Abstract:

With more renewable energy sources (RES) which are inherent intermittent and unpredictable connecting with power grid, various stability problems occur, among which the peak load regulation is the most prominent. Energy storage systems (ESSs) are essential for buffering the electricity grid. Selecting the most suitable energy storage technology among various alternatives is of great importance. In this work, the sustainability of typical energy storage technologies was studied with respect to four aspects for peak shaving scenarios, including technical (i.e. maturity, energy density, round-trip efficiency, duration ranges, life cycles, lifetime and position flexibility), economic (levelized cost of energy, net present value), environmental (i.e. global warming, damage to human health, damage to ecosystems, damage to resource availability) and social (public acceptance) based on the full life cycle. This study evaluated the soft criteria including maturity, position flexibility and public acceptance by Analytic hierarchy process (AHP). Life cycle assessment (LCA) and life cycle cost (LCC) methods were combined to study the life-cycle environmental and economic performance. Technique for order preference by similarity to an ideal solution (TOPSIS) was applied for determining the sustainability prioritization of energy storage technologies. The sensitivity analysis was carried out to investigate the effects of control and economic input parameters on environmental performance and economic performance. In addition, the effects of criteria weights, electricity sources and number of daily cycles were conducted on sustainability ranking of ESSs. The results showed Lithium iron phosphate battery (LIPB) and pumped hydro storage (PHS) had good sustainability performance, which could be the most suitable energy storage technologies for peak shaving scenarios.

Keywords:

Energy storage; Life Cycle Assessment; Life Cycle Cost; Peak shaving; Sustainability prioritization.

1. Introduction

More renewable energy sources (RES) have connected with power grid, but RES is inherent intermittent and unpredictable, which result in various stability problems in which the peak load regulation is the most prominent. Energy storage systems (ESSs) are essential for buffering the electricity grid [1]. There are various ESSs which have different properties and performances. Selecting the most suitable energy storage technology for specific scenario when facing various conflicting criteria is of great importance for the decision-makers [2].

A few studies are available that evaluate the performance of different ESSs in the specific application by multi-criteria decision making approach [1-8]. Vo T.T.Q et al. [1], Ren J.Z et al. [2] and Raza S.S. et al. [3] evaluated the energy storage technologies considering the economic, technical and environmental impacts. Walker S.B.et al.[4] and Petrillo A.et al.[5] assessed the Power-to-Gas technologies and a compressed air energy storage system respectively in technological, economic and social aspects. The performance of 27 energy storage alternatives which were classified into fast response and long-term clusters were assessed by Rostami F. et al. [6] considering the economic, environmental and social indicators using data envelopment analysis. Baumann M. et al. [7] and Cellura S. et al. [8] combined the environmental and economic assessments for batteries and flywheel energy storage, respectively. Davies D.M. et al. [9] assessed the batteries by combining economic and technological evaluation. However, the considered evaluation criteria are not comprehensive in these above studies, the disregarded aspects often also have a certain impact on the sustainability performance.

There are some literatures assessing the sustainability performance of ESSs in terms of comprehensive aspects including environmental, economic, technical and social categories [10-17]. Ilbahar E. et al. [10] proposed a methodology to evaluate the hydrogen energy storage systems. Baumann M. et al. [11] evaluated the overall performance of batteries for four grid services. Seven energy storage technologies including lead-acid batteries, Li-ion batteries, super capacitors, hydrogen storage, compressed air energy

storage, pumped hydro, and thermal energy storage for ten scenarios were evaluated by Albawab M. et al. [12]. Balezentis T.et al. [13] presented a novel multi-criteria utility analysis approach for ranking hydrogen storage, HPS, CAES, Li-Ion batteries, lead acid batteries, flow batteries, and molten salt energy storage. Lin R.J. et al. [14] studied the overall performance of energy storge technologies by innovative indices of sustainability efficiency and super-efficiency. Evaluation of PHS, CAES and NaS for integration with wind power in the Pacific Northwest region of the US was conducted by Turgrul U.D. et al. [15]. The sustainability prioritization of four alternatives including pumped hydro, compressed air, lithium-ion, and flywheel were assessed by Ren J.Z.et al. [16]. Acar C. et al. [17] analysed the sustainability performance of energy storage systems including Pumped hydro, conventional batteries, high−temperature batteries, flow batteries, and hydrogen for residential applications. In these literatures, the considered index are often hard criteria which have exact data and the assessments often rely on existing literatures without considering the varying of the input parameters such as round-trip efficiency, electricity sources in different scenarios.

In addition, the available literatures generally study the economic performance in terms of energy cost and power cost [13,17] or capital and operating cost [12,14-16] and study the environmental performance in terms of CO_2 which are both obtained from the previous literatures or the engineering reports. Mostafa M.H. et al. [18], Hunter C.A. et al. [19] and Chen X.J. [20] point out that levelized cost of energy, payback period and internal rate of return should be used to evaluate the life cycle economic performance of ESSs. Researchers [21-26] often conduct life cycle environmental assessments of different ESS to choose the best environment-friendly alternatives from the aspects of cumulative energy demand, global warming potential, ozone layer depletion potential, marine aquatic ecotoxicity potential, acidification potential, damage to human health, damage to ecosystems and damage to resource availability et al. Moreover, few literatures such as [11] analyze the sustainability of ESSs from the perspective of life-cycle aspect. In consequence, there is a lack of comprehensive assessment of different ESSs that consider not only the life-cycle costing but also quantifying the soft index from the aspects of technical, economic, environmental and social performances.

This study aims at tackling these gaps by providing a comprehensive sustainability assessment of different ESSs. The studied ESSs are pumped hydro storage (PHS), compressed air energy storage (CAES), lithium iron phosphate battery (LIPB) and vanadium redox flow battery (VRFB) which are applicable for the peak shaving scenarios. The soft criteria of technical and social categories are quantified by Analytic hierarchy process (AHP), and life-cycle assessment (LCA) and life-cycle cost (LCC) are adopted to evaluate the environmental and economic performance parameters based on the full life cycle of ESSs.

2. Methodology

2.1. Assessment framework

The sustainability assessment which can incorporate both hard and soft criteria was conducted with respect to technical, economic, environmental and social categories for peak shaving scenarios based on the full life cycle, in order to select the most suitable energy storage option, assessment framework of this study is shown in Figure 1. The technical category included round-trip efficiency, energy density, duration range, life cycles, lifetime, maturity and position flexibility. The environmental category included global warming (GWP), damage to human health (DHH), damage to ecosystem (DE) and damage to resource availability (DRA). The economic category was mainly levelized cost of energy (LCOE) and net present value (NPV). The social category mainly considered public acceptance.

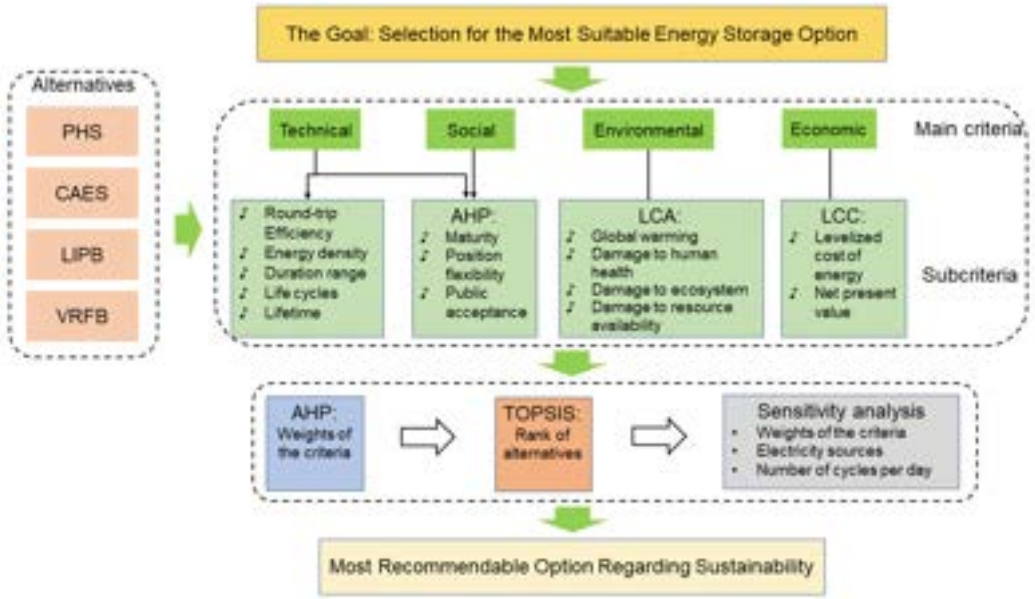

Figure. 1. Overview of the assessment framework.

AHP was applied to evaluate the soft criteria including maturity, position flexibility and public acceptance, it was also employed to determine weights of main criteria and subcriteria in each category. Environmental and economic performance were quantified by Life cycle assessment (LCA) and life cycle cost (LCC) methods, and they have the same system boundary including the raw materials extraction and processing, manufacturing, usage and disposal or recycling stage of ESSs. Technique for order preference by similarity to an ideal solution (TOPSIS) which can rank the alternatives was applied for sustainability prioritization of energy storage technologies. The effects of criteria weights, electricity sources and number of daily cycles on environmental performance, economic performance and sustainability order were conducted in the sensitivity analysis.

The technical and social performance assessment is based on the technology data about ESSs from literature, survey and interviews, and calculated by AHP method and interval approach for uncertainties [2]. Environmental performance assessment is calculated by Recipe endpoint approach in Simapro software whose life cycle inventory data (LCA input) is from literature and engineering reports. Economic performance assessment is conducted by the LCC model which is established by the author in which the life cycle cost inventory is from literature, survey and engineering reports.

2.2. Quantifying the soft criteria and determining the criteria weights

Maturity, position flexibility and public acceptance are important for the alternatives to evaluate the sustainability performance, but they are soft criteria whose data cannot be obtained directly, it is hard to be compared between different alternatives in the TOPSIS process [2], so it is essential to quantify the soft criteria.

AHP method was generally employed to determine the weights of considered four categories as well as that of the subcriteria in each category [13], it could also be used to assess the relative performance of the energy storage alternatives with respect to soft criteria. Table 1 shows the linguistic terms and their corresponding numbers for the pair-wise comparison in the analysis.

Table 1. Linguistic terms and corresponding numbers for the pair-wise comparison.

Numbers	Linguistic terms	Numbers	Linguistic terms
1	Equally important	7	Strongly more important
3	Slightly more important	9	Absolutely more important
5	More important	2,4,6,8	Intermediate values between the two adjacent judgments

2.3. Life cycle cost

Two economic indicators are conducted to compare the economic performance of different energy storage alternatives, namely levelized cost of energy (LCOE) and net present value (NPV) which are important index that be studied by many researchers [18-20]. Figure 2 shows the life-cycle cost of ESSs, it is worth mentioning that costs associated with the environmental impacts were not considered for avoiding the duplication among LCA and LCC indicators. The LCOE and NPV were calculated as equations (1) and (2).

$$LCOE = C_{investment} + \frac{\sum_{t=1}^{T} \frac{(C_{o\&m} + C_c + C_{rc} + C_{dr}) \cdot (1+r_{if})^{t-1}}{(1+r_d)^t}}{\sum_{t=1}^{T} \frac{E_t}{(1+r_d)^t}} \quad (1)$$

$$NPV = -p \cdot C_{investment} + \sum_{t=1}^{T} \frac{(C_{prof} - C_{loan} - C_{o\&m} - C_{rc} - C_{dr}) \cdot (1+r_{if})^{t-1}}{(1+r_d)^t} \quad (2)$$

Where $C_{investment}$ represents the investment cost, $C_{o\&m}$ is the sum of fixed and variable operation and maintenance cost, C_c is the charging electricity cost, C_{rc} is the replacement cost, the replacement time of ESSs is related to the maximum number of cycles, C_{dr} is the disposal and recycling cost, T is lifetime of the power station, r_d is the discount rate which is set as 5.49%[27], r_{if} is the inflation rate which is set as 2%[27], E_t represents the annual power generation, p is the proportion of initial investment which is set as 30%[20], C_{prof} is the annual profit considering the peak valley price difference of power grid, C_{loan} is the annual repayment of debt. E_t and C_{prof} are calculated as equations (3) and (4).

$$E_t = Q_E \times (1 - \eta_{self}) \times SOC \times \theta_{DOD} \times \eta_{dis} \times N_y \quad (3)$$

$$C_{prof} = E_t \cdot (p_s - p_p / \eta) \quad (4)$$

Where Q_E is the designed capacity of ESSs, η_{self} is the self-discharge efficiency, SOC represents the average proportion of capacity over ESSs' lifetime considering the decay rate, θ_{DOD} is the discharge depth, η_{dis} is the discharge efficiency, and N_y is the average number of cycles per year, p_s and p_p are the electricity prices for sale and purchase, η is the round-trip efficiency.

The lifetime of energy storage power station is considered as 20 years, which is inconsistent with the life of ESS, so it may face the problem of replacement of battery and equipment during the operation of power station. The replacement time is related to the number of cycles, number of daily cycles and the calendar life of ESS, the market price change of energy storage components (especially the battery cell) is also considered at the replacement time. Replacement cost C_{rc} is calculated as equation (5).

$$C_{rc} = c_{rc} \cdot (1 - r_b)^{t_r} \cdot Q_E \quad (5)$$

Where r_b represents the cost reduction rate of energy storage components, which is 7.78% for LIPB [20], c_{rc} is the unit replacement cost, t_r is the replacement time.

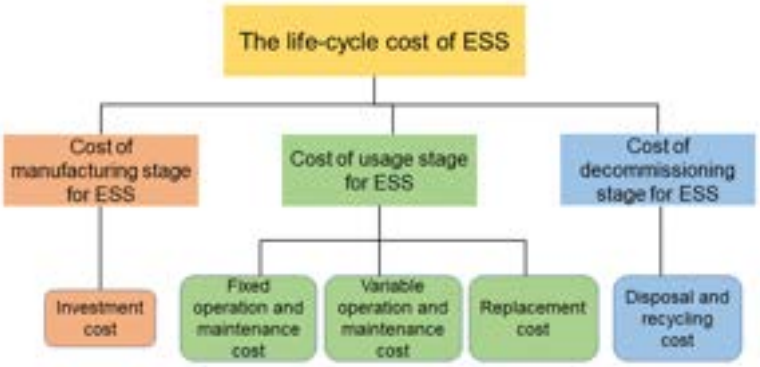

Figure. 2. The main elements of life-cycle cost of energy storage systems.

3. Results and discussions

3.1. Weights

As mentioned above, weights of considered indicators were calculated by AHP method. For the main criteria weights, environmental criteria were assumed to be the most important, followed by economic, technical and social criteria [11, 15], the maturity and position flexibility were the most important, which are followed by round-trip efficiency, duration ranges, life cycles, lifetime and energy density for the technical subcriteria, GWP and DHH were the most important, followed by DE and DRA for environmental subcriteria, the results were shown in Figure 3. The weights of environmental, economic, technical and social indicators were 0.46, 0.28,0.16 and 0.10, respectively. The maturity and position flexibility had the biggest weights which were 0.27, GWP and DHH had the biggest weights which were 0.35.

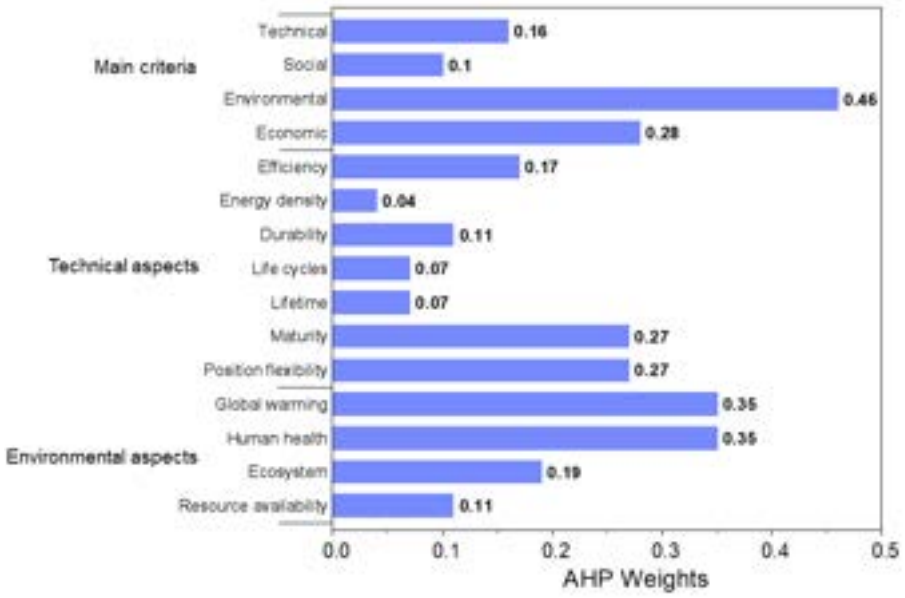

Figure. 3. The weights of the evaluated criteria.

3.2. Environmental aspects

A cradle-to-grave LCA model [21-25] was adopted for evaluating the environmental impacts of typical energy storage technologies, ReCiPe method was applied for the assessment which provides midpoint as well as endpoint indicators by using SimaPro 9.2 software. With the proposal of carbon peak and carbon neutral goal, researchers pay more attention to the contribution of ESSs to this goal, thus GWP was selected as a

separate index. The functional unit was set to one megawatt-hour of electricity delivery over the entire lifetime. The life cycle inventory (LCI) was mainly based on specific engineering reports. The environmental results of LIPB and VRFB were partly based on the previous work [26].

Figure 4 shows the environmental performance of ESSs, including the impacts of GWP, DHH, DE and DRA. Median results are provided including positive and negative whiskers for the 25% and 75% quartiles in Figure 4(a), and the author mainly analysed the median results in the work. What needs to point out is the electricity mix used in the usage process of baseline scenario throughout this work was the Chinese electricity mix in 2020.

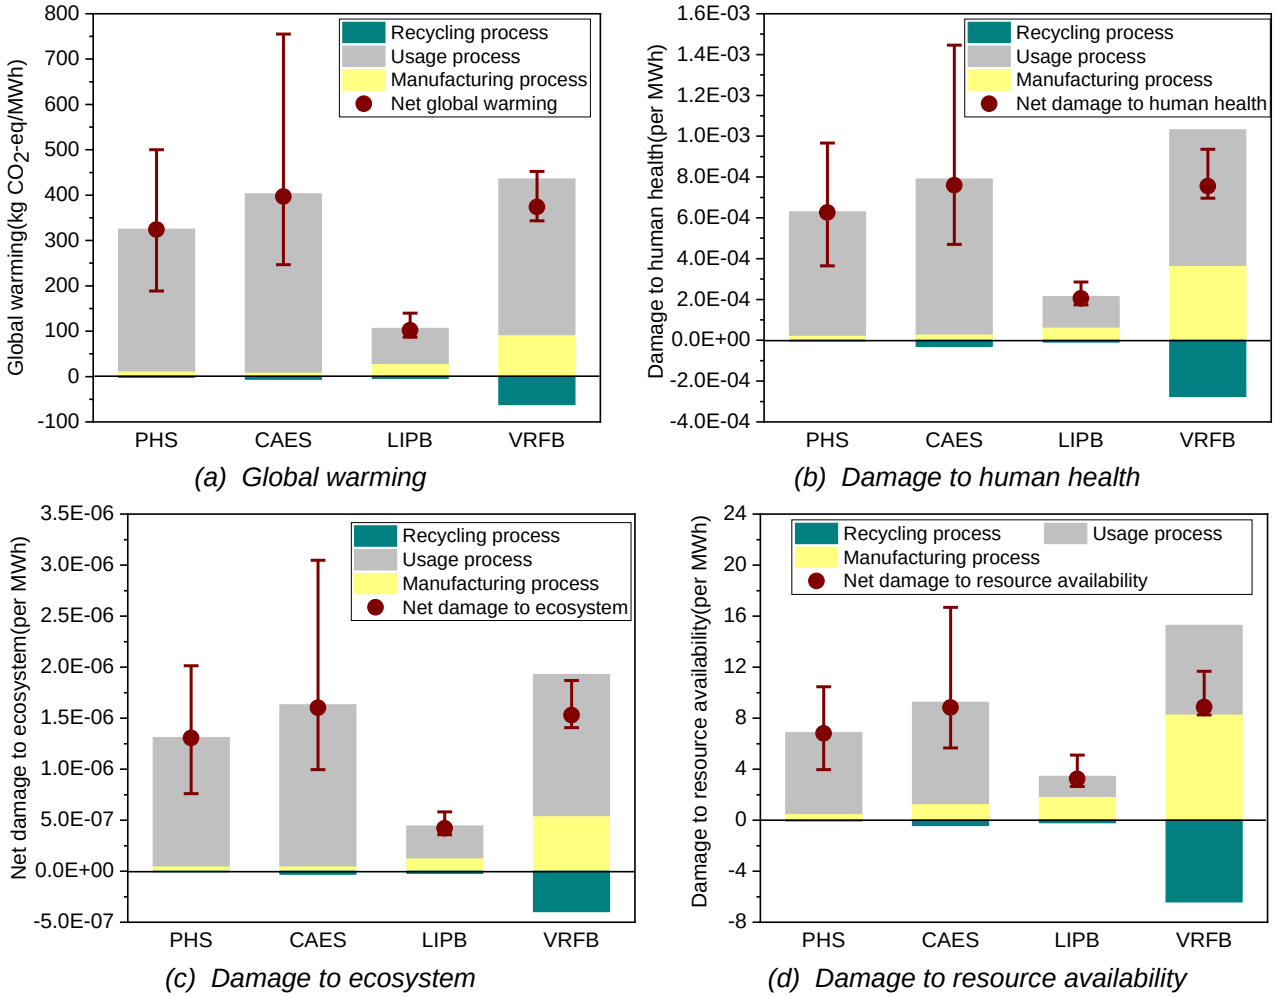

Figure. 4. The environmental performance of energy storage systems in the life cycle. The indicated whiskers in (a) represent 25% and 75% quartiles.

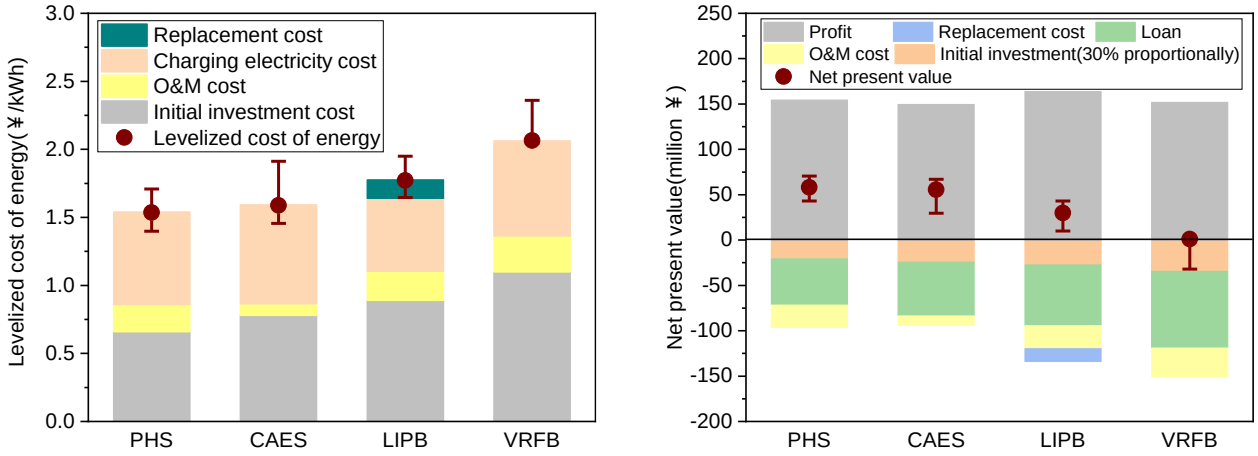
It can be observed that net GWP of PHS, CAES, LIPB and VRFB were 188.4-324.1-500.1, 246.6-397.0-755.4,86.9-102.3-139.8,343.5-374.1-452.4 kgCO_2-eq/MWh. LIPB had the best global warming performance, followed by PHS, VRFB and CAES. In general, the basically same trend was observed for the other three environmental impacts which was not demonstrated here. For the life cycle of ESSs, the usage process had the most impacts of GWP, DHH, DE and DRA, and the proportion of four environmental impacts of LIPB was 75.7%,73.0%,73.7% and 48.5%, respectively. The recycling process had the negative environmental impacts for the recycled materials were beneficial for the environment. Compared with PHS, CAES and LIPB, the recycling process of VRFB provided the greatest environmental benefits.

3.3. Economic performance

Levelized cost of energy (LCOE) and net present value (NPV) for PHS, CAES, LIPB and VRFB were displayed in Figure 5 in which median results are provided including positive and negative whiskers for the 25% and 75% quartiles. It should be noted that LIPB needed to be replaced once.

Figure 5(a) showed LCOE of PHS, CAES, LIPB and VRFB were 1.40-1.54-1.71,1.46-1.59-1.91,1.65-1.77-1.95 and 2.04-2.06-2.36 ¥/kWh, respectively. The performance of LCOE from the best to the worst was PHS, CAES, LIPB and VRFB, the rank results were consistent with the literature [11,18-20]. Take LIPB for example, the proportion of initial investment cost was 50.2%, the charging electricity cost was 30.2%, the O&M cost was 12.1% and the replacement cost was 7.5%. It can be found that initial investment cost and

charging electricity cost contributed most to LCOE. Figure 5(b) showed NPV of PHS, CAES, LIPB and VRFB were 43.1-58.1-70.6,29.5-55.6-67.0,10.1-29.8-43.0 and -31.9-1.1-2.5 million ￥, respectively. The NPV performance of PHS was best and that of VRFB was worst which was same to the LCOE results. LIPB had the least charging electricity cost for LCOE and the biggest profit for NPV, followed by PHS, VRFB and CAES, it was mainly related to the round-trip efficiency which were 95%, 75%,73% and 70% for LIPB, PHS, VRFB and CAES, respectively.



(a) Levelized cost of energy *(b) Net present value*

Figure. 5. The economic performance of ESSs. The indicated whiskers represent 25% and 75% quartiles.

3.4. Technology and social aspects

The results of quantified soft criteria with respect to maturity are presented in Table 2. The maturity of PHS, CAES, LIPB and VRFB were mature, developed/commercial, demonstration and demonstration, while the corresponding scores were 0.45, 0.26, 0.14 and 0.14, respectively. For the performance of position flexibility, PHS and CAES had strict restrictions, LIPB and VRFB had no special restrictions, so the scores were 0.13, 0.13, 0.38 and 0.38. For the performance of public acceptance, PHS has been accepted, CAES was developing, LIPB and VRFB depended on the station scale, so the public acceptance scores were 0.45,0.26,0.14,0.14. It can be found that the better the performance, the higher the score.

Table 2. The relative performances of ESSs with respect to maturity.

Maturity		PHS	CAES	LIPB	VRFB
PHS	Mature	1	2	3	3
CAES	Developed/ Commercial	1/2	1	2	2
LIPB	Demonstration	1/3	1/2	1	1
VRFB	Demonstration	1/3	1/2	1	1
Relative performances		0.45	0.26	0.14	0.14

In addition to the above soft criteria, the other technical indicators of ESSs were basically not definite values, but were in the range, it was also impossible to be compared directly in the TOPSIS process. Therefore, the interval approach for uncertainties proposed by Ren [2] was used to evaluate the technical performance of ESSs, the results were shown in Figure 6. Round-trip efficiency of PHS, CAES, LIPB and VRFB were 65%-85%, 54%-80%, 93.5%-96% and 70%-75%, while the corresponding scores were 1.77, 1.15, 3.5 and 1.58, respectively. Lifetime of PHS, CAES, LIPB and VRFB were 30-60 years, 20-40 years, 7.5-20 years and 10-20 years, while the corresponding scores were 3.3, 2.7, 0.94 and 1.06, respectively. It can be observed that best performance with higher scores of round-trip efficiency, life cycles, lifetime, duration range and energy density were for LIPB, PHS, PHS, CAES and LIPB.

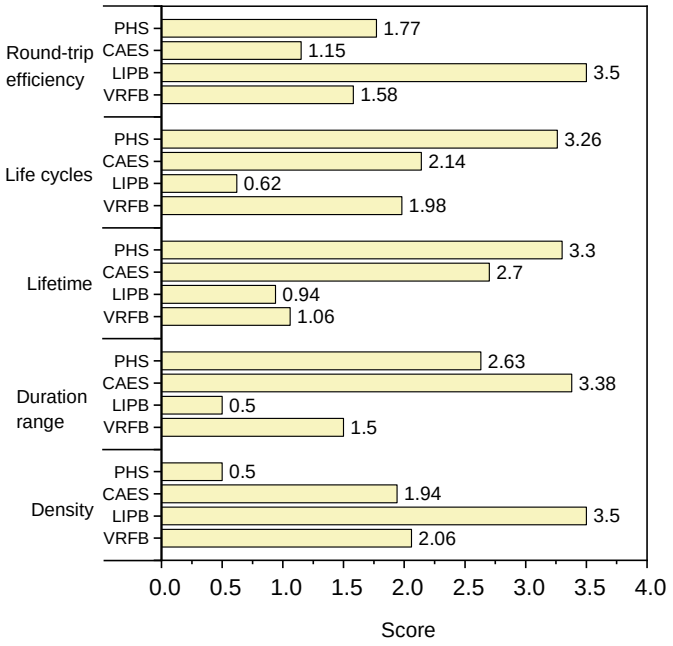


Figure. 6. The technical performance of ESSs.

3.5. Indicative scores and rankings

The considered technical, economic, environmental and social criteria have the inconsistent character, so the results can't be directly comparable, thus a single score was calculated by TOPSIS for multi-criteria decision analysis for sustainability assessment of typical ESSs. The rankings and sustainability scores of ESSs are shown in Figure 7. For environmental aspects, the performance which ranked from 1 to 4 was LIPB, PHS, VRFB and CAES. For economic aspects, the performance of PHS, CAES, LIPB and VRFB ranked from 1 to 4. And PHS performed best, CAES performed worst for technology aspects. The sustainability performance of PHS, CAES, LIPB and VRFB were 0.50, 0.30, 0.64 and 0.13. It was found that LIPB was best for sustainability performance, and VRFB was worst.

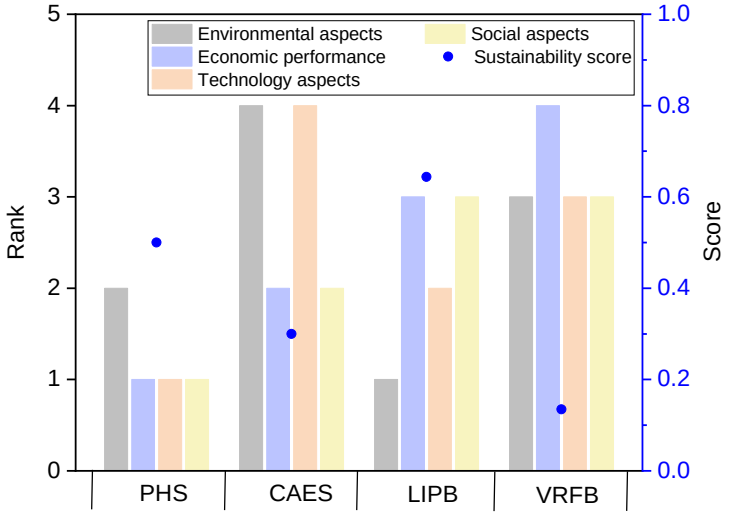

Figure. 7. The ranking and sustainability score of ESSs.

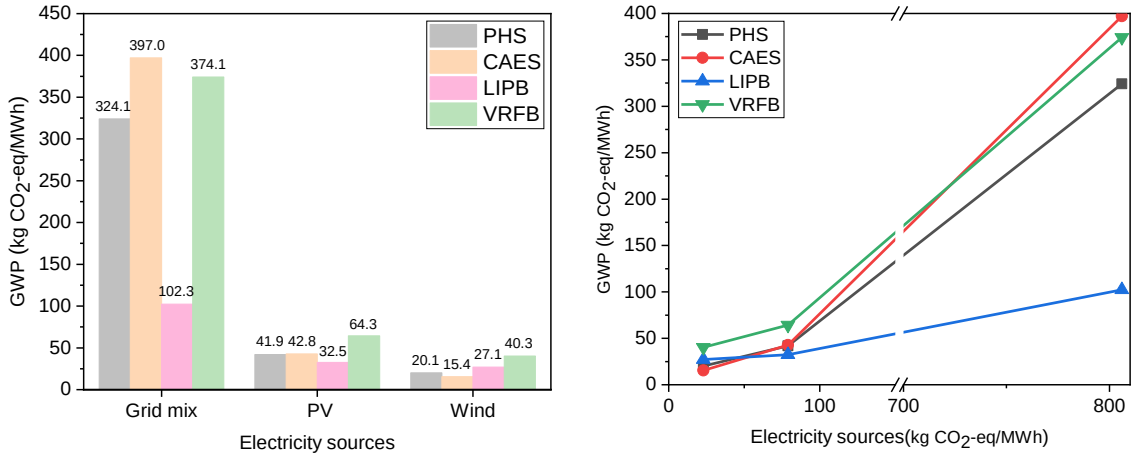
3.6. Sensitivity analysis

3.6.1. Sensitivity analysis of environmental impacts

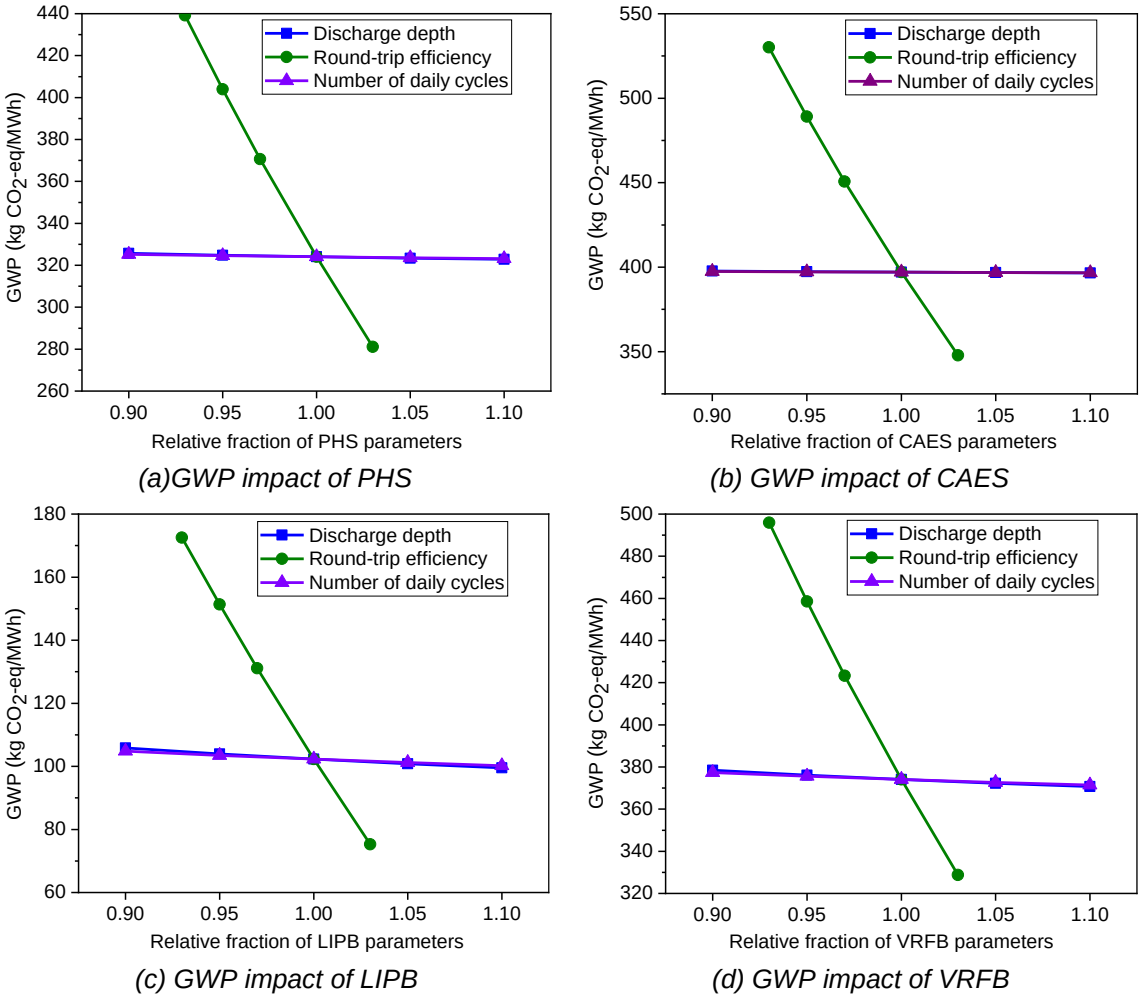
Sensitivity analysis of electricity sources, discharge depth, round-trip efficiency and number of daily cycles on environmental impacts were conducted. Sensitivity analysis result of GWP was displayed here, the variation trend of DHH, DE and DRA were the same with that of GWP. Figure 8 shows the effect of changing the electricity sources on GWP including solar photovoltaic (PV) and wind, it is quite evident that PV and wind scenarios drastically reduced the environmental impacts compared with the grid mix scenario. The GWP for PV and wind scenario was reduced to as little as less than 31.8% and 26.5% of the impacts of grid mix scenario, respectively. Moreover, the relative ranking of the four ESSs changed and CAES became more

competitive in the wind scenario. Figure 8(b) shows the variation of GWP impacts of ESSs with the variation of the GHG emissions of the electricity sources. The GHG emissions of grid mix, PV and wind are 806, 79 and 23 kg CO2-eq/MWh, respectively. Considering the grid mix as the reference scenario, a decrease of one percentage of electricity sources' GHG emissions will lead to a corresponding decrease in GWP impacts of 0.97%,0.99%,0.76%,0.92% for PHS, CAES, LIPB and VRFB, respectively.



(a) *(b)*

Figure. 8. GWP impact of changing the electricity sources.



(a)GWP impact of PHS *(b) GWP impact of CAES*

(c) GWP impact of LIPB *(d) GWP impact of VRFB*

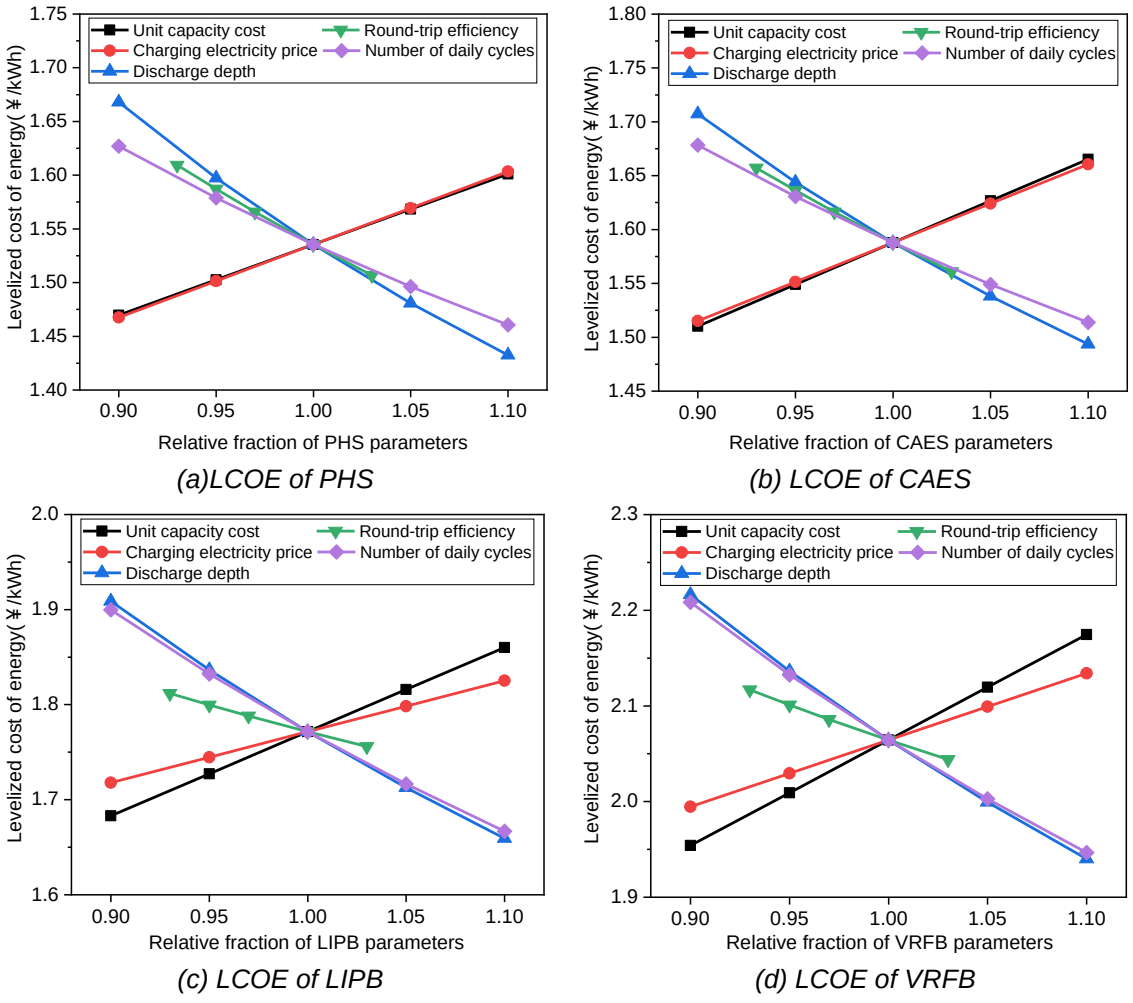
Figure. 9. Sensitivity analysis results of changing the discharge depth, round-trip efficiency and number of daily cycles on GWP impact.

The variation of GWP impact when the discharge depth, round-trip efficiency and number of daily cycles vary from the 0.90 to 1.10 times of reference value are shown in Figure 9. The reference round-trip efficiency values were 75%, 70%,95% and 73% for PHS, CAES, LIPB and VRFB, respectively. It can be found that an

increase of one percentage of round-trip efficiency will lead to a corresponding decrease in GWP impacts of 4.8%,4.5%,9.4%,4.4% for PHS, CAES, LIPB and VRFB, respectively. And the reference discharge depth and number of daily cycles values were 80% and 300 cycles per day for four ESSs, the variation of GWP impact was not changed evidently when the two input parameters varied. Therefore, electricity sources and round-trip efficiency had important impacts on the environmental performance of ESSs.

3.6.2. Sensitivity analysis of economic impacts

The effects of control and economic parameters on LCOE were conducted which is shown in Figure 10. In terms of control parameters, discharge depth, round-trip efficiency and number of daily cycles were selected for analysis, and the economic parameters of unit capacity cost and charging electricity price were analysed. LCOE increased with the increasing of economic parameters and the decreasing of control parameters. For LCOE of LIPB, an increase of one percentage of unit capacity cost and charging electricity price will lead to a corresponding increase of 58.1% and 28.3%. In addition, an increase of one percentage of discharge depth, round-trip efficiency and number of daily cycles will lead to a decrease of 72.1%, 29.3% and 67.3%, respectively. It is illustrated that the control parameters had more influence to LCOE than economic parameters, and LCOE was more sensitive to the discharge depth which was consistent with the literature [20].



(a)LCOE of PHS *(b) LCOE of CAES*

(c) LCOE of LIPB *(d) LCOE of VRFB*

Figure. 10. Sensitivity analysis results of control and economic parameters on LCOE.

3.6.3. Sensitivity analysis of rankings

Sensitivity analysis was carried out to investigate the effects of electricity sources, number of daily cycles and criteria weights on sustainability score and rankings.

The variation of sustainability score of ESSs under different electricity sources is displayed in Figure 11, it can be noticed that the sustainability score and ranking varied while the electricity sources varied from grid mix to renewable energy (wind and solar PV), PHS changed its ranking from two to one and changed the score from 0.50 to 0.82 and 0.74, respectively. Figure 12 shows the sensitivity analysis under different number of daily cycles, the ranking did not change in a qualitative manner yet the sustainability score of ESSs changed, as the number of daily cycles increased, the superiority of LIPB was improved.

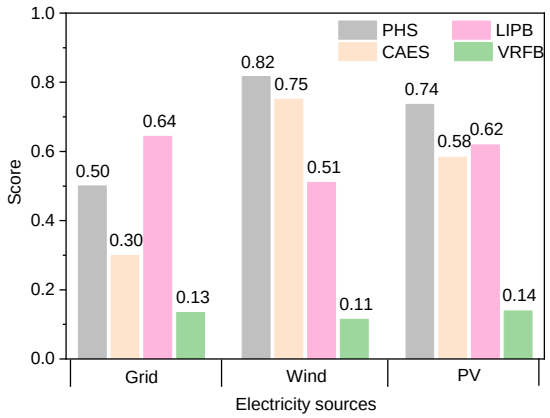


Figure. 11. Sensitivity analysis under different electricity sources.

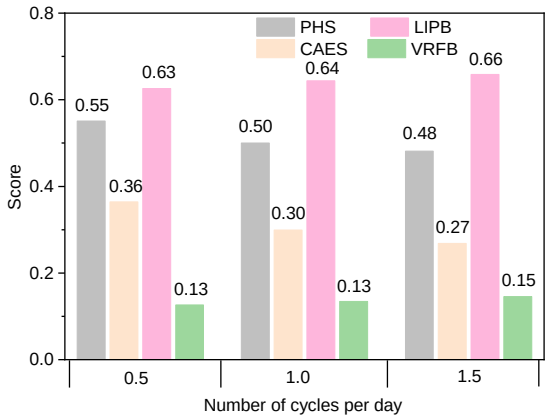

Figure. 12. Sensitivity analysis under different number of daily cycles.

Criteria weights were altered from 0 to 1 by increasing its value 0.1 at a time as shown in Figure 13. When the weight of one criterion was changed, the weights of the remaining three main criteria were kept the same proportionally. As can be noticed from all parts of Figure 13, the ranking varied noteworthily with varying weights of main criteria. For example, LIPB changed its ranking from three to one when environmental weight was given higher weights. As a whole, PHS and LIPB were the most sustainable energy storage option.

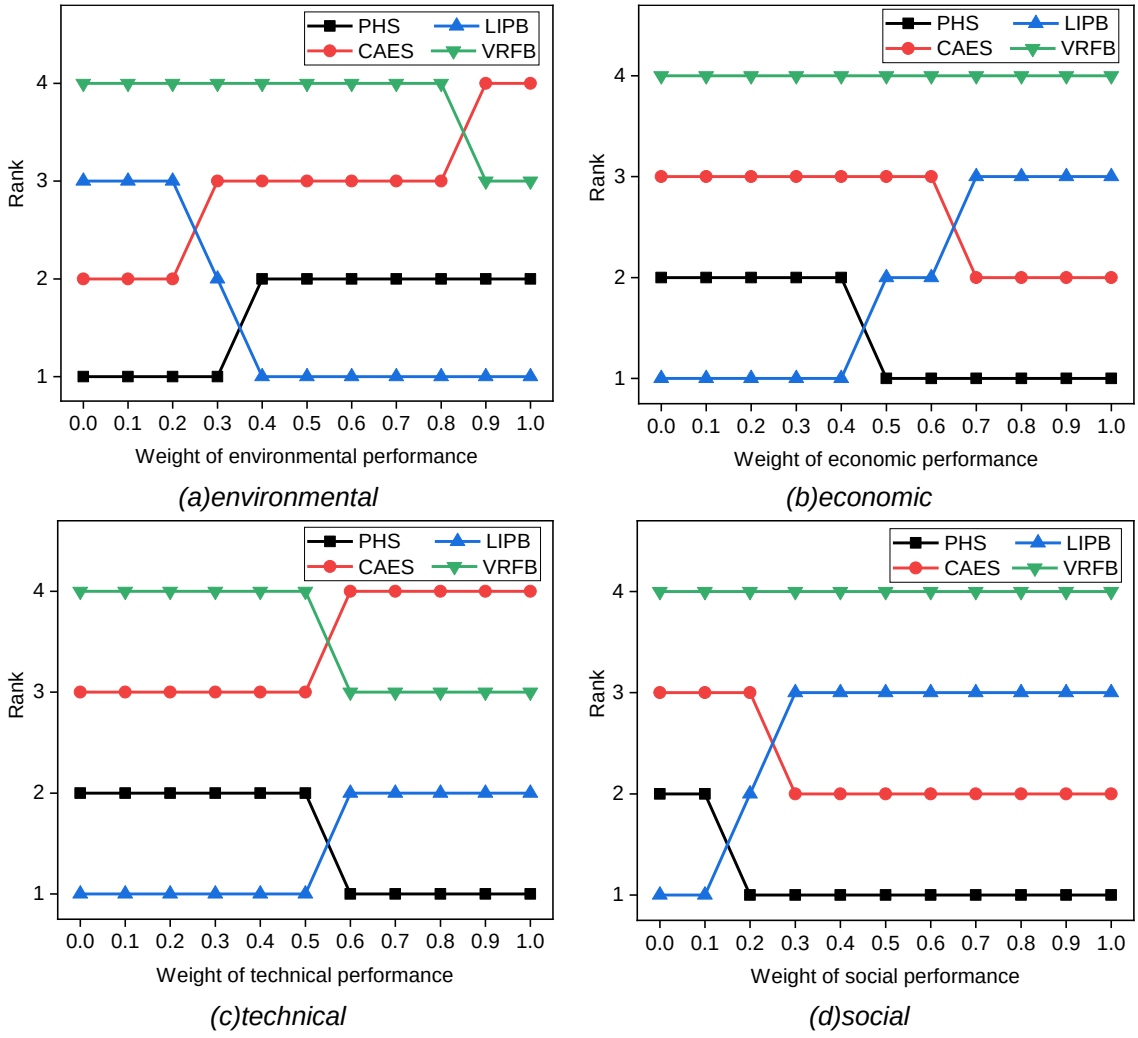

Figure. 13. Sensitivity analysis of varying the main criteria weights.

4. Conclusions

This study provides a sustainability assessment of typical energy storage systems for quantifying the considered environmental, economic, technical and social criteria for peak shaving scenarios, the studied alternatives include pumped hydro(PHS), compressed air energy storage(CAES), lithium-ion phosphate battery(LIPB) and vanadium redox flow battery(VRFB). A combination of life cycle assessment, life cycle cost, quantifying the soft criteria and TOPSIS methodology were applied based on the full life. The conclusions were:

(1) For PHS, CAES, LIPB and VRFB, environmental indicator of GWP for were 324.1, 397.0,102.3,374.1 $kgCO_2$-eq/MWh, economic indicator of LCOE were 1.54, 1.59, 1.77 and 2.06 ¥/kWh, NPV were 58.1, 55.6, 29.8 and 1.1 million ￥, the sustainability performance score were 0.50, 0.30, 0.64 and 0.13.

(2) The sensitivity results point out discharge depth are the main drivers of life cycle cost (LCC), while for the environmental performance, the electricity sources and round-trip efficiency are of paramount importance. The sustainability rank of ESSs depends on the weight of main criteria and electricity sources, PHS and LIPB are the most sustainable alternatives in the sensitivity analysis.

Abstract:
The review of national and international energy strategies forced by recent disruptive events emphasized the importance of developing tailored planning to pursue the increased decarbonization goals. Within this context, the presented article first describes the development of a bottom-up optimization tool tailored for the Lombardy region, in Italy. Then it evaluates different technology mixes to identify the optimal configuration to reach local decarbonization targets at minimum costs. The model has a solid spatial resolution and a wide range of technological options, and it is set to analyse the local energy system at the target year (2030). The work evaluates the response of the system to different decarbonization goals and is carried out by comparing the cost of an avoided ton of CO_2. A $CO_{2\text{-equivalent}}$ emission limit in line with the EU Fit-For-55 package returns a feasible solution with conventional technology options, such as thermal insulation, electrification, energy efficiency and a partial substitution of natural gas with biomethane. Electrification is strongly bound to the expansion of photovoltaics since the additional potential of other sources is negligible. However, at higher decarbonization targets, the cost of avoided CO_2 rises at unsustainable values. Analysis on resources' availability, utility scale photovoltaic power plants and on commodity prices investigate the possibility to overcome this limit and the main results emphasize their strong impact on final energy configuration mix. They suggest the need to promote new photovoltaic installation and increasing the photovoltaic availability by 1,5 GW (+12%) could reduce the cost of avoided CO_2 of about 16%.

Keywords:
Energy system modelling; oemof; bottom-up model; renewable sources availability; high spatial resolution.

1. Introduction

In recent months and years disruptive events have strongly driven the review of national and international energy strategies, to better suit decarbonization pathway with a focus on energy security. In the European Union (EU), more challenging targets are going to be set, by strengthening the importance of differentiating energy supplies. Existing National Energy and Climate Plans are going to be updated with new targets for 2030 set by the "Fit for 55" (FF55) [1] and the "REPowerEU" [2] packages, currently under discussion by EU authorities. In particular the FF55 sets the goal of a reduction of 55% of greenhouse gas (GHG) emissions compared to 1990 levels [3]. It introduces specific targets for each end-use sector: e.g., the upgrade of the European Emission Trading System (EU ETS), with the reduction of total emission allowances (-61%) compared to 2005 [1].
All these targets must be received by national and sub-national authorities, through the development of local plans. In Italy, also each Region (i.e., the highest sub-national administrative level), has the authority to implement specific policies regarding energy and climate themes, in compliance however with national standards.

Within the mentioned context, energy system modelling plays an important role. It can help policymakers to study the decarbonization process of energy systems and to identify minimum cost pathways. Several optimization framework's approaches exist. Fodstad et al. [4] provide a review of the state of the art, with a list of several studies which compare different frameworks and identify possible future developments. They recognize the importance to evaluate interdependencies among energy carriers, focusing on the integration of new energy carriers (e.g., hydrogen) or infrastructures (e.g., carbon capture and storage), to better describe interconnections within the system (e.g., sector coupling). They underline the required trade-off between spatial and time resolution, due to the computational issue related to the high level of detail for both.

1.1. Aim of the paper and outline

Through the development of an optimization tool tailored for the Lombardy region, in Northern Italy, the local energy system is evaluated at a target year (2030), in which the decarbonization targets are reached at the least cost. Within this context, the aim of the study is to evaluate the role of renewable energy sources (e.g., photovoltaic) and energy carriers (e.g., biomethane) and their impact in the GHG emissions reduction process. Multiple configurations of the system are then analyzed, by varying resources availability and prices of commodities. Lastly the work focuses on how system costs are influenced by the variation of boundary conditions (e.g., GHG emission target).
In the remainder of the paper, Section 2 presents the structure of the tool used for the analysis, the setup and the main assumptions of the analyzed case study. The construction of baseline case and sensitivity analyses are reported in Section 3, followed by main results in Section 4, while main outcomes and further developments are summarized in the conclusion (Section 5).

2. Methodology

In this Section the structure of the model is first presented, followed by the main assumptions and the setup of the case study.

2.1. Mathematical model structure

The possibility to evaluate interdependencies among energy carriers (e.g., through a multi-node representation), coupled to its open-source behaviour, led the choice of oemof framework [5], an open-source energy system modelling framework written in Python that can create and solve optimization problems, for the presented work.
To build the structure of an energy system, oemof framework uses different logical components: (i) buses, (ii) transformers, (iii) sources and sinks and (iv) storages. Buses represent energy carriers and commodities, such as electricity, heat or fossil fuels. Transformers represent processes or technologies which consume and/or produce one or more commodities. For example, a transformer may represent a gas power plant, which receives natural gas as input energy carrier and produces electricity as main output. Sources and sinks are two subcategories of transformers, respectively used to represent the production/introduction of a commodity in the energy system (e.g., the import of natural gas) and the final demand of an energy carrier (e.g., the heat demand in the civil sector). The storage component enables the system to decouple demand and supply of a specific energy carrier (e.g., electrochemical batteries). Lastly, the exchanges of a commodity between buses and transformers are named flows.
The objective function to be minimized, which represents the system total cost, is expressed, in a simplified way, as follows in Eq. (1):

$$\text{system total cost} = \sum_{h} \left[\sum_{c} \left(flow_{c,h} \cdot varcost_{c} \right) + \sum_{t} \left(capacity_{t} \cdot invcost_{t} \right) \right] \quad (1)$$

$flow_{c,h}$ is the flow of the commodity c at time-step h,

$capacity_t$ is the capacity of the technology/transformer t related to the investment,

$varcost_c$ is the variable cost of the commodity c,

$invcost_t$ is the investment cost of the technology t.

The constraints of the considered optimization problem guarantee the balance of energy carriers and the satisfaction of demand. Ad-hoc bounds that could be added to the problem might be GHG emission limits or availability of resources. The decision variables of the optimization problem represent the new installed capacity (investments) and the energy and/or mass flows within the energy system.
A point of strength of the framework is the modularity of its components, that can be replicated as many times as needed, in series or in parallel, to build the energy system, as will be presented in the following section.

2.2. Energy system structure and assumptions

The spatial resolution of the tool starts from the aggregation of those local administrative division with similar socioeconomic and environmental characteristics, and results in 17 local areas within the region.

Each area presents differences on the environment (e.g., climatic conditions, morphology and use of the land) and on the economics (e.g., gross domestic production, index per capita, average yearly income). For each area, final demands for end-use sectors, resources' availability and technological options were defined starting from a high spatial resolution and a modular scheme of the energy system was then built. In Figure 1 a simplified graphical representation is shown. Note that the energy efficiency option is modelled as a source of heat in order to quantify heat demand that can be avoided with that solution.

The resulting structure is quite complex, being characterized by more than 6500 exchanges (i.e., flows) between processes and technologies. The complexity of the energy system determines an important computational effort.

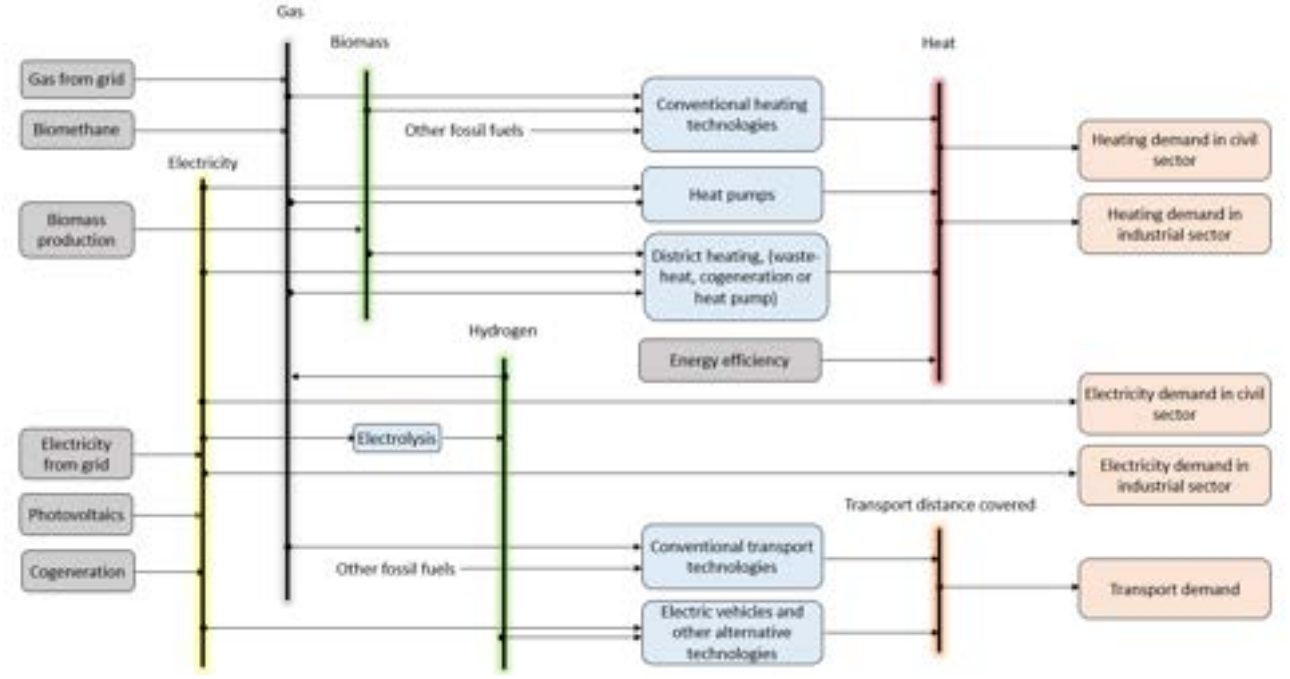

Figure. 1. Simplified scheme of the energy system for each area (commodities and processes are aggregated for sake of representation), represented through buses (vertical lines), sources (grey boxes, mainly on the left side), transformers (light-blue boxes, mainly in the central area) and sinks (pink boxes, mainly on the right); for sake of representation, other fossil fuels supply chain are not shown, as well as hydrogen blending process with natural gas.

Each technology or process is characterized by the following input parameters: (i) capital, variable and fixed costs; (ii) efficiencies, (iii) residual installed capacities in the years, (iv) availability or penetration limit of technologies.

Regarding the commodities and the energy carriers, the model considers: (i) natural gas, (ii) diesel, (iii) liquid petroleum gas for heating and (iv) for transport sector, (v) gasoline, (vi) electricity, (vii) solid biomass, (viii) biomethane, (ix) biodiesel, (x) hydrogen, and (xi) heat.

The end-use sectors are analyzed with different level of detail, strongly due to the availability of input data. The **civil sector** is the one with the highest technological detail, being investigated both the heating and cooling demand and the power demand. For each of the 17 areas, five types of building are identified, each one with its specific characteristics, to provide a realistic picture of the sector: (i) detached houses, (ii) apartment blocks for residential sector with an independent or (iii) a centralized heating system and (iv) tertiary buildings with independent or (v) centralized heating systems. For each one, the model provides different technological solutions to satisfy thermal needs, mainly: boilers, heat pumps, district heating from different sources (i.e., waste-heat from industry, natural gas or biomass fuelled dedicated plants, large size electric heat pumps). Also power self-generation by photovoltaics (PV) is considered in the civil sector. Different combinations of the PV technology (i.e., alone or coupled with an electrochemical storage) and final users (i.e., single users or energy communities) are considered.

Regarding the transport sector three main classes are considered: (i) light mobility, namely cars, with higher level of detail; (ii) light duty commercial vehicles, with an intermediate level of detail and (iii) other transport, which includes heavy road transport, naval and train, with a more aggregated description. For light mobility several technology options are compared: conventional propulsion systems based on internal combustion engines are in competition with plug-in hybrid electric vehicles or pure battery electric ones.

The industry sector has very heterogeneous characteristics, about processes, technologies and energy carriers, which make it difficult to provide a detailed picture. The power and thermal final demands are investigated as aggregated. The supply options for the former are represented by electricity coming from the power grid or from self-generation through dedicated PV. Electricity can be used also to provide heating services, through industrial high temperature electric heat pumps or by synthetizing hydrogen through water electrolysis process.

Being out of the scope of the presented analysis, the conventional power generation of Lombardy (mostly made up of hydro and thermal power plants) is not explicitly depicted, but it is represented as a generic power grid, with an electricity source as component. Emphasis is indeed given to non-sectorial renewable energy sources, meaning those sources that are not exclusively dedicated to a single end-use sector. The first example is represented by PV at utility scale on dedicated surfaces and floating on quarry lakes. For biogas and biomethane, the study considers only the potential related to livestock residues and biodegradable municipal wastes. Ligneous biomass is considered in two different ways: sustainable local biomass and generic imported biomass.

With the resulting model, tailored analyses on resources' availability and on final demands of different energy carriers are then possible, by enabling policymakers to define ad-hoc policies, well suited for the local areas and in this way to adopt and apply on the territory national/international decarbonization strategies.

3. Input data

In this section the definition of a baseline configuration is presented in parallel with the construction of alternative options as sensitivity analysis. The optimal configuration of the system is defined throughout a range of emission reduction targets. This allows to test the optimal configuration in the neighbourhood of the decarbonization targets proposed by EU FF55 package (i.e., -44% vs. 2005, with total allowed emission equal to 43,5 Mt).
A 2030 baseline case is defined starting from a GHG emission-unconstrained energy system, a configuration to evaluate a pure economic optimization, to the minimum emission target allowed by given boundary conditions (e.g., resources' availability). In Table 1 the main input parameters are presented.

Table 1. Main input data for the baseline case (on the left) and for the sensitivity analyses (on the right); note that for each sensitivity analysis only the modified parameters with respect to baseline case are reported [source: elaborations from the authors].

			Baseline case	Modified parameters compared to baseline configuration		
			Medium commodity price	Low commodity price	High commodity price	Very high commodity price
Natural gas		[€/MWh]	95	60	137	179
Electricity	Cost for end-users	[€/MWh]	280	160	460	640
	Price sold to the market	[€/MWh]	140	30	250	386
			Minimum PV utility scale availability	Medium PV availability	High PV availability	Maximum PV availability
Installation capacity potential	PV total	[GW_e]	11,79	13,3	14,8	16,3
	of which PV utility scale	[GW_e]	*1,64*	*3,14*	*4,64*	*6,14*
			Maximum biomethane availability	Medium biomethane availability	Low biomethane availability	Minimum biomethane availability
Biomethane annual availability		[TWh]	11,5	9,7	7,8	6

PV total includes rooftop installation potential in civil sector, industry and utility scale plants (ground and rooftop based).

In baseline case for PV utility scale only unused lands and coverage of quarry lakes are considered [source: elaboration of the authors on RSE [6]]; in sensitivity analysis, the potential of PV rooftop installation on public parking is added. Commodity prices are estimated from historical data (from 2013 to the first half of 2022); the configuration with very high commodity price considers the most recent period (first half of 2022); electricity values represent cost for end-users (first row), and the price of quantities sold to the power market (second row) [source: Italian Authority for the regulation of the energy, grid and the environment ARERA [7]]

For each configuration, the energy system is analyzed at different limits of emissions, each of which is independent from the others. The tool allows to identify the optimal distribution of cost effort (namely the required investments to reduce GHG emissions) between sectors. It returns an optimal configuration mix under specific assumptions, which are strongly related to the estimated evolution of parameters. Each sensitivity analysis presented below focuses on a specific topic. The structure and the assumptions of the energy system are the same of the baseline case, except for the boundary condition that is object of the analysis.

A first sensitivity study is driven on prices of electricity from power grid and natural gas. A second level of sensitivity concerns the availability of resources. Being wind power generation out of the scope (i.e., no potential is identified within the region) and being the installation of distributed PV plants difficult to be controlled by regional authorities, PV utility scale plants is selected. In the baseline case, a potential of 1,64 GW of new installation capacity is estimated for the utility scale PV, by considering available unused lands destined to regeneration and a potential surface coverage of quarry lakes. In the sensitivity analysis the role of potential PV installations on covertures of large size public parking is considered. Through the information provided by OpenStreetMap [8] and QGIS platform [9], open-source geographic database and geospatial data visualization tools, the available surface suitable for rooftop PV installations is estimated. Only parking spaces with a minimum surface area are considered and with assumptions on the eligible surface area to PV installation (e.g., lanes to manoeuvre might not be covered by rooftops) and on the share of total parking suitable for photovoltaics installation (e.g., in short-term large rooftop PV installation is more likely to occur on larger surface areas), a PV utility scale additional potential of about 4,5 GW_e is obtained.

Finally, some considerations can be made on biomethane. Being gas still an important energy carrier in base-case scenario (for example in civil sector, with a significant role in supplying heating systems), the switch from fossil-based gas to bio-based one is strongly promoted. Biomethane from biodegradable municipal waste and especially from livestock residues might be more difficult to be developed. A sensitivity analysis has then been conducted to evaluate lower potential, with a reduction of almost 48% in the worst case.

4. Results

This section returns and compare the main results, with an overview of the energy system first, and then by deepening the system total cost. In particular it presents the main comparison between present time, baseline case and the tested sensitivity analyses. Figure 2 shows the final consumptions, comparing the FF55 emission limit configuration (i.e., 43,5 Mt $CO_{2\text{-eq}}$) in 2030 vs. present time. The chart returns for every tested scenario an overall reduction in final consumption. Energy efficiency and the switch to less emitting technologies are the main drivers to pursue decarbonization targets.

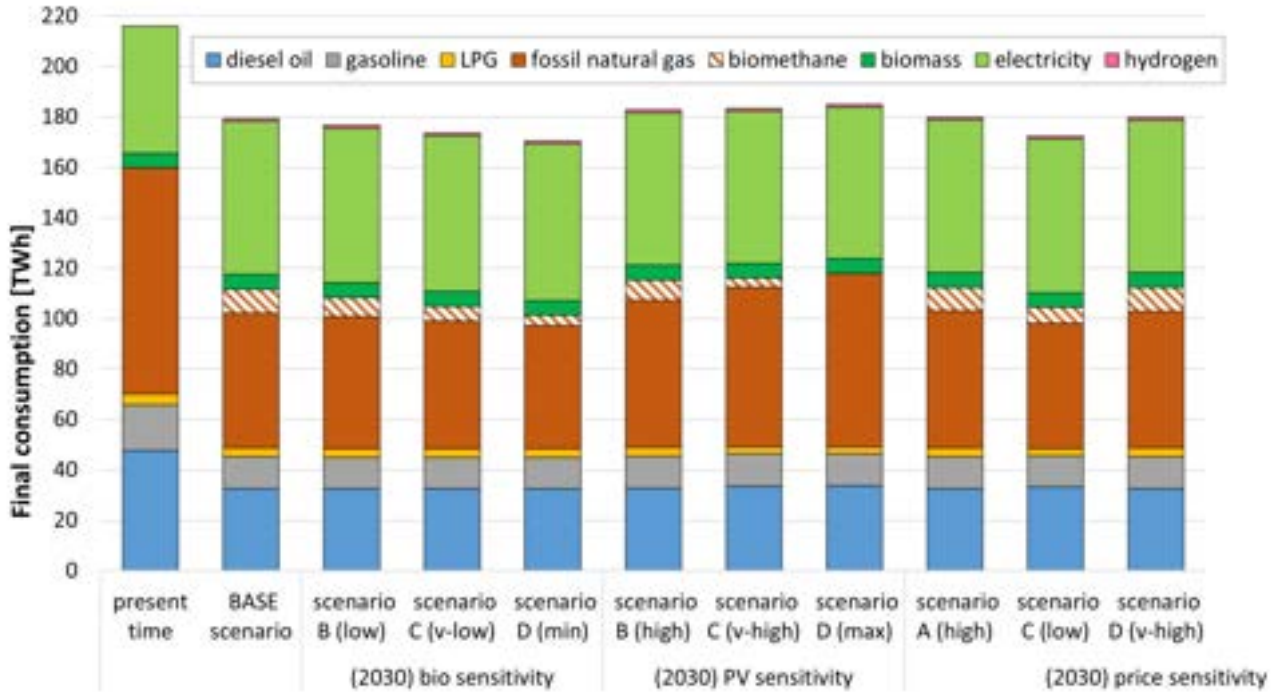

Figure. 2. Final consumption by energy carriers in different scenarios; v-low = very low; v-high = very high [source: elaborations from the authors].

For the baseline configuration a cumulative consumptions reduction of about 17% compared to present time can be observed. The most important contraction occurs in fossil natural gas consumption (-40%), thanks to the introduction of biomethane and to the electrification of different end-use sectors (+20%), such as space heating in the civil sector. The latter is interested by a strong consumption reduction through extended building refurbishments (up to 2% of the buildings/year, i.e., the maximum allowed), coupled with a strong electrification of the heat sector and the construction of district heating networks. Gas boilers keep playing an important role, with however a remarkable substitution with newer systems. The overall effect is a GHG emissions reduction of about 50% in civil sector, vs. 2005 levels. Regarding transport sector, there is a lower reduction in final consumptions (about 10%) between present time and 2030, mainly through the electrification of light road transport and the introduction of less carbon intensive solutions. The resulting configuration mix returns a reduction of about 35% of $CO_{2\text{-eq}}$ emissions in the sector vs. 2005 levels. Industry consumptions are reduced of about 18%, mainly thanks to the switch from gas to electricity.

By focusing on the sensitivity on RES availability, in case of biomethane reduction, an overall reduction of final consumption is observed compared to baseline one. Being PV installations, electrification option and building refurbishment in civil sector all completely exploited, more efficient options, such as electric heat pumps in DH networks or vehicles substitute conventional less efficient options (e.g., gas CHPs, fossil fuel-based vehicles). When the focus is on PV availability, the scenarios analyze the case of gradually additional PV capacity potential, by introducing new installation on rooftops of public parking. Electricity from PV can be self-consumed, shared between groups of local end-users (i.e., energy communities) or sold to the market. In every scenario the PV overall power generation is always at its maximum (about 11 TWh), although with different distributions in end-use sectors. Differences occur in installation of PV utility scale plants. As expected, in PV sensitivity scenarios, the increasing PV utility capacity potential is effectively installed, reaching a total PV electricity production nearly 15,8 TWh in maximum case. The last sensitivity analysis focuses on the price of gas and electricity. In the scenario with low prices the main output is an overall final consumption reduction. The lower cost of gas enables a more widespread use of conventional gas boilers in civil sector (both old and new models) at the expense of electrification and gas CHPs in DH networks. In the scenarios with high and very high commodity prices energy efficiency gains importance (e.g., gas heat pumps in substitution of conventional gas boilers).

To complete the description of the energy system, it might be useful to focus on the cost of the avoided GHG emissions, expressed in €/t_{CO2} avoided. This cost is defined as the ratio between the difference of the system total cost and the difference of total GHG emissions. The former is obtained as the sum of the total cost of annualized investment plus the operation cost of the target year. In Figure 3 the different trends of the cost of avoided GHG emissions are presented, both for biomethane availability (blue lines) and for photovoltaics one (green lines).

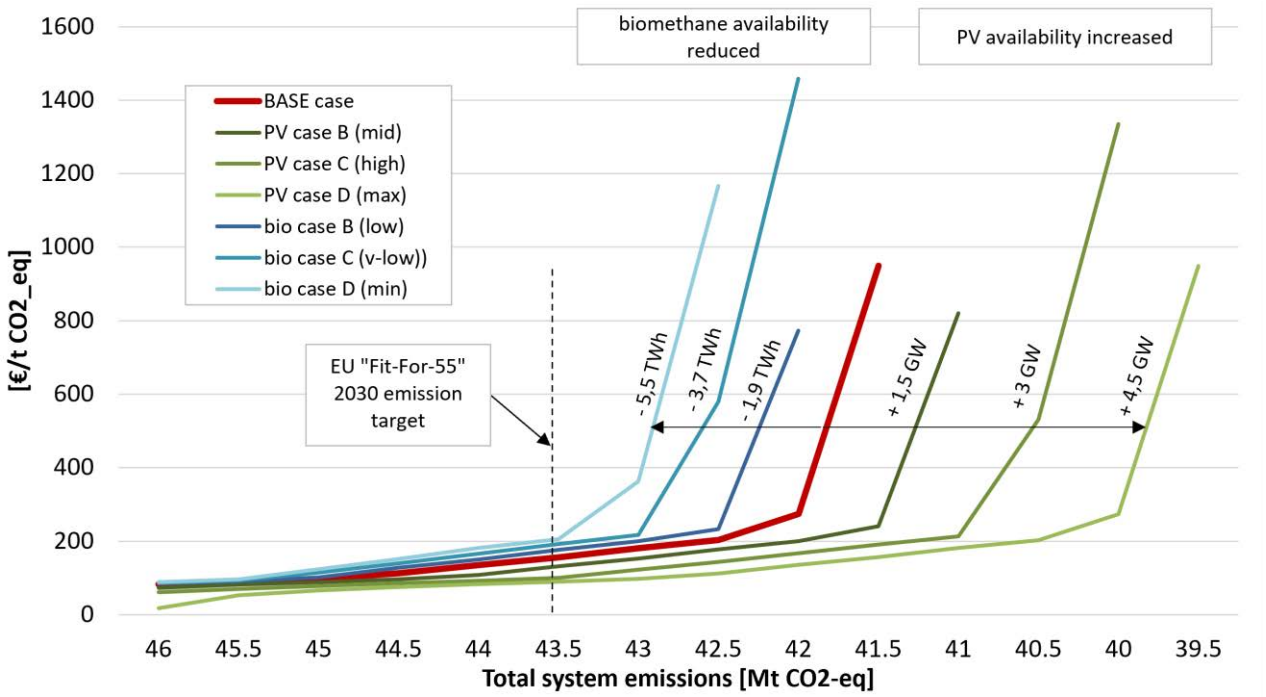

Figure. 3. Comparison of costs for avoided $CO_{2\text{-eq}}$ emissions between 2030 baseline scenario (red line, in the middle) and sensitivity on biomethane availability (blue lines, on the left) and PV availability (green lines, on the right); on X-axis the system total $CO_{2\text{-eq}}$ emission levels are reported, in line with Fit-for-55 package (with the target of 43,5 Mt); v-low = very low [source: elaborations from the authors].

Starting from PV, the graph shows that, at increasing installed PV capacity, it is possible to reach lower total system emission levels. The system's total cost of avoided GHG emissions can be kept at reasonable values in more challenging configurations. Similar trends can be observed in the sensitivity analysis of biomethane availability. The analysis investigates the effect of a less developed biomethane supply-chain. By reducing its availability in the energy system, the minimum emission limit (i.e., the physical limit for the configuration, given its boundary conditions) of the system shifts at higher levels. For both PV and biomethane case, the graph seems to identify a cost range (around 200-270 €/$t_{CO2\text{-eq avoided}}$) above which getting an additional reduction of the system's emission unit becomes economically not viable. In both sensitivity analyses, at the target of 43,5 $Mt_{CO2\text{-eq}}$, differences between costs are still quite limited, meaning that the configuration is not close to the technical limit (at given boundary conditions), except for case of minimum biomethane availability.

Last sensitivity analysis concerns the different prices of commodities. As expected, the variation of commodity costs has an immediate effect on the overall system total cost at every tested GHG system emission level. The differences between scenarios widen as the emission limit is reduced. At the target of 43,5 Mt of $CO_{2\text{-eq}}$ high and very high cost scenarios show an increase of about 97% and 199% compared to base-case levels (around 190 €/$t_{CO2\text{-eq avoided}}$), while a reduction of about 32% in minimum cost configuration can be observed.

5. Conclusion

The presented work aimed to study a possible optimal energy mix for the Lombardy region at the target year 2030 and to evaluate the weight of specific input parameters (e.g., resources' availability, commodity prices) on its composition. In a scenario in line with EU Fit-for-55 package, useful consideration emerged for local policymakers. The process of decarbonization takes place through a combination of electrification of final consumption and improvements thanks to energy efficiency. PV and building refurbishment options are exploited in every tested scenario at their maximum. The GHG emission reduction evolution is mainly driven by civil sector and transport one (-50% for the former, -35% for the latter compared to 2005 levels). Sensitivity analyses were conducted to evaluate the role of (i) commodity prices, (ii) PV potential installation capacity and (iii) biomethane availability.

Regarding the cost of electricity from the power grid and of natural gas, in high-cost scenarios energy efficiency gains importance and enables the introduction of technology options that would otherwise remain excluded by the market (e.g., gas heat pumps in civil sector). Sensitivity analyses on biomethane and PV utility scale seem to suggest the existence of a range of system's total cost of avoided GHG emissions around 210-270 €/tCO2-eq avoided, above which the further emission reduction would become economically unviable (at given boundary conditions). The increase (or the decrease) of RES availability shifts at lower (or higher) minimum GHG emission levels the energy configuration mix.

The main advantages of the developed tool are its replicability and its suitability to evaluate different energy systems, with a free level of customization on technological and spatial level. Further development might couple the results of the tool with frameworks with higher time-resolution, for example to better evaluate infra-day or day/night fluctuations both in demand and supply.

CO_2 capture from flue gases: a possibility to reduce the CO_2 footprint in offshore oil installations

Murilo José Castro[a], Waldyr Luiz Ribeiro Gallo[b]

Abstract:

The production of oil and gas in offshore units (FPSO) requires that all utilities (electricity, mechanical drive, hot fluids for heating and cooling water) must be available in the amount necessary at each operating condition. Lack or surplus of utilities are not allowed. Every production equipment is always sized for the highest demand condition, and then it operates at partial loads most of the time. The entire production of electricity, mechanical power and heating fluids depends on the fuel available in the FPSO – the natural gas produced with oil. Therefore, a typical FPSO has a strong carbon footprint associated with burning fuel. Carbon sequestration in an FPSO is facilitated by the possibility of re-injecting CO_2 into the reservoir, contributing to oil recovery. This work analyzes two possibilities for reducing the carbon footprint in a typical Brazilian FPSO: a) the use of a combined cycle for electrical generation, reducing fuel consumption and consequently the carbon footprint and b) the association of an amine absorption system to capture CO_2 from gas turbine exhaust gases. The analysis is performed for different oil and gas production conditions, and all systems are analyzed operating at partial loads. The combined cycle alone is capable of reducing CO_2 emissions by up to 20%. The CO_2 capture system, together with the combined cycle, achieves impressive results, with a reduction in CO_2 emissions of around 50% during the entire life of the platform. Problems of space and weight of the equipment are also discussed in the work.

Keywords:

Offshore oil and gas production; FPSO; Carbon capture and storage - CCS; Exergy, CO_2 footprint reduction.

1. Introduction

Due to environmental concerns, there is a need to decrease the carbon footprint in every energy-intensive industrial operations. In many cases, the use of renewable energy is possible. However, the production of oil and gas in offshore units (FPSO) far from coast and in deep waters requires utilities such as electric power, mechanical power and hot fluids for heating processes that depend on the use of fossil fuels, especially natural gas. If the fuel is fossil, the CO2 emissions can be reduce by two strategies: increasing the power efficiency in the processes, and/or by carbon sequestration. The electric power and process heat needs in a FPSO are huge. It is usual to adopt waste heat recovery from exhaust gases to supply hot fluid utilities - that is, cogeneration.

The prime movers to electric generators usually are gas turbines. To increase the low efficiency of gas turbines it is common the adoption of combined cycles. This is largely adopted in electric power generation onshore and is a mature technology. However, the available space and allowed weight in a FPSO is a challenge to adopt this technology. Nord et al [1] presented studies for the installation of combined cycle in offshore oil platforms in the North Sea. Again, Nord et al [2] made an optimization of the combined cycle under restrictions of power and weight for offshore oil production. Vidoza et al [3] explored the concept of “Power Island” to produce electricity to various FPSO’s simultaneously, using different combinations of combined cycle groups in a dedicated platform (the “power island”). All results described above showed the direct link of the fuel consumption (efficiency of the system) and the reduction in CO_2 emissions.

The other way to reduce CO_2 emissions is the Carbon Capture and Storage (CCS). The IPCC presented a special report [4] dealing with this option and discussing the technologies to obtain this desired effect, as an option in the portfolio of mitigation actions to stabilize GHG concentrations in the atmosphere. CCS presents two challenges: the transportation from the carbon capture location to the final destination, and the geological stability of the storage location. Offshore oil fields can be interesting to store CO_2, since the injection of CO2 is one of the EOR (enhanced oil recovery) technologies, and the geological structures associated to oil fields

are stable. Risks and costs associated with CO_2 transportation are avoided if the capture is made in the FPSO. Some studies [5-6] present strategies to capture CO_2 in offshore oil production.

Leung et al [7] presented a review on the different technologies and paths to CCS. For post-combustion separation, the CO_2 concentration in the gas mixture is a strong factor to induce the choice of a suitable separation process. Songolzadeh et al [8] indicate that cryogenic distillation and membrane processes are efficient for gas streams with high CO_2 concentration. However, absorption processes may be the best choice for CO2 separation in flue gases, since the gas stream have high temperature, low pressure and low CO2 concentrations.

Petrakopoulou [9] analyzed eight power plant concepts using CO2 capture technologies, both before and after the combustion, which are assessed based on efficiency, economic feasibility and environmental footprint. In the same direction, Madejski et al [10] discusses the CCS technologies and points to the oxyfuel combustion method as a promising solution due to its smaller energy penalty. However, this is not yet a proven technology.

The use of CCS from flue gases for diesel powered ships was proposed by Long et al [11]. An absorption process was optimized and the CO_2 sequestered must be stored in the ship in liquid phase until its final destination. The energy in the flue gases is used to drive the absorption process. Einbu at al [12] presented a similar study, but destined for future liquid CO_2 ships (transport phase of CCS).

The combination of combined cycle with CCS is being studied as a solution to reduce the carbon footprint in offshore oil and gas production. Øi et al [13] presented a study to optimize costs and weight for an absorption process in offshore operations. They suggest the dimensions for the system, as well as the design capture efficiency, fixed in 87%. Nord et al [14] also presented a study for a specific oil field in the North Sea. They defined a design capture efficiency of 90%, using MEA absorption process. Dimensions and weight of the system are also presented.

New separation methods are being proposed. The study of Hammera et al [15] describes the use of supersonic separation process to reduce the carbon footprint from gas turbines. A supersonic nozzle causes an expansion of the gases, and the temperature falls below the solidification point of CO_2, which is then separated from the gaseous stream. However, this method is not yet proven and requires the compression of exhaust gases, which is an energy penalty for the process. Liu et al [16] discusses the chemical absorption technology using rotating packed bed (RPB) instead of vertical static tower. This technology is also called “supergravity” separation, since the mass and energy transfers in the absorption phase are increased as compared with the conventional effect of gravity in the absorption tower.

Sukor et al [17] presents a study dealing with CO_2 separation from the natural gas in a Malaysian gas field, reducing the CO_2 content in the natural gas to acceptable levels. It is important to say that the current Brazilian Pre-Salt FPSO’s already processes natural gas currents and injects the CO2 rich current in the oil field. The world’s first project to implement offshore CO2-EOR was launched in 2011(in the so-called Lula-pilot oil field) and a second one in 2013 (Lula-NE oil field).

Although various studies presented results for combined cycle and CCS in offshore oil production, they are centered in the design and optimization of these systems. The design conditions must deal with the maximum electric power and maximum process heat. For absorption systems (CCS), with the maximum gas flow. However, most part of the time the FPSO operates at partial loads. Ortiz et al [6] presented a study dealing with partial load for the system, following the oil and gas production curve along the time, for a Brazilian oil field.

In this paper, the work of Ortiz et al [6] is revisited, with important changes in the FPSO configuration. One gas turbine acting as a mechanical prime mover is eliminated from the system, increasing the electrical power need, reducing CO_2 emission and liberating space for the steam turbine. This allows for a better combined cycle efficiency. A MEA absorption system can also be incorporated. Part of the steam generated in the HRSG is used as energy source for the separation process. The CO_2 stream coming from exhaust gases is injected in the oil field with the CO_2 stream coming from natural gas separation. This work presents the performance of the system in partial loads, according to the oil and gas production curve. It is important to note that the system to inject CO_2 in the oil field is standard for Pre-Salt FPSO’s. The changes made in the FPSO processes and the analyzed system are described in the Section 3.

2. The FPSO characterization and production curve

The FPSO design adopted for Pre-Salt oil fields is almost standardized. The maximum capacity is 150,000 bpd of crude oil separation. The associated gas is treated until a maximum capacity of 6 MMm^3/day. The FPSO has a capacity to store 1.67 MMb - near 10 days of production. A tanker ship is sent to FPSO each week to bring the oil to onshore refineries. In some cases, the natural gas, after a rough treatment, is delivered to shore by gas ducts.

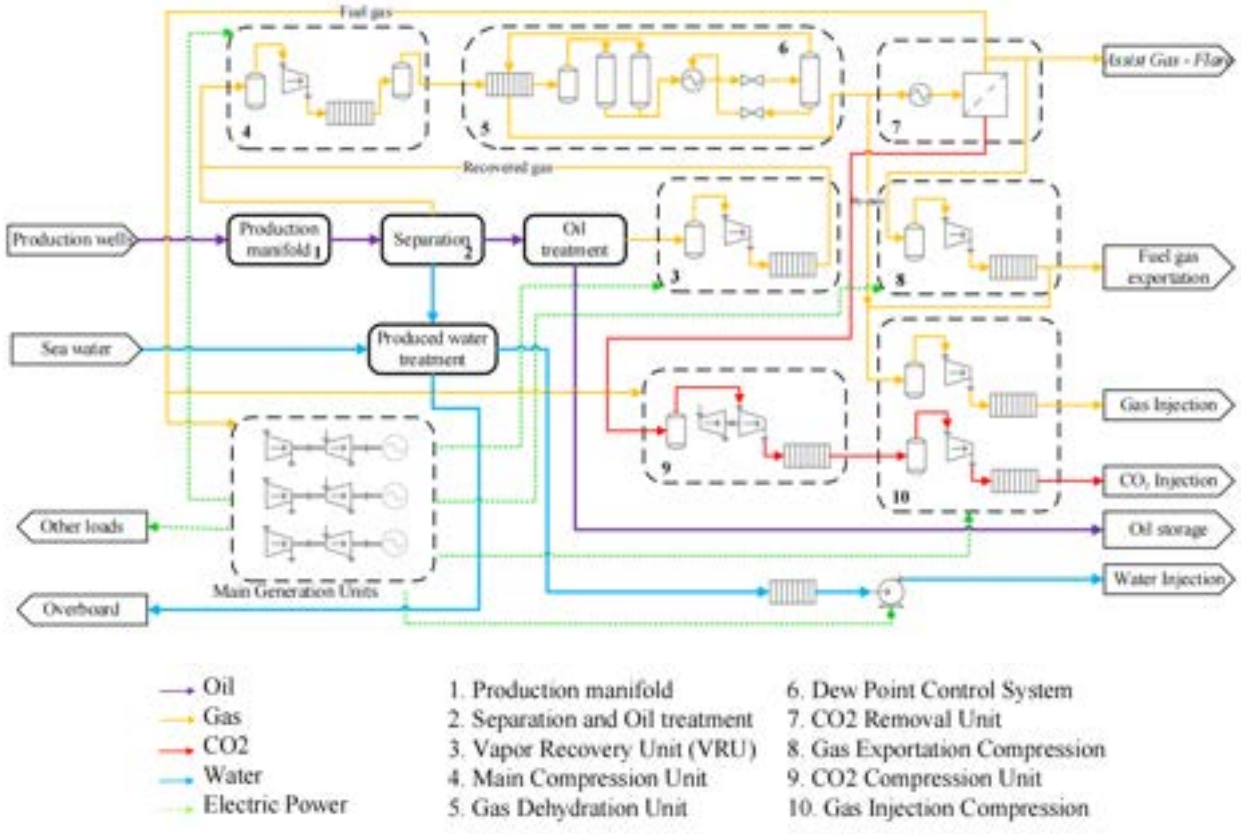

Figure 1. Topside processes in a typical Pre-Salt FPSO. Source: Ortiz et al. [18]

Due to the characteristics of the natural gas obtained, a membrane separation system is adopted to remove excess CO_2 from the natural gas, and the CO_2 rich stream is injected in the oil field. There is also compression systems to deliver the gas to the shore by gas ducts, and to inject natural gas or CO_2 rich streams in the oil field. Figure 1 shows schematically the FPSO topside processes. The electric power generation adopts three gas turbines, and another gas turbine acts as a mechanical driver for the CO_2 stream compression (subsystem 9 in the Fig.1). The exhaust gases from gas turbines generates pressurized hot water in closed circuit, which is the heat utility in the separation process. It is important to say that the FPSO already presents CO_2 capture (from natural gas). The compression equipment is present and CO_2 injection in the oil field is already made.

The oil and gas production of a FPSO is not constant. A typical production curve is presented in the Fig.2. The lifetime of an oil field is in the order of 25 years, and the FPSO is designed to stay anchored all this time. The topside processes are also designed for the entire production period. Therefore, the subsystems in the topside operate almost all the time in partial load, since they were designed for the critical condition for each one.

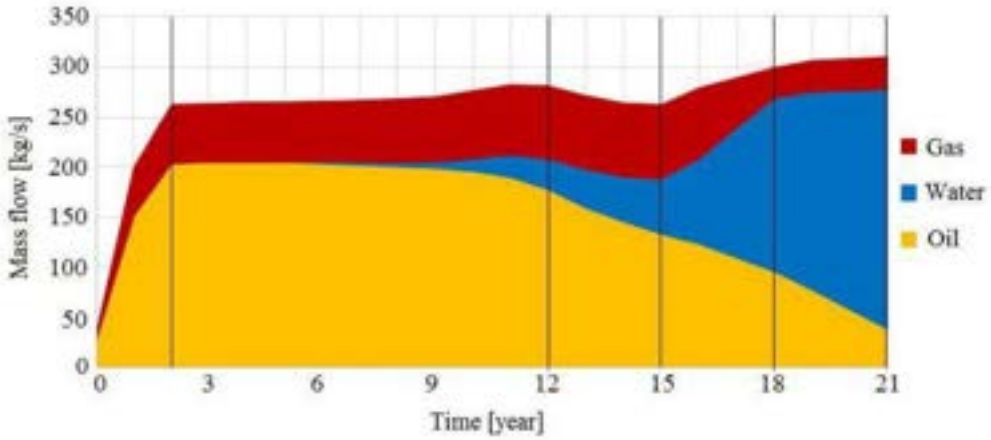

Figure 2. Typical crude oil production curve. Source: Ortiz et al [6]

Table 1. Operating points of the FPSO analyzed in this work. Source: Ortiz et al. [6]

Operating point	Oil production year	Electricity demand [kW]	Platform electric load [77MW max.]	Hot water demand [kg/s]
1	Year 2	72120	93,7	431.1
2	Year 12	73140	95,0	413.7
3	Year 15	70650	91,8	390.2
4	Year 18	48960	63,6	307.2
5	Year 21	46020	59,8	268.7

Table 1 indicates some important points in the oil production curve. The first condition is when the maximum oil and gas production is reached, in the second year of operation. Point 2 presents the maximum liquid capacity. Point 3 indicates a decreasing oil production in the year 15. Point 4 is related to the 50% BWS (basic sediment and water) and point 5 to the condition of maximum BSW. The values were obtained from a comprehensive FPSO operation simulation for each operation point presented in [6].

3. Alternatives to reduce CO_2 footprint from exhaust gases

This paper proposes modifications in the FPSO subsystems to reduce the CO_2 footprint: a) eliminating the mechanical drive gas turbine, substituting it by electric motors; b) introducing a HRSG before the hot water heaters; c) to adopt a steam turbine working in combined cycle; and d) introducing a MEA absorption system to capture CO_2 from flue gases. Captured CO_2 is sent to the already present CO_2 injection system.

The elimination of the mechanical drive gas turbine liberates space to the steam turbine installation and increases the electricity demand. However, the combined cycle can generate this additional demand with greater efficiency. The combined cycle is not designed to maximum power production, since there is no demand for extra power, and the hot water needs must be preserved. Part of the steam is diverted to water heaters, complementing the hot water heaters driven by exhaust gases coming from HRSG. When a CO_2 absorption system is added, more steam is diverted from steam turbine to drive this process. Figure 3 shows the proposed modifications.

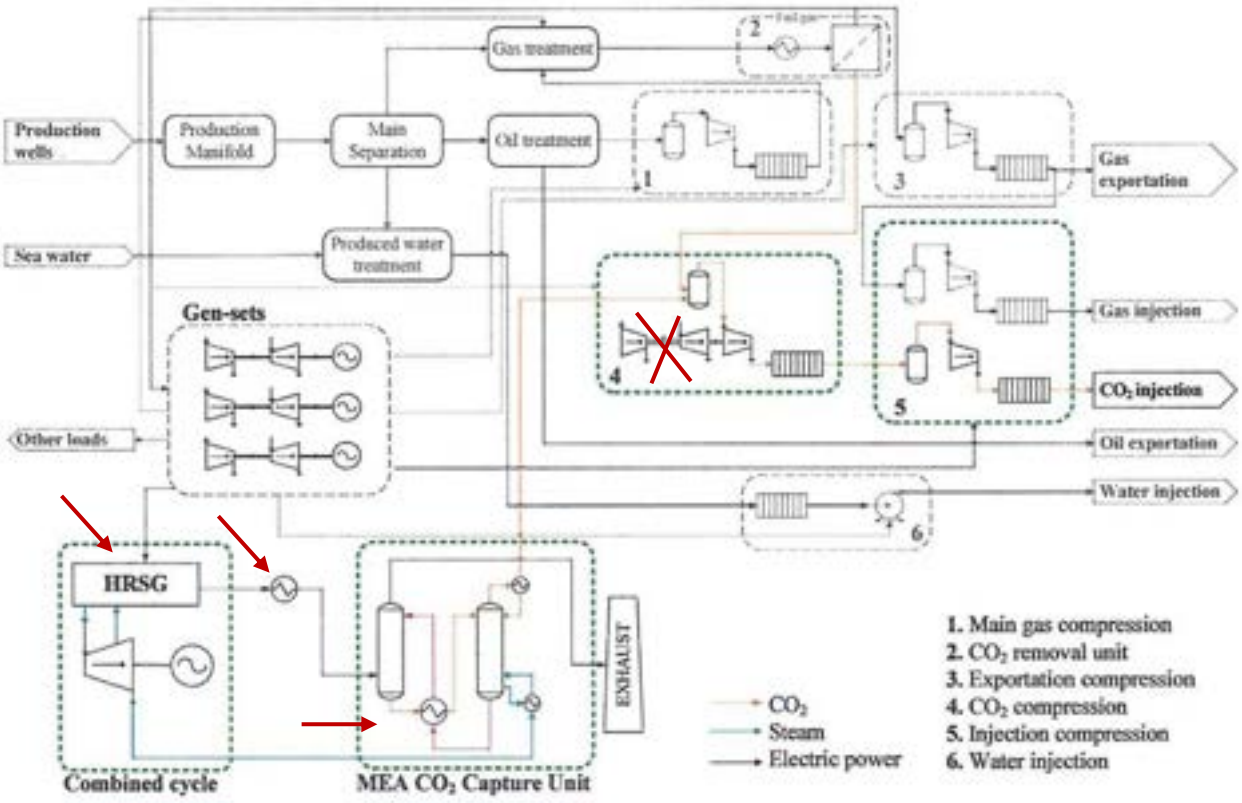

Figure 3. Proposed modifications in the FPSO topside processes. Source: Ortiz [6] modified.

4. Methodology of analysis

The methodology used was based on the mass and energy balances for each equipment or FPSO subsystem and for the process as a whole.

All equipment operate in partial loads, as mentioned before. So, for pumps and gas compressors, the performance curves were parameterized as a function of its load whenever available. Typical adimensional curves were adopted when true performance curves were not known.

Power from gas turbines were modeled first in Thermoflex® software to determine the fuel consumption, exhaust gas temperature and compositions, and energy efficiency as a function of load. This is possible since this software package has the gas turbines performance in the databank (GE-LM2500 for power generation, GE-LM2000 for mechanical drive). An adequate steam turbine was chosen to the steam cycle. Its isentropic efficiency was parameterized as a function of steam mass flow.

The whole processing and utilities subsystems were modeled in Aspen Hysys® software for complete properties and performance calculation. The HRSG and all other heat transfer equipment were modeled adopting the (ε - NTU) method for conditions off-design.

The CCS technology to reduce the CO_2 emissions from flue gases was simulated with Monoethanolamine (MEA) package, with a capture efficiency of 85%. The chemical absorption unit was modeled using the thermodynamic package Acid Gas module in Aspen Hysys software. This subsystem was installed downstream of the cogeneration heat exchangers for hot water. A compression stage for the separated CO_2, which raises the pressure from the atmospheric level to 4 bar, was also introduced since this is the suction pressure of the associated CO_2 booster compressor.

The total CO_2 emissions from flue gases were determined for five FPSO operating points and for three configurations: a) base case - the FPSO as it is today; b) removing the mechanical drive gas turbine and adopting a combined cycle; and c) the combined cycle with CCS as described above. In this way, it was possible to compare the base case with the effect of a combined cycle, and the effect of a combined cycle with CCS on the CO2 emissions.

4.1. Steam cycle characteristics

The combined cycle is composed by the three gas turbines adopted to generate electric power (GE-LM2500), each with its own HRSG and a single steam turbine. The vertical HRSG has one pressure level for steam generation, due to weight and area restrictions. Table 2 presents the design values for the HRSG. After passing the HRSG the flue gases passes through the hot water heaters. The steam turbine is an extraction-condensation with controlled extraction at 4 bar and condensation at 0.07 bar.

Table 2. HRSG design characteristics

Steam pressure [bar]	38.5
Steam temperature [ºC]	480
Pinch point temperature difference [ºC]	25
Approach temperature [ºC]	5
Pressure loss gas side [kPa]	3.5

4.2. Absorption system characteristics

The modeled absorption system is presented in the Fig.4. This is a typical MEA absorption system. In the model developed, some simplifications were assumed: the water wash in the absorber and the reclaimer part in the bottom of the stripper were eliminated. The solvent was assumed to stay inside the system, and do not need substitution. As mentioned before, the CO_2 flow exiting the absorption module are at atmospheric pressure and needs to be compressed to 4 bar. This compressor is not present in the Fig.4, but its power needs were considered in the complete simulation.

The design point for the CO_2 absorption system resulted in a preliminary size as given in the Table 3. It is important to mention that the absorber and the stripper columns are vertical, and the floor area is calculated. The columns are of the type with plates and barriers. Other geometries can be attempted to reduce weight and size.

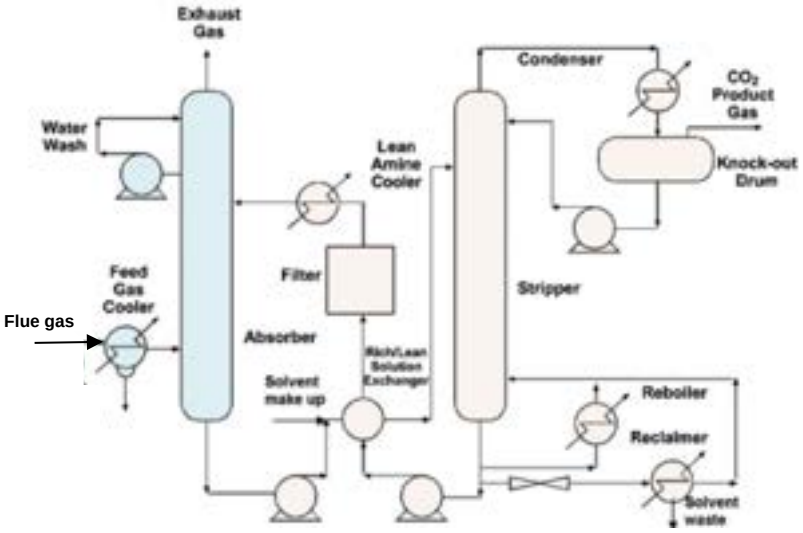

Figure 4. MEA absorption process characteristics. Source: IPCC [2005]

Table 3. Preliminary design for the MEA absorption system.

Dimensions	Absorption tower	Stripper tower
Diameter [m]	6.0	3.1
Height [m]	29.0	7.3
Number of plates	24	11
Plate spacing [m]	1.2	0.9
Barrier height [m]	0.18	0.14
Floor area [m²]	28.3	7.3

Øi et al [13] suggested conditions for an offshore application with 87 % capture efficiency, with 13 m absorber packing height (plus distribution and collecting height) and 15°C minimum approach temperature due to a decrease in equipment cost, size and weight. Nord [14] presents a design with a diameter of 13.6 m and packing height of 18.6 m for the absorber (plus distribution and collecting height). For the stripper, 3 m diameter and 7 m packing height.

4.3. Definition of efficiency calculation

In the next section are presented the obtained values for different efficiencies types. This section presents the definition adopted for each one of them.

Equation (1) presents the definition of electric power generation efficiency:

$$\eta_{\text{elect}} = \frac{\dot{W}_{\text{elect}}}{\dot{m}_{\text{fuel}} \text{LHV}} \tag{1}$$

The cogeneration system can be evaluated by a first-Law efficiency, taking into account each useful energy flow produced in each configuration as presented in the Eq. (2). In the base case, for example, there is mechanical power produced, but no reboiler heat. In the CC and CC+CCS configurations, there is no mechanical power produced. It is important to observe that the hot water heat is the same for each FPSO operating point, for every configuration.

$$\eta_{\text{cogen}} = \frac{\dot{W}_{\text{elect}} + \dot{W}_{\text{mech}} + \dot{Q}_{\text{hot water}} + \dot{Q}_{\text{reboiler}}}{\dot{m}_{\text{fuel}} \text{ LHV}} \tag{2}$$

The definition for the second Law efficiency is shown in the Eq. (3) and is similar to the first-Law, but dealing with exergy flows, instead of energy flows:

$$\varepsilon_{\text{cogen}} = \frac{\dot{W}_{\text{elect}} + \dot{W}_{\text{mech}} + \dot{B}_{\text{hot water}} + \dot{B}_{\text{reboiler}}}{\dot{m}_{\text{fuel}} \, b_{\text{fuel}}^{\text{ch}}} \tag{3}$$

The same observations made for the first Law efficiency applies in Eq. (3).

5. Results and discussion

The results obtained for each FPSO configuration are discussed in this section. Comparisons among the configuration are also presented.

5.1. The base case results - current FPSO configuration

The results for the base case are presented in the Table 4. The conditions 1 to 5 are those already defined in the Table 1. All electrical and mechanical power, as well as the hot water generation are those strictly necessary to the FPSO operation. The CO_2 compressor (CO_2 from natural gas processing) uses a gas turbine as prime mover. The total CO_2 emission from all exhaust gases is the main parameter for comparison purposes.

Table 4. FPSO power generation and CO_2 emission in the base case configuration.

Parameters	***FPSO operation condition***				
	1	**2**	**3**	**4**	**5**
Number of gas turbines (GT) for electricity power	3	3	3	2	2
GT Electrical power produced [MW]	72.12	73.14	70.65	48.96	46.02
GT - electrical power - load [%]	93.7	95.0	91.8	95.4	89.6
Electric power efficiency (LHV based) [%]	36.82	35.77	35.51	36.06	35.56
Number of gas turbines for mechanical power	1	1	1	1	1
GT mechanical power - for CO_2 compressor [MW]	12.21	15.15	14.22	7.00	6.87
GT mech. power load [%]	76.3	94.7	88.9	46.6	42.9
Total fuel consumption - all GT [kg/s]	5.03	5.50	5.41	3.43	3.30
Total CO_2 emission - all GT [Mt/year]	0.432	0.471	0.462	0.293	0.280

The electric power produced for each operation condition are the same as present in the Table 1 and were obtained from a detailed mass and energy balance for the topside processes and general electric loads (illumination, air conditioning, etc.). To compress the CO_2-rich stream separated from the natural gas, a dedicated gas turbine is employed and the mechanical power needed can be seen in the Table 4. The total fuel consumption is the sum of the needs of electric power gas turbines and the needs for the mechanical drive turbine. The total CO_2 emission is calculated from the total fuel consumption.

5.2. Combined cycle configuration results

The first approach to reduce the CO_2 footprint from the prime movers is the elimination of the mechanical power gas turbine, substituted by a steam turbine operating in Combined Cycle configuration with the gas turbines. Oil and gas production are maintained at operation conditions 1 to 5, as in the base case. The hot water need for heating purposes is also verified.

Figure 5 shows the temperature profiles for exhaust gases and the steam generator for operational condition 3, which produces the maximum amount of steam. It must be observed that the combined cycle was not optimized to maximize power, because the exhaust gas (still very hot) must provide the energy to produce the process hot water.

Table 5 shows the results for the combined cycle configuration. The elimination of the mechanical power gas turbine increased the electricity needs, but the combined cycle presents higher efficiency for power generation. The net effect is a reduction in the total CO_2 emission. In the operation conditions 4 and 5, the electric power is substantially reduced and one gas turbine must be deactivated. This reduces the steam mass flow for the combined cycle. The steam needs to water heaters contributes to reduce the power from the steam turbine, and the reduction in the CO_2 emissions are low.

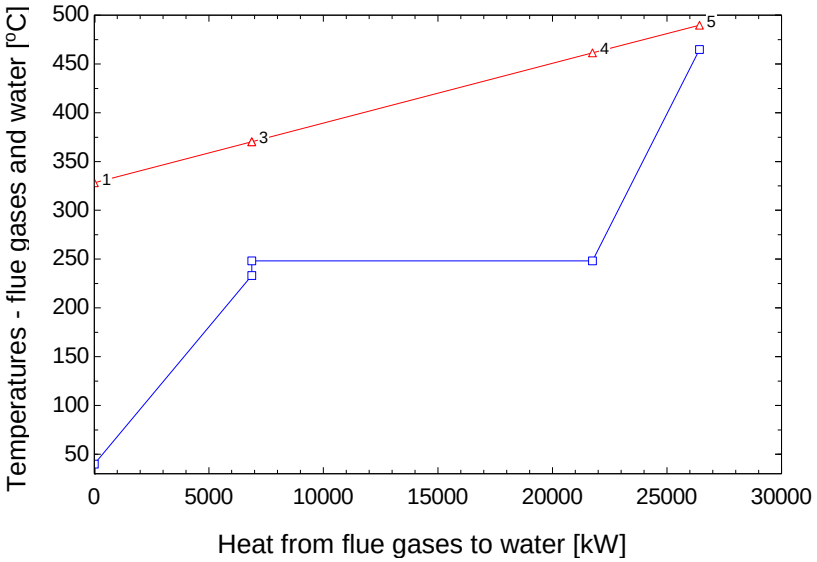

Figure 5. Temperature profiles in the HRSG. Operational condition 3

Table 5. FPSO power generation and CO_2 emission in the Combined Cycle configuration.

Parameters	FPSO operation condition				
	1	2	3	4	5
Number of gas turbines (GT) for electricity power	3	3	3	2	2
GT Electrical power produced [MW]	68.47	72.32	69.70	49.85	45.79
GT - electrical power - load [%]	84.15	89.00	85.70	92.08	84.41
Steam turbine [MW]	15.87	17.05	17.27	6.17	7.15
Electric power efficiency (LHV based) [%]	45.82	46.54	46.62	42.61	43.04
Total fuel consumption - all GT [kg/s]	4.04	4.23	4.12	2.90	2.73
Electric power for CO_2 compression [MW]	12.21	15.15	14.22	7.00	6.87
Total CO_2 emission - all GT [Mt/year]	0.347	0.362	0.352	0.248	0.231

5.3. Combined cycle with exhaust gas CCS

To reduce even more the exhaust gases CO_2 footprint, a third configuration was analyzed: a Combined Cycle with CCS. In this configuration, there is a carbon capture from the exhaust gases by a MEA system, with efficiency in the range 0.75 to 0.80.

The CO_2 separated from the exhaust gases and the CO_2 stream coming from the natural gas treatment are both re-injected in the oil field, after mixing and compression to adequate pressure. Table 6 presents the results.

Although the electricity production efficiency is reduced, the total CO_2 emission drops sharply, due to the sequestration of the CO_2 from exhaust gases. The electric power need for CO_2 compressors increases, due to the increased mass flow in the CO_2 compressors. To operate the separation, there is also a thermal energy utilization in the reboiler of the stripper, to liberate the CO_2 from the rich amine solution.

It is interesting to note that the steam turbine power must be derated when compared with the Combined Cycle configuration, since part of the steam flow must be diverted to supply the heat for the sequestration process. Øi et al [13] estimates the heat consumption to be approximately 5.5 MJ/kg CO2 removed. Nord et al [14] evaluated the specific reboiler duty for the process to be 3.6 MJ/kg CO2. Obtained values in this work are of the same order of magnitude.

Table 6. FPSO power generation and CO_2 emission in the Combined Cycle with carbon capture and sequestration (CCS) configuration.

Parameters	FPSO operation condition				
	1	2	3	4	5
Number of gas turbines (GT) for electricity power	3	3	3	2	2
GT Electrical power produced [MW]	79.65	80.68	79.56	52.72	48.75
GT - electrical power - load [%]	98.21	99.50	98.10	97.50	90.00
Steam turbine [MW]	9.13	11.26	10.16	3.88	5.07
Electric power efficiency (LHV based) [%]	42.80	43.86	43.30	41.37	41.54
Total fuel consumption - all GT [kg/s]	4.55	4.61	4.58	3.02	2.86
Electric power for CO_2 compression [MW]	16.05	17.86	18.35	7.36	7.30
Thermal energy in the CCS / CO_2 captured [MJ/kg]	4.198	3.917	4.155	3.918	3.891
Total CO_2 emission - all GT [Mt/year]	0.185	0.216	0.183	0.209	0.184
Total CO_2 captured by CCS system [Mt/year]	0.206	0.179	0.208	0.049	0.059
CCS system CO_2 capture efficiency [%]	77.59	73.12	76.08	79.21	76.88

5.4. Configurations comparisons

Figure 6 shows the electric power generation efficiency for each configuration, for the different operation conditions of the FPSO. The reduction of the efficiency observed for the CC+CCS configuration is due to the power derating of the steam turbine. The values obtained to CC and CC+CCS are far below traditional combined cycles designed to exclusive power generation because part of the exhaust gas energy must be allocated to generate hot water for FPSO processes, which is a priority.

The Figure 7 presents the first and second-Law efficiencies for each configuration and as a function of the year of FPSO operational phase for the cogeneration system. As usual, first-Law efficiencies are higher than second-Law ones when the driving force is a fuel. Apart from this, the exergy of a heat flow is smaller than the energy flow. It is interesting to note that the higher efficiencies occur for the CC configuration. When a CCS system is adopted, there is a need of extra power to compress the separated CO_2, and the cogeneration efficiency decreases.

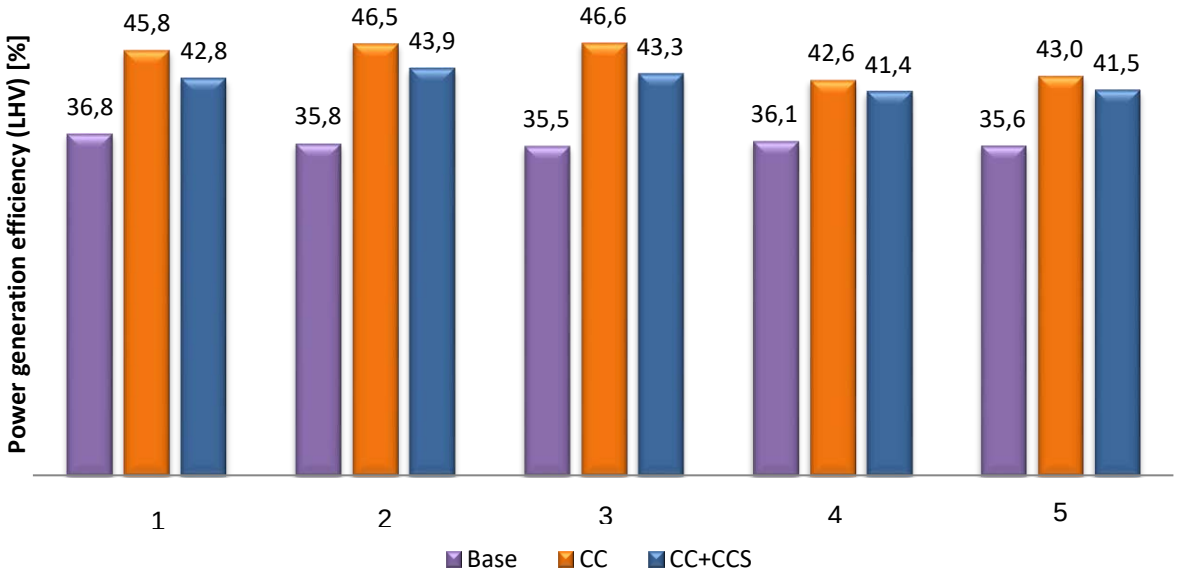

Figure 6. Electric power generation efficiency (LHV based) for different FPSO operation conditions.

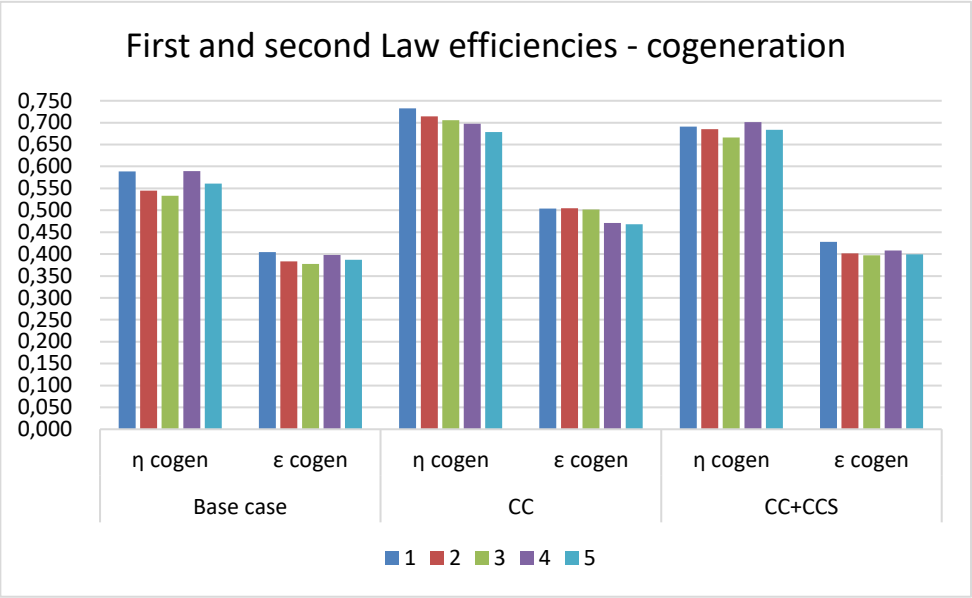

Figure 7. Efficiencies for the three configurations.

The reduction in the CO_2 emissions can be seen in the Fig.8. The reduction in the emissions are greater for the conditions which uses three gas turbines. With only two gas turbines operating, the derating of the steam turbine is high due to less available steam flow and hot water needs, and the benefits are not so evident. Fortunately, condition 4 occurs after 18 years of operation of the FPSO and condition 5 occurs after 21 years, near the end of the oil field lifespan.

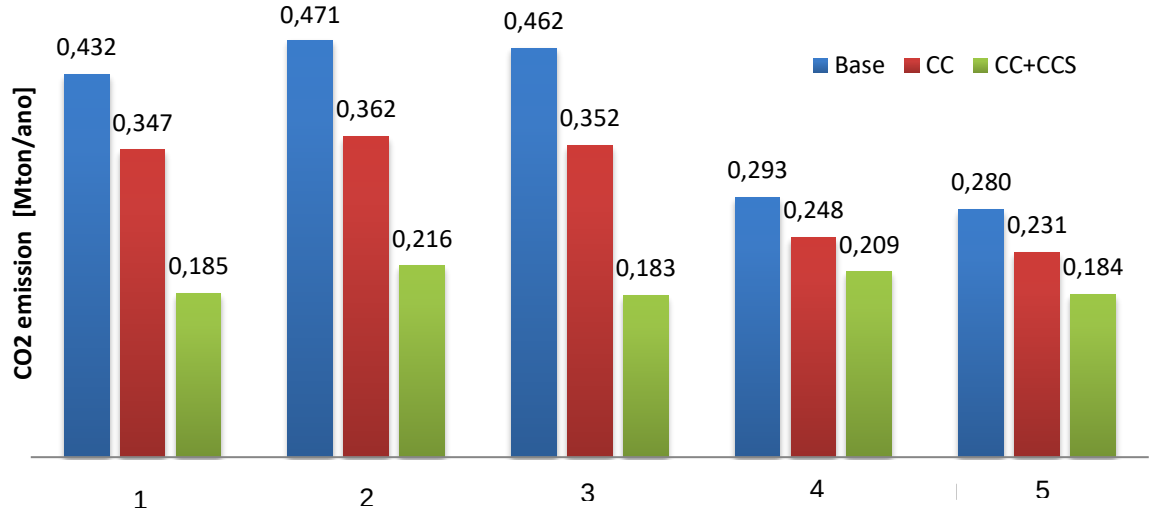

Figure 8. CO_2 emissions for different FPSO operating conditions

To make a comprehensive view of the CO_2 footprint reduction, Table 7 presents the CO_2 emission reduction as a percentage of the base case. The last column is the weighted average reduction for the analyzed period, considering the 21 years. Is to be noted that till the operation year 18, the reduction in the CO_2 emission is higher than 20% for the Combined Cycle configuration (CC) and higher than 50% for the Combined Cycle with CCS configuration (CC+CCS).

Table 7. CO_2 emission percentual reduction compared to Base Case

Configurations	FPSO operation condition					
	1	2	3	4	5	Average
CC to Base case	19,6%	23,1%	23,8%	15,3%	17,3%	21,6%
CC+CCS to Base case	57,2%	54,1%	60,5%	28,6%	34,3%	50,1%

Both alternative configurations presents interesting results. With the Combined Cycle configuration, the CO_2 footprint from exhaust gases is reduced by 20%, while the Combined Cycle with CCS reduced the CO2 emission by 50%. Only near the end of the FPSO lifetime the reduction is smaller, due the fact that only two gas turbines are operating and the hot water for FPSO processes does not reduces proportionally.

6. Concluding remarks

The results obtained in this work are of a prospective nature for new FPSO's, showing the order of magnitude of attainable CO2 footprint reductions. The proposed changes are not feasible for the operating FPSO.

The combined cycle configuration was not optimized for maximum power production, since electric power surplus is not allowed. In the same sense, the combined cycle is not optimized for maximum efficiency, since a compact system with a weight as low as possible is desirable. Apart from this, the need of hot water as an utility to the processes in the FPSO also puts a limitation to the maximum efficiency. Even with these limitations, a combined cycle proved to obtain 20% reductions in the CO_2 emissions.

The configuration with a combined cycle with Carbon Capture and Storage from flue gases can obtain near 50% CO_2 emissions reduction - an impressive figure. The proposed absorption system is a proven technology. The evaluation of the rotating packing bed (RPB) technology, instead of the usual gravitational packing bed, must offer a better weight and space solution for absorption systems. Other technologies, especially in the family of oxi-fuel combustion, may present even better results, provided they become mature.

Whatever the solution chosen, the topside processes in the new FPSO designs must be optimized for weight and size to accommodate the new subsystems.

Nomenclature

Variables

$\dot{B}$	Exergy flow [kW]
b	Specific exergy [kJ/kg]
$\dot{m}$	Mass flow [kg/s]
$\dot{Q}$	Heat flow [kW]
$\dot{W}$	Power [kW]
LHV	Lower heating value [kJ/kg]
η	First-Law efficiency
ε	Second-Law efficiency

Acronyms and abbreviations

BSW	Basic sediment and water
bpd	Barrels per day
CC	Combined-cycle configuration
CC+CCS	CC with Carbon Capture and Sequestration
EOR	Enhanced oil recovery technology
FPSO	Floating production storage and offloading facility
HRSG	Heat Recovery Steam Generator
MMb	Millions of barrels
ε - NTU	Method to evaluate partial load in heat exchangers

Subscripts

elect	Electric
mech	Mechanical
hot water	Hot water for processes
reboiler	Steam to drive the stripper
fuel	Natural gas used as fuel
cogen	Cogeneration system

Superscripts

ch	Chemical

Abstract:

Reducing the environmental impact of anthropic activities is critical and requires a proper analysis of CO_2 emissions. This study focuses on the thermal energy sector's emissions carbon footprint, which is essential for many public and private institutions. The current practice of using average national and annual emission factors (EFs) may lead to inaccurate results on specific local entities, particularly in the case of combined heat and power production. This study aims to refine the EF calculation considering a combined cycle cogeneration plant and an hourly time step for the analysis. The case study chosen is the district heating system (DHS) cogeneration plants of Turin, one of the largest DHSs in Europe. The defined thermal EF is applied to the user case study of Politecnico di Torino supplied by the DHS. The study focuses on the thermal energy needs of the university campus on an hourly and seasonal scale. The results reveal that the emission factor of a DHS calculated with this methodology is different from the one calculated with other methodologies or using national EFs, better representing the real situation. Since the load profile of a university facility represents tertiary sector energy activities, the methodology used in this study is easily replicable in different contexts. This study emphasizes the importance of accurately estimating CO_2 emissions, which is fundamental in reducing the anthropic environmental impact.

Keywords:

Emission factors, sustainable university, decarbonization, district heating system, combined cycle.

2. Introduction

Anthropic activities have a significant environmental impact and reducing carbon dioxide (CO_2) emissions is essential for mitigating climate change. In recent times, there has been an increasingly crucial need for institutions to address their emissions. In this regard, universities play a pivotal role, by reducing their carbon footprint they can contribute to their own sustainability and promote environmental awareness in other sectors. Quantifying carbon emissions is essential to measure progress towards decarbonization goals and one effective way to track progress is using ranking systems such as Green Metric [1]. Many non-governmental actors have joined the Race to Zero campaign, promoted by the United Nations, which encourages the achievement of decarbonization targets aiming to strive for carbon neutrality by the mid-century [2]. The energy sector is the most impactful sector in terms of carbon footprint and emissions [3]; in the European Union (EU), buildings are responsible for approximately 40% of total energy demand and produce 36% of greenhouse gas emissions [4]. Heating, ventilation, and air conditioning play an important role in overall energy demand in Europe, making it crucial to accurately measure and define their emissions [4]. The European heating and cooling sector are characterized by varying building types and relies primarily on decentralized production units within buildings. Natural gas is the predominant fuel, meeting 42% of the heating demand. Additionally, District Heating Systems (DHSs) supply 12% of the building sector's demand for space heating and domestic hot water [5]. Due to the strong electrification trend in the heating sector, recent studies have focused on a more accurate estimation of CO_2 emissions of electricity system. Specifically, emission factors (EFs) have been evaluated on an hourly basis, focusing on technologies such as heat pumps [6]. In parallel, similar studies have investigated the variability of EFs at the national level in electricity production. From this latter study, it appears that European Directives fix values of CO_2 EFs, neglecting their intrinsic temporal variability due to the mix of primary energy sources used in electricity generation hour by hour. The use of a fixed value for these parameters could lead to inaccurate or erroneous results in various processes [7]. Similar to electricity grids, DHSs are characterized by various types of centralized thermal power generation systems, resulting in comparable complexities in defining EFs as with electricity. However, there is a gap in the literature concerning the hourly variability of DHS emission factors.

Additionally, current methodologies used to calculate emissions associated with DHSs do not take into consideration the high efficiency of technologies such as Combine Cycle Plants (CHP). Therefore, the goal of our study is to investigate the temporal variability of emissions produced by thermal energy consumption when a utility is supplied by CHP DHS. The new methodology presented is compered to different method currently in use. Specifically, we apply the methodologies presented to the case of the city of Turin's DHS, which is the most district-heated city in Italy and one of the main ones in Europe. The hourly EF developed with this methodology is then applied to the hourly thermal energy demand profile of the Politecnico di Torino providing an example of replicable application on tertiary sector users. As university facilities are representative of the energy consumption patterns of the tertiary sector, the methodology used in this study can be replicated in other contexts. By demonstrating how the environmental impact of energy consumption can be significantly affected by both the energy mix and the time of energy supply, we contribute to a better understanding of the challenges and opportunities for reducing carbon emissions associated with energy use in university facilities.

3. Methodology

3.1. Current methodologies for calculating CO_2 emissions for cogeneration plants

3.1.1. Allocation of CO_2 emissions in case of cogeneration heat and power combined cycle

Allocating CO_2 emissions in plants that generate both thermal and electrical energy is a complex issue. These plants produce heat as a by-product of electricity production, which adds complexity for a correct allocation of emissions. In Europe, DHS heavily rely on fossil fuel-based Combined Heat and Power plants (CHP), with cogeneration accounting for over 70% of the heat generated by EU member states [8]. Given the importance of cogeneration for district heating (DH), it is crucial to develop a methodology that can accurately account for the resulting CO_2 emissions.

Typically, DHS that supply large urban areas, are characterized by Combined Cycle CHP plants (CC). This type of plant combines two production phases, one based on gas and the other on steam. The high-temperature exhaust gases from the Gas Turbine (GT) are used to produce steam in a Heat Recovery Steam Generator (HRSG), which is then fed into a Steam Turbine (ST) to generate additional electrical power. CCs are typically used both in industrial settings that require the production of steam, superheated or hot water, and for DHS. They come in various sizes, ranging from 50 to 400 MWe, and offer electric efficiencies of approximately 45-58%. DHSs, which utilize combined cycle power plants, typically generate 80-90% of their annual heat energy production through cogeneration [9]. These plants produce thermal energy throughout the heating season but require additional support from backup generators during the coldest months and during peak demand hours. Thermal storage systems, which use hot water tanks to store excess heat generated during low-demand periods, are typically utilized in DH networks to manage the demand and supply of heat efficiently. During peak hours, the stored heat is released to ensure a consistent flow of heat to customers. Furthermore, these thermal storage systems can be charged using renewable sources if available, or by cogeneration plants. This approach not only reduces energy waste and improves the overall efficiency of the system, but also promotes the utilization of renewable energy sources in DH networks.

A simplified diagram illustrating the relationship between fuel input and the resulting output of electricity and heat for a typical DHS with a CC unit is shown in Figure 1. The nomenclature used in the figure is used in the following sections to explain the various methodologies available in the literature for calculating the DHS emission factor. The energy balance shown in the figure is annual.

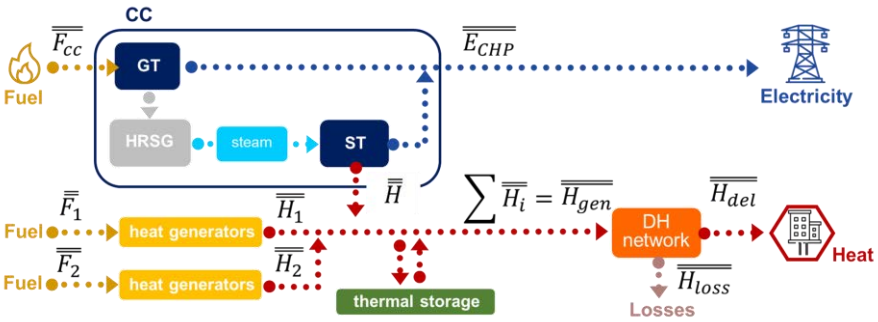

Figure 1. District heating system, CHP general scheme and relative nomenclature

3.1.2. Eurostat, Ispra and IPCC methodology (Method E)

The IPCC's Working Group 3, in Annex 2 Metrics and Methodology [10], defines carbon dioxide emission factors for electricity and heat based on the ratio between CO_2 emissions due to fuel inputs of power plants

and the delivered electricity and heat. The CO_2 emission factors of each fuel type, as defined in IPCC (2006) [11], are multiplied by the fuel inputs. The calculation of CO_2 emission factors for electricity and heat is conducted at the country level. Also the 2020 annual report on emission factors drafted by Ispra[1] and Snpa[2] [12] and Eurostat 2016 annual questionnaire report [13] present the same methodology for allocating the fuel between the electricity and heat generation components.

This methodology can be expressed in the following way:

$$\overline{f_{DHS,HE}} = \frac{\overline{\overline{F_i}}}{\overline{\overline{H_{del}}} + \overline{\overline{E_{CHP}}}} * f_{i,F} \qquad \left[\frac{kg_{CO_2}}{kWh}\right] \qquad (1)$$

According to the 2020 Ispra annual report, this formula is recommended only when national administrations have not adopted a more precise methodology for reporting combined heat and power (CHP) on a unit basis. Using this methodology, that we will call method E, the resulting EF is 0.30 kg_{CO2}/kWh.

3.1.3. UNI EN 15316-4-5:2018 methodology (Method U)

A different methodology for multi-output DHS is detailed in the regulatory document UNI EN 15316-4-5:2018. This approach has been utilized in various publications [14] and has been adopted as a standard methodology for creating CO_2 emission inventories for Italian universities, members of the Italian sustainable development network (RUS[3]). The formula for this methodology is the following:

$$\overline{f_{DHS,H_{del}}} = \frac{(\sum_i \overline{\overline{F_i}} f_{i,F} - \overline{\overline{E_{CHP}}} f_{el})}{\overline{\overline{H_{del}}}} \qquad \left[\frac{kg_{CO_2}}{kWh}\right] \qquad (2)$$

The issue with this approach arises in situations where the production of electrical energy from cogeneration systems is very high, resulting in a negative value of the derived emission factor. In case of negative values, the regulatory document recommends considering these cases as zero-emitting, underestimating the actual emissions from thermal energy consumption.

3.2. Introducing a new methodology for determining emission factors

The emission factors determined by current methodologies don't reflect the actual value that should be utilized in a real DHS supplied by CC CHP. Hence, it is necessary to develop a different approach that combines both hourly and simplified annual analyses for calculating CO_2 emissions in DHS.

3.2.1. Combined cycle cogeneration heat and power plants for district heating systems

As explained in section 3.1.1, in CC systems it is possible to recover heat for industrial purposes or DHS use from the steam cycle. Steam can be supplied by extracting pass-out steam at an intermediate point in the turbine. The rest of the steam continues to the exhaust, thereby generating further power, and exits the process at a lower pressure. Therefore, whenever there is a thermal demand and the plant operates in cogeneration mode, steam extraction results in less electricity production. A typical operating diagram for each plant is shown in Figure 2.

