure 7 compares the operation of the HP in base case with the cost-optimal and CO_2-optimal operation for one day:

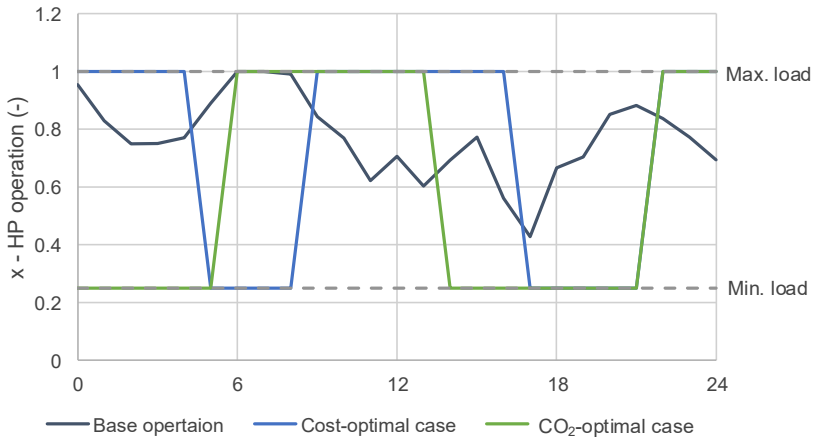

Figure 7: Heat pump operation for one day

In the optimal operation strategy, the HP operates almost independently of the energy level in the tank and instead follows a pattern that inversely corresponds to the electricity price. The HP operates intermittently between maximum and minimum loads, without operating at part-load. While this approach can improve the cost and emissions efficiency of the system, it may also cause more extreme and less smooth operation, potentially reducing the HP's lifetime and limiting its implementation [20]. Nevertheless, the maximum ramp-up and ramp-down speeds are already included in this work, with no significant impact observed.

The efficiency of the HP has the largest impact on results on absolute savings when comparing the optimal operation to the base case operation. While a heat pump with a given efficiency is a reasonable approximation for a preliminary study, a more detailed calculation of the COP and an actual dynamic HP model would be necessary to assess the potential savings in more detail.

4.2. Thermal energy storage operation

In the base case, the operation of the HP is determined by the energy level in the TES. It is designed to maintain an energy level that would avoid energy curtailment from the HR system and avoid emptying the tank as much as possible.

On the other hand, the optimized schedules take advantage of the flexibility given by the tank to optimize the schedule of the HP. In this case, the tank is charged and discharged more frequently, instead of being maintained at a certain energy level. An example of the TES operation is given in for the same day of operation in Figure 8:

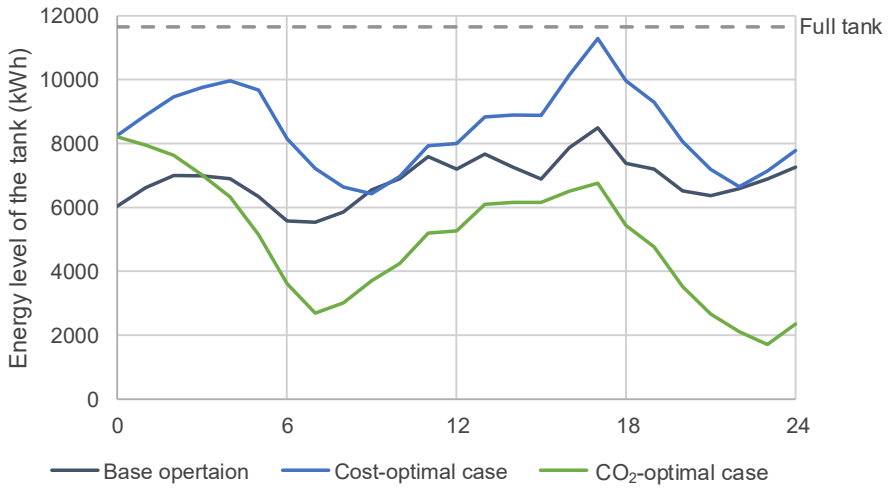

Figure 8:Thermal Energy Storage operation for one day

The model used in this research for the tank is very simple and does not take into account heat losses or mixing in the tank. Although assuming no mixing losses in the tank may seem unrealistic, it is reasonable only when the charging and discharging times are large. In the case of optimal operation, the heat pump (as shown in Figure 7), is working at its maximum or minimum load. Therefore, the tank is charged and discharged at faster speeds, which could lead to an increase in mixing losses of the tank [21].

The synergy of the TES and HP system is highlighted by the investment cost results. The existing tank in the facility was originally intended to be used for heat recovery. However, the investigation on investment costs shows that is largely undersized when it is used as a heat sink of the HP. A larger tank would allow the HP to deliver more heat to the load, and the use of natural gas could be avoided.

4.3. Directions for future research

While the sensitivity analysis demonstrated the significant impact of uncertainty on some parameters, particularly the efficiency of the HP, this study utilized fixed time datasets for the load, electricity consumption, PV power, heat recovery, and electricity price to evaluate the potential of the proposed smart operation. However, uncertainties associated with the accuracy of these parameter predictions must be taken into account when implementing this operational strategy.

To evaluate the actual system performance, it is necessary to incorporate a predictive model for these factors. Predictions on variables such as electricity price, solar radiation, or energy consumption within the brewery are typically only valid over a 24-hour time period. It would be interesting to investigate how such a predictive model would affect the results obtained in this study, thereby assessing the viability of implementing this approach in practice.

Furthermore, the heat pump and TES system considered in this study could be expanded to include more complex features, such as multiple heat sources or loads, and other possible energy storage systems (e.g., batteries) that could be used in conjunction with the TES. In addition, the use of a more detailed model for the heat pump, such as a dynamic model, would provide a more detailed assessment of the system's performance.

Finally, the investment cost analysis showed that a larger TES tank would be more cost-effective, which suggests that the sizing of the TES tank should be a consideration when designing a system of this kind. Further investigation into optimal tank sizing and operation could yield additional insights into system performance and cost-effectiveness.

Overall, this study provides a starting point for the development and implementation of smart energy management strategies and integration of HP with TES. However, additional research is needed to optimize and validate these strategies in practice.

5. Conclusion

The results of this study demonstrate the significant potential for reducing the cost of operation and CO_2 emissions of an industrial heat pump with thermal energy storage. By using an optimal control strategy that takes advantage of the thermal energy storage, load shifting can be achieved, which significantly improves the business case of the heat pump. The results show a significant correlation between the cost-optimal and CO_2-optimal operations of the HP. Optimal scheduling for cost reduction also leads to a reduction in CO_2 emissions

and vice versa. Therefore, regardless of the CO_2 emission policies or electricity purchase agreements, smart operation of the system is both economically and environmentally beneficial.

It is important, however, to carefully evaluate the performance of the system, especially the COP of the heat pump, in order to assess the potential savings. The smart operation of the HP should be investigated further, as its synergy with the TES could change the optimal system configuration and benefit the business case for the overall system.

While the potential of the optimal control strategy has been shown, implementing such a strategy in practice can be challenging. One challenge is making accurate predictions on parameters such as electricity price, solar radiation, and energy demand, especially in complicated industrial settings. The results of this study were based on fixed time datasets, and the actual performance of the system will depend on the accuracy of these predictions. Therefore, implementing a predictive model that can accurately predict these parameters is key to exploiting the potential of the optimal control strategy.

Another challenge is the impact of the optimal control strategy on the lifetime of the heat pump. The results of this study showed that the optimal control strategy resulted in less smooth, more extreme operation of the heat pump. While the maximum ramp-up and ramp-down speed was included in the analysis, the impact of this type of operation on the lifetime of the heat pump is still an open question.

Despite these challenges, the potential benefits of the optimal control strategy cannot be ignored. This study has shown that by using thermal energy storage and load shifting, significant cost and emission reductions can be achieved. These benefits are especially important for industries that have high energy demands and are subject to fluctuating electricity prices.

In summary, the potential of an optimal control strategy for an industrial heat pump with thermal energy storage has been shown to be a promising approach for reducing costs and emissions. However, implementing this strategy in practice requires accurate predictive models and careful consideration of the impact on the lifetime of the heat pump. Nonetheless, this study provides valuable insights into the potential benefits of this approach and sets the stage for further research in this area.

Nomenclature

COP	Coefficient of Performance (-)	Q	Heat (kWh)
CI	Carbon Intensity ($gCO_2eq./kWh$)	T	Temperature (°C)
c_p	Heat capacity (kWh/kg K)	V	Volume (m^3)
E	Energy (kWh)	x	Capacity factor (-)
G	Irradiance (W/m^2)	η	Efficiency (-)
LT	Lifetime of investment (years)	θ	Incidence angle (°)
P	Electrical power (kWh)	ρ	Density (kg/m^3)
p	Price (€/kWh)

Abstract:

With the increasing volatility in natural gas markets and the need for residential heat, research for alternative fuels is necessary for several regions. This paper presents a high-duration thermochemical energy storage system (TCES) based on methanol, evaluating its integration with district heating networks, offering a renewable solar-based storage solution and low-temperature heat generation from the exothermic discharge reaction heat. The system eliminates greenhouse gas emissions by using concentrated solar thermal energy to decompose methanol into synthesis gas. Applying the optimised operational thermodynamic parameters, it is possible to satisfy the thermal demand of 892 households in Spain through 12 MW of concentrated solar energy supported by 10 hours of energy storage. Storage efficiencies exceeding 30% and chemical conversion efficiencies exceeding 65% have been demonstrated, resulting in a combined efficiency of 55% for the heating network and methanol TCES. The results show a levelized cost of storage (LCOS) highly competitive with other storage systems (<100 €/MWh), given the simplicity and flexibility of the proposed system.

Keywords:

Thermochemical Energy Storage, Methanol, Concentrated Solar Power, District Heating

1. Introduction

Global energy consumption has increased significantly in recent decades [1]. IEA expects that the new renewable installed capacity in the next five years (>2300 GW) will be equivalent to that installed in the past 20 years [2]. Despite this effort to contribute to a clean and sustainable generation [3]–[5], many processes still require thermal power and an energy source constant over time.

The challenges posed by the COP21 objectives [6] regarding the control of the global average temperature increase assume the deployment of a storage capacity of 9000 GWh by 2050 [7]. Currently, sensible heat storage systems (SHS) and latent heat storage (LHTES) have gained commercial capacity [8]–[10], but still have high costs and unavoidable environmental losses. In this regard, thermochemical energy storage systems (TCES) are presented as an alternative. Thermal energy decomposes chemical bonds generating products that can release energy when integrated into a discharge cycle through an exothermic reaction [11]. The versatility and flexibility of the system, given various possible storage strategies, offer an additional solution to TES and phase-change material (PCM) systems [12].

District heating systems distribute heat from a central source, such as a power plant or industrial facility, to multiple buildings in a geographical area [13]. Energy storage can be used in district heating systems to enhance efficiency and reduce their environmental impact [14]. For instance, surplus heat generated by a power plant or industrial facility can be stored in a TES system [15]. This heat can then be used to meet the heating requirements of the buildings in the district during peak demand times, reducing the need to generate additional heat from fossil fuels [16], [17]. Furthermore, energy storage can be used in conjunction with renewable energy sources to provide a reliable heat source for district heating systems [18]–[20]. This can help reduce the dependence on fossil fuels and improve the overall sustainability of the district heating system [21]–[24]. Thermochemical energy storage (TCES) can be used in district heating systems to store and discharge heat from clean energy sources, such as solar or geothermal power [25]–[27]. In this application, methanol is heated to a relatively low temperature (<315 ºC) [28], leading to its decomposition into hydrogen (H_2) and carbon monoxide (CO). The heat produced by the synthesis reaction is then stored in a thermal energy storage system, such as a large tank of water or molten salt [29]. When the stored heat is needed, high-pressure hydrogen gas and carbon monoxide are recombined to produce methanol. This reaction releases heat, which can generate steam and power a turbine to produce electricity [30]–[32] or, as proposed in this work, to support permanent district heating operation. The TCES stores renewable energy and releases it when needed in the system, substituting the boilers. Liu and Yabe [30] proposed a system for transporting energy using methanol, which involves a two-stage process for synthesising methanol in a liquid phase. This

process includes the formation of intermediate products, such as methyl formate, achieving a transportation efficiency of 75% for a conversion ratio. In the study by Bai et al. [29], technical feasibility was evaluated for a 20 kW methanol-based thermal energy storage system consisting of a remodelled parabolic through the collector. A novel system proposed by Rodriguez-Pastor et al. [31] involved the conversion of methanol to methane TCES configuration, from its intermediate step to synthesis gas, obtaining an overall efficiency of 40%.

The advantage of using methanol TCES in district heating systems is that it allows surplus heat generated by renewable energy sources to be stored for later use [32], while methanol can be obtained from cheap and clean feedstocks, such as biomass [33]. Integration of district heating networks with storage further increases overall associated costs, but allows for a reduction in fuel consumption, typically natural gas with volatile prices. This can help to enhance the reliability and stability of the district heating system and reduce the need to generate heat from fossil fuels [34]. Therefore, thermochemical storage is a promising technology for storing and releasing heat from renewable energy sources [35], and its potential to improve the efficiency and sustainability of district heating systems is discussed in this work, by presenting a form of thermal energy generation, which is also storable and without greenhouse gas emissions. In addition, this paper demonstrates that its levelized cost of storage (LCOS) is highly competitive with other TCES systems, given the simplicity and flexibility of the proposed system.

2. System Description

The proposed system (**Figure 1**) makes use of methanol decomposition and synthesis reactions. Thermal integration for the endothermic reaction will be done with a central receiver system and a heliostat field. The liquid pumping of methanol at the inlet of the charge cycle will reduce the compressor power [31], bringing the liquid methanol to 10 bar at the reactor inlet.

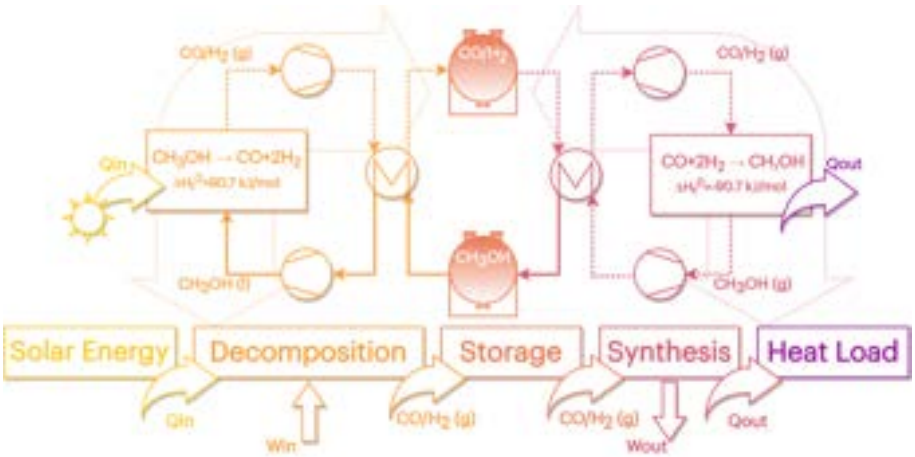

Figure 1. Conceptual process flow diagram of the proposed Methanol-based solar hybrid TCES system.

At the outlet of the charge phase, the synthesis gas (H_2/CO) is stored in tanks, to be discharged into the bottoming cycle, which will synthesise the syngas to methanol at 50 bar. The heat generated in this exothermic reaction will be recovered in a jacket exchanger for the generation of hot water for district heating. The full integration of both charging and discharging cycles is shown in **Figure 2**.

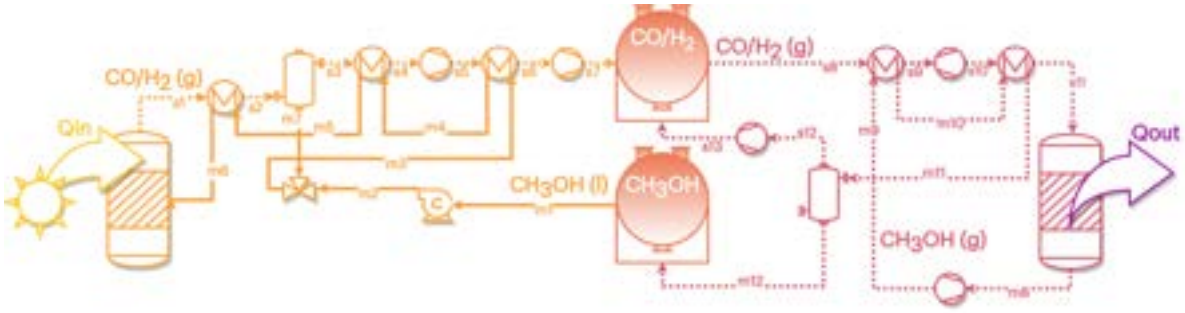

Figure 2. Process flow diagram of the Methanol-based solar hybrid TCES system. m: Methanol, s: Syngas, Qin: Required endothermic heat, Qout: Exothermic heat. Dotted lines: gas-state phase, solid line: liquid-state phase

Methanol-to-syngas conversion can occur in several ways: direct decomposition of methanol [36], steam reforming [37], partial oxidation [38] and auto-thermal reforming [39]. The direct decomposition reaction (Equation 1) is a simple reaction that occurs at temperatures below 350°C [40]. Full methanol conversion is obtained at higher temperatures as the inlet pressure increases.

$$CH_3OH \rightarrow CO + 2H_2 \qquad \Delta H_{298} = 90.7\ kJ/mol \tag{1}$$

Liquid methanol will be pumped into a network of heat exchangers (**Figure 3**), which will use the syngas generated at high pressure and temperature to preheat CH_3OH. Unreacted methanol is separated from a flash separator and recirculating this methanol back into the reactor to ensure complete conversion.

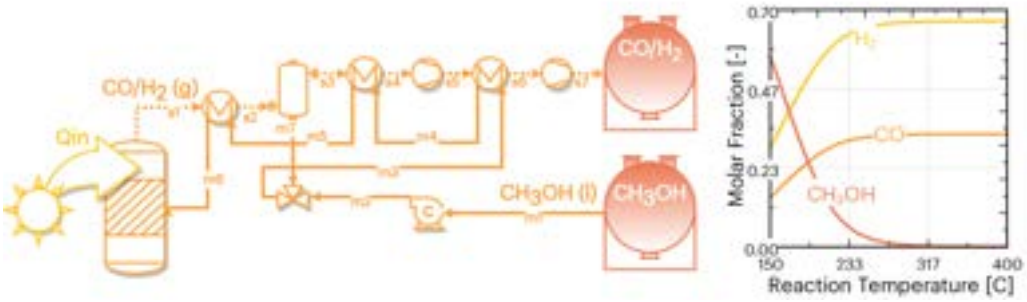

Figure 3. Process flow diagram of the direct solar decomposition of the methanol process (charge phase) and the associated conversion of the molar fraction as a function of reaction temperature. m: Methanol, s: Syngas, Qin: Required endothermic heat. Dotted lines: gas-state phase, solid line: liquid-state phase

The conversion of syngas to methanol releases thermochemical energy. Syngas is produced and stored at 100 bar and ambient temperature, avoiding thermal losses and providing long-term energy storage capability. This paper focuses on the analysis of the former, converting syngas to methanol in a closed-loop approach for TCES systems (Equation 2):

$$CO + 2H_2 \rightarrow CH_3OH \qquad \Delta H_{298} = -90.7\ kJ/mol \tag{2}$$

Syngas-to-methanol (**Figure 4**) is the main route of global methanol production [37]. The reaction occurs in a range of 15-150 bar, 180-300°C, and an H_2/CO ratio< 4.1 [26], [41], catalysed by a standard industrial catalyst ($Cu/ZnO/Al_2O_3$) [42]. This work assumes a quasi-isothermal tubular reactor at 50 bar. The heat released in the exothermic formation of methanol is provided to a heat transfer fluid (HTF) that circulates through a cooling jacket around the reactor [40].

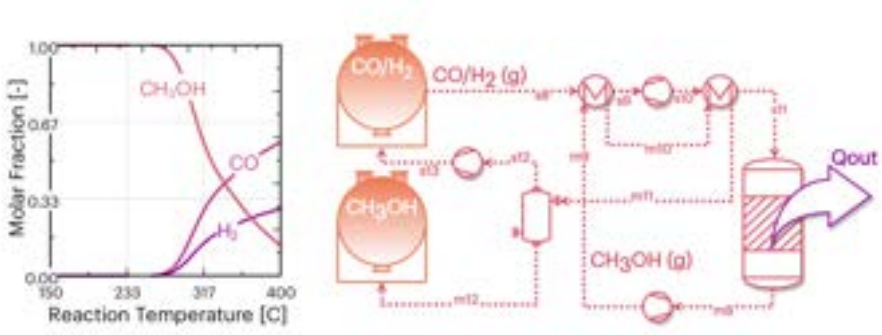

Figure 4. Process flow diagram of the methanol synthesis process (discharge phase) and associated molar fraction conversion as a function of reaction temperature. m: Methanol, s: Syngas, Qout: Exothermic heat. Dotted lines: gas-state phase, solid line: liquid-state phase

3. Simulation

The methanol TCES system has been simulated with the commercial software ASPEN HYSYS [45] using the Peng-Robinson thermodynamic package. The nominal input parameters of the system are shown in **Table 1**. The entire equipment required for the process is well-known in the industry and can be modelled using lumped

volume approaches, as discussed in [43]. However, more detailed kinetics and higher-resolution models maoffer even more precise results [44].

Table 1. Thermodynamic considerations assumed for the simulation of the methanol TCES system.

Variable	Value
Inlet CH_3OH molar flow of the charging process	100 mol/s
CH_3OH storage temperature/pressure	64.67 ºC / 1 bar
Heat Exchangers approach temperature	20 K
Isentropic efficiency of liquid methanol pump	65%
Isentropic efficiency of compressors	89%
Isentropic efficiency of turbines	92%
Endothermic reaction temperature/pressure	315 ºC / 10 bar
Exothermic reaction temperature/pressure	250 ºC / 50 bar
Syngas CO/H_2 storage pressure	100 bar
Discharge pressure	1 bar
Energy storage time	10 hours

Thermodynamic evaluation has been carried out based on the definition of the overall performance (η_{plant}) of the TCES system (Equation 3).

$$\eta_{plant} = \frac{\dot{Q}_{exo} + \dot{W}_T}{\dot{Q}_{CH_3OH} + \dot{Q}_{sol}} \cdot \psi = \frac{\dot{Q}_{exo} + \dot{W}_T}{HHV_{CH_3OH} \cdot \dot{m}_{CH_3OH} + \dot{W}_{PV} + \dot{Q}_{CSP}} \cdot \frac{h_{dis}}{h_{charge}} \quad (3)$$

The performance of the storage system ($\eta_{storage}$) considers the turbine energy outputs in the discharge phase, when considering the solar photovoltaic and thermal input (Equation 4).

$$\eta_{storage} = \frac{\dot{P}}{\dot{Q}_{sol}} \cdot \psi = \frac{\dot{W}_T}{\dot{W}_{PV} + \dot{Q}_{CSP}} \cdot \frac{h_{dis}}{h_{charge}} \quad (4)$$

Chemical conversion (η_{sol-ch}) is described by the solar-to-chemical efficiency, in terms of power (Equation 5).

$$\eta_{sol-ch} = \frac{X_{CH_3OH}\dot{m}_{CH_3OH}\Delta H_{CH_3OH}}{\dot{Q}_{CSP}} \quad (5)$$

Finally, the electrical recovery in the discharge phase turbines is quantified (Equation 6) with the solar-to-electrical efficiency ($\eta_{sol-elec}$) as a function of storage time.

$$\eta_{sol-elec} = \frac{\dot{P}}{\dot{W}_{PV} + \dot{Q}_{CSP}} \cdot \frac{h_{dis}}{h_{charge}} \quad (6)$$

Considering the nominal domestic hot water consumption of a person in the region of Spain, the number of single-family dwellings (4 persons) covered with exothermic heat will be given by Equation 7. The daily by domestic hot water consumption of a person in Spain is estimated to be 28 litres [45].

$$Dwellings = \frac{Q_{exo}/C_p\Delta T}{28} \cdot Persons \quad (7)$$

Where C_p is the specific heat of water (4.184 kJ/kg-K), ΔT is the temperature difference between the cold water return line and the hot water to meet the heat demand, assumed to be 50ºC [46].

Economic analysis depends on the development of component and product markets, which can affect the accuracy of the approximations used to estimate emerging technologies. The expressions presented in **Table 2** form the basis of the economic analysis.

Table 2. Mathematical expressions for estimating equipment costs.

Equipment	Expression	Reference
Compressors	$IC_C = 643.15 \cdot \dot{W}_C^{\,0.9142}$	[47]
Turbines	$IC_T = 4001.4 \cdot \dot{W}_T^{\,0.6897}$	[48]

Pump	$IC_P = 3531.4 \cdot \dot{W}_P^{0.71} \cdot \left[1 + \left(\frac{1-0.8}{1-\eta_{i,P}}\right)^3\right]$	[49]
Heat Exchangers	$C_{HE} = 2546.9 \cdot A_{HE}^{0.67} \cdot p_{HE}^{0.28} \cdot 10^{-6}$	[49]
Cooling Tower	$IC_{Cooling}^{tower} = 32.3 \cdot \dot{Q_{cool}}$	[50]
Endothermic Reactor	$IC_{Dr} = 13140 \cdot \dot{Q}_r^{0.67}$	[51]
Exothermic Reactor	$IC_{Mr} = 19594 \cdot \dot{Q}_r^{0.5}$	[51]
Tanks	$IC_{Tank} = 83 \cdot V$	[52]
Solar Photovoltaic Field	$IC_{PV} = 0.995 \cdot \dot{W}_{PV} \cdot 10^6$	[2]
CSP Tower	$IC_{tower}^{solar} = 57.07 \cdot \Phi_{Receiver}$	[53]

The levelized cost of storage (LCOS) indicator is proposed for the overall economic evaluation (Equation 7), considering a discount rate (r) of 5% and a useful life of the plant (n) of 20 years, and the exothermic reaction energy Q_{exo}.

$$LCOS = \frac{CAPEX + \sum_{i=1}^{n} \frac{OPEX_i}{(1+r)^i}}{\sum_{i=1}^{n} \frac{Q_{exo}}{(1+r)^i}} \quad (7)$$

$CAPEX$ being the initial investment cost of the plant, $OPEX_i$ the annual maintenance costs and Q_{exo} the annual energy produced in the exothermic phase of the synthesis reaction.

4. Results and Discussion

4.1. On-design results

The system design results are shown in **Table 3**. The overall efficiencies obtained for the plant η_{plant} are reduced (<15%) due to the consideration of the methanol input energy and the low exothermic heat of reaction. This fact significantly favours the load cycle since less thermal power is required for the decomposition of methanol to syngas, shown in the solar-to-chemical efficiency η_{sol-ch}, which reaches values above 65%.

Table 3. TCES system results on design for nominal operating parameters.

Parameter	Value
Solar-to-chemical efficiency (η_{sol-ch})	0.677
Solar-to-electrical efficiency ($\eta_{sol-elec}$)	0.071
Overall performance (η_{plant})	0.125
Storage performance ($\eta_{storage}$)	0.356
Required endothermic reaction heat [MW] ($\dot{Q}_{endo}$)	12.658
Exothermic reaction heat [MW] ($\dot{Q}_{exo}$)	-8.686
Dwellings covered	892
Covered annual heat demand [MWh]	53445
CAPEX [M€]	19.72
OPEX [M€]	0.936
LCOS [€/MWh]	85.61

On the other hand, the storage efficiency of the system $\eta_{storage}$ shows competitive values, exceeding 35%, given the recovery of the syngas decompression in the discharge cycle turbines and the reduced PV power output after thermal integration of the streams. With the 9 MW obtained at the output of the synthesis reactor, the demand for 892 single-family houses or the equivalent of a rural village can be covered. Thus, the initial investment of the plant is almost 20 M€, after considering an annual OPEX of almost one million euros in operating and maintenance costs of the plant. This value is lower in terms of fuel consumption compared to District Heating systems based on other fuels [34], although the cost assessment of the heat network has not been considered in this paper. The levelised cost value, LCOS, has been shown to be 60% lower than molten salt systems and competes with future predictions of hydrogen-based storage systems (90-160 €/MWh) [54].

Figure 5 shows the main thermal currents of the system, based on the above thermodynamic assumptions and considerations. Thus, a large amount of energy is returned to the methanol storage, given the low efficiency of the synthesis reactor. This high value is due to the high calorific value of methanol, which is not utilised given the low heat of the synthesis reaction. Heat exchanger losses are assumed to be 3%, and solar field losses are assumed to be 30%.

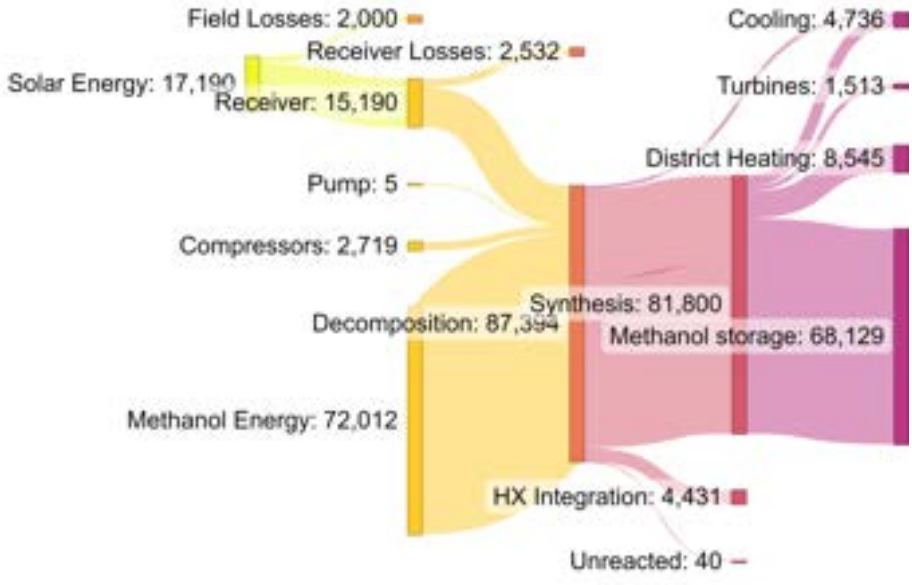

Figure 5. Sankey diagram for the nominal operating conditions of the methanol-TCES system.

Therefore, the solar photovoltaic field will feed 3 MW of compressor and pump consumption and 15 MW of receiver solar power will be required to extract 8.5 MW for the heat network. The efficiency in terms of solar power and DH power will be 47%, whereas the combined efficiency of cogeneration, considering the energy exported from the turbines, will be 55%, 40% lower than in internal combustion reciprocating engines [55].

4.2. Sensitivity analysis

The variation in thermal power from the solar receiver will be crucial in the sizing of the reactor and its auxiliary systems. **Figure 6** evaluates the variation in efficiency as a function of the endothermic temperature of direct CH_3OH decomposition. Chemical conversion efficiency reaches a maximum at intermediate reaction temperatures, although complete conversion cannot be ensured because of a higher molar enthalpy drop in the reactor and an increase in yield. However, maximum decomposition conversion is required for solar-to-electrical yields to ensure better utilisation in the gas turbines of the discharge cycle. This also applies to the overall plant performance, which will be higher as the methanol inlet pressure decreases, i.e., to ensure complete conversion to syngas.

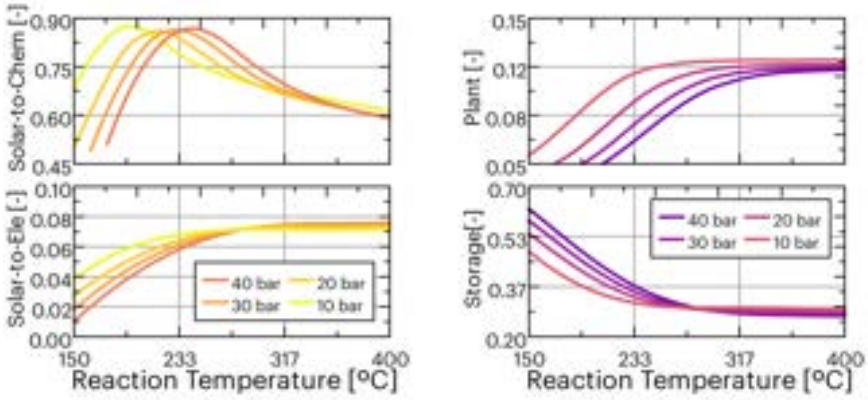

Figure 6. Solar-to-Chemical/Solar-to-Electrical yields on the left, and plant and storage yields (overall) as a function of direct methanol decomposition reaction temperature on the right.

This trend is also reflected when evaluating the performance of the heat network (**Figure 7b**), where higher reaction temperatures (right) will result in greater synthesis gas generation and consequently greater conversion in the exothermic reactor. The increase in covered households for a reaction temperature between 150-250ºC is 650 households, which then stabilises at the nominal value of close to 900 homes with the studied characteristics.

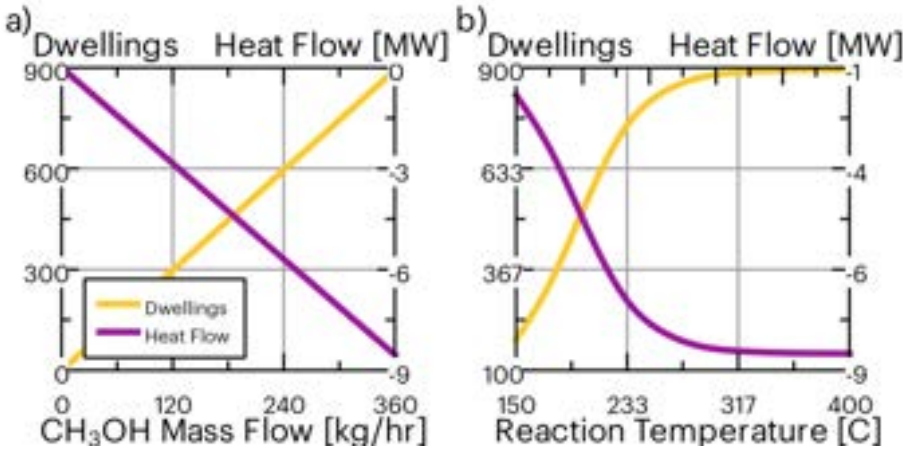

Figure 7. Number of dwellings covered (thermal demand) and exothermic power generated in the synthesis reaction as a function of a) methanol mass flow rate at the inlet of the charging process and b) reaction temperature of the direct decomposition of methanol.

The effect of the mass flow rate of methanol at the inlet is linear with respect to the exothermic power, where for every 120 kg/hr of methanol in the system, the demand of approximately 300 homes is covered (**Figure 7a**).

4.3. Economic Analysis

One of the most remarkable parameters of the proposed system is its low-levelized storage cost, optimised under nominal conditions to be minimal and achieve maximum overall yields. **Figure 8** shows the variation of the LCOS with respect to the operating conditions of the charging phase (**Figure 8a**) and the discharging phase (**Figure 8b**). Opposite trends are obtained, where higher decomposition reaction temperatures result in lower costs, given a higher thermal energy supply to the heat network.

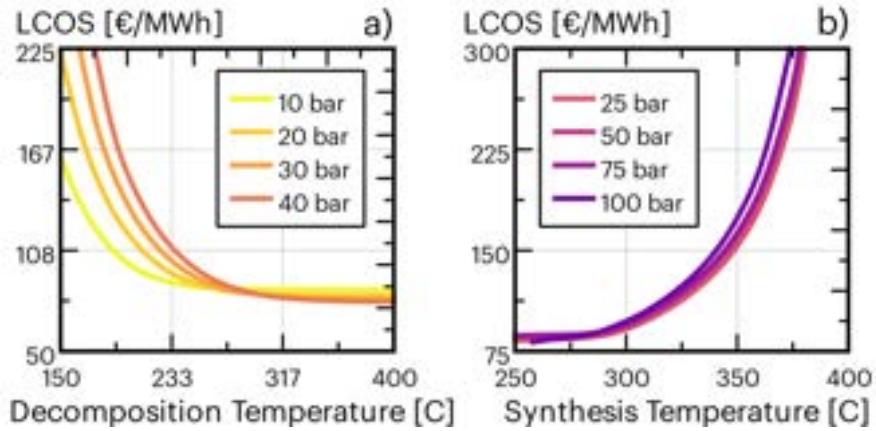

Figure 8. Levelised cost of storage as a function of a) direct methanol decomposition temperature and b) syngas to methanol synthesis temperature.

This LCOS is even lower for higher liquid methanol pressures due to lower compressor consumption. This trend is opposite in the case of the synthesis reaction, where higher temperatures result in lower conversion and lower exothermic energy, and higher pressures imply higher associated conversions but with less influence than in the case of the charging phase.

5. Conclusions

This paper proposes a high-duration thermochemical storage system based on methanol, which evaluates its integration with district heating networks, offering a renewable solar-based storage solution and low-temperature heat generation from the exothermic discharge reaction heat:

i) The system eliminates greenhouse gas emissions by using concentrated solar thermal energy to decompose methanol into synthesis gas.
ii) Given the low heat of the direct methanol decomposition reaction, chemical conversion efficiencies in the charging phase are greater than 65%.
iii) Storage efficiencies are greater than 35%, producing 8.5 MW of exothermic power from 15 MW of solar input that decomposes 100 mol/s of methanol.
iv) The proposed configuration serves 892 4-person single-family homes and can cover a rural town with green methanol.
v) Levelized storage costs are 60% lower than molten salt systems, as the system is simple and has a high associated energy density.
vi) An optimal decomposition temperature of 315°C/10 bar and 250°C/50 bar is demonstrated in the exothermic phase, striking a balance between demand coverage and the levelized cost of the system.

Abstract:

Thermal energy storage (TES) fosters the use of renewable energy, improves the efficiency of existing processes and enhances the flexibility of energy availability. Extensively researched and applied in buildings, TES is still in the early stages of its evolution regarding other relevant applications for which decarbonisation of heat exchange is paramount. This is the case in the maritime sector. Therefore, this research proposes a novel modular latent heat thermal energy storage (LHTES) system functioning with a phase change material (PCM) as an energy storage medium for installation on ships. An analytical model was developed relying on a theoretical approach consolidated in the literature. Firstly, the model was validated through the comparison with a reference case. Then, it was utilised for evaluating the functioning of various configurations of a TES device operating on board a vessel. The performance of the proposed system was investigated during the charging and discharging phases considering operating conditions typical of cruising and cargo vessels. The effects of device length and height were assessed and the influence of these parameters on the amount of energy stored and energy storage density was determined. Overall, the paper provides an innovative application of TES technology and highlights the wider benefits of energy storage in the maritime sector.

Keywords:

Thermal energy storage; latent heat; maritime decarbonisation; waste heat recovery; PCM.

1. Introduction

The functioning of the vast majority of energy systems is currently based on transforming the energy of fuel into useful work for their scopes and waste heat released to the environment. This energy inefficiency is a paramount problem mainly for industrial thermal processes, heating systems and transportation. Heat wastage significantly affects marine applications, especially cruising and cargo vessels. Two-stroke internal combustion diesel engines represent the propulsion system of around 96% of modern civilian ships above 100 t of mass [1]. These engines have values of efficiency lower than 50% with the consequent wastage of at least half of fuel energy through cooling fluid streams and exhaust gases [2]. The thermal energy released is responsible for about 3% of total greenhouse gas emissions (GHG) worldwide and this level is expected to rise together with the global trade through shipping [3]. Since 2011, the International Maritime Organisation (IMO) is applying regulations for controlling air and water pollution with the aim of halving emissions by 2050 [4].

The reduction of GHG emissions can be successfully achieved by enhancing energy efficiency. Improvements to the existing engines and the use of other technologies on board were widely proposed for this purpose [5]. It is estimated that total engine efficiency could be boosted from 50% to 60% and fuel efficiency could be raised from 4% to 16% [1,2]. Regarding the energy source, alternative fuels to the traditional high sulphur fuel such as liquefied natural gas (LNG), hydrogen, ammonia and advanced bio-fuels can be utilised and auxiliary propulsion devices such as modern sails and renewable systems such as solar photovoltaic panels and solar hybrid devices can be placed on board. Concerning the direct limitation of carbon emissions, carbon capture and storage systems can be installed. Integrating these technologies with waste heat recovery (WHR) devices would foster the enhancement of vessel efficiency as at least half of fuel energy is lost by way of heat. Currently, the WHR systems used on vessels are waste heat boilers, steam turbine cycles or turbocharging devices. However, more sophisticated WHR solutions could be effectively installed on board for harnessing thermal energy from exhaust flue gases of diesel engines and their cooling fluids such as jacket water and lubricants.

The main technologies exploiting heat wastage are thermal energy storage (TES) systems, organic Rankine cycles, sorption desalination and refrigeration devices and isobaric expansion engines. They transform the thermal power losses of the engine into mechanical or electrical power (waste heat-to-power), cooling power (waste heat-to-cold), or they upgrade the excess thermal energy to generate added value for on-board demands such as steam or desalinated water.

The presented research regards the development of an analytical model for solving heat transfer in a TES device constituted by a flat plate heat exchanger functioning with air or water as a heat exchange fluid (HTF) and a phase change material (PCM) as an energy storage medium. The Methodology section defines the theoretical model developed and the finite element approximation strategy applied. The Results and discussion section first describes the process of the validation of the model through the comparison with consolidated literature data. Then, it shows the application of the model for evaluating the performance of five configurations of a TES device for the possible installation on board a vessel. Operating conditions typical of cruising and cargo vessels were considered.

2. Methodology

A theoretical model of a latent heat thermal energy storage (LHTES) system was developed for evaluating the behaviour of heat exchangers with multi-layer rectangular plates functioning with a heat transfer fluid to warm or cool a phase change material.

2.1. Modelling equations

The model of the multi-layer rectangular LHTES system relies on consolidated theoretical approaches present in the literature [6,7] and was successfully used for technical applications [8–10]. The methodology is based on three hypotheses regarding the heat transfer transformations.

- The axial conduction in the fluid is negligible during flow.
- The temperature gradients normal to the flow are negligible due to the sufficiently low Biot number.
- The heat losses outside of the domain are negligible.

The schematic of the model developed is illustrated in Figure 1. The heat transfer fluid with mass flow rate $\dot{m}_f$ and inlet temperature $T_{f,inl}$ crosses the device along the axial direction x passing through the cavities delimited by flat plates with PCM. The fluid can be a gas or a liquid. The phase change material is positioned between the flat plates of length L, total cross-sectional area A, and wetted perimeter P.

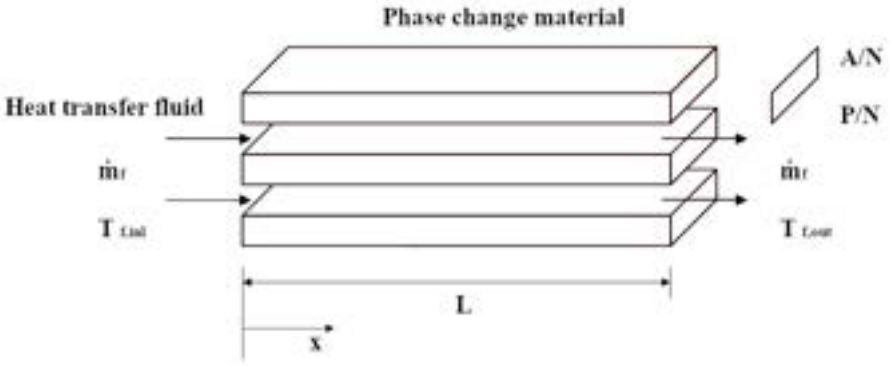

Figure 1. Scheme of a TES device with flat plate containers**.**

The set of equations imposing energy balance for the phase change material and the heat transfer fluid are stated in Eq. (1).

$$\begin{cases} \dfrac{\partial u}{\partial t} = \dfrac{k}{\rho}\dfrac{\partial^2 T}{\partial x^2} + \dfrac{UP}{\rho A}\left(T_f - T\right) \\ \dfrac{\partial T_f}{\partial t} = -\dfrac{\dot{m}_f}{\rho_f A_f}\dfrac{\partial T_f}{\partial x} + \dfrac{UP}{\rho_f A_f cp_f}\left(T - T_f\right) \end{cases} \quad (1)$$

where u, T, ρ and k are the specific internal energy, temperature, density, and thermal conductivity of PCM, T_f, ρ_f, c_{pf} and A_f are the temperature, density, specific heat and flow area of HTF, t is time and U is the overall heat transfer coefficient between the two materials.

The specific internal energy u depends on the temperatures of the HTF and PCM and the thermo-physical properties of the PCM based on Eq. (2).

$$\begin{cases} c_s(T - T_{ref}) & if\ T < T_m \\ c_s(T_m - T_{ref}) + \chi F & if\ T = T_m \\ c_s(T_m - T_{ref}) + F + c_l(T - T_m) & if\ T > T_m \end{cases} \quad (2)$$

where c_l and c_s are the values of the specific heat of the liquid and solid phases of the PCM, χ is its liquid mass fraction, T_m is its melting temperature, F is its latent heat of fusion and T_{ref} is the reference temperature corresponding to the null internal energy.

The general formulation of the energy balance of Eq. (1) can be simplified considering that the heat transfer due to axial conduction in the PCM during flow is negligible and assuming a low capacitance for the HTF. In these circumstances, the energy balance reduces to Eq. (3).

$$\begin{cases} \frac{\partial u}{\partial t} = \frac{UP}{\rho A}(T_f - T) \\ \frac{\partial T_f}{\partial x} = \frac{UP}{\dot{m}_f c p_f}(T - T_f) \end{cases} \quad (3)$$

The governing equations can be reformulated in a non-dimensional form in terms of the number of transfer units *NTU* as in Eq. (4) through the normalisation relying on the temperature difference between the PCM melting temperature and the reference temperature [6].

$$\begin{cases} \frac{\partial \bar{u}}{\partial \tau} = (\theta_f - \theta) \\ \frac{\partial \theta_f}{\partial \zeta} = NTU(\theta - \theta_f) \end{cases} \quad (4)$$

The normalisation procedure is based on the non-dimensional distance ζ defined as the ratio between the axial position x and plate length L and the equations from Eq. (5) to Eq. (9) that provide the non-dimensional temperature differences of the PCM and HTF θ and θ_f, the non-dimensional heat transfer coefficient $\bar{u}$ and the time τ.

$$\theta = \frac{T - T_{ref}}{T_m - T_{ref}} \quad (5)$$

$$\theta_f = \frac{T_f - T_{ref}}{T_m - T_{ref}} \quad (6)$$

$$\bar{u} = \frac{u}{c(T_m - T_{ref})} \quad (7)$$

$$\tau = \frac{tUPL}{\rho ALc} \quad (8)$$

$$NTU = \frac{UPL}{\dot{m}_f c_{pf}} \quad (9)$$

2.2. Finite difference approximation

The solution of the differential governing equations defined in the NTU formulation was achieved through the finite differencing technique [6]. This approach is based on the subdivision of the storage system into a set of *n* axial nodes as illustrated in Figure 2.

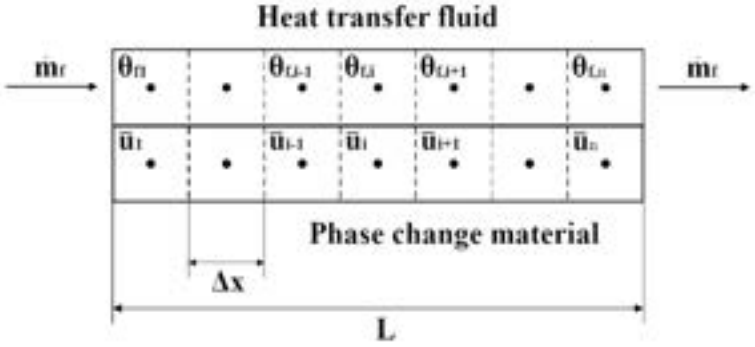

Figure 2. Scheme of the computational domain composed by a set of nodes**.**

At the beginning of each time step, the PCM internal energy, the HTF temperature at the axial nodes and the current inlet fluid temperature are known. Forward differencing techniques are then applied for updating these quantities. Therefore, the energy balance is expressed for each nodal position *i* from 1 to *n* through Eq. (10).

$$\begin{cases} \bar{u}_i' = \bar{u}_i + \Delta\tau\left(\theta_{f,i} - \theta_i\right) \\ \theta_{f,i+1}' = \theta_{f,i}' + \Delta\zeta NTU\left(\theta_i - \theta_{f,i}\right) \end{cases} \quad (10)$$

where the superscript refers to the variable at the new time step, $\Delta\tau$ is the non-dimensional time step and $\Delta\zeta$ is the non-dimensional nodal spacing.

The first formula of the set of Eq. (10) states that the change in PCM internal energy during the time step equals the heat transferred from the HTF to the PCM within this period. In analogy, the second equation indicates that the variation in HTF enthalpy from one node to the adjacent one equals the heat added by convection.

At each time step and for every node, Eq. (10) is applied for computing the non-dimensional values of the PCM internal energy $\bar{u}_i'$ and the HTF temperature at the end of the time step based on the known values of $\bar{u}_i$, θ_i and $\theta_{f,i}$ and the updated inlet flow temperature $\theta_{f,i}'$. At first, the updated HTF temperatures are determined and then the PCM internal energy of every corresponding node is defined.

The temperature and quality of all the PCM nodes are updated with Eq. (11) based on the liquid mass fraction provided by Eq. (12). The assumption of equivalent values of the specific heat of the liquid and solid phases of PCM is imposed.

$$\bar{u} = \theta + \frac{F}{c\left(T_m - T_{ref}\right)}\chi \quad (11)$$

$$\begin{cases} \chi = 0 & if\ \theta < 1 \\ 0 \le \chi \le 1 & if\ \theta = 1 \\ \chi = 1 & if\ \theta > 1 \end{cases} \quad (12)$$

The finite difference solution tends to the exact one by increasing the node number as a procedure for the discretisation of the computational domain is applied. It was shown in the literature that five nodes are sufficient for representing the TES device with a good approximation [6].

3. Results and discussion

The analytical model was validated through the comparison with a reference case selected in the literature regarding multi-layer thermal energy storage systems with PCM. Afterwards, the model was applied for evaluating the functioning of a TES device operating on board a vessel.

3.1. Model validation

A literature reference case was selected to validate the analytical model developed for assessing the process of heat transfer in TES devices operating with a phase change storage medium composed of cavities with parallel flow paths [9]. The schematic of the thermal energy system of the reference literature case is coherent with that of Figure 1 and its main geometric specifications are indicated in Table 1.

Table 1. Geometric parameters of the heat exchanger defined in the reference case [9].

Parameter	Symbol	Value	Unit
PCM layer number	N	3	-
Fluid channel number	N_f	2	-
PCM layer thickness	b	0.005	m
Fluid channel thickness	b_f	0.003	m

The complete definition of the model geometry requires the assumption of the dimensional value of the plate length and width. In the analyses conducted, equal dimensional values of 0.03, 0.04 and 0.05 m were imposed for these parameters. The wetted perimeter and cross-sectional area of the PCM layers were computed based on their width and thickness. The geometric parameters used in the calculations in addition to those defined in the reference case are defined in Table 2.

Table 2. Geometric parameters of the PCM layers assigned in the analyses.

Parameter	Symbol	Value	Unit
Plate length	L	0.03–0.05	m

Plate width	W	0.03–0.05	m
PCM perimeter	P	0.21–0.33	m
PCM area	A	4.50–7.50	cm^2

The heat transfer fluid crossing the cavities of the device is air and the storage medium is Glauber's salt (sodium sulphate decahydrate).

The physical properties and initial conditions of the PCM defined in the literature reference are listed in Table 3. In the reference case, the liquid state specific heat of the Glauber's salt is 3.26 kJ/kg/K. However, in the simplified model developed the specific heat of the liquid state is assumed equivalent to the value of the solid state, which is equal to 1.92 kJ/kg/K. The reference temperature for the simulations was set to 20°C.

Table 3. Physical properties and initial conditions of the Glauber's salt [9].

Parameter	Symbol	Value	Unit
Inlet temperature	T_{inl}	25	°C
Melting temperature	T_m	32	°C
Solid state density	ρ_s	1460	kg/m^3
Liquid state density	ρ_l	1330	kg/m^3
Solid state specific heat	c_s	1.92	kJ/kg/K
Specific latent heat of fusion	F	251	kJ/kg
Solid state thermal conductivity	k_s	0.514	W/m/K
Liquid state thermal conductivity	k_l	0.514	W/m/K

The temperature of the air at the domain inlet is 90°C and the initial temperature of the Glauber's salt is 25°C. Thus, the thermo-physical properties of air were evaluated at the average temperature of 57.5°C and the atmospheric pressure.

The characteristic length *l* of the flow cavities was calculated with Eq. (13). This parameter and the Nusselt number N_u of 8.235 defined in the reference case were utilised to determine the overall heat transfer coefficient *U* between the HTF and PCM through Eq. (14).

$$l = \frac{4A_f}{P_f} \tag{13}$$

$$U = \frac{N_u k_f}{l} \tag{14}$$

where P_f and A_f are the perimeter and area of the fluid channels regarding the PCM layer number and k_f is the air thermal conductivity.

The air velocity v_f was computed with Eq. (15) based on the Nusselt number, the Prandtl number P_r, the Reynolds number R_e, the dynamic viscosity μ and the density of the airflow and the characteristic length of the flow cavities.

$$v_f = \left(\frac{N_u}{0.664 P_r^{1/3}}\right)^2 \frac{\mu_f}{\rho_f l} \tag{15}$$

The time corresponding to the non-dimensional time t^* of 14 of the literature case was determined with Eq. (16) for comparing the results of the two models [9].

$$t = t^* \frac{\rho_s c_s b^2}{4k_s} \tag{16}$$

The values of the above parameters applied in the simulations are resumed in Table 4.

Table 4. Parameters and operating conditions used in the simulations of the reference case [9].

Parameter	Symbol	Value	Unit
Characteristic length	l	0.00545–0.00566	m
Nusselt number	N_u	8.235	-
Overall heat transfer coefficient	U	0.0426–0.0411	$kW/m^2/K$
Average air velocity	v_f	0.66–0.64	m/s
Air mass flow rate	$\dot{m}_f$	0.00013–0.00020	kg/s
Reference non-dimensional time	t^*	14	-

Reference time	t	477.2	s

The validation of the theoretical model was achieved through the comparison with the literature reference [9]. The results of the two models were confronted by analysing the predicted time series of the liquid mass fraction and temperature of the HTF and PCM. In Figure 3(a), the increase of the mass fraction of the liquid phase of the PCM is presented as a function of time. The convective heat transfer coefficient decreases as the plate size increases. The lower rate of heat exchange with growing dimensions determines a rise in the time required for reaching equilibrium. In the reference case, the complete melting of the PCM is obtained at time 477.2 s when the average liquid mass fraction equals the unit and the device is fully charged. For the simulation performed, the melting time is 1102, 1411 and 1710 s based on the increasing plate dimensions. The curves have a similar trend, indicating that the simplified analytical model proposed is capable of evaluating the melting process.
Figure 3(b) illustrates the liquid mass fraction computed at each domain node for the device with a length and a width equal to 0.04 m. The amount of time required for melting rises from the first to the last node due to the reduction of the temperature of the HTF across the flow cavities for the progressive reduction of the heat transfer rate.

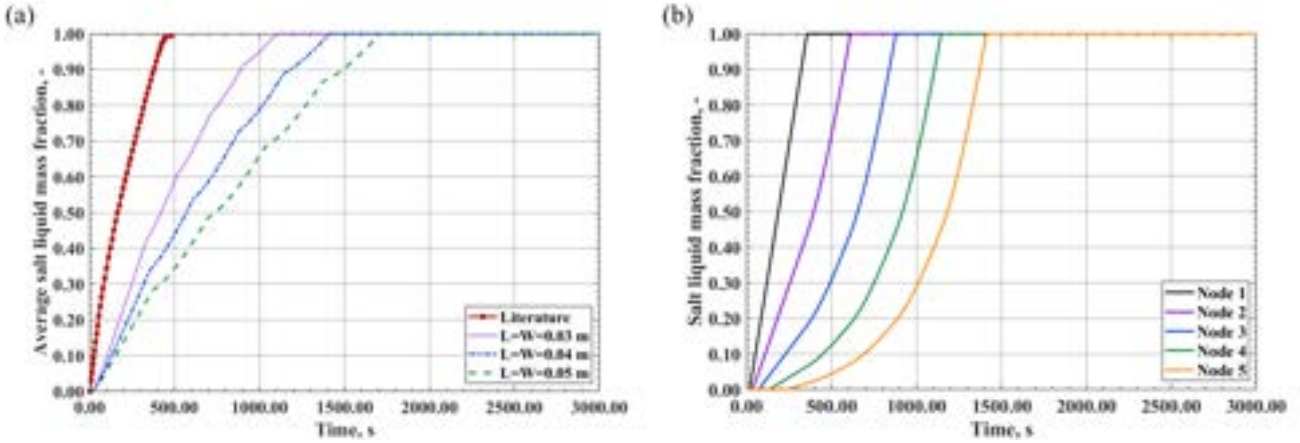

Figure 3. Time series of the liquid fraction of the Glauber's salt: (a) average values for the reference case and different plate dimensions, (b) values at the nodes for the device with the intermediate plate size.

Figure 4(a) depicts the increase in the average temperature of the Glauber's salt for the three configurations analysed. The rate of rise is greater reducing plate size for the higher heat transfer owing to the lower mass airflow rate. The average temperature of the PCM is 54.6°C corresponding to the instant of complete melting for the literature case. For the three configurations analysed, the values obtained for this parameter are 73.53, 75.43 and 76.58°C, respectively. The higher predictions are attributable to the specific heat of the liquid phase of the PCM that is assumed equivalent to that of the solid phase in the simplified model proposed.
In Figure 4(b), the temperature of Glauber's salt calculated at the five nodes is presented as a function of time during the charging process. The time required for heating up the PCM to the temperature of the HTF rises increasing the distance from the domain inlet as the rate of heat transfer decreases along the channel length.

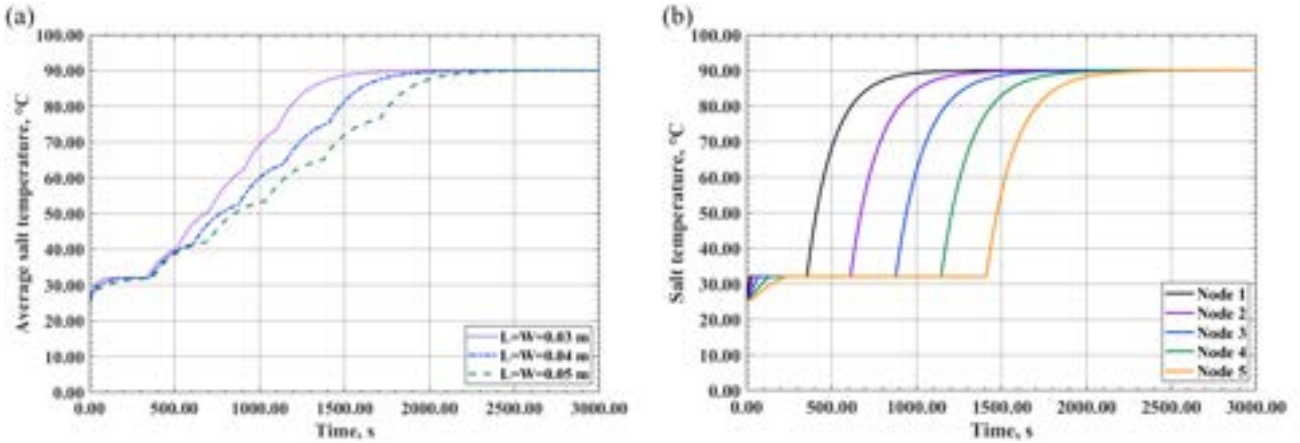

Figure 4. Time series of the temperature of the Glauber's salt: (a) average values for the reference case and different plate dimensions, (b) values at the nodes for the device with the intermediate plate size.

In Figure 5(a), the air temperature at the outlet of the TES device is shown as a function of time for the three configurations analysed. The temperature of the HTF increases with time as the PCM melts. When the PCM is completely melted, the temperature values are 60.55, 55.47 and 49.91°C, respectively. The temperature of the airflow exiting the device approaches the initial temperature of the PCM. The temperature difference reduces by increasing the plate size due to the enhancement of heat transfer.
Figure 5(b) presents the air temperature calculated at the five nodes of the computational domain. In particular, the temperature of node 1 is constant and equals the inlet temperature of 90°C of the charging fluid. The values of the other nodes rise up to 90°C requiring higher time as the distance from the domain inlet grows. The curves of the last three nodes indicate the presence of instabilities at the end of the melting transformation which could be minimised by increasing the number of axial nodes and reducing the time step size.

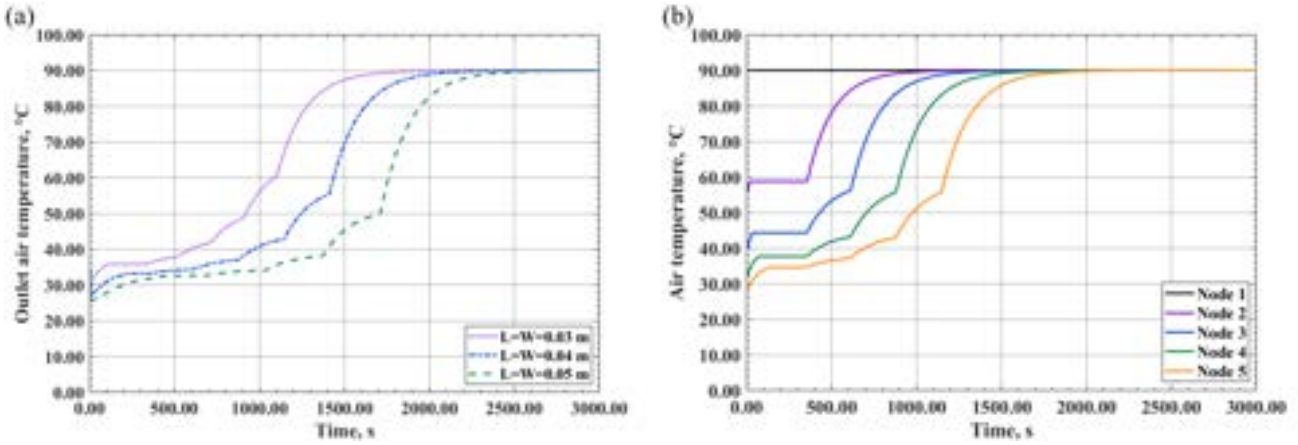

Figure 5. Time series of the air temperature: (a) values at the outlet for the reference case and different plate dimensions, (b) values at the nodes for the device with the intermediate plate size.

3.2. Case study

The TES device considered for the possible application on a vessel is a flat plate heat exchanger similar to the schematic illustrated in Figure 6. The plates are stacked parallel to each other and are bundled in a box where they are submerged in the phase change material. At each upper extremity of the device, a plenum manifold connects the pipe of the heat transfer fluid with all the plates.

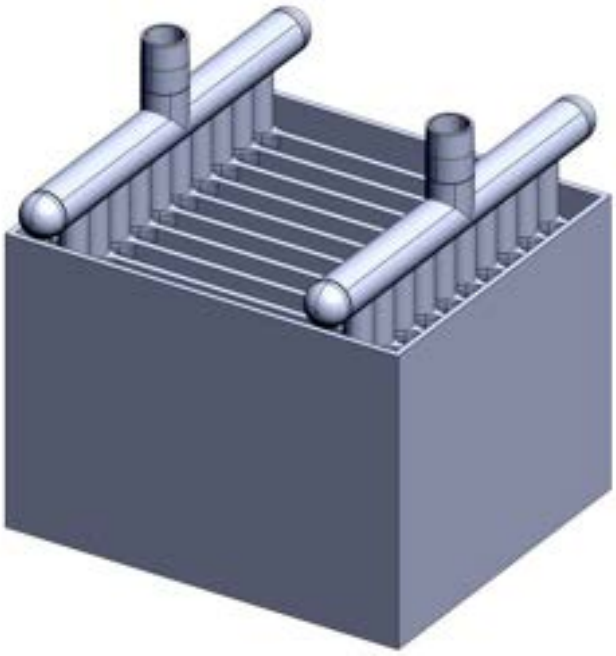

Figure 6. Schematic of the structure of the heat exchanger with the box, plates and pipes.