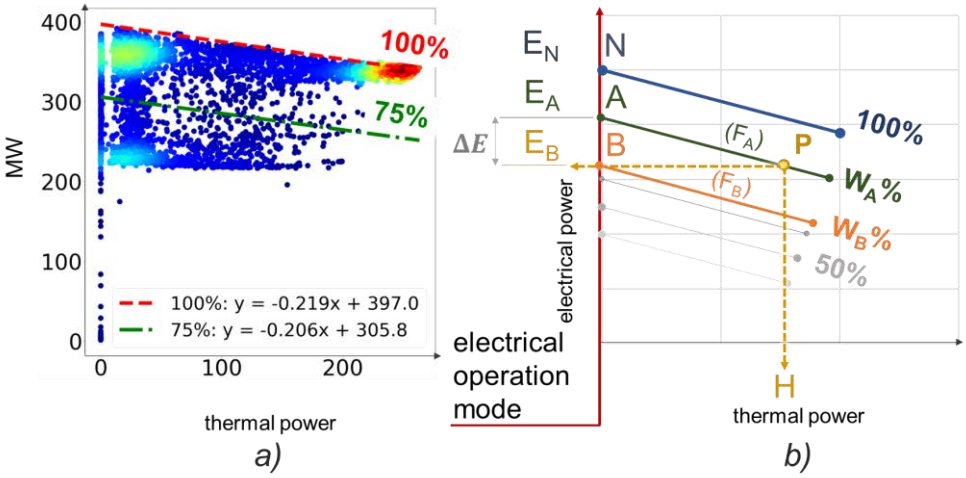

Figure 2. CHP operating diagram partial load. a) real operating diagram: hourly energy production (equation of regression lines *[15, 16]*); b) working point P

[1] Istituto Superiore per la Protezione e la Ricerca Ambientale.
[2] Sistema Nazionale per la Protezione dell'Ambiente.
[3] Rete delle Università per lo Sviluppo Sostenibile.

The y-axis shows the electrical power generated at various nominal loads, while the x-axis represents the corresponding heat output. The point N represents the working condition at nominal load in *electrical operation mode*. Thermal power is not generated, and electrical power corresponds to the nominal value. By working on the 100% load operating characteristic, the heat output increases, and the *cogeneration condition* is reached. Each load has a characteristic regression line whose points are characterized by the same fuel inlet power (F). Figure 2a shows the real hourly operation in one year of operation of a CC. A generic working point P in cogeneration condition at load W_A% is considered. The point is characterized by a thermal power H and an electrical power E_B. At the same fuel input power F_A and considering the electrical operation mode, a higher electrical power equal to E_A would be obtained. The production of thermal energy causes a reduction in the amount of electricity produced.

$$\Delta E = \mathrm{E}_A - \mathrm{E}_B \qquad [MW] \qquad (3)$$

The ratio of the two output energies K is the *cogeneration gain*, expressed in the equation (2). K is inversely proportional to the slope of the loads regression lines and it is approximately constant as leads changes. ΔE can consequently be expressed as in equation (5).

$$K = \frac{H}{\Delta E} = cost \qquad [MW] \qquad (4)$$

$$\Delta E = \frac{H}{K} \qquad [MW] \qquad (5)$$

By analyzing the hourly operating experimental data of a few combined-cycle plants, it was possible to outline a general trend in energy performance in *electric operation mode*. Isolating the hourly data in which the CC operated in electrical mode and excluding the transient operating values, the real operating data were averaged to obtain the percentage trend shown in Figure 3.

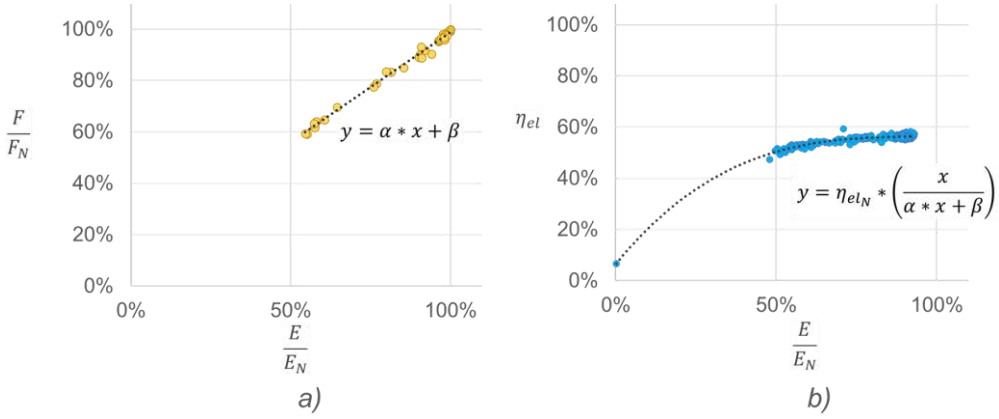

Figure 3. Electrical operation mode working performances of a generic CC unit. a) fuel inlet power; b) CC electrical efficiency.

Figure 3a shows the linear dependence of the fuel inlet power with respect to the load of the generated electrical power (equation (6)). The characteristic equation of CC electrical efficiency with respect to the electrical load variation is obtained. As shown in figure (b) the points of real operation validate the trend.

$$\frac{F}{F_N} = \alpha \frac{E}{E_N} + \beta \qquad [MW] \qquad (6)$$

3.2.2. Combined Cycle emission factor

To determine the *hourly emission factor* of a generic CC supplying a DHS, we consider a generic operating point *P* (Figure *2*b). As explained in the previous section, the generation of thermal energy results in a lower amount of electrical power generated ΔE for the same amount of fuel used. It is possible to allocate ΔE with the additional fuel inlet power ΔF consumed in cogeneration condition. The same electric power E_B could in fact be obtained by working at a lower load W_B% with less fuel input power F_B. From equation (6)(6)**Errore. L'origine riferimento non è stata trovata.** F_A and F_B are defined:

$$F_P = F_A = F_N \left(\frac{\alpha E_A}{E_N} + \beta\right) \qquad [MW]$$

$$F_B = F_N \left(\frac{\alpha E_B}{E_N} + \beta\right) \qquad [MW]$$

The nominal condition N in electrical operation mode at 100% load is characterized by electrical efficiency:

$$\eta_{el,N} = E_N / F_N$$

Therefore ΔF is defined:

$$\Delta F = F_A - F_B = \alpha \frac{\Delta E}{E_N} * F_N = \frac{\alpha}{K} \frac{H}{\eta_{el,N}} \qquad [MW] \qquad (7)$$

The additional amount of inlet power required must be multiplied by the fuel EF and normalized to the heat output:

$$f_{CC,H} = \frac{\Delta \mathrm{F} * f_{NG}}{\mathrm{H}} = \frac{\alpha}{\mathrm{K}} * \frac{1}{\eta_{el,N}} * f_{NG} \qquad \left[\frac{kg_{CO_2}}{kWh}\right] \qquad (8)$$

The remaining amount of fuel inlet power F_B is attributed to CO_2 emission on hourly electrical energy generated. It would, in fact, have been equally produced in the case of electric power generation in the electrical operation mode. In this case in contrast to the thermal EF, the hourly electric emission factor is not constant. It varies following the same trend as the electrical efficiency shown in Figure 3b.

3.2.3. District heating system emission factor

DHSs have different layout configurations based on the served volumetrics and climatic zone. These configurations can vary based on the type of generator employed, the characteristic size of each generator, and the number of generators installed. The various generation groups produce thermal energy with different strategies based on thermal demand and economic and environmental dispatching considerations. Therefore, the CO_2 emissions associated with the use of heat from a DHS depend not only on the type of generators involved in the annual production but also on the way they produce thermal energy hourly and during different seasons. To correctly assess the DHS thermal EF, it is, therefore, necessary to define the amount of thermal energy produced for each generation unit hour by hour. The DHS thermal emission factor is the weighted average of each characteristic EF of the fuel and generator used multiplied by the thermal energy delivered. To express the emission factor $f_{i,H}$ with respect to the energy produced by the generator instead of that of the input fuel F_i as used in methods E and U, we define the relationship between the characteristic EF of the fuel and the efficiency of the generator.

$$f_{i,H} = \frac{f_{i,F}}{\eta_i} \qquad \left[\frac{kg_{CO_2}}{kWh}\right] \qquad (9)$$

For DHS in which a part of thermal energy is generated by a natural gas CC unit in combination with other types of heat generators, CC thermal emission factor is defined in equation (8). The energy delivered by the storage system is associated with the EF of the generator that predominantly charges the storage. Methods E and U calculate the DHS emission factor with respect to the energy supplied to the users H_{del}. Therefore, the heat loss factor $p\%$ on the distribution network is defined:

$$p\% = 1 - \frac{H_{del}}{H} \qquad [\%]$$

The DHS emission factor expressed as the ratio between the tonnes emitted and the energy delivered to the user can be defined as:

$$f_{DHS,H_{del}} = \frac{H * f_{CC,H} + \sum H_i * f_{i,H}}{H_{del}} = \frac{H * f_{CC,H} + \sum H_i * f_{i,H}}{H_{gen}(1 - p\%)} = f_{DHS,H_{gen}} * \frac{1}{1 - p\%} \qquad \left[\frac{kg_{CO_2}}{kWh}\right] \qquad (10)$$

The definition of heat delivered to the user excluding network losses requires specific discussion. Network losses are typically defined as a percentage of the total energy delivered annually. The incidence of losses on an hourly basis cannot be considered constant. In the summer period when the thermal demand is low, the energy that is produced is mainly dispersed to keep the entire network at temperature. Therefore, network losses are very significant, and the EF reaches values much greater than 1.

The emission factor can be expressed as the sum of the emission factor of losses and the emission factor of thermal energy consumptions.

$$f_{DHS,H_{del}} = f_{DHS,H_{gen}} * \frac{p\%}{1 - p\%} + f_{DHS,H_{gen}} = f_{DHS,losses} + f_{DHS,cons} \qquad \left[kg_{CO_2} kWh\right] \qquad (11)$$

3.2.4. SEA Method

The application of hourly emission factor outlined in equation (11), can be difficult for a typical user connected to the DHS. In fact, the method assumes knowledge of DHS's hourly generators production, DHS hourly network losses, and hourly heat demand profile. The hourly load profile of the building may be known or calculable from consumption data with daily or monthly steps. On the other hand, system operating data

may not be public and available. A *simplified method* (SEA[4] method) for calculating emissions is therefore proposed. Equation (12) can be adopted by replacing the hourly energy with the energy delivered annually by each heat generator. The first term of the emission factor relating to network losses is an annual average value. For this reason, in the case of users characterized by winter heat load profile, the value of emitted tons of CO_2 may not be representative. Therefore, it is appropriate to simplify the expression (equation (13)).

$$\overline{f_{DHS,H_{del}}} = \frac{\overline{\overline{H}} * f_{CC,H} + \sum \overline{\overline{H_i}} * f_{i,H}}{\overline{\overline{H_{gen}}}(1 - \overline{\overline{p\%}})} = \overline{f_{DHS,H_{gen}}} * \frac{\overline{\overline{p\%}}}{1 - \overline{\overline{p\%}}} + \overline{f_{DHS,H_{gen}}} \qquad \left[\frac{kg_{CO_2}}{kWh}\right] \qquad (12)$$

$$\overline{f_{DHS,H_{del}}} = \overline{f_{DHS,H_{gen}}} * \left(\frac{1}{1 - \overline{\overline{p\%}}}\right) \qquad \left[\frac{kg_{CO_2}}{kWh}\right] \qquad (13)$$

3.3. Thermal energy demand profile evaluation

To calculate the hourly CO_2 emissions resulting from the Thermal Energy Consumption (TEC) of a tertiary user connected to a DHS, the first step is to gather data on the actual hourly energy consumption of the buildings. If energy demand profile is not available, it is still possible to estimate the energy consumption using specific values that consider external average temperature. A replicable methodology for the creation of a profile for other buildings with a similar occupancy profile is proposed.

3.3.1. Daily thermal energy consumption patterns and relation with external temperature

To investigate the thermal energy demand profile, the first step is to select the buildings to be included in the analysis and gather relevant energy-related data, such as energy consumption, variation in heated volumes, and average external temperature. By obtaining hourly data, it becomes possible to observe variations in consumption over time of day, external temperature, and day of the week. To facilitate year-to-year comparisons, we used the academic year (e.g., October to September) rather than the solar year. This enables the analysis of consumption trends during the same heating season, thereby minimizing potential errors arising from changes in heated volume across different years.

In the present case study, hourly data were collected from October 2021 to September 2022 for the demand side (University energy consumption), and from October 2010 to September 2011 for the production side (DHS data). Hourly consumption data of the university user are recorded in the heat exchange substation of the DHS serving the city and the analyzed user. In recent years, obtaining hourly energy consumption data from buildings has become increasingly accessible, although it is more challenging to obtain such data for the 2010-2011 heating season. With the improvement of data analysis services, it will be easier to perform hourly considerations in the future. In this case, however, we were forced to use the 2010-2011 period as a reference and consequently recalculate the hourly consumption. To do this, we used Energy Signature (ES) and load profile variation. As the variation in heated volumes between these two periods was negligible, this parameter was considered constant.

The analysis has allowed the identification of similar consumption pattern for the working midweek days: Tuesday, Wednesday, and Thursday. Monday consumption is higher due to its early heating starting time, Friday and Saturday have a lower thermal consumption because of a lower occupancy ratio. The midweek days were therefore used as Reference Days (RD) to create a daily ES that more accurately represents the buildings' behaviour of these days.

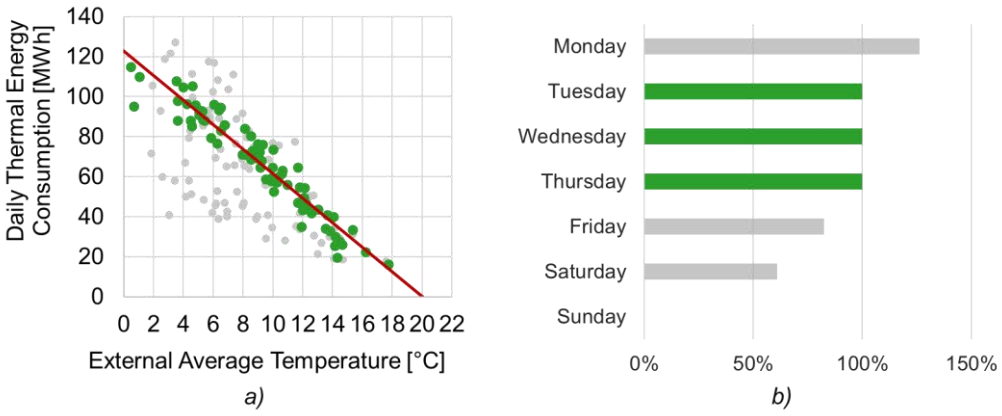

Figure 4. a) Daily Energy Signature, relationship between thermal energy consumption and external average temperature b) Ratio between TEC of a specific day of the week and average TEC of RD

[4] Sistemi per l'Energia e l'Ambiente.

To create a more representative linear regression model from the ES, some data was excluded: National holidays; days right after a day of building closure; and Mondays, Fridays, Saturdays, and Sundays. Daily average external temperature of 2010-2011 was then used in the equation of the ES trend-line. This output enabled the estimation of the daily TEC for all days with behaviour similar to RD.

To allocate the correct daily TEC for each day of the week, the ratio between the TEC of other days in the week and the average TEC of the RD was calculated for each week of the heating season. By taking the trimmed mean of these ratios, more realistic percentages were obtained as shown in Figure 1.b. The following specific considerations were made for the specific case study.

- On Monday, energy consumption is higher than the RD (126%) due to an early start time for heating after Sunday closure.
- On Friday, the occupancy rate of the facility decreases in the late afternoon and shutdown hour is later, leading to lower consumption than the RD (83%).
- On Saturday, the facility is only open in the morning, and its energy consumption is lower (61%).
- On Sunday, the facility is closed, with zero energy consumption.

To obtain the actual daily consumption, the values obtained from the linear regression model were multiplied by the ratios shown in Figure 4.b depending on the actual days of the week in 2010.

$$H_{s_{daily}} = \sum_{0}^{23} H_{hh} \qquad [kWh] \qquad (14)$$

This methodology enabled the calculation of daily heat consumption, denoted as $H_{s_{daily}}$, for the heating season 2010-2011. With these daily data, an hourly consumption profile was created using the methodology described in the following chapter.

3.3.2. A replicable methodology for identifying typical hourly heat demand profiles

A Python-based calculation method was created and developed to define the hourly TEC of a typical user. The model was built using daily energy consumption data obtained as explained in the previous chapter. The aim was to create hourly profiles depending on the days of the week and the months of the year. To express the hourly load, the ratio of hourly consumption to the total daily TEC was calculated (15).

$$L_{hh} = \frac{H_{\mathrm{hh}}}{\sum_{0}^{23} H_{hh}} \qquad [-] \qquad (15)$$

The hourly load was averaged for each month and day of the week. Afterwards, a matrix was extracted that contained the hourly percentage heat load values characteristic of the day of the week and month.

The Python model requires as input the daily energy consumption data, which can be obtained from the provider or using the energy signature and daily average external temperature of the same period for which CO_2 emissions are being calculated. Based on the required year, a usage schedule is developed, which can be modified in case of scheduled closures on non-holiday days.

The energy consumption value is then distributed over hourly values based on the percentage hourly load characteristic of the month and day being analyzed, resulting in the user's daily hourly consumption for the entire thermal season. By utilizing this calculation method, a typical hourly load profile can be obtained, which can be replicated for tertiary utilities that have similar heat management systems.

4. Results

4.1. Case study description

4.1.1. Thermal energy profile in the main campus buildings of Politecnico di Torino

The case study selected to develop and apply the new methodology of CO_2 emissions calculation from a user perspective is the Politecnico di Torino. Specifically, the analysis focuses on the hourly thermal energy consumption of the university's most energy-intensive DH substation. The reference period chosen is the academic year 2010-2011 as hourly data from DHS side was available for that period. Since hourly data of DHS substation was available from 2021 to 2023, the methodology described in section 2.3 was applied using data from October 2021 to September 2022. To ensure a representative heating season, data from the period of extended Covid-19 restrictions was excluded.

By applying the previously described methodology, a typical thermal consumption profile was generated for the reference heating season and hourly TEC data was extracted. The annual consumption of the reference buildings was 11.1 GWh. The aim of the chapter 3.2 is to calculate the resulting CO_2 emission using both hourly and yearly calculation.

The analysis enabled to show that start-up and shut-down times vary based on the month and outdoor temperatures, as well as the day of the week. An earlier start-up time of approximately one hour is observed on Mondays to warm up structures that have cooled down during Sunday, resulting in higher total energy consumption than on other days. Conversely, Friday sees an earlier shut-down time than other days by

approximately one hour. Heating on Saturdays ceases around 1 pm, and no heating is required on Sundays due to the facility being closed.

4.1.2. Turin district heating system

Knowing the hourly thermal load profile of the consumer, to define CO_2 emissions, it is necessary to define what is happening at the energy generation level. Therefore, the DHS in Turin is analyzed from the energy point of view. The data used in this study are divided into two sets. The first set includes information on the production of electric and thermal energy, natural gas consumption, water temperature, and water flow rate inputs into the distribution network for all the generation groups of the Torino DHS from 2001 to 2011. The second set of data covers the period from 2010 to 2015 and is focused exclusively on the combined cycle power plants. Data cover hourly thermal and electric energy production, natural gas consumption, and carbon dioxide and pollutant emissions. The EF is being calculated for the 2010-2011 heating season because data are complete and comparable from both datasets. The DHS is supplied by three plants located in three different areas of the city. In the main plant, two combined cycles (CCs) and three Integration and Backup Boilers (IBBs) are installed. The other two plants consist of IBBs and a storage system (STO). The installed capacities are summarised in Table 1.

Table 1. Turin DHS thermal power installed (2010-2011)

type of generator	number, -	thermal power, MW	electrical power, MW	storage capacity, m^3
CC	2	520	760	-
IBB	9	651	-	-
STO	1	-	-	2'500

To analyse the operation of the two combined cycles, thermal power and electrical power are represented as a set of two-dimensional coordinates x and y (Figure 5). The CC energy output for each hour of operation is represented by a point. Using the *gaussian_kde* class of the *scipy.stats* module in Python, it is possible to estimate the probability density of the two-dimensional data represented by x and y. The mathematical model used by the KDE is based on the convolution of a core function with the input data. In this case, the KDE uses a Gaussian kernel to evaluate the probability density of the data, producing a continuous function that describes the probability distribution of the two-dimensional data. For both CCs (Figure 5 a and b), the point density is highest in the operation region of in cogeneration condition at full load. This is followed in order of frequency by the region in electrical operation mode typical in summer period when users' thermal demand is lowest. A threshold operating zone of 230 MWe can be identified from the graph for both combined cycles. The output points are positioned along the regression lines representing operation from electrical to cogeneration operation at variable loads. As described in section 3.2.1, the slope of regression lines at variable loads are considered approximately constant. A change in slope is not significant to the emissions factor calculation. The slope is inversely proportional to K (equation (4)) and in Figure 5 a and b are equal to 4.5 and 4.3 respectively.

To simplify the simulation of plant operation, the outputs of the two CCs have been summed up (Figure 5c). The average cogeneration gain K_{ave} has been calculated and is equal to 4.4. In Figure 5c, the point density is higher when only one CC operates in electrical mode (summer periods) and when both CCs operate in full cogeneration condition (winter periods).

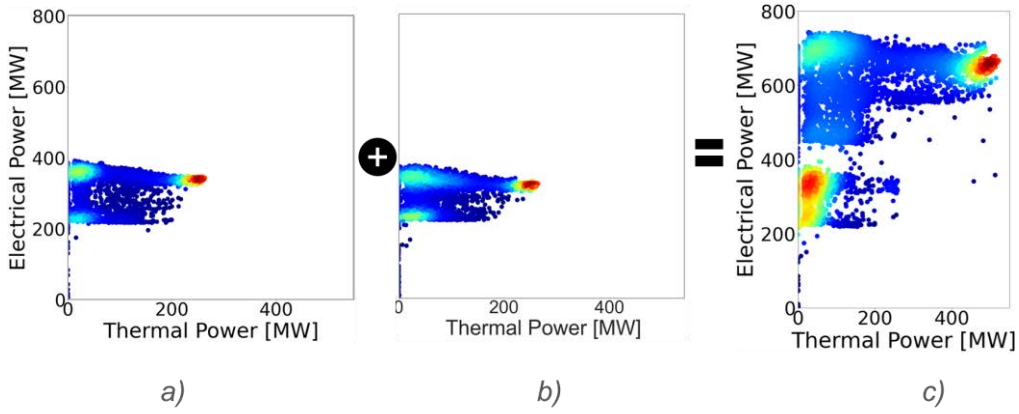

Figure 5. CC hourly energy output. a) CC_1; b) CC_2; c) $CC_1 + CC_2$

CCs produce 85% of the annual thermal energy, the remaining amount is produced by IBBs 13% and STO 2%.

4.2. CO_2 emissions in universities

4.2.1. Turin district heating emission factor

Starting from the overall operating data of the two CCs, the regression line shown in Figure 3a is derived. The characteristic coefficient α of the combined cycle is 0.902. The EF of the combined cycle (equation (8)) is 0.074 kg_{CO_2}/kWh. As shown in Table 1, the Turin DHS is connected with thermal storages. An analysis of the operation of the generation components hour by hour shows that the charging of the storage tanks occurs during night periods and during daytime periods when the thermal demand is lower. During such periods, the only operating generators are the CC units. For this reason, the storage unit also has an EF of 0.074 kg_{CO_2}/kWh.

By analysing the hourly operation of the heat generators of the DHS in Turin and applying equation (9), the hourly emission factor $f_{DHS,cons}$ is obtained. Figure 6a shows the hour-by-hour emission factors for the months of December, January, and February. Three different trends are identified. The points with a constant EF of 0.074 kgCO2/kWh are associated to *operating configuration 1*. It corresponds to the hours in which the thermal energy is exclusively produced by CCs and CCs with STO. As the thermal demand increases, the heat production is integrated by IBBs. The EF increases as the contribution of IBBs becomes more and more relevant. Thermal energy production from CCs, STO, and IBBs is represented by *operating configuration 2*. The 2010-2011 winter season was characterized by a few operation hours in which the thermal demand was satisfied by a single combined cycle CC at which the heat produced from IBBs was integrated. This operating configuration is represented by the *operating configuration 3*. The EF reaches the highest values. The average hourly emission factor $f_{DHS,cons}$ for each month is represented in the graph in Figure 6b.

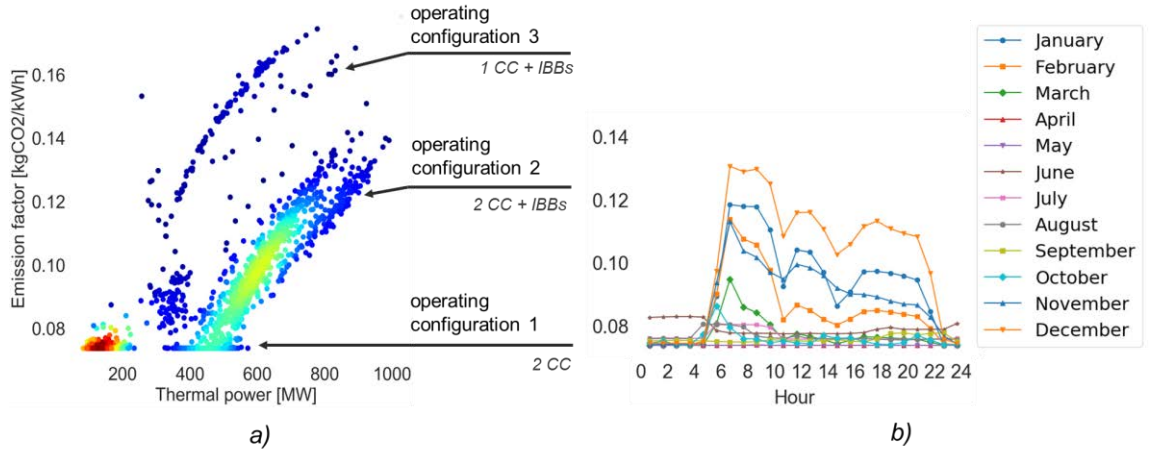

Figure 6. hourly EF (consumption factor). a) EF with respect to thermal energy generated in winter period; b) average EF with respect to time of day in the different months of the year

While in the summer months the emission factor $f_{DHS,cons}$ is lower, this is not true for the emission term related to network losses $f_{DHS,losses}$. Network losses contribution is lowest in the daytime hours of the heating season; it is most relevant in the night-time period, and it is highest in the summer period when the energy delivered is minimal and equal only to that required for domestic hot water production.

4.2.2. Annual emission factors methodologies comparison

To define the annual EF of the Turin DHS in the 2010-2011 thermal season, the annual energy performance is calculated. The total energy produced is 1'760 GWh_t, of which 8% is loss to the distribution network.

Table 2 shows the annual thermal emission factors calculated using the three methodologies presented in the previous sections. *SEA method* allocates the emission factor into two contributions: one related to heat losses in the distribution network, and the other related to actual thermal energy consumption. The EF obtained using this method is significantly lower than those obtained using the other two methods. *Method E* outputs an emission factor that is approximately three times higher than the one obtained using the SEA method proposed, and even higher than the EF of natural gas (0.202 kg_{CO_2}/kWh [17]). This implies that users who satisfy their thermal energy needs using DHS emit more tons of CO_2 than those who use a single natural gas boiler considering the same thermal energy consumption. Finally, *method U* considers electrical energy generated in cogeneration and produced as a substitute for fossil-fuelled non-cogeneration national thermoelectric plants. The electrical emission factor applied is the Italian gross thermoelectric production (fossil fuels only) as of the year 2010 and is equal to 0.565 kg_{CO_2}/kWh [12]. Method U generates a negative DHS thermal emission factor. The EF must be replaced by zero value. This implies that the production of thermal energy from DHS results in an inappropriate cutback of CO_2.

Table 2. annual emission factor comparison

		Losses factor, kg_{CO_2}/kWh	Consumption factor, kg_{CO_2}/kWh	*Total factor* , kg_{CO_2}/kWh
Method E	(eq. (1))	–	–	0.302
Method U	(eq.(2))	–	–	– 0.421 (0)
SEA method	*(eq.* (11))	0.009	0.093	0.102

4.2.3. Application of methodologies to case study and corresponding CO_2 emissions

The emission factors calculated (Table 2) are applied to the consumption of the 2010-2011 heating season of Politecnico di Torino. In the 2010-2011 heating season, the annual thermal energy consumption calculated for the user case study is 11.1 GWh_t.

Table 3. Politecnico di Torino CO2 emission. 2010-2011 heating season

	Thermal losses, CO_2 t	Thermal consumption, CO_2 t	**Total, CO_2 t**
Method E	–	–	**3'350**
Method U	–	–	**0**
SEA Method	96	1'035	**1'131**
Hourly approach	42	1'087	**1'129**

Annual CO_2 emission values are compared with the hourly calculation by applying the *hourly approach.* By applying the SEA method emission factor, the total annual emission value is characterized by a percentage error of less than 1% compared with the value calculated by applying the *hourly approach.* The allocation between emissions from thermal energy consumption and heat losses on the distribution network varies. As anticipated in section 3.2.4, the emission value associated to network thermal losses in the SEA method considers annual percentage losses (8%). The incidence of losses on total emissions is therefore lower for users characterized by an exclusive winter period heat load profile like in Politecnico di Torino case study.

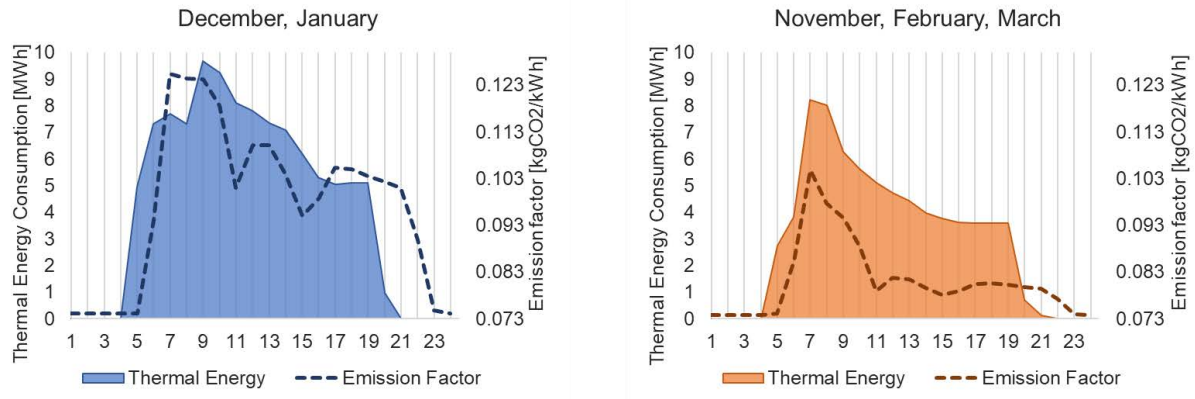

Figure 7. Hourly variation of average daily thermal energy consumption of RD (left axis) and variation of DHS emission factor (right axis).

Figure 9 illustrates the average profile of a typical daily thermal energy consumption at Politecnico di Torino, along with the EF trend shown in dashed lines. The hourly emission factor fluctuations depend on the usage patterns of other DHS users, and therefore the need for backup boilers. These graphs display a similar trend, with a noticeable deviation towards the morning hours. It may be inferred that the Politecnico di Torino begins heating operations earlier and terminates the early in contrast to the average schedule of users.

5. Discussion

This paper presents a new methodology for calculating the hourly variation of CO_2 emissions of DHS, specifically in the case of combined cycle cogeneration plants. A new methodology that enables the calculation of emission factors on an hourly basis and as well as a simplified annual method (SEA method) is presented and compered to existing methodologies. The methodologies described are applied to a representative case study of a tertiary DHS user. The case study selected is Politecnico di Torino. The total CO_2 emissions calculated using the three different methodologies showed a wide variability in the results. In particular, the two methodologies currently in use present two very contrasting results varying from values above that of natural gas to zero values. The need to find an alternative method is therefore confirmed. The emission value obtained with the more accurate hourly analysis is close to the annual value and the error il negligible. The application of the hourly methodology requires knowing the hourly operating data of the generation plants and the hourly heat load of the user. If the user's hourly consumption data is not available, a methodology applicable to tertiary users is proposed to evaluate the user thermal needs. Therefore, SEA method can be used to calculate the total emissions of a structure if thermal energy consumption data has a

yearly approximation or if it is not possible to access the hourly generation data of the DHS. SEA method is a good solution in defining total annual emissions, but as compared to the hourly approach it does not allow for a correct allocation of emissions between emissions due to thermal network losses and effective consumption, therefore one unresolved issue is the allocation of distribution thermal losses. At a regulatory level, it is unclear to whom to attribute the value of losses and in what period (annually or in the period of use only). Furthermore, since it can be challenging to ask local entities to conduct deep and complex analyses to determine their CO_2 emissions, it would be beneficial to require DH companies to include this information on bills. These future developments will help to improve the accuracy of CO_2 emissions calculations for users connected to DHS.

The hourly analysis has also highlighted opportunities for improvement in reducing CO_2 emissions. Knowing the hourly variation in emission factor due to the use of different generators, different energy consumption behavior could be motivated to reduce their emissions. For example, users may choose to adjust their energy demand during hours of less use, or install energy storage systems, to store energy when emissions are low and use it when emissions are high. These approaches could contribute to reducing the overall CO_2 emissions during the transition phase towards a complete decarbonization of energy sources. These analyses will become obsolete when DHS will become completely fossil fuel free.

The integration of hourly analysis of both electrical and thermal energy will become increasingly significant as renewable energy sources continue to grow in importance. Future developments should address this challenge by combining the hourly emission factors for both thermal and electric energy sources. This will enable the development of smarter storage and distribution systems for both thermal energy and electricity, ultimately leading to more sustainable and efficient energy use.

Nomenclature

CC CHP Combined Cycle

CHP Combined Heat and Power Plant

DHS District Heating Systems

E electrical power, MW

E_{CHP} ($\overline{\overline{E_{CHP}}}$) electrical power (energy) produced in CHP and delivered, MW $(kWh/year)$

EF emission factor

ES energy Signature

F fuel inlet power, MW

F_i ($\overline{\overline{F_i}}$) fuel inlet power (energy) used for each energy source *i,* MW $(kWh/year)$

Abstract

Negative Emissions Technologies (NETs), such as Bioenergy with Carbon Capture and Storage (BECCS) and Direct Air Carbon Capture and Storage (DACCS), are potentially valuable to offset carbon emissions and therefore commonly deployed in global climate change mitigation scenarios. However, they are controversial and sometimes seen as a means of delaying or avoiding emissions reduction efforts. Nonetheless, the UK has set an ambitious target of engineering 57 Mt CO_2 per year of removals by 2050 to achieve net zero emissions[1]. This study uses the UK TIMES, technology-rich bottom-up energy system model to investigate the nationwide deployment of NETs in the energy system, while varying model parameters to provide an overview of decarbonisation in line with the UK's net zero ambitions. We investigated DACCS and BECCS NETs technologies with regards to technological uncertainties and sensitivities. We revised the TIMES model structure for NETs implementation to ensure proper integration with industry. Our analysis estimates that the UK can remove 78.5 Mt CO_2 by 2050 under the balanced Net Zero Scenario. However, by integrating an updated characterisation of removal technologies, and enabling tighter integration of DACCS into industrial clusters, we can achieve a removal capacity of up to 209 Mt CO_2 by 2050 based on our preliminary results. Additionally, a 50% reduction in DACCS cost could further increase the removal capacity to 218 Mt CO_2. This study provides valuable insights for policymakers and stakeholders in the UK and beyond, highlighting how NETs can be integrated in industrial strategy.

Keywords: DACCS, BECCS, NETs, Energy System modelling, UK-TIMES, Net-Zero

1. Introduction

The increasing concentrations of greenhouse gases (GHG) in the atmosphere due to human activities have led to the unprecedented challenge of climate change. While mitigation efforts such as reducing emissions are crucial, they alone are not enough to limit the rise in global temperatures to well below 2°C, as carbon dioxide removal scenarios are highly incorporated into modelling scenarios [2]. Negative emission technologies (NETs) have thus emerged as a potential solution to extract and store carbon dioxide from the atmosphere. Two promising NETs are Direct Air Carbon Capture and Storage (DACCS) and Bioenergy with Carbon Capture and Storage (BECCS), which are a common feature of global climate change mitigation scenarios [1]

DACCS technologies remove carbon dioxide (CO_2) directly from the air using a chemical that selectively captures CO_2 molecules. Once the chemical is saturated with CO_2, the captured CO_2 is released and collected for processing. This process allows for CO_2 to be removed from the atmosphere and stored. DACCS can remove CO_2 directly from the atmosphere, regardless of the source of the emissions. This means that it can be used to remove CO_2 that has already been emitted, as well as to remove future emissions from sources that are difficult to decarbonise, such as aviation and shipping. DACCS technologies can be broadly classified into two categories: liquid absorbent (such as potassium hydroxide) and solid sorbents (such as amine-based solid sorbents). Liquid absorbent systems are

associated with high capital investment costs (CAPEX) and energy prices as they are operated at high temperatures, while solid sorbent DACCS is more sensitive to the adsorbent material costs and its performance with high CAPEX as well [3].

BECCS technologies, on the other hand, remove CO_2 from the atmosphere by using biomass production to generate energy and then capturing and storing the CO_2 emissions that are produced during the process. The CO_2 emissions produced during energy generation are offset by the CO_2 absorbed by the biomass during growth, and the captured CO_2 is stored underground, effectively removing it from the atmosphere, which can potentially provide negative emissions. BECCS technologies involve capturing CO_2 emissions from bioenergy facilities such as power plants, using carbon capture and storage (CCS) technology. The captured CO_2 is then stored underground. There are various types of BECCS systems that exist or are under development, including:

- Post-combustion capture: This technology involves capturing CO_2 emissions from the exhaust gas of a bioenergy facility after the combustion process.
- Pre-combustion capture: This technology involves converting biomass into a gas (syngas) before combustion. The CO_2 is then captured from the syngas before combustion.
- Oxy-fuel combustion: This technology involves burning biomass with oxygen instead of air. The resulting flue gas is mostly CO_2, which is then captured and stored.
- Chemical looping combustion: This technology involves using a metal oxide to react with biomass, producing a gas that is mostly CO_2. The metal oxide is then regenerated using air, producing a concentrated stream of CO_2 that can be captured and stored.

The total capacities of NETs deployed in Integrated assessment models (IAMs) show considerable variation. For example, International Energy Agency's (IEA) Net Zero scenario estimate that BECCS and DACCs can globally remove 1.9 gigatons of CO_2 globally by 2050 [4]. The National Academies of Science report [5] estimates that NETs could potentially remove around 10-20 Gt of CO_2 per year by 2050, which is equivalent to around one-third of current global emissions [6]. According to the Sixth Carbon Budget report of Climate Change Committee (CCC), DACCS and BECCS deployed in the UK can remove 57 Mt CO_2 emissions per year in 2050 in the balanced net-zero scenario [1] (Figure 1).

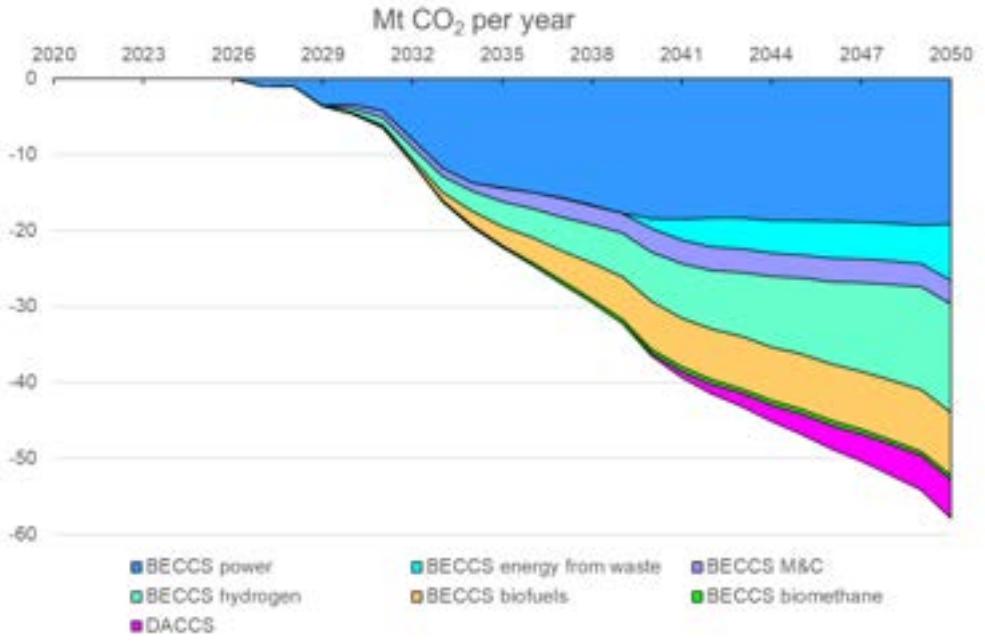

Figure 1. NETs deployment in the UK [7]

In recent years, there has been growing interest in integrating these NETs into industrial clusters in the UK. Industrial clusters are geographic regions of interconnected companies that accrue agglomeration effects from producing goods and services. By integrating NETs into these clusters, it is possible to reduce emissions from multiple sources while also generating economic benefits. Further benefits from co-locating NETs in industrial clusters include the potential availability of CCS infrastructure, potential integration of waste heat, a potentially easier permitting process, and higher

social acceptance. The UK has set ambitious targets for the deployment DACCS and BECCS in its industrial clusters as part of its efforts to reach net-zero emissions by 2050.

The UK has set a target that DACCS capture up to 5Mt of CO_2 per year by 2050, and BECCS remove 22 Mt CO_2 per year by 2035 and 53 Mt CO_2 per year by 2050[1]. The government has also set a target to deploy at least two industrial-scale DACCS facility by 2025 and to scale up deployment to reach 3 million tonnes of CO_2 captured per year by 2030 and world's first zero cluster by 2050[8]. To support the deployment of these technologies, the government has launched a £1 billion Net Zero Innovation Portfolio to fund the development and demonstration of innovative low-carbon technologies, including DACCS and BECCS[9]. The government has also launched a consultation on the design of a UK Emissions Trading System and the potential inclusion of carbon removal credits, generated from NETs, which will provide a financial incentive for industries to reduce their greenhouse gas emissions and encourage the deployment of low-carbon technologies such as DACCS and BECCS.

The future energy system scenarios addressing the transition towards a Net-Zero have been carried out for UK by using the UK-TIMES model. This model is widely used for creating energy system decarbonisation pathways [10-13]. UK-TIMES covers the full energy system and is applied in this study to explore the role of DACCS and BECCS in achieving the UK's net-zero goal, particularly in offsetting industrial cluster emissions. Removal technologies are interesting not only because they appear to be crucial to the achievement of global Paris Agreement mitigation targets in IPCC scenarios, but also at a national level because they may create emissions space for some hard-to-abate industries to survive in a country, with important ramifications for "just" transitions and promoting "place-based" transitions. However, there are still challenges to overcome, including the high cost of these technologies and the need for supportive policies and regulations to encourage their deployment at scale. This paper explores the potential of DACCS and BECCS integrated into industrial clusters in the UK and assesses their potential to contribute to negative emissions targets.

2. Methodology

2.1. DACCS

DACCS technologies pulls air from the surrounding environment and passes it through a pre-filter to remove any particles or contaminants. The air is then passed through a sorbent material, which selectively captures carbon dioxide (CO_2). The sorbent material can be a solid or liquid, depending on the specific DACS system design. Once the sorbent material is saturated with CO_2, it is heated to release the captured CO_2. This process is known as desorption or regeneration, pressure-swing or moisture swing system can also be utilised. The CO_2 is released as a concentrated stream that can be captured and compressed for storage. The captured CO_2 is compressed and transported to a storage site. The CO_2 can be stored in geological formations, such as depleted oil and gas reservoirs or deep saline aquifers, where it is securely stored underground to prevent it from entering the atmosphere.

There are four different DACCS systems defined in the default UK-TIMES model. We introduced an additional four DACCS systems with updated CAPEX and OPEX cost values (see Table 1). Technologies #1,2,3 and 7 already exist in the UK-TIMES model. We changed the commodities for technology #8 to connect with industrial waste heat, to represent industrial cluster integration. The existing data was adopted from a NAS study [5]. Additionally, we introduced new technologies #4,5,6 and 7 [3]. The capacity growth of all DACCS technologies is limited to 10% per year with a five-year seed value of 1 Mt CO_2 captured and stored.

Table 1. Techno-economical characteristics of selected DACCS technologies

#	DACCS Technologies	CAPEX [£/tCO_2], 2020	OPEX [£/tCO_2], 2020	Heat Req. [GJ/tCO_2]	Electricity Req. [GJ/tCO_2]	Lifetime [yr]
1	DACCS-Liquid solvent electric CCS[5]	630.7	25.8	10.68	1.2	30
2	DACCS-Liquid solvent electric NGA CCS[5]	630.7	25.8	10.68	1.20	30
3	DACCS-Liquid solvent electric hydrogen CCS[5]	630.7	25.8	10.68	1.20	30
4	DACCS-Solid sorbent electric CCS[3]	737.9	17.5	3.94	0.84	25

5	DACCS-Solid sorbent electric NGA CCS[3]	737.9	17.5	3.94	0.84	25
6	DACCS-Solid sorbent electric hydrogen CCS[3]	737.9	17.5	3.94	0.84	25
7	DACCS- Solid sorbent waste heat CCS[5]	714.4	10.8	3.94	0.84	30
8	DACCS- Solid sorbent waste heat CCS w/IND[5]	1,093.2	16.5	3.94	0.84	30

Notes: CAPEX: capital investment cost; CCS: carbon capture and storage; OPEX: operational and maintenance cost; Req.: requirement.

These CAPEX and OPEX values of DACCS are attributed to the year 2020. We have assumed a 50% reduction in CAPEX and OPEX by 2050 based on Fasihi et al [14]. As the liquid solvent requires high temperature (900°C) for the regeneration in the calciner, we did allow the integration of industrial waste heat (around 150°C) [15] with this technology.

2.2. BECCS

There are different types of BECCS systems, which vary based on the type of biomass feedstock, the conversion technology, and the carbon capture and storage (CCS) method used. Some of the different types of BECCS systems include:

1. Direct combustion BECCS: This involves the direct combustion of biomass to generate electricity or heat, with the resulting CO_2 emissions captured and stored using CCS technology.
2. Co-firing BECCS: In this system, biomass is co-fired with fossil fuels in power plants to reduce greenhouse gas emissions. The CO_2 emissions from the combustion process are captured and stored using CCS technology.
3. Gasification BECCS: This involves the gasification of biomass to produce a syngas, which is then combusted to generate electricity, heat or hydrogen. The resulting CO_2 emissions are captured and stored using CCS technology.
4. Anaerobic digestion BECCS: This system involves the anaerobic digestion of organic matter to produce biogas, which can then be used to generate electricity, heat or hydrogen. The CO_2 emissions from the combustion process are captured and stored using CCS technology.
5. Pyrolysis BECCS: In this system, biomass is heated in the absence of oxygen to produce a bio-oil and a solid char to produce hydrogen. The bio-oil can be used as a fuel, while the char can be used as a soil amendment. The resulting CO_2 emissions from the combustion of the bio-oil are captured and stored using CCS technology.

Each of these BECCS systems has its own advantages and limitations, depending on factors such as feedstock availability, energy efficiency, and cost-effectiveness. The UK-TIMES model utilises five different BECCS technologies (Table 5). The technologies with techno-economic properties are given in Table 2. The capacity growth of biomass technologies limited to 10% per year with maximum 20% of biomass import growth.

Table 2. Techno-economical characteristics of selected BECCS technologies

#	Technology name	CAPEX [£/kWh]	Var. OPEX [£/kWh]	Fix. OPEX [£/kWh]	EFF [%]	Lifetime year
1	Hydrogen Biomass gasification with CCS	0.254	-	0.018	46	30
2	Hydrogen Biooil SMR with CCS	0.151	-	0.010	54	30
3	Hydrogen Waste gasification with CCS	0.321	-	0.020	41	30
4	Biomass combustion with CCS	0.321	0.003	0.015	31	25
5	Biomass combustion with CCS-retrofit	0.208	0.004	0.009	89	25

Notes: CAPEX: capital investment cost for 2020; EFF: efficiency; Var: variable; Fix: fix; OPEX: operational and maintenance cost; Req.: requirement, AD: anaerobic digestion, SMR: steam methane reforming. The variable and fix operational and maintenance cost are for the year 2020.

2.3. TIMES model generator

The Integrated MARKAL-EFOM System (TIMES) model generator is maintained by International Energy Agency (IEA)- the Energy Technology Systems Analysis Programme (ETSAP) [16] to conduct in-depth energy and environmental analysis [17]. It is used for the analyse the possible future energy system scenarios [18]. The TIMES model is a bottom-up approach that uses a single or multi-regional model with a technology-rich database to analyse and plan energy systems at the national, regional, or city level. It is a techno-economic, partial equilibrium model-generator that assumes perfectly competitive markets and perfect foresight. Its source code, written in GAMS, is available for free download upon signing an ETSAP Letter of Agreement. In this study, we use the UK-TIMES which is built using the VEDA system (developed by UCL Energy Institute [19]) and it is now being utilised by His Majesty's Government departments to inform their climate policy analysis, including the 6th Carbon Budget [1].

The UK-TIMES model is a representation of the technology and fuel options available for various energy-consuming sectors when working towards the goal of decarbonisation. The decisions about these options are determined by what is the most cost-effective while taking into account various constraints that reflect the characteristics of the system. The model considers various factors, including the need to balance the supply and demand of energy over different periods of time, restrictions on the rate of technology deployment, and the availability of resources. One major advantage of this approach is that it trades off action between sectors, and captures interactions between sectors, allowing for more informed policy decision making. The UK-TIMES is structured in eight sectors, divided into three supply side and five demand sectors. The supply side consists of resources and trade, processing and infrastructure, as well as electricity generation transmission and distribution. The demand sectors include residential, services, industry, transport and agriculture. All sectors are calibrated based on the energy balance of the UK in the base year of 2010, and takes into account the existing portfolio of energy technologies in the Reference Energy System (RES). The UK-TIMES has flexible time periods and provides results for five-year periods until 2060. It consists of a total of 16 time-slices, with each of the four seasons being represented by a typical day divided into four time-slices.

The model aims to minimise the total system costs (least-cost solution), which includes investment cost, fixed and variable operation and maintenance cost, import cost, and export revenues for all modelled processes. The capacity of a particular technology remains until the end of its technical lifetime, and its salvage value is subtracted from the objective function if its economic lifetime goes beyond the modelling horizon. The inputs used to develop the UK-TIMES include exogenous service demand curves, supply curves, policies, and techno-economic parameters for each technology. Supply curves show the quantities of primary energy resources or imported commodities available at a specific cost. Techno-economic parameters are assigned to available and future technologies, including transformation and demand technologies. Technical parameters include efficiency and availability factor, while economic parameters include investment costs and interest rates. Policies may include the effects of legislation such as taxes and subsidies on specific technologies or fuels.

The outputs of TIMES models are region-specific and time-specific optimal investments, operations, and import/export levels. The model output includes not only the optimal solution but also costs, environmental indicators, marginal prices of commodities, and energy flows. UK-TIMES models both energy- and non-energy-related CO_2, CH_4, N_2O and HFC emissions, although non-CO_2 GHGs have not been explicitly considered in this study. Overall, the UK-TIMES VEDA model is a comprehensive tool for exploring different pathways to integrate DACCS and BESS into the UK's industrial clusters, providing insights into the costs, feasibility, and trade-offs associated with different options. In this study we have three main scenarios:

1. The default model runs: exploring the update of NETs without updates on technology characterisation.
    - We run the model with existing DACCS and BECCS technologies, including their techno-economic characteristics as described in sections 2.1 and 2.2.
2. The model runs where solid sorbent DACCS is integrated into industrial clusters.
    - We introduced four additional DACCS and integrated solid sorbent DACCS into industrial clusters, considering the low heat demand from industry/
3. The cost sensitivity of NETs deployment

- We changed the CAPEX of DACCS by ±50% to evaluate the cost sensitivity of DACCCS employment as well as NETs.

3. Results and discussion

3.1. Default results from the UK- TIMES model

Results show that 78.5 Mt CO_2 can be captured by DACCS and BECCS in the UK by 2050 under the balanced Net Zero Scenario (see Figure 2). The default DACCS (liquid solvent powered by electricity, electricity and gas, hydrogen; solid sorbent powered by waste heat from electricity generation without integration into industrial clusters) and BECCS (biomass incinerated gasification combined cycle (IGCC); hydrogen generation from biooil gasification with CCS; biomass gasification with CCS; waste gasification with CCS; electricity generation from biomass combustion with CCS) technologies are used to produce these results. In 2050, the most important technologies are:(1) hydrogen generation from biomass gasification with CCS, (2) solid sorbent DACCS, (3) hydrogen generation from waste gasification with CCS, and (4) biomass combustion with CCS for electricity generation following. The liquid solvent powered by electricity DACCS contributes the least to NETS.

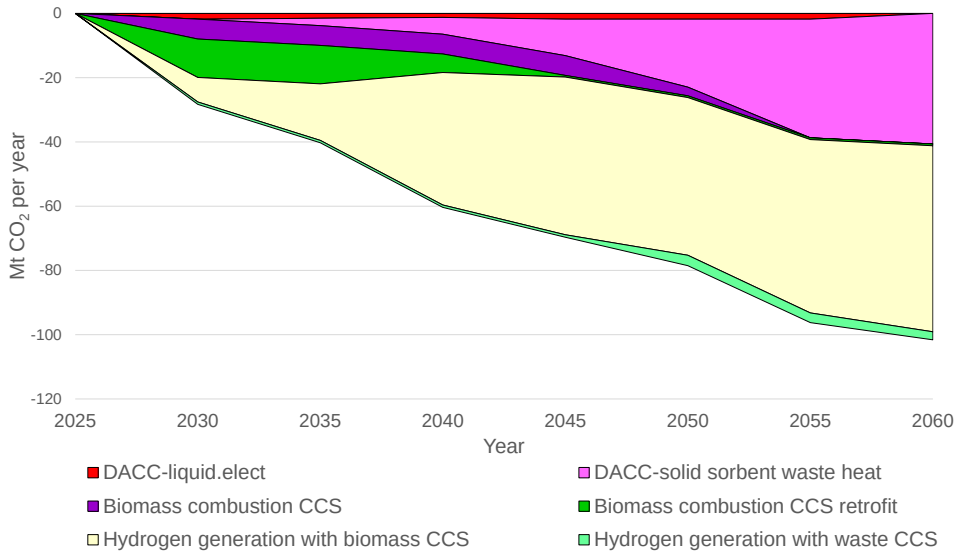

Figure 2. *NETs results from existing UK-TIMES model for Net Zero Balanced scenario*

According to the Net Zero balanced scenario, total positive CO_2 emissions would be 65 Mt CO_2 if DACCS, BECCS and natural negative emissions as well as industrial emissions sequestration are not taken into account (see Figure 3 for a breakdown of emissions by sector). It is evident that the positive emissions remain within the system, and it is not feasible to achieve the net-zero goal without the deployment of NETs, especially hard-to-abate sectors such as heavy industry, transportation, aviation and shipping. These sectors typically emit a large amount of greenhouse gases and require innovative and effective solutions to reduce their emissions and transition to a low-carbon economy.

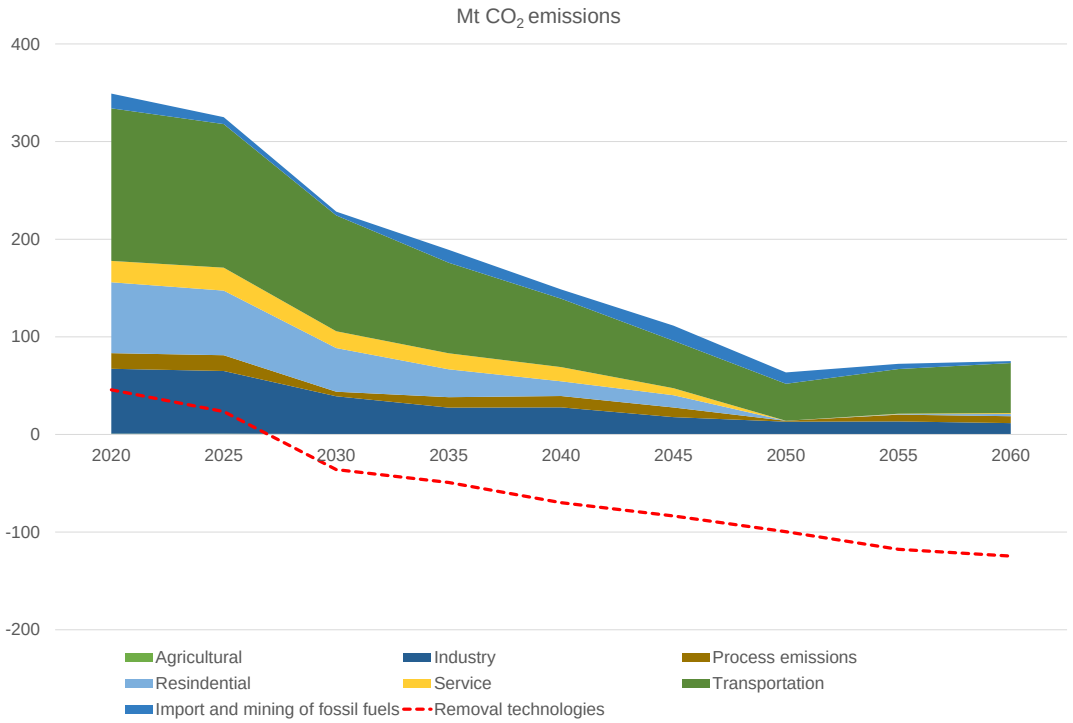

Figure 3. *Total CO_2 emissions from different sector in the UK.*

3.2. DACCS technologies integration into industrial clusters

According to Figure 2, the two leading DACCS technologies are solid sorbent waste heat DACCS and liquid solvent DACCS powered by electricity (as shown in Figures 2 and 3a) in the Net-Zero Balanced scenario. The UK-TIMES has not chosen other liquid solvent DACCS technologies powered by natural gas & electricity and hydrogen due to least-cost solution. In addition, we have included three other solid sorbent DACCS technologies, namely solid sorbent DACCS powered by electricity, natural gas & electricity, and hydrogen. Furthermore, we have explored the option of solid sorbent DACCS powered by low heat from industrial clusters, including the chemicals, food and drink, non-metallic minerals sectors, and other industrial low heat, in addition to waste heat from electricity generation processes.

We have found that DACCS can capture 22.9 Mt CO_2 by 2050 and up to 40.7 Mt CO_2 by 2060, mainly through the use of solid sorbent technology (as shown in Figure 4a), in the case where this DACCS is not integrated with industrial waste heat. There are 2 TWh (for 2050) to 19 TWh (for 2040) of low-grade heat available from industry that can be utilised in the DACCS system. By integrating solid sorbent DACCS with this available low temperature heat from industrial clusters, DACCS potential increases up to 180 Mt CO_2 by 2050 (Figure 4b) based on our preliminary results. Hence, the integration of DACCS technologies into industrial clusters can provide a fourfold increase in CO_2 removal in a net-zero scenario.

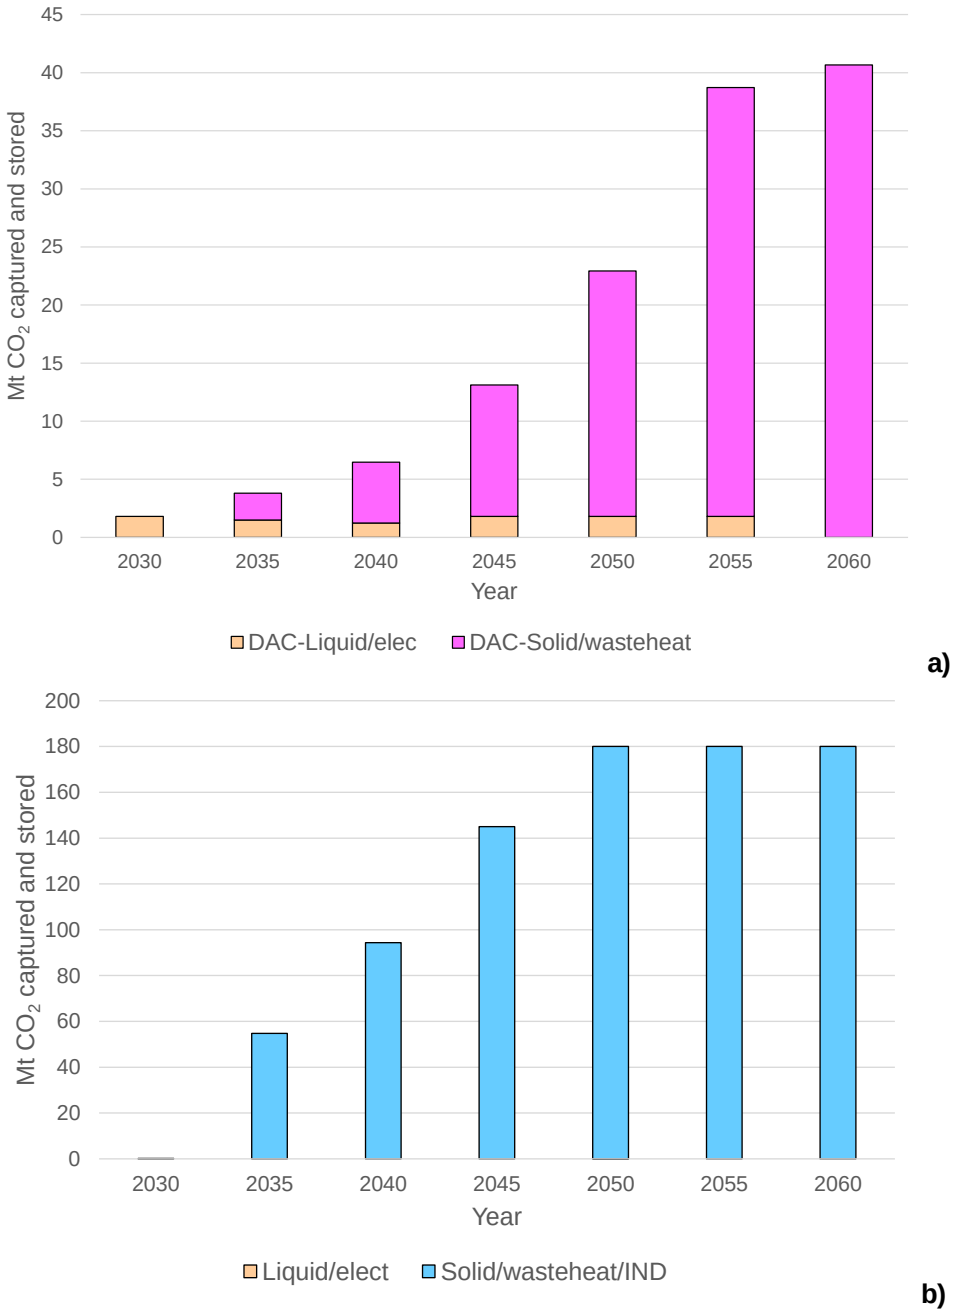

Figure 4. *DACCS technologies changes over time.* ***a)*** *Default results from Net-Zero Central scenario without industrial integration* ***b)*** *DACCS solid sorbent was integrated with industrial low heat. The same cost values are applied in both scenarios.*

It is important to note that increasing the deployment of DACCS will result in an increase in total positive CO_2 emissions (increase to around 178 Mt CO_2 in 2050) almost all sectors, primarily from the industrial, transport and process sectors due to the space created by NETs (see Figure A1 in the appendix). However, even though positive emissions will increase by 2.8 times, the integration of solid sorbent DACCS into the industry will provide a fourfold increase in CO_2 removal amount.

3.3. CAPEX cost impact on NETS

We have also explored the impact of capital cost (CAPEX) on the deployment of DACCS, given the uncertainty in the cost of DACCS in both the short and long term [3]. We varied the CAPEX by ±50% to estimate the amount of CO_2 that can be captured economically (as shown in Figure 5). When we increased the CAPEX, liquid solvent DACCS became less favourable, as CAPEX makes up a larger

share of the total cost compared to solid sorbent DACCS technologies. As we decreased the CAPEX, liquid solvent DACCS was still utilised but to a lesser extent than solid sorbent which is integrated to industrial low heat. Although the model includes DACCS options with and without industrial integration (as listed in Table 1), solid sorbent DACCS with integration of waste heat from industrial clusters is the dominant technology. When we decreased the CAPEX, we could increase the amount of captured and stored CO_2 up to 180.4 Mt by 2050. A 50% decrease in CAPEX resulted in a 7% increase in the capacity for CO_2 removal, whereas a 50% increase in CAPEX decreased the CO_2 removal capacity by 21%.

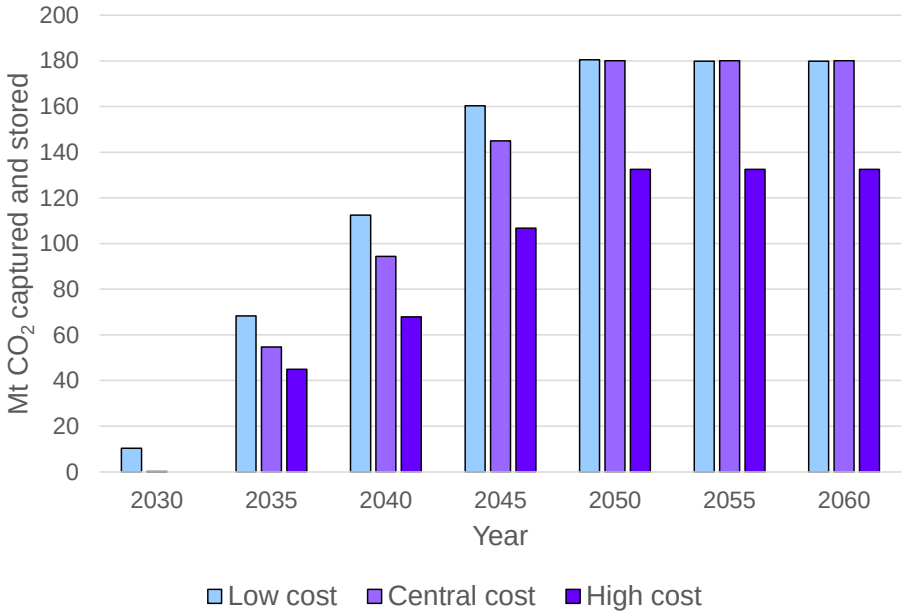

Figure 5. *The impacts of DACCC capital costs on DACCS capacity. The low cost and central scenarios utilise solid sorbent DACC with industrial waste heat integration and liquid solvent electricity powered DACCS. The high-cost scenario only considers the solid sorbent DACCS with industrial cluster integration.*

We have also assessed the overall NETs removal amount based on the range of DACCS CAPEX. A 50% decrease in DACCS CAPEX increases the total NETs removal capacity up to 219 Mt CO_2 by 2055 and 218 Mt CO_2 by 2050 (as shown in Figure 6). This removal capacity is expected to further increase as the BECCS CAPEX also decreases.

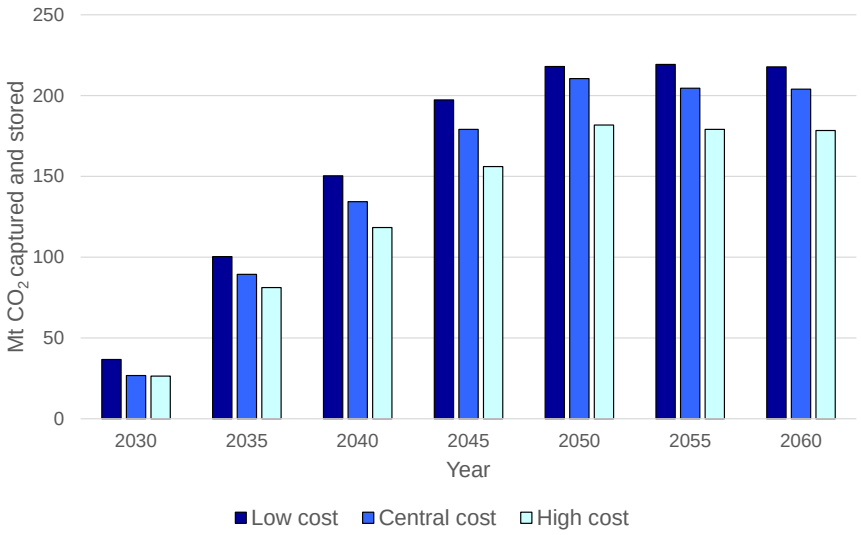

Figure 6. *The impact on DACCS's CAPEX on overall NETs deployment*

4. Conclusion

This study demonstrates the potential of Negative Emissions Technologies (NETs) to help achieve the United Kingdom's net zero ambition by 2050, with a particular focus on Direct Air Carbon Capture and Storage (DACCS) and Bioenergy with Carbon Capture and Storage (BECCS). By integrating additional NETs into industrial clusters and reducing costs, it is possible to significantly increase CO_2 removal amount from the atmosphere. Our findings indicate that solid sorbent DACCS powered by waste heat, ideally industrial low-temperature heat, is the leading DACCS technology. We also discovered that by integrating the solid sorbent DACCS into industrial low heat and reducing the CAPEX of DACCS by 50%, NETs can remove up to 219 Mt CO_2. We anticipate that lowering the CAPEX of BECCS will further increase this removal capacity. Our study underscores the importance of investing in and expanding NETs to combat climate change and achieve a sustainable future. These insights are of great value to policymakers and stakeholders in the UK and beyond.

Abstract:

Hydropower technologies are usually related to low-carbon emissions; however, detail discussion of a different number of environmental concerns is not properly done at the moment especially considering the lifetime phases. There is also a lack of evaluations when comparing with conventional technologies and when comparing with traditional Environmental Impact Assessments (EIA). In this context, this paper explored the environmental impacts using the LCA methodology of a hydropower plant to identify which lifetime phases damage more in health, ecosystems and resource areas of protection. A comparison between the impacts with the grid conventional electricity generation and a comparison with the results of the conventional EIA method are also presented. A database of a cascade hydropower in the tropical region is built using as a case study, the Bolivian project named “Ivirizu” with 290.21 MW of power capacity. Reservoir hydropower plant, campsite and road are analyzed. Data collection considered materials transportation, grave production, construction, maintenance, operation and disposal step. Data was obtained directly from the Governmental energy corporations and Ecoinvent database. Biogenic emissions were determined using the model proposed by Hertwich, 2013. ReCiPe 2016 method was employed to calculate the mid-point and end-points environmental impacts. The construction phase was found to impact most. This phase impacts on the resources depletion by 98.16%. This due to diesel is mainly required during the construction phase. This phase also impacts in 71.17% in human health mainly. The operation has 34.31% of contribution of impacts in ecosystems. This is due to high levels of water consumption during electric generation. The damage on resources is reduced in 63.32 % while hydropower lifetime is increased up to 150 years. Hydropower electricity has more than 79.00% less impacts compared with grid electricity. LCA results could contribute significantly in traditional EIA by providing quantitative information.

1. Introduction

According to International Renewable Energy Agency (IRENA), the electricity generated by renewables was 7468 TWh in the world in 2020, where hydroelectricity represented almost 60.00% of the total [1]. Hydropower is growing up in the last years and some countries like Brazil rely almost entirely on this. However, other countries have not investment in this kind of infrastructure to generate electricity [2]. Global hydropower installed capacity increases in 1.90% in 2021 in comparison to 2020; however, an increase of more than 2% is expected to contribute to the reduction of climate change impacts [3].

Bolivia is a country located in the middle of South America where the base for the electricity generation are thermoelectric centrals. Due to the installation, operation and construction time is lower than for hydropower plants. The natural gas is also subsidized (Cost around 1,3 US$/MPC) representing a problem for the national economy and rapid depletion of gas reservoirs [4]. Bolivia has an Energy Development Plan (PDE) where they proposed the implementation of different alternatives like wind, photovoltaic, and hydropower centrals to cover the energy demand in all the country [5]. According an evaluation made by OLADE, the estimated hydropower potential is 39857 MW, but just the 1.2% was exploited in the country [6]. The majority of this potential are located in Pando, Beni, Tarija, La Paz and part of Cochabamba [7]. The overall effective power capacity at the beginning of 2023 in the country was 3626.27 MW, where 20.24% comes from hydroelectric, 68.17% from thermoelectric, 3.62% from eolic, 1.15% from solar and 3.38% from biomass [8]. Bolivia planned 28 hydroelectric projects, one of them is Ivirizu, located in the tropical region of Cochabamba with 290.21 MW of installed power capacity. This is a hydropower unit in cascade, shaped for two hydropower plants Sehuencas (198.66 MW) and Juntas (91.55MW) [9,10].

Hydroelectric projects bring negative and positive environmental impacts which depends of different variables like, the type of hydroelectric, the materials used during construction among others included the possible socioeconomic local impacts [4].Usually, a hydropower plant is considered a low-carbon option. This represents an attractive option to different governments to cover the electricity demand if they have the potential hydric resources [2]. However, hydropower plants produce greenhouse gases (GHGs) and different emissions to air, water and soil due to different materials, energy, and equipment are employed during the construction and operation stages [11]. Many studies have been focused only on the evaluation of environmental impacts during the electricity generation (i.e. operation phase), in the different types of hydropower plants (reservoir, run of river, and pumped) employing a life cycle assessment; however, the different phases during the lifetime of the plant and a comparison with traditional environmental impact assessment has been rarely done [12].

The life cycle assessment (LCA) is an analytical method to identify the resources flows and different environmental impacts associated with the products and services during their entire lifetime[12,13]. This methodology considers products and technologies from a “cradle to grave”. It can contemplate the raw materials extraction, processing, manufacturing, and use to final disposal [15]. This methodology is one of the most actual tools to carry out environmental impact evaluation and analysis for many process, system and products. This also can help to take decision in organization, industries and governments [16]. It is standardized by ISO 14040 [16–18]

Actually, few LCA studies evaluate hydropower plants focused in a reservoir [11]. In South America most of the analysis are located in Brazil focused on large hydropower plants [18,19]. This current study considers LCA methodology and RECIPE 2016 method applied in Ivirizu project which is a cascade hydropower plant that combines a reservoir and run of river plants. This is located in a tropical region in Bolivia. The main objective to determinate the environmental impacts during 1 KWh electric energy generation and create a detailed life cycle inventory (LCI) with the aim of having the real conditions, inputs and outputs flows. A comparison between the impacts with the grid conventional electricity generation and a comparison with the results of the conventional Environmental Impact Assessment method are also presented.

2. Materials and method

2.1. System description

Ivirizu hydropower project is located in the tropical region of Cochabamba, inside the limits of National Park Carrasco, in Bolivia. The power capacity installed is 290.21 MW. This plant is a cascade model. It is shaped for two plants, Sehuencas (reservoir plant) and Juntas (run of river plant). Figure 1 shows where the different parts of Ivirizu project are planned. The main purpose of this project is to generate electricity and it is still in the construction phase.

Sehuencas is the first plant, it is a reservoir plant with a dam to form a reservoir with a volume of 29.48 Hm^3. The water is transported 5.98 km through a concrete-lined tunnel and reaches a balance chimney with a height of 95.45 m, which balances the air pressure between the plant and the atmosphere. This is connected to a penstock with a length of 1.51 km that leads to the power house, where three hydro turbines, generators, and machines are located. The electricity generated is then transported to a substation. The second run of river plant, Juntas, is located 10 km from Sehuencas and it has an intake structure located in the Ivirizu river. It features elements such as a gravity diversion weir, right bank intake and drain, sediment traps with a flow of 6 m^3/s, a flow regulation float with a capacity of 40000 m^3, and a tunnel intake. To this intake structure also is transported the turbines water from Sehuencas through a discharge canal. The water flow is transported inside a tunnel that it is armored in the final part and then connected to a balance chimney and penstock, which transport the water flow to the power house where two Francis turbines are located. Both power plants have a substation where the electric generation tension of 11.50 kV is increased to the transport tension of 230 kV before being transported to Mizque substation and then to the International System Transmission [9]. The technical details of the Ivirizu hydropower plant are listed in Table 1.

Table 1. Description of Ivirizu Hydropower plant

Characteristics	UN	Sehuencas	Juntas
Installed Capacity	MW	198.66	91.55
Type of Plant		Reservoir	Run-of-river
Turbines	UN	3	2
Type of turbine		Pelton	Francis
Annual Power Production	GWh	805.29	355.6
Design flow rate	m^3/s	26.50	32.50
Heigh	m.a.s.l	1340	1009
Water head	m	843	326

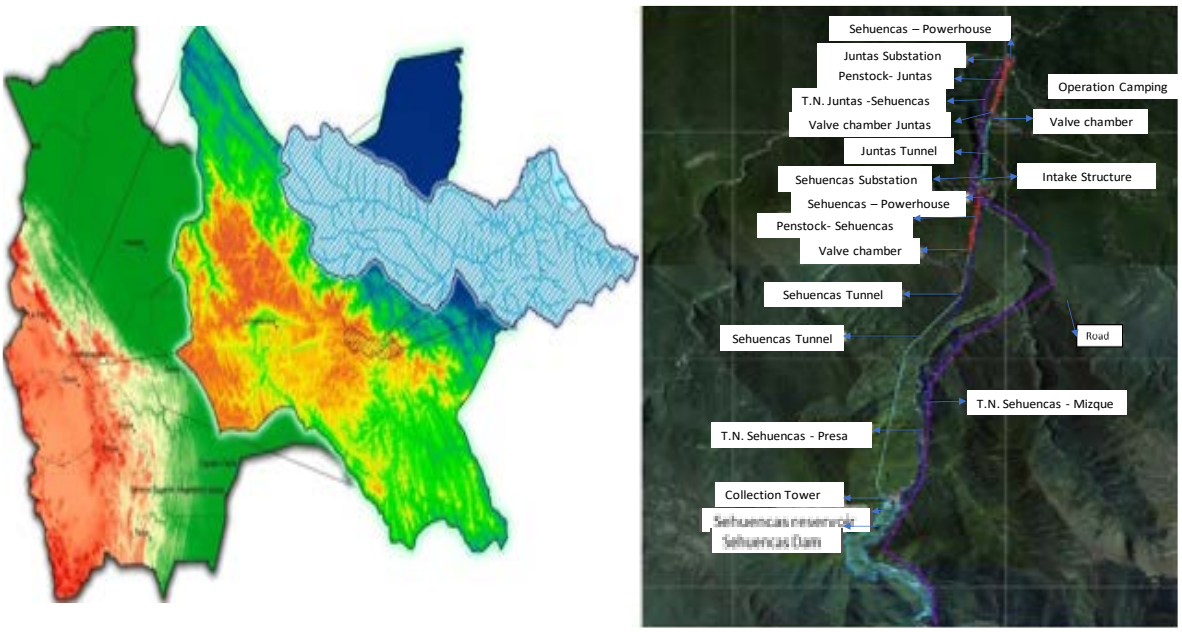

Figure. 1. Geographical location of Ivirizu hydropower plant in Bolivia [9]

2.2. Goal and scope definition

The primary objective of the study was to assess the environmental impacts associated with the generation of 1 KWh of electric energy in a hydropower plant located in Bolivia, using a cradle-to-grave approach and Life Cycle Assessment (LCA) methodology in accordance with ISO 14040 guidelines [18]. This research also aims to create a comprehensive life cycle inventory data, considering all the materials, equipment, transportation, and energy used throughout the entire life cycle. The emissions generated because of decomposition of biomass in the flooded area were also analyzed. All these factors were calculated based on 1 KWh generated defined as the functional unit.

2.3. System boundaries

The overall system boundary is presented in Figure 2. The system boundary includes five phases: construction (buildings, camp, equipment installation, gravel and sad extraction, roads and transmission network), operation, maintenance, transportation and disposal step. The preconstruction activities like deforestation for infrastructure development, materials, energy use from land preparation, materials extraction were part of the construction phase. Operation covers energy and materials require in this step, the emission caused for the biomass decomposition was also determined. The maintenance phase covered the materials throughout the lifespan of the hydroelectric plant. The lifespan of this plant is 50 years according to ENDE Corporation [9]. For the disposal phase was just considered the transport of recyclable materials, equipment and waste to a treatment place.

2.4. Life cycle Inventory Analysis (LCI)

The life cycle inventory (LCI) collect physical information of input and output flows such resources, materials, semi-products, products and the output of emissions [20]. Two kind of data are usually considered; one is the information obtained from the companies that design the plants. The second one is data acquired from different international database and adapted to study case like Ecoinvent [13]. In this study, the inventory considers both type of data and it is described for the five steps to generate 1 KWh of electric energy. Assumptions and limitations are described for each step and all data is presented in Table 2.

Construction: This phase includes the building work, equipment installation, road and camping building. Land preparation using explosives, raw material extraction in the place were considered in this stage. The building work contemplated the dam, penstock, powerhouse, balance chimney, substation, transmission network, waterway canal, etc. of both plants that make up Ivirizu. A diesel generator was considered to provide the required electricity for the equipment used in the construction zones. Ecoinvent data was considered for the diesel generator inventory. Different equipment and components used such generators, turbines, bridge crane, dampers, valves, etc. were discomposed in materials such steel. The description of each building works, materials, electromechanical and hydromechanical equipment were obtained from the final design study of Ivirizu, proportioned for ENDE Corporation.

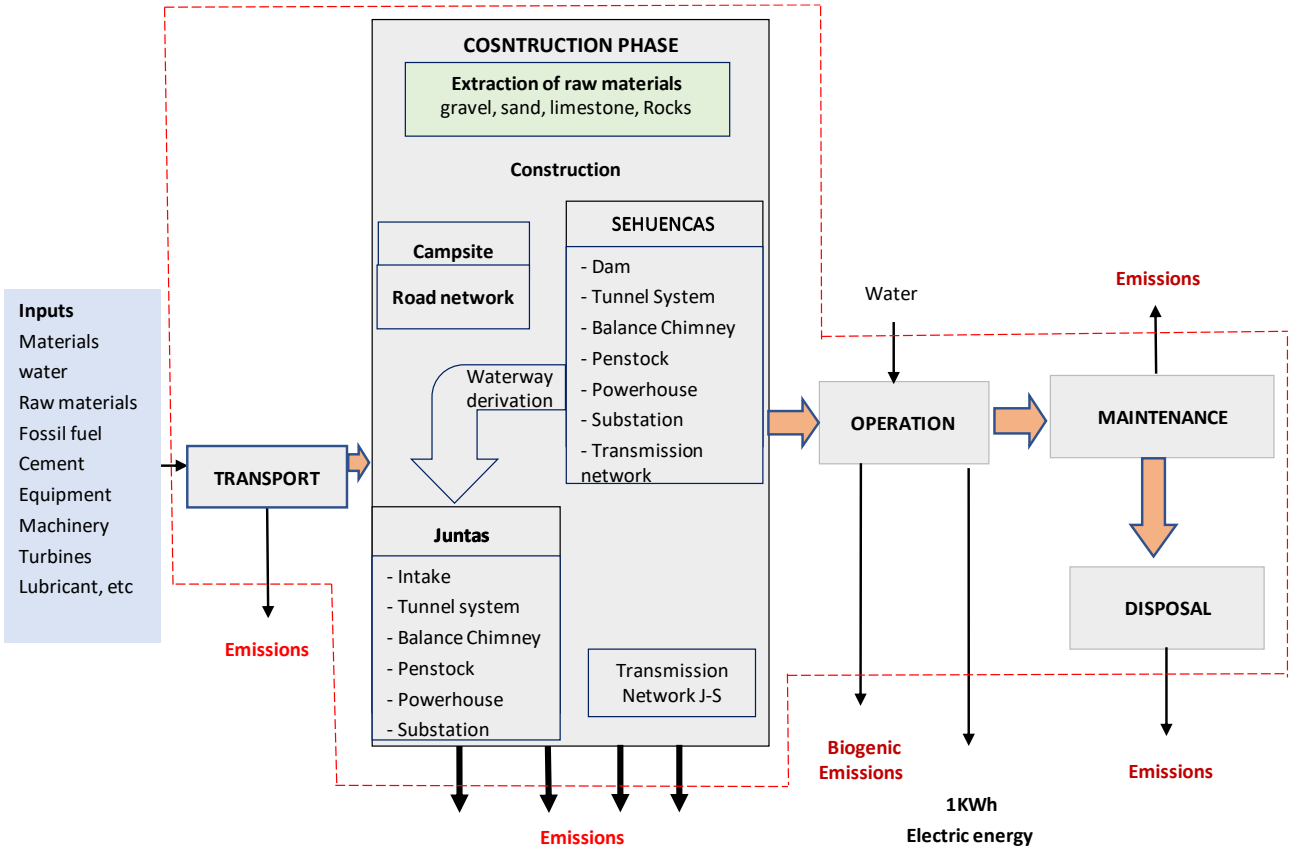

Figure. 2. System boundaries

Operation: This step requires just water flows for electricity generation; the value was achieved from the final design of Ivirizu project proportioned by ENDE corporation. The biogenic emission that are generate due to the degradation of biogenic carbon in reservoirs was included. This is produced by oxidation of organic carbon from biomass, organic carbon matter in soil, or sediments [21]. These were estimated using the methodology presented by Hertwich [21] in the Eq. (1), this model calculates biogenic carbon dioxide and methane emission per 1 kWh.

$$log\ E = const + B_{Land\ use} \times log(Land\ use) + B_{Age} \times Age + B_{NPP} \times log\ (NPP) \quad (1)$$

Where E represents the emission estimated (CO_2 or CH_4), land use is referring to reservoir flooded area, age is the reservoir lifetime, NPP is the net primary production. Const, $B_{Land\ use}$, B_{Age}, and B_{NPP} are constants for CO_2 an CH_4 described in [21]. The age is 50 years, and land use is 8.67E-4 m^2 calculated for 1 kWh. Both data were obtained from Ivirizu final project. NPP is 40000 gC/m2y, employed by Villarroel et.al map [22]

Maintenance: The lubricant oil necessary to perform a good operation for the equipment was considered. The replacement of turbines or generators was not included. The life time for this equipment were assumed to be the same as the hydropower plant. The lubricant data for this step was used from Ecoinvent.

Disposal: This step refers to the recollection of waste mineral oil and the transport to a treatment place, which is considered in this case to be Cochabamba city. After the lifetime of hydropower plant, the infrastructure is assumed to be abandoned but after the siltation of the lake and the dams. The adit systems will not be transported or demolished. The disposal of gravel, cement and reinforced steel were assumed from Ecoinvent data.

Transportation: This includes the transport of different materials used during the construction, maintenance, disposal and the transport of equipment to the plant site considered a freight lorry. The international transportation was not considered because this information is not available and therefore all the materials were assumed that were located in Cochabamba city, at the distance of 140 km. The transport process was employed from Ecoinvent database.

2.4. Life cycle Impact assessment (LCIA)

In this step the purpose was to quantify the environmental impacts of all inventory data recovering in the LCI [16] using the RECIPE 2016 method that evaluates 18 midpoints and 3 endpoint levels [23]. Characterization factors at the midpoint level are located somewhere along the cause-impact pathway, usually at the point after which the environmental mechanism is identical for each environmental flow assigned to that impact category.

The endpoint level reflect damage at one of three areas of protection which are human health, ecosystem quality and resource scarcity [24]. The computation of the environmental impacts was done in the SimaPro Version 9.4.0.2 software [25].

Table 2. LCI data for Ivirizu hydropower plant on 1 kWh of electricity for 50 years lifetime

Variable	Unit	Sehuencas	Juntas	Ivirizu	Total per 1 KWh
Construction					
Volume occupied, reservoir	m3	2.95E+05		2.95E+05	5.08E-04

3. Results and discussion

3.1. Life Cycle Interpretation

This is the last stage of LCA, where results are summarized and discussed according to ISO 14043 [26].

- Midpoints impacts

The average midpoint impact contribution of life cycle phases of Ivirizu hydropower plant is presented in Figure 3. The construction was the mayor contributor on seventeen environmental impacts with more than 98% in each one. This was due to the use of different materials required like diesel for electric generation, for the machinery used and for the raw material extraction.

The operation step had 99.73% of contribution in the water consumption equivalent to 2.03 E-02 m^3 per 1 KWh. The construction step just increased the water consumption in 5.42E-05 m^3 per 1 KWh. The construction phase contributed with 98.00% to the global warming and the operation phase with 0.97%. Those are due to the diesel used for machinery and for the electricity generation in the construction step and the biogenic emission during the operation step. The value of CO_2 in the global warming midpoint impact is similar to other hydroelectric plants quantification [27]

The mayor impacts in the maintenance phase were the Ionizing radiation and Fossil resource scarcity due to amount of the lubricant use in different equipment. For the transportation step, the mayor impact was the terrestrial ecotoxicity because of diesel employed during material transportation. The disposal was the step with the minor impact contribution, because it is just the recollection of materials to a treatment place.

Comparing the results with other authors in [11,28,13,29] construction phase was the mayor contributor to the environmental impacts and the second one was the operation even considering than in those studies the lifetime was among 50 to 100 years. Ecoinvent database for all hydropower plants assume 150 years of lifetime. Therefore, a sensitivity analysis for different lifetime years is presented below.

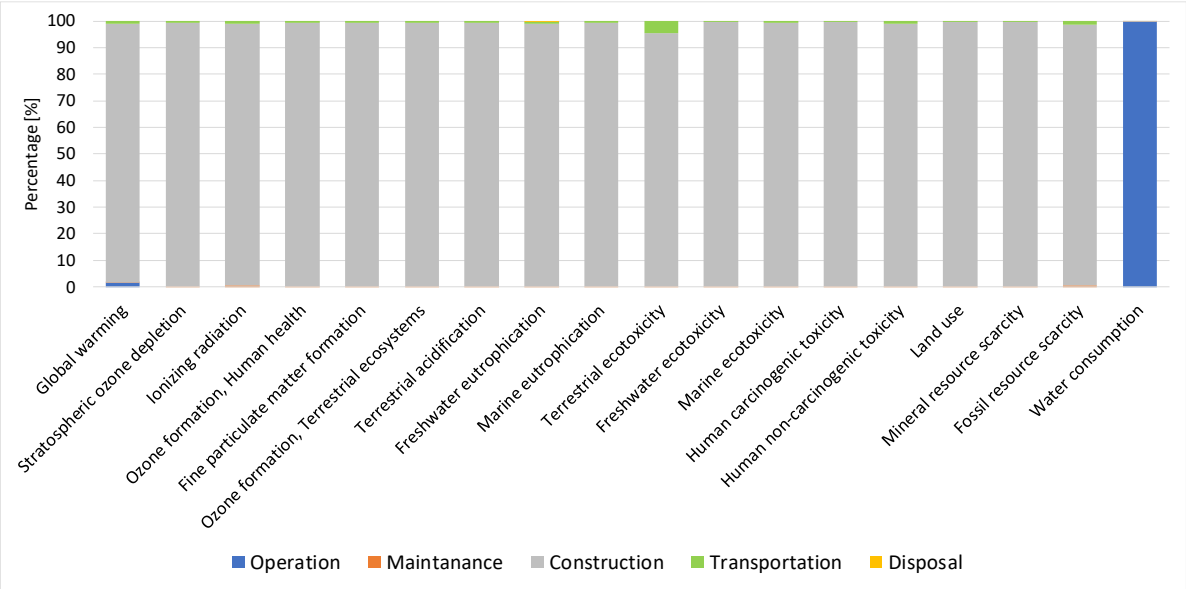

Figure. 3. Midpoints impacts results of 1 kWh hydropower electricity in Ivirizu

- Endpoint impacts

The endpoint results are presented in the Figure 4. The construction and operation phases had mayor damage in human health with 71.17% and 28.28%, respectively. The first one increased de problems in respiratory diseases and different kind of cancer with 2.81E-08 DALY due to the type of materials employed. The operation increased human health damage in 1.11E-08 DALY due to the biogenic emissions which change the water characteristics.

The damage in the ecosystems was 65.10% for the construction phase and 34.31 % for operation phase, this last was equal to 3.13E-11 species.yr induce for the water use and biogenic emission origins damage the freshwater, terrestrial and marine species during the electricity generation.

The construction phase had the mayor contribution in damage to resources availability with 98.16%. This increases the cost in mineral extraction, oil, gas, coal and energy in 8.52E-04 USD2 013 due to this phase uses many and different materials including the raw materials extraction.

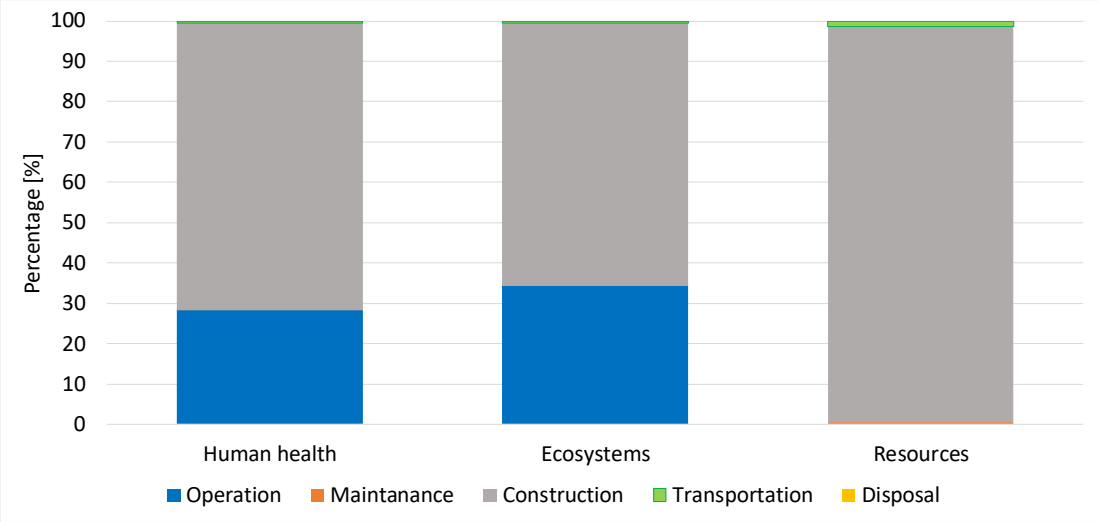

Figure. 4. Endpoints impacts results of 1 kWh in Ivirizu

- Construction

The results presented before shows that the construction phase had mayor impacts during the electricity generation. Due to the large amount and type of materials used and building process. Figure 5 presents the midpoints impacts for construction steps and materials. The mayor impacts were produced for diesel employed to generate electricity to satisfy the demand during the construction phase where Stratospheric ozone depletion had 1.51E+02 kgCFC11eq, Ozone formation Human health had 2.46E+06kgNOx eq and Ozone Formation Terrestrial ecosystems had 2.48E+06 kgNOxeq. The first two increases the damage to human health and the last one increases the damage in ecosystems in 36.57% and 37.74 %, respectively. But, the mayor effect was presented in the damage to resources which increases the cost in 43.15% during the 50 years because of minerals and fossil scarcity.

Water consumption impact increased more due to grave use; this was because the raw materials extraction was considered to be in the same place.

The impacts due to fabrication had more impact in the land use with a 7.31E+7 m^2a crop eq, this is due to activities the construction area.

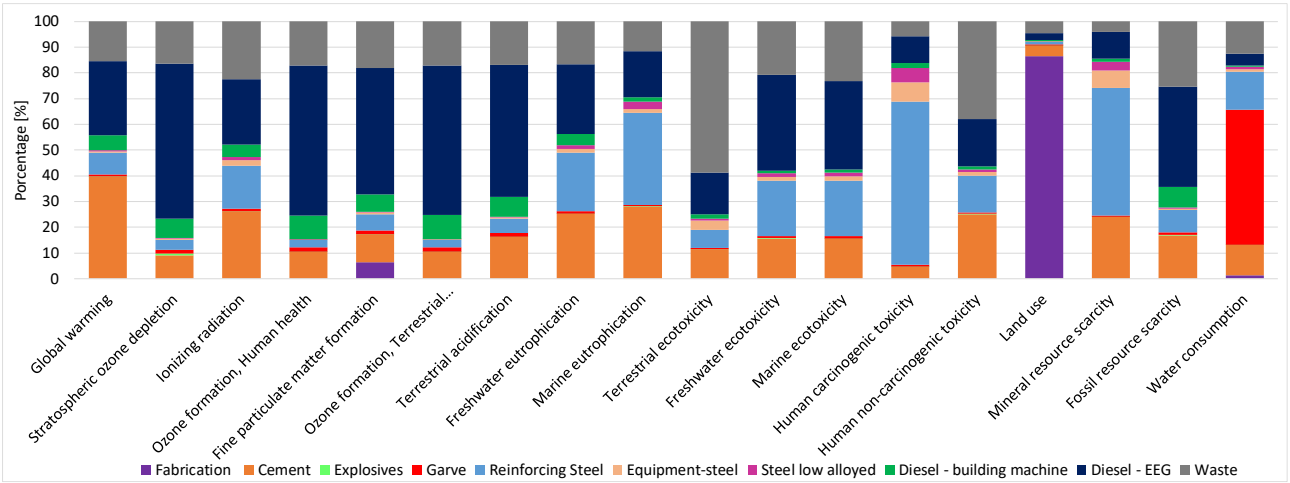

Figure. 5. Midpoints impacts results for Ivirizu hydropower plant construction

3.2. Sensitivity analysis

- Hydropower Lifetime

According the final design of Ivirizu project, the lifetime is 50 years. This value in Ecoinvent database for different hydropower is 150 years and other studies consider 100 years. It depends of each hydropower plant information. Therefore, the endpoint impacts for different lifetimes were evaluated. The results presented in Figure 6 show the decrease of environmental impacts with a mayor lifetime. The mayor reduction in comparison with the 50 years lifetime was for the damage to resources in 37.30%, 49.74% and 66.32 % in comparison to the lifetimes of 80, 100 and 150 years, respectively. For damage to human health and ecosystems, the decrease for the lifetime of 150 years is 55.59% and 54.23%, respectively. These results

show that environmental impacts for the electricity generation in the hydropower plants can be reduced when the lifetime is increased due to the impacts are distributed during these years.

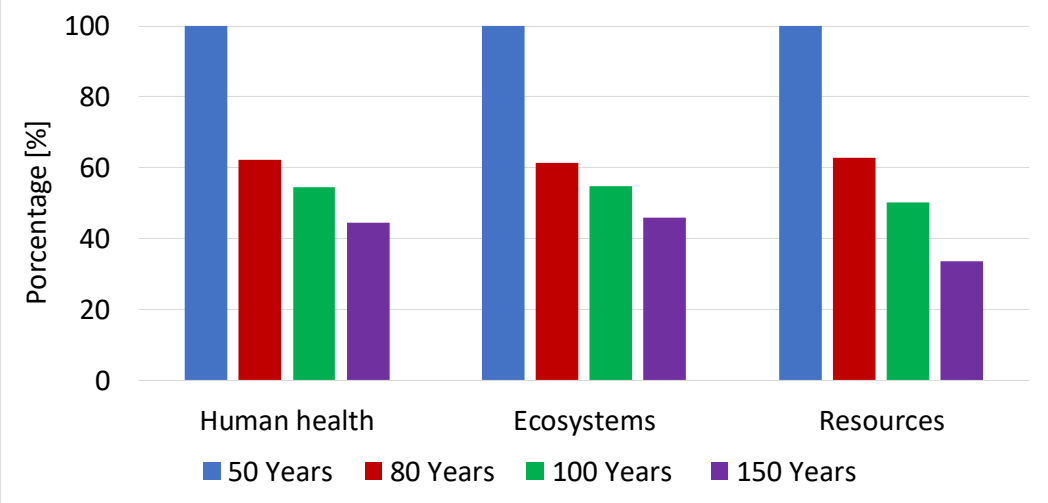

Figure. 6. Endpoint impacts 50, 80,100 and 150 years of lifetime

3.3. Comparison between hydroelectricity Vs Grid electricity generation

The electricity generated in Ivirizu during the operation phase is compared with the conventional grid electricity options in this section. Ecoinvent database for a conventional natural gas and an oil-based power plants were used. The results presented in Figure 7 shows the environmental impacts for 1 KWh. In most of the midpoint impacts, natural gas and oil power plants were higher than the hydropower plant but the water consumption. This is due to water was the principal flow inside the hydropower plant for the electricity generation.

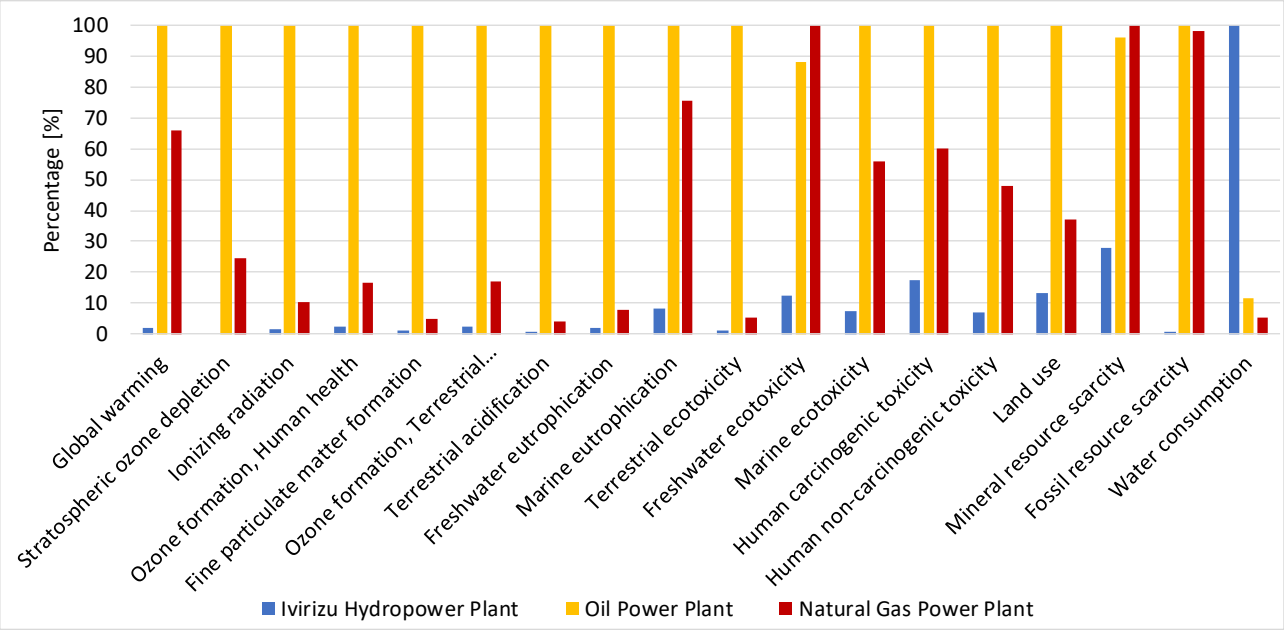

Figure. 7. Comparation between Hydroelectricity vs grid electricity generation

3.4. LCA vs EIA

The results of the traditional environmental impact assessment (EIA) of Ivirizu and the LCA performed in this study were analyzed in this section. The EIA of Ivirizu hydropower plant project includes the identification and assessment of the foreseeable effects on the socio-environmental aspects inventoried in the baseline, taking the area of influence as a reference [30]. Table 3 presents the results of the EIA where the environmental importance is describing according to the following scale:

- Less than 25 are **irrelevant or compatible** with the environment.
- Between 25 and 50 are **moderate** impacts.
- Between 50 and 75 are **severe**.

- More than 75 are **critical.**

According the results show in Table 3, the EIA considers four steps: 1) construction, 2) operation and maintenance, 3) abandon and 4) induced future. Where the construction and abandon step have several impacts in terrestrial flora, fauna, and ecosystems. LCA considers also the same steps except the induced future.

Table 3. Ivirizu Environmental Impact Assessment (EIA)

Environment	Attributes	Construction	Operation and maintenance	Abandon	Induced Future
PHYSICAL	Particulate Matter	32	22	32	24
	Combustion gases	26	20	26	24
	Noise	25	38	25	24
	Erosion	36	24		
	Instability of slopes	32			
	Soil contamination	37	32	37	
	Compaction	34	24	34	23
	Change in morphology	23	24		
	Sedimentation	23	24		
	Flow rate variation	30	39	30	
	Surface water quality	32		32	
BIOLOGICAL	Loss of vegetation cover	35			
	Aquatic flora	36	36	36	
	Terrestrial flora	66		48	20
	Birds	26	25		
	Terrestrial fauna	58	28	58	20
	Aquatic fauna	48	46	48	20
	Ecosystems and landscape	66	32	42	
SOCIO-ECONOMIC	Affectation of public and private properties	18			
	Health and safety (population)	33	20	24	
	Industrial Safety and Occupational Health	33	30	33	22
	Current land use	47			
	Job creation	32		32	25
	Tourism and recreation potential	19			28
	Archeology and cultural heritage	32	21	32	
	Improvement of the local economy	26	24		

Table 4 presents an identification of the major impacts using both methodologies. By applying EIA, several impacts on terrestrial flora, fauna and ecosystem in the construction step were identified to impact with more than 50 points. Those were related to have more impact on the biological environment. While by applying a LCA, the mayor damage was on human health; where 51.42% was due to contribution of global warming and 31.64% was due to contribution of fine particulate matter formation. But, when comparing the results of both methodologies, the particulate matter formation had a moderate punctuation in the EIA, this impact, according to the quantitative data provided by the LCA, should have a severe punctuation because in one of the mayor contributors. The damage on the resources due to fuel scarcity that can increase the cost in 98.12 % of the fuels and it is significant but this aspect is not evaluated in the EIA. The damage on ecosystems were 55.34% for global warming that affect the terrestrial ecosystem. This impact had also a severe punctuation in the EIA. The operation and maintenance step according to the EIA had severe impacts in aquatic fauna. While for LCA shows a mayor damage on ecosystems due to water consumption and global warming impacts. Those are related with EIA because of the impact on the water have effects on the aquatic fauna. The Abandon step according EIA have severe impacts on terrestrial fauna but according to the LCA, this step contributes less to the impacts and trigger more impact in the damage to resources. In this step, LCA analysis is considered as the recollection of materials to the treatment place and EIA considers the demolition of the central.

EIA considers social and economic variables like neighborhood disturbances or economic benefits which are very important for the public acceptability of projects [31]. But, it is limited for the objectives or the study. Global impacts are not considered during the evaluation while LCA considers that [32] EIA also presents qualitative results that depends on the judgment of an expertise while LCA not [31] Both methodologies can be complementary tools [32,33] and provide more information for decision making.

Table 4. EIA and LCA results comparison

Phases	EIA Identification of main local pressures/concerns (qualitative):	LCA Quantification of the impacts
Construction	Terrestrial quality Impacts on flora, fauna, ecosystems and landscape	- Climate change - Fine particulate matter formation - Fossil resource scarcity
Operation and maintenance	Impact Aquatic fauna	- Water consumption - Global warming - Fossil resource scarcity
Abandon	Terrestrial fauna	- Global warming - Fossil resource scarcity - Fine particulate matter formation

4. Conclusion

The LCA presented in this study, demonstrated that the construction phase of a hydropower plant has the largest impact in most of the mid-point environmental indicators. The contribution to global warming was, for this phase, of around 98% while for the operation phase was 0.97%. Fine particulate matter formation, water consumption and global warming are the main impact categories contributing the largest to human health damage. The last two of the midpoint indicators mentioned are also the mayor providers in the damage on ecosystems. Fossil resource scarcity is the mayor contributor in the damage on resources due to the large amount of diesel requirements in the construction step. The environmental impacts of the hydropower plant case decreases with a mayor lifetime. The damage on resources decreases of about 66.32 % when considering a lifetime of 150 years compared with 50 years showing that for this stage the impacts are distributed along the lifetime. The damage in human health and ecosystems reduce in 55.59% and 54.23%, respectively, for the same comparison of lifetime years. The impacts when comparing a hydropower plant with conventional fossil fuels plants are decreased in all the categories but the water consumption due being used for the electricity generation. The use of LCA as a complementary tool for traditional environmental assessment could provide quantitative relevant data.

Acknowledgments

This project is part of Integrated Monitoring of Biodiversity and the Impact of Hydroelectric Megaprojects (MIBIO) program, Project UNIBONN-UCB-UMSS. The authors thank ENDE corporation for sharing the EIA, project description and data for Ivirizu Hydroelectric power plant.

Abstract:

This work presents a tool for developing competencies in sustainability, focusing on evaluating the environmental impact and carbon footprint in schools. The tool is based on sustainability indicators and follows a methodology derived from the ClimAct and ECF4CLIM projects. It is conceived as a support for the users and the schools to identify and evaluate the relative impact of different actions and measures, to engage them in a sustainable pathway to low-carbon schools supporting their decision-making at the different levels of users. The areas are transport, waste, green procurement, green spaces, energy, water, and indoor air quality. The tool aims to support users and schools in identifying and evaluating the impact of various actions and measures, facilitating decision-making for a sustainable and low-carbon school environment. To quantify sustainability performance, Key Performance Indicators (KPIs) have been established for each area. The results from schools that tested the tool revealed low scores in green procurement (0.59/5) and water (2.03/5), while achieving higher scores in green spaces (3.46/5) and indoor air quality (3.92/5). These findings highlight the areas where improvement is needed and provide a basis for targeted interventions. Developed on the PowerApps platform, supported by Microsoft, the tool allows access to users of different ages and knowledge levels. It has been successfully tested in six schools in Andalusia, Spain, obtaining relevant results in the seven sustainable areas defined. Based on the results, this tool will be used within co-creation and co-implementation processes for more sustainable schools and competencies acquisition by the participants.

Keywords:

Methodology; Sustainability; Carbon footprint; low-carbon schools; KPI; PowerApps

1. Introduction

Innovation in sustainable education is a critical issue to consider for the formation of present and future generations. Developing tools that facilitate acquiring sustainable skills is fundamental to achieving these objectives. The development and promotion of sustainability education have become one of the key challenges to be addressed within European society, especially in the wake of the Paris Agreement [1], which recurrently calls for a society that lives and works in a sustainable way. The measures and policies were developed to enhance society's development to promote a low-carbon economy. To this end, programs have been developed ranging from the countries involved in the agreement to measures that affect the entire European community. The incentivization of programs that allow society to develop sustainably is a priority to achieve the objectives set out in the Paris Agreement. Programs such as Horizon 2020, promoted by the European Union [2], have encouraged the promotion of activities that favor sustainable development, seeking to strengthen the relationship between science and society by encouraging, among other things, the participation of civil society [3].

Considering the importance of developing sustainability competencies, the value of education as a fundamental tool to achieve the proposed objectives is emphasized. Developing sustainability competencies

in schools is one of the main ways to promote a low-carbon society. Considering that, in areas such as southern European Mediterranean countries, more than half of the buildings used for school use predate 1990 [4], and taking into account the social situation surrounding schools, there are opportunities to design strategies to trigger action in schools. In order to assess the adequacy of knowledge and skills transfer to schools, it is necessary to design indicators through which sustainability parameters can be determined [5]. To this end, within the framework explained above, projects such as ClimAct [5] have been developed, where a methodology has been implemented for the development of sustainability competencies that have been evaluated by measuring a series of indicators, applied in different schools in Spain, Portugal, France, and Gibraltar. The application of a methodology for monitoring and ensuring adequate knowledge acquisition and monitoring progress through indicators is a key tool for developing sustainability competencies in educational communities [6].

Taking into account the need to apply methodologies in schools to create a sustainable society, and taking advantage of the impetus offered by European projects such as ECF4CLIM - A European Competence Framework for a Low Carbon Economy and Sustainability Through Education, the use of computer applications was proposed with the aim of facilitating the transmission of knowledge and the application of methodologies to support sustainability, which is capable of providing support and content at all possible educational levels, from the beginning of the educational process to the higher stages [7]. The use of platforms developed by Microsoft for the development of multi-platform applications makes it possible to create tools that meet the proposed needs [8]. Combining the determination of performance indicators as well as the use of these results as support material for education, a tool has been designed within the PowerApps environment from Microsoft [9]. The purpose of the application developed is to allow the centres to self-audit their sustainability level and opportunities for improving it within their circumstances. The goal of this work it's to develop and validate a tool for improving the competences in sustainablity in schools, reducing at the same time the carbon fotprint due to the institution diary activity, using for this purpose, a testing process executed in six andalusian schools. The application is conceived to be used at all educational levels with different access levels. The tool allows for assessing the impact of the different actions. Combining the use of the methodology and the creation of the platform developed, we bring to schools a novel tool for identifying and developing sustainable competencies in students, supported by a friendly interface. As a consequence, the co-creation and co-implementation by the students, teachers and managers are expected to allow the acquisition of individual and global competencies in sustainability during the process. [6] The structure of the paper is the following. First, the methodology for sustainability skills acquisition is described. Then the structure of the tools is presented. Follows the application case to 7 seven schools in Andalusia. Finally, the main results of the application case and discussion are presented.

2. Methodology

The tool covers a wide range of sustainability aspects divided into seven areas. KPI behaviour indicators are defined for each area based on the specific school data (such as, for example, the number of students or area covered). These areas are [6]: *Transport, Energy, Water, Garbage, Indoor Air Quality (IAQ), Green Spaces and Green Supply.* The KPIs values provide a quantitative evaluation of different sustainability branches related to the school. It allows the analysis of discussion about the potential actions for improving them, if possible, and their implications. The methodology looks for analysis and debate about the sustainability areas to be improved and the evaluation and proposal of specific actions. The KPIs quantify the impact and provide a reference for assessing the departing point and evolution and the situation compared with other schools to identify the real range of the indicators and their adjustment. Once a roadmap with specific measures is defined, the centres will apply the appropriate actions. After their implementation, the results of the indicators will be reviewed again, being able to identify changes. Throughout this process, all the participants will develop sustainability skills. In addition to skills in sustainability, skills will be developed and acquired around the realisation of small-scale projects, which will allow for marking the objectives of the measure and identifying necessary resources.

2.1. ECF4CLIM Sustainability indicators

Behavioural indicators (KPIs) as support for decision-making is a common practice that aims to carry out actions more efficiently or sustainably. The study carried out and modelled in the PowerApps application is based on sustainability indicators whose concept was defined within the ClimAct project [5]. In total, 27 scores were defined, evaluating aspects related to 7 areas of sustainability. The areas of sustainability for this project are Water, Energy, Transport, Green Procurement, Green Areas, Garbage, and Indoor Air Quality. 34 KPIs distributed in the aforementioned sustainability areas were defined to calculate the scores. Table ***2*** breaks down the definition of the indicators used. Their calculation provides a normalised score in the range between 0 and 5.

2.2. Development of sustainability competencies

A five-step methodology has been developed to acquire capacities in sustainability by the educational community effectively. Sustainability indicators support the process, providing quantitative values for assessing the impact of the different steps and to guide the participants. For the correct execution of the steps, different groups of students will work as a team, carry out the audits, propose and implement measures, evaluate the departing and final situations, and evaluate the impact of the actions. The steps for the application of the methodology are as follows:

1. Determination of the initial situation: The methodology starts with evaluating the departing situation through auditing the centre based on the defined sustainability areas. Templates and forms are provided to guide the data collection process, providing an explanation of the different aspects related to the data collected. Different working groups will focus on specific areas collaborating to cover the whole set.
2. Evaluation of the initial situation: Audit results are analysed and evaluated by the groups, either jointly or separately, identifying those aspects in which the school has the potential to improve. The working groups validate the results and discuss the improvement capacity in relation to the current situation of the school.
3. Co-design of measures to improve sustainability: After completing previous steps 1 and 2, the working groups interact with the rest of the scholar community (students, teachers, administrative) to generate a list of possible measures to implement in the centre. From that list, measures are proposed and selected. The working group develops a specific implementation project for each action, defining the activities, schedule, milestones, resources and expected impacts. The selection includes the evaluation of their feasibility by the management of the centre.
4. Co-implementation of approved measures: The working groups execute the selected projects. Tasks are distributed as a function of the educational level of the participants with external support.
5. Determination of the impact of the measures implemented: The impact of the implemented measure is evaluated. In this phase, the cycle will be closed, returning to the initial phase through the completion of the audit.

The implementation of the methodology promotes the acquisition of competencies in sustainability by the students and staff participating. They evaluate, measure, analyse, discuss, propose and execute different aspects of sustainability in the centre. It generates individual and collective competencies in each stage.

3.3 Key Performance Indicators

The impact of the measures through the analyses is identified using indicators to take decisions. The Sustainability Key Performance Indicators used are defined in the table shown below:

Table 1. Definition of KPIs used.

Sustainable area	Environmental pillars	Key Performance Indicators
Transport	Car park	KPI-T1. No. of parking spaces for electric cars at school or periphery per student (up to a 100m radius)
Transport	Car park	KPI-T2. No. of parking spaces for bicycles at school or periphery per student (up to a 100m radius)
Transport	Public transport network	KPI-T3. No. of public transports passing daily per hour (1000 m radius)
Transport	CO2 emissions	KPI-T4. Annual CO2 Emissions per student (kgCO2/student)
Green procurement	Equipment efficiency	KPI-GP1. No. of equipment A+ or higher EU Energy Label per total no. of equipment
Green procurement	Paper usage	KPI-GP2. Annual paper usage in school per student (kg/student)
Green procurement	Paper usage	KPI-GP3. Recycled paper usage in school (kg recycled /kg consumed)
Green procurement	Training in green procurement	KPI-GP4. No. of staff with training in green procurement per total no. of staff
Green procurement	Organic food	KPI-GP6. Food with biological certificate (kg food with biological certificate/kg total food)
Green procurement	Suppliers	KPI-GP7. Local suppliers (No. local suppliers /total suppliers)
Green spaces	Green areas	KPI-GS1. Number of trees per non-covered area (m2)
Green spaces	Green areas	KPI-GS2. Number of trees per student (student1)
Green spaces	Green areas	KPI-GS3. Green area per non-covered area (%)
Green spaces	Green areas	KPI-GS4. Green area per student (m2/ student1)

Green spaces	CO2 sequestration	KPI-GS5. Annual CO 2 sank per non-covered area (kgCO 2/m2)
Green spaces	Use of chemicals	KPI-GS6. Total kg of chemicals used for green area maintenance (kg/m2)
Green spaces	CO2 emissions in maintenance	KPI-GS7. Annual CO 2 emissions for the space maintenance of non-covered area (kgCO 2/year.m2))
Energy	Energy consumption	KPI-E1. Annual final energy consumption per area (kWh/m2)
Energy	Energy consumption	KPI-E2. Annual final energy consumption per student (kWh/student)
Energy	Use of renewable energy	KPI-E3. Renewable energy production (%)
Energy	Energy cost	KPI-E4. Annual energy cost per m 2 (€/m2)
Energy	Energy cost	KPI-E5. Annual energy cost per student (€/student)
Energy	CO2 emissions	KPI-E6. Annual carbon footprint per student (kgCO2/student)
Water	Water consumption	KPI-H2O1. Water consumption (m3/m2)
Water		KPI-H2O2. Water consumption (m3/student)
Water	Water cost	KPI-H2O3. Water cost (€/m2)
Water		KPI-H2O4. Water cost (€/student)
Waste	Waste produced	KPI-W1. Volume of waste produced (non-recyclables and reusables (m3/student)
Waste	Waste recycled	KPI-W2. Volume of waste recycled (m3/student)
Waste	Waste reused	KPI-W3. Volume of waste reused (m3/student)

The combination of each indicator in each sustainable area, gives a result between 0 and 5. A tool for their evaluation, analyses and discussion has been developed to support the process [5]. Main characteristics are described in the next section.

3. Sustainability KPIs Tool

This section describes the tool developed to support the methdology in the schools.

3.1. Platform description

The tool has been developed based on the combination of two Microsoft solutions, PowerApps and Power Automate[10], tools designed to support the creation of applications. Both applications were framed in an environment created in Azure [11], where user management and license assignment were carried out [12]. On the other hand, database management was carried out for the calculations of indicators and monitoring of the studies from the SharePoint platform [13]. The interaction within the platform is described in the scheme of Figure 1:

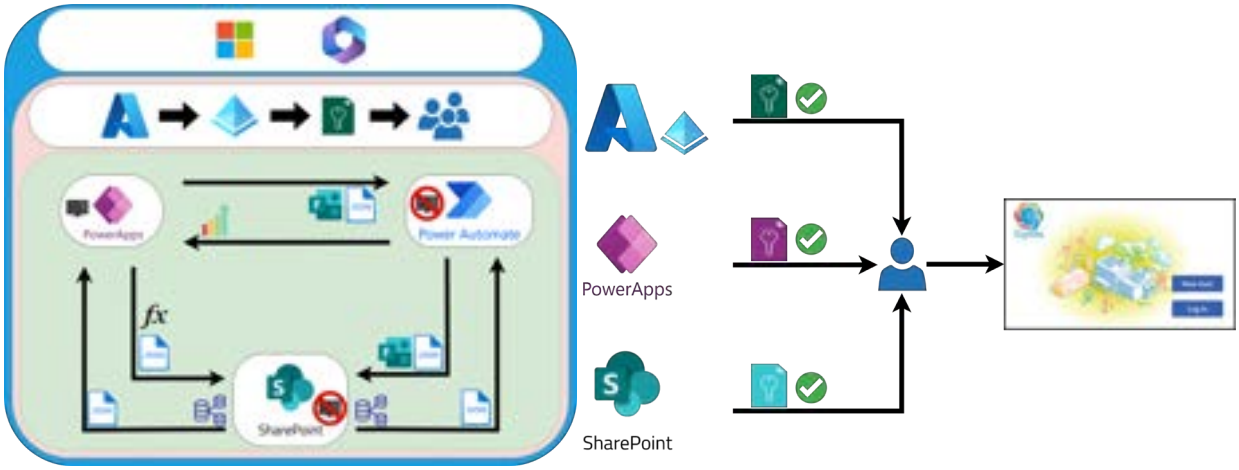

Figure 1.- Application situation diagram.

The use of Azure allowed the management of users, licenses and permissions. Different access levels are provided as function of the user's profile. From the user's point of view, authentication is done with the Microsoft user [14], which contains all the requirements that are requested for access.

3.2 Sustainability areas

For each of the seven sustainability areas, the application works independently. Their specific information is introduced into the study gradually. The data submenus include the possibility to edit or delete the information

entered. School's codes are used to define common characteristics for different studies or users(i.e. buildings parameters). Data introduction and navegation process are explained in the next schema:

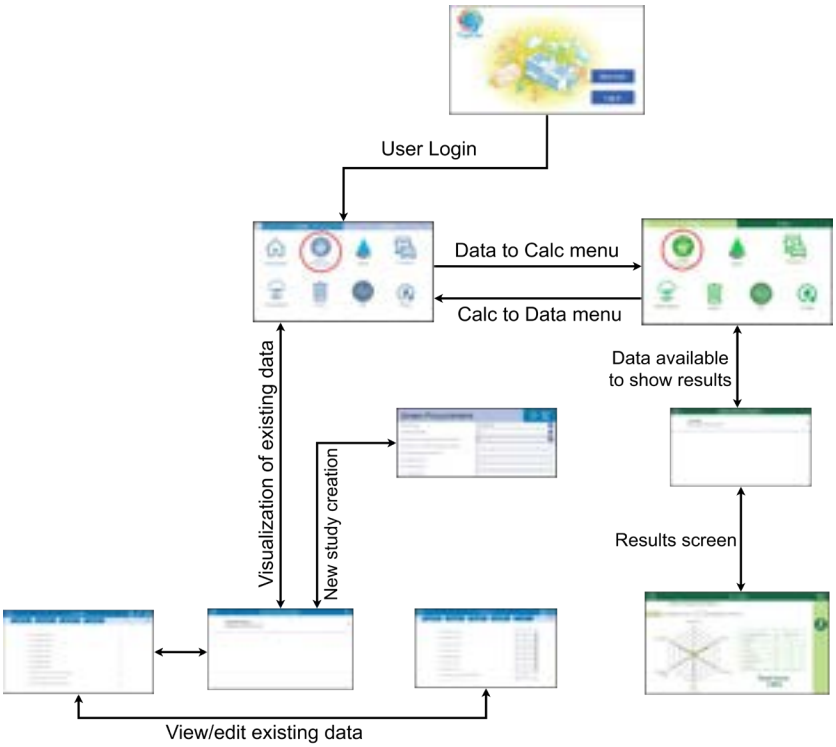

Figure. 2. Navigation scheme of the application.

The application is divided between the data collection part and the sample of results through colours (Blue – data menu; Green – calculations menu). The operation of the application is the same in all areas of sustainability. After login into the application, school study cases are available. The Data menu, blue theme, shows the data introduction menus for the sustainability area to study. For the chosen sustainability area there is a gallery with the created studies (if there are any). New studies are created by pressing the "+" button at the top right of the screen. Existing ones can be viewed/edited by selecting them.

The calculation menu (green theme), where the user, after creating a case in the data section, can represent the results of the sustainability indicators on a radar graph [15]. The application calculates the sustainability indicators based on the existing studies in the databases, allowing the creation of global studies and comparisons. Results are displayed in graphical and numerical form.

3.3.1. Display of scores

The general structure for visualising results is based on radar graphs representing the scores on the indicators related to the sustainability area studied, figure X:

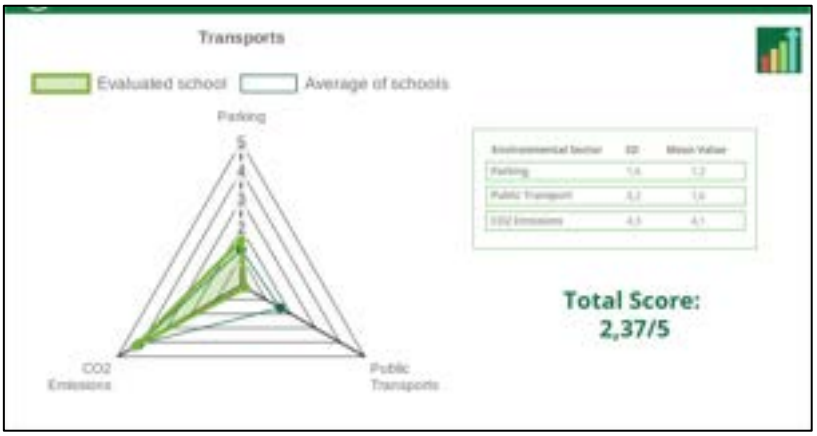

Figure. 3. Example of visualisation of results in the application.

4. Example of real application of the tool in schools

The objective of the application is to support schools in using the methodology for the acquisition of competencies. The application is being launched to the schools involved in the ECF4CLIM project, where the methodology will be implemented and assessed.

4.1 Youth with researchers pilot experience

The tool was tested in a pilot experience in 6 educational centres in Seville, Córdoba and Malaga (Spain). The context has been taken as the realisation of the 8th congress of the Youth with Researchers program convened by diferent organisations such as CSIC, SADC or US [16]. In this activity, 25 students from different centres interacted with University researchers during four seasons, developing research projects in four different groups related to different sustainability areas and applying the tool to different centres. The purpose was double, to identify the perception of the students about the tool, receiving their feedback, and to evaluate its adequateness to the methodology. The projects were:

1. Sustainable mobility in schools. Education, evaluation and proposals.
2. Zero Waste Life. Towards a future in harmony with our planet.
3. Air quality and renewable systems at school.
4. Do we improve our yard? Bioclimatic strategies and environmental education applied in schoolyards.

During the work sessions, students and teachers were guided in using the tool to support the analysis and discussion about measures that improve the sustainable behaviour of the educational community, covering with their activity the first three phases of methodology. The distribution of the participants in the activity are presetned in the next table.

Table 2. Schools participating in the JCI 2023 project.

School Name	Location	Type of school	Nº of students involved in theproject
School 1	Tomares, Seville	Secondary and High School	8
School 2	Camas, Seville	Secondary and High School	2
School 3	Camas, Seville	Secondary and High School	6
School 4	Montequinto, Seville	Secondary and High School	4
School 5	Ronda, Malaga	Secondary and High School	1
School 6	Córdoba	Secondary and High School	4

4.2 Results of the use of tool

After the audit work carried out by the JCI project students, the students determined those aspects in each center in which they obtained a lower score. Based on this result, they proposed sustainability measures, which, in some cases, have begun to be implemented in the centre. During the four sessions developed in the Youth with Researchers program, the students have been able to handle the tool, from which they detected possible ways of improvement in the centre. They were able to propose projects to increase sustainability skills in certain aspects of the centres involved. The developed application was used for all centres in the seven areas of sustainability. Below are the results obtained for the IES Ítaca school as an example of the activity carried out.

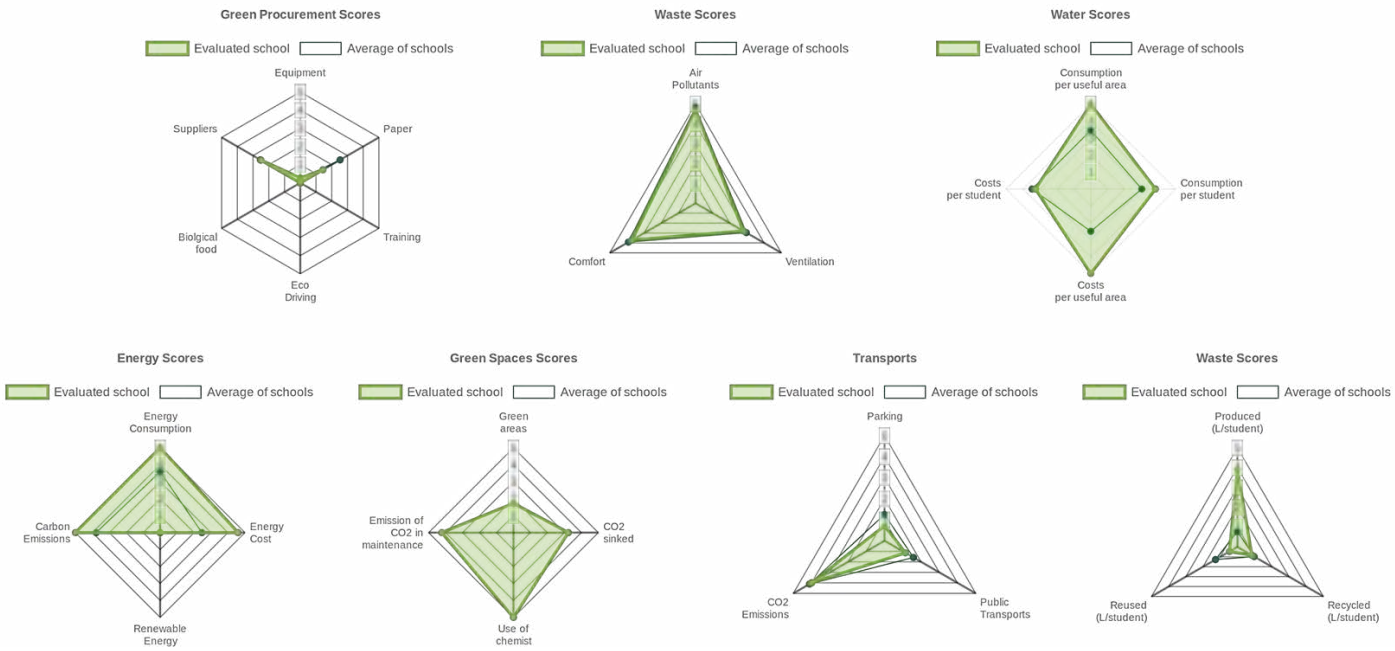

Figure. 4. Audit results for School1.

The students used the graphs of the different schools to discuss and obtain conclusions. First, they were able to interpret what information in the study had greater or lesser validity depending on the characteristics of the school. On the other hand, in areas such as Transport and garbage, students understood that there were sectors in which they could apply improvements. It was also detected that the use of the application in the specific area of garbage was not as expected since the students did not correctly understand the operation of this area of sustainability. Finally, the students who were working on the application could not have enough information concerning the generation of renewable energy in the centres, so they did not add that type of information to the study. However, in the case of School 1, they do have a photovoltaic installation in the school. Below is a graph summarising the results obtained in all centres by sustainability area.

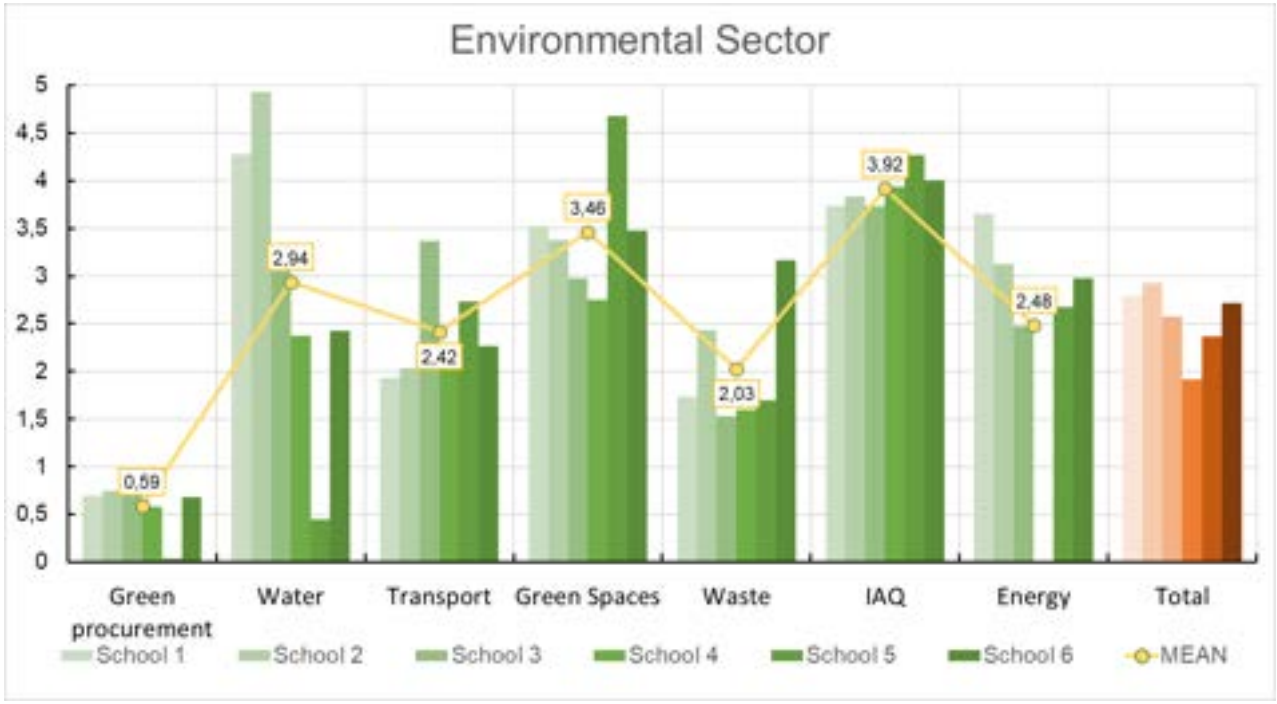

Figure. 5. Global results obtained in the centres by sustainability area.

The graph shows for each centre the overall score that summarises the 34 KPIs and the 27 scores in the 7 areas of sustainability measurable in the application. From this graph, it is possible to determine the collective and specific behaviours of the educational centres studied. In the representation of the results, the centres are sorted by colours, as shown on the labels at the bottom of the graph. On the other hand, the means of the results have been represented together with the value of said result for all the centres studied, as well as the total score of each centre. Next, characteristics related to the origin of the data or the value that the students have provided through the work with the tool will be analyzed, so that, next, considerations made in each area of sustainability will be exposed.

4.2.1. Indoor Air Quality

First, the performance in relation to Indoor Air Quality in the classrooms where the students worked was similar, considering that the measurements focused on determining CO2 concentration and temperature. In the schools 1 and 5, data on the concentration of different particles were available, thanks to previous measurements that were made through the ClimAct project, so these were added to the tool.

4.2.2. Waste

On the other hand, there were centers where it was understood that the information related to the garbage section was not introduced as expected, since inconsistencies were detected in the results. The approach of this area of sustainability assumes that the amount of waste recycled and reused will always be less than or equal to that produced according to the case. This fact was not correctly interpreted by all the students who used the tool, although in the follow-up sessions where the application was used, the results were discussed taking into account this fact. In centers such as IES Ithaca, there is a garbage management system through which they were able to evaluate this area of sustainability.

Figure. 6. Separation of garbage inside the IES ITACA center.

The image shown corresponds to one of the corridors of the school, where there are differentiated bins to carry out the correct separation of garbage. In addition, as transmitted by teachers and students, the same separation system is carried out inside the classrooms, so that students could make measurements based on the information they took from their own waste management system.

4.2.3. Transport

For this area of sustainability, a series of activities were carried out that served the students, among other things, to raise awareness about the CO2 emissions that are undertaken by the simple fact of traveling to school. The access routes to the centers were also studied, as well as the availability of parking in the vicinity of the school. On the other hand, based on the results obtained, the students were able to discuss the transport network available in each case to access the school.

Among the activities carried out in this area of sustainability, a survey was carried out that was introduced in the application, where each student could answer questions about the transport method used to access the

school, as well as behavioral issues related to this topic. The survey was shared with the students of the study schools to increase the data sample as much as possible, with the aim of characterizing the general behavior of the students in each school.

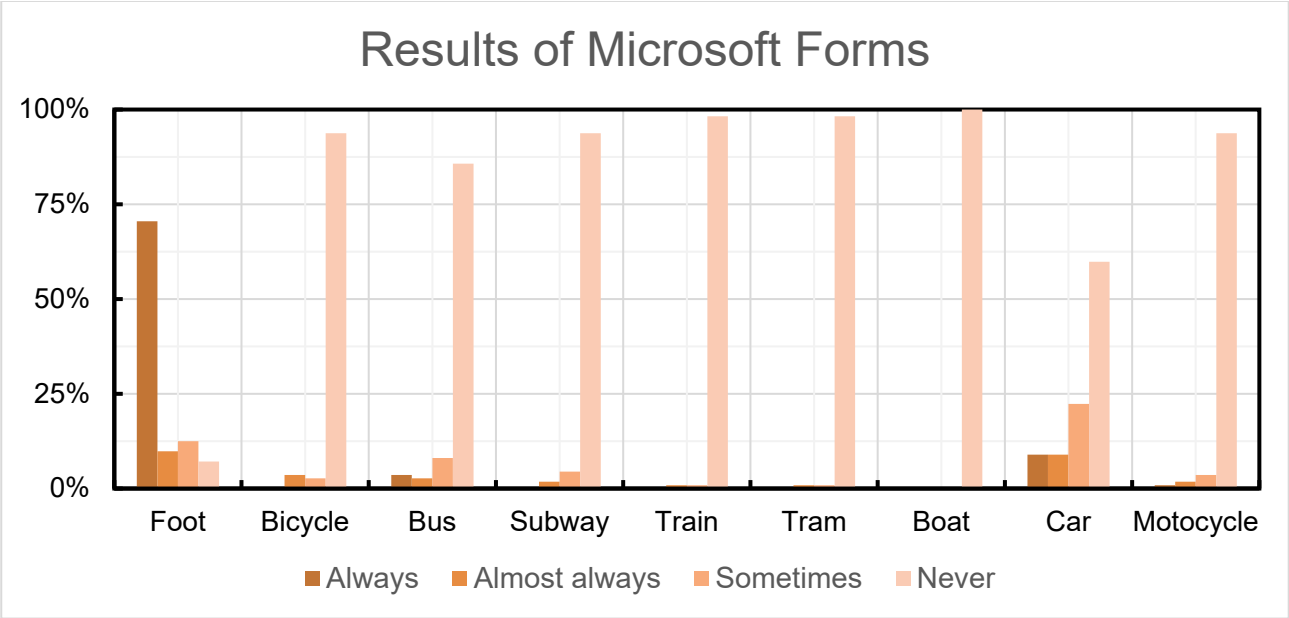

Figure. 7. Results of the user behavior survey launched through Microsoft Forms.

On the other hand, some notions related to the management of Google Earth and Google My Maps were taught with the aim that students could determine the position of the public network within a radius of 100m, 500m and 1000m. From the maps generated, they were able to determine the number of bus, train and metro stations among others, as well as the determination of the number of parking spaces at different distances from the school.

4.2.4. Water

For this area of sustainability, the students relied on the data available in the IES Ítaca and IES Martín Rivero centers in relation to the prices paid for consumption for the determination of their expenses, based on the consumption data they were able to obtain.

4.2.5. Energy

Within the development that the students made of the tool for this area of sustainability, they did not consider the part of the study dedicated to generation due to renewable facilities, although there are centers that do have a photovoltaic installation, as is the case of the IES Ítaca mentioned above.

4.2.6. Green Spaces

To answer the questions posed in the study of green spaces, students had to perform tasks related to tree counting or determining the dominant species. Because they were unable to obtain information about the use of chemicals for maintenance, they did not answer those questions. That is why in the grade entitled "Use of Chemist" all schools obtained a score of 5, although the students debated about the subject, being aware that this result had no validity. For the determination of the dominant tree species in the school, the students made use of the Google Lens tool, through which they could determine the scientific name, which they then selected in the application. Finally, the determination of the score related to "Green Spaces" was obtained from the work done in determining the different types of surface that each school has.

4.2.7. Green Procurement

Finally, for the sustainability area of green procurement, students focused their studies on questions related to suppliers, paper management and the energy level of equipment. The questions of the remaining three tags remained unanswered, so, in these specific cases, unlike what happened in Green Spaces, scores of 0 were obtained. Ittook into account, among other issues, that the centers do not have a dining room, so obtaining a result of 0 in "Biological food" did not imply the proposal of any improvement by the students.

4.3 Discussion of results obtained

The purpose of the students in relation to the use of the tool, was to be able to detect aspects from which to propose measures to support the sustainability of the center, while developing the common project for the JCI contest. After using the tool, and discussing the usefulness and validity of the results in a working session, those aspects in the areas of sustainability that needed a measurement proposal were chosen. For this, all the results obtained in the 6 centers were considered, reasoning the considerations made previously.

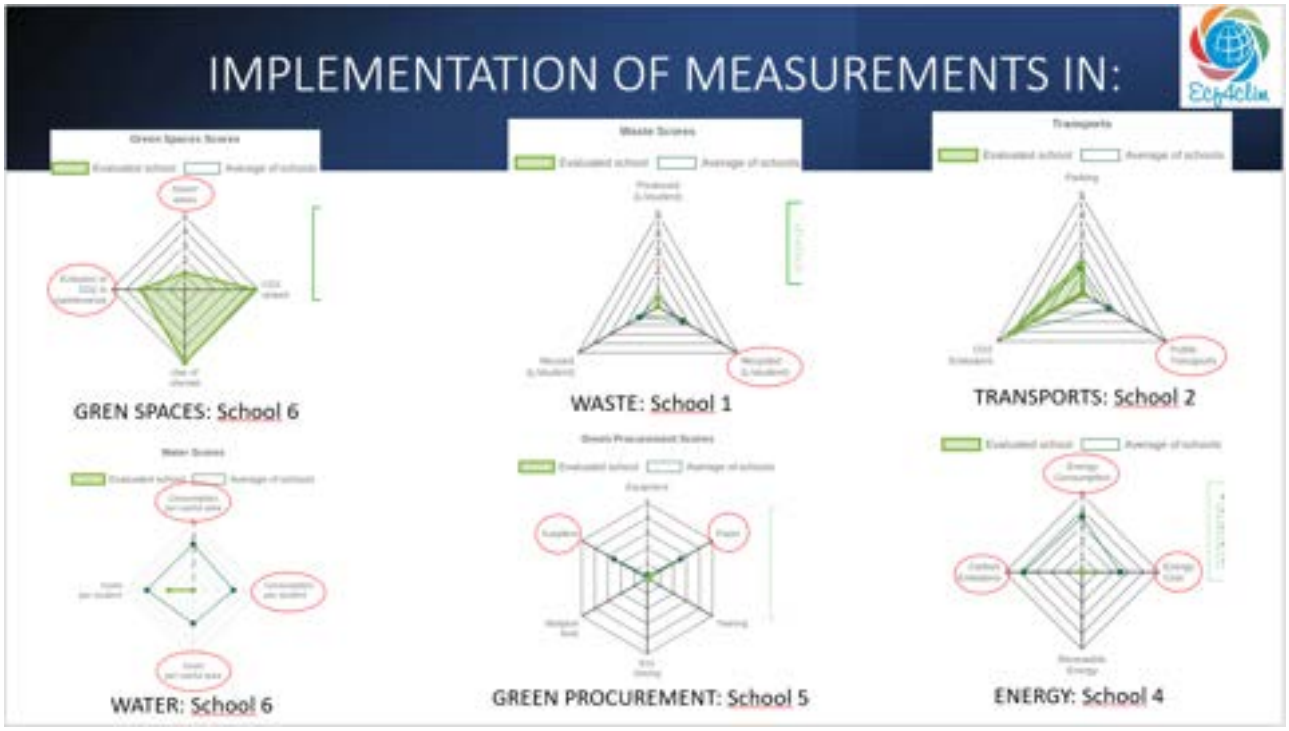

Figure. 8. Sectors in the different areas of sustainability in which to propose measures.

Making a summary of the process explained to obtain these results, the students audited their centres, entered the data in the application, and then compared the results obtained in the different centres. Once this task was performed, those centres in which the score was markedly different from the average were identified. Students noticed that, in certain respects, schools did not behave appropriately regarding sustainability. They also knew how to correctly interpret the results obtained since they understood that obtaining a low score in a specific indicator did not indicate a lack of sustainability skills or carrying out poor behaviour. Within the results obtained, they made an extraction of the graphs in which it was detected that the performance was not adequate. Based on the results obtained, improvement measures were proposed in the centres for which these scores had been detected.

5. Conclusions

Developing solutions that facilitate the development of sustainability skills in schools facilitates the learning-by-doing process that should be carried out by the schools involved in the ECF4CLIM project. This paper shows the tool developed to support the analysis and discussion of sustainability-related actions in schools. It guides and simplifies the process of collecting and analysis of information, providing information in a visual and simple way. On the other hand, through the use of the tool in the JCI program for two months, errors in programming have been detected, and learning has been carried out to identify those points of the tool that have been more complicated to understand. The feedback offered by both the students participating in the project, as well as the professors and the support research staff, has been decisive in identifying ways for improvement. In relation to the learning method, the students have followed a process in which they have been developing skills that have helped them to develop four projects that will be exhibited in the 8th congress of Youth with Researchers, where the tool has been a transversal aspect in work developed. Within the stages defined in the method, the students have managed to complete the first two phases satisfactorily.

Abstract:

The advanced flash stripper (AFS) is proven to have benefits in capital investment and energy saving for carbon capture plants using piperazine, whilst monoethanolamine is still the most used amine in the existing commercial carbon capture plants. The production and use of energy and material consumed during CO_2 absorption and regeneration generate CO_2. In this research, the 130-tonne daily CO_2 capture plants with conventional configuration and AFS configuration are simulated in Aspen Plus. Their total annualized costs are estimated to be 3.33 million USD and 2.87 million USD, respectively. The life cycle assessment is conducted to evaluate the environmental impacts from the cradle and grave of energy and materials consumed during carbon capture, showing 58% equivalent CO_2 in flue gas is generated.

Keywords:

Carbon capture; Monoethanolamine; Advanced flash stripper; Techno-economic analysis; Life cycle assessment.

1. Introduction

Monoethanolamine (MEA) is the widely used amine solvent in commercial post-combustion carbon capture due to its high reaction rate with CO_2, high carbon capture capacity and low cost [1]. Current study related to the amine-based carbon capture process concentrates on the improvement of energy efficiency. The Separation Research Programme (SRP) proposed a novel stripper configuration called Advanced Flash Stripper (AFS) [2] allowing further heat recovery and lower capital investment of the stripper, as the heat duty used to release by a condenser is now partially recovered by a cold bypass stream, and an in-situ reboiler is replaced with a cheaper steam heater. This configuration has been employed in the carbon capture process using 5 m or 8 m piperazine (PZ) [2]. However, the significantly high price of PZ may not be a threat to the position of MEA in the existing commercialized carbon capture plants. Also, the simple but ingenious configuration modification is promising to retrofit the existing plants with low capital investments. Moreover, the CO_2 from flue gas is captured and regenerated in environmental concern, whilst energy and amine solvent is consumed in amine-based carbon capture processes, which may be accompanied by CO_2 emissions again. The impacts of cradle and grave of materials and energy are often ignored in previous work. Therefore, this work aims to investigate the techno-economic and environmental feasibility of AFS configuration in an MEA-based carbon capture process. A rate-based model will be built to validate the plant data from [3] as a base case. The AFS configuration will then be employed. The techno-economic analysis and life cycle assessment will be used to evaluate the equivalent energy for CO2 recovery, total annualized cost as well as environmental impacts.

2. Process description

2.1. Conventional configuration

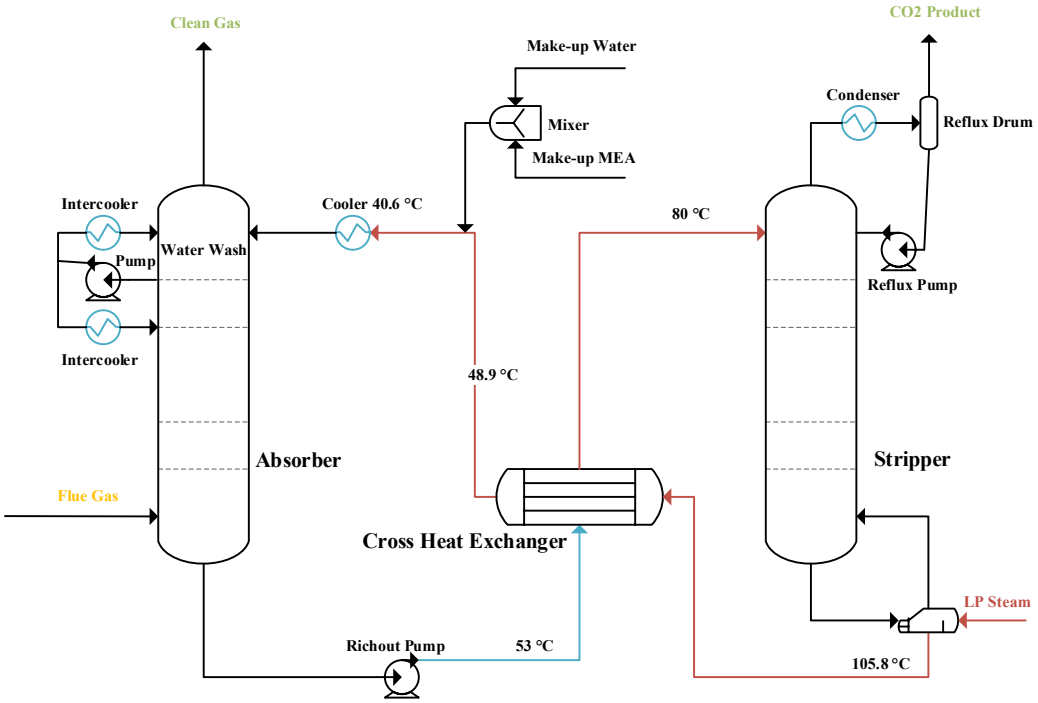

Figure 1. Simplified flowsheet of the carbon capture plant using MEA.

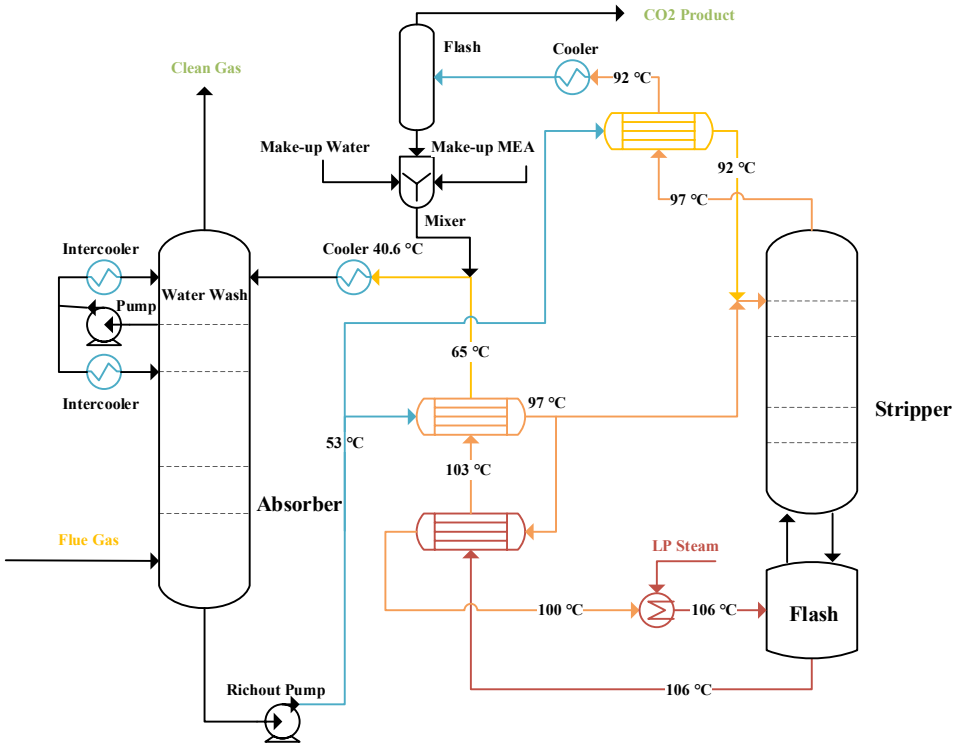

Figure 2. AFS configuration of carbon capture plant using MEA.

This simplified conventional configuration shown in Figure 1 is based on an existing carbon capture plant removing 130 tonnes of CO_2 per day [3]. After exhausted, desulphurized and cooled to 40 ºC, the flue gas (12 vol% CO_2) enters the bottom of the absorber packed with Polypropylene Ring, captured by the amine countercurrent (16%-17 wt% MEA). Around 80% of the liquid in the connection of the wash

section and absorption section is pumped back to the top of the absorber so that the amine loss of MEA can be alleviated. And the liquid is cooled to 40 ºC for the improvement of absorption performance and mitigation of MEA volatility. The clean gas is vented with nearly all nitrogen, oxygen and water. The rich solvent with high CO_2 loading is then heated to 80 ºC and pumped to the top of the stripper for CO_2 and amine regeneration. The 26-tray stripper is equipped with a condenser and reboiler. Approximately 14% of the bottom liquid is boiled up in the kettle reboiler and comes back to the stripper for further regeneration. The thermal energy of lean amine regenerated is recovered by a cross heat exchanger. After releasing the heat to the rich amine exiting from the absorber, the regenerated lean amine is then cooled and returned to the top of the absorber, before being mixed with amine and water makeup.

2.2. Advanced flash stripper configuration

The configuration of the carbon capture plant with an advanced flash stripper is presented in Figure 2. Unlike a conventional configuration where the thermal energy of distillate in the stripper is wasted, the in-situ condenser is replaced with an external cross heat exchanger to recover part of the heat. Moreover, two stream splitters are used to adjust the flowrate of rich solvent, which allows managing the feasibility of heat exchange (assume the minimum temperature approach is 5 ºC). Consequently, cold rich bypass and warm rich bypass are mixed and fed to the top of the stripper, contacting the gaseous countercurrent from a flash tank where part of hot rich solvent is vaporized and CO_2 is released to the bottom of the stripper. The regenerated lean solvent exits as the liquid product from the bottom of the flash tank. Its heat is recovered by a hot cross heat exchanger and a warm cross heat exchanger.

3. Methodology

The rate-based carbon capture process using MEA as an absorption solvent is developed in Aspen Plus V12.1. The property method employs an electrolyte NRTL model with the Redlich-Kwong equation of state [4]. For the rate-based setup, the Onda model is applied to calculate the mass transfer coefficient and interfacial area [5]. The heat transfer coefficient is then obtained from the mass transfer coefficient using the Chilton and Colburn analogy [6]. And the liquid holdup at each packing stage is estimated by the correlation of Stichlmair [7]. The chemistry of MEA absorbing CO_2 is described by a set of equilibrium reactions listed below in eqs. 1-5. The built-in power law expression is used to represent the kinetic reactions for controlling the performance of CO_2 absorption and regeneration. The corresponding kinetic parameters are provided in Table 1.

$$2H_2O \leftrightarrow H_3O^+ + OH^- \quad (1)$$
$$CO_2 + 2H_2O \leftrightarrow HCO_3^- + H_3O^+ \quad (2)$$
$$HCO_3^- + H_2O \leftrightarrow CO_3^{2-} + H_3O^+ \quad (3)$$
$$MEA^+ + H_2O \leftrightarrow MEA + H_3O^+ \quad (4)$$
$$MEA + HCO_3^- \leftrightarrow MEACOO^- + H_2O \quad (5)$$
$$CO_2 + OH^- \rightarrow HCO_3^- \quad (6)$$
$$HCO_3^- \rightarrow CO_2 + OH^- \quad (7)$$
$$MEA + CO_2 + H_2O \rightarrow MEACOO^- + H_3O^+ \quad (8)$$
$$MEACOO^- + H_3O^+ \rightarrow MEA + CO_2 + H_2O \quad (9)$$

Table 1. Kinetic parameter for build-in power law expression (eqs. 6-9)

Reaction No.	k_{abs}	$E_{abs}\ (cal/mol)$	k_{reg}	$E_{reg}\ (cal/mol)$
6	1.33e+17	1.32e+4	1.33e+17	1.32e+4
7	6.63e+16	2.57e+4	6.63e+16	2.57e+4
8	3.02e+14	9.86e+3	3.02e+14	9.86e+3
9	5.52e+23	1.65e+4	6.50e+17	2.28e+4

The cost estimation of the carbon capture process with two configurations is completed by Aspen Process Economic Analyzer (APEA). Instead of using installation factors to evaluate costs, APEA is able to manage that by required materials and labour. Furthermore, the combination of mathematical models and expert systems contributes to a more detailed economic measurement [8]. The parameters for calculating the costs are presented in Table 2. The annual cost is calculated by the summation of operating cost and annualized capital cost [9], which is represented by eqs. 10-11 below.

$$ACCR = \frac{DR \times (DR+1)^n}{(DR+1)^n - 1} \quad (10)$$

$$TAC = ACCR \times CAPEX + OPEX \quad (11)$$

Where ACCR is the annualized capital cost ratio; DR is the discount rate, assumed to be 10%; n is the estimated period; TAC, CAPEX and OPEX represent the total annualized cost, capital cost and operating cost, respectively.

Table 2. Parameters for cost estimation

Parameters	Price
Carbon fee/carbon tax ($/kg)	0.051
Make-up water ($/cum)	3
Make-up MEA ($/ton)	1200
Electricity ($/kJ)	1.60e-5
LP steam ($/kJ)	1.90e-6
Cooling water ($/kJ)	2.12e-7

The life cycle assessment is employed to identify improvement potential for environmental performance. The principles, frameworks, requirements and guidelines can be found in ISO 14040 and ISO 14044. An “operational guide to the ISO standards” was published by the Centre of Environmental Science of Leiden University (CML) in 2001, summarizing a list of impact categories and characterization methods and factors for corresponding substances. Guinee et al. explained these categories [10]. In this work, the ReCiPe method [11] is chosen to evaluate the environmental impact of material and energy consumption for equivalent CO_2 regeneration in two carbon capture processes. All impact indicators are obtained by commercial LCA software SimaPro, and the most 7 influential impact indicators are presented in Table 3. The “global warming potential” refers to the global temperature increment resulting from greenhouse gas emissions, which is measured by the kilogram of carbon dioxide equivalent. The exposure to “ionizing radiation” is detrimental to human health, which is estimated by the equivalent kilobecquerels of Cobalt-60 to air. The “land use” is a composite indicator measuring the use and occupation of land for agriculture, housing, mining, or other purposes, so the unit is square meter in the total period. The essential idea behind “fossil resource scarcity” is that the depletion of fossil fuels forces the extraction of other resources in the future, which is estimated in kilogram of equivalent oil. The following indicators are measured in kilogram of 1,4-dichlorobenzene emitted. Particularly, “terrestrial ecotoxicity” indicates the impact of toxic substances on terrestrial ecosystems (i.e., individual species and the functioning of the ecosystem). The “human carcinogenic toxicity” and “human non-carcinogenic toxicity” reveals the potential health damage leading to cancers and other diseases, respectively.

Table 3. Impact indicators for life cycle assessment

Abbreviation	Indicator	Unit
GWP	Global warming potential	kg CO_2 eq
IR	Ionizing radiation	kBq Co^{-60} eq
TEC	Terrestrial ecotoxicity	kg 1,4-DCB
HCT	Human carcinogenic toxicity	kg 1,4-DCB
HNCT	Human non-carcinogenic toxicity	kg 1,4-DCB
LU	Land use	m^2a crop eq
FRS	Fossil resource scarcity	kg oil eq

4. Results and discussion

The feasibility of the rate-based carbon capture model is validated by the plant data from [3]. The comparison between plant data and modelling results in terms of CO_2 loading, temperature, recovered CO_2 amount, steam usage and clean gas composition, is listed in Table 4. The modelling results show a great agreement with plant data. It is worth noting that the O_2 content takes account for a larger proportion with about 40% deviation. This may result from the oxidative degradation of MEA in reality, which is not considered in the model. Nevertheless, this model is still feasible to predict the absorber and stripper performance.

Table 4. Comparison between plant data and modelling results

	Plant	Model	RD (%)
Lean Loading (mole of CO2/mole of amine)	0.11	0.114	3.77
Rich Loading (mole of CO2/mole of amine)	0.411	0.425	3.33
Rich Amine Discharge temperature from absorber bottom (ºC)	57.22	53.479	6.54
Clean Gas Temperature (ºC)	40	40.57	1.43
CO2 Production (tonne/day)	125.2	127.225	1.62
Steam flowrate to reboiler (kg/hr)	17460	17466	0.03
Clean Gas Composition (mol%)			
CO2	0.223	0.228	2.24
O2	5.762	8.046	39.63
N2	87.315	85.005	2.65
H2O	6.672	6.591	1.22

*RD is the relative deviation.

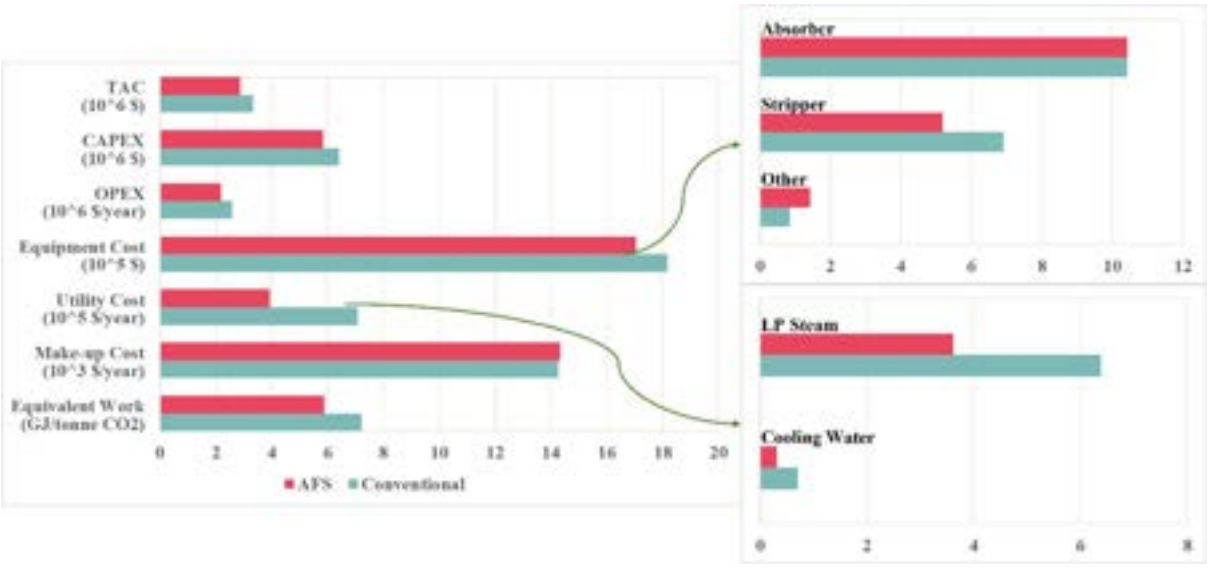

Figure 2. The comparison of conventional process and AFS process related to costs and equivalent work.

The comparison between conventional and AFS configurations is presented in Figure 2 in terms of costs and equivalent energy requirements for CO_2 recovery. The total annualized costs of conventional configuration and AFS configuration are 3.33 million USD and 2.87 million USD, respectively. It is shown that the capital investment costs around 6 million USD, and the annual operating expenditure is 2 million USD. Compared to the conventional configuration, using the AFS configuration will save about 8.94% and 15.1%, receptively for capital cost and operating cost. Although over 24% saving from eliminating the condenser and reboiler of the stripper in AFS configuration is reduced by the additional costs from two cross heat exchangers and one advanced flash drum, making the equipment cost reduction only 6.23%, the energy saving is tremendous due to the significant heat recovery realized by AFS configuration. The LP steam cost, contributing to 90% of the total utility cost, is reduced by 43.24%, and the demand for cooling water is reduced to over half, leading to a 44.55% reduction in utility cost. The same absorber condition and regenerative temperature result in nearly equal thermal degradation, showing great agreement with the negligible difference in make-up cost. As a kettle reboiler is replaced with a steam heater in AFS configuration, the heat duty is significantly reduced, and then the amount of regenerated CO_2 becomes less. Evaluating the energy usage by equivalent work per tonne of CO_2 regenerated is a relatively fair way. The existing carbon capture plant using standard MEA-absorption configuration consumes 7.22 GJ/tonne CO_2, whilst the AFS configuration is able to consume 5.89 GJ/tonne CO_2, saving 18.49% energy usage.

Table 5. Detailed characterization results of two carbon capture configurations

		Electricity	MEA makeup	Water makeup
Fossil resource scarcity	Conventional	30621.65	36.85	0.12
	AFS	24960.77	56.72	0.07
Land use	Conventional	39021.16	4.36	0.03
	AFS	31807.50	6.70	0.02
Human non-carcinogenic toxicity	Conventional	46117.39	43.68	0.52
	AFS	37591.88	67.22	0.32
Human carcinogenic toxicity	Conventional	3396.49	3.78	0.06
	AFS	2768.60	5.82	0.04
Terrestrial ecotoxicity	Conventional	60160.37	50.70	1.38
	AFS	49038.80	78.02	0.85
Ionizing radiation	Conventional	54628.20	7.32	0.04
	AFS	44529.34	11.26	0.02
Global warming potential	Conventional	86344.88	71.27	0.41
	AFS	70382.70	109.70	0.25

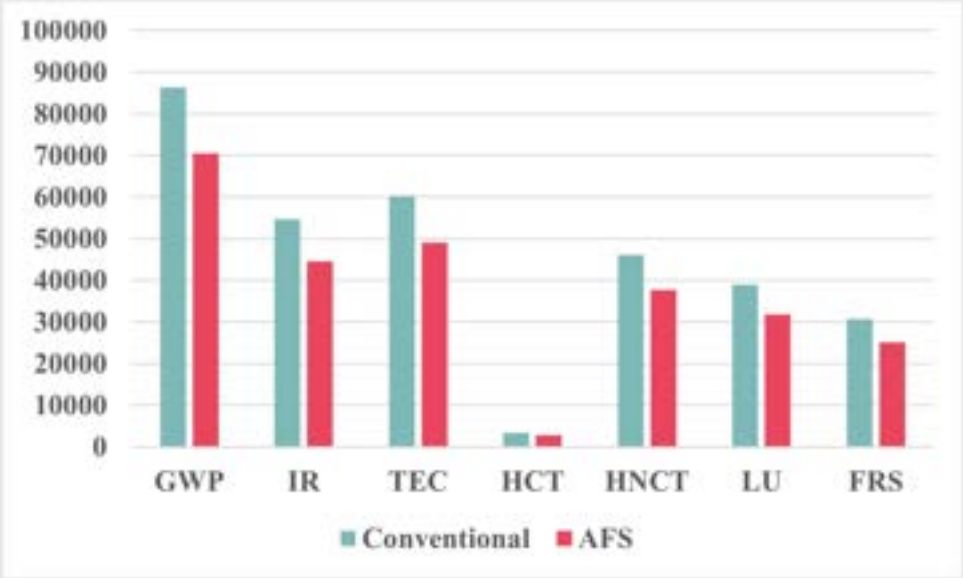

Figure 3. Characterization results of two carbon capture configurations using ReCiPe 2016.

The life cycle assessment measures the environment impacts of material and energy consumption in the carbon capture process quantitively: approximately 78000 kg CO_2, 50000 kBq Co-60, 55000 kg 1,4-DCb, 3000 kg 1,4-DCB, 42000 kg 1,4-DCB, 35000 m^2a cropland and 28000 kg oil. Furthermore, electricity contributes to around 99% of all impact indicators. The general pattern of impact indicators presented in Figure 3 shows that the AFS configuration contributes less to environmental and healthy damage, compared to the conventional configuration. This can be attributable to the significant reduction of energy usage in the carbon capture process using AFS configuration, according to Table 5 electricity (energy consumption is converted to equivalent electricity use) makes the main contribution to environmental influence. The most significant indicator is the global warming potential and the least influential indicator is human carcinogenic toxicity. This is because the cradle to grave of electricity generated by fossil fuels leads to a tremendous amount of greenhouse gas emissions whilst a relatively tiny amount of substance resulting in cancer potential to human health. As the aim of the carbon capture process is to capture CO_2 for sequestration or utilization, and the energy consumption itself leads to 78 tonnes of equivalent CO_2 (responsible for 58% of the flue gas in this work), the emphasis on the improvement of energy saving in carbon capture processes is not only reasonably in economic, but in climate change concern. Measured by the same units, the amount of toxic substances detrimental to

terrestrial individuals and the functioning of the ecosystem is relatively higher than that of toxic substances leading to non-carcinogenic diseases for humans. This is due to a larger scope of the terrestrial system including the living place of the human. Table 5 gives more details related to the impact contribution of electricity, MEA makeup and water makeup. In addition to the aforementioned role of electricity, it is interesting to see some clues from chemical processes and properties: MEA is produced by ammonia which is mainly produced via the energy-intensive Haber-Bosch process, leading to the scarcity of fossil resources and greenhouse gas emissions. Also, the toxic property of MEA corresponds to the detrimental impacts on human health and the terrestrial ecosystem associated with its individuals. Therefore, life cycle assessment gives a new perspective to see the improvement potential in the carbon capture process environmentally.

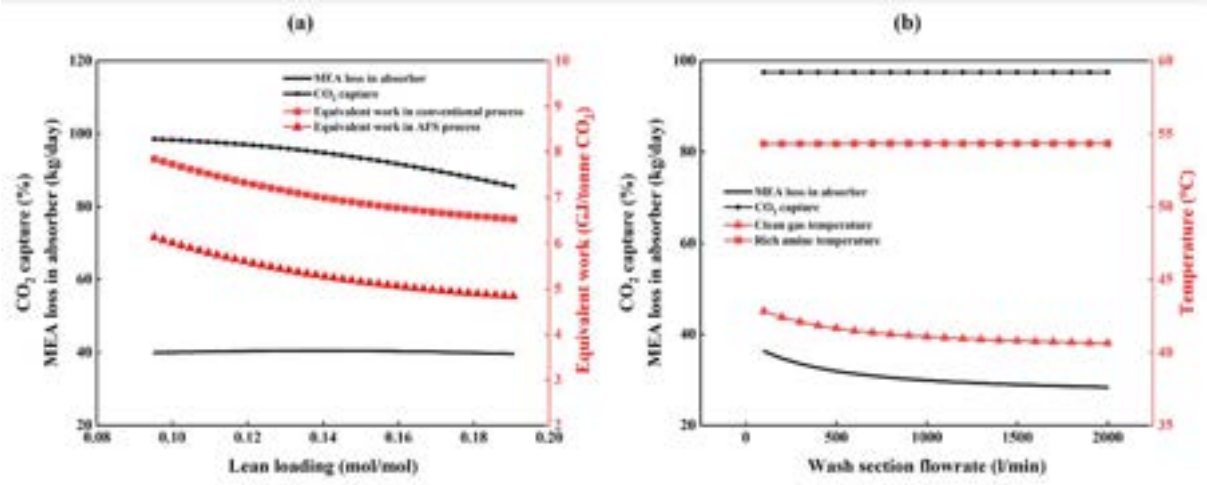

Figure 4. The effects of (a) CO2 loading and (b) water wash amount on CO2 removal, solvent loss and equivalent work.

The sensitivity analysis is conducted to investigate the effects of lean loading and wash section flowrate on absorption performance and energy usage. In Figure 3(a), no effect on amine loss is observed as the CO_2 loading in a lean solvent increases. The significantly decreased curves of equivalent work for CO_2 regeneration in both configurations show great benefits in energy saving. Specifically, with the increment of lean loading from 0.09 to 0.19, the equivalent work in conventional and AFS carbon capture processes reduces by 16.8% and 20.1%, respectively. Albeit the energy benefits, the capability of removing CO_2 is weakened to only 85%. The trade-off of energy saving and carbon penalty is therefore formed when the carbon tax is considered. The MEA loss in clean gas discharged to the atmosphere contributes to potential health and environmental consequences. In addition, the main degraded product of MEA is ammonia, which is soluble in water and detrimental to human health and the environment [12]. Therefore, the wash section is essential in carbon capture processes using MEA. In Figure 3(b), as the flowrate of the wash stream increases from 100 to 2000 litres per minute, the MEA loss decreases by 22%. Moreover, the outlet temperature of the overhead vapour is decreased from 42.8 ºC to 40.6 ºC. However, the wash section flowrate contributes little influence on the removal of CO_2 and the bottom temperature. The off-gas temperature can be a general reference to know the extent of amine loss.

Conclusion

Started with the rate-based simulation to study the operating performance of carbon capture processes with two configurations, the capital costs and operating costs were estimated, followed by the life cycle assessment. Finally, sensitivity analysis was conducted to locate key parameters. The conclusions are as follows:

1. The total annualized costs of the 130-tonne daily carbon capture plant were 3.33 million USD and 2.87 million USD, respectively for the conventional configuration and AFS configuration.
2. Energy consumption contributed to the main environmental impacts, and the cradle and grave of energy and materials consumed in the carbon capture process made approximately half of

the CO_2 capture in vain. Therefore, improving energy efficiency or using renewable energy could be environmentally beneficial.

3. The increment of lean loading reduced energy consumption for CO_2 regeneration but weakened the capability of CO_2 removal. The wash section was able to reduce amine loss significantly.

Abstract:

Geothermal fluid is usually characterized by the presence of water and minor percentages of non-condensable gases (NCG), including CO_2. Relevant CO_2 streams are currently released from the cooling towers of geothermal power plants operating in Tuscany. These emissions are largely of natural origin. The output streams of NCG are treated for removal of contaminants (Hg and H_2S) and consist in nearly-pure CO_2: that is the reason why it is worth to investigate about its potential circular use. Specifically, the possibility of transport and use as a long-distance heating or cooling fluid stream for local communities is investigated; integration with hydrogen production is also considered, with production of methanol to be used as synfuel or energy storage. Hydrogen can be harvested from several sources: a) from the captured H_2S stream b) from industrial facilities already existing along the transport path c) from integrating an electrolyser in the power plant premises thereby providing load flexibility (currently not present in geothermal power plants). The study is tailored on the local geographical, productive structure and population situation. The remaining part of the CO_2 stream is delivered to the sea where it can be finally destinated to transportation (pipeline or ship) and sequestration. The results are encouraging in inspiring a potentially new sustainable economy structure.

Keywords:

Circular use; CO_2 stream; Geothermal power plant; Hydrogen; Methanol.

1. Introduction

A crucial environmental issue related to electricity generation using geothermal fluids is the emission of non-condensable gases. Vent stacks in geothermal plants emit carbon dioxide (CO_2) and methane (CH_4), raising serious concerns in terms of greenhouse gases. The amount of these emissions is quite small compared to carbon and fossil fuel plants, indicating that the contribution of these sources is practically negligible. Geothermal power plants (GPPs) also emit a higher amount of hydrogen sulphide (H_2S), as it is a main constituent of geothermal fluids. H_2S in air, water, soils, and vegetation is a vital environmental concern for geothermal fields [1].

Due to resource depletion, fossil fuels are not capable of compensating for the growing energy need. In addition, easily extractable fossil fuel is facing an increase in their prices. It is worth mentioning that greenhouse gases (mainly CO_2) have accumulated in the atmosphere by burning fossil fuels. Therefore, clean and sustainable energy has become relevant, with intensified research to make it more affordable and productive.

Currently, H_2 (hydrogen) and CH_3OH (methanol) are in the picture to fulfil the role of storable energy carriers [2]. Electricity surplus can be used to produce H_2 from the water via electrolysis, or further react H_2 with CO_2 obtained from the GPPs to synthesize CH_3OH (Power-to-Gas). This would mitigate greenhouse gas emissions and meet renewable energy directives. Methanol is a liquid that may give some advantages (e.g. it can be stored at ambient temperature and atmospheric pressure). Besides blending with gasoline in cars, an application that can be started directly as methanol is compatible with the current fuel infrastructure or using it as fuel in fuel cells, methanol can also be used as feedstock in the chemical industry.

This innovative renewable method for methanol synthesis may be applied in Tuscany, the Italian region with the highest use of renewable sources, thanks to the concentration of geothermal-electrical generation. Geothermal energy covers, in fact, about 33% of the electricity needs in Tuscany with a global nominal capacity of 914.5 MW and meets the electricity demand of about 2 million households [1].

From Tuscan geothermal plants, CO_2 can be easily stored and used for the synthesis of methanol. In addition, methanol can be produced more sustainably by synthesizing it from H_2 recovered from industries in the region as well as from H_2S reduction. The decomposition of hydrogen sulphide (H_2S) with simultaneous hydrogen (H_2) generation offers a sustainable energy production option and an environmental pollution abatement

strategy. Another way to use this carbon dioxide in order to provide additional services to the population is to exploit it for the production and distribution of heat and cold.

All in all, it is important to investigate both the potential exploitation of carbon dioxide emitted by GPPs and its mitigating implications using the Tuscany region as a case. In fact, this study tries to apply the possible circular uses of carbon dioxide just mentioned. Therefore, this document is part of the ecological transition trying to identify new forms of economy, a productive and industrial induced that can be strengthened and that is identified with the Tuscan territory.

2. Overall system configuration

The general configuration of the system includes a water electrolysis section, a unit for the direct splitting of hydrogen sulphide into hydrogen and sulphur, a methanol synthesis section (MSS), and the CO_2 district heating and cooling. Water electrolysis is performed with the commercially mature technology of alkaline electrolysers. The system operates in the charge phase when electricity in excess is stored as chemical power into hydrogen. Figure 1 shows a simplified functional scheme of the general configuration of the overall system.

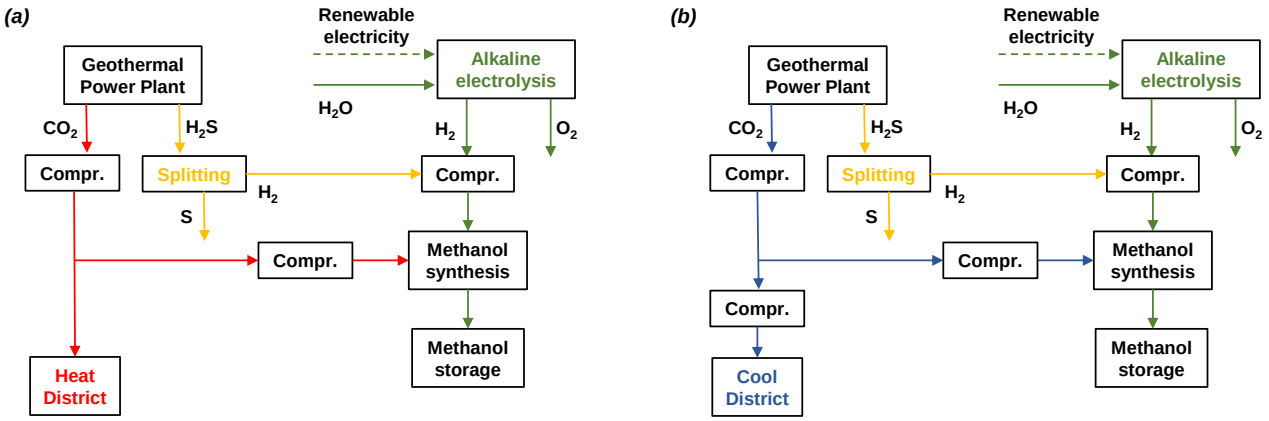

Figure 1. *Scheme of the overall system: a) winter operation, b) summer operation.*

Water and renewable electricity feed the electrolyser to produce hydrogen. Hydrogen sulphide from gaseous emissions in an AMIS system is separated into pure hydrogen and sulphur through the plasma catalytic reactor (PCR). Hydrogen and CO_2 are compressed at the operating pressure of the methanol synthesis reactor in two compressor trains. In the MSS, CO_2 hydrogenation to methanol is performed over a commercial catalyst ($Cu/ZnO/Al_2O_3$) and methanol is separated and purified in a distillation column. The non-synthesized CO_2 arrives in Livorno through a double pipeline: one transports liquid phase in summer operation, and the other, gaseous phase in winter operation. Along the way, the production and distribution of heat and cold is promoted.

3. CO_2 network

Carbon dioxide is practically the only gas that remains after the non-condensable gases have been cleaned with the mercury and hydrogen sulphide abatement system (AMIS®). In this study, one of the two 60 MWe Valle Secolo power plants was considered. The resulting CO_2 flow rate is 3.0 kg/s; with an operational period of 8760 hours/year, the total CO_2 emissions are 95371 t/year [3].

Two extreme seasonal functions were analysed, namely winter and summer operation, for each of which there is a dedicated pipeline. All CO_2 is first compressed up to 4 MPa and cooled to 40°C, in order to enter the steam pipe, which represents winter operation. Part of the stream is sent to the methanol production system. Then in order to enter the liquid pipeline, it is further compressed and cooled to reach winter operating conditions of 10MPa and 20°C. Indeed, the non-synthesized CO_2 will be transported from the GPP to the coast promoting along the way service uses: production and distribution of heat and cold.

Determining the pipeline route and length is the first thing to consider in the design of pipelines. The pipeline route will determine the total length of the pipeline and the bends on it. Even the pipeline pressure drop is dependent among other factors on the length of the pipeline.

The final terminal is identified in the SNAM refinery in Livorno, where there may be other possibilities for CO_2 transformation, or alternatively liquefaction and delivery in port areas for the purpose of confinement (for example, in deep water or underwater saline aquifers). Figure 2 shows the location and extent of the CO_2 pipelines, as well as the inhabited areas crossed. The road network was considered a general scheme for arranging CO_2 pipes. Existing brine ducts between the Saline di Volterra and Rosignano Solvay (dotted in green) have also been highlighted. The route starts from the Vallesecolo plant and passes through the Saline di Volterra, Cecina, Rosignano Solvay, and finally Livorno. It is proposed to implement another MSS along the route near Solvay Chimica S.p.A., located in Rosignano Solvay, where hydrogen is expected to be recovered.

In tracing the route, a possible development of district heating/cooling was considered, when passing through residential and commercial districts. Therefore, a doublet liquid/gas pipeline is proposed, with each pipe sized to transport the non-synthesized CO_2 flow rate. Friction and heat transfer correlations, implemented in the Engineering Equation Solver (EES) software, were used to model the CO_2 transport process.

Figure 2. *CO_2 pipeline and main residential area crossed.*

3.1. Optimization of the CO_2 pipeline system

The flow rate data determine the fluid volume transportation from source to sink and, consequently, the adequate pipeline diameter for transportation. A pipeline diameter too small for the flow rate would cause high velocity of the fluid with attendant high losses in pressure and erosion of the pipe wall. Very large pipeline diameters would reduce pressure losses, have low velocities, and low or non-existent noise and erosion, but result more expensive. The optimum economic pipe diameter was estimated using the following formula [4]:

$$D_{i,opt} = 0.363 m_v^{0.45} \rho^{0.13} \mu_c^{0.025}, \quad (1)$$

where $D_{i,opt}$ is the optimum inner diameter of the pipe, m_v is CO_2 volumetric flow rate in the pipeline, m^3/s; ρ denotes CO_2 density at average temperature through the pipeline, kg/m^3; and μ_c is average CO_2 viscosity.

Applying the above assumptions to Eq. (1) gives an optimum inner diameter of 0.15 m at a CO_2 flow rate of 2.86 kg/s with inlet conditions of 4 MPa and 40°C (vapour pipe); and an optimum inner diameter of 0.08 m at the same flow rate with inlet conditions of 10 MPa and 20°C (liquid pipe). These diameter values ensure that the losses are not too high even when the fluid is returned after the user in conditions of volume different from those designed for injection into the plant.

3.1.1. Pressure drop along the pipeline

An increase in pressure drop means higher operating costs and possibility the need to introduce recompression stations. Hence, it is necessary to estimate the pressure drop along the pipeline: the pressure drop is dependent on the flow rate as well as on the different geometric characteristics of the pipeline such as diameter, length, elevation changes, etc.

Since the CO_2 density is sensitive to pressure and temperature changes, the pressure drop along the pipeline will reduce the CO_2 density and increase the velocity, which will, in turn, increase the pressure drop.

In the simulation, the inlet conditions for CO_2 are fixed; it is transported to the point of arrival considering, as pressure drops, those distributed and those related to the contribution of the difference in height.

3.1.2. Effect of ambient temperature

Optimization of CO_2 transport via pipeline must account for the effect of ambient temperature because of heat transfer along the pipeline between the CO_2 in the pipe and the surroundings. For environmental conditions, atmospheric pressure and a temperature of 10°C and 27°C for winter and summer operations respectively were considered. The pipes are assumed to be carbon steel [5] and placed above the ground. The insulation is made of polyurethane foam (conductivity 0.027 W/mK) with a thickness of 25 mm. To evaluate the heat exchanger between CO_2 and the environment the following phenomena are considered.

Forced convection is present between CO_2 and the internal duct surface, and natural convection between the insulation external metallic surface and the environment (with air temperatures varying from summer to winter operation). Conduction is present in the duct thickness and in the insulation (including the outlet covering).

3.2. Operating conditions of pipes

Two methods were used for CO_2 transport and exploitation, each working under certain operating conditions. The superstructure of the system is represented in Fig 3.

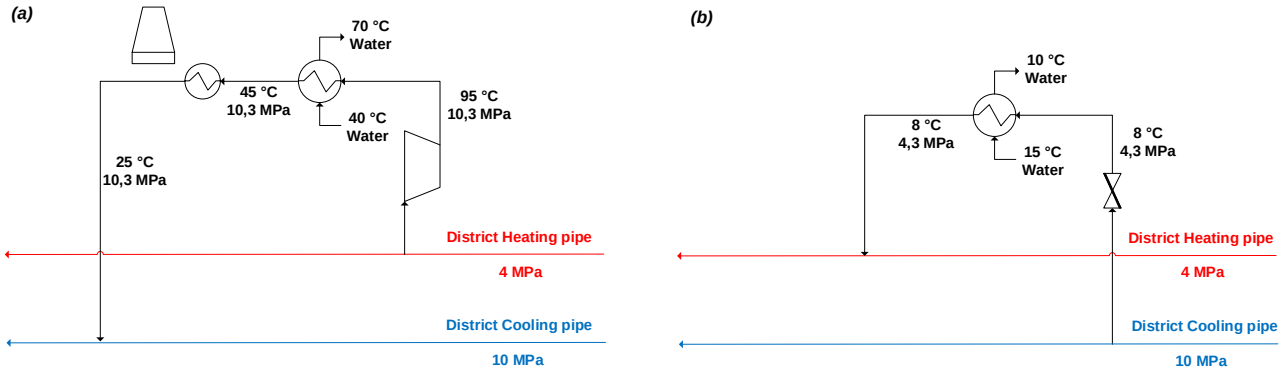

Figure 3. *General scheme: a) Heating mode, (b) Cooling mode.*

In winter operation CO_2 is drawn from the vapour phase pipeline. By setting through a valve the delivery pressure at subcritical values (p_c = 7.38 MPa), the fluid reaches the user at conditions similar to those at the condenser of a closed cycle heat pump. The condenser heat recovery is exploited to heat water for household or commercial building heating. The layout corresponds to a trans-critical heat pump operating directly with CO_2: typical pressures of these applications are 9-10 MPa at the condenser and 3.5-4.5 MPa at the evaporator. The trans-critical CO_2 heat pump solution is attractive because it is possible to operate with common radiator temperatures; also, the heat transfer match with the resource is good (30°C temperature glide on the cold utility side; 50°C on the resource (CO_2) side). The CO_2 leaving the heat recovery exchanger is still in vapour phase, therefore it is necessary to further cool it at least down to 25 °C to bring it to liquid conditions (recovery of the CO_2 stream in the liquid transport pipe, at supercritical pressure). The liquid CO_2 stream will not thus undergo phase changes along the way but will remain liquid despite the pressure drops along the pipeline

For the steam pipe, the inlet temperature is set at 40 °C to avoid two-phase formation due to the lowering of the temperature (T_s = 5 °C at 4 MPa). The pressure value of 4 MPa was selected considering the operation conditions of the heat pump. At higher pressures the saturation temperatures, T_s, are higher and thermal dispersion could determine a temperature below the saturation value (at 5 MPa T_s = 14.5 °C and at 6 MPa T_s = 22 °C) leading to the formation of liquid droplets along the pipe.

The same assumptions were made for summer operation: CO_2 is delivered to the user (needing cooling) in the liquid phase. The liquid pipeline is operated at high pressure in summer (10 MPa); a partial flowrate is laminated to low pressure and brought to the right saturation temperature for cooling (at 4.3 MPa T_s = 8 °C). The pressure of 10 MPa ensures that pressure drops do not lead to steam formation along the pipeline, with an inlet temperature of 20 °C. Expansion of the fluid to 4.3 MPa allows to cool a water stream from 15 to 10°C, which is used for cooling the rooms. After use as a coolant, the CO_2 stream can be recovered without pumps in the vapour phase pipe which is operated at 4 MPa.

4. Thermal energy needs

The main urban centres crossed along the pipeline were analysed to consider them as possible users for heating and cooling. Among the main ones, we find Cecina, Rosignano Solvay, and the final terminal located in Livorno. Referring to these towns, the winter and summer thermal loads have been estimated precisely to consider them as possible users. A shopping centre was also included - the only one that is present on the path to Livorno: is the Acquerta shopping centre, located near Cecina. Considering the available flow rate, we will discuss as an example the shopping centre of Acquerta and the thermal needs of part of the neighbouring residential area of San Pietro in Palazzi, which were evaluated as users.

The CO_2 infrastructure was considered to be possibly connected to representative buildings located in the San Pietro in Palazzi area, to study their different operating modes and performances. The Acquerta shopping centre and the San Pietro in Palazzi area are presently heated by natural gas, with an efficiency assumed as 0.9. For the energy performance index for cooling, no efficiency was considered because it is not supplied in terms of primary energy. In fact, that parameter does not take into account the efficiency of the installation providing the service and is therefore not primary energy.

From the climate conditions and the characteristics of the typical dwelling in this zone, heating (primary energy) and cooling demands throughout the year can be obtained. The characteristics of the representative buildings can be seen in Table 1. The Heating Degree Days (HDD) values are obtained using a base temperature of 20°C. For the calculation of the Cooling Degree Days (CDD), a base temperature of 24°C is assumed. It has to be mentioned that in Italy and unlike for heating, no national standard defines how to compute CDD.

Table 1. *Representative block of flats characteristics.*

San Pietro in Palazzi population	3141
Surface per dwelling [m^2]	100
Number of inhabitants per dwelling	3
Number of dwellings	1047
Heating efficiency with natural gas	0.9
Volume Acquerta S.C. [m^3]	48000

The area here studied falls within climate zone D, so heating systems can be operated from November until April 15 for 12 hours a day, or 1992 hours a year. 610 hours of annual cooling operation were assumed (no legislation limits exist in Italy for this), i.e. about 5 hours per day for four months, while for the shopping centre, 1342 hours per year were assumed, i.e. 11 hours per day for four months. For the two and a half months in which there is no need for thermal energy, it is assumed that the transport of CO_2 takes place with the methanol synthesis along the path.

5. Hydrogen recovery and production

A notable opportunity for circular economy based on CO_2 recovery is the production of synfuels using hydrogen. Here, the production of methanol through hydrogen reaction is considered attractive, as it produces a liquid synthetic fuel already used in the formulation of vehicle fuels. The hydrogen required for this reaction is partly recovered from geothermal and industrial activities, and partly produced. A recovery option is indeed possible at the GPP: considering the entire 120 MW plant operated by ENEL GP in Vallesecolo, it was assumed to produce hydrogen from the hydrogen sulphide present in the geothermal fluid. At the plant premises, it was hypothesized to produce hydrogen through electrolysers when substantial input to the grid from photovoltaics was present: this makes the GPP effectively operate as a substitute storage capacity, as the plant would be operated full load at night (when no PV input is available), and effectively decrease its nominal power feeding a large electrolyser at daytime. The most important industrial recovery option for H_2 takes place at Rosignano Solvay, where in the Solvay Chimica S.p.A. alkali plant hydrogen is a by-product in the soda-chlorine process. This section assesses the potential for recovering and producing hydrogen.

5.1. Plasma catalytic reactor section

The hydrogen sulphide emissions of both groups of Valle Secolo (120MW) are here considered as possible circular economy resources for the production of H_2 and S. The production of H_2S from the plant – currently captured by the AMIS plant - was taken from public monitoring reports [3], a value of 199 kg/h. The power plant emission treatment abatement system was ideally modified by adding a PCR (Fig 4) [6]. The stream to be processed is from the extraction compressor of non-condensable gas, which is currently being sent to the AMIS treatment (with oxidation and alkaline scrubbing for removal of sulphur species), finally delivering a nearly-pure CO_2 stream at the cooling towers (where dispersion profits from the highly buoyant plume).

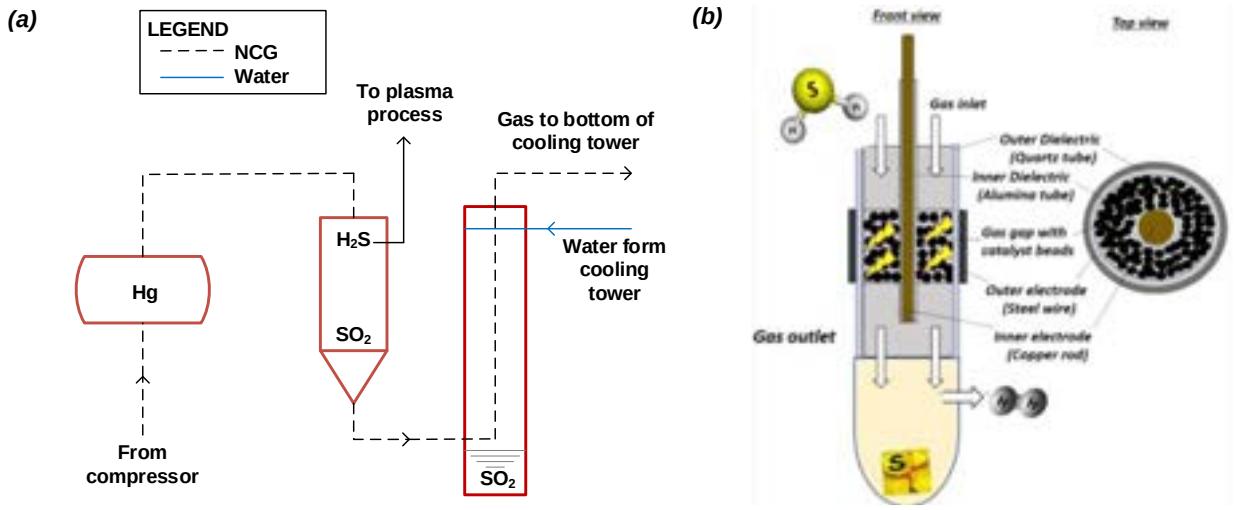

Figure 4. *Schematic illustration of the: a) modified AMIS system (modified from [7]), b) PCR [8].*

The electrified PCR is an innovative technology for H_2 production for waste streams or H_2S: compared to other technologies, it allows to achieve a good conversion at low temperatures (100-200°C). In addition, the purity of hydrogen is very high (99%) [6].

The plasma-assisted catalytic H_2S decomposition is performed at atmospheric pressure in a non-thermal dielectric barrier discharge (DBD) plasma reactor consisting of one or two coaxial dielectric tubes (quartz, alumina). The DBD plasma is created between two electrodes surrounded by the dielectric material (direct electric heating of the catalyst located between the two electrodes). The main electrode is connected to the high voltage supplied by an AC generator [8]. From stoichiometry ($H_2S \rightarrow H_2+S$), the amount of H_2 obtainable from hydrogen sulphide is 11.78 kg/h with a specific electricity consumption of 1.2 kWh/Nm^3 of H_2 [6]. The estimated production of H_2 is 103.2 t/year, so the energy demand would be 1378 MWh/year.

5.2. Alkaline water electrolysis section

Alkaline water electrolysis (AEL) is a low-temperature process to produce hydrogen in a commercially mature technology, namely the alkaline electrolyser. This type of electrolyser is here considered in place of the PEM technology, as large-scale units are needed. Water electrolysis is carried out in a liquid alkaline electrolyte solution of a base (KOH or NaOH), where hydroxide ions OH^- cross a diaphragm separating the electrodes. Typically, AELs operate between 60 and 90°C, while the operating pressure spans from ambient pressure up to 3.5 MPa [9]. In the present case, we assumed to perform the AEL at 3 MPa and 85°C, with a power consumption of 3.6 MW for a hydrogen flow rate of 72 kg/h, leading to a specific energy consumption of approximately 50 kWh/kgH_2 (4.5 kWh/Nm^3H_2), which is consistent with values reported in the literature [10].

Inside the reactor, water electrolysis is accomplished with the following reaction (R1):

$$H_2O \rightarrow H_2 + 0.5O_2, \quad \text{(R1)}$$

which is given by the combination of the cathode reaction (Eq. R2) and anode reaction (Eq. R3, R4):

$$H_2O + 2e^- \rightarrow H_2 + O^{2-}, \quad \text{(R2)}$$

$$O^{2-} \rightarrow 0.5O_2 + 2e^-, \quad \text{(R3)}$$

$$O + O \rightarrow O_2. \quad \text{(R4)}$$

In this case, three electrolysers are used along the CO_2 pipeline path, requiring on the whole an electricity consumption of 31536 MWh/year. It is assumed that electrolysers are powered by renewable energy, thereby enabling the possibility of producing at the end of the process green synfuel: this corresponds to the category of Power-to-X technologies. The electrolysers are assumed to be operational an average of 8 hours per day, thereby using with profit the photovoltaic energy available in Italy (2920 h/year equivalent operational time per year). In this way, it is estimated that it would be possible to produce 215 kg/h of hydrogen (630 t/year).

5.3. Hydrogen from the soda-chlorine process

Some of the hydrogen needed can be harvested from the soda-chlorine process at the Rosignano Solvay plant. Hydrogen is here a co-product of the electrolysis of brine (approximately 28 kg of H_2 per ton of chlorine). This high-quality hydrogen (purity > 99.9%) is currently used on-site (mainly as a fuel in co-firing steam boilers) or is sold to a distributor.

The alkaline electrolyser works following a membrane cell technology [11]. The basic principle in the electrolysis of a sodium chloride solution is the following:

- at the anode, chloride ions are oxidised and chlorine (Cl_2) is formed;
- at the cathode, water decomposes to form hydrogen (H_2) and hydroxide ions (OH^-).

The anode reaction is:

$$2\,Cl^- \rightarrow Cl_2 + 2e^-. \quad \text{(R5)}$$

The cathode reaction is:

$$2Na^+ + 2e^- + 2H_2O \rightarrow 2NaOH + H_2. \quad \text{(R6)}$$

The overall reaction is:

$$2NaCl + 2H_2O \rightarrow 2NaOH + H_2 + Cl_2. \quad \text{(R7)}$$

The products of the electrolysis are 1070–1128 kg of NaOH (100 wt-%) and approximately 28 kg of H_2 per ton of Cl_2 produced. The plant operates in a continuous cycle for 24 hours/day, for a nominal 350 days/year. The theoretical capacity of the plant is about 14.5 tons/hour of Cl_2, which correspond to about 125 kton/year of chlorine gas [12]. Considering the molar mass of chlorine gas equal to 70.906 kg/kmol, stoichiometry shows

that the amount of hydrogen resulting is 3.463 kton/year or 412.2 kg/h. The calculated consumption of electrical energy is equal to about 2600 kWh/t Cl_2 [11], or 6,23 kWh/Nm^3 of H_2.

6. Methanol synthesis section

The MSS allows the production of liquid fuel, which is used to store energy. The main blocks are the adiabatic reactor, where the catalytic CO_2 hydrogenation process is carried out, and the distillation column, where the purification process is carried out. Methanol is produced through the three main reactions of the CO_2 hydrogenation process: CO is given by the water gas shift reaction (R8) and converted into methanol by the CO hydrogenation reaction (R9), while methanol is also produced through the CO_2 hydrogenation reaction (R10).

$$CO_2 + H_2 \leftrightarrow CO + H_2O, \quad \text{(R8)}$$

$$CO + 2H_2 \leftrightarrow CH_3OH, \quad \text{(R9)}$$

$$CO_2 + 3H_2 \leftrightarrow CH_3OH + H_2O. \quad \text{(R10)}$$

At equilibrium conditions only two of these three reactions are sufficient to describe the composition [13]. Only Eqs. (R8) and (R10) were thus considered in the developed model.

The production of methanol was set considering the hydrogen production and recovery. It is supposed to locate two methanol production systems along the pipeline path, one near the GPP to exploit the hydrogen produced by electrolysers and that recovered from hydrogen sulphide (MSS1), the other plant is instead near Solvay Chimica S.p.A. (MSS2). Assuming the stoichiometric molar ratio of reactants (reaction (R10)), Table 2 was been obtained.

Table 2. *Stoichiometric reactants and products flow rates for MSS reactors [kg/h].*

Flow rate Species	MSS1	MSS2
H_2	83.68	412.2
CO_2	609.04	3000
CH_3OH	443.43	2184

The methanol production system is supposed to operate 8760 hours per year and the production was based on the study of [14]; the simulation was performed in the UNISIM DESIGN (Honeywell) modelling environment.

The methanol synthesis reactor operates at 6.5 MPa requiring the hydrogen and CO_2 to be compressed. CO_2 is compressed only when it is taken from the vapour pipeline at 4 MPa from the vapour pipe. Since MSS1 always takes carbon dioxide in the vapour phase, in this study we consider that CO_2 is taken from the vapour pipe for both MSS. A future investigation should concern the case of CO_2 withdrawal from the liquid pipe; when it is taken from the liquid tube at 10 MPa it must be laminated and then heated to have only steam entering the reactor. The number of compressor stages for the H_2 stream depends on the source. The hydrogen obtained from the reduction of hydrogen sulphide is compressed to the operating electrolysis pressure, and then joins the flow of hydrogen produced by the alkaline electrolyser.

Figure 5 shows a simplified functional scheme of the methanol synthesis and purification section. The compressed H_2 (2) and CO_2 (5) are mixed with the re-circulated gases (23) and preheated (HX1) to 210 ◦C prior to entering the synthesis reactor (R1). Within the adiabatic reactor, the exothermal CO_2 hydrogenation reaction increases the temperature up to about 280 °C and 231 °C for MSS1 and MSS2 respectively. The reactor outlet is mainly composed of hydrogen (about 85% by vol in MSS1 and 97% by vol in MSS2), whereas the methanol content is 4.1% by volume in MSS1 and 1.5% by volume in MSS2. To boost the production of methanol, two flash processes are performed (F1 and F2) and the un-reacted incondensable gases (18 and 21) are re-circulated back to the reactor. The first flash occurs at 6.5 MPa, after reducing the temperature to 50 °C in two heat exchangers (HX1 and HX2), that supply heat to other points in the process, and a cooler (C1). Here the gases are separated to liquid raw methanol and non-reacted gases. The non-reacted gases (18) are recycled to the reactor after purging 1% in order to prevent the accumulation of by-products and inert gases in the system. The second flash process takes place reducing the pressure and temperature of the liquid stream to about 0.12 MPa and 22 °C. Here raw methanol is expanded to further remove the non-reacted gases, especially CO_2, and by-products in order to ease the distillation process. The resulting liquid product (12), namely crude methanol, is mainly composed of methanol and water (both about 50% by vol in both systems) with a small content of CO_2. To boost the methanol purity, the separation of water and methanol takes place in a distillation column (D1). From the bottom of the distillation column, water (15) is recuperated in the liquid phase and can be recycled back to the electrolysers. The distillate at the top of the column (14) is

pure methanol; the CO_2 in the residue (16) is recycled to the inlet and mixed along with fresh CO_2 (3). Methanol is then sent to the storage tank. The resulting methanol has a purity greater than 99.85% in both systems and is therefore compliant with the IMPCA specification [15]. Table 3 reports the main MSS operating parameters.

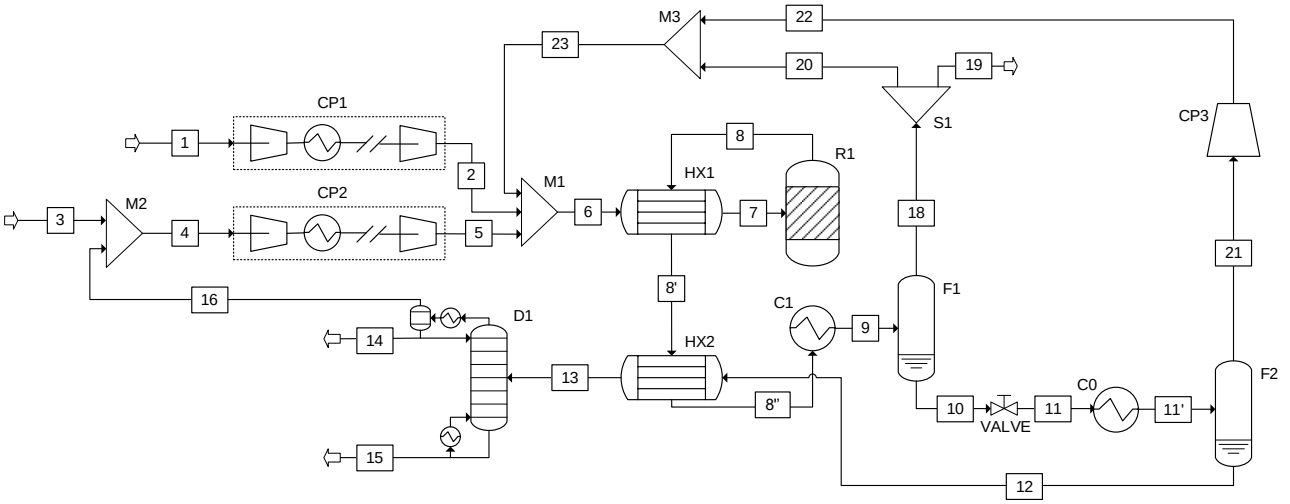

Figure 5. *Simplified functional scheme of the MSS, modified from [14] (C=Cooler; CP=Compressor; D=Distillation column; F=Flash; HX=Heat exchanger; M=Mixer; R=Reactor; S=Splitter).*

Table 3. *MSS main operating parameters.*

Parameter	Value
Reactor type	Adiabatic
Reactor pressure [bar]	65
Reactor inlet temperature [°C]	210
F1 pressure [bar]	65
F1 temperature [°C]	50
F2 pressure [bar]	1.2
F2 temperature [°C]	22
Methanol storage pressure [bar]	1
Methanol storage temperature [°C]	25

Since the reactor products are characterized by a high temperature, they can be employed to provide heat to some processes within the system, reducing the thermal energy that otherwise would be provided by an external source. Thermal energy is required by the following processes:

- the preheating of the reactants (6) from 80 to 210 °C;
- the heating of crude methanol (12) up to the inlet temperature of the distillation column (80°C).

Firstly, the reactor products are cooled (HX1) from 280 °C (8) to 144 °C (8') in MSS1 (from 231 °C to 84 °C in MSS2). Finally, the reactor products (8') are cooled (HX2) to about 132 °C in MSS1 and 80°C in MSS2, with the preheating of the crude methanol (12). To reach the first flash condition (50 °C), heat should be further removed from the reactor products in cooler C1. If a cooler heat recovery in the distillation column were also considered, the thermal self-sustainability of the section could be achieved.

7. Results and discussion

Drawing on the methodology presented in the previous section, the thermal energy demand and the district heating and cooling performance are discussed in detail as a first step. Then, the results of the two methanol production plants are shown. Finally, the energy requirements of the system and the emissions avoided are assessed.

7.1. Energy demand

Heating Degree Days (HDD) and Cooling Degree Days (CDD) patterns are presented in Fig 6 (a). The maximum daily values for HDD and CDD are 13.82 °C and 2.73 °C respectively. Moreover, the annual accumulated HDD is 1602°C and for CDD is 48°C.

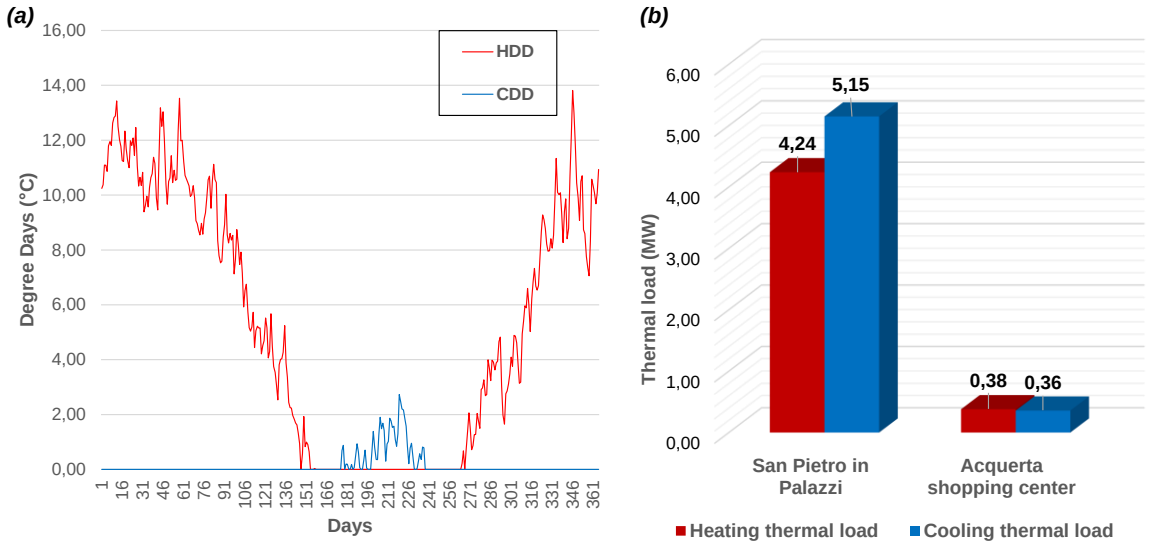

Figure 6. *a) Annual evolution of heating and cooling degree days in the selected location, b) Energy demand for the area studied.*

Figure 6 (b) illustrates the thermal needs of the Acquerta shopping centre - the main user to be satisfied - as well as those of the San Pietro in Palazzi community. The total thermal energy required annually by the shopping centre is 0.74 MW. 51.5% of which is for heating and 48.5% for cooling.

7.2. Heating and Cooling district

The CO_2 leaving the AMIS is brought to the desired conditions for the entrance to the steam pipe through three inter-refrigerated compressors up to 4 MPa and subsequent cooling up to 40 °C. A portion of the flow rate is sent to the methanol production system: the remaining CO_2 flow rate to be transported is 2.86 kg/s. The flow rate that must instead be introduced on the liquid side undergoes a further compression up to 10 MPa and subsequently, an absorption cooling (it is proposed the use of geothermal water for CO_2 cooling) is used to bring its delivery temperature to 20 °C.

The initial three compressors are about 300 kW each, the fourth – operational for the final liquid flow delivery rate - needs about 173 kW; the flow rate of water required (sets a maximum outlet temperature of 95 °C) for the two inter-refrigerations is a total of about 2 kg/s, that for cooling the steam up to 40 °C is 1.2 kg/s, while the thermal power that must be dissipated with the absorption cycle is 851 kW.

During winter operation, given the potential of the available CO_2 flow rate, it is possible to satisfy a 430kW thermal user. In this condition, therefore, the system is able to meet the heating needs of the Acquerta shopping centre, with the possibility of distributing about 50kW of heat to San Pietro in Palazzi buildings.

Figure 7 shows the representation of the system just described on the T-s diagram. The subcritical vapour at 4 MPa is compressed to 10.3 MPa (1-2 process) and then is cooled in the trans-critical heat pump to 45°C by rejecting heat to an external fluid (2-3 process, useful heating effect). Carbon dioxide at high pressure is further cooled to 25°C in the air heat exchanger (3-4 process).

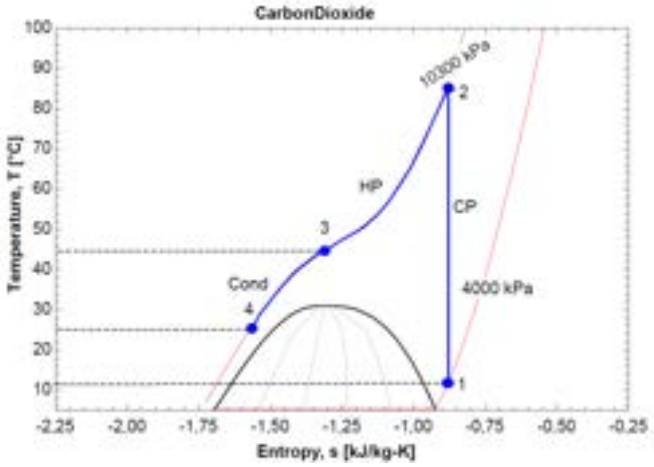

Figure 7. *Representation of winter operation on the T-s diagram (CP=Compressor, HP=trans-critical Heat Pump, Cond=Condenser).*

The conditions of the CO_2 entering the heat pump, which represents the user, depend on the losses that occurred upstream. In particular, the pressure remains at 4 MPa, but the temperature drops along the pipeline to an estimated value of 10.5 °C, despite the insulation of the pipeline. The power required by the compressor to compress CO_2 to 10.3MPa is 147.3 kW. The calculated COP of the heat pump is about 3. The thermal power required to cool down the CO_2 stream in the air exchanger to bring it back to the liquid state is 229.8kW. Figure 8 (a) illustrates the heat transfer profiles of the first heat exchanger, showing a good coupling between the resource and the user (a result of the selection of a trans-critical Heat Pump). Figure 8 (b) shows the heat transfer profile of the air exchanger that produces the liquid CO_2 recovery stream.

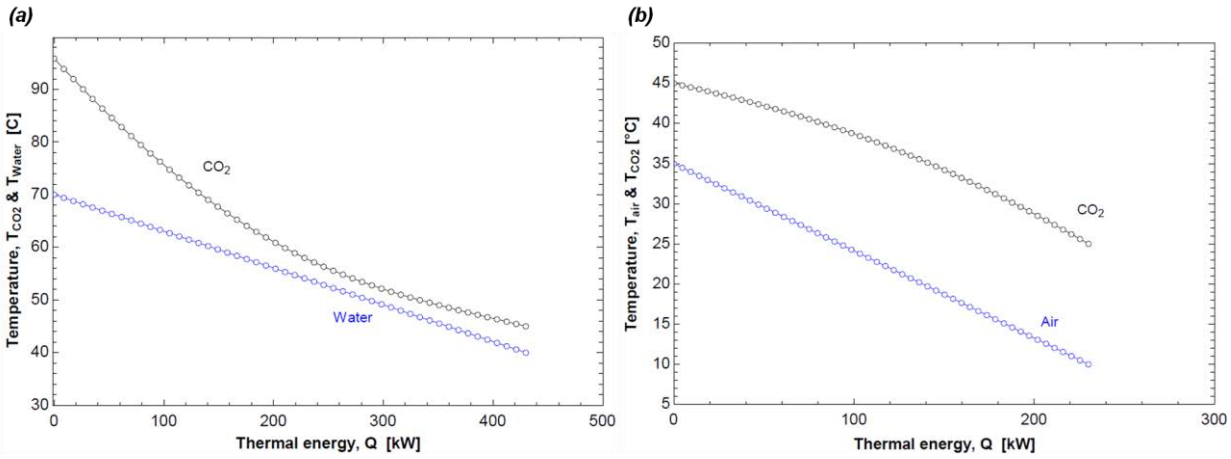

Figure 8. *Heat exchange profiles of a) the transcritical heat pump, and b) the air exchanger.*

During summer operation, given the potential of the available CO_2 flow rate, it is possible to satisfy a 480kW cooling load. In this condition, therefore, the system meets the cooling needs of the Acquerta shopping centre, with the possibility of distributing about 122kW of cold to the San Pietro in Palazzi households. The difference between summer and winter is dictated by the fact that in summer for cooling the load is greater for the individual user, especially considering the shopping centre.

7.3. Methanol Synthesis Systems

For the MSS1 system, hydrogen from H_2S is compressed to 3MPa in order to combine the hydrogen stream produced by the electrolysers. Then the hydrogen flow is further compressed up to 6.5 MPa, the working pressure of the MSS. The power consumed is equal to 81.72 kW. Since de compression power required by the CO_2 is equal to 9.4 kW, the total power absorbed by all compressors in the MSS1 is about 93 kW.

Also for the MSS2 system, located at the Solvay Chimica S.p.A. premises, hydrogen must be compressed to 6.5 MPa. In this case, the power consumed is equal to 329.6 kW. As previously specified, it is supposed to take CO_2 from the vapour phase pipe (4 MPa); therefore, it must also be compressed. The total compressor power for the MSS2 is about 193.3 kW. For both MSS systems, the overall power requirement of the compressors is mainly due to hydrogen compression.

As described previously, several heating and cooling processes take place in different sections of the system, requiring an accurate analysis to identify a correct coupling between the different flows to enhance the system's performance. An internal heat recovery was performed to reduce the external requirements of thermal energy (Fig 5). In Table 4 the heating and cooling processes within the MSS are summarised.

Table 4. *Main heat transfers in the MSS1 and MSS2.*

Heat requirement	Process	Fluid	Thermal power [kW]	
			MSS1	MSS2
Heating	HX1	Reactor inlet	440	8100
	HX2	Methanol and water	46.65	211.5
Cooling	C1	Reactor product	559.6	2368
	C0	F1 liquid product	22.10	107.9

As shown in Table 4, since the MSS does not need external heat input (HX1 and HX2), the main thermal energy load can be identified in the cooling process of the synthesis reactor products (C1) that need to be cooled to about 50°C to separate methanol and water from incondensable gases.

436.55 kg/h of methanol are obtained for the MSS1 system and 2078.6 kg/h of methanol for the MSS2 system, which correspond to 98% and 95% of stoichiometric methanol, respectively. Considering an operation of 8760 h/y, the annual methanol production of the plants is equal to 22 kton. Bearing in mind that the annual carbon

dioxide emissions of the Valle Secolo plant are about 95 kton/year, the two MSS allow using of about 33% of these emissions.

7.4. Mass and energy balance

Table 5 collects the results from the mass balance of the system, showing that the yield is 0.7kg of methanol per kg of CO_2 supplied. The production of oxygen is 0.47kg per kg of CO_2 supplied. A further development of the MSS could be the combustion of the purge stream 19 (Fig 5) and thus the production of electrical energy. The results from the energy balance of the system are gathered in Table 6, which shows that water electrolysis corresponds to 87.6% of the net electricity consumed by the entire process.

Table 5. *Mass balance (not including the remaining CO_2 transported to the final terminal).*

Compound	In (t/h)	Out (t/h)
CO_2	3.61	0.0121[a]
CO	0	0.0036[a]
H_2	0	0.1278[a]
H_2O	1.928	1.45
Methanol	0	2.52
O_2	0	1.71[b]

[a] Contained in stream 19 (purge)

[b] Oxygen generated by water electrolysis

Table 6. *Energy balance.*

Unit	Operation	Amount [MW_{el}]	Amount/tMeOh [kJ/ton MeOh]
Water electrolysis	Power to AEL	10.8	0.604
H_2S reduction	Power to PCR	0.157	0.003
CO_2 preparation	CO_2 Compression	1.09	0.02
Methanol synthesis and purification	Compressors	0.29	0.005
Total net electricity consumption		12.332	0.633

7.5. CO_2 emissions avoided

The assessment of avoided CO_2 emissions is done by investigating the difference between two scenarios: the conventional and the innovative. In the conventional scenario, emissions are due to conventional methanol production: most of the commercial methanol produced today comes from fossil fuels, typically using steam reforming from the natural gas feedstock. CO_2 emissions from conventional methanol generation are assumed equal to 0.555 kg CO_2/kg methanol [16]. In the innovative scenario, the emissions are only those of the scheme to produce methanol with the H_2+CO_2 reactor, i.e. 0.005 tons CO_2/t of methanol. It should be emphasized that the energy sources necessary for the processes described must be assumed consistently with the purpose of this investigation, therefore the use of electricity from renewables is necessary.

The total CO_2 emissions of both MSS are 105.7 tons/year, considering 8760 operating hours, and with a production of 22 kton/year of methanol; with the conventional system, on the other hand, 12kton/year of CO_2 would be emitted considering the same methanol production and the same operating hours.

The emissions avoided for utilities were calculated for heating from the values of the energy performance index already calculated in primary energy and assuming the use of natural gas with emissions of 199 g CO_2/kWh [17]. For the production of cold, the use of electricity for the supply of the refrigeration cycle with a COP 3 with emissions of 355 g CO_2/kWh for electricity was assumed [18]. Therefore, this results in a reduction in emissions related to the heating and cooling services provided of about to 237 tons of carbon dioxide per year.

8. Conclusion

This work tackles the problem of the greenhouse effect, which is a global problem, and something important on a regional scale. The Tuscany region has almost 1000MW of geothermal energy installed, the only region in Italy with a long tradition on this. Geothermal energy has raised problems, but it has also brought a lot of wealth: at present, geothermal is supplying the largest share (over 78%) of renewable energy in the Tuscany region [19]. The energy transition towards carbon waste-free urban districts relies on local renewable energy assets. As part of the ecological transition, some things will have to change, and this document investigates the possible circular uses of geothermal carbon dioxide, which represents a waste in electricity production, but also a fraction that would still have been released naturally from underground [20]. The scenario investigated in this study lies in some fundamental pillars:

- hydrogen recovery along the way: 103.2 tons/year of hydrogen from the reduction of hydrogen sulphide and 3463 tons/year from Solvay S.p.A.
- production of green hydrogen by electrolysers powered with renewable energy: 630 tons/year of green hydrogen are produced;
- implementation of Power-to-X technology: 22033 tons/year of methanol are produced by converting about 32 kton/year of carbon dioxide (about 33% of the Valle Secolo total emissions);
- promote the co-generation and distribution of heat and cold for users: 869 MWh/year of thermal load for heating and 543 MWh/year of cooling demand are satisfied. In this way, 100% of the thermal and cooling requirements of Acquerta S.C. and 1.2% and 2% of that of San Pietro in Palazzi are fulfilled during winter and summer operations, respectively.

The circular use of CO_2 also makes it possible to reduce emissions due to heating and cooling operated in an unconventional way: about 240 t/year of CO_2 would be saved. There is also a saving of emissions in the methanol cycle because if the same amount of methanol had to be produced through fossil fuels, about 12 kton/year of CO_2 would be emitted. Hypotheses of sequestration of CO_2 not converted along the route could also be evaluated, as well as bottling, liquefaction and shipment from the port of Livorno. A further future study will concern the economic feasibility of the system.

In conclusion, this work focused on the Tuscany region represents a screening of interesting possibilities for sustainable development.

Abstract:

In order to mitigate climate change, the expansion of renewable sources especially in the fossil-dominated heating sector is necessary. Geothermal sources represent a promising low-carbon alternative for heat supply. In this study, a Life Cycle Assessment of an operating deep geothermal heat plant in the Southern German Molasse Basin is conducted according to ISO 14040 and 14044. The plant utilizes a hydro-geothermal source and consists of a total of two production wells and one injection well with thermal water temperatures of up to 107 °C and an output of 16.7 MW. For peak load and redundancy, three oil boilers with a total capacity of 17 MW are installed. The heat plant is connected to a 48.5 km district heating network for the supply of 1800 customers. As functional unit 1 kWh net heat at the customer is chosen. For the impact categories Global Warming Potential (GWP), fossil resource scarcity and terrestrial ecotoxicity are considered. The environmental impact amounts to 78.5 g CO_2-eq./kWh, 29.2 g oil-eq./kWh and 399.0 g 1,4-DCB/kWh, respectively. In addition to the main results, selected scenarios have been analyzed with regard to the potential of switching the electricity mix and the peak load coverage between oil, natural gas and biomethane. The results show that switching to a renewable electricity mix leads to the biggest reduction with 57.8 % for the GWP.

Keywords:

Geothermal heat plant, district heating, Life Cycle Assessment; peak load coverage, electricity mix, Sustainability

1. Introduction

In order to meet the objective of the IPCC and limit the anthropogenic impact on the environment, it is essential to decarbonize the heating sector. In Germany, especially, the share of renewable sources for heat is considerably low with only 16.5 % [1]. Geothermal energy has great potential and could substitute up to 40 % (7 655 MW) of the heat demand in the state of Bavaria [2]. Therefore, the technology has gained political interest also due to the independence of fossil fuel supply.

However, even with this technology, which is characterized by the costly deep drilling, the question of how well it is compatible with the climate is open. The Technical Expert Group on Sustainable Finance has set a threshold of 100 g CO_2-eq./kWh that makes a technology compatible with the Paris climate agreement [3]. Additionally, this threshold decreases every 5 years until net zero in 2050. This ensures the necessity to identify strategies for the reduction of Global warming potential (GWP).

In this study, a LCA is conducted analyzing the categories GWP, fossil resource scarcity (FRS) and terrestrial ecotoxicity (TE) for a currently operating geothermal heat plant in the Southern German Molasse Basin in the greater Munich area. Additionally, the influence of auxiliary energy is investigated and the potential of reducing the environmental impact is analyzed through scenario analyses regarding electricity mix and peak load coverage.

2. Goal and Scope

The LCA in this study is conducted according to ISO 14044 and 14040 [4,5] which include the four phases: definition of goal and scope, inventory analysis, impact assessment and interpretation. These phases are explained in detail in the next sections.

2.1. Objective

The objective of this study is to conduct an LCA of a currently operating geothermal heat plant and its district heating network (DHN) in the Southern German Molasse Basin which includes the impact categories GWP; FRS and TE. Furthermore, the use of auxiliary energy is analyzed by conducting scenarios regarding the electricity mix and the peak load coverage. For the applied electricity mix the location based German electricity mix is compared to two renewable mixes (see Table 6). With the peak load coverage, the fuels light fuel oil, natural gas and biomethane are weighted up.

For the LCA, all energy and material flows for the life cycle stages construction, operation and decommission are considered. Thus, a cradle to grave approach is applied. To ensure comparability with other LCAs, a lifetime of 30 years is chosen, as is suggested by [6]. According to [7] and [8] DHNs exceed the life time of the heat plant with respectively minimally 40 and 50 a. Therefore, it is assumed that the DHN either will be used for another heat plant right away or remains unchanged in the ground until a new use. Either way there is no decommissioning scenario attributed to the life-cycle of the geothermal plant.

For operators of geothermal heat plants and decision makers the results can be of interest for developing strategies for the reduction of the environmental footprint along with planning future plants.

2.2. Functional unit

In order to present the result in a comparable way, all energy and material flows are related to one variable according to [4]. In this study, 1 kWh of net energy at the consumer has been selected for this purpose. This means that both DHN losses and the generation of auxiliary energy for peak load coverage and redundancy by oil boilers were considered.

2.3. Geothermal heat plant

In this section, the analyzed geothermal heat plant is presented. It is located in the Southern German Molasse Basin which is characterized by a porous water-bearing carbonate rock layer at a depth of 2000 to 3000 m in the greater Munich area, sloping down to the south [2]. Therefore, the plant relies on hydrothermal energy. It went into operation in 2005. The 104 °C hot water is drawn from two production wells and after the heat transfer at the heat exchangers it is fed back into one injection well. The heat exchangers are connected to the district heating network (DHN) as well as light fuel oil fuelled boilers which cover peak load and redundancy in case of maintenance or component failure. Through the DHN the heat plant supplies heat to 1800 customers. Relevant parameters can be found in Table 1.

Table 1. General Parameters of the geothermal heat plant [9]

Parameter	Value
Maximal geothermal energy	16.7 MW
Maximal energy by peak load and redundancy boilers	17 MW
Average operating hours full load	4234 h
Proportion of heat from geothermal energy	95 %
Proportion of heat from peak load and redundancy boilers	5 %
Production well 1 measured depth	4666 m
Production well 2 measured depth	4120 m
Injection well measured depth	3984 m
DHN	
DHN total length	48.5 km
DHN users	1800
Total installed load (2021)	29.75 MW

2.4. Data source and methodology

In this section, the important matter of data quality is addressed which needs to be included in any report for a LCA according to [4]. As far as possible for this study, primary data provided by the plant operator was used. If no data was available suitable literature was utilized. Thereby, it was ensured that the applicability was granted, e.g. through suitable geographical and time related similarity.

To conduct the LCA, the software SimaPro (version 9.4.0.1) and the database ecoinvent (version 3.8) were utilized. Within ecoinvent, the system model “allocation cut-off by classification” was selected. This database provides an extensive selection of processes including pre-chain emissions in addition to direct emissions. ecoinvent provides the characterization factors to allocate environmental effects to conduct the life-cycle impact assessment (LCIA), which considers for example for the impact category GWP how much greenhouse gas is emitted for every energy and material in- and output collected in the LCI-phase. For the results the method ReCiPe midpoint (hierarchist) [10] is applied. Thereby, as impact categories, GWP (with a time horizon of 100 years, according to the hierarchist view) TE and FRS are selected.

3. Results and Discussion

3.1. Base Case

For the base case, the construction of the subsurface with the boreholes and the surface components are included. This involves the heat exchangers and peak load and redundancy boilers and plant parts. Additionally, the DHN is considered. The extensive LCI can be found in [9], any changes to the original LCI can be found in Table 7 in the appendix.

In Figure 1 the results for the base case are shown. Hereby, the general results are 78.6 g CO_2 eq./kWh for GWP, 399.0 g 1,4-DCB/kWh for TE and 29.3 g oil eq./kWh. It is apparent, that the operation phase dominates the environmental impact for all categories whereas for FRS the construction of the DHN also has a significant impact with 27 %. This is due to the light fuel oil product bitumen that is used for the asphalt which needs to be replaced for the installation of the pipes under streets (see also [9]).

Taking a closer look at the operation phase it is apparent that the main impact comes from the electricity consumption and the peak load and redundancy coverage. The latter has a high impact since it is oil based. The electricity consumption’s high impact is due to the high share of fossil sources like coal and natural gas in the German electricity mix. For the lifetime from 2005 to 2035 this amounts to 55.8 % (electricity mix based on [6] and [11]).The greatest influence of the operation is seen for the GWP: hereby the electricity consumption of the pumps leads to 62.0 % and the peak load and redundancy coverage to 21.2 %. For the TE the peak load coverage and redundancy have the biggest impact with 48.0 % and for FRS the electricity consumption dominates the impact with 43.1 %.

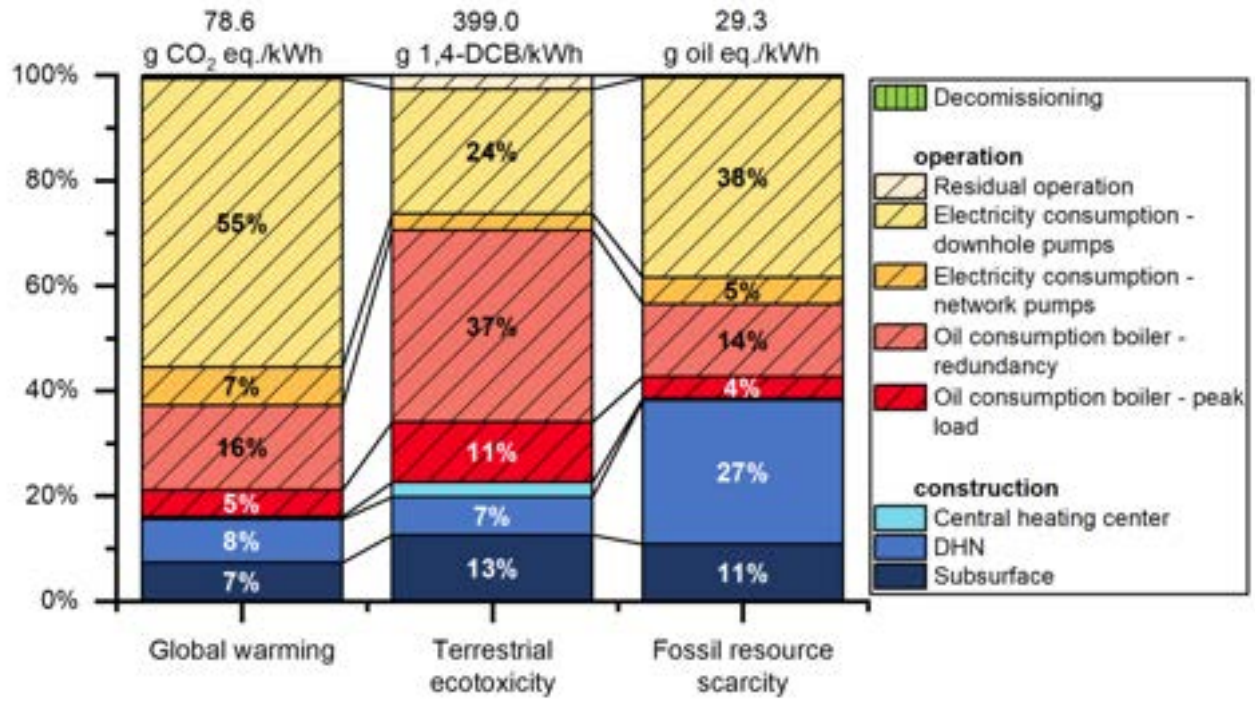

Figure 1. LCA results of a geothermal heat plant with DHN for the operating years of 2005-2035.

With these general results for GWP the threshold of 100 g CO_2/kWh proposed by [3] can be met with ease. They also propose an annual decrease in emissions until net zero 2050. Therefore, strategies should nevertheless be developed to further reduce the environmental impact. Since the single biggest contributors prove to be within the auxiliary energy namely electricity consumption as well as peak load and redundancy

coverage, the impact of these is further examined by the following scenario analyses in the sections 3.2 and 3.3.

3.2. Peak Load Scenarios

Within this section, various technologies for managing peak energy demand are compared, with particular emphasis on those utilizing fuel-based solutions. The comparison is centered around the base case of oil-fuelled boilers for peak energy coverage, contrasted against the conventionally used natural gas alternative. Additionally, consideration is given to the renewable fuel source of Biomethane, which is derived by upgrading biogas through chemical means, increasing its methane content to match that of natural gas [12].

For the use of biomethane two scenarios are created, one with the sole use of biomethane as fuel and the second with a mixture of biomethane and natural gas. The latter is created as a realistic approach since the production volume of biomethane in Germany is limited which is due to being based on agricultural and animal waste as well as energy plants. The latter are in competition for cultivable land for food or feed crops as well as the use of biogas for electricity production (7.8 % of the electricity mix in 2022 [13]) [12,14]. The 10 % value is based on biomethane shares that are already currently commercially offered in the state of Baden-Württemberg in Germany [15]. Furthermore, it also fits within the range (8-12%) Arnold et al. [16] propose as realistic share of biomethane in the German gas grid by 2030. The following Table gives an overview over the different scenarios that are analysed.

Table 2. Peak load scenarios

Scenario	**Base Case**	**Natural gas**	**Biomethane**	**90NG 10BM**
fuel	Light fuel oil	Natural gas	Biomethane	90% natural gas and 10% Biomethane

For the LCI plant parts necessary for using light fuel oil, like the oil storage and catch basin are no longer needed and are therefore excluded. Through the ecoinvent data the gas production and the natural gas grid is considered proportionally. The material and energy input for the boilers are assumed to be the same for the fuel oil and gas, analogous to [17]. Since biomethane is used to substitute natural gas, the same infrastructure as for natural gas (gas network and boilers) is assumed as well as the same emissions for the burning in the boilers. The greenhouse gas emissions for the burning of biomethane, however, are considered as biogenic and are therefore not part of the GWP. The extensive LCI with the selected ecoinvent data for the components and the process of burning of the fuels can be found in the appendix in Table 8. An overview of the relevant parameters and considered infrastructure for the respective scenarios is shown in Table 3. For the scenario with 10 % biomethane and 90 % natural gas the models for natural gas and biomethane from Table 3 are considered proportionally.

Table 3. Parameters for the peak load scenarios with the base case (light fuel oil), natural gas and biomethane

Parameter	**Base case**	**Natural gas**	**Biomethane**
Degree of utilization	91 %[a]	96 %[b]	96 %[c]
Plant components	Boiler	Boiler[d]	Boiler[d]
	chimney	chimney	chimney
Fuel supply	Oil storage and catch basin	Natural gas network	Natural gas network
Direct emissions per kg light fuel oil/m^3 high pressure gas according to ecoinvent process	heat production, light fuel oil, at industrial furnace 1MW	heat production, natural gas, at boiler modulating >100kW	heat production, natural gas, at boiler modulating >100kW[e]

a: degree of utilization for the year 2019, assumed to remain the same over the life time
b: for a modulating, not condensing boiler according to [18]
c: Same value assumed as for natural gas
d: the same inputs are considered as for the oil fuelled boiler analogous to [17]
e: all emitted greenhouse gases are biogenic and are therefore not relevant for the GWP

In Figure 2 the LCA results for the peak load coverage are shown considering the different scenarios. Hereby, only the results for heat generation by the peak load boilers are shown as opposed to the heat generation of the whole geothermal plant.

The results are depicted relative to the oil fuelled base case (BC). The other scenarios are the coverage by natural gas (NG), biomethane (BM) and the realistic scenario with 90 % supply by natural gas and 10 % biomethane (90NG10BM).

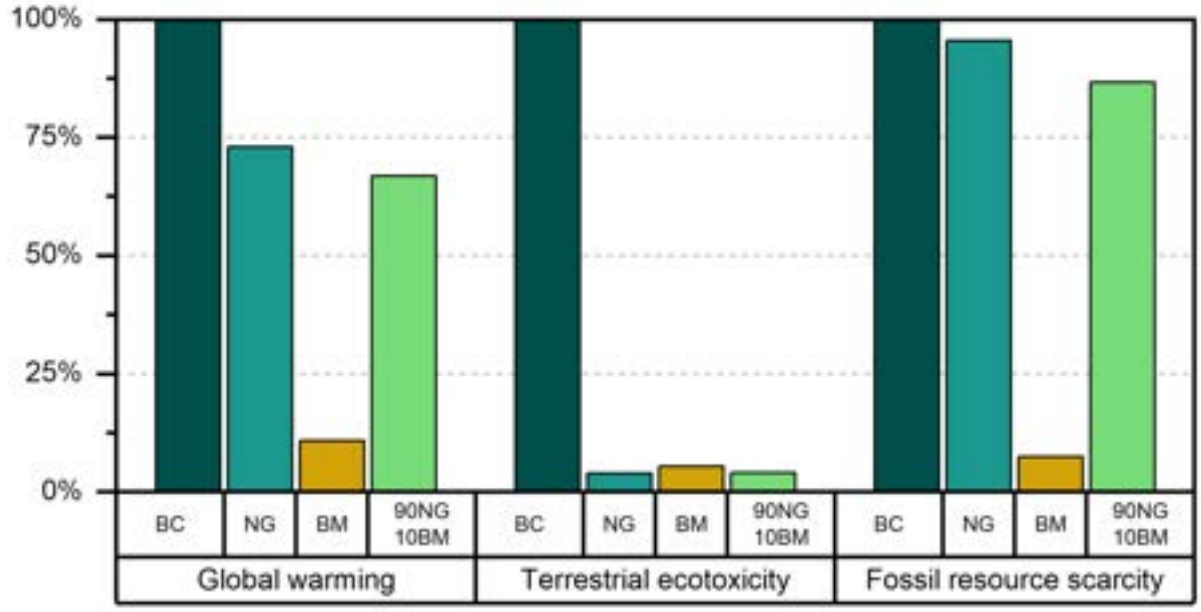

Figure 2. LCA Results of heat generation of different peak load coverage technologies: base case with light fuel oil (BC), natural (NG) and biomethane (BM) as well as a realistic mixture of 90 % natural gas and 10 % biomethane (90NG10BM) relative to the biggest contributor.

The relative results from Figure 2 are also shown in Table 4 as absolute values per kWh generated heat at the plant. In general, all gaseous fuels lead to a reduction of the environmental impact. Beside the higher emissions from burning oil compared to natural gas, this can be partly explained by the difference in utilization factors (that are generally higher for gas boilers than for using oil [19]). Additional contributions are the reduced fossil sources and emissions for biomethane compared to light fuel oil as well as reduced plant components. As expected, the biggest reductions for FRS and GWP are achieved by using biomethane. With the realistic scenario the GWP can be reduced by 33.3 % and the RRS by 13.4 %. For the TE the switch to the gaseous fuel in general leads to the biggest reduction since the oil combustion has a very high TE comparably.

Table 4. Results of the environmental impacts GWP, RE and FRS of the peak load coverage scenarios per kWh produced heat at the boilers (i.e. without DHN heat losses) considering construction, operation and decommissioning of the peak load components

	Base case	**Natural gas**	**Biomethane**	**90ng 10bm**
GWP [g CO_2/kWh]	353.5	257.9	38.2	235.9
TE [g 1,4-DCB]	4497.6	173.0	239.3	179.6
FRS [g oil eq]	110.9	105.8	8.2	96.1

If now the whole heat plant is considered again (see Table 5), with using 100% biomethane a reduction in GWP of 20.4 % can be achieved compared to the base case. Whereas the use of natural gas only reduces the total GWP by 3.2 %. Increasing the amount of biomethane in the gas network would lead to a significant reduction in GWP whereas for TE the switch to either gas greatly decreases the impact (49.4 % for natural gas) with natural gas having a slightly higher reduction potential than pure biomethane. The great effect on the heat plant concerning FRS can be again achieved with biomethane with a reduction of 17.6 %. Since FRS is based on the caloric value of the fossil fuels, the difference between oil and natural gas is mainly due to the higher degree of utilization assumed for the use of natural gas (see Table 3).

Table 5. Results of the environmental impacts GWP, RE and FRS of the peak load coverage scenarios per kWh produced heat by the whole geothermal plant

	Base case	Natural gas	Biomethane	90ng 10bm
GWP [g CO_2/kWh]	78.6	74.1	62.2	73.0
TE [g 1,4-DCB]	399.0	201.8	202.9	201.9
FRS [g oil eq]	29.3	29.1	24.2	28.6

To conclude, switching to natural gas has a small positive impact for GWP and FRS and a significant reduction for TE. Except for TE an increase of biomethane in the gas pipelines significantly decreases the environmental footprint of the plant. Although it has to be considered that the biomethane share in the gas network is dependent on the development of the gas market.

3.3. Renewable Electricity Mix Scenarios

To analyse the ecological potential of changing the consumed electricity mix, the base case is compared to two scenarios with renewable electricity mixes. The base case includes the location-based electricity mix in Germany for the respective electricity demands for each year over the plant's life time of 2005-2035. Whereas the future German electricity mix is obtained from the projection of [20]. To show the difference to a fully renewable mix, the base case is compared to the scenario with the mix of renewable energy of the year 2022 (RE22) [13]. Additionally, as an example of a commercial mix, a scenario containing 90 % hydro and 10 % wind power is created. The average shares of power sources can be found in Table 6.

Table 6. Composition of the examined electricity mixes with the base case displaying the general German electricity mix for the years 2005-2035 considering the differing yearly energy demands of the heat plant over the life time. Future mixes are modelled according to [20]. 90H10W displays an example of the potential of commercially available composition. RE22 is the market of renewable electricity in 2022 according to the German Federal Network Agency [13].

	Share [%]		
Energy source	**Base case**	**90H10W**	**RE22**
Fossil sources	55.8	0	0
Biomass	8.4	0	17.0
Hydro	3.6	90.0	5.3
Wind offshore	6.4	0	10.7
Wind onshore	17.4	10.0	43.3
Solar	7.8	0	23.8
Other renewables	0.6	0	0

In Figure 3 the environmental impacts in regard to GWP, TE and FRS are shown. The results are depicted as normalised to the base case with it being 100 %. With the renewable scenarios a big reduction can be achieved for the GWP with 50.6 % for EE22 and an even bigger reduction for 90H10W with 57.8 %. For FRS there is also a substantial reduction of 40.6 % for EE22 and 42.7 % for 90H10W. The TE is not influenced in the same way. There is only a reduction of 10.8 % for 90H10W and RE22 even exceeds the base case by 13.5 %. This can be explained by looking at the TE of the considered renewable technologies: Solar power has a TE of 3207 g 1.4-DCB/kWh, which is much higher than the other technologies which are located at most in the three-digit range. With this data it is clear that it cannot simply be assumed that environmental compatibility will always be improved by switching to renewable energy sources. Therefore, the technologies must be carefully selected.

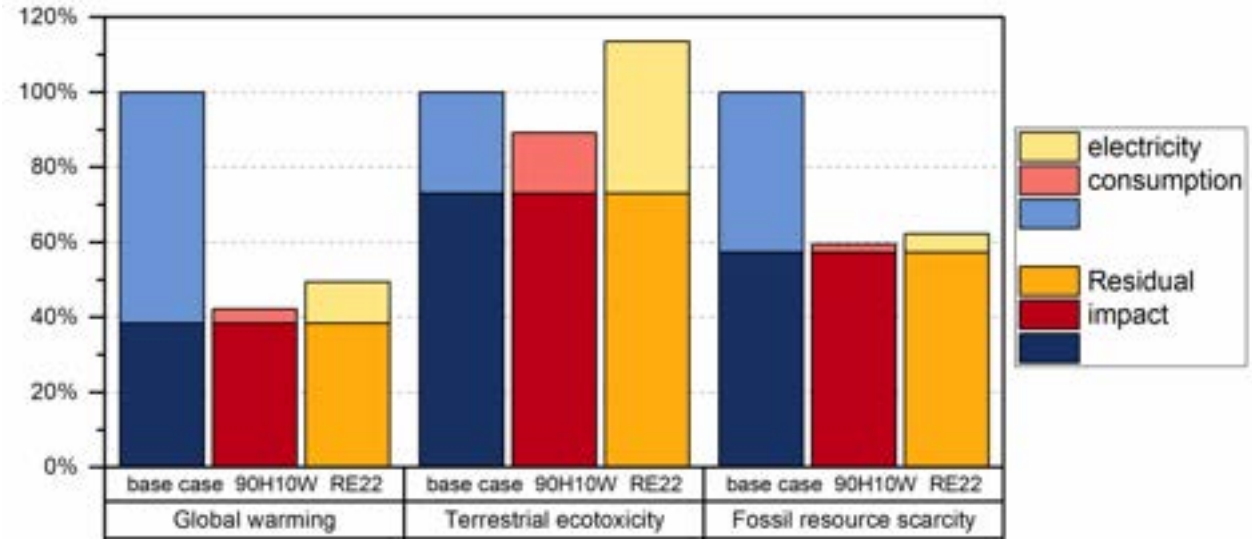

Figure 3. LCA results for the categories GWP TE and FRS for the Variation of the consumed electricity mix; comparison of the German electricity mix and the renewable mix for 2022 RE22 as well as a mix with 90 % hydro power and 10% wind.

The results reveal the potential of choosing an electricity contract with renewable energy. Even though there has to be close look at the composition of the renewable energy mix to ensure a substantial reduction for a holistic environmental improvement.

4. Conclusion

In this study a LCA for a currently operating heat plant in the Southern German Molasse Basin was conducted. Thereby the impact categories GWP, TE and FRS were chosen as well as the method ReCiPe Midpoint (H) [10]. All environmental impacts are related to the functional unit of 1 kWh net thermal energy. The environmental impact of the heat plant amounts to 78.5 g CO_2-eq./kWh, 29.2 g oil-eq./kWh and 399.0 g 1,4-DCB/kWh. The biggest contributor for all categories is the use of auxiliary energy with electricity consumption and peak load coverage by oil boilers. For FRS the DHN also has a significant share with 27.3 %. Therefore, the electricity mix and peak load coverage are analyzed with scenario analyses.

In the base case the electricity is modelled according to the electricity mixes for every year and the demand over the plant's life time. The future mix is modelled according to [20]. For a renewable energy mix the German mix of renewables of 2022 is applied as well as a mix of 90% hydro and 10 % wind power. The biggest reduction is achieved with the scenario 90H10W with 57.8 % for GWP, 10.8 % for TE and 40.5 % for FRS. Surprisingly, the RE22 scenario leads to a TE that is even bigger than the base case due to the high impact of solar power on that category.

For the peak load coverage, the base case with oil fueled boilers is compared to the fuels natural gas, biomethane and a realistic mixture of both with 90 % natural gas and 10 % Biomethane. Peak load coverage with gas always performs better than with oil, with biomethane having the largest effect for GWP and FRS, thus reducing the base case by 20.4% for GWP and 17.6% for FRS. For TE, the reduction by gaseous energy materials is the highest, with natural gas performing slightly better than biomethane with a reduction of 49.4%. The mixed scenario 90NG10BM was investigated, since a supply of pure biomethane from the gas pipelines is unrealistic due to the limited capacity of producing biogas sustainably [21]. Even if the biomethane share is low, significant reductions can still be achieved.

These findings show that deep geothermal heat plants are able to comply with the threshold of 100 g CO_2/kWh by the [3]. Additionally, it also proves the potential of the choice of auxiliary energy in terms of electrical energy mix and peak load coverage to effectively reduce the environmental impact and thus meet the objectives of ongoing GWP reductions until 2050 of the Technical Expert Group. This could be used as incentive for the operators to switch to electricity contracts with renewable sources to further decrease the GWP and FRS.

In future work the potential of peak load coverage other fuels and technologies will be considered. For example in [21] there were also scenarios considered in which the gas demand is covered mainly by e-methane and hydrogen. It would be interesting to investigate these fuels as a basis for peak load. Additionally, other peak load technologies that are not based on fuels should be considered like electric boilers, high-temperature heat pumps or thermal storages.

Additionally more impact categories as suggested in [6] can be considered, especially regarding biodiversity which is also a pressing issue alongside climate change.

Abstract:

In this paper, the utilisation of groundwater heat pumps for residential heating and cooling purposes is presented. A case study located in Florence (Italy) is discussed. First, a building energy analysis has been performed to obtain the thermal loads. Then three heat pump systems (system 1: air-to-water, 2: groundwater-to-water, 3: surface water-to-water) have been designed and compared in terms of electric energy consumption, taking into account the dynamic changing of boundary conditions of the building. Finally, a Life Cycle Assessment analysis has been conducted to evaluate the environmental impacts of the systems. To ensure a yearly heating energy request of 2 780 kWh (peak load of 5 kW) and a yearly cooling energy request of 630 kWh (peak load of 4.4 kW) the systems present a yearly electricity consumption of 1 088 kW, 770 kW and 872 kW for system 1, 2 and 3 respectively. So the groundwater-to-water solution is the most efficient in terms of energy consumption. Based on LCA evaluation, system 2 is the environmentally less impacting system, with a Climate Change factor of 0.15 kg CO_2 eq/kWh against the 0.21 kg CO_2 eq/kWh of system 1. In terms of single score level, system 2 and system 3 are characterised by a reduction in impacts of about 24 % compared to system 1. The dynamic energy and LCA studies clearly show that the solution based on groundwater exploitation, in this context, is a very effective way to reduce electricity consumption and environmental impacts, confirming that the large-scale implementation of groundwater heat pump systems could be a promising option for the decarbonisation of residential heating and cooling sector.

Keywords:

Groundwater heat pump, Heating&Cooling, Energy-efficiency, Energy-saving, Decarbonisation, Dynamic energy analysis, LCA

1 Introduction

Energy requirements for refrigeration and air conditioning (AC) sectors are becoming wider and wider, with AC systems that account for 20-30 % of the electricity consumption of buildings [1–4]. To obtain large-scale decarbonisation, it is evident that it is necessary to reduce the energy needs of AC systems. The utilisation of efficient heat pumps, instead of the classic thermal power generation devices (e.g. boilers), has represented an important step forward [5]. Heat pumps consume electricity to operate, that in many cases is produced from fossil fuels. To reduce the consumption of this form of primary energy in heat pumps operation, it is possible to implement two main strategies: producing electricity starting from renewable sources (e.g. photovoltaic), and enhancing the efficiency of the system through the utilisation of favourable external thermal sources. This last point is crucial: if the external heat exchanger of a heat pump (evaporator in heating season, condenser in cooling season) works with a source at a temperature close to the one of the user, a consistent increase in the efficiency happens. In this sense, a very promising solution is coupling heat pump devices with ground (or geothermal) sources. This is the concept of a Ground Source Heat Pump (GSHP). At depths of a few meters, the ground temperature is stable during the year and it is in contrast with the trend of air temperatures, as in the hot months ground is cooler than the outdoor air, conversely, in cold months the ground is warmer than the outdoor air. The quasi-constant temperature, quite close to the setpoint temperature of indoor environments, leads to obtaining very high values of the Coefficient Of Performance (COP) of the systems, with consequent energy savings [6]. A GSHP system consists mainly of a ground heat exchanger, a heat pump, and a heating/cooling distribution network [7]. The type of geothermal source used for heat exchange, like ground, groundwater and surface water, defines the type of system: ground heat pump (GHP), groundwater heat pump (GWHP) and surface water heat pump (SWHP) [8]. The last two systems are the object of this study. In a GWHP system, the groundwater is extracted from a water source and it exchanges

heat with the heat pump, then is discharged. A GWHP could be built in different configurations: *open loop with aquifer reinjection*, *standing column wells* and *open loop systems discharging to waste*. In an SWHP there is the presence of a reservoir in which the groundwater is pumped. In this case, there is the possibility to realise an *open loop* or a *closed loop* configuration.
In this paper, the utilisation of groundwater heat pumps for heating and cooling purposes in a residential building located in Florence (Italy) is analysed. The work aims to show, considering real and dynamic boundary conditions, how the exploitation of a natural, renewable and local source such as groundwater could improve the performance of heat pumps. An energy analysis of the building has been performed, in order to obtain the heating and cooling loads necessary to design the systems. Three systems have been studied and compared: a traditional air-to-water heat pump, a groundwater-to-water heat pump and a surface reservoir water-to-water heat pump. With specific dynamic calculations, the energy needings of the three systems have been evaluated. Then, a Life Cycle Assessment analysis has been conducted. The obtained results lead to consider the utilisation of groundwater-driven heat pumps as a very energy-efficient solution in this case study and in general a promising option for the decarbonisation of the residential heating and cooling sector.

2 Materials and methods

The studied building is located in Florence (Italy). The analysis has been conducted assuming a revamping of the existing building envelope, able to bring it to respect the prescriptions of Italian standards [9] in terms of thermal insulation. Three heating/cooling systems are proposed: an air-to-water heat pump (system 1, AHP), a groundwater-to-water heat pump (system 2, GWHP) and a surface reservoir water-to-water heat pump (system 3, SWHP). The system 3 solution has been considered because the building is located in the proximity of a reservoir used for irrigation. Alongside the heating/cooling systems, it is supposed the utilisation of a mechanical ventilation system to ensure high indoor air quality. Two software have been employed to conduct the energy analysis of the building: *Design Builder* and *EC700*. Once the heating and cooling loads have been calculated with these software, they have been used to design the different schemes. Moreover, an hourly dynamic energy analysis (with *Design Builder* and *Matlab*, specifically for the surface reservoir water heat pump) has been performed to obtain the input data necessary to simulate the behaviour of the devices during the heating and cooling season. To evaluate the consumption, a switch-on profile of the systems is defined. In this way, taking into account the presence of people during the day and consequently the real behaviour of a heating/cooling system of a residential building, it has been possible to estimate the yearly consumption of the different schemes. The environmental analysis has been carried out according to ISO 14040 and ISO 14044 standards [10,11], employing the software *OpenLCA* with the *Ecoinvent 3.7* database [12] and following these steps: Goal and scope definition, Life Cycle Inventory (LCI), Life Cycle Impact Assessment (LCIA), Interpretation. The aim was to define which of the three proposed solutions is the least environmentally impactful. The system boundaries are the heating and cooling equipment, considering all necessary devices for the different systems (in particular, for GWHP and SWHP, the pipelines necessary for water withdrawal from the wells and the water reservoir). The functional unit is 1 kWh of the total energy exchanged in the building by the heating and cooling system. This case has been considered a multiproduct system because the product that is generated is both heating and cooling. For this reason, an energy allocation factor equal to 0.81 is assigned, and it represents the produced fraction of heat compared to cold. The LCI has been derived from literature [13] and adequately scaled to the size of the case study. The different piping lengths for GWHP and SWHP have been also appropriately related to this situation. LCIA has been carried out following the Environmental Footprint 3.0 methodology. The analysis focused on the CO_2 emissions produced during the entire life cycle of the three systems. Then to investigate the causes of this impact, a contribution analysis has been conducted. Finally, results have been normalised and weighted to perform a single score comparison.

2.1 Climate and groundwater conditions

The local climatic conditions, necessary for the calculation of thermal loads and simulations, are directly defined by the energy analysis software, based on the indications of ASHRAE and Italian standards. The outdoor air conditions for the heating and cooling design have been set as follows (Table 1).

Table 1. Climatic conditions for heating and cooling design.

Mode			
Heating	T_o	0.0	°C
Cooling	T_o	32.0	°C
	RH_o	45.0	%
	R	0.85	kW

For the cooling design, the climatic conditions are referred to the hour of highest thermal load (deriving from the energy balance of equation (5) presented in the following). Moreover, the temperature of groundwater is assumed constant throughout the year and equal to 15.0 °C.

2.2 Indoor setpoint conditions

The indoor setpoint conditions, ensured during the operativity of the systems, are set as follows (Table 2).

Table 2. Indoor setpoint condition.

Mode			
Heating	T_i	20.0	°C
Cooling	T_i	26.0	°C
	RH_i	50.0	%

For the heating mode, there is not a setpoint value for indoor relative humidity because the systems do not include devices able to control humidity during the heating season. For the cooling mode, it is possible to control also the humidity with the regulation of heat pumps and heat transfer devices (fan coils).

2.3 Characterisation of the building

2.3.1 Geometric and envelope characteristics

The geometric characteristics of the simulated building (Figure 1) are reported in the following Table 3.

Table 3. Geometric characteristics of the building.

Number of floors	2	
Total volume	845.0	m^3
Floor occupied area	210.0	m^2

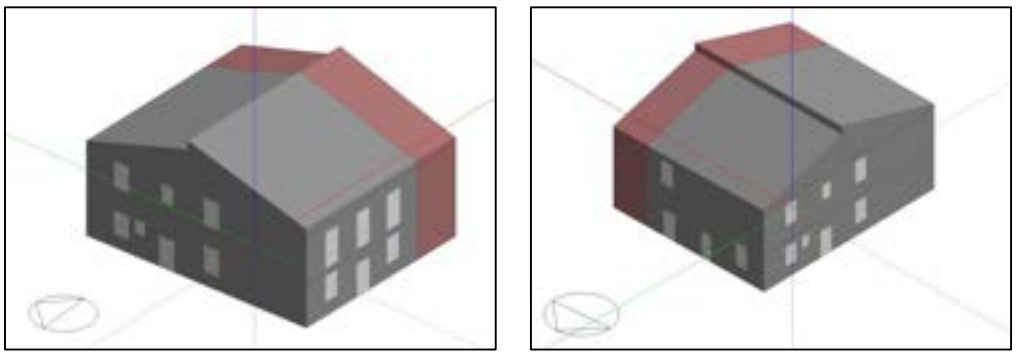

Figure 1. Models of the building (Design Builder).

The characteristics of opaque and transparent elements of the building are reported in the following Table 4.

Table 4. Thermophysical properties of opaque and transparent surfaces.

Element		
External wall		
Thermal transmittance	0.25	$W/m^2/K$
Infrared absorption-emission coefficient	0.9	
Solar radiation absorption coefficient	0.6	
Window (including frames)		
Thermal transmittance	1.0	$W/m^2/K$
Solar radiation transmission coefficient	0.4	

2.3.2 Internal generation, infiltration and ventilation loads

In the calculation of the thermal loads, it is necessary to consider the contributions of internal generation (only for cooling), accidental infiltration and ventilation. The input data are reported in the following Table 5.

Table 5. Heat generation contributions.

Contribution		
Household appliances, electronic devices, lightning		
PD	2.5	W/m^2
People		
OD (full occupancy)	0.03	$people/m^2$
$q_{s,p}$	50.0	W
$q_{l,p}$	50.0	W
Infiltration		
N_{inf}	0.1	vol/h
Ventilation		
$V_{v,p}$	11.0	L/s

The various contributions of thermal loads are calculated as follows:

$$Q_{dev} = PD \cdot S \quad (1)$$

$$Q_p = OD \cdot S \cdot (q_{s,p} + q_{L,p}) \quad (2)$$

$$Q_{inf} = m_{inf} \cdot |j_o - j_i| \quad (3)$$

Concerning the repartition of the terms:

- The internal generation due to appliances and electronic equipment contributes to sensible load.
- People load is divided between sensible and latent.
- Infiltration load is divided between sensible and latent. The value of air changes per hour derived from the accidental infiltration is assumed low due to the refurbishment of the building.
- The ventilation load is evaluated taking into account the presence of people and the air change per person. The effective value of ventilation load depends on the functioning of the air-to-air recuperator, which is explained in the paragraph dedicated to the mechanical ventilation system. This load is divided between sensible and latent.

2.4 Heating and cooling loads and needs

2.4.1 Heating load calculation

The design heating load (calculated in the worst condition) is determined by thermal losses through opaque and transparent surfaces, accidental infiltration and ventilation:

$$Q_h = Q_{bs} + Q_{inf} + Q_v \quad (4)$$

2.4.2 Cooling load calculation

The design cooling load (calculated in the worst condition) is determined by thermal gains through opaque and transparent surfaces, solar radiation, appliances generation loads, people presence, infiltration and ventilation:

$$Q_c = Q_{bs} + Q_r + Q_{dev} + Q_p + Q_{inf} + Q_v \quad (5)$$

2.4.3 Heating and cooling needs throughout the year

Thanks to the dynamic simulation performed by the software, it is possible to calculate the yearly heating and cooling energy needs. For each hour of the simulation, the two software take into account the different contributions of the building energy balances: the heating and cooling energies are the sum of the hourly needings during the respective season.

2.5 Systems description

Three heating/cooling systems have been analysed and compared. Regardless of the thermal sources, they are reversible heat pumps equipped with scroll compressors. The choice of the scroll compressor is dictated by its noiselessness with respect to a reciprocating compressor, making it very suitable in a residential context. All of them have fan coils as distribution terminals: the heat pumps produce hot/cold water that circulates in the indoor water loop and exchanges heat with the indoor air at the fan coils. Moreover, a mechanical ventilation system serves the building, in order to ensure the necessary air changes with outdoor air. A global schematisation of these systems and a general representation of the heat pump schemes are proposed in Figure 2.

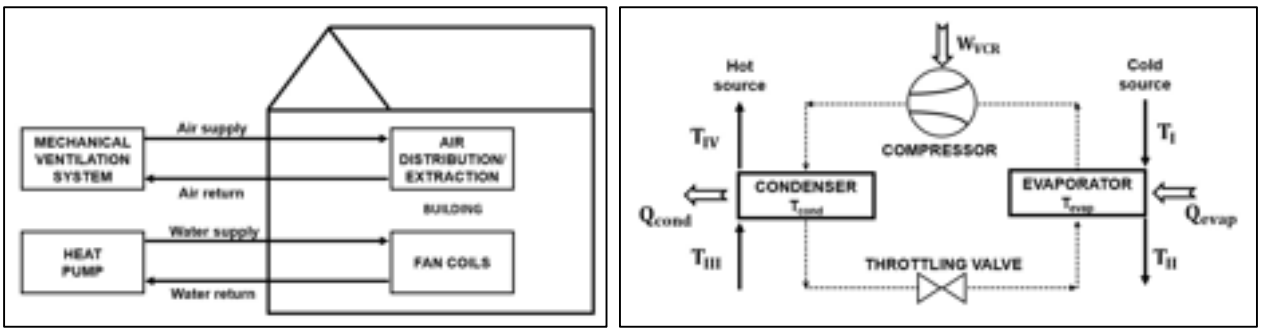

Figure 2. General representation of the systems serving the building (left) and heat pumps simulated in the systems (right).

The evaporator and condenser temperatures are defined by the following equations:

$$T_{evap} = T_{II} - DT_{evap} \quad (6)$$

$$T_{cond} = T_{IV} + DT_{cond} \quad (7)$$

The consumption of the compressor in cooling mode is defined as:

$$W = Q_{evap} / COP_c \quad (8)$$

while in heating mode is:

$$W = Q_{cond} / COP_h \quad (9)$$

Q_{evap} and Q_{cond} correspond to the cooling and heating power exchanged between the heat pump and the internal water loop, so to the requested cooling and heating load. COP has been evaluated taking into account the change in boundary conditions: evaporator and condenser temperatures, evaporator or condenser power. So it is possible to write these general equations for the COP variation:

$$COP_c = F\,(T_{evap}\,,\, T_{cond}\,,\, Q_{evap}) \quad (10)$$

$$COP_h = F\,(T_{evap}\,,\, T_{cond}\,,\, Q_{cond}) \quad (11)$$

The mathematical formulation of COP_c and COP_h, which assumes the form of polynomials, depends on the commercially available models derived from [14].

2.5.1 Air-to-Water Heat Pump (system 1)

In this system:

- In heating mode, the outdoor coil acts as an evaporator taking heat from outdoor air and the indoor coil acts as a condenser releasing heat to the indoor water loop.
- In cooling mode, the outdoor coil act as a condenser releasing heat to outdoor air and the indoor coil acts as an evaporator extracting heat from the indoor water loop.

2.5.2 Groundwater-to-Water Heat Pump (system 2)

In this system:

- In heating mode, the outdoor coil acts as an evaporator taking heat from groundwater and the indoor coil acts as a condenser releasing heat to the indoor water loop.
- In cooling mode, the outdoor coil act as a condenser releasing heat to groundwater and the indoor coil acts as an evaporator extracting heat from the indoor water loop.

This system has 150 m of horizontal pipeline and 30 m of vertical pipeline.

2.5.3 Surface reservoir water-to-Water Heat Pump (system 3)

In this system:

- In heating mode, the outdoor coil acts as an evaporator taking heat from the surface water reservoir and the indoor coil acts as a condenser releasing heat to the indoor water loop.
- In cooling mode, the outdoor coil act as a condenser releasing heat to the water reservoir and the indoor coil acts as an evaporator extracting heat from the indoor water loop.

This system has 300 m of horizontal pipeline.

To perform the dynamic analysis of the heat pump, it is necessary to understand the variation of water reservoir temperature during the system activation. For this purpose, the energy balance of the reservoir is defined as follows [15]:

$$E_{res} = c_w * M_{res} * DT \quad (12)$$

where the reservoir energy content E_{res}, evaluated at each hour of systems activation, depends on the following terms of the thermal balance:

- Thermal power exchanged with the make-up water from the well, with turn-on time defined by the irrigation needs.
- Thermal power received by solar radiation.
- Thermal power exchanged by natural convection with the outdoor air.
- Thermal power exchanged by evaporation through the surface of the reservoir.
- Radiative thermal power in the infrared wavelength exchanged with the outdoor environment.