Five configurations of the TES devices for vessel application were investigated for evaluating the effects of plate dimensions on performance. A set of 10 plates with fixed values of thickness of the PCM layers and fluid channels was considered. The length and height of the device were varied to explore sizes comparable with traditional heat exchangers with submerged flat plates [11]. The length was assigned in the range from 0.8 to 1.2 m with intervals of 0.1 m and the height was set at 80% of the length. The geometric parameters defining the configuration of the case study are listed in Table 5.

Table 5. Geometric parameters of the TES device configurations considered for operating on a vessel.

Parameter	Symbol	Value	Unit
Plate length	L	0.80–1.20	m
Plate height	H	0.64–0.96	m
PCM layer thickness	b	0.030	m
Fluid channel thickness	b_f	0.018	m
PCM layer number	N	11	-
Fluid channel number	N_f	10	-
PCM perimeter	P	14.74–21.78	m
PCM area	A	0.2112–0.3168	m^2

The system uses water as heat transfer fluid and H105 as phase change material. This is an inorganic salt with the chemical formulation KNO_3 which is in the form of granules. This storage medium was selected as its melting temperature has a value close to the average of the charging and discharging temperatures of the water [12].

The physical properties and initial conditions of the PCM are provided in Table 6. The hypothesis of equal values of the specific heat of the solid and liquid phases was applied. The reference temperature of 20°C was considered in the calculations.

Table 6. Physical properties and initial conditions of the H105 [12].

Parameter	Symbol	Value	Unit
Inlet temperature	T_{inl}	90	°C
Melting temperature	T_m	104	°C
Solid state density	ρ_s	1700	kg/m^3
Solid state specific heat	c_s	1.50	kJ/kg/K
Specific latent heat of fusion	F	125	kJ/kg
Solid state thermal conductivity	k_s	0.500	W/m/K
Liquid state thermal conductivity	k_l	0.500	W/m/K

The water charges the device at 120°C and discharges it at 90°C in compliance with typical scenarios of heat wastage on vessels. A total mass flow rate of 1.50 kg/s was selected, resulting in a mass flow rate of 0.15 kg/s for each plate. The thermo-physical conditions of the water charging the device were evaluated at the average temperature of 105°C and the pressure of 3 atm.

The formulation of Eq. (13) was applied to determine the characteristic length *l* of the device. Since the mass flow rate of the device was imposed, the average velocity of the water flowing through the cavities was determined relying on the water density and the cross-sectional area of the cavity. Thus, the Nusselt number was calculated with Eq. (15) and then the overall heat transfer coefficient between the HTF and PCM was computed with Eq. (14). The parameters applied in the simulations and the duration of the analyses are listed in Table 7.

Table 7. Parameters and operating conditions used in the simulations of the case study.

Parameter	Symbol	Value	Unit
Water mass flow rate	$\dot{m}_f$	1.50	kg/s
Average water velocity	v_f	0.0136–0.0091	m/s
Characteristic length	l	0.03502–0.03534	m
Overall heat transfer coefficient	U	0.6298–0.5119	$kW/m^2/K$
Nusselt number	N_u	32.48–26.64	-
Time	t	6000	s

In Figure 7(a), the process of the phase change of the H105 is shown in terms of variation in time of the liquid mass fraction. Increasing the dimensions of the plates, the convective heat transfer coefficient reduces extending the time required for the charge. The duration of the melting process is 701, 819, 946, 1082 and 1226 s as the size increases. In analogy, the time for the solidification process is 797, 929, 1072, 1225 and 1386 s. Therefore, the charging phase is faster than the discharging phase. This is caused by the different contributions of heat transfer for conduction and natural convection in the melting and solidification processes.

Figure 7(b) indicates the variation in time of air temperature along the plate length at each domain node. The device with an intermediate size with a length of 1 m and a height of 0.8 m was considered for presenting the results. The time of melting and solidification increases from the first to the last node as the water temperature decreases flowing through the cavities. This determines a progressive reduction of heat transfer along plate length.

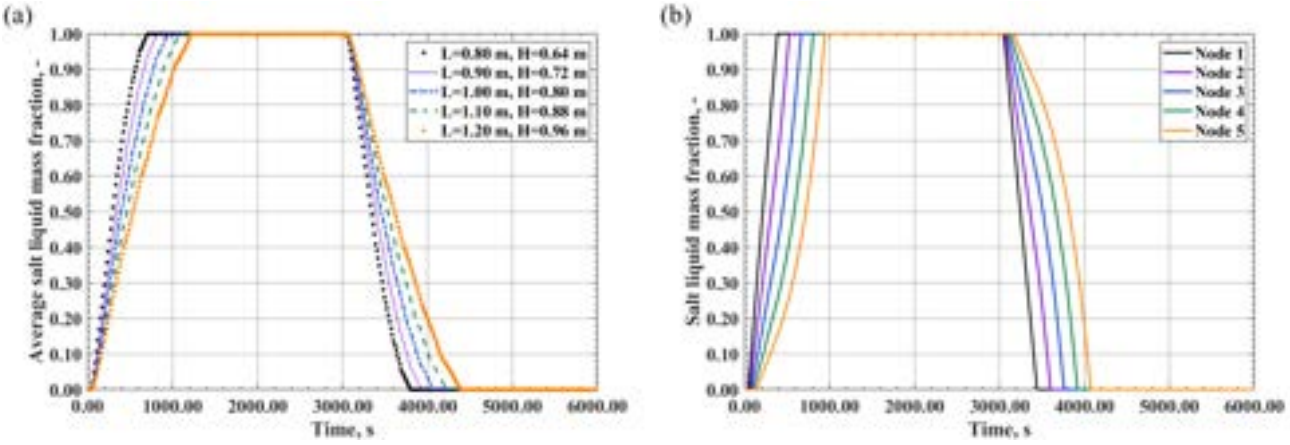

Figure 7. Time series of the liquid fraction of the H105 salt: (a) average values for the configurations investigated, (b) values at the domain nodes for the device with the intermediate size.

In Figure 8(a), the variation in the average temperature of the H105 salt during charging and discharging is depicted. The temperature gradients of both phase transformations are higher for the nodes close to the domain inlet for the reduction of the heat transfer in the direction of plate length. The discontinuities in the rate of rise of the temperature gradients of the salt are attributable to the presence of the interface between solid and liquid and to the duration of phase change along plate length, which is visible in Figure 8(b). The temperature gradients are higher during melting than solidification in accordance with the different duration of the two transformations. The average values of the temperature of the PCM at complete melting are equal to 115.90, 116.16, 116.35, 116.49 and 116.57°C for the various configurations. At complete solidification, the average temperatures correspond to 93.39, 93.25, 93.09, 92.97 and 92.95°C.

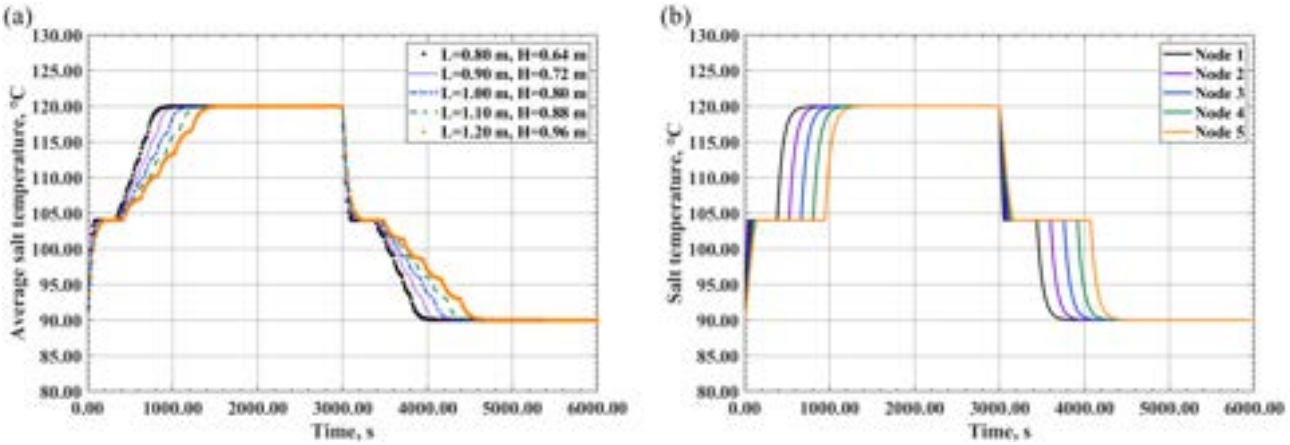

Figure 8. Time series of the temperature of the H105 salt: (a) average values for the configurations investigated, (b) values at the domain nodes for the device with the intermediate size.

The time series of the water temperature at the domain outlet is illustrated in Figure 9(a) for the five TES configurations. The HTF temperature rises during charging and decreases during discharging. The rate of rise is higher in the former process and it increases by reducing plate size due to the greater heat transfer.

The outlet water temperature in the charging phase is 115.45, 114.91, 114.31, 113.66 and 112.95°C based on the increasing device size, while it is 93.83, 94.33, 94.87, 95.45 and 96.09°C in the discharging phase. Figure 9(b) shows the water temperature computed at the five nodes along the domain. The temperature of the first node equals the values of the charging and discharging fluid during the relative phases. For the other nodes, the rate of variation increases moving from the inlet to the outlet.

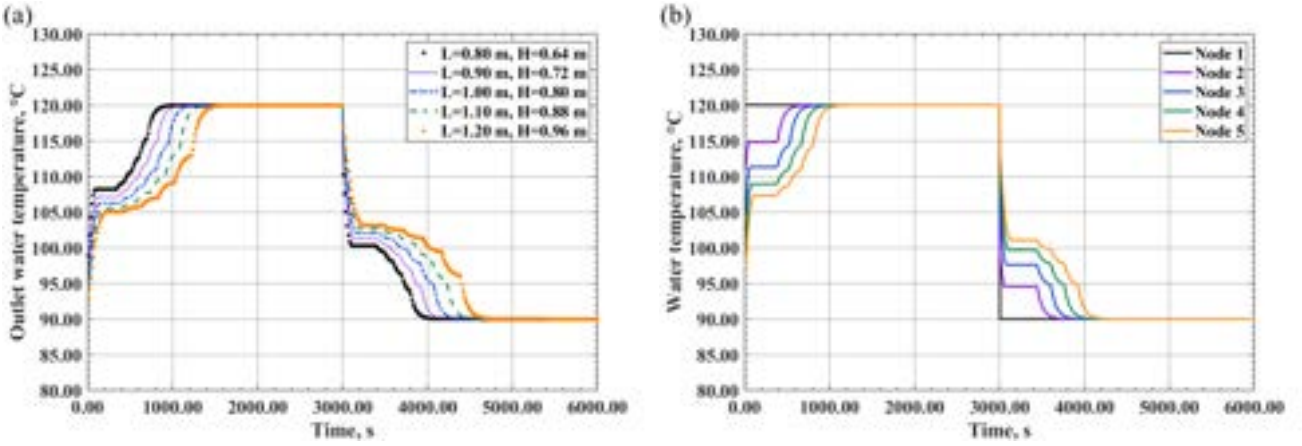

Figure 9. Time series of the water temperature: (a) values at the outlet for the configurations investigated, (b) values at the domain nodes for the device with the intermediate size.

The performance of the TES devices was evaluated in terms of volume and mass of the TES device, energy storage of the PCM and energy storage density, defined by the ratio between the first two parameters. The data achieved for the five configurations investigated are listed in Table 8. The selection of the best-suited configuration for the vessel application depends on the availability of thermal energy and the space and weight constraints on board vessels. The energy storage density slightly increases with device dimensions for the design space explored.

Table 8. Performance parameters of the TES devices analysed for the vessel application.

Parameter	Case 1	Case 2	Case 3	Case 4	Case 5	Unit
Volume	0.30	0.37	0.46	0.55	0.66	m^3
Mass	474	594	727	874	1034	kg
Energy storage	13.56	17.17	21.19	25.64	30.52	kWh
Energy storage density	45.57	45.85	46.07	46.26	46.41	kWh/m^3

4. Conclusions

A novel modular latent heat thermal energy storage (LHTES) system was proposed for the installation on cruising and cargo vessels. The main aim of the research is to increase the energy efficiency of ships for reducing the carbon emissions of the maritime sector. Moreover, these devices allow stabilising energy availability on board by smoothing the intermittency of thermal energy wastage. A theoretical methodology consolidated in the literature was applied to develop a fast and reliable analytical model capable of investigating a wide variety of geometric configurations and operating conditions. The code solves the heat exchange between the heat transfer fluid (HTF) and the phase change material (PCM) during the charging and discharging phases. It was found that the discharging time is longer than the charging time, which stems from the different contributions of conduction and natural convection heat transfer in melting and solidification. Operating conditions characteristic of cruising and cargo vessels were considered for evaluating the performance of a set of thermal energy storage (TES) device configurations. Geometric parameters suitable for their on-board application were selected to analyse a proper design space. The effects on the main performance indicators were assessed by varying the plate length between 0.80 and 1.20 m and the plate height from 0.64 to 0.96 m while keeping fixed the number of plates and the thickness of the HTF channels and PCM layers. The energy stored is between 13.56 and 30.52 kWh and the energy storage density ranges from 45.57 to 46.41 kWh/m^3.

Nomenclature

Roman symbols

A	area, m^2
b	thickness, m

Greek symbols

ζ	non-dimensional distance, -
θ	non-dimensional temperature difference, -

c	specific heat, J/kg/K
cp	constant pressure specific heat, J/kg/K
F	specific latent heat of fusion, kJ/kg
H	height, m
k	thermal conductivity, W/m/K
L	length, m
l	characteristic length, m
$\dot{m}$	mass flow rate, kg/s
N	plate number, -
NTU	number of transfer units, -
N_u	Nusselt number, -
n	node number, -
P	perimeter, m
P_r	Prandtl number, -
R_e	Reynolds number, -
T	temperature, °C
t	time, s
t^*	non-dimensional time, -
U	overall heat transfer coefficient, kW/m^2/K
u	specific internal energy, kJ/kg
$\bar{u}$	non-dimensional heat transfer coefficient, -
v	velocity, m/s
W	width, m
x	axial position, s
μ	dynamic viscosity, Pa·s
ρ	density, kg/m^3
τ	non-dimensional time, -
χ	liquid mass fraction, -

Subscripts and superscripts

f	fluid
i	node index
inl	inlet
l	liquid
m	melting
out	outlet
ref	reference
s	solid
$'$	new time step

Acronyms

GHG	greenhouse gas emissions
HTF	heat transfer fluid
IMO	International Maritime Organisation
LHTES	latent heat thermal energy storage
LNG	liquefied natural gas
PCM	phase change material
TES	thermal energy storage
WHR	waste heat recovery

Abstract:
The penetration of renewable energies into the electricity system is making it increasingly cheaper, cleaner, and safer. It poses specific challenges, such as dispatchability periods and grid frequency stability.
Storage systems are needed to meet these challenges. Thermochemical reactions have great potential for energy transport and storage. Their integration into solar energy systems is of great interest due to the possibility of achieving high energy densities and seasonal storage. This work analyses the integration of a thermochemical storage system based on ammonia looping into a concentrating solar power (CSP). Energy storage is based on a charging phase, where heat is provided for ammonia decomposition and a discharging phase, where heat is recovered from ammonia synthesis. This work aims to evaluate the thermodynamic performance of a reference plant with a total capacity of 6.2 MW of CSP integrated into an ammonia loop power system. The performance and LCOS curves are discussed as a function of synthesis and decomposition temperatures.

Keywords:
TCES, Ammonia looping, CSP, Thermochemical energy storage

1. Introduction

Energy storage systems are used to ensure the availability of energy supply. Thermal energy storage (TES) and Thermochemical energy storage (TCES) systems are promising technologies for renewable energy storage [1]. In recent years, several thermal storage technologies for medium- and high-temperature CSP systems have been developed based on the use of materials in which energy is stored as sensible heat [1]–[5] or latent heat [6].The third form of storage is through thermochemical storage, in which the heat from the sun drives an endothermic reaction, which decomposes a compound into other species, storing the energy in chemical bonds. This has the advantage that it can be used for long-term energy storage. Different thermochemical energy storage approaches have promising results[7]–[9] based on the methanol decomposition into syngas [10] or iron carbonates [11].

They have an optimum operation at different temperature levels, offering solutions to efficiently convert, store and transport solar energy. They allow seasonal storage capacity allowing long mismatch between resource availability and discharge for covering demand. Depending on the involved reactions, they can have high energy densities [12]. The thermochemical energy storage system based on the ammonia looping is based on the decomposition and synthesis of the pair NH_3/H_2. It has an energy density of 131 MJ/m^3 with a turning temperature of 195 ºC [7] [11]. From the point of view of thermochemical storage, the reactions of synthesis and decomposition of ammonia are opposite reactions that share the absorption and desorption of dinitrogen stage.

Ammonia is a carbon-free hydrogen carrier with a reasonably good volumetric and gravimetric energy density compared to hydrogen. It has an energy density of 13.1 GJ/m, whereas hydrogen has an energy density of 3.5 GJ/m [13], and it is used as a feedstock and raw material to produce other chemicals [14].

The ammonia chemical industry has a high environmental impact and needs the integration of renewable energy to reduce it [15]. There are several possibilities for integrating renewables in the ammonia industry: using biomass gasification systems [16]–[18], solar energy [19], [20], and wind energy [21], [22]. Another option is to use biogas produced from the decomposition of organic material, such as agricultural waste or animal excrement [23], as a source of hydrogen.

Ammonia-based solar thermochemical storage systems can help ensure the stability of solar thermal power generation systems 24-h basis, offering a high potential for long-term energy storage. Besides, ammonia, the main raw material for fertiliser production, can be integrated into a thermochemical storage system. *Carden et al.* pioneered the idea of the ammonia-based energy storage system in 1974 [24]. Subsequent exergy analyses studies conducted concluded that the main irreversibility is the heat recovery process. The main losses are concentrated in the reaction, the heat transfer within the exothermic reactor and the losses of the exothermic reactor countercurrent heat exchanger[25]. In 2019, *Chen et al.* [26] studied the effects of dissociation reactor geometry by performing a 2-dimensional pseudo-homogeneous cylindrical 2-dimensional model of a dissociation reactor, concluding that converging conical reactors can achieve the highest conversions. *Lovegrove et al.* proposed an ammonia looping system which operates at a nominal power level of 1 kW_{chem} solar dissociation reactor kW_e [27], [28].

This work proposes a novel and flexible system in which the renewable energy produced by the sun can be stored for a long time. Subsequently, this stored energy is released in the form of heat. This can be used for power generation or to provide heat to a process. It is a carbon-free process where ammonia is produced based on renewables [29]–[31], thus reducing the consumption of fossil fuels. The efficient and simple form of the system results in a competitive levelised cost of storage.

2. System description

The system consists of a charging cycle, where the ammonia decomposition reaction is carried out, and a discharge cycle, where the ammonia synthesis reaction is carried out. The concentrating solar power and a heliostat field are integrated into the charge phase to generate syngas through endothermic decomposition. In the discharge phase, the syngas is released to the synthesis phase and is converted into ammonia, releasing heat to a power cycle.

In the charging phase, ammonia is stored at 30°C and 25 bar and released to a pump that raises the pressure to 100 bar. The ammonia is preheated with the outlet of the decomposition reactor. This ammonia feeds the endothermic reactor at 382.3 ºC and 100 bar. The outlet of the reactor contains syngas and unreacted ammonia at 500 ºC and 100 bar[13], [32]–[34]. This outlet stream is cooled with the ammonia inlet to the reactor to 94.31 ºC.

Figure 1. Conceptual process flow diagram of the ammonia cycle system

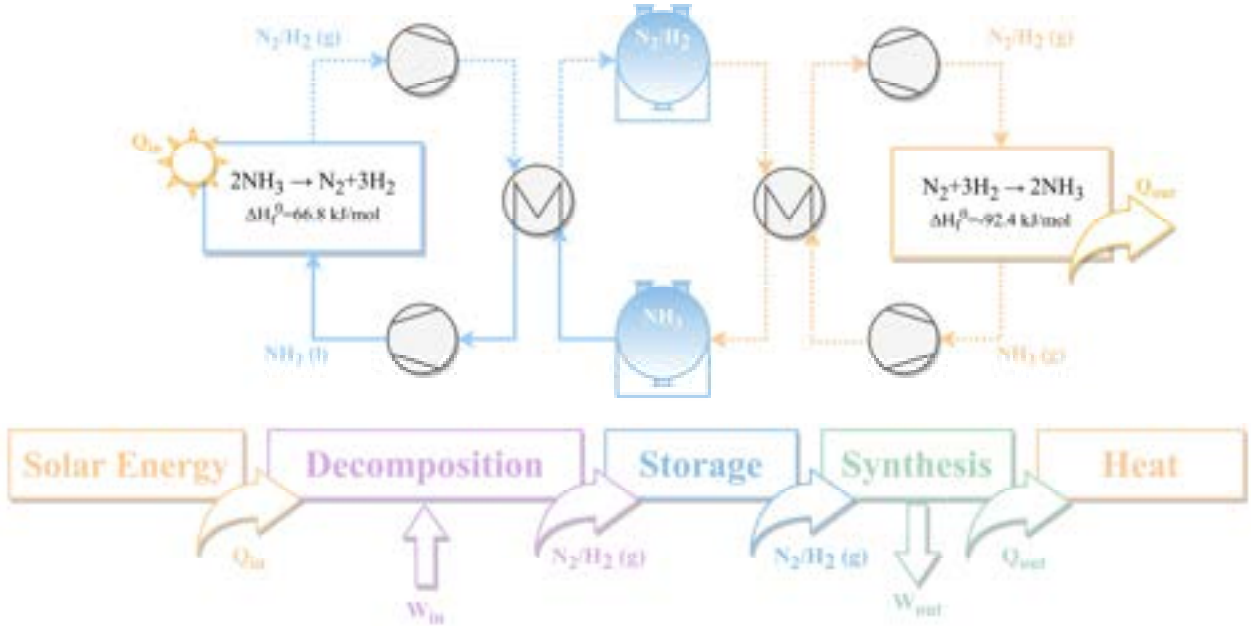

Figure 2. Process flow diagram of the ammonia cycle system

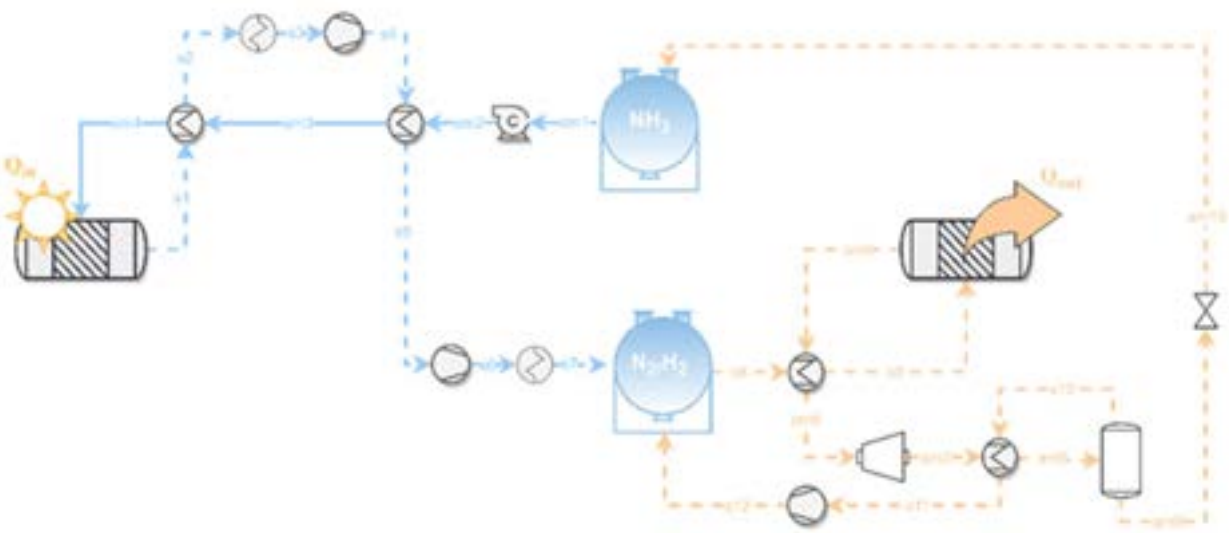
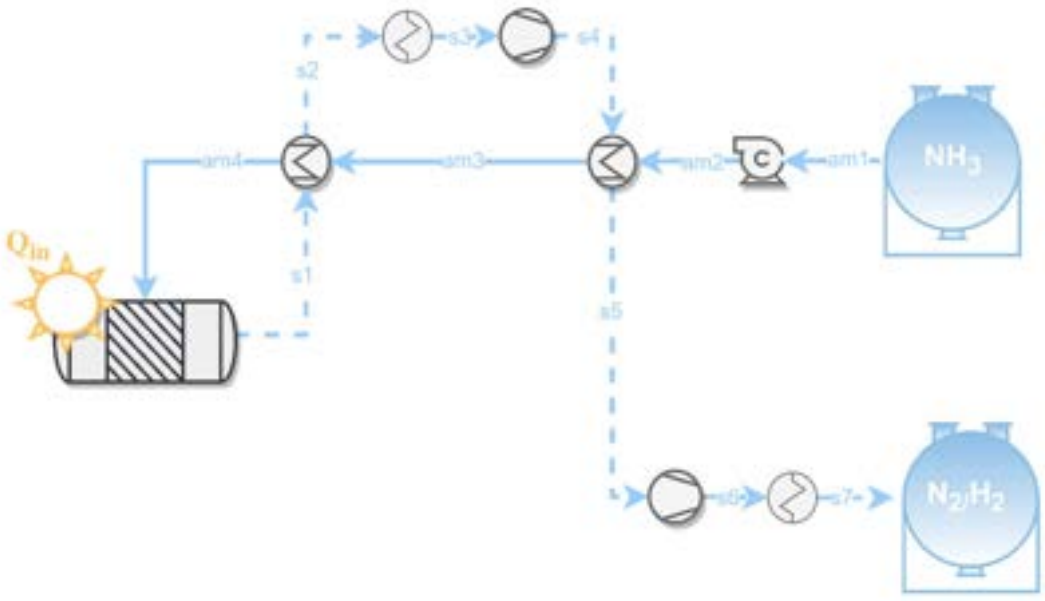


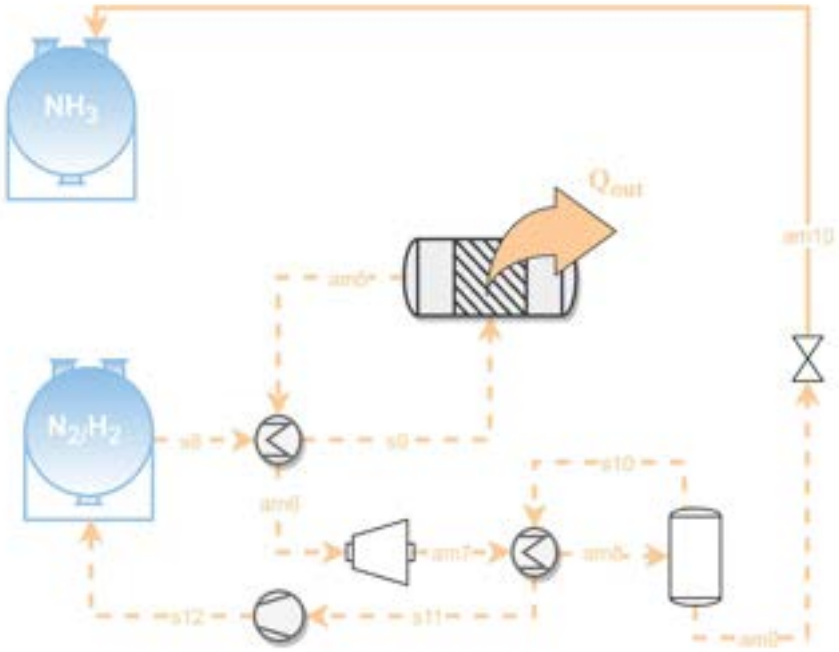
In the loading phase, ammonia is stored at 30°C and 25 bar and released to a pump that raises the pressure to 100 bar. The ammonia is preheated with the outlet of the decomposition reactor. This ammonia feeds the endothermic reactor at 382.3 ºC and 100 bar. The reactor outlet contains syngas and unreacted ammonia at 600 ºC and 100 bar. This outlet stream is cooled with the ammonia inlet to the reactor to 94.31 ºC and raises its pressure to 200 bar. Then, the syngas at 200 bar is stored [35].

Figure 3. Process flow diagram of the ammonia decomposition (charge phase)



In the discharge phase, the synthesis gas is released from the tank, and this stream is cooled with the reactor outlet. The inlet stream to the synthesis reactor is at 189.4 °C and 200 bar [36] with a catalyst converter Ba/Ru/BN [35]. The reactor outlet stream is at 300 ºC and 200 bar [36]. It separates in a flash into ammonia and unreacted synthesis gas. At a steady state and with a sufficiently long residence time in the reactor, the syngas would tend to be zero in the synthesis reactor outlet stream.

Figure 4. Process flow diagram of the ammonia synthesis (discharge phase)



3. Simulation

In this section, simulations of the proposed system layout will be carried out. These simulations will be carried out in the Aspen Hysys commercial software.

A series of operating conditions were previously defined to simulate the model, both in the loading and discharging phases.

a. Steady-state model.
b. Sufficient residence time to achieve an overall conversion of 100%.
c. The minimum approach temperature for all heat exchangers is 20 ºC.
d. The efficiencies of the pumps, compressors and turbines are 80, 89, and 90%, respectively.
e. The global, solar-to-chemical and solar-to-electric efficiencies have been defined according to equations 1, 2 and 3.

Table 1. Main parameters of the plant

Parameter	Value	Unit
NH_3 storage temperature/pressure	30/25	ºC/bar
Syngas CO/H2 storage pressure	200	bar
Endothermic reaction temperature/pressure	500/100	ºC/bar
Exothermic reaction temperature/pressure	250/200	ºC/bar
Inlet NH_3 molar flow of the charging process	100	mol/s

The global performance of the plant is defined as follows.

$$\eta_{plant} = \frac{\dot{Q_{exo}} + \dot{W_T}}{HH\dot{V}_{NH_3}\dot{m_{NH_3}} + \dot{W_C} + \dot{Q_{CSP}}} * \frac{h_{discharge}}{h_{charge}} \text{ [1]}$$

The numerator represents the outputs, which are the energy extracted from the ammonia synthesis and the power generated by the expansion turbines, while the denominator represents the heat flow of the ammonia stream from the synthesis reactor outlet, the energy consumption by the compressors and the pump, and the heat supplied by the CSP. This is affected by a ratio of discharge hours to charge hours.

Also, equations [2] and [3] define a solar-chemical yield and a solar-electric yield. The former represents the thermal recovery of the dissociation reaction compared to the CSP power input, while the solar-electric yield represents the electrical energy recovery compared to the CSP power and the energy consumption of the compressors and pump. Both efficiencies are in terms of heat and electrical energy, respectively.

$$\eta_{sol-ch=} \frac{X_{NH_3} m_{NH_3} \Delta h_{NH_3}}{\dot{Q_{CSP}}} \text{ [2]}$$

$$\eta_{sol-elec} = \frac{\dot{W_T}}{\dot{W_C} + \dot{Q_{CSP}}} \text{ [3]}$$

3.1 Economic model

The technical-economic analysis was carried out by evaluating the CAPEX and OPEX and then evaluating the LCOS of the system.

The levelized cost of storage (LCOS) according to equation 4.

$$LCOS = \frac{CAPEX + \sum_{i=1}^{n} \frac{OPEX}{(1+r)^n}}{\sum_{i=1}^{n} \frac{Q_{exo}}{(1+r)^n}} \text{ [4]}$$

It is assumed a discount rate (r) of 3% and a useful life of the plant (n) of 20 years.

The CAPEX was evaluated using equipment costs. These equipment costs are calculated based on the correlations shown in **Table 2**. OPEX is assumed to be 20% of CAPEX.

Table 2. Correlations for estimating equipment costs.

Equipment	Scaling parameter	Expression	Reference
Pump	Brake power [kW] and isentropic efficiency	$IC_C = 6898 \cdot \dot{W}_{Compressor}^{0.7865}$	[37]
Compressor	Power [kW]	$IC_P = 750 \cdot (\dot{W}_p)^{0.71} \cdot \left[1 + \left(\frac{0.2}{1-\eta_{i,P}}\right)\right]$	[38]
Turbine	Power [kW]	$IC_T = 4001.4 \cdot \dot{W}_{Turbine}^{0.6897}$	[37]
Endotermic reactor	Power [kW]	$IC_{DR} = 193000 \cdot \dot{Q}_{endo}^{0.65}$	[39]

Exotermic reactor	Power [kW]	$IC_{SR} = 19594 \cdot \dot{Q}_{exo}^{0.5}$	[38]
Tank	Volume [m^3]	$C_{tank} = 83 \cdot V_{tank} \cdot 10^{-6}$	[40]
Heat exchangers	Exchanger Area [m^2] pressure [bar]	*Table*	[38]
Solar tower and receiver	$\Phi_{Receiver}\ [kW]$	$IC_{tower}^{solar} = 57.07 \cdot \Phi_{Receiver}$	[41]
Electric generator	Power [MW]	$IC_{EG} = 106 \cdot P_G^{0.95}$	[38]

4. Results

The results of the system at nominal conditions are shown in **Table 3**. The solar-to-chemical performance is high (>90 %) due to the high conversion achieved in the decomposition reactor regarding the power input by the sun. The global performance is low compared to other TCES, as expected by the temperature levels. However, it the LCOS is remarkable, which is fairly low compared to other technologies.

Table 3. Results at the operation point

Parameter	Value	Unit
Global performance	11.55	%
Solar to chemical performance	91.84	%
Solar to electrical performance	1.753	%
Exothermic reaction heat	-3.78	MW
Endothermic reaction heat	6.207	MW
CAPEX	3.964	M€
OPEX	0.793	M€
LCOS	63.98	€/MWh

It can be observed that the LCOS of the plant is 63.98 €/MWh, which is a competitive value, in comparison with other types of long-term thermochemical energy storage, such as H_2 and CH_4 storage with levelized cost of electricity of 260-430 €/MWh and 360-550 €/MWh, respectively. Table 4 shows the LCOS of the different technologies for long-term and short-term storage. [42]

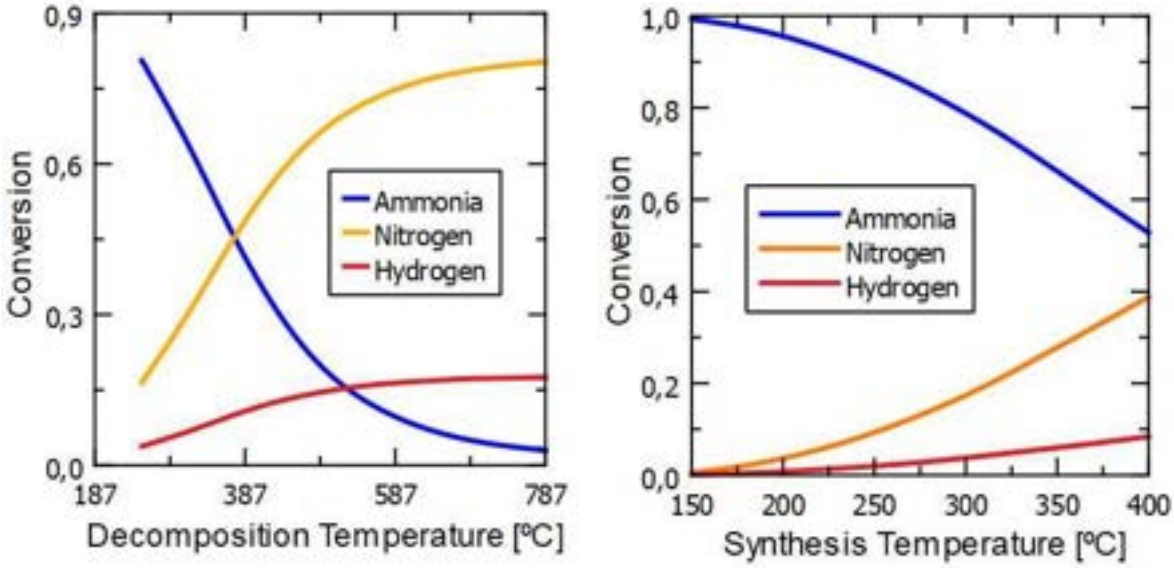
Table 4. Comparison table of LCOS for the different technologies for long-term storage

Technology	Type of storage	LCOS [€/MWh]
PSH (Pumped Storage Hydroelectricity)	long-term	930-1850
dCAES (Diabatic Compressed Air Storage)	long-term	20
aCAES (Adiabatic Compressed Air Storage)	long-term	20-40
H_2 Storage	long-term	260-430
CH_4 storage	long-term	360-530
NH_3 storage	long-term	64

4.1. Sensitivity analysis

Different sensitivity analyses were performed as a function of endothermic temperature. **Figure 5** shows the effect of the molar fraction as a function of the decomposition temperature and synthesis temperature. As the decomposition temperature increases, the molar fraction of ammonia increases, whereas as the synthesis temperature increases, the conversion of ammonia to syngas decreases to a lesser extent than the decomposition reaction. These conversions justify performance trends.

Figure 5. Concentration profiles as a function of decomposition temperature (on the left) and synthesis temperature (on the right)

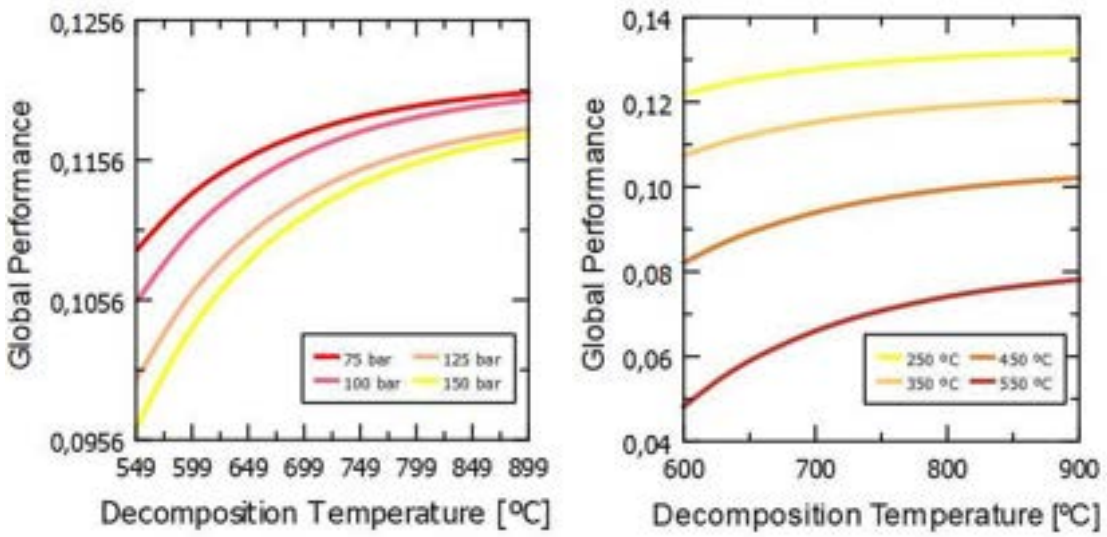


The next analysis is the global performance as a function of the decomposition and synthesis temperatures parametrised at four pressures. It has been shown that the higher the operating temperature, the higher the overall plant performance. Also, as operating pressures increase, lower overall plant performance. Increasing the endothermic temperature increases the conversion of ammonia to syngas, thus increasing the conversion in ammonia synthesis, releasing more heat of reaction, and increasing the yield. Likewise, the increase in pressure in the discharge phase increases the compression power, affecting the denominator and lowering the yield.

Figure 6 follows the same trend of the overall yield as a function of the decomposition temperature, but as the reaction temperature increases, the yield decreases. Increasing the reaction temperature the conversion decreases. Therefore, the heat flow of the reactor outlet stream is lower, affecting the numerator of the yield and decreasing it.

From these graphs, the optimum operating conditions that optimise the overall performance of the plant can be selected. The higher the decomposition temperature and the lower the synthesis temperature, the higher the overall plant performance.

Figure 6. Global performance as a function of decomposition temperature parametrised at four pressures (on the left) and parametrised at four synthesis temperatures.



In figure 7 it is shown the exothermic heat release as a function of synthesis temperature parametrised at four decomposition temperatures. As a synthesis temperature increases, the exothermic heat released decreases. In the opposite trend, as the decomposition temperature increase, the heat releases increase. This fact is because as the decomposition temperature increases, the syngas produced is higher. Then, the conversion of syngas to ammonia in the synthesis reactor is greater, releasing more heat.

Figure 7. Exothermic heat release as a function of synthesis temperature parametrised at four decomposition temperatures.

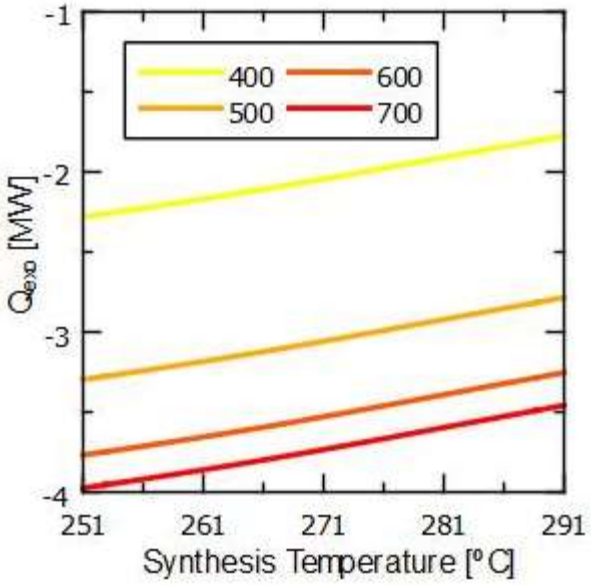


Figure 8 shows the levelized cost of storage as a function of the decomposition temperature and the synthesis temperature. As the decomposition temperature increases, the LCOS decreases. Likewise, as the synthesis temperature increases, the LCOS takes an opposite trend, decreasing.

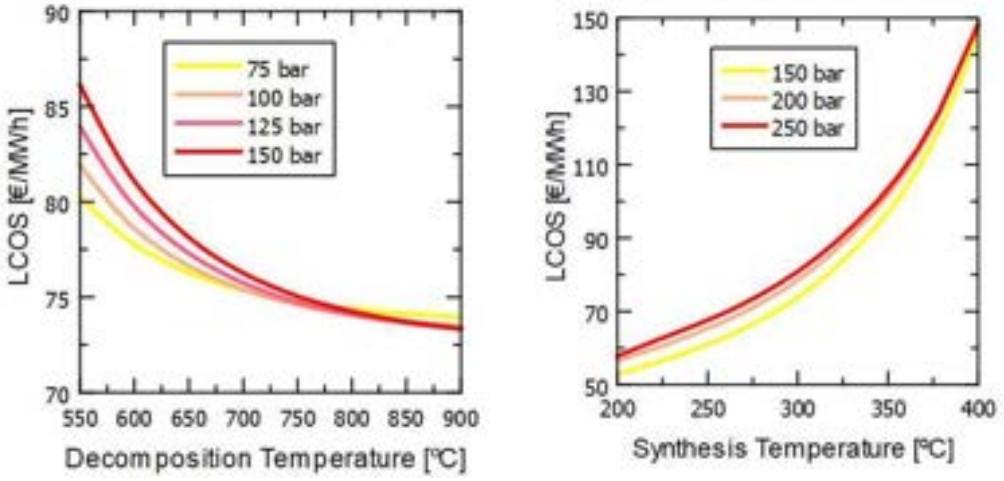
Figure 8. LCOS as a function of decomposition temperature parametrised at four pressures (on the left) and synthesis temperature (on the right).



It is shown the higher the ammonia pressure at the reactor inlet, the higher the LCOS because the OPEX of the installation increases as the pressure drop in the pump increases. This trend is equal in the discharge phase.

When the decomposition temperature rises, the reaction is favoured and shifts to the right, producing more syngas. Then the heat released in the synthesis reactor will be higher. This increases the denominator of the LCOS by lowering it. As the synthesis temperature increases, the heat of reaction decreases, resulting in a rise in LCOS. The rise in the OPEX is reflected mainly in the pressure in both analyses. As the pressure increases, the LCOS increases.

5. Conclusions

A thermochemical storage system is proposed, based on the decomposition and synthesis of green ammonia, being a CO_2-free solution and a very dispatchable system in terms of energy production.

There are several advantages of the proposed system that can be mentioned.

i. The solar-to-chemical performance is high (92%) due to the high conversion of ammonia in the decomposition reaction. In contrast, the overall thermal efficiency of the system is 11.55%, which is low due to high compression consumption in relation to the exothermic energy generated in the synthesis reaction and the temperature levels.

ii. The system produces 3.78 MW of exothermic heat, with 6.2 MW of power input in the CSP, based on 100 mol/s of green ammonia.

iii. The system has a competitive LCOS value of 63.98 €/MWh for the design conditions. It is a competitive position concerning other long-term thermochemical systems storage, such as H_2 or CH_4 storage.

iv. The temperature/pressure torque for the load plus phase is 30ºC/25 bar, and for the discharge phase 250ºC/200 bar, making a compromise between overall plant performance and LCOS.

Abstract:

With significant percentages of worldwide energy consumption occurring in the building sector, it is intended to reduce energy consumption and, in turn, satisfy the demand with renewable energies. However, renewable energies suffer from high variability, so energy accumulation systems become relevant for adjusting the time gap between energy supply and demand. In recent years, air conditioning facilities with geothermal heat pumps have been on the rise, as they reach higher coefficients of performance (COP) than aerothermal heat pumps. In addition, they provide the opportunity to use the ground as a thermal reservoir. A first analysis of the feasibility of using the ground as a temporary energy accumulator has been performed in this work. To this end, tests have been carried out in an experimental facility with vertical buried pipes to evaluate the evolution of ground temperature after heat injection. Temperature probes were placed on the pipe surface and monitored at 5 different depths, with tests performed in three different months to observe seasonal effects. Dimensional analysis led to the identification of the influencing variables of the problem: depth, tube length, tube diameter, time and soil thermal diffusivity. An apparent thermal diffusivity was defined to characterize the soil from the thermal measurements. The results allowed identifying a subterranean water stream at a particular depth, as well as observing the effects of ambient conditions in the system. It was observed that the upper ground layers were heavily affected by ambient conditions, discouraging their use for thermal energy storage, whereas depths below the ground water table seemed suitable for storing heat efficiently. Differences were found between wet and dry soil, with wet soil better suited for the storage of higher energy amounts, but dry soil better suited for keeping the stored energy for longer periods without further isolation.

Keywords:

thermal energy storage; thermal reservoir; energy supply; temporary energy accumulator; experimental testing.

1. Introduction

Almost half of global energy use is employed for heat generation purposes, being the building sector one of the highest contributors to global emissions. In the current energy and environmental context, both the reduction of energy consumption and the use of renewable energy sources are critical issues. When renewable energy sources are used, the availability of energy often does not coincide with its need [1], so an accumulation system is interesting to absorb the gap between energy production and demand [2].

Among renewable energies, geothermal energy has been widely used from prehistoric times to the present day [3]. As the ground temperature keeps more constant along the year than the ambient temperature, it is very interesting for heating and cooling applications in buildings. This feature, combined with high COP heat pumps consists of a reliable solution itself. Furthermore, the geothermal facility can be used to store surplus production by other renewable sources, as it is the case of solar thermal projects [4,5]. Although ground has usually been used for long term accumulation purposes [6,7], Cruickshank and Baldwin [8] studied the diurnal performance, showing the interest in using the ground not only for long term accumulation purposes.

In the first decade of this century, five “Office Buildings Prototypes for Research and Demonstration” were constructed or retrofitted within the Singular Strategic Project ARFRISOL [9], showing the construction of more environmentally respectful buildings. As a complement to that project, the Gijón Solar Cooling Laboratory (GSCL) [10] was installed at the University of Oviedo. The GSCL is a modular plant that allows the testing of diverse equipment and technologies, including a geothermal installation with vertical buried pipes. With the fundings of the project RehabilitaGeoSol [11] the experimental equipment was completed, and the first test of the vertical pipes circuit has been obtained.

In this work, experimental results obtained during months of testing in the vertical buried pipes of the GSCL are analysed, and first impressions on the influence of the season on the thermal behaviour of the soil are discussed.

2. Materials and methods

2.1. Description of the vertical pipes circuit

The GSCL was designed and implemented for testing different technologies for solar cooling production in buildings. The laboratory is in the facilities that the University of Oviedo has in the Gijon Polytechnical Engineering School. The core of this facility is an absorption machine ClimateWell-CW10, connected to several heat sources and sinks. The absorption machine has two different barrels of lithium chloride and water, enabling the possibility of storing energy in one of the barrels while the other one is discharging. The heat dissipation from the absorption machine can be configured through different technologies: an air heat exchanger, an evaporative cooling tower, a water reservoir or different ground heat exchangers with horizontal or vertical buried pipes. Figure 1 shows the conceptual scheme of the vertical pipes circuit tested in this paper.

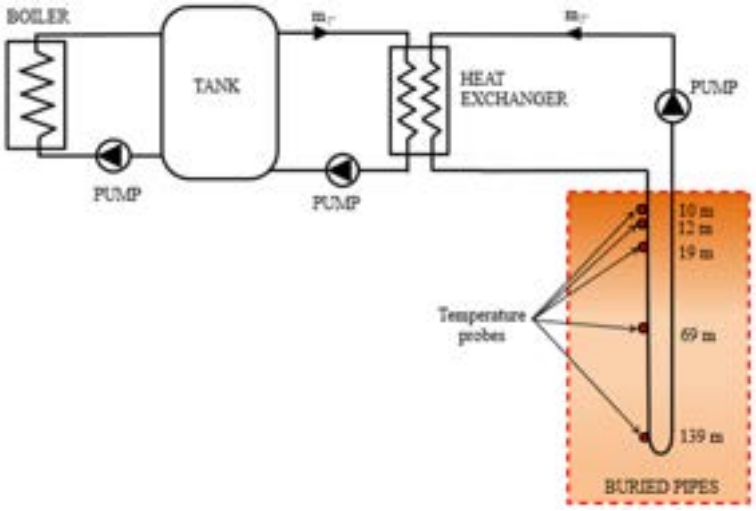

Figure 1. Conceptual scheme of the vertical pipes circuit.

The vertical pipes circuit consists of 2 U circuits of 32 mm diameter pipes, placed together into a 140 mm diameter hole filled with gravel, as can be seen in Figure 2. The pipes are buried down to 140 m depth, and 3-wires PT-100 probes are fitted to the outer surface of the pipes at five different depths (10 m, 12 m, 19 m, 69 m and 139 m), whereas flowrates were monitored with Kobold inductive flowmeters. PT-100 probes and flowmeters are connected to a Keithley 2700, multimeter equipped with a Keithley 7700 acquisition board and a GPIB/USB interface to be connected to a PC which records data every 5 minutes.

Figure 2. Detail of the pipes entering the ground.

2.2. Variables influencing in the problem

As a first approximation to the complexity of the problem, the temperature and physical properties of the terrain are assumed to be scalar functions with cylindrical symmetry. It is also assumed that the thermal conductivity of the terrain is isotropic. On the other hand, pending evaluation of the possible influence of environmental conditions by experimental results, the ground surface is assumed to be adiabatic.

At a point in the ground at distance r from the pipes and depth z from the surface, the temperature difference ΔT with respect to a point at the same depth and away from the influence of the pipes, depends on the physical properties of the ground, namely thermal conductivity k, specific heat capacity c and density ρ, the

diameter D and length L of the pipes, the temperature difference ΔT_0 at the beginning of the cooling, and the elapsed cooling time t. Therefore, a functional relationship of the following type can be written:

$$\Delta T = f(r, z, D, L, k, \rho, c, \Delta T_0, t) \quad (1)$$

The application of Buckingham's pi theorem to this equation, with the classical dimensional basis $\{L, M, T, \theta\}$ and using L, ρ, c and ΔT_0 as reference quantities, leads to the following functional relationship between dimensionless groups:

$$\frac{\Delta T}{\Delta T_0} = F\left(\frac{r}{L}, \frac{z}{L}, \frac{D}{L}, \Pi_k, \Pi_t\right) \quad (2)$$

where $\Pi_k = k/\left(\Delta T_0^{1/2} \rho\, L\, c^{3/2}\right)$ and $\Pi_t = \Delta T_0^{1/2} c^{1/2}\, t/L$.
Since the product of Π_k and Π_t is equal to the Fourier number $Fo = \alpha t/L^2$, equation (2) can be rewritten as follows:

$$\frac{\Delta T}{\Delta T_0} = F\left(\frac{r}{L}, \frac{z}{L}, \frac{D}{L}, Fo, \Pi_t\right) \quad (3)$$

The influence of Π_t is neither theoretically nor experimentally justified in the literature applicable to similar problems. In Appendix A it can be seen that spatially discriminated dimensional analysis predicts that such a monomial is spurious. Furthermore, variables r, D and L are constants in the case study, so the following functional relationship can be proposed as the basis of the experimental analysis:

$$\frac{\Delta T}{\Delta T_0} = F\left(\frac{z}{L}, Fo\right) \quad (4)$$

2.3. Data curation and postprocessing

The tests performed may be divided into two stages, as depicted in the example of Figure 3. In the first stage, heat was injected into the geothermal circuit below the ground until stationary conditions were obtained. After that, the heat supply was cut off and the evolution of the system was monitored. Specifically, the evolution of the temperature probes placed on the tube walls at 10, 12, 19, 69, and 139 m of depth was measured, and at first sight no influence of ambient temperature oscillations was found, even at the lower depth probes. The summary of the experimental tests performed is collected in Table 1. The tests were performed in May and September 2019 and February 2020, to observe seasonal effects in the behavior of the system.

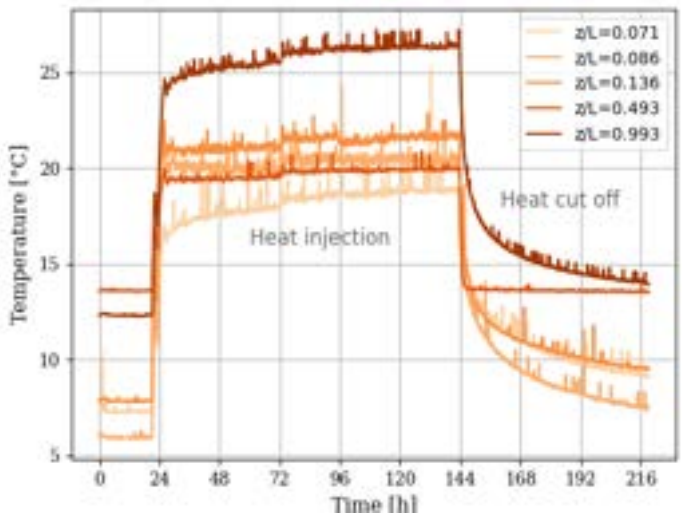

Figure 3. Loading curves performed in the experiments of May 2019.

Table 1. Summary of experimental tests

	February	May	September
Heat injection time	10,110 min	8,685 min	20,000 min
Heat injection flowrate	11.6 L/min	19.2 L/min	22.5 L/min
Average heat injection power	14 kW	17.5 kW	15.5 kW
Heat cut off monitoring time	21,690 min	4,515 min	19,315 min
Total experiment time	31,800 min	13,200 min	39,315 min

The measurements obtained were firstly filtered with a third order one-dimensional median filter [12] to eliminate possible outliers and obtain a clean signal for its subsequent analysis. An example is shown in Figure 4 for illustration.

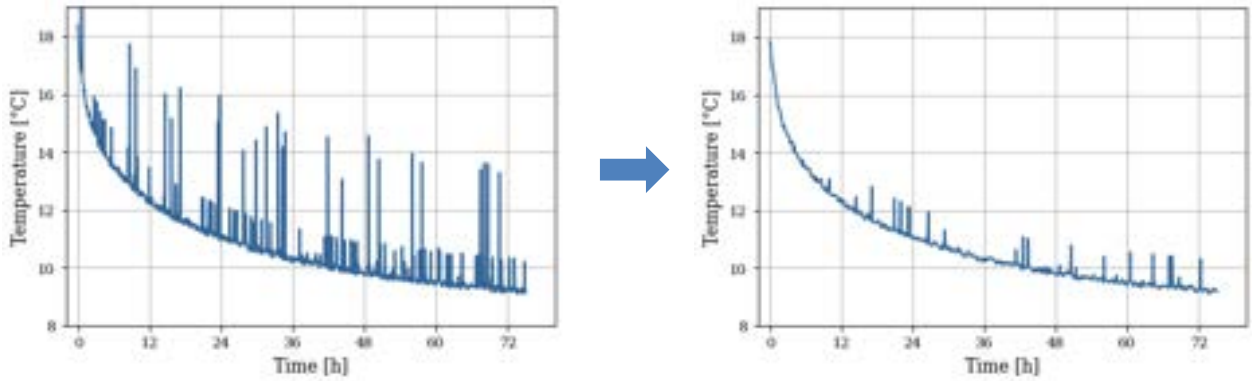

Figure 4. Postprocessing of measurements with 3rd order 1-D median filter

Then, the data were made dimensionless to compare measurements from different depths and periods. As the exact thermophysical properties of the soil are unknown, a constant apparent thermal diffusivity $\alpha_{ref} = 5.288 \cdot 10^{-7}$ m²/s was firstly used to make the data dimensionless. This value was estimated from the values obtained in the RehabilitaGeosol project [11] for the area of the experiments: a density of 3200 kg/m³, a specific heat of 1300 J/(kg·K), and a thermal conductivity of 2.2 W/(m·K). Thermal diffusivity was considered constant, and the underground soil isotropic.

It is possible, though, that each ground layer has different thermophysical properties. Therefore, with the aim of obtaining an estimative characterization of each ground layer, different apparent thermal diffusivities α_a were allowed for each ground depth (i.e., data series). The estimations of apparent thermal diffusivity α_a were obtained from the fitting of temperature measurements with respect to time. As a first approximation, in this work, an equation based on the proposed in [13] for transient heat conduction in semi-infinite solids was used, considering the soil as such:

$$\Delta T(t) = \Delta T_0 \, \mathrm{erf}\left(d/\sqrt{4\alpha_a t}\right) \quad (5)$$

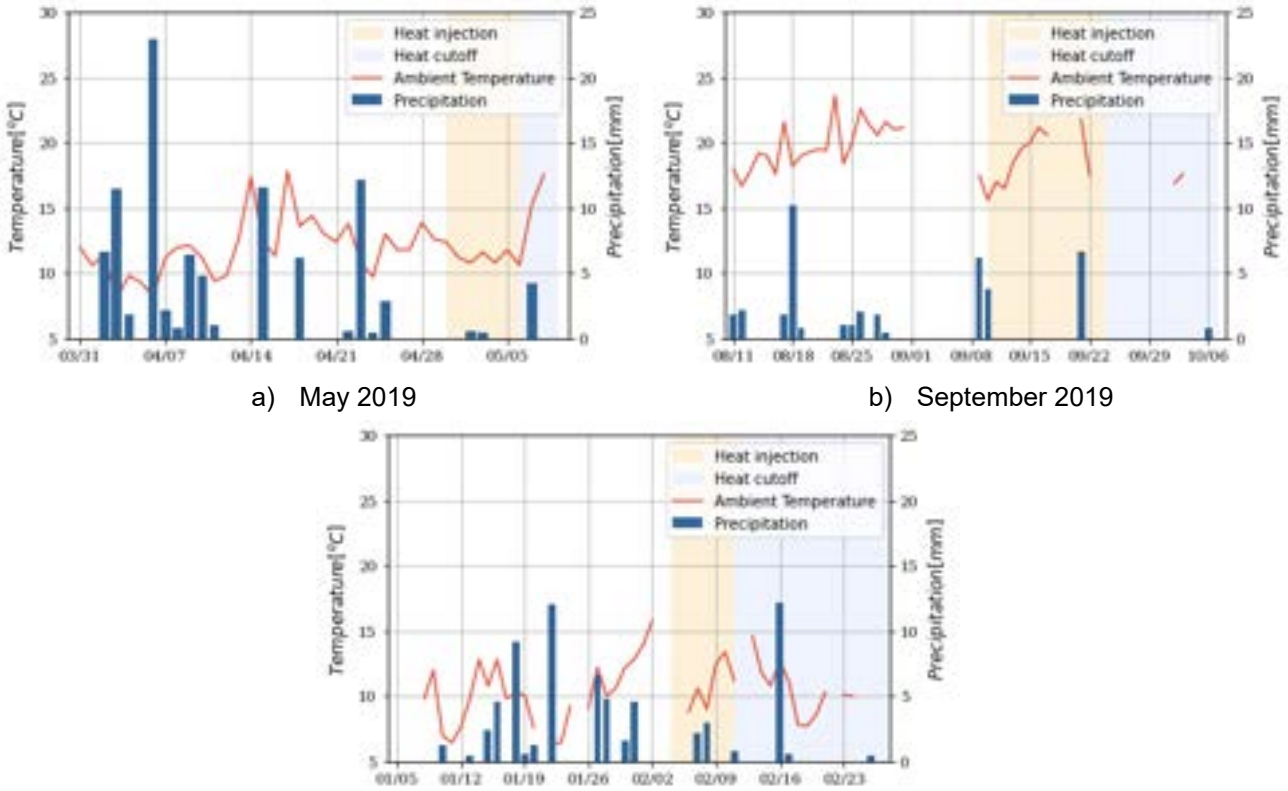
Where T_0 is the initial temperature in K, T_∞ is the steady-state temperature in K, d is the distance between the tube center and the probe position, 0.07 m, α_a is the apparent thermal diffusivity of the soil in m²/s and t is the time in s. Typical values for soil thermal diffusivity are in the range of $5 \cdot 10^{-7}$ m²/s, [14,15,16] so values of α_a in the order of magnitude of 10^{-7} are expected.

2.4. Influence of ambient conditions

The soil is constituted by different minerals and rocks of different sizes, leaving gaps in between that may be filled with liquids and gases [17]. The estimation of soil thermophysical properties becomes a challenge due to this heterogeneous composition of the soil, which affects density, thermal conductivity, heat capacity and thus thermal diffusivity. When air is displaced by water from the gaps between solid fractions, the soil thermal conductivity is bound to increase. The increase of moisture also increases thermal conductivity due to the changes in the bond between water and soil, as well as the peculiar characteristics of water interfaces [18]. Volumetric heat capacity also increases with the addition of water. Once the thermal conductivity reaches a maximum value, the addition of more water continues increasing the soil heat capacity. As a consequence, thermal diffusivity exhibits an increasing trend for the addition of water at low moisture values, reaching a maximum for a particular moisture content, and then decreasing with further addition of water [19,20]. Apart from the composition, soil temperature affects its properties. Heat capacity and thermal conductivity are lower at lower temperatures, leading to variations in the thermal diffusivity of soil depending on the relative rate of change between these two variables.