- Thermal power exchanged by conduction with the walls of the reservoir.
- Thermal power exchanged with the outdoor coil of the heat pump.

The energy balance of the reservoir has been written for each hour of activation of the systems and has been solved with the software Matlab.

2.5.4 Mechanical Ventilation System

The system has been designed taking into account the prescription of Italian standards [16]. The airflow rate, in the case of full occupancy of the building, is defined as:

$$V_v = n_p * V_{v,p} \tag{13}$$

In order to reduce the ventilation load (both in heating and cooling mode), the system has been equipped with an air-to-air recuperator, at which the outdoor air, before entering the building, exchanges heat with the air extracted by indoor environments (Figure 3).

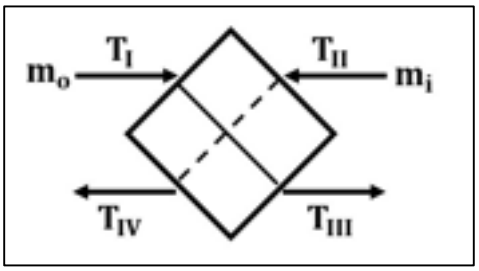

Figure 3. Representation of the air-to-air recuperator of the mechanical ventilation system.

The air-to-air heat exchanger operates on the sensible load, so it is possible to evaluate the temperature of outdoor air exiting the recuperator in heating mode as follows:

$$T_{III} = T_I + \varepsilon * (T_{II} - T_I) \tag{14}$$

and in cooling mode as:

$$T_{III} = T_I - \varepsilon * (T_I - T_{II}) \tag{15}$$

where ε is the efficiency of Kays and London, evaluated knowing that outdoor and indoor air flow rates are equal and with the same specific heat.

The thermal load (heating or cooling) generated by ventilation is equal to:

$$Q_v = m_v \cdot |j_{III} - j_i| \tag{16}$$

The ventilation load in heating mode is only in the sensible form, while it is sensible and latent in cooling mode. The energy consumption of fans for air moving has not been taken into account, due to the fact it is the same in all three systems.

2.5.5 Indoor water loop

The temperatures of the indoor water loop (as presented in the scheme of Figure 2), necessary to maintain the setpoint conditions in heating and cooling mode, are reported in the following Table 6.

Table 6. Temperatures of the indoor water loop.

Mode	Temperature		
Heating	Supply (T_{IV})	45.0	°C
	Return (T_{III})	40.0	°C
Cooling	Supply (T_{II})	7.0	°C
	Return (T_I)	12.0	°C

3 Results and discussion

In this chapter, the yearly performances of the three systems are presented. It is given attention to:

- Electric energy requirements to ensure heating and cooling needs.
- Environmental impacts (considering both the construction and operation of the schemes).

The results have been obtained considering a standard residential utilisation profile of the heating/cooling systems. For all the systems analysed, also the variation of COP (heating and cooling mode) alongside typical days as a function of sources temperatures is reported. The graphs presented for COP do not account for the switching-on profile, but show the behaviour of the systems during an entire day, in order to present the response of the systems to the variation of boundary conditions in a general utilisation of the devices.

3.1 Heating and cooling design loads and energy requirements

For the design of systems, the following peak loads (Table 7) deriving from the resolution of equations (4) and (5), have been obtained:

Table 7. Thermal load contributions for the design of the systems.

Mode	Contribution		
Heating	Q_{bs}	4.2	kW
	Q_{inf}	0.5	k**W**
	Q_v	0.3	kW
	Q_h	**5.0**	**kW**
Cooling	Q_{bs}	0.5	kW
	Q_r	1.7	kW
	Q_{dev}	0.5	kW
	Q_p	0.5	kW
	Q_{inf}	0.4	kW
	Q_v	0.8	kW
	Q_c	**4.4**	**kW**

These values are perfectly similar between Design Builder and EC700. It is useful to note that, during the cooling season, a consistent part of the thermal load depends on solar radiation and ventilation, while the contribution of the surfaces is limited, as expected from a building with an energy-efficient envelope. In terms of necessary heating and cooling energy, the results of Table 8 have been obtained:

Table 8. Yearly thermal energy requirements.

Mode		
Heating	2 780.0	kWh
Cooling	630.0	kWh

The ratio between heating and the sum of heating and cooling requirements is 0.81, which justifies the utilisation of this value for the energy allocation factor in the LCA analysis.

3.2 Air-to-Water heat pump

The design conditions of the system are as follows (Table 9):

Table 9. Design condition for the air-to-water heat pump (system 1).

Mode			
Heating	$T_{II,d}$	-5.0	°C
	$T_{evap,d}$	-10.0	°C
	$T_{IV,d}$	45.0	°C
	$T_{cond,d}$	50.0	°C
	$COP_{h,d}$	2.6	
Cooling	$T_{II,d}$	7.0	°C
	$T_{evap,d}$	2.0	°C
	$T_{IV,d}$	37.0	°C
	$T_{cond,d}$	42.0	°C
	$COP_{c,d}$	3.0	

The changing of outdoor conditions (both in the heating and cooling season) leads to an appreciable variation of COP, as shown in the following Figure 4 referred to the heating and cooling design days.

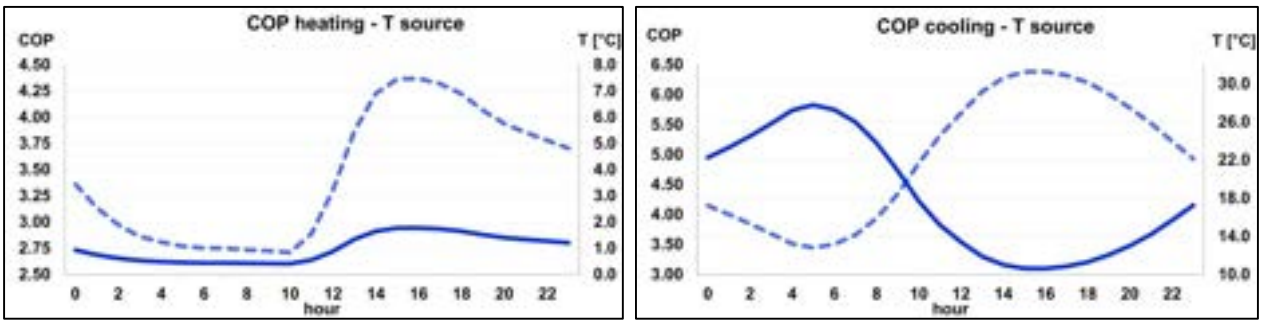

Figure 4. Heating (left) and Cooling (right) COP (left axis, continuous) against source temperature (right axis, dashed), system 1.

It is easy to note that the air-to-air heat pump is particularly penalised in the hours of the cooling season in which the systems should be switched on to ensure the control of thermal loads, with a negative consequence on electricity consumption.

In terms of electric energy consumption, the system presents the following values (Table 10).

Table 10. Electric energy requirements for the air-to-water heat pump (system 1).

Mode	**Energy consumption**	
Heating	915.1	kWh
Cooling	173.0	kWh
TOTAL	1 088.1	kWh

3.3 Groundwater-to-Water heat pump

The design conditions of the system are as follows (Table 11):

Table 11. Design condition for the groundwater-to-water heat pump (system 2).

Mode			
Heating	$T_{II,d}$	12.0	°C
	$T_{evap,d}$	7.0	°C
	$T_{IV,d}$	45.0	°C
	$T_{cond,d}$	50.0	°C
	$COP_{h,d}$	3.9	
Cooling	$T_{II,d}$	7.0	°C
	$T_{evap,d}$	2.0	°C
	$T_{IV,d}$	18.0	°C
	$T_{cond,d}$	23.0	°C
	$COP_{c,d}$	6.4	

The constant temperature of the groundwater throughout the year leads to obtaining a constant value of COP during the heating and cooling season (Figure 5).

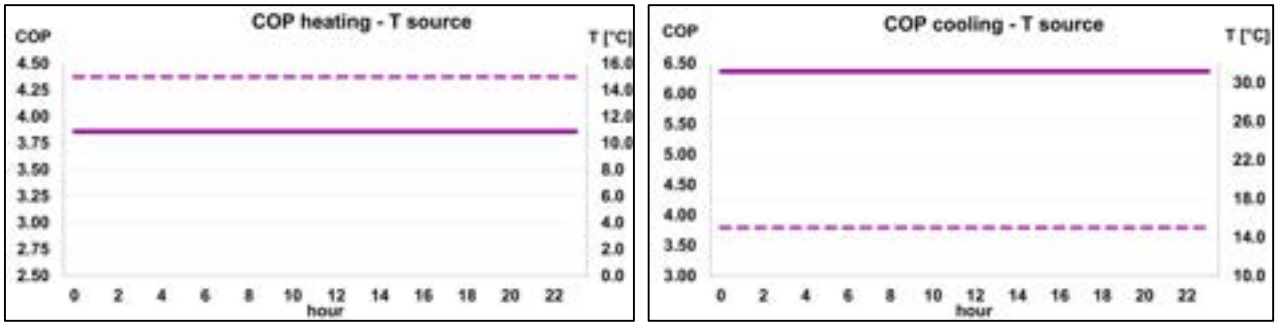

Figure 5. Heating (left) and Cooling (right) COP (left axis, continuous) against source temperature (right axis, dashed), system 2.

In the hours of the highest request for the system, the value of COP remains at the high design value without any influence of the outdoor air. This is the great advantage of a groundwater solution, i.e. the system can work with a very high COP also in the worst conditions of thermal loads. In terms of electric energy consumption, the system presents the following values (Table 12).

Table 12. Electric energy requirements for the groundwater-to-water heat pump (system 2).

Mode	**Energy consumption**	
Heating	679.8	kWh
Cooling	90.2	kWh
TOTAL	770.0	kWh

3.4 Reservoir water-to-Water heat pump

The design conditions of the system are as follows (Table 13):

Table 13. Design condition for the reservoir water-to-water heat pump (system 3).

Mode			
Heating	$T_{II,d}$	5.0	°C
	$T_{evap,d}$	0.0	°C
	$T_{IV,d}$	45.0	°C
	$T_{cond,d}$	50.0	°C
	$COP_{h,d}$	3.1	

Cooling	$T_{II,d}$	7.0	°C
	$T_{evap,d}$	2.0	°C
	$T_{IV,d}$	28.0	°C
	$T_{cond,d}$	33.0	°C
	$COP_{c,d}$	4.6	

The variation of reservoir water temperature is limited with respect to outdoor air, so the fluctuation in COP is quite limited in this case, even if COP is not constant as in the case of direct exploitation of groundwater (Figure 6). Nonetheless, the COP remains high also in the worst conditions for the system, making this technology an energy-efficient solution.

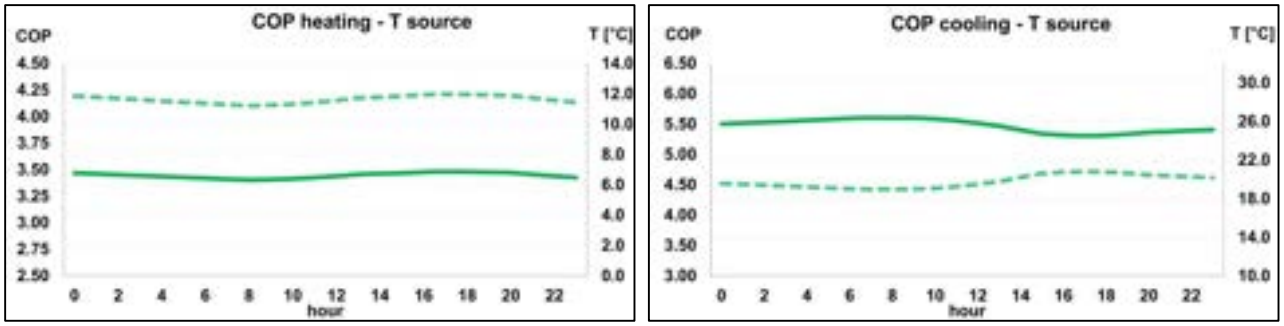

Figure 6. Heating (left) and Cooling (right) COP (left axis, continuous) against source temperature (right axis, dashed), system 3.

In terms of electric energy consumption, the system presents the following values (Table 14).

Table 14. Electric energy requirements for the reservoir water-to-water heat pump (system 3).

Mode	**Energy consumption**	
Heating	764.4	kWh
Cooling	107.2	kWh
TOTAL	871.6	kWh

3.5 Comparison of the energy requirements

Resuming the obtained results, it is possible to clearly show a comparison between the energy consumption of the systems (Figure 7).

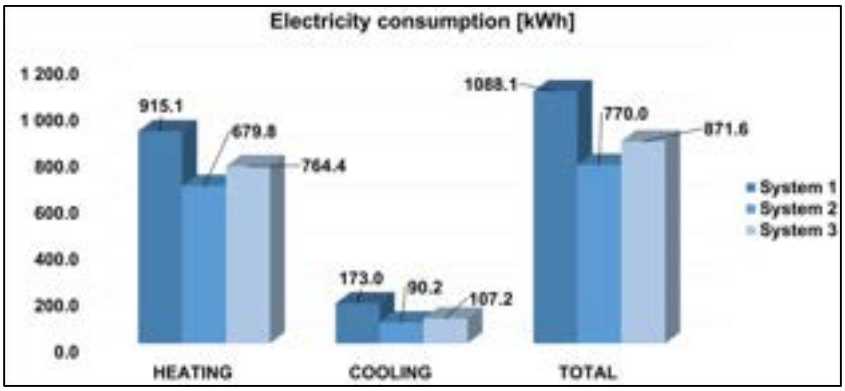

Figure 7. Comparison of electricity consumption for the different systems.

The GWHP (system 2) is the more energy-efficient system, with a yearly electric energy consumption of 770 kWh, which represents a saving of 30 % with respect to a traditional AHP (system 1). The SWHP (system 3), in turn, offers interesting savings (a reduction of 20 % in energy consumption compared to the traditional heat pump). Summing up, if the direct exploitation of groundwater is the most efficient solution in this context, the exploitation through the reservoir might be appropriate where the reservoir is already present, e.g. for irrigation purposes.

3.6 Life Cycle Assessment

The environmental analysis focuses on CO_2 emissions: the Climate Change category is shown in Figure 8. From the obtained results, it is evident that the largest CO_2 emission to the atmosphere is attributable to the AHP system equal to 0.21 kg CO_2 eq/kWh. The second largest system in terms of CO_2 eq emissions is SWHP, with 0.16 kg CO_2 eq/kWh, while GWHP emits slightly less, with 0.15 kg CO_2 eq/kWh.

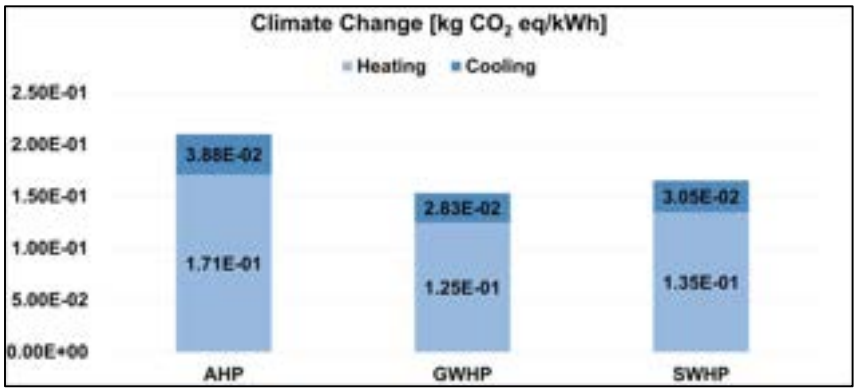

Figure 8. Comparison of the Climate Change LCA category for the different systems.

The contributions analysis (Figure 9) of the environmental impact categories shows that, for all three systems, the main impact comes from the operation phase, particularly in terms of electricity consumption. The construction and commissioning phase has much less impact, except for the categories of HTc, HTnc, and Rumm in which the use of metallic materials assume a great significance and covers about 44.4 %, 47.4 % and 72.2 % of the impacts, respectively. In the case of GWHP and SWHP, the presence of the piping required for water withdrawal assumes additional importance in the environmental impact. Particularly in the case of GWHP, where part of the piping is drilled into the ground to well realisation. Also, to be highlighted is the contribution that the working fluid assumes for the OD category of about 40 % for all three systems.

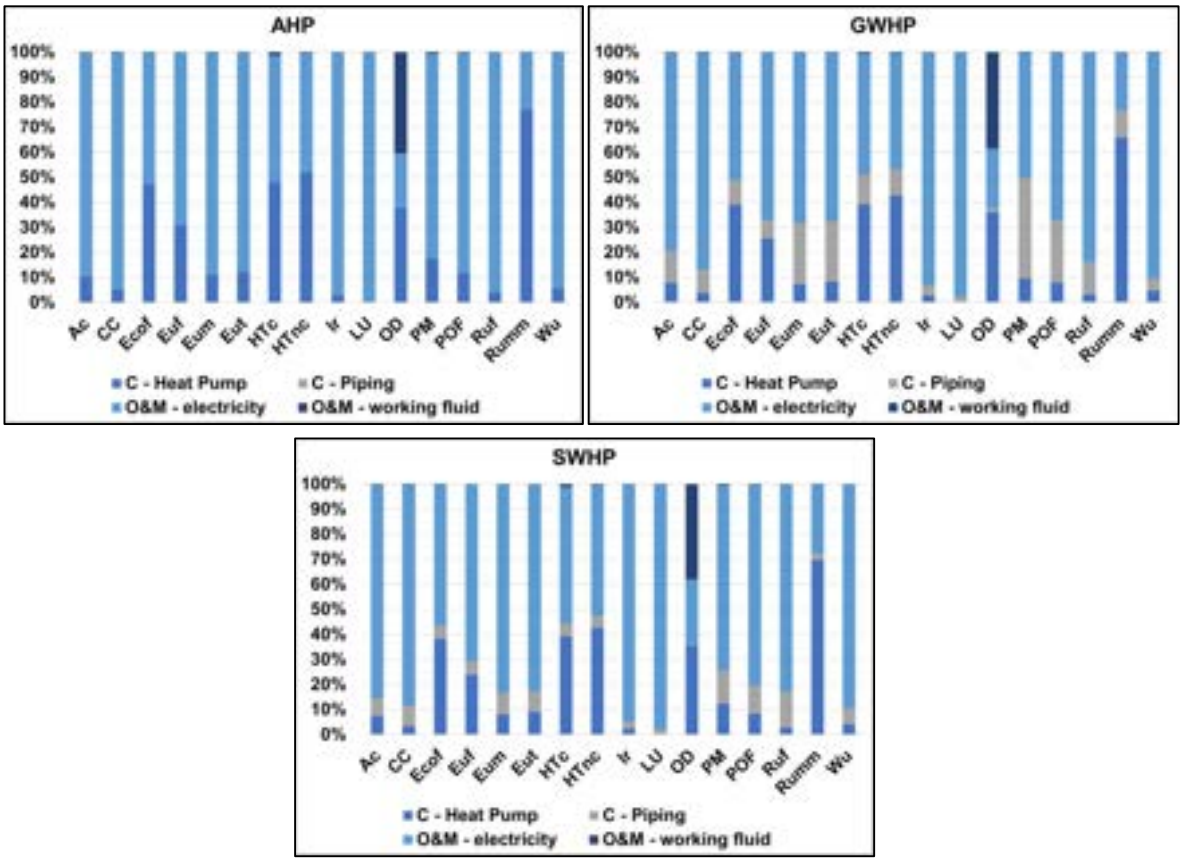

Figure 9 - Contribution analysis of all impact categories for the different systems.

Figure 10 shows the comparison of the three systems at the single score level. The single score shows the overall performance of the three systems. A similar trend to the Climate Change indicator is obtained. Indeed, AHP turns out to be the most impactful system, while GWHP and SWHP are less impacting. A reduction in impacts for both the ground source solutions is evident: about 24 % compared to AHP.

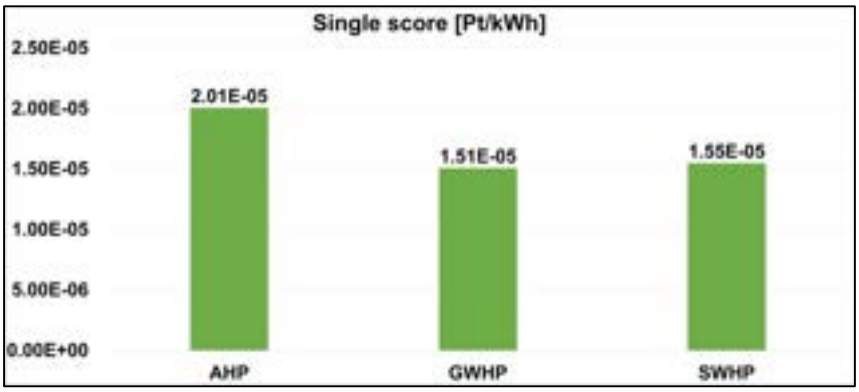

Figure 10 - Single score comparison for the different systems.

4 Conclusions

In this paper, the benefits of using groundwater as a thermal source for residential heat pumps have been discussed. In residential heating and cooling applications heat pumps are widely used, and for the reduction of energy consumption, groundwater represents a very favourable source for the external coils (evaporator in heating mode, condenser in cooling mode) of heat pumps. Three systems have been compared in the context of a specific case study located in Florence (Italy): air-to-water heat pump, groundwater-to-water heat pump and reservoir water-to-water heat pump. For the design of the systems, a detailed energy analysis of the building has been performed, in order to obtain the heating and cooling loads. Then the three systems, of which mathematical models have been presented, have been analysed considering the variation of boundary conditions (thermal loads, sources temperatures), that has been taken into account through a dynamic simulation of the building. Finally, an analysis with Life Cycle Assessment has been performed to show the environmental benefits of the proposed groundwater-based solutions with respect to a traditional heat pump. The analysis has demonstrated that the use of groundwater (direct or through the reservoir) greatly increases the COP (in particular the direct exploitation) of the devices, which results in consistent energy savings. In particular, the dynamic evaluation has shown that: with the groundwater solution it is possible to achieve a saving of 30 % with respect to the traditional air-to-water heat pump, while with the reservoir technology, the saving is 20 %. So the groundwater heat pump is the most energy efficient. Its utilisation is the best choice in terms of energy performance, but in the reality, due to its good results, also the reservoir option could be considered. In particular, a surface water heat pump can be used in all the situations in which the reservoir is already present and could be expensive to build the underground network, or the reservoir is necessary for irrigation needs. LCA analysis confirms, also under the environmental perspective, the advantages of using groundwater. As shown by the focus on the Climate Change category and the comparison to the Single Score, the most impactful system turns out to be AHP, while very little difference is made between the other two systems. GWHP and SWHP allow obtaining a global reduction of impacts of 24 %. The savings achieved with the groundwater solution also suggest a further management strategy for the system. Indeed, as this technology has a much lower electricity consumption than traditional air-to-water ones, it is much easier to integrate it with electricity production from renewable sources such as photovoltaics. In the heaviest situations of thermal or cooling demand of the building, since the groundwater heat pump works at higher COP and therefore lower energy demand, photovoltaic production would be advantaged. Moreover, the LCA analysis of the contributions shows the relevance owned by the electricity that is consumed for every environmental impact, encouraging the utilization of photovoltaic sources. It is therefore evident that, with the perspective of the realisation of *NZEB* buildings that may be integrated into energy communities, the adoption of groundwater technology, where exploitable, is an absolutely desirable strategy.

Abstract:

Buildings are responsible for a significant portion of the global energy use and carbon emissions. There is great potential to reduce a building's environmental impact in the early stages of design. Over the past decade, there has been a concerted effort to create energy-efficient and net-zero buildings by reducing operating energy. However, additional materials and new applications are needed to reduce energy demand. This may result in an increase in embodied carbon, which is the carbon emitted during the materials and construction phase. Since there is a trade-off between embodied and operational environmental environment, it is important to consider both in the design process. However, there is a lack of research that addresses this issue. To help with this challenge, a multi-objective optimization model that combines machine learning, building information modelling, and life cycle assessment has been developed. This model can help in making design decisions that balance embodied and operational carbon emissions. An actual building project has been used to verify the model developed. The findings reveal that early design stage has the potential to save 32.5% emissions for mid-rise buildings in hot summer and cold winter climate zone in China. Moreover, window-to-wall ratio and number of floors largely affecting the trade-off between embodied and operational impacts. The findings of this study can provide low-carbon and energy-efficient design solutions for residential buildings in the early stages of design.

1. Introduction

A significant share of the global negative environmental effects (e.g., use of resources and environmental consequences of releases) are caused by the building sector. The International Energy Agency stated that in 2020, the construction industry accounted for 36% of world energy consumption and 37% of carbon dioxide emissions [1]. The environmental impacts of a building over its life cycle can be divided into embodied environmental impacts and operational environmental impacts. Operational impacts are caused by energy usage during building operation, whereas embodied impacts are connected to the raw material extraction, construction, end-of-life treatments, recycling, and final disposal [2]. The embodied impacts are significant and occasionally equal operational environmental impact levels [3]. It is therefore a pressing need to simultaneously minimize embodied and operational environmental impacts for creating environmentally preferred buildings. However, there is a reciprocal relationship between the embodied and operational environmental impacts. This relationship can be attributed to additional materials and new applications and systems are required to reduce the resources consumption and energy demands during building operational stages [4]. The extra materials and equipment may lead to a decrease of impacts due to operational energy use while increasing embodied environmental impacts. As a result, buildings with energy-efficient measures may cause more total environmental impacts [4,5]. Therefore, it is of great importance to focus on the trade-off between embodied and operational environmental impacts whilst lowering the total environmental impacts.

The environmental impacts of a building over its life cycle are largely influenced by the decisions made during the early stages of design [6]. Creating an eco-friendly building design in the early design practice presents a significant opportunity to lower the total environmental impact of a building and find the optimal trade-off between embodied and operational impacts. However, the early design of a building involves making decisions on numerous design variables, such as floor height, floor area, building shape, building orientation, window-to-wall ratio (WWR), and number of floors. Accordingly, thousands of design alternatives can be generated by varying these design variables. It becomes a significant challenge to determine the most appropriate design that reduces the total environmental impact of a building and achieves an optimal trade-off between embodied and operational impacts. The complexity of building design constraints and the large number of design options make it difficult to find out the optimal design solution.

Life cycle assessment (LCA) is a powerful tool to quantify the environmental impacts of a building over its lifetime [7,8]. On the other hand, building information modelling (BIM) digitally represents the physical and functional characteristics of a facility and related information of the building project [9]. BIM model includes all the necessary information for the assessment of embodied environmental impacts and the simulation of energy demand [10]. BIM applications in the environmental impact assessment of a building enable to improve assessment quality [11]. Moreover, the integration between BIM and LCA has been widely accepted and proven effective for assessing the embodied environmental impact assessment. However, the complexity of assessment process using BIM-LCA integration approaches makes it impractical to identify the optimal design solutions that balance embodied and operational impacts. The repetitive procedures and processes involved in the combined use of BIM and LCA make it challenging to determine the optimal design solutions.

Multi-objective optimization methods allow for different trade-offs between conflicted objectives and have been widely used in the construction industry in a variety of practical topics and contexts. These include, for example, designing building facades [12], selecting building shape [13], and choosing building components or materials such as type of glazing [14] and window type [15]. Multi-objective optimization methods have also been employed to balance the embodied and operational energy in buildings [4]. In the context of building design, multi-objective optimization methods addressed with the parametric design issues [16]. Additionally, multi-objective optimization methods have been applied to address environmental impact topics such as bridge maintenance [17], energy and investment costs management [18], and green building rating systems [19]. For a more comprehensive overview of multi-objective optimization methods applied in the construction industry, see the review articles by Guo and Zhang [20]. The optimization methods have also been used to address other issues such as prefabrication, supply chain, work safety and risk management.

Above discussion reveals that despite the significance, there has been limited focus on the use of multi-objective optimization methods to find the optimal design solutions in linking embodied and operational environmental impacts in early design practice. To address the research gap, this study aims to develop a multi-objective optimization model by using a combination of multi-objective optimization methods and BIM-LCA integration programs to identify optimal solutions that balance the embodied and operational impacts of a building during early design practice. The findings can provide designers with more comprehensive and in-depth understanding on the potentials to save carbon emissions and the relationships between embodied and operational impacts.

2. Research methodology

To fulfil the research aim, this research developed a multi-objective optimization model based on a BIM-LCA integration approach and a meta-based multi-objective optimization method. There are three modules in this developed model: 1) embodied and operational impacts evaluated by a BIM-LCA integration approach, 2) environmental impact prediction based on a machine learning method, and 3) multi-objective optimization of embodied and operational impacts.

2.1. Environmental impact assessment based on integration between BIM and LCA

The first module involves conducting the environmental impact assessment of a building over its life cycle, following a standard process for life cycle assessment outlined in ISO 14040 framework. This process consists of four phases: 1) goal and scope definition, 2) life cycle inventory analysis, 3) life cycle assessment analysis, and 4) life cycle interpretation [21]. In this study, the environmental impact assessment of a building starts with creating a BIM model of the design solutions selected. The goal and scope definition phase includes assumption about the system boundary of life cycle assessment and the building's lifespan. The system boundary in this study includes the product stages (A1-A3), the use stages (B2-B6), and the end-of-life stages (C2-C4), while environmental impacts produced in construction phase (A4) are excluded due to their small proportion of the total environmental impacts [6]. During the life cycle inventory analysis and life cycle assessment phases, the environmental impacts are assessed. Tally is used to assess the embodied impacts by manually matching BIM objects to the building components in Tally. If identical building components cannot be found, similar ones would be used. Moreover, Tally is also used to assess the operational environmental impacts by importing the amount of energy consumption which is simulated by Green Building Studio. Specifically, the physical parameters and thermal properties of the building components, derived from Autodesk Revit database of building components and the common practice in local building projects, are incorporated into the BIM mode to ensure the accuracy of energy simulation. Then, BIM model is transferred into an energy analysis model. Energy analysis parameters are determined such as the operational time of a building, the way of Heating, Ventilation, and Air Conditioning (HAVC) operation. Then, the energy analysis model is imported into Green Building Studio for energy simulation. Green Building Studio is a flexible cloud-based service that uses the DOE2 simulation engine and allows to run building performance simulations to optimize energy efficiency in the design process. In addition, the climate files of the building are set in the performance simulation process. The simulation results are manually input into Tally to assess the operational impacts. In life cycle interpretation phase, the environmental impacts of a building over its life cycle are expressed by environmental impact indicators based on the TRACI 2.1 characterization method [22]. TRACI 2.1 method covers ten different environmental impact indicators by default, such as the global warming potential, non-renewable energy consumption, ozone potential and others. For our calculation, this study considers global warming potential (expressed in the amount of carbon dioxide equivalents (CO_2-eq) to indicate the total environmental impacts of the building.

2.2. Environmental impact prediction by machine learning method

Support vector machine (SVM) developed by Vapnik and Cortes [23], is a machine learning technique based on the statistical learning theory. This technique can solve nonlinear problems very well and is suitable for small sample sizes studies [24]. Least squares linear machine (LSSVM) was developed based on SVM by using a least squares linear system as a loss function to transform the inequality constraints of the optimization problem into equality constraints, thus yielding better performance than an SVM. A training and design of an LSSVM model is an iterative algorithm, and it basically involves four steps: (1) define the problem as the classification or the regression problem, (2) pre-process the input data, (3) determine the model parameters, and (4) validate the model obtained [25]. This study attempts to learn the input-output relationship from the training data, where the inputs are n-dimensional vectors, and the outputs are continuous values. The details about developing the LSSVM model are presented as follows:

The raw data was randomly divided into 80% training data and 20% test data. Given that the units, value domains, physical meanings of independent variables in raw dataset vary substantially, z-score normalisation was performed on raw data to eliminate the influence of different eigenvalue dimensions on the prediction accuracy by applying Equation (1)

$$x' = \frac{x-\mu}{z} \quad (1)$$

Where x denotes the raw data, μ is the average of the sample data, and z represents the standard deviation of the sample data. The processed data follows the standard normal distribution. The average value and the variance of the processed data are 0 and 1 respectively.

The Gaussian kernel function has excellent anti-interference ability [24]. Therefore, Gaussian kernel function Equation (2) was adopted for the prediction model in this study.

$$k(x_i, x) = e^{-\frac{\|x_i - x\|^2}{2\sigma^2}} \quad (2)$$

Where x_i is the input variable, x is the output variable, and σ^2 is the variance of the Gaussian kernel.

Penalty parameter C controls the trade-off between generalization capacity (wide margin width) and the empirical error of the prediction model. Large C leads to small number of misclassifications and consequently to the smaller margin (good generalization capacity) and vice versa [25]. The selection of penalty parameter C and variance σ^2 greatly affects the prediction error of the model. Normally, the parameters were determined by a trial-and-error process.

Cross validation is often used to optimize the selected values of model parameters (i.e., C and σ^2 in this study) in a refined scale. The process is also called tuning, which is generally empirical, with various values for the parameters systematically evaluated, and the combination of values that generate the highest overall accuracy is assumed to be optimal [26]. K-fold cross-validation method was adopted to search for the optimal combination of C and σ^2. Specifically, the sample data is divided into K sample subsets, where one sample data is selected for testing and the other (K-1) samples are used for training. The cross-validation is repeated K times to obtain the optimal parameter values. Accordingly, the LSSVM model can be obtained by using the optimal C and sigma for training.

To the end, the prediction accuracy of the LSSVM model is measured by coefficient of determination (R^2) in this study, which are defined as Equation (3). The higher the R^2, and the less difference between two sets of data.

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y}_i)^2} \quad (3)$$

Where y_i is the assessment value of i^{th} training example by BIM-LCA integration approaches, $\hat{y}_i$ is the predicted value by the LSSVM model, $\bar{y}_i$ is the arithmetic mean of y_i, and n is the number of training examples passed to LSSVM model.

2.3. Multi-objective optimization based on NSGA-II algorithm

The third module is the multi-objective optimization that deals with the optimization problem related to the environmental impacts of a building.

For this study, the LSSVM-trained model is adopted as the objective functions in the multi-objective optimization process. The relationships between design variables and embodied and operational environmental impacts of buildings are presented as Equation (4):

$$lssvm(x_1, x_2, \dots, x_n) = \sum_{i=1}^{n}(\partial_i - \partial_i^*)\, e^{-\frac{\|x_i - x\|^2}{2\sigma^2}} + b \quad (4)$$

Where $x_1, x_2, \dots, x_n$ are the design variables. ∂_i and ∂_i^* are Lagrange multipliers, b is the bias term, x_i is the input variable, and x is the output variable (i.e., embodied or operational impacts in this study).

Then, the objectives in each design stage are expressed as follows:

$$\begin{cases} \min f_{embodied}(\, lssvm(x_1, x_2, \dots, x_n)) \\ \min f_{operational}(\, lssvm(x_1, x_2, \dots, x_n)) \end{cases} \quad (5)$$

Where $x_1, x_2, \dots, x_n$ are the design variables in early design stage, $f_{embodied}(lssvm(x_1, x_2, \dots, x_n))$ is the embodied environmental impacts of a building, and $f_{operational}(lssvm(x_1, x_2, \dots, x_n))$ is the operational environmental impacts of a building in early design stage.

Constraints on the objective functions are used to ensure the generated solutions reasonable and feasible. The value ranges of design variables according to the design codes, standards and rules were set as the constraints of the objective functions. The constraints on the design variables can be expressed in inequation (6):

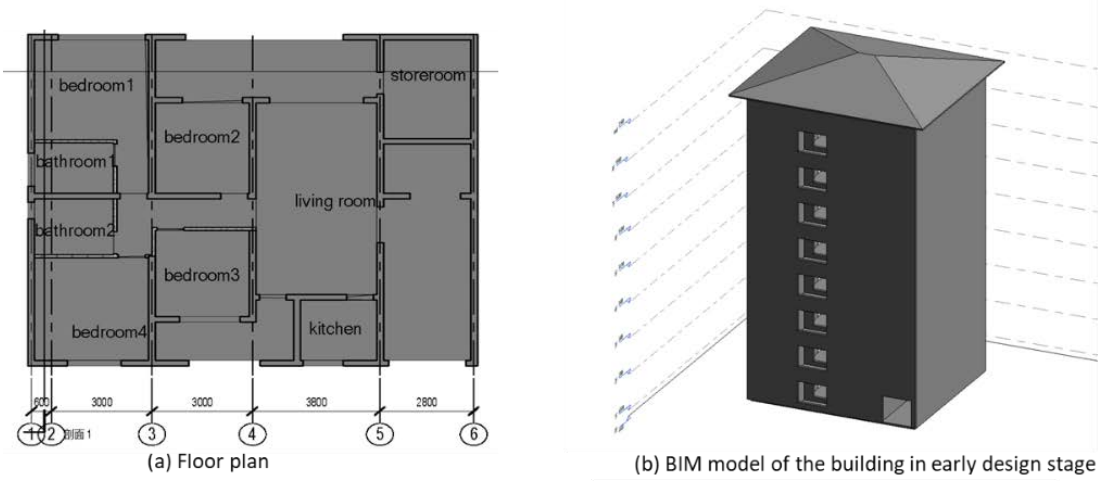
$$a_{i1} \le x_i \le a_{i2} \quad (6)$$

Where x_i denotes the i^{th} design variables in each design stage, while a_{i1} and a_{i2} are the low and up bounds, respectively of the i^{th} design variable.

The non-dominated genetic algorithm II (NSGA-II), developed by Deb [27] was adopted to solve the multi-objective optimization problems in this study. The NSGA-II genetic algorithm can be coupled easily with a backbox model and can handle a set of solutions simultaneously allowing to obtain several pareto frontiers in a single run. The optimization model was used to select the optimum building alternatives with minimum embodied and operational environmental impacts. After obtaining the pareto optimal solution set, the technique for order preference by similarity to an ideal solution (TOPSIS), a multi-criteria decision-making approach was employed to the determine the optimal trade-off point. The TOPSIS method figures out the positive-ideal option in which the maximum gain from each of the objectives is taken and the negative-ideal option in which the maximum loss from each of the objectives is taken. Towards the end, the option that is closest to the positive-ideal solution and farthest away from the negative-ideal solution is selected by the TOPSIS method.

3. Case study

The proposed model was verified by using a mid-rise residential building (refer to a residential building between 4 and 8 floors). The purpose of the case study is to identify the optimal design solutions that balance the trade-off between embodied and operational impacts at early design stage. The case selected for this study was adapted from an actual residential apartment built in Chongqing, China. This project is located in a hot summer and cold winter climate zone, which was built in accordance with the Design Code for Residential Buildings [28]. The long sides of the building are facing north and south. The project is an 8-story, reinforced concrete frame building, and the floor height is 2.8m. The construction methods and building elements from the second floor to the seventh floor are the same. Each floor of the building has a single family which owns four bedrooms, a kitchen, a living room, a storeroom, a balcony and two bathrooms. The building has a total above-basement floor area of 1297.12 m^2 with a life expectancy of 50 years. The building project is a typical example of an apartment building in Chongqing, China representing common building materials and construction techniques for walls, floors, and other building components. Figure 1shows the sketches and 3D model of the building.



(a) Floor plan (b) BIM model of the building in early design stage

Figure. 1. Sketches and 3D model of the building in early design stage.

There are four design variables affecting the environmental impacts of a building in early design practice [29]. The design variables include: (1) floor height, (2) building orientation, (3) window-to-wall ratio (WWR) and (4) number of floors in early design stage. The variables can be continuous or discrete, and the values or value ranges are determined by national building design and construction standards, regulations and codes [30,31]. The values of the design variables in early design stages are shown in Table 1.

Table 1. Characteristics of design variables for the building in early design stage.

Design variables	Value/value domain	Variable types	Number of options
Floor height	[2.4m, 2.8m]	Continuous	0.1m uniform step (5 options)
Building orientation	[15°, 75°]	Continuous	10° uniform step (7 options)
Window-to-wall ratio	[0.1, 0.5]	Continuous	0.05 uniform step (9 options)
Number of floors	4, 5, 6, 7, 8	Discrete	5 options

4 Results and Discussion

Having examined the design variables and values, possible design alternatives in each design stage are generated by varying design variables. Orthogonal experiment was then conducted to obtain the design samples. In this study, there are 4 design variables and 9 levels in early design stage. Accordingly, 65 design samples were obtained. In referring to the life-cycle environmental impact assessment, BIM models of the design samples were created in Revit. They were then imported into Green Building Studio and Tally for the life-cycle carbon emissions through the BIM-LCA integration approach. The building operating schedule, HVAC system, and outdoor air information are out of the scope of this research, and therefore the building service system is assumed to satisfy the ideal conditions for heating and cooling. As a result, the amount of embodied and operational impacts, expressed by kg CO2eq/m2 for design samples are presented in Figure 2.

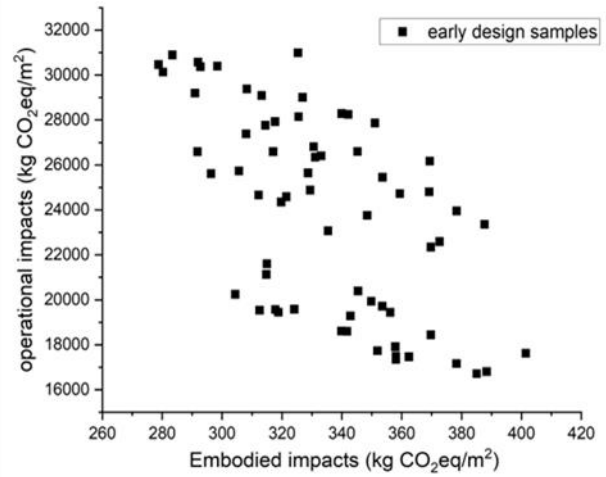


Figure. 2. Environmental impacts of early design alternatives.

As shown in Figure 2, the operational environmental impacts account for a large portion of the life-cycle environmental impacts (over 90% in each design stage). Having obtained the environmental impact assessment results of design samples at each design stage, the MATLAB has been used to train and develop the LSSVM model for predicting the embodied and operational impacts of a building over its design process. 80% of the sample cases (52 cases for early design stage) were used to train the LSSVM model. All inputs and outputs were normalized according to Equation (1). The training results for embodied and operational impact assessment of three design stages are shown in the left of Figure 3. The goodness-of-fit R^2 is 0.97997 for embodied impact assessment and 0.90934 for operational impact in early design stage. They were found very close to 1 for the output studied, thus demonstrating a very good correlation between outputs and target values.

Subsequently, the developed LSSVM model was validated with 13 cases, the rest 20% sample cases. The results of the LSSVM prediction on the testing set are basically consist with the assessment result, as shown in the right of Figure 3. The goodness-of-fit R^2 is 0.9068 and 0.91751 for embodied and operational impact prediction in early design stages, which shows a high prediction accuracy. Therefore, the relationship between design variables and environmental impact established by LSSVM model enables to be used as the objective function of the multi-objective optimization.

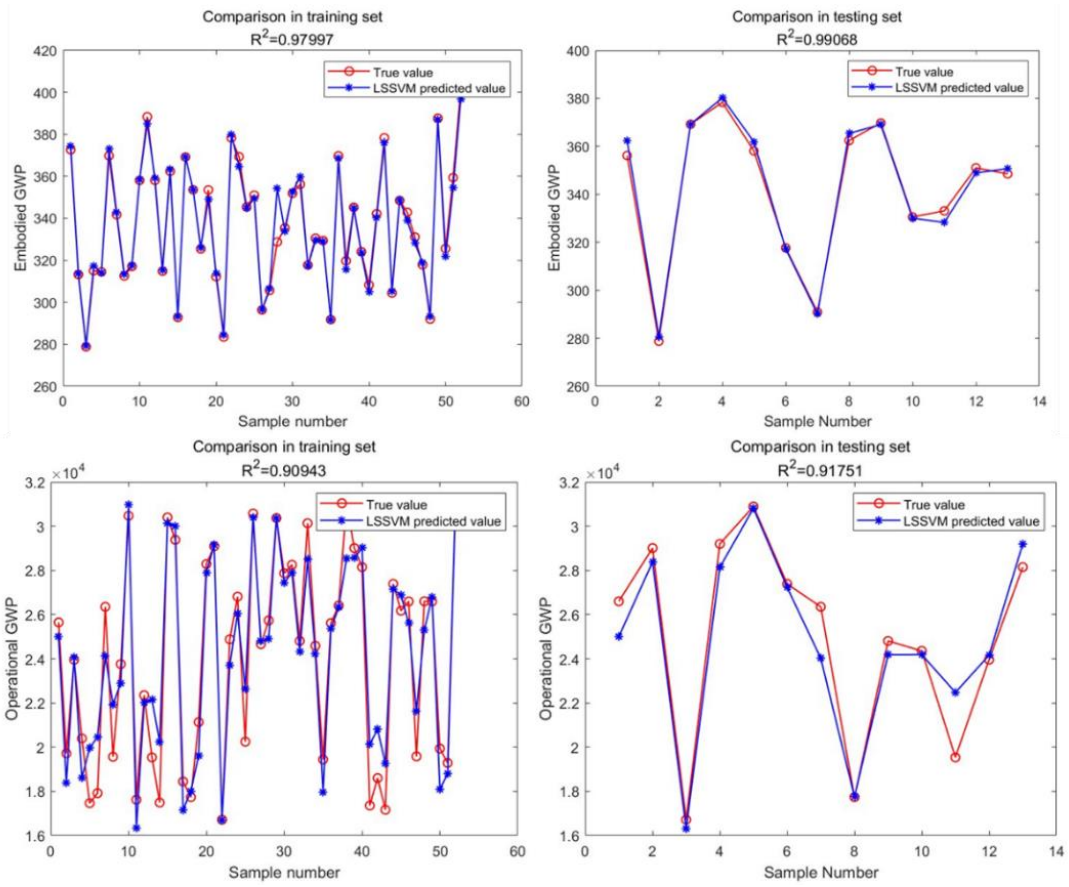

Figure. 3. Environmental impact prediction model.

The combination of LSSVM models and NSGA-II was conducted in Matlab environment to explore the optimal design solution in each design stage. The initial population was set as 100 due for 200 generations based on recommendation. A high mutation rate and a large population size were chosen to avoid getting stuck in local optima. The progress of the objectives was always supervised during the optimization, and if no major improvement could be observed, the algorithm was stopped.

The optimal design solutions are elaborated according to the following optimization cases: (1) Single-objective optimizations for total life-cycle environmental impacts; and (2) A multi-objective optimization considering the operational and the embodied environmental impacts with equal weights. The optimal design solutions are illustrated in Figure 4 and Table 2.

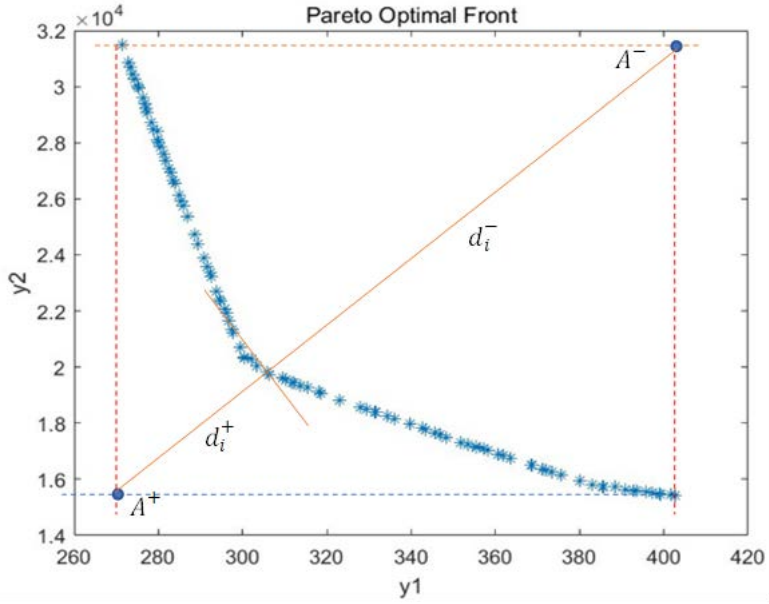

Figure. 4. Pareto optimal front in early design stages.

Table 2. Optimization design solutions.

	Floor height(m)	Orientation (°)	WWR	Number of floors	Embodied impacts	Operational impacts	Total impacts
Original design	2.8	0°	0.25	8	335.38	23070.34	23405.72
Design solution with minimum total environmental impacts	2.8	15°	0.1	4	402.6102	15403	15805.61
Design solution with trade-off between embodied and operational impacts	2.8	15°	0.4	8	322.9659	18831	19153.97

The Pareto frontier in early design stage is illustrated in Figure 4. It indicates that there is a trade-off between embodied and operational environmental impacts in early design stage. As embodied impacts (denoted as y1 in Figure 4) increase, the operational impacts (denoted as y2 in Figure 4) decrease. In referring to the single objective optimization for total life-cycle environmental impacts, the minimum total impact (15805.61 kg CO_2eq/m^2) is obtained in the design option where there are 4 number of floors with floor height of 2.8 m, the WWR is 0.1, and the orientation of building is 15° south to west, as shown in Table 2. The total CO_2eq generated by the optimal design equals to 67.5% of that from the original building design. In other words, it is possible to reduce 32.5% of the environmental impacts for the original design by varying the design parameters in early design practice. The difference between the optimal design solution and the original one lies in the building orientation (15° vs. 0°), WWR (0.1 vs. 0.25) and number of floors (4 vs. 8).

In referring to the trade-off between embodied and operational impacts, the TOPSIS analysis results reveal that the trade-off design solution is the case (number of floors: 8, floor height: 2.8m, orientation: 15° south to west, and WWR: 0.1). The total environmental impact is 19153.97 kg CO_2eq/m^2, which consists of an embodied impact of 322.97 kg CO_2eq/m^2 and an operational impact of 18831 kg CO_2eq/m^2. The operational impact of trade-off design increases by 8.8% while the embodied impact decreases by 25.8%, compared with the original design. Since the trade-off solution intends to simultaneously minimize the embodied and operational impacts of the original design, its total environmental impacts are larger than “the minimum total impacts” (15805.61 kg CO_2eq/m^2). Interestingly, the difference between the “trade-off solution” and the

"solution with minimum total impacts" only lies in the design values of "WWR" and "number of floors" (The floor height and orientation of the building keep constant). This indicates that WWR and number of floors seem to have a strong influence on the trade-off between embodied and operational impacts of a building.

5 Conclusion

This research developed a multi-objective optimization model based on the combined use of BIM-LCA integration approaches, machine learning method and NSGA-II algorithm to find out the balance between embodied and operational impacts of a building in its early design practice. The man conclusion based on the case study are as follows: 1) early design stage has the potential to save 32.5% emissions for mid-rise buildings in hot summer and cold winter climate zone in China. 2) window-to-wall ratio and number of floors largely affecting the trade-off between embodied and operational impacts. Further research needs to investigate other design stages throughout the entire design process. Moreover, future research can also explore other building types in different climate zones.

Energy cost and carbon footprint of metals. Implications for PV-Silicon panels

Jorge Torrubia[a], Alicia Valero[a] and Antonio Valero[a]

[a] Instituto CIRCE (Research Centre for Energy Resources and Consumption) – Universidad de Zaragoza, Zaragoza, Spain, jtorrubia@unizar.es

Abstract:

The demand for low-carbon technologies such as photovoltaic panels, wind turbines or batteries is increasing rapidly due to the energy transition, triggering the demand for metals needed to achieve the sustainable goals. Therefore, it is important to assess the energy consumption and carbon footprint of mining and metal production, as the environmental impact of future energy infrastructures will depend on them. This paper evaluates the energy cost and carbon footprint of one MW of PV panels considering a cradle-to-gate approach from a life-cycle perspective. The focus is on the metals since these are the largest contributors to energy costs (80%), distinguishing between the different stages of production: mining, metal production and the energy cost of the chemicals, and indicating the four most used fuels: coal, diesel, natural gas and electricity. To evaluate the total energy cost and carbon footprint, three different material intensity scenarios are proposed, considering a decrease over time: 2018, 2030 and 2050, and two electricity emissions scenarios: one mainly based on fossil fuels, and another based on renewable electricity. The energy return on investment (EROI) increases from 8.4 to 15.9 and carbon emissions decrease from 40 to 22 gCO_2/kWh, considering the material intensity of 2018 and 2050, respectively. If electricity from renewable sources is used, carbon emissions can be halved, reaching 11 gCO_2eq/kWh with the 2050 material intensity. Therefore, material intensity must be reduced and energy-intensive processes decarbonized to minimize the impacts of future renewable infrastructures.

Keywords:

Energy Cost; Carbon Footprint; Energy Transition; Life cycle assessment; Metal production; Photovoltaic panels.

1. Introduction

Technologies that enable the harnessing of renewable energy contain various metals that facilitate specific functionalities [1]. For instance, one MW of wind energy requires 113 to 132 tons of steel, 1 to 5 tons of copper, 0.5 to 1.6 tons of aluminum and up to 200 kg of REE; while, to manufacture one MW of photovoltaic (PV) panels 60 to 67 tons of steel, 4 to 5 tons of copper, 6 to 8 tons of aluminum and up to 20 kg of Ag are needed. This significant material intensity and the increasing demand for these technologies are triggering the demand for metals in the coming years [2]. Thus, in the case of wind energy, annual material demand is expected to increase by a factor from 2 to 15 in 2050 compared to 2018 values. In the specific case of some metals, such as rare earths elements (REE), the global demand could increase 8-9 times in 2030 and 11-14 times in 2050 compared to 2018 values. The case of solar PV technologies is similar. The most optimistic scenarios indicate a 3 to 8-fold increase in demand for materials by 2050. However, demand for specific metals such as silver or silicon could increase by 4 and 12, respectively [3].

On the other hand, mining and metal production are one of the most energy-intensive industries worldwide. It consumes about 38% of global industrial energy use, 15% of the global electricity use, and 11% of global energy use. This consumption is still based on fossil fuels since it comprises about 19% of global coal and coal products, 5% of global gas, and 2% of global oil supplied [4]. In addition, the energy required in mining is expected to increase in the future due to lower ore grade, finer grain and increasing ore complexity of newly discovered deposits [5,6]. Moreover, the trend of this growth is exponential. For example, a decrease in copper ore of 0.2% to 0.4% requires 7 times more energy [7]. Due to these facts, the energy demand in mining operations could grow 36% by 2035 [4].

Thus, it is observed that manufacturing the infrastructure to achieve the energy transition requires a large amount of metals, which in turn require fossil energy consumption and can generate significant carbon emissions. Other authors have studied this problem from different approaches. One of the most common approaches is through the Energy Return on Investment (EROI). In these studies, EROI at the final energy stage is used to calculate how much of the total energy is required by the energy system to extract, process,

convert and deliver a unit of energy [8–10]. Another approach focuses on life cycle analysis (LCA). It is based on the accounting of the energy required and emissions generated to manufacture and commission an energy system. Generally, this analysis has only been used to estimate the impacts of current technologies in specific case studies [11,12]. One of the advantages of this methodology is that it permits to identify the processes from which the energy consumption or emissions originate [11]. Generally, most energy and emissions are consumed or emitted during the metal extraction and processing [3]. In addition, this methodology also allows the assessment of possible future scenarios with a dynamic approach, although few studies focus on it [13]. Thus, it is possible to establish different variable assumptions such as the material intensity, the energy consumed in the processes or the carbon intensity of the energy system.

In this study we use the life-cycle approach focusing on the energy cost and carbon footprint of the metals needed to manufacture PV panels. The methodology is based on accounting for the resources required for the extraction and production of Ag, Si, Al, Cu, Sn, Fe, and some of their alloys used in steel, such as Cr, Mn, Nb and Ni. The scope covers cradle to gate, i.e., from extraction of raw materials to their use as finished products, in this case, one MW of PV-Silicon panels. In addition, the energy cost is classified by the main energy sources used in mining and metal production: natural gas, diesel, coal, and electricity. Here it also includes the energy and emissions due to the chemicals needed for manufacture. The disaggregation of the processes is sufficient to differentiate the two main stages of metal production: mining and metal production. Thus, it is possible to determine which processes are most critical for decarbonization. Following this idea, two carbon emission scenarios are proposed, depending on electricity's carbon intensity: One based mainly on fossil fuels and the other on renewable energies. The energy used to manufacture PV panels and the energy cost of other materials, such as cement or glass, are also considered. Besides the carbon emission scenarios, three material intensity scenarios are also proposed. Thus, it is possible to study the link between material intensity - energy - carbon emissions, applied to one of the fastest growing technologies, the photovoltaic panels.

2. Data and methodology

Figure 1 shows the main processes and intermediate products required to obtain silver from lead and zinc mines. This Figure is an example to explain the methodology used to calculate the energy cost of metals and the allocation method since there are several different products, such as Pb, Zn or Ag.

As can be observed, each process (M&C and MP in Figure 2) has inputs (materials, energy and chemicals) and outputs (materials for the next process or the final metal). M&C refers to those processes belonging to the mining and concentrating step and MP to those belonging to the metal production step. The cradle-to-gate approach is used; thus, the analysis begins with mining and ends with the product ready for its use in another industry. The reference product is one kg of silver. If there were no co-products, it would be sufficient to sum all the energy (natural gas, diesel, coal and electricity) and chemical resources (also measured in energy cost units) to calculate the energy cost of one kg of the reference product. This is the case for the other metals in this study. But in the silver production more metals are produced simultaneously, which makes it necessary to allocate the silver its corresponding share through an allocation method.

The allocation method depends on the criteria of the authors. Most studies use allocation methods based on the economic benefit provided by the metals. However, its disadvantage is the strong fluctuation of the metal's price in the market [14]. Therefore, this study uses a physical allocation method based on the elements' geological scarcity, which has been successfully used in other studies [15–17]. The main advantage of this method is that the energy or environmental cost of metals is allocated through physical criteria, reflecting their value according to their scarcity in the earth's crust.

The allocation factor is calculated through equation 1, where M_i is the extracted mass of metal i, measured in kg-metal, and CC_i is the concentration of metal i in the earth's crust, measured in kg-metal/kg-crust.

$$Allocation_i\ (\%) = \frac{CC_i^{-1} \cdot M_i}{\sum_{i=1}^{n} (CC_i^{-1} \cdot M_i)} \quad (1)$$

Table 1 lists the parameters used to calculate the allocation factors, which in the case of silver is 12%. Once the allocation of each individual metal es calculated, the allocation of each process can be derived. Thus, the 34% of footprint of the mining and concentration stage is allocated to Pb and Ag, and then the 35.8% of the footprint of the lead production is allocated to Ag, as shown Figure 1.

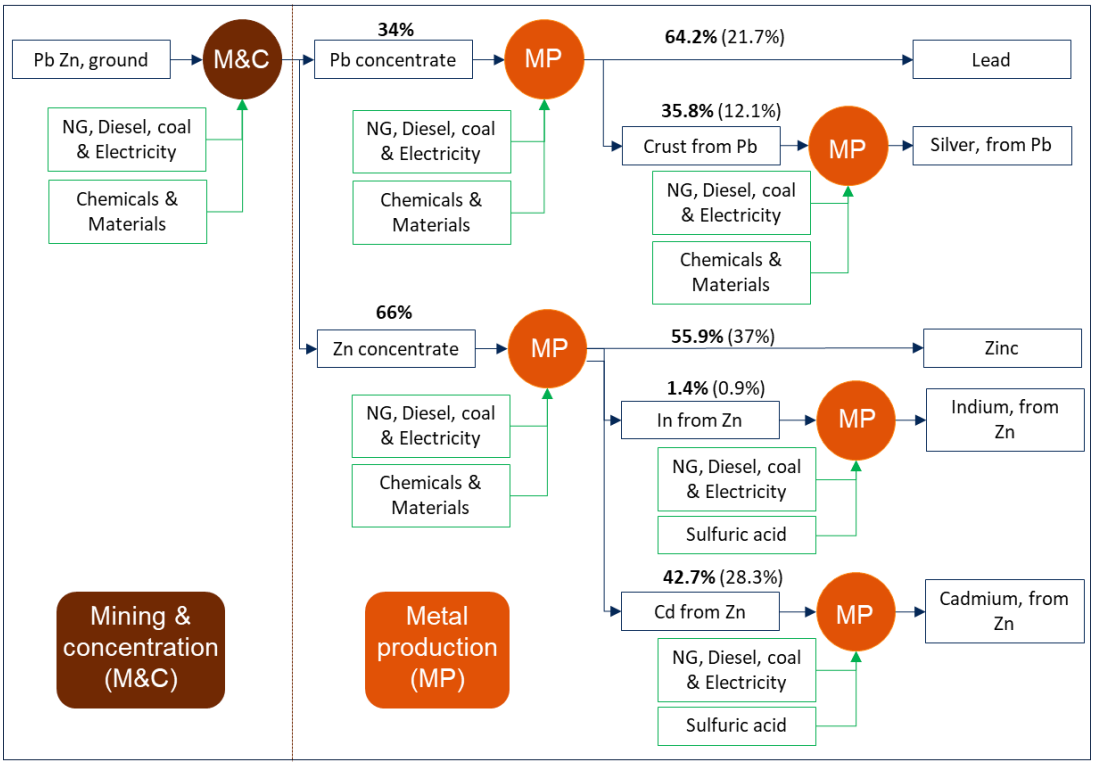

Figure 1. Block flow diagram of silver production from Pb-Zn mines.

Table 1. Mining production, crustal concentration and allocation factors of Pb-Zn mines.

Metal (i)	Mining (M_i) (kg_i)	Crustal concentration (CC_i) $\left(\frac{kg_i}{kg_{crust}}\right)$	Allocation factor
Ag	1	5.0E-08	12%
Pb	717	2.0E-05	22%
Zn	4333	7.1E-05	37%
In	0.08	5.0E-08	1%
Cd	4.6	9.8E-08	28%

As previously discussed, the remaining metals in this study do not require allocation since there are not co-products. The same applies to the calculation of the energy cost of chemicals. The process data inventories were taken from the Ecoinvent database version 3.9.1 [18], except for the Silicon processes, which are from the reference [19].

Once the energy cost is known, separated by fuel type, it is possible to estimate the carbon footprint through equation 2. Where, CF_i is the carbon footprint of metal i, measured in kg CO_2 eq; EC_j the energy cost of fuel j and EF_j is the emission factor of such fuel.

$$CF_i = \sum_{j=1}^{n}(EC_j \cdot EF_j) \quad (2)$$

Table 2 shows the data on the emission factors EF_j used. Two scenarios were established to study the impact on the carbon footprint of a decrease in electricity generation emissions. One scenario is based on fossil fuels; its emission factor is 0.488 kgCO_2eq/kWh. The other is based on renewable sources, and its emission factor is reduced to 0.021 kgCO_2eq/kWh.

Table 2. Emission factors for High Emission Scenario (HES) and Low Emission Scenario (LES)

		Emission factor HES	Emission factor LES	Source
Natural gas	kgCO_2eq/MJ	0.057	0.057	[20]
Diesel	kg CO_2eq/MJ	0.075	0.075	[20]
Coal	kg CO_2eq/MJ	0.1	0.1	[20]
Electricity	kg CO_2eq/kWh	0.488	0.021	[21,22]

The same procedure was used to calculate the energy cost of 1 MW of PV solar panels. Thus, a cumulative sum of all the energy sources needed to manufacture and install is made. In this case, the inventory data were obtained from Ecoinvent database version 3.9.1 [18] and Méndez et al. [12]. In addition, the material

intensity, i.e., the amount of materials that constitute the solar panels, is fundamental to determining their energy cost and, consequently, their carbon footprint. Thus, three material intensity scenarios (Table 3) have been established based on the following study [3], where a decrease in material intensity is estimated for PV panels in 2030 and 2050 compared to 2018. Hence, two electricity emission scenarios and three material intensity scenarios are assessed.

Table 3. Material Intensity of the three scenarios assessed per MW of PV panel

kg/MW PV	Concrete	Plastic	Glass	Steel	Sn	Al	Cu	Si	Ag
2018	60700	8600	46400	67900	139	7500	4600	4000	20
2030	58400	8300	44700	65300	139	7200	4500	2750	6
2050	48600	6900	37100	54300	139	6000	3700	1000	1

To compare the results with the literature, two parameters of the solar panels are calculated: Energy Return of Investment (EROI) and carbon intensity, through equations 3 and 4, respectively.

$$EROI = \frac{Supplied\ energy}{Energy\ cost} = \frac{1MW \cdot t_{operation} \cdot life}{Energy\ cost\ 1MW\ PV} \quad (3)$$

The EROI represents the amount of energy units obtained from an energy system for each unit of energy invested on it, so it has no units. In this case, 1 MW of PV was taken as a reference. Thus, equation 3 shows in the numerator the amount of energy that 1 MW of PV will supply, assuming an operation of 1000 hours per year ($t_{operation}$) for 25 years ($life$). On the other hand, the denominator shows the energy cost required to manufacture and install 1 MW of PV.

$$Carbon\ intensity = \frac{Carbon\ footprint}{Supplied\ energy} = \frac{Carbon\ footprint\ 1MW\ PV}{1MW \cdot h \cdot life} \quad (4)$$

Equation 4 shows the calculation of the carbon intensity, which represents the CO_2 emissions produced by each energy unit. The numerator shows the entire carbon footprint of 1 MW PV measured in g of CO_2. At the same time, the denominator represents all the energy generated by one MW PV (measured in kWh), assuming 1000 hours per year and 25 years of life.

3. Results and discussion

The results of the energy cost and carbon footprint of metals used in a PV panel are presented, discussing their decarbonization possibilities. The specific case of 1 MW of photovoltaic panels is then analyzed.

3.1. Energy cost of metals

Figure 2 shows the energy cost of metals used in photovoltaic panels. The results are ordered from highest to lowest value in MJ/kg. Thus, the most energy-consuming is silver (11,000 MJ/kg), followed by Si (1,400 MJ/kg), Al (75 MJ/kg), Sn (64 MJ/kg), Steel (32 MJ/kg), Cu (23 MJ/kg). In addition, the energy cost is disaggregated into the four most common fuels (natural gas, diesel, coal and electricity), the most important steps (mining and concentration (M&C), and metal production (MP)) and the energy cost of chemicals used these processes.

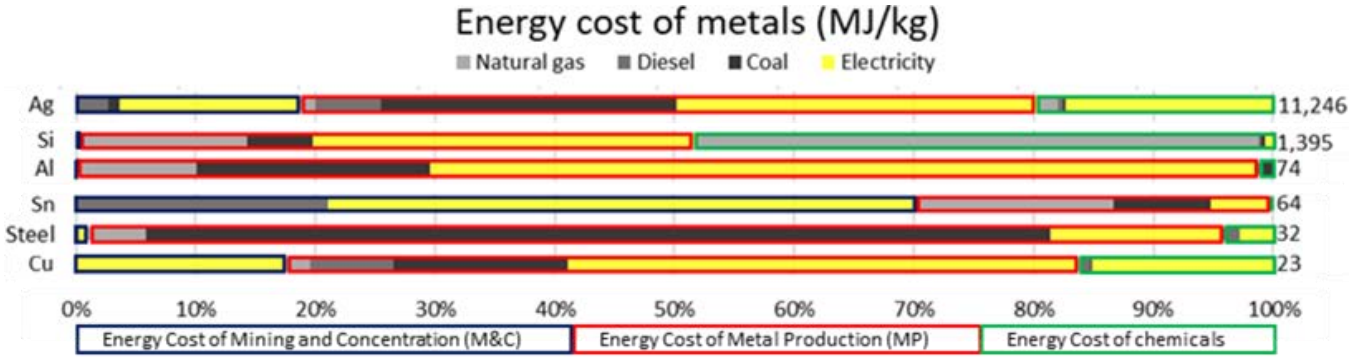

Figure 2. Energy cost of metals used in PV panels.

The mining and concentration step comprises all the processes from the rock extraction until the ore concentrate is obtained. As shown in Figure 2, this step's contribution is considerably lower than the metal production since it is always less than 20%. The exception is the case of Sn, where the M&C contribution is about 70% may be because the underestimation of the amount of chemicals used in this case, which is only 0.25%. On the other hand, for Si, Al and steel (mainly Fe) the contribution is very low (less than 1%) since these elements are very abundant in the earth's crust and therefore, their main energy cost is their metal production. These results are consistent with the literature since, as stated in Norgate et al. [5]: “Mineral

processing & concentration, usually have much less impact than metal extraction and refining in terms of energy".

However, in the future, the energy cost of the mining and concentration step is expected to increase due to two factors: (1) a decrease in ore grade, (2) finer grain of many newly discovered deposits. First, this increase is because additional energy is needed to extract the waste material in low-grade ores [6,23]. Secondly, finer grains require grinding to finer sizes resulting in higher energy consumption [5]. Nevertheless, in some cases, technological improvement may play an important role. For instance, despite the decrease in niobium ore concentration between 2017 and 2019 in Brazil, total energy consumption per kg FeNb was lower in 2019 [24]. However, the exponential trend of energy consumption with decreasing ore grade suggests that increasing energy consumption will prevail despite technological improvements [7]. Thus, for example, a decrease in copper ore grade between 0.2% to 0.4% requires seven times more energy [4].

On the other hand, the energy consumption increase in the mining step need not increase the energy consumption of the metal processing steps since a fixed-grade concentrate is produced in concentrating stage regardless of the initial ore grade [5]. Thus, metal production processes start from the ore concentrate until the elements are produced in their metallic form. This is usually the step with the highest energy consumption, as can be appreciated in Figure 2, and as evidenced the literature [25,26].

In order to verify that the energy cost data are comparable with the literature, Table 4 has been constructed. The "This study" column shows the energy cost results obtained, the "mean" column contains the mean of all the samples from the literature (References column) and the "min", "max" and "SD" columns represent the minimum, maximum and standard deviation, respectively. It is possible to observe that all the metals studied are found between the minimum and maximum (Al, Cu, Fe) or in values close to the minimum (Si, FeCr, FeMn, FeNb) except for Ag and Sn. Instead of comparing the footprint of steel, its more important metallic components (iron and some alloys such as FeCr, FeMn or FeNb) have been compare with literature.

The difference with the Sn results could be due to the underestimation of the energy consumed by the chemicals, as previously explained. This would also reduce the percentage of energy used in mining and concentrating. The reason behind the differences lies in the use of different data inventories. However, in the case of Sn there is only one reference for comparison, so it is not easy to draw accurate conclusions with this comparison.

The case of Ag is different since is a by-product of Pb-Zn, Cu or Au mining. Therefore, allocating the share of costs corresponding to silver in the common processes is necessary, as explained in section 2 data and methodology. Thus, in this case, in addition to using different data inventories, a different allocation system has also been employed. The studies in the literature use an economic allocation, but in this study, we have used the physical allocation described in section 2 data and methodology. This adds more uncertainty in comparing the results. Thus, the higher energy cost of silver in this study may also be because this metal has a lower price relative to its concentration in the earth's crust when compared to its co-produced metals (such as Pb or Zn). However, the impact of this fact on the energy cost of PV panels is low, given the reduced silver content compared to other metals.

Table 4. Comparison of the energy cost of metals with literature

MJ/kg	This study	Mean	Min	Max	SD	Samples	References
Ag	11,246	1,745	210	3,280	2,171	2	[25,27]
Si	1,396	5,242	1,490	9,350	3,039	5	[28,29]
Al	74	169	23	263	66	16	[4,6,25,27,30–34]
Sn	64	321	321	321	--	1	[25]
Cu	23	59	18	168	41	18	[4,6,25,31,35,36]
Steel	32	--	--	--	--	--	--
Fe	24	19	7	30	7	8	[25,31,34]

FeMn	20	29	24	34	7	2	[25,31]
FeNb	75	127	82	172	63	2	[25,37]

3.2. Carbon footprint of metals

To estimate the carbon footprint of metals, it is essential to know which type of fuel is used, since each of them has different emissions per unit of energy. For this reason, the fuel types in Figure 2 are discussed below. Firstly, the mining and concentration step and secondly the metal production step, pointing out the difficulties of decarbonization.

3.2.1. Fuels used in Mining and Concentration

In the mining and concentration step, the predominant fuels are diesel and electricity since other fuels never exceed 10%. Diesel is primarily used in heavy mining machinery, such as drilling rigs, trucks, etc. For example, according to Sanjuan-Delmás et al. [36], 99% of the fossil fuels used in a copper mine were diesel in the trucks. Regarding electricity, its main use in mining and concentration step is comminution, a high-energy consumption stage. For instance, comminution uses an average of 15% of the total energy demand of iron production [4]. Another important electricity use is HVAC systems in underground mines [38].

Decarbonization of diesel use is a major challenge. However, some studies [36,39] propose using electric or fuel cell vehicles, but only a few mines currently operate such vehicles, and on a very small scale [40]. On the other hand, decarbonizing electricity is more accessible because renewable energies generate it directly. However, there are two main challenges to decarbonizing electricity from mining operations. The first challenge is integrating renewable energy in remote off-grid mining operations, which usually use fossil fuels for electric generation. However, the number of renewable projects has been increasing. In 2015 there were 600 MW, but by the end of 2019 about 5 GW were projected. But this renewable capacity is still a fraction of the total energy demanded by mining operations, showing a slow-paced development [4]. The second challenge is increasing renewables' share in the grid for connected mining operations.

3.2.2. Fuels used in Metal Processing

As mentioned in the previous section, the metal processing step usually has the highest energy cost. Therefore, its decarbonization would have a greater impact on reducing the carbon footprint. As shown in Figure 2, the most common fossil fuels are natural gas and coal since provide at least 70% of the fossil energy in all the metals. They are used as a source of heat and reducing agents. The use of coal in steel production is noteworthy, as 73% of the total energy comes from this fuel, since its use is inherent to the steel-making process [31].

On the other hand, electricity is mainly used in electrolysis or electrorefining processes. The use of electricity is particularly important in copper and aluminum since contributes to 42% of the total energy cost of copper and 70% in aluminum case. In copper, it is due to its electrorefining stage and in aluminum to the electrolysis process.

Bioreducers and hydrogen are the most promising substitutes for natural gas and hydrogen [26], although with some problems, for example, the sustainable production of bioreductants (such as charcoal) on a global scale, the costs of transporting them or other problems due to their physical characteristics [4]. On the other hand, the use of hydrogen as a reductant is much better in terms of an environmental impact than biomass when it is produced using renewable electricity [41]. However, its generation is still expensive [4], and new infrastructure designed for its use needs to be developed due to its different properties than other fossil fuels [42]. Again, electricity is the most accessible source to decarbonize since metal production plants are usually connected to the grid, not being in remote locations.

3.2.3. Chemical consumption

Chemicals and other auxiliary materials considerably contribute to the energy cost of the processes. This share is significant in the case of Si, Ag and Cu, with a contribution of 48%, 20% and 16%, respectively. In the case of Si, this is mainly because silicon for solar panels must have very high purity, for which a large amount of chemicals is consumed. In the case of Ag and Cu, chemicals are mainly used in electrolysis processes.

In this case, decarbonization depends not on the mining industry but on the chemical industry that provides the products necessary to manufacture metals.

3.2.4. Carbon footprint scenarios

Due to the limitations of substituting fossil fuels (either diesel from mining trucks or coal and natural gas as heat sources and reducing agents in metal processing), this study proposes only the decarbonization of electricity as a first approach to decarbonization. For this purpose, two scenarios are considered: one with high emissions (HES) and the other with low emissions (LES), based on renewable energies. The carbon footprint results are shown in Table 5. The "HES" (high emissions scenario) column shows the results of the scenario in which the electricity has higher emissions; the "LES" (low emissions scenario) column shows the results of the scenario with lower emissions; and the "Diff" column shows the percentage difference between the two scenarios. In addition, a comparison is made with other sources in the literature: the "mean" column shows the mean of all samples; in the "min" column, the minimum; in "max" the maximum; in SD "Standard Deviation", in "simple" the number of samples and finally in “references”, the sources used.

As in Table 4, Table 5 shows that all metals have a carbon footprint in the range of the literature when compared to the "HES" scenario, except for Ag and Sn. The reasons for these exceptions are the same as those explained in section 3.1 above. As seen in Table 5, significant reductions can be achieved just by using renewable energies in electricity generation. The smallest reduction (29%) corresponds to steel due to the large contribution of coal in its energy cost. In addition, the use of coal is inherent in the manufacturing process. However, the footprint of the remaining metals can be reduced from 50% (for Si) to 78.8% (for Cu).

This can have significant implications in the energy transition since using renewable energies in mining reduces the carbon footprint of metals that will later be used in the renewable energy infrastructure, following a feedback process. The following section uses the example of solar panels to expose this idea.

Table 5. Comparison of the carbon footprint in the HES and LES scenarios of metals with literature.

Metal	HES	LES	Diff	Mean	Min	Max	SD	Samples	References
Ag	1333	422	68.4%	283	34	815	301	10	[15,25,43,44]
Si	119	59	50.0%	461	114	775	238	5	[28,29]
Al	8.9	2.2	74.8%	16	5.9	41	9	21	[4,25,30–35,44,45]
Sn	6.8	2.3	65.6%	17	17	17	--	1	[25]
Cu	2.8	0.6	78.8%	5.1	1.1	64.9	9	46	[4,15,25,31,34–36,46]
Steel	3.3	2.3	29.2%	--	--	--	--	--	--
Fe	2.4	1.9	22.3%	3.9	1.2	23.3	7	11	[25,31,34,47]
FeCr	3.5	1.8	48.8%	2.4	2.4	2.4	--	1	[25]
FeMn	2.3	1.1	52.7%	5.2	1.0	9.6	3	10	[25,31,35,43,45]
FeNb	8.8	3.1	64.8%	8.4	5.1	12.5	4	3	[24,25,37]

3.3. Energy cost and carbon footprint of PV Power

Figure 3 shows the Sankey diagram of the energy cost embedded in one MW of solar panels, which amounts to about 10.7 TJ. The diagram allows the analysis by the different stages of the production processes and by the types of fuels. For the first, three phases can be identified:

- Manufacturing and installation: This phase includes all the energy consumption related to the manufacture and installation of a solar panel, but not the energy embedded in the components needed. The energy cost is about 846 GJ, contributing to 7.9% of the total cost.
- Other materials: Besides metals, materials such as concrete or solar glass contribute to energy costs. In this case, they account for 1295 GJ, i.e., 12 % of the total.
- Metals: Metals contribute the most to the energy cost, with 8,623 GJ and 80% of the total. Silicon and steel alone account for 52% and 20% of the total footprint, respectively. Furthermore, the cost of the metals has been divided according to their production steps. As mentioned above, the metal production step is the most important, with 52% of the total cost, followed by the cost due to chemicals, contributing 27%. Finally, the cost of mining is very low, only 0.8%, although, as mentioned in section 3.1, it is expected to grow exponentially in the coming years due to the decrease in ore grades.

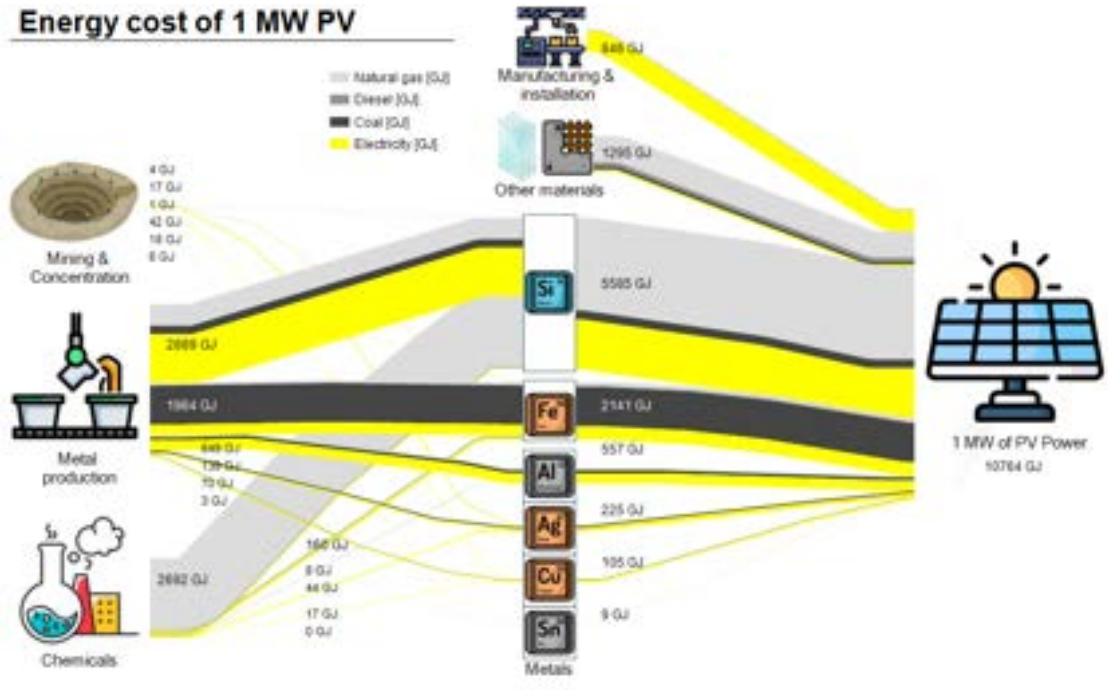

Figure 3. Sankey diagram of energy cost distribution of 1 MW of PV Panels.

Regarding the types of fuels:

- Natural gas is the most consumed fuel (43% of energy), mainly due to the energy cost of chemicals and crystalline silicon production. Another important consumer is manufacturing other materials, such as concrete or solar glass.
- Electricity holds the second highest share (35%). It is used primarily in the solar panel manufacturing process itself, as well as in the production of the metals such as silicon.
- Coal accounts for 19% of the energy cost. Its main use was in steel production, the second largest contributor to the total footprint after silicon.
- Finally, diesel consumption is residual, as it contributes only 2% of the energy cost and is mainly used in mining and concentrating the metals.

Table 6. Material intensity (kg/MW), Energy cost (GJ), Carbon footprint (kg CO_2 (HES & LES), EROI and Carbon Intensity (C.I.) of 1 MW of PV panels according to the contribution of metals or other materials.

		Other materials	Si	Steel	Al	Ag	Cu	Sn	EROI	C.I g/kWh
	kg/MW	115700	4000	67900	7500	20	4600	139	-	-
Case 1	GJ	1,295	5,585	2,141	557	225	105	9	8.4	-
2018	kg CO_2 (HES)	86309	474478	223850	66950	26653	12971	949	-	40.0
	kg CO_2 (LES)	77716	237382	158381	16855	8434	2748	326	-	20.4
	kg/MW	111400	2750	65300	7200	6	4500	139	-	-
Case 2	GJ	1,267	3,840	2,059	535	67	103	9	10.3	-
2030	kg CO_2 (HES)	84317	326204	215278	64272	7996	12689	949	-	32.8
	kg CO_2 (LES)	75940	163200	152316	16181	2530	2688	326	-	16.9
	kg/MW	92600	1000	54300	6000	1	3700	139	-	-
Case 3	GJ	1,141	1,396	1,712	446	11	84	9	15.9	-
2050	kg CO_2 (HES)	75324	118620	179014	53560	1333	10433	949	-	21.9
	kg CO_2 (LES)	67917	59346	126658	13484	422	2210	326	-	11.2

As was done for metals, two scenarios are established, one conventional, with high emissions due to electricity generation, and the other with low emissions. Additionally, three other scenarios are established depending on the demand for materials for photovoltaic generation: one for 2018 and others for 2030 and 2050, based on literature forecasts [3]. The results are shown in Table 6 and the 2018 scenario is the same represented in the Sankey diagram of Figure 3. In addition, the EROI (see section 2 data and methodology) and the carbon intensity (gCO_2/kWh) have been estimated depending on each case. Thus, Table 6 shows the effect of decreasing material intensity in the EROI, which increases from 8.4 in the 2018 scenario to 15.9 with the most optimistic forecasts for the year 2050. The opposite happens with carbon intensity, decreasing from 40 gCO_2/kWh to 22 gCO_2/kWh. These results are obtained only with the reduction of the material intensity. If low-carbon electricity were additionally used, the carbon intensity of solar panels could be halved. That is, from 40 gCO_2/kWh in 2018 scenario, it could decrease to 20 gCO_2/kWh and in 2050 scenario from 22 gCO_2/kWh to 11 gCO_2/kWh. This emission reduction is limited because electricity contributes 35% of energy costs and is the only energy source that reduces emissions according to our assumptions. Therefore, to achieve complete decarbonization, replacing natural gas and coal in metal production processes with other fuels, such as hydrogen, is necessary. However, this would imply the use of more materials, as new infrastructure would need to be developed. Thus, the total energy costs could increase, although it would reduce the carbon footprint. Furthermore, complete substitution should not only occur in the metal industry, but also in the chemical industry, since a large part of natural gas consumption comes from it (Figure 3). This is an example of the strong interconnection between industries and shows that decarbonization of one industry cannot be achieved without decarbonizing others. For instance, manufacturing solar panels with a lower carbon footprint would require reducing the footprint of metal mining, but also reducing the footprint of the chemical industry that supplies it with essential materials for its production.

The results obtained are comparable to those in the literature. EROI only includes the extraction and operation of the energy source, so it is defined as standard [8]. According to Raugei et al. [48], the standard EROI of photovoltaics is between 6 and 12, with numbers on the range from 8 to 10 obtained in this study for the 2018 and 2030 scenarios. Regarding carbon intensity, the 2018 scenario (20 to 40 gCO_2eq/kWh) is comparable to those obtained 25-40 gCO_2eq/kWh by the reference [49].

However, this study has some limitations. First is the quality and detail of the data inventory used. Although results comparable with the literature have been obtained for most of the metals and the solar panels, this has not been the case for some metals such as Sn. In addition, when using the physical allocation, silver has a much higher cost than reported in the literature. However, these deviations have not influenced calculating the PV energy cost much due to the low material intensity of Sn and Ag. Another problem lies in the global

view of this study since the electrical energy mixes vary greatly depending on the regions. However, this study has simplified it by taking two carbon intensity scenarios. In addition, the cost of transportation has not been considered due to the global view. Therefore, in future studies, the estimated origin of the metals should be considered since the energy cost and carbon footprint also depend on it.

Finally, it is important to remark that this study has been limited to studying solar panels. Still, other technologies, such as wind turbines, are required to achieve complete electrification and decarbonization. In addition, studying batteries and electrolyzers (for hydrogen production) is indispensable for continuous electricity supply and for substituting fossil fuels. However, their consideration will decrease the EROI and increase the carbon intensity of the system because, despite consuming a large amount of metals and materials, these technologies do not provide any extra energy.

4. Conclusions

This study estimates silicon solar panels' energy cost and carbon footprint from a life cycle perspective cradle-to-gate. It focuses on the required metals, i.e., Fe, Al, Si, Cu, Ag and Ag, which contribute 80% of the total energy cost together. Si and Fe have the highest contribution with 52% and 20%, respectively, while Al, Ag, Cu and Sn have only 5%, 2%, 1% and 0.1%, respectively. The great impact of Si is not due to its mass contribution (only 2%), but to its high energy cost, which amounts to 1,400 MJ/kg. In contrast, Fe contributes 32% of the mass, but its energy cost is much lower, 32 MJ/kg. The remaining 20% of the cost corresponds to energy consumption due to the manufacture of other materials, such as concrete or glass, and to the manufacture and installation of the photovoltaic panels. At current material intensity, 10.8 TJ is required to produce and install 1 MW, which results in an EROI of 8.4. However, the material intensity of the future PV panels is expected to be lower, which could reduce the energy cost to 8.7 TJ by 2030 and 5.6 TJ by 2050, driving a direct increase in EROI, reaching 10.3 and 15.9, respectively. Nevertheless, it does not consider the effect of the decrease in ore grade, which could lead to an increase in energy consumption in the mining process, and therefore to a decrease in EROI.

On the other hand, the type of fuel and the stage at which it is used is also important, as it indicates the current carbon footprint and the potential ease of decarbonization in the future. Thus, the most consumed fuel is natural gas, accounting for 43% of energy, followed by electricity (35%), coal (19%) and finally diesel (only 2%). Diesel is mainly used in mining, which is the phase that contributes least to the energy costs. Coal has an important share due to steel production. Natural gas owes its contribution mainly to the refining of silicon and the chemical production. And the electricity consumption is the most distributed among all the processes. In addition, two scenarios of electricity system emissions have been established, one with high and the other with low emissions. Under the last scenario, the carbon footprint is reduced by half in all cases of material intensity.

Thus, two variables affect the EROI and the carbon intensity of solar panels: the material intensity and the emissions associated with the types of fuel. Material intensity influences both EROI and carbon intensity. If material intensity decreases, EROI increases and carbon intensity decreases. On the other hand, fuel-related emissions only affect carbon intensity. If the former decreases, the latter also decreases. With the best material intensity and using renewable electricity the carbon intensity is 11gCO_2eq/kWh, thus to achieve an even lower impact it would be necessary to decarbonize all fuels, either through the electrification of processes or the use of alternative fuels such as green hydrogen. In conclusion, future variations in the material intensity and the fuels used in the production of metals, chemicals and other materials will determine the sustainability of future energy sources.

Nomenclature

Ag	Silver
Al	Aluminium
CO_2eq	Carbon Dioxide equivalent emissions
Cu	Copper
EROI	Energy Return on Investment
Fe	Iron
FeCr	Ferro Chromium
FeMn	Ferro Manganese
FeNb	Ferro Niobium
HES	High emissions scenario

LES	Low emissions scenario
M&C	Mining and concentration stage
MP	Metal production stage
Pb	Lead
PV	Photovoltaic
REE	Rare Earth Elements
Si	Silicon
Sn	Tin
Zn	Zinc

Abstract:

The sustainability of the electric power generation system worldwide is undoubtedly one of the main challenges of our era. This will be achieved through the massive incorporation of renewable energy sources, but also using highly efficient non-renewable sources. These latest technologies are still necessary today to guarantee the supply of electricity. To optimize its operation in a sustainable way, it is required to minimize both the consumption of primary energy and the water necessary for cooling. In this work, the Hygroscopic Cycle Technology is presented as an alternative to traditional thermal cycles and that allowing to minimize the use of water in refrigeration processes. Thus, assuming the incorporation of this technology to existing thermal power plants in the Canary Islands, cooling water savings were calculated. In this way, the total savings achieved in this subtropical climate amounted to 1.6 Mm^3 annually. A very high value that reinforces the interest of this technological improvement in the thermal processes of thermoelectric plants avoiding the consumption of water.

Keywords:

Hygroscopic Cycle Technology; Energy; Savings in Water Consumption; Sustainability; Thermodynamic Cycles.

1. Introduction

The interest in the use of renewable energies as sources of electricity generation has been strongly increased in recent years. The policies against climate change [1,2] agreed by the main producing and consuming countries of energy, as well as the increase in the price of these raw materials have been decisive. However, electricity production with these "clean" sources has not yet succeeded in displacing traditional energy production using fossil fuels such as coal or gas. Furthermore, in developing countries the use of these traditional energy sources has increased significantly in recent years. According to the Global Electricity Review 2022 [3], the world supply of energy through "clean" sources reached 38%, but nevertheless, there was an unprecedented growth in the level of polluting emissions linked to electricity generation and the energy production with coal. Therefore, the need to improve the efficiency of processes and reduce the environmental impact of power generation with non-renewable sources is paramount. In this direction, the investigations presented in this article are directed and that present an improvement of the thermal cycles used in thermoelectric plants fed with hydrocarbons or coal. The Rankine cycle (RC) used in these plants operates with steam, and despite being a mature technology, due to its wide and extensive use in various industrial processes over time, it still has an improvement rate in its performance. Because of its widespread use, the improvement in efficiency derived from RC constitutes an important global impact in the improvement of energy production processes and in the reduction of related polluting emissions, and also, in the economic viability or increased financial profitability of power plants that use it [4]. In Figure 1 [5], an RC used in thermoelectric installations is represented.

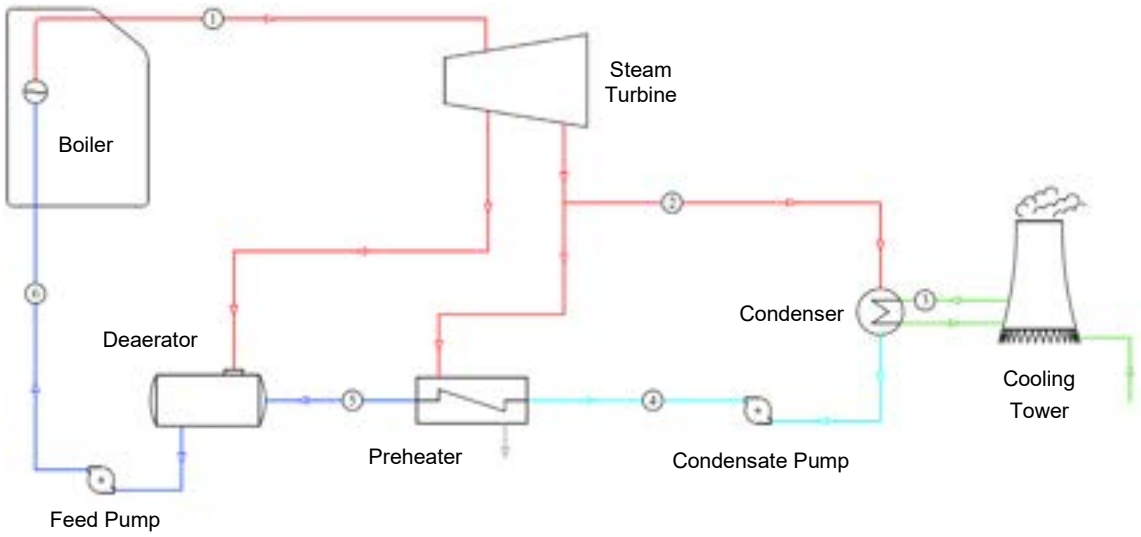

Figure. 1. Diagram of the Rankine Cycle in a thermoelectric power plant.

In this line of cycle improvement [6,7], recent research has focused on reducing irreversibilities and their associated losses, proposing improvements in supercritical, regenerative, superheated, and binary steam cycles. In addition to trying to maintain the quality of the steam above 90% at the outlet of the steam turbine and avoid the entry of steam into the process pumps. Other lines of research have worked on improving efficiency, substituting the pure water used in the cycle with other fluids entering the turbine. Thus, the Organic Rankine Cycle (ORC) appeared [8], which shares its configuration with the traditional RC but is designed to generate work with low-energy heat, with temperatures between 80 and 400 ºC. The ORC [9] uses so-called pure organic fluids, which can be different types of refrigerants and organic compounds. The use of "dry" fluids avoids the need to overheat the steam [10], as is done in the Rankine Cycle Technology (RCT), making the working temperatures and evaporation pressures much lower and increasing the efficiency of the cycle.

Zeotropic mixtures or fluids with different boiling points have also been used in the ORC, but to a lesser extent. The investigations [11,12] carried out comparing the efficiency obtained in the cycle with the use of zeotropic mixtures or dry fluids, have concluded that the use of the former only presents improvements in the efficiency of the process when the operating circumstances are very specific, for example, when the Cooling of water is done at fixed temperatures. However, its use may be interesting based on the growing concern for the environment. An interesting case of zeotropic mixtures is the one formed by ammonia and water and used in the so-called Kalina cycle (KC). This KC presents greater freedom in terms of the composition of the mixture, but its configuration is more complex. However, it is an important alternative [13] to pure ORC due to the use of low heat sources and achieves higher efficiency values due in part to its lower level of irreversibilities. On the other hand [14-18], it also presents limiting factors such as the optimization of the process, the working fluid and the heat sources.

Other cycles [19] that take advantage of the energy from low-medium heat sources are the Goswami cycles (GC), which use binary mixtures. In addition [20], they incorporate mixtures of ammonia and water as a fluid, combined with a RC and an absorption cycle (AC). Other investigations [21] carried out with different zootropic mixtures and working conditions of the RC, have achieved improvements of up to 15% in the performance of the ORC.

Additionally [22], it should be borne in mind the fact that environmental conditions significantly influence the viability of the different types of thermodynamic cycle. From this point of view, the situations of scarcity of water used both in the power generation and cooling processes of the last stages of the cycle, together with high ambient temperatures, can make the application of thermodynamic cycles impossible. This situation of rising temperatures and water scarcity is being aggravated by the current situation caused by climate change. Therefore [23], power generation must be carried out with the least possible use of water, since worldwide electricity generation consumes 10% of the available water, mainly in its cooling stage.

Thus, the so-called Hygroscopic Cycle Technology (HCT) [7,24] arises as an improvement to the traditional thermoelectric generation cycles, improving the thermal efficiency of the cycle, reducing the consumption of cooling water and enabling the implementation of thermal cycles in areas that, due to their high ambient temperatures would make electricity generation very difficult or impossible. In Figure 2 [5], the HCT, which is based on a RC but incorporating improvements in the refrigeration zone to use absorption physicochemical processes, is represented.

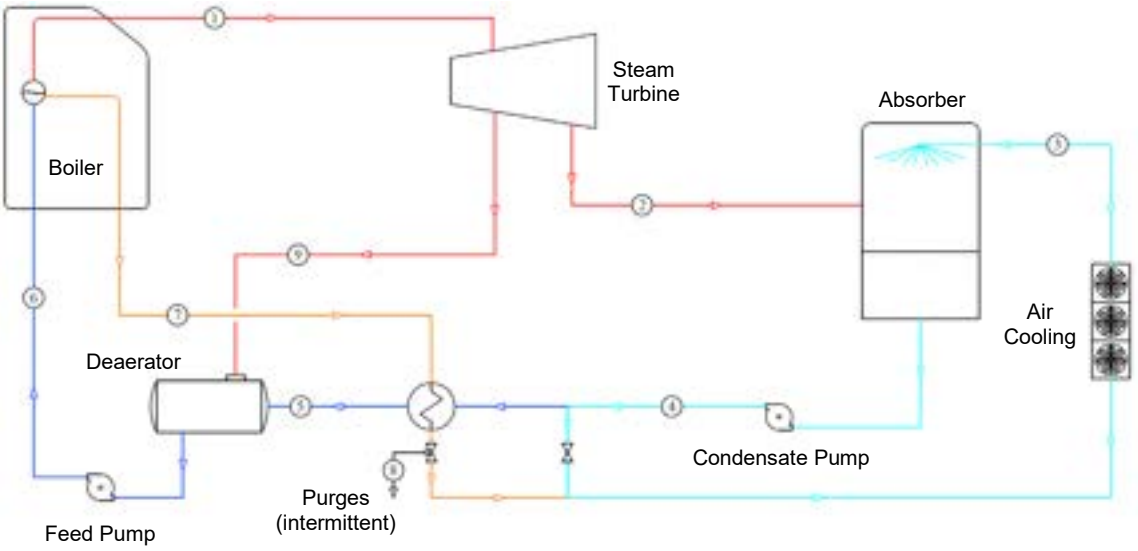

Figure. 2. Diagram of the Hygroscopic Cycle Technology in a thermoelectric power plant.

The HCT [25] uses hygroscopic compounds as part of the working fluids to optimize steam condensation at the turbine outlet through absorption processes. The hygroscopic substances [26] used must meet a series of characteristics to be used in the HCT. They must be non-flammable, have a lower vapor pressure than pure water and therefore less volatile than water, attract surrounding water vapor, and be easily separable to facilitate subsequent vapor desorption (reversible retention). In addition, these substances must be non-toxic and chemically stable under the working conditions of the HCT. The mixtures proposed by [27] consisted of LiBr-H2O as a suitable working fluid for the HCT. This hygroscopic and soluble salt in all stages of the HCT allowed to achieve the best results in the cycle. LiBr [28] increased its solubility considerably with increasing solution temperature. Additionally [26], the separation of the vapor and the hygroscopic compound did not require the use of special desorption technology or additional heat sources. The HCT [29] has already been successfully used in real installations with generated powers between 12.5 MW and 50 MW.

The direct steam condensation process is achieved in the HCT inside the absorber where the pure steam exhaust stream from the turbine (state 2 in Figure 1) is mixed with a solution of hygroscopic compounds in water (state 3 in Figure 1). The improvements [7,30] achieved by this direct condensation are the following:

- Due to the lower condensing pressure necessary at each cooling temperature, the electrical power at the turbine outlet is increased with reference to RC and therefore the general electrical performance of the cycle.
- For a given condensing pressure, the condensing temperature and therefore the cooling temperature are increased. In this way [31], a thermal dissipation of the condensation energy is possible only with air and therefore without the need for the use of water. By not using traditional water-cooling processes in cooling towers, the use of water is avoided and savings are made in cooling tower maintenance.
- At the same time, since the use of cooling water is not necessary, it allows the generation of energy with thermoelectric processes in areas with little water availability.
- Less demand for electrical energy [32] by the cooling system, made up of dry-coolers, since the increase in condensation temperature requires less dissipated thermal energy.

With all these features, the HCT allows improving the traditional RC and increasing electrical efficiency by approximately 2.5%, saving up to 50% in the consumption of demineralized water and additives, reducing investment costs by 5% and 25 % the costs of Operation and Maintenance (O&M) and increase the availability of the technology and its useful life [6]. These characteristics and improvements achieved with HCT technology are of special interest in areas with subtropical climates and possible water scarcity, as is the case in certain areas of the Canary Islands. It must be taken into account that in the Canary Islands the aquifers have been over-exploited, which is why the water table has dropped. As a result [33-36], numerous springs have dried up, wells and galleries have had to be deepened, and the danger of desertification has increased.

Currently [37], the Canary Islands are highly dependent on fossil fuels. According to data from the energy yearbook of the Canary Islands for the year 2021, renewable energies only represent 19.5% of electricity production. The energy is obtained in hundreds of units distributed in gas-fired power plants, diesel engines or steam turbines. Figure 3 shows the dispersion of plants along the islands.

Figure 3. Thermoelectrical power plants and installed capacity in the Canary Islands.

Additionally, a detailed list of these Canarian thermoelectric plants ordered by island with their group type, cooling system, number of units and their power capacity can be found in Table 1.

Table 1. The Canarian thermoelectric plants.

Island	Power Plant	Group Type	Cooling System	Units	Power Capacity (MW)
El Hierro	Llanos Blancos	Diesel	Close cycle desalinated water	10	14.91
Fuerteventura	Las Salinas	Diesel	Open cycle seawater	9	107.92
	Las Salinas	Gas	Adiabatic cooling	3	79.1
Gran Canaria	Jinámar	Diesel	Open cycle seawater	5	84
	Jinámar	Gas	Adiabatic cooling	3	98.45
	Barranco Tirajana	Gas	Adiabatic cooling	6	376
	Jinámar	Steam	Open cycle seawater	2	120
	Barranco Tirajana	Steam	Open cycle seawater	4	320.73
La Gomera	El Palmar	Diesel	Open cycle seawater	6	13.38
	El Palmar	Diesel	Adiabatic cooling	3	7.79
La Palma	Los Guinchos	Diesel	Open cycle seawater	10	82.84
	Los Guinchos	Gas	Adiabatic cooling	1	22.5
Lanzarote	Punta Grande	Diesel	Open cycle seawater	11	199.76
	Punta Grande	Gas	Adiabatic cooling	2	62.5
Tenerife	Candelaria	Diesel	Open cycle seawater	3	36
	Granadilla	Diesel	Open cycle seawater	2	48
	Candelaria	Gas	Adiabatic cooling	3	92.2
	Granadilla	Gas	Adiabatic cooling	6	382.9
	Arona	Gas	Adiabatic cooling	2	50
	Isora	Gas	Adiabatic cooling	1	44
	Candelaria	Steam	Open cycle seawater	2	80
	Granadilla	Steam	Open cycle seawater	4	313.4

For all these reasons, in the present investigation the implementation of HCT in the existing thermoelectric plants and in operation in the different Canary Islands is simulated in order to obtain the potential of water savings for each installation. The application of the HCT is assessed according to the characteristics of each thermal power plant and the specific hydrological needs of the different island areas. All of this would translate into significant environmental savings and would allow the consideration of the use of HCT in areas where the viability of traditional thermoelectric cycles is not feasible or not convenient due to water scarcity.

2. Methodology

The methodology used to calculate the savings obtained with the application of the HCT in the Canary Islands thermoelectric plants consisted of:

1º.The refrigeration system data [38] and the power of the different units were obtained from the environmental declaration of each power generation plant and from the State Registry of Emissions and Polluting Sources [39]. It was also necessary to know the equivalent operating hours. These hours were calculated from the annual production data for each type of plant and island, which are included in the 2021 Canary Islands energy yearbook [37]. These data are shown in Table 2.

Table 2. Equivalent hours and annual production of the Canary thermoelectric plants.

Island	Power Plant	Group Type	Power Capacity (MW)	Annual production (MWh)	Equivalent hours (h)
El Hierro	Llanos Blancos	Diesel	14.91	26 133	1 752.7
Fuerteventura	Las Salinas	Diesel	107.92	477 165	4 421.5
	Las Salinas	Gas	79.1	31.563	399
Gran Canaria	Jinámar	Diesel	84	199 206	2 371.5
	Jinámar	Gas	474.45	1 814 728	3 824.9
	Barranco Tirajana	Gas			
	Jinámar	Steam	440.73	647 519	1 469.2
	Barranco Tirajana	Steam			
La Gomera	El Palmar	Diesel	21.17	71 022	3 354.8
	El Palmar	Diesel			
La Palma	Los Guinchos	Diesel	82.84	238 590	2 880.1
	Los Guinchos	Gas	22.5	499	22.2
Lanzarote	Punta Grande	Diesel	199.76	632 746	3 167.5
	Punta Grande	Gas	62.5	12 581	201.3
Tenerife	Candelaria	Diesel	84	177 029	2 107.5
	Granadilla	Diesel			
	Candelaria	Gas	569.1	1 905 502	3 348.3
	Granadilla	Gas			
	Arona	Gas			
	Isora	Gas			
	Candelaria	Steam	393.4	595 497	1 513.7
	Granadilla	Steam			

2º. In order to obtain the performance of power plants, research developed by [40-43] were considered. In this way, the performances were 34% for the groups with steam, 38% for the groups with gas and 45% for the groups with diesel.

3º. The heat that would have to be dissipated by the cooling system of each plant was obtained by applying equations (1) and (2).

$$\dot{Q}_C = \frac{\dot{W}}{\eta} \quad (1)$$

$$\dot{Q}_F = \dot{Q}_C - \dot{W} \quad (2)$$

Being:

$\dot{Q}_C$: thermal power supplied to the cycle of the plant.

$\dot{Q}_F$: heat rejected by thermal cycle of the plant.

$\dot{W}$: plant power capacity (Table 2).

η: power plant performance. Obtained in previous point 2º.

4º. The necessary water flow for the cooling process was calculated using the following equations and technical data:

$$\dot{Q}_F = \dot{m} \cdot (h_{out} - h_{in}) \quad (3)$$

$$T_{out} = T_{in} + \Delta T \quad (4)$$

Being:

h_{out}: cooling water outlet enthalpy.

h_{in}: cooling water inlet enthalpy.

$\dot{m}$: cooling water mass flow.

T_{in}: cooling water inlet temperature.

T_{out}: cooling water outlet temperature.

ΔT: Temperature difference of the cooling water between the inlet and outlet of the adiabatic cooling equipment. A value of 14 ºC has been taken according to the common industrial values [6].

4º According to [45-46], for processes with open cycle the average consumption of water in thermal power plants such as existing in the Canary Islands (Gas, Diesel or Steam group type) is 0.38 m^3/MWh.

3. Results and conclusions

In this way, the current annual water needs or cooling water consumption (m^3/year) per MWh of each thermoelectric plant in the Canary Islands were obtained and represented in Table 3. For processes with adiabatic coolers, it has been considered that the water consumption was 0.1 percent of the water used in the cooling system [47].

Table 3. Annual water consumption for the cooling system in thermoelectric plants from the Canary Islands.

Island	Power Plant	Water Consumption for the Cooling System (m^3/h)	Equivalent hours (h/year)	Annual Water Consumption for the Cooling System (m^3/year)
El Hierro	Llanos Blancos	5.67	1 752.7	9 930.45
Fuerteventura	Las Salinas	41	4 421.5	181 323.95
	Las Salinas	7.94	399	3 167.78
Gran Canaria	Jinámar	31.92	2 371.5	75 698.28
	Jinámar Barranco Tirajana	47.62	3 824.9	182 144.81
	Jinámar	45.60	1 469.2	246 057.80
	Barranco Tirajana	121.88		
La Gomera	El Palmar	5.08	3 354.8	19 022.10
	El Palmar	0.59		
La Palma	Los Guinchos	31.48	2 880.1	90 663.24
	Los Guinchos	2.26	22.2	50.14
Lanzarote	Punta Grande	75.91	3 167.5	240 441.12
	Punta Grande	6.27	201.3	1 262.79
Tenerife	Candelaria	13.68	2 107.5	127 883.10
	Granadilla	18.24		
	Candelaria Granadilla Arona Isora	57.12	3 348.3	191 257.83
	Candelaria	30.4	1 513.7	226 286.04
	Granadilla	119.1		

Therefore, the minimum potential for savings in water consumption by refrigeration systems would be 1.6 Mm^3 per year. It means that the average minimum water consumption is 0.23 m^3/MWh in thermoelectric plants of the Canary Islands.

All this use of water can be avoided by using the HCT. In this way, the environmental problems associated with the consumption of water for industrial processes or returning water at high temperatures to ecosystems that can be seriously affected, as occurs in open refrigeration systems, would be avoided.

Currently, the total energy generation of the thermoelectric plants of the Canary Islands is 6 829 780 MWh/year. The efficiency is increased by 2.35% when HCT is used instead of traditional Rankine cycle [6]. Therefore, the increment of the total energy generation would be of 160 499.80 MWh/year. In addition to the increase in the efficiency, the application of HCT technology would reduce the costs associated with the maintenance of the cooling systems existing in the current thermoelectric plants in the Canary Islands. On the other hand, the reduction of installation costs would also have been achieved in the new built systems. This economic improvement would reduce the price of energy associated with its generation. Definitely, in the current economic context of high electricity prices it would be very interesting from both a social and a business point of view.

As future work, it is proposed to analyse the economic cost of the incorporation of the HCT in the different plants of the Canary Islands as well as the necessary time to recover the investment.

Nomenclature

$\dot{Q}_C$ heat supplied to the thermal cycle of the plant, kW

$\dot{Q}_F$ heat rejected by thermal cycle of the plant, kW

$\dot{W}$ plant power capacity, kW

h_{out} cooling water outlet enthalpy, kJ/kg

h_{in} cooling water inlet enthalpy, kJ/kg

$\dot{m}$ cooling water mass flow, kg/s

T_{in} cooling water inlet temperature, ºC

T_{out} cooling water outlet temperature, ºC

ΔT temperature difference of the cooling water in the dry-cooler, ºC

Greek symbols

η power plant performance.

Abstract:

The search for new electronic appliances, the urgent need for renewable energy technologies and on the multiple uses in the society have produced a high demand for metals. The copper claim has increased significantly in the last centuries. Chile is the world´s largest copper producer. However, the higher production of copper has been accompanied by a considerable decay of ore grades in the Chilean copper mines. That is why it is required to appropriately assess the loss of mineral (LMW) wealth. Methodologies to determine the LMW based on the second law of thermodynamics and the Exergy, have provided valuable information on the scarcity of minerals. The methodology proposed in this paper is based on the simulation of mineral processes for the concentration of copper using HSC from an average mineral composition of the leading in some mines in Chile. One approach to estimating LMW has been utilising the exergy replacement cost (ERC). Although this procedure has been effective in establishing an ultimate scenario of mineral depletion, named Thanatia, it needs to correlate appropriately with the current market conditions to develop a framework for a fairer scheme for the prices of metals. In this paper is proposed a new approach to estimate LMW for the case of copper.

Keywords:

exergy replacement cost (ERC), metal demand, copper, mineral depletion, Exergia

1. Introduction

The transition towards a more sustainable society requires more clean energy technologies, therefore, more minerals and metals are needed. A report of the International Energy Agency [1], it was highlighted the importance of such minerals. Some of them, are categorized as critical for some clean energy technologies. In this report, it is pointed out that the rise of demand for copper and rare earths to more than 40% in the next two decades.

Authors such as Mudd [2]–[6], Craig et. al [7] and Norgate [8] have mentioned the issue of the decline of ore grade in mines over time. In a research [9], the peak production of copper is estimated from 2031 to 2042. A study by Calvo et al. [9] investigated the reduction of ore grades in 25 mines in Chile, Australia, and Peru. The production of these mines accounted for 32% of the total copper production at that time. In addition to this, it was also observed a 25% reduction in average of the ore grade from 2003 to 2013. The decrease in the concentration of copper in mines produced an increase in 46% in energy consumption. On one side, more metals are required, but on the other rich metal deposits have been already extracted. Therefore, the supply of cooper for the next generations is compromised to actions that must be taken for sustainable production in present generations.

In 2020, China had 33,2% of the global share of copper production, and Chile 20,5%. This country had a robust worldwide industry of copper with an essential impact in its economy. In 2020, the share of the copper industry in Chile accounted for 11,2% of its Gross Domestic Product (GDP) [10].

In Chile, the decline of ore grade has been also notorious (Figure 1). The average ore grade in the copper mines was about 1.4% in 1999, which decreased to about 0,6% in 2018.

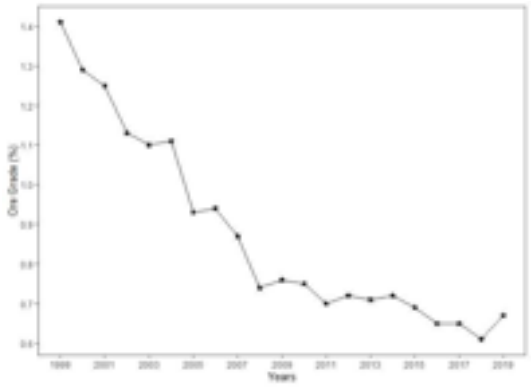

Figure 1. Decline of the average ore-grade of copper mines in Chile.(Calculated based on:[11], [12])

The need for more metals will also produce more extraction of minerals in countries, for example, Chile, where the rich deposits have been already extracted as shown in Figure 1. This will also cause a rapid loss of mineral depletion. It is important to know that mineral endowment was defined by Harris and Agterberg [13] as the amount of metals in a given region. This accumulation of minerals, traded later as commodities, means abundance for a country. Because of the growing need for minerals, they are extensively extracted, producing a loss of mineral wealth (LMW). The LMW represents a quantitative indicator of mineral depletion in that country [6] [37] [38].
As can be seen, it is crucial to have an approach to estimate the LMW. In a publication [17], in this paper is used the exergy replacement cost (ERC) concept to estimate the loss of mineral extraction in 22 countries in Latin America. In this investigation, it was used values of ERC previously reported in [18]. The concept of ERC and its methodological approach will be reviewed in the next section. Nevertheless, this value of ERC for copper will provide a certain sense of the importance of mineral depletion; it fails to give some hints towards a fairer price of minerals.
This paper will provide a new approach based on simulation with HSC Chemistry 9 and HSC Sim software [19] to estimate a new value of ERC for copper as a valuable indicator to evaluate mineral depletion more appropriately.

1.1 The concept of the exergy replacement cost

The traditional way to value minerals has been through the market price. However, prices fluctuate and are unstable because they depend on many factors [19]. Therefore, prices are not sufficient to give an appropriate value to minerals. The mass has been another approach to valuing minerals. Nevertheless, they do not consider the geological scarcity or the difficulty of the production process. An alternative method is using the concept of the exergy replacement cost, which stands for ERC. This concept has its basis on Exergy. For fossil fuels, when they are burned the liberation of energy is accompanied with their higher heating value (HHV) [20], [21].On the other hand, non-fuel minerals are not combustible the HHV is no longer valid. The use of exergy for non-fuel minerals has two perspectives; a traditional way to treat them has been using their chemical exergy. On this perspective, Szargut has published chemical exergy of different elements [22]. These values have been used by Ayres [23], Dewulf et al. [24] and Szargut et al. [15], [25], [26] to evaluate mineral resources. However, this perspective is not valid to allocate the fair value of minerals. A study [28] clearly pointed out the fact by showing that the chemical exergy of precious metal gold is 60 kJ/mol is considerably lower than aluminium 796 kJ/mol. Exergo- ecology, a discipline postulated by Valero [27], can give a more appropriate scheme to value minerals. Physical Geonomics, one Exergoecology´s division, deals with the application of exergy to assess non-fuel minerals. The exergy of minerals has two components: one is related to chemical composition (chemical exergy) and the other is associated with the relative concentration in the Earth´s crust (concentration exergy). The latter makes minerals more valuable than the former. Nature provides a “free bonus” or in economic terms a “hidden cost” just for having minerals concentrated in mines and not dispersed throughout the Earth´s crust. This “free bonus” significantly reduces the costs associated with mining processes. When higher-ore grade mines become depleted, a reduction in this free bonus occurs, leading to an extensive exergy consumption to extract a similar quantity of metal. The bonus provided by nature can be measured through the ERC.
ERC is postulated as the energy that would be required to extract and concentrate a mineral from a completely dispersed state at a crustal concentration (xc) to the conditions of concentration and

composition found in the mine (xm) by using available technology. Thanatia represents a state of total mineral dispersion into the Earth´s crust. Thanatia´s composition is made up of 324 species, 292 minerals and 32 diadochic elements included in the crystal structure of other elements [28], [29].
The exergy required to concentrate minerals from a concentration found in Thanatia (xc) to the average concentration (xm) for different minerals can be found in [18]. This research, will be focused to the ERC for copper. To estimate the ERC for copper, Valero et. al assumed the concentration of copper in the Earth´s crust xc = 6.64x10-5 g/g [30] which corresponds to 0.006 wt-%. Also, an average ore grade assumed xm = 1.67x10-2 (0.5 wt-%) [31]. The ERC for copper reported in [18] was 292 GJ/t-Cu. They considered that 60% of the total energy was for the mining and concentration [32].

1.2 The need of a new approach

The ERC of different minerals were calculated by Valero et al. [32] by observing the behaviour of the decrease of ore grade and increase in energy consumption for some metals, such as cobalt, copper, gold, nickel, and uranium. Valero et al. proposed a function that portrayed the relationship between the energy consumption as a function of the ore grade, Equation (1).

$$E_{(X_m)} = A \,.\, X_m^{-0.5} \quad (1)$$

Where $E_{(X_m)}$ is the energy for the concentration and extraction of minerals at the ore grade (xm), and the coefficient A is determined for each mineral.
In [33] the LMW was estimated for a series of mineral produced in 22 countries in Latin America by using conventional ERC. A remarkable result of this investigation was market prices do not compensate the LMW in the region. As forthcoming, it was established the need to have a scheme to estimate fairer prices for minerals.
The methodology proposed to estimate ERC is limited to the experience of observing historical data of some metals. In this approach, as reported in [34] geological principles prevailed over metallurgical considerations.
An upgrade to the ERC for iron, copper and gold based on simulations of a specialized software HSC Chemestry [35] by considering mineral processing was reported in [36], [37], [38], respectively. These new values of ERC varied in orders of magnitude to the previous ones conveyed in [18]. They differ in the method of calculation from observation to simulation in HSC.
Previous ERC [18] and new ERC for iron, copper and gold [36], [37], [38] are higher values in GJ/t that would lead to numerous errors to estimate a fairer price of minerals. The reason for such magnitude of values is that Thanatia is used as starting point to determine the ERC. Therefore, a new approach is required to have an intermediate scenario that provides more appropriate ERC in this copper case.
This research will be focused to establish this intermediate scenario, which will be described in the next section.

1.3 An intermediate scenario for a new ERC for copper

In order to establish a scenario, first, it is presented an ideal scenario of mineral dispersion in which all minerals are diluted through the Earth´s crust total mineral dispersion named Thanatia. On the other hand, it is described the cut-off grade as the minimum grade in a deposit in which a metal can be economically extracted [39], [40]. Therefore, an intermediate scenario can be found between the concentration of copper in Thanatia and the cut-off grade. In Figure 2, the exergy needed for the concentration of metals is presented as function of the ore grade [28], XB represents the concentration of metal at the beneficiation process (c.a. 99 wt-%), XM the ore grade in mines, for instance, the average ore grade in copper deposits is 0.5 wt-%. Then as the ore-grade decreases, the exergy rises exponentially, Xcut-off the cut-off grade at which the extraction of minerals in deposits is not economically viable. We will consider the cut-off grade for Chile. This value was estimated as average value of 0.2 wt-% of copper [41], [42], [43]. Afterwards, XC is the concentration of metal. As written in section 1.1, in Thanatia de concentration of copper corresponds to 0.006 wt-%. The intermediate scenario (Xin.) of analysis for the new ERC for copper is located between a concentration XC and Xcut-off. For the cut-off grade, since our objective is to estimate a new ERC for copper, we choose Xin for copper at a composition of copper of 0.02 wt-%.
Mine La Escondida, in 2020, produced 30% of the total copper production in Chile [10]. Hence, the model in this paper, will be taken a similar mineral composition to La Escondida as input. A literature review was performed, and the most representative minerals were identified. The most predominant mineralogical composition was based on copper sulphides [44] accompanied by a series of minerals, mostly silicates, as is shown in Table 1.

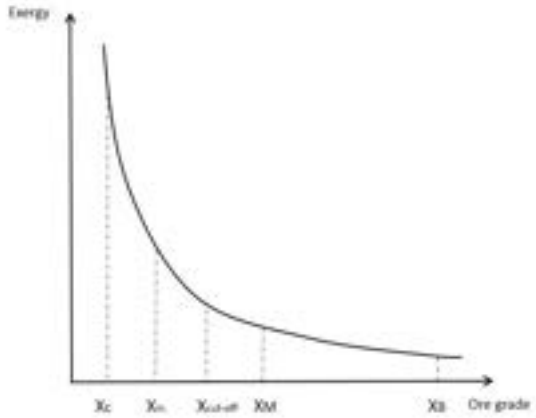

Figure 2. Description of the intermediate scenario for the new ERC for copper.

Estimations were performed on the basis of the abundance of the deposits La Escondida reported in [45], [46]. It was also considered QEMSCAN analysis developed by [47] and [48]. For the model it was allocated each mineral for an average ore-grade of 0.02 wt-% Cu.

2. Methodology

In this section, the stages of determining the new ERC for copper based on HSC Sim 9 [35] are explained.

The target of the model is to estimate the specific energy needed to concentrate copper, in this copper known as the new ERC for copper, from a concentration of copper in the intermediate scenario (0.002 wt-% Cu) to an average concentration in mines (0.5 wt-% Cu). The model was developed to concentrate copper mainly from sulphides, specially Chalcopyrite. Also, the model takes some procedures for the layout reported in previous work to determine ERC from Thanatia [37].

Prior to the model, a literature review was performed [8], [40], as well as state-of-the-art technologies for copper concentration [51]. On the basis of the analysis of operating data for concentrators of copper in La Escondida [57], a flow rate of 6 500 tons per hour was chosen. A top size in the ore feed of 6 E5 µm was considered for the feed.

The new ERC will also consider the energy for ore handling and the concentration of copper. For the ore-handling, it was assumed a minimum distance from an open pit mine to the concentrator so that the fuel consumption per ton of ore prevailed over the distance. For this task, it was supposed a fuel consumption of 0.6 L/ton of rock taken from [58].

The comminution circuit was modelled by following guiding principles reported in [59]. It consisted of three circuits primary crushing, grinding and regrinding. A jaw crusher reduced the 80% of feed particle size (F80) to P80, equal to 10 000 um. Then semi-autogenous (SAG) crushed the rock to 2 000 um Afterwards, a screen is used to separate the oversized particles. The latter went to a pebble mill, where they were reduced to 1 500 um.

During comminution, a fundamental equation to calculate the specific energy required for the mills is Bond´s equation [39], [60] Eq. (2):

$$W = 10\, W_i \left(\frac{1}{\sqrt{P_{80}}} - \frac{1}{\sqrt{F_{80}}} \right) EF_x \qquad (2)$$

where W is the specific energy consumption of the mill (kWh/t), Wi represents the work index (kWh/t), P80 and F80 are the product and feed passing sizes, respectively measured in µm. The last term, EFx is the product of the Rowland efficiency factors, which depend upon mill, size and type of media, type of grinding circuit, etc. [39], [60]–[63]. Then, the theoretical power draw by the mill (kW) is calculated by W x T, where T is the throughput tonnage (t/h) [39].

A hydrocyclone separated the fines to the flotation circuit with F80 lower than 130 um. The coarse of the hydrocyclone went directly into a ball mill that reduced the oversized particles to 600 um. The flotation circuit mainly separated the higher-copper minerals (sulphides), especially Chalcopyrite. To do

this, fast kinetics constants (kf) were set up for Chalcopyrite in the range of 1 to 2.5. These figures were in harmony with values reported in [64] and [65].

The volume and number of cells for the flotation tanks, roughers and scavengers, were established based on data reported by Weiss [51], and Wills and Finch [39].

3. Results and Analysis

The results of the simulations are described in this section. In addition to this, outputs of the model were validated through a comparison between parameters of the comminution and flotation processes with the respective ones found in the literature. As a final point, based on the methodology previously defined in the later section, the specific energy for the concentration of copper from an intermediate scenario (in.) between Thanatia and the cut-off grade, the new ERC for copper is identified.

3.1 Simulation results

From the model, the results were particle size for feed (F80) and output (P80) of the crushers and mills for the comminution processes, Table 1. The reduction ratio (Rr) is calculated by dividing F80 to P80 for every mill. Furthermore, the total reduction ratio is the product of Rr for every mill as specified in [52].

Table 1. Feed and product size, F80 and P80, respectively for the comminution process.

Stage	Equipment	F80 (μm)	P80 (μm)	Reduction ratio (Rr)
Crushing	Primary crusher	15302	10000	2
	SAG mill	4374	2000	2
Grinding	Pebble mill	2968	1500	1
	Ball mill	750	600	2
Re-grinding	HIG mill	131	34	4

The Rr for our model was 32 after the comminution process comes the flotation, which main results of retention time and power consumption are shown in .
Table ***2***.

Table 2. Retention time and power consumption for the flotation process.

Stage	Retention time (min)	Power (kW)
Rougher	14	2250
Scavenger	10	1850
Cleaner	9	185
Scavenger	14	55
Re-cleaner 1	13	75
Scavenger	18	90
Re-cleaner 2	7	150

The outcome of the flotation process had a mass flow rate of 210.10 t/h with a concentration of copper of 0.462%. For the flotation process, the recovery of copper was about 92%, followed by gold 46% and silver 39%.

3.2 Validation of the model

The validation consisted of the comparison between the main results of the model, particularly for comminution and flotation with those reported in the literature. In this sense, for comminution

For the flotation, the parameter for validation was the retention time in flotation. In [51, Ch. 10] the retention time for the roughing circuit was in the range of 13 to 16 minutes. In comparison to the values of our model, they are in the range except for the Cleaner and Re-cleaner 2. They are relatively smaller, nevertheless not so far from the values reported in the literature.

An essential parameter for the validation of the model was final metal recovery. Haque et al. [66] modelled pyro and hydrometallurgical for low-grade copper deposits. In this publication, the recovery of copper was assumed to have a yield between 86% to 89%. The recovery obtained from our model was about 92%. This figure agrees with the previous values reported in the literature. With this comparison, we can see that our model delivers logical and reliable results.

3.3 The new ERC for copper

The energy for comminution depends on the Bond´s work index (Wi), as it was explained in Section 2. In order to have a value that would be used as a reference for faired prices for copper, only one value of the new ERC will be required. Therefore, we assumed an average representative value for Wi equal to 14 kWh/t. This value was in agreement with models for copper in [67].

With these considerations, the power demand for the comminution and the flotation processes was estimated Table 3 .

Table 3. Power draw for comminution and concentration processes.

Stage	Power Demand (MW)	Power Demand (%)
Crushing	10.1	4.3
Grinding	21.3	90.3
Re-grinding	8.2	3.5
Concentration	4.7	2.0
TOTAL	236	100

As can be seen in Table 3, most of the power demand is mostly concentrated in the comminution process (94% approx.). The grinding circuit was the largest consumer.

The specific energy for the concentration process was calculated by following the methodology previously explained, Table 4.

Table 4. Specific energy to concentrate copper from an intermediate scenario.

	Cu concentration (wt-%)	Flow rate (t/h)	Specific Energy (kWh/t)	Specific Energy (MJ/t)
Feed Ore	0.036	6500	36	131
Conc. metal	0.462	220.10	1074	3867

By making a comparison of the average concentration of energy per ton of ore reported for different mines in [58], it can be seen that the value of 36 kWh/t-ore is in the range of those reported for mines such as La Escondida, Michila, Salvador [58]. This also supports that our model delivers reliable results.

In addition to the values of the specific energy shown in Table 5, the ore-handling must be added. For that, a value of 1.2 litres of diesel per ton of rock was considered for the specific fuel consumption. This was reported in [58] as an average value for the energy consumption in the Chuquicamata open-pit mine. The new ERC from the intermediate scenario is shown in Table 5.

Table 5. Specific energy for the concentration of copper from an intermediate scenario in GJ per ton of element.

Phase	Specific Energy (GJ/t)
Ore handling	128
Concentration	3.87
TOTAL	131.87

As can be seen, most of the energy is spent on the transportation of the ore to the concentrator. It is explained because a low ore grade ore (Table 1) is transported.

In Table 6, is made a comparison among values of the exergy replacement cost (ERC) for copper from Thanatia reported in [18]. Also values are compared of ERC based on HSC simulation, considering the starting point Thanatia in [37]. In addition, also is compared the average energy intensity for the Chuquicamata mine from 2000 to 2013, published in [58]. Then it was converted into GJ per ton of copper. Then with this and the exergy replacement cost (ERC) for copper reported in [18], a comparison with the specific energy of the current paper was done, Table 6.

The new ERC for copper is between the ERC from Thanatia in [18] and the specific energy for Chuquicamata [58], Table 8. The new ERC is more than three times the specific energy for Chuquicamata and almost a half of the previous ERC from Thanatia [18]. With regard to the values of

ERC for copper from Thanatia, also based on models in HSC, reported in [37], they differ by one to two orders of magnitude.

Table 6. Comparison of the specific energy of the current work with other reported values in GJ per ton of element.

	Ore	Specific Energy (GJ/t-Cu)	Source
New ERC	Intermediate scenario ($X_{in.}$)	132	current work
Based on HSC-model	Thanatia (X_C)	3100 - 30890	[37]
ERC	Thanatia (X_C)	292	[18]
Chuquicamata		42	[58]

4. Conclusions

More metals are needed to conduct a more sustainable energy transition through renewable energy technologies. The growing need for metal has produced that rich deposits have been exploited. The fact of the mineral exploitation should also be a concern in this path towards a decarbonisation of the society. In this regard, it is vital to have reliable means for the assessment of minerals. One non-conventional way to do this is by applying the concept of the exergy replacement cost (ERC). As a concept ERC has revealed its strengths compared to traditional methods, such as market-price and mass balance. Nevertheless, previous approximations to calculate the ERC for metals do not provide values that can be useful when calculating a market price of metals that consider aspects of mineral depletion. In this regard, the present work is novel in considering an intermediate scenario to estimate a new ERC for a metal widely used and key for an energy transition, copper. In this research, it has been considered an intermediate scenario, one that is located between an approach of total mineral depletion, Thanatia, and the scenario when economic feasibility for the exploitation of metals is not viable, the cut-off ore grade. This research considered the mineralogical composition of a representative copper mine in Chile, La Escondida, as key to developing the intermediate scenario.

The method of calculation of this new ERC for cooper has been based on the use of a reliable software HSC Sim 10.0.7.9 software [35]. This software has been helpful to develop new procedures to estimate ERC a more rigorous approach with mining considerations, as reported in [38].

The new ERC for copper from an intermediate scenario is an appropriate indicator for mineral depletion. It can be helpful to be considered a key indicator of mineral degradation towards the estimation of a fairer scheme for prices. In this scheme is required to have a clear picture on what parameters are the real drives for market prices. They should take into account the more need for energy to extract metals in the near future, as well as the loss of mineral wealth.

A key message of this and previous publications points out the need to give more importance to esteeming current copper deposits, particularly those located in South America. These countries should re-examine their significance as crucial mineral suppliers, particularly when discussing an energy transition.

Abstract:

The energy consumption of buildings presents a significant concern, which has led to a demand for building materials with better thermal performance. For this reason, determining the thermal properties of materials is essential information in the search for more energy-efficient materials. However, many time-consuming characterization experiments associated with high costs are required to ensure high accuracy and precision. Thermal conductivity (TC) is among the most relevant properties, which allows for measuring the material's heat transfer resistance. Due to the impracticality of predicting this thermal property in experimental tests, this study seeks to develop a methodology based on artificial neural networks (ANN) to predict the thermal conductivity of different types of concrete through its chemical composition. This work is broken down into two parts. The first one contains a feedforward backpropagation neural network (Multilayer Perceptron, MLP) to predict TC based on 200 experimental data sets of various types of concrete. Then, a Generative Adversarial Network (GAN) is used to expand the size of the training dataset to improve the performance of the first neural network. Currently, the model is implemented in Python, and different ANN structures varying the number of layers and neurons have been tested to find the best accuracy. The MLP model was developed using two hidden layers containing 200-100 neurons. It performed reasonably well on the training and validation dataset with an RMSE of 0.176, 0.183 W/m-K, and R^2 of 0.98 and 0.96, indicating a remarkable consistency between the predicted and the tested results. Furthermore, early GAN results show that it can generate data with reasonable accuracy with R^2 of 0.7. In the near future, we intend to increase the dataset and improve the model. Furthermore, the outcomes from this model can be helpful for the development of materials required for more energy-efficient buildings, providing quantitative information and helping the decision-makers in the construction sector.

Keywords: Artificial neural networks, MLP, GAN, Building materials, Concrete, Thermal conductivity.

1. Introduction

Due to the constant concern about the energy consumption of buildings, there is a growing demand for building materials to improve thermal performance. Utilizing thermal efficiency materials in the construction sector is necessary as they preserve indoor thermal comfort, despite fluctuations in the outdoor environment conditions [1]. Many building materials, such as concrete, masonry, and specific stones, can also be used as thermal energy storage materials. As energy efficiency relies on the material's thermal properties, an accurate prediction of their properties is vital for optimizing their performance in a building.

Concrete is one of the most used materials in construction and as a thermal energy storage material (TES) due to its unique features, such as high compressive strength, heat capacity, and low cost. However, as its chemical composition can vary significantly, its properties can undergo significant variations. For this reason, and in order to be effective as a TES material, it is crucial to have an ideal composition to ensure that its thermal properties meet the required design specifications [2].

Due to the search for more energy-efficient materials, many studies focus on analyzing the thermal properties of construction materials, such as thermal conductivity. This property is essential when evaluating

the ability to transfer and store heat, which is directly related to finding and developing more energy-efficient materials. Therefore, a predictive model that can accurately estimate the thermal behavior of these materials would be beneficial in optimizing their use. In addition, several areas of engineering have used machine learning to perform data processing and analysis tasks due to its high efficiency.

Machine learning (ML) models can be used to develop such predictive models by learning from large datasets and finding patterns that can be used to make predictions. By incorporating ML, the predictive models can adapt to varying conditions and continuously improve their accuracy, making them a valuable tool in optimizing the performance of building materials [3]. Among the machine learning-based models, the Artificial Neural Network (ANN) is one of the most employed ones to solve complex problems and has various applications in several fields [4], [5]. The importance of ANNs lies in their ability to learn and make decisions based on data, which makes them highly valuable in different areas. ANN is composed of a set of networks of interconnected nodes, which work together to learn complex relationships between a group of inputs and outputs, making them well-suited for predicting some values based on a variety of parameters. In this way, ANNs can be used to solve problems that conventional or other computational methods have difficulties [6].

ANNs provide an alternative method for predicting concrete properties that is faster, cheaper, and more accurate than traditional methods. Although it has been applied to properties prediction, a few papers are progressing on models to determine the thermal properties. Additionally, the papers do not have a generalist model, which only focuses on specific types of concrete. This work intends to fill this gap, and the novelty is the development of a methodology using an ANN model to predict the thermal properties of concrete containing different types of materials such as slag, lightweight and recycled aggregates, fibers, and others. For this methodology, a Neural Network model for predicting thermal conductivity will be developed based on the constituents' composition and the concrete's density. The objective of the developed model is to extend it to other building materials, which can improve the performance and efficiency of these materials, making them more effective and cost-efficient.

2. Background

Concrete is a composite material made of cement, water, and fine and coarse aggregates, which let the designers select the components and create mixtures with distinct physical and chemical characteristics [7]. Adjusting these materials and their quantities allows the properties of both fresh and hardened states to be tailored to achieve the design specifications. For this reason, some works have developed an ANN to predict the properties of concrete. Over the years, ANN has been applied to predict different properties of concrete due to its ability to model complex non-linear relationships. After training the neural network, it can predict concrete properties such as compressive strength, slump, and workability with high accuracy. Many works have been published using different structures of a neural network, such as a backpropagation neural network (BPNN) [8], multilayer perceptron (MLP) [9], and radial basis function neural network (RBNN) [10].

Regarding the property predictions, the mechanical properties are the most evaluated, with compressive strength being the most investigated in different machine learning models. For example, Kandiri et al. estimated the compressive strength using a hybrid model of ANN and salp swarm algorithm [11], Abellán-García trained an MLP model to forecast the compressive strength for a given ultra-high-performance concrete (UHPC) mixture design [12]. Besides that, another work also developed an ANN with a feedforward backpropagation algorithm to predict the slump flow and compressive strength of UHPC while incorporating silica fume, limestone powder, recycled glass powder, and FCC [13].

Although many studies are developing new models to predict the properties of concrete, only a few papers investigated thermal conductivity or other thermal properties. Fidan et al. [14] trained different structures of an ANN model to predict thermal conductivity through five parameters – density, compressive strength, tensile strength, porosity, and ultrasonic pulse velocity. The best solution performance was achieved with a neural network with three layers and the following neurons sequence of 5, 25, and 1 in each layer. Sargam et al. [9] evaluated nine machine learning models, and MLP showed the highest prediction accuracy using the maxout activation function and three hidden layers, each containing 100 neurons. Kurpińska et al. [15] also investigated the influence of varying the number of neurons in the hidden layer to forecast the thermal conductivity of lightweight concrete. The model presented a sigmoid function and a structure with four layers: an input layer with two neurons, the first hidden layer varying from 2 to 12, the second hidden layer ranging from 2 to 17, and the output with one neuron. Kursuncu et al. [16] used ANN and ANOVA to investigate the effect of partial replacement of waste marble powder and rice husk ash instead of fine aggregate and cement into foam concrete. The results indicated ANN as the most adequate to estimate the thermal conductivity. Gence et al. [17] compared two neural networks RBNN and MLP to predict the thermal conductivity of concrete with vermiculite and concluded that RBNN had greater accuracy.

Different types of ANNs have been successfully applied to predict the thermal conductivity of concrete. ANN with a backpropagation algorithm is the most popular method for prediction. In order to show the effectiveness of ANN, some comparative studies have been conducted, as listed in Table 1.

Table 1. Comparative studies of different ANN-based methods to predict thermal conductivity.

Reference	ML method	Concrete	Number of inputs	Number of hidden layers	Neurons of hidden layers	Number of outputs	Number of datasets	Activation function	Evaluation criteria
Sargam et al. [18]	MLP	Concrete containing modern constituent materials	3,5,6,8,9,10,13	3	100 100 100	1	213	Maxout	MAE

Besides the literature review, a generic bibliometric analysis was performed to identify the most relevant and influential literature in the research domain of the employment of machine learning to predict the properties of concrete, which can facilitate the identification of critical research gaps and areas for future investigation. To proceed with this analysis, VOSviewer was used. It visually represents the research and enables researchers to find insights into the research domain [21]. Consequently, it can lead to more effective development of prediction models of thermal properties.

In order to evaluate the development of the research regarding property predictions using machine learning, a bibliometric study in the Web of Science database was performed. The following query, "concrete" AND "properties" OR "thermal conductivity" AND "machine learning" OR "artificial neural network" OR "ANN", and

search criteria that were used in this bibliometric study summarized a total of 1508 documents that were published between 2000 and 2023. Then, the overall results were inserted in VOSviewer to analyze the keywords present in each paper's title or abstract, which generated the overlay cluster representing the development of the research over the years (Figure 1).

Figure 1 depicts the trend of integrating machine learning techniques with optimization for property prediction over the years, proving that machine learning models are a very actual research line with great expectations of development in this area. Although the ANNs are dated between 2018 and 2019, they are still being explored due to their effectiveness. Although many works employ ANN to predict mechanical properties, it is possible to observe the investigation of some chemical properties.

Therefore, after the literature and the bibliographic review, we noticed a gap in prediction models regarding thermal properties using machine learning models. This study aims to fill this gap and develop a method to predict the thermal conductivity of concrete. Additionally, we intend to build a model for data augmentation that has been used in many fields.

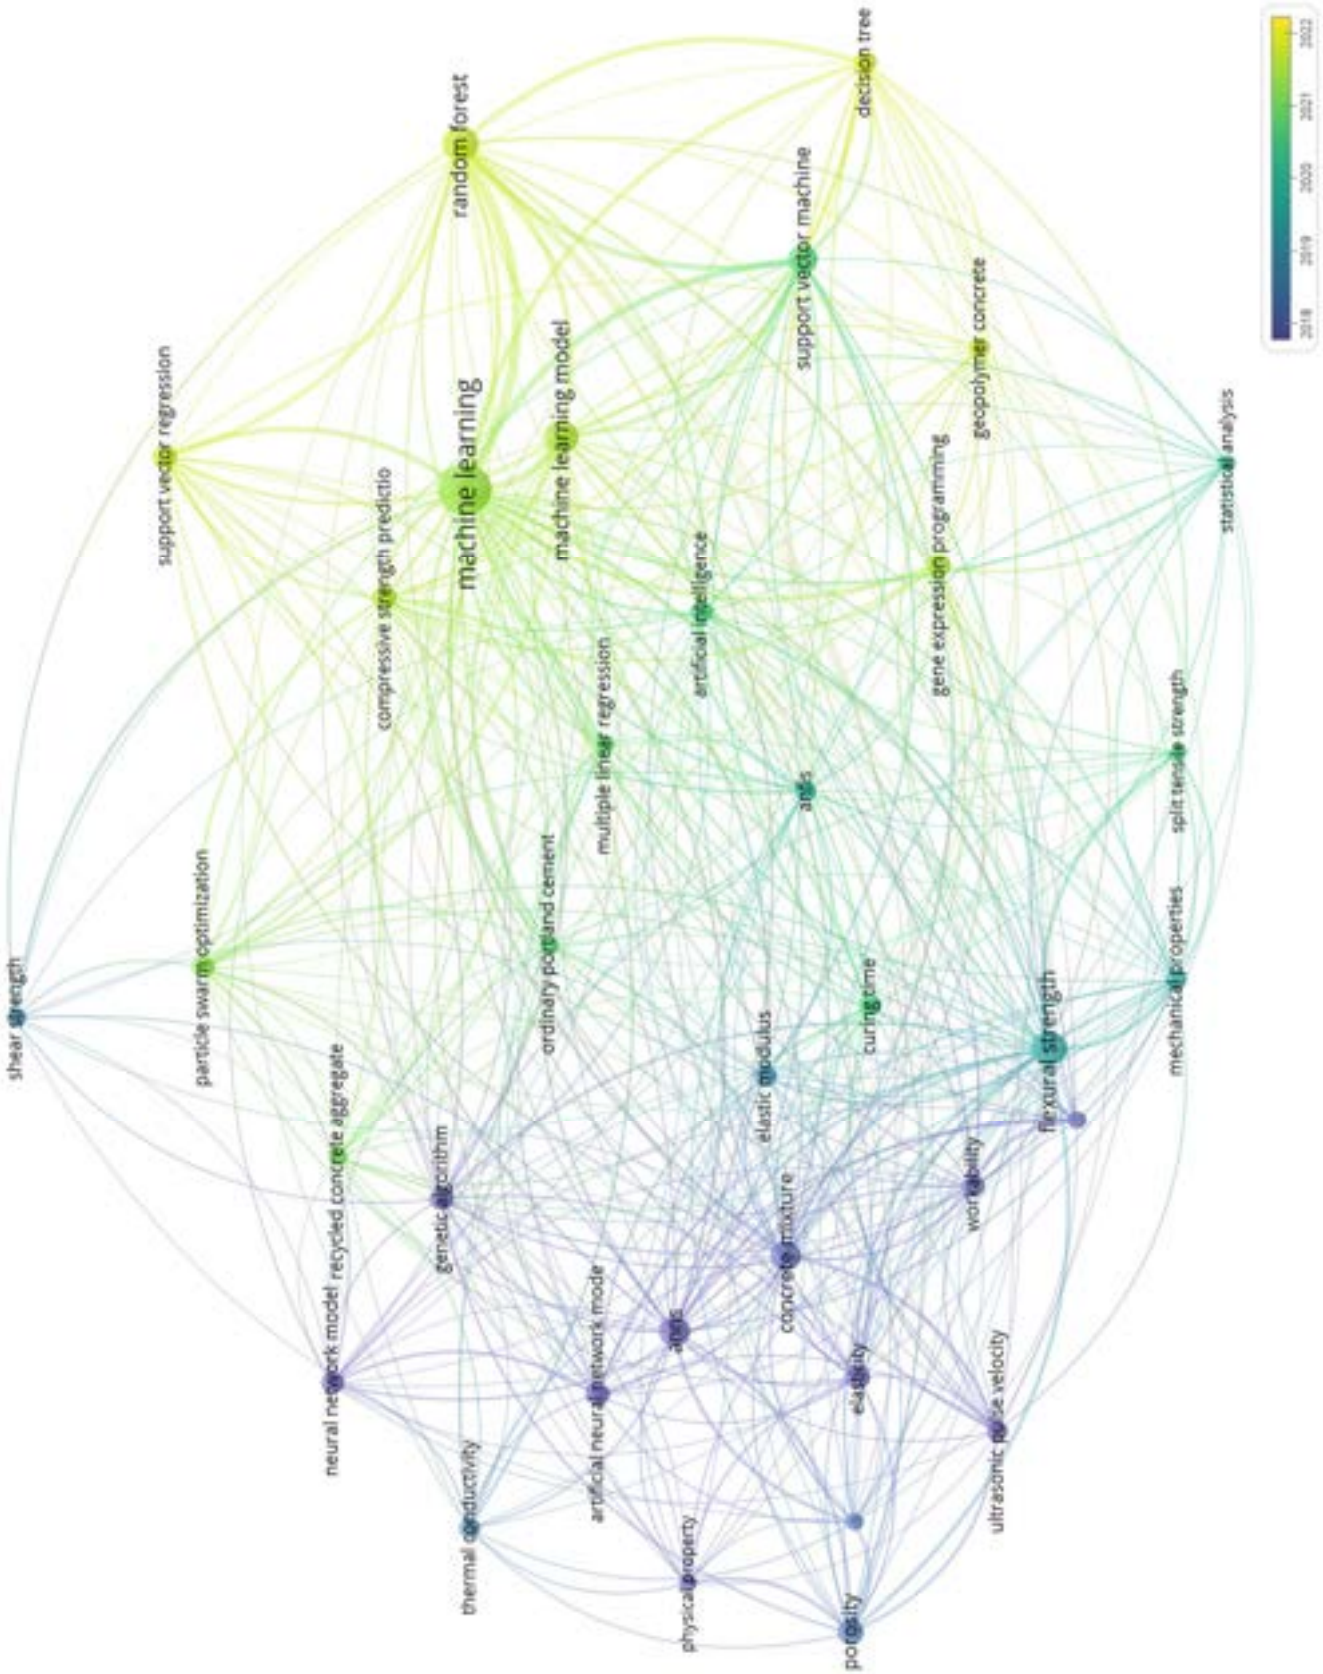

Figure 1. Cluster based on keywords (Overlay visualization).

3. Methodology

The following methodology outlines the development of an ANN model for predicting the thermal conductivity of concrete based on its features, which enables the evaluation of the model potential to foresee this property and shows the efficiency in the prediction speed when compared to the time-consuming experiments, which will provide a reliable model to predict the concrete's thermal conductivity. This methodology is broken down into three steps (Figure 2).

The first one corresponds to the literature review and data collection of a diverse variety of concrete. Collecting the database is the primordial step in building the predictive model, as the ANN will learn from this data. If it presents an inadequate representation of the problem, the model cannot predict the property effectively, thus reducing the model's reliability. Furthermore, for the model to be representative, there must be a sufficiently large amount of data to ensure diversity. In this step, it is necessary to define the dependent and independent variables, that is, to recognize which properties affect the output response of the model. First, the model's inputs and outputs are defined according to the available data and the dependent variables. Then, the available data sets from the literature are organized in a CSV file to develop the ANN model. The second one is related to the general process of building the ANN model to predict thermal conductivity, i.e., the selection of an appropriate neural network architecture for the prediction task, defining the learning rate of the neural network, the number of hidden layers and neurons in each layer, and the metrics to find the best model for the dataset. The last step is analyzing a case study, where the dataset based on previously published works is plugged into the model to evaluate its accuracy. Besides that, a Generative Adversarial Network (GAN) is also developed for data augmentation to improve the model and guarantee a good prediction. Then, both neural networks are implemented to strengthen the final model. Figure 3 summarizes the key steps and the necessary data.

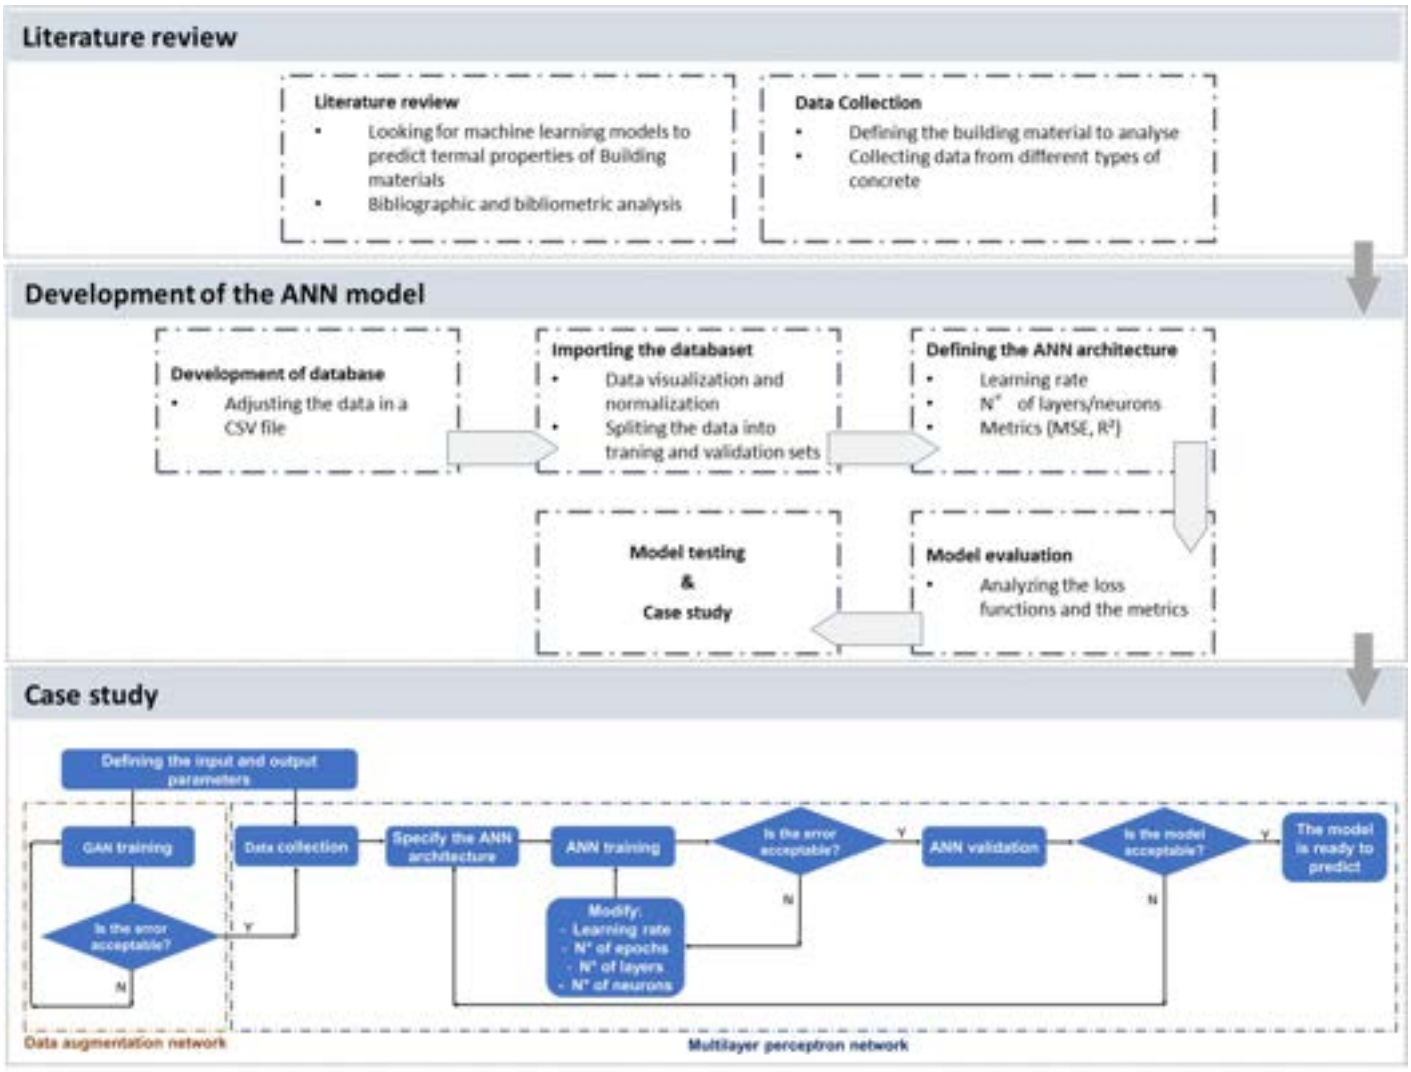

Figure 2. Methodology framework

4. Case study

This case study demonstrates the potential for ANNs to improve the accuracy and efficiency of material property predictions, with important implications for energy-efficient building construction. The case study explores the use of ANNs to predict the thermal conductivity of different types of concrete.

4.1. Database

The database for developing the neural network model was obtained from the literature. This work conducted a comprehensive literature review to create a dataset of 200 points from various relevant articles published in the literature. Furthermore, in order to build an ANN model, data related to the composition and density of each type of concrete were collected and organized to plug into the model. Table 2 presents a sample of the training dataset obtained from the literature.

Table 2. Sample of the training dataset

4.2. Artificial Neural Network Model

A neural network is a structure of layers of interconnected artificial neurons, which receive an initial input, process the information, and produce an output. Figure 3 represents a graphical representation of this mechanism. Each input (X_i) is multiplied by the weight (W_i) and summed with each other and added the bias value (b). Then, the result is transferred to the activation function, which adjusts the final output. The essential elements of a neural network are the inputs, outputs, artificial neurons, weights, activation functions, and hidden layers. According to the problem to be solved, these elements are varied until the model obtains outputs closer to the actual values. For example, and the activation functions, there are several possibilities, which are tangent sigmoid (tansig), linear (purelin), tri-angular basis (tribas), radial basis (radbas), and logarithmic sigmoid (logbas) [14]. During training, the complex relationships between the input data and the target values are trained to find specific patterns, and the weights are updated according to the learning technique until the predicted values reach a tolerance limit.

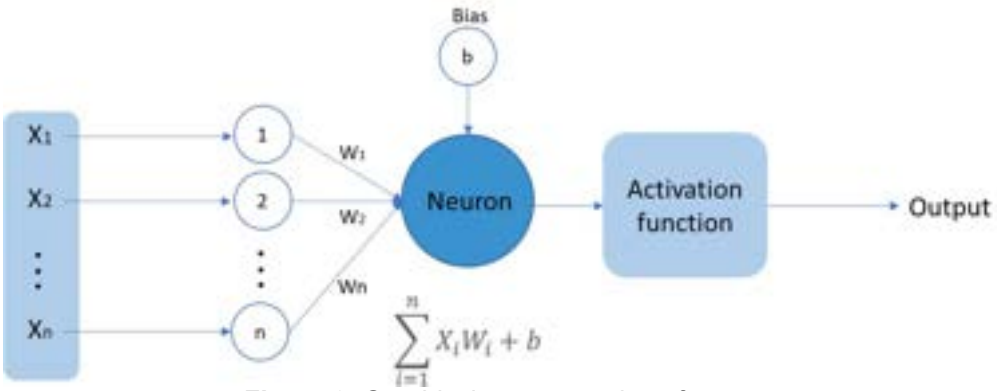

Figure 3. Graphical representation of a neuron

The developed artificial neural network model was built to predict the thermal conductivity of concrete based on chemical properties. To train the ANN with thermal conductivity as the output, this research utilized experimental data reported by previous researchers with thirteen parameters: the water-cement ratio, the unit water weight, the unit cement weight, the unit of ceramic powder, the unit fine aggregate weight, the unit coarse aggregate weight, the unit natural aggregate weight, the unit fly ash weight, the unit silica fume weight, the unit slag weight, the unit fiber weight, the unit superplasticizer weight, and density.

The ANN implemented was a Multilayer perceptron (MLP). It is a feedforward network that consists of an input layer, one or more hidden layers, and an output layer, as shown in Figure 4. Various combinations of network architecture were examined to evaluate the optimum model. The MLP model was built with an input layer with 13 neurons, some hidden layers varying the neurons in each layer, and 1 output layer with 1 neuron. In order to determine the best performance values, different activation functions, neuron numbers, and hidden layers were designed to perform the property prediction. This study tested different activation functions and used the backpropagation algorithm as the learning algorithm because it had been extensively used in previous studies.

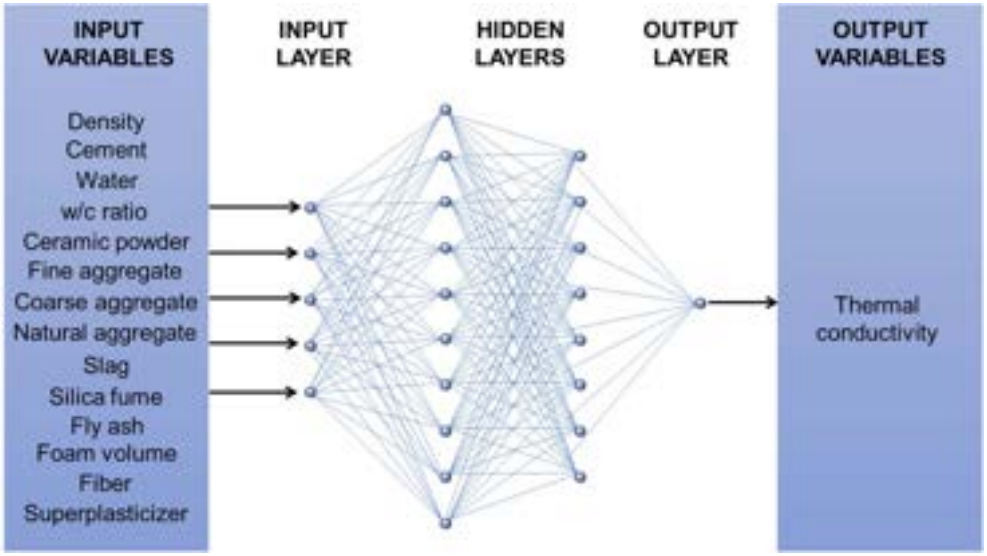

Figure 4. Example of the MLP model

4.3. Generative Adversarial Network

A Generative Adversarial Network (GAN) aims to generate new data based on a real database. The GAN captures the distribution patterns of the real data and creates new examples from this distribution. Its framework comprises two distinct deep neural networks: the generator and the discriminator network, which work together to train the GAN to produce realistic data that are difficult to differentiate between the generated and the data (Figure 5). First, the generator initiates the process, which takes a random noise as an input, creating samples similar to the original dataset. Following this, the discriminator tries to distinguish the data and inform which ones are real or fake. During the training, the generator loss and the discriminator loss are evaluated, allowing the generator to get better and better at producing new artificial data and the discriminator to find if they are real.

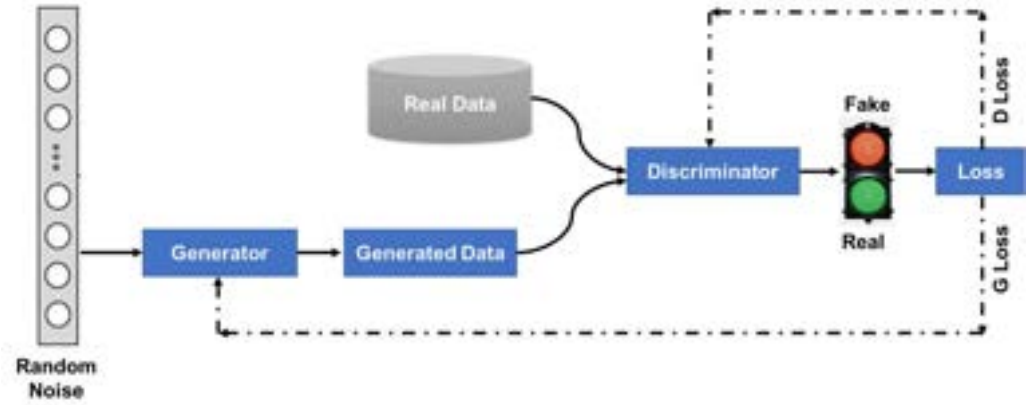

Figure 5. Flowchart of a Generative Adversarial Network (GAN)

5. Results

The first part of this study implemented an MLP model using Fastai, the most updated library to develop neural networks in deep learning. As previously mentioned, the model was developed to predict the thermal conductivity of concrete by utilizing the different compositions and densities as the input parameters.

Firstly, the dataset was plugged into the model and divided into two categories: training (80%), validating, and testing (20%), also used to train the GAN. Then, some features of the model were specified, such as the hyperparameters, metrics, activation, optimization, and loss functions. Table 3 summarizes the main features of this model.

For this study, some hyperparameters were varied during training to achieve the lowest value of the loss function and the highest values of the metrics selected. It used a combination of metrics to compare the model's overall performance. The chosen metrics were the Root Mean Squared Error (RMSE) and the coefficient of determination (R^2); both are frequently adopted to evaluate the prediction quality regarding the variations in the dataset. The learning rate and the number of epochs were kept fixed.

Table 3. Main features of the MLP model

Hyperparameters
Hidden layers = [1, 2, 3, 4]
Batch size = 32
Learning rate = 0.001
Epochs = 40
Metrics
RMSE

R^2
Activation function

Optimization function
Stochastic Gradient Descent (SGD)
Loss function
MSE

The numbers of the hidden layers and the neurons have been tested to determine the optimal structure of the ANN model. In order to select the best architecture, it was evaluated the loss function and the metrics. Table 4 displays some of the neural network architecture tested in this work. It can be observed that the best model presents a structure of 2 hidden layers with 200 and 100 neurons, achieving an RMSE of 0.111 W/m.K and R^2 of 0.984 for the training dataset. Regarding the test dataset, the metrics values were 0.183 and 0.96, respectively.

Table 4. Performance indices and metrics of the MLP model

Layers	ANN Architecture	Train Loss	Valid Loss	RMSE	R^2
4	200 – 100	0.083	0.012	0.111	0.984
5	200 – 100 – 50	0.107	0.024	0.155	0.968
5	200 – 100 – 40	0.099	0.037	0.192	0.950
5	200 – 100 – 30	0.087	0.028	0.167	0.960
5	200 – 100 – 20	0.012	0.037	0.191	0.949
6	200 – 100 – 50 – 25	0.102	0.064	0.253	0.918

To the best model evaluated, the loss function versus the number of epochs was analyzed, as seen in Figure 6. Although the number of epochs during the training was set as 40, we can observe the decreasing rate of the loss function over the epochs numbers, and after the setpoint, the loss function tends to be the smallest value in both datasets.

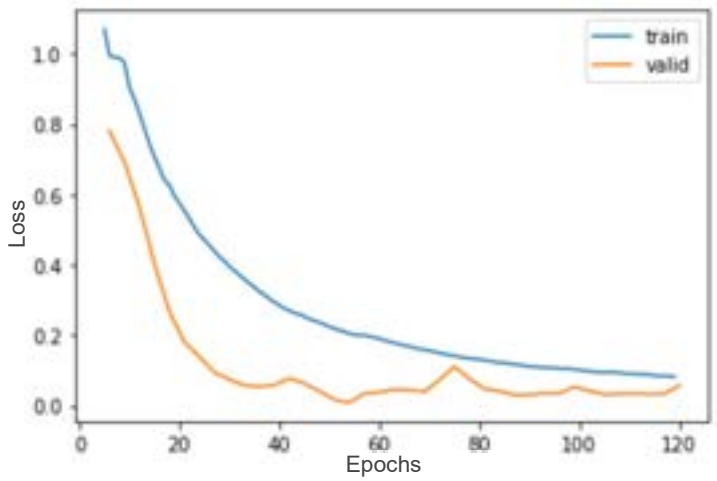

Figure 6. Loss function during the training

Comparing our results with previous works, although the model developed presents an accuracy as high as the other papers, this work brings a greater variety of the constituents of concrete. Fidan et al. [14], using a dataset with 132 entries, developed an ANN with an R^2 performance of 0.996. Sargam et al. [18], the only one to implement a neural network with a larger dataset, presented RMSE and R^2 of 0.117 and 0.964 for the training set and 0.215 and 0.894 for the validation set.

The second part of the study considered the implementation of a GAN for data augmentation. As can be observed in Table 4, increasing the number of layers did not improve the model's learning capacity or performance. If we increase the hidden layers of the model with a small dataset, the model can overfit. For this reason, the metrics and the loss function exhibited higher values. In order to solve this issue, we intend to develop GAN to increase the dataset, creating new synthetic data based on the real data used to develop the MLP model. It will avoid the overfitting process and make the model more robust with extensive dataset training.

This part of the study is broken down into two steps. The first step of GAN training is the generation of a synthetic dataset, and the second is the integration of the MLP and GAN to train the model on both real and artificial datasets. The implementation of GAN used a specific library to create tabular data (Tabgan). The first result showed a promisor result with R^2 of 0.710. The next step of this work will include this new data and verify the performance of the MLP model and if the neural network structure will change.

6. Conclusion

Determining the thermal conductivity of concrete is vital to analyze the thermal behavior of the concrete. Nonetheless, the conductivity value depends on various variables, including composition, porosity, temperature, etc. Thus, a dataset containing the thermal conductivity values of concrete and other parameters related to its composition was developed from published works. This paper proposed a prediction methodology integrating a Multilayer Perceptron (MLP) and Generative Adversarial Network (GAN) models. The first part of the study showed that MLP predictions agree with the thermal conductivity values found in the literature, presenting RMSE and R^2 values of 0.183 and 0.96 for the validation dataset. Therefore, it can be used to predict thermal conductivity with high accuracy. Besides that, the first step of GAN indicated that it could generate reliable synthetic data to be included in the original dataset.

This work is part of a broader effort to develop a methodology for predicting the thermal properties of building materials using ANN. As the contribution of this study, the authors intend to demonstrate the feasibility of the proposed method to predict the thermal conductivity of different types of concrete and show that a GAN model can be used for data augmentation based on a small dataset and present a reliable model. Then, the ultimate goal of this research is to extend the model developed for concrete to other materials, thereby advancing the field of energy efficiency and enabling the development of new energy storage solutions that can meet the growing demands of the future. Additionally, integrating artificial intelligence techniques enhances the intelligence and feasibility of TES systems. By developing models that can predict thermal properties, researchers can improve the performance and efficiency of these materials, making them more effective and cost-efficient. Besides that, the ability to predict the thermal properties of building materials will also facilitate the development of new energy storage solutions that can meet energy demands, ensuring a more sustainable and energy-efficient future for the next generations.

Abstract

Implementing a recycling route for vehicle plastics surely represents a challenging mission for a company. In general, the recyclability of automotive plastic is influenced by the nature of the polymer (i.e. the material cannot be recycled or recycling would cause deterioration of its properties) or by the lack of an industrial recycling system. In general, there are several technological and economic barriers that must be overcome through design innovation and logistical measures. Based on these factors, an arbitrary scale has been first developed to translate the qualitative indicators into a numerical score that can be useful for comparing different plastic components in a vehicle. Then, the various indicators have been translated in exergy terms, for giving an idea of the order of magnitude of the resources invested in developing the recycling process. Therefore, a new methodology for including critical recycling factors in the total exergy recycling cost is here presented.

Keywords

Exergy, Resource assessment, Recycling, EoL vehicles, Eco-design

1. Introduction

The correct final disposal of End-of-Life Vehicles (ELVs) is still a crucial worldwide issue. At European level, many directives have been implemented in order to regulate the materials used in vehicles and the steps of their end of life (i.e. depollution, dismantling, shredding, and landfill). In particular, the EU Directive 2000/53/EC has set the recycling/recovery target for vehicle to 85% by 2006 and 95% by 2015. This means that from 2015, recovery requirements should achieve the target of at least 95% (with a maximum energy recovery of 10%) and a minimum of 85% of the total material must be reusable and recyclable. The compliance of the EU Directive has been accompanied by a changing in the material composition of cars. According to the EU 2000/53/EC definitions, reuse means “any operation by which components of ELVs are used for the same purpose for which they were conceived”, while recycling means “the reprocessing in a production process of the waste materials for the original purpose or for other purposes but excluding energy recovery”. In this view, plastic materials comply with this standard, since they are theoretically reusable and recyclable. Moreover, their low cost and weight make them even more appealing for cars manufacturers. As a consequence, in the last 10 years, the percentage of plastic in vehicle increased, being the reduction in weight also justified by a decrease in fuel consumption [1]. The current amount of plastic is between 15-17% of the car total weight and 50% of its volume [2]. Currently, the 10% of the global European demand of plastic is for the automotive sector [3][4]. In the last 15 years, an impressive enhancement of End of Life Vehicles (ELVs) occurred, due to the shortening of the cars average life, estimated in 10-12 years [5]. According to a survey delivered by the EU commission [6], the ELVs legally deregistered produce every year between 7 and 8 million tonnes of wastes; anyway, considering also the number of estimated ‘unknown whereabouts’ vehicles, the total increase to 13-15 million tonnes of wastes. Apart from sporadic cases, plastics in ELVs are not recycled. During the pre-shredding phases of depollution and dismantling, the amount of plastic that can be ‘incidentally’ reused (e.g. tyres, bumpers, tanks) does not exceed 25% of the total [7]. Considering an average weight of vehicle of 1250 kg, it means that 150 kg of mixed plastics per

vehicle are discarded, shredded and ultimately landfilled. Therefore, only in EU about 2 millions of tonnes of plastic are dispersed every year due to the automotive sector, approximately 4 kg per person. For comparison, the average production of plastic packaging per year in EU is 31 kg per person [8]. The fact that plastics in vehicle are merely reused or recycled leads to ah huge dispersion of resources. An estimation of the resources embodied in the polymeric content of the ELVs has already be presented in Russo et al. [9], where the concept of Embodied Exergy (EE) is used for assessing the material and energy consumption in each step of polymers production and recycling routes. It resulted that, for the analysed vehicle, about 18.3 GJ of exergy are embodied in the plastic content, only considering the polymers processing and feedstock contribution.

1.1 Recycling practices

The inclusion of recycling in the automotive sector can follow various paths, which can be eventually linked in a closed-loop vision: (i) recycling of plastics to be used in non-automotive applications (i.e. open-loop recycling); (ii) recycling of plastics to be re-integrate in vehicle components (i.e. closed-loop recycling); (iii) integration of recycled plastic from other waste sources, e.g. municipal solid waste (i.e. reverse open-loop recycling. The more diffused practice is the integration of recycled plastic from external sources [10]. However, between the recycling schemes, the closed-loop might assure a predictable and secure source of material, overcoming the problem of scarcity in recycled plastic supply. The recycled material can be used for the same component fabrication or for lower mechanical performance applications. In fact, since mechanical recycling always leads to partial degradation of polymer mechanical properties, solutions have to be adopted. The options are the blending with virgin plastics or the incorporation of additives.

1.2. Recycling issues

Implementing a recycling path for vehicle plastics surely represents a challenging mission for a company. In general, the recyclability of automotive plastic is influenced by the nature of the polymer (i.e. the material cannot be recycled or the recycling would lead to deterioration in its properties) or by the lack of an industrial recycling system. Therefore, there are a series of technological and economic barriers that must be overcome by design innovation and logistic measures**.** A list of the main limits and issues of recycling is reported below.

- ***Compatibility of polymers.*** Nowadays, vehicles contain from 20 to 40 types of polymers [11]. Different polymeric materials are often incompatible at the time of recycling. Mixing of incompatible plastics leads to a recycled material with degraded properties, that cannot be re-used for the same noble application; the tolerance rarely exceeds 2% of contaminants in a mixture; compatibility can change according to the types of polymers [12]. Vehicle parts are practically always made of more than one plastic, but many times this is due to aesthetic reasons. This is the case of the polymer-based surface coatings, films or paint, which are included for obtaining the textile or leather appearance to plastics. Even if the use of compatibility additives is lately gaining attention in recycling practice [], they still represent an extra cost for recyclers and are generally not used, aside from antioxidants.

- ***Use of additives and fillers.*** Additives and fillers are incorporated into the polymers for enhancing mechanical characteristics, strength, fire resistance and for colouring. Additives can hinder the recycling for several reasons: health hazards due to presence of heavy metals and halogens (Br, Cl, F) or incompatibility of different flame retardants; impossible separation of fibres (glass or natural) from the polymer; lack of information on additive composition, which makes impossible the plastic sorting. It is not easy to find information on the degree of tolerance of additives in the recycling process. The fact that many of them are not declared means that the resulting polymer composition is unclear. In addition, given the wide use of additives, the combinations can be multiple and the final composition very varied. For each case, experimental studies must be carried out to quantify the degradation of the material and its possible re-use for different applications. In general, many types of additives migrate from one polymer to another during recycling []. For the purposes of this paper, we will focus on the declared additives found in large quantities in vehicle components: glass fibres, talc, titanium and carbon oxides. The objective is to find out the tolerance range of these additives in the recycling process. The benchmark studies used are as follows. In [13], Pegoretti et al. describe the various recycling alternatives (i.e. mechanical recycling, use of recycled matrices, use of

recycled fibres, use of waste composites, chemical recycling) and provide a literature review on various recycling processes of reinforced polymers. It is highlighted that in mechanical recycling processes the percentage of glass fibres never exceeds 40% of the total polymer matrix, while for talc we report examples with samples up to 20%; data on mechanical characteristics of recycled materials are also reported. The study of Scaffaro et al. [14] focuses more on a review of the various recycling processes of carbon and glass-fibre reinforced polymers and the modification of the mechanical characteristics of the material that affect the field of reuse. Among the results, it is highlighted that recycled composites can be reused for the same applications, when the properties do not change much after recycling, or recycled to applications that require less performance. The main disadvantage lies in the loss of fibre structure and length due to fibre size reduction. The need for milling and grinding steps before the remanufacturing process can also increase the operational cost (even non-standard equipment may be required, able to withstand the wear caused by the fibre during milling). Still, the authors were able to obtain compression-moulded panels with good tensile strength and the same flexural properties as virgin composites by adopting a 'sandwich', multilayer configuration in which virgin material was used as the outer layers and recycled material was used as the core layer. By doing so, 50% of the volume of the virgin material could be replaced by recycled material while maintaining good mechanical properties. An experimental estimation of the additional energy required for the recycling process of PET with 30% glass fibres is given in [15]. In [16], the authors analyse the effect of titanium oxide on the plastic matrix up to concentrations of 12%. A general resume of the allowed additives, in the hypothesis of excellent quality of the recycled products is given in [..]; according to this review, flame-retardants, high concentrations of glass fibres (> 10%), vegetable fibres, nano-particles, pigments with heavy metals are totally not tolerated; small fibres concentrations (< 5%) are partially tolerated, while talc, calcium carbonate, barytes and TiO_2 are admitted for recycling. In general, in order to have noble outlets, i.e. with a property loss <5%, the impurity rate during the sorting process must be <3%. As for carbon, no studies have been found that analyse the criticalities in the recycling phase (apart from the problems of optical separation due to the black colour), so a good tolerance is assumed.

- ***Recycling volumes and dismantling time***. In order to make the recycling process economically viable, consistent recycling volumes of the same polymer have to be achieved. In fact, the investment in dismantling operations must be offset or exceeded by revenues from the sale or reuse of dismantled plastics. Polymer recovery for recycling can take place both upstream and downstream of shredding phase. The degree of precision in polymer recovery at the 'pre-shredding' stage determines the extent and therefore the cost of the dismantling stage. The number of different polymers and vehicle subcomponents, the compatibility of polymers in recycling and the presence of mechanical or adhesive connections between parts of different materials are the influencing factors of the dismantling time. For evaluating the dismantling cost, it would be necessary to have empirical data on dismantling operation and to know the type of dismantling methodology (e.g. manual, mechanized). The energy and monetary cost of the labour could then be accounted with various methodology. As an example, Sciubba et al. [17] have included labour and capital in the exergy assessment.
- ***Supply stability and lack of market demand.*** One of the major limits of plastic recycling is the lack of an industrial and well-assessed market for recycled materials. The relative low-cost of virgin plastic material is still a barrier to the development of a circular economy of plastics, since the costs of installing a new recycling plant is not compensated by the revenues. As consequence, often the companies have doubts about including recycled plastics, because of the concerning of not having stable supply.

1.3. Aim of the analysis

The aim of the present work is to assess methodologies for evaluating the recyclability of polymers in vehicles, including all the factors that influence the process and giving an order of magnitude of the exergy cost associated to recycling of EoL vehicle components. In order to do that, a first qualitative analysis is developed for assessing all the recyclability crucial factors, followed by a translation of some of them into exergy terms.

2. Methodology

2.1. Recyclability table

First, based on the critical factors expressed above, an arbitrary scale (Table 1) has been developed to translate the qualitative indicators into a numerical score that can be useful to compare different polymeric vehicle components. The number of polymers and subcomponents and the compatibility of polymers in recycling influence the dismantling time; the compatibility of additives and fillers in recycling and the presence of adhesives or coatings influence the effective recycling of the polymers, while the compatibility in density separation has an effect on the post-shredding recovering. The scale is arbitrary, decided after empirical attempts in comparing resulting scores for different components. In fact, the main goal is to quantify the qualitative characteristics influencing recyclability and to compare different vehicle parts. For this work, data on vehicle plastic composition have been provided by Seat-SA for a 350 Seat Leon. Four components have been chosen for the analysis: rear bumper, dashboard, floor covering and rear seats. The analysis of vehicle components starts with the identification of the main polymeric materials (present in quantities higher than 1 g) and the main subcomponents containing them. If the same polymer is present but containing different additives, it counts as a different polymer. Resins, adhesives and not-declared additives are not included in the computation of polymers. Then, the recyclability table factors have been identified and a total score from 0 to 5 is assigned to each category. For the compatibility indicators, the main polymers (i.e. the polymers that embodied the majority of the weight) are taken as reference; a weighted average is calculated for assigning the final score, considering that the presence of recycling technologies has a relatively higher importance than the other factor (weight percentages are reported in Table 1). Obviously, this procedure is not based on an absolute criterion, but it is based on common practice and empirical considerations.

Table 1 – Recyclability table for score assigning according to critical factors

	Score	0	1	2	3	4	5
A	**Number of main polymers:** polymeric materials present in quantities higher than 1 g are identified [10%]	≥8	7	6	5	4	≤3
B	**Number of main subcomponents**: only subcomponents containing polymers are considered [10%]	≥16	13-15	10-12	7-9	4-6	≤3
C	**Compatibility of polymers in recycling:** mean value based on the main polymer compatibility with each of the others [10%]	If not compatible		2.5 If limited compatibility for moderate quantities			If 100% compatible
D	**Compatibility of additives and fillers in recycling:** mean value based on the main polymer compatibility with their additives [10%]	Prohibited additive	>60%wg	40-60%wg	20-40%wg	≤20%wg	No additive
E	**Compatibility in density separation:** mean value based on the main polymer compatibility [10%]	Overlapping densities					No overlapping densities
F	**Presence of coatings:** paint and skin can be present and should be chemically removed [10%]	Prohibited coatings	On the main polymer (main part)	On the main polymer (secondary parts)	On the other polymers (main part)	On the other polymers (secondary parts)	No coatings
G	**Presence of adhesives:** adhesives in high quantities can hinder the recycling [10%]	Prohibited adhesives	On the main polymer (main part)	On the main polymer (secondary parts)	On the other polymers (main part)	On the other polymers (secondary parts)	No adhesives
H	**Presence of recycling technologies** for the main polymer for the same application (closed loop) [30%]	No recycling technologies		2.5 If limited technologies are present			Well developed recycling technologies

2.2. Exergy cost of recyclability

The score may be important for a first comparison, but it does not give an idea of the order of magnitude of the energy and resources invested to develop the recycling process. For this reason, the attempt has been trying to translate some indicators using exergy. The initial idea is that all indicators express characteristics that make recycling more difficult and consequently more expensive in terms of resources and money. The recycling routes assessed in [10] referred to 'standard' recycling process, namely they refer to basic polymers (those generally used for packaging), without additives or in percentages compatible with recycling. Due to the lack of information on the effective additional energy burden associated to vehicle dismantling, polymer separation and recovering and coatings and adhesives removal, the analysis has been focused on the recycling of polymers with additives and fillers. According to the review presented in Section 1.2., a set of rules has been chosen as reference for evaluating additives presence in vehicle components and hypothesis of recycling, as presented in Table 2. No declared additives in plastic components are generally lower than 5%, even if it is not possible to know their composition. Concentrations higher than the ones reported in Table are supposed to be not allowed. Therefore, three recycling scenarios are analyzed; every scenario is analyzed in terms of Embodied Exergy in the operations of dismantling of the old vehicle polymeric component and making of the new one, as follows.

Table 2 – Admitted additives and recycling options

Additive		**Recycling**
Talc <20%	Admitted	Polymer 100% recycled
Titanium Dioxide <15%	Admitted	Polymer 100% recycled
Glass fibers <5%	Admitted	Polymer 100% recycled
Glass fibers 5%<GF<40%	Partially admitted	Multilayer - Polymer 50% recycled 50% virgin
No declared additives >5%	Partially admitted	Multilayer - Polymer 50% recycled 50% virgin

- **1st scenario: No recycling.** In case of no recycling all the EE of the polymers in the vehicle component is lost and it is necessary the same amount of EE for remanufacturing them
- **2nd scenario: Recycling only the main polymers in closed-loop,** according to the limitations and the recycling options reported in Table 2. The other polymers are reintroduced as new, so their EE is lost; in case of multilayer configuration, also the EE of the 50% of polymer is lost. The same amount of EE is necessary for remanufacturing them.
- **3rd scenario: Recycling the main polymers in closed-loop and inclusion of recycled polymers from open loops,** according to established markets**.** The EE of the replaced polymers is lost but less exergy is required for their new production, since they come from recycling routes.

In all three cases, the total EE (EE_{tot}) is taken as comparison indicator, being the sum of the EE lost (EE_{lost}) within the old vehicle component and the EE necessary for its new production ($EE_{new\ prod}$), Equation 1.

$$EE_{tot} = EE_{lost} + EE_{new\ prod} \quad (1)$$

In order to perform the calculation the values of EE associated to polymers production and recycling reported in Table 3 are considered [10]. The EE values of production refer to the process only (i.e. from naphtha steam cracking to polymerization), without including the feedstock part or the exergy replacement cost of fuel in the environment. The EE values of recycling refer to standard recycling processes found in literature. The values of EE_{lost} and $EE_{new\ prod}$ were then calculated as the sum of the products of the EE of polymers for the respective quantity in the vehicle part

Table 3 – Production and recycling Embodied Exergy

Polymer	**EE of production (MJ/kg)**	**EE of recycling (MJ/kg)**
PP	39	3
PE	24.3	3
EPM	32.3	11.4
PVC	25.5	1.1
PU	41	5.3
PA	59.3	10.3
PET/PES	51.2	4
SBR	73	11.4
EPDM	55.9	11.4
ABS	69.8	2.3
PC	48.8	3
PMMA	48.8	3

3. Results

3.1. Qualitative indicators

First, the material composition of the four plastic components have been analyzed, mapping the distribution of polymers among the subcomponents. Results are reported in Tables 3-6. If the same polymer is present with different additives, it counts as a different polymer.

Table 3 – Plastic composition and distribution in rear bumper

Then, a score is assigned to each component according to the recyclability table. Results are shown in Table 7, where details on the presence of each indicator are reported. An average value is also calculated. According to this scoring, the best component in terms of recyclability is the rear bumper. More detailed comments are reported below.

Table 7 – Results of application of recyclability table

	Rear bumper		Dashboard		Floor covering		Rear seats	
		Score		**Score**		**Score**		**Score**
A	7	2/5	8	0/5	7	1/5	5	3/5
B	11	1/5	14	0/5	5	4/5	2	5/5
C	PP has a limited compatibility with PC+ABS, PA, PMMA and PET and is not compatible with EPM and PE fiber.	1.7/5	PP has a limited compatibility with PVC and PU. PP compatible with PE and not compatible with EPM and PET fiber.	2/5	PET not compatible with any polymer	0/5	PU foam is not compatible with any polymer	0/5
D	Talc, TiO_2 and not declared additives.	4.5/5	Talc admitted and GF not allowed in this percentage.	2.5/5	GF not compatible in this percentage	4.7/5	Only not declared additives in small percentage are present	4/5
E	PP and EPM not compatible	4/5	PP only compatible with PU, PET fiber and PVC	2.5/5	PET not compatible with PA66	4/5	PP has no overlapping densities with other polymers	5/5

	Average value	**3**		**2.4**		**1.9**		**2.1**

3.1.1. Comments

- **Rear bumper.** The main polymer is PP, even if EPM is present in a consistent amount. These two polymers have overlapping densities, so they should be separated before shredding. This means that the diffuser, the mobile guides, the hook cover and the plaque cover should be removed and processed separately. PP has a limited compatibility with the other polymers, even if the level of impurity in recycling should not exceed 2%. For reducing the impurities, some parts should be removed, such as the lens and the catadioptric or the soundproofing. The possibility of dismantling the various parts of the bumper depends on the facility of removing the adhesives and the mechanical junctions. Coatings are present on the surface of the main PP bumper part in a weight percentage of 3.9%; they should be chemically removed before shredding and recycling.
- **Dashboard.** The main recyclable polymer is PP filled with GF or talc, followed by EPM with GF. Since these two polymers have overlapping densities, they should be separated before shredding. Glass fibres content in these percentages hinders the recycling. Even if PP has a limited compatibility with low volumes of PVC and PU, the quantities of PVC and PU are in the same order of magnitude. Flexible PVC and PU foam are all concentrated in the IP carrier subcomponent and they should be separated and recycled separately, as well as PVC and PET fibre contained in the airbag hinge. PU of the gasket could be eventually processed with PP, since they represent an impurity lower than 2%.
- **Floor covering.** This is a component where polymeric materials are mainly used as textiles. The main burdens are represented by the scarce compatibility of PET and PP fibres, the poor practice in polymer fibres recycling and the presence of PE coatings and films. The main material is PET fibre, which is present in the floor carpet and the propylat support. PET is not compatible with PP fibre so these materials should be separated. PE powder used for coating should be removed. Moreover, SBR and PA filled with these percentages of glass fibres are not compatible for recycling and have to be separated and processed separately. Recycling of PET and PP fibres is scarcely diffused, even if the process is possible and some technologies are available; however, many times these materials are reemployed in secondary application (e.g. filling, insulation). For all these reasons, the recoverable volume for this component is pretty low.

- **Rear seats**
  This is a component where polymeric materials are mainly used as fillers (i.e. foam). The main burdens are represented by the absence of closed loop recycling options for PU foam and the scarce compatibility in recycling PU with other polymers. The only advantages are the few number of polymers and sub-components that facilitates the dismantling and the not overlapping density of PU with the other polymers, for an eventually separation after shredding. PU foam can be reused for secondary applications of filling, even if closed loop practices for vehicle applications are not documented.

3.2 Quantitative indicators

The methodology described in Section 2.2 is then applied to the four components, analyzing the three scenarios. Table 8 reports the results of calculation of the lost and new production EE and the total value with an explication for each component. Values of EE are given in MJ.

Table 8 – Results of calculation of EE for the three scenarios

	1st scenario No recycling			**2nd scenario Recycling only the main polymers in closed loop**			**3rd scenario Recycling the main polymers in closed loop and inclusion of recycled polymers from open loops**		
	EE_{lost}	$EE_{new\ prod}$	EE_{tot}	EE_{lost}	$EE_{new\ prod}$	EE_{tot}	EE_{lost}	$EE_{new\ prod}$	EE_{tot}
Rear bumper	154.5	154.5	**309**	42.9	54	**96.9**	42.9	52.1	**95**
	All the EE of the component is lost, and it is necessary the same amount of EE for reproducing it			PP and EPM are recycled in closed loop; PP is totally recycled since 5% of additives are allowed, while recycled EPM is included in percentage of 20/80 ratio; other polymers are reintegrated as new			PP and EPM are recycled in closed loop as in the 2nd scenario; PET is included as recycled material, so their 'first' EE is lost but less exergy is required for their new production		
Dashboard	175.7	175.7	**351.4**	147.2	150	**297.2**	147.2	57.8	**205**
	All the EE of the component is lost, and it is necessary the same amount of EE for reproducing it			PP and EPM cannot be recycled in closed loop with these percentage of GF. Talc is admitted so PP+talc is totally recycled and EPM+talc is included in 20/80 ratio.			PP with GF is included as recycled material (only PP part). EPM is included as recycled in 20%. PET and PE are included as recycled, but not PU and PVC		
Floor covering	122	122	**244**	-	-	-	122	13.3	**135.3**
	All the EE of the component is lost, and it is necessary the same amount of EE for reproducing it			Closed loop recycling is not assessed for the main polymers (PET fiber); SBR cannot be recycled with this percentage of GF			SBR is partially introduced as recycled material (20/80 ratio), while PET and PP fibers and PE are 100% substituted. PA is always included as new material		
Rear seats	152.2	152.2	**304.3**	-	-	-	152.2	132.9	**285.1**
	All the EE of the component is lost, and it is necessary the same amount of EE for reproducing it			Closed loop recycling is not assessed for the main polymers (PU foam)			PU foam is not reccyled in general; only recycled PET/PES can be included		

A graphical representation of the results is shown in Figure 1, while a comparison between the scenarios is presented in Figure 2. The four components have been chosen because they are examples of different cases that can occur when recycling vehicle parts. As expected, there is always a saving in performing some type of recycling; the amount of saving depends on the polymeric composition. In the rear bumper the difference is evident (- 68.6% in the 2nd scenario), since it is composed mainly of PP, which could be completely recycled, and of EPM which can be included in multilayer configuration. ncluding PET from recycled material in the 3rd scenario leads to a further saving of 2%. The step is less evident for the dashboard; here the main polymers, PP and EPM, are present both with talc and GF. Polymers with GF in these percentages cannot be recycled for closed loop application, so only the polymers with talc can be substituted in the second scenario (-16.8% of EE). PET, PE and the polymeric matrix of PP and EPM with GF can be introduced as recycled material in the 3rd scenario, being the saving more evident (-41.6%). The floor covering is an example of component made mainly of textile; in this case the majority of fibers are of PET and PP. Closed loop fiber recycling is not industrially well assessed, so the second scenario is not analyzed. On the other hand, recycling from plastic to fiber is very common, so recycled fibers can be 100%

substituted leading to a saving in 44.5% in the exergy of new production. Finally, rear seats are an example of component made of filler material (i.e. foam) and fibers. Since PU foam is generally not recycled, 2nd scenario is not analyzed; in the 3rd scenario PU is included as new polymer, so that the savings are not so consistent (-6.3%).

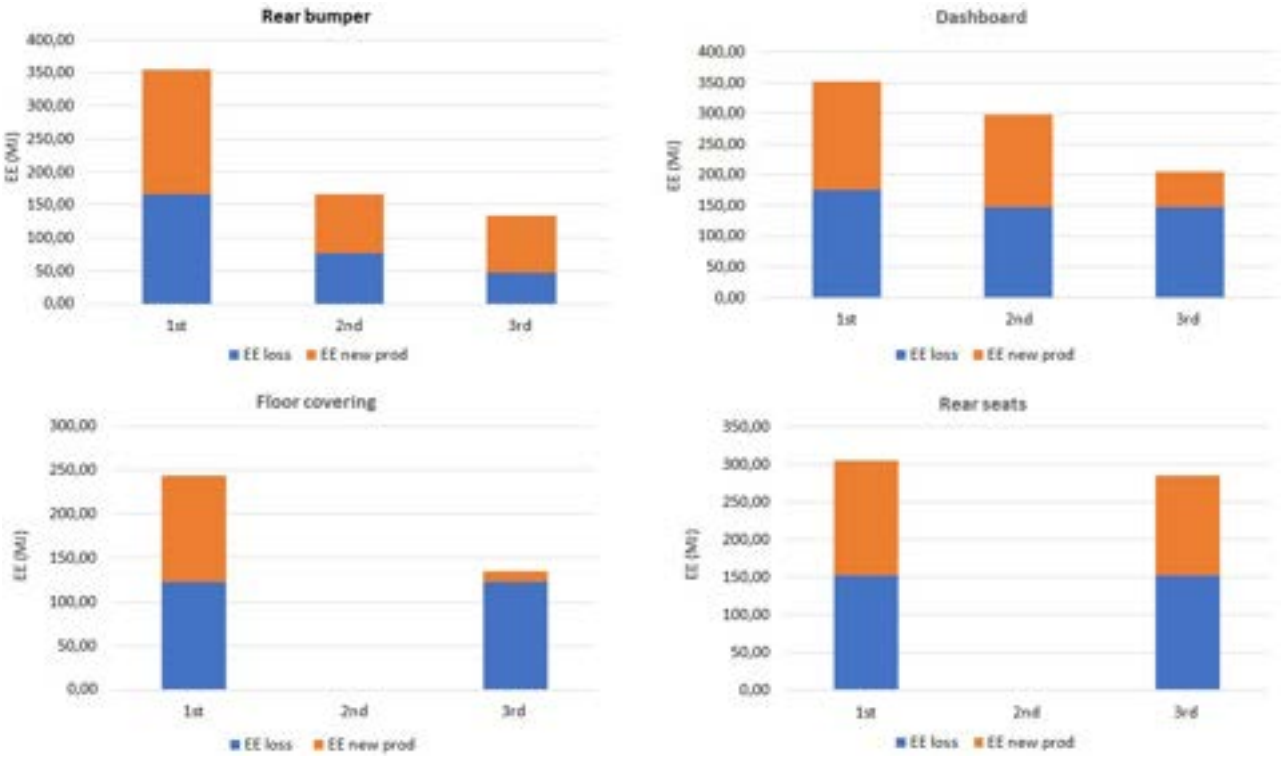

Figure 1 – EE values for the four components in the three scenarios

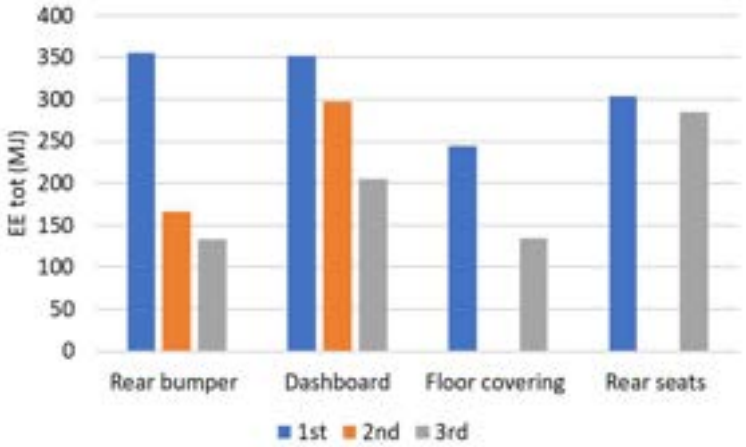

Figure 2 – Comparison between the total EE for the three scenarios

4. Conclusions

The aim of the present work was to assessing methodologies for evaluating the recyclability of polymers in vehicles, including all the factors that influence the process and giving an order of magnitude of the exergy cost associated to recycling of EoL vehicle components. In order to do that, a first qualitative analysis is developed for assessing all the recyclability crucial factors, followed by a translation of some of them into exergy terms. In order to do so, first, based on the critical factors, an arbitrary scale has been developed to translate the qualitative indicators into a numerical score that can be useful to compare different polymeric vehicle components. Then, some of these indicators have been translated using exergy and the values of total EE have been calculated for three recycling scenarios. Results show that, according to the scoring, the best component in terms of recyclability is the rear bumper, due to the high percentage of PP with no additives, while the worst is the floor covering, mainly due to the absence of recycling process for PET fibers. The analysis of the recycling scenarios underlines that savings between 1st and 2nd scenarios are more evident for the rear bumper and floor covering.

Abstract:

The use of nanomaterials in water treatment is an alternative for the development of new materials that optimize the purification process. Heterogeneous photocatalysis is used for the treatment of wastewaters contaminated with recalcitrant pollutants that cannot be removed in conventionally. Ag_3PO_4 has been reported to use visible light. Another important challenge of heterogeneous photocatalysis is to find a proper support for the photocatalysts to reduce the expense associated with the separation and reuse of these materials. However, the immobilization of the catalyst leads to lower reaction rates because the surface area exposed decreases and the material used as support can also interfere. In the last years, the use of magnetic materials to support photocatalysts has attracted special attention because it allows high surface areas to be exposed. Only few authors have reported the use of Ag_3PO_4/magnetic nanocomposites for photocatalysis and these need to be continued to improve their efficiency. In this work we synthesized Ag_3PO_4 and supported it on Fe_3O_4.
Fe_3O_4 was synthesis at pH 12 by the addition of $FeCl_3$ and $FeCl_2$. The magnetic material was washed with water and dried at 80ºC. Ag_3PO_4 was synthesised over Fe_3O_4 from the reaction between $AgNO_3$ and Na_2HPO_4. The final material was washed, recovered magnetically and dried at 80ºC. For characterization, a SEM and XRD studies were carried out.
Ag_3PO_4 was synthesised and satisfactorily supported over $Fe_3O_4/\gamma\text{-}Fe_2O_3$. The photodegradation of 10 mg·L-1 of methylene blue was achieved, although the apparent reaction rate constant was slightly lower for the magnetic composite than for the Ag_3PO_4 alone. This is explained because the composite contained 48% of the active Ag_3PO_4 material, as depicted form DRX studies.

Photocataysis, wastewater treatment, magnetic nanomaterials,

1. Introduction

Water is a scarce resource and for many countries supply is not enough to satisfy demand. Water resources location and their quality are factors that limit their availability. This problem is further complicated by climate

change, rapid industrialization, population growth and pollution of existing water resources [1]. To solve this question different solutions are proposed which include repairing water distribution infrastructures and conservation of existing water sources. However, these options can not increase resources. Supply water can only be increased beyond hydrological cycle by desalination and water reuse. For this, a series of conventional water treatment technologies are used which include among others: ultraviolet radiation, chemical treatments, distillation and membrane processes (reverse osmosis, ultrafiltration, microfiltration, electrodialysis...), but all of them show specific disadvantages [2].

The continuous deterioration of the environment is a problem with greater relevance every day, and that requires short-term solutions. Most of the harmful contaminants found are anthropogenic compounds that have low biodegradability and therefore cannot be eliminated by conventional treatments. This is the case of the so-called emerging pollutants, which are found in low concentrations in the environment; these have the potential to carry an ecological impact, as well as adverse effects on health [3]. These contaminants include: drugs, additives, pesticides and a wide variety of compounds that, even at low concentrations, can alter endocrine functions [4] and increase the presence of resistant bacteria [5].

Elimination and control of these substances in aqueous media is complex due to their presence in large bodies of water. In recent years, emerging contaminants have been found in practically all the bodies of water studied. In Spain, among others, more than 30 emerging contaminants have been found in groundwater [6], 100 in wastewater treatment plants [7], more than 100 in wastewater already treated in conventional treatment plants [8], several in aquaculture areas [9] and 144 in river water fish [10].

Due to the nature of these contaminants, most have proven to be poorly biodegradable, and cannot be eliminated by conventional purification systems and therefore require advanced oxidation processes for their treatment [11]. Advanced oxidation processes are part of the tertiary treatment of purified water and seek to eliminate compounds that are difficult to biodegrade and reduce microbiological contamination, often with the aim of reusing the water. Among the most common tertiary processes we find ozonation, photocatalysis or membrane filtration, among others.

Based on this situation and nanotechnology development, nanomaterials use for water treatment is an alternative that allows solving drawbacks of methods traditionally used. Due to their new properties nanomaterials can contribute in obtaining stronger, lighter, cleaner and smarter surfaces and systems [12]. They have many applications ranging from automotive and aircraft (for example, reinforced and lighter materials, antifouling paints or more durable pneumatic) to biomedicine (drug released as specific organs, biosensors or prosthesis).

In water treatment, nanotechnology is finding applications through different routes [13] such as the use of large surface area of nanoparticles to adsorb contaminants (they allow retaining a higher rate of contaminants than conventional adsorbent), the use of membranes with nanomaterials (several studies have fixed nanomaterials to different polymer membranes and have obtained a greater water flow than conventional membranes) and the use of catalytic nanoparticles to decompose contaminants (nanomaterials have a higher photoactivity than conventional catalysts). Nanomaterials such as silver nanoparticles [14], TiO_2 nanoparticles and carbon nanotubes [15] have bactericidal effects that make it possible to eliminate microorganisms present in water. They also have better adsorption capacities than conventional adsorbents for low concentrations of heavy metals: porous carbon nanomaterials have been used efficiently for lead, cadmium, nickel and zinc elimination [16]. Another application is oils and organic solvents treatment: SiO_2 nanoparticles fixed to a polysulfone membrane improve antifouling properties and increase permeability from 1.08 to 17.32 $l/m^2 \cdot h$ [17]. On the other hand, boron nitride nano-slides have been shown to adsorb up to 33 times their own weight in oils and organic solvents while repelling water [18]. The use of nanomaterials has also been evaluated for emerging contaminants in water treatment: a combination of titanium dioxide nanotubes on a graphene base eliminates, with the help of the sun, traces of drugs and pesticides that escape from the current purification systems.

Of all the mentioned water treatment processes, we will focus on the use of nanomaterials in heterogeneous photocatalysis.Heterogeneous photocatalysis is used for the treatment of wastewaters contaminated with recalcitrant pollutants that cannot be removed in conventionally. One of the main drawbacks is that most photocatalysts need to be illuminated with wavelengths shorter than 388 nm [19]. Ag_3PO_4 has been reported to use visible light [20]. Another important challenge of heterogeneous photocatalysis is to find a proper support for the photocatalysts to reduce the expense associated with the separation and reuse of these materials. However, the immobilization of the catalyst leads to lower reaction rates because the surface area exposed decreases and the material used as support can also interfere [21]. In the last years, the use of magnetic materials to support photocatalysts has attracted special attention because it allows high surface areas to be

exposed. Only few authors have reported the use of $AgPO_4$/magnetic nanocomposites for photocatalysis [20], [22], [23] and these need to be continued to improve their efficiency.

In this work we synthesized Ag_3PO_4 and supported it on Fe_3O_4, performing the characterization of the synthesized material

2. Bibliometric Analysis

Bibliometric analysis is defined as a statistical evaluation of published scientific documents that enables the measure of the influence of publication in the scientific community.
The data obtained from the bibliometric analysis of the terms "silver nanoparticles" and water treatment are presented below. The scientific database used to search for the terms was Scopus (search conducted on May 23, 2021), and the software used to analyze the results was VOS Viewer®.

A growing trend is observed in the number of documents published as of 2008, with the number of documents published up to that date being less than 200. Regarding the countries with the most publications on this subject, Spain is in position number 10 , with 265 publications. Regarding the research groups or institutions with the greatest scientific production in the field, the first Spanish institution is found in position 23, this being the Higher Council for Scientific Research (CSIC).

However, if we add the term “emerging pollutants” to the previous search, the number of documents is reduced to 454 (from the year 2000 to the present). Thus, up to the year 2010, only 6 references were found in Scopus related to the study of silver nanoparticles for the treatment of emerging contaminants in water. As of that year, the number of documents begins to increase, finding in 2020, 90 documents published on this subject. In this regard, Spain is the fourth country with the most documents (27 documents in total).

Figure 1 shows the bibliometric network obtained from the keywords found in the documents resulting from the search. It is observed that the most commonly used materials for the application of silver nanoparticles are membranes (95 occurrences), graphene oxide (192 occurrences), titanium dioxide (327 occurrences) or magnetite (122 occurrences). Regarding the final application of these materials, we mainly found keywords related to disinfection processes (E. coli, antibacterial activity, etc.), although words related to emerging contaminants (antibiotics, tetracycline) and dyes (blue of methylene, dyes).

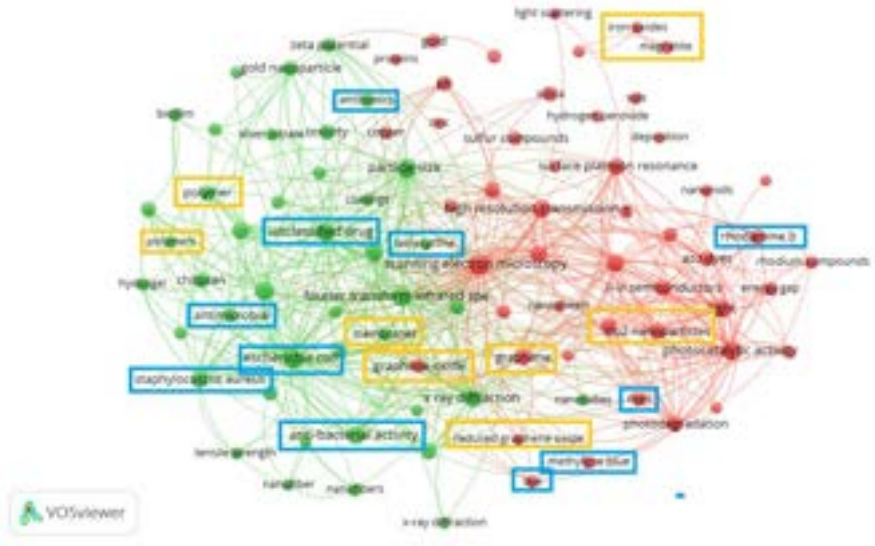

Figure 1. Bibliometric analysis of the terms “silver nanoparticles” and “water treatment”.

3. Experimental

3.1. Sample preparation

Fe_3O_4 nanoparticles were synthesized using a solvothermal method [24], Fe_3O_4 was synthesis at pH 12 by the addition of $FeCl_3$ and $FeCl_2$. The magnetic material was washed with water and dried at 80ºC.

The synthesized Fe_3O4 nanoparticles were then dispersed in distilled water, and added to the NaH_2PO_4 solution (0,15M, pH = 4.12). And then, $AgNO_3$ aqueous solution (0.15 M) was added with drop by drop to the above solution under continuous mechanical vibration, and then the solution was maintained at room temperature and under continuous mechanical vibration for 4 h. The magnetic material was dried at 200ºC.
The as-prepared Fe_3O_4@ Ag_3PO_4 nanoparticles were separated by an external magnetic field, The final material was washed with water to remove excess phosphate ions. The obtained Fe_3O_4@Ag_3PO_4 was separated by an external magnetic field, then dried for 6 h at 80 °C.

3.2. Analysis

Powder X-ray diffraction (XRD) measurements were obtained on an X-ray diffractometer PANalytical Empyrean diffractometer (Cu Kα1, λ = 1.5406 Å). Crystallite sizes were estimated using the Scherrer equationand the fractions of the different phases were obtained from analysis with Match! 3® software.
UV-vis diffuse reflectance spectra (DRS) was measured using a Varian Cary E5 spectrophotometer in the range 200 – 2000 nm.
SEM microscopic observation allowed the visualization of the ground material surface morphology. For scanning electron microscopy (SEM) measurements a Sigma 300 VP FESEM Zeiss instrument was used. It was equipped with energy dispersive X-ray spectroscopy (EDX).

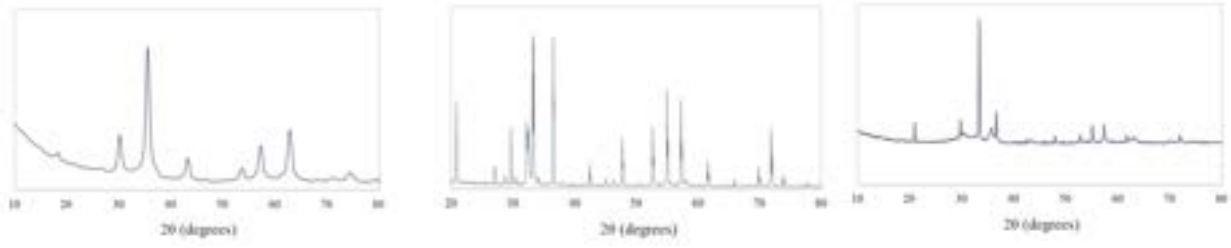
3.3. Degradation experiment

The photocatalytic activities of the samples were evaluated by degradation of MB under a simulated solar lam. A 60 W Hapro Solarium HB175 equipped with four 15 W Philips CLEO fluorescent tubes with emission spectrum from 300 to 400 nm (maximum around 365 nm) and with an average irradiation of about 90 $W \cdot m^{-2}$ was used.. A photocatalyst (0.1 g) was added to an aqueous solution of MB (100 mL, 10mgL−1) at room temperature in air. The suspension was magnetically stirred for 30 min in the dark to establish an adsorption desorption equilibrium to eliminate the influence of adsorption. A lamp was switched on to initiate the reaction. During irradiation, samples were taken at different time intervals for 180 min or until complete degradation was observed. Samples were centrifuged and then the decolorization of MB was measured with a UV–vis spectrophotometer (Cary 60, Varian, USA). To investigate the stability and recyclability of the as-prepared composite magnetic photocatalysts (Fe_3O_4@Ag_3PO_4), recycling experiments were also performed. In the recycling experiments, after the photocatalysts were separated from the solution by an external magnetic field, the remaining solution was removed. Separated photocatalysts were washed five times with distilled water, and then used in the next degradation experiment

4. RESULTS AND DISCUSSION

4.1 Characterization

XRD was used to investigate the phase structures of the samples. Fig. 2. shows typical XRD patterns of the samples at various stages. Fig. 2 shows the XRD pattern of Fe_3O_4 nanoparticles, Fig. 2B shows the XRD pattern of Ag_3PO_4. The successful coating and subsequent crystallization of Ag_3PO_4 and Fe_3O_4 were also confirmed (Fig. 2C).



(a) *(b)* *(c)*

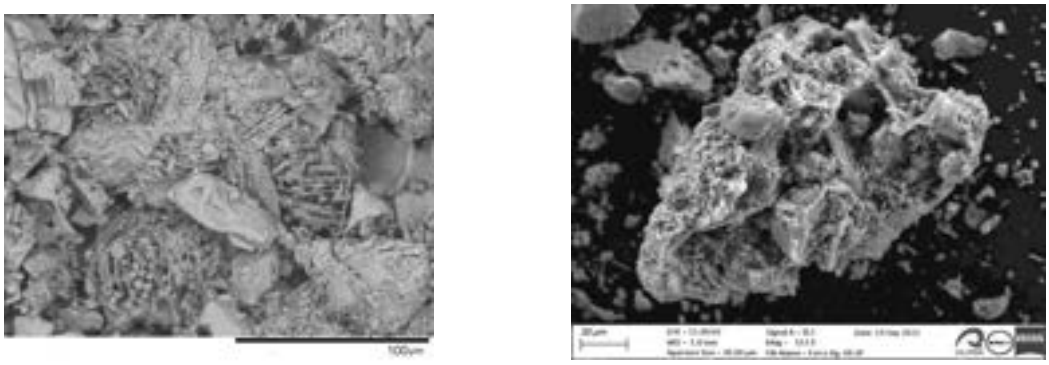
Figure 2. XRD patterns of the samples: (a) Fe_3O_4 spheres, (b) Ag_3PO_4, (c) Ag_3PO_4/Fe_3O_4/γ-Fe_2O_3

For the Ag_3PO_4 material alone, DRX studies revealed that 100% Ag_3PO_4 was present. For the magnetic composite, the phases found in DRX studies were Ag_3PO_4 (47,8%), magnetite, Fe_3O_4 (42,6%) and maghemite, γ-Fe_2O3 (9,5%). Although we initially synthesized Fe_3O_4, it is known that this structure can oxidize to γ-Fe_2O_3, also magnetic, even at ambient temperature. The size of the crystals obtained from Ag_3PO_4 is 54 nm and in the case of Fe_3O_4 and γ-Fe_2O_3 crystals it is 18 nm.

Thus, the maghemite crystalline phase (γ-Fe_2O_3) can be intuited in the diffractograms of the catalysts synthesized by calcination in a nitrogen atmosphere. The formation of maghemite can occur as a consequence of the oxidation of magnetite particles, according to equation 1 [25]. This process can occur at room temperature [26], although it usually occurs more favorably in an oxidizing environment above 200 ºC, with the optimum temperature for maghemite formation being between 375-400 ºC [27].

$$2\ Fe_3O_4 + ½\ O_2 \rightarrow 3\ \gamma\text{-}Fe_2O_3 \qquad (1)$$

The SEM image of the $Ag_3PO_4/Fe_3O_4/\gamma\text{-}Fe_2O_3$ composite is shown in Fig. 3.



(a) *(b)*

Figure 3. SEM Images of: (a) Ag_3PO_4 (b) $Ag_3PO_4/Fe_3O_4/\gamma\text{-}Fe_2O_3$

It is observed that there is a coating of silver phosphate on the ferromagnetite. Table 1 shows the elemental composition of $Fe_3O_4@Ag_3PO_4$ synthesized material.

Table 1. Composition of $Fe_3O_4@Ag_3PO_4$

Element	Weight %	Atomic %	Error %
O K	38.97	71.81	11.71
P K	9.23	8.78	7.67
Fe K	20.63	10.89	7.56
Ag L	31.17	8.52	6.87

UV–vis absorption spectra of the studied catalysts are depicted in Fig. 4. Pure Ag_3PO_4 absorbs solar energy with a wavelength shorter than approximately 500 nm. In contrast to pure Ag_3PO_4, the absorption edge of $Fe_3O_4@Ag_3PO_4$ and Fe_3O_4 generates red shift, $Fe_3O_4@Ag_3PO_4$ and Fe_3O_4 also exhibit higher absorption in the visible region than the pure Ag_3PO_4.

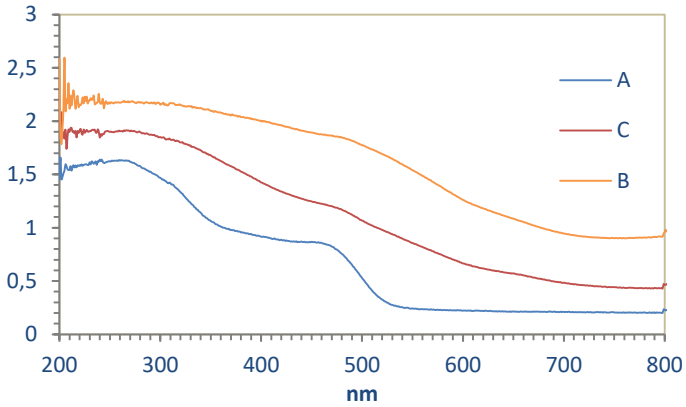


Figure 4. UV–Vis absorption spectra of: (A) pure Ag_3PO_4, (B) pure Fe_3O_4 and (C) $Ag_3PO_4/Fe_3O_4/\gamma\text{-}Fe_2O_3$

The hysteresis curves of the magnetic materials are shown in Fig. 5. We observe that the magnetization saturation is 43 emu·g^{-1} for Fe_3O_4 and 15 emu·g^{-1} for $Ag_3PO_4/Fe_3O_4/\gamma\text{-}Fe_2O_3$.

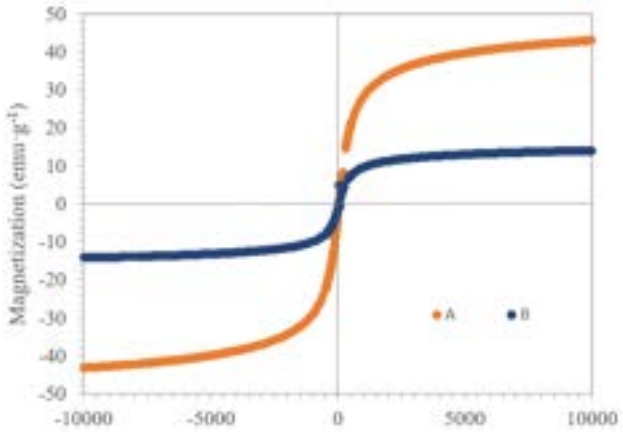

Figure 5. Hysteresis curves of: (A) Fe_3O_4 and (B) $Ag_3PO_4/Fe_3O_4/\gamma\text{-}Fe_2O_3$

4.2 Degradation Experiment

The photocatalytic degradation of MB by $Fe_3O_4@Ag_3PO_4$ under simulated solar irradiation at room temperature was investigated (Fig. 5). For comparison, the Fe_3O_4 and Ag_3PO_4 photocatalyst was also investigated. About 48% of MB was removed by $Fe_3O_4@Ag_3PO_4$ after 180 min irradiation. In contrast, pure Ag_3PO_4 exhibited the highest photocatalytic activity of the catalysts, about 96% of MB within 180 min under simulated solar irradiation.

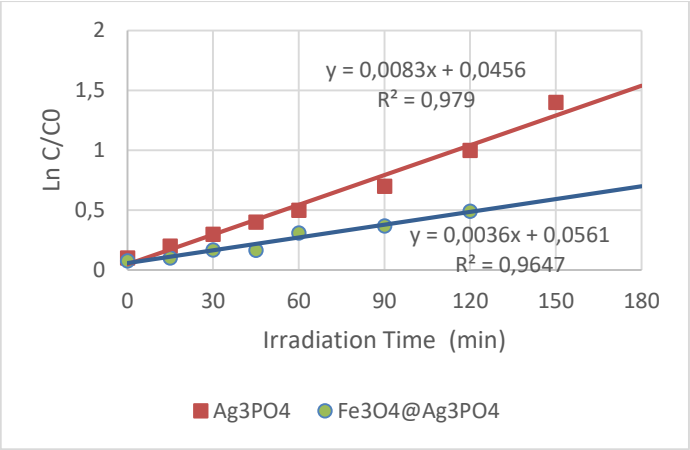

Figure 5. Photocatalytic degradation of MB over Fe_3O_4 spheres, pure Ag_3PO_4 and Fe_3O_4@Ag_3PO_4

The apparent fist-order reaction rate constant for the degradation of methylene blue was 0.0077 min^{-1} for Ag_3PO_4 and 0.0034 min^{-1} for Ag_3PO_4/Fe_3O_4/γ-Fe_2O_3. No photolysis was observed under the studied conditions.

4.3 Separation and reuse

The recyclability of the magnetic photocatalysts was investigated. The Fe_3O_4@Ag_3PO_4 photocatalysts can be rapidly separated under an applied magnetic field in 20 s.

Fig. 6 shows the recyclability of the Fe_3O_4@Ag_3PO_4 for photocatalytic degradation of MB. The degradation activity of Fe_3O_4@Ag_3PO_4 decreased sharply only after 1 cycle.The decoloration efficiency decreased to about 32%, 25%, 19% and 14% for the 2nd, 3rd,4th and 5th degradation cycles, respectively.

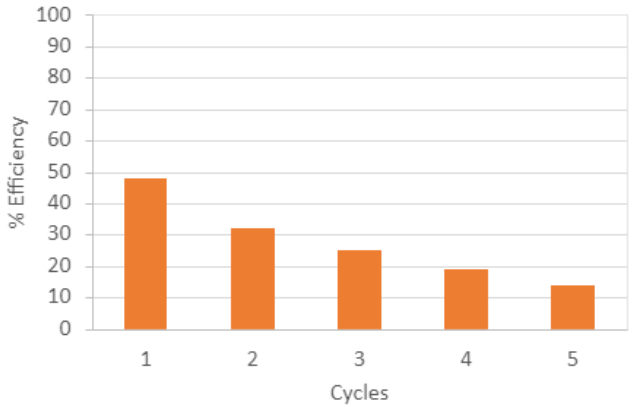

Figure 6. Recyclability of the Fe_3O_4@Ag_3PO_4

Efficiency decreases with reuse, it can be observed that the catalyst darkens due to the photocorrosion of silver by irradiation. This occurs because silver phosphate is slightly soluble in water, and silver ions can react with the generated photoelectrons reducing to elemental silver [28].

5. Conclusions

Ag_3PO_4 was synthesised and satisfactorily supported over Fe_3O_4/γ-Fe_2O_3. The photodegradation of 10 mg·L^{-1} of methylene blue was achieved, although the apparent reaction rate constant was slightly lower for the magnetic composite than for the Ag_3PO_4 alone. This is explained because the composite contained 47.8% of the active Ag_3PO_4 material, as depicted form DRX studies.

Acknowledgments

This research was funded by Fundación Cajadecanarias and Fundación La Caixa through the project “Aplicación de nanopartículas a los procesos de tratamiento de aguas” (NAPLAGUA), with grant number 2021ECO14, Call for Research Projects 2021, with the collaboration of the company Ancor Tecnologica S.L. This project began in February 2022 until February 2024, with José Jaime Sadwani Alonso as the principal investigator.

Abstract:

Membrane technologies are currently one of the promising strategies to face the continuously increasing CO_2 accumulation in the atmosphere and the associated environmental impact. They have become an alternative for separating and absorbing CO_2 due to their low cost and relatively more straightforward preparation. Polysulfone (PSf) is one of the most common polymers for its commercial availability, processing, and favourable selectivity-permeability characteristics. PSf were blended with a commercial hyperbranched polyethyleneimine Lupasol, modified with benzoyl chloride or phenyl isocyanate with several percentages to improve their performance in terms of direct CO_2 capture. All the membranes were prepared by phase inversion precipitation. The morphology, thermal properties, molecular motion, and conductivity were analyzed. The blended membranes show differences in the microstructure, and the presence of urea and amide groups promoted a considerable increment in the efficiency of the CO_2 capture process compared to the neat membrane due to the enhancement in hydrophilicity and chemical stability. In composite membranes, the absorption capacity is controlled by the conductivity, chemical affinity to CO_2, and morphology of the membranes. The phenyl isocyanate improves the motions of hyperbranched polyethyleneimine in blended membranes facilitating CO_2 direct air capture.

Keywords:
CO_2 air absorption, Asymmetric Polysulfone/hyperbranched polyethyleneimine membranes, morphological, thermal, dielectric, and conductivity analysis.

1. Introduction

Since the beginning of the 21st century, global Greenhouse gas (GHG) emissions have been increasing. GHG traps heat and makes the planet warmer. Human activities such as burning fossil fuels for electricity, heat, and transportation are responsible for almost all of the increase in GHG in the atmosphere over the last 150 years. The Emission Database for Global Atmospheric Research indicated that in only two decades, the global emissions from carbon dioxide have been increasing, rising by approximately 50% of emissions to the atmosphere. If carbon dioxide emissions are not drastically reduced, the increase in temperature is accelerating and is projected to be at the 1.5 °C level within 15 to 20 years. The United Nations International Panel on Climate Change (IPCC) indicated that exceeding a 1.5 °C temperature increase will be catastrophic with consequences of unprecedented flooding, drought, rising sea level, heat waves, and famine [1-2].

There is no single solution to remove carbon dioxide from the air and reduce GHG; no technology is enough to avoid the effects of climate change. Between them, capturing and storing carbon dioxide and its subsequent use may be a possible solution. Nevertheless, this implies that the carbon dioxide must first be captured at atmospheric pressure and stored efficiently.

An interesting technology is a membrane separation-based CO_2 capture system. It uses permeable and semipermeable materials that selectively transport and separate CO_2 from other components in the gas

stream. This separation process is efficient because it does not involve a phase change, leading to low energy consumption. Other advantages over other capture technologies are their compact design and simplicity since adding chemical agents is unnecessary. However, this method also presents disadvantages; it must resist impurities and harden ageing. Recently, a new hybrid technique has been developed; it combines membrane separation and solvent absorption processes with an effective CO_2 absorption in a contactor device. It is also a tiny modular system that can be easily assembled and integrated into other devices [3-6].

Currently, amines are the most efficient and cost-effective materials for carbon dioxide capture. It is commonly mentioned that primary amines are more reactive toward CO_2. However, the basicity of amines is the most critical factor affecting CO_2 capture performance due to the acid/base reaction between CO_2 and amines. Therefore, capturing CO_2 using solid polymeric adsorbents, such as polyamines, is a promising alternative to avoid the problems associated with aqueous amine adsorbents. Amines and aminic compounds have found wide applications as CO_2-removing agents due to the reversible reaction between aminic groups (basic) and CO_2 (acidic). Other commercial options are used Polysulfone (PSf) as basic material because have remarkable hydrolytic stability that sets them apart from other thermoplastics. In addition, it is a high-performance thermoplastic polymer with excellent physical properties at high temperatures. Their characteristics are rigidity, excellent thermal, mechanical, and oxidation resistance, and a high glass transition temperature [6].

This paper aims to increase the performance of Polysulfone membrane contactors by blending comercial PSf with a commercial, hyperbranched polyethylene imine, specifically. Lupasol G20 is a water-soluble polymer; this could prevent membrane preparation from a water coagulation bath as previously described for neat PSf and membrane stability in contact with the storing aqueous. The presence of the basic nitrogen atoms should increase the membrane affinity for carbon dioxide, thus improving its capture and permeability concerning PSf. On the other hand, hyperbranched polyethyleneimine Lupasol G20 is, modified with benzoyl chloride or phenyl isocyanate to enhance the molecular motion and facilitated CO_2 direct air capture. Broadband dielectric spectroscopy (BDS), through the analysis of the molecular motions and the dielectric conductivity, is a suitable technique to determine the reorientation of the permanent dipoles present on the side chains and on the backbone of polymeric materials, which might provide insights into the mobility of the CO_2 in the membranes and tuning the suitable composition of benzoyl chloride or phenyl isocyanate in the blend.

2. Materials and Methods

2.1. Materials and membrane preparation

The used materials are:

Polysulfone (PSf), with a molecular weight of 35,000 Da, was purchased from Sigma-Aldrich.
Lupasol G20, provided by BASF, has a molecular weight of 1300 Da.
Additive 1 is a chemically modifying Lupasol G20 with benzoyl chloride.
Additive 2 is Lupasol G20 chemically modified with phenyl isocyanate.
A phase inversion process at ambient conditions prepared all polysulfone-based membranes. 1-Methyl-2-pyrrolidone (NMP), purchased from Sigma-Aldrich, was used to dissolve 20 g of PSf/G20 mixture (1 and 2,distinctly) so that the total polymer concentration was set at 20% by weight concerning the total weight of the polymer solution. The polymer mixtures were stirred for 48 h. The polymer solutions were then cast on glass support using a 250 µm thick caster blade. Immediately afterward, they were placed in a coagulation bath containing non-solvent water, where the membranes were precipitated by the exchange between the solvent (NMP) and the non-solvent. The resulting flat membranes were removed from the coagulation bath, washed with distilled water, and air-dried overnight [7].

In this way, five different membranes were prepared, one of pure Polysulfone M0, two membranes with 2% and 10% of additive 1 (M1-2%; M1-10%), and two membranes with 2% and 10% of additive 2 (M2-2%; M2-10%).

2.2. Field Emission Scanning Electron Microscopy (FE-SEM)

The surface of the prepared membranes was evaluated through Field Emission Scanning Electron Microscopy (FE-SEM). The membranes, previously vacuum dried, was platinum sputter-coated for 10 s using a Leica EM MED020 coater. Surface electronic micrographs were taken in a Zeiss Ultra 55 at 295 K with a 1 kV voltage.

2.3. Differential scanning calorimetry (DSC)

The surface of the prepared membranes was evaluated through Field Emission Scanning Electron Microscopy (FE-SEM). The membranes, previously vacuum dried, was platinum sputter-coated for 10 s using a Leica EM MED020 coater. Surface electronic micrographs were taken in a Zeiss Ultra 55 at 295 K with a 1 kV voltage.

2.4. Broadband Dielectric Spectroscopy (BDS)

The impedance measurements were conducted using a Novocontrol Broadband Dielectric Impedance Spectrometer (BDS) connected to a Novocontrol Alfa-A Frequency Response Analyzer. All the measurements were obtained under isothermal conditions by increasing in steps by 10 K. The sample electrode assembly (SEA) consisted of two stainless steel electrodes filled with the sample and was directly placed in the cell.

The dielectric spectra were analyzed in terms of the complex permittivity (e*) using as many Havriliak Negami (HN) functions as needed. All the characteristic parameters of each relaxation process were determined as shown in Equation 1:

$$\varepsilon^* = \varepsilon_\infty + \frac{\Delta\varepsilon}{(1 + (i\omega t)^a)^b} \qquad (Eq.1)$$

Where:

τ is the Havriliak-Negami relaxation time. The a and b parameters correspond to the width and asymmetry of the relaxation peak. Δε is the value of the relaxation strength [8-10].

The conductivity response to an applied electric field of a polymer consists mainly of frequency-dependent and frequency-independent components. The former is ascribed to the DC conductivity and shows a frequency independent plateau. In contrast, the latter is attributed to the AC conductivity and is characterized by a high dispersion at higher frequencies. This behaviour can be modelled by the universal dynamic response model, as shown in Equation 2.

$$\sigma(\omega) = \sigma_{DC} + A\omega^n \qquad (Eq.2)$$

3. Results and Discussion

3.1. Morphology

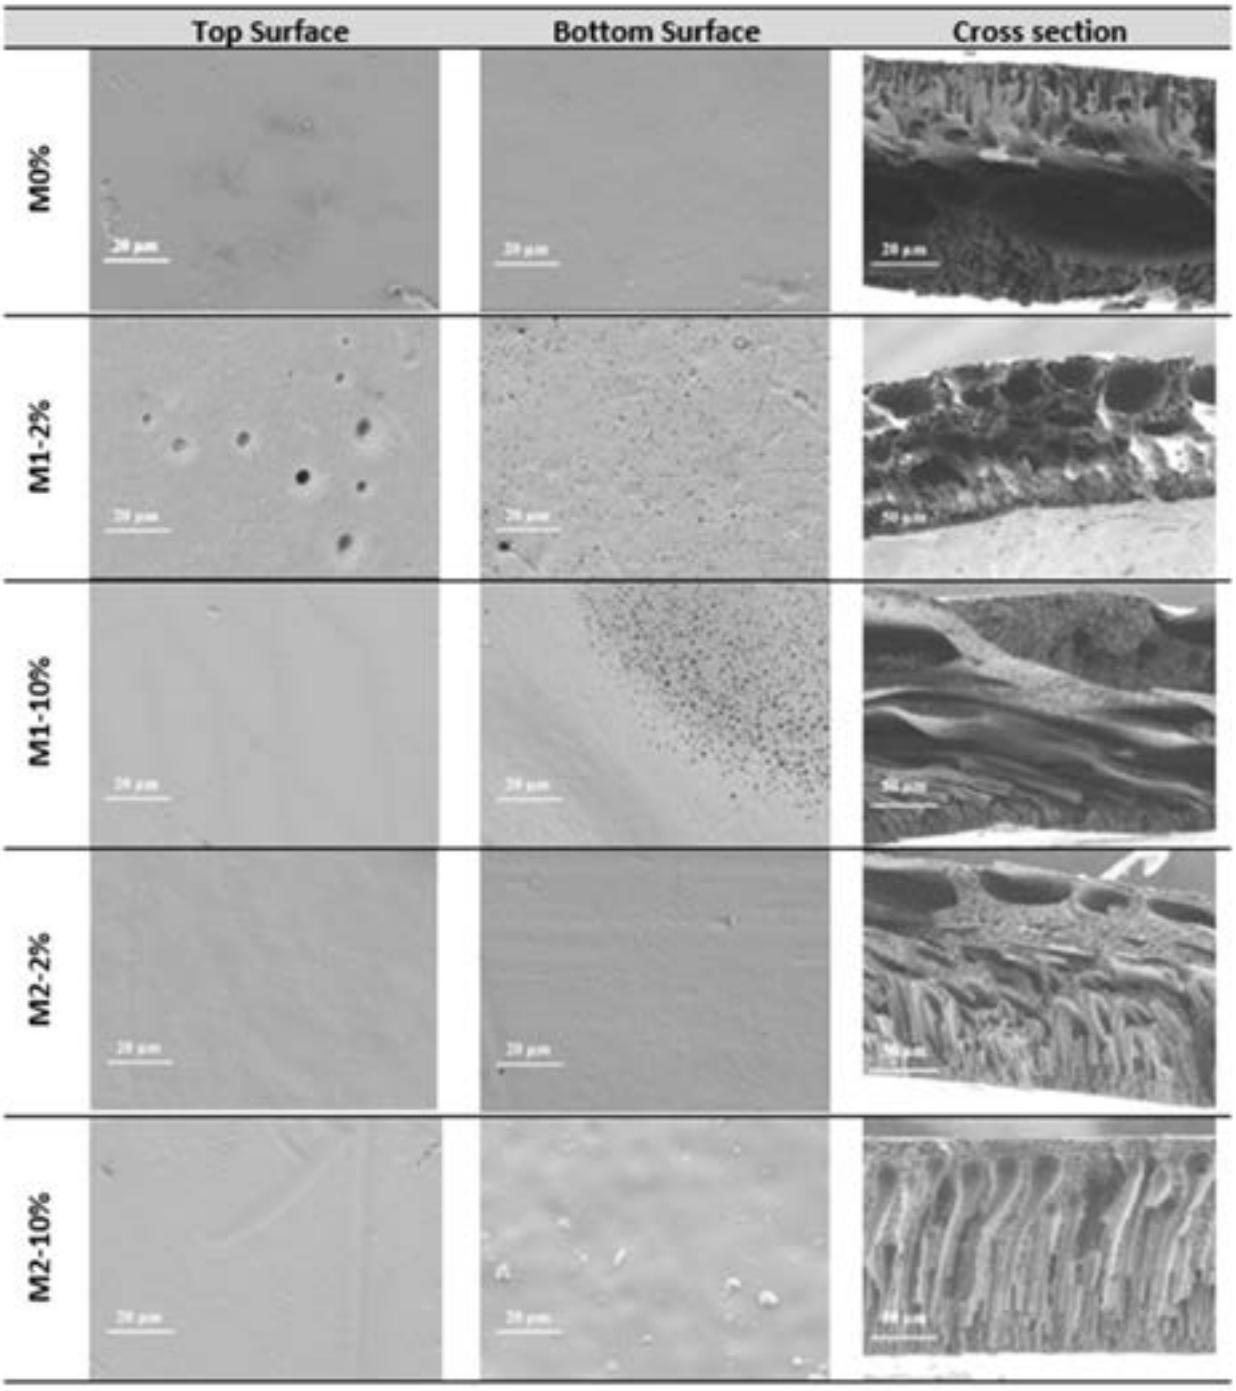
The surface of the samples was analyzed at a microscopic level. Table 1 displays these results. All the membranes present a smooth appearance, with minor roughness marks that could be due to the phase inversion process. The membrane M1-2% shows an active layer with small holes. The back layer of the pure membrane without additive, M0, and the M2-2% membrane, the surface is practically smooth, without any defects. However, the M2-10% membrane presents minor flaws. In contrast, tiny pores are observed along all or part of the surface in membranes with additive 1, M1-2%, and M2-2%.

The cross-section shows that the pure membrane without additive, M0, presents a channel-shaped structure on a porous and dense matrix. In contrast, the channel-shaped structure disappears in the M1-2% membrane, only observing that porous matrix. On the other hand, by increasing the amount of modified Lupasol additive, the morphology of the membrane changes, with the M1-10% membrane showing an evident spongy layer with a much denser layer.

Therefore, it can be affirmed that the morphology of the membrane becomes denser with a higher content of additive 1. The precipitation rate during the phase inversion process predominantly affects the membrane morphology.

Table 1.

Superficial morphology of blended polysulfone membranes



Rapid precipitation is determined by the rapid penetration of the non-solvent into the polymer solution and gives rise to highly asymmetric structures with channel-shaped macrovoids; a slower penetration of the coagulant, and consequently slower precipitation, produce spongy and more symmetrical structures. Thus, the more closely related the polymer and coagulant are, the slower the precipitation and the more symmetrical structures can be expected. The modified Lupasol additive is a relatively hydrophilic and polar polymer; when mixed with PSf, it decreases the polymer solution's precipitation rate [7].

Regarding the samples with additive 2, it can be observed that the M2-2% membrane presents a morphology very similar to the pure sample, M0, with a structure of finger-shaped channels and a dense porous layer. By increasing the additive content, M2-10%, it can be seen that the porous matrix disappears, leaving only the finger-shaped structure for the pores. The number of microvoids remains the same as the modified Lupasol content increases. The membrane's rapid precipitation can explain the pores' internal

structure during phase inversion. This internal structure is due to the rapid penetration of water, as a non-solvent, into the solvent-containing polymer solution.

Consequently, the morphology of the membrane is an asymmetric structure with finger-shaped pores. Since modified M2-10% is a hydrophilic polymer, it should contribute to faster precipitation of PSf-based membranes and leads to a more porous structure, which may enhance CO_2 absorption. Nevertheless, the additive structure and composition favour the interaction and absorption of CO_2.

3.2. Thermal properties

Table 2 presents the glass transition temperatures obtained from the corresponding thermogram in the different heating and cooling scans.

Table 2.
Glass transition temperature values of membranes (M0, M1-2%, M1-10%, M2-2%, and M2-10%).

	1st Heating	Cooling	2nd Heating
	T_g (K)	T_g (K)	T_g (K)
M0	475	452	474
M1-2%	469	437	465
M1-10%	473	446	469
M2-2%	471	444	469
M2-10%	476	447	475

The first heat shows the material with this thermal history. The cooling step imposes a standard thermal trace on the material, so the second heat makes it possible to compare the materials directly. Table 2 shows that glass transition values in the second heating are lower than in the first heating and more uniform among themselves. Considering the DSC curves corresponding to the second heating cycle, it can be observed that the glass transition temperature of the pure membrane without additives, M0, is higher than blended membranes. However, the glass transition temperature increases again as the additive increases. In both cases, the additives have a. Nevertheless, the hyperbranched polyethyleneimine might block the movement of the main chain and reduce the plasticizing effect.

3.3. Analysis of the dielectric spectra

The dielectric relaxation spectrum of each of the membranes (M0, M1-2%, M1-10%, M2-2%, and M2-10%) was studied in terms of loss tangent (tan d), the real and imaginary part of the complex dielectric permittivity (e'), (e'') respectively as a function of frequency and temperature. Figure 1 shows the values of (e ') increase when the temperature increases and the frequency decreases in all the membranes. However, the dielectric spectrum is more complex in the blended membranes due to the motions of hyperbranched polyethyleneimine together with polysulfone chains. It is especially relevant for lower frequencies because the relaxation of both components is more separated.

Figure 2 presents the isothermal dielectric relaxation spectrum in terms of the loss tangent as a function of frequency. Since all isothermal curves are represented on the same scale, the M0 membrane without additive shows higher loss tangent values than M1-2%, M1-10%, and M2-2% additive membranes. Specifically, the loss tangent values are very similar at low temperatures for all the membranes studied. In contrast, the isothermal curves that present the most similar behaviour at high temperatures correspond to the membranes M0, M1-2%, and M1-10%.

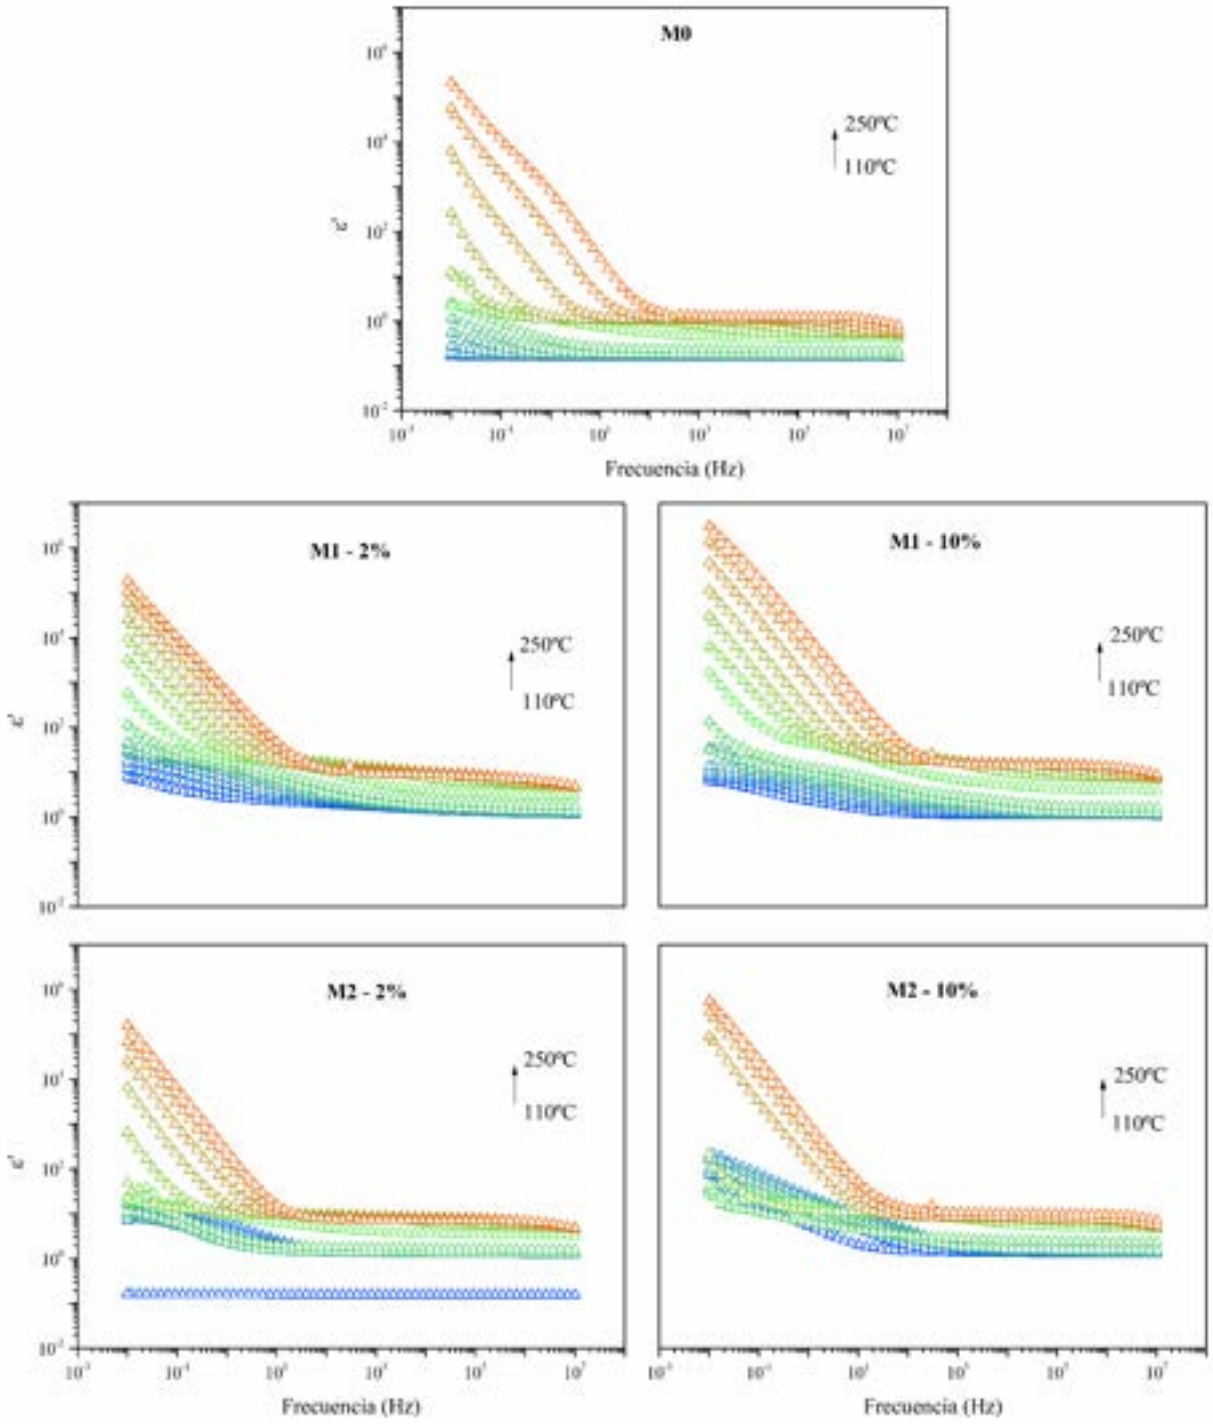


Figure 1. Isothermal curves in terms of the real part (ε') of the complex dielectric permittivity (ε*) for the membranes (M0, M1-2%, M1-10%, M2-2%, and M2-10%).

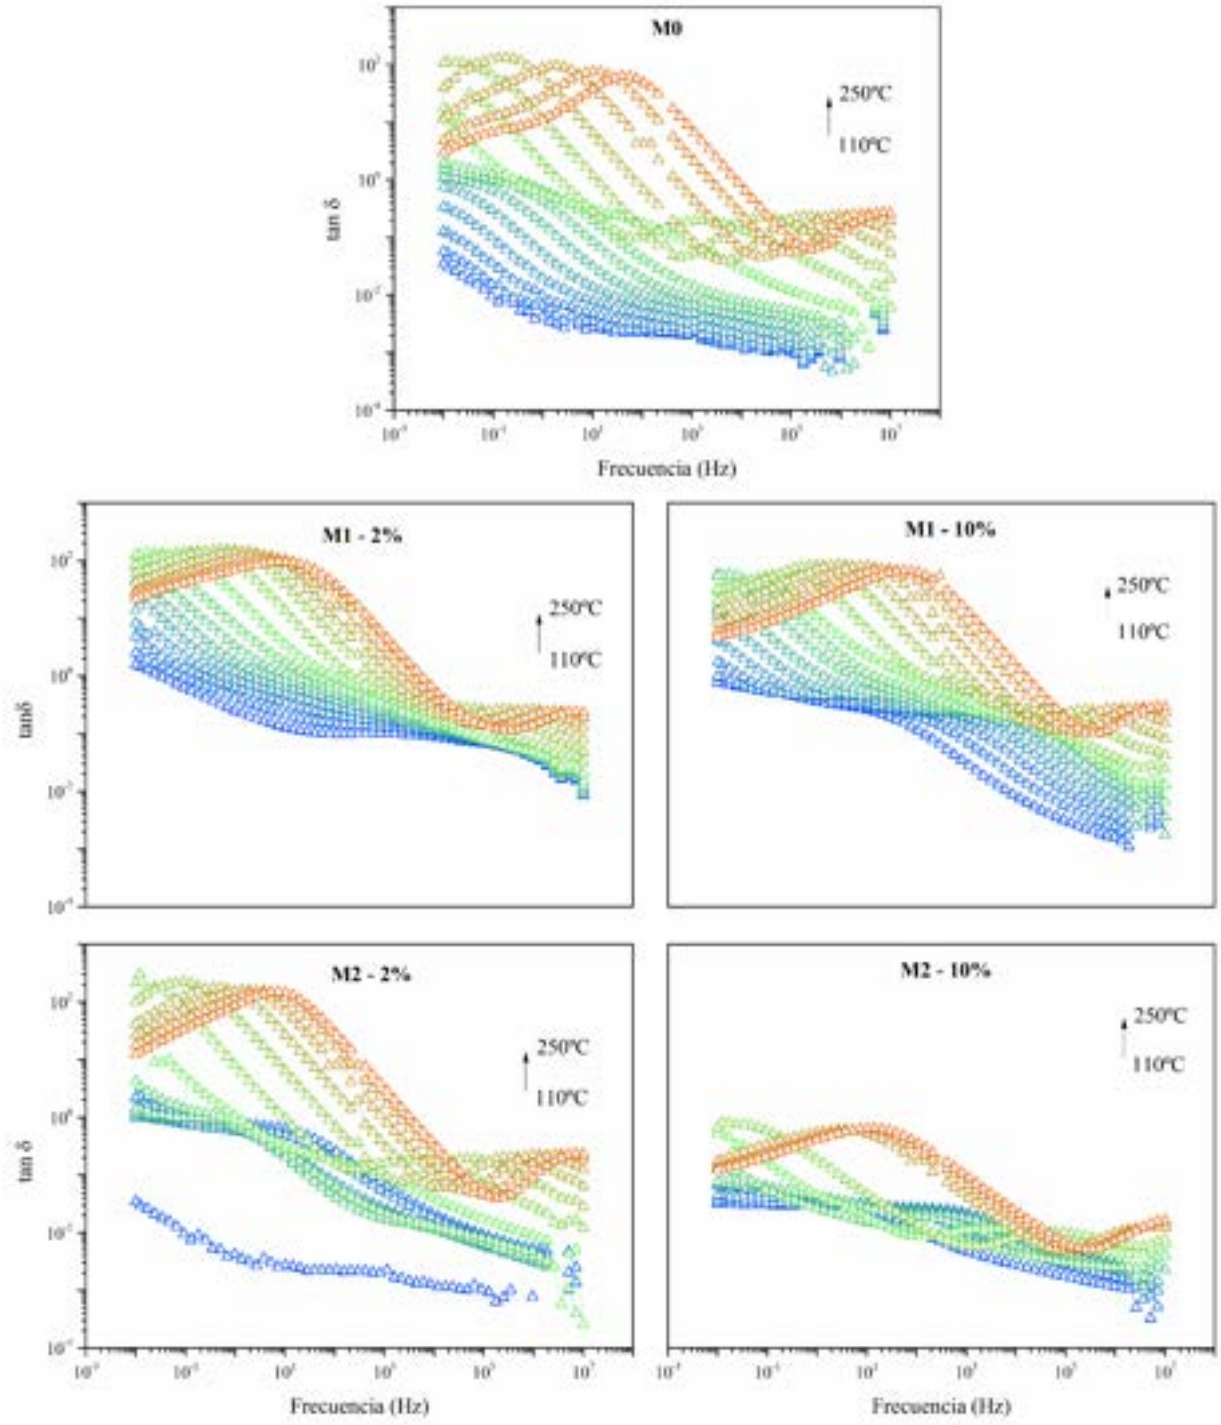

Figure 2. Isothermal curves in terms of the loss tangent (tan δ) for the membranes (M0, M1-2%, M1-10%, M2-2%, and M2-10).

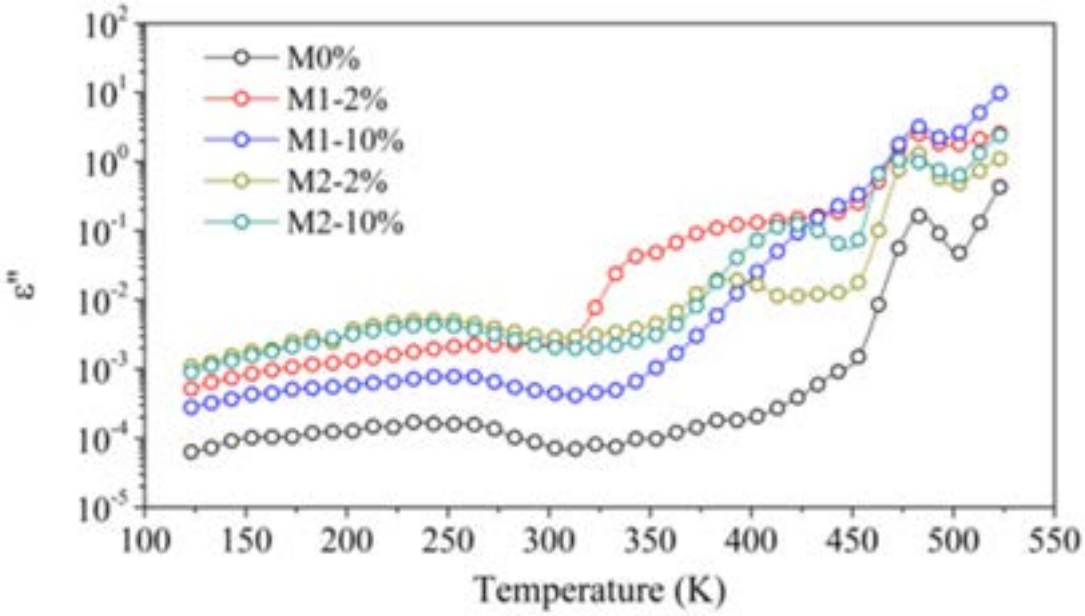

Figure 3. Isochronal curves of the imaginary part (ε'') of the complex permittivity (ε*) of the pure (M0) and blended membranes (M1-2%, M1-10%, M2-2%, M2-10%) at 10 Hz.

Figure 3 presents the dielectric spectrum of the M0 no blended membrane in terms of the imaginary part of the complex permittivity at 10 Hz. Three dielectric relaxation zones γ, ß, and a, with increasing temperature order, are observed to consist of three dielectric relaxations that might be ascribed to motions of local groups and the glass transition of polysulfone (PSf). However, the dielectric spectra of the blended membranes are more complex. Dielectric relaxations corresponding to molecular motions of local and segmental origin of the hyperbranched polyethyleneimine (HPEI) emerge together with the (γ, $ß_{PSf}$, and $α_{PSf}$) dielectric relaxations (transition of polysulfone PSf. The loss factor is higher for the M2-2% and M2-10% membranes than M0, indicating greater mobility of the molecular chains of the mixed membranes.

In order increasing temperature, γ relaxation zone appears between 125K and 223K, and it seems that the loss tangent is independent of the additive concentration in M2-2% and 10%. At higher temperatures, between 393K and 523K, the most prominent relaxations, $α_{PEI}$, and $α_{PSf}$ arise from the motion of the main chains produced by the glass transition of PSU and PEI, respectively. The temperature of $α_{PSf}$ relaxation peak around 483K slightly decreases with the additive concentration, whereas the most remarkable differences appear in the $α_{PEI}$ relaxation. These results confirm the plasticizing effect of hyperbranched polyethyleneimine modified with benzoyl chloride or phenyl isocyanate. The additive imposes fewer steric restrictions on molecular movement. Still, it simultaneously increases the number of chains that can move by plasticizing effect, therefore facilitating the ability of the membrane to diffuse CO_2.

3.4. Analysis of the dielectric spectra

Jonscher's model (Equation 2) quantified the electric conductivity. Table 3 presents the electrical modulus of conductivity, which increases as the temperature increases. Regarding M0, the n-parameter in both regions is equal to 1 and, therefore, is considered the ideal case where long-range pathways for ion transfer are available. Concerning the blended membranes, a more significant dispersion is found regarding the n-parameter.

M1-2% displays the lowest values that are not equal or less than 0.5, which would suggest a high degree of tortuosity, but it reflects that the landscape for ion transfer might not be as favourable as in the case of M1-10%, M2-2%, and M2-10%.

The membranes with phenyl isocyanate additive have the highest values. Note that in this region, the conductivity is higher for the membranes blended with phenyl isocyanate are more polar than benzoyl chloride.

Table 3.
Jonscher's parameters of the pure (M0) and the blended (M1-2%, M1-10%, M2-2%, M2-10%).

	T (K)	σ_{DC} x 10^{15} ($S \cdot cm^{-1}$)	A · 10^{13}	n	R^2
M0%	443	1.7 x 10^1	6.9 x 10^1	1	0.99
	463	1.6 x 10^2	4.3 x 10^1	1	0.99
	503	2.9 x 10^5	3.8 x 10^1	1	0.99
	513	1.5 x 10^6	3.2 x 10^1	1	0.99
M1-2%	373	4.4 x 10^1	1.5 x 10^2	0.86	0.99
	393	2.8 x 10^2	1.7 x 10^2	0.86	0.99
	503	1.1 x 10^7	6.6 x 10^3	0.83	0.99
	513	1.8 x 10^7	2.3 x 10^3	0.89	0.99
M1-10%	373	3.3 x 10^3	1.3 x 10^1	0.95	0.99
	393	1.3 x 10^4	1.7 x 10^1	0.95	0.99
	503	2.5 x 10^7	1.2 x 10^4	0.83	0.99
	513	5.8 x 10^7	5.4 x 10^3	0.89	0.99
M2-2%	373	1.1 x 10^3	4.5 x 10^1	0.96	0.99
	393	1.3 x 10^4	4.9 x 10^1	0.96	0.99
	503	4.3 x 10^6	1.0 x 10^3	0.94	0.99
	513	8.0 x 10^6	1.3 x 10^3	0.93	0.99
M2-10%	373	5.2 x 10^4	4.9 x 10^1	0.96	0.99
	393	3.9 x 10^5	6.2 x 10^1	0.95	0.99
	503	6.0 x 10^6	1.1 x 10^3	0.94	0.99
	513	1.4 x 10^7	1.1 x 10^3	0.94	0.99

The dielectric relaxation spectrum demonstrated that the molecular chain motions of blended membranes are higher than polysulphone membranes. The additive has a plasticizing effect and decreases the glass transition, but this temperature increases as the phenyl isocyanate and benzoyl chloride amount increases. These results agree with the direct air capture CO_2 absorption test carried out in a gas-liquid membrane contactor with the homemade module, as described elsewhere.

Briefly, the prepared membranes were placed in the module, where the top surface was exposed to ambient air by holes in the side of the module. The bottom surface of the flat sheet membrane is in contact with 100 mL of 0.64 M KOH solution as a liquid absorbent in a different flow rate range from 40 to 340 mL/min at room conditions (25 ºC and 1.013 x 10^5 Pa). After one hour, samples were collected, and the absorbed CO_2 amount was determined through a carbon dioxide ion-selective electrode (Hanna HI4105 connected with Thermo Scientific Orion Dual Star pH/ISE Benchtop meter, Thermo Scientific, Waltham, Massacusetts, USA) [11-12].

The CO_2 solubility increases with the addition of modified hyperbranched polyethyleneimine. It is regardless of the additive used (benzoyl chloride or phenyl isocyanate), according to the high affinity of the additive to carbon dioxide. The presence of basic nitrogen enhances the interaction between both molecules. Nevertheless, phenyl isocyanate exhibits higher CO_2 solubility concerning benzoyl chloride. The hyperbranched polyethyleneimine and phenyl isocyanate reaction produce urea groups with more affinities to CO_2. This has been validated through a CO_2 capture device, where a remarkable improvement in comparison with neat PSf (30%) is found. Overall, additive 2 determined better characteristics in terms of CO_2 permeability and capture when compared with additive 1. This information is unpublished (pol.20220773), and the authors are preparing a patent application for the absorption device.

4. Conclusions

Asymmetric polysulfone membranes blending with hyperbranched Lupasol G20 grafted with benzoyl chloride or phenyl isocyanate with 2% and 10%wt were prepared via phase-inversion precipitation to increase their ability for carbon dioxide capture at ambient pressure.

The resulting morphology of the blended membrane presents finger-like macropores together with meso- and micropores and a dense layer, which increases as the additive amount increases. The phenyl isocyanate awards a suitable morphology to improve CO_2 permeability and capture.

The glass transition temperature decreases with the addition of a lower amount of modified hyperbranched polyethyleneimine due to plasticizing effect of the additive. However, this temperature increases as the additive percentage increases.

The dielectric relaxation spectrum demonstrated additives' plasticizing effect and improved the molecular chain motions of blended membranes. The membranes with phenyl isocyanate additive have the highest values of conductivity.

All these results, in turn, indicate the importance of considering all these factors to find the most suitable composition to prepare polysulfone membranes which could favour gas permeation of CO_2.

Abstract:

District energy systems provide many options for integrating renewable energy sources and energy storage systems into residential and commercial buildings. Solar district heating systems (SDHSs) contribute to the deployment of large-scale solar energy-based technologies. SDHS technical challenges during operation may occur due to not optimal control. Nevertheless, they can be overcome with smart control of an integrated heat pump. To address this problem TRNSYS (transient system simulation) software was used to develop the SDHS model; the system operates by employing a smart control approach for the heat pump, which is coupled to thermal storage tanks for domestic hot water and space heating to meet community demand. The methodological approach has been applied to an SDHS in Madrid (Spain) to provide for the heating demands of a neighbourhood that consists of 280 apartments in order to more effectively illustrate the abilities of the proposed control strategy. The present work focuses on the development of a co-simulation framework based on TRNSYS and Python for offline training of a control strategy based on deep reinforcement learning algorithms for a smart agent that will control the integrated heat pump into SDHS with seasonal storage system. The work will consider the life cycle cost analysis for the technical economic evaluation for the proposed control strategy. Results will show if the heat pump DRL-based control offers significant techno-economic benefits, compared to traditional control strategies.

1. Introduction

District energy systems offer various options for integrating energy storage and renewable energy sources into residential and commercial buildings [1]. Solar communities with seasonal thermal energy storage [2] and solar thermal systems [3] are examples of such systems that can facilitate the advancement of fourth and fifth-generation district heating systems [4], [5]. Systems for district heating powered by solar energy help in the deployment of large-scale solar energy-based solutions. In fact, several prosperous large-scale solar district heating systems (SDHSs) are currently in use in nations including Austria, Canada, China, Germany, and Denmark [6]. Tian et al. [7] highlighted two successful large SDHSs. Even though the modeling and design of these systems have been thoroughly studied recently [8], [9], more research is needed to develop advanced control techniques for solar district heating systems.

Techniques for controlling HVAC (heating, ventilation, and air conditioning) are complex due to the way the system's components interact with one another and with the thermal dynamics of buildings. The continuous adjustment of the heating or cooling system while maintaining the comfort levels set by the occupants is one technique to reduce the amount of energy used for space conditioning. The conventional method for control, which is rule-based control (RBC), typically involves simple hysteresis loops that reheat or cool the building every time the temperature reaches a threshold.

Model predictive control (MPC) improves the control technique by allowing the use of predictions from outside variables like the weather, the electricity price, etc. This leads to a wider range and more efficient control compared to RBC. The primary aim is to control building temperature, with cost optimization being a secondary goal. While MPC outperforms RBC regarding its operation capability, it complicates the system and requires the availability of a model that accounts for the system dynamics. Due to the complexity of building thermal dynamics and heterogeneous environment disturbances, the classical rule-based and model-based approaches are frequently ineffective in practice [10].

Another control method is reinforcement learning (RL) which is a model-free approach where the agent learns the optimal action to take by "trial and error" without the need for previous knowledge of the system or process. Model-free methods can operate without a model of the environment [11]. RL techniques can learn by interacting with its environment and do not require any supervision. In recent years and within many fields, RL has become a strong alternative to MPC. The fundamental idea behind RL is that the optimal behavior or action is encouraged by way of a positive reward, while the least desirable action is punished by a negative reward [12], [13].

The drawbacks of conventional RL can be overcome by deep reinforcement learning (DRL), which enhances RL with deep neural networks to approximate the value function and policy function when those are hard to model due to the dimensionality of the problem. Therefore, the DRL approach is more suitable and flexible in terms of control strategies than traditional control approaches. DRL has been utilized extensively in both the business and academic fields, such as, in robotics [14], gaming [15], industrial systems [16], and autonomous vehicles [17].

The present work focuses on the development of a co-simulation framework based on TRNSYS (transient system simulation) and Python for offline training of a control strategy based on deep reinforcement learning algorithms for a smart agent that will control the integrated heat pump and seasonal storage system of a SDHS. The work will consider the life cycle cost analysis for the technical economic evaluation of the proposed control strategy.

2. Materials and method

This section describes the system’s details and the methodology used for system modeling and control.

2.1. Energy system description

An overview of the analyzed systems is presented in Figure 1. The main components of the system are the solar thermal collector (COL), the DHW storage tank (DHWT), a half-buried sensible seasonal storage tank (SST), an auxiliary natural gas heater (AUX), and a water-to-water heat pump unit (HP). This SDHS model was designed and based on the system proposed by Abokersh et al. [18] and Tulus et al. [19].

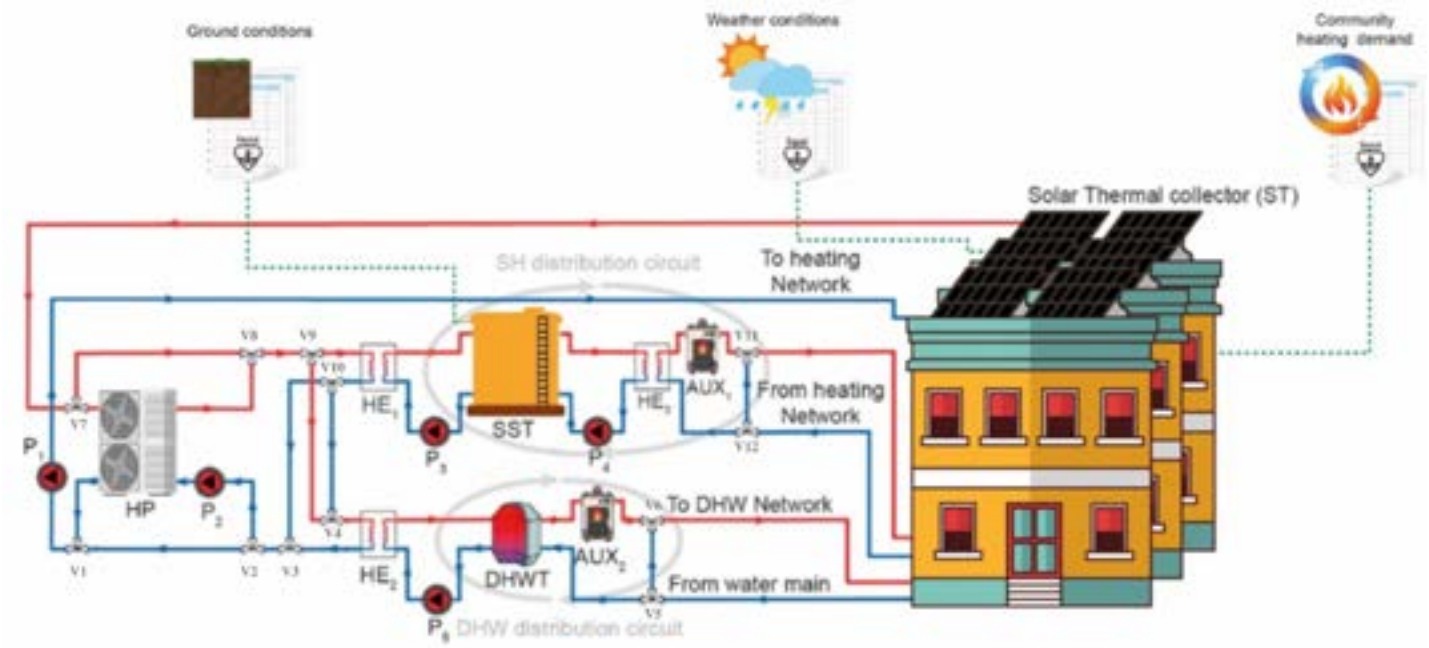

Figure. 1. An overview of the HP with SDHS integration's design.