In addition, it has been verified that ambient conditions influence the behavior of the upper ground layers and that both temperature and the amount of moisture influence soil properties [17], so meteorological data from the period in which the experiments were performed were collected from the Spanish State Agency for Meteorology [21] to provide a better insight into the results and their implications. Figure 5 shows the temperature and precipitation conditions at ground level from a month before starting the experiments until the experiments were finished. The exact dates in which the heat injection and cutoff processes for the experiment took place have been highlighted in the graphs. These data should help to generate the

landscape for understanding the initial conditions for the experiments and the evolution of the system throughout the heat injection and heat cutoff processes.



a) May 2019

b) September 2019

c) February 2020

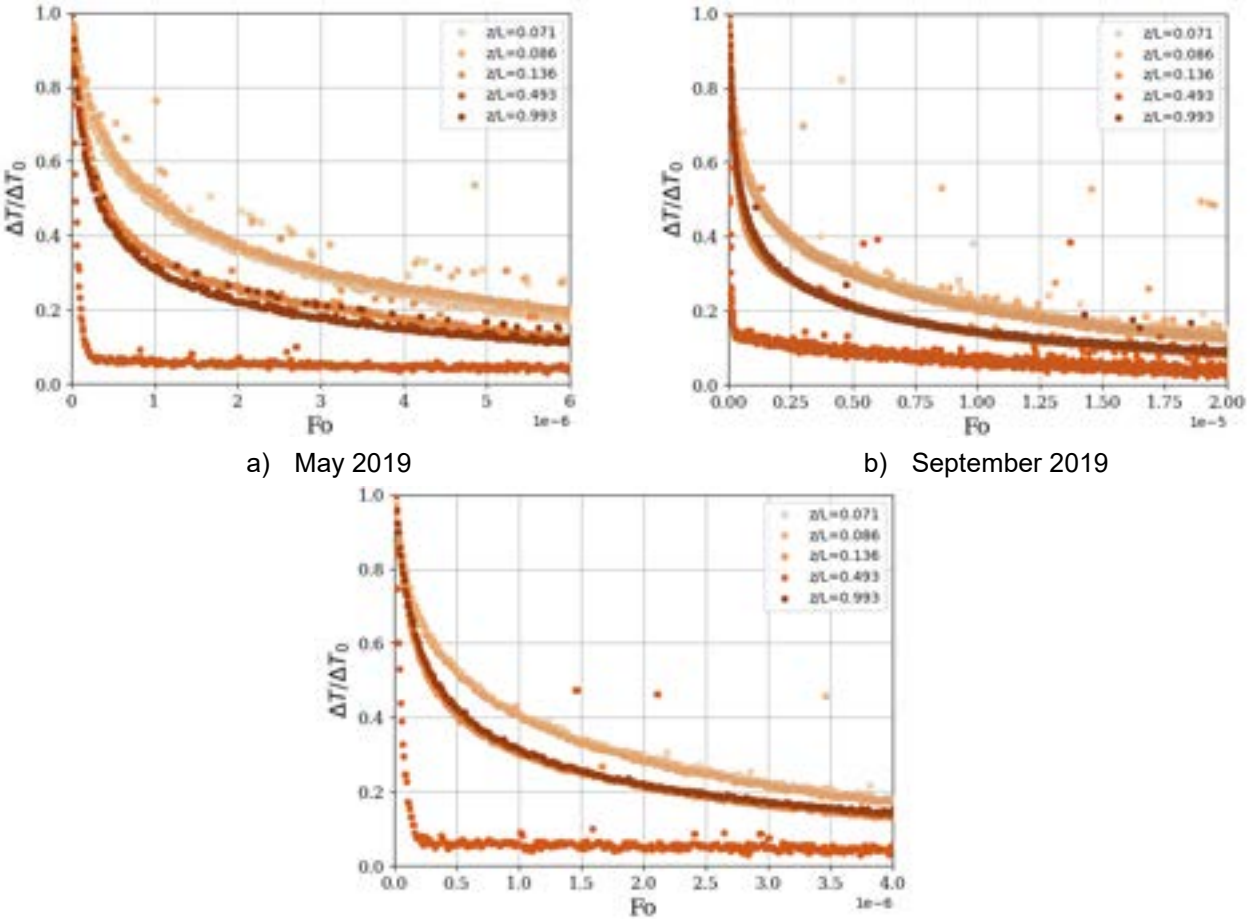
Figure 5. Climate conditions above ground level at the experiment dates

Regarding the measurements from the meteorological station, it may be appreciated that there was a high period of rain before the experiments in May took place, with 91.9 mm, followed by February, with 49.2 mm and September, with 29.2 mm. Nevertheless, during the experiments, May had the driest conditions, 5.2 mm, followed by September, with 11.2 mm and February with 19.2 mm. Average temperatures are almost constant in the case of February, showing an increasing trend in May and a decreasing trend in September. Particularly, during the experiments, average ambient temperatures were 12.4 ºC in May, 18.4 ºC in September, and 10.7 ºC in February.

3. Results

3.1. Influence of depth

Figure 6 shows the evolution of dimensionless temperatures at all measured depths for the three seasons studied. It may be observed that there is an upper zone ($z/L \leq 0.086$), the temperature evolution is slower than in the lower zone ($z/L \leq 0.136$). This effect could be attributed to the fact that the water table where the experiments were performed is at 15 m underground ($z/L \leq 0.107$), so this depth could mark the fringe between both behavior types. A very different behavior may be appreciated for the temperatures at $z/L = 0.493$, which decrease abruptly as soon as heat injection is stopped. This behavior might be representative of a subterranean water stream, that draws heat at a higher rate than underground soil, as a result of the combination of conduction and also convection mechanisms. Comparing the three periods, the size of the gap between the upper and lower zones of the ground seems bigger in the case of May 2019. This could be attributed to the drier ambient conditions during the experiments, as the introduction of rainwater during the experiments in September and February may have helped to increase the slope of the cooling curves in these periods.



a) May 2019

b) September 2019

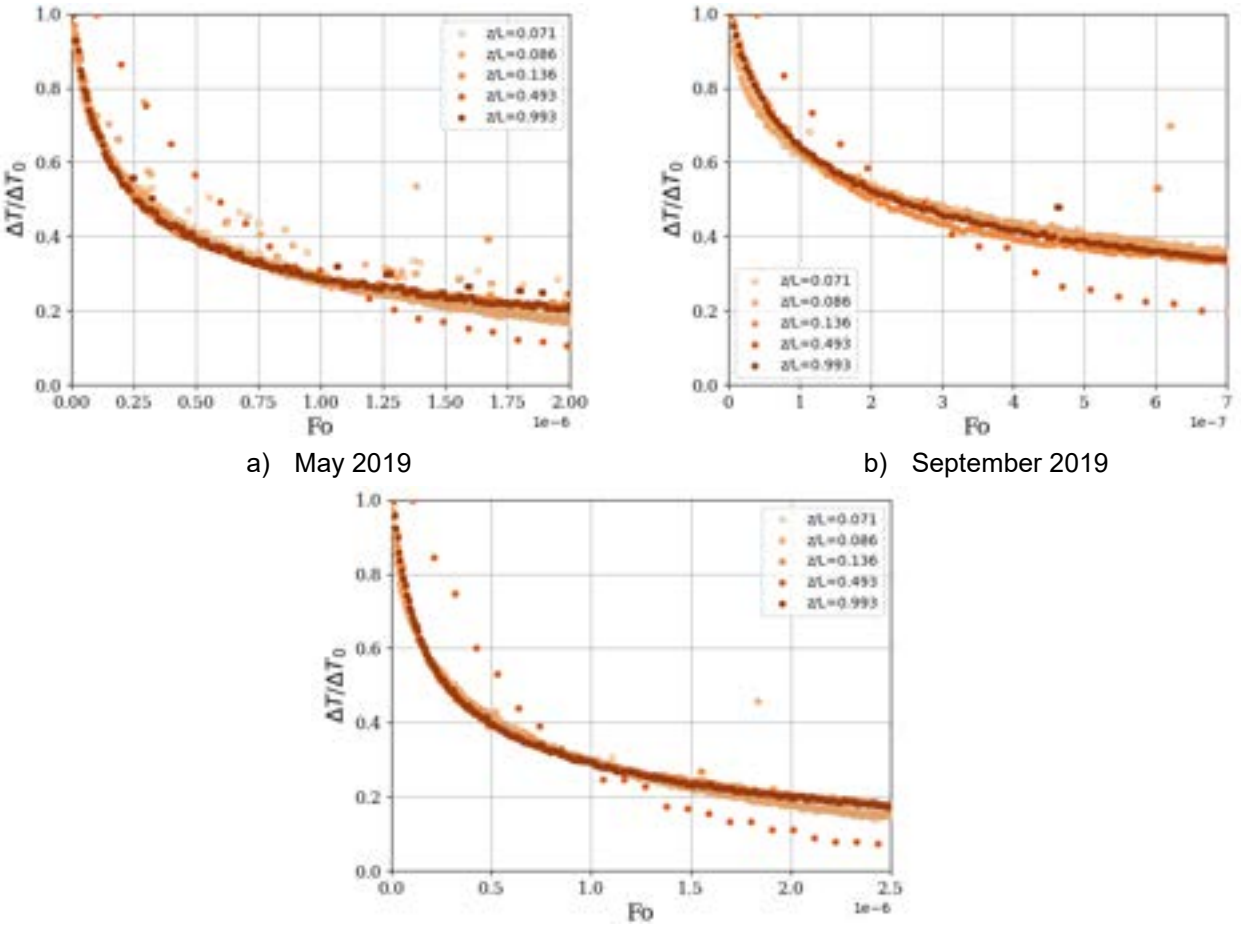
c) February 2020

Figure 6. Evolution of dimensionless temperatures in different seasons (same layer diffusivities)

When different apparent thermal diffusivities were allowed for each ground depth, an interesting result was obtained: all curves, apart from the one with the alleged underground stream, collapsed into one in the dimensionless representation, as shown in Figure 7. This might suggest that the heat transfer physical mechanism could be the same for the collapsing curves, considering the different initial conditions and soil thermophysical properties. The results also lead to think that the physical mechanism of heat transfer at the specific depth z/L = 0.493 could be different from the others, so the presence of a subterranean water stream drawing heat by convection seems more feasible. In addition, different behaviors for the whole system arise in different seasons. The values of the apparent thermal diffusivity obtained for each season and depth have been collected in Table 3.

Table 3. Apparent thermal diffusivities as a function of dimensionless depth and season

	May	September	February
z/L	$\alpha \times 10^7$ [m²/s]	$\alpha \times 10^7$ [m²/s]	$\alpha \times 10^7$ [m²/s]
0.071	1.75	1.10	2.69
0.086	1.52	1.10	2.83
0.136	3.54	2.45	4.95
0.493	64.97	25.53	69.15
0.993	5.52	1.74	8.50



a) May 2019

b) September 2019

c) February 2020

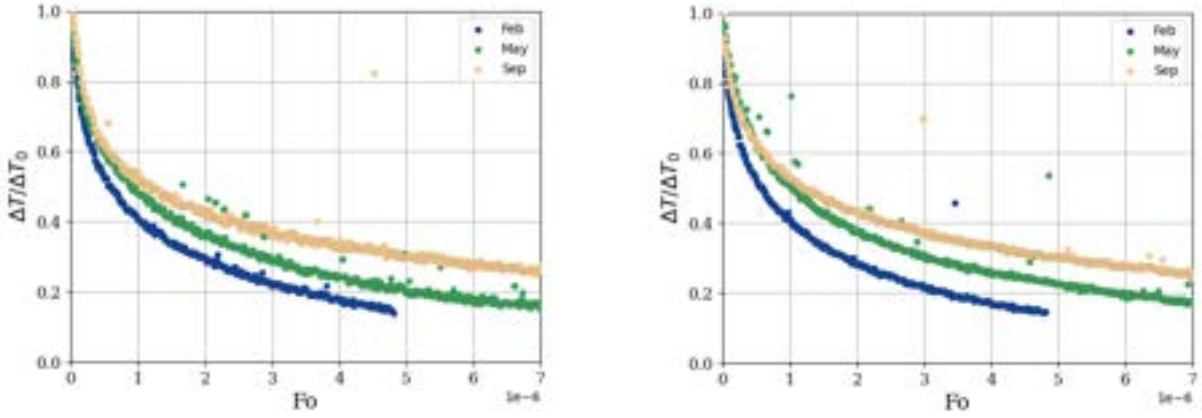
Figure 7. Evolution of dimensionless temperatures in different seasons (different layer diffusivities)

Note that for z/L = 0.493, apparent thermal diffusivity is much higher than for water, air, and typical soil values; this could be a last hint that there might be an underground water stream carrying heat away from the ground by convection, also affecting heat conduction speeds in the nearest ground layers.

3.2. Influence of seasons

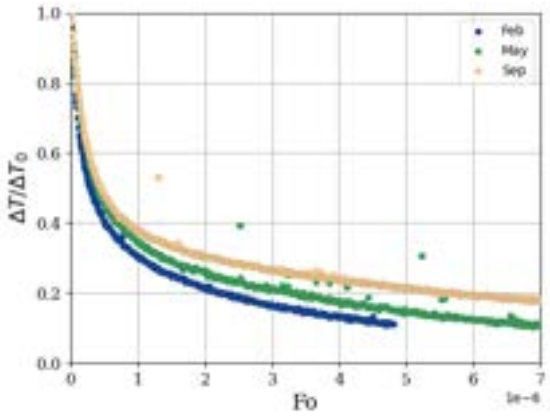
Due to the differences observed between different seasons, the results of the temperature evolution at different depths as a function of the season were studied, as shown in Figure 8. February was found to be the season in which temperatures were lower. This difference, which is more apparent in the upper layers of the ground, may be ascribed to the fact that the air in contact with the ground surface is colder in that month, as seen in the meteorological data. In addition, during winter season, the ground temperature profile is near its minimum values. On the other hand, higher target ground temperatures are found in May and September, because of higher ambient temperatures. In May, the ground is getting warmer each day, as spring advances towards the summer, whereas in September, before the summer ends, the ground is still relatively warm. In addition, as seen in the climate data presented in Figure 5, more rain intensity was found in February and May, leading to possibly more drenched ground layers in which water displaces air from the soil pores, resulting in potentially higher thermal diffusivities. From this analysis, it seems that the energy potentially stored at such small depths would be very influenced by ambient conditions and could be easily dissipated, so it would not be recommended to store energy above the water table of the ground, unless adequate isolation systems are provided.

At higher depths, nevertheless, there is almost no difference between the temperature evolution in February and May. It seems reasonable to think that the effect of ambient temperature and the humidity caused by the rain stops having an influence at such depths. The difference between the behavior at such depths in September with respect to the other months may be ascribed to the higher temperatures reached at steady conditions in the ground, but a probably more reasonable explanation could be the less amount of water carried by the underground stream that certainly circulates near z/L = 0.493. The amount of water carried by this stream depends ultimately on the amount of rain, which is definitely lower towards the end of summer (see Figure 5), reducing the capability of the stream to cool the ground by convection.

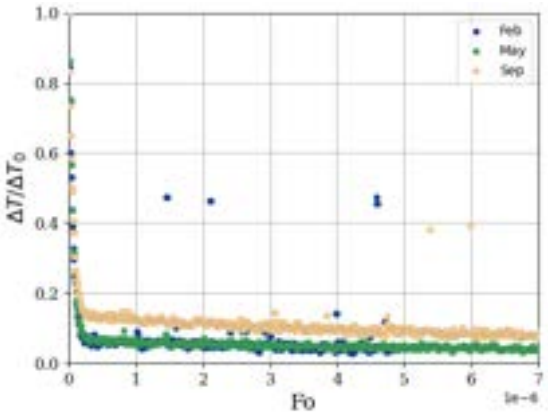


a) $z/L = 0.071$

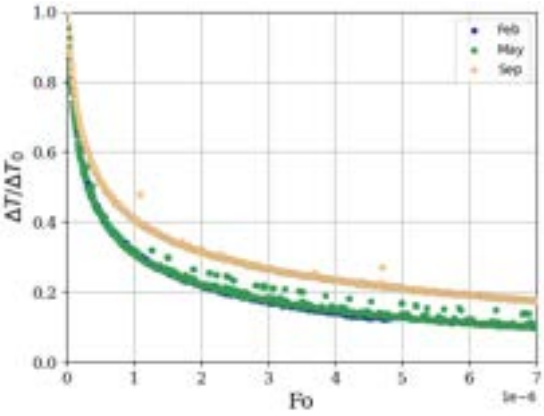
b) $z/L = 0.086$



c) $z/L = 0.136$



d) $z/L = 0.493$



e) $z/L = 0.993$

Figure 8. Evolution of dimensionless temperatures in different seasons at different depths

To summarize, wet soil tends to have a higher apparent thermal diffusivity up to a certain amount of moisture, allowing for faster loading and unloading curves for energy storage. Dry soil, on the other hand, needs more time for storing and releasing heat. This may be appreciated in the heat injection times depicted in Figure 5 for the drier seasons, and the higher Fourier numbers necessary to bring the soil back to its original temperature presented in Figure 6, which were substantially higher in September, when the soil was drier. Depending on the application and the required heating power, wet soil might represent an advantage for storing a higher amount of thermal energy and delivering it at higher speeds, thanks to the higher thermal diffusivity and specific heat. Isolating materials might help to keep the heat stored for longer times if seasonal storage is planned. Nevertheless, if heat delivery speed is not a limiting factor, dry soil should be able to keep heat stored during longer times, preventing its diffusion throughout the ground, without additional works for isolation.

4. Conclusions

A preliminary analysis of the feasibility of using the ground as a temporary energy accumulator has been performed in this work. To this end, experimental tests have been carried out with vertical buried pipes in the

Gijón Solar Cooling Laboratory (GSCL) facility, monitoring the temperature evolution of probes placed at different depths. The methodology proposed in this work may be used to characterize the ground thermal behavior and its feasibility as a temporary energy accumulator. Particularly, the soil composition, soil moisture and the presence of underwater currents have been found as variables of interest influencing the possible design and operation of storage systems.

Experimental measurements were represented against the dimensionless depth and the Fourier number, finding that depth has a significant influence in the evolution of temperatures, with differences between the behavior at the upper and lower layers of the ground, probably as a consequence of the water table depth.

In the upper zone, temperature evolutions were relatively slower than in the lower zones. A very different behavior was observed at z/L = 0.493, where heat was dissipated at a much higher speed, hinting at a different physical heat transfer mechanism, such as a subterranean water stream dissipating heat by convection. The numerical results presented in this work must be interpreted in a qualitative way, allowing the comparison between different measurements, but they must not be considered as an exact characterization of the thermophysical properties of the soil.

Different behaviors for the whole system were found depending on the season. An explanation may be provided by the different thermal conductivity values of water and air, which fill ground pores. A relationship between the meteorological historical data for temperature and precipitation and the behavior of the upper layers of the ground might be inferred with colder air leading to colder target values for the temperature and higher rain levels related to higher soil thermal conductivity and diffusivity values. Ambient conditions seemed to influence the system behavior at low depths, discouraging their use as a heat reservoir. However, at higher depths, ambient conditions did not show such a high influence, with practically the same behavior in February and May. There were, indeed, differences with September, but they are likely more related to the effects of a lower water mass flow at higher temperatures in the subterranean stream than the seasonal change in the soil conditions. Hence, heat storage at higher depths may be more reliable. Regarding soil moisture, wet soil might represent an advantage for storing a higher amount of thermal energy and delivering it at higher speeds, thanks to the higher thermal diffusivity and specific heat. Nevertheless, if heat delivery speed is not a limiting factor, dry soil should be able to keep heat stored during longer times. Finally, considering the impracticability of a total characterization of the soil characteristics, including pore geometry, along all the ground to be used as storage, heat loading and cutoff curves as the ones presented in this work may prove useful to assess the feasibility of using the ground as a temporary energy accumulator.

Future works will focus on the development and application of accurate models for heat transfer in buried U-vertical pipes to improve the characterization of the thermophysical properties of the ground, the study of the heat injection stage, and the development of more experimental tests at other ambient conditions to try to obtain more generalizable results.

The authors would like to thank the AEMET OpenData system from the Spanish State Agency for Meteorology (AEMET), for making available the meteorological data used in this work.

Appendix A

The classical method of dimensional analysis does not take into account the algebraic characteristics of the influencing variables in a physical problem. The first references to the idea of considering differences between spatial dimensions are attributed to Williams [22] and Huntley [23]. Later, Palacios [24] deals rigorously with this topic and lays the foundations of discriminated dimensional analysis (DDA). There are recent examples of the use of the DDA method for various applications [25,26]. Spatial discrimination increases the order of the dimensional basis so that, in general, spurious dimensionless groups that might occasionally be deduced from the classical method are eliminated.

Using the DDA method, only the scalar variables in equation (1) have equal dimensional exponents in each of the three spatial directions. The dimensional formula for the thermal conductivity is derived from Fourier's Law and the definition of the heat flux Q:

$$\vec{q} = -\bar{\bar{k}} \otimes \nabla T \quad \text{(A.1)}$$

$$Q = \int \vec{q} \cdot \overrightarrow{\mathrm{d}S} \quad \text{(A.2)}$$

Using cylindrical coordinates and the dimensional basis $\{L_r, L_\varphi, L_z, M, T, \theta\}$ (Figure A1), the following equations can be written:

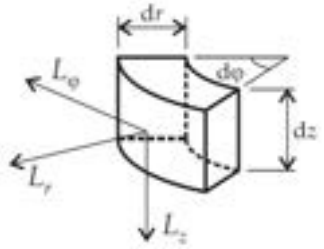

Figure A1. Spatial discrimination for Dimensional Analysis.

$$\vec{q} = \begin{bmatrix} k_{rr} & k_{r\varphi} & k_{rz} \\ k_{\varphi r} & k_{\varphi\varphi} & k_{\varphi z} \\ k_{zr} & k_{z\varphi} & k_{zz} \end{bmatrix} \begin{bmatrix} \partial T/\partial r \\ \partial T/(r\partial\varphi) \\ \partial T/\partial z \end{bmatrix} \quad \text{(A.3)}$$

$$\dot{q}_r = k_{rr}\,\partial T/\partial r + k_{rz}\,\partial T/\partial z \quad \text{(A.4)}$$

$$\dot{q}_z = k_{zr}\,\partial T/\partial r + k_{zz}\,\partial T/\partial z \quad \text{(A.5)}$$

where it has been assumed that the temperature has cylindrical symmetry, i.e.: $T = T(r,z) \leftrightarrow \partial T/\partial\varphi = 0$

Therefore, the following dimensional formulae for the components of the thermal conductivity tensor are derived:

$$[k_{rr}] = \frac{[\dot{q}_r]}{[\partial T/\partial r]} = \frac{\left(L_r^{2/3}L_\varphi^{2/3}L_z^{2/3}MT^{-2}\right)/(TL_\varphi L_z)}{L_r^{-1}\theta} = L_r^{5/3}L_\varphi^{-1/3}L_z^{-1/3}MT^{-3}\theta^{-1} \quad \text{(A.6)}$$

$$[k_{rz}] = \frac{[\dot{q}_r]}{[\partial T/\partial z]} = \frac{\left(L_r^{2/3}L_\varphi^{2/3}L_z^{2/3}MT^{-2}\right)/(TL_\varphi L_z)}{L_z^{-1}\theta} = L_r^{2/3}L_\varphi^{-1/3}L_z^{2/3}MT^{-3}\theta^{-1} \quad \text{(A.7)}$$

$$[k_{zr}] = \frac{[\dot{q}_z]}{[\partial T/\partial r]} = \frac{\left(L_r^{2/3}L_\varphi^{2/3}L_z^{2/3}MT^{-2}\right)/(TL_r L_\varphi)}{L_r^{-1}\theta} = L_r^{2/3}L_\varphi^{-1/3}L_z^{2/3}MT^{-3}\theta^{-1} = [k_{rz}] \quad \text{(A.8)}$$

$$[k_{zz}] = \frac{[\dot{q}_z]}{[\partial T/\partial z]} = \frac{\left(L_r^{2/3}L_\varphi^{2/3}L_z^{2/3}MT^{-2}\right)/(TL_r L_\varphi)}{L_z^{-1}\theta} = L_r^{-1/3}L_\varphi^{-1/3}L_z^{5/3}MT^{-3}\theta^{-1} \quad \text{(A.9)}$$

As a result, the following matrix of dimensional exponents is obtained:

	r	D	z	L	ρ	c	k_{rr}	k_{rz}	k_{zz}	ΔT_0	t	ΔT
L_r	1	1	0	0	-1	2/3	5/3	2/3	-1/3	0	0	0
L_φ	0	0	0	0	-1	2/3	-1/3	-1/3	-1/3	0	0	0
L_z	0	0	1	1	-1	2/3	-1/3	2/3	5/3	0	0	0
M	0	0	0	0	1	0	1	1	1	0	0	0
T	0	0	0	0	0	-2	-3	-3	-3	0	1	0
θ	0	0	0	0	0	-1	-1	-1	-1	1	0	1

As the rank of this matrix is 6, and taking D, L, ρ, c and ΔT_0 as reference variables, the following 6 dimensionless numbers are obtained:

$$\Pi_\theta = \frac{\Delta T}{\Delta T_0}; \qquad \Pi_r = \frac{r}{D}\ ; \qquad \Pi_z = \frac{z}{L}$$

$$\Pi_{k_{rr}} = \frac{k_{rr}t}{\rho c D^2} = \frac{\alpha_{rr}t}{D^2}; \qquad \Pi_{k_{rz}} = \frac{k_{rz}t}{\rho c L D} = \frac{\alpha_{rz}t}{LD}; \qquad \Pi_{k_{zz}} = \frac{k_{zz}t}{\rho c L^2} = \frac{\alpha_{zz}t}{L^2}$$

Thus, the following relationship can be written:

$$\frac{\Delta T}{\Delta T_0} = F\left(\frac{r}{D}, \frac{z}{L}, \frac{\alpha_{rr}t}{D^2}, \frac{\alpha_{rz}t}{LD}, \frac{\alpha_{zz}t}{L^2}\right) \quad \text{(A.10)}$$

Assuming isotropy, $\bar{\bar{\alpha}} = \alpha\bar{\bar{I}}$ would be satisfied, i.e. $\alpha_{ij} = \alpha(r,z)\cdot\delta_{ij}$, being δ_{ij} the components of Kronecker delta tensor, and the following numerical, but not dimensional, equalities are verified:

$$\alpha_{rr} = \alpha_{zz} = \alpha(r,z) \quad \text{(A.11)}$$

$$\alpha_{rz} = 0 \quad \text{(A.12)}$$

Then:

$$[\delta_{rr}] = \frac{[\alpha_{rr}]}{[\alpha]} = \frac{L_r^2 T^{-1}}{L_r^{2/3} L_\varphi^{2/3} L_z^{2/3} T^{-1}} = L_r^{4/3} L_\varphi^{-2/3} L_z^{-2/3} \quad \text{(A.13)}$$

$$[\delta_{zz}] = \frac{[\alpha_{zz}]}{[\alpha]} = \frac{L_z^2 T^{-1}}{L_r^{2/3} L_\varphi^{2/3} L_z^{2/3} T^{-1}} = L_r^{-2/3} L_\varphi^{-2/3} L_z^{4/3} \quad \text{(A.14)}$$

$$\Pi_{k_{rr}} = \frac{\alpha t}{D^2} \cdot \delta_{rr} = \frac{\alpha t}{L^2} \left(\frac{L}{D}\right)^2 \cdot \delta_{rr}; \qquad \Pi_{k_{rz}} = 0; \qquad \Pi_{k_{zz}} = \frac{\alpha t}{L^2} \cdot \delta_{zz}$$

$$\frac{\Delta T}{\Delta T_0} = F\left(\frac{r}{D}, \frac{z}{L}, \frac{\alpha t}{L^2}\left(\frac{L}{D}\right)^2 \cdot \delta_{rr}, \frac{\alpha t}{L^2} \cdot \delta_{zz}\right) \quad \text{(A.15)}$$

which can be rewritten as:

$$\frac{\Delta T}{\Delta T_0} = F\left(\frac{r}{D}, \frac{z}{L}, \frac{\delta_{rr}}{\delta_{zz}}\left(\frac{L}{D}\right)^2, \frac{\alpha t}{L^2} \cdot \delta_{zz}\right) \quad \text{(A.16)}$$

Experimental results can therefore be expressed in terms of $\alpha t/L^2$ and geometrical parameter ratios.

Abstract:
The ever-increasing electricity production from non-programmable Renewable Energy Sources (RES) requires flexible and sustainable solutions for energy storage. In this paper, the design, and the performance of a Low Temperature Adiabatic Compressed Air Energy Storage (LTA-CAES) system are presented. The design of this system is optimised to better utilise the energy produced by either a photovoltaic (PV) power plant and an onshore wind farm in order to meet the energy demand of a small town of about 10,000 inhabitants, considered as the case study. To ensure efficient operation of the turbomachines, the mass flow rate during both the charge and discharge phases was fixed, allowing most of the compressors and turbines to operate at design conditions. Two packed-bed Thermal Energy Storage (TES) systems are used to store the thermal energy produced during the compression phase: the first exchanges heat directly with the compressed air, while the second uses Therminol-66 as a heat transfer fluid. A mathematical model of the LTA-CAES system was developed using MATLAB/Simulink to simulate its performance, considering the off-design behaviour of the turbomachines and the TES systems over a year. The results demonstrate that the LTA-CAES system increases the share of the yearly energy demand covered by renewable energy, from 41.8% to 60.7% when coupled with the PV plant, and from 48.0% to 56.5% when coupled with the wind farm.
Keywords:
Adiabatic Compressed Air Energy Storage (A-CAES); LTA-CAES; Energy Storage; Renewable Energy Sources; Thermal Energy Storage.

1. Introduction

The intermittent nature of Renewable Energy Sources (RES) results in significant fluctuations in energy production, often not aligned with the power demand of the end-users. Balancing the production and consumption of electrical energy is a highly debated issue, especially as RES penetration in the grid increases. To address this issue, various energy storage systems were developed, including chemical, electrochemical, mechanical, electrical and thermal storage systems [1]. Among the energy storage technologies characterised by medium-high storage capacities, Compressed Air Energy Storage (CAES) systems are one of the most promising options, with a lower cost per kWh than batteries [2], and comparable to pumping hydro systems. The system works by using a compressor to convert electrical energy into compressed air, which is stored in a reservoir. Later on, the process can be reversed by expanding the high pressure air through a turbine, generating electricity. However, one of the biggest challenges in the widespread adoption of CAES technology is the need for suitable reservoirs to store high-pressure air. For this reason, CAES plants are a promising option in regions with geological formations or disused mines. In particular, the island of Sardinia presents an ample availability of primary energy sources like solar and wind and numerous disused mines, potentially suitable for the storage of compressed air. Therefore, CAES plants are a very interesting option to repurpose a disused mine by storing the surplus energy generated by an RES plant and enhance the energy self-consumption of an end-user, such as small communities in the same area.

CAES configurations can be classified as Diabatic CAES (D-CAES), which is the first to be developed, Adiabatic CAES (A-CAES), and Isothermal CAES (I-CAES) [3]. In D-CAES systems, electrical energy is utilised by the compression train to compress the air, which is stored in a suitable reservoir. The compressed air is subsequently heated by using fossil fuels in a combustion chamber and expanded in the turbine train, generating electricity. In the I-CAES configuration, both the compression and expansion processes occur at approximately constant temperature, allowing an increase in the efficiency of the cycle. In the A-CAES configuration, a Thermal Energy Storage (TES) unit is utilised to store the thermal energy recovered by cooling the compressed air; the stored thermal energy is subsequently used to heat the air before expansion, thus

eliminating the need for the combustion section. As a result, an A-CAES plant is characterised by very low emissions, and it is well suited to be coupled with an RES power plant. Adiabatic CAES plants can operate at different TES temperatures and, in general, they can be divided into high-temperature (HTA-CAES) and low-temperature (LTA-CAES) systems. As described by Wolf and Budt [4], the round-trip efficiency tends to increase with the maximum temperature, but high-temperature systems are limited by the availability of suitable components. In fact, HTA-CAES systems operate at high temperature (around 600 °C) and high pressure (around 70 bar), leading to significant thermal and mechanical stress on the TES equipment, while LTA-CAES systems operate at lower temperatures (100 – 200 °C) and at atmospheric pressure. Due to limitations of the current centrifugal compressor technology, temperatures in the order of 600 °C cannot be achieved. As a result, the use of heat exchangers is necessary to maintain lower temperatures.

In the field of A-CAES systems, Grazzini and Milazzo [5] proposed one of the first models, characterised by a variable configuration system allowing for compressors and turbines to be arranged in different series and parallel configurations, to achieve the desired air pressure and charge time. A significant benefit of the system was the ability to use commercially available components. Hartmann et al. [6] investigated various configurations for A-CAES plants and concluded that the highest round-trip efficiencies are achieved with a two-stage compressor train and by reaching high temperatures in the thermal energy storage system, upwards of 600 °C. Wolf and Budt [4] designed an LTA-CAES system utilising multistage radial compressors and expanders with intermediate cooling, and storage temperatures ranging from 95 °C to 200 °C with a non-thermocline two-tank system. The system was estimated to reach a round-trip efficiency of 52 – 60%, with a start-up time of less than 5 minutes. Wang et al. [7] presented the results of the first experimental setup for an LTA-CAES, featuring a 5-stage compressor train and a 3-stage expansion train. Heat exchangers were utilised to transfer heat between air and water. The thermal energy generated during the charge phase was stored in two water tanks, while the air compressed at 9.34 MPa was stored in two steel tanks. The round-trip efficiency of the system was reported to be 22.6%. Budt et al. [3] devised a techno-economical model that utilises reversible turbo and piston machinery to reduce the capital cost of the LTA-CAES plant, resulting in enhanced competitiveness. They proposed a modular design, with a 2 MW_{el} compressor power input for each module. These modules can be coupled with any compressed air storage volume, whether natural (such as a cave) or artificial (such as tanks or pipes). In their study, Zhang et al. [8] examined an A-CAES system that employs a variable configuration in order to accommodate fluctuations in the production profile of a wind farm in China. The system consists of a 4-stage centrifugal compressor, a 4-stage radial expander and two pressure reservoirs (a low-pressure and a high-pressure one). The variable configuration enables the compressors and the expanders to operate under various modes, thus extending the operational range of the A-CAES. The authors reported that this system increases the wind power capacity factor from 26.29% to 71.02%. Arabkoohsar et al. [9] investigated the impact of part-load operation on the overall performance of an LTA-CAES, utilising real performance maps of all system components. For optimal efficiency, the energy storage system must operate close to design conditions. At nominal conditions, the round-trip efficiency can reach up to 68% at full load, while at 50% and 10% loads, the efficiency decreases to 52% and 28%, respectively.

The LTA-CAES configuration proposed in this work was developed with the aim of maximising the electrical energy utilisation between an RES power plant and a small town located in the south-west of Sardinia, a region with many decommissioned mining tunnels. The LTA-CAES was developed with the aim of utilising components already available on the market. To maximise the round-trip efficiency, the plant operation was studied by operating the turbomachines at mostly constant design conditions during both the charging and discharge phases. Moreover, differently from most LTA-CAES configurations, that typically incorporate a heat exchanger after each compressor to recover the thermal energy from the compressed air using a heat transfer fluid [10], this study proposes the use of two different TES units. In the first TES, the air stream directly exchanges heat with the storage material, thus eliminating the need for two heat exchangers, resulting in a more efficient heat transfer process. The second TES uses a thermal oil as a heat transfer fluid and therefore operates at low pressure. To study the operation of the LTA-CAES system integrated with RES power generation plants, a mathematical model was developed to simulate the performance of the system over an entire year. The model takes into account the off-design performance of the turbomachines, the TES units, and the heat exchangers. In this paper, the plant configuration, the mathematical models, the energy management strategy and the optimization method are described in detail. Moreover, the performance of the of the plant is then presented and discussed with reference to a case study.

2. Materials and methods

In this chapter, the configuration of the plant and the mathematical modelling of its components are presented. Moreover, the power demand and production profiles for the end-user and the RES power plants are discussed, with a description of the energy management strategy and of the optimization problem.

2.1. System description

The configuration of the LTA-CAES plant is presented in Fig 1. The power required by the end-user can be supplied either by the RES power plant, by the grid, or by the LTA-CAES plant itself. The plant operates in a

cyclical manner, with the excess energy produced by the RES plant used to compress the air, which is later used by the turbine when the end-user demand exceeds the RES production. When the LTA-CAES output power is higher than the end-user demand, part of the electrical energy is sent to the grid. The plant includes three main sections: the compression section, the expansion section, and the energy storage section. In the compression section, the air is compressed using four centrifugal compressors. The multistage low-pressure compressor (LPC) and the two multistage medium-pressure compressors (MPC1 and MPC2) are driven by the motor M1, while the single-stage centrifugal high-pressure compressor (HPC) is driven by the motor M2. Two intercoolers, IC1 and IC2, are located at the outlet side of MPC1 and MPC2 respectively, to cool the air by using thermal oil (Therminol-66) [13]. The energy storage section includes the TES system and the underground Compressed Air Storage (CAS) cavern. The TES system is based on two different thermocline packed-bed units, which are utilised to store the thermal energy recovered by cooling the compressed air. The TES1 unit exchanges heat directly with the air stream while the TES2 utilises the thermal oil as heat-transfer fluid (HTF). The heat transfer oil is stored at low temperature (25 °C) in a dedicated tank, and operates in a closed loop system, flowing through the heat exchangers on the compression and expansion sides during the charge and discharge phases, respectively. Both TES units are filled with gravel, selected for its low cost and widespread availability. At the outlet of the compression train, the high-pressure air is stored in an underground cavern obtained from a decommissioned coal mining tunnel. The expansion section of the plant includes three turbines. The high-pressure turbine (HPT), the medium-pressure turbine (MPT), and the low-pressure turbine (LPT) are connected to the generator G1. To maintain a constant mass flow rate during the discharge phase, the turbine inlet pressure is regulated using three valves, V1, V2, and V3. Two heat exchangers, HX1 and HX2, are utilised to heat the air before expansion. The aftercoolers AC1, AC2, AC3, AC4, and AC5 are used to regulate the temperature in some key sections of the plant and to ensure proper operation of the downstream components.

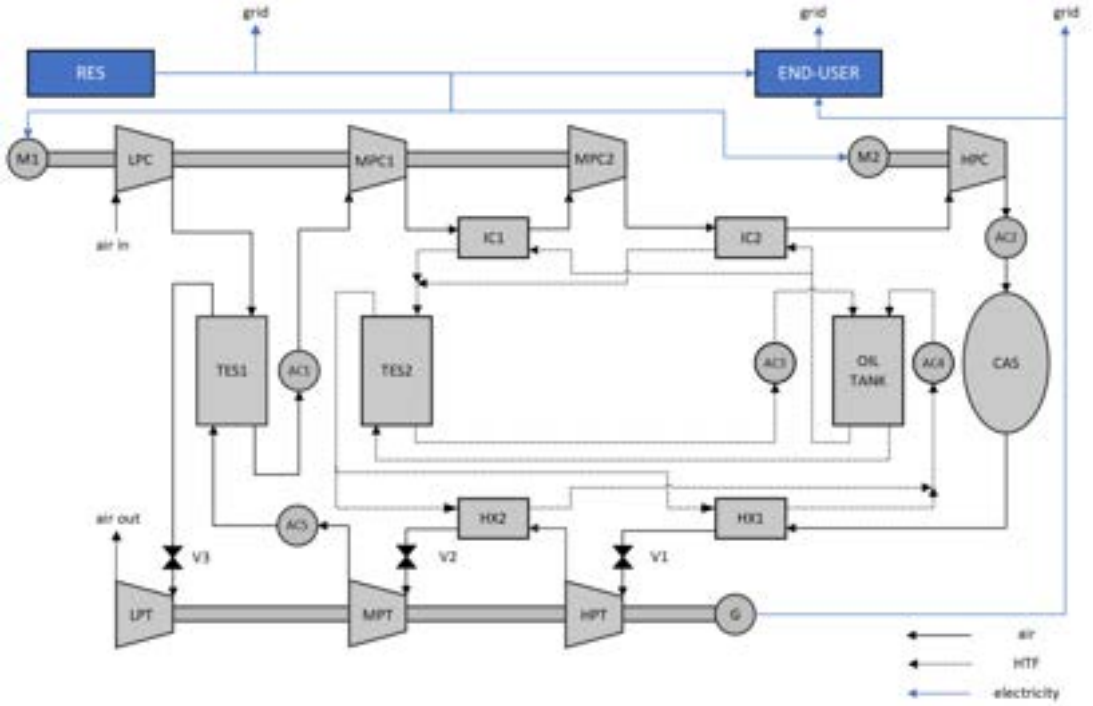

Figure. 1. Functional scheme of the LTA-CAES plant.

During the charge phase, the pressure inside the storage cavern increases, with a corresponding increase of the pressure ratio of the compression train, leading to off-design operating conditions. To mitigate this effect, the plant was designed to keep the air mass flow rate constant during the charge phase. Moreover, the LPC, MPC1, and MPC2 operate with a constant pressure ratio while the HPC regulates the pressure in the cavern by varying its rotational speed. For this reason, LPC, MPC1, and MPC2 are driven by the fixed-speed motor M1, while the HPC is driven by the motor M2 which can vary its rotational speed. The maximum pressure in the cavern is set to 100 bar, while the minimum pressure, which is strictly related to the minimum pressure ratio of the HPC, is set to 70 bar. During the discharge phase, the pressure at the inlet side of each turbine is regulated by a throttling valve.

2.2. Mathematical model

In the present section, the mathematical model used to simulate the LTA-CAES plant is presented. The mathematical models were developed on Matlab/SIMULINK by solving the mass and energy balances of all plant components and of the overall system for each time step (15 minutes, in this case) of the year.

2.2.1. Compressor model

The Casey and Robinson method [11] was utilised to estimate the design and off-design performance of the compressors. For each compressor, the number of stages is determined by equally dividing the enthalpy difference between the stages. With the Casey and Robinson method, the pressure ratio, the tip Mach number, the polytropic efficiency, and the non-dimensional factors were calculated for each stage of the compressor. The power required by each compressor, is calculated as:

$$P_c = \dot{m}_{air,ch} \frac{\gamma}{\gamma - 1} R_{air} T_{c,in} \left(\beta_c^{\frac{\gamma-1}{\gamma \eta_c}} - 1 \right) \quad (1)$$

Where $\dot{m}_{air,ch}$ is the mass flow rate of the compressor during the charge phase, γ is the specific heat ratio, R_{air} is the gas coefficient of air, $T_{c,in}$ is the temperature at the inlet side of the compressor, β_c is the pressure ratio of the compressor, and η_c is the polytropic efficiency of the compressor.

All compressors were designed imposing a maximum outlet temperature of 200 °C. The main performance parameters of the compressors are listed in Table 1.

Table 1. Main performance parameters of the compressors.

	LPC	MPC1	MPC2	HPC (design)
Pressure ratio	4.38	3.55	3.43	1.72
Number of stages	3	3	3	1
Inlet pressure [bar]	1.00	4.38	35.00	53.33
Outlet pressure [bar]	4.38	35.00	53.33	91.73
Inlet temperature [°C]	15	35	35	35
Outlet temperature [°C]	199.64	199.23	199.78	110.26
Polytropic efficiency	0.85	0.86	0.86	0.81

For the LPC, the inlet temperature is equal to the atmospheric temperature, set to 15 °C. For the other compressors, the two intercoolers are utilised to reduce the compressor inlet temperature to 35 °C. The HPC maps are shown in Fig 2, in terms of pressure ratio (a) and polytropic efficiency (b) as a function of the mass flow rate and the rotational speed. The blue circle indicates the design point, while the operational range of the compressor is highlighted by the double headed arrow. During the charge phase, the pressure ratio is controlled by varying the rotational speed. As shown by Fig 2, for a fixed mass flow rate, the compressor work point moves by changing the rotational speed between 70% and 110% of the design speed. The maps are generalized with the reference values, i.e., the design values. In Fig 2(b), can be observed that, at very low rotational speeds, the efficiency decreases rapidly. As a low-pressure ratio drastically reduces the efficiency, the minimum storage pressure was set to 70 bar.

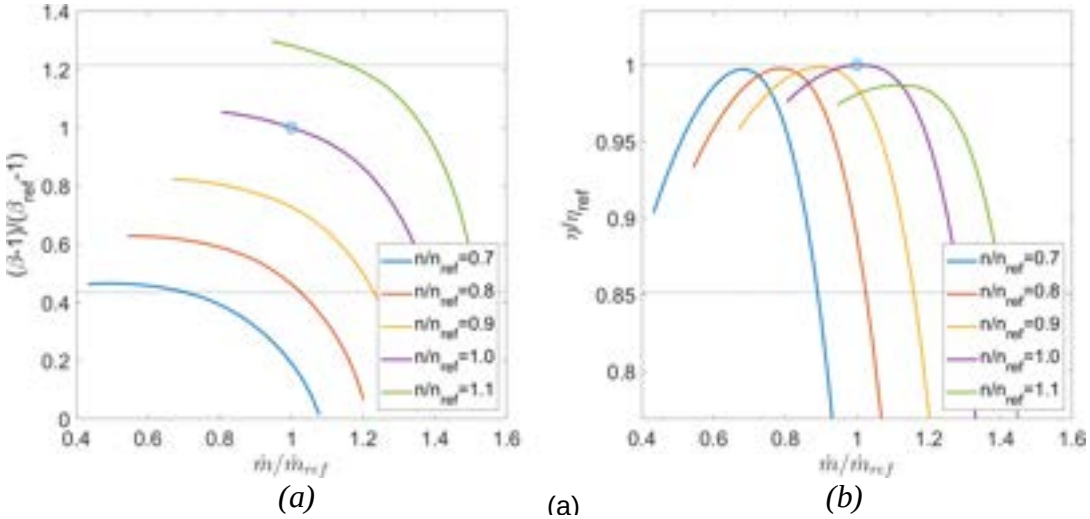

Figure. 2. High pressure compressor maps, with (a) generalised pressure ratio and (b) generalised efficiency as a function of the generalised mass flow rate for different rotational speeds.

2.2.2. Turbine model

The power produced by each turbine is calculated as:

$$P_t = \dot{m}_{air,dis} \frac{\gamma}{\gamma - 1} R_{air} T_{t,in} \left(1 - \beta_t^{\frac{\gamma-1}{\gamma} \eta_t} \right) \quad (2)$$

Where $\dot{m}_{air,dis}$ is the mass flow rate of the turbines, $T_{t,in}$ is the temperature at the inlet of the turbine, β_t is the turbine expansion ratio, and η_t is the polytropic efficiency of the turbine.

The design of the three turbines was based on [12], assuming a polytropic efficiency of 0.86 for each turbine. Throughout the discharge phase, as the pressure in the cavern decreases, a throttling valve located at the inlet side of each turbine regulates the pressure in order to maintain constancy in the mass flow rate and the reduced mass flow rate. The valves also account for the temperature variation caused by the thermocline profile of the TES units. Hence, the turbines operate in a choked flow condition throughout the entire discharge phase, achieving maximum efficiency.

The throttling valve model is based on the calculation of the reduced mass flow rate $\dot{m}_{rid}$, expressed as:

$$\dot{m}_{rid} = \dot{m}_{air,ch} \frac{\sqrt{T_{in}}}{p_{in}} \quad (3)$$

Where T_{in} and p_{in} are the inlet temperature and pressure.

2.2.3. Heat exchanger model

The following equations allow to calculate the thermal power and the heat transfer area of the heat exchangers:

$$\dot{Q} = \dot{m}_{air} c_{p,air} (T_{air,out} - T_{air,in}) \quad (4)$$

$$A = \frac{\dot{Q}}{U \, \Delta T_{ML}} \quad (5)$$

Where $\dot{Q}$ is the exchanged thermal power, $\dot{m}_{air}$ the mass flow rate of air, $T_{air,out}$ and $T_{air,in}$ are the outlet and inlet air temperature, respectively, A is the heat exchange area, U is the heat transfer coefficient, and ΔT_{ML} is the logarithmic temperature difference.

Two intercoolers recover the heat from the MPC1 and MPC2 allowing to store the produced thermal energy inside the TES2. Therminol-66 was selected as the heat transfer fluid because of its maximum temperature of 345 °C [13]. The intercoolers were designed to keep an outlet temperature of the hot fluid (air) at 35 °C assuring a steady inlet temperature for the compressors. Moreover, the approach temperature and the heat transfer coefficient were set to 10 °C, and $0.2 \frac{kW}{m^3 K}$, respectively [14].

The heat exchangers on the expansion side were designed to account for fluctuations in inlet pressure and temperature of the air during the discharge phase. This was achieved by using the same equations and parameters applied to the intercoolers and considering the lowest exchangeable thermal power $\dot{Q}$.

2.2.4. Thermal Energy Storage model

The volume of the TES tank is then calculated as:

$$V_{TES} = \frac{m_s}{\rho_b (1 - \epsilon)} \quad (6)$$

Where ρ_b is the density of the filler material, ϵ is the void fraction and m_s is the mass of the filler material, calculated based on the energy balance of the TES between the charge and discharge phases. A system of two equations, derived from the model developed in [15], is used to describe the operation of the two thermal energy storage (TES) units. The temperature of solid bed (T_b) and the heat transfer fluid (T_f), calculated in the direction of the air flow, are determined with the following equations (7) and (8):

$$\frac{\partial T_f}{\partial t} + \frac{G\gamma}{\rho_f \epsilon} \frac{\partial T_f}{\partial z} = \frac{h_v}{\rho_f c_{v,f} \epsilon} \left(T_b - T_f\right) + \frac{k_f}{\rho_f c_{v,f} \epsilon} \frac{\partial^2 T_f}{\partial z^2} \quad (7)$$

$$\frac{\partial T_b}{\partial t} = \frac{h_v}{\rho_b c_{v,b} (1 - \epsilon)} \left(T_f - T_b\right) \quad (8)$$

Where ρ_f is the density of the HTF, $c_{v,f}$ and $c_{v,b}$ are the volumetric specific heat of the HTF and the bed, respectively, h_v is the volumetric transmission of heat through convection, G is the mass velocity, and k_f is the thermal conductivity of the HTF.

The mathematical model, developed to simulate the behaviour of the two TES units, allows for calculation of the thermocline profile along the axial length of the tank, accounting for its variation during cyclical operation [16]. The mass flow rate of oil during both the charge and discharge phases was calculated based on the mass and energy balance equations.

2.2.5. Compressed Air Storage model

The compressed air storage (CAS) volume is calculated by solving the following system of equations:

$$\begin{cases} p_{min} V_{tot} = m_{min} R_{air} T_{st} \\ p_{max} V_{tot} = (m_{min} + \dot{m}_{air} t_{ch}) R_{air} T_{st} \end{cases} \quad (9)$$

Where p_{min} and p_{max} are the minimum and maximum air pressures, respectively, V_{tot} is the total storage volume, m_{min} is the mass of air in the cavern at minimum pressure, $\dot{m}_{air}$ is the mass flow rate of air, t_{ch} is the charge time, and T_{st} is the storage temperature inside the cavern.

An abandoned coal mine located in Sardinia was selected as the compressed air storage reservoir. The CAS, characterised by a depth of about 500 m and a diameter of 5 m, is assumed to be suitable for the high-pressure storage of air up to 100 bar [17]. Moreover, state-of-the-art lining of the internal volume was assumed, minimising air leakage [17]. The temperature inside the cave is set to 35 °C by the heat exchanger AC2 and was assumed to be constant during idling phases between charge and discharge phases.

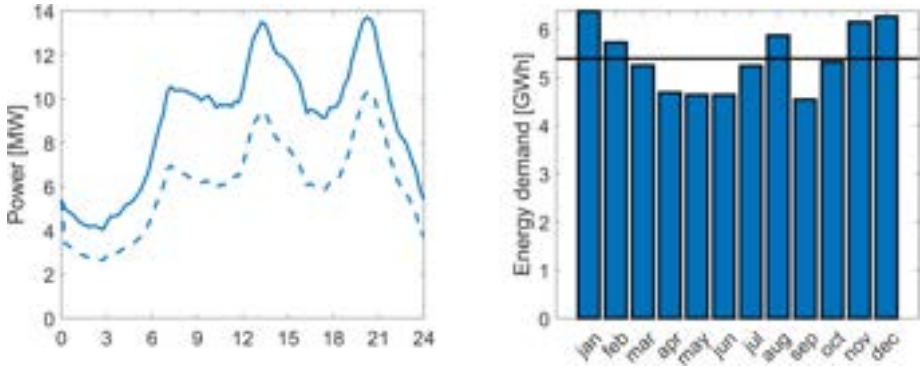
In this study, a single pipe was used to transfer air from the turbomachines to the underground storage cavern and back, considering that the charging and discharge phases never occur simultaneously. The pipe is a welded steel tube, with a length of 500 m (equivalent to the distance from the surface level to the underground cavern) and an internal diameter of 0.3 m. For the sake of simplicity, the pressure losses (about 0.10-0.15 bar) were assumed to be negligible.

2.3. Power demand and production profiles

The LTA-CAES system was designed to better match the energy production of an RES power plant to the energy demand of an end-user. This section provides a comprehensive examination of the power demand profile of a small town, assumed as the end-user, and the energy generation from a wind farm and a photovoltaic plant. Subsequently, an optimisation problem is defined and solved to determine the optimal size of the LTA-CAES plant for maximum energy yield.

2.3.1. End-user electrical energy demand

The end-user in this study is assumed to be a small town with a population of about 10,000 inhabitants, for which the energy consumption data is available on a quarterly-hour base for a year. Residential, industrial, and commercial users contribute to the energy demand of the town together with the public lighting. Figure 3 displays (a) the typical load profile of the town for both a week and weekend day and (b) the overall monthly energy demand. The latter is a representative profile to be expected on a regular basis, used as reference to understand the energy consumption patterns. From Fig 3(a), it is evident that the load fluctuates rapidly throughout the day, reaching a maximum of 13.7 MW. Fig 3(b) highlights the seasonal nature of the energy demand, where energy consumption is generally higher in winter and lower in summer, except for July and August, because of the increase in energy consumption for cooling. The total annual energy demand is 64.67 GWh, with a mean monthly demand of about 5.39 GWh, as indicated by the horizontal line in Fig 3(b).



(a) *(b)*

Figure. 3. (a) Load profiles for a typical week (continuous line) and weekend (dashed line) day, (b) Monthly energy demand for the entire year and average annual energy consumption.

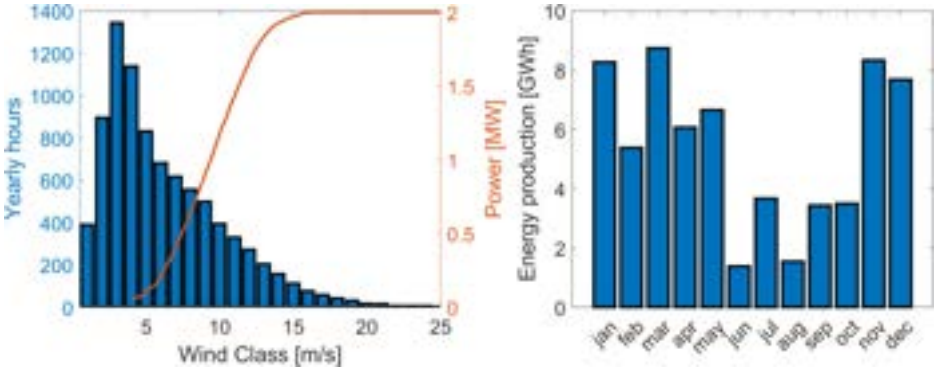
2.3.2. Wind power production

The wind power production profile was built according to data of a real wind farm located in Sardinia. The wind farm is composed of 15 Vestas V80 wind turbines with a nominal power of 2 MW each, with a cut-in speed of 4 m/s, a cut-off speed of 25 m/s and a rated wind speed of 16 m/s. The total yearly energy production is 64.70 GWh. Figure 4 shows (a) the wind speed distribution and the wind turbine nominal power profile and (b) the overall monthly energy production of the wind farm. According to the wind speed distribution depicted in Fig 4(a), the power production of the wind turbine tends to be low throughout the year, as most of the available wind speeds fall below the turbine's cut-in speed, or at levels resulting in low energy production. Figure 4(b) shows that the monthly energy production is generally higher during winter and lower during summer, with a trend similar to that of the end-user demand displayed in Fig 3(b).

2.3.3. Photovoltaic power production

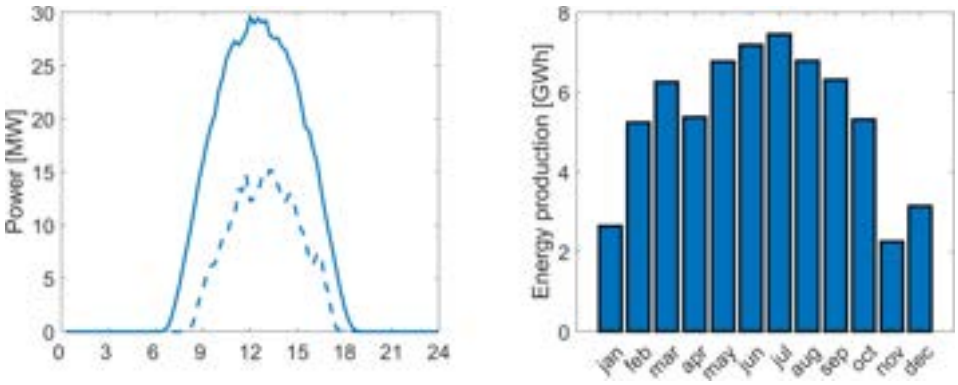
The photovoltaic power plant is based on 62,272 monocrystalline Si modules, each rated at 650 W_p, with a conversion efficiency of 20.9% [18], for a total power of 40.5 MW. The plant was modelled using the System Advisor Model (SAM) [19] software and utilising data from the NREL database [20], recorded in 2019 for a site close to Nuraxi Figus (Sardinia, Italy). Considering the various efficiency losses, the yearly energy production of a 1 MW_p plant is approximately 1.6 GWh, with a capacity factor of about 18%. Figure 5 shows (a) the typical

daily power production profile during both a summer (continuous line) and a winter day (dashed line), and (b) the monthly energy production of the PV plant. As shown in Fig 5(a), the daily power production increases in the morning, reaching a maximum around 13:00, and decreases to zero in the evening. Figure 5b shows that the energy production is greater during the summer months, revealing a seasonal nature that is inverse to that of the end-user (displayed in Fig 3(b)). For this reason, a higher surplus energy is available for the LTA-CAES system during the summer months in comparison to winter months, as discussed in the following sections.



(a) *(b)*

Figure. 4. (a) Wind speed distribution and wind turbine nominal power curve, (b) Monthly energy production of the wind farm.



(a) *(b)*

Figure. 5. (a) Power production profile of the PV plant for a typical summer (continuous line) and winter (dashed line) day; (b) Monthly energy production of the PV plant during a year.

2.4. Energy management strategy

The aim of the LTA-CAES system studied is to optimise the usage of renewable energy sources for the end-users by directly connecting the RES power plant, either photovoltaic or wind, to the end-user. Surplus RES energy is used to charge the LTA-CAES plant if the RES output exceeds the end-user's demand, and the air storage is not full. If the excess RES production cannot be stored, it is sent to the grid. On the contrary, when the RES power output is less than the end-user's demand, the LTA-CAES plant operates in discharge mode. If the total power supplied by the RES and LTA-CAES plants is still lower than the overall demand, the remaining power is sourced from the grid. Several constraints were introduced to manage the energy flows. Firstly, a limit of the maximum charge or discharge time was set to 24 hours, in order to complete a full charge or discharge of the cavern in a day or less; the charging and discharging processes have minimum power requirements to start, depending on the power required by the compressors and by the grid, respectively; buying/selling electrical energy to/from the grid during these processes was not permitted. Consequently, the charging process can only start when the available RES power is sufficient to power the compression train, and the discharging process can only start when the end-user's load demand is greater than the RES power plant production.

Due to the fluctuating nature of power production and demand profiles, the charging and discharging processes may sometimes not be completed, and they can begin or end at various cavern pressure levels. Interruptions during the charging or discharging processes also affect the thermocline profile inside the TES tank. If the charging process is terminated before full capacity, the thermocline profile stops early, causing lower air temperatures and less power output during the subsequent discharge phase. Similarly, if the discharging process cannot be completed, the thermocline profile stops early, resulting in a high level of thermal energy retained in the TES. These two phenomena occur frequently during the cyclical operation of the LTA-CAES plant and reduce the performance of the TES system and of the entire plant.

2.5. Optimisation

The LTA-CAES plant is designed to optimise the use of the electrical energy generated by an RES power plant by maximising the share of renewable energy consumed by the end-user. The performance and size of the plant components were evaluated based on three key design variables: the air mass flow rate of the compressor train, the charge time, and the discharge time. These design variables influence the size of the compression and expansion trains, as well as the volume of the air storage reservoir and TES units. Furthermore, these variables affect the main energy flows, including the energy used for compression, the energy produced during expansion, the energy supplied to the end-user, and the energy dispatched to the grid [21]. The optimization problem was solved with the Genetic Algorithm (GA), included in the Matlab Optimization Toolbox [22]. The three design variables were calculated to maximize the total energy sent from the LTA-CAES to the end-user, considered as the objective function. The design variables were set as integers only, and the optimization was carried out with a stopping condition of 20 generations without improvement on the best fitness function value, with default settings.

3. Results and discussion

As mentioned, this study examines the performance of an LTA-CAES plant designed to better match the energy production of an RES power plant to the energy demand of an end-user. In particular, the LTA-CAES design variables have been evaluated for an RES power plant based either on a PV power plant or a wind farm. The results are presented in Table 2.

Table 2. Optimal design parameters for the analysed LTA-CAES plants.

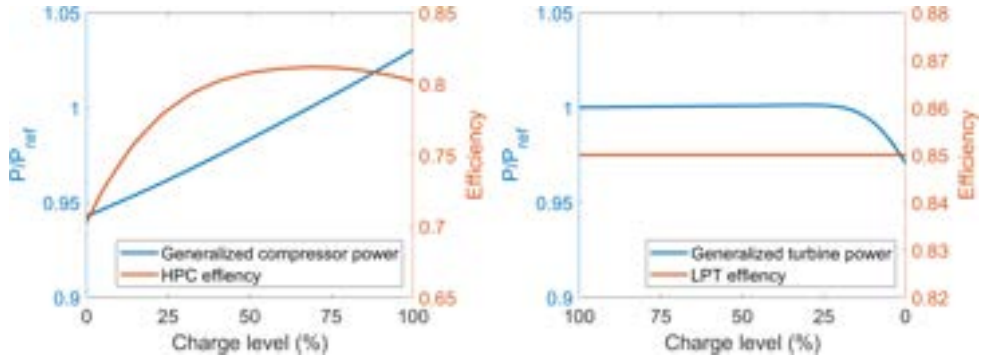
	PV	Wind
Mass flow rate (kg/s)	24	16
Charge time (h)	10	24
Discharge time (h)	24	24

The results of the optimisation process are used to determine the size of the LTA-CAES plant. The size of the plant can be characterised by the input and output power of the plant, the volume of the TES units, and the length of the cavern (considering a diameter of 5 m). Table 3 shows the size of the main components of the plant. For the system coupled with the wind farm, the entire energy storage system (TES and cavern) is characterised by a larger volume, thus storing more energy. For the system coupled with the PV plant, the optimisation process results in a higher input power and lower output power compared to the system coupled with the wind farm. In the case of the PV, the surplus power is high, and the power demand is low, resulting in a high input power and low output power for the LTA-CAES plant.

Table 3. Main parameters for the LTA-CAES combined with a PV or wind power plant.