As seen in Figure 1, the heat pump (HP) functions as a heat source for the SST when connected with the solar field circuit. In this arrangement, the district's space heating (SH) or domestic hot water (DHW) demand can be accomplished efficiently by the thermal energy collected from the COL or it can be stored in the SST. An adequate design of the heat pump that is incorporated in SDHS is required to meet the SH and DHW needs of a hypothetical residential neighbourhood throughout the year. The heat from solar collectors is transferred to the DHWT in the DHW operation mode, with the intervention of P1, P2, and P5 pumps through and switching on the following valves V1, V2, V3, V4, V5, V6, V7, V8, and V9. The AUX2 is activated with the help of V5 and V6, when solar thermal energy is insufficient to meet the demand in the DHW network. The HP unit is inactive while in DHW mode. In SH operation mode, heat is transferred from ST to SST through HE1 using pumps P1, P2, and P3 and valves V1, V2, V3, V8, V9, and V10. Under particular circumstances, the heat generated by the HP is either provided to the SST for charging up the heat stored or delivered directly to the SH. While the daily DHW demand is supplied by the short-term storage DHWT, the SH demand is supplied throughout the winter by the SST. Here, it is crucial to remember that the heat provided for the SH is at a low-temperature level (50 °C), whilst the heat supplied for the DHW is at a high-temperature level (60 °C). Finally, the auxiliary heater acts as a supplement if the solar field, SST, and HP are incapable of providing the required amount of heat.

2.2. Co-simulation TRNSYS-Python framework

TRNSYS (transient system simulation) program is a tool, for simulating an energy system's dynamic behavior. In the simulation studio, TRNSYS's components are linked graphically to solve algebraic and differential equations. The TRNSYS simulation environment's dynamic nature helps to introduce the SHDS model in a more realistic manner. This software does, however, have significant limitations when it comes to the development and optimization of HVAC system control. Some intelligent control algorithms, such as DRL-based control approaches, are inconvenient and difficult to use directly in the built-in software [20].

In order to address this issue, a co-simulation testbed with a SDHS TRNSYS model and DRL-based control approach has been built in order to enable dynamic data transfer and interaction between these two systems as depicted in Figure 2. As DRL-based training requires a large amount of training data, (i.e., of simulations), those simulations would have to be done in parallel to maximize computational resources usage and to reduce the required time for the experimentation. In order to control such simulations and to be able to train the DRL control software, they have been developed, following the de facto standard for DRL training, as a Gym environment [21].

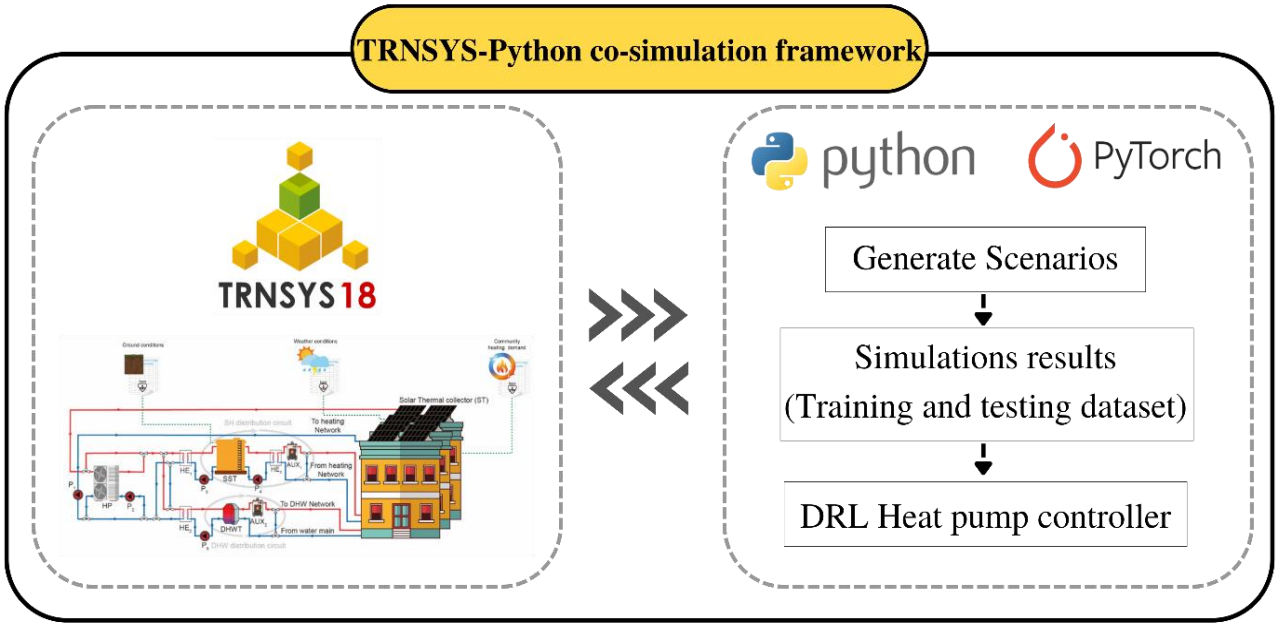

Figure. 2. TRNSYS-Python co-simulation framework.

2.3. Life cycle cost analysis

In the present study, the life cycle costing (LCC) methodology is employed to conduct the economic evaluation of the proposed control strategy of the integrated heat pump integration into a community sized SDHS, which is based on the work of Tulus et al. [19] and Abokersh et al. [18].

The fundamental concept of the LCC technique involves using a future cost approach. This involves calculating the present value of all the expenses incurred over the lifespan of the system, using a discounting method. By adding the initial capital cost (IC), operational cost (OC), maintenance cost (MC), and total equipment replacement cost (RC), we can estimate the net present cost (NPC).

$$NPC = IC + OC + MC + RC \tag{1}$$

The initial capital cost refers to the cost of investment at the beginning of a project. This cost includes the cost of purchasing the equipment, its installation and transportation, as well as any contingencies expenses:

$$IC = (1 + \alpha_{CF}) + \sum_K (PEC_K . FBM_K) \tag{2}$$

In the given equation, PEC_k refers to the initial cost of purchasing equipment unit k, FBM_k represents the bare module factor that takes into account the costs associated with installation and transportation, while α_{CF} is the contingency fees factor. The PEC_k value is adjusted to its present value from the base year (year A) to the year of installation (year B) using the Chemical Engineering Plant Cost Index (CEPCI) [19], with the help of the following equation:

$$PEC_K = PEC_K^{year\ A} \frac{CEPCI^{year\ B}}{CEPCI^{year\ A}} \quad \forall k \tag{3}$$

The operational cost (OC) refers to the total amount of yearly operating expenses that includes the maintenance costs for various equipment units and facilities, the consumption of electricity by hydraulic equipment, and the usage of natural gas by auxiliary heaters. This cost can be stated using the following equation:

$$OC = C_M PWF_M + C_P PWF_P + C_{AUX} PWF_{AUX} \tag{4}$$

In the given equation, C_M, C_P, and C_{AUX} represent the yearly expenses associated with maintenance, hydraulic equipment (such as pumps), and auxiliary consumption costs, respectively. To account for inflation and the time value of money, the present worth factor (PWF) is calculated, taking into consideration the proposed system's lifetime (Ne), inflation rate (i), and discount rate (d), which can be expressed as follows:

$$PWF = \begin{cases} \frac{1}{d-i}\left[1-\left(\frac{1+i}{1-d}\right)^{N_e}\right] & \forall_i \neq d \\ \frac{N_e}{1+i} & \forall_i = d \end{cases} \quad (5)$$

During the operation of the proposed SDHS, certain pieces of equipment have a high rate of depreciation and will require replacement. The cost of replacing them can be calculated using the following equation, which takes into account the present value of the equipment:

$$RC = PVF_n \sum_K (PEC_K . FMB_K) \quad (6)$$

The present value factor of future cash flows in year n is denoted as PVF_n. In this present work, the solar collectors, DHW storage tank, heat pump, heat exchangers, and auxiliary heaters are among the equipment that will require replacement due to their fast depreciation rate over the system's lifetime. PVF_n can be expressed as follows:

$$PVF_n = \frac{(1+i)^n}{(1+d)^n} \quad (7)$$

2.4. Case study

The methodological approach has been applied to an SDHS in Madrid (Spain) to provide for the heating demands of a neighborhood that consists of 10 buildings in order to more effectively illustrate the abilities of the proposed framework. This case study has already been described in a former article where more details can be found [18]. Each building has 28 apartments, each of which has 90 m^2 of usable space [22] and is equipped with a DHW system and radiant underfloor heating system to meet the requirement for space heating (SH) and domestic hot water (DHW) at 50 °C and 60 °C, respectively. Each building requires yearly 191.34 MWh of heating. Based on Tulus et al. [19] and Abokersh et al. [18], the proposed SDHS was previously validated.

2.4.1. Heating demand profiles

In order to compare the proposed DRL-based control strategy to the rule-based control strategy in Abokersh's study [18] the SH and DHW inputs will remain the same. Figure 3 shows the monthly DHW and SH demand for a neighborhood in Madrid that consists of 280 residential apartments.

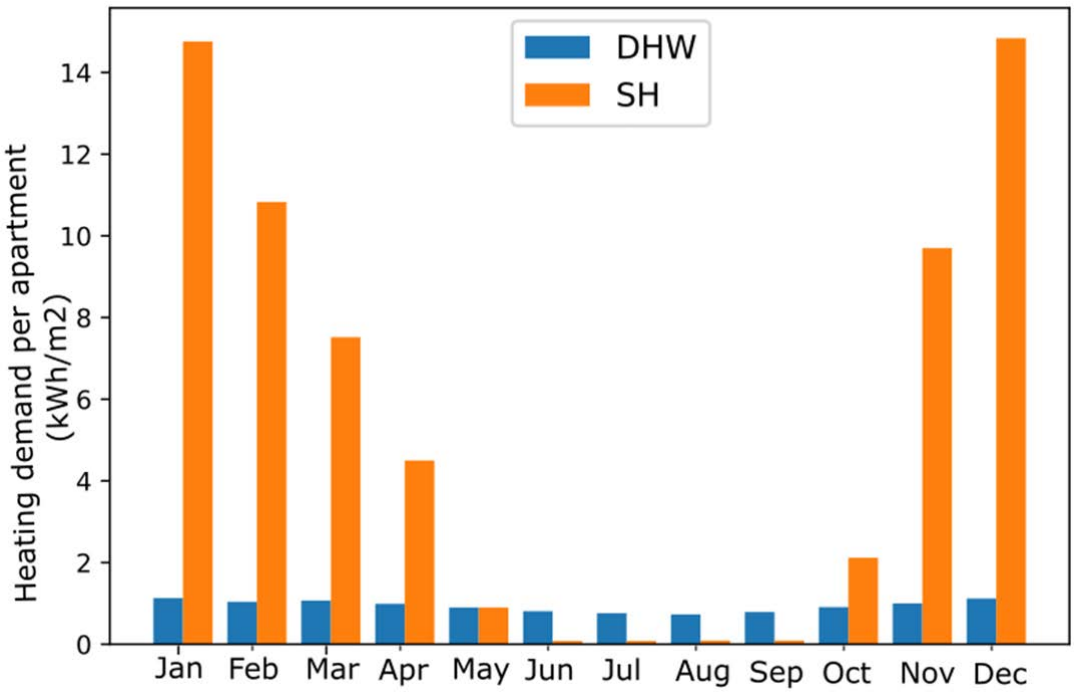

Figure. 3. Demand profiles for domestic hot water and space heating per month for a neighbourhood of 280 apartments in Madrid.

The Energy Plus database is used to gather the weather data for Madrid. This includes the incident solar radiation, ambient temperature, relative humidity, and other pertinent information.

3. Results

In this phase, using the Madrid case study in a residential community of 280 apartments the design variables of various equipment components are taken into account. While formulating the optimization problem, we are testing whether the HP smart control strategies can improve the techno-economic viability of SDHS.

Figure 4 illustrates the optimum system costs for various Net Present Cost terms and payback periods. A clear tradeoff between the proposed objective functions is indicated since the movement from scenario 1 to 5 at both traditional controls (A) and (B) increases the total cost. Thus, Abokersh et al.[18] Pareto's optimal solutions appear to provide a modest economic benefit that provides an opportunity to make improvements on system controlling, which is the objective of our proposed smart control strategy using the deep reinforcement learning algorithm.

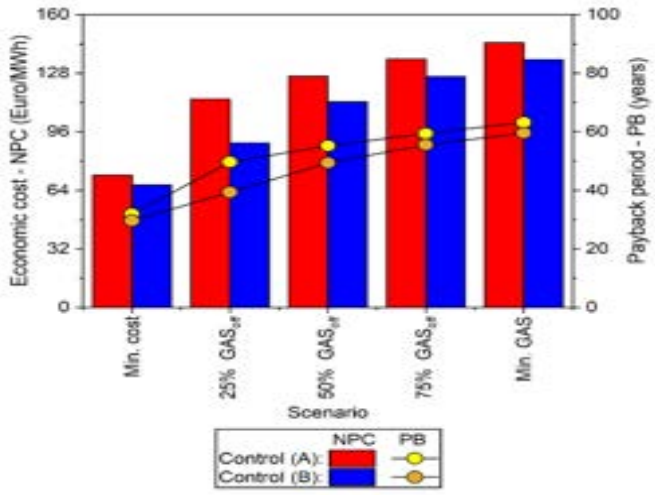

Figure. 4. The economic benefits and the payback period for the optimal Pareto solutions of the HP integrated with SDHS under control strategy (A) and (B) *[18]*.

In addition to calculating the financial gains, the proposed methodology also determines how each technology can operate at its optimal level. Hence, a figure will be illustrated to depict the percentage of grid electricity, fossil fuels (natural gas), and solar energy, following the example in Figure 5.

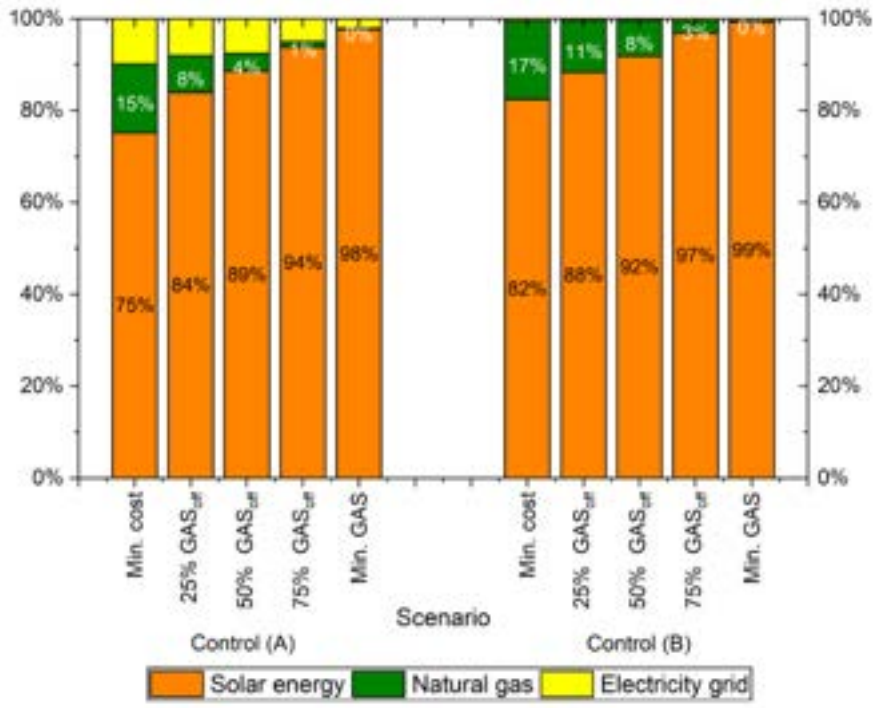

Figure. 5. The share of technologies for the optimal Pareto solutions of the HP integrated with SDHS under control strategy (A) and (B) *[18]*.

We are currently starting the model training and hope to have the results ready when the conference takes place.

4. Conclusions

The current study aims to develop a dynamic model for a solar district heating system (SDHS) integrated with a heat pump in Madrid (Spain), to provide the heating demands of a small community of 280 apartments. A co-simulation framework using TRNSYS, and Python was developed to evaluate the benefits of a smart control strategy based on a deep reinforcement learning algorithm, which will control the heat pump. The current situation can be characterised by concluding the methodology development and initiating the model training. The following step will be to evaluate the control strategy from an economic point of view by way of the life cycle cost analysis.

The aim of this study is to assess the advantages of the proposed smart control strategy using artificial intelligence in terms of technical performance and cost-effectiveness, as well as to determine if the control strategy offers significant benefits over traditional methods. The results of the study could make the solar district heating system a more feasible solution in the market, particularly in light of current policy changes on natural gas prices.

Abstract:
The building sector is responsible for a large part of the final energy consumption in Europe. One of the most relevant steps in the process of reducing energy consumption in buildings is the energy performance diagnostic. In this paper, a data-driven methodology to obtain early energy performance assessment of commercial buildings using the energy signature approach is used. As a result, a web-dashboard and API that can analyse user data input and produce streamlined outputs like suggestions for energy-saving measures is developed. In order to prove the correct functioning of the tool, a demo site of a commercial building in Dublin has been used.

Keywords:
Data-driven tool, building performance diagnostic, energy signature, commercial buildings

1. Introduction

The building sector is one of the largest consumers of resources at European level in terms of both material and energy aspects throughout all stages of a construction project [1], contributing to 40% of energy consumption and 36% of carbon emissions. An estimated 75% of buildings in the European Union are inefficient, yet only 1% undergoes renovation each year [2]. Non-residential buildings account for approximately 25% of Europe's 25 billion m^2 of useful building floor area, with 28% being wholesale or retail premises, 23% offices, 11% hotels and restaurants, and 4% sports facilities [3]. Commercial landlords often own these types of buildings and rent or lease them to one or more tenants. The split incentive problem is a significant obstacle to energy-efficient renovations in commercially rented buildings, where the benefits of a transaction do not go to the person who pays for it [4]. In this context, it is necessary to develop, test, validate and exploit new business models that lead to greater uptake of Smart Energy Services deployed via performance-based contracting in the commercial rented sector, supported by more accurate and dynamic measurement and verification of energy savings and flexible consumption in order to identify and develop business opportunities.

There are already protocols such as the guide proposed by ASHRAE [5] which set a reference frame for measurement of energy and demand savings of heating, cooling and air-conditioning. In the commercial building context, ASHRAE [6] developed a book providing standardized set of performance measurement protocols that can be applied internationally. Regarding heat load forecasting alternatives for buildings, one of the most suitable alternatives is provided by data-driven demand forecasting models. A wide variety of data-driven models exist and have been successfully implemented for early building performance diagnosis. Moreover, several authors have implemented this approach at district scale [7-9]. Data-driven models can be classified in different groups and one of them is the black-box models, which are purely based on data and statistical techniques with no physical interpretation of the building. In this sense, one of the more common types of black-box models are the energy signature models, which can provide successful results for monthly and seasonal data as demonstrated in several research [10-14]. Energy signature models predict a building's energy consumption based on external climate data. They are usually represented as a graph of overall energy use versus outdoor air temperature [15]. Furthermore, using daily or hourly intervals can provide further insights into typical energy demands in comparison to monthly or weekly patterns, allowing for a more accurate analysis [16].

Therefore, smart solutions are needed to identify potential flexibility opportunities and energy efficiency upgrades with high energy saving potential and communicates estimations of their expected added value to both tenants and building owners.

2. Objectives

This paper presents a new data-driven energy diagnostic approach to identify the most significant energy streams in commercial buildings using a minimal dataset. The algorithms consider general information about the building, such as location, size, usage, and HVAC characteristics, as well as overall facility energy consumption. The diagnostic provides granular data for integration with energy tariffs in real practice, dividing energy use by energy carrier and electricity use by billing schedules. The methodology for the energy use diagnostics is detailed in section 3. The present paper summarizes the work performed, including the development of a user-friendly web-dashboard and Application Programming Interface (API) that allows users to upload specific building information and datasets for early building energy diagnostics. The resulting baseline is cross-referenced against current building performance databases for benchmarking, and key performance metrics are calculated to identify energy-saving measures. Data from a real case study is used to test the algorithms. The outputs from this case study are included in section 6.

3. Methodology

This section details a data-driven methodology approach for carrying out early energy performance diagnostics of commercial buildings by considering energy building signature models. In this case, the developed algorithms are later made available for general use via a web-dashboard and an API. The calculation of the energy signature, the diagnostic requirements and main input and outputs from the developed tool are detailed in following subsections.

3.1. Energy building signature

Energy patterns in buildings are typically represented by one of the behaviours depicted in Figure 1. This model is a general approach to modelling energy loads in buildings and can be considered a good approximation in cases where heating and cooling are provided by the same energy source and where the heating and cooling loads do not overlap in temperature range.

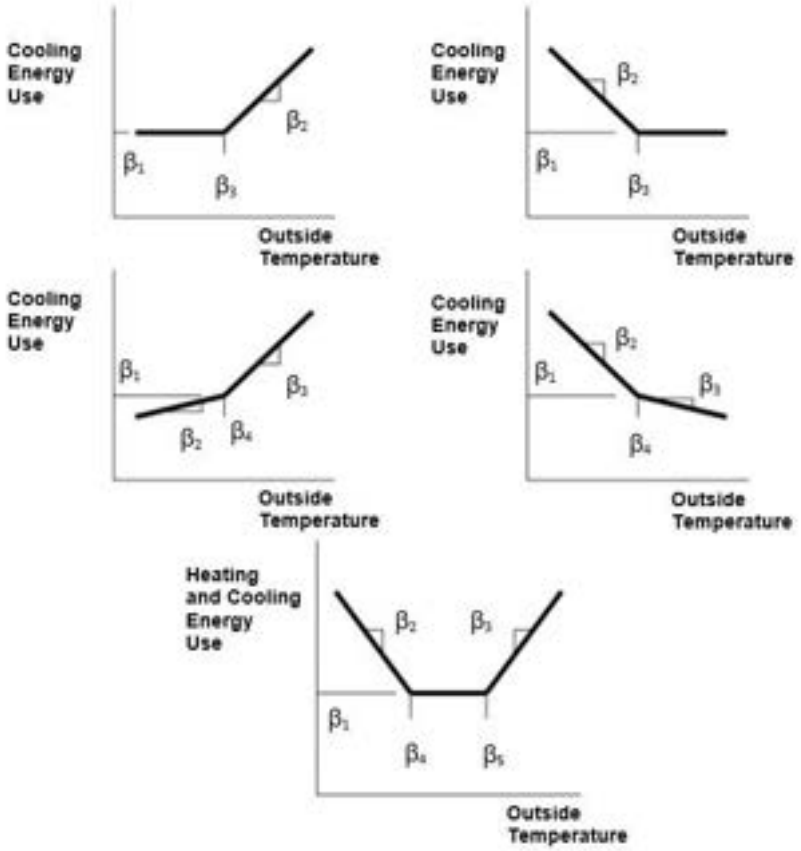

Figure 1. Overall approach to changepoint models. Top row: 3 parameter cooling and heating models. Second row from top: 4 parameter cooling and heating models. Bottom row: five parameter heating and cooling model. Adapted from [17].

Therefore, a regression model has been incorporated to depict the average performance of the commercial buildings on working days. The calculation method chosen to generate the energy signature is a segmented linear regression, in particular, the piecewise regression. Piecewise regression involves fitting a linear regression model to data that has one or more breakpoints where the slope changes. In the Python package used to perform this task, this type of regression follows the approach described by [18], where the breakpoint positions and the linear models are simultaneously fitted using an iterative method. According to [19], the general form of a one breakpoint model is implemented as in Eq. (1). As it is a non-linear relationship, it cannot be solved directly through linear regression. To take a linear approximation it is necessary to use a Taylor expansion around some initial guess for the breakpoint, ψ (0).

$$y = ax + c + \beta(x - \psi)H(x - \psi) + \zeta \quad (1)$$

This results in a linear relationship and thus a new breakpoint estimate, ψ (1), which can be used to perform ordinary linear regression using the stats models Python package [20]. After that, the process must be iterated until the breakpoint estimate converges and the algorithm stops. For multiple breakpoints, the same approach can be used with a multi-variate Taylor expansion around an initial guess for each breakpoint.

The resulted regression will just consider the outdoor temperature but no other significant factors such as solar radiation, occupancy, ventilation, etc. For that reason, 10% upper and lower boundaries are added to account those other aspects.

3.2. Energy use diagnostics

The purpose of the energy use diagnostics is to assess the energy consumption and associated costs of commercial buildings in this case. To adapt the diagnostics to the methodology scope, some requirements have been considered:

- Data sources. Available data sources such as on-site Building Energy Management Systems and data from utilities or energy suppliers.
- Time intervals. The processes should be frequency adaptable to match different time intervals (hourly, monthly data, etc.).
- Subsystems. Assign different energy use to specific areas and/or subsystems in the building.
- Benchmark. Compare energy consumption with other buildings of similar size, configuration, use and climatic conditions.
- Measures. Identify energy-saving measures and determine their potential.

By applying the developed algorithms in section 3.1, a regression with 10% boundaries is obtained. In this case, data located out of that boundary will be considered as misuse energy and some energy saving measures will be given to match the regression boundaries. These measures include optimizing heating and cooling schedules, upgrading lighting systems and heating/cooling equipment, and improving the building envelope.

3.3. Tool description

The above detailed methodology enabling early building performance diagnostics is accessible via a web-dashboard. To ensure user-friendliness, the API facilitates communication with the algorithms by simplifying the underlying calculations and exposing only the necessary objects to stakeholders without requiring knowledge of the operations that occur behind the scenes. Consequently, the web-dashboard enables users to upload specific building information and datasets to obtain early building energy diagnostics through the API, which accesses the developed algorithms.

3.3.1. Input data

To enhance user-friendliness, the input data has been simplified. While additional data such as bank holidays and HVAC characteristics could enable more functionalities and analysis, simplicity has been prioritized to make the application more appealing to potential users. The minimal dataset needed includes the following information.

- Building characteristics:
    - Building location (city): this information will be used to load the weather file of the indicated city or location. The developed API presents a set of 3 preloaded locations; Dublin (Ireland), Madrid (Spain) and Thessaloniki (Greece).
    - Building size (m^2): the total area of the building will be used to normalize its consumption and to compare it to the reference values.
- Energy data with hourly granularity (electricity, natural gas, or other fuels) in kWh.
- Service provided: it is necessary to indicate whether the energy data loaded corresponds to heating, cooling, or heating and cooling.

- Actual building usage:
    - Opening and closing hours.
    - Working days.

3.3.2. Data analysis

Before proceeding to the analysis of the uploaded data, a pre-processing step is performed. This includes a study that analyses the validity of the uploaded data, eliminates possible outliers and erroneous measurement values, transforms the hourly data to a daily frequency and indicates whether the final data quantity, after cleaning, is sufficient for further analysis. If the pre-processing gives satisfactory results, the analysis of the data is performed to generate the building's energy signature.

Three different analysis processes are performed on the uploaded consumption data:

- Non-working hours consumption analysis: based on the hourly frequency data as well as the information provided on days and times of use of the building, a study of the building's consumption is carried out to determine how much is consumed during non-working periods.
- Benchmarking: if the uploaded data cover a whole year, a comparison of the total consumption with the reference values is made.
- Energy signature: daily frequency data is classified according to whether it is a working or non-working day. A piecewise regression is applied in the working day dataset. The information of whether the provided data corresponds to heating, cooling or both is used to determine the number of breakpoints of the regression.

3.3.3. Output

The different results of the analysis are reflected in a graph where the regression line, the 10% boundaries and the uploaded data are shown. The outputs are listed below:

- Energy misuse in non-working hours.
- Energy consumption comparison against reference values.
- Energy signature of the building.
- Qualitative analysis of the building and its system based on the calculated breakpoint in the piecewise regression.

4. User interface of the tool

Figure 2. Web-dashboard, serving as interface between users and algorithms.

As a result of the detailed methodology, an API and web-dashboard were developed. The user interface is linked to the developed algorithms via API. Once the calculations are performed, some recommendations are offered to the user.

This tool allows to users to provide data to obtain an early building performance diagnostics web-dashboard. The user enters the building characteristics through the different available options as shown in Figure 2. As stated above, data must be introduced in hourly frequency.

5. Case study

The proposed methodology is applied to a demo site located in Dublin (Ireland), consisting of six floors with a classical façade constructed in reconstituted stone precast concrete panels. The building was constructed in 1996 and was retrofitted in 2014, after a prolonged period of being unoccupied. After the refurbishment, the building was partially occupied in 2015 for office uses in the following portions of floor area as shown in Table 1. The landlord area includes the ground floor reception, stair cores, toilets, basement level, and subbasement level.

Table 1. Floor areas per occupancy.

	Area (%)	Area (m^2)	Occupancy (persons)
Landlord	29.14%	1,809.00	
Tenant 1 (Investment Services)	43.72%	2,714.36	265
Tenant 2 (Private Banking and Asset Management)	12.97%	805.20	65
Tenant 3 (Hedge Fund)	14.18%	880.44	120

A site survey of the case study building was conducted to gather the necessary information required for applying the tool, such as HVAC system components, occupancy, and schedules information, available monitored data, etc. Due to the building use, there are no energy intensive processes associated to the normal operation of the building. Therefore, main consumptions are related to lighting and HVAC systems. The opening times of the offices are from 8h to 18h from Monday to Friday. There is no occupancy during weekends or holidays. The input data of the case study building have been introduced via the developed web-dashboard as shown in Figure 3.

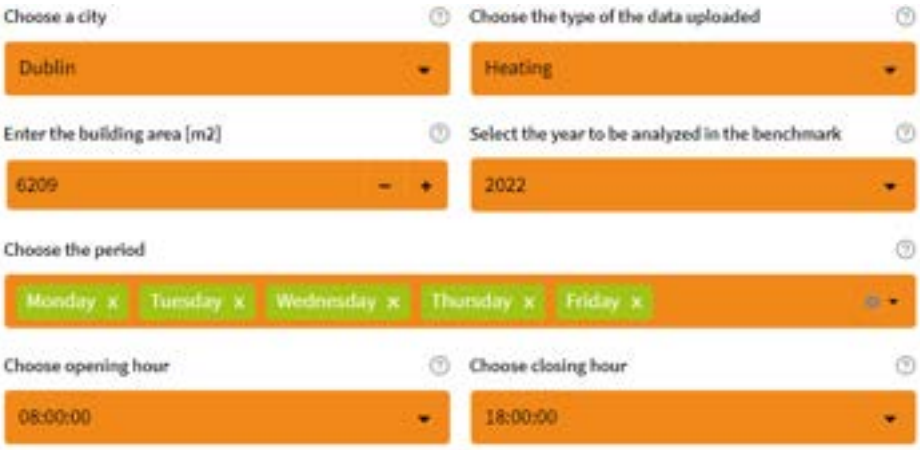

Figure 3. Input data introduced for the Irish demo-site in the web-dashboard.

Apart from input data detailed in Figure 3, heating consumption data (see Figure 4) were also obtained in hourly basis from 26th January 2022 to 14th December 2022 (both included). The boxplot graph shows the statistical distribution of the consumption for each day of the week.

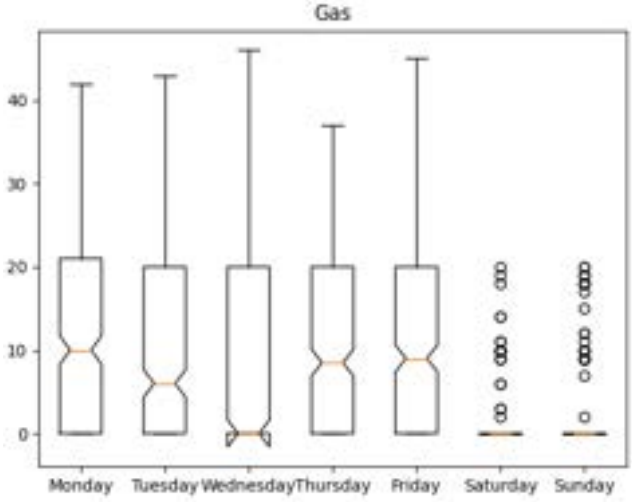

Figure 4. Heating energy consumption distribution during a typical week in the Dublin building.

6. Results

The present section includes the early building diagnostic for a demo site located in Ireland. Once the required input data have been uploaded (see Figure 3), the API provided results analysis as shown in Figure 5. The graphic shown in Figure 5 represents the daily aggregate values of heating consumption (kWh) versus daily average outdoor temperature, where red points belong to weekend and other non-working days. On the other hand, grey points represent heating consumption for working days. As detailed in methodology, 10% upper and lower boundaries have been added to the model and are represented in the graphic with a grey shadow. Data out of this boundary represents energy misuse.

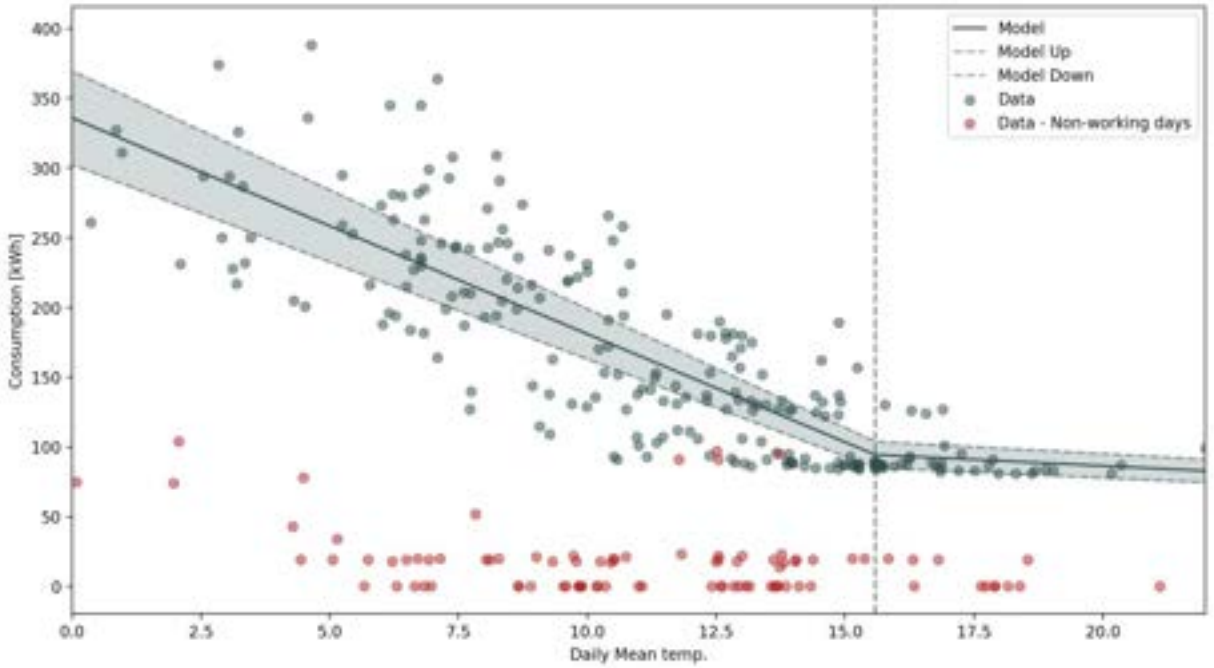

Figure 5. Daily aggregated values of heating consumption (kWh) versus daily average outdoor temperature.

As observed in the figure, heating consumption is weather dependent and increase with low outdoor temperatures. The changepoint corresponding to the regression model take place for a mean outdoor temperature of 15.58ºC. That means that the building heating demand starts for outdoor temperature under 15.58ºC, which could be considered as high. Some consumption peaks have been observed for non-working days (see red dots in Figure 5), which are assumed to be failures on the monitoring system and can be neglected.

7. Conclusions and discussion of results

This paper presents the development of an API and a web-dashboard which allows users for an early building performance diagnostic.

The creation of the API that accesses the developed algorithms highlights the critical role that data availability and synchronization play in this context. The recommended diagnostic procedure heavily relies on utility meters (which are still being delivered with some difficulties) and climate data, which is available from open sources. However, obtaining data from energy sub-meters, building usage, and indoor comfort conditions is still of interest and would significantly enhance performance assessment.

The algorithms created for its implementation in the API have been employed to evaluate the data provided by a commercial demo building in Dublin. The evaluation of this data has been thoroughly presented and analysed in this document to serve as an exemplary case study of the methodology. By application of the developed methodology, it is possible to identify the most significant energy streams in the building using minimal information.

After the application of the regression model, it has been proven that it correctly represents the average performance of the offices during operational days. Data collected in days where the heating consumption is out of a 10% boundary from the model are identified as misuse days and might be separated from non-operational days. Some recommendations can be made based on the analysis performed.

The early building diagnostic outcomes involve the computation of key performance indicators, which enable the automatic identification of energy-saving measures when compared against current building performance databases.

Abstract:
Pumped storage power plants compensate for fluctuations in the electricity grid and improve the stability through grid services. By increasing the flexibility of pumped storage power plants, they could compensate fluctuations in an even greater extent and thus accelerate the shift to a fully renewable energy system. One way to do this is to accelerate the switching between operating modes within pumped storage stations. For this, we propose to apply reinforcement learning (RL) to control the start and stop processes within a hydraulic machine. RL has been shown to outperform traditional optimal control methods, however, safety concerns are stalling research on applying RL for process control in safety-sensitive energy systems. To enable the safe and reliable transfer of the algorithm's learning strategy from a virtual test environment to the physical asset, we present a concept for applying RL via a digital twin platform. To demonstrate this concept, we set up a simulation model for the operating behavior during the start and stop processes of a lab-scale pump-turbine and validate it with experimental data. On this virtual representation, we test the application of RL to optimally control the blow-out process within pump-turbines. We present the structure of the deep Q-learning (DQN) RL algorithm we trained and the necessary problem formulations. Our results show that the DQN algorithm is suitable for finding the optimal operating strategy to blow-out the pump-turbine runner. We discuss the viability of our approach for the control of a pump-turbine and outline the next steps to test RL on a lab-scale model machine.

Reinforcement Learning, Digital Twin, Hydro Power, Process Control, Pump-Turbine, Transfer Learning.

1. Introduction

To reach the transition to a clean energy future, renewable energy systems, and especially wind and solar power technologies, will be expanded massively over the next years [1]. The energy sector is thus confronted with the growing share of volatile renewable energy systems in the grid. To balance out fluctuations, other energy sources and storage systems, such as pumped storage power plants, will need to increase not just in capacity but also in flexibility [2].

An approach to make pumped hydro storage systems more flexible is the acceleration of the switching between operating modes of pumped hydro machine units. Pumped storage power plants can be equiped with ternary sets, consisting of a pelton or francis runner and a storage pump, or with reversible pump turbines, where the machine unit can act as a turbine as well as as a pump. When switching from turbine to pump mode in pump-turbines, the runner is typically being blown-out, i.e. the water is being displaced by air, to minimize the start-up torque. This blow-out process is also necessary for both generator types when operating in synchronous condenser mode, which is used for compensating reactive power in the power grid [3].

To reveal optimization potential for faster changes of operating conditions in general and the blow-out process in particular, we propose to use a reinforcement learning (RL) algorithm for process control within the machine unit. RL is a type of machine learning (ML) in which an agent interacts directly with its environment. It aims to learn an optimal decision policy, guided by a scalar reward signal [4]. The application of RL in industrial control settings has received a lot of attention in recent years because it has been shown to outperform traditional optimal control methods [5]. However, safety concerns limit most use cases to simulated environments [6]. While research in the areas of robotics (e.g. [7, 8]) and manufacturing (e.g. [9]) seems to be leveraging the transition

of simulated to real-world applications of RL for process control, the implementation of an RL algorithm to critical infrastructure, such as hydropower systems, is still far from being realized [6].

To enable RL for flexible energy systems, we recently proposed a three-step learning method that uses transfer learning (TL) to transfer a pre-learned RL algorithm via a digital twin (DT) platform from a simple data model over the virtual representation of the machine to the real world machine unit [10]. Based on this method, which will be explained in Section 2.1., we will present the simulation model that was set up to act as the virtual representation of the lab-scale reversible pump-turbine where we plan to test the control of the blow-out process through RL in the future. We then describe the structure of the RL algorithm that we used and discuss our results for implementing the RL agent to control the blow-out process within the simulation model. Finally, we give an outlook on future research and draw a conclusion.

2. Methods

2.1. Reinforcement Learning on a Digital Twin Platform

When operating critical infrastructure, reliability and safety are crucial. Simultaneously, the replacement of standard controllers with RL algorithms to control processes is gaining in attention [6, 11, 12], which may be of interest for continuously revealing optimization potential and automating a flexible operation within energy systems. Hence, to enable the application of RL for process control within safety-sensitive energy systems, requirements for the trustworthiness of the RL algorithm need to be established and satisfied. Therefore, we propose a three-step learning method, that combines the benefits of RL and TL on a DT platform, as presented in our recent journal publication [10]. Figure 1 shows the concept for applying RL on a DT platform.

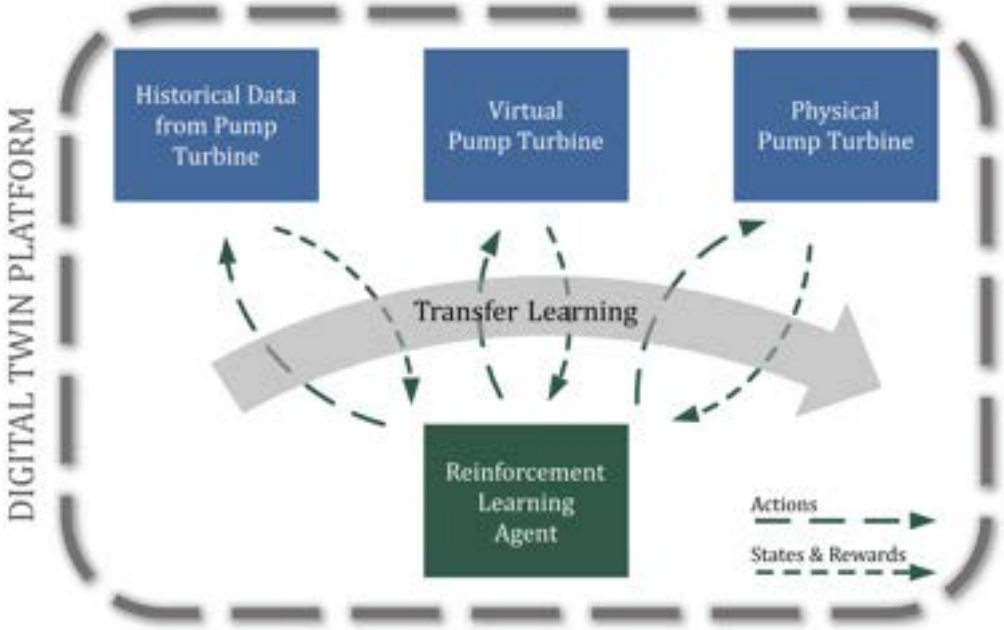

Figure 1: Concept for the application of reinforcement learning (RL) on a digital twin (DT) platform, adapted from [10].

Firstly, pre-training is done with a basic data model, followed by, secondly, training on an exact simulated replica of the actual asset. Thirdly, the pre-learned strategy is being adapted to the real machine unit. This pre-training can substantially reduce technical safety concerns related to learning and operating the actual power system by efficiently limiting the RL agent's action space. Figure 2 shows the general concept of a DT platform, as proposed by Kasper et al. [13], that integrates all three environments for the three-step RL approach: the historical data model, the virtual replication, and the physical unit, allowing TL to be used as a service to continuously enhance the RL agent's strategy.

2.2. Simulation Model

The virtual entity of our DT platform consists of a simulation model of the pump-turbine test rig at the laboratories of the Institute of Energy Systems and Thermodynamics (IET) at TU Wien (see Figure 3). The model pump-turbine consists of seven runner blades and is equipped with 20 guide vanes and 20 stay vanes. The simulation model is built using the Simscape language together with blocks from the Simscape standard libraries within the MATLAB/Simulink environment [14–16]. The model allows for the simulation of various operating

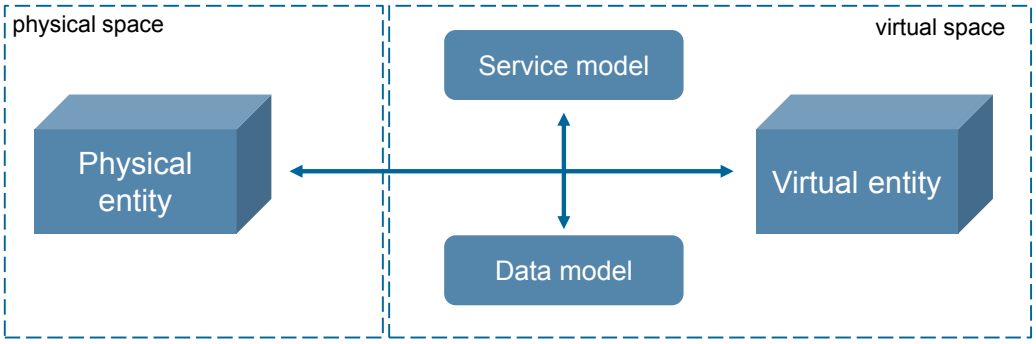

Figure 2: Schematic representation of a generic DT platform, adapted from [13].

Figure 3: Test rig with scale reduced model of a radial pump-turbine at the hydraulic lab of IET, from [10].

conditions. The pump-turbine characteristics were modeled following the assumption of the affinity laws for the behavior of pumps and turbines with variable speeds. Equation 1 describes the linear dependence between the flow rate Q and the rotational speed n, and the cubic relation between n and the pressure difference built up by the pump-turbine Δp_{PT}.

$$\frac{Q_1}{Q_2} = \frac{n_1}{n_2} \approx \sqrt{\Delta p_{\mathrm{PT}}} \tag{1}$$

To make up for deviations between the simulated and the measured values for the flow rate Q, a representative fitting rate η, similar to an efficiency rate, depending on the rotational speed was introduced. The resulting Equation 2 for the pressure difference Δp_{PT} therefore comprises the efficiency rate $\eta(n)$, the scaling factors k_{PT} and k_ω, all compensating for actual flow conditions in the real machine unit, and the angular speed ω.

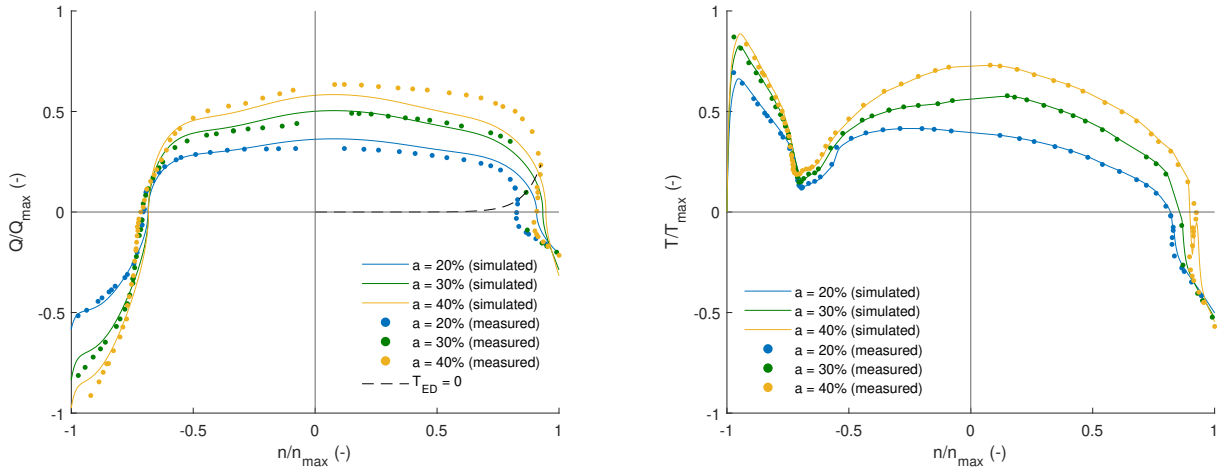
$$\Delta p_{\mathrm{PT}} = \eta(n) k_{\mathrm{PT}} (\omega - k_\omega)^2 \tag{2}$$

For the calculation of the shaft torque, the experimentally captured Tn- characteristics were directly implemented within the simulation model. To account for the influence of the water level in the draft tube cone on the torque, Equation 3 calculates the shaft torque T by multiplying the measured values T_{ch}, which are dependent on the rotational speed n and the the guide vane opening a, with the fraction between the actual water level x and the maximum water level in the draft tube cone x_{max}.

$$T = \frac{x}{x_{\mathrm{max}}} T_{\mathrm{ch}}(n, a) \tag{3}$$

The simulation model sufficiently replicates the measurements on the real model pump-turbine for the flow rate Q and shaft torque T for different guide vane openings a and rotational speeds n. Figures 4b and 4a show the comparison of the simulated curves with the measured data for the Qn- and Tn-characteristics, respectively.

The relative error for the simulated flow rate compared to the measured data is shown in Figure 5 for an exemplary guide vane opening of a = 30%. The deviations between simulated and measured data are comparable for other guide vane openings. Overall, the model is able to simulate three of the 4-quadrant characteristics (pump, pump brake and turbine) within acceptable relative error tolerances of $\pm$20%. Only when operating as turbine break and reverse pump, the relative error exceeds 20%. As our first use case for enabling increased flexibility within machine operation is on the pump start-up and the operation in synchronous condenser mode,



(a) *Qn*-characteristics (b) *Tn*-characteristics

Figure 4: Comparison of *Qn*- and *Tn*-characteristics from measured data with simulated curves for different guide vane openings.

the focus of the simulation is on operation as a pump and the blow-out process with speeds from $-n_{max}$ to around $-0.7n_{max}$. Deviations between the simulated and the experimentally measured data are thus more accepted in the other operation modes, resulting in non-sufficient representation of the operating range below the ”zero torque” ($T_{ED} = 0$), the so called ”S”-characteristic, as it can be seen in Figures 4 and 5. Here, the

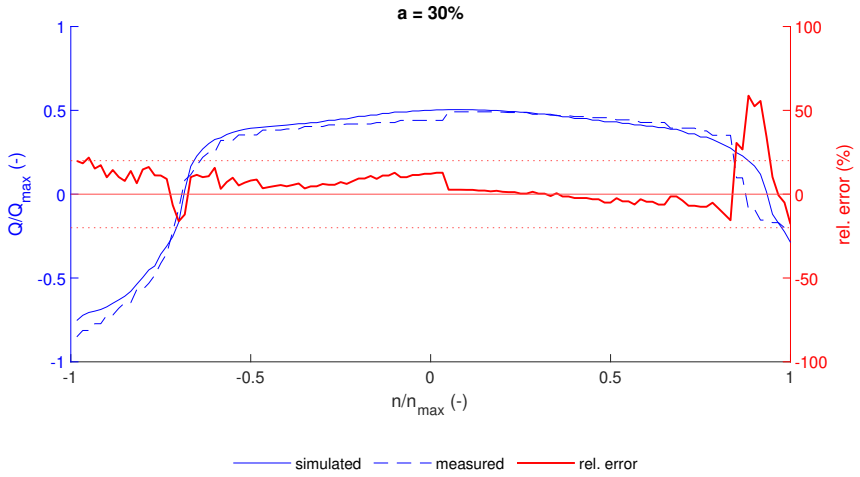


Figure 5: Relative error for the simulated flow rate compared to measurement data.

operating condition is not clearly defined and the area should be avoided in real operation. Nevertheless, the model is easily adaptable and correct representation of all pump-turbine operation modes needs to be ensured before the model is eligible as the complete virtual entity of the DT platform.

The blow-out of the runner is modeled through the lowering of the water level when air is blown into the draft tube. The machine is considered as blown-out as long as the water level is below the threshold $x_{\text{blow-out}}$. If the water level drops too low, air can leak into the tailwater vessel. Therefore, the water level should never fall below the critical level x_{crit}. Figure 6 illustrates the relevant water levels in the model pump-turbine, and Table 1 lists the according values.

2.3. Reinforcement learning algorithm

The objective of an RL agent is to interact with its environment to determine the best possible strategy, which is referred to as the optimal policy [4]. As illustrated in Figure 7, the agent makes a decision on what action to take at each time step t, resulting in a change in the environment. The environment's current state S_t is passed to

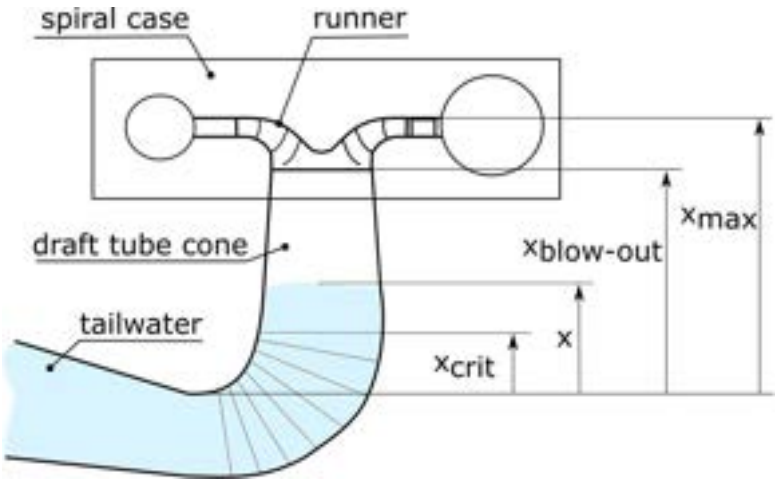

Figure 6: Illustration of relevant water levels inside pump-turbine.

Table 1: Water level values in draft tube of model pump-turbine.

x_{max}	0.807 m
$x_{blow-out}$	0.639 m
x_{crit}	0.227 m

the agent, along with a reward R_t that serves as a measure of the state's quality and provides feedback for the agent's learning algorithm. Based on the observation of the new state, the agent determines the subsequent action. By repeating this sequence, the agent acquires knowledge on how to effectively associate states with actions, with the objective of maximizing the cumulative rewards obtained over time (also known as return G). After a sufficient number of training sessions, this process leads to the development of the optimal policy π^*, with $\pi(A|S)$ indicating the probability of selecting action A when presented with state S [10].

Figure 7: Agent-environment interaction within an RL algorithm, adapted from [4].

During training, an RL algorithm needs to balance between exploring the state space through selecting random actions and exploiting of actions that have already proven to yield high rewards. Only through exploiting on past actions, the agent's performance can be improved. However, prematurely focusing on exploitation may lead to the algorithm settling on a sub-optimal policy [17]. Therefore we use epsilon-greedy exploration following an epsilon decay function. In this way, the exploration probability ϵ decreases continuously during training, ensuring that the agent explores the whole state space in the beginning, but still manages to converge to the optimal policy when training progresses.

For our use case, we use a deep Q-network (DQN) training algorithm, which is a value-based RL algorithm that trains a so-called critic $Q(S, A; \phi)$ with parameters ϕ to predict the return for a given state S and action A. During training, the agent adjusts the parameters in ϕ. When training is finished, the optimal policy can be derived from the trained value function approximator, the critic $Q(S, A)$, with now tuned parameter values ϕ [18]. The general training algorithm for a DQN agent is described in Algorithm 1.

Algorithm 1 Deep Q-Network (DQN) Training Algorithm [18]

Initialize critic Q with random parameter values ϕ
for each episode **do**
  for each training time step **do**
    With probability ϵ select a random action A
    otherwise, select the action, for which the critic value function is greatest:
    $A = \arg\max_A Q(S, A; \phi)$
    Execute action A. Observe the reward R and the next state S'
    Store the experience (S, A, R, S') in the experience buffer
    Sample a random mini-batch of M experiences (S_i, A_i, R_i, S'_i) from the experience buffer
    if S'_i is a terminal state **then**
      Set value function target $y_i = R_i$
    else
      Set $y_i = R_i + \gamma \max_{A'} Q(S'_i, A', \phi)$
    end if
    Update the critic parameters ϕ by one-step minimization of the loss L across all sampled experiences:
    $L = \frac{1}{M} \sum_{i=1}^{M} (y_i - Q(S_i, A_i; \phi))^2$
    Update the probability threshold ϵ for selecting a random action based on the ϵ-decay rate
  end for
end for

3. Results

The goal of our use case is to have the RL algorithm control the blow-out process for pump start-up within the virtual model of our scale reduced pump-turbine in the lab of IET. In doing so, we seek to demonstrate how RL can enhance the flexibility of hydropower systems, by training the agent to minimize the usage of compressed air while blowing out the machine as fast as possible.

As RL algorithm, a DQN agent from the MATLAB Reinforcement Learning Toolbox [18] with the default vector Q-value deep neural network as critic was used. The DQN agent has a discrete action space, $A = [0, 1]$. If the action $A = 0$, no air is blown into the draft tube and if action $A = 1$, air gets blown into the draft tube with a constant pressure of p_{air}. At each time step, the agents receives the state of the environment $S = [x(t), A(t-\Delta t)]$ through a continuous value for the current water level x and the binary value for the previous action A. This informs the agent whether the water level is rising or falling, allowing it to make an informed decision on the next action. The reward at each training step is calculated with a reward function that consists of four weighted terms, as described in Equation 4. Hereby, $R_{\text{waterlevel}}$ is positive if the water level x is between $x_{\text{blow-out}}$ and x_{crit} and negative otherwise. R_{air} accounts for the penalty the agent receives every time $A = 1$, indicating that air is blown into the draft tube cone. $R_{\text{switching}}$ encourages mores stable operation through penalizing the agent whenever it switches the air valve. If the compressor's limit is reached, i.e. if the total mass flow of air blown into the draft tube during the whole training episode reaches the limit of $\dot{m}_{\text{air}} = 1\text{kg}$, the agent receives a high penalty $R_{\text{compressor}}$ and the episode is aborted.

$$R = w_1 R_{\text{waterlevel}} - w_2 R_{\text{air}} - w_3 R_{\text{switching}} - w_4 R_{\text{compressor}} \tag{4}$$

The final cumulative reward, the return, for one training episode can be calculated by summing up over the reward received during each training time step t (Equation 5).

$$G = \sum_{i=1}^{t_{\text{end}}} R(t) \tag{5}$$

All the important parameter and hyperparameter settings for the training of the DQN agent are listed in Table 2. Note that the guide vane opening $a = 1\text{mm}$ and not 0, as it would be expected during the blow-out process. This intentional gap between the guide vanes should indicate leakages, as they are common in real world constructions, leading to air dissipating and therefore the need to repeatedly blow air into the draft tube to remain in blown-out condition.

Figure 8 shows the training progress of the DQN agent for learning how to control the blow-out process while balancing between rapidly reaching and remaining in blown-out operation mode and, simultaneously, minimizing the air mass blown into the draft tube. The large fluctuations for the first 200 training episodes represent the exploration phase of the learning algorithm, during which the agent chooses many random actions to explore the state space and evaluate the value function. As training progresses, the exploration probability ϵ decreases and the average return converges. The drops in the episode return curve in episodes 315 and 433 come from further random action decisions, as the probability for selecting a random action over the action for

which the critic value function is greatest, never decreases to 0 but converges to a minimum value ϵ_{min} = 0.1%. During numerous previous training sessions it was discovered that the highest achievable return is limited to G_{max} = 93. Therefore, a return of G_{stop} = 91 averaged over 20 training episodes was chosen as termination criterion. After the 542 training episodes, this criterion was reached and training was stopped.

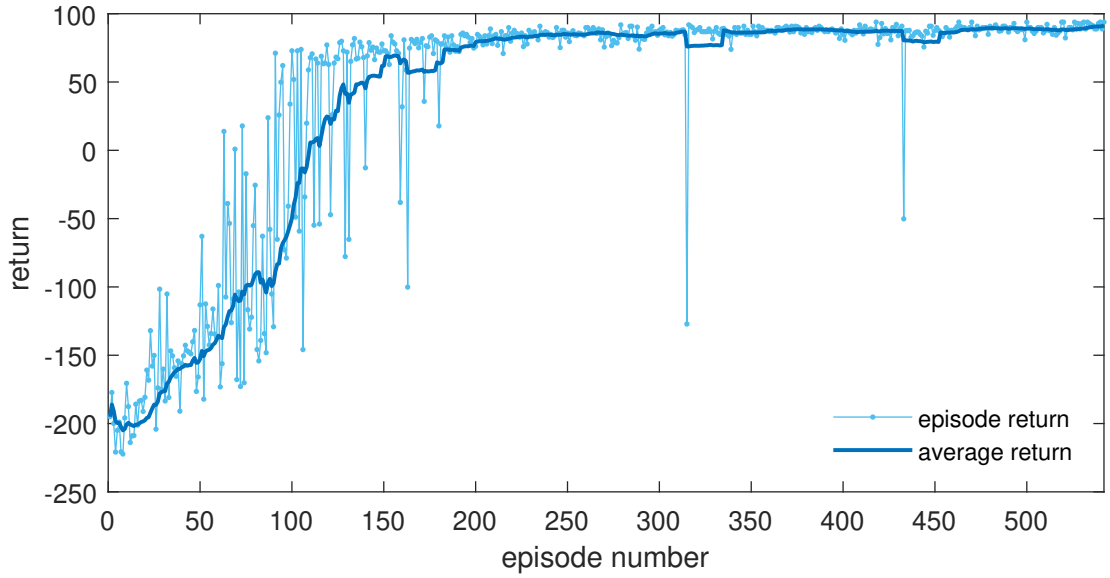

Figure 8: Episode and average return over training episodes.

The simulation results for the blow-out process when controlled by the trained DQN agent are shown in Figure 9. The rotational speed of the motor-generator was set to n = 0rpm, for simulating the machine at standstill. Since a leakage between the rotational guide vanes of a = 1mm was assumed, the flow rate Q is not 0, but a constant water flow of roughly 18 l/s was calculated by the simulation model. The final strategy of the RL algorithm for controlling the blow-out process can be seen in the sub-figures for the action, the mass flow rate and the water level over time. Air gets blown into the draft tube for a certain amount of time (A = 1). Subsequently, the air valve is being closed again (A = 0) and the water level rises again due to leakage effects. When the threshold $x_{\text{blow-out}}$ is reached, the valve opens again (A = 1). This sequence is repeated until the maximum simulation time of t_{sim} = 120s is reached.

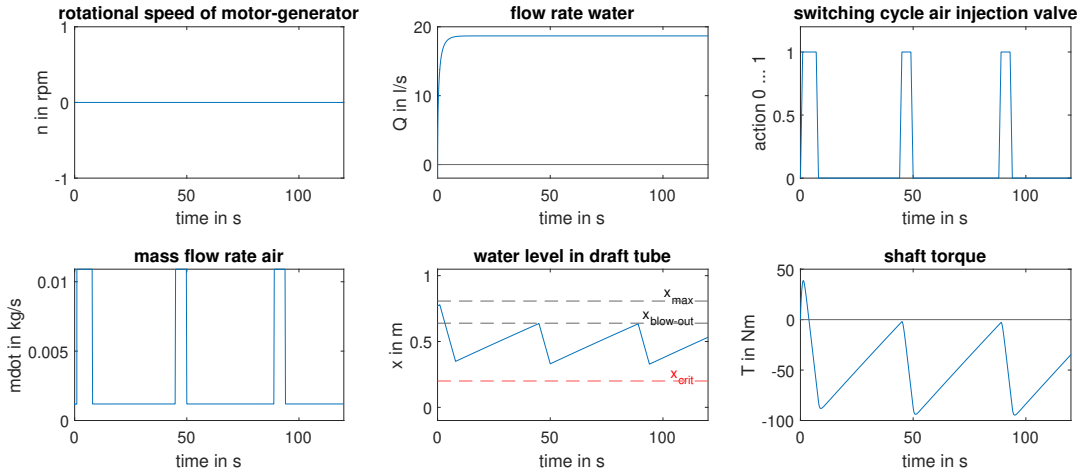

Figure 9: Simulation results for the blow-out process.

4. Discussion

The control of the blow-out process within the simulation model of a model pump-turbine through a DQN RL agent was successfully implemented. However, the algorithm' optimal policy does not yet reveal much optimization potential. Nevertheless it results in a rather logical blow-out sequence that could have also been achieved easily by a simple hysteresis controller. The results therefore show that the DQN agent and our RL problem formulation is suitable for finding the optimal blow-out operation strategy.

Considering that the current water level in the draft tube of the model pump-turbine at our lab facilities is hard to be measured directly, future research will deal with finding a solution for representing the blow-out conditions in the simulation model more accurately. Then, the control of the process will most probably increase in complexity and the optimal policy won't be as straightforward. We assume TL to be beneficial in transferring the DQN agent's policy to handle model adaptations.

Further, in this work we only considered the blow-out process during machine downtime. Blowing out a rotating runner, as it is being done for operation in synchronous condenser mode, may result in different findings. Investigations of different operation parameters are thus recommended and will be a part of our future research.

5. Conclusion

We presented a method to enable the use of RL for process control in pumped hydro storage systems. Concerns for letting a ML algorithm interact with safety-sensitive industrial equipment are among the biggest research barriers for RL for process control. We argue that through the transfer of a pre-learned RL algorithm through the use of a DT platform, safety concerns can be reduced and reliability of the RL algorithm's policy can be increased. In this paper, we showed the first results for the training of a DQN RL agent on a simulation model of a reversible pump-turbine, which acts as the virtual entity of our DT platform. The model was fitted to represent the behavior of a lab-scale model pump-turbine, which is located at the laboratory of the IET at TU Wien with satisfactory accuracy. Training of the RL algorithm was successfully carried out. The results confirm the expected optimal operation of the blow-out process. Future research will address increasing model complexity, exploration of different action and state spaces for the learning of the agent and, ultimately, the transfer of the RL algorithm to the model machine in the lab and use the autonomously learned optimal strategy to control the blow-out process.

Clustering and typification of urban districts for energy system modelling

[a] EPFL, Lausanne, Switzerland, joseph.loustau@epfl.ch

Abstract:
The interest in Urban Systems has been growing due to the necessary decarbonisation of city energy systems. Decision tools are developed using mathematical optimisation to enable proper decision-making in the transition process. The concept of energy communities - or district energy hub - is expected to have an impact on the energy system at both regional and national scales. However, the shift towards distributed energy systems complexifies the model due to more integrated subsystems and requires larger spatial boundaries to increase self-consumption and decrease grid stresses. The computational power required to model and optimise such systems is to rise drastically.
This work proposes to curtail the large computing needs by typifying the districts of a city, using clustering techniques. Accordingly clustered districts can be optimised by solving a typical district from the group and scaling its solution to the others. The clustering features considered are the districts energetic characteristics: the energy demands on one side, and the endogenous resources on the other. Data are normalised and a principal component analysis is conducted. Two clustering algorithms are investigated: a centroid-based (Kmedoids) and a density-based (GaussianMixture). The ideal number of clusters is determined by maximising the intra-cluster similarity and minimising the inter-cluster similarity, and the final clustering stability is evaluated through the Rand Index.
The method is applied on the case study of a typical European urban area and the two algorithms lead to two distinct typification. The clusterings are used to run an energy hub optimisation for the whole region and the results are compared to the one obtained without archetypes for validation. The results between the two approaches show no significant differences while a considerable computing time reduction is achieved.

Keywords:
Urban energy systems, clustering, energy modelling, energy communities.

1. Introduction

1.1. Background

Among all, the building and construction industry accounts for an estimated 37% of the global operational energy and 37% of the process-related CO_2 emissions, worldwide [1]. Additionally, the world urban population represents 55% of the total and is expected to grow to 6 billion people [2] by 2050 (70% of total). Today, two-thirds of the global energy consumption come from cities, which emit more than 70% of the total greenhouse emissions [2]. Priority needs then to be put on city energy systems decarbonisation. Those considerations lead to a growth of interest in Urban Energy Systems. According to the *Net Zero Emissions (NZE) by 2050* report [3],

decarbonisation should be driven by high electrification. The conventional energy systems (*e.g.* fossil-fuels and boiler for Space Heating (*SH*)) would be replaced by devices and technologies that require renewable energy vectors. In the *NZE* scenario, 1.8 billion heat pumps and 1.2 billion solar thermal systems combined to 7'500 TWh of building-integrated PV would need to be installed [1].
Consequently, the exploitation of local energy resources is expected to grow, shifting the current electrical grid to a more decentralised one; households or organisations will consume energy from the grid at times, while at other times they will produce surplus energy that they can injected into the grid. The installation of energy devices must then be carefully done so that it answers the grid constraints. To ensure the stable operation of the grid at nominal frequency, the grid must always be balanced. While the current system - where few plants are responsible for the production, from the higher voltage level - can easily adapt the plant turbines frequency to keep the balance, with non-drivable inputs on the grid at the low-voltage level, it would be much more difficult to reequilibrate the imbalances [4]. Moreover, high peak production power can also overload the transformers or cause transmission bottlenecks [5]. The grid restrictions make it challenging to determine what technologies should be installed for a building to meet its demand, as optimal solutions depend on the context. Thus, the energy problem must be solved on a case-by-case basis.

To enable good energy-wise policies to help the renewable technologies penetration, an important lever for action is to provide efficient decision tools, able to propose a set of solutions to a specific energy context [6]. The decision-making tools model the system design (*energy hub*) and its possible components and provide an analysis, leaning on mathematical optimisation or simulation. Traditionally, the building is considered as the energy hub perimeter.

1.2. Gaps and contribution

However, to obtain results at a city scale, solving each hub would be too demanding in terms of computational power. To tackle this issue, either the model has to lose accuracy or the data volume must be reduced. [7, 8] developed the use of Machine Learning techniques to cluster the buildings of a city. The building stock is thus simplified using archetypes (i.e. average reconstructed buildings or sample buildings). But, the change towards distributed energy systems encourages the extension of the *energy hub* spatial boundaries so that a higher self-consumption can be achieved, hence releasing some stress over the grid. Indeed, [9] shows that when maximising the electricity generated locally (e.g., solar panels), the interaction of the building energy system with the grid should be lowered. To do so, the *energy hub* considered in this research is the district, which allows interactions between buildings.

This research proposes a method to typify urban districts using clustering techniques, thus combining the benefits of buildings interactions and typification. An application of the method is proposed using the canton of Geneva in Switzerland as a case study.

2. Methods

The method's premise is that by modelling a reduced number of districts, elected as *representative districts*, the results obtained draw the same conclusion as the ones that would be obtained by modelling every districts.
From this premise, the workflow proposed to enable large scale urban energy modelling is described in Figure 1. This paper covers the methods to find the representative districts.

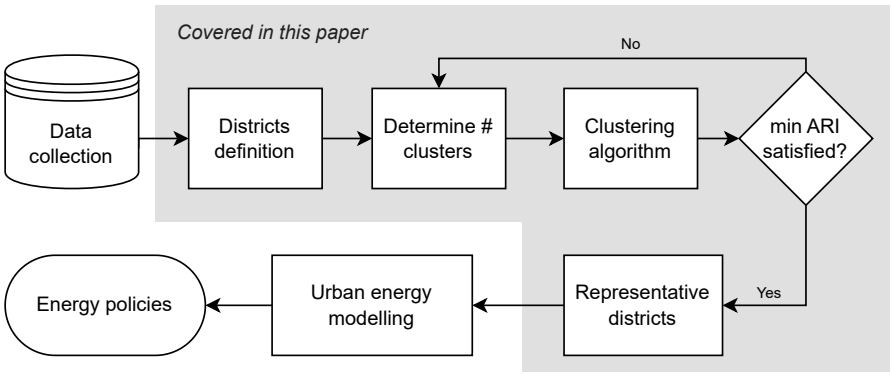

Figure 1: Workflow diagram for large scale urban energy modelling for integrated and distributed systems.

2.1. Definition of a district energy hub

Intuitively, a district is an area. Defining the *District Energy Hub (DEH)* consists in defining its spatial boundaries. A spatial attribute that must be common to all the buildings to consider within the same district is investigated. Because the initial target of the *DEH* is to limit exchanges with the grid, it is necessary that the buildings within the district boundaries can interact. Also, the aggregated load that the transformer has to handle must be taken realistically into account. Hence, the low-voltage transformer is the common attribute within a district in this research.
To be relevant, the clustering is designed so that its input features are the same as the input variables that describe the energy system in the model. A *DEH* is characterised by its infrastructures, the energy imported, the resources, and the on-site energy demands, as detailed in Fig. 2.

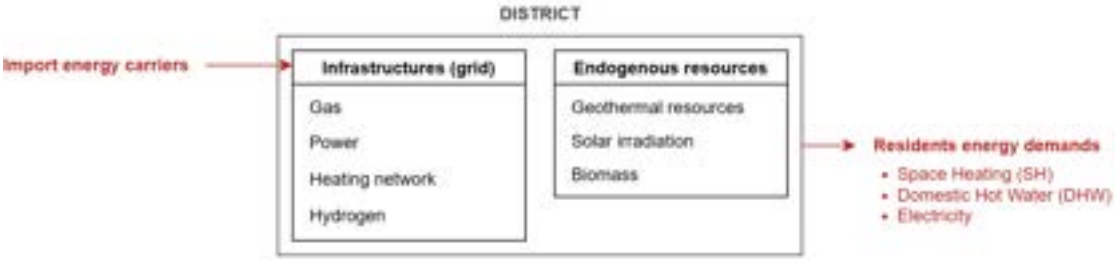

Figure 2: Key characteristics describing a district.

To restrain the number of features and facilitate the solving, the data go through a *Principal Component Analysis (PCA)* before the clustering. A PCA allows reducing a dataset dimensionality while preserving as much of the variability (*i.e.* the statistical information) as possible [10]. It also helps to interpret which features have the most impact on the clustering result. It is implemented in Python, using the *scikit* library.

2.2. Clustering

In *Urban Building Energy Modelling (UBEM)*, the algorithm that comes up most often and that has proven its effectiveness is *Kmeans* [11]. In this method, a derivative of Kmeans is implemented: the *Kmedoids* algorithm. It uses the concept of medoids instead of the mean, which diminishes the influence of the outliers, making it more robust. To make it operational to elliptical distribution, a second algorithm is proposed, the *GaussianMixture* algorithm. Those two algorithms are implemented in Python, using the *scikit-learn* library [12].

2.2.1. *Kmedoids*

Kmedoids require an initial number of clusters to run. If no previous knowledge of the dataset allows knowing this parameter, performance measures are used to determine which number of clusters gives the best result. Three validity indexes are proposed in this method. To put in equations those indexes, the following notation is used:

- The set of clusters $\mathbf{C} = \{C_1, ..., C_I, ..., C_K\}$ with $1 \leq I \leq K$,
- The set of observations $\mathbf{y} = \{y_1, ..., y_i, ..., y_n\}$ with $1 \leq i \leq n$,
- The subset of observations attributed to the cluster $y_i \in C_I$, $i \leq n$, $\mathbf{y_I} = \{y_{I,1}, ..., y_{I,j}, ..., y_{I,n_{C_I}}\}$ with $1 \leq j \leq n_{C_I}$,
- $\bar{y}$ is the centroid of $\mathbf{y}$. Similarly, $\bar{y}_I$ is the centroid of $\mathbf{y_I}$.

- **Elbow index:** the elbow method consists in computing the sum of squared distances (distortion score or inertia (1)) for each point to its assigned centroid [13]. The optimal number of clusters is the one where the drop in the distortion score is the most important.
- **Silhouette index:** for a given observation and $y_{I,j}$, the silhouette score measures the mean distance to all points of its cluster (3a) and compares it to the mean distance to all points of the neighboring cluster (3b). $s(I,j)$ has a score of 1 if $y_{I,j}$ is a perfect match with cluster C_I and a score of -1 with the neighboring cluster. The silhouette index is the mean of all coefficients $s_{I,j}$ (3d).
- **Calinski-Harabasz index:** it estimates the cohesion of clusters. It evaluates the distance from points in a cluster to the centroids and the distance from the centroids to a global centroid (2).

  The elbow index is commonly used. However, according to [14], *CH index* and *silhouette index* are the ones performing the best to evaluate a Kmeans clustering.

$$SS(\mathbf{C}) = \sum_{C_I \in \mathbf{C}} \sum_{y_{I,j} \in \mathbf{y_I}} (y_{I,j} - \bar{y}_I)^2 \quad (1)$$

$$CH(\mathbf{C}) = \frac{n-K}{K-1} \frac{\sum_{C_I \in \mathbf{C}} n_{C_I} \cdot d(\bar{y}_I, \bar{y})}{\sum_{C_I \in \mathbf{C}} \sum_{y_{I,i} \in \mathbf{y_I}} d(y_{I,i}, \bar{y}_I)} \quad (2)$$

$$a(I,j) = \frac{1}{n_{C_I} - 1} \sum_{m \in C_I,\, j \neq m} d(y_{I,j}, y_{I_m}) \quad (3a)$$

$$s(I,j) = \frac{b(I,j) - a(I,j)}{max(a(I,j), b(I,j))} \quad (3c)$$

$$b(I,j) = \min_{J \neq I} \frac{1}{n_{C_J}} \sum_{y_{J,m} \in C_J} d(y_{I,j}, y_{J_m}) \quad (3b)$$

$$S(\mathbf{C}) = \frac{1}{n} \sum_{C_I \in \mathbf{C}} \sum_{y_{I,i} \in C_I} s(I,i) \quad (3d)$$

With this being defined, algorithm 1 is used to determine the optimal number of clusters k_{opt}.

Once k_{opt} is determined, the clustering in itself can be done. It is repeated 500 times and the one with minimal inertia is kept as the final clustering. If the right number of clusters was used, the clustering should be *stable*, *i.e.* observations should be labeled the same way from one iteration to the other. Rand [15] has created an index to evaluate this stability. When two clusterings (obtained from different algorithms or number of clusters) are to be distinguished, the one with the higher Rand index is kept. Moreover, for a clustering to be valid, it should have a minimum level of stability. [16] stated equation (4), defining it depending on the clustering sizes (r and s). If $ARI \leq min\ ARI$, clustering is rejected.

$$min\ ARI = \left[1 - \frac{1}{2}\binom{r+s-1}{2}\left[\binom{r}{2}^{-1} + \binom{s}{2}^{-1}\right]\right]^{-1} \tag{4a}$$

$$if\ r = s:\ min\ ARI = \frac{-r}{3r-2} \tag{4b}$$

2.2.2. *GaussianMixture*

The process is similar to the one for *Kmedoids*. The *GaussianMixture* algorithm needs a number of components and the shape of the covariance matrix to work. Again, if no previous knowledge helps to determine those parameters, scores are used to find them.
Because the *GaussianMixture* relies on probabilities, the best clustering is the one that maximises the likelihood. The likelihood function evaluates the joint probability of observed data as a function of the chosen statistical model. Given a set of n training vectors **y**, the GMM likelihood function can be written as in (5).

However, adding components helps increase the likelihood while it may lead to overfitting the data. Criteria introduce penalty terms on the number of parameters to solve the issue.

- **Akaike Information Criterion (AIC):** defined by (6a), it should be as small as possible. It is an efficient criterion when the model is very complex and is chosen in this context.
- **Bayesian Information Criterion (BIC):** defined by (6b), the BIC should also be as small as possible. It has consistency (meaning it would asymptotically select the candidate model having the correct structure), as its penalty term contains n.

$$p(y \mid \lambda) = \prod^{n} p(y_i \mid \lambda) \tag{5}$$

$$AIC = 2 \cdot ln(k_\lambda) - 2 \cdot ln(\hat{L}) \tag{6a}$$

$$BIC = k \cdot ln(n) - 2 \cdot ln(\hat{L}) \tag{6b}$$

where $\hat{L}$ is the maximised value of the likelihood function of the GMM defined in (5), k the numbers of estimated parameters of the model.

Algorithm 2 describes the steps to determine the key parameters. Once they are selected, as for *Kmedoids*, the Rand index is computed.

2.3. Case study: the Canton of Geneva

In this research, data are collected over the canton of Geneva, an area containing a typical mid-size European city, a peri-urban area, and some rural areas.
The districts are defined according to the LV transformers to which the buildings are connected.

Because the position of transformers is not publicly available, this research uses the synthetic grid approach from the work of [17], which estimates the position of transformers based on the buildings' energy demands. Most of the data concerning buildings comes from **QBuildings**, a database developed at the IPESE laboratory. The buildings data are aggregated over districts and normalised by the total *Energetic Reference Area (ERA)* by district.

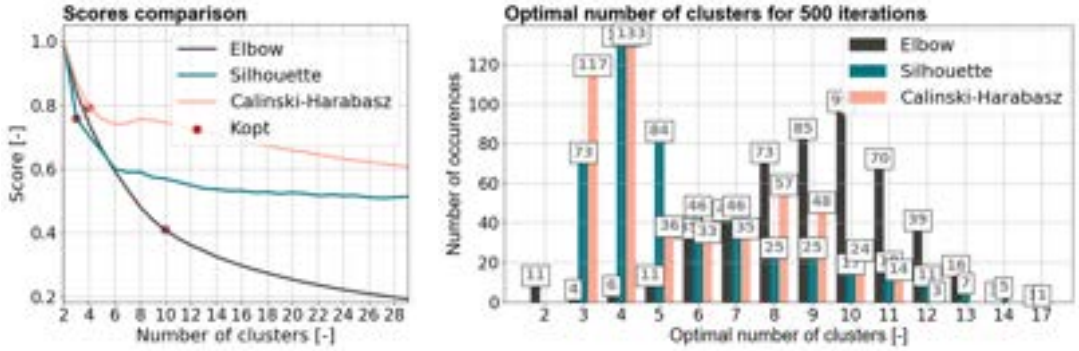
3. Results and discussion

The results and discussion seek to demonstrate the applicability of the method developed on a typical European city intending to subsequently run an energy system optimisation model. First, the clusterings obtained with the two algorithms are analysed. Second, the results of the optimisation with and without the clustering are compared to ensure the validity of its use for decision-making purposes.

3.1. Clustering results

3.1.1. Optimal number of clusters

As a first step, the optimal number of clusters should be determined to run the algorithm. Figure 3(a) shows the mean score obtained for each number of clusters for the three indexes and Fig. 3(b) shows the number of occurrences where each number of clusters gives the best score, with the *Kmedoids* algorithm.



(a) Mean scores obtained for the three indices.

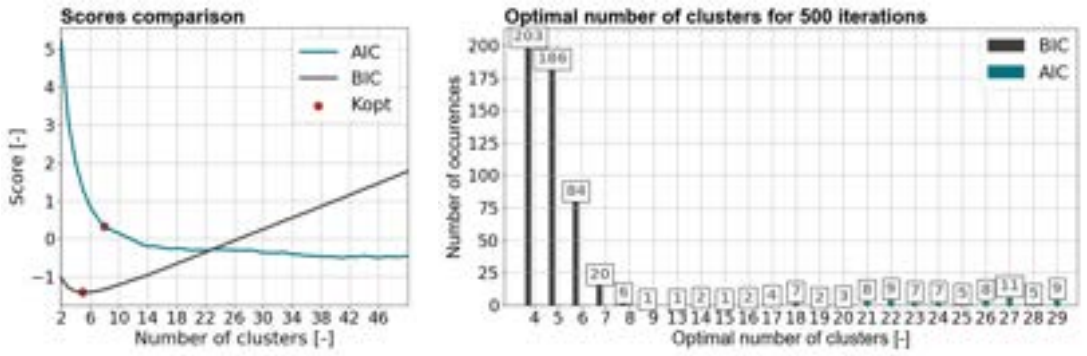
(b) Occurrences where a number of clusters is found optimal.

Figure 3: Results of the optimal number of clusters investigation, Kmedoids, repeated 500 times.

The silhouette and the CH index agree on 2 as the optimal number. However, 2 clusters are insufficient to discriminate between the different optimisation problems that may be posed. Therefore, the next optimum is looked at. According to Fig. 3(a), for CH, the line breaks at 4 and then there is a new local maximum at 8 and for the silhouette index, the break is at 3. This is confirmed by Fig. 3(b). The elbow occurs the most between 8, 9, and 10.

In comparison, Figs. 4(a) and 4(b) indicate an optimal number of clusters between 4, 5, or 6 for the BIC index. The AIC obtains an elbow-like shape curve where the main change of curvature happens at 5 and 8. Note that only the full covariance matrix shape is shown, as it has always obtained the best score.

From those two results, 3, 4, 5, and 8 are the best number of clusters to investigate.



(a) Mean scores obtained for the two indices. (b) Occurrences where a number of clusters is found optimal.

Figure 4: Results of the optimal number of clusters investigation, GaussianMixture, repeated 500 times.

3.1.2. Clustering

With the k_{opt} search results, algorithms are run to compute the Rand index and keep the most stable clustering. Table 1 displays the Rand index computed by repeating the clustering 1000 times, with the different numbers of clusters. The most stable clustering is obtained with the *GaussianMixture* algorithm and in particular when the requested number of clusters is 4 and 5.

Table 1: Rand index by clustering 1000 times, varying number of clusters.

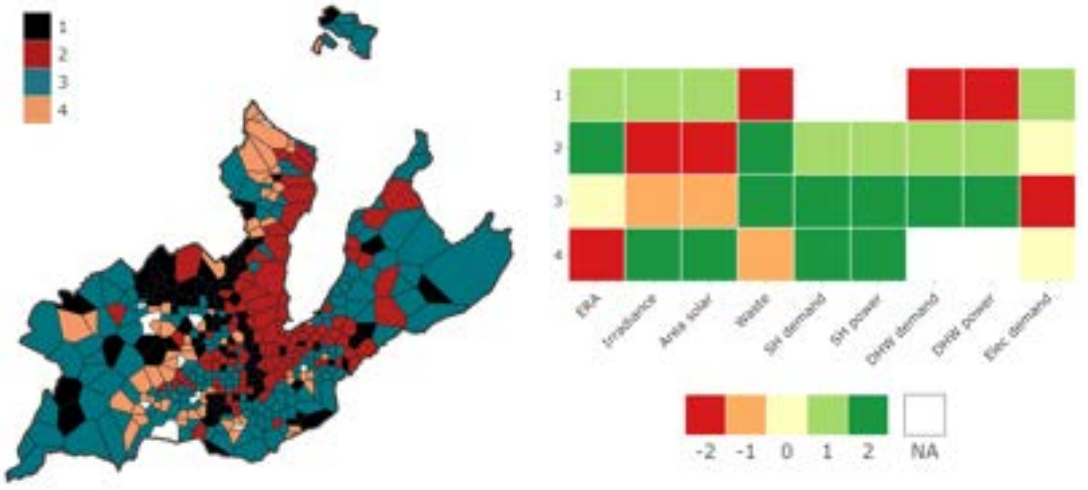
Number of clusters	3	4	5	8
Mixture	-	0.717	0.693	0.399
Kmedoids	0.331	0.383	0.287	0.388

Because they were the best options according to the BIC index and they have a satisfying Rand score, the 4^{th} and 5^{th} options are kept. While doing the clustering with 5 different clusters, it often resulted in an empty 5^{th} cluster. Therefore, 4 different clusters is the selected optimal number. The result of this clustering can be visualised in Fig. 5(a). A heat map from the input features (Fig. 5(b)) is used to understand what differentiates clusters from each other.

Looking at those elements, the clusters can be characterized and described in the following way:

Cluster	DESCRIPTION
1	Districts dominated by industrial, commercial, and administrative buildings
2	Residential belt around the lake, with high buildings density and low solar potential per capita
3	Peri-urban residential buildings, with low ERA density (i.e., single-family detached houses)
4	Peri-urban buildings with important solar availability (high roof on ERA ratio)

The hot water demand, along with the electrical demand, have the biggest influence on the clustering as they can vary a lot according to the building type.



(a) Map of the canton of Geneva coloured by clusters.

(b) Heat map evaluation of each feature for each cluster. Features are evaluated on a scale of -2 to 2.
-2: Very low, -1: Low, 0: Average, 1: High, 2: Very High.
Missing cells correspond to a non-decisive case, indicated by parsed values inside the cluster.

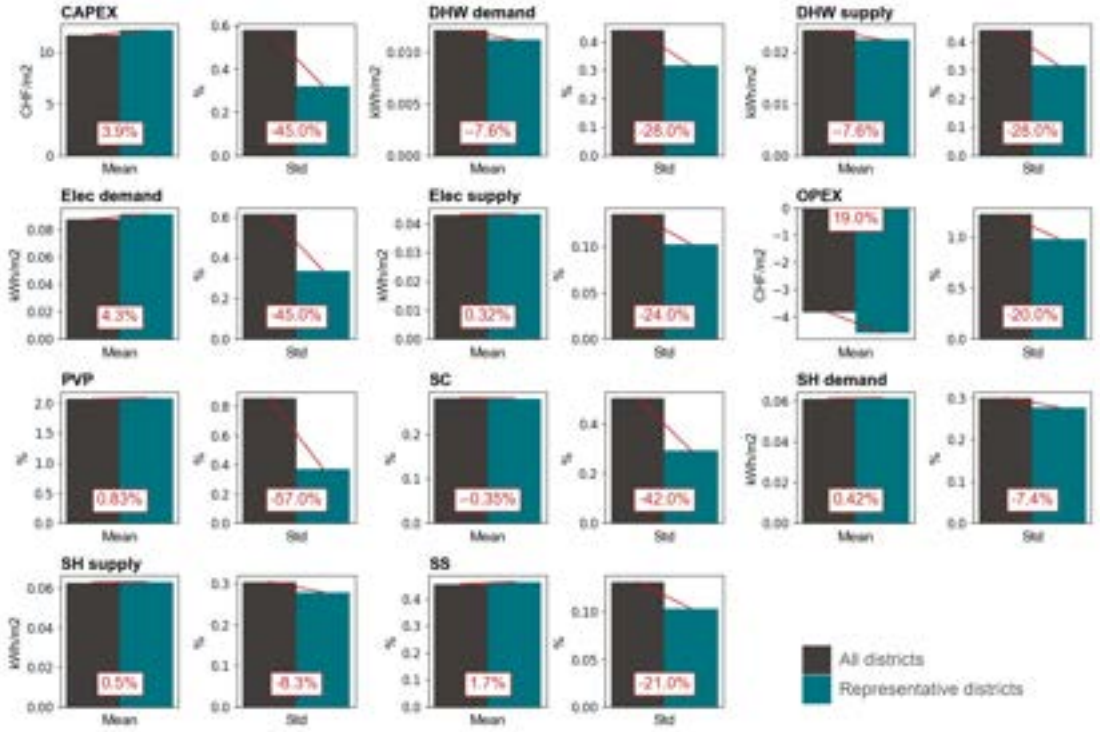
Figure 5: Clustering results and analysis on the canton of Geneva, operated with *GaussianMixture*, 4 components and full covariance matrix.

3.1.3. Comparison of optimisation results with and without district typification

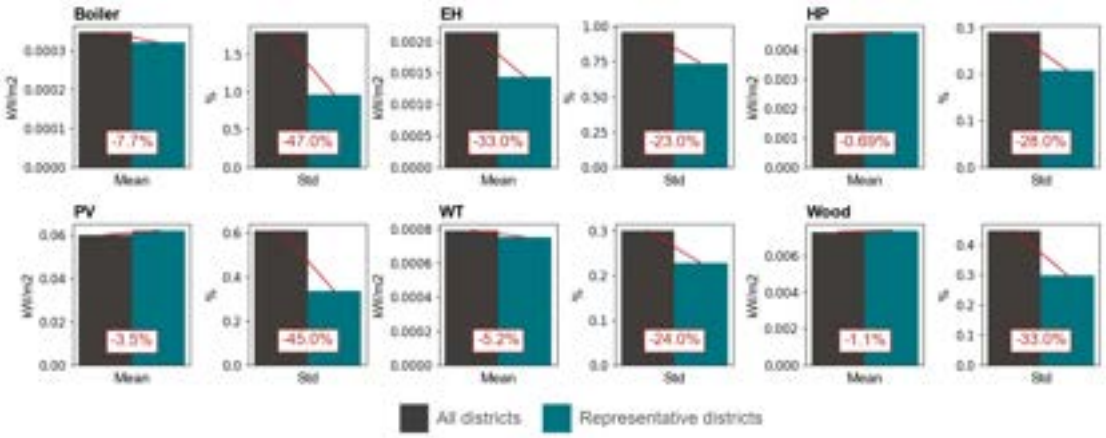
To ensure the validity of the method, one should ensure that when using typical districts to do the optimisation (namely *Representative districts (RD)* approach in what follows), similar results are obtained as the ones where every district has been optimised specifically (*All districts (AD)*).

To do so, the decision variables of the model and the resulting *Key Performance Indicators (KPI)* are compared between the two approaches. The global mean obtained on the canton of Geneva should show no significant distinction. The mean is weighted by the total ERA that each cluster represents for *RD*. The intra-cluster variabilities are also compared to the standard deviation computed over the whole canton.
Using an optimisation tool that models an energy hub and determines the best energy system, finding the optimal energy system for the 468 districts of Geneva took 54h21m23s with *AD* and 48m18s with *RD*, i.e. a reduction in the calculation time of 98.5%. The comparison of their respective decision variables and *KPIs* are shown in Fig.6(a) and Fig.6(b). The major diminishing of the standard deviation for each evaluated metric confirms that the patterns among the inputs that participated to create the district clusters are meaningful as well for patterns in the optimisation results. Moreover, there was no significant difference between the mean obtained using the *AD* or the *RD* approach, with two exceptions: the OPEX and Electrical Heater installation size, which have high variability within the canton. Therefore, it is more difficult to accurately represent these indicators with typical districts.

Nevertheless, the overall results obtained show an excellent performance of the method to facilitate the optimisation of districts over a large scale.



(a) Main KPIs. *CAPEX*=Capital Expenditure, *DHW*=Domestic Hot Water, *Elec*=Electricity, *OPEX*=Operationnal Expenditure, *PVP*=Photovoltaïc Panel Penetration, *SC*=Self-Consumption, *SS*=Self-Sufficiency



(b) Installed capacity for the energy technologies. *Boiler*=Natural Gas Boiler, *EH*=Electrical Heater, *HP*=Heat Pump, *PV*=Photovoltaïc Panel, *WT*=Water Tank

Figure 6: Comparison of results obtained with the two approaches. *All districts* stands for the results obtained by optimising every district in the canton of Geneva, while *Representative districts* is obtained by running the representative districts and scaling their solution to the districts of their cluster. The figures in red indicate the representative difference between the two approaches.

4. Conclusion

The objective of this paper was to provide a method to enable urban energy modelling at a large scale and high accuracy, for integrated and distributed systems. It uses the concept of archetypes, introduced for buildings, and adapts it to the district scale by defining the low-voltage transformer as the reference energy hub.
The method suggests the use of two clustering algorithms - *Kmedoids* and *GaussianMixture*, depending on the data set - and provided as output the list of the districts labeled by cluster. It was validated on a case study (the canton of Geneva), with the following conclusions:

- It can be delicate to determine the optimal number of clusters;
- The model solving computation time over the whole region was reduced by 98.5%, with respect to the classic approach;
- The results between the two approaches show no significant difference with 4 clusters, although the high variability of certain decisions can lack a good representation with this approach.

The presented work opens up possibilities in the solving of more complex systems at an even larger scale. However, its main limitation is the selected number of clusters, this parameter being the most critical into the analysis of the energy system model results. Therefore, when planning urban energy systems with this method, it will be essential to carry out a correct analysis of the neighbourhood typology.

5. Fundings

The research published in this report was carried out with the support of the Swiss Federal Office of Energy SFOE as part of the SWEET project acronym. The authors bear sole responsibility for the conclusions and the results of the presented publication.

Abstract:
The exponential growth in the number of papers published annually in the field of machine learning applications in energy systems presents a challenge to researchers seeking to conduct comprehensive and effective literature reviews. To address this issue, we took a systematic literature review approach with three distinct smaller case studies focusing on the application of machine learning in energy systems, namely:

1. Machine learning in drilling
2. Machine learning for rooftop solar energy potential quantification, and
3. Machine learning in district heating and cooling in the context of seasonal thermal energy storages.

In each case, we employed a systematic literature review methodology. For topic one, we utilized an existing comprehensive review to generate further insights and information. For topics two and three, we used predefined search criteria to conduct relevant publications in a systematic and reproducible manner. We investigate the state of the art of the use of machine learning in these distinct areas of inquiry, thereby facilitating the identification of research gaps. Ultimately, we compare approaches and models utilized in each field, identified common best practices, and propose methods to address potential challenges.

Keywords:
Energy systems, Machine Learning, Drilling, ATES, Roof Potential, Geothermal, Aerial Imaging, Renewable Energy, District heating and cooling, Seasonal Thermal Energy Storage

1. Introduction

Energy systems are the backbone of modern civilization and are critical to promoting environmental, economic, and social sustainability [1]. As energy systems become increasingly complex, they require higher reliability demands and offer greater degrees of freedom for practical enhancement of integrated multi-energy systems [2]. Machine learning-based data-driven models have emerged as a promising approach for significantly improving the overall usage rate of multiple energy sources, especially including renewable energies [3]. Machine learning can capture complicated mechanisms to increase prediction accuracy, make optimal choices based on detailed state information, and reduce computational time needed for energy system optimization [4, 5]. In addition, machine learning has been applied to develop advanced energy storage devices and systems [6]. In this review, we explore three impactful applications of machine learning in energy systems and the challenges and limitations that must be addressed for further progress in this field.

Case Study Approach

We adopt a systematic literature review approach to investigate the state-of-the-art in application of machine learning by conducting three distinct case studies. The aim is to provide valuable insights into the potential of machine learning to solve complex problems across different fields. In the first case study, an analysis of a recent review paper on machine learning in drilling by Li et al. 2022 [7] is conducted to provide additional insights. The second case study focuses on the use of machine learning in rooftop solar energy quantification, while the third case study examines the use of machine learning in district heating and cooling in the context of seasonal thermal energy storages. These case studies showcase the application of machine learning in different sectors, such as load demand forecasting, design, cost, and control optimization. The specific machine learning techniques used, challenges faced, and an outlook in each field are presented. By exploring these case studies, this review paper aims to provide a comprehensive understanding of the state-of-the-art in the application of machine learning and its potential for solving complex problems in various fields. After introducing the applied methodology for each case study and the subsequently chosen selection of papers,

we provide in the results section for each case study a case study results subsection followed by a short case study conclusion and outlook. We conclude with a summarizing conclusion and outlook across the case studies.

2. Methodology

Organizing and planning literature searches is a complex process that requires careful attention to several key categories. These include defining the scope of the literature, conceptualizing the topic, conducting a literature analysis, searching for relevant literature, and developing a research agenda. Various search processes have been introduced to enhance the quality of literature reviews, such as journal and database searches, keyword searches, backward and forward searches, and evaluation of the title and abstract of relevant literature [8]. To ensure effective literature searches, it is also recommended to gain a thorough understanding of the subject matter, test and apply a combination of search parameters, and use seminal sources to build the backbone of the literature review [9]. Our paper employs the Concept Matrix Method [10], which is aligned with these guidelines to ensure accurate and efficient collection, study, and categorization of the survey. In our case studies, we use relevant keywords to conduct literature searches on Google Scholar.

The first case study focuses on machine learning in drilling, which is an enormously active research field. As one can see in Figure 1, the number of papers published per year on machine learning in drilling shows an exponential increase. A very recent and comprehensive review of Li et al.2022 [11] will here be our base of research, whose content we will analyze further in the following.

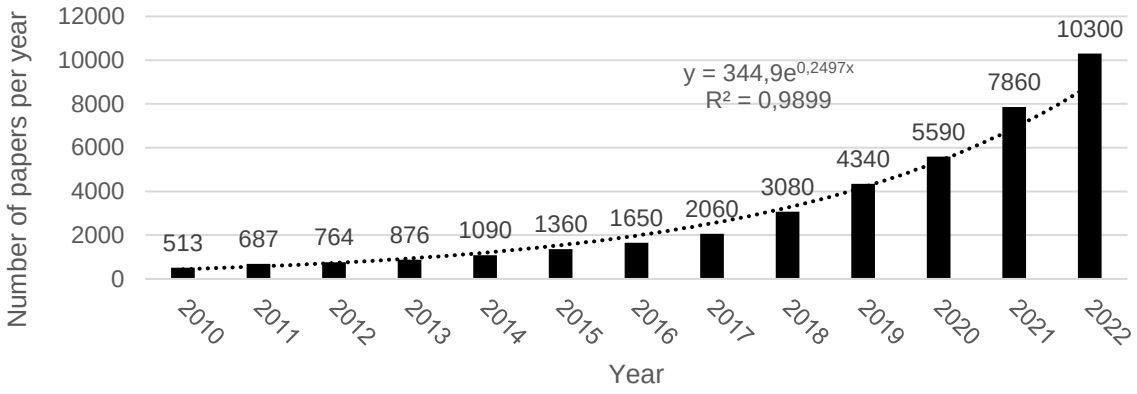

Figure 1: Number of papers published for per year when searching for “machine learning” + “drilling” showing an exponential increase.

The second case study explored the field of solar rooftop potential quantification by finally narrowing down to the search string "machine learning" + "solar energy" + "rooftop" + “quantification” + “urban” + "aerial image" + "geographic information system" (cf. Figure 2).

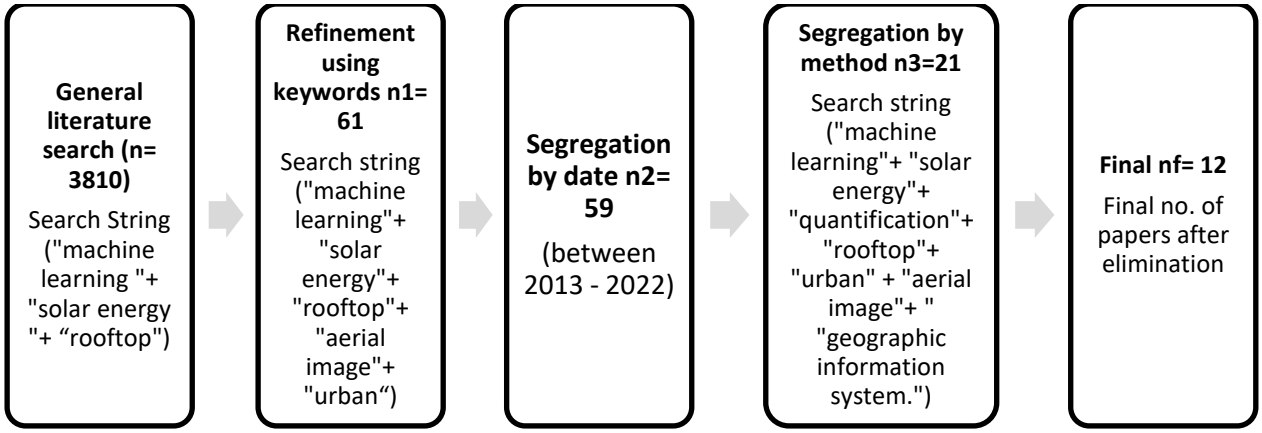

Figure 2: Steps involved in the refinement process for the case of solar rooftop potential quantification using machine learning.

The systematic literature search was undertaken in Google Scholar. Using the search string "machine learning "+ "solar energy "+ “rooftop yielded 3810 papers. The number of results was then reduced by inserting the term "urban" and “aerial image” to the search string to 61, resulting in the search string "machine learning"+ "solar energy"+ "rooftop"+ "aerial image"+ "urban". The results were narrowed down to 59 by excluding publications published on or before 2012. Adding the term "geographic information system" decreased the results to 21 for the search string "machine learning"+ "solar energy"+ "rooftop"+ “quantification” + "urban" + "aerial image"+ "geographic information system", which then where finally reduced to 12 papers due to accessibility (i.e. not open access) and relevance.

During the systematic refinement process, it was observed that there is also an exponential increase in the number of papers published in the research area selected for systematic reviewing for the more general search string "machine learning "+ "solar energy "+ “rooftop" over the years (cf. Figure 3).

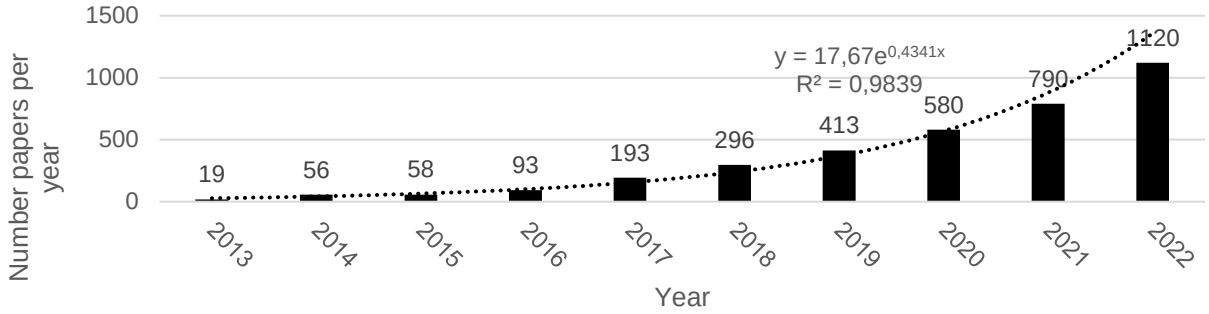

Figure 3: Number of papers published for per year when searching for "machine learning "+ "solar energy "+ “rooftop" showing an exponential increase.

The third case study examined the application of machine learning in district heating and cooling in the context of seasonal thermal energy storages. Be employing the search string "machine learning" + "district heating and cooling" + "seasonal thermal energy storage" and limiting to articles published between 2010 and 2022, we obtained 46 potential articles. Figure 4 displays the number of articles in each year from 2010-2022. The 46 papers were aging reduced to 7 papers based on the following criteria 1. papers that are not open access (21), 2. paper without machine learning application (11), 3. Papers without STES (6), 4. other papers (2), which were not relevant to the study.

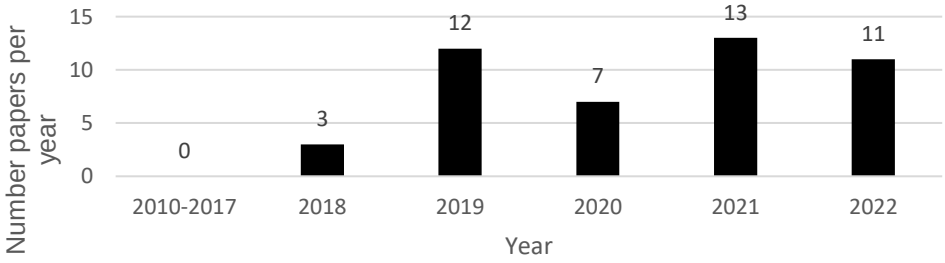

Figure 4: Number of papers published for per year when searching for "machine learning" + "district heating and cooling" + "seasonal thermal energy storage" showing an increase over the years on average.

3. Results

3.1. Machine Learning in Drilling

The application of machine learning or artificial intelligence (AI) has become increasingly prevalent in various industries in recent years [11]. The transition from fossil fuels to renewables to reduce greenhouse gas emissions has led to the rise of renewable energy sectors, such as solar and wind energy, that provide heat and electricity [12,13]. While the share of renewable energy in Europe was 22.2% in 2021 [14], this is still insufficient to meet the renewable energy demands with respect to a climate neutral energy system in the near future [15]. As a result, new technologies are emerging and being developed to support this transition. One sector that requires attention and research to make it a mainstream energy source is geothermal energy, as the energy generation is marginal in both the European Union (3.2%) and Germany (2.5%), despite its potential [16,17,18]. The critical aspect of accessing geothermal energy is developing the reservoir using drilling techniques, which represent nearly 30% to 50% of the costs for a hydrothermal geothermal project and more than half of the total cost on Enhanced Geothermal Systems (EGS) [19]. However, there are also emissions in the drilling process which should be minimized, too [20]. The development of intelligent drilling and

completion technologies using machine learning has shown potential to improve the drilling process's efficiency and accuracy [7]. Our study builds upon the comprehensive literature review conducted by Li et al. [7] and strives to offer insights into the particular domains of drilling where machine learning can be applied, as well as the types of algorithms that can be leveraged for specific tasks to enhance efficiency [7]. Li et al. 2022 [7] cite a total of 160 papers, include a number 137 in their analysis over the research fields (cf. Table 1), from which we further analyze 124 while excluding papers where machine learning is not used.

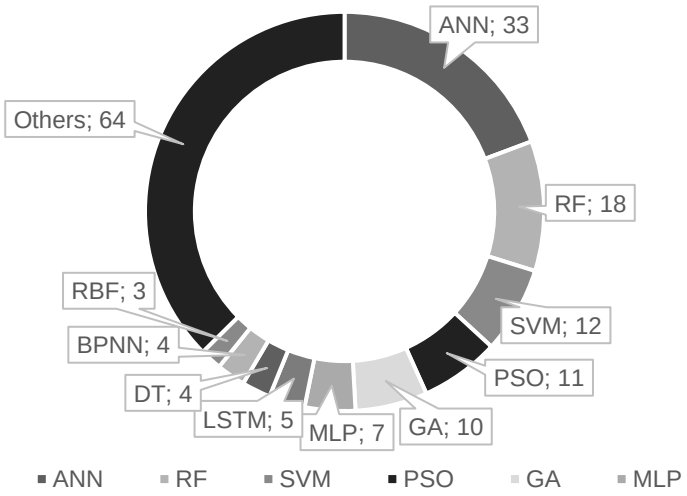

Figure 5: Number of used machine learning algorithms in the 124 papers cited in Li et al. 2022 [7] applying Machine Learning in Drilling

Case Study Results

There are numerous algorithms which have been used in the different papers analyzed by Li et al. 2022 [7] (cf. Figure 5) but among those only five algorithms are highly utilized in most of the fields, which are Artificial Neural Networks (ANN), Random Forests (RF), Support Vector Machine (SVM), Particle swarm optimization (PSO) and Genetic algorithms (GA) (cf. Table 1). These five commonly used algorithms are defined by us based on the repetition and total usage count not less than 10 times across the whole research fields in Li et al. 2022 [7]. Overall, ANNs define the by far most widely used approach and the usage of ANNs is popular in most fields (cf. Figure 6).

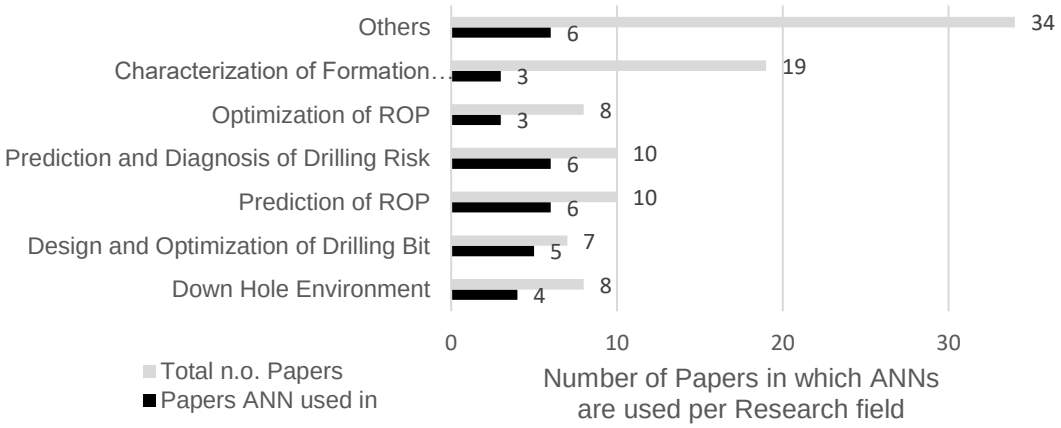

Figure 6: Number of papers per research field in which ANNs were applied in comparison to the total number of papers addressing machine learning in Li et al 2022 [11]

Research Fields	Algorithms				
	ANN	RF	SVM	PSO	GA
Down Hole Environment	4	1	0	0	1
Design and Optimization of Drilling Bit	5	1	0	1	1
Intelligent Prediction of ROP	6	3	3	3	1
Intelligent Optimization of ROP	3	3	0	1	3
Intelligent Design of a well trajectory	0	0	0	1	2
Real time evaluation and optimization of a well trajectory	0	2	0	2	0
Intelligent decision making and control of well trajectory	0	0	0	0	0
Intelligent Characterization of formation properties	3	1	1	0	0
Intelligent Description of wellbore flow behaviour	2	0	1	0	1
Intelligent prediction and diagnosis of drilling risk	6	4	5	1	0
Intelligent control of drilling process	0	0	0	0	0
Intelligent design of hydraulic fracturing	1	1	0	1	1
Intelligent warning and identification of fracturing event	0	1	1	0	0
Productivity prediction and fracturing parameter optimization	1	1	0	0	0
Intelligent completion design and optimization	2	0	1	1	0
Total	33	18	12	11	10

Table 1: Research fields and number of the five most commonly used algorithms in each of these for the analyzed papers from Li et al. [7].

From Table 1, we get an impression of extensively and non-extensively used algorithms in different fields for the five commonly used algorithms. Li et al. [7] analyzed 15 research fields in drilling where machine learning and physical models are used, and from those, whereas 13 fields utilized machine learning for various purposes [7]. Next to the five commonly used algorithms there are few others which are equally often used in some of the research fields, which we want to highlight in the following.

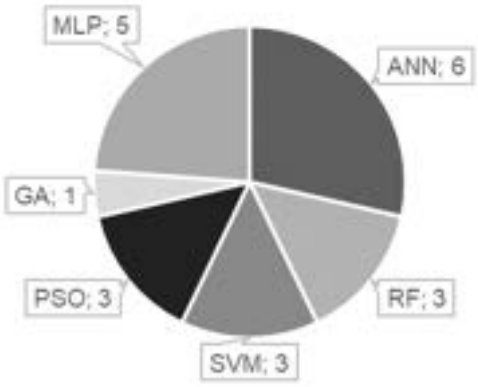

Figure 8: Algorithms used in Prediction of ROP

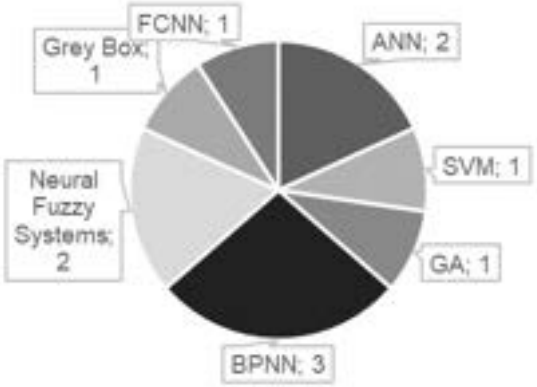

Figure 7: Algorithms used in Wellbore Flow Behavior

From Figure 8, we observe that next to the five widely used algorithms, Multi-Layer Perceptrons (MLP) are commonly applied to predict the rate of penetration (ROP). Back Propagation Neural Networks (BPNN) outnumber the five common algorithms in the field of well bore flow behavior (cf. Figure 7). Of course, there are other fields where utilization algorithms next to the five highlighted ones is common - in any case, to achieve the desired results, multiple algorithms should be tested, and there might be no need to choose an algorithm over another. This analysis gives us an impression on how the different research fields of drilling are commonly approached with machine learning techniques.

Depending on the type of process and thus data (dynamic and static) the selection and application of machine learning models is adapted also with respect to performance and robustness. In the two research fields “control of the drilling process” and “well trajectory design”, physical models and control systems were used for stability, control efficiency of the well, and as a strategy to control the trajectory [7]. There are also few fields where machine learning is partially used or not used at all, but instead, physical based models have been used, mostly to control the well trajectory from real time steerable systems (RSS) [7].

Case study Conclusion and Outlook

The analysis which has been made shows that ANNs are highly used approach in most of the fields, the highest usage of ANNs is in “Intelligent prediction of ROP”, “Intelligent prediction and diagnosis of drilling risk” followed by “Design and optimization of drilling bit” and “Downhole environment perception”. There are few research fields where there is no use of ANNs like “Real time evaluation and optimization of a well trajectory”, “Intelligent design of a well trajectory”, “Intelligent warning and identification of fracturing event” instead other approaches like RF, SVM, PSO were used. As the dominance of ANNs is high one can try implementing them in fields where it has not been used much, yet. Furthermore, RF and SVM approaches were used highly only in “Intelligent prediction and diagnosis of drilling risk” and “Intelligent prediction of ROP”, thus, more studies and implementations could be made in other fields. In the research fields “Intelligent warning and identification of fracturing event” and “Productivity prediction and fracturing parameter optimization” the total use of machine learning is still quite low regarding the total number of papers analyzed by Li et al. 2022 [7], and thus maybe provide good research opportunities for the application of machine learning in drilling.

3.2. Solar Rooftop Potential Quantification

The utilization of solar energy for heat or electricity generation is a highly promising and sustainable alternative to the use of fossil fuels, and the rooftops of buildings represent an underutilized resource for solar power generation [21, 22]. To quantify the potential of rooftop solar energy at a large scale, it is necessary to determine the roof area of buildings that can receive solar radiation, calculate the total solar radiation obtained within the region based on meteorological conditions, and estimate the total solar energy potential with carbon emissions savings and the economic recovery period [23, 25]. However, determining the total roof area can be a challenging task, especially for large regions such as cities or countries [23]. To overcome this challenge, machine learning techniques have been developed to identify and quantify the roof area using aerial and satellite images [24, 26, 28]. This involves collecting initial data from sources such as Google Earth and Copernicus and using semantic segmentation architectures like U-net and Inception-resnet-v2 to identify and segment roofs in the images based on their pixel characteristics [21, 24]. The benefits of utilizing rooftop solar energy are significant, as it enables the local production of renewable power and has enormous potential for reducing greenhouse gas emissions [22, 27]. Studies have shown that rooftop solar energy has the potential to meet a significant portion of a region's energy demands, such as 22% of Europe's energy demand and 15-45% of the energy needs of countries like the United States, Israel, Canada, and Spain [27]. Furthermore, in individual cities like Hong Kong and Seoul, rooftop solar energy has the potential to meet up to 14.2% and 30% of energy demand, respectively [27]. Therefore, there is a clear need to further investigate the potential of rooftop solar energy at a large scale using machine learning and other innovative techniques. This study seeks to provide a systematic literature review of rooftop solar energy measurement based on aerial imaging and machine learning, analyzing various research papers published in this field to compare and address the advantages and disadvantages of different quantification strategies [21, 24, 26, 28]. By doing so, we hope to contribute to the development of more effective methods for quantifying rooftop solar energy potential, which can play a crucial role in the transition from fossil fuels to sustainable energy sources.

Case Study Results

All twelve articles obtained from the systematic literature review process in this study used Google earth as a source for input data. It was also observed that some studies also utilized open-source resources like Copernicus, Open Street Maps (OSM), technical details of PV systems, and aerial pictures accessible using Google Maps' static API. However, the article [24] states that private sources provide high-definition aerial photos for rooftop detection rather than public ones like Google earth.

Semantic segmentation is a major step in the quantification process. It was observed that U-Net is used in most of the studies for semantic segmentation. CNN built on the U-Net is employed, because of its higher performance on small datasets [25]. The paper [26] compared EfficientNet-B3, Inception-resnet-v2, and VGG-19, and Inception-resnet-v2 was chosen due to its superior performance. For semantic segmentation approaches with traditional supervised learning. The article [27] compared three semantic segmentation frameworks: U-Net, PSPNet, and Deeplabv3+ and U-Net was found to be performing better than the others.

In a study conducted by [28] Rooftop Photovoltaic potential has been evaluated using a quick-scan yield prediction technique. It consisted of three primary components. Aerial footage was used to rebuild virtual 3D roof segments for each roof, which were then automatically fitted with PV modules using a fitting algorithm, followed by the calculation of predicted yearly production. After the results were obtained some of the studies had tried to check the accuracy. Twenty randomly chosen roofs were chosen by [29] to compare the model's predictions with estimated real values to assess the findings' accuracy.

Some common challenges in in the application of machine learning for rooftop solar potential quantification are:

- **Failure to identify pre-existing solar panels:**

  As observed in most of the papers, when the roof area was calculated, much research failed to consider pre-existing solar panels. No differentiation between rooftop space and other surfaces is conceivable within building footprints. This can result in incorrect categorization[30]. When we consider a large area with numerous buildings for the study, they can affect the final output. A machine learning model which can identify and discriminate solar panel area from the rest is crucial to obtain correct results. Apart from solar panels, the machine learning model must be able to distinguish objects like water tanks, Chimneys etc.

- **Limited resolution in the available data:**

  Another Challenge faced by semantic segmentation is the least pixel count. Since the least count is restricted to a pixel, if the major portion of pixel is dominated by a particular object, the Machine Learning model identifies the entire pixel to be that object. Most of the studies though uses public sources like Google earth where semantic segmentation can only be done on available images in given course resolution.

- **Failure to identify inclined roofs:**

  Since only the top view is taken into consideration, the calculated roof area of an inclined roof will be always less than the actual value. This can also have a huge impact on the final output. The machine learning model must be taught to consider this factor, while processing the data, as in some research like the one carried out by [31].

Case Study Conclusion and Outlook

We have systematically reviewed papers in the field of application of machine learning rooftop solar energy quantification and One of the major challenges faced in the quantification process is the identification of preexisting solar panels during semantic segmentation. A solution to this was not identified in any of the papers reviewed and could subject to future research.

.

3.3. Machine Learning in District Heating and Cooling in the Context of Seasonal Thermal Energy Storages (STES in DHC)

District heating and cooling (DHC) systems are an important part of the energy sector, providing sustainable solutions to communities. To improve the efficiency of DHC systems, machine learning techniques have been increasingly applied [33]. To supply energy to DHC systems, a source is required, and Seasonal Thermal Energy Storages (STES) can act as an energy source for DHC [34]. STES can help to manage the mismatch between the supply and demand of renewable energy systems, which may occur over seasonal and inter-annual periods. There are four different types of STES: Borehole Thermal Energy Storages (BTES), Aquifer Thermal Energy Storages (ATES), Pit Thermal Energy Storages (PTES), and Tank Thermal Energy Storages (TTES) [35]. Therefore, this study focuses on investigating the application of machine learning in DHC networks with STES, with load/demand prediction, design, and control optimization as the main research categories [33]. This research is motivated by the need to improve the efficiency and reliability of DHC systems while reducing their environmental impact.

Case Study Results

The algorithms used in the seven articles are Artificial neural networks (ANN), genetic algorithms and Non dominant Sorting Genetic Algorithm NGSA-II, which is a multi-objective optimization algorithm which is again the extension of an original NGSA develop by Kalyanmoy Deb in 2022 [4]. Figure 9 gives number of articles used by machine learning methods.

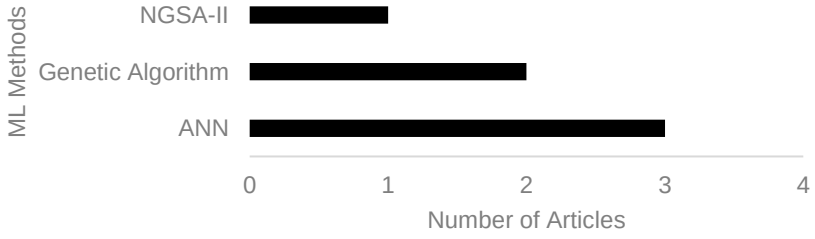

Figure 9: Number of articles with respect to the applied machine learning methods in District Heating and cooling in context of Seasonal Thermal Energy Storages

Various machine learning applications have been applied in different domains, including predictive maintenance, energy demand forecasting, control optimization, and anomaly detection. The papers addressed in this case study had application of machine learning in energy demand forecasting, control optimization, design, and fault detection, specifically in the context of Seasonal Thermal Energy Storages (STES), Aquifer Thermal Energy Storages (ATES), and Borehole Thermal Energy Storages (BTES). However, studies on other types of thermal energy storages, such as Pit Thermal Energy Storages (PTES) and Tank Thermal Energy Storages (TTES), were not present in the papers analyzed and thus not considered in this study. presents the distribution of studies across the various machine learning application categories.

Machine learning applications are applied in differrent ways such as preditcitve maintanence, energy demand forcasting , control optimization, anomaly detection. Here in the study of the selected articles we came accros with the energy demand forecasting, control optimization, design and fault detection. Studies undergo with STES and Aquifer Thermal Energy Storages and Borehole Thermal Enrgy Storages are peformed here, whereas other thermal energy storages such PTES and TTES studies did not show up in the considered papers and are thus neglected. Table 2 shows the three different applied machine learning algorithms in the different categories of application.

Table 2: Applied machine learning algorithms in different categories of application

Category	ANNs	GA	NSGA-II
Energy demand forecasting	1		
Control Optimization		2	1
Design, fault detection	1	1	

Further adressed aspects are:

- In [37], the model predicts the signal of charging and discharging operation and belongs to the category of energy demand forecasting. It was validated to be used in other similar projects; both charging and discharging models have an average accuracy over 95%.
- In [38], optimal based control and model predictive control were applied. MATLAB and a genetic algorithm were used to find an estimate of the global minimum, and a local non-linear minimization routine was used afterwards to refine the calculation.
- In [39], TRNSYS system models and a so-called multi-objective building optimizer (MOBO) are combined to perform the optimization. For this study, the NSGA-II algorithm is used, because it can take care of the constraints, discrete and continuous variables for a multi-objective problem [39].
- In [40], the main objective is to development of a modeling environment able to effectively compare configurational and design choices for multi-energy systems. The core of the Model Predictive Control, that is the optimization function which is Genetic Algorithm, receives information on its settings from the MATLAB organization layer. The role of the Genetic Algorithm is to find the optimal set of instructions for the generation units of the Test Facility for the next prediction horizon. The Genetic Algorithm firstly defines a starting set of instructions following some preset rules. The optimizer then communicates the first set of instructions to the MPC-model.
- In [41], artificial neural networks and geentic algorithms support the fault detection diagnosis. Since the models were trained with laboratory data or data coming from simulations only, they do not achieve a sufficient performance when working with online data. On the other hand, these kind of Fault Detection Diagnosis (FDD) applications show a very promising growth and may be a good option to solve complex FDD problems soon.

In the papers analyzed there are different tools applied for modeling and for data collection. Among these, Transient System Simulation Tool (TRNSYS) seems to be a popular simulation tool within the selected papers which can provide simulated data, if no measured data is available.

Case Study Conclusion and Outlook

The application of machine learning in the energy sector is of utmost importance in the current context. The aim of this study was to provide insights on the use of machine learning in district heating and cooling (DHC) systems, specifically with regards to seasonal thermal energy storages (STES). Despite some research on STES, a comprehensive investigation on this topic remains limited, although Figure 4 depicts an upward trend from 2010 to 2022. The survey highlights the potential field of application of machine learning in various areas such as load demand forecasting, design, fault detection, and control optimization. Artificial Neural Networks

were found to be the most used method due to their superior performance over other machine learning algorithms. Additionally, the TRNSYS simulation tool was predominantly applied for data simulation. Nevertheless, there is a need for more extensive research in the future to better apply machine learning in DHC with STES, including the development of innovative approaches to improve the collection and analysis of data.

4. Discussion and Outlook

This review paper has addressed applications of machine learning in three different energy systems. In all three case studies, we see a smaller to wider range of machine learning models used for various scenarios in developing the technologies, where ANNs are highly utilized machine learning approaches in both STES in DHC and Drilling. The ANN approach seems to have a high accuracy where prediction is involved as in STES in DHC the energy demand forecast model's average accuracy is over 95%, also in drilling a lot of studies were made using ANNs, e.g. in the prediction of ROP and drilling risk. Genetic Algorithms (GA) on the other hand are mostly used in optimization scenarios in both drilling and STES in DHC. However, in the case of rooftop solar quantification, U-Net and inception resnet - v2 is highly used for semantic segmentation as they have higher performance on small datasets compared with others like PSPNet, Deeplabv3+, and VGG-19.

Some of the possible prospects for development and future research in the considered three case studies would:

1. Machine learning in drilling: application of promising machine learning algorithms in fields, where they were not applied, yet (cf. e.g., Table 1).
2. Machine learning for rooftop solar energy potential quantification: developing techniques to identify pre-existing solar panels and improving various methods to recognize inclined roofs.
3. Machine Learning in district heating and cooling in the context of seasonal thermal energy storages: Due to the limited number of studies, there is a good potential for future research on the of application of machine learning in load demand forecasting, design, fault detection, and control optimization.

5. Nomenclature

AI	Artificial Intelligence
ANN	Artificial Neural Network
ATES	Aquifer Thermal Energy Storages
BHA	Bore Hole Assembly
BPNN	Back propagation neural network
BTES	Borehole Thermal Energy Storages
DHC	District heating and Cooling
DT	Decision tree
EGS	Enhanced Geothermal Systems
FCNN	Fully convolutional neural network
FL	Fuzzy logic
GA	Genetic algorithm
LSTM	Long short-term memory neural network
LWD	Logging While Drilling
ML	Machine Learning
MLP	Multi-layer perceptron
MWD	Measured While Drilling
PSO	Particle swarm optimization
PTES	Pit Thermal Energy Storages
RBF	Radial basis function
RF	Random Forest
RSS	Real-Time Steerable System
STES	Seasonal thermal energy storages
SVM	Support Vector Machine
TTES	Tank Thermal Energy Storages

Abstract:

The decentralisation and unpredictability of new renewable energy sources require rethinking our energy system. Data-driven approaches, such as reinforcement learning (RL), have emerged as new control strategies for operating these systems, but they have not yet been applied to system design. This paper aims to bridge this gap by studying the use of an RL-based method for joint design and control of a real-world PV and battery system. The design problem is first formulated as a mixed-integer linear programming problem (MILP). The optimal MILP solution is then used to evaluate the performance of an RL agent trained in a surrogate environment designed for applying an existing data-driven algorithm. The main difference between the two models lies in their optimization approaches: while MILP finds a solution that minimizes the total costs for a one-year operation given the deterministic historical data, RL is a stochastic method that searches for an optimal strategy over one week of data on expectation over all weeks in the historical dataset. Both methods were applied on a toy example using one-week data and on a case study using one-year data. In both cases, models were found to converge to similar control solutions, but their investment decisions differed. Overall, these outcomes are an initial step illustrating benefits and challenges of using RL for the joint design and control of energy systems.

Keywords:

Energy systems, Design, Control, RL, MILP.

1. Introduction

1.1. Background and related work

The current transition to renewable energy sources requires rethinking new energy systems, characterized by decentralized and intermittent production. The development of these systems typically occurs in two distinct steps, namely the design and control of these systems. The design problem involves identifying the design variables which are the optimal size of energy system components. The control problem aims to determine the control variables which are the optimal actions to operate the energy system components. Both design and control problem should jointly minimize a cost function and are typically solved sequentially. This paper explores the value of solving the design and control tasks, using a reinforcement learning (RL) method as appropriate design is intrinsically linked to subsequent operation. To evaluate the effectiveness of this approach, its performance are compared with that of the Mixed Integer Linear Programming (MILP) method.

On the one hand, RL is a data-driven approach where an agent learns to make decisions in a dynamic environment through trial-and-error experience. It involves an agent interacting with an environment and receiving feedback in the form of rewards or penalties based on its actions, with the goal of maximizing its cumulative reward over time. On the other hand, Mixed Integer Linear Programming (MILP) is a mathematical optimization technique used to solve problems with linear constraints and integer variables. It involves formulating a mathematical model of the problem and using an optimization algorithm to find the best solution. Both RL and MILP methods will be used to benchmark the results of a one-year time series.

As highlighted in a recent review [1], RL-based approaches have significant potential, yet not fully exploited, in the energy field. Specifically, the review points out that energy systems are typically designed using either MILP or heuristic methods, with RL approaches dedicated to their control. Integrating RL beyond energy flow control would open new interesting research questions. In [2], RL is used to support distributed energy system design due to its flexibility and model-free nature, which allows it to be adapted to different environments at different

scales. However, they did not simultaneously address the dispatch and design problem as a distributed reward problem, as done in this work. Instead, they used a cooperative coevolution algorithm (COCE) to assist the optimization process. Jointly addressing the design and operation of energy systems is a key issue, especially for multi-energy systems, as discussed in [3], where multi-objective evolutionary algorithms (EMOO) and MILP are used to integrate biomass technologies in a multi-energy system. In [4], the focus is on evolution algorithms and their comparison with deep reinforcement learning strategies. After clarifying the fundamental differences between the two approaches, the discussion revolves around their ability to parallelize computations, explore environments, and learn in dynamic settings. The potential of hybrid algorithms combining the two techniques is also investigated, along with their real-world applications.

RL-based frameworks are successfully applied to the operation of energy systems [5], although these methods have not, to the authors' knowledge, been extended to solve real-world design problem in energy system. As reviewed in [6], RL-based frameworks are popular for addressing electric vehicle (EV) charging management, mostly with variants of the DQN algorithm, and outperform other traditional methods. In [7], various deep RL algorithms are benchmarked against rule-based control, model predictive control, and deterministic optimization in the presence of PV generation. The study, which aims to increase PV self-consumption and state-of-charge at departure, demonstrates the potential of RL for real-time implementation. For solving V2G control under price uncertainty, [8] modeled the problem with a Markov Decision Process (MDP) [9], a mathematical framework for modeling system where stochasticity is involved. Additionally, a linear MDP formulation is also used in [10] to address the coordination of multiple charging points at once. Finally in [11], a data-driven approach is defined and evaluated for coordinating the charging schedules of multiple EVs using batch reinforcement learning with a real use case. In conclusion, these studies provide valuable insights and tools for optimizing and improving energy systems, demonstrating the potential of RL to tackle the operation of complex energy systems.