	Input power [MW]	Output power [MW]	TES1 volume [m^3]	TES2 volume [m^3]	Cavern length [m]
PV	14.9	4.2	1005	1683	1655
Wind	9.9	6.7	1683	2613	2647

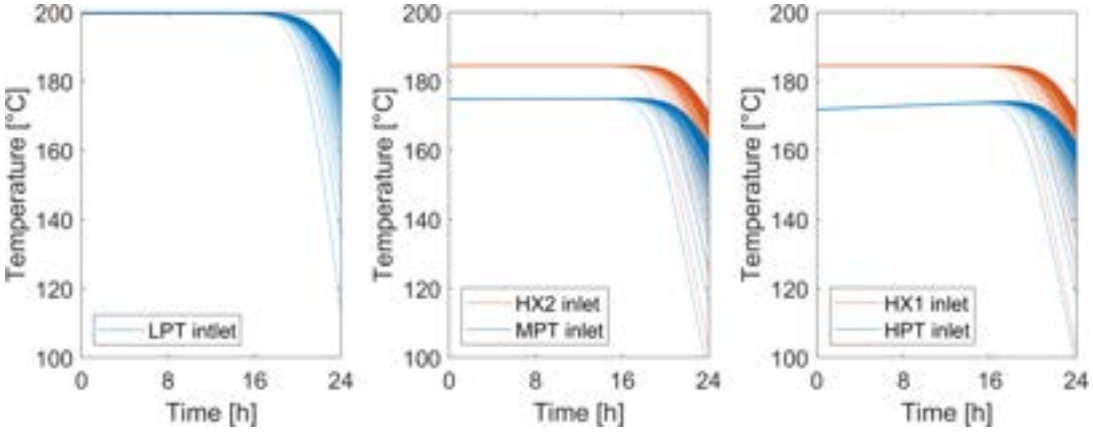
The energy balances of the system were solved with a time step of 15 minutes for one year, considering the power output of the two RES plants and the power demand of the end-user. The performance of the compression and expansion trains of the LTA-CAES plant, throughout the full charge and discharge phases, is illustrated in Fig 6, where the reference power, denoted as P_{ref}, represents the nominal power of the turbomachine. This plot shows the generalised power (the ratio between the actual power and the reference power) as a function of the charge level of the storage volume. During the charge and discharge phases, variations in pressure within the cavern and temperature within the TES systems cause variations of the compression and expansion power. It can be observed that the power variation is limited: the compressors power curve shows a steady increase of about 8.4% throughout the charge phase, while the turbine power production remains mostly constant, decreasing only by 2.9% at the end of the discharge phase. The compressor profile increase is mainly due to the increase in the HPC compression power, as shown in Fig 6(a). The compression ratio increases from 1.31 to 1.87 during the charge phase, leading to a subsequent increase in the required compression power. The power curve shows a steady increase due to the relatively small variation in efficiency, ranging between 69% and 80%. Furthermore, most of the compression energy (88%) is required by the LPC, MPC1, and MPC2 that operate at design conditions, while the HPC is responsible for the remaining share of the total compression work. The power output of the turbines, shown in Fig 6(b), remains constant until it starts to drop towards the end of the discharge phase. This power reduction is caused by the temperature reduction at the outlet of the TES units. As the HPT and MPT operate at design condition, their polytropic efficiency remains constant. Similarly, the efficiency of the LPT is mostly constant since the variation in power of the turbines is low.



(a) *(b)*

Figure. *6.* (a) Generalised total compressor power and HPC efficiency during the charge phase and (b) Generalised total power production of the turbine train and LPT efficiency.

Figure 7 shows the key temperature profiles throughout a complete discharge phase and its evolution over fifty charge and discharge cycles. The temperature profile at the turbine inlet is shown in Fig 7(a) for the LPT, in Fig 7(b) for the MPT, and in Fig 7(c) for the HPT. The reduction in temperature towards the end of the discharge phase is responsible for the power reduction depicted in Fig 6(b). During the discharge phase of the first cycle, a substantial temperature decrease is observed. However, the minimum temperature gradually increases with each cycle, ultimately reaching a saturation state after about 50 cycles. Figures 7(b) and 7(c) additionally show the temperature difference between the inlet and the outlet (coincident with the turbine inlet) of the heat exchangers. By comparing the maximum temperature in Fig 7(a) with those of Fig 7(b) and 7(c), it is evident that the direct TES (TES1) results in improved energy utilisation. This is due to the fact that the indirect heat transfer section involves two temperature drops: one for the heat exchangers of the charge section (IC1 and IC2) and one for the heat exchangers of the discharge section (HX1 and HX2).



(a) *(b)* *(c)*

Figure. 7. Temperature profile during the discharge phase and its evolution over fifty full charge and discharge cycles at (a) the LPT inlet, (b) the MPT inlet (blue) and HX2 inlet (red), and (c) the HPT inlet (blue) and HX1 inlet (red).

Figure 8 represents the power production profile of the PV plant, the power demand profile of the end-user, and the input and output power profiles of the LTA-CAES plant, for both a typical high irradiance day (Fig 8(a)) and a low irradiance day (Fig 8(b)). During the daytime, when the PV power production (in blue) exceeds the demand (in orange) and is sufficient to drive the compressors, the excess energy is stored by the LTA-CAES (in yellow) for later use during the night (in purple), when the PV plant is not generating power. On a high irradiance day (typically during summer), the LTA-CAES plant can store enough energy during the day to meet the entire end-user demand during the night. In contrast, during a low irradiance day (typically during winter), the plant cannot fully satisfy the end-user demand.

Figure 9 displays the power production profile of the wind power plant, the power demand profile of the end-user, and the input and output power profiles of the LTA-CAES plant, for both a high wind speed day (Fig 9(a)) and low wind speed day (Fig 9(b)). Unlike the PV plant, the power production profile of the wind farm is highly variable, resulting in a less predictable behaviour of the LTA-CAES system. During a windy day (Fig 9(a)), the power generated by the wind power plant is sufficient to meet the end-user demand and fully charge the LTA-CAES system, which stores the excess energy for later use since the energy produced by the RES power plant is enough to cover the energy demand of the end-user. In contrast, during a low wind speed day (Fig 9(b)), the power production is lower, making it difficult for the LTA-CAES system to satisfy the end-user demand. The energy stored inside the CAES is enough to cover only a part of the demand of the end-user (in

purple). Unlike in the case of the PV plant, when the LTA-CAES is coupled with the wind power plant, the charge and discharge phase are not dependent on the time of day, since the wind power plant can generate energy throughout the day and night.

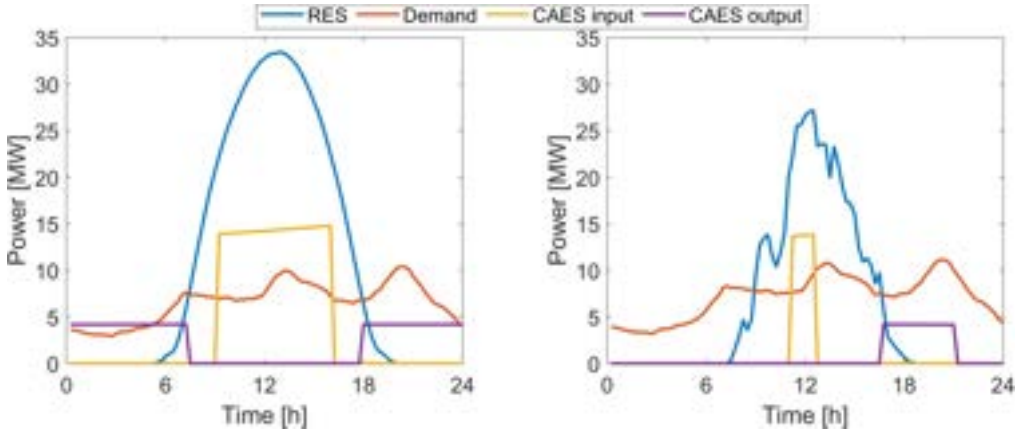


Figure. 8. Main power flows of the LTA-CAES plant for a high irradiance day (a) and a low irradiance day (b), when combined with a PV power plant.

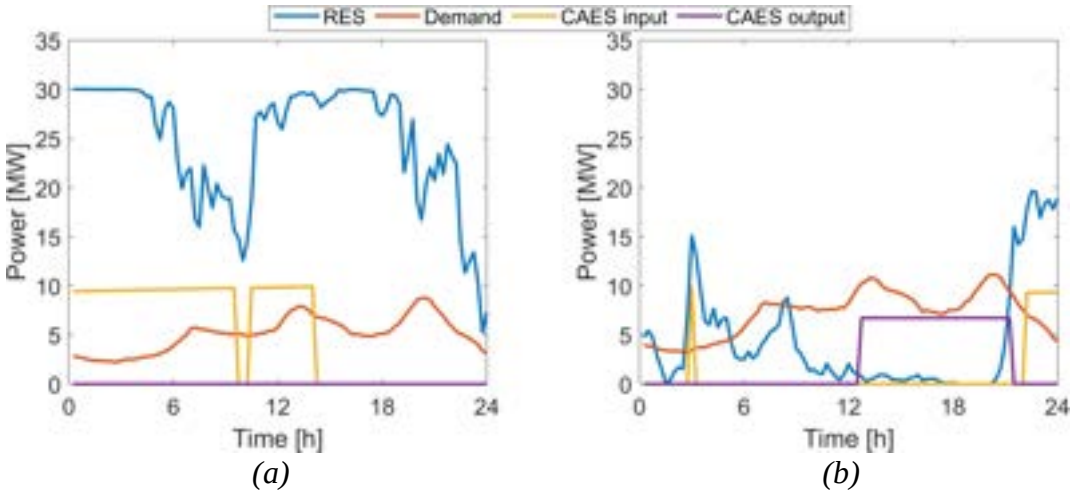

Figure. 9. Main power flows of the LTA-CAES plant for a high wind speed day (a) and a low wind speed day (b), when combined with a wind power plant.

Based on the power production and demand profiles, the mathematical simulation of the system allows evaluation of the operation of the LTA-CAES plant throughout the year. Figure 10, where the level of charge in the cavern is shown for the entire year, illustrates that the charging and discharging processes are frequently interrupted and rely heavily on power availability and demand throughout the day. As demonstrated in Fig 10(a), during the summer, the PV plant generates more energy than the end-user requires, resulting in surplus power that allows the LTA-CAES plant to charge more frequently. Conversely, during the winter, the PV plant's energy production is insufficient, and the LTA-CAES plant must compensate for the deficit. The trend is almost reversed for the wind plant in Fig 10(b), where production is greater during the winter.

Figure 11 shows the yearly energy balance of the system, where the yearly energy demand of the users amounts to 64.6 GWh. When coupled with the PV plant, the LTA-CAES system can supply a total of 39.2 GWh to the end-users (60.7% of the yearly energy demand). In particular, 41.8% of the total energy demand is directly provided by the PV plant and 18.9% by the LTA-CAES system, while the remaining 39.3% is covered by the grid. When coupled with the wind farm, the LTA-CAES is capable of supplying a total of 36.7 GWh of energy to the end-user (56.5% of the yearly energy demand). In this case, 48.0% of the energy demand is provided by the wind farm and the 8.4% by the LTA-CAES system, while the remaining 43.6% by the grid. The total energy produced by the LTA-CAES is 13.5 GWh and 8.0 GWh when coupled with the PV and the wind farm, respectively. The share of energy produced by the LTA-CAES and sent directly to the users is 90.6% and 68.2% for the plant coupled with the PV and the wind farm respectively, while the remaining produced energy is sent to the grid. The amount of energy produced and sent directly to the grid is higher for the system coupled with the wind farm, because the output power of the system is higher than the end-user power demand. The round-trip efficiency is about 67% for both plants. For the LTA-CAES coupled with the PV, the total charge time is equal to 1,388 h/year and the total discharge time is 3,328 h/year. For the LTA-CAES

coupled with the wind farm, the total charge and discharge time is 1,235 h/year. The total energy production of the LTA-CAES system coupled with the PV plant exceeds that of the system coupled with the wind farm by 8%. Hence, coupling the LTA-CAES system with the PV plant appears to be the optimal choice in terms of energy efficiency. Furthermore, the system coupled with the PV plant has a higher share of energy produced by the LTA-CAES and sent directly to the end-users compared to the system coupled with the wind farm. This suggests that the former configuration enables a greater degree of energy self-sufficiency for the end-user.

4. Conclusions

This paper proposed an LTA-CAES configuration for efficient utilisation of the electrical energy between an RES power plant and a small town in Sardinia. The plant configuration utilised readily available components in order to minimise costs and ensure efficient operation of the turbomachines during both charging and discharge phases. This was achieved by fixing the mass flow rate of air, allowing most of the compressors and turbines to operate at constant speed and at design conditions. The plant features two TES units to store the thermal energy while maintaining a low operative pressure inside the tanks. A dedicated circuit for the heat transfer oil is utilised in combination with heat exchangers to guarantee optimal working conditions for the turbomachines. To account for pressure and temperature variations during discharging, a throttling valve is located at the inlet side of each turbine. Mathematical models were developed to correctly size the plant and to simulate its operation under different conditions, accounting for off-design performance of the various components, i.e., the turbomachines, the TES units, and the heat exchangers.

Simulation results demonstrated the effectiveness of the proposed integrated LTA-CAES plant in managing energy production and consumption over the course of a year, when coupled with wind or photovoltaic power plants. With a wind power plant, a larger share of energy can be directly supplied to the end-user compared to the PV power plant. However, the LTA-CAES system coupled with the PV plant yields a higher total energy production. In fact, the results show that the LTA-CAES system increases the share of renewable energy supplied to the end-user from 41.8% to 60.7% when coupled with the PV plant, and from 48.0% to 56.5% when coupled with the wind farm.

Overall, the system was shown to be a viable low-emission energy management solution for a small community of about 10,000 people on the island of Sardinia. To increase the performance of the system, an integration of

the PV and wind power plants will help to determine the optimal RES plant configuration to be coupled with an LTA-CAES plant. Moreover, the development of a techno-economic analysis of the components of the plant will allow determination of the overall cost of the system.

Abstract:

With the efforts to decarbonize the energy sector comes a growing demand of electricity, most of which is to be supplied by renewable generation in a carbon-neutral future. To balance the variability inherent to most renewable energy sources, some form of energy storage is required. In this work, a short review of current systems is made with a particular focus on Carnot Batteries, whose operating characteristics, long life and low environmental footprint make them competitive for daily energy storage. A transient model was developed to simulate the full operation of a Carnot Battery composed of a Vapour Compression Heat Pump and Organic Rankine Cycles in conjunction with sensible thermal storage. The key performance parameters were identified, and a Pareto optimization was carried out by balancing costs and performance across 25 configurations of storage temperature spread and heat exchanger pinch point. It was concluded that the wider storage spreads and higher pinch points lead to lower costs as they decrease the size of the water tank and the heat exchangers, and to lower efficiencies as unfavourable temperature gradients are created for the heat pump and heat engine. A Pareto front was identified, consisting of 10 configurations that were able to either optimize one criterion, or balance of two or more criteria, and conclusions were drawn as to the applicability of each configuration.

Keywords:

Carnot Battery, Thermal Energy Storage, Electric Energy Storage, Heat Pump, Organic Rankine Cycle

1. Introduction

According to the IPCC (Intergovernmental Panel for Climate Change), human-induced warming has already reached approximately 1ºC, in 2017. If all human emissions were to be immediately reduced to zero, it's estimated that the total rise in temperature in the time scale of a century would fall under 1.5ºC, in relation to pre-industrial levels. The Paris Agreement has set a goal to limit this global temperature rise to 2ºC, and preferably to keep it under 1.5ºC, as this would substantially reduce the effects of climate change in relation to a future in which no action is taken.

According to the RNC2050 (Roteiro para a Neutralidade Carbónica – Roadmap for Carbon Neutrality), a long-term plan for achieving net-zero emissions by 2050, the biggest drivers for decarbonization of the energy sector are the use of renewables, increased energy efficiency (which translates into reduced demand from sources), electrification, and new energy vectors such as hydrogen and other synthetic fuels. It states also that the inherent variability of most widespread renewable sources (namely wind and solar PV) creates problems of dispatchability and energy security. The document states that strong grid interconnection with the European Union, smart energy management, and increased usage of Energy Storage Systems (ESS) are key to solving these issues. This notion is supported by the scientific community, as current papers highlight the necessity for energy storage, often in conjunction with an interconnected and smart grid, to effectively manage the supply variability (on many time scales) resulting from large-scale renewable integration.

1.1. The Challenges of decarbonization in terms of energy storage

The need for inertia in our energy systems is clear – to mitigate variability in supply. However, while most issues caused by integration of Variable Renewable Energy (VRE) sources fall into this category, the features that characterize each problem vary in terms of power requirement, storage duration, discharge time, response time, and other technical characteristics.

The load Shifting and Seasonal Storage is the most important application of energy storage in the context of decarbonization. Because of the largely uncontrollable nature of VREs, supply of electric energy will rarely

match demand, so, in these cases, we often require storage systems to shift the supply to more favourable periods of time, to satisfy demand and prevent curtailing.

The needed storage duration will vary depending on the characteristics of the generation source, but it should fit roughly in the time scale of its natural variation; this can range from a few hours – the case for solar variation [1] – to days, weeks or even months – the typical long-term variation in wind speeds [2], [1].

Power requirements must also match the generation source, in the order of 10-100 MW for grid scale applications, with lower values for localized/consumer-scale situations. Maximum response times must be in the scale of minutes, and the capacity should be sufficient to absorb excess power and satisfy demand. For large scale applications with seasonal storage, it may reach values in the order of 100-1000 MWh [2]. At a very small-time scale, fluctuations in supply and demand can affect the properties of electric currents, such as voltage and frequency [2]. To maintain the power quality of the supplied energy, storage systems are often used. For these applications, storage duration and capacity may be limited, however, power and response time are critical parameters, as power (in the order of kW to several MW, depending on the scale of consumption) is to be processed almost instantaneously, in the order of milliseconds.

The Transmission and Distribution Management is extremely important. With increasing loads being placed on electric grids, bottlenecks may appear in periods of peak consumption. Alongside other measures, such as economic incentives for shifting consumption, storage systems may be used to absorb excess loads and delay costly investments into power grids. The storage duration required should fit the variations in demand (several hours). Power and capacity requirements depend on the scale of the application but are like those of grid-scale load-shifting. Response times of up to a few minutes should be sufficient.

Another major feature of ESS is the Backup Power. At the consumer scale, energy storage may be desired to maintain an uninterrupted power supply in case of an outage. In this case, power requirements should match the consumption load (from a few kW to tens of MW), and storage capacity and duration should match the expected outage period (usually up to a few hours, with enough capacity to satisfy power requirements over this period – up to the order of 10 MWh). Response time is a critical parameter as the grid power must be replaced immediately – a response in the order of milliseconds is ideal.

Lastly, to effectively replace fossil fuels in the transportation industry, the storage medium to be used must have high specific energies and energy densities, along with a quick response time. Power-To-Fuel technologies that produce fuels compatible with current fossil-based systems are a good solution for this sector [1].

1.2. Classification of Existing Technologies

Energy may be stored in various forms, the most common being chemical potential, magnetic fields, electric fields, pressurized gas, gravitational potential, thermal energy, and synthetic fuels, as showed in Table 1 [1], [2]. In the literature, the classification of storage systems varies slightly from author to author, as the mechanisms employed by storage systems, as well as the perspectives from which we classify them, are diverse.

Table 1. *Classifications of ESS*

Stored Energy	Storage Mechanism	Examples
Electric	Electric and magnetic fields	Supercapacitors, SMES
Electrochemical	Reversible chemical reactions	Conventional Batteries, Flow Batteries, High-Temperature Batteries, Metal-Air Batteries
Mechanical	Gas pressure, gravitational potential, kinetic energy	CAES, PHS, Flywheel
Thermal	Heat capacity of a material, latent heat of phase change, endothermal and exothermal reactions	TES (Sensible, Latent, Thermochemical)
Chemical	Production of synthetic fuels	P2G, P2L

Pumped Hydro Storage (PHS), exploits the change in elevation between reservoirs of water in order to store energy in the form of gravitational potential. In charge mode, water is moved to a high elevation, increasing its potential energy, and in discharge mode this energy is converted into kinetic energy as the water flows back to the lower reservoir, passing through a turbine which generates electricity. PHS has a good degree of maturity and commercial exploitation [1], [3], and is suitable for high power and high energy applications. It has low energy costs and a relatively high efficiency; however, it comes with the downsides of high environmental impact, and geographical restrictions. Additionally, this technology is becoming increasingly difficult to exploit, as in most developed countries the potential for new installations is nearly exhausted [3], [4].

Compressed Air Energy Storage (CAES) is a system which stores energy in the form of gas pressure. In the charging process, air is compressed and sent into an underground reservoir, and in the discharge process this pressurized air is expanded in a gas turbine to generate electricity. These systems benefit from a very low

environmental impact (if fossil fuel use is avoided), and excellent power and storage capacities. However, they suffer from geographical limitations, as they most often require an underground cavern for storage.

Electrochemical batteries store energy in the form of a reversible chemical reaction – in the discharge process, a redox reaction generates an electric current between the two electrodes. For charging, the reaction is reversed, absorbing electric current. Due to the speed of the reactions, the response time of these batteries is nearly instantaneous, making them adequate for applications requiring some agility, such as power quality and managing quick changes in renewable generation; however, this kind of battery generally suffers from environmental issues, high costs, and limited cycle life. In the realm of conventional batteries, the most commonly used are lead-acid, lithium-ion, nickel-cadmium and nickel-metal hydride. Other less common types of batteries are flow batteries and high-temperature batteries.

Other types include: Flywheel Energy Storage, that is one of the simplest forms of storage where storage takes the form of kinetic energy of a rotating mass; Supercapacitors that are an upgrade of regular capacitors, which store energy by accumulation of positive and negative charges on either side of a dielectric; and Superconducting Magnetic Energy Storage (SMES) systems that store energy in the form of a magnetic field, induced by a dynamic electric field passed through a coil.

Finally, Thermal Energy Storage systems store energy in the heat capacity of a solid or liquid material (Sensible Heat Storage), the latent heat of a phase change (Latent Heat Storage) or in a reversible thermochemical reaction (Thermochemical Storage). These systems can also vary by the method through which the storage medium is charged. Concentrated Solar Power (CSP) plants, if coupled with thermal storage, use solar radiation to heat a storage medium, which can then discharge to a heat engine for electricity production [13]. Another possibility is Wind-powered Thermal Energy System (WTES), in which wind power is converted directly to heat, which is stored in a TES and later used to power a heat engine [13]. The thermal storage may also be charged using electricity, in which case the whole system may be designated a Carnot Battery, and if a heat pump is used to charge the system it is designated a Pumped Thermal Electricity Storage (PTES), so long as the heat is used to produce electricity in the discharge phase. The Carnot Battery presents several advantages that make it competitive with other forms of ESS, mainly in terms of environmental impact, flexibility and efficiency, and so it will be the focus of this work.

2. Carnot Batteries

Carnot Batteries work by establishing a thermal gradient between a high temperature (HT) reservoir and a low temperature (LT) reservoir. Electric energy is used to charge the system by forcing heat flow against the natural gradient, thus storing thermal exergy. In the discharge phase, the heat flows from the hot environment to the cold one, and this flow is used to produce work in a heat engine. According to O. Dumont et al. [3], a Carnot Battery (CB) is defined as an EES technology where there is always an electric input, and an electric output. A thermal input may be used to improve the performance of the CB; however, its primary purpose remains the storage of electric energy. Similarly, the battery may output useful thermal energy, but the electric output must be comparable with the electric input. In practice, the reservoirs may be physical ones, such as water tanks or solid materials, or their role may be taken up by the environment (for example, the ambient air). Similarly, electric heat pumps or resistance heaters may be used for charging, and any heat engine (Rankine, Brayton, others) or even a thermoelectric generator may be used for discharging.

Carnot Batteries offer roundtrip efficiencies (ε_{rt}) in a wide range depending on their boundary conditions [3], [5–7], low energy costs [1][3], and high lifetimes [1][3]. These systems are mostly competitive for electricity storage on the scale of several hours, in situations that demand low Power/Capacity ratios, with values of 1 kW /4 kWh and lower. They have a very low environmental impact, and no dependence on geographical conditions [1], making them a suitable competitor to PHS and CAES, whose geographical constraints pose a considerable limit to their exploitability on a large scale. For local, small-scale implementations, Carnot Batteries may also present an adequate replacement for chemical batteries, which are often expensive and environmentally unsafe. Additionally, an important advantage of Carnot Batteries is the ability to integrate additional thermal reservoirs (such as industrial waste heat), which act as additional exergy sources [3]. This thermal integration increases the ε_{rt} of the system, potentially to values greater than unity (>100%), by decreasing the work input or increasing the work output. In Table 2 a brief summary is given of the technical characteristics of some different Carnot battery technologies.

Table 2. Technical summary of Carnot Battery technologies (adapted from [3]).

Cycle	Brayton Cycle	Electrical heater and Rankine Cycle	Heat Pump and Rankine Cycle
Power [MW]	Up to 100	Up to 100	Up to 10*

Typical fluids	Argon, Air	Water	R1233zd(E), CO_2, NH_3, water

* Possible to extend by association in series ** Thermally integrated

If a heat pump is used to charge the thermal storage, the system is designated Pumped Thermal Electrical Storage. These systems may use Brayton heat pumps (HP) with Brayton heat engines (HE), Vapour Compression Heat Pumps (VCHP) in conjunction with Rankine Cycles (RC), or Brayton heat pumps with Rankine Cycles [4]. The presence of a heat pump for the charge cycle is advantageous if the Coefficient of Performance (COP) is higher than one, as the roundtrip efficiency of a PTES is generally the product of the COP with the HE efficiency (if thermal storage efficiency is not considered). The use of a heat pump brings advantages in terms of thermal integration, as it can increase the performance of the heat pump and/or the heat engine. This thermal integration allows an increase in efficiency without complex modifications to the thermodynamic cycles and makes the PTES more flexible, as it may now receive two inputs (electric and thermal) instead of just one – in this sense, Thermally Integrated PTES (TI-PTES) may be seen as a hybrid energy storage and waste heat power plant.

Brayton PTES is usually comprised of a Brayton heat pump, based on the inverse Brayton cycle, and a Brayton heat engine, typically working between two sensible reservoirs [3]. The typical layout contains two thermal reservoirs and four machines (two compressors and two expanders), however in a reversible system this number could reduce to two. In a Brayton cycle, the working gas is compressed, heated and expanded, and then cooled before the next compression. As the work produced by expansion is greater than the work used in compression, the expander drives the compressor with a net positive work output (as with any heat engine, the driving force is a temperature gradient between the two reservoirs) – this is the cycle followed in the discharge process. For charging, the inverse process occurs – the gas is heated and compressed, drawing heat from the LT reservoir, and then cooled, storing heat in the HT reservoir, followed by expansion [3].

HP/RC systems combine Vapour Compression Heat Pumps with Rankine Cycles, where the VCHP charges the reservoirs with thermal exergy, and the Rankine Cycle produces work by harnessing the temperature difference between HT and LT reservoirs. By comparison with Brayton systems, Rankine-based PTES offers the advantages of high energy density and low temperature operation – these features allow for more compact storage, lower self-discharge, and potentially more efficient integration of waste heat. One of the advantages of HP/ORC systems is the use of commercially available equipment (pumps, compressors, expanders, heat exchangers, valves), which facilitates their construction [3], [4], [8]. The schematic configuration for HP and ORC systems and the corresponding T-s diagrams are shown in Figure 1.

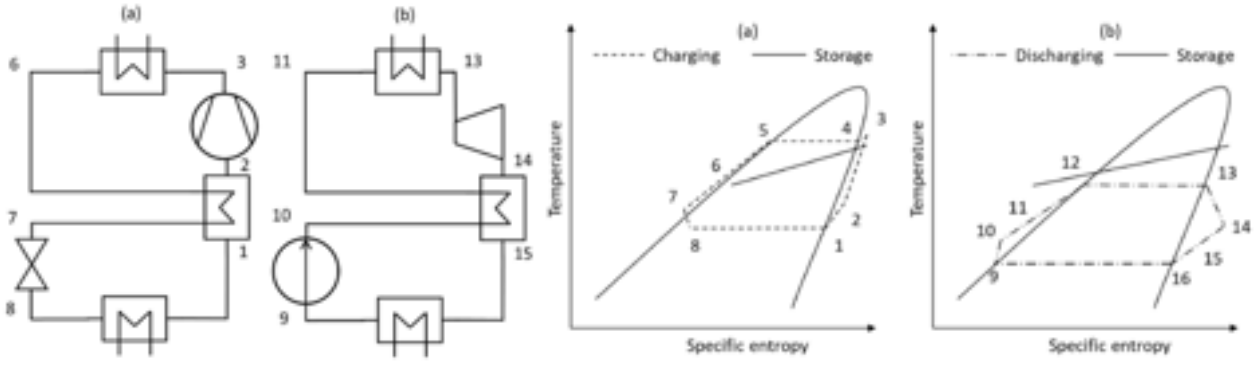

Figure. 1. Heat pump and ORC schematic diagrams (a) and T-s diagrams (b) [9]

3. Thermodynamic modelling

For the study of Carnot Battery systems, the HP/ORC architecture was chosen due to its simplicity and practical feasibility, as well as its low temperatures that facilitate thermal integration; this is also one of the most widely studied types of Carnot Battery, so reference values are readily available.

To study the performance of HP/ORC PTES, each thermodynamic cycle was modelled in MATLAB, with resort to the REFPROP database to calculate fluid properties. Following that, a transient model was developed to simulate the behaviour of a TES coupled to each cycle.

The effectiveness of the Carnot battery process is evaluated through the roundtrip efficiency. The value of this variable is affected by the behaviours of the two sub-cycles of vapor compression heat pump (COP) and the organic Rankine cycle (η), and is expressed by:

$$\varepsilon_{rt} = \mathrm{COP} \times \eta, \tag{1}$$

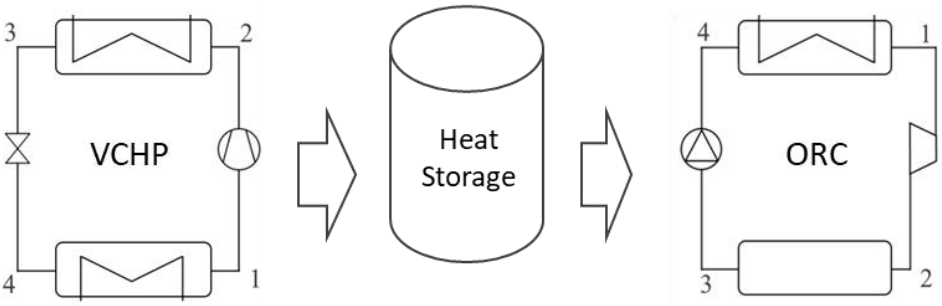

Figure. 2. Schematic representation of the Carnot battery with a simple VCHP, the sensible thermal energy storage and the simple ORC

3.1. Vapor Compression Heat Pump (VCHP)

The standard VCHP cycle is shown in Figure 3 In this cycle, almost all processes involve changes in enthalpy in which case, by definition, heat and/or mechanical work (associated with pressure and volume changes) are being exchanged, neglecting changes in kinetic and potential energy of the fluid.

From points 1 to 2, the enthalpy of the vapour is increased through compression, and the specific work performed on the system is equal to the enthalpy variation:

$$\dot{W}_c = \dot{m}_f(h_2 - h_1), \tag{2}$$

Between 2 and 3, the fluid cools and condenses in a condenser, releasing heat into the HT reservoir at the condensation temperature:

$$\dot{Q}_{cd} = \dot{m}_f(h_2 - h_3), \tag{3}$$

Between 3 and 4, the liquid is expanded into the two-phase region. If this happens in a throttling valve, the process is isenthalpic as heat exchanges can be neglected, and no work is performed on the surroundings. This process is highly irreversible, so it can never be isentropic.

$$h_3 = h_4, \tag{4}$$

Finally, the two-phase mixture receives energy in the evaporator and the fluid returns to a gas state, removing heat from the LT reservoir at the evaporation temperature:

$$\dot{Q}_{ev} = \dot{m}_f(h_1 - h_4), \tag{5}$$

The COP of the heat pump in heating mode is given by the ratio between the heat released from the condenser and the energy consumed in compression. This value is generally greater than unity.

$$COP = \frac{\dot{Q}_{cd}}{\dot{W}_c} \tag{6}$$

In reality, compression may be non-isentropic and there may be superheating of the vapour at point 1, as well as subcooling of the liquid at point 3, in which case the cycle is as shown in Figure 3.2. When the compression process is non-isentropic, which is the case with all real compression processes, the specific entropy of the fluid increases from 1 to 2 – this translates into higher compression work for the non-isentropic process. The isentropic efficiency of a compressor $\eta_{s,c}$ can thus be defined as the ratio between the specific work of the compressor in the isentropic scenario and that of the real scenario:

$$\eta_{s,c} = \frac{w_{c,s}}{w_c} = \frac{(h_{2,s} - h_1)}{(h_2 - h_1)} \tag{7}$$

3.2. Organic Rankine Cycle (ORC)

In the ORC, all processes involve enthalpy changes, as heat and/or mechanical work are exchanged at every step. Between 1 and 2, the vapour is expanded, generating mechanical work – the enthalpy variation is equal to the specific work produced by expansion:

$$\dot{W}_{exp} = \dot{m}_f(h_1 - h_2), \quad (8)$$

From 2 to 3, the working fluid is condensed, rejecting heat to the LT reservoir:

$$\dot{Q}_{cd} = \dot{m}_f(h_2 - h_3), \quad (9)$$

Subsequently, the liquid is pumped to the high-pressure level. The enthalpy variation is equal to the specific work performed by the pump; however, this value is very low as the entire process happens in the liquid phase.

$$\dot{W}_{pump} = \dot{m}_f(h_4 - h_3), \quad (10)$$

Finally, the pressurized liquid is heated and vaporized in the evaporator, drawing heat from the HT reservoir and returning to the state of point 1.

$$\dot{Q}_{ev} = \dot{m}_f(h_1 - h_4), \quad (11)$$

The efficiency of the ORC is given by the ratio between the net energy output, and the heat input at the evaporator:

$$\eta = \frac{\dot{W}_{exp} - \dot{W}_{pump}}{\dot{Q}_{ev}}, \quad (12)$$

As with the vapor compression cycle, the real Rankine cycle involves irreversibilities, some of the most significant being the non-isentropic behavior of the expander and the pump. The isentropic efficiencies of these machines are defined the same way as with the compressor – a ratio between an ideal and a non-ideal amount of work between two states:

$$\eta_{s,exp} = \frac{\dot{W}_{exp}}{\dot{W}_{exp,s}} = \frac{(h_1 - h_{2,s})}{(h_1 - h_{2,s})}, \quad (13)$$

$$\eta_{s,pump} = \frac{\dot{W}_{pump,s}}{\dot{W}_{pump}} = \frac{(h_{4,s} - h_3)}{(h_4 - h_3)}, \quad (14)$$

3.3. Storage Simulation

The TES may use a Sensible Heat Material (SHM), or a Phase Change Material (PCM). PCMs are more energy dense and work well with isothermal processes, however they're often costlier than SHMs [3]. For each case the choice of storage material should be based on several technical, economic, and environmental criteria, a process which is largely outside the scope of this work. Water was chosen as a SHM in the present case, as it presents a high specific heat capacity, low costs and no environmental concerns.

The thermal loss coefficient for the water tank is calculated by the inverse of the sum of a series of thermal resistances corresponding to the thermal barriers that were considered - conduction through a layer of steel and a layer of insulation material, and a convective resistance on the outside of the tank.

$$U_{storage} = \left(R_{cond,steel} + R_{cond,insulation} + R_{conv}\right)^{-1}, \quad (15)$$

The rate of heat loss from the storage to the environment $\dot{Q}$ is determined from the following equation:

$$\dot{Q} = U \cdot A \cdot \Delta T, \quad (16)$$

After the thermodynamic cycles have converged, the energy balance is calculated for the current time step (t) based in the heat transfer rates of charge, discharge and loss to the environment:

$$E_t = E_{t-1} - \left(\dot{Q}_{loss} \times \Delta t\right) + \left(\dot{Q}_{charge} \times \Delta t\right) - \left(\dot{Q}_{discharge} \times \Delta t\right), \quad (17)$$

The updated temperature of the water is obtained, using the equation

$$T_t = \frac{E_t}{m \cdot c_p}, \quad (17)$$

3.4. Dynamic MATLAB model

A dynamic model was developed in MATLAB software which considers the energy content in an insulated cylindrical tank at several points inside a specified time interval, applying an energy balance that considers charge power, discharge power, and losses to the environment.

The cycle begins by considering the first inputs provided by the user, then it proceeds to preliminary simulation of the VCHP and ORC. This determines reference values for mass flow and VCHP/ORC condenser and evaporator power, which are then used to design heat exchange areas for these components in the next step.

After this step, the thermal loss coefficient for the water tank is calculated, its value calculated by the inverse of the sum of a series of thermal resistances corresponding to the thermal barriers that were considered – conduction through a layer of steel and a layer of insulation material, and a convective resistance on the outside of the tank. After this, the iterative cycle begins, each iteration starts by simulating the HP and ORC cycles dynamically, varying the condenser and evaporator temperatures according to the storage tank temperature until the heat exchange rate matches the thermal power associated with phase change. The temperatures of the various points in the thermodynamic cycles, as well as the storage temperature, are constantly updated. The cycle stops when a stopping criterion (for example, a maximum/minimum temperature) is reached, or when it reaches the end of the specified time interval, and then final values are logged and plotted depending on the user's needs. The predefined time interval between two consecutive iterations is 30 seconds but it can be automatically for lower values if a higher resolution is needed, which depends mainly of the thermal energy storage capacity.

The capacity of the storage, nominal power of the compressor and expander, and components' efficiencies are defined inputs of the model as showed in Table 3. The algorithm needs to adjust these input parameters based on the output of the cycle, running the program several times until the desired results are achieved.

4. Results and discussion

4.1. Case study

Using the model presented in Section 3, the case of a solar PV power plant will be analysed. Excess power from the PV array is to be stored as thermal exergy in the water tank and used at night when the solar panels cannot provide any energy. As a means of thermal integration, a solar thermal system is used in conjunction with a secondary hot water tank to boost the temperature of the VCHP evaporator to 70°C. The VCHP compressor receives excess electric energy from the solar PV panels and uses it to upgrade the heat from the evaporator to the required temperature at the condenser. The hot water from the main water tank is then used as a heat source for the ORC, which produces electric energy in the expander as it discharges this heat to the environment. Figure 3 shows the layout of the proposed system.

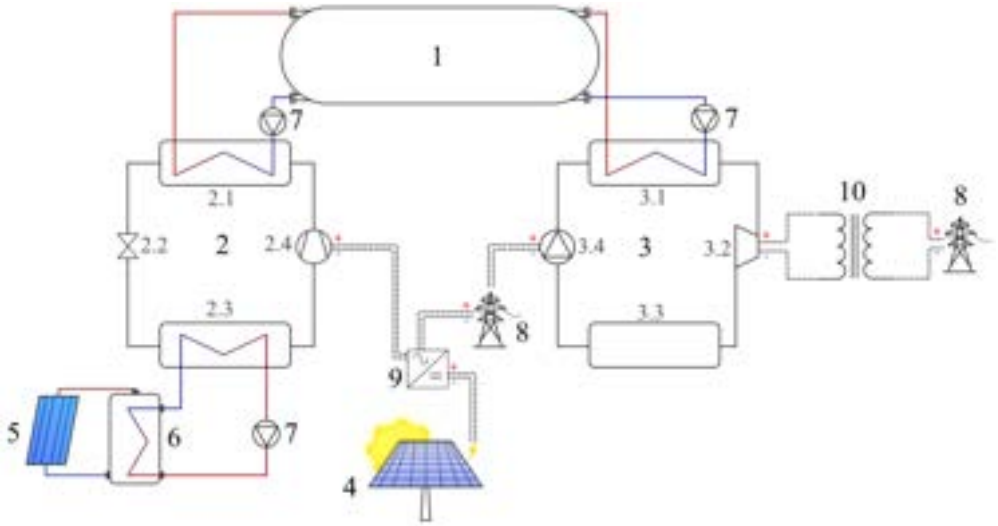

Figure. 3. Schematic representation of the proposed system (1 - Water Tank; 2 - Heat Pump; 2.1 - HP Condenser; 2.2 - HP throttling valve; 2.3 - HP Evaporator; 2.4 - HP Compressor; 3 - ORC; 3.1 - ORC Evaporator; 3.2 - ORC Expander; 3.3 - ORC Condenser; 3.4 - ORC Pump; 4 - PV Array; 5 - Solar thermal panel; 6 - Hot water tank; 7 - Pump; 8 - Power grid; 9 - DC/AC Converter; 10 - AC Transformer).

4.1. Modelling Validation

A first charge/standby/discharge cycle was performed to compare with other studies and obtain initial results and a primary validation, using the values in Table 3. For this first run, a full charge was simulated, followed by 4 hours of standby, and finally a complete discharge of the storage, returning to the initial temperature.

Table 3. *Validation Simulation Parameters.*

Water Tank		**ORC**	
Volume [m^3]	5	Condenser Temperature (design value) [ºC]	35

Aspect Ratio (Length/Diameter)	2	Evaporator Temperature (design value) [ºC]	60

Condenser Heat Transfer Coef. (U) [ºC]	1000		
Condenser Temperature (design value) [ºC]	100		

The charge phase brought the storage up to a temperature of 90°C in about 17 hours and 46 minutes, with 123.6 kWh of thermal energy variation in the water. With a total electrical consumption of 13.54 kWh, this leads to a global COP of 9.13, factoring in thermal losses to the environment during the charge; if the losses are not considered, the COP is 10.41

The exact values change throughout the charge, as shown in Figure 4. The increase in compressor work and the decrease in condenser thermal power lead to a decrease in the COP as the temperature and pressure in the condenser increase. It can be observed that the VCHP has taken a relatively long time to charge the storage – the charging time mostly depends on the ratio between the total storage heat capacity and the charge power of the heat pump.

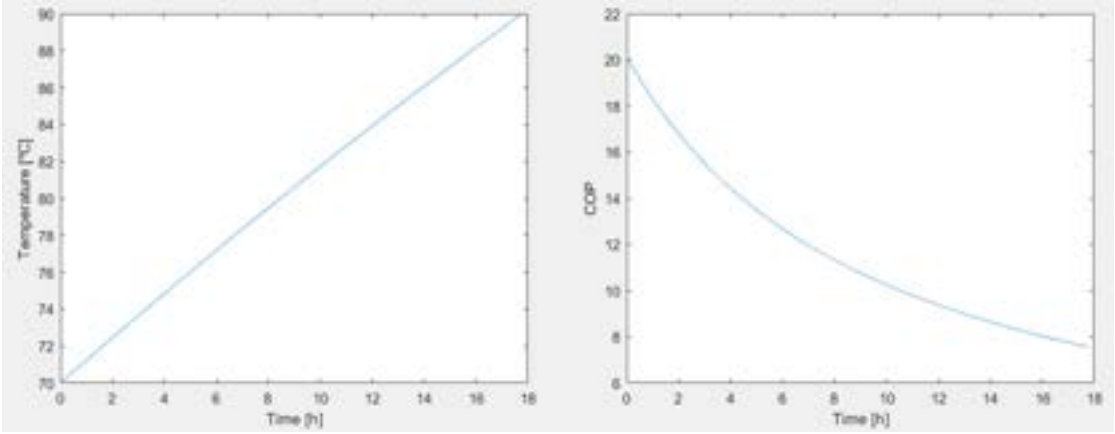

Figure. 4. Evolution of key parameters in the charge phase.

During the standby phase, the temperature of the storage tank decreased slightly due to losses to the environment, with a reduction from 90°C to 89.28°C. This decrease of 0.72°C corresponds to a loss of 4.53 kWh of thermal energy. Figure 5 shows the evolution of the temperature and the thermal loss power from the water tank over the 4-hour period.

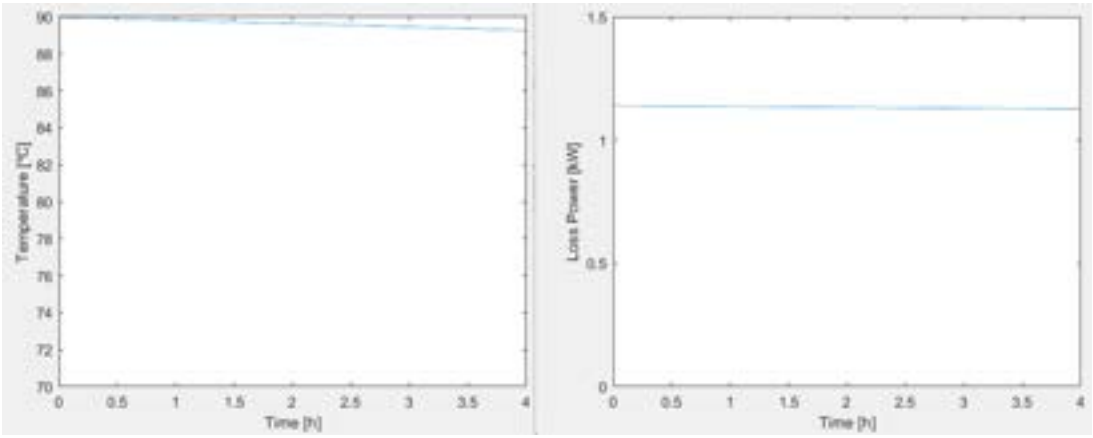

Figure. 5. Evolution of key parameters in the standby phase.

Finally, the discharge phase (Figure 6) brought the storage temperature back down to 70°C in about 10 hours and 27 minutes, with a thermal energy reduction of 119.06 kWh, and a net electrical generation of 8.08 kWh, leading to a global ORC efficiency of 6.8%; factoring out losses to the environment, the global ORC efficiency is 7.4%. With the decrease in evaporator temperature and pressure comes a decrease in evaporator thermal and pump power consumptions, and expander power generation, with an overall decrease in efficiency.

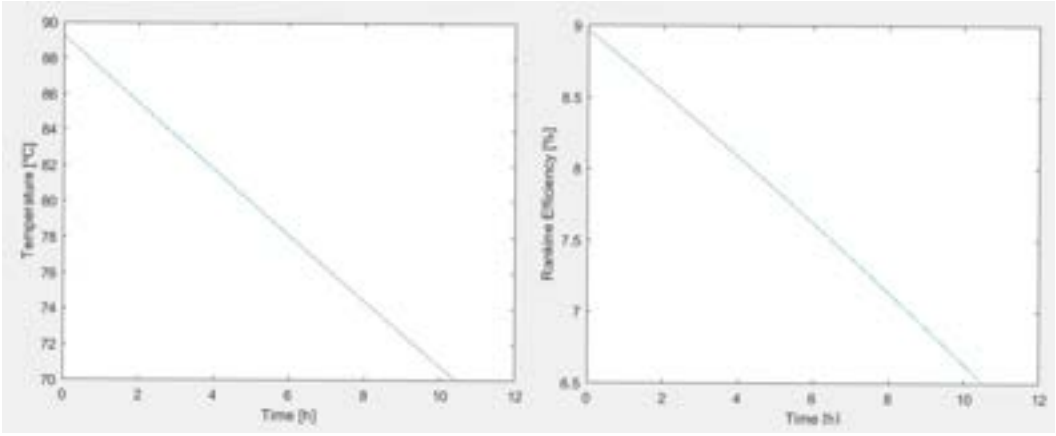

Figure. 6. Evolution of key parameters in the discharge phase.

Roundtrip efficiency is often estimated as the product of the COP with the Rankine efficiency, however this becomes inaccurate when thermal losses from the storage are considered. The use of a dynamic model allows the calculation of a precise value – in this first case, an ε_{rt} of 59.7% was obtained – a value consistent with those obtained in previous studies, and a satisfactory value for a non-optimized situation.

4.2. Optimization Method

The main driving parameters are: expander power, discharge time and charge time. The first two parameters determine an energy requirement, allowing the design of an adequate storage size. The heat pump can then be designed for a power that allows a full charge in 8 hours – roughly the time during which solar energy is available for the PV array.

In terms of optimization, the main objectives are the storage size/temperature variation and heat exchanger surface areas/pinch points. The optimization of these pairs of parameter involves a balance between cost and performance, as the best performance results from the largest surface areas and storage volumes, as these reduce the temperature differences, but they also lead to greater costs. To evaluate the effect of these parameters, a full discharge and a full charge were simulated for five nominal pinch point values (10K, 8K, 6K, 4K, 2K), and five storage temperature spreads at each pinch point (70°C – 75°C, 70°C – 80°C, 70°C – 85°C, 70°C – 90°C and 70°C – 95°C), resulting in a total of 25 charge simulations and 25 discharge simulations. For each case, the storage size was optimized for a 4-hour discharge with a nominal expander power of 20kW, and then a nominal compressor power was chosen to allow a full charge of the storage in 8 hours – these reference powers correspond to the maximum values that will be encountered throughout the simulation.

In terms of costs, the correlations in Table 4 adapted from Santos [10] were used to provide a rough estimate for capital costs in order to make the cost/performance optimization possible. The total cost of the system is given by the sum of the costs for each component.

Table 4. *Cost Correlations for components used in the Carnot Battery.*

Component	Cost Correlation [€]	Unit of Independent Variable
Storage Tank	$2000 + (625 \times Vol._{storage})$	m^3
Heat Exchangers	$150 \times Area$	m^2
ORC Expander	$1.5 \times (225 + (17000 \times \dot{V}_{in}))$	m^3/s
ORC Pump	$900 \times (\dot{W}_{pump}/300)$	W
VCHP Compressor	$225 + (17000 \times \dot{V}_{in})$	m^3/s
Control Electronics	4000	-

4.3. Results

As expected, lower pinch points lead to higher roundtrip efficiency for any storage spread, as this minimizes the temperature gradient of the VCHP and maximizes it for the ORC. A lower storage spread also improves efficiency, as it greatly increases the COP, with only a small decrease in ORC efficiency.

In terms of costs, while the lower pinch points and lower storage spreads lead to higher values (larger heat exchangers and storage tank), the effect of the storage spread seems far greater than that of the pinch point, so the best cost/efficiency ratios are mostly found with the lower pinch points and higher storage spreads – the highest value was obtained for the 10K pinch point and 70°C – 75°C storage spread, at 3979.70 [€/% roundtrip efficiency], with an ε_{rt} of 43.32%. By contrast, the best cost/efficiency ratio was obtained for the 2K pinch point and 70°C – 85°C storage spread, with a value of 586.73 [€/% roundtrip efficiency], and an ε_{rt} of 141.54%. For the 2K pinch point, all storage spreads above 70°C – 75°C return cost/efficiency values below 605 [€/% roundtrip efficiency], with roundtrip efficiencies between 173-105%. At this pinch point, the highest performance is reached with a 70°C – 75°C spread, at a cost/efficiency of 734.37 [€/% roundtrip efficiency], but with an ε_{rt} of 225.54%. In all cases for the 2K pinch point, the system becomes a hybrid between energy storage and a solar thermal power plant, as the efficiency exceeds 100%.

Figure 7 shows how the storage spread (70 – maximum temperature) and pinch point influence the cost/efficiency ratio. It can again be seen that most points along the 2K line are close to the optimal value.

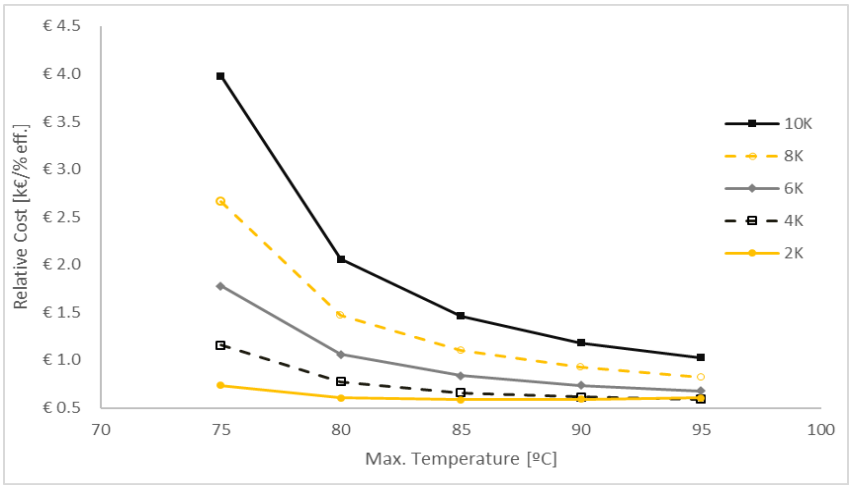

Figure. 7. Maximum storage temperature vs. relative cost for various pinch points.

Finally, payback time was analysed for the various configurations, as shown in Figure 8. The daily profit was calculated as the total electric energy of the discharge phase multiplied by a price of 0.20 €/kWh – a value assumed based on the costs of a few energy providers available in Portugal as well as reference values from the Energy Services Regulatory Authority (ERSE), for a contracted electric power up to 20.7 kVA. Furthermore, the system was assumed to generate this daily profit for 12 months of the year. In reality the performance would generally worsen in the winter months leading to lower profits. Even with enough solar thermal panels to offset unfavourable climate conditions, this fact could potentially affect the payback period in a real situation.

For all storage configurations, the shortest payback times are generally achieved with the 4K, 6K and 8K pinch points, and the shortest payback time between all the simulations is obtained with the 70°C – 95°C spread: approximately 9 years and 2 months. For a payback time of 4 years or lower, the average price of electricity would need to be at least 0.46 €/kWh.

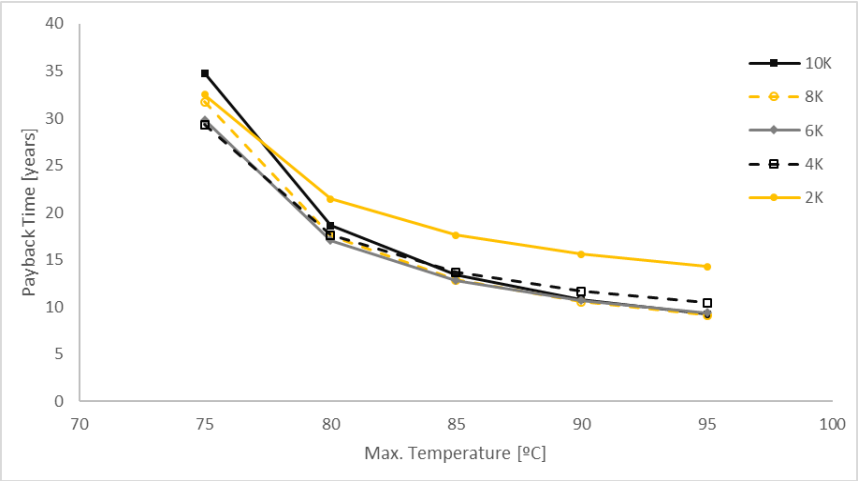

Figure. 8. Maximum storage temperature vs. payback time for various pinch points.

It can be concluded that a select few configurations optimize one parameter or another – the lowest pinch point (2K) and lowest storage spread (70°C – 75°C) optimize performance, the highest pinch point (10K) and the highest spread (70°C – 95°C) optimize costs, the 2K pinch point and 70°C – 85°C spread optimize the cost/performance ratio, and the 8K pinch point and 70°C – 95°C spread optimize the payback period. In this case, all of these solutions are ideal in one form or another – these configurations belong on the so-called Pareto Front (Figure 4.15), the set of all Pareto-optimal solutions. In other words, by moving between the points on this line it is impossible to improve any criterion without deteriorating another. This means that any point on this line represents a valid choice, and the selection should depend on the most relevant priority, or a balance of relevant priorities for a given implementation. For example, from a technological perspective, the best choice is the one with the highest efficiency. In terms of budget alone, the best choice has the lowest cost. For an efficient capital investment, one would select the machine with the best cost/performance ratio, and to minimize the risk of investment the machine with the lowest payback time should be chosen.

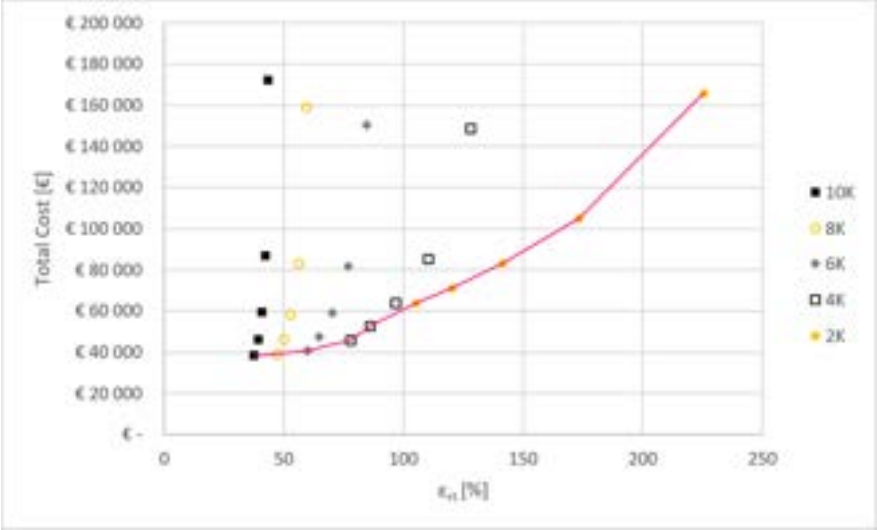

Figure. 9. Pareto Front for the tested configurations.

5. Conclusions

In this study, a case was made for the Carnot Battery as a suitable technology to replace current systems with relatively low Power/Capacity ratios, and a storage duration in the range of a few hours. A MATLAB script was developed which is capable of simulating the performance of a Carnot Battery composed of simple Vapour Compression Heat Pump and ORCs in dynamic charge/discharge conditions, as well as the thermal behaviour of a sensible storage in a standby situation. Despite the limited scope of the present study, the flexibility the developed model should allow its use in diverse situations with little to no modification, including off-design performance, thermal storage material selection, analysis of different thermal integration strategies, as well as more detailed techno-economic studies. Moreover, the model was used to study several configurations, taking into account the most critical parameters of the system, in an effort to discover an optimized arrangement; in the end, the optimal configuration depends on a balance of priorities – if performance is the only criterion, the

lowest pinch point (2K) and lowest storage spread (70°C – 75°C) should be selected despite the high costs; to minimize costs alone, one would select the highest pinch point (10K) and the highest spread (70°C – 95°C) in spite of the low efficiency, and for the best cost/performance ratio, the optimal choice would lie in between these two, with a 2K pinch point and a 70°C – 85°C spread. Additionally, for a minimized payback period the choice would be the 8K pinch point and a 70°C – 95°C spread. It was concluded that these four points belong on the Pareto front, in which all points represent either the optimization of one parameter, or a compromise between multiple parameters, and conclusions were drawn as to the applicability of each configuration.

Abstract:

As energy and environmental policies for 2030 and 2050 are encouraging several Countries to investigate the viability of alternative green fuels to replace fossil one and help decarbonizing energy sector, hydrogen and ammonia are two promising solutions.

Green hydrogen production is investigated considering both alkaline and PEM electrolysers commercial products, comparing the market solutions from the energetic standpoint considering three different plant sizes, representative of small (1 MW), medium (10 MW) and large (60 MW) scale applications. Hydrogen compression and storage in pressurized tanks is included in the analysis. Considering the drawbacks in hydrogen storage, a second plant lay-out is investigated considering an Air Separation Unit (ASU) and ammonia synthesis plant for the three different sizes. Ammonia is then stored in liquid form. For each solution, a techno-economic analysis is performed to evaluate: (i) CAPEX; (ii) OPEX; (iii) hydrogen and ammonia production costs. Authors evaluate the economic feasibility comparing final costs for green hydrogen and ammonia with market values, considering different scenarios and different green electrical energy prices. Finally, the authors investigate the influence of electrolysers' CAPEX decrease in a next future scenario (2030) on economic feasibility.

Keywords:

Hydrogen production; Energy; techno-economic analysis; green ammonia.

1. Introduction

To mitigate climate change in an effective and timely manner, rapid decarbonization of the global economy is needed. The transformation is already well advanced in the electrical energy sector in several industrialized countries, where competitive renewable energy technologies are increasingly replacing coal and gas-fired power plants [1]. Focusing on EU-27 Countries, total CO_2 emissions reduced from 4000 Mtons in 2005 to 3000 Mtons in 2020, with a strong increase in Renewable Energy Sources (RES) share on gross electrical (from 16.4% in 2005 to 37.4% in 2020), thermal (from 12.4% in 2005 to 23% in 2020) and transport consumptions (from 1.8% in 2005 to 10.3% in 2020) [2]. In the next years, according to the ambitious targets set for 2030, RES contribution is expected to further increase, helping the decarbonisation process.

In this context, the production [3][5] and transport [6][4] of hydrogen, ammonia [7][8][9] and other energy carriers [10][11] are receiving increasing attention, as they have the potential to replace coal, oil, and fossil gases as a global energy feedstock. Both hydrogen and ammonia do not contain carbon atoms, thus they do not impact in terms of CO_2 emissions, and they are considered very interesting alternatives to mitigate GHGs growth if they are produced starting from renewable electricity by the water electrolysis process. In this context, both Power to Hydrogen (P2H) and Power to Ammonia (P2A) are two of the most interesting emerging technologies having great potential as renewable energy storage for long periods, producing a chemical that can be considered as both an effective energy carrier and, in case of ammonia also an effective hydrogen carrier, and as alternative carbon free-fuel [10]. Both P2H and P2A have the potential to play an important role in the transition to a low-carbon economy [7]. They offer a way to store and use renewable energy, which can help to reduce greenhouse gas emissions and improve energy security. Furthermore, both technologies offer a pathway to decarbonize sectors such as transportation and industry, which have traditionally been difficult to decarbonize.

Despite the promising potential, there are still several technical and economic challenges that need to be addressed. For example, both processes are currently energy-intensive, and the production cost is still

relatively high compared to traditional methods. However, ongoing research and development in this area are expected to reduce costs and improve efficiency, making P2H and P2A increasingly viable options for a low-carbon future.

In this paper, in-depth research and evaluation of the market available technologies are reported. Moreover, the analysis and comparison of energy and economic feasibility for both hydrogen and ammonia production processes are carried out. The study is developed considering different plant sizes to evaluate the impact of the economy of scale. The fuel production cost for both the P2H and P2A is calculated for each plant size and considering different economic scenarios and different energy sources. The results are then compared with the market price of hydrogen and ammonia produced from fossil fuels.

2. Technologies

2.1. Electrolysers (hydrogen production)

Electrolysers are electrochemical devices that are used to split water molecules into hydrogen and oxygen using electricity. As fuel cells, electrolyzers are made by a certain number of electrolytic cells, each cell includes two electrodes and an electrolyte. More cells are connected in series to produce a stack to have the desired hydrogen production. Electrolysers' subsystems include equipment for cooling, hydrogen purification, DC/DC, and a supply system for demineralized water. Electrolysers are classified as Alkaline (AEC), Proton Exchange Membrane (PEMEC), and Solid Oxide Electrolysers (SOEC) [12]. The main features are reported in Table 1.

Table 1. Electrolysers' comparison

	AEC	**PEMEC**	**SOEC**
Electrolyte	Liquid (solution 20-30% KOH)	Solid (Polymeric membrane)	Solid (Ceramic)
Operating temp. [° C]	60 – 80	60 - 80	800 - 900
Efficiency [%]	70 - 75	70 - 75	85 - 90
Lifetime [hours]	100,000	80,000	< 20,000
Start-up time	Fast (minutes)	Very fast (seconds)	Slow (hours)
Current density [mA -cm^2]	0.2 – 0.4	1 – 2	0.5 – 1
Maturity	High (TRL9, Market solutions)	High (TRL9, Market solutions)	Medium (TRL7, Demonstration, early market)

While SOEC are still in development, AEC and PEMEC are experimenting a significant market diffusion in the last years, and commercial solutions are available from many producers also for significant sizes (multi-MW solutions). AEC are the most mature technology (developed in the last 50 years), they have lower costs than PEMEC and higher lifetime. However, compared to PEMEC, they have some drawbacks, as they have longer start-up time and dynamic response, which can represent a drawback in case of coupling with intermittent RES, such as wind and solar. Furthermore, PEMEC have higher compactness and allow for very high H_2 purity (99.99% vs 99.5% for AEC). Table 2 reports the main electrolysers' products, for sizes higher or equal to 1 MW, available on the market and their features in terms of technology, efficiency, and volume. It is worth observing that PEMEC performance are very similar to AEC and that both the technologies offer high power solutions in a wide range.