1.2. Contribution

This work aims to evaluate the relevance of jointly designing and controlling an energy system using a deep RL approach. To achieve this purpose, two methods are benchmarked to address jointly the design and control problem of a real-world PV-battery system. The first method, MILP, computes the optimal design and control solution over a sequence of historical data. The second method, RL, computes the optimal design and a control policy through interactions with a simulator by trial and error. The specific RL algorithm used in this study is referred to as Direct Environment and Policy Search (DEPS) [12]. DEPS extends the REINFORCE algorithm [13] by combining policy gradient with model-based optimization techniques to parameterize the design variables. In this framework, an agent looks for the design and control variables that jointly maximize the expected sum of rewards collected over the time horizon of interest. The outcomes of both methods are discussed in the subsequent sections of this paper.

This paper is structured as follows. Section 2. provides two formulations of the energy system, one designed for MILP and the other for RL, and discusses the methodology used to benchmark the results. In Section 3., the outcomes of the study are presented, and these results are discussed in Section 4., with a focus on the potential of RL for joint design and control of energy systems. Finally, the paper concludes with a summary in Section 5..

2. Method

2.1. Problem statement

The study is carried out for the energy system illustrated in Figure 1, whose components are detailed in the subsections below. Overall, the system refers to an office building that has been fitted with a PV installation and a stationary lithium-ion battery to meet its own electricity consumption. Additionally, the building is connected to the electricity grid.

The objective of the study is to jointly propose a design of the PV and battery components, as well as a control strategy of the described energy system in order to minimize the total cost of its ownership. In the following Subsection 2.2., the system is expressed as a mathematical program made-up of constraints and objectives. To be more precise, it is tackled as a Mixed-Integer Linear Program. Subsection 2.3. formulates a surrogate environment as an MDP. The latter represents the same dynamics and rewards as the original problem but the objective is to maximize the sum of rewards gathered over one week on expectation over the 52 weeks of the year of data. By doing so, it allows the use of the RL algorithm and expects the optimal solution to be close to the solution of the original problem. Results are discussed in Section 3.. Finally, for both methods, the energy system is studied over a finite time horizon T, on which all costs are evenly distributed across each time step t. The methodology and the context of the experiments conducted are specified in Subsection 2.4..

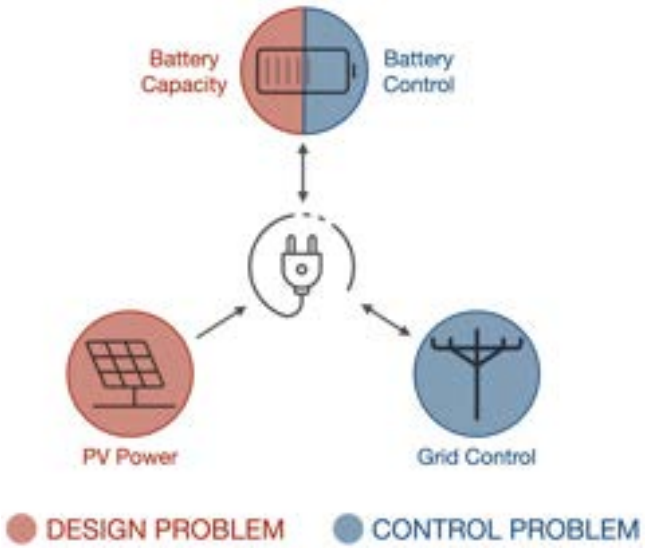

Figure 1: The energy system to be jointly designed and controlled is characterized by an electrical consumption, a battery, a photovoltaic system, and a grid connection. The design problem consists of determining the photovoltaic power and battery capacity, while the control problem aims to regulate the charging and discharging of the battery, as well as the import (resp. export) of electricity to (resp. from) the grid. The overall objective is to meet the electrical consumption needs while minimizing the costs of installing and operating the system.

2.2. Energy system

This subsection describes the physical constraints that apply to the components of the energy system. Theses components, in sequential order, consist of the PV panels, the battery, the electrical load and the power grid. The set of design and control variables and the parameters of the whole system, which is modeled as a discrete-time system, are gathered respectively in Table 1 and 2, respectively.

	Variable	Set	Unit	Description
GRID	P^{IMP}	$\mathbb{R}_+^T$	kW	imported power (from the grid)
	P^{EXP}	$\mathbb{R}_+^T$	kW	exported power (to the grid)
PV	P^{NOM}	$\mathbb{R}_+$	kW_p	nominal power of the PV installation
BATTERY	B	$\mathbb{R}_+$	kWh	nominal capacity of the battery
	SOC	$\mathbb{R}_+^T$	kWh	state of charge of the battery
	P^B	$\mathbb{R}^T$	kW	power exchanged with the battery

Table 1: Set of design and control variables of the energy system studied.

PV system

The objective of the PV installation is to generate electricity on-site to fulfill the local electricity demand. The design of this component is one of the two design variables that will result from the optimization process. The range of the suitable nominal power P^{NOM}, corresponding to its design variable, is set in Eq. (1) and the production at time t is directly proportional to this nominal design variable as shown in Eq. (2). The normalized annual curve $\overline{p}_t^{\text{PROD}}$ corresponds to the actual hourly averaged PV production power of the building.

$$P_{\text{MIN}}^{\text{NOM}} \leq P^{\text{NOM}} \leq P_{\text{MAX}}^{\text{NOM}} \tag{1}$$

$$P_t^{\text{PROD}} = P^{\text{NOM}} \cdot \overline{p}_t^{\text{PROD}} \tag{2}$$

The CAPEX and OPEX values, which are respectively the initial investment and the annual maintenance cost, of the installation are made up of a fixed and a variable part to take account of potential scale effects.

$$\text{CX}_{\text{PV}} = \text{CX}_{\text{PV}}^{\text{FIX}} + \text{CX}_{\text{PV}}^{\text{VAR}} \cdot P^{\text{NOM}} \tag{3}$$

$$\text{OX}_{\text{PV}} = \text{OX}_{\text{PV}}^{\text{FIX}} + \text{OX}_{\text{PV}}^{\text{VAR}} \cdot P^{\text{NOM}} \tag{4}$$

	Parameter	Value	Set	Unit	Description
GRID	$C^{\text{IMP}}_{\text{GRID}}$	1	$\mathbb{R}$	€/kWh	imported electricity price
	$C^{\text{EXP}}_{\text{GRID}}$	-0.05	$\mathbb{R}$	€/kWh	exported electricity price
	C_{GRID}		$\mathbb{R}^T$	€	electricity network cost
	$P^{\text{MAX}}_{\text{GRID}}$	10'000	$\mathbb{R}_+$	kW	grid connection power
PV	$P^{\text{NOM}}_{\text{MIN}}$	0	$\mathbb{R}_+$	kW_p	minimal nominal PV power
	$P^{\text{NOM}}_{\text{MAX}}$	200	$\mathbb{R}_+$	kW_p	maximal nominal PV power
	P^{PROD}		$\mathbb{R}^T_+$	kW	generated PV power
	$\overline{P}^{\text{PROD}}$		$\mathbb{R}^T_+$	kW	expected generated PV power
	$\overline{p}^{\text{PROD}}$		$\mathbb{R}^T_+$	kW	normalised PV power
	L^{PV}	20	$\mathbb{N}$	years	PV lifetime
	R_{PV}		$\mathbb{R}_+$	-	annuity factor
	$\text{OX}^{\text{FIX}}_{\text{PV}}$	3	$\mathbb{R}_+$	€	OPEX PV fixed cost

Battery

To maximize the potential for on-site self-consumption, a stationary lithium-ion battery is available. The design of this component, corresponding to its capacity B, is the second design variable to determine during the optimization process. This battery capacity can vary in the range of Eq. (5).

$$B_{\text{MIN}} \leq B \leq B_{\text{MAX}} \tag{5}$$

The state of charge variable, SOC_t, changes as a function of the power exchanged with the battery denoted P^B_t. This power is constrained, for charging, by the nominal capacity, Eq. (6), and, for discharging, by the energy stored, Eq. (7). Additionally, the battery efficiency, denoted η^{B}, is assumed identical for both the charging and the discharging processes.

$$P^B_t \leq \frac{\text{B} - \text{SOC}_t}{\Delta t} \qquad \text{if } P^B_t \geq 0 \tag{6}$$

$$P^B_t \geq \frac{-\text{SOC}_t}{\Delta t} \qquad \text{if } P^B_t \leq 0 \tag{7}$$

Knowing the power exchanged with the battery, the state of charge can be updated:

$$\text{SOC}_{t+1} = \begin{cases} \text{SOC}_t + P^B_t \cdot \eta^{\text{B}} \cdot \Delta t & \text{if } P^B_t \geq 0 \\ \text{SOC}_t + \frac{P^B_t}{\eta^{\text{B}}} \cdot \Delta t & \text{if } P^B_t < 0 \end{cases} \tag{8}$$

At the beginning of the optimization, i.e., $t = 0$, the battery SOC is set to half of its capacity value, to initialize the model. Moreover, to avoid any artificial benefit, the final SOC is constrained to be equal to the initial value,

as formulated in Eq. (10).

$$\mathrm{SOC}_{t=0} = \frac{B}{2} \tag{9}$$

$$\mathrm{SOC}_{t=0} = \mathrm{SOC}_{t=T} \tag{10}$$

Similar to the PV plant, the CAPEX and OPEX of the battery consist of both fixed and variable parts.

$$\mathrm{CX_B} = \mathrm{CX_B^{FIX}} + \mathrm{CX_B^{VAR}} \cdot \mathrm{B} \tag{11}$$

$$\mathrm{OX_B} = \mathrm{OX_B^{FIX}} + \mathrm{OX_B^{VAR}} \cdot \mathrm{B} \tag{12}$$

Electrical load

The electrical load used in this project is real data from an office building in Switzerland. This consumption is monitored on an hourly basis and reflects the consumption patterns of office days. This building load power, P_t^{LOAD}, is provided as input and corresponds to an actual measurement sampled by hours over a year.

Electrical grid

To absorb excess solar production or to meet the electricity consumption in the absence of local production, the system is connected to the low-voltage electrical grid. This connection is modeled here as a single balance equation, called the conservation of electrical power, shown in Eq. (13). The power imported from the grid is referred to as P_t^{IMP} and the power injected is referred to as P_t^{EXP}.

$$P_t^{\mathrm{PROD}} + P_t^{\mathrm{IMP}} = P_t^{\mathrm{LOAD}} + P_t^{\mathrm{B}} + P_t^{\mathrm{EXP}} \tag{13}$$

The grid power value at each time t is derived from Eq. 13, and the power limit can be described as follows.

$$0 \leq P_t^{\mathrm{IMP}} \leq P_{\mathrm{GRID}}^{\mathrm{MAX}} \tag{14}$$

$$0 \leq P_t^{\mathrm{EXP}} \leq P_{\mathrm{GRID}}^{\mathrm{MAX}} \tag{15}$$

Based on the import and export power, the total cost of supplying electricity through the network C_{GRID} can be computed.

$$C_{\mathrm{GRID}} = \sum_{t=0}^{T-1} C_{\mathrm{GRID},t} = \sum_{t=0}^{T-1} P_t^{\mathrm{IMP}} \cdot C_{\mathrm{GRID},t}^{\mathrm{IMP}} - P_t^{\mathrm{EXP}} \cdot C_{\mathrm{GRID},t}^{\mathrm{EXP}} \tag{16}$$

Objective function

The objective of this study is to propose a design for the PV and battery components, along with their dispatch, with the aim of minimizing the total cost of ownership. This objective function, of minimizing the overall cost of the system, can be formulated as follows.

$$\min \quad \mathrm{TOTEX} \tag{17}$$

The total cost of the system, denoted TOTEX, is composed of the CAPEX and OPEX of both PV and battery components, as well as the grid cost.

$$\mathrm{TOTEX} = \mathrm{OPEX} + \mathrm{CAPEX} + C_{\mathrm{GRID}} \tag{18}$$

$$\mathrm{OPEX} = \mathrm{OX_{pv}} + \mathrm{OX_B} \tag{19}$$

$$\mathrm{CAPEX} = \mathrm{CX_{pv}} \cdot R_{pv} + \mathrm{CX_B} \cdot R_B \tag{20}$$

The OPEX and grid cost are computed over a finite time period T. However, the CAPEX is an investment cost that is independent of T. To enable the adaptation of the investment cost to the project duration, an annuity factor R adjusts the CAPEX for the finite time horizon T. This annuity factor is computed according to Eq. (21), by taking into account the values of T, the annual discount rate r, and the lifetime L of the component. This formula includes a scaling factor $\frac{T}{8760}$ to adapt R to the period T, based on the assumption that T is expressed in hours since 8760 is the number of hours in a year.

$$R = \frac{r \cdot (1+r)^L}{(1+r)^L - 1} \cdot \frac{T}{8760} \tag{21}$$

2.3. MDP formulation

This section presents an alternative formulation of the problem as a Markov Decision Process (MDP), which is a well-established framework for modeling sequential decision-making problems. This alternative formulation is required for applying DEPS. More precisely, an MDP(S, A, P, R, T), as presented below, consists of the following elements: a finite set of states S, a finite set of actions A, a transition function P, a rewards function R, and a finite time horizon T.

State Space

The state of the system can be fully described by

$$s_t = (h_t, d_t, \mathrm{SOC}_t, \overline{P}_t^{\mathrm{PROD}}, \overline{P}_t^{\mathrm{LOAD}}) \tag{22}$$

$$\in S = \{0, ..., 23\} \times \{0, ..., 364\} \times [0, B] \times \mathbb{R}_+ \times \mathbb{R}_+ \tag{23}$$

- $h_t \in \{0, ..., 23\}$ denotes the hour of the day at time t. The initial value is set to 0.
- $d_t \in \{0, ..., 364\}$ denotes the day of the year at time t. The initial value is set randomly.
- SOC_t is the state of charge of the battery at time t, this value is upper bounded by the nominal capacity of the installed battery B. The value is set initially to a random value during the training process and to half of its capacity during the validation process.
- $\overline{P}_t^{\mathrm{PROD}}$ represents the expected PV power at time t. This value is obtained by scaling normalized historical data $\overline{p}_t^{\mathrm{PROD}}$ with the total installed PV power (P^{NOM}) and considering h_t and d_t values.
- $\overline{P}_t^{\mathrm{LOAD}}$ denotes the expected value of the electrical load at time t. The load profile is determined using historical data that corresponds to the same hour and day as the PV power.

Action Space

The action of the system corresponds to the power exchanged with the battery.

$$\widetilde{a}_t = (\widetilde{P}_t^B) \tag{24}$$

After projecting the action to fall within the acceptable range specified by Eq. (6) and (7), the resulting value is used as a_t, as shown in Eq. (25). This corresponds to the power exchanged with the battery, denoted P_t^B, this value is positive when the battery is being charged and negative when it is being discharged.

$$P_t^B = \begin{cases} \frac{\mathrm{B} - \mathrm{SOC}_t}{\Delta t} & \text{if } \widetilde{P}_t^B > \frac{\mathrm{B} - \mathrm{SOC}_t}{\Delta t} \\ \frac{\mathrm{SOC}_t}{\Delta t} & \text{if } \widetilde{P}_t^B < -\frac{\mathrm{SOC}_t}{\Delta t} \\ P_t^B & \text{otherwise} \end{cases} \tag{25}$$

Transition Function

Each time step t in the system corresponds to one hour, which implies the evolution specified in Eq. (26) of the state variable h and every 24 time steps, the day is incremented by 1.

$$h_{t+1} = (h_t + 1) \bmod 24 \tag{26}$$

$$d_{t+1} = \mathrm{Int}(\frac{h_t + 1}{24}) \tag{27}$$

where the function *Int* takes the integer value of the expression in Eq. (27).

The SOC_t of the battery is updated as Eq. (8), based on the projected action value, and all other state variables are taken from input data.

$$\overline{P}_{t+1}^{\mathrm{PROD}} = \overline{p}_{h_{t+1}, d_{t+1}}^{\mathrm{PROD}} \cdot P^{\mathrm{NOM}} \tag{28}$$

$$\overline{P}_{t+1}^{\mathrm{LOAD}} = \overline{p}_{h_{t+1}, d_{t+1}}^{\mathrm{LOAD}} \tag{29}$$

Reward Function

The reward signal to optimize the agent's actions in RL serves a similar aim as the objective function in the MILP formulation. Therefore, the reward here is the opposite value of the TOTEX defined at Eq. (18). This cost is composed of (i) the investment cost, (ii) the operating cost and (iii) the cost from the purchase and resale of electricity from the grid defined in Eq. (16).

$$r_t = -\mathrm{TOTEX}_t \tag{30}$$

$$= -\mathrm{CAPEX} - \mathrm{OPEX} - C_{\mathrm{GRID},t} \tag{31}$$

$$= -\mathrm{CAPEX} - \mathrm{OPEX} - P_t^{\mathrm{IMP}} \cdot C_{\mathrm{GRID},t}^{\mathrm{IMP}} + P_t^{\mathrm{EXP}} \cdot C_{\mathrm{GRID},t}^{\mathrm{EXP}} \tag{32}$$

where the grid cost is the only time-dependent factor, while CAPEX and OPEX are fixed values for a specific value of P^{NOM} and B.

2.4. Methodology

This subsection discusses the fundamental differences between the two methods (i.e., MILP and RL), along with the experimental protocol that was employed to compare the results. As discussed briefly earlier, although the same problem is aimed to be solved, the methods under study are fundamentally different.

MILP is a method for solving problems that involves optimizing a linear function of variables that are either integer or constrained by linear equalities, as the problem described in Subsection 2.2. The MILP algorithm solves the optimization problem by iteratively adjusting the values of the design and control variables, subject to the constraints, until it finds the optimal solution that maximizes or minimizes the objective function, depending on the problem's goal. This method is applied to the problem described in Subsection 2.2. over a one-year time horizon (T = 8760). The solution is said to be computed with perfect foresight meaning that all variables are selected accounting for the future realization of (normally unknown) events in the time series, providing an optimistic upper bound on the true performance of the control and design. Concretely, the MILP problem is here encoded in the Graph-Based Optimization Modelling Language (GBOML) [14] paired with the Gurobi solver [15].

In contrast, RL is a stochastic optimization method that learns from experience through trials and errors. In this study, we use DEPS [12], an algorithm optimizing design and control variables in an MDP, as the one described in Subsection 2.3., with a finite-time horizon. The agent receives feedback in the form of rewards when it selects a particular design and performs specific actions. The objective of the agent is to maximize the expected cumulative reward, which drives it to learn a design and a control policy. Ideally, as with MILP, the time horizon should be annual, or cover the entire lifetime of the system, taking into account seasonal production and consumption fluctuations and/or equipment aging. However, such extended time horizons are unsuitable for this RL approach. Therefore, to strike a balance between a horizon that is short enough for DEPS and long enough to observe the consequences of decisions on the system, a horizon of T = 168 hours, i.e., 7 days, is defined. Additionally, for each simulation, the initial day is sampled uniformly from the year-long data set and the initial state-of-charge of the battery is also sampled uniformly at random. As the reward is optimized on expectation over all days, the resulting design and control policy is expected to account for the seasonality and other different hazard in the historical data. The DEPS algorithm is trained on a predetermined number of iterations. The PV power and battery capacity values obtained from the last iteration of the algorithm are then taken as the values of the design variables and the final policy is used for the control.

Unlike MILP, the RL method does not secure optimality, therefore the experimental protocol aims to compare both results to see how far the RL solution is from the optimal one. The experimental protocol is conducted in two distinct scenarios to differentiate the impact of adding the design variables in the joint problem. The first control-only scenario (CTR) assessed the control variables when the design variables are fixed. The second scenario, considering both the control and design (CTR & DES) problem, allows for flexibility in designing the battery capacity and PV power, the two design variables. To benchmark the performance of both methods in each scenario (i.e., CTR and CTR & DES), the reward and income value are reported. The reward value is computing according to Eq. (32) for the RL method. To estimate the average reward value for the MILP method, all reward values r_t are averaged over time horizons of T = 168. Comparing the average cumulative reward value of the MILP method to that of the RL method provides a first benchmark for evaluating the performance of both approaches. However, as shown in Eq. (32), only the grid cost is time-dependent, while the CAPEX and OPEX depend solely on investment decisions. Therefore, the income value is defined as the average reward value, but it only includes the grid cost and can be computed as follows:

$$Income = \sum_{t=0}^{T-1} -P_t^{\text{IMP}} \cdot C_{\text{GRID},t}^{\text{IMP}} + P_t^{\text{EXP}} \cdot C_{\text{GRID},t}^{\text{EXP}} \tag{33}$$

Finally, the experiments are performed in two steps. First, to perform a simple comparative study, working on a same finite time horizon T = 168, both methods are conducted using data from a single summer week. Second, the data set is extended to include the one-year data set.

3. Results

The energy system presented in Section 2. is solved using the RL and MILP approaches with parameter values listed in Table 2. To differentiate the performance of the DEPS algorithm for control and design aspects, the study is conducted in two distinct scenarios. The first control-only scenario (CTR) assessed the control aspect for fixed design variables, meaning that the PV power and battery capacity are fixed. The second scenario, considering both the control and design (CTR & DES) aspects, allows for flexibility in designing the battery capacity and PV power. The two following subsections describe the results of the study performed in two steps, over the one-week and one-year data set, respectively.

3.1. A one-week toy example

In order to perform a simple comparative study, both CTR and CTR & DES analyses were conducted using data from a single summer week. This enables to optimize both methods on the same time horizon. This means training the RL algorithm on the same 168 time steps, with an initial day uniformly randomly selected over the week but an initial hour fixed at midnight. Additionally, during the training phase, the battery's initial SOC is uniformly sampled such that the RL algorithm is presented with a large variety of scenarios for improving the quality of the learned policy. The results for both the CTR scenario, where the design variables (i.e., the PV power and battery capacity) are fixed, and the CTR & DES scenario, where the PV and battery design variables are optimized in addition to control, are presented in Table 3.

		Unit	Optimal RL solution	Optimal MILP solution	MILP solution based on RL design
CTR	T	hours	168	168	
	Reward	€	-66	-66	
	Income	€	-30	-30	
CTR & DES	T	hours	168	168	168
	Reward	€	-40	-46	-53
	Income	€	-4	0	-17
	Battery capacity	kWh	62	40	62
	PV power	kWp	41	103	41

Table 3: Results of RL and MILP solutions on one-week data for control-only (CTR) and control and design (CTR & DES) scenarios. T denotes the time horizon in hours, while *income* represents the cost of buying and selling electricity from the grid, *reward* is the average cumulative reward value, and *battery capacity* and *PV power* indicate the values of design variables, which were set to 31.89 kWh and 55.81 kWp, respectively, in the CTR scenario. In the RL model, reward and income values were obtained by reloading the trained model with the determined design variables. Results were computed using an initial state of charge of the battery set to 50% of its capacity for both models. However, the RL model does not take into account the Eq. (10).

3.1.1. RL and MILP optimal objective values are similar in both scenarios but with different designs in the control and design scenario.

Table 3 shows that in the CTR scenario, the results of the RL approach are similar to those of MILP. This confirms that the DEPS algorithm is able to converge to the optimal solution of this specific problem. In the CTR & DES scenario, RL design variables differ from the MILP solution, resulting in an unexpected higher reward value (-40) than the MILP optimal one (-46). A detailed analysis reveals that this unexpected higher value is due to Eq. (10), which is not imposed in the MDP. In order to validate this analysis, the additional grid cost needed to fulfill Eq. (10) has been computed, taking into account the battery's final SOC obtained with the RL approach. As a result, the reward value has increased to -67 (instead of -40). This clearly highlights the importance that Eq. (10) plays in term of overall objective.

3.1.2. The CTR & DES scenario highlights differences in RL and MILP strategies.

It is seen from Table 3 that in the second scenario, the optimal design variables of the RL and MILP solutions differ. Finding different values in design variables shows that the DEPS algorithm is able to identify solutions with comparable reward but using different design strategies. In order to study the sensitivity of the optimal solution, the MILP method was applied by imposing the design variable values obtained with the RL, as it can be seen in the last column of Table 3. This indicates that the RL design solution is less optimal (-53) than the MILP one (-46).

3.2. A one-year case study

Optimal solutions of RL and MILP methods in both scenarios are now computed using data from a full year. The time horizon for the RL algorithm is still equal to $T = 168$, but the starting days are uniformly randomly selected over the year. The RL algorithm is trained over a pre-determined number of 100'000 iterations and the values of the RL design variables considered are the ones from the final iteration. The results are shown in Table 4.

3.2.1. The difficulty of generalizing a policy with stochasticity in the model and on the estimation of the expectation

It can be seen from Table 4 that in both the CTR and CTR & DES scenarios, the optimal reward obtained by the RL method is poorer than the MILP optimal rewards. Furthermore, as depicted in Fig. 2, due to the significant variations in the input data, the reward and income values exhibit substantial fluctuations across

		Unit	Optimal RL solution	Optimal MILP solution	MILP solution based on RL design
CTR	T	hours	168	8760	
	Reward	€	-268	-228	
	Income	€	-220	-196	
CTR & DES	T	hours	168	8760	8760
	Reward	€	-250	-205	-247
	Income	€	-208	-164	-218
	Battery capacity	kWh	44	95	44
	PV power	kWp	57	81	57

Table 4: Results of RL and MILP solutions on one-year data for CTR and CTR & DES scenarios. T denotes the time horizon in hours, while *income* represents the cost of buying and selling electricity from the grid, *reward* is the (expected) cumulative reward value, and *battery capacity* and *PV power* indicate the design variable values, which were set to 64.9 kWh and 63.65 kWp, respectively, in the CTR scenario. The RL solution is based on the trained model to determine the reward and income values, based on an average of 1'000 simulations over T = 168. The MILP solution is computed for a one-year time horizon (T = 8760). Both models use an initial state of charge (SOC) of the battery set to 50% of its capacity. However, the MILP model has an additional constraint specifies in Eq. (10).

iterations.

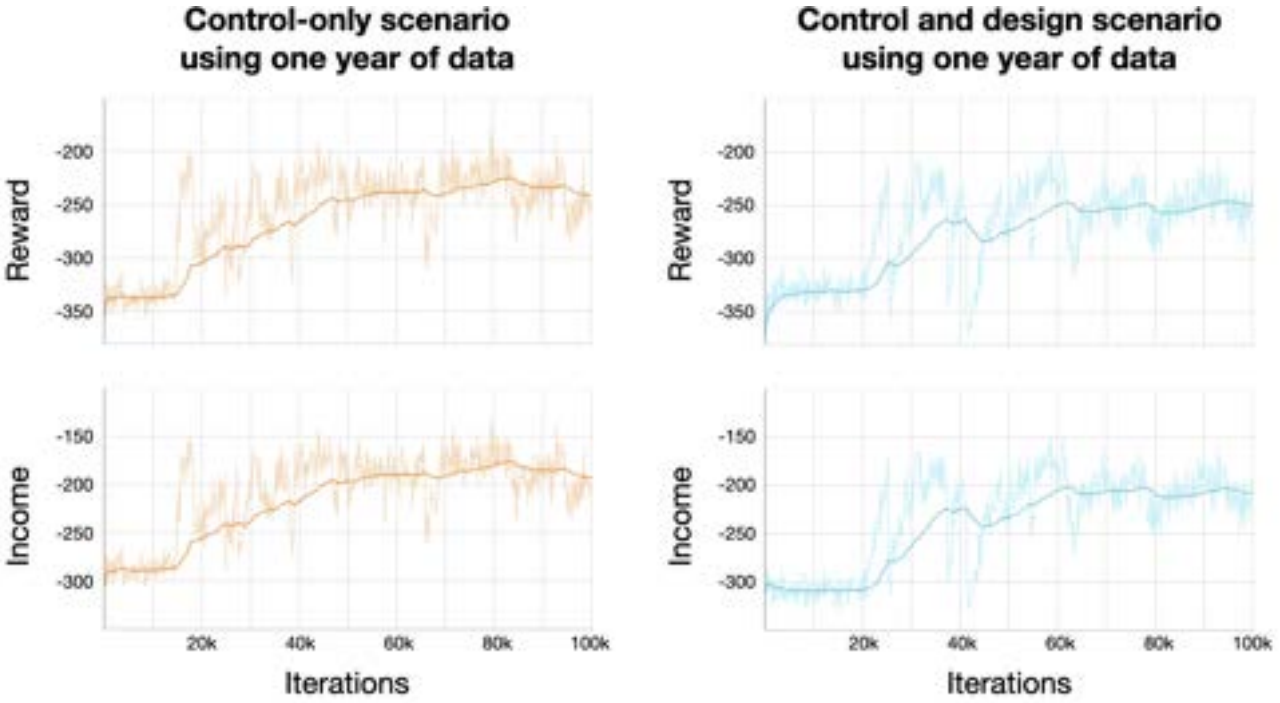

Figure 2: Value of reward and income obtained by the DEPS algorithm at each iteration for both scenarios. The left plots show the reward and income values for the CTR scenario, while the right plot shows the same values for the CTR & DES scenario. The light curve shows the exact values for each time step, while the dark curve displays the corresponding smoothed values. In the CTR scenario, the difference between the reward and income values remains constant at 31.93 due to fixed design variables, with a battery size of 64.9 kWh and a PV power of 63.65 kWp. However, in the CTR & DES scenario, the battery size and PV power output vary from 0 to 200 kWh and kWp, respectively.

During training in the CTR scenario (Fig. 2, left), the RL model achieved maximum reward and income values of -180 and -131, respectively, which are significantly better than the final results obtained from both methods in Table 4. This could suggest that depending on the set of weeks that are averaged at each iteration, it is possible to obtain a better or worse reward. Therefore, it seems important to work with a sufficiently representative number of weeks throughout the year. A similar observation can be made in the CTR & DES scenario, where the maximum reward and income values achieved were -195 and -148, respectively (Fig. 2, right).

3.2.2. The RL method seems to promote lower design variable values

From Table 4 it is also seen that the RL approach seems to promote solutions involving lower values of design variables. To further investigate the reasons underlying this result, the design variables for the evolution of the battery capacity and PV power, during the training process, are reported in Fig. 3 in the CTR & DES scenario.

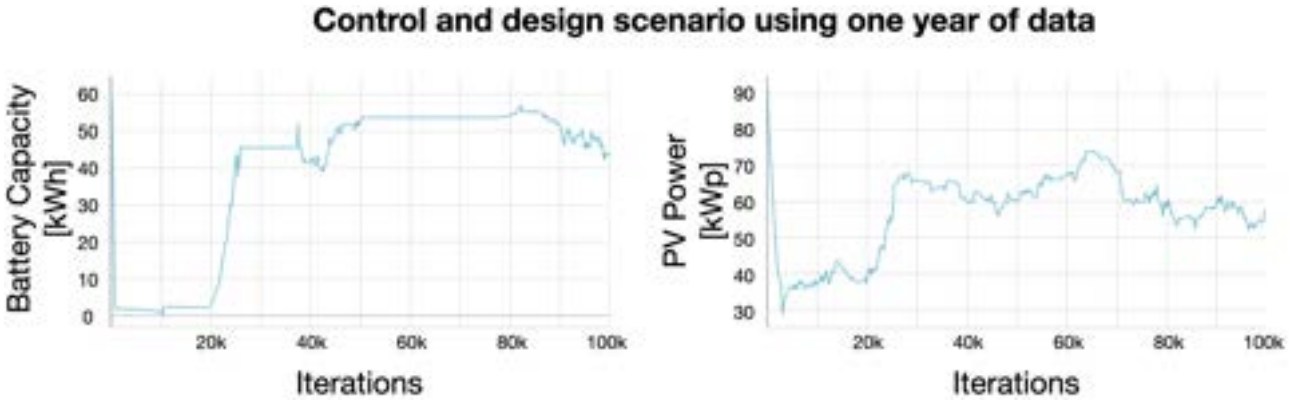

Figure 3: Value of design variables in the RL approach at each iteration, in the CTR & DES scenario. The RL algorithm converges at the final iteration to a battery capacity of approximately 44 kWh and a PV power output of around 57 kWp.

As indicated in Table 2, the design variable values can range from 0 to 200. However, it can be seen that higher values are not explored by the RL method. This latter resulted, at the last iteration, in design variables of 44 kWh for battery capacity and 57 kWp for PV power. During the training phase, the maximum values reached were 59 kWh and 90 kWp for battery capacity and PV power, respectively. This maximal explored battery capacity value is lower than the optimal one found by the MILP approach (95 kWh). Thus, the RL solution of the PV power value is expected to be lower. Indeed, the reward value is penalized if the RL agent injects PV production into the grid, since the cost of exported energy into the grid (C_{grid}^{exp}) is defined as a negative value in Table 2. Consequently, limited battery capacity intrinsically causes a lower PV power value.

4. Discussion

This section discusses the main observations that can be drawn from solving a battery-PV system with both RL and MILP approaches using the one-week and one-year data set.

4.1. The promises of RL for joint design and control of energy systems

The motivation for this study was to explore the potential of RL to enable joint control and design of energy systems. Tables 3 (one-week data) and 4 (one-year data) show that RL provides a solution that is close to the optimal MILP one. This is encouraging as it suggests that despite RL relying on a different optimization strategy, it is able to identify a meaningful solution in a simple case. However, the difference of reward value between MILP and RL increases when integrating design variables to the optimization problem, i.e., CTR & DES scenarios in Tables 3 and 4. Interestingly, the solutions for design variables are consistently smaller in RL as compared to MILP. Furthermore, from Fig. 3, it can be seen that the RL algorithm did not explore higher design variable values in the one-year case study. This observation can be explained by two possibilities: first, DEPS is a local-search method that is thus subject to converging towards local extrema. Once the control policy is too specialised to the investment parameters (under optimization too), these parameters are thus expected to be locally optimal and the algorithm is stuck. Second, the RL algorithms is subject to many hyperparameters to which the final results are sensible, it is possible that a different policy architecture, learning rate, or simply more iterations would ameliorate the performance of the method. Supporting the first explanation is the similarity between the reward values of the RL (-250) and MILP, based on same investments, (-247) approaches for the CTR & DES scenario with T = 8760 (Table 4). Hence, in this specific energy system case study, it could be likely that the RL algorithm did not deem it advantageous to enhance the value of the design variables for either one or both of the two reasons stated.

Overall, these results show that RL provides realistic control and design strategies. Based on this, RL could be used to define new real-time control strategies integrating design constraints, and that are less sensitive to linearization inaccuracies [16], [17]. Given the differences in how uncertainties are accounted for by both methods, RL could also be a better candidate to integrate resources coming with high levels of uncertainty such as electric mobility.

4.2. Technical challenges and future directions

The main technical challenges encountered in this study are essentially the ones inherent to RL methods. First, various parameters need to be tuned: neural network architecture for the policy, the batch size for the optimization, the learning rate, or the different scaling among others. These parameters were tuned by trial and error and would need to be adapted to each new application. For example, the number of layers required in the one-year case study was larger than for the one-week toy example. Second, convergence of the RL method is not guaranteed, and when convergence happens, the solution is not guaranteed to be globally optimal. Third, as illustrated here above for the results of Figure 3, determining the number of iterations (set to 100,000 for the training phase in all our experiments) is also crucial and might affect RL solutions. Therefore, comparing RL and MILP solutions is not trivial because its is difficult to compare perfect foresight with policy based decisions. This should be accounted for when analyzing results from Tables 3 and 4.

From a technical point of view, future work will aim at using more advanced RL methods. In particular, the RL algorithm used here is a modified version of the REINFORCE algorithm [13], which was developed in 1992 and is one of the earliest RL algorithms. Today, more advanced algorithms are available for control problems, which can converge more rapidly or account for infinite time horizons, such as actor-critic algorithms (e.g., PPO [18] and GAE [19]), but are yet to be adapted to joint design and control. In terms of applications, future work will aim to better evaluate the added value of RL by assessing the long-term performance of real-time sized systems. For example, a control framework could be developed to establish an operation strategy for the MILP-sized system. The framework would then be evaluated using several years of real-time data from the same system used for design. The same exercise would be applied to the trained model of the DEPS algorithm and performance obtained from several years of system control would be benchmarked, and the impact of design decisions could be discussed with more perspective.

5. Conclusions

In most studies, MILP is used for the design of energy systems and RL for the control. On the one hand, MILP assumes a perfect foresight of the future and is difficult to generalize to new data. On the other hand, RL methods proved to be efficient in other tasks linked to design and control but not on energy systems. In this study, we assessed the potential of an RL method, DEPS, i.e. an RL algorithm proven efficient for designing and controlling complex systems, for the joint design and control of energy systems.

The energy system studied is a PV-battery system used to answer a real-life demand in order to minimize the overall cost. In order to assess the efficiency of the RL method, we compared the outcomes with those obtained with a MILP. As these two approaches are fundamentally different, the optimization problem was formulated in two distinct ways: first as a MILP and second as an MDP. The methodology and experimental context were clarified to facilitate the discussion of results and have a fair comparison. Both approaches are discussed in terms of their strengths and weaknesses.

The findings show that RL can produce control strategies that are close to optimal, while using different values of design variables. This highlights the potential of RL for joint design and control of energy systems, particularly in scenarios where stochasticity is a key factor. However, the study also highlights the difficulty of tuning and using theses methods. Moving forward, there are several challenges to address, including the need to ensure that the RL solution converges to a global optimum. However, the promising results obtained in this study suggest that RL has the potential to be a valuable tool for jointly designing and controlling energy systems.

Abstract:

Model predictive control (MPC) has proven to be a promising method to exploit energy saving potentials in building energy systems. However, they are not widespread in practice due to high hard- and software requirements, high computational effort, and missing trust and know-how among practitioners. Approximate MPC can address these challenges by replacing the hard- and software-intensive optimization program by black box models. Machine learning models such as Artificial Neural Networks or tree-based algorithms have been widely investigated by the scientific community. However, a comparison of Artificial Neural Networks with advanced tree-based models like Random Forest and Gradient Boosting is still missing. In addition, the relation between the models' training and the resulting control performance has not yet been assessed. We close these gaps by investigating the optimal control based on an MPC of a PV-battery system in a non-residential building. The MPC optimizes the battery's power based on a preceding peak load optimization. The MPC is imitated by three machine learning models, namely, an Artificial Neural Network, a Random Forest, and Gradient Boosting, whose performance is subsequently evaluated open- and closed loop. While Gradient Boosting results in the highest open-loop performance with an R^2 of 0.83, it deviates more significantly from the optimal control trajectory than, e.g., the Artificial Neural Network. Nonetheless, Gradient Boosting even outperforms the teacher MPC when considering the system's annuity. This is explained by its ability to push beyond the peak load constraints which are set within the optimization. A rule-based backup controller is, therefore, included for all approximator-based controllers. Based on this, the approximators result in a peak load reduction between 5 % and 7 % compared to the benchmark and a change in annuity between -1 % and 4 % compared to the MPC. To summarize, all approximators can retain most of the MPC's advantages but do not surpass its overall performance.

Keywords:

Approximate Optimal Control, Model Predictive Control, Machine Learning.

1. Introduction

In 2022, the United Nations Environment Program published its global status report for the buildings and construction sector, highlighting the need for immediate action to cut emissions [1]. Following a slowdown caused by the global pandemic, the CO_2 emissions from building operations in 2021 even exceeded their all-time maximum of 2019 by 2 %. When taking into account the emissions of building material production, buildings made up around 37 % of the global CO_2 emissions in 2021 [1]. In addition to investing in refurbishment strategies, optimizing building energy system operation can contribute to the goal of an emission-free building sector by 2050 [1, 2].

Model predictive control (MPC) as a representative of advanced control methods has proven to optimize building operation tremendously. In a review study, Drgoňa et al. [2] find that the realized energy savings range between 15 % and 50 % based on selected case studies [3–6]. MPC is also a valuable method for providing grid flexibility services by, e.g., exploiting price incentives or providing demand response services [2]. The latter is crucial for future grid operation as the building sector will be electrified and, hence, interact with the grid more intensely. However, despite its significant potential MPC is not widespread in practical applications. The reasons lie in the high requirements of hard- and software and data infrastructure, missing know-how among the operating personnel, time-consuming modeling and maintenance, and network and privacy security concerns [2, 7–10]. This is why conventional rule-based and PID controllers are still state-of-the-art in nowadays buildings. A method that bridges the gap between the performance of MPC applications and the simplicity of rule-based controllers is approximate MPC. The idea is to imitate the MPC's output using black box models. The MPC serves as a teacher that generates training data. The implicit MPC-based controller is finally replaced by an explicit controller [11]. The black-box-based explicit controller requires less advanced hard- and software as well as data infrastructure. The used black box models in building energy systems range from

simple linear regression models [9,12], over decision trees [11,13–16] to sophisticated machine learning models like Artificial Neural Networks (ANNs) [11, 17–20]. These so-called approximator-based controllers have proven to retain most of the MPC's performance while significantly reducing the required computational effort and processing time [11]. In this context, decision-tree-based approximators are favorable as they resemble the rule-based controller-like "if-condition-then-action" structure and, hence, promote comprehensibility and address the challenge of missing know-how. However, decision trees tend to overfit data and are very sensitive to input data [21]. Consequently, advanced methods like ANNs are often selected as approximators [11, 19, 20]. High-performing ensemble methods like Random Forest (RF) and Gradient Boosting (GB) can address the decision trees' disadvantages of overfitting. However, to the authors' best knowledge, studies investigating high-performing, tree-based machine learning algorithms like RF and GB in the context of approximate MPC are still missing. Furthermore, even though approximate MPC has been successfully applied to building energy systems, there exists no use case focusing on a grid-connected PV-battery system as a part of a building energy system.

In contrast to that, the scientific community has come up with related methods targeting purely grid-related challenges. Smart grids will play a key role in the energy transition to guarantee safe grid operation. The underlying concept is referred to as the optimal power flow problem, which can focus on AC- and DC-based applications. Here, the main challenge lies in the real-time solution of a highly complex optimization problem that optimizes power flows in a grid, e.g., the optimal power that a set of generators have to produce [22–25]. [23] and [24], e.g., both focus on an AC optimal power flow problem. For example, Zamzam et al. [23] learn the mapping of system loading and optimal generation values using an ANN serving as an input for the subsequent power flow solver. Doing so, they speed up the calculation process by a factor between 8 and 15 while still achieving near-optimal results compared to directly solving the optimal power flow problem. Furthermore, the authors of [24] approximate the cost function and give a feasibility prediction for the AC optimal power flow problem. Again, the accuracy is high and the computational effort is reduced significantly. As approximators, they compare the performance of linear regression, piecewise regression, Gaussian Processes, and ANNs. Apart from that, [22] use graph NNs and [25] test deep NNs, and obtain similar trends for an AC and DC optimal power flow problem, respectively. The aforementioned grid-focused studies all apply their method to simplified use cases and learn the output of static optimal power flow problems. De Jongh et al. [26] are the first to use ANNs to learn a dynamic MPC-based problem of a smart distribution grid. The distribution grid covers 15 nodes and 13 households and considers electric vehicles and heat pumps. The MPC optimizes the power schedule for all flexible devices. The ANN is trained based on a full-year simulation with three months of testing. This time, the closed-loop performance is evaluated and, again, near-optimal results are achieved with a 55 times quicker processing time.

In addition to these aspects, the training process for the approximators differs significantly among the studies. While the grid-focused studies generate randomized training samples using distribution assumptions for their inputs [22,24,25], the building-focused ones tend to use closed-loop operation results [11,12,14]. The training performance is usually evaluated open-loop, i.e., the true and predicted outputs are compared without system interaction. However, it is unclear how the open-loop performance affects the closed-loop one, which we identify as an additional research gap.

1.1. Contributions and structure of this study

To summarize, the state of research highlights that approximate MPC applications are promising for building energy systems. However, we detect a gap in studies focusing on building energy systems while considering their interaction with the grid. In addition, studies are missing that compare sophisticated machine learning models like ANNs to advanced tree-based ones like RF and GB. Furthermore, the scientific literature has not yet presented a detailed investigation of the relation between the open- and closed-loop performance.

This study closes these gaps through the following aspects:

- We present a PV-battery system of a non-residential building in Berlin, Germany (see subsection 2.1.). The battery's operation is optimized based on an MPC, used as teacher MPC, that has been presented in previous work [27] (see subsection 2.2.).
- The teacher MPC is taken as a training basis for three machine learning models, namely, an ANN, an RF, and GB. They are trained based on a full-year simulation of the MPC-controlled system (see subsection 2.4.).
- section 3. presents the open- and closed-loop performance of these approximators, which are used as substitutes for the MPC. For this, we define open- and closed-loop metrics (see subsection 2.5.).
- We finally discuss the relation between the open- and closed-loop performance as well as the comparison of the machine learning models in section 4., conclude our findings (see section 5.), and give an outlook into future work (see section 6.).

By investigating these aspects, we try to answer the two following research questions in the context of approximate MPC:

1. Can advanced tree-based machine learning models outperform the most prominent Artificial Neural Network?
2. Is there a correlation between open- and closed-loop performance?

2. Methodological approach

2.1. Use case: PV-battery system of a non-residential building

The use case is the electrical system of a laboratory and office building in Berlin, Germany. Figure 1 illustrates the central components and their interaction. The energy supply for heating, ventilation, and air conditioning (HVAC) is solely based on electricity. A battery energy storage system aims at reducing potentially arising peak loads and maximizing the electricity generation of the PV power plant. In addition to the demands caused by the HVAC system, the electrical load of the building contains the electricity consumption of the building's, i.e., its tenants', equipment (servers, laboratory equipment, etc.) and lights. The overall system can exchange electricity with the grid.

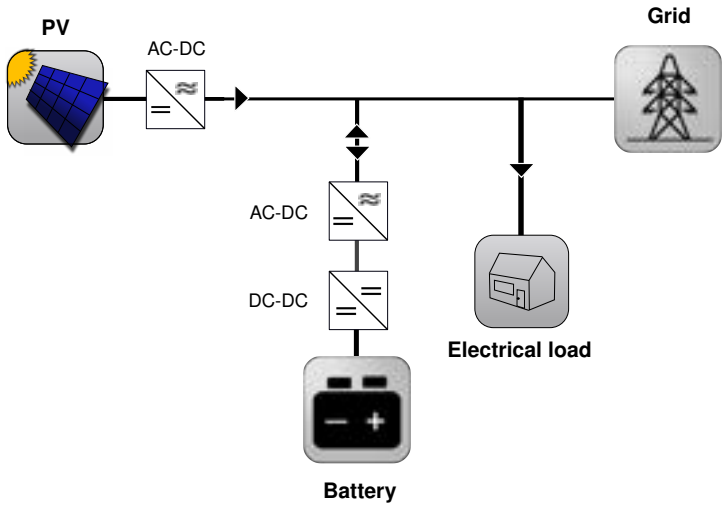

Figure 1: Use case: electrical system setup of the non-residential building including a battery energy storage system, a PV power plant, the building load, and the grid.

The building's electrical loads have been simulated using Modelica as a modeling language. The underlying toolchain to obtain realistic electrical profiles has been presented in [28]. The simulated electrical load is illustrated in Figure 2. The resulting maximum electrical load of the building is 955 kW, the battery's capacity is 2500 kWh and its maximum discharging and charging power is 1250 kW. The PV power plant has a peak power of 500 kWp.

2.2. Model predictive control and data base

In Figure 3, the MPC and AMPC toolchain is illustrated. The target system, which is described in subsection 2.1., is simulated in the modeling language Modelica using the functional mock-up interface. The battery's charging and discharging powers are the manipulated variables that are transferred using the open-source Python package *fmpy*. For every iteration, these manipulated variables are optimized by an mixed-integer linear program (MILP). The MILP is formulated in the Python-based optimization modeling language *Pyomo* [29]. Based on perfect forecast of the disturbances, the battery's state of charge and other state variables, the optimization is solved for two different prediction horizons, resulting in an hierarchical structure. The upper optimization layer is a full-year optimization that determines the optimal electrical peak. This electrical peak is subsequently transferred as a constraint to the second optimization stage that follows the receding horizon scheme. Here, a prediction horizon of 16 h and a timestep of 900 s are applied and the control loop is repeated on an hourly basis. The lower layer optimization optimizes the battery's power based on the PV generation, the building load, as well as economic boundary conditions, such as the electricity price. Since the MPC-based battery operation deals with different sources of revenue, we refer to it as multi-use PV-battery system. Further details on the MILP and the hierarchical MPC are presented in [27].

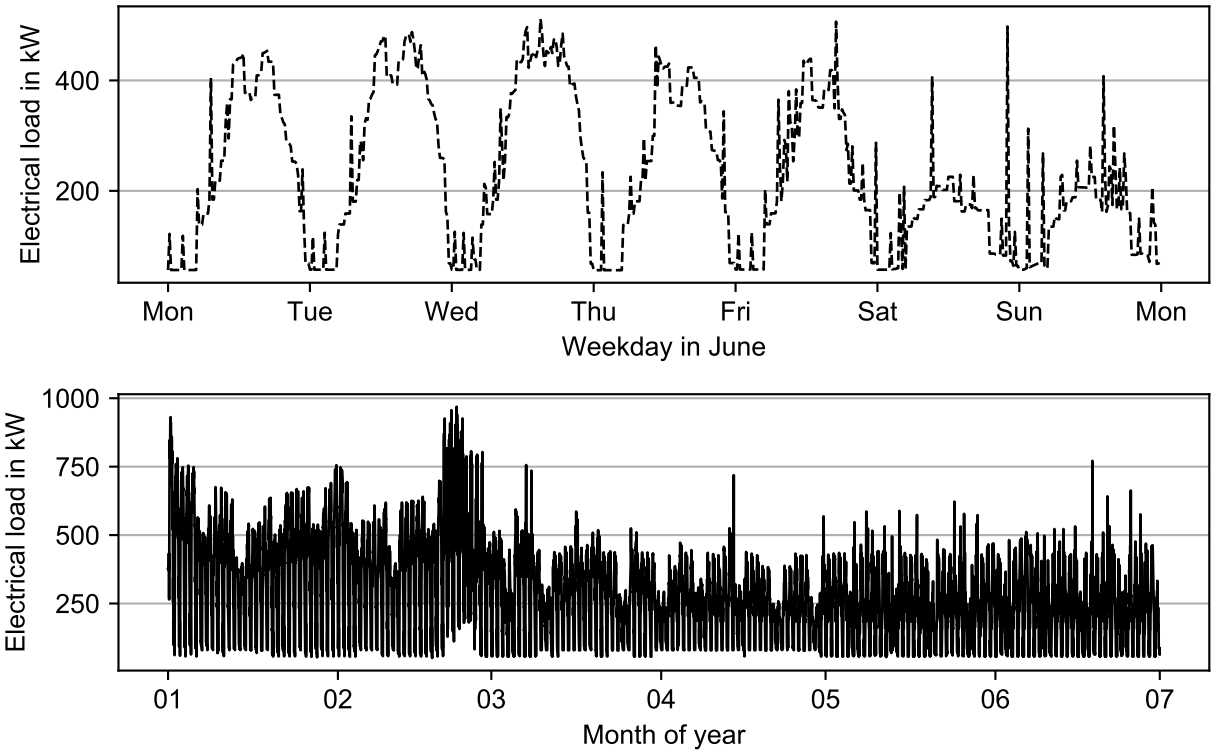

Figure 2: Simulated electrical building load for an exemplary week (top) and the first 6 months (bottom).

The perfectly predicted disturbances comprise:

- **Weather forecasts:** Ambient temperature, global irradiation, and wind speed to compute PV power output based on standardized test reference years [30]
- **Real time electricity prices:** Time-varying EEX electricity prices of 2019 are taken as a basis [31].
- **Electrical building load:** The electricity consumption of the building is simulated in the modeling language Modelica using typical user profiles [28, 32].

This study's aim is to replace the implicit optimization-based controller by an explicit black-box-model-based one. Therefore, we use the open-source machine learning package scikit-learn [33].

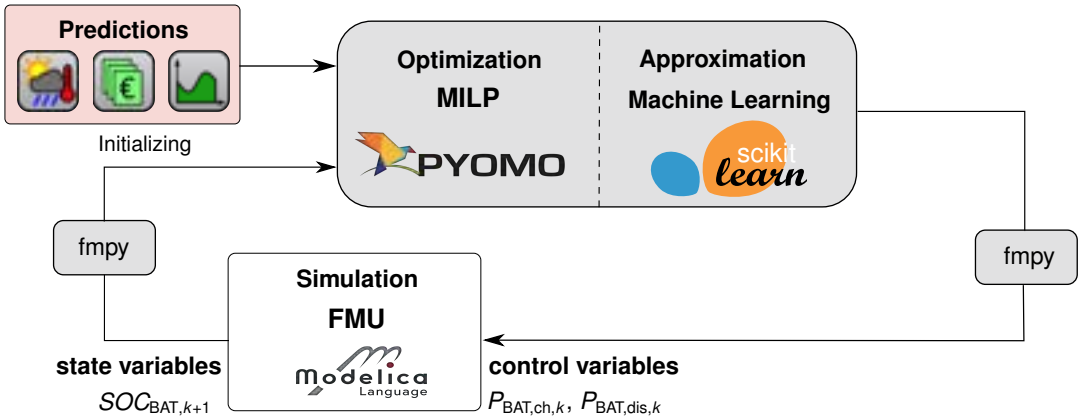

Figure 3: MPC and approximate MPC framework and control loop that calculates the battery's charging $P_k^{BAT,ch}$ and discharging power $P_k^{BAT,ch}$ to the simulation model for each timestep k. Based on measurements like the battery's state of charge SOC_k^{BAT}, the next iteration starts.

2.3. Feature construction and selection

The general approach for approximate MPC is to provide the MPC's input data for the approximator so that it can learn the MPC's output. However, it is recommended to include additional features that support the imitation learning process. For the present study, 14 features have been selected, which are derived based on sensitivity analyses and listed in Table 1. The features comprise measurement data (simulated), set points of a former optimization, synthetic data, and disturbance predictions. The measurements of the previous $k-1$ timestep are used to predict the next timestep's k output. Among these measurements are the simulated battery charging or discharging power, its SOC, the cells' temperatures, the voltage as well as the power from or to the grid. Furthermore, the top layer optimization's computed optimal peak load of timestep k as well as future timesteps serves as input to the approximators. In addition to the measurements, disturbance predictions for 64 timesteps are included, standing for a time period of 16 h, i.e., the MPC's prediction horizon.

Table 1: Overview over features selected to predict the MPC's output.

Feature	timestep	Type
Power of battery (charge or discharge)	k-1	Measurement
State of charge of battery	k-1	Measurement
Temperature of battery cells	k-1	Measurement
Voltage in battery stack	k-1	Measurement
Power to/from grid	k-1	Measurement
Maximum allowed grid demand	k,...,k+63	Optimization set point prediction
Building's electrical load	k,...,k+63	Disturbance prediction
PV electricity generation	k,...,k+63	Disturbance prediction
Electricity price	k,...,k+63	Disturbance prediction
Ratio of building load to maximum allowed grid demand	k,...,k+63	Synthetic (measurement and disturbance prediction)
Ratio of PV generation to building load	k,...,k+63	Synthetic (measurement and optimization set point prediction)
Hour of day	k	Synthetic
Day of week	k	Synthetic
Month of year	k	Synthetic

2.4. Imitation learning process

In approximate MPC applications, the optimization is replaced by an approximated model that imitates the so-called teacher MPC. Machine learning models are the most common approximators in this context. This study deals with a continuous manipulated variable, namely the charging $P_{\text{BAT,ch}}$ and discharging $P_{\text{BAT,dch}}$ power of the battery. We simplify the manipulated variable to P_{BAT}. Due to the continuous nature of the variable, the approximator needs to perform a regression task. The objective of this regression task is to find a regression function $f_\theta : \mathbb{R}^{n_\varepsilon} \rightarrow \mathbb{R}$ that minimizes the squared error between the true manipulated variable P_{BAT} being the MPC's output and the predicted one $\hat{P}_{\text{BAT},k}$ by tuning the parameters θ:

$$\min_{\theta} \sum_{k=1}^{n} (\hat{P}_{\text{BAT},k} - P_{\text{BAT},k})^2, k \in \mathbb{N}, \theta \in \mathbb{R}^{n_\theta} \tag{1}$$

The training data is discretized for each timestep k over the number of relevant samples n.

The regression parameter fitting process is carried out using the open-source Python framework *AddMo* (Automated data-driven modeling) [34]. *AddMo* comprises all relevant steps needed to obtain a well-trained machine learning model. The steps cover the data tuning including data preprocessing, period selection, and feature construction. Subsequently, the tool enables automatic feature selection and hyperparameter tuning. The framework's basis is the open-source machine learning library *scitkit-learn* [33] and covers ANNs, GB, Lasso, RF, and Support Vector Regression as potential model choices. The interested reader is referred to [34] for a more detailed framework presentation.

This study selects ANNs, GB, and RF as approximators as motivated in section 1.

2.5. Open- and closed-loop evaluation scheme

The evaluation includes both the open- and the closed-loop performance of the MPC- and approximator-based controllers. The open-loop performance aims at assessing the approximator's ability to predict the MPC's output, i.e., the charging and discharging power of the battery. As the training process is categorized as supervised machine learning for regression tasks, the coefficient of determination R^2 and the mean absolute

error *MAE* are selected as key performance indicators. Specifically, for each timestep k, the true and predicted output are compared and the respective error metrics are determined. As a simplified initial comparison, these statistical metrics are also computed for the closed-loop operation even though the focus should lie on system- and control-specific metrics and should, thus, be oriented towards the MPC's objectives. For the MPC, the economic evaluation is based on the PV-battery system's annuity. The annuity C_{ANN} simultaneously considers the investment costs (CAPEX, C_{CAPEX}) as well as the operating costs (OPEX,C_{OPEX}). In the context of this study, the following calculation scheme is applied, which is based on the German pricing and regulatory system:

$$C_{\text{ANN}} = f_{\text{AF}} C_{\text{CAPEX}} + C_{\text{OPEX,energy}} + C_{\text{OPEX,power}} \tag{2}$$

$$C_{\text{CAPEX}} = c_{0,\text{PV}} P_{\text{PV,peak}} + c_{0,\text{BAT}} E_{\text{BAT,cap}} \tag{3}$$

$$\begin{aligned} C_{\text{OPEX,energy}} = {} & E_{\text{grid,load}}(c_{k,\text{EEX}} + c_{\text{Tax}} + c_{\text{EEG}}) + E_{\text{grid,BAT}}(c_{k,\text{EEX}} + c_{\text{Tax}} + 0.6 c_{\text{EEG}} \eta_{\text{BAT}}^2) \\ & + 0.4(E_{\text{PV,load}} + E_{\text{BAT,load}}) c_{\text{EEG}} + c_{\text{Network}}(E_{\text{grid,load}} + E_{\text{grid,BAT}}) - E_{\text{BAT,grid}} c_{k,\text{EEX}} - E_{\text{PV,grid}} c_{\text{PV,feedin}} \end{aligned} \tag{4}$$

$$C_{\text{OPEX,power}} = P_{\text{peak}} c_{\text{Peak}} \tag{5}$$

The associated costs of Equation 2 to Equation 5 are listed in Table 2. In the context of this paper, we define costs as positive quantities. In Equation 2, C_{CAPEX} includes the specific investment costs of the battery $c_{0,\text{BAT}}$, the PV power plant $c_{0,\text{PV}}$, including the required DC-DC and DC-AC inverters, respectively (see Equation 3 and Table 2). The battery's investment costs depend on its expected lifetime that is affected by aging. Calendrical and cyclical aging is considered in the simulation model. More specifically, keeping the battery on high SOCs or triggering many cycles leads to a degradation of its capacity and performance. For more details, the interested reader is referred to [27]. The CAPEX are multiplied with the annuity factor f_{AF} that depends on the interest rate i and the observation period T. We assume that all components except for the battery have a lifetime of T. If the battery's lifetime is shorter than the observation period, we consider a price degression d. The operation-related costs are further divided into energy demand- $C_{\text{OPEX,energy}}$ and power-related operating costs $C_{\text{OPEX,power}}$ (see Equation 2). For $C_{\text{OPEX,energy}}$, the energy flows of the PV-battery system, the building, and the grid must be distinguished since different pricing schemes apply. Equation 4 denotes energy flows from source to sink. For example, $E_{\text{grid,load}}$ is the building's consumed electrical energy covered by the grid. In addition to taxes c_{Tax} and network charges c_{Network}, the German pricing scheme includes a charge to support renewable energy sources c_{EEG}, whose quantity depends on the energy source. Therefore, Equation 4 differentiates between flows of the PV power plant, the grid, and the battery. Furthermore, the operation-related costs depend on the EEX market prices of each timestep k. The EEX prices also serve as source of revenue if electrical power is fed back into the grid. As an additional revenue, fed-in electricity from the PV power plant is rewarded with the feed-in price $c_{\text{PV,feedin}}$.

Apart from the purely economic evaluation, this study also focuses on the system's peak load P_{peak} . The system's peak load is taken as an additional metric because the teacher MPC's aims to determine the system's optimal maximum peak load and control the battery's power accordingly. The associated costs are calculated based on a peak power price c_{Peak} (see Equation 5).

Table 2: Assumptions of economic boundary conditions.

Type	Mathematical description	Quantity
Initial invest in battery including DC-DC inverter	$c_{0,\text{BAT}}$	725 €/kWh
Initial invest in PV power plant including DC-AC inverter	$c_{0,\text{PV}}$	1170 €/kWp
Lifetime of battery	T_{BAT}	Simulated
Observation period	T	20 a
Relative price degression	d	6 %/a
Interest rate	i	1.3 %
Real-time pricing	$c_{k,\text{EEX}}$	EEX 2019
PV feed-in pricing	$c_{\text{PV,feedin}}$	6.62 ct /kWh
Tax-related charges	c_{Tax}	3.17 ct /kWh
Network charges	c_{Network}	1.65 ct /kWh
Peak power charges	c_{Peak}	53.53 €/kW

3. Results

The following section presents both the open- and the closed-loop results. The open-loop results stem from comparing the approximator's and the MILP's output regarding the battery's charging and discharging power. Consequently, the control loop is not closed. In contrast, the second part of this section focuses on closed-loop simulation results, for which the approximators are used to control the PV-battery system.

3.1. Open-loop performance

The open-loop analysis compares the predicted output $\hat{P}_{\mathrm{BAT}}$ with the true MPC output P_{BAT} based on a time series comparison. Open-loop training serves as an indicator of how well the machine learning models imitate the controller's output. However, since there is no interaction with the system, we cannot conclude on the closed-loop performance. Figure 4 illustrates the coefficient of determination R^2 as well as the mean absolute error *MAE* for the testing period for both open- and closed-loop operation. For this section, we concentrate on the open-loop results, i.e., the red bars and line graphs. The models are trained based on six months of training data and tested on six months of unseen data. The first half of the year serves as training data, while the second half serves as a testing period. The overall open-loop accuracy is high for all three models. GB results yields the highest R^2 of 0.83 and the lowest *MAE*, while ANN results in the lowest R^2. The ANN and RF yield a similar performance when taking the *MAE* as a basis. However, the ANN's R^2 is slightly lower than the RF's one. Consequently, the GB is favorable from an open-loop performance perspective. Nonetheless, the variations in performance are slight.

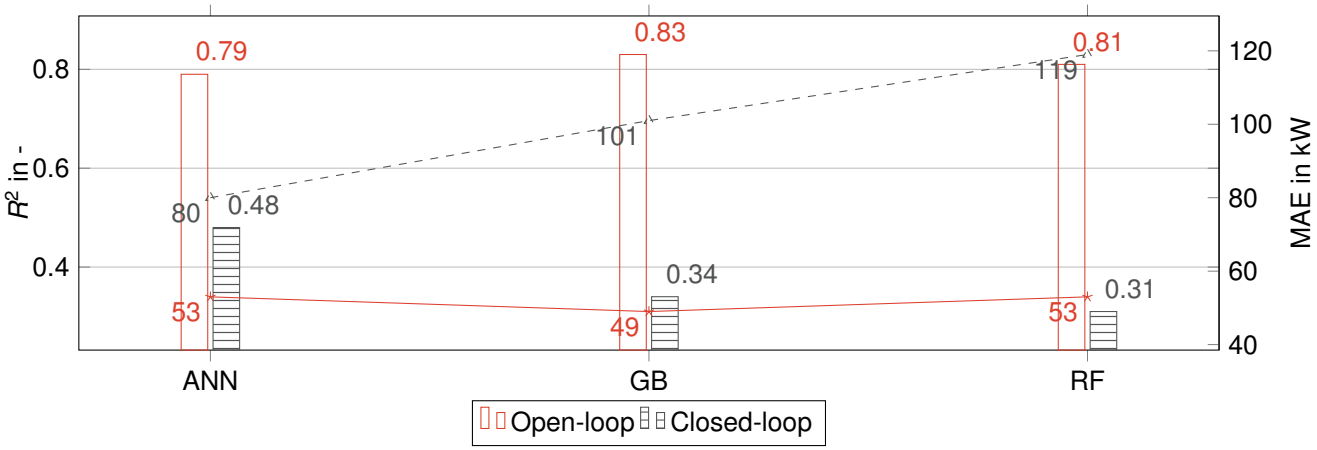

Figure 4: Time-series-based open- and closed-loop prediction results for 6 months training and testing.

3.2. Closed-loop performance

In addition to the open-loop performance not considering any interaction with the simulation model, this section investigates the closed-loop performance. At first, we focus on a purely time-series-based comparison between the open- and closed-loop performance. For this evaluation, Figure 4 also shows the statistical metrics for the closed-loop operation in addition to the open-loop comparison. The data is based on a closed-loop simulation of 6 months, from January to the end of June. The metrics derive from comparing the controllers' outputs, i.e., the battery's set charging and discharging power. The results indicate a different picture compared to the open-loop performance. The ANN clearly outperforms the tree-based models with an R^2 of 0.48 compared to 0.34 for GB and 0.31 for the RF, respectively. The same trend applies to the *MAE*. Based on this, we cannot see any correlation between the open- and the closed-loop performance of the approximators. However, the comparison above is based on time series only and does not consider any MPC performance metrics.

For this reason, we analyze the actual closed-loop performance taking MPC relevant objectives into consideration (see subsection 2.5.). The bar chart on the left of Figure 5 illustrates the resulting annuity of the PV-battery system for the MILP and the approximators, i.e., the ANN-, GB-, and RF-based controller. We like to highlight at this point that the annuities are negative because we mainly consider costs and the rewards through electricity feed-in are small for our use case. The resulting annuity ranges between $-425\,\mathrm{k€}$ for the GB-controlled and $-440\,\mathrm{k€}$ for the ANN-controlled system. Among the approximators, the GB performs best, followed by the RF. The ANN results in the lowest annuity. The GB-controlled system even outperforms the MILP regarding the annuity.

Figure 6 further illustrates the resulting operation for an exemplary week in June. The top plot shows the manipulated variables, namely, the battery's set power for the MILP- and approximator-controlled system. In the middle, the resulting grid load is depicted. As a reference, the optimized peak load is marked, too. A

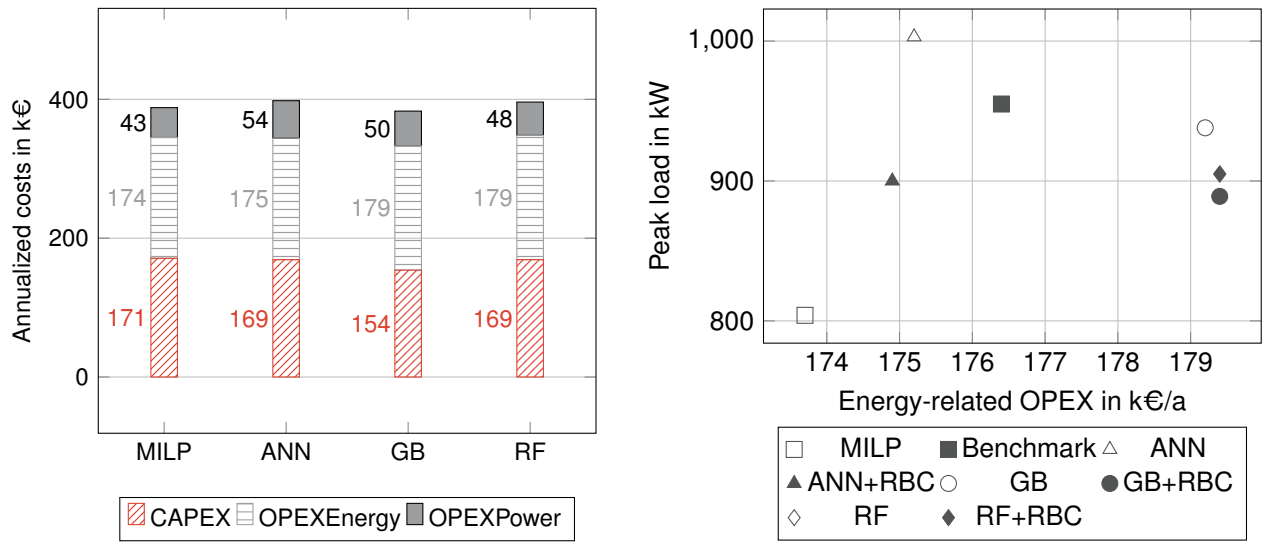

Figure 5: Closed-loop simulation results: The figure illustrates the holistic annuity of the PV-battery system without backup controllers (left) and the comparison of the resulting electrical peak load and demand-related operating costs with (+RBC) and without backup controllers (right).

positive battery power denotes battery charging, while a negative one signifies discharging. Furthermore, positive grid loads denote an energy flow from the grid to the system and vice versa. The bottom part of Figure 6 shows the variable electricity tariff. We observe that the approximators sufficiently imitate the teacher MPC's output. However, the resulting grid load shown in the middle part highlights that some approximators exceed the optimized grid limit. The tendency to overshoot the grid limit applies the most for the ANN-based controller. On the illustrated Saturday afternoon, the ANN lets the battery charge due to low electricity prices. This trend is partially observed for the residual controllers but to a smaller extent. The high charging power results in a grid load exceeding the optimized peak load. This behavior is also present on Thursday and Friday afternoon. Again, the ANN triggers a charging period due to low electricity prices even though the teacher MPC's output is 0 kW. Here, we detect the approximator's correlation between the in- and output without considering the constraints set within the MILP.

Figure 6 highlights the need for an additional backup controller that reinforces the optimized peak. To support the approximators in reducing the peak power, an additional rule-based backup controller is considered. The controller is non-predictive, meaning it relies on present or past measurements of the system. Based on the current grid load and the approximator's output, the rule-based controller limits the battery's set charging or discharging power. The result is depicted on the right-hand side of Figure 5. Here, we illustrate the realized electrical peak load and the energy-related OPEX for two sets of an approximator-controlled, the MILP-controlled system, and a benchmark model. The two sets of approximators consider the machine learning models with and without additional rule-based backup controllers ("X+RBC"). The MILP, i.e., the MPC, runs a pre-optimization for a whole year to determine the optimal peak load. This peak load is 803 kW for the given scenario and a constraint for the MILP. Hence, the MILP does not surpass the optimal peak, so the maximum peak for the 6-months simulation is 803 kW, too. In addition, the MPC also yields the lowest energy-related operating costs $C_{\text{OPEX,energy}}$ of approximately 174 k€. Apart from that, we determine a benchmark model that does not include a battery. We solely include the benchmark model in the right-hand side plot of Figure 5 because the benchmark does not involve an investment in the PV-battery system. Consequently, a comparison based on the annuity is not expedient. The benchmark control does not shift any load and consequently solely depends on the variable electricity price. It yields a peak load of 955 kW and operating costs of 176 k€. Thus, the MPC achieves a peak load reduction of 16 % and a decrease in energy-related operating costs of 1 %. In general, the energy-related operating costs do not vary significantly among the controllers. However, it is noteworthy that high peak loads lead to higher power-related OPEX $C_{\text{OPEX,power}}$. Combining both energy- and power-related OPEX, the MPC results in OPEX savings of 5 %.

In contrast, we observe a great difference in the peak loads. Without integrating a rule-based controller, only the GB- and the RF-based approximators realize a smaller peak load than the benchmark model of 938 kW and 905 kW, respectively. For the RF, the integration of a backup controller has only a negligible effect on the peak load of 0.3 kW. For the GB and the ANN, the effect is more significant. While the peak load is reduced from 938 kW to 889 kW in the case of GB, it decreases from 1003 kW to 900 kW for the ANN. The ANN's tendency to overshoot the peak load is also apparent in Figure 6. Nonetheless, when considering the rule-based controller, the annuities decline by 2 % for the ANN, increase by 0.5 % for GB and by 0.5 % for the RF.

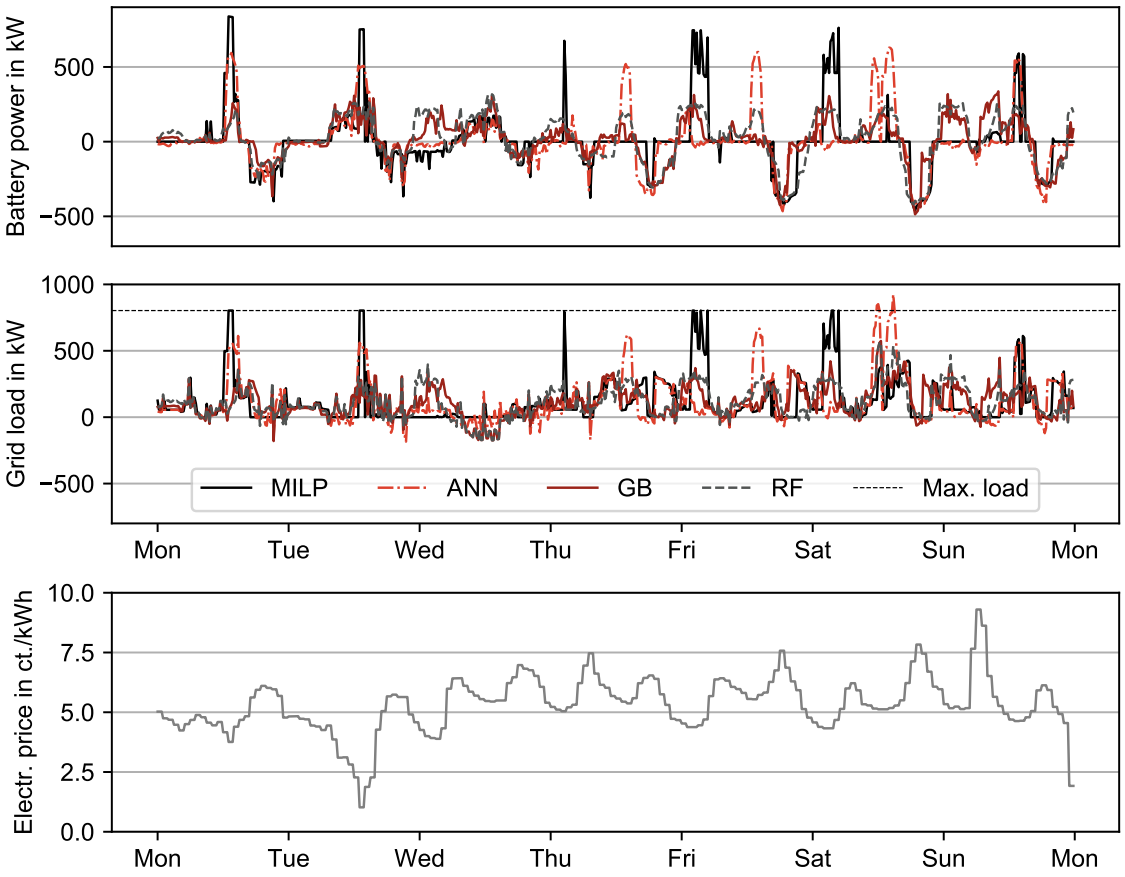

Figure 6: Closed-loop simulation results for the first week in June. The top plot shows the manipulated variables, i.e., the set battery power. In the center, the resulting grid load is depicted. Here, we also mark the optimized peak load as a reference. The bottom plot presents the EEX electricity tariff. The approximators control the system without the rule-based backup controller.

4. Discussion

The results of section 3. highlight that the relation between open- and closed-loop performance is difficult to assess. While a purely time-series-based comparison as shown in Figure 4 supports the conclusion that there is no correlation between open- and closed-loop performance, the subsequent analysis of the MPC-related objectives partially proves the opposite. When considering the annuity, the GB-based controller outperforms the ANN- and RF-based one (see Figure 5). Yet, the GB's resulting battery operation significantly differs from the MILP-based one, which is further supported by the low R^2 of 0.34 and the high *MAE* of 101 kW as illustrated in Figure 4. The ANN realizes the highest conformity with the teacher MPC's set points, which is apparent in Figure 6. Nonetheless, it tends to overshoot the optimized electrical peak due to the correlation with the electricity price. The other machine-learning-based approximators do not adopt this behavior as strongly. This is also why integrating the rule-based backup controller as shown on the right-hand side of Figure 5 has the most significant effect on the ANN-based controller's peak load.

Furthermore, it becomes evident that despite the integration of a rule-based backup controller that reduces the peak load, the optimized peak load of 803 kW is still surpassed by the approximators (see Figure 5). This behavior is explained by the rule-based controller's dependence on past measurements. Consequently, if the building load is higher than the load of the previous timestep, the battery's charging and discharging power in addition to the building load might still exceed the set upper limit. This disadvantage could be mitigated if the rule-based controller was based on building load predictions rather than past measurements. However, integrating these predictions would further increase the approximators' complexity. Still, we see great potential in developing a hybrid approach with a more sophisticated backup controller.

Another aspect is that the GB-based controller seems to slightly outperform its teacher MPC when taking the annuity as a basis (left plot in Figure 5). However, this behavior is only possible because the GB-based controller does not consider the MILP's constraints. A pre-optimization is carried out to obtain the optimal electricity peak. Subsequently, the MILP-based MPC uses this as an upper boundary and manipulates the

charging and discharging powers accordingly. Consequently, the GB extrapolates the defined solution space. Even though the GB-based controller does indeed achieve the lowest annuity, it is still not favorable compared to the MILP from an operator's point of view. It exceeds the optimal peak by approximately 100 kW and results in higher OPEX. Its low annuity mainly derives from low investment costs. The low investment costs are primarily caused by a longer battery lifetime due to reduced cycling and calendrical aging (see subsection 2.5.). When solely focusing on the operation, the ANN- and MILP-based controller are favored.

5. Conclusions

In the present study, we developed an approximate model predictive control approach for a PV-battery system in an office and laboratory building. The study is based on the preceding development of a hierarchical MPC in [27]. The hierarchy is based on prediction horizons so that different time scales can be considered. In the case of the PV-battery system, the MPC aims at optimizing the electrical peak load in a first step and incorporate it in the battery energy management in the second step (see subsection 2.2.). The hierarchical MPC serves as teacher to generate training data for machine learning models. These machine learning models are the approximators that replace the optimization problem after successful training. I.e., they function as controllers instead of the optimization program leading to a speed-up in processing time and lower hard- and software requirements in practice. Since the scientific literature is still missing a comparison of advanced machine learning models in the context of approximate MPC, we investigate an artificial neural network as well as the sophisticated tree-based models Random Forest and Gradient Boosting (see section 1.). In addition to that, we detect a research gap in in-depth analyses of the open- and closed-loop performance of the approximators. In the context of this study, the open-loop performance refers to the purely time-series based comparison of the true, i.e., the MPC output and the predicted, i.e., the approximators' outputs without any system interaction. The closed-loop performance is calculated based on the system interaction between the MPC or the approximators with the target system.

Our results prove that the machine-learning-based approximators all result in relatively high open-loop performances (see Figure 4). While the Gradient Boosting model slightly outperforms the other approximators open-loop, the same trend is not apparent when comparing the closed-loop performance solely based on the respectvie time-series. Here, we compare the MPC's output, i.e., the manipulated variables, with the approximator's one without evaluating the control-oriented metrics as defined in subsection 2.5.. Here, the Artificial Neural Network results in the highest accuracy metrics. When taking into consideration the PV-battery system's annuity, however, the Gradient Boosting model even surpasses the MPC results. The effect that the approximator outperforms its original teacher, is explained by the machine learning models' missing constraints. The MPC considers the maximum electrical peak as a constraint within the optimization. Hence, the MPC does not exceed the pre-optimized peak of 803 kW (see right-hand side of Figure 5). Nonetheless, the MPC performance is still considered the best when taking into account all relevant operation metrics. This behavior can be mitigated by an addtional rule-based backup controller that has been implemented in this study (see right-hand side of Figure 5). The integration of the backup controller results in a decrease in the electrical peak load while achieving almost the same annuity as the purely approximator-controlled system.

All in all, all three approximators result in a reliable closed-loop performance. Even though their control output clearly differs from the MPC's one, they outperform a benchmark model regarding the peak load. No clear relation between open- and closed-loop performance is apparent considering that the approximators all perform best regarding other metrics. Nonetheless, we detect that high open-loop performance supports a robust closed-loop performance. Finally, we go back to the stated research questions in subsection 1.1. as follows:

1. Advanced tree-based machine learning models like Gradient Boosting and Random Forest can outperform Artificial Neural Networks as controllers in an approximate MPC application. In addition, they are favourable from a comprehensibility point of view as they resemble the conventional "if-condition-then-action" structure of rule-based controllers.

2. The open-loop performance is an indicator for a good closed-loop performance, however, no generalizable conclusions can be drawn. A purely time-series-based comparison of controller outputs, i.e., the control trajectory, can be misleading regarding the closed-loop performance.

6. Outlook

The simulative assessment of the PV-battery system is based on a hierarchical MPC with a rolling horizon of 1 h. I.e., the control loop is repeated every hour with a timestep of 15 min and a prediction horizon of 16 h. The approximators, however, learn the in- to output relations based on every timestep, i.e., 15 min. This means that the approximators inheretly learn the model uncertainty of the MPC's process model for 3 out of 4 timesteps. Thus, we recommend future work to use a 1-step MPC to mitigate the model uncertainty. We expect the open-loop performance to increase for this case.

Apart from that, the overall profitability of the PV-battery system is not existent when taking the annuity into account. This is caused by the provided regulatory framework from Germany. Future work should focus on additional sources of revenue such as frequency control reserves. In addition, the interaction with the building energy system should be more closely investigated and synergy effects between the battery and the HVAC system identified.

Abstract:
With growing concerns about climate change and increasing energy costs, energy-efficient use of buildings offers an opportunity to decrease CO_2 emissions and costs. The behavior of building occupants plays a significant role in the process of improving this efficiency both for new and existing buildings. Therefore, we introduce a suite of web-based software applications that aim to encourage energy-efficient building occupant behavior in an office environment under the Living Lab Energy Campus (LLEC) initiative, using the campus of Forschungszentrum Jülich as a demonstration. The suite of applications, developed via a co-design process, provides means to view energy consumption data at various levels of aggregation, and to receive real-time recommendations and incentives for behavior change. Through the *Energy Dashboard*, users can monitor and analyze heating, cooling, and electrical energy consumption at building level. Leveraging IoT-enabled sensors and actuators, *JuControl* offers an interface to view room-specific indoor environmental, heating and ventilation data, and allows occupants to control the room heating by specifying a personal temperature setpoint range. Occupants also receive real-time feedback via recommendations for energy efficiency improvement, alongside periodic behavior evaluation in the form of ratings. The serious game *JuPower* gives users the opportunity to compete in teams to design a CO_2-minimal alternative virtual energy system for the campus, whilst the users' real-world energy-related behavior is translated into in-game effects, thereby providing incentives for energy-efficient behavior via game rewards and social interaction. The interrelations among the applications, deployment strategies, and first outcomes are discussed.

1. Introduction

In the EU, the building sector contributes 40% of the energy consumption and over 30% of the CO_2 emissions [1], [2]. According to estimations, 75% of the buildings in the EU are energy-inefficient [3].

Within the building sector, occupant behavior has been identified as a key factor in the energy efficiency of buildings and is often implicated in the difference between modeled and actual (post-occupancy) energy consumption of buildings [4, 5, 6]. According to the PROBE studies (Post-occupancy Review of Buildings and their Engineering), this difference is usually a factor of two: the actual consumption is twice the modelled consumption [4, 7]. Similar results are also reported by other studies (e.g. as cited in [8]). Furthermore, in one simulation study of energy behaviors of office occupants with profiles classified as one of austerity, standard, or wasteful, it was estimated that the wasteful profile can use up to 90% more energy than the standard energy profile in a one-person office, while the austerity profile can use up to 50% less energy than the standard profile [9].

Clearly, there is potential for the improvement of energy efficiency in buildings through energy-efficient occupant behaviour. However, there are challenges in engaging occupants and triggering behavior change. First, building occupants in public buildings are usually indifferent to the energy efficiency of their behavior because they are not conscious of their impact on the energy consumption and are not responsible for the energy costs [10]. To solve the consciousness issue, energy consumption should be monitored through measurement data. But this leads to issues of privacy and data security, especially for a country like Germany where privacy is taken more seriously than in most other European countries, with supporting structures like the works

council and Data Protection Officers serving to protect employees from privacy infringements [11, 12, 13, 14].

Furthermore, the issue of occupant apathy to energy consumption in public buildings is not easy to address in a top-down, management-initiated and sustained fashion in a European country like Germany. Only in the light of the energy crisis occasioned by the Russia-Ukraine conflict was there more assertive drive from government to save energy across the country. In spite of this, occupant behavior still requires more intrinsic motivation for its transformation.

In this work, the objective is to develop and test applications that are effective in influencing building occupants' behavior through intrinsic motivation. We focus on occupant interactions with the heating, cooling and air conditioning (HVAC) system in naturally ventilated office buildings under real-world conditions. This work is incorporated in the Living Lab Energy Campus (LLEC), in which a part of the infrastructure of Forschungszentrum Jülich GmbH (FZJ) is transformed to a test-bed for e.g. monitoring and control approaches for future building and district energy systems. Our case study consists of a subset of office buildings in FZJ with different years of construction (ranging from the 1970s up to recently completed buildings), which are representative of the office building stock. Figure 1 gives an overview of the chosen setup in the equipped buildings. All selected buildings, like all FZJ buildings, were already equipped with digital calibrated meters to measure electricity, heating and cooling demand, e.g. for billing purposes. For research purposes, an interface was set up between the facility management's proprietary system and the research ICT platform. In addition, all offices, meeting rooms and kitchenettes in the selected buildings were equipped with wireless indoor air quality sensors (to measure CO_2 concentration, temperature and relative humidity), window and door status sensors, and wireless thermostats. Due to the heterogeneity of the buildings and in order to limit the retrofitting effort in the existing buildings to a sensible level, the sensor network makes use of wireless (EnOcean) sensors. On top of this, a subset of the selected buildings was equipped with wired (KNX) actuators for shading, lighting and underfloor heating control and push buttons with integrated displays. To allow for transfer of the developed approaches to buildings in the outside world, all sensors and actuators used are commercially available. More details can be found in [15].

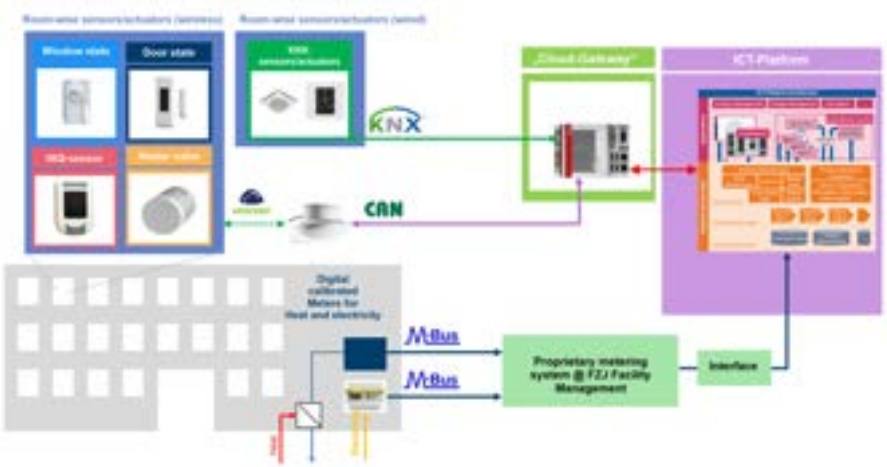

Figure 1: Setup of digital meters, sensors and actuators in buildings

To meet the challenges in bringing about behavior change, we develop applications for building occupants for visualization and control of the building energy system through a human-machine interface (HMI). Additionally, we introduce real-time behavior evaluation and recommendations for the occupants, supported by *gamification* and a serious game. We evaluate the effectiveness of various combinations of these behavior intervention measures. Only initial results from the individual parts of the system are available as at the time of this writing, the fully coupled system has only just been deployed.

1.1. Literature Review

The interaction of occupants with the building and its energy system is the focus of several large-scale studies. For example, the DataFEE project[1] focuses on the development of tools and methods for the analysis of the interaction of occupants with buildings. Likewise, the IEA EBC Annex 66 project [2] and the IEA EBC Annex 79 project [3] focused on modelling occupants and occupancy, as well as the integration of occupancy in building models. Related to these occupant-centric studies, various behavioral intervention projects have

[1] Available at https://www.ebc.eonerc.rwth-aachen.de/cms/E-ON-ERC-EBC/Forschung/Forschungsprojekte2/Projekte-Nutzerverhalten-und-Komfort/ cviyk/DataFEE/?lidx=1

[2] http://www.annex66.org/

[3] Available at https://annex79.iea-ebc.org/

been carried out to address energy efficiency of occupants in buildings. These interventions take one of several forms, including provision of information through visualization, active feedback through various means of communication, and numerous gamification and serious games. One main element for providing information and visual feedback in energy systems is the use of *energy dashboards* [16]. These dashboards provide a Graphical User Interface (GUI) for visualizations regarding energy-related data. Additionally, interactive dashboards provide good User Experience (UX) and encourage interactions with the information being presented. To make such GUIs effective, their design follows Human-machine interface design principles. Rogers, Sharp and Preece [17], who worked extensively on these design principles, highlight the principles of *visibility*, *feedback* and *constraints*. The principle of visibility refers to making actions and functionalities obvious to the user, while the principle of feedback prescribes that the interface should give users notifications when an action has to be performed or has been completed. The principle of constraints refers to limiting user actions in the interface if they are not valid. In the context of energy behavior interventions, these principles encourage the use of energy dashboards. Whilst some studies show that dashboards are beneficial, other studies indicate, however, that visualization alone does not lead to sustainable energy-saving behavior [18, 16]. Most studies related to occupant behavior interventions focus on gamification and serious games.

Gamification is defined as "the use of game design elements in non-game contexts" [19]. A distinction exists between *serious games*, which is the development of full-fledged games for non-entertainment purposes, and gamification, which just involves the use of game elements or "atoms" in an otherwise non-game context [19]. Such game elements include leaderboards, badges, and points. Gamification aims to achieve real-world behavior change by means of an engaging and fun experience.

Several studies have used different gamification concepts with the intention of motivating users to take action for enhanced energy efficiency. In the review by Johnson et al. [20] the authors investigated 25 gamified applications and serious games in the domestic energy consumption sector. The results of the behavioral interventions are classified into four categories: behavioral, cognitive, learning and knowledge acquisition, and user experience. Behavioral interventions refer to real-world and in-game actions and aspirations to save energy, while the cognitive aspect refers to affective and motivational elements, including energy-related opinions, self-awareness about energy saving and motivation to engage in energy-conserving measures. Learning and knowledge acquisition refers to learning effectiveness and knowledge accumulation, and finally user experience refers to the perspective of the user towards the game, including engagement, usability and satisfaction. The results of the majority of the studies (a total of 17 out of 25) fall into more than one result category. The user experience is the most frequent, followed by cognitive, real-world behavioral, knowledge, then in-game behavioral categories.

Across the studies, the results were not exclusively, but mostly, positive. About half of the reviewed interventions explored serious games and the other half explored gamified applications. Among the employed applications were seven mobile apps, nine browser apps and five computer games. While around half of the applications feature integrations with the real world, the others are completely digital without real-world integration.

AlSkaif et al. [21] introduces a conceptual framework based on gamification for residential building user engagement. They classify the framework requirements and link them to corresponding high-level gamification objectives. The five groups of game design aspects implemented are information provision (statistics, messages, tips), rewarding system (electricity bill discounts, virtual currency, prizes/offers/coupons), social connection (competition, collaboration, energy community), user interface (dashboards, leaderboard, progress bar, message box, notifications, degree of control), and performance status (points, badges, levels).

1.2. Research Contributions

The contributions of this paper are as follows. First, we report on various implementations of user behavior interventions with respect to energy efficiency, starting with visualization of energy systems at different levels of spatial granularity, through to provision of a Human-Computer Interface (HCI) for controlling the energy system. Furthermore, we discuss the application of gamification and user behavior evaluation, and the coupling of these to a serious game. When the experimental results are complete, we intend to extensively analyze and discuss the contributions of the various combinations of these interventions to occupant behavior improvement. In this paper, however, we only discuss initial results, since the full-fledged experiment has only been running for a very short time as at the time of writing.

This work is organized as follows: Section 2. describes the purpose and features of the applications developed, Section 3. presents results and discussion of the co-design process of the applications as well as the occupant behavior evaluation. Section4. summarizes and draws a conclusion.

2. Methodology

The LLEC Energy Dashboard suite includes multiple web applications that interact with each other to provide a wide range of functionalities.

2.1. The Energy Dashboard: Visualization of Energy Data

The Energy Dashboard provides an interface through which staff members and visitors can gain insight into the energy demand of the campus. Via the Dashboard, users can view both historical and real-time heating and electricity data at the campus level as well as for individual buildings, see Figure 2.

Additionally, the Dashboard shows operation data of so-called *energy demonstrators*, which are proof-of-concept energy systems for generation, conversion, and storage of renewable energy and waste heat. The goal of the Dashboard is to drive user awareness regarding energy systems in general, as well as to improve the public understanding of the represented systems.

Figure 2: Screenshots of the Energy Dashboard. *Left*: Exemplary building page showing live electricity and thermal demands. *Right*: Comparison of buildings demands for thermal power.

2.1.1. Data

Currently, the two main data measures are electricity and heating demand. Timeseries data for those measurements is visualized on the dashboard at one-minute resolution. The main landing page of the energy dashboard shows the overall consumption of electricity and heating energy for the whole campus using a mix of chart types. This is the highest-level data that is visible on the dashboard. More details for the same consumption data for electricity and heating is also available on the building-level. Via an interactive campus map or a list of building IDs, a single building can be selected to view its data. This data is also available in the form of the same 2-hour-live-chart. Additionally there is a 48-hour historical data bar chart, in which the data is hourly aggregated.

2.1.2. Access rights

One important aspect of the whole framework is data security. There are different levels of access for the energy dashboard, as not all data is visible to every user. Authentication is via Shibboleth, and roles are assigned based on the authenticated user. The basic staff role can view data for the whole campus and single buildings, but buildings in restricted areas on the campus are not available. Admins can escalate their authentication level to view more data like number of sensors reporting for each data point, additional plots, and access to the restricted buildings. The guest role uses login credentials without Shibboleth authentication, and is only permitted to view the campus-level consumption and a special subset of buildings.

2.2. JuControl: Visualization, Control and Gamification

The effects of the behavior of a single office occupant in the context of a whole building are not necessarily directly visible. To account for that, selected buildings were equipped with additional sensors and actuators for data acquisition and control at room level. This allows the collection of more datasets like CO_2 concentration, humidity or window states. The measurement data on room level is visualized via the web-based application *JuControl* (see Figure 3), which is integrated into the Energy Dashboard.

Besides the more detailed visualization of data, *JuControl* also enables users to control actuators in their room via an online interface, in addition to the physical controls available at the actuators themselves.

2.2.1. Automatic heating control

Within LLEC, the equipped rooms form a test-bed for testing different innovative control approaches, e.g. model predictive control-based room controllers. In addition to the control options in the rooms, *JuControl* provides the central user interface for the comfort preferences of the room occupants that are taken into account by

Figure 3: JuControl: Exemplary room view

Figure 4: JuControl: User specific time schedule for the expected presence in the office

the tested automated controls. Regardless of the control algorithms tested, the user interface itself already offers a great deal of savings potential through options that go far beyond the previous manual adjustment of thermostats. Office spaces are usually only used in a clearly limited time frame. Therefore, they offer a good opportunity to save heating energy by lowering the room temperature to an appropriate level while the office is not occupied, for example after working hours and over the weekend. However, for the comfort of employees, it is important to restore the correct temperature within the rooms in time. For this, *JuControl* offers users the ability to create an individual time schedule in which they enter their expected presence; see Figure 4.

In order to accommodate different needs, every user can also define their own comfort temperature range. Based on the schedules of all occupants of an office, *JuControl* then calculates a heating plan for the room. A controller script can query this heating plan via *JuControl*'s API and perform optimal heating control based on the desired temperature setpoints.

2.2.2. Manual control mode

Naturally, an occupant's schedule may not always match the actual presence in the office, for example when the schedule changes temporarily on short notice. For scenarios such as these, the occupant always has the option to switch to "manual control", in which the schedule and the associated desired temperature setpoints are overridden by the manual setting. Manual control can be triggered via the *JuControl* web interface or by physically operating the thermostats. In both cases, the new user-specified setpoint temperature is then targeted by the heating control. After a maximum of 8 hours, the control automatically returns to automatic mode, in which the presence schedule is used once again.

2.2.3. User Consent

Compared to the general building consumption, the parameters measured here are very sensitive data, as they allow drawing direct conclusions about individual persons or small groups of persons. For example, the CO_2 concentration in an office can be used to determine how many people were present in the office at a specific time. The data is only visible to an occupant if all the other occupants of an office agree to the usage of this tool. This poses an additional challenge when users change offices. Basically the following rules are applied: a user only has access to the data of the office they are officially assigned to, and only if all other occupants of this room have given their consent. If someone leaves an office, the person also no longer has access to newly generated data of this office. (However, they can view historical data.) If a new employee joins an office, everyone automatically loses their access rights until this new employee has also agreed to the data processing.

2.2.4. Gamification

JuControl features a gamification section, in which the energy efficiency of occupants' offices is evaluated based on predefined behavioral patterns related to ventilation habits and indoor temperature setpoints. The evaluations, which are currently limited to heating demand, are carried out by *Juracle*, an evaluation engine discussed in Section 2.4.. Corresponding penalties are awarded in the form of "wasted thermal energy" scaled to the size of the FZJ campus. Groups of office rooms compete in teams against groups from the same or other buildings. A leaderboard shows the ranking of teams based on performance and places each room's performance in the context of the team's and global performance. Additionally, a three-color traffic-light feedback system is used to convert the raw energy penalty values to normative feedback that allows occupants to determine if their performance is relatively good or bad.

Social interactions (competitions, teams) have been shown to be key elements of effective gamification [22, 23, 20]. To this end, gamification in *JuControl* is designed around teams and competition. Additionally, the

performance of teams is coupled to a serious game *JuPower*, discussed more in Section 2.3. below. The *JuControl* gamification interface is shown in Figure 5 below.

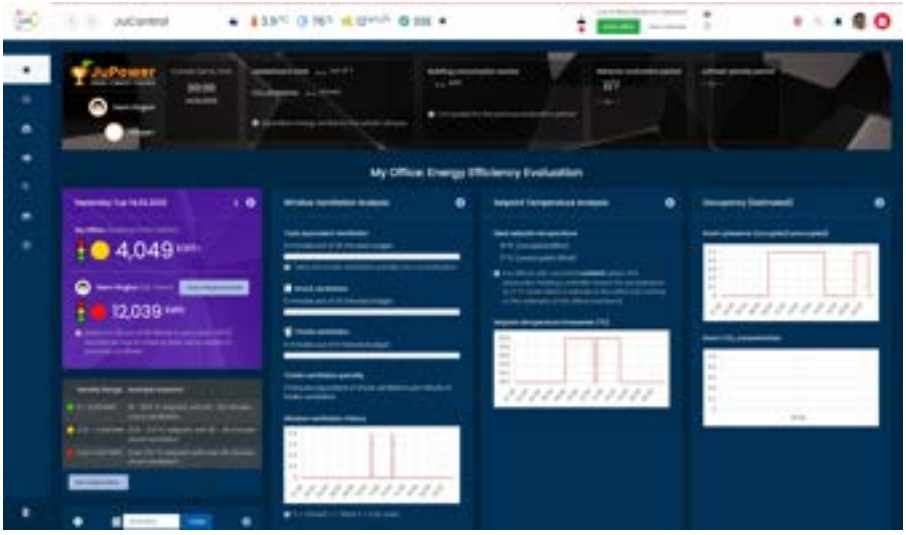

Figure 5: *JuControl* gamification interface showing integration with a serious game, *JuPower* (top dark bar), and evaluations obtained from *Juracle*. The charts show the timeseries for the input quantities for behavior evaluation – window state, setpoint temperature, and presence profile.

2.3. JuPower: A Serious Game

JuPower is a *serious game* developed to enable players appreciate the trade-offs involved in energy system design. A *serious game* is a game developed for non-entertainment purposes, whilst ideally retaining the fun and engaging nature of entertainment games. The purpose of the gamification approach is to engage users and draw attention to the way their behavior affects their energy consumption.

2.3.1. Game design

In the game, the mission for players is to design a more climate-friendly energy supply system for a virtual version of the Forschungszentrum Jülich campus having heating and electricity demand. The electrical demand data is derived from actual historical data for the campus, while the thermal demand data is derived from a mix of Modelica [24] models of the actual buildings developed using the TEASER [25] tool, and historical data. The building models allow players to apply realistic retrofits at a cost in the game.

By design, the default energy source for heating in the virtual campus is an oil boiler, with electrical power being drawn from the virtual electricity grid. This assumption is different in many respects from the actual energy sources in the real campus.

To reduce the CO_2 emissions arising for the supply of energy to the buildings, new installations can be made in the game. Players have a fixed budget with which they can purchase new energy systems and components to replace the default energy system. The resulting energy system for the virtual campus is simulated afterwards for each team, and the teams are ranked continuously based on the total operational CO_2 emissions generated over the simulation period.

2.3.2. Game modes

JuPower admits three different modes of play that can coexist independently. These are:

- Sandbox mode, in which players try out features and learn the system without teams, competitions, or external time pressure. Essentially, the players' game actions and its effects are visible to the player alone.
- Standard game mode, in which players participate in teams in a predefined gameplay instance that is governed by a time schedule. In this mode, outcomes of the real-world behavior evaluation are fed into the game.
- Real-time mode, which is intended for more experienced energy system designers. Here, the game clock is synchronized to the real clock, and boundary condition inputs into the game, like weather and demand data, are derived in real-time from real-world data.

Figure 6: JuPower home page during simulation showing the energy widget (center) and the leaderboard (right).

Figure 7: JuPower simulation page

2.3.3. Gameplay

A game run consists of *game phases*, each of which provides a defined set of interaction opportunities for the players. In the *design phase*, players design an energy system by installing energy system components on a stylized aerial view of the campus via drag-and-drop. The aerial map view faithfully mimics the main features of the landscape of the real campus. Each installation of a component requires cash and real-estate, and is subject to the availability of these resources. Players propose their designs to their teams and cast votes to determine which proposed design is adopted for the team. To enhance coordination and communication amongst players within a team, a rich-text chat functionality with mentions is available in the Proposals page. Furthermore, players tag and optionally describe their designs prior to proposing them.

The *pre-simulation phase* follows the design phase. In this phase, the most-upvoted design is automatically adopted for each team. Based on this design, the operation of the energy system over a certain period is projected by computing the dispatch of the components. The dispatch is the result of a Mixed-Integer Linear Program (MILP) optimization problem, solved using the Gurobi^{TM} [26] solver. Afterwards, the *simulation phase* starts, during which various system data and performance indices are shown in "real game-time" as the simulation progresses. The Key Performance Index (KPI) is the accumulated operational CO_2 emissions, and teams are ranked on a leaderboard based on this KPI. Figure 6 and Figure 7 below show the home page and simulation page, respectively, during simulation. The *post-simulation phase* allows players to take stock and reflect on their design choices.

2.3.4. Coupling with Real-world Behavior Evaluation

The real-world behavior penalties computed as part of the JuControl gamification described above, are transferred to JuPower as additional building demands. Specifically, for each team, the average weekly performance penalty is added to the thermal demand of the buildings in JuPower for that team. This has the effect of a proportional increase in CO_2 emissions in the game, and by extension a worsening of the performance of the energy system in the game.

2.4. Juracle: Occupant Behavior Evaluation Engine

Juracle is an engine that evaluates the thermal energy-related aspects of occupant behavior based on two criteria: window interaction (ventilation) and room heating (temperature setpoint). First, it defines the notion of an ideal occupant, and then computes the deviation of a given instance of occupant behavior from this ideal. Finally, it expresses this deviation in energy terms (kWh) as wasted energy. Two different but related focuses of such a behavior evaluation tool can be identified: behavior modification to conform with some predefined norm, or energy wastage estimation. These two goals are not necessary congruent, since aiming for one could imply violating the other. For example, previous research has shown that *trickle ventilation* during the heating season (i.e. with windows opened only a small angle while hinged on the bottom side) leads to severe energy losses, compared to the so-called *shock ventilation* (with windows fully opened while hinged on the side) [27]. (These multi-modal windows are commonplace in Germany.) However, trickle ventilation leads to more energy wastage only because occupants tend to leave windows in that state for long periods due to its poor efficiency in refreshing the room air, leading to the cooling down of the walls. Evaluation with focus on behavior modification discourages *patterns of behavior* like trickle ventilation, while focus on energy evaluation judges the energy impact of particular instances of behavior that lead to energy wastage.

Effectively, the behavior modification-focused method of intervention tends towards a rule-based system, in which a consistent set of relatively simple rules are defined by which user behavior is judged. These rules do not have to be accurate in the physics sense in its assumptions, but only need to be *self-consistent*, that is – roughly speaking – given similar inputs, they produce similar outputs. On the other hand, model-based systems are more appropriate when the focus is estimating energy wastage. Here, the physical processes

involved and their relationships are represented using laws of physics.

2.4.1. Hybrid Evaluation Model

Juracle uses a hybrid approach: it focuses on the behavior modification goal, and derives a set of physics-informed rules with the following attendant characteristics. First, the ideal occupant is defined in terms of duration of window opening, and the chosen setpoint temperature. A quota is assigned for the ideal occupant and deviations are computed from this quota for real occupants. Secondly, trickle ventilation as a pattern of behavior is discouraged. Therefore a penalty factor scales the trickle ventilation duration to deplete the quota more quickly. Thirdly, the computed deviations based on the measured criteria are applied to a reference model to derive an estimate of the energy "cost" of the deviations (in kWh). Finally, since the rule-based system has fewer parameters than a model-based system, it tends to be more easily scalable than a purely model-based system which has to take into account the variations of the physical properties of the different buildings and interactions.

The penalty derived from *Juracle* is applied to *JuPower* game as a demand increase for which CO_2 emissions must be minimized in the game.

2.5. Experiment Design

In order to evaluate the effectiveness of the suite of applications in concert, an experiment design has been conceived and the experiments are currently ongoing. Some of the questions that the experiment design aims to answer are:

- What are the effects of the behavior evaluation strategy on behavior, both in terms of user actions as compared to the ideal scenario, and in terms of actual energy savings?
- What additional effect does the JuPower serious game have when coupled with behavior evaluation, and what is its stand-alone effect?
- What are the effects of visualization and control, without evaluation?

To this end, the experiment design strategy involves grouping nearly 500 offices across more than ten buildings into teams with various combinations of features enabled for each team. Depending on the set of enabled features, these teams are grouped into independent experiment sets on the basis of feature compatibility. The design of each of these experiment sets provides the potential to answer specific research questions, such as those outlined above.

3. Results and Discussion

The *Energy Dashboard* has been used by more than 1,300 staff members since its release in mid-2020, or about one-fifth of the population of the campus. *JuControl* has been available in one building for well over a year, and has formed a core part of the heating regulation of the rooms in the building. However, as mentioned earlier, the main experimental run and evaluation of the suite of applications only just began, and only limited initial data on user evaluation is available. The *JuPower* game has only been played in test phases, and the development of *Juracle* was only recently concluded. Nevertheless, the results of the evaluations of the apps as stand-alone units are presented in the following sub-sections, covering mainly the user interaction and user experience evaluation and feedback obtained through co-design workshops.

3.1. Co-Design Process

The energy dashboard suite was developed using a co-design process. In this way, future users of the dashboard were actively involved in the development cycle and feedback and results were collected at several points in the process. A total of four co-design workshops targeting different aspects and developmental stages of the Energy Dashboard suite have been carried out, apart from various additional less-structured usability tests. During the co-design workshops, volunteers were granted alpha- and beta-stage access to test the dashboard components and provide feedback on existing features. Furthermore, during the co-design workshop events, potential features and further development concepts were discussed in detail. The results of these four workshops are summarised in the following paragraphs.

3.1.1. Co-Design Results: Energy Dashboard and JuControl

Beyond the standard requirements for user friendliness, the barrier to on-boarding for the applications should be as low as possible. By following a web-based approach, the applications do not require a separate installation step. Additionally, the responsive design that caters to different device sizes and orientations for the Energy Dashboard and *JuControl* made it possible to view these apps on mobile devices and tablets. Furthermore, to ease the burden of password management and mitigate potential security issues related to credentials, we integrated authentication via the institution-wide Shibboleth authentication. Thus, the authentication process was the same for the users as for most other services they access in their regular work.

Figure 8: $C0_2$ health chart developed as a result of feedback from users, in order to understand the values shown.

Figure 9: JuPower screenshot showing main actions and their completion status.

Again, users expressed the wish to have data shown on a spatial granularity level below the campus or building level, i.e. the floor or room level, so that they can reconcile the data to their own contributions. The implementation of this wish was the development of *JuControl*.

Furthermore, given the diverse range of specializations in the campus, it was necessary to not assume a knowledge of energy systems on the part of the users. This meant that all necessary information needed to understand the visualizations were made available in the application. For example, in *JuControl* a health chart is shown alongside the CO_2 concentration for the room, as shown in Figure 8. This was the result of feedback.

Yet again, whilst the applications are designed to maximize user interaction, users expressed fears about the apps being a distraction from work by requiring too much attention. To this end, a notifications management system was developed that allows users to be notified by email about certain events (e.g. when CO_2 concentration is above their defined threshold), or even turn off notifications completely. When the notifications are on, their frequency is throttled.

3.1.2. Co-Design Process for JuPower

For the JuPower game, for which two co-design workshops were conducted, the feedback were received and implemented. In general, the game was well received. Some key aspects are outlined as follows.

First, the game application included a manual that explained the objectives and functionalities in the game. However, multiple test users reported that they found this manual too long and not easily readable, and preferred scan-only help information with relevant information highlighted. In response, we introduced the Quick Start section with selected bolded text that summarized the most important points, alongside visual aids like images and illustrations. In the same vein, to reduce the risk of information overload, an *Actions* widget was introduced, which showed the three main steps involved in the gameplay and their completion status (see Figure 9). Additionally, a short tutorial video of about 15 minutes was made to introduce the main features of the game, which several participants found helpful.

Secondly, since the game usually runs over several weeks, and each stage of user interaction can be spread of several days, it was helpful to notify users of the game phase transitions and impending deadlines by email. The emails contained the relevant description for the phase, and any actions that were necessary were included as clickable links in the email.

Finally, to reduce the cognitive load required to play the game, we reduced the range of component options available to the player in the design of an energy system, based on feedback. Furthermore, the number of exposed parameters for each component was reduced to the bare essentials, in order to make decision making easier for the players.

3.2. Occupant Behavior Evaluation

The main experiment phase of the project for evaluating the energy efficiency of occupant behaviour ran from 13.03.2023 to 28.04.2023 (inclusive). Figure 10 shows the number of offices activated in *JuControl* by occupants (after all occupants in each office digitally granted consent for data visualization), broken down into pre-experiment and experiment periods. In about half of the teams, an activation level of at least 50% was achieved in the end, and more than 70% activation in a quarter of the teams.

Figure 11 below shows the evaluation results for one working week for an office, as well as the team average and the global average of all teams in the experimental group, while Fig 12 compares the average penalties for all teams in the given experimental group for a given working week. The colored regions correspond to a three-color traffic-light rating scheme, in which the energy penalties are assigned to traffic-light colors based on a predefined scheme. The color boundaries are: Green: up to 2,120 kWh; Amber: 2,121 kWh to 4,146 kWh; Red: over 4,146 kWh. The energy penalty value represents the amount of energy *lost* in a day in the campus, if *all offices in FZJ* would have a similar occupant behavior profile as the evaluated office or team.

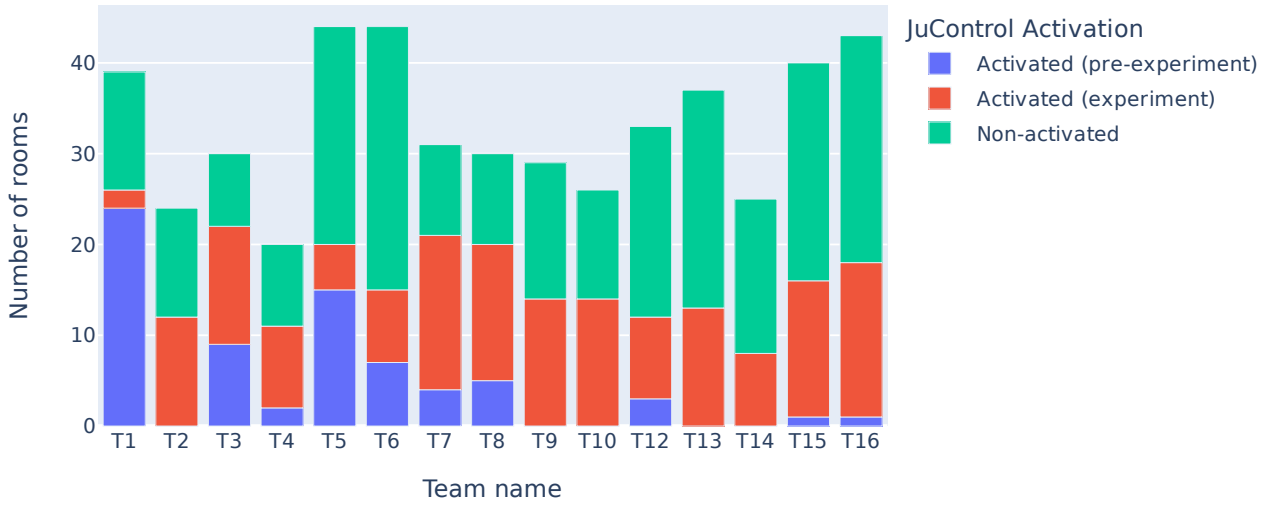

Figure 10: Activation of JuControl in offices by occupants, according to team. The pre-experiment status is shown (blue), along with the additional activation due to the experiment run (red), and non-activated offices (green). Teams T1 and T5 are located in pilot buildings, in which the initial test installations were carried out prior to subsequent extension to other buildings.

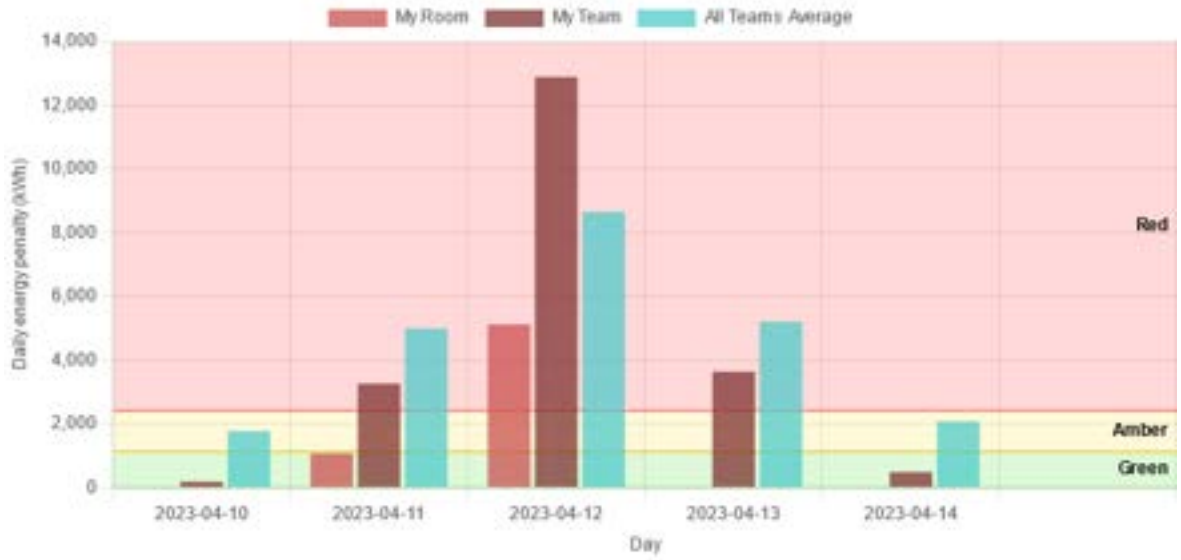

Figure 11: Evaluation penalties for the FZJ campus based on the occupant behaviour for an office (”My Room”), within a team (”My Team”), and for all teams in an experiment group (”All Teams Average”) for one evaluation week (week days).

4. Conclusion

In this paper, a suite of user-facing applications that were developed at Forschungszentrum Jülich to drive user engagement with the overall goal of improving occupant energy behavior was described. With the *Energy Dashboard*, the user has access to building and campus level energy-related data, including consumption data for heating and electricity. Furthermore, comparisons can be made across buildings based on the data. *JuControl* increases the spatial granularity to the room level, and introduces data about other measures like indoor air quality. Furthermore, it enables the control of the occupant's heating energy system. These applications have successfully been used in the field for several months (extending up to 4 years in some cases). The *JuPower* game has been successfully tested and applied in the experiment phase, as well as *Juracle*'s behavior evaluation. In conclusion, the suite of software applications and the strategy of combining and deploying them hold great potential for influencing user behavior towards increased energy efficiency.

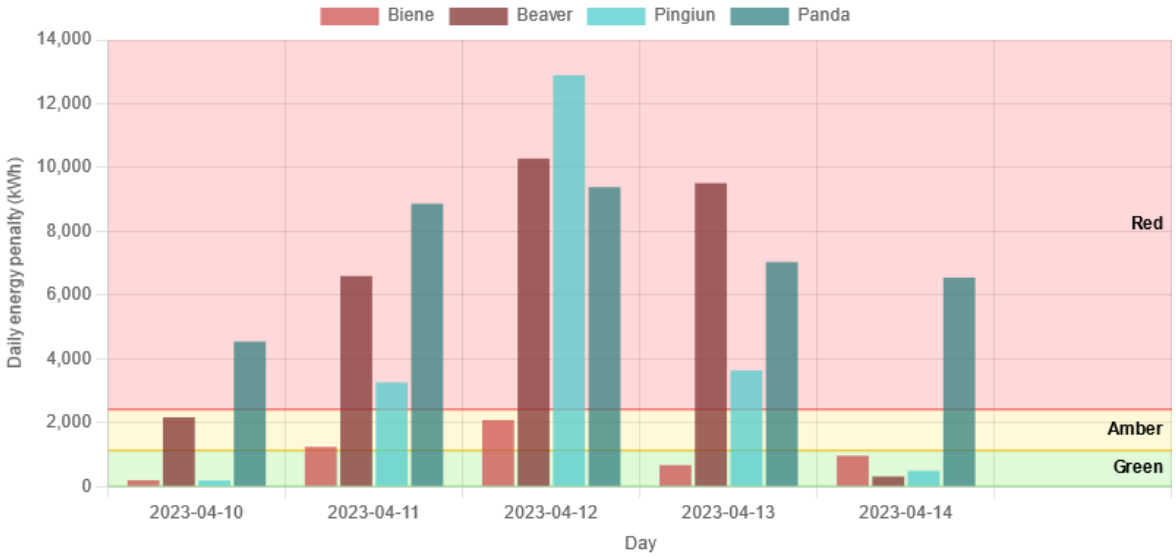

Figure 12: Evaluation penalties for the FZJ campus based on the average occupant behaviour within each team in an experiment group for one evaluation week (week days).

Declaration of Competing Interest

We have no conflict of interest.

Abstract:

Heat pump systems are a key technology towards the decarbonisation of district heating systems as they can leverage renewable energy sources and industrial excess heat. Large-scale heat pumps are prone to a variety of faults related to the heat source. Heat exchanger fouling is one of the most common types of faults, which corresponds to the undesired deposition of material on heat transfer surfaces. This fault can be mitigated by the use of different cleaning procedures such as cleaning-in-place. The optimization of the time interval between cleaning periods requires the estimation of the effects of fouling on the heat pump performance, which are often difficult to determine. The present study proposes a framework for online monitoring of a large-scale heat pump affected by evaporator fouling based on a quasi-steady-state simulation model. Model parameters related to the heat transfer coefficients and fouling were repeatedly adjusted by means of a dynamic calibration approach. The framework retrieved operational data from a cloud-based data management system and leveraged existing sensors and controllers in the heat pump. The results indicated that fouling had a larger effect on the thermal resistance than on the pressure drop in the evaporator. The framework also allowed to identify the extent to which a cleaning-in-place system enabled to reduce the evaporator thermal resistance caused by fouling. Overall, the results from the proposed framework showed its potential to describe the operation of the heat pump and to determine the effects of fouling on a real-time basis.

Heat pump, District heating, Fouling, Operation monitoring, Digital twin

1. Introduction

Heat pumps (HPs) are expected to play a major role in the decarbonisation of district heating systems. Today, around 90 % of the global heat supply derives from fossil fuels [1]. HPs enable waste heat recovery and utilization of renewable energy sources. Further, they couple the power and heating sectors, which can support the accommodation of large shares of electric energy from renewable sources in the system. The performance and/or availability of HPs is often negatively affected by faults related to the heat source, as described by HP operators and service providers in [2]. A literature study [3] distinguished fouling in the source side of heat exchangers to be among the most common faults in large-scale HPs. This fault consists of the deposition of material on heat transfer surfaces and in pipes, which can increase the pressure drop and thermal resistance in heat exchangers. As mentioned in [4], the characterization of fouling is challenging, particularly due to uncertainties on the initialization of the deposition process and its growth rate.

Commonly used technologies for the mitigation of fouling are cleaning-in-place (CIP) systems. These include mechanical and chemical cleaning processes [5], which are often off-line i.e. are applied while the heat pump is not in operation. Hence, finding the optimal moment and duration of the CIP activation represents a techno-economic optimization problem. This requires information about the extent to which a particular CIP is able to remove the deposited material as well as information about downtime and CIP implementation costs. A study [6] highlighted the challenge of predicting the thermal resistance attributed to fouling in the source stream heat exchanger of a large-scale wastewater heat pump. This study used data-driven regression models for the prediction of the thermal resistance caused by fouling. The data-driven regressions model were designed for the purpose of optimizing the cleaning procedures.

Physics-based simulation models are useful for the design of HPs and their components, mainly because they are applicable to a wide variety of boundary conditions and system configurations. However, the structure and parametrisation of such models is often fixed and does not adapt to time-dependent variations in the HPs they

represent. Such variations can be caused by faults or wear of components. In order to overcome this limitation, physics-based models may be complemented with numerical models derived from observations or data-driven models for the provision of services for HPs. Examples of such services include fault detection and diagnosis [7,8], operation monitoring [9], and defrosting optimization [10].

The provision of model-based services for HPs used for district heating supply still remains limited. A model-based monitoring and optimization framework has the potential to characterize the operation of a HP for a wide range of operational conditions and identify parameters that could enhance the HP performance. In particular, a thermodynamic model that could adapt its structure based real-time monitored data may enable the characterization of incipient faults affecting the HP, which has not been found in previous studies. The present study aimed at the increase of a HP performance through an improved CIP planning procedure characterized by an automatic model calibration framework. This framework was based on the integration of a physics-based model of the HP with data-driven optimization methods for model calibration.

2. Method

2.1. Case study heat pump

The operation of a two-stage ammonia HP with a design heating capacity of 2 MW was analysed in this study and its layout is shown in Figure 1. The HP is used for the provision of heat at around 68 °C to a local district heating network located in Copenhagen, Denmark. The heat source is industrial wastewater at around 23 °C originated from a biochemical plant. The desuperheater (DSH), condenser, receiver and subcooler (SC) are embedded in a single shell-and-plate heat exchanger unit. The evaporator is also a shell-and-plate heat exchanger and is in direct contact with the industrial wastewater. Each of the two stages in the HP includes a reciprocating compressor and an electronic expansion valve. An open intercooler connects both stages. The HP is controlled by means of the six controllers shown in Figure 1.

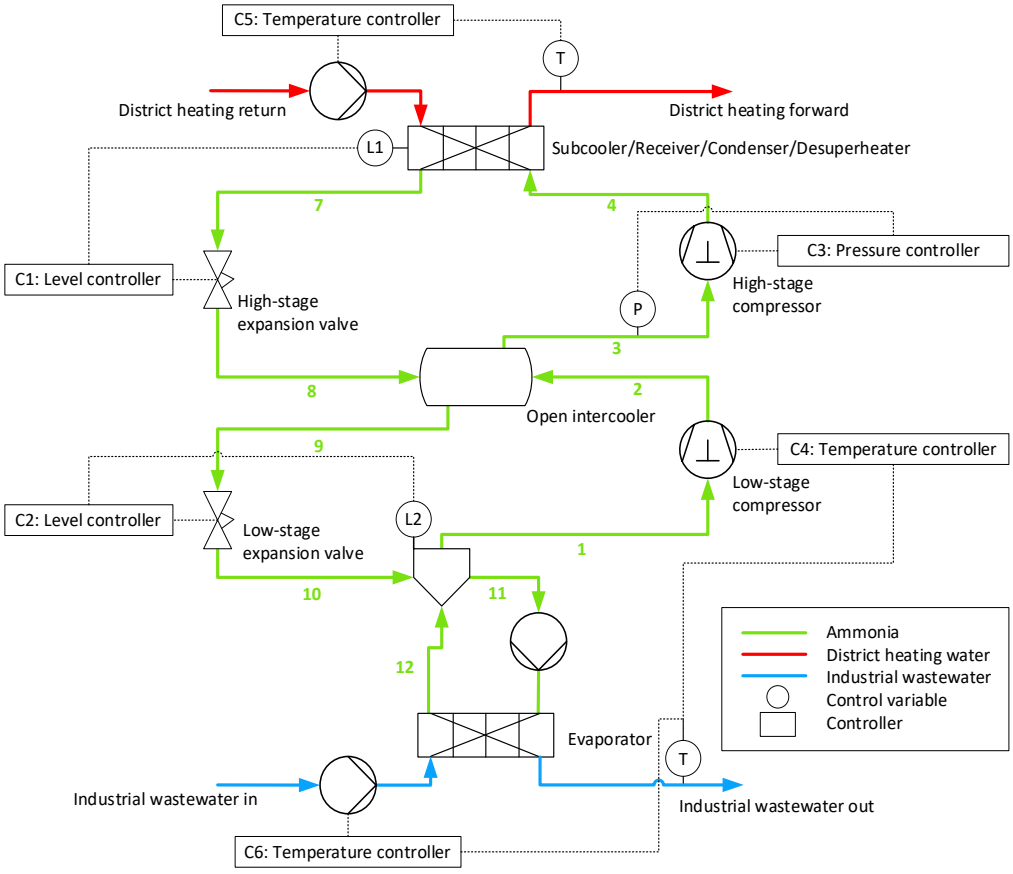

Figure 1: Layout of the two-stage ammonia HP used as case study

The direct contact between the industrial wastewater and the evaporator leads to the presence of fouling in this component, which is mitigated periodically by means of a CIP system. The CIP is used off-line and circulates a chemical solution for the removal of deposited inorganic and organic materials. These materials derived from the industrial processes performed in the biochemical plant. Currently, the frequency of the CIP implementation is defined heuristically by the HP operator based on observations on a decrease in the evaporation pressure (p_e).

2.2. Simulation model

The quasi-steady-state model of the HP shown in Figure 2 was developed in the programming language Python. The model took as input variables the source inlet and outlet temperatures ($T_{source,in}$ and $T_{source,out}$, respectively), the sink inlet temperature ($T_{sink,in}$), the set point for the intermediate pressure ($p_{m,sp}$) as well as the volume flow rates in the source and sink streams (V_{source} and V_{sink}, respectively). The refrigerant states and mass flow rates, heat output and power intake from the HP were determined through an iteration routine that solved the mass and energy balances of the components shown in Figure 2. This was done by the Newton-Raphson method with a tolerance of 10^{-9}, which identified the condensation and intermediate and pressures (p_c, and p_m, respectively), as well as the speed of the low-stage (LS) compressor (N_{LS}). Here, the residuals were the difference between the estimated and real area of the condenser ($A_{cond,calc}$ and A_{cond}), the estimated and real cooling capacity ($\dot{Q}_{source,calc}$ and $\dot{Q}_{source}$) and the LS mass flow rate estimated from the intercooler and the LS compressor models ($\dot{m}_{LS,IC}$ and $\dot{m}_{LS}$). An upper level iteration process enabled to identify the speed of the high-stage (HS) compressor that led to a minimum difference between the intermediate pressure (p_m) and its set point ($p_{m,sp}$). This was performed by the least-squares method with a tolerance of 10^{-5}. The Python module SciPy [11] was used for the implementation of the least-squares method. The refrigerant state calculations were performed with the Coolprop database [12]. The simulation of the quasi-steady-state model was done through multiprocessing, where 10 processing units were used in parallel within a single computer. Here, a simulated period was divided into 10 segments. All segments were simulated by different processors and the guess values were adjusted dynamically within each processor, namely the simulation results from a point in time *i* were used as guess values for the following point *i*+1. As a reference, the simulation of one hour of HP operation (i.e. 60 one-minute data points) required approximately 10 seconds when using multiprocessing an dynamically adjusted guess values, whereas it took around 113 seconds with a single processor and fixed guess values.

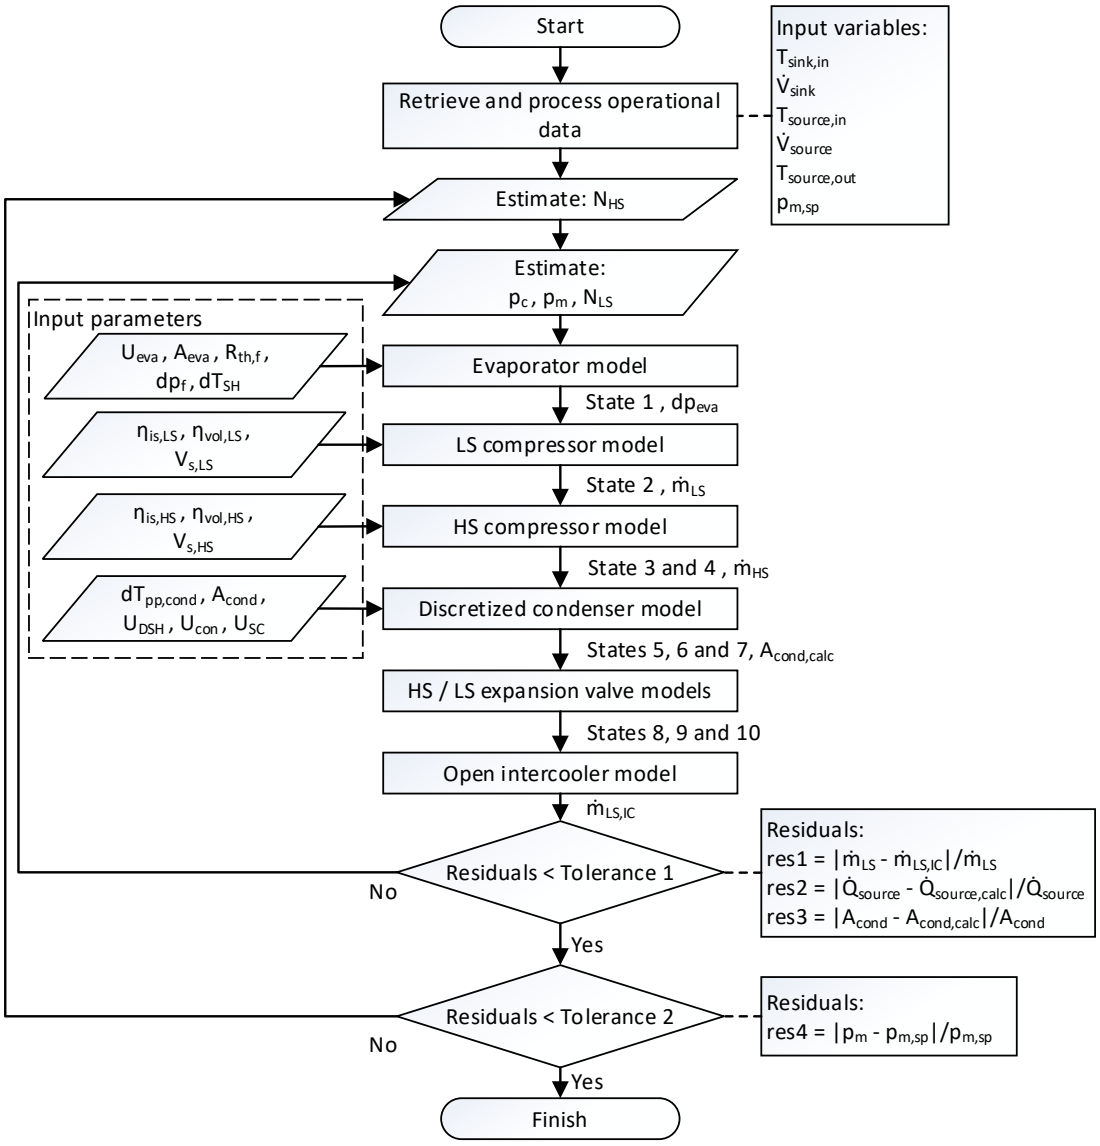

Figure 2: Flow diagram of the HP simulation model

The thermal resistance ($R_{th,f}$) and source stream pressure drop due to fouling (dp_f) were included as input parameters in the evaporator, which were later adjusted based on measurements through the calibration process described in Section 2.3.2. The $R_{th,f}$ was calculated based on Eq. (1), where the thermal resistance of the evaporator under clean conditions ($R_{th,eva,clean}$) was subtracted to the total thermal resistance ($R_{th,eva}$). Both thermal resistances were obtained as the inverse of the UA-value of the evaporator. Similarly, dp_f was determined based on Eq. (2) as the total pressure drop in the evaporator source side (dp_{eva}) minus the source stream pressure drop that was not caused by fouling ($dp_{eva,clean}$). The latter was determined by fitting a quadratic regression model between the volume flow rate in the source stream and the pressure drop in the evaporator right after the CIP was applied. Thereby, the influence of fouling was neglected in such a regression model.

$$R_{\mathrm{th,f}} = 1/\mathrm{UA}_{\mathrm{eva}} - 1/\mathrm{UA}_{\mathrm{eva,clean}} = R_{\mathrm{th,eva}} - R_{\mathrm{th,eva,clean}} \quad (1)$$

$$dp_{\mathrm{f}} = dp_{\mathrm{eva}} - dp_{\mathrm{eva,clean}} \quad (2)$$

The design parameters used in the model are shown in Table 1 and were provided by the HP manufacturer. , the pinch point temperature difference in the condenser ($dT_{pp,cond}$) was assumed to be 5 K. The isentropic and volumetric efficiencies of the compressors (η_{is} and η_{vol}, respectively) were calculated as a function of the compressor speed and the pressure ratios by using polynomials that were determined from information provided by the HP manufacturer.