Table 2. Main AEC and PEM electrolysers' commercial products [13-18]

PEMEC	Cummins Hy Lizer 1000	30 bar	4.6 MW	1000 Nm^3/h	4.6 kWh/Nm^3	77%	N/D
PEMEC	Cummins Hy Lizer 4000-30	30 bar	20MW	4300 Nm^3/h	4.6 kWh/Nm^3	77%	N/D
PEMEC	ITM POWER 3MEPCUBE	30 bar	2 MW	400 Nm^3/h	5 kWh/Nm^3	70%	N/D
PEMEC	ITM Power 2GEP Skid	30 bar	5MW	1002 Nm^3/h	5 kWh/Nm^3	70%	N/D
PEMEC	H-TEC Systems HCS	30 bar	10 MW	2100 Nm^3/h	4.8 kWh/Nm^3	74%	20-100%
PEMEC	Plug Power EX-4250D	40 bar	10 MW	2000 Nm^3/h	5 kWh/Nm^3	70%	N/D
PEMEC	H-TEC Systems ME450	30 bar	1 MW	210 Nm^3/h	4.8 kWh/Nm^3	74%	20-100%

Considering that PEMEC and AEC products available products on the market are similar from the efficiency, size, outlet pressure standpoints, PEMEC are chosen for the present study, considering that they guarantee higher purity and the have an advantage in terms of response, which make them more feasible for coupling with RES (i.e. wind energy) [5].

2.2. Air Separation Unit (ASU)

The required Nitrogen for the synthesis of Ammonia is usually obtained from the air (i.e. a mixture of N_2, O_2, and other gases) utilising an Air Separation Unit (ASU). The commercially available technologies for the nitrogen production are three: (i) Cryogenic Fractional Distillation; (ii) Pressure Swing Adsorption (PSA); (iii) membrane separation. All of them differs in operating principle, capacity, and energy consumption. The ASU is based on the Cryogenic Fractional Distillation approach starting from the liquefaction of the air and then the distillation and separation in its main components (O_2, N_2, Ar, etc). This process is usually employed for medium to large capacity plant (200 – 400,000 Nm^3/h of N_2), allows to obtain a very high purity level (up to 99.999%), the energy consumption ranges between 0.25 and 0.4 kWh/Nm^3 of N_2 and, considering the complexity of the process, the load range is quite limited (60%-100%). The PSA system is a discontinuous mechanical process based on the adsorption principle by means of vessels packed with Carbon Molecular Sieves that retains a specific molecule. The adsorption process depends on the operating pressure and the higher the pressure, the higher the N_2 purity at the outlet and the higher the energy consumption. Commercially, the PSA units operate at 6-8 bar, the N_2 purity can reach the 99.999% and the related energy consumption is up to 1.25 kWh/Nm^3 for very high purity nitrogen. Such a system is usually employed for medium-small applications (5-5000 Nm^3/h of N_2). As for the PSA, also the Membrane Separation is a pressure-driven process. The working principle is based on a selective gas permeation through a membrane substance that allows specific molecules to flow. The driving force is the difference in partial pressure between the two sides of the membrane. In the case of nitrogen production, when compressed air pass through the membrane's fibres, oxygen, water vapour, and carbon dioxide are selectively removed, creating a nitrogen-rich product stream. However, the purity grade that is achievable with membrane separation is usually in the range of 95%-99.5% resulting not suitable for ammonia synthesis via Haber-Bosch process. In the present work, considering the size and the purity required, the PSA technology is considered for the production of the nitrogen needed for the ammonia synthesis.

2.3. Haber-Bosch reactor

The SoA process for the synthesis of ammonia is known as Haber-Bosch process developed in the early 20th century. It is a thermochemical Fe-based catalytic process in which H_2 and N_2 (almost in stoichiometric ratio, 3:1) react at high pressure (140-250 bar) and temperature (300-500°C) according to the following reaction:

$$N_2 + 3H_2 \rightarrow 2NH_3 \qquad \Delta H_0 = -92\ kJ/mol$$

The ammonia synthesis reaction is exothermic and the number of moles decreases, thus it is favoured by low temperature and high pressure. Traditional process reach single-pass conversion around 15%-30% at typical working conditions (i.e 200 bar and 400-500°C, respectively). The overall conversion reach up to 95% with a recirculation factor around 7 to 10. The most used catalyst is Fe-based and therefore it is very susceptible to poisoning in presence of oxygen and water, and, for this reason, the required reacts purity is very high. In order to overcome the drawbacks of Fe-based catalysts and to reduce the operating conditions, new catalyst mostly based on ruthenium has been developed.

2.4. Hydrogen storage

Hydrogen storage represents one of the most critical aspects for the development of the hydrogen economy on global scale. In fact, despite its high energy content in mass terms (LHV 120 MJ/kg), hydrogen has a very

low density (0.09 kg/m^3 at ambient conditions), thus its energy content in volume terms is low (3.0 kWh/m^3). Today, there are three commercial solutions for hydrogen storage: (a) compressed gas; (b) liquid; (c) metal hydrides. Solution (a) is the most employed, as it presents high maturity for different scales [19]. Depending on the employed materials and to the final pressure storage, it is possible to identify four different tanks typologies for the storage. Type I consists in iron tanks (max pressure 200 bar), type II in aluminium tanks (max pressure 300 bar), type III in composite pressure vessel made of a metallic liner fully-wrapped with a fiber-resin composite (max pressure 700 bar) and Type IV in pressure vessel made of polymeric liner fully-wrapped with a fiber-resin composite (max pressure 700 bar). Type III and IV guarantee the best performance in terms of energy content (about 1300 kWh/m^3), thus they are considered in this study. In case of compressed gas storage, compression has to be considered. Since hydrogen is produced by electrolysers at 30 bar, the energy to bring it to 700 bar is estimated in 2.2 kWh/kg [20].

2.5. Ammonia storage

The ammonia presents physical characteristics very similar to the LPG and therefore they can share both the storage solutions and the infrastructure.

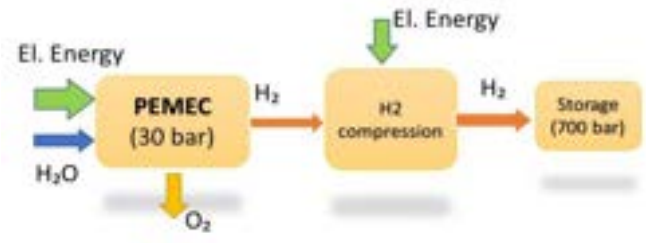
The ammonia can be stored in three main solutions: (i) fully-refrigerated tank; (ii) semi-refrigerated tank; (iii) pressurised tank. The first one is usually adopted in case of very high-capacity storage (10-50 ktons). In this case, the ammonia is stored at ambient pressure and saturation temperature (-33°C). The tank is equipped with a refrigeration circuit to maintain the design temperature and manage the blow-off. Such a solution is usually used as local storage at the production site or for the transportation into tanker ship, as well for the semi-refrigerated system. In this case, the ammonia is stored in liquid form at around -5°C - 0°C and saturation pressure (3-5 bar). The pressurised ammonia tank stores the ammonia as a liquified compressed gas at ambient pressure and related saturation pressure till a maximum of around 20bar. Inside this type of storage, both the liquid and vapour phase co-exist in equilibrium as function of the ambient temperature. This solution is mostly used for small-medium capacity, and for truck and rail transportation.

3. Case studies

In the present section, different case studies are analysed, considering:

- Small size case (1 MW electrolysers)
- Medium size case (10 MW electrolysers)
- Large size case (60 MW electrolysers)

For the three sizes, both green H_2 and NH_3 plant layouts are investigated. An energy and volume analysis is carried out, trying to minimize electrical energy consumption and occupied space for each configuration, considering the available products on the market. Figure 1 presents a simplified plant layout for green hydrogen production in a Power-to-Hydrogen (P2H) process. RES electrical energy gives power to electrolyser, splitting water in hydrogen and oxygen at a certain pressure (assumed 30 bar in this case). At the outlet, a compression system brings the hydrogen to the desired pressure level for the storage (from 200 to 700 bar, according to the scenario). The so produced H_2 has a very high purity and can be used in fuel cell electric vehicles, or for industrial/chemical applications. In P2A configuration, green hydrogen is compressed up to 200 bar and mixed with N_2, sequestered by ASU and then compressed; the reactants are sent to a Haber-Bosch synthesis loop and the so produced ammonia is stored in liquid form [21].



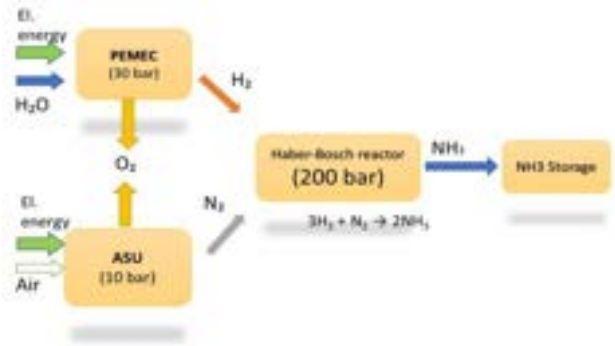


Figure. 1. Simplified plant layouts for P2H and P2A configurations

3.1. Small size (1 MW)

The 1 MW size is well-established in today's electrolyser market for both AEC and PEMEC technologies, as reported in Table 2. Considering PEMEC, the H-TEC PEM ME450 model is investigated as possible solution. Assuming the P2H plant operating for 4000 equivalent hours per year (considering average capacity factor for wind energy production, according to IRENA data), consumptions are nearly 700 ton/year of H_2O and 4165 MWh of electrical energy (4000 MWh for PEMEC, 165 MWh for H_2 compression up to 700 bar) for hydrogen production equal to 75 ton/year. The required space is about 87 m^2, including PEMEC (53 m^2) and storage (34 m^2).

In case of P2A configuration, operating for the same equivalent hours per year, water consumptions are the same, while electrical energy are slightly increased up to 4360 MWh (4000 MWh for PEMEC, 130 MWh for ASU, 230 MWh for nitrogen and hydrogen compression up to 200 bar for Haber-Bosch process), for ammonia synthesis equal to 425 ton/year. In this configuration, the required area results 87 m^2, including PEMEC (53 m^2), Haber-Bosch plant (26.5 m^2), ASU (1.4 m^2) and storage (6.1m^2).

3.2. Medium size (10 MW)

The medium size analysed in the present study is 10 MW, which is a capacity that is available for the single products for both PEMEC and AEC technologies (Table 2). However, considering that the minimum load is usually around 10-20%, this would imply a minimum available electrical energy from RES equal to 1-2 MW, which can decrease the operation time during the year. Thus, the combination of more commercial units in parallel is considered to guarantee higher plant flexibility. Considering PEMEC, two Cummins HyLYZER® 1000-30 (4.5 MW each) and one H-TEC PEM ME450 (1MW) models. Assuming the P2H plant operating for 4000 equivalent hours per year, consumptions are nearly 7000 ton/year of H_2O and 42470 MWh of electrical energy (40720 MWh for PEMEC, 1750 MWh for H_2 compression up to 700 bar) for hydrogen production equal to 795 ton/year. The required space is about 373 m^2, including PEMEC (113 m^2) and storage (260 m^2). It is worth noting that, in this case, the storage is the most influent voice in terms of area.

In case of P2A configuration, operating for the same equivalent hours per year, water consumptions are the same calculated for P2H 10 MW configuration. Electrical energy consumption slightly increases to 4360 MWh (40720 MWh for PEMEC, 1300 MWh for ASU, 2300 MWh for nitrogen and hydrogen compression up to 200 bar for Haber-Bosch process), for ammonia synthesis equal to 4250 ton/year. In this configuration, the required area results 242 m^2, including PEMEC (113 m^2), Haber-Bosch plant (56.6 m^2), ASU (11.4 m^2) and storage (61 m^2).

3.3. Large size (60 MW)

The large size analysed in the present study is 60 MW, corresponding to the size in the Tees Green Hydrogen project in UK for the production of green hydrogen using electrical energy generated by the Teesside offshore wind farm provided to local corporate customers to support decarbonisation [22]. Two options are investigated for the present case study: (a) 3 PEMEC units Cummins HyLYZER® 4000-30, 20 MW each; (b) 28 PEMEC units Cummins MC500, 2.2 MW each.

Assuming the P2H plant operating for 4000 equivalent hours per year, consumptions are nearly 38500 ton/year of H_2O and 247 GWh of electrical energy (237 GWh for PEMEC, 10 GWh for H_2 compression up to 700 bar) for hydrogen production equal to 4640 ton/year. In case of option (a), the required space is about 1842 m^2, including PEMEC (450 m^2) and storage (1392 m^2). Adopting solution (b), the required space results considerably higher (2232 m^2) due to the higher modules number.

In case of P2A configuration, operating for the same equivalent hours per year, water consumptions are the same calculated for P2H 60 MW configuration, while electrical energy consumption slightly increases to 4360 MWh (237 GWh for PEMEC, 5.2 GWh for ASU, 13.9 GWh for nitrogen and hydrogen compression up

to 200 bar for Haber-Bosch process), for ammonia synthesis equal to 25500 ton/year. In this configuration, the required area results 1060 m^2, including PEMEC (450 m^2), Haber-Bosch plant (225 m^2), ASU (10 m^2) and storage (375m^2).

4. Economic analysis

An economic analysis is then carried out to calculate the cost of green hydrogen and ammonia. The discussion continues by comparing the cost of producing hydrogen and ammonia obtained from green sources and the price on the market in the years 2021/2022. In addition, an analysis is performed on the possible incentives to be provided and the LCOE break-even in order to bridge the gap between the cost of fuels from fossil fuels and renewable energy sources.

To evaluate the economic viability [10], the Fuel Production Cost (FPC) is considered for both green hydrogen and ammonia, calculated as follows and expressed in €/kg:

$$FPC = (Annual\ Fixed\ Costs + Annual\ Variable\ Costs)/(Total\ Annual\ Production) \quad (1)$$

Where Annual Fixed Costs (AFC) are determined starting from the Total Capital Investment (TCI), considering the plant lifetime in years (n) and the WACC as rate (r):

$$AFC = TCI \cdot (r * (1+r)\text{^}n)/((1+r)\text{^}n\ -1) \quad (2)$$

Annual Variable Costs (AVC) include electrical energy cost and the OPEX of each plant component

$$AVC = \sum\_i \text{▒}\ 〖OPEX\_i〗\ + El.Energy\ cost \quad (3)$$

Economic analysis is performed considering the main assumptions reported below:

- Equivalent Operating Hours (EOH) for all the plant configurations are estimated in 4,000 h/year, considering that the renewable energy is produced by wind farms [23].
- Levelized Cost Of Electricity (LCOE) depends on the application scenario, assumed for the present analysis from IRENA 2021 report [23]. More in detail, for onshore wind farms LCOE is assumed 42 €/MWh for Europe, 31 €/MWh for USA, 28 €/MWh for China scenarios; for offshore wind farms LCOE is assumed 65 €/MWh for Europe, 78 €/MWh for USA, 79 €/MWh for China scenarios.
- Plant lifetime 20 years, corresponding to 80,000 equivalent operating hours, which is the guaranteed lifetime for electrolysers according to literature and producers [12][24].
- WACC 5%.

Capital Expenditure (CAPEX) for both alkaline and PEM electrolysers represents one of the most important voices for the economic feasibility, as electrolysers have a significant investment cost, as reported also in recent studies. Thus, a cost function is determined for both technologies based on recent data collected by IRENA in 2020 report as function of the installed power *P*, expressed in MW. The obtained cost functions are reported in Table 3. For the considered sizes, alkaline technology has a CAPEX of 1002 €/kW, 600 €/kW and 400 €/kW for 1 MW, 10 MW and 60 MW respectively, while PEMEC technology has higher CAPEX of 1155 €/kW, 742 €/kW and 526 €/kW for the same sizes [24].

The main assumptions for CAPEX and OPEX calculations are reported in Table 3.

Table 3. Main CAPEX and OPEC estimations for economic analysis [10][12][24]

Component	CAPEX	OPEX
PEMEC	$1155{\cdot}10^3 \cdot P^{0.808}$ [€]	4.5% CAPEX
AEC	$1002{\cdot}10^3 \cdot P^{0.778}$ [€]	4.5% CAPEX
H_2 compressors	16000 M_{H2} [€]	2% CAPEX
H_2 storage tanks	480 M_{H2} [€]	-
ASU	1450 M_{N2} [€]	2% CAPEX
Ammonia synthesis loop	50890 $M_{NH3}^{0.65}$ [€]	2% CAPEX

Ammonia storage	0.9 M_{NH3} [€]	-

4.1. Main techno-economic results

4.1.1. Annual costs breakdown

The first analysis is performed in order to evaluate the main costs distribution for both P2H and P2A configurations for 1 MW, 10 MW and 60 MW PEMEC sizes, respectively. For this first analysis, an average LCOE for electrical energy equal to 50 €/MWh is considered.

Figure 2 shows the cost breakdowns for green hydrogen production. Annual costs, including both CAPEX and OPEX contributions are about 0.48 M€/year for small size (1 MW), 4.00 M€ for medium size (10 MW) and 20.81 M€ for large size (60 MW). It is worth noting that the most relevant component is the cost of electrical energy for all the investigated sizes, followed by electrolysers' CAPEX and OPEX: these voices impact for 85-90% of total annual costs. Observing the three case studies, it is evident that, as the size increases, due to the decrease in the electrolysers CAPEX (sizing up), their incidence on the total percentage tends to diminish; in percentage terms, electrical energy cost influence increases more and more.

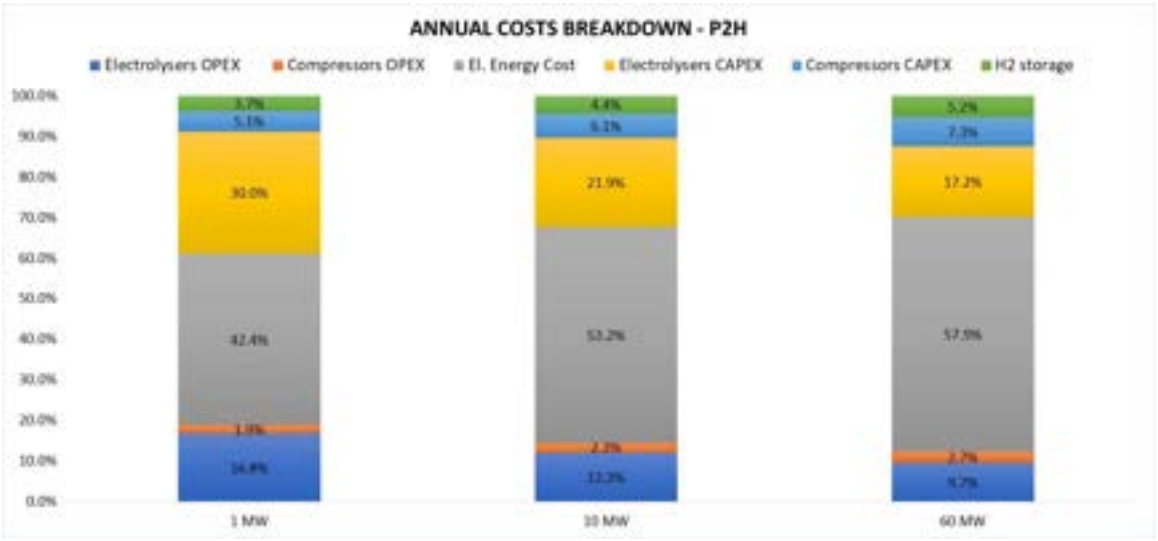

Figure. 2. Costs breakdown for P2H solutions

Figure 3 shows the main results for P2A configuration. Costs are slightly higher than in the P2H case: 0.56 M€/year for 1 MW size, 4.31 M€/year for 10 MW size and 21.12 M€/year for 60 MW size.

In the 1 MW case, most of the total annual cost (80%) is related to the electrolysers and the electrical energy costs. In the 10MW case, due to the sizing up of the electrolysers, the electricity cost, in percentage terms, becomes increasingly preponderant, around 53.5%. For the 60 MW size, as electrolysers and ammonia synthesis unit installed powers increase, their cost incidence decreases more and more, while electrical energy cost gains even more importance (61.7%).

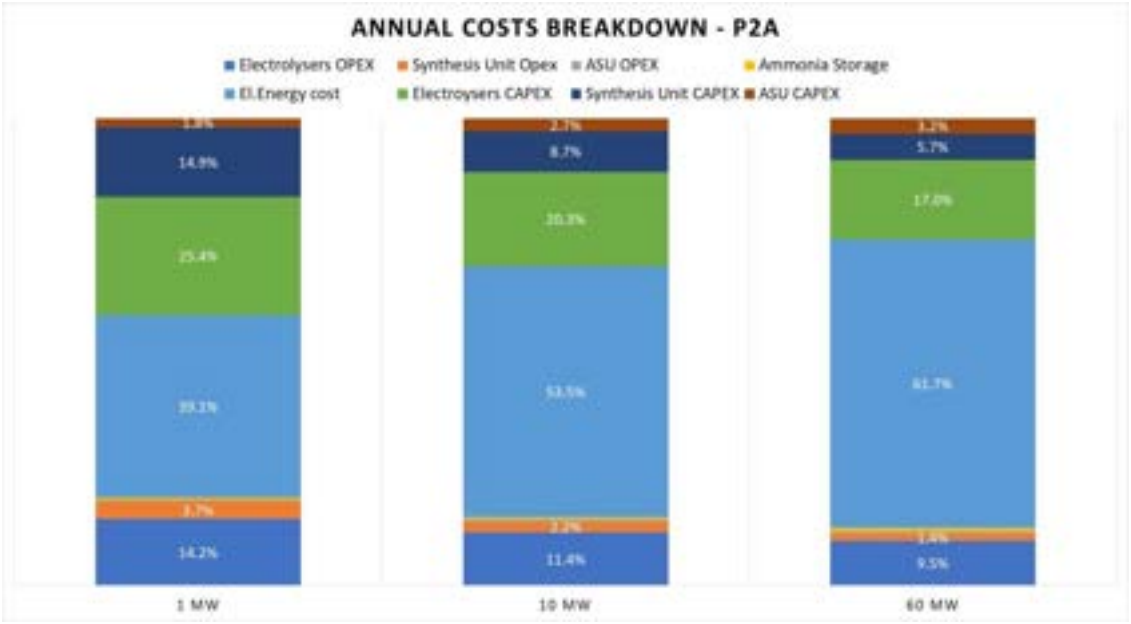

Figure. 3. Costs breakdown for P2A solutions

4.1.2. Results for different scenarios

In the previous analysis for costs breakdown, an average LCOE value of 50 €/MWh was assumed. In the present research the electrolysers are powered by renewable electricity generated by on shore/offshore wind turbine; thus, different LCOE values are investigated, according to the operating scenario. In this way, it is possible to investigate the influence of electrical energy cost. In this study, three geographic scenarios are considered: Europe, China and USA. LCOE values are obtained by 2021 data published by IRENA, reported in Table 4 [23]. Offshore wind plants are characterized by higher costs: in EU Countries the technology is well developed, thus costs are slightly lower for this kind of technology.

Table 4. LCOE estimations for economic analysis in different scenarios

	LCOE Wind on shore [€/MWh]	LCOE Wind offshore [€/MWh]
Europe	42	65
China	28	79
USA	31	78

For each scenario, the FPC for Hydrogen and ammonia are calculated. Figure 4 and Figure 5 show the main results. Production costs are positively affected by LCOE decrease and size increase (which lead to lower specific CAPEX for installed MW). As far as Hydrogen production is concerned, the lowest value is 3.1 €/kg (China, wind on shore, 60 MW) and the highest is 7.9 €/kg (USA, wind offshore, 1 MW). For P2A configuration, the FPC ranges between 0.6-1.2 €/kg for large size (60 MW) and 1.2-1.6 €/kg for small size (1 MW), depending on the cost of electricity.

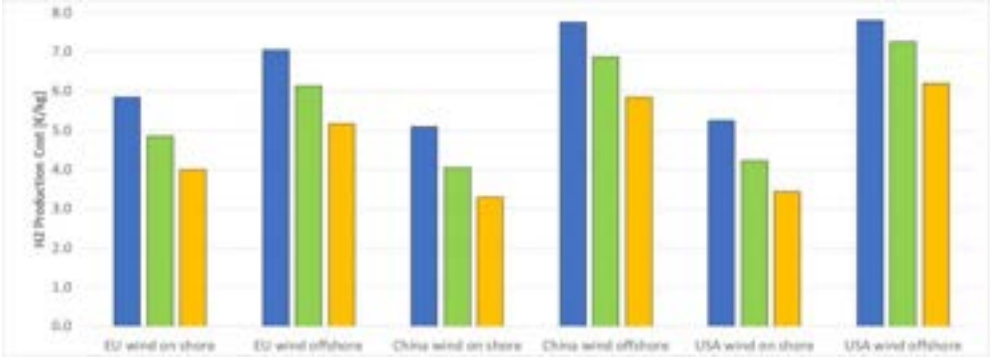

Figure. 4. Hydrogen production costs for different sizes in China, Europe, USA

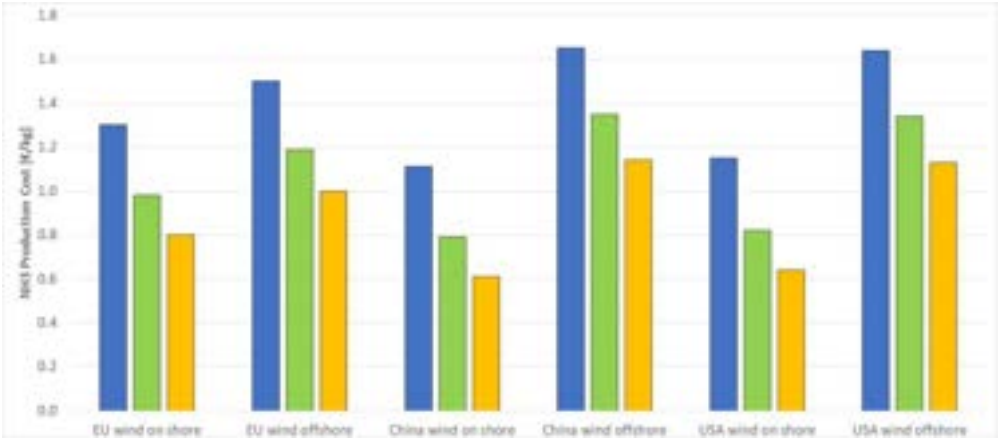

Figure. 5. Ammonia production costs for different sizes in China, Europe, USA

4.1.3. Comparison with actual H_2 and NH_3 market costs

In order to evaluate the economic feasibility of the proposed solutions, it is interesting to provide a comparison between the cost of green hydrogen/ammonia and their market prices in the last two years. Concerning Hydrogen, the most of it is produced by steam reforming of natural gas (grey hydrogen), thus its market price strongly depends on natural gas price [25]. Figure 6 compares the different H_2 production costs in the EU scenario with grey H_2 market price. While in a scenario with low-medium NG prices (until September 2021) green H_2 solutions are not economically feasible, the situation is different in a scenario characterised by high fossil fuels cost (2022). In this case, most of the green H_2 solutions, in particular the medium and large size ones become competitive from the economic standpoint.

Figure. 6. Comparison with market (grey) Hydrogen prices (2021-2022) in Europe

Figure 7 shows a similar trend for ammonia solutions, also in this case for EU scenario [26]. It is worth noting that green solutions are not affected by the fossil fuel market price variations.

Figure. 7. Comparison with market ammonia prices (2021-2022) in Europe

4.1.4. Next future scenario (2030)

In this section, the feasibility economic analysis is performed considering a next future European scenario (2030). To carry out the analysis, CAPEX reduction for PEM electrolysers is considered, starting from the study recently published by Gorre et al. [27]. In particular, according to new assumptions, specific CAPEX is 665 €/kW for 1 MW size, 470 €/kW for 10 MW size and 415 €/kW for 60 MW. LCOE from wind energy is assumed the same, considering that wind energy power plants are today a fully mature and developed technology, at least in the EU scenario. As Figure 8 shows, for on shore wind plants hydrogen costs range from 3.7 to 4.4 €/kg, with a significant reduction compared to actual costs shown in Figure 4 (from 4 to 5.8 €/kg); for offshore wind farms, H_2 costs range from 4.9 to 5.7 €/kg: also in this case, a significant reduction can be noted. The same trend is found for P2A configurations, with a minimum cost for 60 MW onshore (0.73 €/kg vs 0.8 €/kg in today scenario) and a maximum cost for 1 MW offshore (1.47 €/kg vs 1.50 €/kg in today scenario).

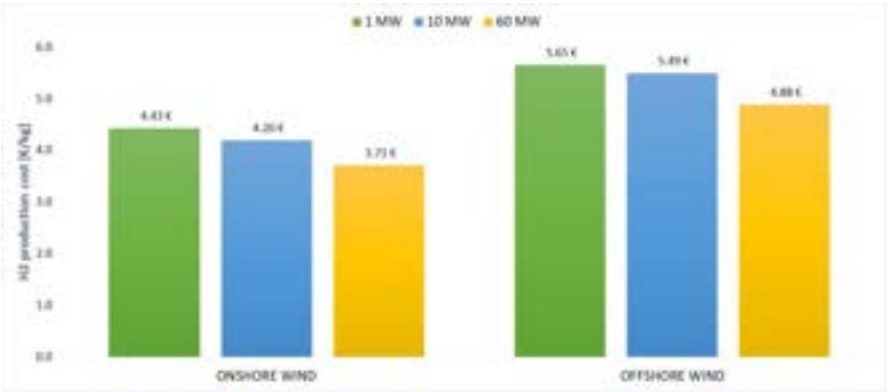

Figure. 8. Hydrogen production costs in Europe from RES (2030)

5. Conclusions

Green hydrogen and ammonia are considered among potential candidates to replace fossil fuels in the next future. However, hydrogen is still facing challenges for storage and transport. Green ammonia is another promising alternative.

The present study focused on different types of feasibility analyses:

- *Energy analysis*: for both green fuels, three different plant sizes are investigated, representative of small (1MW), medium (10 MW) and large (60 MW) electrical energy input. For the same size, electricity consumption varies within very limited ranges. The most impacting term is due to the PEM

electrolysers, which is common to both the configurations, while the impact of hydrogen compression (for P2H) and ASU/ammonia synthesis for (P2A) have a limited influence.

- *Volume analysis*: in the analysis of the overall dimensions, different results are obtained depending on the sizes. For 1 MW size, similar results are obtained for P2H and P2A configurations. In the case of medium and large sizes (10 and 60 MW), the impact of storage for P2H configuration becomes dramatic, thus this kind of solution seems not to be the best option. For large size, it is important to consider to couple different PEMEC modules, in order to guarantee also higher plant flexibility, in particular in presence of not constant/programmable RES electrical energy input.
- *Economic analysis*: the first analysis is performed to evaluate annual costs breakdown for all the sizes and the configurations investigated. The most relevant voices are electrical energy and PEMEC costs (together 75-85% of the total, depending on the configuration). Then, a scenario analysis is performed to investigate the influence of LCOE, considering both on shore and offshore wind farms, in EU, China and USA scenarios. Finally, production costs for hydrogen and ammonia are compared with market prices (2021-2022), finding out that small scale plants (1MW) are not economically feasible, if not encouraged by proper incentives. On the other hand, medium and large scale configurations (10MW and 60MW) are worthy solutions, in particular in a scenario (2022) characterized by higher natural gas cost and consequent larger production costs for grey hydrogen and ammonia.
- *Future scenarios*: in next future scenario (2030), it is realistic to assume a decrease in PEMEC market costs, which should lower green H_2 and NH_3 production costs. Furthermore, their lifetime may be extended, LCOE from offshore wind farms may be lower too and fees related to grey fuels production (or incentives to green fuels) may be included by some Countries: these latter factors may increase the economic feasibility of the solutions investigated in the present paper.

Acknowledgments

The Authors would like to acknowledge Simone Damanti, graduated student at University of Genoa, for his contribution to this research activity.

Nomenclature

AEC	Alkaline Electrolysers
AFC	Annual Fixed Costs
ASU	Air Separation Unit
FPC	Fuel Product Cost (€/kg)
IRENA	International Renewable Energy Agency
LCOE	Levelized Cost of Electricity (€/MWh)
LHV	Lower Heating Value (MJ/kg)
n	Plant lifetime (years)
PEMEC	Proton Exchange Membrane Electrolysers
P2A	Power to Ammonia
P2H	Power to Hydrogen
PSA	Pressure Swing Adsorption
RES	Renewable Energy Sources
SOEC	Solid Oxide Electrolysers
TCI	Total Capital Investment (M€)
WACC	Weighted Average Cost of Capital

External control strategy for Seasonal Thermal Energy Storage

Jarosław Milewski, Olaf Dybinski, and Arkadiusz Szczesniak

Warsaw University of Technology, Warsaw, Poland, jaroslaw.milewski@pw.edu.pl

Abstract:

The paper presents the results of using an external control strategy to optimize seasonal thermal energy storage (STES). Literature studies have been carried out related to design and optimization of the STES. Two STES configurations were considered with adequate constraints. The objective function was defined as minimum operational costs of the entire system. A structural external strategy is proposed which optimizes all heat flows based on the simplex method (Solver(R)). Simulations of system operation were carried out with and without the proposed external strategy for randomly generated outside temperatures in a 5-year horizon.

Keywords:

STES; heat management; dynamic simulation; control strategy

1. Introduction

Rising fuel prices and increasing electricity consumption are driving research into more efficient electricity and heat generation sources [1]. Energy used for space and domestic water heating constitutes 1/3 of the total energy used in industrialized countries like Poland. Fossil fuel consumption and emissions may be reduced by using solar-based technologies. For electricity generation, solar energy may be used directly (PV panels) or indirectly utilizing biofuels [2–4] applying, for example, fuel cell technology which additionally features high efficiency due to the direct transformation of chemical energy into electricity [5–14]. However, the largest market for solar energy is now connected with the absorption of solar radiation into heat up media that are flowing through solar collectors.

Optimization of seasonal thermal energy storage dates to the times when these types of installations were being constructed. According to the design idea a seasonal heat accumulator does not operate separately and is an element of a power system composed of other devices that are typical for the system. The system comprises equipment like solar collectors, heat pumps, conventional gas or solid fuel boilers, pumps, etc. Sometimes, depending on technical conditions, the system may relate to an urban heating network. This creates additional possibilities for altering the amount of heat accumulated in the storage tank and makes the whole system more elastic. It should be noted that, particularly in the case of smaller installations, the urban heating network has an incomparably larger capability of storing heat when compared with the heat accumulator. Considering the set of parameters and external factors influencing the operation of devices and the whole system, a respective operation optimization algorithm for the system seems to be indispensable.

It should consider the specific features of all devices. In addition, it should be matched to the nominal design point of the system when applying it to an existing object or be given the flexibility to select individual devices (their size, operating parameters, etc.) if it is used at the design stage. During optimization particular attention should be focused on the accumulator itself and its interplay with other objects. Devices mentioned earlier that are part of the system, like solar collectors, heat pumps, boilers, etc., are generally commercially available and their operation characteristics and parameters are known. This does not however apply to the storage tank. There are several types of storage [15] that should be taken into consideration. Moreover, insulation plays a vital role here—its thickness, conductivity and above all resistance to ground humidity, which significantly increases the conductivity (this type of storage tank is usually partly or totally immersed in the ground). In the available literature there are few papers that include the optimization of system operation with a storage tank. There are however articles where a significant emphasis was put on optimization of the cooperation between an accumulator and an external network as well as with a co-generation plant, as in [16]. The authors use the commercial Excel (R) environment and the Monte Carlo method to select the optimal size of the accumulator. The analysis was made for three cases: for the cogeneration system electric power of 40 kW, 80 kW and 160 kW. Some authors present modelling methods and optimizing algorithms for storage equipped systems cooperating with a central air conditioning system in public utility buildings [17,18]. This case is somewhat different as cold instead of hot water is stored, but the idea remains substantially similar. The accumulator is charged during the night using cooling units (when electricity prices are lower) and discharged during the day,

when the cooling demand and electricity prices are higher. The authors analysed 5 operation scenarios for the system: cooling, storage charging, storage charging with operation of cooling units, discharging, discharging with operation of cooling units. It should be mentioned that the storage tank operates diurnally, and not seasonally. In other work [19] operation optimization of the accumulator is performed including economic conditions like variable electricity prices and climate changeability.

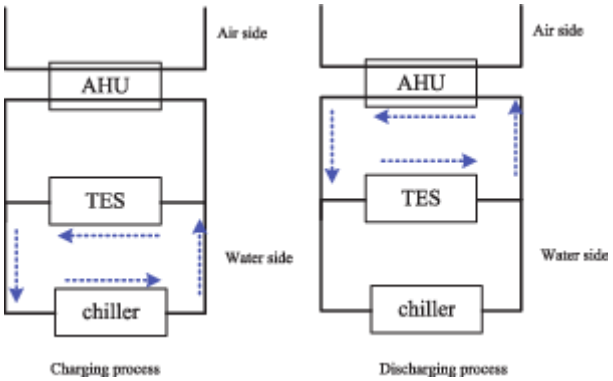

Figure 1: Diagram of charging and discharging processes for a thermal energy storage tank (TES) [18]

In fig. 1 a diagram of the charging and discharging process for a storage tank was presented according to [18]. In the paper, seasonal storage was analysed, where additional parameters considered during the modelling and optimization process were considered, e.g., variable ambient and ground temperatures.

Seasonal heat storage was analysed in the study [20], where the discussed installation was placed in a public utility building with a surface area of 3,700 m2. In contrast to the device investigated in this paper, a UTES (Underground Thermal Energy Storage) equipped with a heat pump was used.

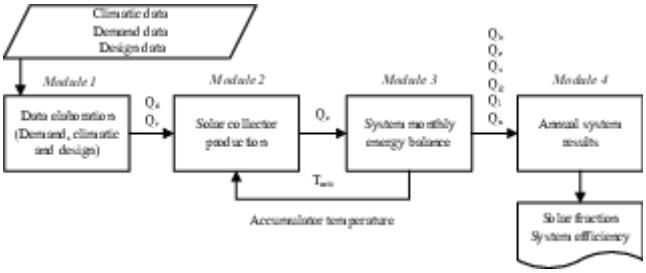

Figure 2: The block diagram used for calculations for the system analysed in [21]

In the paper [21] the authors proposed a simplified method for Central Solar Heating Plants with Seasonal Storage systems. The simplified method was graphically depicted in Fig. 2. Additionally a dynamic analysis of the system in TRNSYS [22] and an economic analysis were done by the authors.

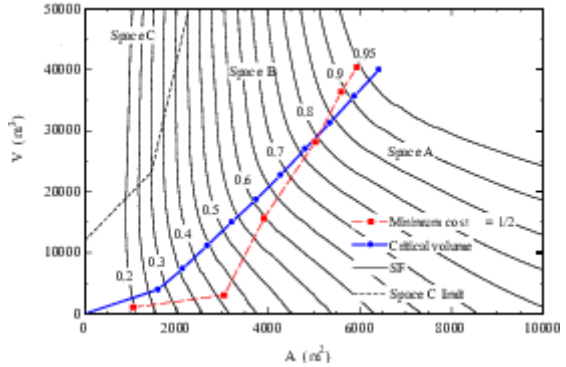

Figure 3: Solar collector area and volume of seasonal storage, isoquant lines of solar fraction [23]

In the same study, an authorial relationship diagram between the storage volume and the solar collector surface area was presented. In the diagram the Space C limit was presented that, according to the analysis made by the authors, is ineffective from the aspect of cooperation between the collectors and the storage tank. The authors also estimated that if the cost of the storage tank alone was decreased by about 50% and the investment costs that need to be borne for solar collectors and other, auxiliary devices, then the introduction

of a storage critical volume could become an attractive idea from the economic viewpoint (also shown in the graph).

In the study [23] a comparison was made of various modelling methods for systems comprising seasonal thermal energy storage. These methods were used in Engineering Equation Solver [29], which was also used to generate yearly operation characteristics for a system with storage. Except for the simplified method presented by the authors, two others were also analysed. One of them is a 1979 method proposed by Lunde [24,30], and the other from 1981 by Braun, Klein and Mitchell which they named BKF [16]. The list of modelling methods was presented in the Table 1. An integral element of this research was comparison of the results with simulations performed in the previously mentioned TRNSYS software (it is also mentioned in the table 1).

2. Base for calculations

2.1 Optimization method—Solver(R)

Optimization of the storage operation was performed using Solver(R) available in Excel(R)environment; detailed information on this topic may be found in [31]. When linear optimization is conducted using Solver

a numerical procedure is used called a simplex algorithm [32–35]. The simplex method, first proposed by George Dantzig in 1947, is the first algorithm of numerical optimization developed for the American army and widely used (in many variations) till the present day. The simplex method is basic and universal and enables one to solve all kinds of linear models. This is an analytical method allowing for computing models independent of their size. There are several versions of realizing the simplex algorithm, but, except for different ways of calculating and methods of improving the algorithm convergence, the idea remains unchanged. This method requires however that many calculations be made during the solving of the model and the calculation itself is iterative.

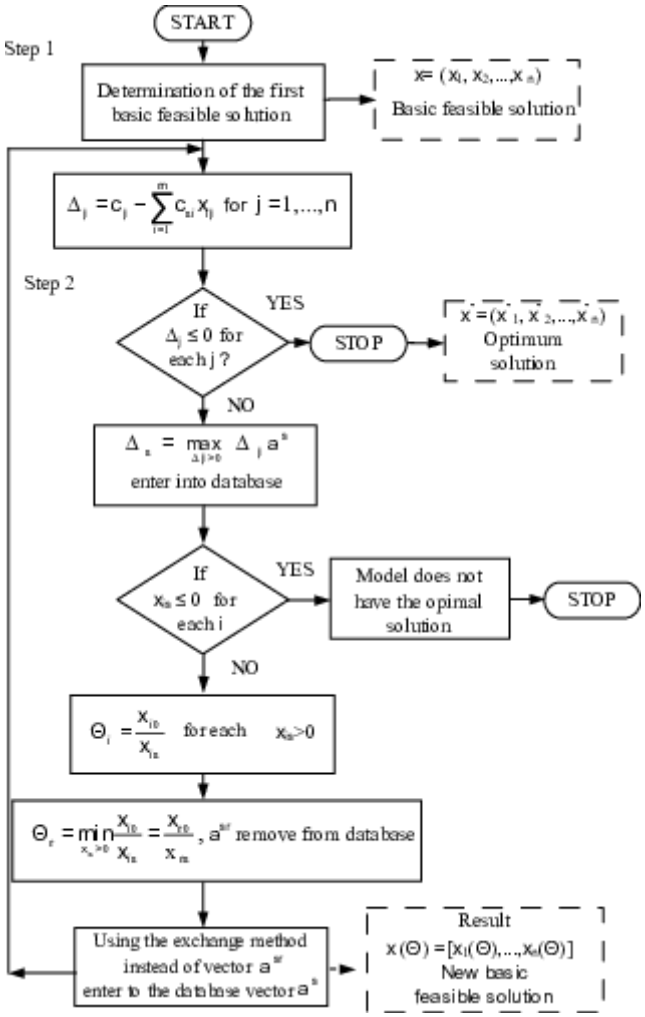

Figure 4: Block diagram of the simplex method (example for a model where the objective function is maximized) [36]

In the simplex algorithm, two basic stages may be distinguished. The first one consists of determination of the basic allowable solution. This may be achieved by introducing additional decision variables into the model. The second stage comprises correction of subsequently performed iterations of the basic allowable solution until an optimal solution is found if the solution exists. The correction of solutions is in fact tantamount to the generation of new basic allowable solutions and checking them from the angle of optimality. The value of the goal function for the subsequent solution (when the objective function is maximized) is often higher than the one before. It is possible that during computations the objective function value will be equal to the objective function value from the previous solution. It may not however be lower. There is a clear analogy in the case of minimizing the objective function. Calculations made with the simplex method have an iterative character. There are two criteria in the method, giving the possibility of terminating calculations and assessing whether the base solution is an optimal one or not; and if not, whether more solutions may be generated. The simplex algorithm is quite labour–intensive, particularly for large–scale models. Computer applications of the algorithm are used to solve such models. Many programs assisting mathematical calculations allow for the development of calculation procedures for the simplex method or are equipped with ready-made simplex modules, like Solver. The simplex method allows one to solve continuous models of linear programming. A block diagram of the method is presented in Fig. 4; in the next iteration of the simplex method the following cases are possible:

- $\Delta_j \leq 0$ for every j = 1, 2, ..., n is a basic, allowable solution,

- $x_{is} \leq 0$ for every $i = 1, 2, ..., n$ then the model does not have an optimal solution,
- there exists $\Delta_S > 0$ and there exists $x_{is} > 0$ then a new basic allowable solution may be obtained.

The simplex algorithms make it possible to go from one basic solution to subsequent ones, usually more correct due to the value of the objective function. Iterations are made if the optimal solution is obtained, if it exists. The quantity of iterations that need to be made when solving a model and achieving an optimal solution cannot be precisely specified. It is known that for a set of n decisive variables and m substantial limiting conditions, the number of base solutions is at a maximum:

$$\binom{n}{m} = \frac{n!}{m! \cdot (n-m)!}$$

The simplex method does not search all the base solutions, merely selected ones. The way of selection is directed. For most cases the algorithm is convergent within a finite number of iterations. From calculation experience it may be concluded that the number of iterations performed is embraced within the limits of the number of substantial limiting conditions to the triple of the number of conditions. Iteration number estimation commonly present in the literature is equal to $2 \cdot (n + m)$. All the data result mainly from computational experience and are solely estimated values.

It must be noted that the simplex method included in the Solver package is based on differential calculus, which has the effect that for significantly non–linear tasks, it does not give correct results. For this reason, the temperatures in the accumulator were set at 60°C before every optimization (mean value between the extreme values 40/80°C). In the future, methods based for example on artificial intelligence should be used [37–42].

2.2 The objective function

The operation criterion for the optimizer may be an economic function that will, for example, minimize the operating costs of STES operation. Therefore, the optimization goal will be to maximize the profit, which may be understood in different ways. A total profit/loss balance includes many various elements, including income or costs of a typical financial origin. Optimization does not influence these costs and it is not sensible to include them in the optimization process. Optimization influences operating costs. For this reason, the total operating cost in the analysed period will be the objective function, i.e., for periods n (from the beginning of calculations), n+1 till periods n+3 or n+6 respectively depending on the selected calculation mode. It may present mathematically as:

$$\mathrm{K_o} = \sum \mathrm{K^i_{Fuel}} + \Delta \mathrm{K_{HeatStorage}} - \sum \mathrm{K^i_{Penalty}} - \sum \mathrm{K^i_{Power}}$$

where: i —index of the following calculation steps; $\Delta K_{HeatStorage}$ —cost resulting, and amount of heat accumulated at the beginning and at the end of the analyzed time period (or from the price difference); K_{Fuel} —fuel cost in the subsequent calculation steps; $K_{Penalty}$ —penalty for heat not taken from the collectors; K_{Poweri} —cost of the consumed electricity.

Cost of fuel used for supplying other heat sources in consecutive settlement periods will be calculated as:

$$\mathrm{K^i_{Fuel}} = \mathrm{B^i_{NG}} \cdot \mathrm{k_{NG}}$$

where: B^i_{NG} —use of natural gas in respective calculation step; k_{NG} —unit price of the natural gas.

Cost of electricity supplied to auxiliary devices and the heat pump in consecutive settlement periods will be calculated as:

$$\mathrm{K^i_{Power}} = \frac{\mathrm{Q_{STES}}}{\mathrm{COP_{HP}}} \cdot \mathrm{k_{Power}}$$

where: Q_{STES} —heat taken from the accumulator; COP_{HP}—heat pump COP; k_{Power} —unit price of electricity.

Heat supplied to the buildings must maintain the right temperature level, which may not be achieved directly from the storage tank when its temperature drops below the returning water temperature.

Coefficient of Performance of the heat pump depends on the temperature difference between the upper and lower heat sources and its perfectness (with respect to the Carnot cycle); in the calculations the following relationship was assumed:

$$\mathrm{COP} = \eta_{\mathrm{HP}} \cdot \frac{\mathrm{t_{DH}} + 273.15}{\mathrm{t_{DH}} - \mathrm{t_{STES}}}$$

where: η_{HP} —heat pump perfectness; t_{DH} —temperature of water fed to the heating grid; t_{STES} —temperature in the storage tank.

The heat stream fed to the local heating grid was not optimized. It is not set and is independent of the control system operation. This value is not included in the objective function. The system incorporates a heat storage tank, therefore heat generation is not equal to the heat sale. Heat generation in the period for which forecasts were made may be different than the heat sold. As a result, it is necessary to consider the difference between

heat sale and heat generation. Heat prices are not variable in time, so only the total heat difference was included. It will be calculated as the difference between the heat kept in storage at the beginning of the analysed period and the heat at the end. Presented below is the relationship describing the cost resulting from the change:

$$\Delta K_{HeatStorage} = (Q_{Final} - Q_{Initial}) \cdot k_{HeatStorage}$$

where: $\Delta K_{HeatStorage}$ —cost of avoided heat sale that was accumulated in the storage tank during the analysed period; Q Begin —amount of heat accumulated at the beginning of the analysed period; Q Final —amount of heat accumulated at the end of the analysed period; $k_{HeatStorage}$ —unitary heat price of the heat accumulated in the storage tank. On the other hand, optimization with the condition that the amount of heat stored at the end must be equal to the heat stored at the beginning may be conducted.

In the period n or n and n+1 storage operation will be optimized by controlling its work so that it will be possible to realize the planned heat production and to recover all the heat generated in the solar collectors. Should the forecasts alter to the extent that it will not be able to balance the production, then the costs of heat generation from other sources or of heat lost that was generated by the collectors will be considered. The objective function contains a penalty element for unrecovered heat from the solar collectors and for over cooling of the storage tank in the following form:

$$Q^i_{Solar} > Q^i_{Plan} \text{ then } K^i_{Penalty} = K_{Overload} + k_{Overload} \cdot t \cdot Q^i_{Overload}$$

$$Q^i_{Overload} = Q^i_{Solar} - Q^i_{Plan}$$

$$Q^i_{Solar} = Q^i_{Plan} \text{ then } K^i_{Penalty} = 0$$

$$Q^i_{Solar} < Q^i_{Plan} \text{ then } K^i_{Penalty} = k_{Subcooling} \cdot t \cdot Q^i_{Subcooling}$$

$$Q^{\{i\}}_{\{Subcooling\}} = Q^{\{i\}}_{\{min\}} - Q^{\{i\}}_{\{Plan\}}$$

where: Q^i_{Solar} —heat recovered from the solar collectors in the i^{th} time interval for current heat forecast; Q^i_{Plan} —heat supplied to consumers in the i th time interval resulting from the forecast; $K^i_{Penalty}$ —penalty value; t — length of the time interval, month, week, day, hour; $k_{Overload}$ —coefficient of the penalty function for heat overproduction; $k_{Subcooling}$ —coefficient of the penalty function for heat underproduction (cost of heat supplied to the storage tank from auxiliary sources); Q^i_{min} —minimum of heat kept in storage; $Q^i_{Overload}$ —heat not recovered from the collectors in the i^{th} time interval.

Table 2: Objective function parameters for optimization processes

Parameter	Value*	Comment
kNG, EUR/GJ	12	cost of natural gas fed to the central heating boiler
kPower, EUR/GJ	44	cost of electricity supplied to the heat pump
kSubcooling, EUR/GJ	kNG	heat of additional heating of water in the boiler by a gas/coal boiler/heating grid or/and the heat pump
kOverload, EUR/GJ	6.0	cost of heat lost, full storage charging at positive balance of heat production from the collectors and heat demand

*at conversion rate EUR/PLN=4.2

Table 2 contains selected coefficients used in the developed objective function. The coefficients may vary depending on the season of the year and geographic location (country) as well as local conditions. The cost of natural gas supplied to the central heating boiler was calculated on the assumption that boiler efficiency was 80% and the gaseous fuel tariff was according to [43]: w-5 (gas) and E-1A (distribution) after PGNiG S.A. (in total 1.3678 PLN/Nm3); LCV was assumed to be 35 MJ/Nm3.

The cost of electricity supplied to the heat pump was assumed to be equal to the value mentioned in [44]— one–zone tariff C11 (“Simplest for your company”) after RWE Poland S.A. (0.6587 PLN/kWh). Heat lost in the case when the storage tank is fully charged and the collector heat production exceeds the amount of heat consumed was calculated for Hewalex KS2000 TP AC flat collectors [45]. The net price for this device is 151.04 EUR per m2 of working surface. It was assumed that the lifetime of solar collectors ranges from 15 to 25 years [46]. The cost of lost heat was calculated on the assumption that the collectors will work for 15 years (safer variant). All the above costs as well as other parameters and results presented in this work were determined using the currency conversion rate of PLN 4.2 = 1 EUR.

The presented methodology is also valid for other—not necessarily cost balance based—criteria. These could be the CO2 emission criterion [47,48], minimization of fossil fuel consumption or the idea of energy storage of external origin (e.g. at low electricity prices, which might even be negative as a Danish example showed).

2.3 Limitations

Optimization limitations

1. Water temperature in the storage tank: 40 .. 80C
2. Maximum storage charging/discharging rate, Δt_{STES}/month
3. Maximum heating power of the grid, Q_{DH}/month
4. Maximum heating power of the solar collectors, Q_{Solar}/month
5. Maximum heating power of the gas boilers, Q_{Boiler}/month

Except for limitations regarding the sole optimization process, the system model contained internal constraints not allowing the overheating or over-cooling of the storage tank, ti.e. it did not allow t_{values} outside of the range of 40 .. 80°C, however shut-off of those limitations was also possible.

2.4 Analysed case

To determine the possibility and test the proposed solutions a structure containing all typical devices cooperating with seasonal heat storage tanks was selected. Hence, the analysed system contained the following elements:

- flat solar collectors [45]
- heat pump of COP 3.5 [49]
- fossil fuel boilers (natural gas)

a: Variant I b: Variant II

Figure 5: Tentative depiction of both analysed variants

Two configuration cases for the whole system were considered:

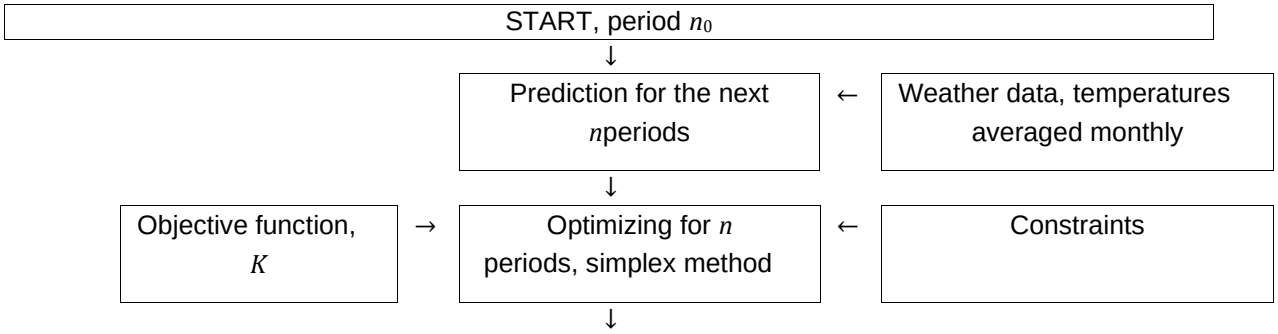
1. Variant I, where the collector area was selected in such a way that their heat production corresponded to 100% of the heat demand in a yearly cycle—heat losses from storage were not covered by solar energy.
2. Variant II, where STES had to cover 100% of the heat demand and the solar collector area was chosen so that it also covered the heat losses from the accumulator.

Both cases differ in collector size and the heat capacity of the storage tank—see fig. 5.

3 Optimizing algorithm for the Seasonal Thermal Energy Storage system

3.1 Description of the main algorithm

A structural (hierarchical) optimizing algorithm is proposed for a Seasonal Thermal Energy Storage system. Based on the algorithm several layers cooperate with each other to obtain a solution of the previously defined problem.



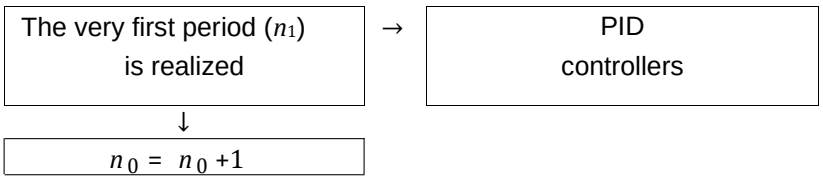


Figure 6: Optimizing algorithm for STES

Fig. 6 presents a block diagram of the proposed optimizing algorithm for STES. In the very first step, the prediction of heat consumption for the next n periods (e.g., 11 months) is made. The prediction may be based on forecast weather, temperatures, etc.; in the calculations randomly generated temperatures at the average level for Warsaw are used. Based on the forecast heat consumption and possible heat production/accumulation, the optimizing process is utilized for the chosen objective function while fulfilling the given limitations.

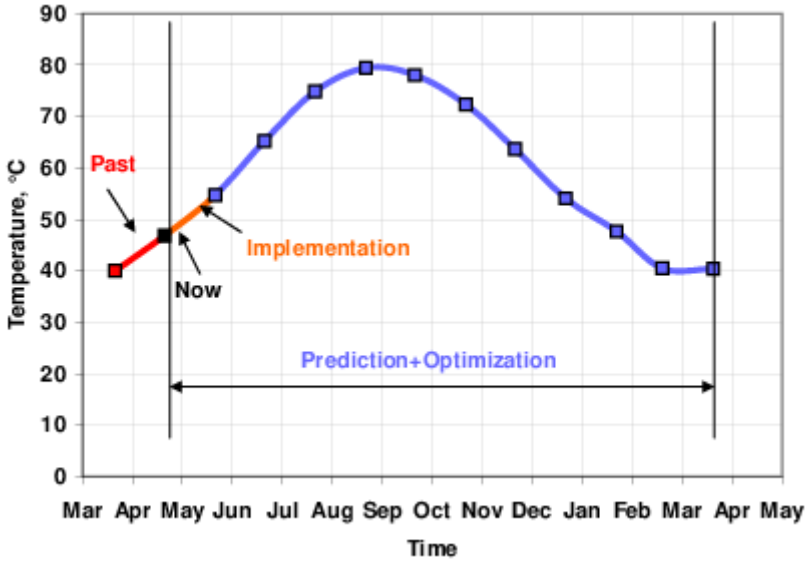

Figure 7: An example of utilization of the optimizing algorithm

Based on the obtained operational line for the next n periods (11 months), only the very first period is really done—see Fig. 7—and adequate PID controllers are set to fulfil the ending point. The rest of the operational line is deleted and no longer considered, but the whole process is repeated.

3.2 Choosing a design point of the system

The optimizing procedure regards the current period and next n periods (e.g., 11 months, so it is possible to use the algorithm to determine a design point for the whole system (solar collector area, water tank volume, etc.) based on the chosen/known heat consumption profile and averaged monthly weather data.

- In this case, the optimizing algorithm needs to be supplemented by two independent variables:
- solar collector area in relation to heated area, m2/m2
- water tank volume in relation to heated area, m3/m2

Table 3: Design point parameters chosen during the optimizing processes

Parameter	Case I	Case II
Heated area, m2	100	100
Solar collector area, m2	17	25
Tank volume, m3	70	102
Objective function value, EUR/a	113	52

By utilizing the optimizing algorithm, the design point parameter of the STES system was found as well as the temperature distribution during the year. (see Table 3).

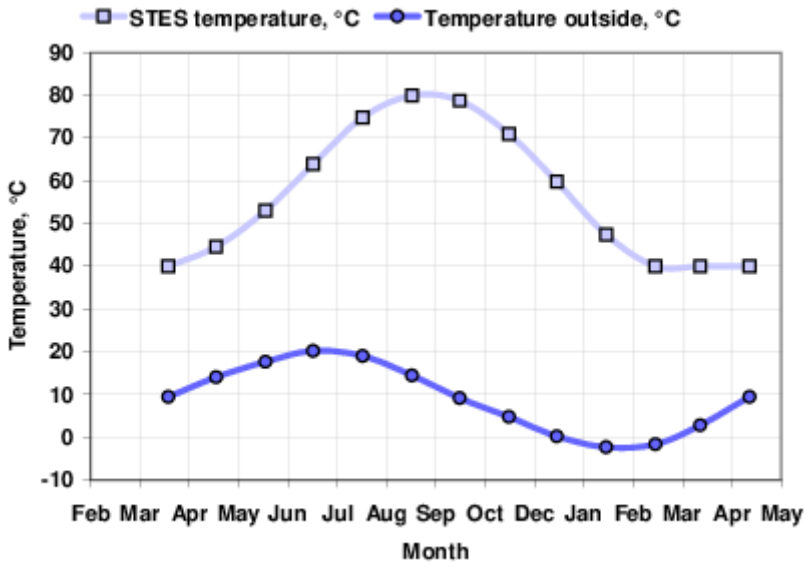

Figure 8: Monthly averaged temperatures distribution at the design point for Case I

Fig. 8 presents the temperature forecast at the design point, and related water temperatures in the tank.

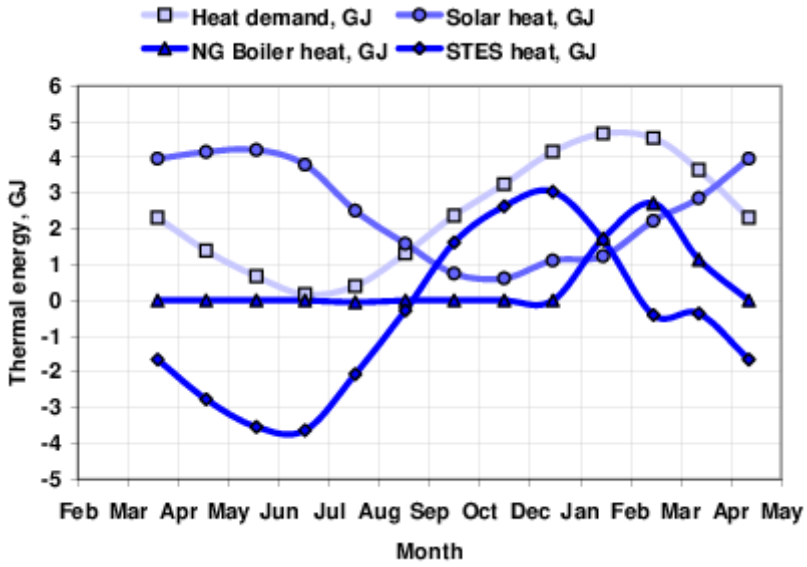

Figure 9: Heat generated by the system elements at the design point for Case I

Fig. 9 presents the amount of heat generated by the system elements in order to cover heat demand at the design point and chosen heat consumption profile. The negative values of heat fluxes denote that the charging process of the STES tank is in progress.

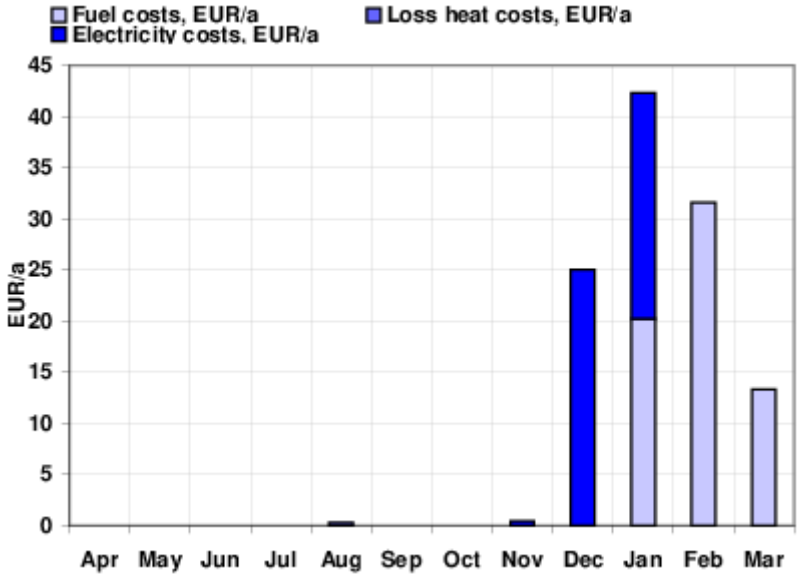

Figure 10: Objective function at the design point for Case I

At the design point for Case I, the value of the objective function is 113 EUR/a (for 100 m2); specific components of the function are presented in Fig. 15, the highest cost is electricity delivered to the heat pump in the periods when the water temperature in the tank falls below 60○C, the second highest cost is the fuel used in the boilers to cover heat demand when there is a fully discharged heat storage tank.

4 Conclusions

An external control strategy and optimizing algorithms are proposed for supporting the STES operation.

Table 4: Summary of all analyzed scenarios

Parameter	Case I limited	Case I optimized	Case II	Case II limited	Case II optimized
Averaged yearly costs, EUR/a	113	109	52	60	57
Water tank volume, m^3	70	70	102	102	102
Solar collector area, m^2	17	17	24	24	24
Minimum water temperature, °C	40	40	36	40	40
Maximum water temperature, °C	80	80	84	80	80
Maximum charging speed, GJ/month	3.8	3.9	5.3	5.3	5.3
Maximum discharging speed, GJ/month	3.3	3.3	3.4	3.4	3.0
Maximum heat produced by Natural Gas boiler, GJ/month	3.9	3.8	–	1.3	1.1
Maximum heat produced by solar collectors, GJ/month	4.2	4.2	5.8	5.8	5.8
Maximum heat demand, GJ/month	5.2	5.2	5.2	5.2	5.2

Table 4 presents a summary of all analyzed cases. The operating costs of systems with smaller sized devices (solar collectors by 41%, and water tank volume by 45%) are two times smaller than for the bigger sized system. Profits from utilization of the external control strategy are relatively small, on level 4...5%. Apart from economic profits, using the proposed external control strategy lowers the maximum heat produced by the natural gas boiler in the range 3...18%.

Use of the external control strategy does not provide spectacular profits, but theoretically a huge water tank can be run without any control system merely by applying a simple regulation system.

Acknowledgments

The research results presented in the paper were achieved within the project entitled “Development of the underwater autonomous transport system” (no. POIR.01.01.01-00-1514/19), co-financed by the Polish National Centre of Research and Development.

Abstract:

Thermochemical energy storage is the least investigated thermal energy storage technology. Nowadays, research on this technology's development is very intensive, including high, medium, and low-temperature applications. However, for thermochemical energy storage technology to get market maturity, still many problems must be solved, and reliable design and optimization tools must be developed. The concept of such a tool, i.e., the multi-dimensional numerical model of the charging/discharging low-temperature thermochemical storage unit, is presented in this paper. The model considers hydration/dehydration reactions in the thermochemical medium working in the open system. It accounts for local hygric and thermal non-equilibrium at the macroscale by treating heat and moisture carrier fluid (moist air) and reactive porous bed separately. Therefore, two sets of governing equations have been derived, i.e., one dealing with moisture and heat transfer in the air flowing through the porous bed and the second one with phenomena occurring in the reactive porous bed. The model assumes regular regimes of heat conduction and moisture diffusion in the bed particles and a fast sorption/desorption rate in thermochemical materials. Moreover, it is assumed that the water removal from the bed particle surface controls the chemisorption process as being slower than reaction kinetics. The proposed model was simplified to heat storage using sorption/desorption phenomena and implemented in 2D axisymmetric space using commercial software. Such an approach allows for easy adjustment and modification of the reactor geometry in the design and optimization path. Then the model in simplified form was applied for the simulation of a sorption-based thermal energy storage unit. Parts of the charging and discharging phases were simulated. However, the long simulation time is the particular issue limiting the current broader testing and applications of the model.

Thermochemical energy storage; Hydration/dehydration; Numerical modeling; Non-equilibrium model; Sorption/desorption;

1. Introduction

To date, global energy consumption significantly relies on fossil fuels which are closely related to carbon dioxide (CO_2) emissions, contributing to climate change. Increasing global energy demands caused by rapid industrialization and population growth and, therefore, acceleration of fossil fuel depletion and the additional need for environmental protection attracts attention to the effective use of the other available energy sources, including renewable ones. These sources often deliver energy in times and locations different from its demand. This leads to an economically unjustified loss of useful energy.

The crucial role of energy storage systems is to reduce the time or rate of mismatch between energy supply coming from different sources and energy demand at a specific time and location. Among the energy storage systems, thermal energy storage (TES) is an important energy conservation technology to store heat and cold for later use [1]. Thermal energy can be stored as sensible heat, latent heat, and thermochemical energy or combinations of these methods [2]. Much research and development work has been carried out in the first two methods of the TES. The sensible heat storage associated with increased temperature of the storing material

is used in many domestic and industrial applications. The method requires a high heat capacity of the storing materials and very good thermal insulation of the storage system to reduce heat losses. These two features are the most significant drawbacks and limitations of sensible heat storage. The latent heat storage uses phase transformations associated with the absorption or release of heat during, e.g., melting/freezing. Therefore, it needs phase change materials (PCMs) of high latent heat and good thermal transport properties to effectively transfer heat to and from the storage. This storage technology has many lab-scale and market applications, including PCM in storage tanks [3] and in different elements of building envelopes [4-7]. However, the drawback of this storage technology, among others, is the low thermal conductivity of PCMs, which significantly limits the heat transfer rates during charging/discharging and heat storing at temperatures different than the temperature of the surroundings and related heat losses. Thermochemical energy storage (TChES) is one of the least investigated heat storage methods. However, it is the most promising and attractive technology because it offers the highest energy storage density of the three methods and allows for storing thermal energy at negligible heat loss for a long time by species separation [2]. Another difference between PCM-based storage and TChES in which gaseous product appears is that the former depends on temperature only, while the latter has an extra control parameter, namely the gas pressure, which follows from the equilibrium curve in the phase diagram of thermochemical material [8]. Recent developments in low/zero energy buildings promote the development of low-temperature TChES systems.

Mathematical models of TES units/systems using sorption and chemical reactions pose many difficulties in mathematical formulations and equations solutions. These processes are complicated and differ from the well-known and analyzed classical flow phenomena with heat transfer. In the TChES, it is required to simultaneously deal with the fluid flow and heat and mass transfer in the porous bed accompanied by sorption or chemical reactions, the dynamics of which also affect the system's operation [9]. Due to the large number of physical phenomena that need to be modeled and the need to combine equations that describe fluid flow, thermal, and chemical processes, modeling these phenomena was significantly simplified.

Several numerical approaches have been proposed to investigate the heat and mass transfer processes in the reactive packed bed and in the whole TChES units/systems. The most simplified are purely thermodynamic approaches based on energy and exergy methods to assess the closed or open-loop TChES systems/units [10, 11] or reaction cycles for the TChES systems/units [12]. The second group of the models is lumped-element or 0D models [13, 14], which provide general information on the TChES unit/systems operation. The next group is the 1D models, which can simulate the variation of the working medium and reactor parameters along the flow path [2, 9, 15, 16]. The most complex approaches are multi-dimensional (2 and 3D) models [17-21] capable of predicting fluid flow and thermal and chemical states at any time of the process and any point in the storage unit/system and, therefore, are applied for multi-criteria analyses of TChES units/systems.

Most of the TChES units/systems models assumed many simplifications. For example, local thermal equilibrium between working gas and the porous bed was applied [17-19, 21], the gas flow was modeled as isothermal [17-19], the flow of the gas in the porous bed was evaluated through Darcy law [17-19, 21], vapor transfer dynamics was omitted [17-21]. These simplifications are understandable and justified. The phenomena controlling the TChES process are very complex, and their modeling requires many assumptions to solve the problem. However, this paper will try to alleviate some of the mentioned assumptions by treating simplified or omitted phenomena more rigorously than in the previous works [17-21]. The proposed new 2D macroscale model, based on the previous 1D approach [9], considers low-temperature hydration/dehydration reactions in the TChES unit working in the open system. It assumes hygric and thermal non-equilibrium between the working medium (moist air) and the reactive porous bed and, in this way, accounts for the peculiarities and dynamics of heat and mass transfer processes in a porous bed. The model may be applied to simulate the chemical and physical sorption-based storage process.

2. Macroscopic mathematical model of TChES unit

This chapter contains a description of the complex TChES unit model. The model consists of the unsteady equations set describing the transport of momentum, mass, energy, and moisture in the gaseous phase and the transport of energy and moisture in the solid phase (porous bed). The first equation, i.e., the continuity equation for moist air in the storage, is written as follows:

$$\varepsilon_b \frac{\partial \rho_m}{\partial t} + \nabla \cdot (\rho_m \vec{u}) = 0, \tag{1}$$

where: ρ_m is the moist air density, ε_b is the reactive bed porosity, $\vec{u}$ is the velocity vector, and t is the time. The laminar flow was assumed to simplify the case. Therefore, the momentum equation is the following:

$$\frac{\partial \rho_m}{\partial t} + \nabla \cdot (\rho_m \vec{u}\vec{u}) = -\nabla p + \nabla \cdot \mu_m \left[(\nabla \vec{u} + \nabla \vec{u}^T) - \frac{2}{3} \nabla \cdot \vec{u} I \right] - \frac{\mu_m}{k} \vec{u} + C_2 \frac{1}{2} \rho_m |\vec{u}| \vec{u}. \tag{2}$$

In the equation above, p is the static pressure, I is the unit tensor, and μ_m is the moist air dynamic viscosity. The two last terms of Eq. (2) are source terms accounting for the porous zone region. The factor k is the permeability of the reactive bed, and coefficient C_2 is used to include inertial pressure losses. The moisture

must be properly managed in the reactive bed for proper storage work. During the charging cycle, dry air flowing through the bed should remove moisture from the system. In the discharging cycle, the moisture is supplied to the system as water vapor in the moist air. The following non-equilibrium equation describes the moisture transport in the air in a porous bed:

$$\varepsilon_b \frac{\partial \rho_g \omega}{\partial t} + \nabla \cdot \left(\rho_g \vec{u} \omega\right) = \nabla \cdot \left(D_{vb,eff} \nabla \omega\right) + A_b \alpha_{m,eff} \left(\rho_{v,e} - \rho_v\right), \tag{3}$$

where: ρ_g is the density of dry air, ω is the specific humidity (per mass of dry air), $D_{vb,eff}$ is effective vapor diffusivity in air, A_b is the specific surface area of the porous bed, $\alpha_{m,eff}$ is the effective mass transfer coefficient for water vapor, $\rho_{v,e}$ is equilibrium density of water vapor at the surface of bed particles, and ρ_v is the density of the water vapor in moist air. The non-equilibrium thermal model is applied to account for the porous zone's energy transport. The source term in the energy equation includes heat transport between the bed and gaseous phase and the energy transport caused by moisture exchange. Therefore, the energy equation for the moist air is written as:

$$\varepsilon_b \frac{\partial \rho_g \left(c_{v,g} + \omega c_{v,v}\right) T_f}{\partial t} + \nabla \cdot \left[\rho_g \vec{u} \left(c_{p,g} T_f + \omega c_{p,v} T_f + \frac{p}{\rho_g}\right)\right] = \nabla \cdot \left(\lambda_{m,eff} \nabla T_f\right) +$$

$$A_b \left[\alpha_{m,eff} c_{p,v} \left(\rho_{v,e} - \rho_v\right) + \alpha_{T,eff}\right] \left(T_s - T_f\right), \tag{4}$$

where: $c_{v,g}$ and $c_{p,g}$ are the specific heats of dry air at constant volume and pressure, respectively, $c_{v,v}$ and $c_{p,v}$ are the specific heats of vapor at constant volume and pressure, respectively, T_f is the temperature of moist air (working fluid), $\lambda_{m,eff}$ is the effective heat conductivity of moist air, $\alpha_{T,eff}$ is the effective heat transfer coefficient between gaseous phase and solid particles, and T_s is the temperature of the porous reactive bed. In the mass balance equation for the solid phase, the formation of new substances during the chemical reaction is taken into account. It is assumed that water in particles occurs only in the bound state of component A (hydrate). There is no diffusion between hydrated component A and dehydrated component B. Therefore, the mass balance equation can be written as:

$$\left(1 - \varepsilon_b\right) \frac{\partial \left(\rho_A + \rho_B\right)}{\partial t} = -A_b \alpha_{m,eff} \left(\rho_{v,e} - \rho_v\right), \tag{5}$$

where: ρ_A is component A's density and ρ_B is component B's density. The degree of transformation of species A into B varies with the location and time. The equation describing this parameter is the following:

$$\beta(\bar{x}, t) = \frac{C_{A0}(\bar{x}) - C_A(\bar{x}, t)}{C_{A0}}, \tag{6}$$

where: $\bar{x}$ is the position vector, C_{A0} is the initial molar concentration of component A, and C_A is the actual molar concentration of species A. The final expression describing the degree of transformation of species A into B is as follows:

$$\frac{\partial \beta}{\partial t} = \frac{A_b \alpha_{m,eff} \left(\rho_{v,e} - \rho_v\right)}{C_{A0} M_{AB} \left(1 - \varepsilon_b\right)}, \tag{7}$$

where M_{AB} is defined as:

$$M_{AB} = M_A - \frac{v_B}{v_A} M_B. \tag{8}$$

In the equation above, M_A is the molar mass of component A, M_B is the molar mass of component B, and v_A and v_B are stoichiometric coefficients. The energy equation for solid particles considers the heat and mass exchange with flowing air and energy released (or absorbed) during the chemical reaction. Therefore, this energy equation can be written using the formula:

$$\left(1 - \varepsilon_b\right) \left[\frac{v_B}{v_A} \frac{\partial H_B}{\partial T_s} + \left(1 - \beta\right) \frac{\partial H_{AB}}{\partial T_s}\right] = \nabla \cdot \left(\lambda_{s,eff} \nabla T_s\right) +$$

$$-A_b \left[\alpha_{m,eff} c_{p,v} \left(\rho_{v,e} - \rho_v\right) + \alpha_{T,eff}\right] \left(T_s - T_f\right) + \left(1 - \varepsilon_b\right) H_{AB}(T_s) \frac{\partial \beta}{\partial t}, \tag{9}$$

where H_{AB} is defined as:

$$H_{AB} = H_A - \frac{v_B}{v_A} H_B. \tag{10}$$

In Eq. (9) and (10), H_A is species A's molar enthalpy, H_B is species B's molar enthalpy, and $\lambda_{s,eff}$ is the effective heat conductivity of solid particles in the reactive bed. Equations (1)-(10) allow for calculating velocities, temperatures, and moisture molar concentration fields. Due to the high complexity of the proposed model, caused by the presence of chemical reaction in the bed and the coexistence of both species A and B, the above model was simplified and reformulated to account for a sorption/desorption-based heat storage, which mathematical description is much simpler, and in such form was implemented and tested. The model given by Eq. (1)-(10) will be implemented and tested in future work.

3. Model simplification to sorption/desorption-based heat storage

The proposed in section 2 TChES model was simplified, assuming that sorption/desorption phenomena are used to store heat instead of thermochemical reactions. The simplified mathematical model for sorption/desorption-based heat storage, presented below, replaces the mass balance equation, Eq. (5), with the equation describing water transport in the porous bed. It assumes that, during the sorption, the water vapor is adsorbed from moist air and bound with solid porous particles in liquid form. No other species are created in the bed because only physical adsorption occurs. Therefore, the density of the solid phase is constant, and the mass changes of particles arise only from the amount of adsorbed water. The following equation can describe the sorption phenomenon:

$$(1-\varepsilon_b)\rho_s \frac{\partial a_w}{\partial t} = (1-\varepsilon_b)\rho_s A_b \alpha_{m,eff}\left(a_{w,eq} - a_w\right), \tag{11}$$

where: ρ_s is the real density of solid particles, a_w is the mass of adsorbed water (per mass of adsorbent particles), and $a_{w,e}$ is the equilibrium amount of water. Both sides of Eq. (11) are multiplied by the mass of the adsorbent per volume to obtain the SI unit compatible with the moisture transport equation for moist air, i.e., kg H_2O m^{-3} s^{-1}. The source term of Eq. (3) also was changed because of replacing the driving force of water transfer. It is assumed that there will not be condensation, and water in the system occurs only in the form of water vapor in moist air and water adsorbed by porous particles. Therefore, Eq. (3) and (11) have the opposite source terms. The modified equation of moisture transport in the air is the following:

$$\varepsilon_b \frac{\partial \rho_g \omega}{\partial t} + \nabla \cdot \left(\rho_g \vec{u} \omega\right) = \nabla \cdot \left(D_{vb,eff} \nabla \omega\right) + (1-\varepsilon_b)\rho_s A_b \alpha_{m,eff}\left(a_w - a_{w,eq}\right). \tag{12}$$

In the energy equation for the moist air, Eq. (4), the only change will occur in the source term connected with energy transport as enthalpy of exchanged water. The modified equation can be written as:

$$\varepsilon_b \frac{\partial \rho_g \left(c_{v,g} + \omega c_{v,v}\right) T_f}{\partial t} + \nabla \cdot \left[\rho_g \vec{u} \left(c_{p,g} T_f + \omega c_{p,v} T_f + \frac{p}{\rho_g}\right)\right] = \nabla \cdot \left(\lambda_{m,eff} \nabla \mathrm{T}_f\right) +$$

$$A_b\left[(1-\varepsilon_b)\rho_s \alpha_{m,eff} c_{p,v}\left(a_w - a_{w,eq}\right) + \alpha_{T,eff}\right]\left(T_s - T_f\right). \tag{13}$$

The energy equation for the porous bed in the simplified model considers the specific heat of adsorbed water in porous particles and the heat of sorption. Therefore, the energy Eq. (9), is replaced by the following one:

$$\rho_s(1-\varepsilon_b) \frac{\partial \left(c_{p,s} + a_w c_{p,\mathrm{H2O}}\right) T_s}{\partial t} = \nabla \cdot \left(\lambda_{s,eff} \nabla \mathrm{T}_s\right) + (1-\varepsilon_b)\rho_s A_b \alpha_{m,eff}\left(a_{w,eq} - a_w\right) H_r +$$

$$-A_b\left[(1-\varepsilon_b)\rho_s \alpha_{m,eff} c_{p,v}\left(a_w - a_{w,e}\right) + \alpha_{T,eff}\right]\left(T_s - T_f\right), \tag{14}$$

where: $c_{p,s}$ is the specific heat of solid particles, $c_{p,\mathrm{H2O}}$ is the specific heat of liquid water, and H_r is the heat of sorption reaction (per mass of exchanged water). Flow equations, Eq. (1) and (2), remained the same in the simplified model.

4. Numerical implementation

4.1. Storage unit geometry and mesh

The sorption/desorption TES unit of cylindrical shape is investigated. During the modeling of the TES unit, the focus was not only on processes occurring in the porous medium but also on the part through which the air reached the reactive bed and flowed out of it. The 2D geometry of the modeled part of the TES unit consists of a circular inlet channel, a diverging nozzle, a cylindrical reactor with a porous material, a converging nozzle, and an outlet channel (see Figure 1). This geometry is axisymmetrical.

The axial symmetry of the geometry enabled a significant reduction in the number of mesh elements by treating the problem as a 2D axisymmetric. Consequently, only the upper part of the axial section needs to be prepared and meshed. A detailed view of the storage geometry with all dimensions is presented in Figure 2. The geometry of the TES unit was created using the ANSYS DesignModeler software.

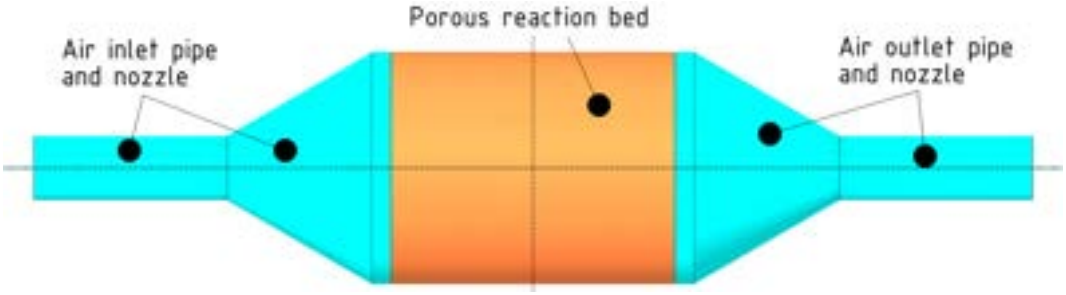

Figure. 1. The schematic view of investigated sorption/desorption TES unit.

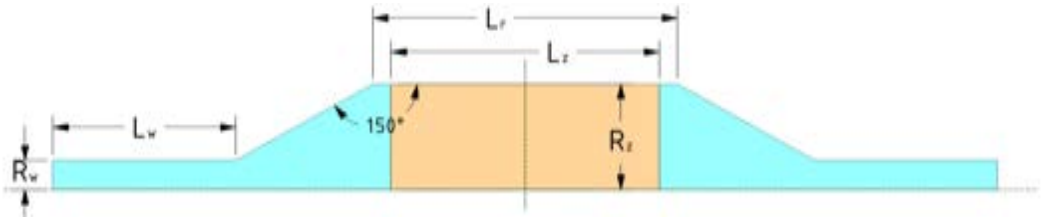

Figure. 2. The view of the upper axial section of the TES unit with all dimensions.

Table 1. Geometric dimensions of the investigated TES unit.

Geometrical parameters	Value
R_w (m)	0.05
R_z (m)	0.18
L_w (m)	0.30
L_r (m)	0.50
L_z (m)	0.44
Inlet/outlet surface (cm^2)	78.54
System volume (dm^3)	76.31
Reactive bed volume (dm^3)	44.79

Table 2. Mesh elements' quality properties.

Element property	Mesh 1 (15 680 elements)	Mesh 2 (273 570 elements)
Maximum aspect ratio	11.35	11.38
Minimum orthogonal quality	0.84	0.86
Maximum skewness	0.33	0.33

The TES unit's regular geometry allowed to generate meshes with 2D quadrangular elements. The meshes were created using the ANSYS Meshing software. Two computational grids, i.e., coarse and dense, were considered for testing the model's stability and solution sensitivity to the mesh size. The equations' convergence levels were also checked. Three factors were considered, i.e., aspect ratio, orthogonal quality, and skewness, to assess the quality of grid elements. As seen from the data presented in Table 2, the qualities of meshes are very good. During grids generations, refined meshes were created at the pipe and nozzle walls, thanks to which processes occurring in the boundary layers were simulated more accurately. For this reason, the aspect ratio level close to the walls was higher than in the rest of the domain. The reactive bed is the region with the best quality elements to decrease the meshing impact on equations convergence rates.

The coarse and dense meshes comprised 15 680 and 273 570 elements, respectively. But, this is not the final element numbers ANSYS Fluent used during the solution. Since a non-equilibrium approach was applied in solving the energy equation in the porous zone, ANSYS Fluent required a copy of the mesh in the porous region. The copied mesh consisted of the same number of elements as in the area of the porous medium, but these elements belonged to the solid material and used solid material properties during calculations. In this work, these were the properties of silica gel. The final sizes of meshes used for calculations were 21 344 and 346 170 elements. Because meshes in the porous media were copied, the elements' quality did not change.

4.2. Numerical implementation

The ANSYS Fluent 2022 R2 software was applied to solve the set of governing equations, Eq. (1), (2), and (11)-(14), utilizing parallel calculations. For the mesh with 21 344 elements, 4 computational nodes were used, and in the case of 346 170 mesh elements, 16 computational nodes were involved. Equations (1) and (2) were solved using a laminar flow model built-in within ANSYS Fluent software. The advanced customization interface, i.e., user-defined scalars (UDS), user-defined functions (UDF), and user-defined memory (UDM),

were applied to solve Eq. (11)-(14), along with all closing relationships presented in the next section. The model implementation using ANSYS Fluent software makes changing the geometry and computational mesh very easy, allowing for future optimization of the TES unit performance.

4.3. Closing relationships and input data

Several closing relationships and a set of input data are required to solve governing equations, Eq. (1), (2), and (11)-(14). These are the following. The density of the dry air in the system was calculated with the following incompressible ideal gas model:

$$\rho_g = \frac{p_{op}}{R_g T_f}, \tag{15}$$

where: p_{op} is the operating pressure assumed constant, and R_g is the individual gas constant of dry air. The density of the moist air changes with the amount of water vapor contained and is calculated using the relation:

$$\rho_m = \rho_g \frac{1+\omega}{1+\frac{R_v}{R_g}\omega}, \tag{16}$$

where: R_v is the individual gas constant of water vapor. The moist air's dynamic viscosity also varies with the contained water vapor as follows:

$$\mu_m = \mu_g + \left(\mu_v - \mu_g\right)\frac{\omega}{\frac{M_v}{M_g}+\omega}, \tag{17}$$

where: μ_g is the dynamic viscosity of the dry air, μ_v is the dynamic viscosity of water vapor, and M_g and M_v are molar masses of dry air and water vapor, respectively. The permeability of a porous medium composed of spherical particles can be calculated using a relationship that considers the grain diameter and the porosity of a given medium. The formula is the following:

$$k = \frac{d_p^2 \varepsilon_b^3}{150(1-\varepsilon_b)^2}, \tag{18}$$

where d_p is the diameter of the particle, i.e., silica gel granules. The coefficient of inertial resistance must be found to calculate the source term of the momentum equation in a porous medium. This coefficient can be calculated using the following formula:

$$C_2 = \frac{2C_F}{\sqrt{k}}, \tag{19}$$

where C_F is the dimensionless Forchheimer drag coefficient. This coefficient value can also be found based on the diameter of the silica gel granules and the porosity of the medium from the following equation:

$$C_F = \frac{1.75}{\sqrt{150}}\varepsilon_b^{-\frac{3}{2}}. \tag{20}$$

A model that considers the bed's porosity, tortuosity, and current air humidity is applied to find the effective diffusivity of moisture in the air in the reactive bed. The reference diffusivity was the one of water vapor in the atmospheric air, which depends only on the air temperature and is described by the following equation:

$$D_{v,a} = 2.6 \cdot 10^{-5}\left(\frac{T_f}{298}\right)^{\frac{3}{2}}. \tag{21}$$

Then the effective diffusivity of vapor in the air in the porous bed was calculated from the following relationship:

$$D_{vb,eff} = \frac{\rho_g D_{v,a}\varepsilon_b}{(1+\omega)\tau_b}, \tag{22}$$

where τ_b is the tortuosity of the bed. The effective thermal conductivity of the porous material was modeled with a simple equation in which the thermal conductivity between the bed's granules depends on the medium's porosity. The equation describing this conductivity can be written as follows:

$$\lambda_{s,eff} = (1-\varepsilon_b)\lambda_s, \tag{23}$$

where: λ_s is the real thermal conductivity of the solid material. The thermal conductivity of moist air was modeled similarly to the dynamic viscosity (see Eq. (17)) using the following equation:

$$\lambda_m = \lambda_g + \left(\lambda_v - \lambda_g\right)\frac{\omega}{\frac{M_v}{M_g}+\omega}, \tag{24}$$

where: λ_g is the thermal conductivity of the dry air, and λ_v is the thermal conductivity of water vapor. The effective thermal conductivity of moist air was modeled in a similar way to the effective conductivity of silica gel, and the equation that describes it is the following:

$$\lambda_{m,eff} = \varepsilon_b \lambda_m. \tag{25}$$

The specific surface area for a bed that consists entirely of spherical grains can be expressed as follows:

$$A_b = \frac{6(1-\varepsilon_b)}{d_p}. \tag{26}$$

The effective heat transfer coefficient was calculated assuming a regular regime and was based on dimensionless relations containing similarity numbers. The equation describing this coefficient can be written in the following form:

$$\alpha_{T,eff} = \frac{\alpha_T}{\sqrt{\mathrm{Bi}_T{}^2 + 1.437\mathrm{Bi}_T + 1}}, \tag{27}$$

where: α_T is the heat transfer coefficient, and Bi_T is the thermal Biot number. This Biot number can be calculated using the following formula:

$$\mathrm{Bi}_T = \frac{\alpha_T L_c}{\lambda_{p,ef}}, \tag{28}$$

where: L_c is the solid particle characteristic length, and $\lambda_{p,ef}$ is the effective thermal conductivity of the grains. The solid particle characteristic length can be found using the following relationship:

$$L_c = \frac{3d_p}{2\pi^2}. \tag{29}$$

The effective thermal conductivity of the grain is the average value between the minimum and maximum thermal conductivity in the porous particle expressed by the following formula:

$$\lambda_{p,ef} = \frac{1}{2}\left\{(1-\varepsilon_p)\lambda_s + \varepsilon_p\lambda_m + \left[\frac{(1-\varepsilon_p)}{\lambda_s} + \frac{\varepsilon_p}{\lambda_m}\right]^{-1}\right\}, \tag{30}$$

where ε_p is the porosity of a solid particle. The following Nusselt number correlation was employed to calculate the heat transfer coefficient:

$$\mathrm{Nu}_d = \frac{2.06}{\varepsilon_b}\mathrm{Re}_d^{0.425}\mathrm{Pr}^{\frac{1}{3}}, \tag{31}$$

where: Re_d is the Reynold number, and Pr is the Prandtl number. These dimensionless numbers can be calculated locally (for each mesh cell) with the following formulae:

$$\mathrm{Re}_d = \frac{\rho_m u d_p}{\mu_m}, \tag{32}$$

$$\mathrm{Pr} = \frac{\mu_m(c_{p,g} + \omega c_{p,v})}{\lambda_m}. \tag{33}$$

The Nusselt number allows finding the heat transfer coefficient using its following definition:

$$\alpha_T = \frac{\mathrm{Nu}_d \lambda_m}{d_p}. \tag{34}$$

The effective mass transfer coefficient was calculated using the heat and mass transfer analogy by applying the following formula:

$$\alpha_{m,eff} = \frac{\alpha_m}{\sqrt{\mathrm{Bi}_m{}^2 + 1.437\mathrm{Bi}_m + 1}}, \tag{35}$$

where: α_m is the coefficient mass transfer coefficient, and Bi_m is the mass Biot number found using the following relationship:

$$\mathrm{Bi}_m = \frac{\alpha_m L_c}{D_{vp,eff}}, \tag{36}$$

where: $D_{vp,eff}$ is the effective vapor diffusivity in the air filling the porous particle. This effective diffusivity is calculated with the formula:

$$D_{vp,eff} = \frac{D_{va,s}\varepsilon_p}{\tau_p}, \tag{37}$$

where: $D_{va,s}$ is the reference moisture diffusivity calculated by Eq. (21) with the silica gel temperature T_s instead of the moist air temperature, and τ_p is the tortuosity of the solid particle. Formulae similar to those used to determine the heat transfer coefficient were used to calculate the mass transfer coefficient. In these equations, the Sherwood number was used instead of the Nusselt number, and the Schmidt number instead of the Prandtl number. By applying the analogy between heat and mass transfer, the correlation given by Eq. (31) can be modified, obtaining the following one:

$$\mathrm{Sh}_d = \frac{2.06}{\varepsilon_b}\mathrm{Re}_d^{0.425}\mathrm{Sc}^{\frac{1}{3}}. \tag{38}$$

The Schmidt number can be found using the following relation:

$$\mathrm{Sc} = \frac{\mu_m}{\rho_m D_{va,s}}. \tag{39}$$

The Sherwood number allows finding the mass transfer coefficient using its following definition:

$$\alpha_m = \frac{\mathrm{Sh}_d D_{va,s}}{d_p}. \tag{40}$$

Table 3 Fixed physical properties of the model.

Property	Symbol	Value
Porosity of the bed (-)	ε_b	0.6
Porosity of the particle (-)	ε_p	0.6
Diameter of the particle (m)	d_p	0.004
Tortuosity of the bed (-)	τ_b	1000
Tortuosity of the particle (-)	τ_p	1000
Specific heat of dry air at constant volume (J kg^{-1} K^{-1})	$c_{v,g}$	719.53
Specific heat of dry air at constant pressure (J kg^{-1} K^{-1})	$c_{p,g}$	1006.43
Individual gas constant of dry air (J kg^{-1} K^{-1})	R_g	286.9
Thermal conductivity of dry air (W m^{-1} K^{-1})	λ_g	0.0242
Dynamic viscosity of dry air (Pa s)	μ_g	0.000017894
Specific heat of water vapor at constant volume (J kg^{-1} K^{-1})	$c_{v,v}$	1408.5
Specific heat of water vapor at constant pressure (J kg^{-1} K^{-1})	$c_{p,v}$	1870
Individual gas constant of water vapor (J kg^{-1} K^{-1})	R_v	461.5
Thermal conductivity of water vapor (W m^{-1} K^{-1})	λ_v	0.0182
Dynamic viscosity of water vapor (Pa s)	μ_v	0.000010057
Specific heat of liquid water (J kg^{-1} K^{-1})	$c_{p,\mathrm{H2O}}$	4186
Specific heat of solid particles J kg^{-1} K^{-1})	$c_{p,s}$	975
Density of solid particles (kg m^{-3})	ρ_s	2200
Maximum amount of water the silica gel can absorb (-)	$a0$	0.35
Characteristic activation energy (J mol^{-1})	βE	3780.8
Heat of sorption reaction (kJ kg^{-1})	H_r	2415
Correction parameter (-)	n	1.016
Operating pressure (Pa)	p_{op}	101325

The equilibrium moisture content in the solid was modeled based on the Dubinin-Astakhov equation and is expressed by the following formula:

$$a_{w,eq} = a_0 \exp\left[-\left(\frac{A_{ad}}{\beta E}\right)^n \right], \tag{41}$$

where: a_0 is the maximum amount of water the silica gel can absorb, A_{ad} is the adsorption potential coefficient, βE is the characteristic activation energy, and n is the equation parameter. The adsorption potential can be found with the following formula:

$$A_{ad} = BT_f ln\left(\frac{p_{sat}}{p_v}\right), \tag{42}$$

where: B is the universal gas constant, p_v is the pressure of water vapor, and p_{sat} is the saturation pressure of water vapor at temperature T_f calculated by the following expression:

$$p_{sat} = 3567 \exp\left[-5232\left(\frac{1}{T_f} - \frac{1}{300}\right)\right], \tag{43}$$

and the actual water vapor pressure in the moist air can be found by applying the following relationship:

$$p_v = \frac{\omega p}{\frac{M_v}{M_g} + \omega}. \tag{44}$$

Some of the physical properties of moist air (used as the working medium), silica gel (used as the thermochemical material filling the TES unit), and the structure of the porous bed were assumed to be fixed. These properties are listed in Table 3 with their respective descriptions and physical units. Table 4 summarises assumed initial and boundary conditions. Initial conditions were the same for the whole domain. All the walls of the TES units were assumed adiabatic.

Table 4 Initial and boundary conditions for charging and discharging.

Initial and boundary conditions	Symbol	Value (charging/discharging)
Initial velocity of the moist air in the unit (m s^{-1})	u	0 / 0
Initial gauge pressure of the moist air in the unit (Pa)	p	0 / 0
Initial specific humidity in the unit (-)	ω	0.025 / 0.00062
Initial mass of adsorbed water in the unit (-)	a_w	0.32 / 0.035
Initial temperature of moist air in the unit (K)	T_f	303 / 303
Initial temperature of solid particles in the unit (K)	T_s	303 / 303
Inlet velocity of moist air (m s^{-1})	u	2.5 / 2.5
Inlet temperature of moist air (K)	T_f	363 / 293
Inlet specific humidity (-)	ω	0.0095 / 0.0125

5. Results of the simulations

The model validation was not conducted at the current model development state, while model verification was limited to initial mesh size sensitivity analysis and assessing mass and heat conservation principles. But the experimental stand is under development, and the model will be validated in the future. The implemented model was used to simulate the charging and discharging of the sorption-based TES unit. Both simulations were run twice, using a smaller and larger computational grid. A small time step of 0.02 s was used for all tests to improve the equations' convergence rates. Preliminary simulation results were to verify that the implemented numerical model is stable and satisfies the basic mass and energy conservation principles. In addition, it was checked whether the size of the computational grid impacts the calculated characteristics of heat and mass transfer between the reactive bed and moist air. Due to the high complexity of the model, many coupling between equations and other parameters, and the resulting huge demand for computing power, the actual computation times were about a month for TES discharging and another month for charging. For this reason, simulations were stopped at the early stages of the process, and only several minutes of the charging and discharging process were simulated. The simulated charging times on the small and large grids are 2630 s (131 500 time steps) and 632.54 s (31 627 time steps), respectively. For discharge, the simulated times reached 2089.94 s (104 497 time steps) on the small grid and 821.4 s (41 070 time steps) on the large grid.

After the calculations, it was verified whether the implemented model obeyed the basic mass and heat conservation laws at each time step. To do so, the exact amount of masses and energies that were contained, entered, and left the system were recorded after each time step. The energy sources in the system were the entering air and the heat of the sorption reaction. Water was supplied to the system only through moist air. The overall energy balance in the system was calculated in each time step using the following formula:

$$(H_{in} - H_{out}) + H_r = \left(U_{gas}^{t} - U_{gas}^{t-1}\right) + (U_{sol}^{t} - U_{sol}^{t-1}), \tag{45}$$

where: H_{in} and H_{out} are entering and leaving air enthalpies, respectively, U_{gas} is the internal energy of air contained in the system, and U_{sol} is the internal energy of solid particles and bounded water. The superscript t means the value taken at the actual time step, while t-1 at the previous time step. Similarly, the water and moist air balances in the system can be written as:

$$\left(m_{w,in} - m_{w,out}\right) = \left(m_{w,gas}^{t} - m_{w,gas}^{t-1}\right) + \left(m_{w,sol}^{t} - m_{w,sol}^{t-1}\right), \tag{46}$$

$$\left(m_{a,in} - m_{a,out}\right) = (m_a^t - m_a^{t-1}), \tag{47}$$

where: $m_{w,in}$ and $m_{w,out}$ are the masses of water vapor entering and leaving the system, respectively, $m_{w,gas}$ is the mass of water vapor contained in the system, $m_{w,sol}$ is the mass of water contained in the silica gel bed, $m_{a,in}$ and $m_{a,out}$ are the masses of moist air entering and leaving the system, respectively, and m_a is the mass of moist air contained in the system. The right-hand sides of Eq. (45)-(47) have been moved to the left to simplify the balance evaluation. Thus, properly balanced quantities should take values close to zero.

Table 5 Balances of the energy, the mass of water, and the mass of moist air.

Average residues per time step	Value	Simulation time (s)	Number of grid elements
Average residue of energy during charging (J)	$1.0092 \cdot 10^{-3}$	632.54	21 344
	$4.2618 \cdot 10^{-3}$	632.54	346 170
	$4.0947 \cdot 10^{-5}$	2630	21 344
Average residue of water mass during charging (kg)	$5.0959 \cdot 10^{-12}$	632.54	21 344
	$-1.1001 \cdot 10^{-10}$	632.54	346 170
	$1.1861 \cdot 10^{-10}$	2630	21 344
Average residue of moist air mass during charging (kg)	$1.9798 \cdot 10^{-11}$	632.54	21 344
	$-2.3261 \cdot 10^{-9}$	632.54	346 170
	$3.4112 \cdot 10^{-12}$	2630	21 344
Average residue of energy during discharging (J)	$-7.0426 \cdot 10^{-4}$	821.4	21 344
	$-1.2043 \cdot 10^{-3}$	821.4	346 170
	$-1.7621 \cdot 10^{-4}$	2089.94	21 344
Average residue of water mass during discharging (kg)	$9.2381 \cdot 10^{-13}$	821.4	21 344
	$4.9613 \cdot 10^{-11}$	821.4	346 170
	$3.2810 \cdot 10^{-12}$	2089.94	21 344
Average residue of moist air mass during discharging (kg)	$-1.1574 \cdot 10^{-12}$	821.4	21 344
	$-3.2515 \cdot 10^{-11}$	821.4	346 170
	$5.6194 \cdot 10^{-12}$	2089.94	21 344

Table 6 Differences between results obtained applying a smaller and larger computational grid.

Simulation result	Value	Number of grid elements
Water adsorbed by silica gel during discharging (kg)	0.2261280	21 344
	0.2261438	346 170
Water desorbed by silica gel during charging (kg)	0.1712517	21 344
	0.1712699	346 170
Energy released during the adsorption reaction (J)	546099.10	21 344
	546123.98	346 170
Energy absorbed during the desorption reaction (J)	413572.40	21 344
	413616.44	346 170

The results in Table 5 confirm that the implemented model satisfies the mass and energy conservation principles. Although the residues of the energy equation seem quite large, and after multiplying the average per time step by the number of time steps, the result on the order of magnitude of 100 J was obtained. But this amount is a very small part of the energy released or absorbed during the sorption reaction. For example, the average energy residue per time step during charging was $4.2618 \cdot 10^{-3}$ J, and after 31 627 time steps amounted to 134.79 J. But solid particles absorbed 413 616 J of the heat during the desorption reaction. This means the error is insignificant and does not affect the simulation result.

Next, it was also checked whether the size of the computational grid impacted the simulation result, i.e., the initial mesh sensitivity analysis was performed. For this purpose, differences in the amount of water exchanged between the air and the porous bed as well as stored and released heat in sorption reactions, were checked. The operating period that was considered was 632.54 s of charging and 821.4 s of discharging. As can be seen in Table 6, the size of the computational grid has a very small effect on the simulated amounts of adsorbed and desorbed water as well as absorbed and released heat.

Exemplary simulation results are shown in Figures 3 and 4. However, only the initial charging and discharging phases were simulated due to the long computational times resulting from the model and its implementation complexity. Figure 3 shows how the moisture content of the silica gel granules changed as the TES unit was loaded. It can be seen that dehydration occurs best on the axis of the storage and near its outer wall. Figure 4 shows how the temperature of the moist air in the TES unit changes as it is unloaded. The silica gel granules adsorb water and, as a result, warm up and transfer heat to the flowing air. Here, too, it can be seen that the process is faster at the axis and near the wall of TES. Sorption and heat transfer processes occur fastest in axial and wall regions, most likely due to higher air velocity than in other storage zones. This higher velocity

results in a higher local Reynolds number making mass and heat transfer coefficients more intensive there. The air velocity distribution at the entrance to the porous bed results from the shape of the diffuser before the bed. The air with the highest momentum flows in the axis (the core of the flow), while at the outer walls, vortices are formed just in front of the bed in the central part of the diffuser, which improves mass and energy convection in the bed close to walls.

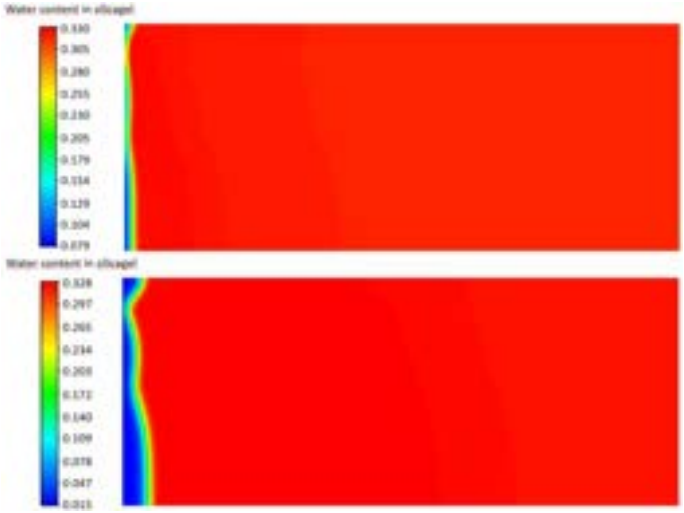

Figure. 3. The contour of water content a_w in silica gel during charging at 2 min (upper) and 10 min (lower) of simulation.

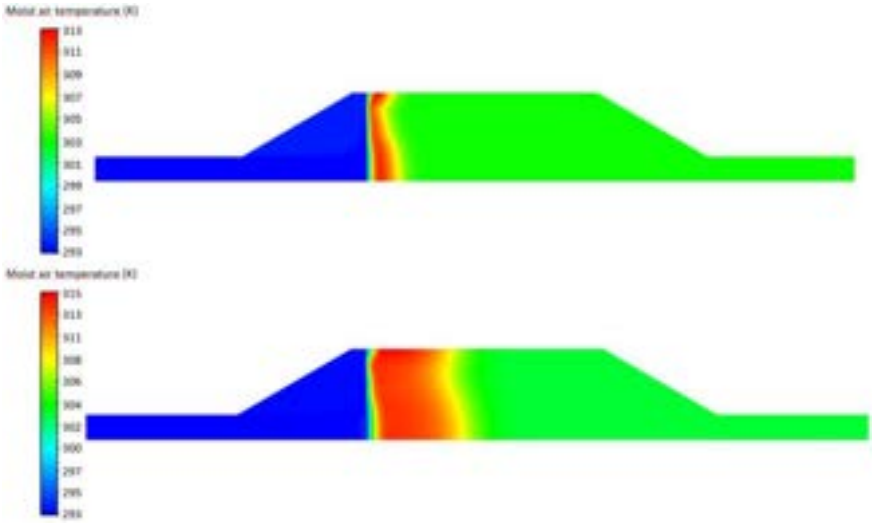

Figure. 4. The contour of moist air temperature during discharging at 2 min (upper) and 10 min (lower) of simulation.

6. Conclusions

The paper presents the concept of an advanced multi-dimensional TChES system model. The model simulates the charging/discharging of a low-temperature TChES unit that operates in an open system. The gaseous working medium (moist air) provides and removes heat and moisture from the unit. The porous thermochemical material stores the heat due to hydration/dehydration reversible reactions. The model's main feature is that it treats rigorous phenomena occurring in the TChES unit. It accounts for local hygric and thermal non-equilibrium by treating heat and moisture carrier fluid and reactive porous bed separately. Therefore, two sets of governing equations have been derived, i.e., one dealing with moisture transfer in the air flowing through the porous bed and the second one with phenomena occurring in the reactive porous bed. The model can simulate the chemical and physical sorption process occurring in the TES unit.

Currently, the proposed model has been simplified and modified to simulate the sorption/desorption TES unit. It was implemented in 2D axisymmetric space by applying commercial software ANSYS Fluent and its advanced customization options, i.e., UDS, UDF, and UDM. The model was tested regarding the initial mesh size sensitivity and obeying mass and energy conservation principles. The obtained results were physical. It turned out that the current model implementation is very computationally inefficient, i.e., the computational time is very long. Therefore, only several minutes of the discharging and charging processes were simulated.

These problems with long simulation times were probably related to many couplings between different equations and properties, which are not necessarily required and have not necessarily meaningful impacts on the model's accuracy. But they could significantly decrease the convergence rates. So further work will be devoted to optimizing model implementation and improving convergence rates by decoupling model equations and properties and testing different numerical techniques for solving governing equations.

Abstract:
Thermal energy storage (TES) is a key issue in efficient energy system applications, especially in the context of renewable energies. In this respect, phase change materials (PCM) have attracted interest as an active solution for efficient energy management, particularly in the building sector. This paper presents a modeling of a thermal battery based on PCM in the case of solar systems assisted by heat pump (SAHP). The storage tank allows to store the heat produced via unglazed solar panels (Batisol®) and represents the heat source of the heat pump. The heat pump can supply the heating and domestic hot water (DHW) needs of a building. The storage consists of a block of PCM contained between two plates of heat transfer fluid (HTF). A 2D model is used to describe the behaviour of the PCM and a 1D model is preferred for the HTF plates. The objective of the study is to dynamically simulate the thermal behaviour of this storage for different hot inlet temperature profiles: step, trapezoidal functions and profile of the temperature at the outlet of the thermal panels for a winter and summer period of 8 days. This 2D model would be useful to validate a simpler model for optimisation of the operational parameters of the system.

Keywords:
Thermal energy storage, Phase change material, Solar system assisted heat pump, Domestic hot water, Low-temperature heating.

1. Introduction

In order to limit temperature rise, it is important to reduce the environmental impact of energy production and consumption. According to the International Energy Agency [1], the building sector is considered to be one of the largest energy end-use sectors in the world. The growing demand for energy is increasing the pressure on the environment. One of the main challenges to reduce the environmental impact of buildings is therefore to replace fossil fuels with renewable resources. Thermal energy storage (TES) has been particularly studied in recent years as it is essential to compensate for the intermittency of renewable energies, by correcting the mismatch between energy supply and demand [2]. Moreover, TES are increasingly used to meet the heating and cooling needs of buildings. There are three types of TES: sensible, latent and thermochemical [2]. Phase Change Materials (PCM) are materials that can store large amounts of thermal energy in the form of latent heat of fusion when they change from a solid to a liquid state for example at a specific phase change temperature or temperature range if the PCM is not a pure compound. This phase transition process is reversible, allowing thermal energy to be stored and released at relatively constant temperatures. Compared to sensible heat storage materials, PCM offer several significant advantages, like a higher heat storage density at small temperature ranges [3]. PCM can store between 5 and 14 times more thermal energy per unit volume than sensible heat storage materials [4]. As a result, the use of PCM can help to reduce the size of heat storage systems, making them more suitable for residential applications. Thermochemical storage is more interesting in terms of storage density. However, this technology is less mature than that with PCM.

Solar systems assisted by heat pump (SAHP) can provide an efficient and environmentally friendly heating

and cooling solution for residential and commercial buildings. The role of a heat pump in the heating system is to increase the thermal energy from a lower temperature level to a higher temperature level [5]. Moreover, the use of PCM heat storage between the solar facade and the heat pump can improve the overall performance of the SAHP. Several studies have been conducted to assess the benefits of using PCM in SAHP [6–9]. Firstly, the solar energy stored in the PCM unit can be used as a heat source for the evaporator in the heat pump. As a result, the temperature of the evaporator is almost constant and the heat pump can operate under more stable conditions. This leads to a better Coefficient of Performance (COP) for the heat pump.

Depending on the type of application at the output of the heat pump (heating, cooling), the temperature levels are not the same and therefore the PCM used changes [6]. Four temperature ranges have been listed by Du *et al.* [6]: low (-20 to 5 °C), medium-low (5 to 40 °C), medium (40 to 80 °C) and high (80 to 200 °C) temperatures. For a heating or domestic hot water applications, the medium temperature level is considered since the buffer tank temperature setpoint is usually expected at 60 °C. Many studies have been carried out on such systems [6, 8–10]. However, as each storage is different (size, design and PCM used in particular), it is important to model its thermal behaviour correctly in order to explore the optimal operating parameters later.

The objective of this paper is to dynamically simulate a TES based on PCM integrated on SAHP. In a first part, the methodology and the case study will be presented. Then, several operating scenarios will be investigated in the results section. The profile of the hot temperature entering in the thermal battery will be a step, then a trapezoidal function, and finally this of the outler temperature of thermal panels in winter and summer periods using measured climatic conditions as boundaries. Finally, last part will conclude.

2. Material and Methods

This section is divided in three parts. Firstly, the global system is described, composed by solar thermal panels, PCM battery and heat pump. In next steps, the models of the different components of the system are defined. Dynamic models are based on the conservation of mass and energy equations.

2.1. Definition of the system

The studied system is composed of solar panels, a TES based on PCM, and a heat pump, as illustrated in Fig. 1. The system is divided in three circuits. The first, connecting the solar facade to the buffer tank, is made up of glycol. The second circuit, connecting the thermal battery to the heat pump, is composed of water. An air heater is integrated in parallel with the solar storage to supply heat to the heat pump when the temperature of the thermal battery is not high enough. The last circuit, also made of water, connects the PCM battery for heating and domestic hot water (DHW) to the heat pump.

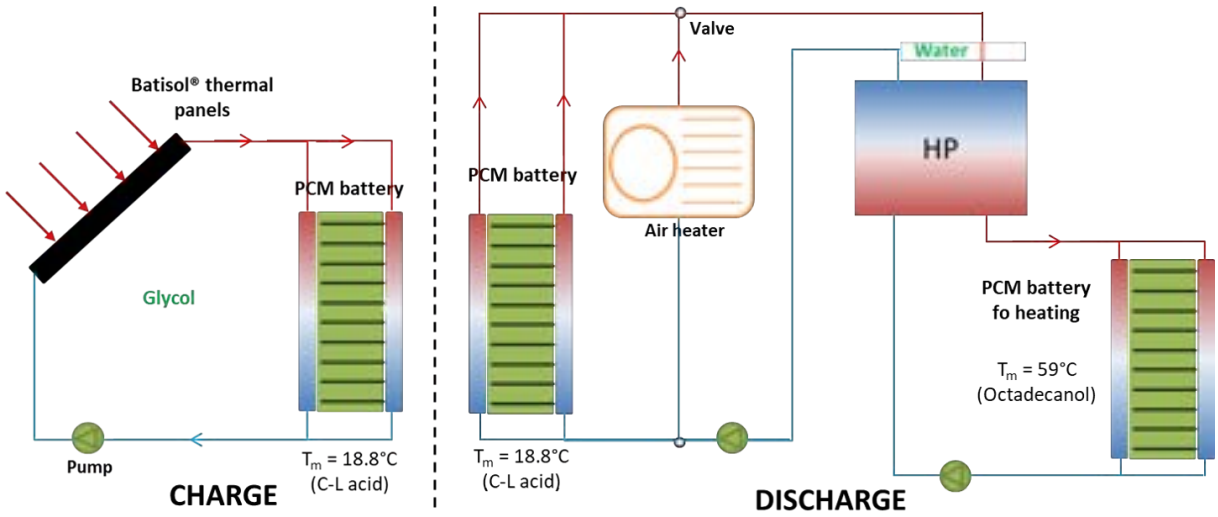

Figure 1: Global diagram of the solar assisted heat pump with thermal battery based on PCM.

The solar facade is composed of unglazed thermal panels (Batisol®) [11, 12], developed by Nobatek/INEF 4 [13]. The dimensions of the PCM-based storage are 0.4 m x 0.4 m x 0.4 m (Fig. 2a). The heat pump can produce both low temperature heating and DHW for a building application. The same thermal battery is used for the DHW and buffer tanks. Only the PCM changes between the two batteries, to match the desired temperature level. For the buffer tank, a mixture of 61.5% capric acid and 38.5% lauric acid (C-L acid) is used. Its melting temperature is 291.95 K. For the heating PCM battery, octadecanol is prefered. Indeed, its melting temperature is 332.46. The thermophysical properties of these materials are depicted in Table 1.

Table 1: Thermophysical properties of C-L acid [14] and octadecanol.

Name	Value for C-L acid	Value for octadecanol	Unit
T_m	291.95	332.46	K
L	$140.8 \cdot 10^3$	$208.45 \cdot 10^3$	J/kg
ρ_{PCM}	897.5	850	kg/m^3
$c_{p,l}$	1970	1750	$J/kg/K$
$c_{p,s}$	2240	2150	$J/kg/K$
λ_s	0.143	0.301	$W/m/K$
λ_l	0.139	0.205	$W/m/K$

2.2. Model of the Batisol® panels

The model of the thermal solar facade was described previously by Bouzouidja *et al.* [15]. From the time-varying input parameters, taken from a weather file, and the operating parameters, the temperature at the panel outlet is determined [15]:

$$T_{out,sol} = \frac{T_{in,sol} \cdot \dot{m} \cdot c_{p,H} + \alpha \cdot A_{sol} \cdot (0.5 \cdot T_{in,sol} - T_{ext}) + G_{sol} \cdot A_{sol} \cdot \gamma}{\dot{m} \cdot c_{p,H} - 0.5 \cdot \alpha \cdot A_{sol}} \tag{1}$$

Where $T_{in,sol}$ and T_{ext} are the temperatures at the entrance to the solar facade and outside (K), A_{sol} the surface of the solar facade (m^2), G_{sol} the solar flux (W/m^2), $\dot{m}$ the low rate of the Heat Transfer Fluid (HTF) circulating in the thermal panels (kg/s) and $c_{p,H}$ the specific heat capacity of the hot fluid (glycol) ($J/(kg \cdot K)$). The coefficients α and γ have been determined experimentally (γ = 0.63). The first one depends on the wind speed:

$$\alpha = -(7.84 + 3 \cdot v_{wind}) \tag{2}$$

2.3. Model of the thermal energy storage based on phase change material

In order to model the behaviour of latent heat storage, the following simplifying assumptions have been made:

- Natural convection is neglected. Only conduction is considered,
- No supercooling or superheating,
- Incompressible and Newtonian HTF,
- Kinetic and potential energy variations are neglected,
- Isothermal phase change (Octadecanol is a pure body so this assumption is correct. Since C-L acid is a mixture, the phase change temperature range is between 291.65 and 292.25 K [16]. As the melting temperature of this PCM is considered to be 291.95 K, the uncertainty of this assumption is +/- 2%),
- Density variation of PCM neglected during the phase change,
- Thermophysical properties are independent of temperature, but different for liquid and solid phases,
- The storage walls are assumed to be perfectly insulated (adiabatic boundary conditions) (Fig. 2b).

The shape of the thermal battery and its operation are described schematically in Fig. 2. The PCM is placed between two plates where the HTF circulates. Thus, a symmetry plane is visible in the middle of the battery. During the charging step, hot fluid is injected into the two plates. During the discharging step, cold fluid is injected. As a result, the charging and discharging steps are carried out separately. The plates where circulates the HTF are modelled in one dimension, a plug flow being assumed. The PCM part located between two plates is modelled in 2D because the heat diffusion operates in axial and longitudinal directions.

Fins are added to the plates to increase the contact area between the PCM and the HTF. To account for the fins, the effective conductivity of the PCM is expressed as:

$$\lambda_{eff} = a \cdot \lambda_{PCM} + (1 - a) \cdot \lambda_{fin} = a \cdot (\lambda_s + f_l \cdot (\lambda_l - \lambda_s)) + (1 - a) \cdot \lambda_{fin} \tag{3}$$

Where a is the proportion of PCM in the volume under consideration ($-$), λ_{PCM}, λ_s, λ_l et λ_{fin} are respectively the thermal conductivities of the PCM, the solid and liquid phases of the PCM and the fins ($W/m/K$), and f_l the liquid fraction of the PCM ($-$).

The enthalpy, the temperature and the liquid fraction of the PCM (according to x and y), and the temperature of the hot HTF (according to y) are determined with 4 to 11.

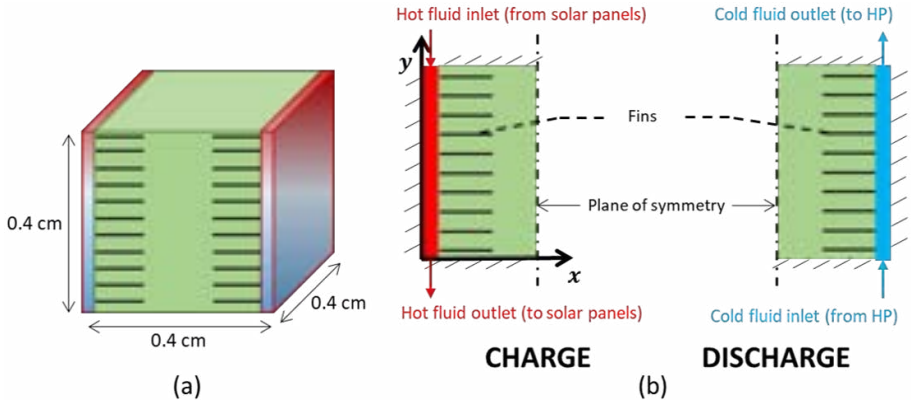

Figure 2: Diagram of the dimensions of the PCM-based thermal battery (a), and diagram of the PCM-based thermal battery with two plates for the charging and discharging steps (b).

- **Exchanges between the HTF (hot or cold) and the PCM:**

  For hot fluid:

$$\rho_H \cdot V \cdot c_{p,H} \frac{\partial T_H}{\partial t} - \dot{m}_H \cdot c_{p,H} \cdot \frac{\partial T_H}{\partial y} \cdot P = h_H \cdot A \cdot (T_H - T_{PCM}) + \lambda_H \cdot V \cdot \frac{\partial^2 T_H}{\partial y^2} \tag{4}$$

  For cold fluid:

$$\rho_C \cdot V \cdot c_{p,C} \frac{\partial T_C}{\partial t} + \dot{m}_C \cdot c_{p,C} \cdot \frac{\partial T_C}{\partial y} \cdot P = h_C \cdot A \cdot (T_C - T_{PCM}) + \lambda_C \cdot V \cdot \frac{\partial^2 T_C}{\partial y^2} \tag{5}$$

- **Exchanges in the PCM:**

$$\frac{\partial H_{PCM}}{\partial t} = \frac{\partial \lambda_{eff}}{\partial x} \cdot \frac{\partial T_{PCM}}{\partial x} + \frac{\partial \lambda_{eff}}{\partial y} \cdot \frac{\partial T_{PCM}}{\partial y} + \lambda_{eff} \cdot \frac{\partial^2 T_{PCM}}{\partial x^2} + \lambda_{eff} \cdot \frac{\partial^2 T_{PCM}}{\partial y^2} \tag{6}$$

$$H_{PCM}(T_{PCM}) = f_l \cdot H_l + (1 - f_l) \cdot H_s = \rho_{PCM} \cdot ((c_{p,s} + f_l \cdot (c_{p,l} - c_{p,s})) \cdot T_{PCM} + L \cdot f_l - f_l \cdot (c_{p,s} + f_l \cdot (c_{p,l} - c_{p,s})) \cdot T_m) \tag{7}$$

$$f_l = \begin{cases} 0 & for\ H_{PCM} < H_s \\ \frac{H_{PCM} - H_s}{H_l - H_s} & \\ 1 & for\ H_{PCM} > H_l \end{cases} \tag{8}$$

- **Boundary conditions for the PCM in contact with hot (during charging step) or cold (during discharging step) HTF:**

  For hot fluid (for x = 0 and 0.4 m):

$$h_H \cdot (T_H - T_{PCM}) = -\lambda_{eff} \frac{\partial T_{PCM}}{\partial x}\ for\ x = 0\ m \quad and \quad h_H \cdot (T_H - T_{PCM}) = \lambda_{eff} \frac{\partial T_{PCM}}{\partial x}\ for\ x = 0.4\ m \tag{9}$$

  For cold fluid (for x = 0 and 0.4 m):

$$h_C \cdot (T_C - T_{PCM}) = -\lambda_{eff} \frac{\partial T_{PCM}}{\partial x}\ for\ x = 0\ m \quad and \quad h_C \cdot (T_C - T_{PCM}) = \lambda_{eff} \frac{\partial T_{PCM}}{\partial x}\ for\ x = 0.4\ m \tag{10}$$

- **Boundary conditions for the PCM in contact with the outside (adiabatic conditions):**

$$\lambda_{eff} \frac{\partial T_{PCM}}{\partial y} = 0\ for\ y = 0\ and\ 0.4\ m \tag{11}$$

- **Initial conditions:** All temperatures are fixed at 283.15 K. The enthalpy of the PCM is determined by 7 at 283.15 K. The liquid fraction is considered equal to 0.

Where h_H and h_C are the convective exchange coefficients of the hot and cold fluid respectively ($W/m^2/K$), T_H, T_C, T_{PCM} and T_m are the hot and cold temperature, the temperature of the PCM and the melting temperature of the PCM, L the latent heat (J/kg), ρ_{MCP} the PCM density (kg/m^3), $c_{p,l}$ and $c_{p,s}$ are the specific heat capacity of the liquid and solid phases respectively ($J/kg/K$), P the exchange perimeter (m), A the exchange area (m^2) and V the volume of the representative element considered (m^3). The convective exchange coefficients are determined from the Nusselt number, assuming that the wall thickness of the plate is very thin and therefore negligible.

The boundary conditions of the thermal battery depend on the configuration studied. Four scenarios have been investigated. Firstly, the profile of hot temperature entering the thermal battery follows a step. In a second stage, it is a trapezoidal function. Finally, the battery based on PCM is connected to the Batisol® panels and two periods of 8 days are simulated: winter (from January 1 to 8) and summer (from July 1 to 8). In the latter two cases, the profile of the outlet temperature of the solar panels is used as input to the PCM:

$$T_H(x, y = 0.4, t) = T_{out,sol} \tag{12}$$

2.4. Resolution of the differential algebraic equations and software used

The software used to model the system is OpenModelica v1.18.0. The Modelica library (v3.2.3) is considered. The spatial discretisation is performed manually while the temporal discretisation is performed via the DASSL integrator available on OpenModelica. The tolerance used in the DASSL integrator is 10^{-6}. For the PCM-battery model, equations are discretised using an explicit second-order discretisation scheme with finite differences. For the boundary conditions (9 to 11), second-order decentred schemes are used.

3. Results and Discussion

This section is divided into three parts. The first one aims at studying the behaviour of PCM-based TES for a hot inlet temperature profile following a ramp (case 1). The second part investigates the behaviour of the system under trapezoidal loads (case 2). Finally, the battery is connected to the Batisol® solar facade and an 8-day simulation is performed for two periods of the year: from 1 to 8 January (winter, case 3) and from 1 to 8 July (summer, case 4). The hot HTF temperatures investigated at the buffer tank inlet are shown in Fig. 3. The colours red, green, blue and yellow refer to cases 1, 2, 3 and 4 respectively. For the next figures, the coordinates (x = y = 0 m) are placed at the bottom left of the PCM in Fig. 2.

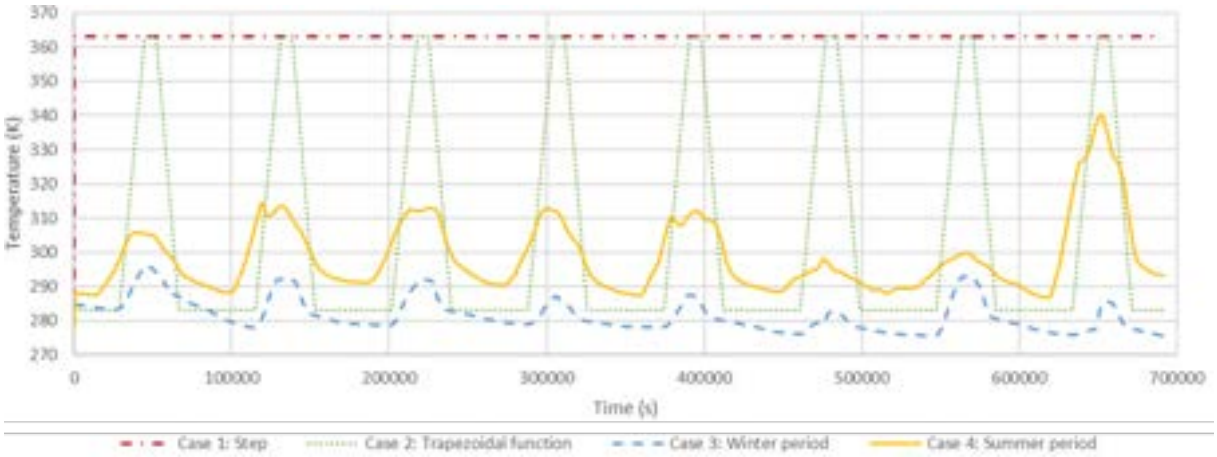

Figure 3: Four hot temperatures profiles considered at the input of the PCM-based TES battery.

The simulation times are relatively fast for simulating 8 days ($6.912 \cdot 10^{-5}$ s) on a standard laptop (processor: 12th Gen Intel®Core(TM) i7-12700H 2.69 GHz and RAM: 32 Go). They amount to 30 s and 2 min for cases 1 and 2 respectively. When the weather file is used and the Batisol® thermal panel model is added, the simulation times are slightly longer but remain below 5 min.

3.1. Profile of the hot inlet temperature following a step

For the case 1, the input temperature profile follows a ramp from 283.15 to 363.15 K in the first second of the simulation. The evolution of the liquid fraction and the temperature of the PCM in the tank are studied in Fig. 4 over time for the first slice of PCM in contact with the hot plate (for x = 0 m), according to the vertical. The colours purple, green and red refer to the high (y = 0.4 m), middle (y = 0.2 m) and low (y = 0 m) parts of the PCM respectively. Solid lines are used for the temperature and dashed lines are preferred for the liquid fraction. The same marking and colour code will be used in the following sections. Initially, the PCM is in the solid state

(f_l = 0) at 283.15 K. Its temperature increases until it reaches the melting temperature (291.95 K) at 18.2 s for y = 18 (in purple), the top of the PCM in contact with the hot plate. This temperature is reached at 20.8 s for the middle of the PCM (in green), and 23.2 s for the bottom of the PCM (in red). From these times onwards, the temperature of the PCM remains constant while the liquid fraction increases until it reaches unity, indicating that all the PCM has changed from the solid to the liquid state. This event occurs at 78.0, 82.1 and 87.5 s for the top, middle and bottom of the PCM respectively. From then on, the liquid fraction remains constant and the temperature of the PCM gradually increases, while approaching the temperature of the hot HTF.

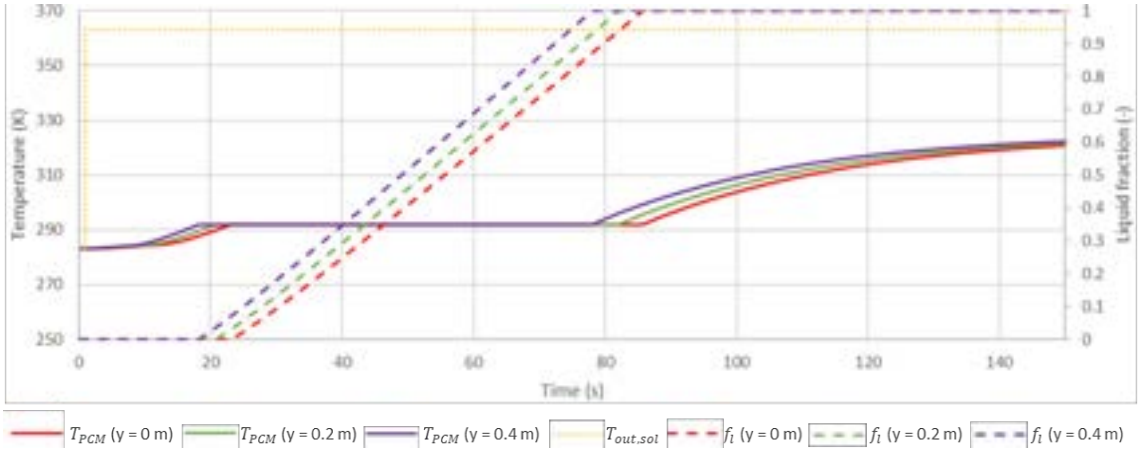

Figure 4: Case 1: Temperature and liquid fraction evolution for the first PCM layer in contact with the hot plate (x = 0 m) and for y = 0, 0.2 and 0.4 m.

The evolution of these two variables has also been studied for different values of x in Fig. 5. As the battery is symmetrical, only the coordinates at x = 0 (in red), 0.06 (in yellow) and 0.2 m (in green) are presented for the sake of clarity. In this case, the profiles are clearly different. The phase change from solid to liquid state is clearly visible for the first layer in contact with the hot plate. For x = 0.06 m, the temperature evolves linearly without reaching the melting temperature. As a result, the liquid fraction remains constant and equal to zero. For the PCM in the middle of the battery (x = 0.2 m), the temperature remains almost constant (283.15 K), indicating that the heat has not reached the core of the battery in 150 s.

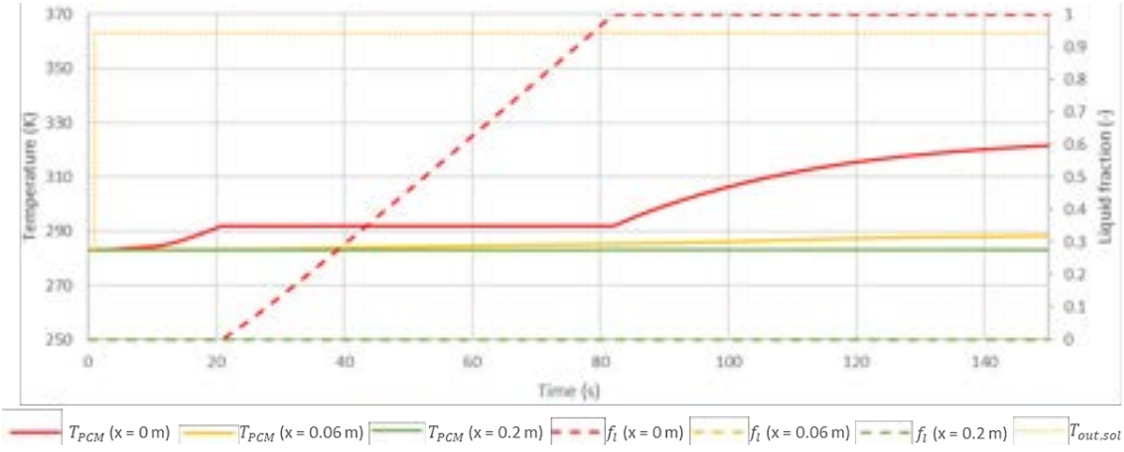

Figure 5: Case 1: Temperature and liquid fraction evolution in the longitudinal direction (for x = 0, 0.06 and 0.2 m) for the PCM layer in the middle (y = 0.2 m).

Figures 4 and 5 show the interest of considering a 2D model for PCM tank, according to longitudinal (x) and vertical (y) directions, since the temperatures in the PCM are different in both directions.

3.2. Profile of the hot inlet temperature following a trapezoidal function

Before studying the thermal behaviour of the storage connected to the solar facade, a trapezoidal function is used to simulate the evolution of the hot temperature at the battery inlet (Fig. 3). The period of this function is decomposed on 28800 s of width, 16200 s of rising , 7200 s of width, 14400 s of falling, for a total period of 86400 s. The temperature and liquid fraction are studied as before, for the first slice in contact with the hot

plate (for x = 0 m) (Fig. 6), and the slice in the middle of the PCM (for y = 0.2 m) (Fig. 7). The same evolution as for the ramping test is observed. In a first step, the temperature of the PCM increases until it reaches the melting temperature of the PCM (at 30634 s) (Fig. 6a). Then the liquid fraction increases until it reaches unity (Fig. 6b). At this point (31049 s), the temperature of the PCM increases again (Fig. 6a). The temperature of the PCM follows the temperature of the hot HTF at the battery inlet, with an average difference of less than 6%. In order to store as much heat as possible and not send it to the solar circuit, it can be interesting to stop the charging step when the temperature of the PCM becomes higher than that of the hot coolant. Figure 6 shows that this moment occurs at 52200 s.

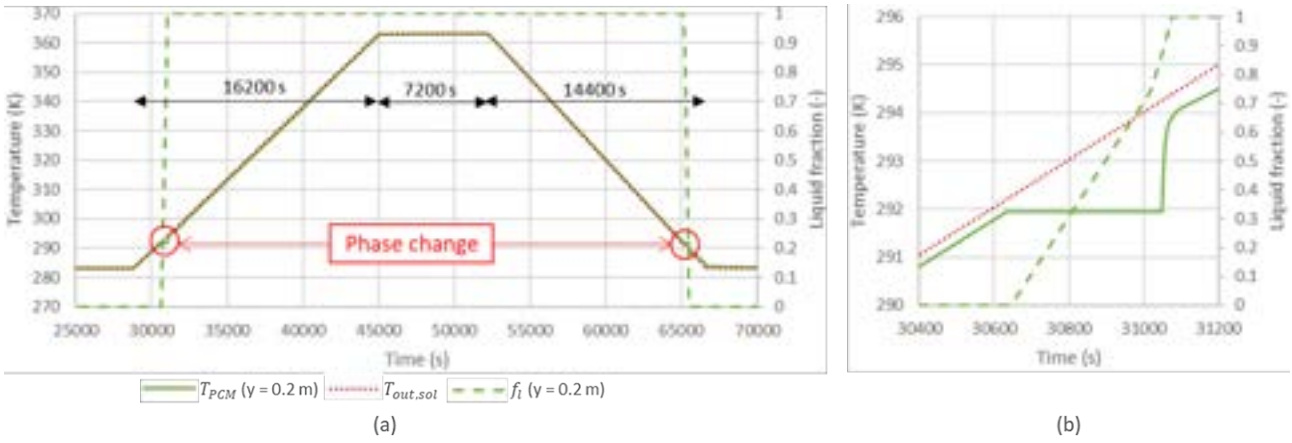

Figure 6: Case 2: Temperature and liquid fraction evolution for the first PCM layer in contact with the hot plate (x = 0 m) and for y = 0.2 m (a), focus on the phase change between 30634 and 31049 s (b).

Figure 7a shows the evolution of the temperature and liquid fraction of the PCM in the longitudinal direction (x = 0, 0.06 and 0.2 m) for the PCM layer at y = 0.2 m. The difference in temperature is clearly visible for the three curves. The further the PCM is from the hot plates, the lower its temperature and the longer the phase change takes. The heat propagation is thus clearly visible along the PCM. The core of the PCM (x = 0.2 m in green) takes the longest time to melt, but also to solidify as the hot inlet temperature decreases. The change from liquid to solid state is thus much longer (13 times longer) than for the PCM layers closer to the hot plate. For the yellow curve (x = 0.06 m), after the phase change, slight instabilities are visible in the PCM temperature. This must be due to the discretisation step and/or the discretisation scheme, whose order should be increased to be more accurate, and/or the DASSL integrator whose tolerance must be increased. The phase change step is significantly larger for x = 0.2 m. This is because the heat propagates from layer to layer. During the phase change of a PCM layer, all the energy required to achieve the phase change is absorbed. Therefore, for the liquid fraction of the layer x = 0.2 m to fluctuate, the liquid fractions of the previous layers must already have reached an equilibrium (solid or liquid state). This is illustrated in Fig. 7b, which shows a zoom of the transition from solid to liquid state (between 31000 and 35000 s) for the layers x = 0 (in red), 0.02 (in purple), 0.04 (in blue) and 0.06 m (in yellow). It can be seen that the liquid fraction of the next layer increases when the liquid fraction of the layer under consideration has reached 1. As a result, even if the melting temperature of the PCM has been reached for a PCM layer, it is necessary to wait until the change of state has taken place in the layers closer to the hot plates before the phase change begins in the PCM layer.

3.3. Profile of the hot inlet temperature following the outlet temperature of the Batisol® panels

When the PCM-based storage is connected to the Batisol® thermal panels, the temperature of the inlet hot HTF is calculated by 1. The surface area of the thermal panels is 25.5 m^2 (5 m wide by 5.1 m long). The surface area consists of 16 panels with 24 channels. Meteorological data from Cholet (next to Nantes) in 2021, in the northwest of France, are used. Figure 8 presents the evolution of the solar power and the outdoor temperature for the 2 periods (winter and summer) considered. The solar power amounts to 112 W/m^2 over the 8 winter days considered, whereas over the summer period considered this value is 2.5 times higher. The average outdoor temperature is 280 K and in summer 291.83 K. These two periods were chosen to represent different types of days, with more or less sunshine and wind, cold or hot outside temperatures (Fig. 8). In addition, 8-day periods were considered in order to determine the capacity of the battery to store heat during renewable energy intermittencies and day/night alternations.

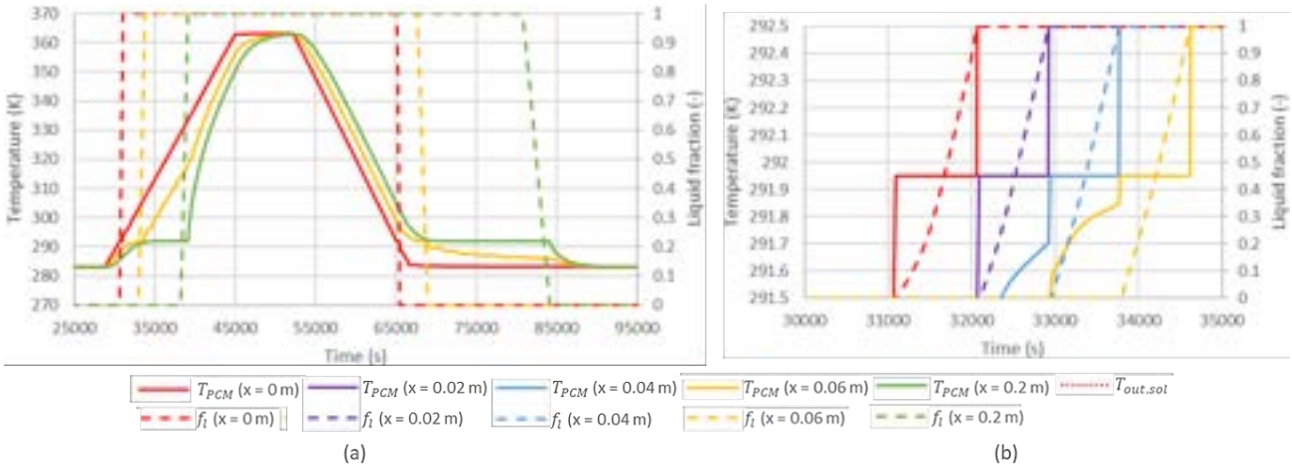

Figure 7: Case 2: Temperature and liquid fraction evolution in the longitudinal direction (for x = 0, 0.06 and 0.2 m) for the PCM layer in the middle (y = 0.2 m) (a), focus on the phase change of the first four PCM layer (from x = 0 to 0.06 m) (b).

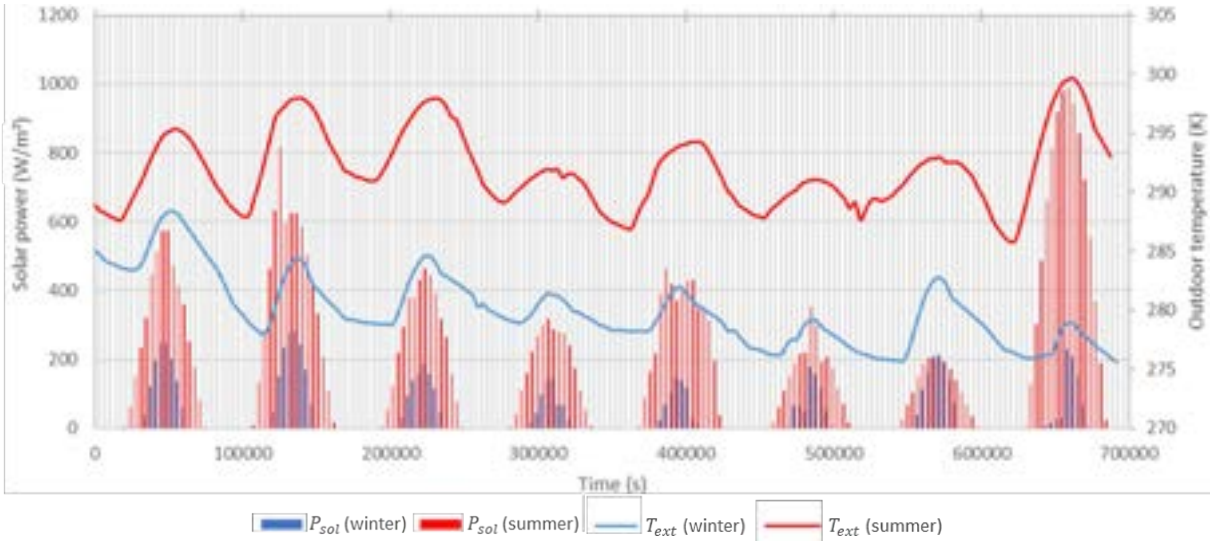

Figure 8: Cases 3 and 4: Evolution of solar power and outdoor temperature over the 8 days studied in winter and summer.

3.3.1. Winter period

The winter period chosen to simulate the behaviour of the PCM battery is from January 1 at 0am to January 8 at 23pm. In order to simplify the understanding of the graphs over longer periods (8 days), only the temperature and liquid fraction of the middle cell (y = 0.2 m) of the layer in contact with the hot plate (x = 0 m) are considered in Fig. 9. Over the 8 days simulated, the temperature at the exit of the solar facade is only higher than the melting temperature of the PCM on four days (Fig. 3). The PCM temperature exceeds the melting temperature only on January 1, 2, 3 and 7, as shown in Fig. 9. Indeed, the liquid fraction remains zero except between 11.15am and 4.5pm on January 1st, between 12.4pm and 16pm on January 2, between 14pm and 15.15pm on January 3, between and 13pm and 15.5pm on January 7. On other days, the PCM never reaches the melting temperature. Nevertheless, heat is stored in the solid state, as with sensible TES but with low efficiency. Fig. 9 shows that it is important to choose a material with a melting temperature that is not too high in order to take advantage of the phase change. If the melting temperature was 298.15 K (291.95 K for C-L acid), the PCM would not have changed state during the winter period under consideration. As a result, the use of PCM-based storage would not be interesting.

The temperature of the PCM in contact with the hot plate is almost as high as that of the hot HTF at the inlet, with an average difference of 0.3% over the 8 days. Figure 10a shows the evolution of the temperature and liquid fraction for the PCM layer at y = 0.2 m and for x = 0 (in red), 0.06 (in yellow) and 0.2 m (in green). As seen earlier, the temperatures are lower and lower from the outside of the PCM towards the inside. Indeed,

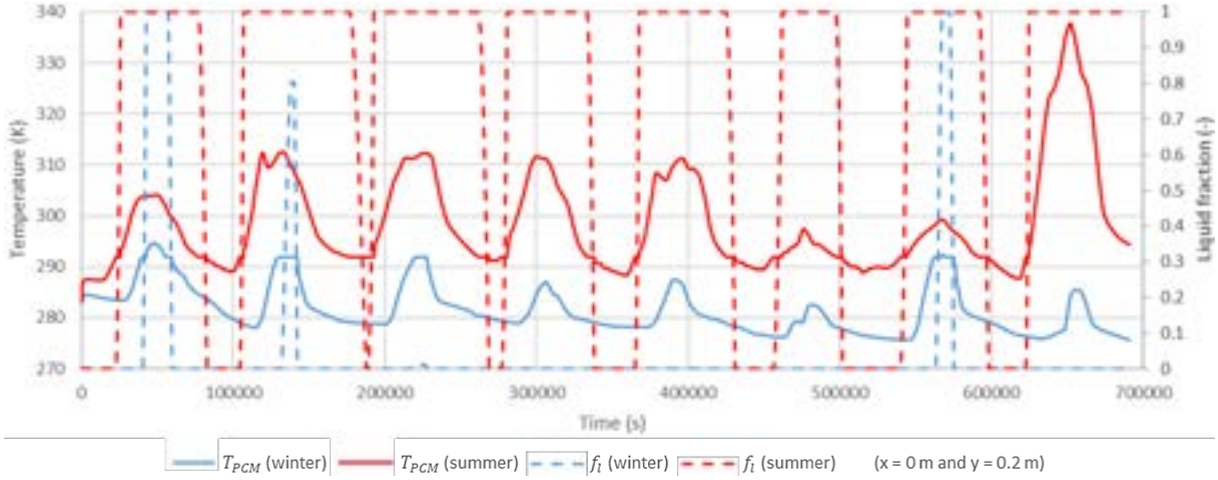

Figure 9: Cases 3 and 4: Temperature and liquid fraction evolution for the first PCM layer in contact with the hot plate (x = 0 m) and for y = 0.2 m.

the green curves show that the PCM has not changed state in the middle of the thermal battery. Furthermore, Fig. 10 shows the heat propagation along the PCM, with lower temperatures at the ends of the PCM, after the hot temperature at the inlet is decreased (after 60000 s). In general, the heat propagates well in the PCM, since the temperature differences between the different layers of PCM in the hot HTF are less than 0.8%. The instabilities visible at x = 0 and 0.06 m are due to the slight change in temperature at the outlet of the thermal panels (red dotted line in Fig. 10a), which of course depends on the weather conditions. These instabilities appear at the extremities of the PCM close to the hot plates (such as at x = 0 and 0.06 m) but not at the centre of the PCM (at x = 0.2 m). As seen previously, the liquid fraction of the x = 0.2 m layer remains zero while the melting temperature has been reached (291.95 K at 53100 s). This is due to the liquid fractions of the layers closer to the hot plate, which have not all reached unity. The output temperature of the solar panels decreases from 47483 s onwards, and consequently the energy supplied to the PCM. As a result, the middle layer (x = 0.2 m) has not received enough energy to make its phase change. Figure 10b is a zoom of the phase change (solid to liquid) in Fig. 10a. Before a layer changes phase, it is necessary that the liquid fraction of the previous layer has reached unity. Figure 10b shows this clearly, with the increase from 0 to 1 in the liquid fraction at x = 0 m (38900 to 40440 s), then that at x = 0.02 s (40440 to 42747 s), then that at x = 0.04 m (42747 to 44826 s) and finally that at x = 0.06 m (44826 to 47470 s).

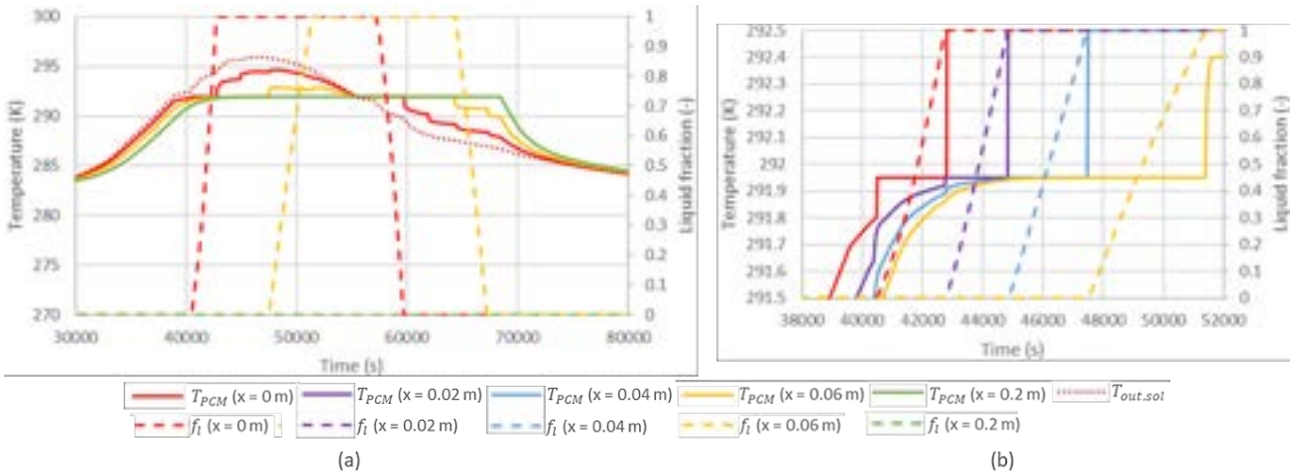

Figure 10: Case 3: Temperature and liquid fraction evolution in the longitudinal direction (for x = 0, 0.06 and 0.2 m) for the PCM layer in the middle (y = 0.2 m) (a), focus on the phase change of the first four PCM layer (from x = 0 to 0.06 m) (b).

3.3.2. Summer period

The summer period chosen to simulate the behaviour of the PCM battery is from July 1 at 0am to January 8 at 23pm. The temperature and liquid fraction at x = 0 m and y = 0.2 m are shown in the same figure as the winter period (Fig. 9). The temperature of the hot HTF at the storage inlet is significantly higher than during the winter

period (up to 340 K vs 296 K as illustrated in Fig. 3). The differences between the maximum temperatures expected by the hot fluid at the outlet of the thermal panels range from 2% (January 7 and July 7) to 16% (January 8 and July 8). On average the temperatures are 8% higher in summer. As a result, the behaviour of the PCM is also different between winter and summer periods, with phase changes occurring less often in winter. The advantage of using PCM in summer is therefore much greater, since it is possible to limit the size of the battery thanks to the change in the state of the material, unlike the use of sensible storage. Even on less sunny days such as July 6, when the temperature of the hot HTF does not exceed 297 K, there is enough heat to allow the PCM to change state. The PCM remains in a liquid state longer than in winter, between 7am and midnight on average over the 8 days considered.

As for the winter period, the difference between the temperature of the PCM in contact with the plate and that of the hot HTF is small (0.5% difference on average over the 8 days). Figure 11a shows the evolution of the temperature and liquid fraction for the PCM layer at y = 0.2 m and for x = 0. (in red), 0.06 (in yellow) and 0.2 m (in green). The temperature differences from the outside to the inside of the PCM are also clearly visible. From 16.4pm onwards, the temperature of the PCM in the core of the battery is higher than that of the PCM in contact with the hot plate. It would therefore be interesting to stop the charging step and start the discharging step by switching the hot (solar system) and cold (heat pump) inputs. The same instabilities as for winter period appear in Fig. 11a for the same reasons (small fluctuations of the temperature at the outlet of the thermal panels due to climatic conditions). The phase change zoom of the first four layers is illustrated in Fig. 11b (for x = 0 (in red), 0.02 (in purple), 0.04 (in blue) and 0.06 m (in yellow)).

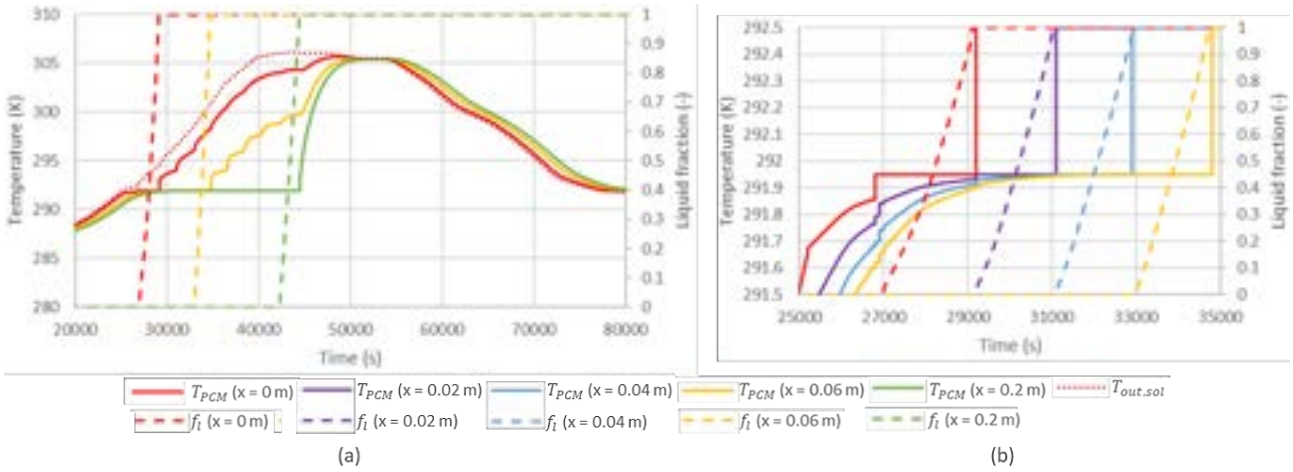

Figure 11: Case 4: Temperature and liquid fraction evolution in the longitudinal direction (for x = 0, 0.06 and 0.2 m) for the PCM layer in the middle (y = 0.2 m) (a), focus on the phase change of the first four PCM layers (from x = 0 to 0.06 m) (b).

The energy stored by the thermal battery for the two periods considered (winter and summer) is given in Table 2. During the winter period under consideration, the average stored energy is 164 Wh per day. In summer, this value is 6 times higher. The sunniest days (January 1st in winter and July 8 in summer) store 5 to 7.5 times more energy than the days less suitable for thermal collectors (January 6 and July 6). On average, the PCM battery can store 2.6 kWh/m^3 per day of energy in winter and 6.6 kWh/m^3 for January 1st. In summer this value reaches 15.1 kWh/m^3 per day on average and 29.3 kWh/m^3 for July 8. The benefit of PCM is clearly visible in summer, with almost 6 times more energy stored by the battery than in winter, partly due to the more frequent phase changes.

Table 2: Energy stored in the thermal battery per day (Wh).

Period	Minimal value	Maximal value	Mean
Winter	56 (January 6)	423 (January 1st)	164
Summer	385 (July 6)	1877 (July 8)	964

4. Conclusion

A dynamic model of a SAHP based on the use of thermal panels (Batisol®) and a latent heat storage was presented. This system aims to provide the heating and domestic hot water needs of a building. The TES is

composed of a PCM contained between two plates where HTF circulate. During the charging step, the hot HTF is fed by the thermal panels. During the discharging step, the direction of the fluid is reversed and the cold HTF is fed by the heat pump.

The thermal behaviour of the PCM tank is studied for four different profiles of the charging temperature: ramping, trapezoidal functions, temperature at the outlet of the thermal panels in winter (from January 1 to 8) and in summer (from July 1 to 8). The simulations carried out in OpenModelica showed the behaviour of the PCM during the phase change. The developed model showed the importance of choosing a PCM with a melting temperature range suitable for the studied application. In winter, only the sunniest days allows the PCM to melt while in summer the phase change occurs every day. On average, this thermal battery can store 6.6 and 15.1 kWh/m^3 per day of energy in winter and summer respectively.

The simulations showed that the 2D model of the system is necessary to take into account the horizontal and vertical temperature variations in the battery. This model will be further validated with experimental data. It will also allow the development and the validation of a simpler model. The final goal will be to optimise the SAHP system on its operational parameters with the simpler model.

Abstract:

The present work focuses on two particular performance indicators for hydrogen storage solutions based on the thermal integration of metal hydrides (MH) with phase-change materials (PCMs): i) the (specific) discharge power and ii) the system-level volumetric capacity. The paper first condenses available literature data from modelling and experimental activities, and then analyses a basic numerical benchmark of a low-temperature MH-PCM system.

Findings from the literature review show that, due to the interrelation between efficient thermal management and hydrogen desorption rate, the selected performance indicators are not independent one from another. It is also confirmed that simultaneously achieving high-power (flexibility) and specific capacity (compactness) is a challenging goal for such kind of hydrogen storage systems. The parametric analysis of the numerical benchmark system suggests that, for a given MH operating pressure-temperature envelope, special care should be given in the PCM accurate characterisation and selection, as well as in the quantification of the optimal trade-off between the PCM volume and desorption kinetics performance. Furthermore it is found that the geometrical distribution of the MH and PCM volumes have a larger than expected impact on the specific discharge power.

Hydrogen Storage; Metal Hydrides; Phase Change Materials; Power; Volumetric Capacity.

1. Introduction

In order to attain a net zero-carbon footprint, it is imperative to produce a substantial share of energy from sustainable sources (IPCC, 2022). Hydrogen is currently recognised as an essential element in facilitating the incorporation of large-scale renewable energy sources (Bartolucci et al., 2021). It also has the potential to become a primary energy carrier, being capable of transporting and distributing energy across various sectors and regions while also improving the energy system's resilience by serving as a buffer (Bartolucci et al., 2023; Kovač et al., 2021). To establish a commercially sustainable H2 economy, it is crucial to store, transport, and distribute H2 as needed for power and heat generation in various applications (Abohamzeh et al., 2021a). Recent research published through the H2 Technology Collaboration Program of the International Energy Agency has provided a positive outlook on the future prospects of H2-based energy storage. Several studies have explored the integration of renewable energy systems with H2 storage to achieve net-zero-emission energy systems and sustainable development goals (Petkov & Gabrielli, 2020). The increasing affordability of H2 utilization technologies, such as fuel cells, may replace battery storage through electrolysers/H2 storage due to their higher efficiency, reliability, and performance (Yue et al., 2021). To present, the cost of H2 systems is higher compared to battery systems, but recent research activities on the H2 value chain for various applications are anticipated to make them competitive by 2030 (Abbasi & Abbasi, 2011).

H2 storage techniques can be broadly categorised into two groups: physical storage and material storage. Physical storage relies on the principle of compression and liquefaction. In contrast, material storage encompasses several systems and provides various utilization methods based on service conditions. Currently, the accepted standard for H2 storage is in high-pressure gaseous form, with storage pressures of up to 700 bar in steel or carbon fibre reinforced polymeric vessels (Nazir et al., 2020). Compressed H2 (CH) technology offers the advantage of fast filling and release rates, as well as lower storage costs. However, CH has several well-known limitations, including reduced storage efficiency, limited volumetric storage capacity, and safety concerns. Compressing H2 from typical production conditions (20 bar) up to 700 bar results in a 9-

12% reduction in net energy stored (Nazir et al., 2020). If Type 4 vessels are considered, the effective volumetric storage capacity of CH at 700 bar is approximately 25 kg/m3. For stationary applications, it is preferable to storage pressures as low as 50 bar or less, for a better integration with renewable H2 generation and to operate under safer conditions. However, at 50 bar, the volumetric capacity of CH systems falls below 2 kg/m3, which would require very large vessels for long-term storage (Abohamzeh et al., 2021b; Maestre et al., 2021).

Metal hydrides (MH) are a promising alternative to replace compressed hydrogen (CH) for stationary applications due to their inherently higher volumetric storage capacity and moderate operating pressures and temperatures (Bellosta von Colbe et al., 2019; El Kharbachi et al., 2020). Mg-based and intermetallic hydrides are the focus of recent MH storage technology development (Ben Mâad et al., 2016; El Mghari et al., 2019, 2020; Garrier et al., 2013; Marty et al., 2013; Mellouli et al., 2015). Mg-based hydrides have attractive reversible gravimetric capacities, material safety, and low cost, but their high reaction enthalpy, high equilibrium temperature, and slow kinetics require catalyst particle additions (Pasquini et al., 2022). Intermetallic hydrides of the AB2 or AB5 types are preferred thanks to their ease of activation, good reversibility, and comparatively fast kinetics (Pasquini et al., 2022). Due to the highly exothermic/endothermic hydrogen absorption/desorption reactions, proper active or passive thermal management is necessary for high-power applications involving MH storage systems (Facci et al., 2021; Nguyen & Shabani, 2021). Active thermal control allows for effective performance tuning, but generates energy losses and may add significant mass and volume at system level (Motyka, 2014). Passive thermal control, specifically through the adoption of phase-change materials (PCMs), is a promising solution due to its energy efficiency gains and inherent simplicity (Nguyen & Shabani, 2021).

Darzi et al. (Rabienataj Darzi et al., 2016) examined how hydrogen is charged and discharged into and from a cylindrical metal hydride tank made of LaNi5, while also studying the heat transfer to a surrounding jacket filled with PCM. El Mghari et al. (El Mghari et al., 2020) analysed five different PCMs and emphasised that the ratio of the total heat of diffusion of the PCM to the total heat of reaction of the MH is a significant factor in achieving complete hydrogenation of the tank. Alqahtani et al. (Alqahtani, Mellouli, et al., 2020) used numerical methods to investigate the hydrogenation and dehydrogenation processes of an MH reactor surrounded by PCM. They doubled the number of interfaces between the MH reactor and PCM by encompassing the MH reactor with a cylindrical sandwich bed filled with PCM, resulting in an 81.5% and 73% improvement in the time required for hydrogenation and dehydrogenation processes, respectively, compared to a conventional MH-PCM system that includes only a single PCM tank (Alqahtani et al., 2020b). Ye et al. (Ye et al., 2020, 2021) proposed a novel MH-PCM unit where a PCM layer is sandwiched between two layers of MH, which exhibited average absorption and desorption rates about 4.5 and 2.4 times higher, respectively, than the traditional cylindrical configuration.

Several authors have examined the advantages of increasing the thermal conductivity of PCMs to improve the performance of hydrogen storage. To achieve this goal, various methods have been explored. For example, Nguyen et al. (Nguyen et al., 2022) investigated the application of an organic PCM for the thermal management of MH hydrogen storage and found that the use of embedded copper foam to enhance thermal conductivity is crucial for achieving an adequate power performance. Chibani et al. (Chibani et al., 2022) conducted numerical analysis to examine the impact of incorporating PCM into metal foam on the performance of hydrogen desorption from MH. Lewis and Chippar (Lewis & Chippar, 2021) studied the charging and discharging of hydrogen in a LaNi5-based reactor equipped with PCM and emphasised the influence of metal foam and its morphology on hydrogen storage and thermal performance, which can enhance hydriding/dehydriding reaction rates. Bourzgarrou et al. (Bouzgarrou et al., 2022) demonstrated that a well-designed U-type heat pipes insert in the metal and PCM media can significantly reduce loading time by up to 88%, depending on the melting temperature.

Although the majority of the papers discussed various methods to improve the power and capacity of MH tanks, they usually did not consider the overall H2 storage capacity at the system level, neither the power/capacity ratio. To address this gap, the authors conducted a thorough analysis of the relevant parameters for some of the studies mentioned above, selecting the ones where all the information required was directly or indirectly available. The purpose of this analysis was to illustrate the difficulty of simultaneously achieving a high discharge power/capacity ratio and a high system-level H2 volumetric storage capacity, as depicted in Figure 1. The current paper aims, therefore, in highlighting capacity and power enhancement factors through a representative MH-PCM computational framework, targeting at the optimisation of both performance indicators.

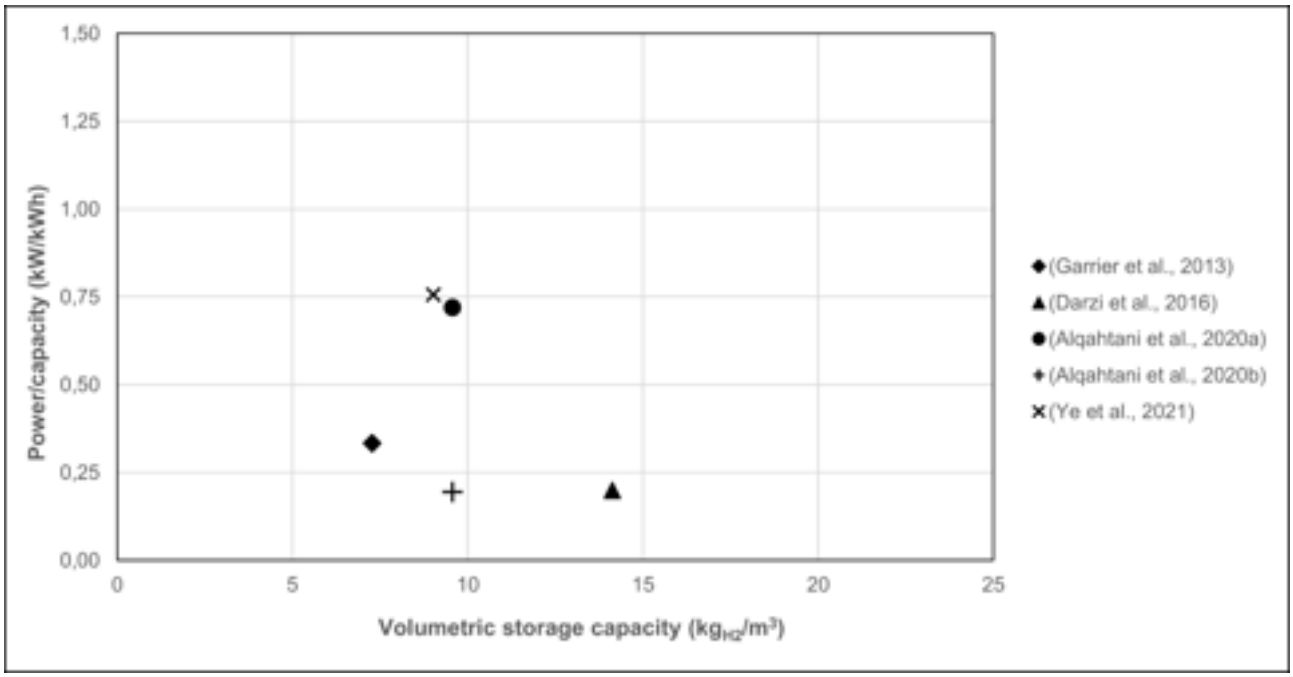

Figure 1. Specific discharge power vs. volumetric storage capacity of MH-PCM systems, literature review.

2. Numerical benchmark

2.1. Problem and setup description

A simple vertically oriented cylindrical MH reactor geometry, surrounded by a PCM-filled jacket, has been taken as a reference for the numerical analysis part of the present work (Figure 2). An analogous MH-PCM system has already been studied during hydrogen filling by two of the authors in a previous publication (Bartolucci & Krastev, 2022) , as well as by other researchers (Alqahtani, Bamasag, et al., 2020b) but none of them focusing on the specific discharge power vs. volumetric capacity performances. The selected MH is a low-temperature intermetallic $LaNi_5$-H_2 system, while the PCM is an inorganic $LiNO_3$-$3H_2O$ salt hydrate. The latter has been recognised in previous research works as one of the best performing PCMs for pairing with low-temperature MHs (Bartolucci & Krastev, 2022; El Mghari et al., 2020). The most relevant MH and PCM properties are listed in Tables 1 and 2. The baseline geometry is exactly equivalent to the one already investigated in (Bartolucci & Krastev, 2022), while it has been subsequently altered to optimise the PCM quantity and to test different slenderness factors H/D, with $D = 2R_i$ (see Table 3).

All the simulations here presented are based on the following main assumptions:

a. the MH-PCM reactors are represented as 2D axisymmetric geometries;
b. the MH bed volume is kept constant for all reactor geometries;
c. the external boundaries of the MH-PCM reactor (except for the hydrogen outlet boundary) are all adiabatic;
d. hydrogen is released from the MH bed at a known and constant pressure (atmospheric pressure);
e. gaseous hydrogen is assumed to follow the ideal gas law;
f. the MH bed is considered as an isotropic porous medium with uniform porosity and permeability;
g. local thermal equilibrium is assumed to hold within the $LaNi_5$-H_2 system;
h. buoyancy is not considered for the heat transfer and melting phenomena within the PCMs;
i. density of the PCM is considered constant and equal to the average between solid and liquid values;
j. other thermophysical properties of PCMs vary with temperature according to the available data, unless differently specified.

The MH-PCM system bed simulation framework has been implemented in ANSYS® Fluent (*ANSYS® Academic Research CFD, Release 2020 R2, Fluent User's Guide*, 2020), combining ad-hoc developed User

Defined Functions (UDFs) for hydrogen desorption with the enthalpy-porosity method (Voller & Prakash, 1987; Voller & Swaminathan, 1991) for phase transition. For a detailed explanation of model equations and of the UDF implementation procedure, the reader is redirected to (Bartolucci & Krastev, 2022). References for the phase transition modelling can be found also in (Krastev & Falcucci, 2021). All the numerical predictions reported here adopt a numerical time step equal to 0.1 s, with a physical simulated time of 10^4 s. All computational grids are made of quad-uniform elements with a 0.5 mm spacing. At the beginning of each simulation, the initial temperature of the system is set to 313 K and the pressure inside the MH tank is set at the equilibrium value for that temperature. Discharge pressure at the tank outlet is 1 bar.

Table 1. Main thermophysical and reaction properties of the $LaNi_5$-H_2 system.

Parameters	*Description*	*Values*

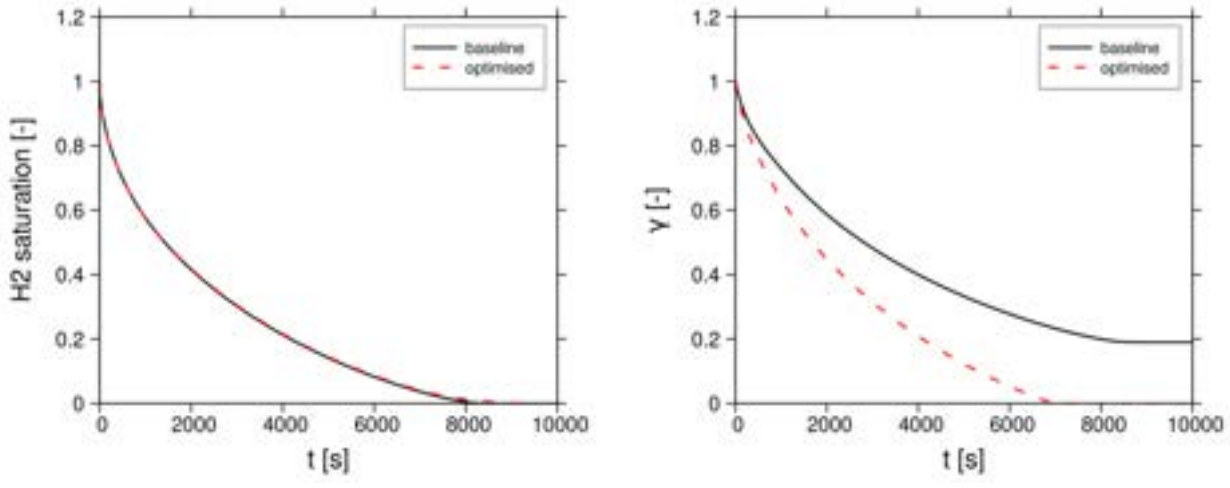
2.2. Results

In this Section, numerical prediction results are shown in terms of the hydrogen discharge dynamics, PCM liquid fraction and temperature evolution in the MH and PCM tanks. Figures 3 and 4 compares the baseline and mass-optimised reactor configurations, where the same slenderness factor (H/D = 2) for the MH container is assumed for both. Note that the PCM mass optimisation was obtained through the following simple relationship between the total enthalpy of reaction of the desorbed H2 mass and the PCM latent heat of fusion:

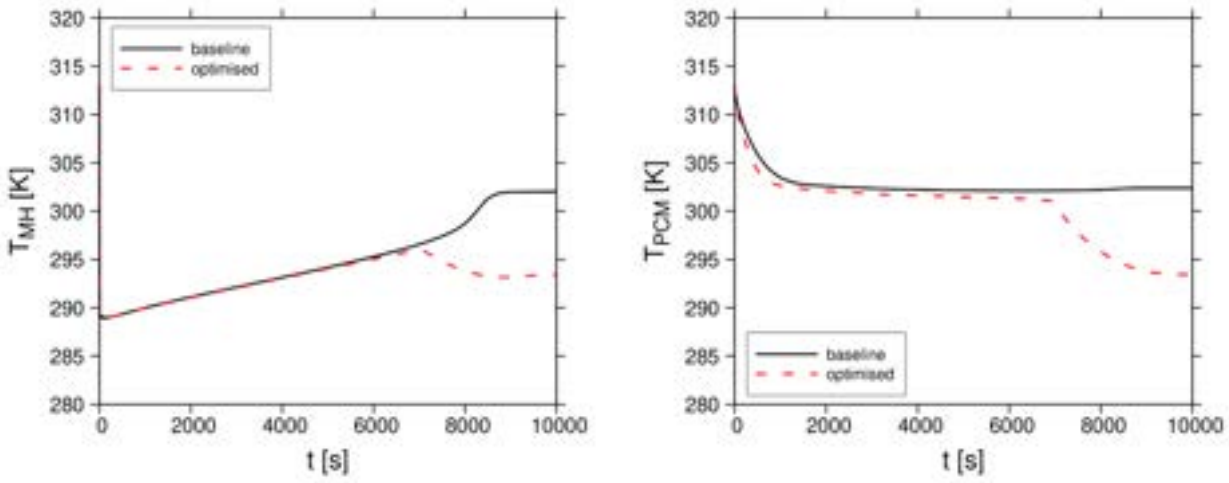
$$m_{PCM} = \frac{m_{H2} \cdot \Delta H_R}{L_f} . \quad (1)$$



(a) (b)

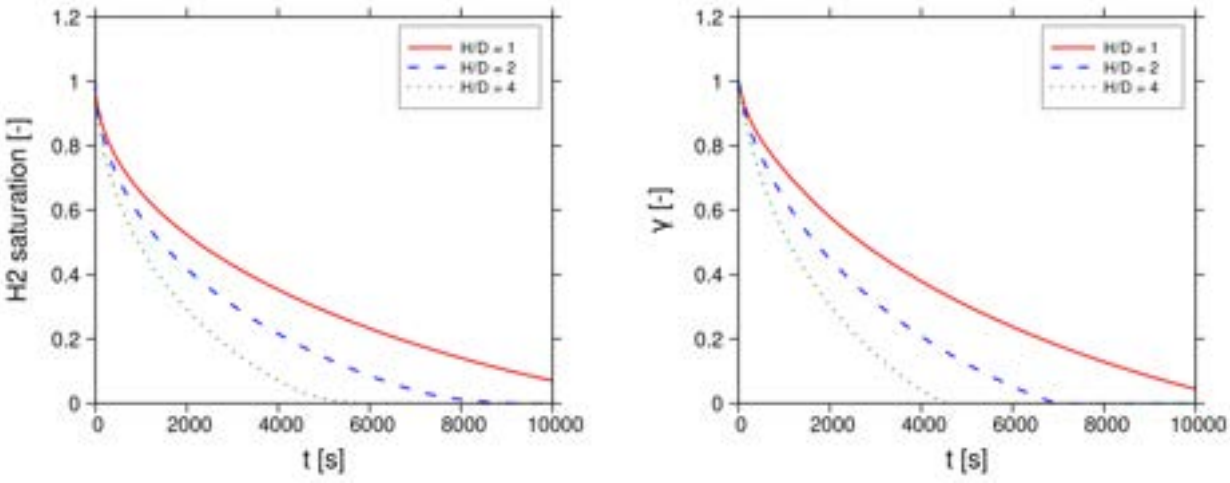
Figure 3. Comparison between the baseline and mass-optimised MH reactor configurations, in terms of a) hydrogen discharge curve and b) PCM liquid fraction over time.

Figure 3a confirms that the baseline and mass-optimised configurations have essentially equivalent H2 discharge performances (both are able to discharge 95% of the absorbed H2 mass within 6800 s, with a 1.2 % deviation among the two), while Figure 3b evidences that around 20% of the PCM latent heat capacity is not exploited in the baseline case. Figures 4a and 4b show that, if the PCM has not undergone full phase transition, the MH-PCM system finds its thermal equilibrium close to the melting temperature. Conversely, if the PCM fully melts before all the H2 mass is completely desorbed, the system's equilibrium temperature is significantly lower (around 294 K vs. around 302 K) and closer to the MH equilibrium temperature at the discharge pressure (around 289 K for this case). The latter is beneficial for a subsequent H2 filling of the MH bed, as it would ensure larger temperature gradients between the MH and PCM containers during the initial phase of the exothermic H2 absorption process.



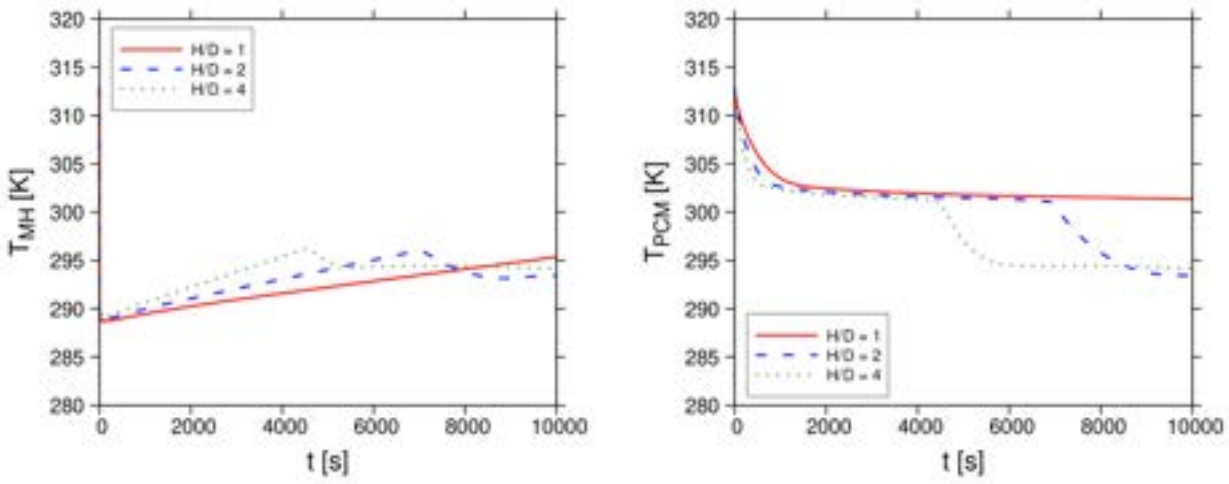
(a) (b)

Figure 4. Comparison between the baseline and mass-optimised MH reactor configurations, in terms of a) volume-averaged MH reactor temperature and b) volume-averaged PCM jacket temperature over time.



(a) (b)

Figure 5. Effects of the slenderness factor H/D on the hydrogen discharge performances: a) hydrogen discharge curve; b) PCM liquid fraction over time.

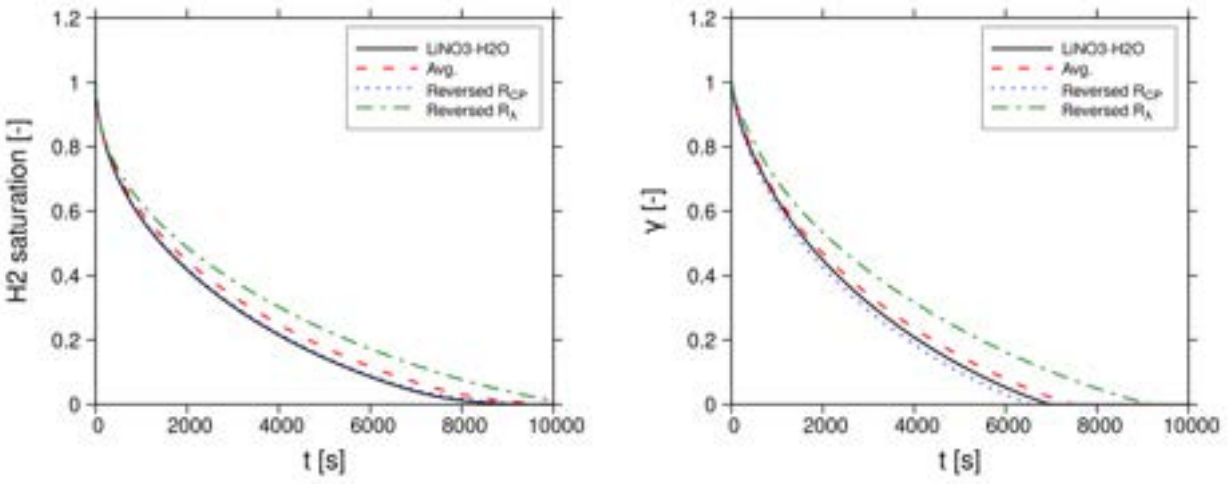


(a) (b)

Figure 6. Effects of the slenderness factor H/D on the temperature evolution: a) volume-averaged MH reactor temperature and b) volume-averaged PCM jacket temperature over time.

Figures 5 and 6 allow to evaluate the effect of the slenderness factor H/D on the MH-PCM system discharge dynamics, given the same MH and (optimal) PCM volumes. Raising H/D from 2 to 4 accelerates the hydrogen mass discharge by 37% and thus the average discharge power by 57%. On the opposite, the case with H/D = 1 has a 58% slower discharge dynamics compared to H/D = 2, with the 95% mass discharge actually occurring around 10700 s after the start of the simulation. These differences are most likely to be related to the changes in the radial-wise conductive thermal resistance, as the assumptions listed in Section 2.1 consistently suggests a quasi-1D conductive heat transfer regime in the radial direction, which is also well in line with findings from previous research on cylindrical MH-PCM systems (Bartolucci & Krastev, 2022).

A last series of computations has been performed on the H/D = 2 optimised geometry, changing some of the PCM properties within the simulations. Tests have been made with all constant properties and equal to the solid-liquid average, as well as with reversed Cp and λ liquid-to-solid ratios compared to the actual $LiNO_3$-$3H_2O$ material characteristics. Figure 7 condenses the results obtained, pointing out that: i) using constant and averaged properties introduces acceptable deviations from the actual material behavior (less than 10% deviation on the 95% discharge time); ii) the PCM Cp phase variations have little to no effect on the H2 discharge dynamics; iii) during H2 discharge, the PCM starts to immediately solidify at the PCM-MH heat transfer interface: the solid-phase radial thermal conductivity has, therefore, a dominant effect and when it falls below the MH effective radial conductivity (Reversed R_λ case) it might significantly slow down discharge dynamics.



(a) (b)

Figure 7. Effects of changes in the PCM properties on the hydrogen discharge performances: a) hydrogen discharge curve; b) PCM liquid fraction over time.

Figure 8 resumes the major findings from the numerical simulations, within the context of the literature review already presented in the Introduction Section. Unsurprisingly, to reach system-level volumetric capacities above 15 kg_{H2}/m^3 it is essential to optimise the minimum required PCM mass and an effective first-level optimization can be made through simple latent heat-based principles. In that regard, selecting PCMs with high densities and latent heat of fusion, such as salt hydrates in the low-temperature PCM range, brings obvious additional benefits.

In terms of specific discharge power, an accurate geometrical optimization of the MH-PCM system, which must take into account the actually dominant heat transfer mechanisms, is crucial. Significant improvements can be potentially achieved even for very simple cylindrical layouts, with no complex conduction-enhancing solutions (e. g. metal fins or foams, blends with graphite fibres or other nano-particles). Still, theoretical and simulation based results has to be verified in realistic engineering environments, taking into account some complex material behaviour that might have been purposely omitted at modelling level: a typical example, related to the findings of the present work, is the well known tendency of salt hydrates to undesired vertical phase separation, which might be difficult to control or minimise in slender vertical containers.

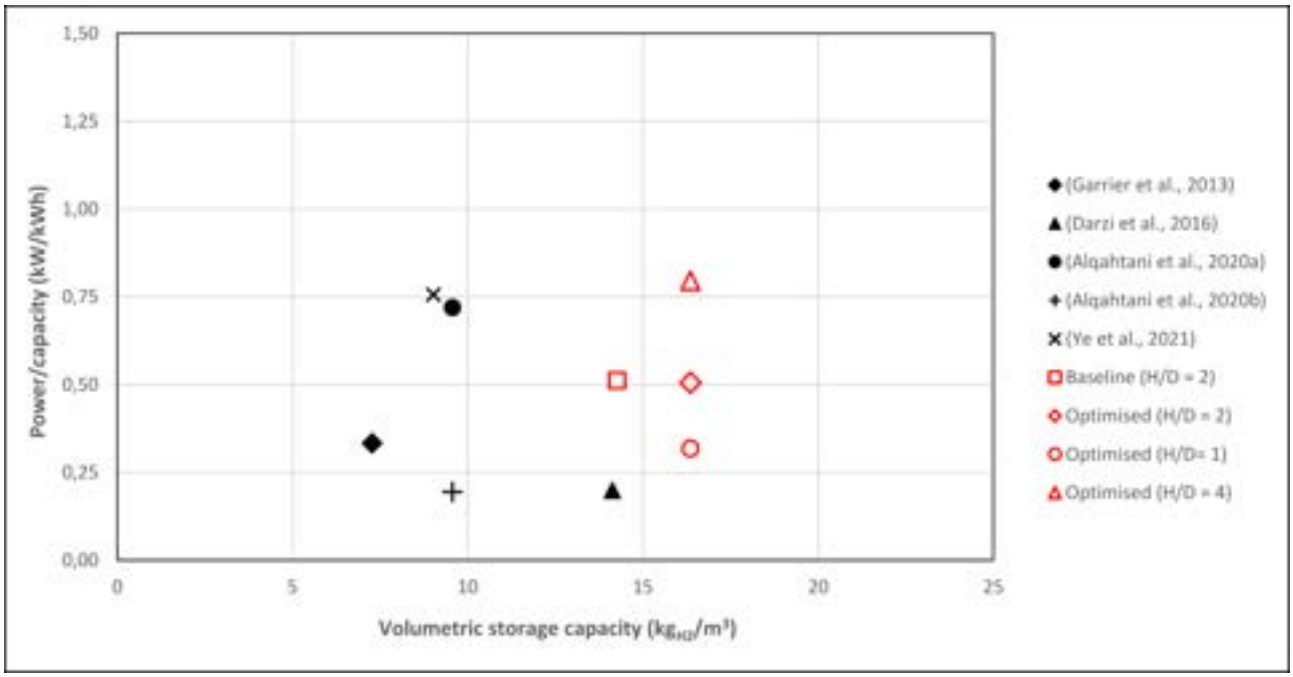


Figure 8. Specific discharge power vs. volumetric storage capacity of MH-PCM systems, literature review (black symbols) and results from the numerical benchmark analysed in the present work (red symbols).

4. Conclusions

From the literature analysis and numerical simulation results shown in this paper, the following conclusions can be drawn regarding MH-PCM system performances during hydrogen discharge:

- although it is often difficult to extract reliable performance indicators from the published works, the previously proposed systems cannot generally simultaneously achieve power/capacity ratios and system-level volumetric storage capacities above 0.75 kW/kWh and 15 kg_{H2}/m^3, respectively;
- the proposed numerical benchmark demonstrates that, in the case of jacket-like cylindrical MH-PCM configurations, these threshold can be exceeded through relatively simple optimization steps, like PCM mass optimization and system shape (slenderness factor H/D) optimization;
- mass optimization of the PCM is essentially linked to the latent heat of fusion, volume optimization comes as a consequence once the PCM density is also considered;

- for vertically-oriented jacket-like systems, higher slenderness factors significantly increase specific discharge power for a given volumetric capacity: is reported that moving from H/D = 1 to H/D = 4 produces a 150% power gain, peaking at a power/capacity ratio of 0.8 kW/kWh;
- the influence of the slenderness factor is explained by the quasi-1D nature of the heat transfer phenomena in this specific discharge case: heat transfer is dominated by conduction in the radial direction and, as such, it is accelerated by lowering the thermal resistance in that direction (smaller radial thicknesses);
- following the previous point, increasing the thermal conductivity in the radial direction both in the MH bed and PCM is also beneficial for a power increase; in that sense, on the PCM side the solid phase thermal conductivity plays the major role during hydrogen discharge (PCM solidification);

Future developments will include a further expanded literature research and the analysis of additional performance influence factors, such as the hydrogen discharge pressure, alternative MH-PCM system geometries, MH pressure-temperature-kinetics envelope.

Abstract:

In the current electricity grids, it is becoming pivotal to install a large amount of storage capacity in order to maximize the deployment of renewable energy sources, stabilize the grid, and mitigate electricity price volatility. Engineering research focused on improving storage technologies performance aiming to improve the round trip efficiency and increase the utilization opportunities. Besides storage implementation, power plant flexibility is pursued as well to support electricity grids in the transient stage towards a decarbonized energy mix. Recent studies have investigated the possibility of enhancing the flexibility of Combined Cycle Gas Turbine (CCGT) power plants by means of a heat pump and a cold thermal energy storage, this solution demonstrated a relevant potential, especially in those locations characterized by warm climates and volatile electricity markets. In such a situation is possible to fully exploit the cold thermal energy storage, decreasing the net power output, during storage charging in off-peak periods, and boosting it, through inlet cooling, during the most profitable periods. This paper performs a techno-economic comparison between cold thermal energy storage for gas turbines air inlet cooling and other established energy storage technologies (such as pumped hydro, batteries, compressed air, and pumper thermal storage) for time load shifting and energy arbitrage on the day ahead market. The analysis is based on Linear Programming (LP) and Mixed Integer Linear Programming (MILP) models for the optimization of the dispatch. The impact of market parameters on storage technologies performance is investigated and discussed, selecting the best option for each considered scenario.

Storage; Flexibility; CCGT; Heat Pump; Optimization; Electricity Market;

1. Introduction

The awareness about the ongoing climate change due to emissions of Green House Gasses (GHG) has led in the last decades almost every country to pledge drastic GHG emission cuts [1] and a complete transition to a decarbonized economy is commonly scheduled for the horizon of 2050 or 2070 [2]. The first step of the Energy Transition has been the massive installation of electricity generation capacity from Renewable Energy Sources (RES). Approximately 2 TW have been installed globally in the period 2010-20, and the overall share of electricity generation from RES reached 28%, overcoming 40% in many advanced economies even considering a significant contribution of hydropower [3]. Even a higher amount of RES capacity is forecast to be installed in the near future (between 2.4 and 3.7 TW by 2027 [4]); indeed, carbon intensity targets have been set more and more challenging and the demand for low-carbon electricity is expected to grow following the coupling of different energy sectors, such as Heating or Transportation [5].

Nevertheless, since the hydropower growth potential is limited, most RES capacity addiction depends on solar and wind sources, strongly characterized by discontinuity and stochasticity. Although forecasting of RES production in advance has improved significantly, especially thanks to artificial intelligence and data-driven modeling [6,7], the mismatch between demand and production remains a severe issue and a significant amount of green electricity is often curtailed because of an overgeneration or a lack of transportation capacity of electricity grids [8]. Curtailments are negligible for PV generation but are relevant for wind, Especially in countries characterized by high wind energy shares, i.e., above 30%, up to 10% of wind generation can be curtailed [9]. Within this context, energy storage became a pivotal technology that must be implemented massively at the grid scale to support the energy transition and maximize the dispatch of renewable energy [10]. To be impactful on energy system management, storage must present adequate both power and energy sizes, there is no unique definition of grid-scale storage size. However, in this paper, 1 MW discharge power for at least 1h is assumed as a threshold value. For such applications pumped hydro,

electrochemical batteries, compressed air, and pumped thermal energy storages are the most promising technologies, there many other solutions have been investigated, but currently present a too-low technology readiness level (TRL) on such a scale.

Besides bulk energy arbitrage, i.e., the action of buying cheap energy during off-peak price periods, storing it, and selling it during price-peaking periods, storage technologies can be employed to provide services to the grid. This paper focuses only on load time shifting by energy arbitrage as the most relevant use considering the energy involved and the pivotal importance to maximize the RES dispatch and reduce the carbon footprint of electricity generation.

Historically the first form of energy storage implemented on a large scale was pumped hydroelectric storage (PHS), it represents a variation of conventional reservoir hydroelectric power plants. Energy is stored in the form of potential energy of water that is pumped from a lower reservoir to an upper reservoir [11]. PHS is a consolidated technology, already implemented widely at the grid scale since the 1970s to absorb the excess base load production from coal and nuclear power plants [12]. PHS plants have been installed especially in those regions characterized by an existing hydroelectric potential, such as the Alps in Europe, and along both the East and West Coast in the US [13]. However, within a liberalized electricity market, oligopolistic ownership, especially if both PHS and conventional power plants are managed by the same operator, may lead to an under-exploitation of it, as in the case of Italy [14]. In fact, a strategic operation of PHS could reflect in social welfare losses [15]. From a technological perspective, PHS is characterized by a Round Trip Efficiency (RTE) typically ranging between 70% and 80% even if up to 87% have been claimed [11]. One of the major issues of PHS implementation concerns site identification that must satisfy criteria of technical and economic feasibility together with social acceptance. A systematic approach for new PHS site identification has been developed and applied by Connolly et al. [16]. An interesting variance application concerns seawater PHS whose main advantage is to be not subject to the constraint of water availability in the lower reservoir [17].

Battery Energy Storage (BES) are probably the technology expected to grow more in the next years. The International Energy Agency states that, according to the Net *zero emission by 2050* scenario, 680 GW of BES must be installed by 2030. 16 GW were already installed in 2021 [18]. Various BES types exist, the most interesting for large-scale applications include lithium-ion (Li-ion), sodium-sulfur (NaS), lead acid (Pb-acid), lead-carbon batteries, as well as zebra batteries (Na-$NiCl_2$), and flow batteries. Li-ion BESs represent almost the totality of installed grid-scale capacity (92% in the US [19]) mainly because of the round trip efficiency of up to 97% DC-DC [20,21], corresponding to 85-95% AC-AC [22]. NaS batteries are available since the early 2000s at MW scale [23] and are particularly appreciated for their achievable depth of discharge (up to 90%) [21], while the main drawback is the thermal management since they operate in the range of 300-350°C, causing up to 20% per day of parasitic losses during idle periods [24]; similar issues are presented by Zebra BES [23]. Lead-acid BESs are appreciated for their high recyclability [25] and reduced CAPEX even if characterized by a reduced lifespan [21]. Flow batteries use aqueous electrolytes with one or more dissolved active species; the electrolytes are stored in tanks, and, pumped through an electrochemical cell where energy conversion takes place, because of this architecture this kind of battery shows a unique capability to decouple energy and power [26], however, they are characterized by significantly higher energy density and lower efficiency. Vanadium redox flow batteries show the best values of RTE but are still limited to 75-85% [27]. A relevant issue of BES is the relevance of system degradation and aging: this strongly depends on usage mode and should be considered for optimal dispatch [28].

Compressed air Energy Storage (CAES), store energy as compressed air, for large applications typically underground reservoir are used. Even if porosity and permeability are mandatory requirements, geological constraints are not as strict as for PHS [29]. The clean medium, the moderate CAPEX for a unit of stored energy, and scalability are the most appreciated features. In contrast, low RTE, reduced depth of discharge, and a considerable response time are the main drawbacks [30]. RTE may be increased by advanced techniques for managing heat generated during the compression phase. According to these, CAPEX can be classified into Diabatic-CAES, more mature but less efficient, wasting compression heat and burning fuel, typically natural gas to preheat air before the expansion during the discharge phase, Adiabatic-CAES adopting a TES to store the compression heat and release it during the expansion without any fuel consumption, and Isothermal-CAES claiming RTE up to 70% but characterized by low TRL [31].

Pumped Thermal Energy Storage (PTES), also known as Carnot Batteries, is a type of energy storage system that uses thermal energy to store and release energy. PTES systems store energy by pumping a heat transfer fluid between two reservoirs at different temperatures. During the charging phase, power is used to drive a heat pump and transfer heat from the colder reservoir to the hotter one. To discharge the storage, the process is reversed, and the heat transfer fluid is pumped back from the hotter reservoir to the colder one, generating electricity in the process. PTES potential advantages for grid-scale applications include long cycle life, low life-cycle environmental impact, and appreciable energy density. However, the main drawback is a low RTE, which is typically in the range of 40-70% [32]. Additionally, PTES implies relevant specific CAPEX €/kW for the power and charging unit. PTES can be classified according to the discharging method, exploiting Brayton or Rankine cycles; the charging methods, mainly including reverse

thermodynamic cycles and or the use of electrical resistance; and type of Thermal Energy Storage (TES), sensible, latent, or chemical [33,34].

Besides these technologies, an interesting application was studied in recent years to couple a Combined Cycle Gas Turbine (CCGT) with an Inlet Conditioning Unit (ICU) consisting of a heat pump (HP) and a cold (5°C) TES, connected as in the scheme (Figure 1). The ICU could work i) continuously, employing the HP to conditionate the CCGT intake, ii) as equivalent energy storage indeed using cheap electricity to drive the HP and charge the cold TES and using it to cool down the CCGT intake and boost the power output during the price peak periods without additional auxiliary losses. Preliminary works assessed the impact of intake temperature on the CCGT performance to investigate the potentialities of an ICU integration [35]. Subsequently, by means of a Mixed Integer Linear Programming (MILP) approach, it was developed a methodology to optimize the scheduling of an integrated ICU-CCGT power plant on the day-ahead market only [36] or considering the potentialities from an ancillary services provision [37]. Finally, a comprehensive assessment was carried out considering different European and US market and climate scenarios [38]. Considering that an ICU can be installed retrofitting existing CCGT plants and that those plants currently represent the backbone of many electrical systems, installing an ICU is equivalent to an investment in energy storage technology since it may be employed for the purpose of energy arbitrage and increasing the ability of the plant to supply grid services.

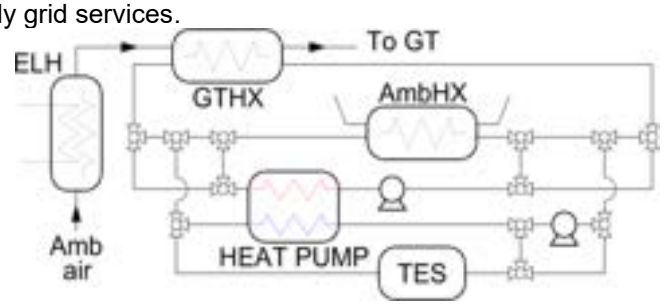

Figure. 1. Inlet Conditioning Unit (ICU) scheme

The present paper aims to carry out a marked-based economic comparison between grid-scale available storage technologies, including the ICU-CCGT integration. Even if the participation of storage in the flexibility markets is today an interesting perspective, such markets are strongly characterized by uncertainties and are hard to generalize among different country rules, therefore the proposed comparison only considers the possibility for storage to perform energy arbitrage on the day-ahead market. The novelty of the approach is to compare pure storage technologies against a flexible solution for refitting CCGT.

2. Methodology

A previous work identifies 9 market clusters in Europe and USA characterized by similar profit opportunities for ICU-CCGT integration [38]. In this paper, a techno-economic comparison between available grid-scale storages is carried out on the same markets (i.e., the centroids of previously identified clusters). The approach consists in determining the best scheduling of dispatch for each storage maximizing the Net Operational Profits (NetOP). Historical electricity price data have been used for this purpose [39,40]. Net Operational Profits are then used to compute techno-economic indicators: Pay Back Period (PBP) and Internal Rate of Return (IRR) are used for the economic assessment because of their independency of the storage size and the interest rate. Net Operational Profits, eq. (1), are defined as Revenues from selling electricity minus costs of charging and any cost associated with the degradation of the storage itself. Equations (2) define the PBP, and equation (3) the NPV such as the IRR is the value of i to which it follows NPV=0. Where N is the lifetime in years.

$$NetOP = \sum \left(Revenue - C_{charging} - C_{degr} \right) = \sum \left(OP - C_{degr} \right) \quad (1)$$

$$PBP = \frac{CAPEX}{OP} \quad (2)$$

$$NPV = -CAPEX + \sum_{n=1}^{N} \frac{OP_n}{(1+i)^n} \quad (3)$$

Storage operations are scheduled daily adopting an hourly resolution and an optimization horizon of 36h, as suggested by Vasylyev et al. [41]. According to this strategy price information beyond the daily horizon is provided to the optimizer. While the output concerning the first 24h is maintained, the scheduling from the 25th to the 36th will be overwritten by the following day optimization.

For the ICU-CCGT integration, the optimization of dispatch is carried out by means of the developed Mixed Integer Linear Programming (MILP) optimizer presented in detail by Mantilla et al. [36], and updated in the following works [37,38]. The objective function, equation (4) accounts for electricity price [39,40], gas cost (assumed as Henry Hub and TTF spot price for US and Europe respectively), CO_2 emission allowance cost [42], O&M cost, and cost associated with start-ups.

$$max \sum_{i=1}^{36} p_{el_i} \cdot (P_i^{out} - P_i^{HP} - Q_i^{elh}) - C_{gas_i} \cdot (Q_i^{fuel}) - C_{hs} V_{ji}^h - C_{ws} \cdot V_i^w - C_{CO2} \cdot e \cdot (Q_i^{fuel}) - O\&M_{var} \quad (4)$$

The first term in (4) represents the revenues from selling on the market the net power output, i.e., the algebraic sum of CCGT, HP, and electric heater power. The second term represents the cost of fuel, then two different start-ups are considered, hot (hs) and warm (ws), C is the cost associated with the start-up and V is a binary logic variable. The cost associated with CO_2 emission is computed as the unitary cost of allowance times the emission factor *e* times the fuel consumption. Finally, Operation and Maintenance costs are included.

For the other storage technologies, a linear Programming (LP) optimizer is proposed. The problem is formulated by equation (5). x represent the array of solutions, the first 37 elements are the solution itself, i.e., the State of Charge (SOC) before and after each of the 36 time intervals, elements from 38 to 73 represent the values of the first auxiliary variable (C_{degr}) dealing with the cost associate with degradation at each time step, finally, elements from 74 to 109 represent the second auxiliary variable (C_{ineff}) dealing with the cost of charge and discharge inefficiency at each time step.

$$\min_x f^T x \ \ s.t. \begin{cases} A \cdot \mathrm{x} \leq \mathrm{b} \\ A_{eq} \cdot \mathrm{x} = b_{eq} \\ lb \leq \mathrm{x} \leq \mathrm{u}b \end{cases} \quad (5)$$

$$x^T = \left(SOC_1 \quad \dots \quad SOC_{37} \quad , C_{degr_1} \quad \dots \quad C_{degr_{36}} \quad , C_{ineff_1} \quad \dots \quad C_{ineff_{36}}\right) \quad (6)$$

f is the array of coefficients of objective function expressing the linear dependence between the solution array x and objective, i.e., the sum of net operational profits over the optimization period.

The first 37 elements of f directly link the SOC and revenues from discharging and the cost due to charging, while the elements from 38 to 109 are equal to -1.

$$f^T = \left(\left(-p_{el_1}\right) \cdot \frac{E_{max}}{100} \quad \left(p_{el_1} - p_{el_2}\right) \cdot \frac{E_{max}}{100} \quad \dots \quad \left(p_{el_{36}}\right) \cdot \frac{E_{max}}{100} \quad , \quad -1 \quad \dots \quad -1 \, , \quad -1 \quad \dots \quad -1\right) \quad (7)$$

The linear constraints, expressed by the matrix A and array b, relate the auxiliaries variables C_{degr} and C_{ineff} to the difference of SOC within the relative time interval. More in detail 5 different types of constraints are imposed. The two first limits the maximum difference, respectively upward (equation(8)) and downward (equation (9)), the limit is imposed by the maximum admissible power (even expressed as C-rate for BESS) during charge and discharge. These constraints are expressed by means of the time constant τ, i.e., the minimum time [h] required by a complete charge or discharge, equal to the ratio between nominal capacity E_{max} and the maximum charging and discharging power.

$$SOC_i - SOC_{i-1} \leq \frac{100}{\tau_{ch}} \quad (8)$$

$$SOC_{i-1} - SOC_i \leq \frac{100}{\tau_{disch}} \quad (9)$$

Secondly, matrix A imposes the C_{degr} at each time interval. For some kinds of storage, such as BES, lifetime is determined by the maximum number of cycles. Consequently operating the storage has a cost since once the maximum number of equivalent cycles is reached the storage must be replaced paying again the CAPEX. Each equivalent cycle has, therefore, a cost equal to the ratio between CAPEX and the maximum number of equivalent cycles, equation(10), then the degradation cost at the time interval i depends on the fraction of equivalent cycle performed on that interval, equation (11).

$$C_{cycle} = \frac{CAPEX}{N_{cycle_{max}}} \quad (10)$$

$$C_{degr_i} \geq C_{cycle} \cdot \frac{|SOC_{i+1} - SOC_i|}{100} \quad (11)$$

Finally, the cost of charging and discharging efficiency is considered.

$$C_{inef_i} \geq \begin{cases} (SOC_{i+1} - SOC_i) \cdot p_{el_i} \cdot \frac{E_{max}}{100} \cdot \left(\frac{1}{\eta_{ch}} - 1\right), & (SOC_{i+1} - SOC_i) > 0 \\ (SOC_i - SOC_{i+1}) \cdot p_{el_i} \cdot \frac{E_{max}}{100} \cdot (\eta_{disch} - 1), & (SOC_{i+1} - SOC_i) < 0 \end{cases} \quad (12)$$

Furthermore, A_{eq} and b_{eq} impose the SOC at the initial time: for the first optimization, the minimum SOC allowed is used, while for the subsequent optimizations the SOC_{25} of the previous day is set. Lower bounds and upper bounds are imposed consistently as follows.

$$lb^T = (100 - DoD_{max} \quad \dots \quad 100 - DoD_{max} \, , \quad 0 \quad \dots \quad 0, \quad 0 \ \dots \ 0) \quad (13)$$

$$ub^T = (100 \quad \dots \quad 100, \quad inf \quad \dots \quad inf, \quad inf \quad \dots \quad inf) \quad (14)$$

3. Storage preliminary sizing

The ICU-CCGT integration design is a fairly complex process that must take into account the site market and meteorological specificity, even when focusing on just continuous cooling [43]. However, the size indicated by previous works (i.e., 10 MWh and 10 MW of Thermal Energy Storage and a 3.5 MW Heat Pump) as the preferable value was used to maintain comparable results. The corresponding CAPEX has been estimated at 6.3 M€ [36,44]. To proceed to a fair comparison between this solution and pure storage technologies a preliminary sizing of the latter is required.

Sizing is diriment because it directly impacts capital expenditure. The overall CAPEX depends on the storage size [MWh], the charging, and the discharging power [MW]. Table 1 reports assumed values for this paper from an existing literature survey. As a consequence, the specific CAPEX [€/kWh] depends on the storage duration τ_{disch} and the ratio between charging and discharging time constant, τ_{ratio}. Figure 2 shows the trend of specific CAPEX versus τ_{disch} considering τ_{ratio} between 1 and 6. However, BES CAPEX is typically expressed as an exclusive function of the storage capacity since capacity and power are strictly correlated and typically increased power does not imply extra costs, especially considering that if an hourly time interval is assumed, as in this paper, there is no advantage in adopting C-rate beyond 1 that are therefore not investigated. Thus BES curve in Figure 2 is flat.

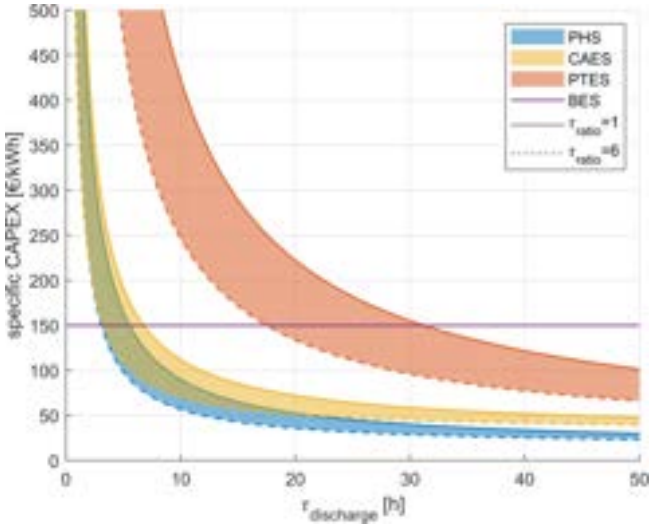

Figure. 2. Storage specific CAPEX versus duration of discharge

Figure 2 shows that BESs are the most economical storage for a short duration, generally, the other technologies CAPEX are very sensitive to the duration when it drops below 10h since the cost of power units becomes predominant. Increasing τ_{ratio} leads to savings in CAPEX decoupling charging and discharging power. Charging equipment cost weights more than the discharging one, so the impact of the τ_{ratio} is crucial in balancing the effect of reducing the CAPEX by decreasing the size of the charging equipment by a factor $1/\tau_{ratio}$, while increasing the operational charging time accordingly. This can be exploited if the duration of the off-peak price period is greater than the peak duration and if the off-peak price profile is constant, so $\tau_{ratio}>1$ is not directly reflected in an OP decrease. For a short duration, capital expenditure implied by CAES and PHS are comparable, nevertheless considering increased τ values the weight of storage cost itself is much more relevant if compared to the charging and discharging power units CAPEX, consequently in this case PHS is more advantageous because the cost per kWh is almost half of CAES.

Table 1. Technical and economic assumptions for each storage technology

	BESS	**PHS**	**CAES**	**PTES**
E_{max} [MWh]	1MWh	7 GWh	250 MWh	250 MWh

$CAPEX_{disch}$	-	350€/kW	300€/kW	1900€/kW
Lifetime_max	25yr	80yr	35yr	35yr
$N_{cycle\ max}$	7500	-	-	-
ref	[28,45]	[46]	[46]	[47]

To preliminary size BES, PHS, CAES, and PTES, yearly optimizations are performed to quantify OP, PBP, and IRR. Different scenarios have been investigated, considering years from 2018 to 2022 and the 9 market zone identified as a relevant statistical sample for the ICU-CCGT integration [38]. The driving market factor for energy arbitrage is the price difference that can be exploited. Equation (15) expresses in a general form the minimum discharge price to be worth operating storage, it depends on the charging price, the efficiency of charging and discharging, and the degradation costs.

$$p_{el_{disch}} > \frac{C_{degr}}{\eta_{disch}} + \frac{p_{el_{ch}}}{\eta_{disch}\eta_{ch}} \tag{15}$$

Therefore to characterize each market scenario the average daily variability $\overline{\Delta p_{el_d}}$ is adopted highlighting the distance between the discharging price $p_{el_{disch}}$ and the charging price, $p_{el_{ch}}$, on a daily basis. Table 2 reports the values of $\overline{\Delta p_{el_d}}$ and the yearly average price, $\overline{p_{el_y}}$, for each year and zone. Optimizations have been performed considering data synthesized in Table 1 as input of the LP scheduler described in the Methodology section.

Table 2. Average daily electricity price spread and yearly price average [€/MWh] in the considered years and zones.

Table 3 reports the Utilization Factor (UF) as the first output of storage dispatch optimizations, the reported τ_{disch} and τ_{ratio} are selected as the best in the following economic analysis for each storage technology. The UF is defined as the ratio between the discharged energy and the energy discharged if a cycle until the maximum allowed depth of discharge was performed daily.

$$UF = \frac{\sum_1^{n_{days}} E_{disch}}{E_{max} \cdot \frac{DoD_{max}}{100} \cdot n_{days}} \tag{16}$$

Table 3. UF [-] computed on a yearly basis for the best storage duration

Table 3 indicates that the highest UFs are reported by BES in 2022, under considerably favorable market conditions. This occurs especially in those bidding zones, typically as southern and central Europe, characterized by two distinct and prominent price peaks, in the morning and early evening, and presenting the opportunity to perform two cycles in a day. On the opposite side, other markets, e.g. Texas, even characterized by a relevant daily variability, typically show only one peak in a day, thus the second daily

discharge is very rare. Finally, markets characterized by flat electricity price and reduced variability, e.g., Norway, shows reduced potential for arbitrage for all the storage technologies.

If BES scored the UF highest values, CAES UF is considerably robust (around 1) even under less favorable market scenarios. However, CAES is characterized by a very low allowed DoD (50%), which means that, designing τ_{disch}=12h, just 6h are required to discharge until the maximum allowed depth. 12h and 10.8h are required by PTES and PHS respectively. The operativity of storage would depend only on the frequency with equation (15) is satisfied, consequently BES has a great advantage thanks to high efficiency, and low τ_{disch} and τ_{ch} but, differently than other technologies, it pays the impact of degradation costs, especially in low and moderately variable markets. If the amount of energy discharged is considered, PHS operates more than CAES because of the highest efficiency, while PTES is almost unutilized because of the too low efficiency and therefore excluded by the following analyses.

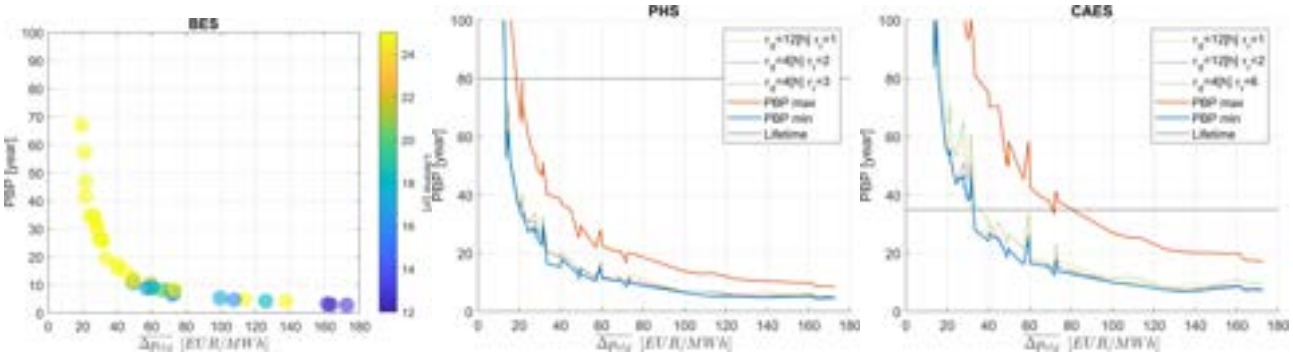

Figure. 3. BES, PHS, and CAES Pay Back Period (PBP) vs the average daily variability of electricity price

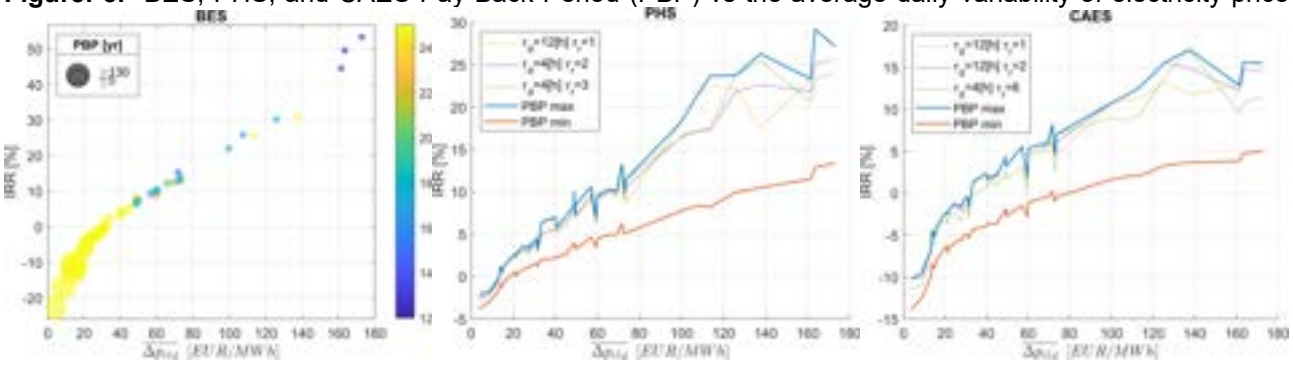

Figure. 4. BES, PHS, and CAES Internal Rate of Return (IRR) vs the average daily variability of electricity price

Figures 3 and 4 show the PBP and the IRR assessed by means of the annual cash flow, as an output of the yearly optimizations. Consequently, trends are drawn considering 45 values and the relative $\overline{\Delta p_{el_d}}$, from 5 years and 9 bidding zone reported in Table 2. Trends appear smooth enough to confirm the outcome of [38], identifying $\overline{\Delta p_{el_d}}$ as the best predictor for energy storage economic performance.

BESs present the lowest PBP; for $\overline{\Delta p_{el_d}}$ >50-55 €/MWh it drops below 10 years, however, the expected lifetime reduces as well because of the increased utilization. Besides the cycling aging of BES, calendar aging must be considered. According to the model presented by Stroe et al. [28], the maximum calendar life for an idling battery is about 25 years, this value is assumed as ceil even if the maximum number of cycles is not reached. Such an underutilization is typical of those markets with daily variability below 50€/MWh. The IRR increases with $\overline{\Delta p_{el_d}}$ and it is positive beyond 30€/MWh of daily variability.

For PHS and CAES the ranges of τ_{disc} and τ_{ratio} (i.e., the ratio between τ_{ch} and τ_{disc}) indicated in Table 1 are investigated. The blue and the red lines in Figures 3 and 4 represent the envelope of best and worst points respectively, moreover, three other lines are plotted for the three combinations of τ_{disc} and τ_{ratio} that more often result as the best possible. Both for PHS and CAES the best couple is τ_{disc}=12h and τ_{ratio}=1, while the second and the third rank differ for the two technologies showing that selecting τ_{ch} about 12-24h is preferable for CAES to limit CAPEX. PBP shows similar trends for CAES and PHS, even if under extremely favorable conditions (right side of charts) the PBP stabilizes at a slightly lower value for PHS (about 5 years, while 8 years are required to pay back the CAES) because of the lower specific CAPEX, as shown by Figure 1, and the higher efficiency. Moreover, it must be considered that the expected lifespan is significantly higher for PHS and this is reflected in the IRR which is positive even for reduced $\overline{\Delta p_{el_d}}$ (>10-15€/MWh).

For the purpose of the comparison between traditional storage technologies and the CCGT-ICU integration in Section 3, the best τ_{disc} and τ_{ratio} are selected.

4. ICU-CCGT comparison

The comparison is carried out on the three market zones that showed the highest potential for the integration of an ICU in an existing CCGT: SCE in California, northern Italy (NORD), and LZ_CPS in Texas[i] [38]. Respective reference locations for historical climate data are Los Angeles, Milan, and San Antonio. The previous section highlights how the bidding zone is not relevant for BES, PHS, and CAES but what is diriment is the exploitable variability in electricity price on a daily basis. Thus, for these technologies, is proposed an aggregated analysis, Figure 5 shows trend lines both for PBP and IRR built on rational 3rd-degree function fitting all 45 available values.

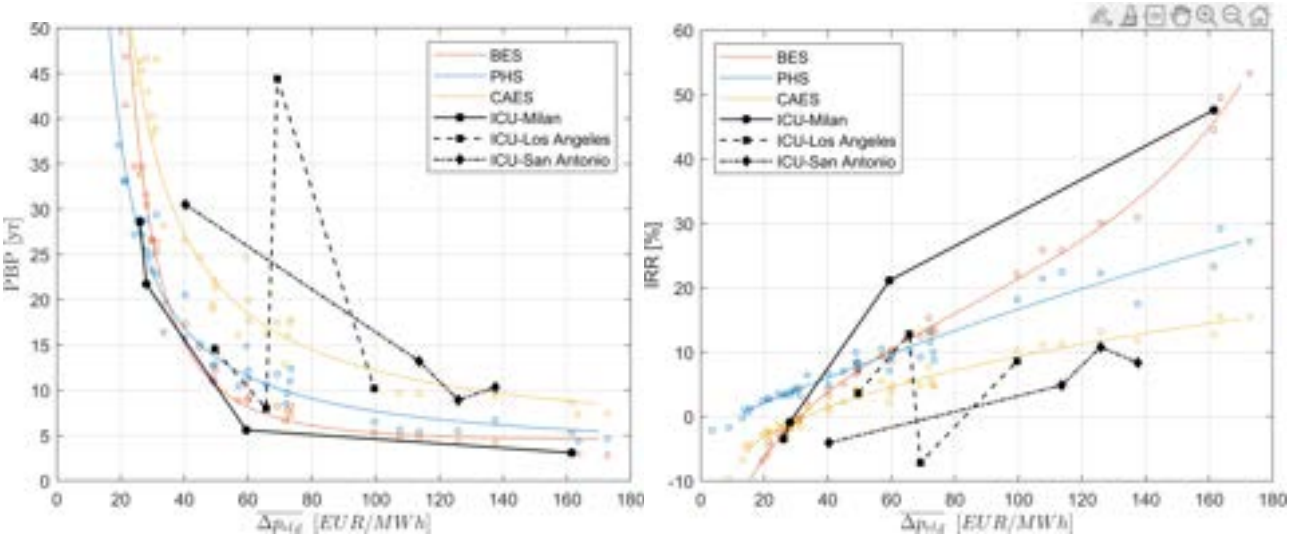

Figure. 5. PBP and IRR comparison for BES, PHS, CAES, and ICU-CCGT in three different locations

The analysis reported in a previous paper [38], was focused on one year and highlighted structural differences between market zone clusters considering both markets and climate parameters. On the other hand, this paper considers several years of operations highlighting that for systems with ICUs, an in-depth analysis is necessary and the expected economic outcome it is difficult to generalize because of the additional influence of ambient temperature and, secondly, of electricity price-gas price relationship, often synthesized by the Clean Spark Spread, the difference between the electricity price and the CCGT production cost, including CO_2, as defined in eq. (18). However, $\overline{\Delta p_{el_d}}$ confirms to be an effective indicator and the economic performance constantly improves as it increases. The only exception is represented by Los Angeles in 2020 due to the low Clean Spark Spread that year.

Even if in Texas and California higher $\overline{\Delta p_{el_d}}$ values are more common historically, for the same value the ICU-CCGT potential is higher in northern Italy. As Confirmed by Figure 6 and Table 4, in this location the potential for using directly the HP for heating and cooling the inlet air is higher (about 30% of operating hours for each of these operational modes), conversely, the TES is more exploited in California and Texas. In this last location is common to discharge the TES more than once a day and the inlet cooling by means of TES discharging is adopted for about 15% of operational modes. Despite the typical single peak price profile of this zone, this is possible because the value of energy discharged by the TES depends both on the electricity price and the potential CCGT power increase following the cooling depending on the ambient temperature. Thus, if the daily trends of ambient temperature and electricity price present two peaks characterized by sufficient prominence and temporal shifting, the resulting profits opportunities may result in a two peaks profile allowing a UF beyond 1.

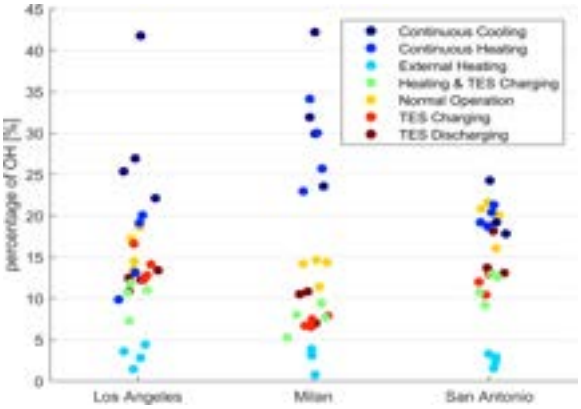

Table 4. Inlet Conditioning Unit TES UF [-]

	Bidding Zone (State/Country)		
	SCE (CA)	**NORD (IT)**	**LZ_CPS (TX)**
2019	0.706	0.372	1.01
2020	0.627	0.311	1.032
2021	1.056	0.783	1.548
2022	0.819	0.5991	1.139

Figure. 6. Operating mode as a percentage of overall operating hours

More in detail, from an economic perspective the main difference between the ICU-CCGT integration and the other storage technologies relies on the value at which the discharging power is awarded. The thermal energy discharged by the TES is reflected in an extra power output of the CCGT and a slight variation in efficiency since the fuel consumption increases as well, a detailed investigation of the dependence on the ambient temperature and the GT load is provided in [35]. Thus the economic value of the discharged energy is the power increment, due to inlet cooling by TES discharging, times the Clean Spark Spread (CSS), i.e., the profit margin of a CCGT power plant considering the fuel consumption and the cost of carbon dioxide allowance emissions, equation (18). Conversely, the cost of charging the TES is proportional to the ratio of electricity price on the HP COP. Analogously to equation (15), is possible to state the minimum condition to be worth operating the TES of an ICU. For the sake of simplicity, equation (17) neglects the variation in efficiency and thus in CSS following the TES discharge.

$$\Delta P \cdot CSS_{disch} = E_{disch} \cdot f(T_{amb}, Load_{GT}) \cdot CSS_{disch} \geq \frac{E_{disch} \cdot p_{el_{ch}}}{COP(T_{amb})} \tag{17}$$

$$CSS = p_{el} - C_{gas} \cdot \left(\frac{1}{\eta_{CCGT}} - C_{CO2} \cdot e \right) \tag{18}$$

Finally, Figure 7 confirms the pivotal importance of CSS reporting the boxplot distributions versus $\overline{\Delta p_{el_d}}$ for each year in the analyzed locations, in the hours in which the TES is discharged, CSS_{disch}. It is immediate to appreciate the strict correlation between the trend lines connected the CSS median values and the IRR or the opposite of PBP in Figure 5. CSS can be considered as a carrier signal, then on the right part of the chart trends diverge because the extra benefits on economic KPIs of increased $\overline{\Delta p_{el_d}}$.

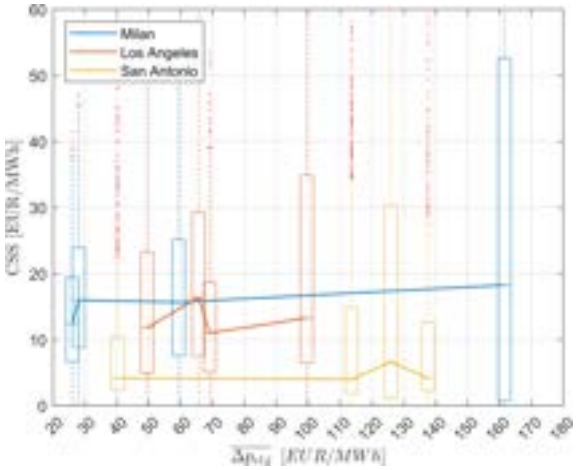

Figure. 7. Yearly Clean Spark Spread distribution versus the average daily variability

5. Conclusions

This paper performs a market analysis by means of Linear Programming and Mixed Integer Linear Programming optimizer of different storage technologies for energy arbitrage on the day-ahead market. Battery Energy Storage (BES), Pumped Hydro Storage (PHS), Compressed Air Energy Storage (CAES), and Pumped Thermal Energy Storage (PTES) are compared against the integration of a Combined Cycle Gas Turbine with an Inlet Conditioning Unit consisting of a Heat Pump and a cold Thermal Energy Storage (CCGT-ICU). Different scenarios have been analyzed considering historical data from different bidding zones and years.

First, it was observed how the operativity of energy storage depends on the conversion efficiency and any possible cost associated with the degradation of the storage itself, this is an important issue for batteries. It was observed that PTES presents a very low utilization factor, because of the low round trip efficiency profit opportunities from arbitrage with PTES are very rare and it is not possible to pay the investment back. PTES is then excluded by the following analysis.

A sizing procedure applied to PHS and CAES identifies both an optimal charging and discharging duration of about 12h, highlighting how limiting the charging power is an effective approach to reduce CAPEX and enhance economic KPIs. The daily electricity price variability is the driving factor for storage opportunities. Thanks to the absence of degradation costs and a good round trip efficiency, PHS performs better on markets characterized by moderate variability (<40-60 €/MWh), while batteries are the best solutions when the price is extremely variable (>60 €/MWh), in such a condition the high efficiency represents an advantage despite the cost associated to the storage degradations; performing even two cycles per day. CAES may find an application in low variable markets (<30-40 €/MWh), if there is no site availability for PHS. However in such conditions, the PBP is close to the expected lifespan, thus the viability of investment for CAES is still uncertain if only arbitrage profits are considered.

Introducing the ICU-CCGT integration in the comparison requires separately analyzing bidding zones because of the impact of local climate and the Clean Spark Spread (CSS). The proposed integration wins

the comparison against other storage technologies in northern Italy and demonstrates to be competitive in California while it shows lower performance in Texas. It was demonstrated that what drastically impacts this outcome is the CSS and the opportunities to use the ICU also for direct inlet cooling and heating.

It is possible to conclude that, as pure storage, the ICU integration presents low performance if compared to a system designed for this purpose. However, within the ICU investment, an HP is included that, if exploited in continuous heating and cooling mode, can increase the extra profits generated by the ICU retrofitting. Moreover, it must be considered that such an investment can avoid the closure or mothballing of the CCGT power plant, therefore keeping available to the Transmission System Operator a relevant capacity for supplying services to the grid, including the rotational inertia typical of turbomachinery-based power plants and essential for the purpose of frequency regulation.

Nomenclature

Acronyms

BES	Battery Energy Storage
CAPEX	Capital Expenditure
CAES	Compressed Air Energy Storage
CCGT	Combined Cycle Gas Turbine

Abstract:

Electricity prices have increased significantly in Europe and other regions due to the recent energy crisis. Latent heat thermal energy storage (LHTES) implemented in residential heating systems has attracted attention for its role in peak/load shifting to reduce heating costs. A new layout with LHTES integrated with a heat pump (HP) is proposed here to store low grade heat during off-peak demand periods, later used as heat source for the heat pump during peak demand periods. This novel layout is assessed for its heat capacity variation and levelized cost of energy (LCOE). The results show that increased amount of power input is required when a storage component is integrated into the heating system, while it can be compensated by shifting to off-peak electricity usage.

1. Introduction

The Paris Agreement targets reductions in greenhouse gas emissions and tacklinge climate change [1] where the largest source of greenhouse gas emissions is carbon emissions from energy use [2]. To comply with this agreement, Sweden has set a long-term goal of achieving zero net emissions of greenhouse gas by 2045 at the latest [3]. In 2020, the Sweden's final energy use in the residential and service sector was 140 TWh, of which district heating and electricity accounted for more than 80% [4]. As of December 2021, 2.6 million dwellings in Sweden were multi-family buildings, accounting for 52% of the total residential sector, and they were responsible for a third of total energy use [5,6]. Space heating in terms of energy use in buildings plays a pivotal role in decarbonisation [7–9]. The transition towards low carbon society requires novel energy technologies and solutions. Heat pumps with their high coefficient of performance (COP) have gained increasing attention for emission reduction, as they can reduce energy demand and increase the uptake of variable renewable energy in electricity grid [10–12].

Many research efforts have focused on improving heat pumps in space heating. Fraga et al. [13] compared heat pumps with different heat sources implemented in non-retrofitted, retrofitted and new multi-family buildings. Sun et al. [14] focused on the mixed-refrigerant recuperative heat pumps, suitable for large temperature lift in space heating, and introduced an assisted-cycle to improve the system performance. Dongellini et al. [15] studied the effects of control strategies of different air-to-water heat pumps on seasonal heating system. Blázquez et al. [16] analysed the suitability of air source heat pump and ground source heat pump in different climate conditions. Manuel et al. [17] also studied these two kinds of heat pumps and analysed the performance by reducing heating system circuit temperature.

Heat pumps consume a small amount of power to shift larger amount of heat from a heat source, but at the same time, they also become the major consumer of household electricity [18]. Due to the recent energy shortages and inflation [19], electricity prices have increased significantly. Figure 1 shows the hourly electricity trading price of SE3-Stockholm region in November 2022 (blue line) and its monthly average electricity trading price in November each year from 2018 to 2022 (orange bar). The electricity price is highly fluctuating during November 2022. Due to the impact of wind power generation, there are cases where the electricity prices is very low. While through the comparison of electricity prices in different years, it can be clearly seen that the overall electricity price has risen significantly. Thermal energy storage implemented in residential heating

systems has attracted attention for its role on peak load shifting to reduce heating costs [20,21]. The LHTES is favourable due to the high energy density, small volume change of phase change material (PCM) in melting and in solidification processes [22,23]. The heat transfer rate of PCM affects the thermal performance of LHTES. To counter the low conductivity of PCM, a number of heat transfer area enlargement techniques with spherical mini & micro encapsulations, metal fin extensions and matrix foam impregnations have shown good results [24–28]. The melting and solidification temperature should be carefully selected to match the operating temperature range. For space heating, paraffin and sodium acetate tri-hydrate based PCMs have been tested [9,29].

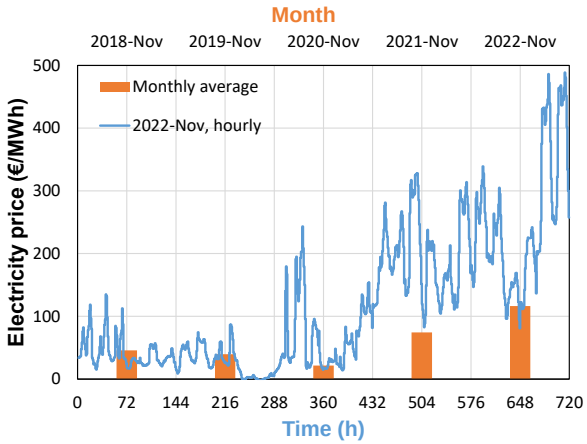

Figure 1. Electricity trading price in SE3-Stockholm region (exclude any fees, charges or taxes) [30].

Different layouts of integrated LHTES and HP systems have been studied for space heating. Yu et al.[5] presented an integrated heat pump & LHTES system and proposed a mathematical model including energy, environmental and economic analysis for four typical cities in China. The LHTES component was a bulk storage configuration, in which the refrigerant directly transfers heat to PCM during the charging process and the circulated water absorbed heat during the discharging process. The results showed that the integrated systems had a good application prospect. Xu et al. [20,32,33] conducted the experimental and numerical investigation on cylindrical macro-encapsulated PCM. Different integrated LHTES-HP layouts by introducing desuperheater, subcooler were displayed, and the assessment of their technical, economic and environmental performance showed that the heat performance and operational expense were improved. Olympios et al.[10] established a heat pump system powered via a solar PV system. The heat pump is coupled with two different PCM thermal storage components, one for domestic hot water and one for space heating. The system showed large potential of economical savings. Zhang et al. [34] proposed a CO_2 heat pump system integrated with ejector and LHTES system. The new system had better thermodynamic and economic performance than conventional CO_2 heat pumps. Despite these research efforts the integration of heat pumps in multi-family buildings still faces many barriers, such as high heating temperature requirement for non-retrofitted building, complicated access to geothermal sources and high capital costs [35,36]. Therefore, further studies are needed.

This paper proposes a novel layout of integrated LHTES and HP to cover the heating requirement of a typical multi-family building. LHTES component is connected to the return side of radiator to absorb low-grade heat during off-peak periods. The stored energy then transfer to the ambient air through a shell-and-tube heat exchanger during on-peak periods to improve the inlet temperature of evaporator. The performance of heat pump thus will be improved and the economic outcome will be better through the on-peak/off-peak price scheme.

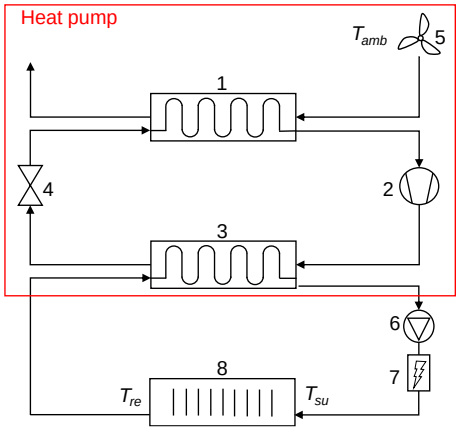
2. Methodology

In this work, the techno-economic performance evaluation of integrated LHTES and heat pump system was conducted with MATLAB (R2022b) and COMSOL (6.0) as follows: (1) the heating demand and heat pump supply were matched based on a typical heat pump heating system; (2) a novel layout of LHTES and heat pump system was proposed; (3) a cylindrical LHTES component was designed with spherical encapsulated PCM; (4) the techno-economic performance of this integrated system was assessed.

2.1. Heat pump heating system

A typical heat pump heating system in serial configuration is shown in Figure 2. The air source heat pump (ASHP) is connected to a hydronic radiator, which is the most common combination for space heating due to its simple operation and low maintenance cost [37,38]. The evaporator absorbs heat from ambient air, and evaporates the refrigerant. After being compressed in the compressor, the high-temperature refrigerant transfers heat to water in the condenser. The end users are assimilated into one hydronic radiator as shown

in Figure 2. The heated water is pumped to demand-side radiator with the supply temperature (T_{su}) for the indoor space heating. The water is forwarded to condenser at the radiator return temperature (T_{re}). The supplementary electric heater is used to cover the heating gap between heat pump supply and user demand.



1. evaporator; 2. compressor; 3. condenser; 4. throttle valve; 5. fan; 6. pump; 7. supplementary electric heater; 8. hydronic radiator.

Figure 2. Typical heat pump heating system.

A Multi-family building with heated area of 1420 m^2 built before the 1960's [39] is considered. The calculation parameters of the retrofitted building are listed in Table 1. The total UA-value includes the heat transfer through building envelope and ventilation losses. The indoor comfort temperature was set at 20 °C during the heating season [40]. The heating demand is 51.8 kW at designed outdoor temperature (*DOT*) of -16 °C according to Eq. (1). The heating demand of the multi-family building at ambient temperature is calculated with Eq. (2).

$$q_{bd,DOT} = UA_{bd} \cdot (T_{ind} - DOT) \quad (1)$$

$$q_{bd} = UA_{bd} \cdot (T_{ind} - T_{amb}) \quad (2)$$

Table 1. Calculation parameters of the general retrofit multi-family building [39].

Parameters	Units	Value
UA-value by transmission (including roof, wall, floor, window, door and thermal bridge)	W/K	824
UA-value by ventilation	W/K	616
Total UA-value of building, UA_{bd}	W/K	1440

Based on logarithmic mean temperature difference (LMTD) method, the heating capacities of radiator at DOT and ambient temperature were given by Eq. (3)-Eq. (6). The radiator exponent (*n*) due to non-linear heat transfer [37] is 1.25 in this study.

$$q_{rad,DOT} = UA_{rad} \cdot LMTD^{n}_{rad,DOT} \quad (3)$$

$$LMTD_{rad,DOT} = (T_{su} - T_{re}) / \ln\left[(T_{su} - DOT)/(T_{re} - DOT)\right] \quad (4)$$

$$q_{rad} = UA_{rad} \cdot LMTD^{n}_{rad} \quad (5)$$

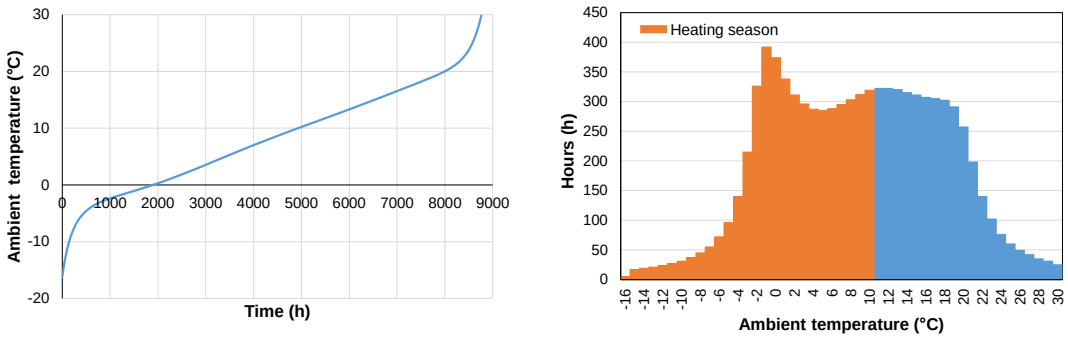
$$LMTD_{rad} = (T_{su} - T_{re}) / \ln\left[(T_{su} - T_{amb})/(T_{re} - T_{amb})\right] \quad (6)$$

The hydronic radiator heating system was designed with constant water flow rate ($\dot{V}_{rad}$). The supply temperature and return temperature are commonly 55 °C/45 °C ($T_{su,DOT}$ / $T_{re,DOT}$) at DOT [41]. The heating capacity of water through radiator can be calculated with thermodynamic parameters by Eq. (7) and Eq. (8).

$$q_{hs} = \dot{V}_{rad} \cdot \rho_w \cdot c_{p,w} \cdot (T_{su,DOT} - T_{re,DOT}) \quad (7)$$

$$q_{hs} = \dot{V}_{rad} \cdot \rho_w \cdot c_{p,w} \cdot (T_{su} - T_{re}) \quad (8)$$

Fehrm and Hallén proposed a curve-fitting model for the ambient air temperature [37]. The duration curve for Stockholm condition with annual average temperature of 8.2 °C [42] is presented in Figure 3. The hours through a year at a certain temperature (bin hours) is accounted for the discrete temperatures in Figure 3. November with monthly average ambient temperature of 3 °C (T_{amb}) [43] was selected for the assessment, which can cover around 50% hours when the heating seasons starts at the temperature below 10 °C.



(a) *(b)*

Figure 3. Ambient temperature through a year and bin hours in Stockholm: (a) Duration temperature curve for Stockholm; (b) bin hours in Stockholm.

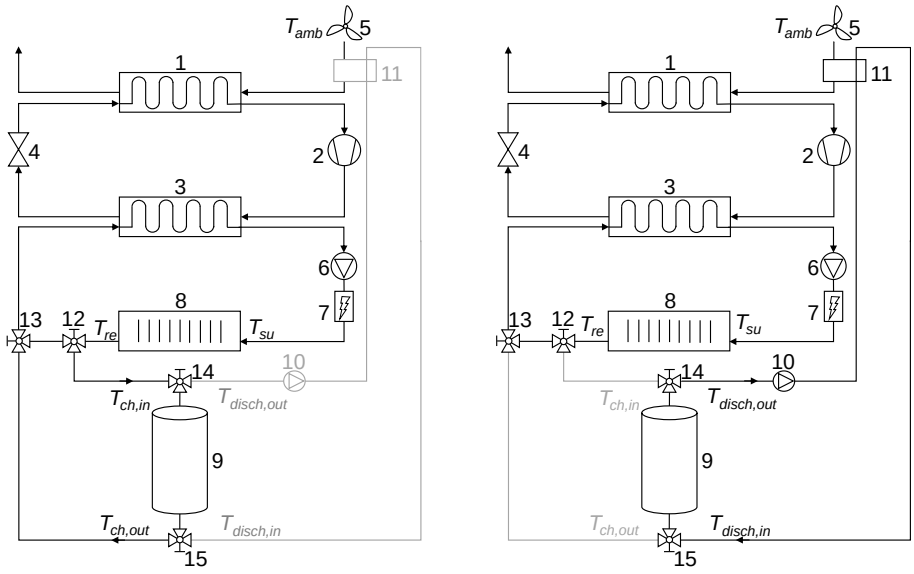
The heat pump system was assumed as quasi-steady state. Based on energy balance, the heating demand of building, heating capacity of radiator and heat capacity of water are equal [20,37]. The parameters of the heat pump heating system were calculated with Eq. (1)-Eq. (8). The results are exhibited in Table 2.

Table 2. Parameters of heat pump heating system.

Parameters	Units	Value
Heating demand, q_{bd}	kW	24.5
Volume flow rate, $\dot{V}_{rad}$	m³/h	4.52
Supply temperature, T_{su}	°C	38.8
Return temperature, T_{re}	°C	34.1

2.2. Integrated system

A novel layout of integrated system is proposed in this paper. LTHES with auxiliary heat exchanger and pump are introduced in a typical heat pump heating system acting as the heat source during off-peak hours. The schematic of the integrated system is shown in Figure 4.



(a) *(b)*

1. evaporator; 2. compressor; 3. condenser; 4. throttle valve; 5. fan; 6. pump; 7. supplementary electric heater; 8. hydronic radiator; 9. latent heat thermal energy storage component; 10. pump; 11. heat exchanger; 12-15: three-way valve.

Figure 4. A LHTES component integrated HP system: (a) charging mode, (b) discharging mode.

The LHTES component is placed inside the building and connected to the return line of the radiator. The charging and discharging processes are controlled based on the off-peak and on-peak periods, as shown in Figure 5. The off-peak is from 00:00 to 7:00 (exclusive) and from 21:00 to 24:00 (exclusive). The on-peak is

from 16:00 to 20:00 (exclusive). When the electricity price is in the off-peak periods, the three ports of three-way valve 12 are all open and a proportion (pro) of the return water as heat transfer fluid (HTF) flows into the LHTES component from the top to charge the storage. The water after the heat release flows out from the bottom and merges into the remaining return water at the position of three-way valve 13. The flow then enters the condenser. When the LHTES is fully charged, the valve controlling the flow into the LHTES closes. When the electricity price is at the on-peak periods, the discharging process of LHTES starts, also using water as HTF. The HTF flows into the LHTES from the bottom and is heated by the PCM. After absorbing heat, HTF flows out from the top. In this study, a shell-and-tube heat exchanger with counter flow was selected. The ambient air used as the heat source to the heat pump discharges heat from HTF resulting in a rise in temperature, hence an increase in COP. After that, the cooled HTF flows back to the LHTES.

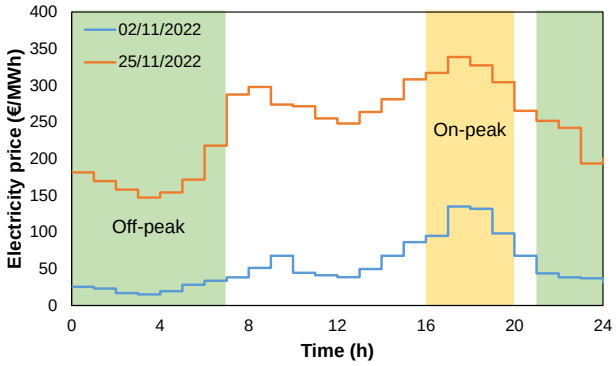


Figure 5. Off-peak and on-peak based on hourly electricity trading price.

2.3. LHTES component

Based on the optimal return temperature of the radiator, ATP 28 organic material was selected as the PCM. The thermophysical properties of ATP 28 are listed in Table 3.

Table 3. Thermophysical properties of PCM [44].

Parameters	Units	Value
Melting temperature	°C	27~29
Solidification temperature	°C	26~28
Latent heat (charging/discharging)	kJ/kg	220/225
Specific heat capacity	kJ/(kg·K)	2
Thermal conductivity	W/(m·K)	0.2
Liquid density (solid/liquid)	kg/m^3	864*/760

*calculated from the volume expansion

Height-to-diameter ratio (H/D) is a crucial parameter in designing a thermal energy storage tank. The increase of H/D can improve the charging and discharging efficiency and reduce the occupied area, while it also results in increased weight and cost of the tank, and in increased heat loss [45–47]. Considering the charging/discharging time and required heat capacity, the H/D was set as 1.7 with inner diameter of 0.6 m. A 2D axis-symmetrical model was built to simulate the thermal processes of LHTES, shown in Figure 6.

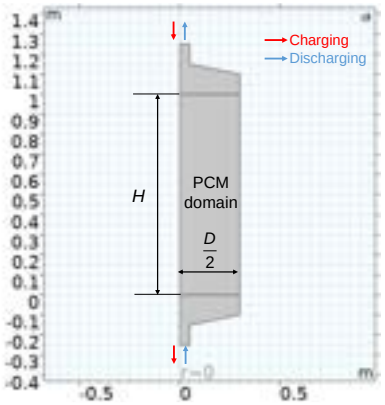

Figure 6. The 2D model of packed bed storage tank.

Spherical encapsulated PCMs, which are easier to maintain [48], were placed in the packed bed tank. The melting and solidification processes of the 2D model were simulated with the following simplifying assumptions:

(1) incompressible flow of water; (2) homogenous and isotropic PCM; (3) neglected density difference of PCM in phase and liquid phases; (4) heat loss coefficient (h_{loss}) of 5 W/(m^2·K) from outside shell to surrounding air [49]. The main parameters used in the simulation are displayed in Table 4. The thermophysical properties of Aluminum for outside shell and Water for HTF were taken from the Material Library in COMSOL [50]. The heat convective coefficient (h_{sf}) between water and PCM was calculated with Eq. (9) [51].

$$h_{sf} = \left[d_{pe} / \left(k_f \mathrm{Nu} \right) + d_{pe} / \left(10 k_s \right) \right]^{-1} \tag{9}$$

Table 4. Parameters of LHTES component.

Parameters	Units	Value	Reference
Height/diameter of PCM domain	m	1/0.3	
Porosity of PCM domain	-	0.4	
Diameter of PCM encapsulation	mm	50	
Quantity of PCM encapsulation	-	324	
PCM weight	kg	138	
Shell material	-	Aluminum	
Specific heat capacity of shell	kJ/(kg·K)	900	[50]
Thermal conductivity of shell	W/(m·K)	238	[50]
Shell density	kg/m^3	2700	[50]
Shell thickness	mm	3	
Shell weight	kg	20	

The charging and discharging thermal power of LHTES component was calculated from the temperature difference of HTF from inlet and outlet, as shown in Eq. (10) and Eq. (11). The stored or released thermal energy in the LHTES component were obtained with Eq. (12) and Eq. (13).

$$q_{ch} = \dot{m}_{ch} c_{pf} \left(T_{ch,in} - T_{ch,out} \right) \tag{10}$$

$$q_{disch} = \dot{m}_{disch} c_{pf} \left(T_{disch,out} - T_{disch,in} \right) \tag{11}$$

$$Q_{ch} = \int_0^t q_{ch} \mathrm{d}t \tag{12}$$

$$Q_{disch} = \int_0^t q_{disch} \mathrm{d}t \tag{13}$$