Table 1: Input parameters used in the simulation model

Component	Input parameter	Symbol	Value	Unit
DSH	Overall heat transfer coefficient	U_{DSH}	230	W/m²K
	Heat transfer area	A_{DSH}	27.8	m²
Condenser	Overall heat transfer coefficient	U_{con}	1210	W/m²K
	Heat transfer area	A_{con}	100.6	m²
	Pinch point temperature difference	$dT_{pp,cond}$	5	K
SC	Overall heat transfer coefficient	U_{SC}	452	W/m²K
	Heat transfer area	A_{SC}	23.1	m²
Evaporator	Overall heat transfer coefficient	U_{eva}	3000	W/m²K
	Heat transfer area	A_{eva}	91.96	m²
	LS suction superheat	dT_{SH}	1	K
Low-stage compressor	Swept volume	$V_{s,LS}$	1018	m³/rev
	Speed	N_{LS}	700-1800	rpm
High-stage compressor	Swept volume	$V_{s,HS}$	532	m³/rev
	Speed	N_{LS}	700-1800	rpm

After the calculation of all the refrigerant states and water outlet temperatures, the model calculated the total heat output ($\dot{Q}_{sink}$) and the coefficient of performance (COP) of the HP based on Eq. (3) and Eq. (4). Here, it was assumed that the specific heat capacity ($c_{p,w}$) and density of water (ρ_w) were constant and equal to 4.18 kJ/(kg·K) and 998 kg/m³, respectively.

$$\dot{Q}_{\mathrm{sink}} = c_{\mathrm{p,w}} \cdot \rho_{\mathrm{w}} \cdot \dot{V}_{\mathrm{sink}} \cdot (T_{\mathrm{sink,out}} - T_{\mathrm{sink,in}}) \quad (3)$$

$$\mathrm{COP} = \dot{Q}_{\mathrm{sink}} / \dot{W}_{\mathrm{total}} \quad (4)$$

2.3. Monitoring framework

The framework proposed in this study consisted of the main components presented in Figure 3. Data from the HP controllers and sensors was accessed by the HP operator through a supervisory control and data acquisition (SCADA) system. The data from the SCADA system was made available to third-party actors through a cloud data management system, which enabled the storage and retrieval of operational data in real-time through an application programming interface (API). Such operational data from the HP was used to calibrate the simulation model described in Section 2.2.

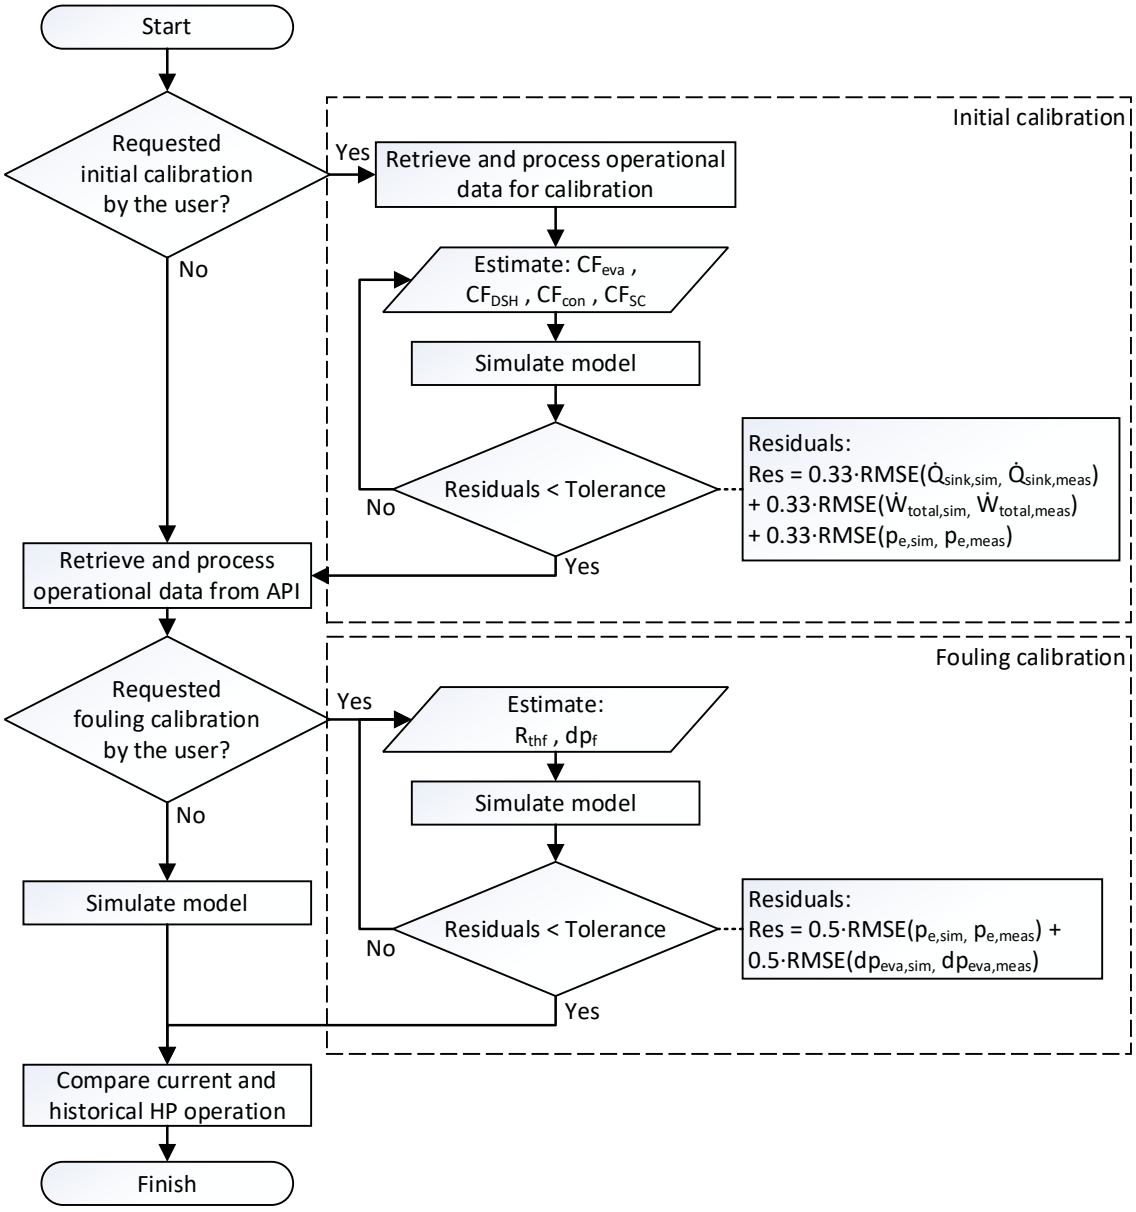

Figure 3: Flow diagram of the proposed monitoring framework

2.3.1. Data retrieval and processing

In the present study, the operational data from the case study HP was retrieved with a one-minute interval. The retrieval and processing of data was performed through Python. Here, the data processing consisted on the calculation of all the refrigerant states shown in Figure 1, for which the Coolprop database was used. This allowed to determine the COP and $\dot{Q}_{sink}$ from the HP by the use of Eq. (3) and Eq. (4). The total operational period included in the present study was 19 days. That period incorporated the activation of the existing CIP system for approximately 3 days, where the HP was not in operation.

2.3.2. Model calibration

Two calibration processes were applied in the proposed framework, namely the initial calibration and fouling calibration processes. The initial calibration was performed based on operational data obtained from the HP manufacturer. Here, the HP was tested under controlled conditions before it was delivered to the end user and thereby fouling was not present. The fouling calibration was based on operational data obtained from the SCADA system through the API. The specific period used for fouling calibration could be selected by the user and should represent periods where is required to analyse the effects of fouling on the HP. In this study, two different operational days were used for fouling calibration, one day before and one day after the CIP implementation. The initial and fouling calibration were comprised of an optimization process where the parameters shown in Table 1 were adjusted. This process minimized the normalized root mean square error (NRMSE) between measured and simulated outputs of interest or calibration targets over a period n, as shown in Eq. (5) and Eq. (6). The normalization was performed through the mean of the measured calibration target over a period n ($\overline{\mathrm{Target}}$). Multiple targets were used in a single optimization process, where each CT was

related to a specific weight (w). The targets for the initial calibration were $\dot{Q}_{sink}$, the total power intake from both compressors ($\dot{W}_{total}$) and the evaporation pressure (p_e), with weights equal to 33.3 % for each target. For the fouling calibration, the targets were the source pressure drop in the evaporator (dp_{eva}) and p_e, where each one had weights equal to 50 %. The weights were determined heuristically were all targets where assumed to have the same relevance.

Table 2: Parameters calibrated in the initial and fouling calibration processes.

Calibration process	Calibration parameter	Symbol	Variation range	Unit
Initial	Correction factor for DSH U-value	CF_{DSH}	0.3 to 1.7	[-]
	Correction factor for condenser U-value	CF_{con}	0.3 to 1.7	[-]
	Correction factor for SC U-value	CF_{SC}	0.3 to 1.7	[-]
	Correction factor for evaporator U-value	CF_{eva}	0.3 to 1.7	[-]
Fouling	Fouling-related evaporator thermal resistance	$R_{th,f}$	0 to 0.02	[K/kW]
	Fouling-related evaporator pressure drop	dp_f	0 to 0.5	[bar]

$$\min f(\text{Parameter}) = \sum_{i=1}^{n} w_i \cdot \text{NRMSE}_i \quad (5)$$

$$\text{NRMSE}_i = \overline{\text{Target}}_{\text{meas}}^{-1} \cdot \sqrt{n^{-1} \cdot \sum_{i=1}^{n} (\text{Target}_{\text{sim,i}}(\text{Parameter}) - \text{Target}_{\text{meas,i}})^2} \quad (6)$$

Time-invariant parameters were adjusted in the initial calibration, which corresponded to correction factors (CFs) for the overall heat transfer coefficients or U-values in the heat exchangers. In the fouling calibration, time-dependent parameters related to fouling were calibrated, namely $R_{th,f}$ and dp_f. The bounds for the calibrated parameters are shown in Table 2. The solution of Eq. (5) and Eq. (6) was obtained through the sequential least squares minimization algorithm available in the SciPy module in Python. The tolerances for both the initial calibration and the fouling calibration process were 10^{-5}.

3. Results

This section shows the results of the proposed monitoring framework, where the operation of the case study HP was monitored and analysed.

3.1. Simulated HP operation

Figure 4 and Figure 5 shows the time-series of the simulated and measured operational variables for a period of 19 days. The initial calibration reduced the difference between simulated and measured COP, $\dot{Q}_{sink}$ and p_e. This difference was reduced even further after the implementation of fouling calibration before the CIP. After the CIP was used, the fouling calibration process reduced the difference between the simulated and measured p_e, but not to the extent seen before the CIP. Moreover, the difference between simulated and measured $\dot{Q}_{sink}$ increased slightly after the second fouling calibration process. The results of the initial calibration process were probably not completely applicable for the period after the CIP, where the effects of fouling on the HP were low. Before the CIP, the mismatch between simulation and measured variables was likely to be lumped into the evaporator thermal resistance attributed to fouling. Regarding the pressure drop in the source stream, only the fouling calibration processes before the CIP led to a higher correspondence between the simulated and measured dp_{source} compared to the period before calibration. This indicated that the CIP did not have a significant effect on the removal of the effect of fouling on the source stream pressure drop.

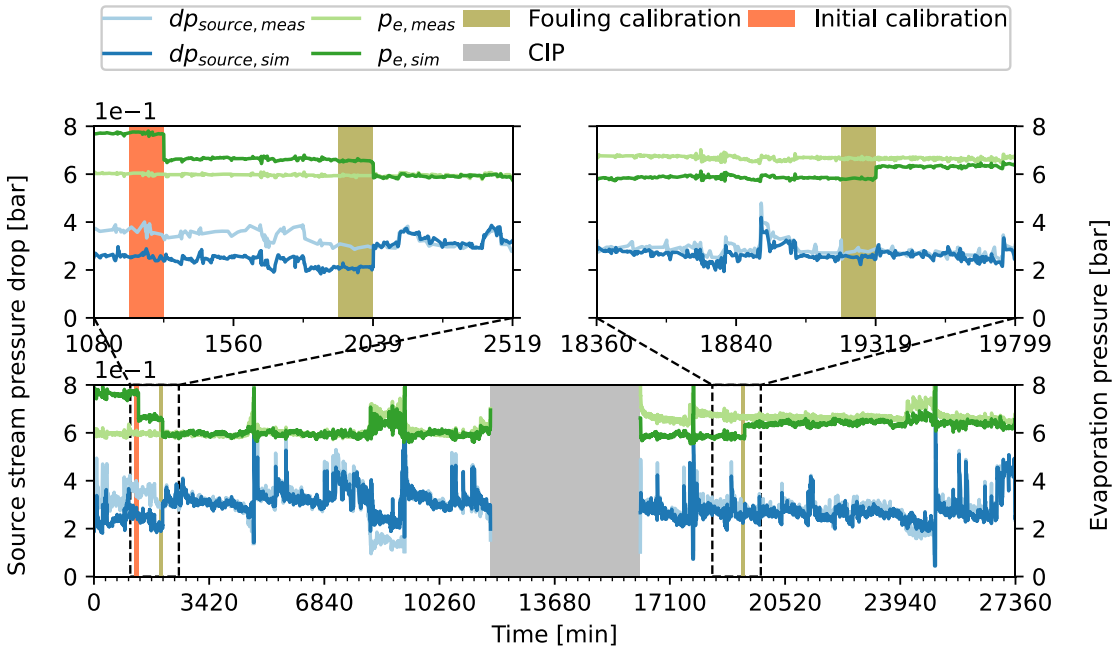

Figure 4: Time-series of the measured and simulated source stream pressure drop as well as evaporation pressure.

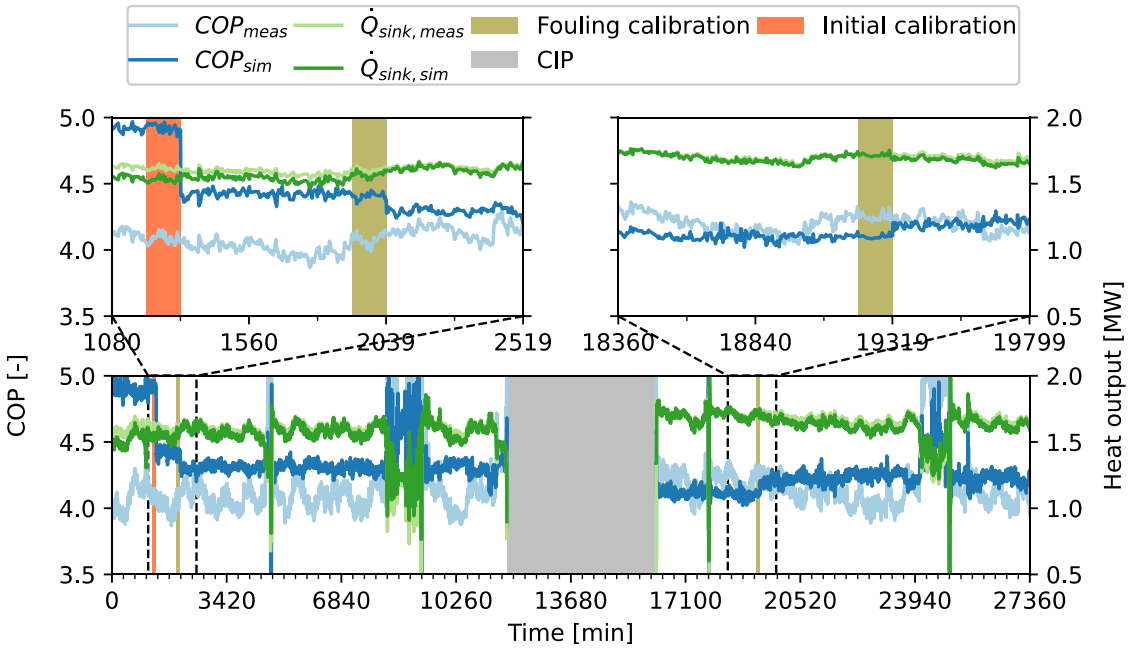

Figure 5: Time-series of the measured and simulated COP as well as heat output.

3.2. Residual analysis

The residuals shown in Figure 6 represent measured operational variables minus their respective simulated values. These residuals were not those presented in Section 2, as they were not normalized and were not used in the iteration processes for simulation (Figure 2) or calibration (Figure 3). The results from Figure 6 indicated that the fouling calibration implemented before the CIP period reduced the absolute value of the residuals related to dp_{eva}, p_e, $\dot{Q}_{sink}$ and $\dot{W}_{total}$. This was also valid for the fouling calibration applied after the CIP, except for dp_{eva}, which did not change significantly as a result of such a calibration. This was possibly an indication the CIP did not have a significant effect over the pressure drop caused by fouling. The initial calibration was observed to have a larger effect on the reduction of the discrepancies between measured and simulated values of COP and $\dot{W}_{total}$. This was expected given that the correction factors for the UA-values were calibrated in the initial calibration process. This led to an improved estimation of the pressure levels in the HP and thereby the total power intake from the compressors. The residuals shown in Figure 6 also showed that the dynamic behaviour of the case study HP was not completely represented by the simulation model. This was observed by the biased patterns in the residuals from the p_e, $\dot{Q}_{sink}$, COP and $\dot{W}_{total}$, which can be seen in Figure 6 at around 8000 min and 24000 min of operation.

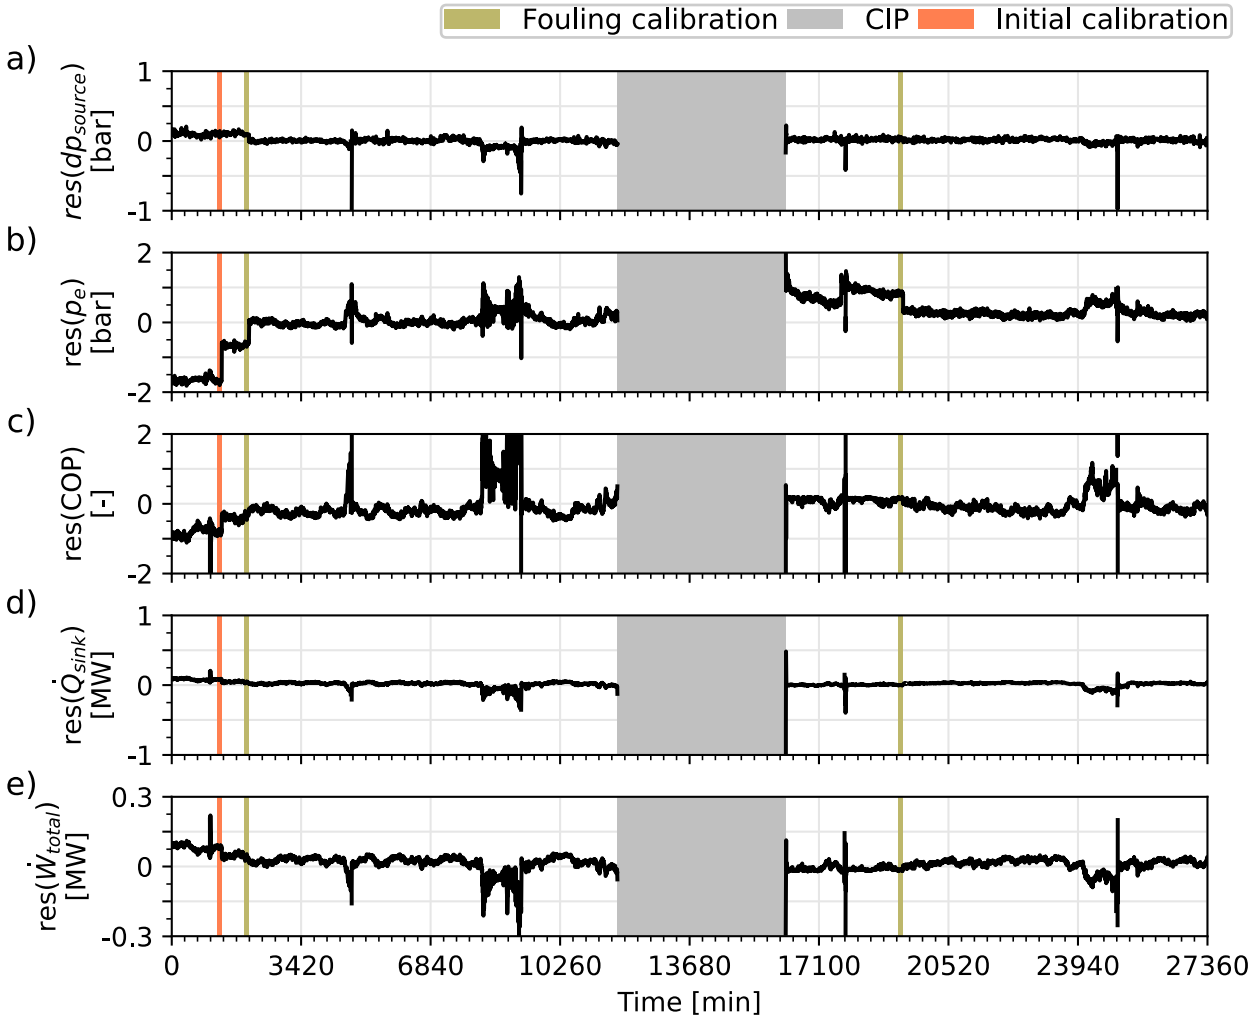

Figure 6: Residuals between simulated and measured operational variables of the HP.

3.3. Calibration results

Table 3 shows the parameters obtained from the calibration processes illustrated in Figures 4, 5 and 6. The calibration results of the correction factors showed that the U-values of the condenser, SC and evaporator presented in Table 1 were over-estimated, whereas they were underestimated for the DSH. This may also relate to a disagreement between the design and actual flow velocities as well as the temperature difference at the pinch point, which was assumed to be 5 K (see Table 1). The correction factors for the other heat exchangers were not significantly adjusted. The results showed that the $R_{th,f}$ and dp_f were reduced significantly as a result of the CIP (around 41 % and 100 %, respectively). However, the value of dp_f represented only around 15 % of the total source stream pressure drop shown in Figure 4. This was in agreement with the limited effect that the fouling calibration had on the calibration of the total source stream pressure drop, observed from the residual analysis shown in Figure 6.

Table 3: Parameters obtained from the calibration processes

Calibration process	Calibration parameter	Symbol	Result value	Unit
Initial	Correction factor for DSH U-value	CF_{DSH}	1.12	[-]
	Correction factor for condenser U-value	CF_{con}	0.96	[-]
	Correction factor for SC U-value	CF_{SC}	0.36	[-]
	Correction factor for evaporator U-value	CF_{eva}	0.47	[-]
Fouling (before CIP)	Fouling-related evaporator thermal resistance	$R_{th,f}$	$2.2 \cdot 10^{-3}$	[K/kW]
	Fouling-related evaporator pressure drop	dp_f	0.09	[bar]
Fouling (after CIP)	Fouling-related evaporator thermal resistance	$R_{th,f}$	0	[K/kW]
	Fouling-related evaporator pressure drop	dp_f	0	[bar]

4. Discussion

The automatic calibration method from the proposed framework reduced the discrepancy between the simulated and measured evaporation pressure, COP, heat output and source pressure drop (see Figures 4, 5 and 6). The results also indicated that the influence of fouling over the source stream pressure drop was significantly lower than the effect over the evaporator thermal resistance and that the CIP implementation led to a larger reduction of the latter than the former.

The relatively short simulation time used by the model applied in this study (around 10 seconds for the simulation of one hour) suggested its applicability for operation and fouling monitoring in a large-scale heat pump on a real-time basis. However, this would require the periodic verification of the validity of multiple factors that affect the simulation and calibration processes. These factors include the tolerances defined for the iteration residuals, the initial guess values and variation ranges for the calibration parameters, the optimization algorithm for NRMSE minimization, the selected calibration targets as well as the size and variability of the time-series data used for calibration. Those factors should be such that the best compromise is found between the required calculation time for calibration and the difference between simulation and measured data.

The results obtained from the proposed framework did not provide an estimation of the amount of deposited material on the heat transfer surface of the evaporator. This can be estimated with dedicated sensing devices for fouling examination such as ultrasonic probes [13] or infrared thermography equipment [14], which are unlikely to be available in large-scale HPs. In this context, the proposed model-based monitoring framework leverages existing sensing devices such as pressure and temperature sensors in the evaporator to estimate the effects of fouling. However, the results from the proposed monitoring framework were not contrasted with measurements from dedicated sensing devices for fouling characterization. This represents an opportunity for future studies.

The disagreements between the outputs of the model and the measured operational variables were probably lumped into the parameters adjusted in the calibration processes. For example, the difference between the heat transfer area of the heat exchangers in the model and in the case study HP was possibly included in the correction factors for the U-values in the model. Moreover, the assumption that those correction factors were calibrated based on an operational period when the evaporator was not affected by fouling due to the CIP usage, was not necessarily correct. Ideally, the initial calibration process should be based on an operational period right after fouling has been completely removed from the evaporator. In the present study, the correction factors obtained from the initial model calibration were also likely to include discrepancies between the model and the HP due to fouling. However, the evaporator of the case study HP could not be dismantled for cleaning, which prevented the complete removal of fouling.

The model used in this study led to a suboptimal representation of the dynamic off-design operation of the HP, which was indicated by the biased patterns observed in the simulation residuals (see Figure 6). It would require the use of a dynamic model to capture most of the dynamics present in a HP. The development of a dynamic simulation model may require information about the volumes and materials of the vessels, control-related parameters, refrigerant charge estimations as well as heat transfer and pressure drop correlations. The development of a quasi-steady-state model does not require such a comprehensive description about the design of a HP. Moreover, the present study focused on fouling monitoring, which often affects the operation of a HP at a slower rate than abrupt faults like the presence of condensed refrigerant in the suction line of a compressor.

The pumps in the secondary streams of the HP were not included in the simulation model. It is expected that the simulation residuals related to the estimation of power intake of such pumps will be reduced after the proposed fouling calibration framework is implemented. Modelling of the pumps could also indicate how the source side pressure drop affects the mass flow rate in the source stream. However, this adds complexity to the model, which may increase the time required for each simulation. Another limitation of the proposed framework was that it only enabled the analysis of historical data from the HP. The authors expect to complement the present version of the framework with forecasting methods that will enable the estimation of the future operation of a HP and the optimization of the time of CIP.

5. Conclusion

A quasi-steady-state simulation model of a heat pump used for district heating supply was calibrated based on operational data obtained from a cloud-based data management system. This framework enabled the estimation of the performance and the effects of fouling on the heat pump, even when the model did not represent accurately the dynamics of such a system. Particularly, the re-calibration of the model based on time-dependant parameters related to fouling allowed to obtain simulation results that were in agreement with measurements over a period of nearly three weeks. This allowed to assess the degree to which a CIP implementation reduced the evaporator thermal resistance and source stream pressure drop caused by fouling. The proposed framework could be used for real-time monitoring of large-scale heat pumps, where the relatively short simulation time achieved, automatic model calibration and leverage of existing sensing devices could be beneficial.

Abstract:

Large thermal electric generation systems based on the Rankine cycle require monitoring the reduction of pipe wall thickness caused by vapor flow due to aging processes such as erosion and accelerated corrosion processes. The inspection difficulties are related to hostile environment (50 ºC and 100 % relative humidity), and spaces with complicated geometry such as pipeline curves and their support structures. This work presents a monitoring program which integrates wall thickness inspections carried out with a robotic system and Industry 4.0 technology to handle collected data and to disseminate information throughout the organization. The robotic system is developed utilizing the digital twin technology, a very realistic virtual modeling scheme which allows interaction with the real-world environment. They include equipment and all the steps to carry out the inspection process. The pipe wall thickness monitoring system is to be utilized in Angra 1 (Brazil) nuclear power plant.

Keywords:

robotics; pipe wall thickness; nuclear power; Digital Twin; Industry 4.0

1. Introduction

In 2025, the Angra 1 nuclear power plant, located in Rio Janeiro state in Brazil, completes 40 years of operation and the owner Eletronuclear requested the Brazilian nuclear regulatory body to extend its operational life and renew the operating license for another 20 years. For life extension, it is necessary to carry out a wide range of plant aging management activities which may end up requiring to replace vessels and pipes which operate under high pressure and do not meet the regulatory agency's criteria to remain in service [1-3]. Large nuclear power plants have hundreds of meters of pipes under this situation and their wall inspection is among the ones more time-consuming procedures, around 300 hours. Erosion and flow accelerated corrosion processes induced by fluid flow are monitored through ultrasound inspections that seek to determine the reduction in pipe wall thickness [4-6].

This work presents the project of pipe inspection automation using a robot integrated with the Industry 4.0 technology through wall thickness measurements using the ultrasound technique. The pipes belong to the secondary system from Angra 1 nuclear power plant, which include those under high pressure connecting the steam generators, turbines, condensers and all associated instrumentation and ancillary systems. The inspection environment is hot and humid (50 degrees Celsius and 100% relative humidity). The field space has complicated geometry and access to inspection locations due to support structures. The pipes have different diameters varying from 50 cm to 65 cm some are straight, and others curved and positioned in horizontal, vertical, or inclined directions. During a shutdown, more than 50,000 measurement points are performed [7,8]

Robotic systems are used in different field applications and environments such as manufacturing activities but also in aerial inspection of structures [9], submarine inspections of structures [10,11] and even rubber tapping in plantations [7]. What they all have in common is that they feature a vehicle-handler system for inspection or other necessary on-site activity. The remotely operated vehicle contains a manipulator support platform, a robotic arm containing in its end effector with specific characteristics to carry out the activity, i.e. sensors to

carry out the measure of interest [12] or the production activity as rubber tapping [13]. To enable the inspection, the vehicle is moved to the designated locations for carrying out the activity. To control the trajectory of the robotic arm, the end-effector normally has sensors for vision and contact with surfaces [14-16].

The digital twin [6] is a project realization concept in which the environment, process or a single physical object is reproduced first in the virtual world and then in the real world. In the case of robotics, its function is to map the main characteristics of the object or physical process previously via virtual simulation and subsequent real implementation whether they are system maintenance [17,18], design and manufacture of products [19–21] or processes [22].

2. Robotic system requirements

It is desirable that the system has a communication interface with intelligence to process the data in the manner established by Eletronuclear and that allows identifying possible locations with thicknesses closer to acceptable limits or simply failures in the process of measuring the thickness of the pipe. In these cases, the robotic system can perform a sweep with more qualified inspection or repeat measurements.

Figure 1 shows the inspection environment in the turbine building of the nuclear power plant Angra 1. Figure 1a shows the current situation of manual thickness measurement. It is necessary to place scaffolding at the various measurement locations so that the technician has access to the measurement locations. It is seen that the environment has a flat floor that allows the movement of a vehicle. Figures 1b and 1c show pipe segments with indications of the places where thickness measurements will be taken and also the difficulty of access due to interference from other equipment and pipes in the vicinity.

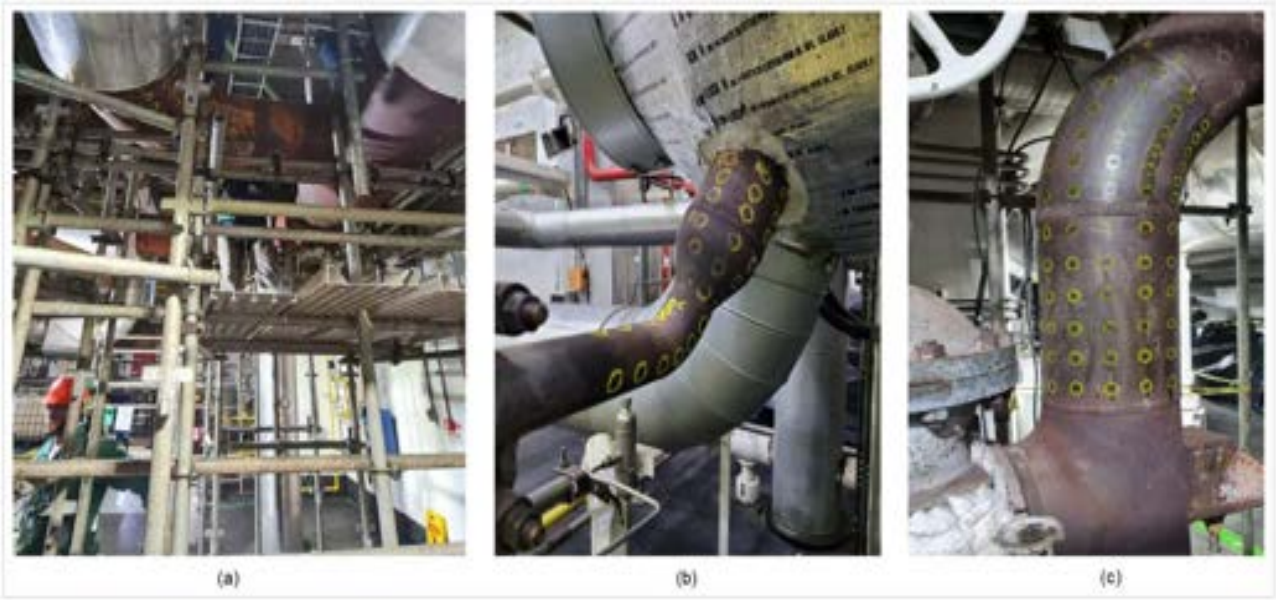

Figure 1. Environment in which measurements of the wall thickness of the pipes in the turbine building are carried out. (a) Flat floor site with scaffolding to allow access to pipes for manual measurements. (b) Pipe segment of different diameters inclined and difficult to access. (c) Piping in vertical position. The yellow circles indicate the locations where thickness measurements are performed using ultrasound.

The industrial manipulator (robotic arm) must be able to access the external wall of the pipe and position the sensor installed in the end-effector in an appropriate way to carry out the measurements. Other sensors present in the end-effector are the contact and distance sensors between the surface that act as the “vision” to avoid collisions with the pipe and the correct positioning of the ultrasound sensor for measurements. A human operator is also foreseen to provide cognitive assistance for vehicle movement and inspection actions. The thickness measurement procedure is as follows: the UROV is moved and parked at certain locations. In

these places, the robotic arm moves and performs inspection on the surface and all thickness measurement procedures.

The vehicle requirements are reduced size to allow access to the different measurement locations and have mechanical strength and space to accommodate the systems of the other two units. Piping access is a great challenge because there are positions where some “elbows” are close to walls and hostile places, making it difficult to position the robotic equipment for measurements in curved surfaces.

3. Robotic system for measuring pipe wall thickness

The Robotic System for Measuring the Wall Thickness of the Secondary Piping of the Angra 1 Nuclear Power Plant (SRME) is composed of 3 units. The first unit, called the Remotely Operated Vehicle Unit (UROV), is a vehicle that can be operated remotely to allow displacement of the SRME to tubes of different diameters and allow thickness measurements. The second unit, called Thickness Measurement Robotic Cell Unit (UMRC), is a robotic work cell indexed in the UROV, equipped with a robotic arm that performs the movements and inspection actions and that has sensors installed that allow the movement of the measurement points and the external measurement of the pipe wall thickness. The third unit, called the Communication, Power Supply and Ancillary Services Unit (UCPA), contains all other SRME systems such as power supply cables, data transmission cables, real-time information, computers and ancillary equipment. The study on automatic thickness measurement uses the GP-7 robot from the manufacturer Yaskawa-Motoman [23]. This robot weighs 34 kg, has a reach of 927 mm horizontally and 1693 mm vertically and has a payload capacity of up to 7 kg. With these attributes, this robot can be used in the field. The robot programming is done using the digital twin technique using the Process Simulate software version 15.1.2.

The Remotely Operated Vehicle Unit (UROV), shown in Figure 2, is designed to access as many pipe runs as possible. The UROV is moved by the human operator to the closest possible location to the measurement point and makes it possible to move the end-effector via remote actuation for displacements in the x-y-z axes for the best positioning of it for carrying out thickness measurements.

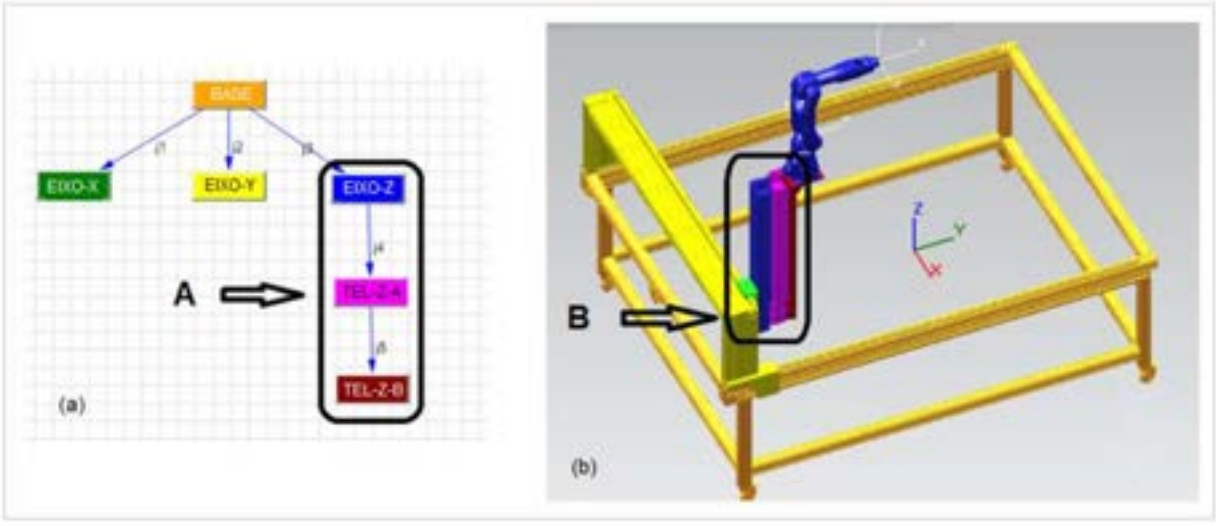

Figure 2. Unit Remotely Operated Vehicle (UROV) with caster system: (a) The X-AXIS describes the horizontal translation movement of the mechanism in the X direction, the Y-AXIS in the Y direction and the Z-AXIS describes the vertical translation movement of the mechanism in the Z direction. The TEL-Z-A-AXIS describes the vertical translation movement of the mechanism in the Z direction with retractable or telescopic articulation and the TEL-Z-B AXIS describes the vertical translation movement of the mechanism in the Z direction with retractable or telescopic articulation telescopic after displacement of the AXIS-TEL-Z-A. (b) In this figure, the yellow color describes the horizontal translation movement of the mechanism in the Y direction, the green color describes the horizontal translation movement of the mechanism in the X direction, and the blue color describes the horizontal translation movement of the mechanism in the X direction. Y direction. In

figures “A” Mathematical modeling in x-y-z by means of horizontal movements, x and y, and telescopic elevation in z with two additional prismatic movements and “B” the corresponding movement of the end-effector on the robotic arm with five degrees of freedom of the measuring robotic cell with teleoperation system.

Figure 3 shows the URMC Robotic Thickness Measuring Cell Unit with a robotic arm having six degrees of freedom to reach a 65 cm diameter pipe and the end-effector. After marking with points offset by 30 degrees, thickness is measured on a 144-point grid. A reservoir installed at the base of the robotic arm with coupling liquid that varies according to the type of material, but is essential to perform the thickness measurement.

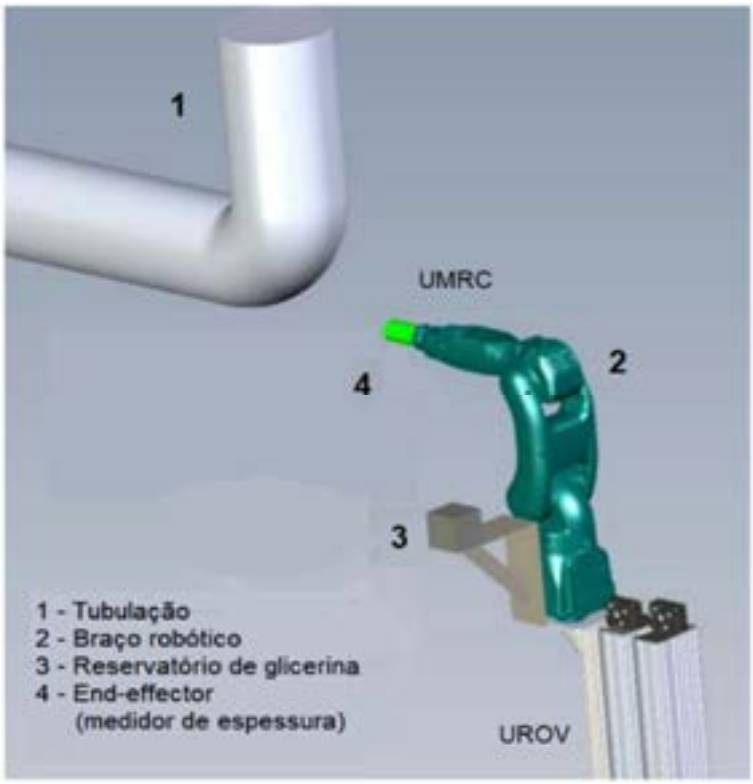

Figure 3. Thickness Measurement Unit (URMC): 1) Piping is where the process of measuring thickness using the ultrasound technique is concentrated and requires the preparation of the surface of the external piping to carry out the measurement, instrumentation, specification and calibration of the ultrasound measurement system point transducer type and surface scanning type ultrasound. 2) Robotic arm and end-effector. 3) Reservoir with coupling liquid. 4) End-effector (thickness gauge) can accurately and quickly measure the thickness of the walls of the pipes at the determined points.

The design challenge consists of integrating thickness measurement, analysis, treatment and storage of information in a safe and reliable way. The industrial robot needs to receive measurements from the electronic transducers of the system that performs the measurement and store them in variables. These variables need to be defined and the technologies that enable Industry 4.0 follow data security protocols and interface communication that can be customized according to the needs of the company, in this case, Eletronuclear.

Robotic manipulators have positioning problems, speeds and forces applied in any type of movement. The definition of the trajectory of the GP-07 robot in three-dimensional space, called direct kinematics, is done with the SIMULATE software. Figure 4 shows the relationship of programming via Digital Twin with the SIMULATE software and the movement of the robotic arm that determines the location of the end-effector. This software uses the Denavit-Hartenberg notation to assign to the robotic system an orthonormal coordinate system for each link of the kinematic chain [4,5,24].

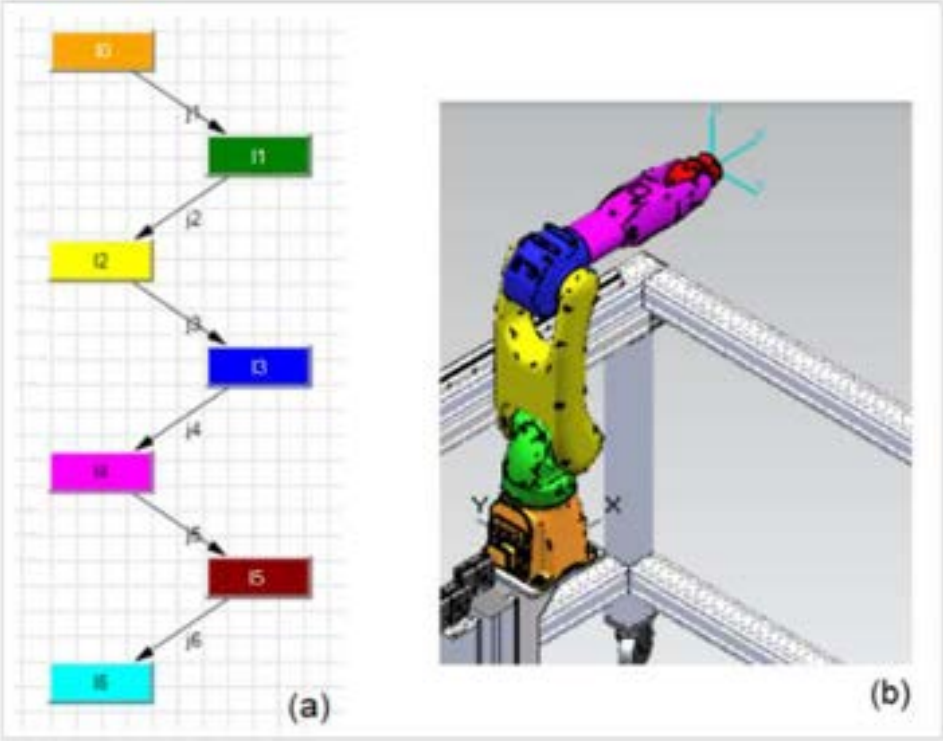

Figure 4. (a), Symbols I0, I1, I2, I3, I4, I5 and I6 in a chain representing the homogeneous transformation matrices according to the Denavit-Hartenberg notation from the base of the robot to axis six, respectively. The symbols J1, J2, J3, J4, J5 and J5 represent the links between the rotation joints of the six degrees of freedom of the robot, respectively. (b) In this figure, the colors of each physical joint of the robot correspond to the same colors as the matrices in figure (a).

The development of the kinematics is done after obtaining the Denavit-Hartenberg parameters of the GP-07 robot [5]. This robot has a reach of 927 mm horizontally and 1693 mm vertically with a payload capacity of up to 7 kg. Once this coordinate system for adjacent links is established, it can be represented by a homogeneous coordinate transformation matrix. With this information, the kinematics of the robotic movement is built, precisely defining the position and orientation of the end-effector next to the surface for carrying out the measurement.

The method used to obtain the results of direct kinematics in virtual space (Digital Twin) showed good precision performing joint, linear, circular and spline interpolated trajectories.

4. Conclusions

To ensure that the prototype results are suitable for the effective use of SRME in Angra 1, all prototype design requirements must take into account the environment where thickness measurements take place in the Turbine Building. This article presents a work stage that considered important aspects of the Angra 1 power plant project. It was possible to model the virtual commissioning activities, transfer all information and project data automatically to the physical project of the SRME. Access to the measurement sites occurs through two movements: the UROV and the UMRC. The UROV is moved by the robotist to the closest possible location to the point of movement. From this point, via remote actuation, the robotist can move the support base of the robotic arm in x-y-z by means of horizontal movements, x and y, and elevation, z.

The second movement is provided by the UMRC robotic arm. This allows greater access to the pipes. The movement of the support base of the robotic arm has a mathematical model with a telescopic concept of the z axis. It is expected a significant productivity gain in this process, as the entire programming of the physical

robot, an important part of the project to carry out the process of measuring the thickness of the pipes, is transferred directly from the virtual project (digital twin) to the real robot.

Abstract:

This paper presents an optimal management strategy, called *Building Optimizer*, based on a Model Predictive Control (MPC) approach with self-learning capabilities for buildings. This research is framed in the development of an agent-based architecture to provide demand response services in an Energy Community to optimise the management of renewable energy sources and provide grid stability. The proposed MPC is a key enabler of cooperative demand response strategies at community level, ensuring the allocation of an optimal demand profile at each participating member of the community according to an optimal consumption reference defined by a complementary agent at community level. The MPC calculates the optimal setpoints of the HVAC system's terminal units, considering the expected usage of the buildings and the outdoor conditions, and exploiting the building's thermal inertia. The models embedded in the MPC are grey-box models representing a thermal zone of the building. To reduce measurement and model uncertainties, these models incorporate self-learning capabilities implemented as Moving Horizon Estimators that perform a continuous calibration based on real-time operational measurements. This solution allows full automation for model calibration and management of the terminal units. This paper presents a case study in which a baseline MPC with fixed model parameters obtained by an offline calibration is compared to the *Building Optimizer* with self-learning capabilities. The *Building Optimizer* is able to track a requested power consumption providing up to 20% of flexibility compared to the reference consumption without demand management and guaranteeing thermal comfort, at least 98% of the time. For this scenario, the *Building Optimizer* proves more reliable in guaranteeing the thermal comfort and a better match to the requested consumption compared to the baseline MPC. Demand-side management by the MPC can be translated into up to 15% energy shift from peak hours to valley hours.

Optimization; MPC; Building; Energy Community; Demand Response; Self-learning; Renewable Energy

1. Introduction

Building sector represents 40% of European energy consumption, of which 80% is covered by fossil fuels [1]. This sector also accounts for 35% of EU greenhouse gas (GHG) emissions [2]. In consequence, European decarbonization policies and strategies have this sector as one of the most relevant ones [3]. The renewable energy sources (RES) play a fundamental role in this decarbonisation path for switching to greener energy sources and lowering CO2 emissions. However, the increase in the renewable energy share in the energy generation entails some challenges due to the inherent unpredictability and intermittency of RES and the mismatch between the peak production periods and the peak demand periods, which can even lead to grid stability problems [4]. Demand Response (DR), which aims at modifying the consumption load curve, is a crucial tool for RES penetration in the electric system [5]. The residential sector has a great potential for DR that is still unlocked [6]. The residential sector's main end-use, accounting for between 60 and 80% of total energy consumption, is space heating [2]. Thus, there is a huge potential for the application of DR for heating

[7], by exploiting buildings' thermal inertia. Moreover, considering the flexibility of a cluster of buildings, such as a Citizen Energy Community [8] or Renewable Energy Community [9], potentially increases the capacity to exploit flexibility [10]. Several studies focus on Demand response applied at building level. Most of these studies consider electric tariff prices to perform peak shaving actions. They often use *Model Predictive Control* (MPC) technique for the optimal management of the building, a widely used predictive technique for buildings [11]. The MPC uses a predictive model of the building that allows it to anticipate peak demand and take advantage of the building's inertia, thus improving thermal comfort compared to simpler controllers based on PIDs or on/off controllers. It also allows the inclusion of additional targets to be optimized, which opens a wide range of possibilities. The most widely used approach among MPC types is the so-called economic MPC that minimises the power consumption or energy cost consumption [12,13]. Some examples are [14] that manages the cooling demand of a house to reduce the peak periods, and [15] which proposes an economic MPC based on electricity variable prices. Some studies focus on demand response actions instead of a direct reduction on the power, such as [16] in which a hierarchical MPC is used for load shifting in a building, and [17] to perform DR actions at a building taking advantage of installed PV. However, less attention has been paid to DR oriented to a cluster of buildings, such as Energy Communities (EC), as [18] states. A few studies focusing on applying DR actions in an aggregated way can be found, such as [19] and [20]. The challenge for this approach is the scalability of the problem when the number of buildings increases. This paper proposes a solution for an MPC at building level, but which considers objectives at community level by allocating the requested power consumption at household level while guaranteeing the thermal comfort. This enables disaggregating the problem into the optimization of the Community and the building management, alleviating the scalability problem and facilitating the achievement of the community's energy-related objectives.

Another important aspect tackled by this work is the handling of the uncertainties inherent to building modelling. The MPC performance is dependent on the reliability of the embedded model. In the case of the building modelling, this aspect is crucial as many uncertainties are present, especially those derived from the time-variant parameters, occupant behaviour characterisation and measurements [21]. A detailed physical modelling approach that captures all the parameter variations with time is not feasible as this would result in a computationally too expensive model that would not be suitable for optimization purposes. Thus, this paper proposes an approach based on integrating self-learning capabilities to the *Building Optimizer* to cope with these uncertainties in a computationally cheaper way. These capabilities consist of re-calibrating the model parameters during the operation with the latest measured data. This functionality is integrated through the Moving Horizon Estimation (MHE) technique [22], which has proven to give good results in studies such as [23–25].

The novel contributions of this paper include the following:

- An MPC-based solution that goes beyond the typical economic MPC for cost or energy savings. It acts as a key enabler of a cooperative DR solution at community level by managing the demand side and allocating the optimal power consumption at household level that contribute to achieving goals at community level.
- The proposed solution includes self-learning capabilities to reduce the uncertainties of the problem, such as those sources of uncertainty due to the time-variant and uncertain physical characteristics and occupant characteristics.

Finally, the paper is organised as follows: section 2 describes the methodology followed to define the *Building Optimizer*, section 3 describes a case study with the aim of illustrating the contributions of the *Building Optimizer* and section 4 gathers the main conclusions and future work.

2. Methodology

2.1. Agent-based architecture for residential demand response

The proposed MPC with self-learning capabilities for buildings, which is called *Building Optimizer* from this point onwards, is part of an agent-based architecture to provide DR services in an EC to effectively maximise the exploitation of RES and demand-side flexibility and provide grid stability. This multi agent-based architecture includes a Demand Response Optimizer (*DR optimizer*) which deals with both energy supply and demand side in a holistic manner and decides the optimal energy use profile of each household considering EC objectives. This agent-based architecture is proposed in EU HESTIA project, which develops holistic demand response services in European residential communities. The *Building Optimizer* acts as a key enabler, assuring that the optimal energy use calculated by the *DR Optimize*r is allocated at household level while respecting thermal comfort. Thus, the *Building Optimizer* manages the thermal demand in each household to assure they contribute to the EC goals.

To manage the building's thermal demand and assure the optimal consumption allocation, the *Building Optimizer* considers predictions on the weather conditions and estimates the internal heat gains, as both will influence the building's indoor conditions evolution. The *DR Optimizer* provides a day-ahead reference optimal power consumption that the *Building Optimizer* will have to allocate. The *Building Optimizer* solution must also be able to comply with the constraints defined by either the building operator or the users. To complete the

inputs to the *Building Optimizer*, it will also receive real measurements from the system. The general scheme of the solution is presented in Figure 1.

Figure. 1. Building Optimizer's input and output signals.

The *Building Optimizer* is prepared to work in two modes: (1) *explicit mode* with an automated DR actuation, and (2) *implicit mode* through manual DR actions suggested to the users. For the *explicit mode*, the automatic control signal is obtained (scalar value for on/off or modulated signal, depending on the HVAC actuation equipment capabilities). This actuation will cause the room temperature to be adjusted in a way that meets comfort but allows the demand to be reallocated in the requested way. For the *implicit mode*, the optimal temperature profile is translated into DR suggestions to the users. These suggestions would consist of requests to adjust their indoor temperature setpoint, and the users would oversee introducing this new setpoint manually. In this case, the HVAC is not commanded; the low-level controller of the thermostat would be working to operate the HVAC. This paper focuses on the first approach based on the automatic actuation.

An important point to highlight is that the *Building Optimizer* can work as a part of the agent-based optimization architecture with the aim of achieving goals at community level, but it could also be used as a stand-alone solution for building operation. This paper will propose a procedure to generate a reference curve that aims for economic targets at building level.

2.2. Building Optimizer: technical solution definition

The *Building Optimizer* solution must comply with challenging technical requirements as the controlled system is a building, a highly nonlinear system with great inertia and with many uncertainty sources such as internal heat gains.

In this regard, the MPC is a type of controller adequate for this type of application. The MPC is an optimal control strategy that works with a prediction model of the system to be controlled and calculates the optimal setpoints of the controllable units in order to minimise an objective function [26]. In this case, it has a building model embedded and calculates either the optimal indoor temperature setpoint or the HVAC actuator setpoint, depending on the actuation mode. The MPC works with the expected usage and occupancy of the building, forecast and current measurements of the outdoor and indoor conditions and includes user- and system-defined constraints. Even if the MPC optimises the operation in the entire prediction horizon, just the setpoints of the first point are commanded. It works in a closed loop by receiving the real values of the controlled variables and applies the receding horizon control principle.

The MHE is an optimization-based state-estimation technique where the current states and the parameters of the system, henceforth referred to as variables of interest, are inferred based on a finite sequence of past measurements. It uses dynamic optimization and a backward time horizon of measurements to optimally adjust the variables of interest of the problem [27]. The MHE is integrated to work in coordination with the MPC: the MHE is used prior to the execution of the MPC to calibrate the parameters of the model embedded in the MPC. Moreover, in addition to the model parameter estimation, the MHE can also estimate other model variables that are difficult to initialise beforehand or are unmeasurable, which presents a great advantage for building applications.

The following subsection will describe more in detail the main technical parts of the solution: the reduced order models for optimization, the MPC for optimal control, the MHE for self-learning capabilities and the software used for the problem implementation.

2.2.1. Reduced order models for the building and the HVAC

One of the key points in the development of an MPC is the system model that is embedded, as the reliability of the system predictions and the achievement of the control and optimization objectives will directly be impacted by the model accuracy. One of the main challenges is reaching a trade-off between the accuracy of the model (that represents in a detailed and accurate way the dynamics and other complexities of the model) and the computational burden as the optimization problem should be solved in a time that allows real-time application (typically every 15 minutes for this paper's application).

The proposed model considers thermal building envelope, internal heat gains, and heat losses, caused by heat conduction, convection, and ventilation. Modelling is underpinned by calibrated reduced-order data-driven grey box models. The grey-box model used is based on an Resistance-Capacitance (RC) network for a thermal zone defined by [28], which considers both the physical parameters and disturbances that characterise unmeasured inputs, but that can be calibrated with other measured variables. The performance of this model has been demonstrated experimentally in [29].

Figure 2 illustrates the embedded RC network model structure for a single thermal zone. The thermal zone is defined as the area controlled by a thermostat and served by the HVAC, i.e., it can represent several rooms that are controlled by a unique thermostat. T_z is the indoor zone air temperature and T_w is a wall temperature representing averaged behaviours of the enclosures (walls, roof, and floor). T_o is the outdoor air temperature. C_z and C_w represent the respective thermal capacitances of the zone and wall, and R_{zw} and R_{zo} are thermal resistances between the zone air and wall, and between the zone air and outdoor air, respectively. Q_g represents unmeasured internal heat gains. u is the modulation signal for the HVAC system, and Q_{av} the available heat, so the resulting input heat from the HVAC system is Q_u.

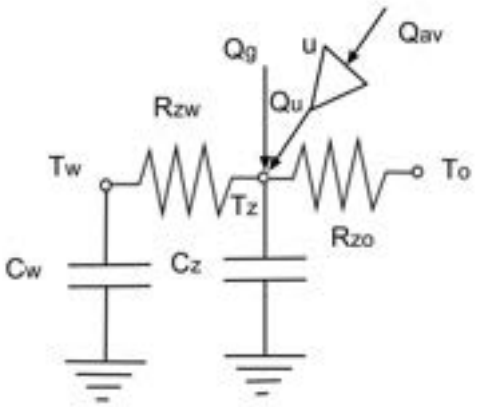

Figure. 2. Reduced order RC model for the building.

Equations (1) and (2) are the corresponding differential equations representing the thermal balance in the zone.

$$C_z \cdot \frac{dT_z}{dt} = \frac{T_w - T_z}{R_{zw}} + \frac{T_o - T_z}{R_{zo}} + Q_g + u \cdot Q_{av}, \quad (1)$$

$$C_w \cdot \frac{dT_w}{dt} = \frac{T_z - T_w}{R_{zw}}, \quad (2)$$

A simplified model for the HVAC is used, consisting of an equation to model the HVAC control, Eq. (3), and the power consumption of the HVAC, Eq. (4). This model will need to be further developed in future work to have a more accurate model of the air conditioning, but the present work focuses on the building part.

$$Q_u = u \cdot Q_{av}, \quad (3)$$

$$P_{HVAC} = \eta \cdot Q_u, \quad (4)$$

where P_{HVAC} is the power consumption of the HVAC and η its efficiency.

2.2.2. Model predictive control for building consumption and indoor conditions management

The dynamic optimization problem defined in the MPC can be formulated as follows:

$$w_{hi}^T e_{hi} + w_{lo}^T e_{lo} \quad (5)$$

subject to:

$$0 = f(\frac{dx}{dt}, x, y, u), \tag{6}$$

$$0 \leq g(\frac{dx}{dt}, x, y, u), \tag{7}$$

Equation (5) is the objective function of the MPC problem and represents the sum of the terms to be minimised through the prediction horizon, in this case, the higher e_{hi} and lower e_{lo}errors of the controlled variables, that is, the indoor temperature in the room and the HVAC power consumption. It is defined based on the l_1-norm so that the absolute difference between the current measured value and the desired target value is computed. This operator does not have a continuous first and second derivative at x=0, but the software used, that is GEKKO, poses the problem in a way that this discontinuity is avoided, as explained in [30]. The lower error is computed as the difference between the variable and the lower bound, and the higher error is defined analogously. When the variable is between the defined limits, there is no penalty.

Equation (6) represents the equality constraints of the problem, derived from the model presented in section 2.2.1, and Eq. (7) the inequality constraints at which the problem is subjected, which consists of physical limits for the variables.

In the problem definition, x represents the state variables, that is, the indoor zone temperature and the wall temperatures: $x^T = [T_z, T_w]^T$. The output is the HVAC power consumption $y = P_{HVAC}$. The manipulated variable is the modulation signal of the HVAC represented by u.

In the problem definition, an important tuning aspect is the weighting factors assignment in the objective function, represented in Eq. (5) by w_{hi} and w_{lo} for each of the variables. These weighting factors enable prioritising either the thermal comfort or the power consumption, and between the lower and higher errors.

The other important tuning factor is the prediction horizon, that is, the length of the forward time window for which the MPC computes the solution.

2.2.3. Moving horizon estimator for incorporating self-learning capabilities

The basic idea of MHE is to minimise the discrepancy between the measured outputs of the system and the outputs predicted (target measurements) by a model of the system, subject to a set of constraints on the states of the system. This is formulated through a dynamic optimization problem, defined as follows:

$$w_{hi}^T e_{hi} + w_{lo}^T e_{lo}, \tag{8}$$

subject to:

$$0 = f(\frac{dx}{dt}, x, y, u), \tag{9}$$

$$0 \leq g(\frac{dx}{dt}, x, y, u), \tag{10}$$

Equation (8) is the objective function of the MHE problem and represents the sum of the terms to be minimised through the backward window of past measurements: the absolute difference between the real measurements of the controlled variables (indoor temperature and HVAC power consumption) and the predicted value with the calibrated model. Both the higher and lower errors are considered, and a dead-band or region around the measurement in which the error is not penalised is included in the problem formulation. This reduces the impact of the noise from the measurements in the model calibration. In this case, the objective function is also defined through the l_1-norm.

Equation (9) represents the equality constraints of the problem, derived from the model presented in section 2.2.1, and Eq. (10) the inequality constraints at which the problem is subjected, which are used to limit and penalise the rate of change of the variables that are adjusted by the MHE and to set absolute bounds.

The most relevant tuning consideration are the weighting of the terms in the objective function (w_{hi}^T and w_{lo}^T) and the length of the time window of past measurements. Including more points in the time window allows the MHE to reconcile the model to more data but also increases computational time.

The outputs of the MHE are the model parameters, R_{zo}, R_{zw}, C_z, C_w, that are *fixed variables*, the available heat for the HVAC system and the estimated internal heat gains. These are the estimated values through the prediction horizon.

2.2.4. Software for problem implementation

Python 3.11 is used to address this development. The algorithms for MHE and MPC have been implemented using the GEKKO library [31] for Python. This library is based on APMonitor [32]. IPOPT is the solver used in the *Building Optimizer*.

3. Results and discussion

This section presents the simulation results of the *Building Optimizer* for a case study.

3.1. Case study description

The presented case study has the following aims:

- Demonstrate that the *Building Optimizer* can guarantee thermal comfort.
- Evaluate to what extent the *Building Optimizer* can adjust to a requested power consumption.
- Evaluate if the *Building Optimizer* incorporating self-learning capabilities outperforms an MPC with fixed model parameters.

In order to assess these points, the case study will consider as a baseline an MPC with fixed parameters, and its performance will be compared to the *Building Optimizer* with self-learning capabilities.

The following subsections present the building that is considered for the case study, the boundary conditions, the uncertainty modelling to generate virtual forecast and the modelling of the flexibility request signal.

3.1.1. Study building description

In order to consider an actual building and to work with realistic values, the values of the case study presented in [28] and [33] are used, consisting of a single-story wood-built house having a floor area of 60m^2 with crawl and roof space. The main thermal characteristics of the building are: $C_z = 1.18\ \left(\frac{kWh}{℃}\right)$, $C_w = 3.99\ (kWh/℃)$, $R_{zo} = 0.48\ (℃/kW)$, $R_{zw} = 7.35\ (℃/kW)$. These values are considered as the real values of the building. The space is considered as a single thermal zone with one thermostat to monitor the indoor temperature and a controllable HVAC that can be modulated through a u signal between 0-100%.

3.1.2. Boundary conditions description

For the weather conditions, the building is considered as located in Bilbao (Spain). The data of the outdoor temperature for February from the Typical Meteorological Year (TMY) of Bilbao (Spain) [34] is used for the simulations, which represents a typical winter heating demand situation.

The internal heat gains of the building are calculated using the ASHRAE standards [35] considering the profile for internal heat gains from people with a Hotel pattern (equivalent to a residential building), assuming the following values: *23.226 m^2/person*, and *73.268 W/person*. The profiles differentiate between weekdays, Saturdays, and Sundays. These profiles are represented in Figure 3.

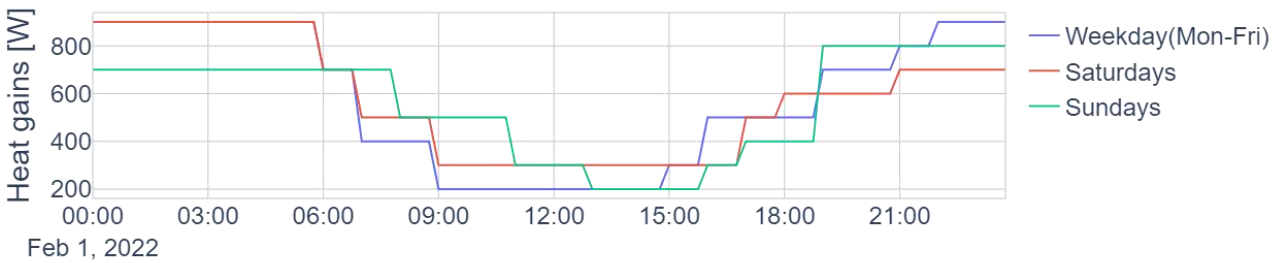

Figure. 3. Internal heat gains hourly profile for weekdays, Saturdays, and Sundays for a residential house.

3.3.3. Forecast uncertainty modelling

Modelling the errors in the weather and internal heat gain predictions is crucial, as they are a great source of uncertainty in the problem and its impact in the solution needs to be assessed.

The uncertainty in the indoor temperature is modelled through an autoregressive model shown in [36]. This generates a realistic error in the outdoor temperature prediction, trying to replicate a low-medium uncertainty scenario. For the error modelling, it is assumed that the outdoor temperature forecast is updated every 24h. Figure 4 shows the real outdoor temperature and the synthetic forecasts for the first week of February.

Figure. 4. Real outdoor temperature for Bilbao for 1-7 February and simulated forecasts.

The internal heat gains profiles for the building are defined based on the ASHRAE profiles shown in section 3.1.2. The difference that can be found between the real occupancy patterns and the ones proposed by ASHRAE are modelled by modifying the ASHRAE curve. White noise is added to the internal heat gains through a gaussian distribution, and it is smoothened so that it resembles a real pattern. The synthetically generated data for the internal heat gains is used as the real profile of the internal heat gains and the ASHRAE profiles are considered as the forecasts for a whole week. Both profiles are illustrated in Figure 5.

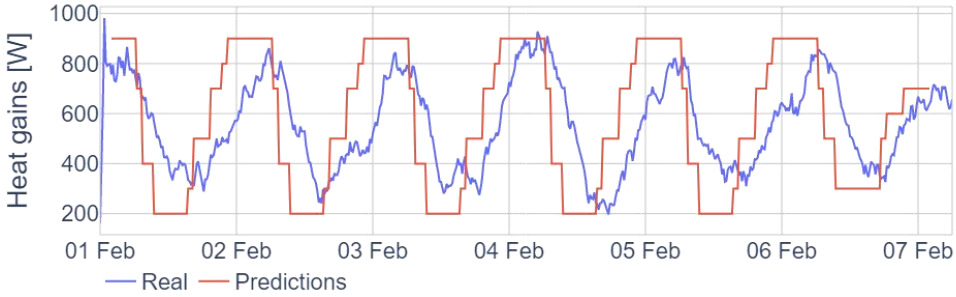

Figure. 5. Simulated internal heat gains for the building and the forecasts.

3.2. Building Optimizer with fixed parameter: model calibration

The Building Optimizer version that integrates an MPC with fixed parameter requires the values of the RC parameters (R_{zo}, R_{zw}, C_z, C_w). An offline calibration is performed to calibrate these parameters based on simulation data of the study building, which is used as if it was operation data. The steps followed for the calibration are:

1. The plant model (building space with the HVAC) is simulated for a whole month with the real parameters from section 3.1.1 and the boundary conditions (weather, internal heat gains) presented in section 3.1.2. The model includes an on/off hysteresis controller, with a constant setpoint of 21.5 ºC, and a dead band of 0.5 ºC for the hysteresis that is used to control the indoor room temperature by calculating the HVAC operation.
2. An offline calibration is performed using the data of a whole week as reference. The fixed values of the model parameters (R_{zo}, R_{zw}, C_z, C_w) are calculated minimising the deviation between the reference values from in Step 1 and the predicted values with the model for the whole week. The problem defined for the MHE is adapted so that it can be used for this calibration. The internal heat gains are set to a fixed value for the whole week. The results are verified by calculating metrics for the errors in the indoor temperature and the HVAC power consumption compared to the reference values.

Different reference errors are calculated for the indoor temperature deviation and the power consumption deviation, as the nature of these variables is different. The temperature is a potential variable, so the most suitable error to be applied to this variable is the *Normalised root-mean-square deviation* (NRMSD), which is defined in Eq. (11).

$$NRMSD(T_z) = \frac{RMSD(T_z)}{T_z^{max} - T_z^{min}} = \frac{\sqrt{\frac{\sum_{t=1}^{T}(\hat{T}_z(t) - T_z(t))^2}{T}}}{T_z^{max} - T_z^{min}}, \quad (11)$$

where $RMSD(T_z)$ is root-mean square deviation of the indoor temperature, T_z^{max} and T_z^{min} are the maximum and minimum value of the indoor temperature, respectively, $T_z(t)$is the real indoor temperature value, $\hat{T}_z(t)$ is the indoor temperature obtained with the calibrated model, and T is total simulation time.

In the case of the power consumed by the HVAC, it is a non-negative scale variable which cannot have negative values, so the mean value is used to normalise the error. Thus, the *Coefficient of Variation of the root-mean-square deviation* (CV(RMSD)) is used as reference, which is described in Eq. (12).

$$CV(RMSD(P_{HVAC})) = \frac{RMSD(P_{HVAC})}{\bar{P}_{HVAC}} = \frac{\sqrt{\frac{\sum_{t=1}^{T}(\hat{P}_{HVAC}(t) - P_{HVAC}(t))^2}{T}}}{\bar{P}_{HVAC}}, \quad (12)$$

where $RMSD(P_{HVAC})$ is root-mean square deviation of the power consumption, $\underline{P}_{HVAC}$ is the mean value of the power consumption, $P_{HVAC}(t)$ is the real power consumption value, and $\hat{P}_{HVAC}(t)$ is the power consumption obtained with the calibrated model.

Table 1. Calibration errors for the building fixed parameter model.

	$NRMSD(T_z)$, %	$CV(RMSD(P_{HVAC}))$, %
Verification, weekdays	20.96%	0.73%
Verification, Saturdays	25.76%	0.72%
Verification, Sundays	14.73%	1.85%
Verification, general	16.50%	1.89%

The errors in the temperature are greater than in the power consumption. This introduces a great uncertainty in the modelling part, especially in the indoor temperature modelling. Nevertheless, the errors in the power consumption are low, which may be due to the simplified HVAC model that makes it easier to be adjusted.

3.3. Flexibility provision evaluation

Both the baseline MPC with the fixed model parameters calculated in section 3.2 and the *Building Optimizer* incorporating the self-learning capabilities are simulated for the same boundary. A simulation of a whole week of February is conducted, with the real and virtually generated forecasts of outdoor temperature, and the synthetic internal gains described in section 3.1.3.

The flexibility request is sent to the *Building Optimizer* through a power consumption reference profile that the optimizer needs to track to allocate the power consumption. This signal, in the solution structure presented in section 2.1 and shown in Figure 1, comes from the DR optimizer. In this case, the signal will be synthetically generated. The procedure explained here also reflects how the *Building Optimizer* can work as a standalone solution by including the generation of the signal as a part of the solution.

The flexibility request is generated considering the Spanish electricity tariff schemes that apply an hourly discrimination and divides the day into the following consumption periods: the peak period (with higher tolls and charges), the flat period (with intermediate values for the costs) and valley periods (with the lowest costs) [36]. The procedure is the following one:

1. The case study model is simulated with the *Building Optimizer* applying just thermal comfort objective, so no actions are taken regarding the power consumption. In this way, a baseline of the typical power consumption in the building is achieved, without demand-side management. This profile is used as a reference for the power consumption.
2. The following assumption is made regarding the flexibility requests that are expected: the power consumption is requested to be reduced in the peak periods, this power consumption should be reallocated in the valley period, and the flat periods should not be modified. This would match with the general requests from the grid point of view but would also be in line with the electric tariff periods, so the benefits would not be just flexibility share increase, but also economic benefits.
3. The baseline power consumption from step 1 is decreased in a percentage in the peak periods, it is maintained in the flat periods, and it increases in the valley. A set of simulations are defined varying the percentage of flexibility request from 10% to 30% by increasing a 5% in each step.

The scenarios requesting different percentages of flexibility are simulated for both the baseline MPC and the *Building Optimizer* incorporating self-learning capabilities.

For the assessment of the thermal comfort guarantee, the thermal discomfort duration is evaluated. This is measured as the percentage of the time that the indoor temperature is outside the defined thermal comfort limits (21-22ºC). The accuracy in the power consumption tracking is evaluated by the deviation compared to the reference curve, using the CV(RMSD) defined in Eq. (12). Table 2 presents these metrics for the different flexibility scenarios. The first simulation day is not considered as it is highly dependant on initialization conditions and does not reflect the normal operation.

Table 2. Temperature and power consumption error comparison for different flexibility scenarios.

Flexibility request	Thermal discomfort duration [%]		Power deviation [%]	
	Baseline MPC	Building Optimizer	Baseline MPC	Building Optimizer
10%	7.07%	0%	2.22%	0%
15%	14.14%	0%	3.31%	3.29%
20%	18.71%	1.25%	7.44%	6.63%
25%	25.37%	8.12%	9.24%	9.35%
30%	31.11%	17.9%	12.1%	12.16%

The results from Table 2 show that the *Building Optimizer* can track the requested power demand with a lower impact in the thermal comfort. It can even reach a 20% flexibility provision with a minimum impact on the thermal comfort (guaranteeing it 98% of the time) and a 25% flexibility provision with a thermal discomfort duration below 10% of the total time. For higher percentage of flexibility requests, there is an accuracy loss in temperature tracking to achieve the other objective of the cost function, that is, the power tracking.

The difference in performance to guarantee thermal comfort between the two analysed scenarios is due to the capacity of the *Building Optimizer* to reduce the uncertainty. The main sources of uncertainty in the problem come from both the inherent uncertainties to the modelling and the input predictions. In the case of the baseline MPC with fixed parameters, the calibrated model parameters present an error when predicting the real building behaviour, as explained in section 3.2. Even if the MPC can reduce this uncertainty using the real measurements of the system, this uncertainty cannot be completely avoided. The *Building Optimizer* tackles this problem by updating the model parameters based on the last real measurements of the system. Regarding the predictions, both scenarios are simulated with outdoor temperature predictions with an uncertainty integrated, which deviates the response from the predicted one. In the case of the internal gains, the baseline MPC uses the predictions of the internal gains from ASHRAE (Figure 5), which introduces a great uncertainty source. On the contrary, the *Building Optimizer* uses the estimated last value of the internal gains by the MHE as prediction. Even if this is an approximation that introduces also considerable uncertainty, this approximation gives better results than using the ASHRAE predictions according to the results.

The scenario for a flexibility request of 20% is analysed to illustrate the performance of both controllers. In Figure 6, the comparison of the indoor temperature of the thermal zone for both the baseline MPC and the *Building Optimizer* is shown, together with the upper and lower thermal comfort limits.

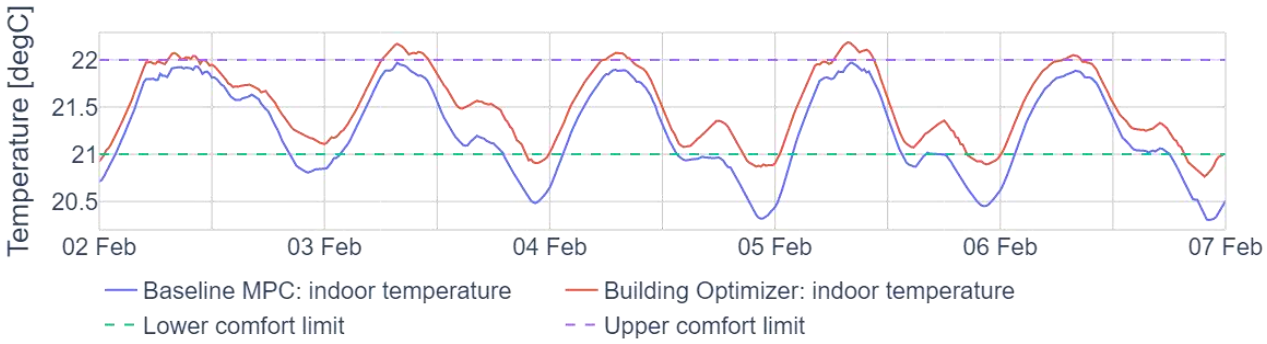

Figure. 6. Indoor temperature with the baseline MPC and the Building Optimizer.

Figure 6 shows how the indoor temperature deviates for longer periods from the thermal comfort conditions in the baseline scenario, for the reasons explained above.

Figure 7 presents the same comparison between the baseline MPC and the *Building Optimizer*, but for the power consumption.

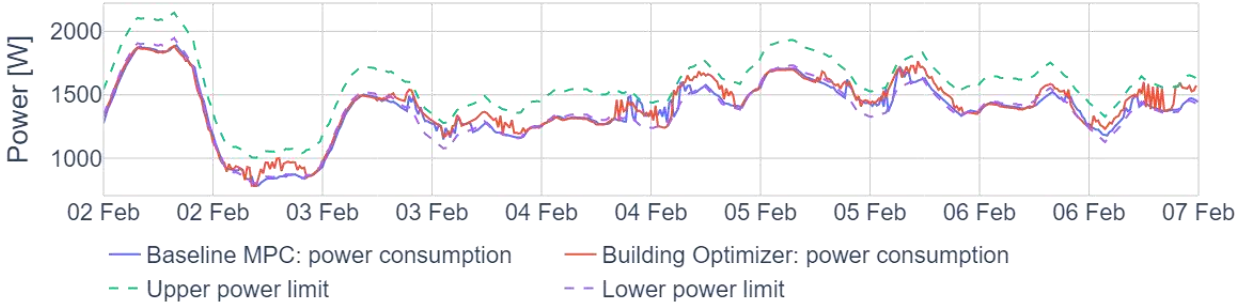

Figure. 7. HVAC power consumption with the baseline MPC and the Building Optimizer.

The power tracking shown in Figure 7 reflets that the power is deviated very similarly in both scenarios. This is the expected conclusion as the calibration errors for the baseline MPC were lower for the power consumption.

Another important aspect to consider is the percentage of energy that is displaced from peak periods to valley periods. This indicator is also a reflection of the ability to perform power shifting actions. This percentage is presented in Table 3.

Table 3. Percentage of energy consumed during peak periods shifted.

Flexibility request scenario	Peak period shifted energy, %
10%	8.06%
15%	11.03%
20%	14.22%
25%	15.21%
30%	16.77%

This reduction in the peak periods could be directly translated into economic benefits and a flexibility provision capacity in accordance with the typical request that may appear from the grid side.

4. Conclusions and future work

In the present work, a control strategy called *Building Optimizer* is developed, consisting of an MPC with self-learning capabilities to manage the thermal demand of a building. The Building optimiser can allocate a requested power consumption in a building while guaranteeing thermal comfort so that an objective at community level is achieved. The capacity for the power consumption management is crucial to integrate demand response in the residential sector, with a great unlocked potential. This boosts the integration of RES in the current energy system as a better match between the intermittent production of renewable sources and the demand at building levels can be achieved. The moving horizon estimation technique is used for incorporating self-learning capabilities, which uses real-time measurements from the plant to recalibrate the model at real time and calculate unmeasurable inputs, such as the internal heat gains. This functionality is relevant for buildings, a system with a wide range of uncertainties due to its characteristics and the occupancy patterns.

A case study is presented for a building represented by a single thermal zone with a controllable HVAC. The performance of an MPC with fixed parameters model is compared to the *Building Optimizer* including the self-learning capabilities. To calibrate the MPC with fixed parameters, a calibration technique is proposed, using the data for a whole week of the study building. A flexibility request scenario is simulated, generating this request through a curve that decreases the power consumption at peak electric prices periods and increases them in valley periods with respect to a reference curve in which demand side management is not performed. The scenario is simulated for different percentages of flexibility request with both the *Building Optimizer* and the fixed-parameter baseline MPC. The simulations are conducted including uncertainty sources in the used predictions for the boundary conditions. It is concluded that 20% is the maximum flexibility at which the deviation in the indoor temperature with respect to the thermal comfort boundaries has a duration lower than 2% of the time. In this scenario, the *Building Optimizer* improves the temperature tracking and the power consumption allocation compared to the baseline MPC, and it can shift up to 14% of the energy that is consumed during peak hours to valley periods. This demonstrates that incorporating self-learning capabilities can improve the performance of this type of controllers.

The studied building is of residential type, but the proposed reduced order model can be extended to other type of buildings, such as commercial buildings or offices. The solution is scalable in terms of the number of buildings, as each building would have its own MPC to ensure that it consumes what is required by the community. The scalability of the solution in terms of the building size and the number of thermal zones to be modelled within the building will be one of the crucial challenges to analyse in further work, as including more thermal zones increases the computational cost of the problem. Future work should expand the inclusion of a more detailed model of the HVAC too.

Abstract:

Decarbonisation of heat generation has become a priority for district heating network operators. In order to avoid the use of fossil-fired boilers, operators need to know peaks in heat demand in advance. Accurate thermal load forecasting is playing an increasingly important role in this respect.

This paper presents the final results of the research project “deepDHC” (deep learning for district heating and cooling) funded by the German Federal Ministry for Economic Affairs and Climate Action (BMWK). The three-year project focused on systematically benchmarking thermal load forecasts for district heating networks, based on state-of-the-art machine learning methods. The analysis covers a variety of machine learning techniques, such as neural networks – including latest deep learning methods – (e.g. LSTM, TFT, ESN, RC), decision trees (random forests, adaptive boosting, XGB) and statistical methods (SARIMAX). In addition, the impact of combining methods by so-called “stacking” was investigated. Training and validation of the machine learning algorithms was based on historical operating data from the district heating network for the city of Ulm in Germany, in combination with historical weather data, and weather forecasts. Thermal load forecasts – typically for three days ahead – are presented and compared against one another. An automatic tuning routine was developed as part of the project, which enables regular re-training of the machine learning algorithms based on the latest operating data from the heating network. Furthermore, a web interface for real-time forecasting was developed and implemented at the power station.

Keywords:

District heating; load forecasting; machine learning; dispatch optimisation.

1. Introduction

Half of Europe’s entire energy consumption is used for heating and cooling, with 75 percent derived from fossil sources. Thus it is important to provide heat as efficiently as possible, also producing the lowest possible greenhouse gas emissions. District heating networks play a key role in this context, as they are currently used to supply 60 million Europeans with heat.[1] However, with total lengths often spanning several hundred kilometres, supplying district heating networks efficiently presents a considerable challenge. Typically, heating network operators maintain several power plants with different technical and economic features. District heating or cooling can be provided more cost-effectively, efficiently and with fewer emissions, the more precisely the expected load can be estimated. In addition to a comprehensive understanding of individual power plants and a dispatch optimisation strategy, this requires a precise forecast of the thermal loads that can be expected in the network during the next few days. In industrial practice, however, generally only simple forecasting methods with comparably high uncertainties are used for district heating load forecasts

Previously established methods, which are based on typical days or reference load profiles, [2] currently lead to an estimated 15-30 percent load forecasting error rate over a 72-hour horizon. In addition, heating load forecasts have been considerably less intensively studied to date than, for example, electricity load forecasts.

Accurately predicting the district heating load is essential for district heating network operators in order to optimise the utilisation of available power plants, thermal storage facilities and “power-to-heat” plants, thus boosting efficiency. The quality of district heating load forecasting directly impacts plant dispatch quality, making it a critical factor to consider. Nevertheless, quantifying the economic advantage of reducing load forecasting errors is difficult, due to the fact that different load forecasts cannot be relied on to accurately repeat the actual plant dispatch during a specific period. The economic benefit of improved thermal load forecasting was shown in in a previous publication.[3]

New methods in the field of artificial intelligence, especially in machine learning and "deep learning", offer considerable potential for improvement, in particular since machine learning techniques have become easy to deploy due to increasing amounts of training data coupled with cheaper and improved computing power.[4–7]

This work is based on operating data from the district heating network for Ulm, a medium-sized city in southern Germany with about 125,000 inhabitants, as provided by the local utility company “Fernwärme Ulm GmbH” (FUG), which operates a district heating network about 150 km in length supplying some 600,000 MWh of thermal energy per year, equivalent to 45 percent of the city’s heat requirements. Table 1 lists all the major heat generation units operated by FUG. In addition, a pressurised hot water thermal storage of 2,427 m³ volume, equivalent to 150 MWh thermal energy storage capacity, and with 20 MW discharge power, is used.

Table 1. Heat generation units operated by FUG.

Plant type	Thermal load, MW	Electrical load, MW	Fuel type
Biomass CHP plant 1	58	9	Waste wood
Biomass CHP plant 2	25	5	Waste wood
Waste incineration CHP plant	30	11	Waste
Peaking boiler (w/ connection to turbine)	230	15	Coal, gas or oil

2. DeepDHC system structure

The DeepDHC system structure in Figure 1 below shows the developed process for load forecasting. The basis for training the models is historical data on the heat load of the district heating networks, as well as historical and current weather forecasts, which are obtained from the German Meteorological Service (Deutscher Wetterdienst, DWD) and stored in a database. In addition, the weather data currently measured for the Ulm site are obtained from the DWD’s Climate Data Center (CDC) and saved together with the actual district heating load in an hourly resolution. Operational data is rarely available in the correct format or ideal quality. Deviations such as missing measured values, outliers, or data with a different interval (time frames) must be corrected or optimised with statistical methods as part of a pre-processing step. During the machine learning process, features are generated, datasets are divided into test and training data, and the corresponding models are initially trained and optimised. Based on the trained model, a live forecast of the heat load is generated and made available to the power plant operator via a web interface. In addition, an automated learning routine was developed in the project. This routine helps to always provide the best model with optimal parameters, including retraining the forecasting models whenever new training data become available.

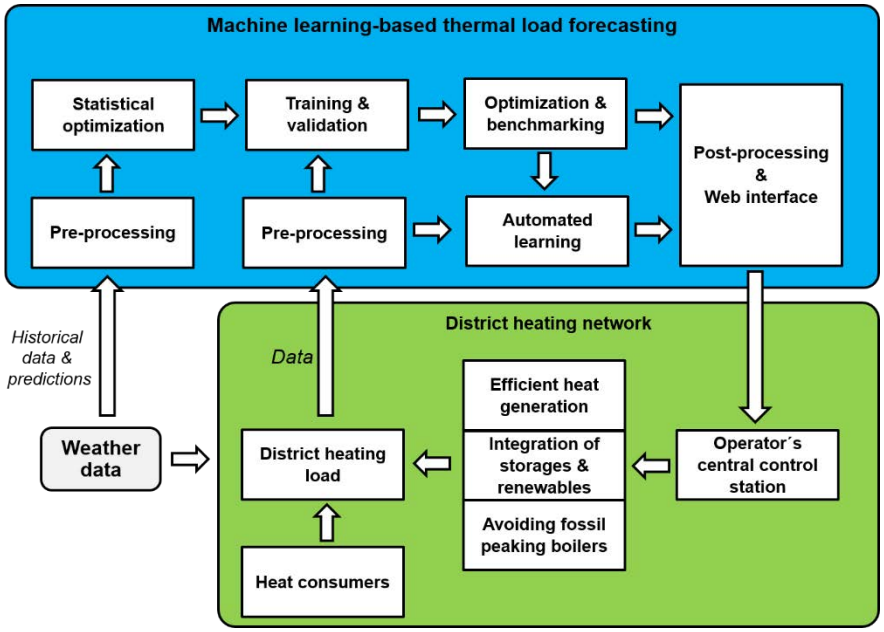

Figure 1. The deepDHC machine learning process for thermal load forecasting

3. Analysed machine learning methods

The objective of this chapter is to provide a concise overview of the analysed machine learning methods, including their characteristics, and to specify the software packages that were used for their implementation.

3.1. Seasonal Auto-Regressive Integrated Moving Average (SARIMAX)

In contrast to neural networks or decision trees, SARIMAX (“Seasonal Auto-Regressive Integrated Moving Average)” is based on statistical calculation models. SARIMAX extends the ARIMA model by adding a

seasonal counterpart to each component.[8] Compared to ARIMA, SARIMIX offers a “seasonal order”, which offers advantages for the type of forecasts examined. There are terms that capture the pattern of the data over a seasonal period, such as a week, a month, or a year. SARIMAX was implemented in this study using the “statsmodels” python library.[9]

3.2. Echo-State Networks (ESN)

Echo-State Networks (ESN) are one of the simplest implementations of a neuron-based reservoir computer. Reservoir computing is a machine learning approach to training recurrent neural networks (RNN). At its core, RNN cells contain an internal memory state which acts as a compact summary of past information. A unique characteristic of the ESN model is its efficiency in terms of the required computing power.[10, 11] Modern machine learning methods are becoming increasingly complex and require increasingly powerful hardware. In contrast, the development of reservoir computers focuses on reducing complexity and solving large machine learning tasks with minimal computing power. Recently, reservoir computers have proven to be a powerful and resource-efficient alternative in the field of classic forecasting of complex dynamic systems.[12] The Python package ReservoirPy was used in implementing this project.[11]

3.3. Next Generation Reservoir Computing (NGRC)

Like the “classic” ESN model, the NGRC model belongs to the group of neuron-based reservoir computers. [12] [13] In the background, a nonlinear vector autoregression (NVAR) algorithm automatically delivers the best possible classic ESN model with the associated hyperparameters. Like the classic ESN model, the NGRC model is very efficient and very easy for the programmer to implement. The Python package ReservoirPy was used in implementing this project.[11]

3.4. Temporal Fusion Transformer (TFT)

In the area of machine learning, transformers are a subtype of neural network. A common obstacle for machine learning algorithms is the inability to handle data in the dimension of time. Commonly, the algorithms weight the relevance of data at each location equally, thus preventing the extraction of usable knowledge in the time dimension. The architecture of the Temporal Fusion Transformer is specialised for performing such time-series prediction tasks. To learn temporal relationships on different scales, TFT uses recurrent layers for local processing and interpretable self-attention layers for long-term dependencies.[14] TFT offers powerful forecasts with customisation options, and unlike other machine learning methods it is not a “black box”. TFT is able to independently recognise dependencies within a data set and also includes tools for selecting relevant or irrelevant features. Originally developed by Google, several TFT implementations are now available. Further details of the TFT-related work in this study have been published separately.[14] The TFT used in this project was implemented using the PyTorch API.[15]

3.5. Long Short-Term Memory (LSTM)

LSTM is a gradient-based, recurrent neural network with feedback connections. LSTM neurons can hold values over any length of time, making them an attractive option for time-series prediction.[16] The standard recurrent neural network (RNN) architecture has difficulties in handling long-term dependencies, more precisely with the ability to adapt to recalling information late in the sequence. LSTM models address this limitation by introducing a memory cell, an internal state that can be updated and read by the network, and "gates" that control the flow of information in and out of the cell. This structure allows the LSTM to selectively store and update information across many time steps, making it well suited for time series forecasting.[16] The LSTM model was implemented using Keras LSTM layers.[17]

3.6. Adaptive Boosting (Adaboost)

Adaptive boosting, also known as AdaBoost, is a machine learning algorithm that belongs to the family of ensemble learning methods. Ensemble methods combine multiple models to improve their predictive power. The basic idea behind AdaBoost is to combine several “weak” learning models into a single “strong” model by iteratively learning from the mistakes of the weak learners. The algorithm can handle non-linear relationships between the input features and the target variable. It is also able to cope with missing data and outliers.[18] AdaBoost was implemented using the scikit-learn library.[19]

3.7. Extreme Gradient Boosting (XGBoost)

XGBoost is an open-source implementation of the decision tree gradient-boosting algorithm. The basic idea of gradient boosting is to train a series of weak models, where each model is trained to correct the previous model’s errors. By iteratively fitting the trees, XGBoost is able to build a highly accurate ensemble of decision trees that can capture complex nonlinear patterns in the data.[20] This ensemble of decision trees is based on gradient tree boosting, i.e. the trees grow sequentially with the knowledge gained from their predecessor. But this method is prone to overfitting, which XGBoost reduces by applying regularisation objects, shrinkage, and feature subsampling. XGBoost was implemented using the open-source python library XGBoost.[21]

3.8. Stacking

With the stacking method, the strengths of multiple individual models are harnessed by combining them into a single meta-model.[22] In this project, different combinations of base forecasting models such as Random Forest, ESN, TFT and LSTM models were analysed. The individual base models' predictions are fed as features into a meta-model, which then makes the final prediction.[22] This can be done in different ways. The stacking methods examined in this project were k-fold variation, bagging and averaging. All three methods were implemented via the scikit-learn library.[19]

4. Data characteristics and their effects on forecasting performance

When assessing a model's ability to make predictions, it is not only the quality of the training data that must be considered, but also its relevance to the current situation. In the context of district heating supply, certain factors influence demand independently of the events that can be planned and modelled. The outbreak of the Covid-19 pandemic was a major unforeseeable event that impacted energy needs, shifting the demand from industrial areas and educational institutions to residential areas. This presents a challenge for cities that operate separate networks for different urban areas, since previous regularities in the data are no longer valid. Additionally, it is uncertain whether the end of an event will restore the previous conditions, or whether changes in energy requirements caused by increased working from home during lockdowns will persist. Old training data may no longer be suitable for training models based on weight adjustments when networks expand or new urban areas are connected, leading to an increase in demand. Seasonal effects, along with the energy consumption of industrial plants that require hot water for their processes, must also be taken into account.

To account for these changes in the model, data must be collected for the altered consumption profile and used to train a new model. In addition to sudden changes such as grid expansion, primary energy shortages, and shifts in user behaviour, long-term global transformations such as climate change must also be considered. These changes occur continuously and can be compensated for with appropriate methods, as described in section 6.

In summary, numerous factors strongly influence the demand presented by a supply network. This project only utilised quantifiable influences to train the models. While it would be possible to incorporate additional data e.g. from climate models, economic forecasts, political events, crisis models, stock prices, and other forms of news into a model, it would be a time-consuming process that would not guarantee long-term improvement. Nevertheless, these factors should be taken into consideration when evaluating and using a forecasting technique. While machine learning models can recognise patterns in data that humans cannot see, it is important to note that there are no conscious trains of thought behind these mathematical models and that only information contained in the machine learning features used can be taken into account.

5. Benchmarking results

Fifteen years of operating and weather data in hourly resolution were used to train the machine learning algorithms. All eight subnetworks in the city of Ulm were analysed, each providing different challenges in terms of demand profiles, data quality and consumer structure. The data used in the following analysis came from a subnetwork of Fernwärme Ulm GmbH spanning a total length of 40 km and representing an annual heat demand of 75 GWh or 1,100 households. Hence a total of 131,400 data sets were used, each consisting of twenty parameters, i.e. measurement data from the district heating network and weather information such as air temperature, wind direction and wind speed. The correlation between individual parameters and the associated district heating load was previously checked by means of a correlation analysis.[23]

When optimising and comparing the quality of forecasting algorithms, the characteristics of the metrics used must be taken into account. In this project, mainly the mean absolute percentage error (MAPE) was investigated because it is easy to interpret and dimensionless. However, a weakness of the MAPE becomes apparent when the forecast values are very low, as during the summer months. The metric is skewed at values close to zero.[24] Therefore, the mean average error (MAE) is used in addition. In the following analysis, the forecasting methods for the heating period winter 2021 (December 2020 and January and February 2021) are examined and compared using the MAPE. This period is also the economically most interesting part of the year for heating network operators. If precise forecasts make it possible to avoid operating fossil-fuelled peaking boilers, the largest proportion of fossil fuels and thus CO_2 emissions can be saved during this period. The bar chart in Figure 2 below shows a final comparison of the forecasting errors of all analysed machine learning algorithms.

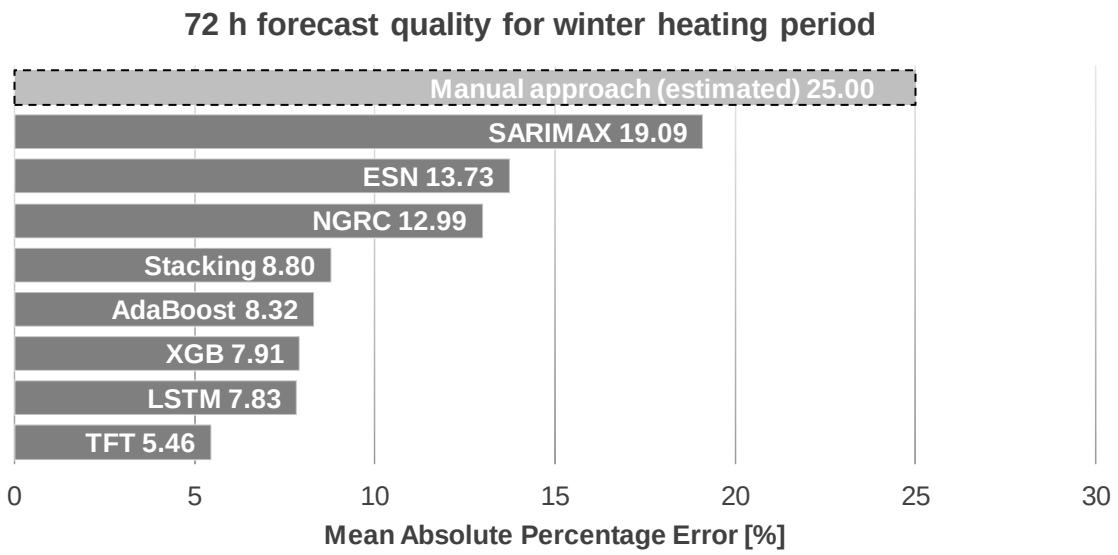

Figure 2. Final results of the 72 h forecast machine learning benchmarking

In the graph above, an estimated error of traditional forecasting methods where no machine learning algorithms is indicated for comparison. Although the SARIMAX model performs only slightly better than the estimated manual approach, it has the advantage of requiring only a small amount of data and still being able to produce a relatively good forecast (3.1 %-8.25 %) for a short time horizon of 12-24 hours (not shown in the graph). However, when predicting over a longer time horizon of 72 hours, the SARIMAX model performs significantly worse, with a MAPE of 19.09%. The NGRC and ESN recurrent neural networks show a similar performance, with NGRC slightly outperforming ESN with a MAPE of 12.99%. Similarly to SARIMAX, these algorithms also have other advantages besides a competitive forecasting error, such as the lower calculation power required and faster training time, which is briefly discussed at the end of this chapter. Throughout the project, it was found that stacking does not necessarily lead to better forecasts than the best individual method. Among the various stacking methods that were examined, such as k-fold variation, bagging, and averaging, simple averaging led to the lowest error value of 8.8%. However, stacking was found to be computationally expensive and required careful tuning of hyperparameters in order to avoid overfitting. Of the examined learning methods, AdaBoost, XGB, and LSTM are amongst the best and most stable, with a forecasting error of around eight percent. The LSTM model, in particular, achieves excellent forecasting quality and has lower memory requirements compared to XGB and AdaBoost, making it one of the most attractive models, but it requires significant implementation effort due to the many hyperparameter options and complex data pre-processing. However, the LSTM model demonstrated excellent adaptability when it was faced with new data. For example in scenarios that were previously unknown to the model, such as the Covid-19 pandemic or the increase in gas prices in 2022, which caused a reduction in heat demand, the LSTM model showed consistent results.

Overall, TFT delivers the best result for the examined subnetwork, with approximately 5.5% MAPE. Figure 3 illustrates the forecasting quality by showing the actual thermal load, the load prediction of the best TFT algorithm, and the percentage deviation for this method over a 72-hour period.

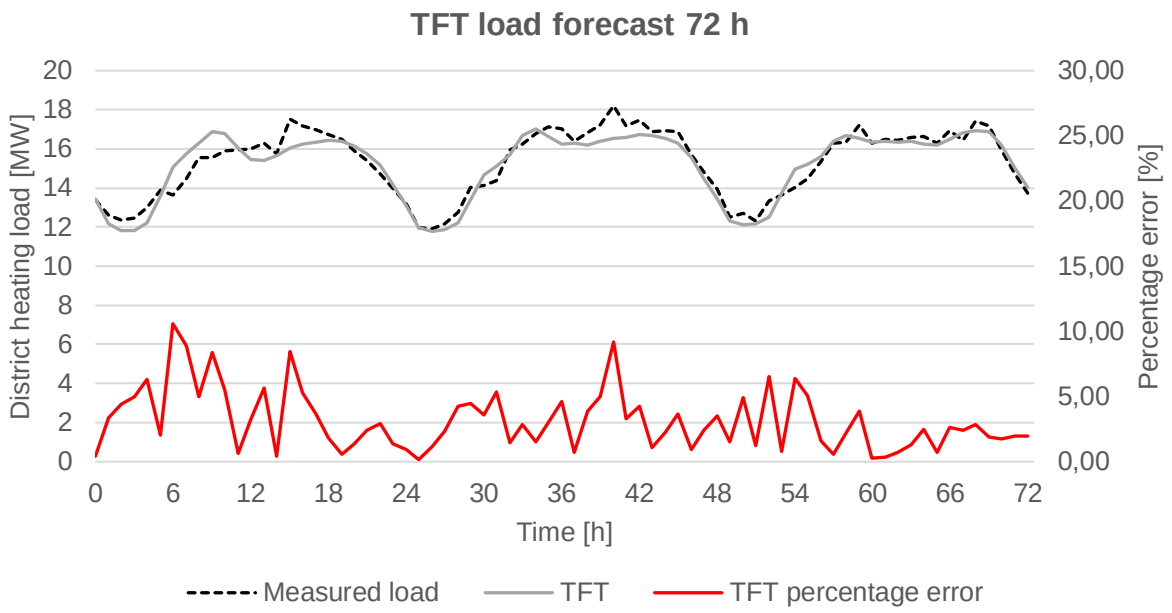

Figure 3. Example of a 72h thermal load forecast using the TFT model.

During live operation at a different grid operator, similar successful forecasting results have been observed. TFT is also one of the most complex algorithms to implement. But on the other hand, TFT offers the ability to predict multiple time series with a single model. If a district heating supplier operates several networks, which is usually the case, a separate model would have to be trained for each network when using a classic machine learning model. With the TFT model, this would no longer be necessary, since the model can assign features to different target predictions by classifying features into groups.[25] As a result, it is only necessary to train a single model for several use cases, which ideally saves time and money.

Benchmarking in terms of calculation power and training time is not straightforward as it depends heavily on the complexity of the model and various other factors such as the size and quality of the data and the hardware used for computation. However, the ESN and NGRC models proved to be exceptionally efficient, even if they do not provide the best forecasting quality. A monthly forecast with approx. 60,000 training data sets can be carried out using a simple office notebook (Intel Core i7-6600U, 16GB RAM, Windows 10) in a period of a few seconds. In comparison, the TFT model computed on a server with comparatively powerful hardware (NVIDIA Quadro RTX 6000 graphics card) needs about 30 minutes for the same training and forecasting process. In addition, the ESN model is very easy to implement and is one of the most user-friendly algorithms analysed.

6. Automated optimisation routine

During the initial setup of each model, various parameters need to be determined such as the choice of subnetwork, training timeframe, and the suitable dataset features. Adjusting the model-specific hyperparameters is usually part of “fine tuning” process, which enables the model to be adapted to the specific network in question. Each district heating network presents its own issues and characteristic properties, such as consumer structure, data quality and consumption patterns (households, industrial customers). A model that delivered very good results for one network might possibly deliver poor to unusable results for a network unknown to the model. Hence a network-specific approach with an automated optimisation routine was developed.

The developed routine is based on a random search algorithm.[26] The best model up to that point is loaded from the database and used as a reference. With the random search method, an n-dimensional parameter space is searched intelligently. By considering the effects of individual changes, parameters with a high impact are examined more intensively. This results in greater efficiency in contrast to a structured grid search. After a comparison, the best model is saved in the database and the process repeated. The system can use this routine to react to changes (network expansions, intensive savings measures, lengthy sub-network failures), in a limited scope, within a few intervals.

6. Live operation and web interface

In addition to benchmarking thermal load forecasting itself, a software system and web interface for live forecasting at the operator's site was developed. This covered a process of data aggregation, including a fully automated routine for regularly fetching required data from different sources, and combining them in a data warehouse. It included a step of screening and cleaning invalid data using methods such as imputation or other replacement strategies. Besides robust backend systems aiding the training and usage of machine learning models, a means of presenting the predictions and additional information to the operator of the district heating network is required. Thus a user-friendly web interface, capable of displaying 72-hour time frames of predictions together with corresponding data for any given date, was developed in cooperation with the district heating system operator. A screenshot of the thermal load forecasting web interface, which was installed at the operator's facilities in summer 2021 and has been in operation since then, is shown in Figure 4 below.

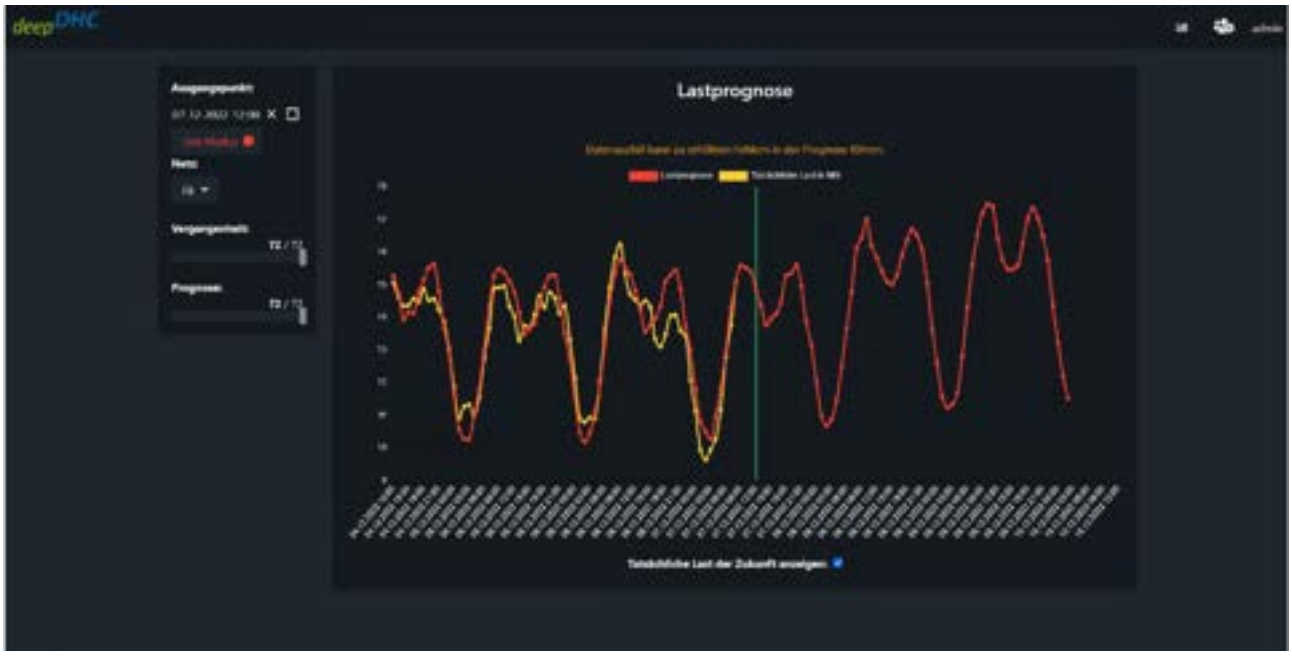

Figure 4. Web-based user interface developed for live operation of load forecasting.

7. DeepDHC user guide

A short guide was created to show the basic steps necessary to implement any of the described models. It is accessible via the code hosting platform GitHub under the following link:

https://github.com/deepDHC/deepDHC-user-guide

This guide will go through an example scenario that will use the historic thermal load and weather data to train a LSTM model. This model will then be saved and loaded from disc to do load predictions for another timeframe. Moreover, it shows how to calculate errors of the predictions compared to the real load demand, thereby providing a brief overview about all basic components needed to create models for district heating demand predictions.

8. Conclusion

The research project deepDHC systematically benchmarked thermal load forecasts using state-of-the-art machine learning methods, such as neural networks, decision trees and statistical methods. The study utilised long-term historical operating data from the district heating network in Ulm, Germany, combined with historical weather data and weather forecasts. Thermal load forecasts were predicted for three days ahead, in comparison against one another, and an automatic tuning routine was developed to retrain machine learning algorithms based on the latest operating data.

A key takeaway from the analysis is that a proper database has at least the same influence on forecasting quality as the model selection. Each and every district heating network is different and requires a model that is tailored to the specific network and database (see "No Free Lunch" theorem [27]).

Over a time period of 72 hours in advance, the developed forecasting tools were able to predict the thermal load within a mean average percentage error of five to eight percent for the investigated district heating subgrid. In summary, the TFT model performs best in the examined subnetwork with respect to forecasting accuracy. An attractive option is also the LSTM model, since it turned out to be computationally more efficient compared to the TFT model, whilst still ranking amongst the best and most stable algorithms in this study.

As part of a plant dispatch optimisation process, the forecasting methods that were analysed in this study can help to operate district heating networks more efficiently and cost-effectively.[3] By developing a web interface, the best analysed forecasting models could be made available for use in live operation and optimisation by the district heating system operator.

Acknowledgments

Abstract:

Decarbonization and sustainability urge the deployment and utilization of distributed energy systems for high-efficiency gains. The dispatchable devices (gas turbines or diesel engines) are integrated with a waste-to-energy system to harness the energy lost or waste heat and support heat and cold loads. This paper investigates the characteristics of a waste heat recovery system and its performance degradation mechanism to assess its maintenance necessity and optimize maintenance frequency and the associated maintenance and downtime costs. The effectiveness of the waste heat recovery system (WHRS) is regularly estimated using the measured inlet and outlet parameters (flow and temperature) to identify the need for maintenance. The effectiveness changes not only with degradation but also with inlet conditions that deviate from the design conditions. Therefore, the operators are instructed to operate this system at the rated inputs and gauge its actual effectiveness. However, this approach did not provide much information on the root-cause parameters, i.e., the fouling formation and thickness in the shell and tube sides, which are quite important to decide the type of maintenance and the associated cost and duration. This paper studies the performance characteristics of the waste heat recovery system with reference to all critical and influential parameters (i.e., fouling thickness, heat transfer coefficients, and off-design inlet conditions) using a rigorous physics-based model. An AI model was developed using the derived performance characteristics to predict the fouling thickness estimation. The developed prediction model is able to accurately estimate the fouling thickness on the gas and water sides, and the error or deviation is within ±0.3 mm. By deploying this prediction model, the critical parameters can be monitored in real-time, and the performance degradation trajectory paves the way to understand degradation status and estimate the right maintenance time frame to schedule maintenance proactively, considering the maintenance cost and downtime effects.

Waste Heat Recovery; Performance degradation; Fouling Prediction Model; Predictive Maintenance; Sustainability.

1. Introduction

Wide deployments of renewables and distributed energy systems show promising efficiency gains toward decarbonization and sustainability goals. The local power generation reduces transmission and distribution losses, paves the way to harness the waste heat from the dispatchable turbines (gas or diesel) to support thermal loads at a competitive price, and greatly increases the overall energy efficiency ([1], [2]). Unlike turbines and chillers, the waste-heat recovery system, i.e., an apparatus of heat exchangers, is not standard equipment; it is usually passive and primarily designed based on specific process requirements. Over time, the heat exchanger faces fouling issues due to the continuous deposition of impurities or particles on the heat transfer area, which affects efficiency [3]. Most heat exchangers undergo corrective maintenance on a need-based basis or preventive maintenance at periodic intervals. The corrective approach causes equipment downtime and high maintenance costs; preventive maintenance, which proactively entails regular maintenance, does not account for the actual condition of the system and the maintenance needs accurately. This paper focuses on developing a fouling prediction model for waste heat recovery systems (specifically exhaust gas-driven WHRS) to support predictive maintenance planning and reduce maintenance costs and downtime.

1.1 Background – Fouling & Maintenance of Heat Recovery System

Numerous studies have discussed various maintenance methods and their evolution in diverse processes [4]. Corrective or reactive maintenance is a primitive method popularly called "run-to-failure," usually conducted after the system fails, whereas preventive maintenance performs routine periodic inspections to trigger necessary replacement well in advance to avoid any failure. Unlike reactive and preventive maintenance, the predictive approach is more tied to system performance, and it requires concrete measurement to quantify the root cause and key indicators and initiate a suitable maintenance plan. In energy systems, especially in a WHR system, fouling (carbon deposit on the gas side, salt deposit on the water side) occurs gradually over time and affects the heat recovery performance and degrades the system efficiency. The underlying root cause of fouling is the impurities in the inlet streams and their affinity for the heat exchanger surface. Unfortunately, the fouling cannot be measured directly in real-time; some of the available handheld devices support offline measurement that requires perforating the equipment ([5], [6]). Notable studies investigated different heat exchangers and their fouling characteristics. Most of the studies utilized data from experiments and exploited analytical and thermodynamic models. Riverol et al. [7] used a neural network to estimate fouling in a plate heat exchanger for the pasteurization application. The simple neural network (two inputs and one output) developed reads and processes data to detect critical operation conditions and advise on the necessity of cleaning (maintenance). The fouling in heat exchangers and the effect of various factors such as velocity, temperature, concentration, and pH influencing the fouling growth [8]. This study highlighted the variation in fouling thickness over the pipe length. Other possible root causes of fouling are particulates, biological reactions, chemical reactions, corrosion, and decomposition. The NN and RSM models were developed using one-year experimental data to predict the fouling resistance of the crossflow heat exchanger system in a phosphoric acid concentration plant [9]. Elwerfalli et al. [10] estimated the probability of failure in the heat exchangers using risk-based inspection, a ranking matrix, and the associated rectification cost. This approach helps to identify high fouling and plan the shutdown maintenance activity. A few studies investigated the suitability of various machine-learning algorithms for predicting fouling resistance in plate heat exchangers [11]. Interestingly, the focus was mainly on predicting the combined resistance but not the individual resistance and its root cause parameters. Deep learning techniques [12] were adapted to predict the resistance on the gas and water sides as well as the combined resistance with reasonable accuracy. This study considered all critical measurements in the NN model, including flow at fouled conditions, but did not provide much information on translating the derived resistance into maintenance decisions.

Most of the above studies focused on improving the accuracy of the prediction model by using rigorous and sophisticated machine learning and artificial intelligence algorithms using limited real-time data or adequate data from analytical and thermodynamic models. In the majority of processes, upstream processes supply the inlet gas and water; in such cases, fouling mainly imposes an additional pressure drop when the inlet and outlet flow remain the same. This paper aims to study the influence of each measurement (feature) on the prediction results and discover the crucial measurements that can provide acceptable accuracy. Identifying the key inputs prevents needless sensor and instrumentation costs and mainly reduces the complexity of the prediction model to apply in real-world applications. By deploying the prediction model in the process monitoring system, it helps the operator identify the fouling thickness and growth phenomenon regularly. The continuous prediction and monitoring of fouling thickness helps identify the fouling growth rate and type (linear, falling, asymptotic, or saw tooth) [13] that depends on the inlet streams, such as velocity, impurities, and affinities towards the heat exchange surface [14]. By projecting the fouling trend at every time period (monthly or quarterly), the operator can estimate the fouling status for the next time period and decide the need for maintenance activity by comparing it with the tolerance level. Identifying the right time well in advance allows the operator to plan the maintenance activity efficiently, i.e., devise the right maintenance schedule or frequency (washing, purging, antifouling agents, etc.), conduct a cost analysis covering maintenance cost, performance gain cost, and downtime cost, and accordingly trigger the necessary redundancy and alternative operation choices to reduce the production loss.

2. Methodology

2.1 Predictive maintenance concept

The concept of the proposed preventive maintenance methodology for the waste heat recovery system (WHRS) is illustrated in Figure 1. The actual operational data for the duration of a year is the prerequisite for this methodology to model the system's performance and study the effect of scaling parameters. The expected outcome is a maintenance schedule recommendation considering all critical factors such as maintenance cost, downtime effects, and energy efficiency gains. Generally, the actual operation data can

be extracted from the process energy management system (EMS). Data pre-processing is required to remove measurement noise and outliers and mainly extract the required steady-state values from the time-series operation data [15]. In WHRS, the flow, pressure, and temperature of the exhaust gas and water are the critical variables that can be easily measured using appropriate sensors at the inlet and outlet streams. The challenge is measuring the fouling thickness on the interior and exterior of the tubes. Real-time measurement is not possible to measure fouling readily; some of the available hand-held devices require dismantling the system, which is expensive, and regular measurement is not possible [6]. In such cases, leveraging thermodynamic models is very relevant for the user to generate system performance at various inlet, surrounding, and fouling conditions. The minimal computational resources, fast computation, and freedom from measurement noise are additional benefits. Alternatively, in cases of limited operational data, it is good to supplement additional data from thermodynamic models, mainly to account for atypical operation conditions.

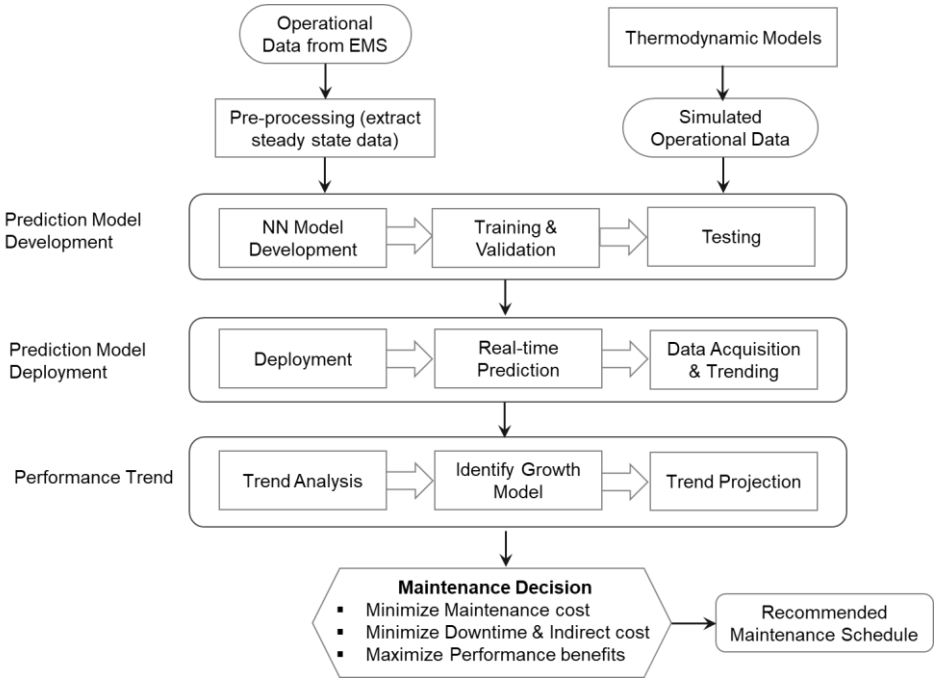

Figure. 1. Schematic of proposed preventive maintenance methodology

Numerous AI-based data-analytic algorithms are emerging to understand and capture system behavior from the data. Interestingly, in certain situations, AI-based data-analytic model development outperforms conventional physics-based models in terms of development time, resources, and prediction accuracy, especially for complex multi-variate systems. However, a data-analytic model requires substantial data for model training, validation, and testing, and the representative data should cover wide ranges to capture the system behavior comprehensively [16].

Deploy the developed data-analytic model in the process EMS and estimate the essential variables using the measurements available in real-time. Of course, the estimated variable may show some variations due to measurement noises, system dynamic behavior, and different inlet conditions. The key takeaway is the trend of the estimated variable on a long run (i.e., on a weekly, monthly, or even quarterly basis) to understand the scaling growth or build-up and performance deterioration trends. Incorporating or configuring a few processing techniques in EMS helps to remove the noise and outliers in the trend so that the system operator can identify the trend and extrapolate for future timeframes of interest. This projection will give an indication of the time when the system performance could fall below the acceptable tolerance and enable the operator to decide the maintenance schedule accordingly. Mainly, this insight or alert comes well in advance so that the operator has adequate time and operation flexibility to plan the maintenance schedule optimally by considering key factors such as system performance, expected downtime, downtime implications, maintenance cost, and benefits.

2.2 WHRS Performance

Figure 2 illustrates a cross-section and elevation view of a tube surface and pinpoints the type of fouling formation on the inner and outer surfaces of the tubes. The exhaust gas flows inside the tube, and water flows outside the tube (i.e., in the shell). Various thermodynamic models, such as the e-NTU method and physics-based ODE and PDE approaches, can estimate heat exchanger performance in diverse inlet scenarios. The e-NTU method [17] is widely employed to estimate the outlet conditions (T_{go} and T_{wo}) of the WHRS for the given inlet conditions (M_g, T_{gi}, M_w, T_{wi}), system (U_{ref}, A), and fouling parameters (t_{shell}, t_{tubes}). The e-NTU model, the pressure drops, and the performance of WHRS are described in Eq. 1 – 11, these equations can be either solved simultaneously using the EES or sequentially and iteratively using MATLAB or Python. The Cp_g and Cp_w represent the heat capacities of exhaust gas and water at their arithmetic mean temperatures. The U_{ref} and U_{calc} refer to the overall heat transfer coefficient of clean and fouled WHSR. The U_{ref} and A are taken from the specification sheet of the pilot plant facility. To simplify and balance the complexity of the thermodynamic model, a few key assumptions were incorporated, such as (i) uniform scaling along the tube length, (ii) fouling causes additional heat resistance and the effect on the heat transfer area is insignificant, and (iii) negligible heat losses to the surrounding area due to perfect insulation on the shell side.

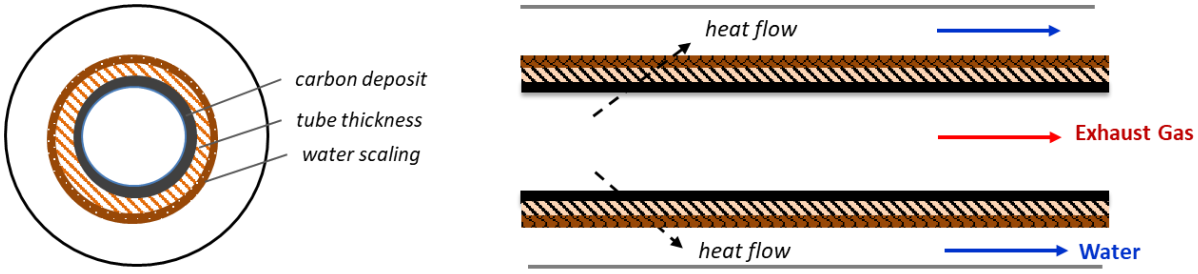

Figure. 2. Cross-section and elevation view of heat exchanger section

$$Q_g = Q_w = Q_{LMTD} \tag{1}$$

$$Q_g = M_g Cp_g\left(T_{gi} - T_{go}\right) \tag{2}$$

$$Q_w = M_w Cp_w (T_{wi} - T_{wo}) \tag{3}$$

$$Q_{LMTD} = U_{calc} A \Delta T_{LMTD} \tag{4}$$

$$Cp_g = \frac{1}{2}\left(Cp_{g,@T_{gi}} + Cp_{g,@T_{go}}\right) \tag{5}$$

$$Cp_w = \frac{1}{2}\left(Cp_{w,@T_{wi}} + Cp_{w,@T_{wo}}\right) \tag{6}$$

$$\Delta T_{LMTD} = \frac{(\Delta T_1 - \Delta T_2)}{ln\left(\frac{\Delta T_1}{\Delta T_2}\right)}, \quad \Delta T_1 = T_{gi} - T_{wi},\ \Delta T_2 = T_{go} - T_{wo} \tag{7}$$

$$\frac{1}{U_{calc}} = \frac{1}{U_{ref}} + \frac{R_{f,g}}{A_i} + \frac{ln\left({D_o}/{D_i}\right)}{2\pi kL} + \frac{R_{f,w}}{A_o} \tag{8}$$

$$P_{go} = P_{gi} - \Delta P_{tubes,foul} \rightarrow \frac{\Delta P_{tubes,foul}}{\Delta P_{tubes,clean}} = \frac{f_f}{f_c}\left(\frac{d_{tubes,clean}}{d_{tubes,foul}}\right)^2 \tag{9}$$

$$P_{wo} = P_{wi} - \Delta P_{shell,foul} \rightarrow \frac{\Delta P_{shell,foul}}{\Delta P_{shell,clean}} = \frac{f_f}{f_c}\left(\frac{d_{eff\_shell,clean}}{d_{eff\_shell,foul}}\right)^2 \tag{10}$$

$$\eta = \frac{Q_{act}}{Q_{opt}} \times 100\% = \frac{Q_{act}}{UA(\overline{T_g} - \overline{T_w})} \times 100\% \qquad \overline{T_g} = \frac{1}{2}\left(T_{gi} + T_{go}\right),\ \overline{T_w} = \frac{1}{2}\left(T_{wi} + T_{wo}\right) \tag{11}$$

Equation 9 and 10 estimate the pressure drop of the gas and water streams (adapted from Kakac et al. [3]). The efficiency of the heat exchanger is the ratio of the actual and optimal heat transfer rates expected in the heat exchanger. The optimal (maximum) heat transfer rate is the product of the UA of the heat exchanger and the arithmetic mean temperature difference (AMTD) of the inlet and outlet streams [18]. Deploying the e-NTU model in the process EMS to estimate the fouling thickness in real-time is challenging because the e-NTU model requires accurate measurement of all critical measurements and computation resources. On the other hand, the AI model can be easily deployed in EMS and is capable of estimating the fouling thickness in real time with minimal computation effort without facing any convergence issues.

2.3 Fouling Prediction Model

The AI-NN architecture (as shown in Figure 3) comprises seven inputs and two outputs used for fouling prediction on the inner (gas fouling) and outer (water fouling) surfaces of the tubes. The inputs (features) are gas flow, gas inlet and outlet temperature, water inlet and outlet temperature, and the pressure drop on the gas and water streams. The water flow remained at its designed condition. The operational data is the requirement for the prediction model development, and the data should cover the board operation range, i.e., all possible operation scenarios such as design and off-design conditions.

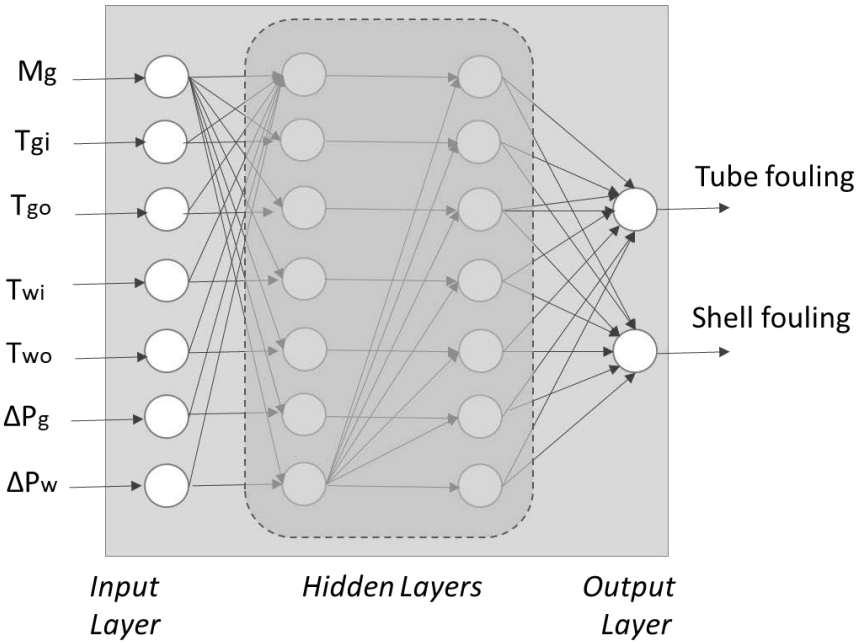

Figure. 3. Schematic of Neural Network architecture used for the fouling prediction.

The number of hidden layers and epochs are the tuneable parameters to balance the model complexity and achieve the desired prediction accuracy. In addition to the fouling prediction, this study aims to understand the importance of inputs (features) and their effects on prediction accuracy. By comprehending the importance of the inputs, they can be categorized as primary and secondary; eventually, the secondary inputs can be either eliminated or wisely chosen to simplify the prediction model and the associated data and instrument requirements without losing the accuracy of fouling prediction. The workability of the proposed methodology will be discussed in the following section using a case study problem.

3. Case Study – Combined Heat & Power (CHP) System

The proposed preventive maintenance methodology is applied in a pilot plant facility at NTU's Experimental Power Grid Centre (EPCG), Singapore. EPGC has a unique test facility, rated above 1 MW of distributed energy resources that allows test-bedding and research, development, and demonstration (RD & D) of a variety of energy technologies. Figure 4 shows the schematic of the integrated electrical and thermal grid facility at EPGC [19]. The generators serve the electrical load, and the exhaust gas from the generators powers the thermal grid to harness waste heat and convert it into useful energy. The thermal grid comprises critical systems such as a WHRS, an adsorption chiller, and thermal storage responsible for recovering waste energy and generating useful forms of thermal energy. The WHRS recovers heat in the form of steam or hot water, depending on the heat potential of the exhaust gas and the type of thermal load. Figure 5 shows a shell and tube heat exchanger as WHRS based on the generator size and the thermal and chemical properties of exhaust gas. The designed WHRS recovers 55%–80% of heat from the exhaust gas, whereas the rest is rejected to the atmosphere, considering the thermodynamic and design limits. The real benefits occur when the heating loads are located near the WHRS; otherwise, the pumping cost needs to be considered. When the generated steam or hot water is higher than the heating loads, either thermal storage is a preferable option to store excess energy for later use or convert it to other forms of useful energy, such as chilled water for air conditioning purposes. This integrated system improves overall energy efficiency by recovering the waste heat from the exhaust gas and converting it into various useful forms of thermal energy [20].

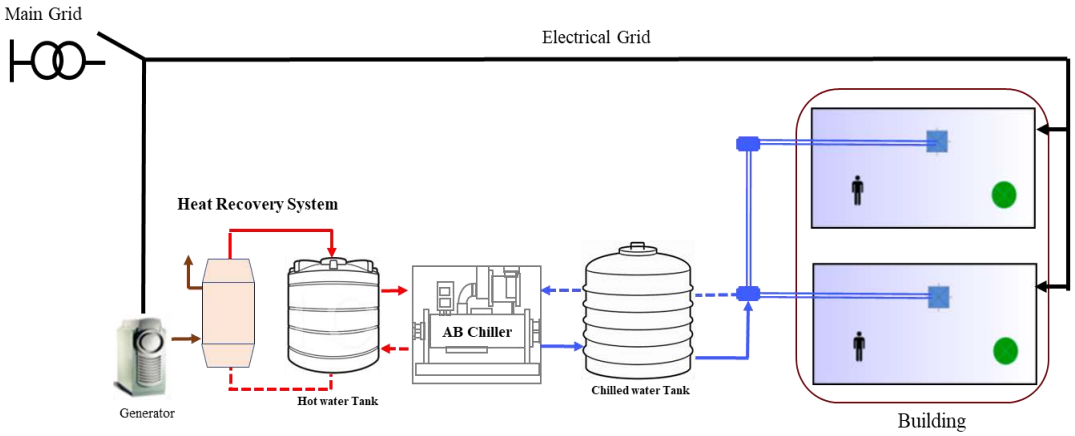

Figure. 4. Schematic of integrated electrical and thermal grids at EPGC

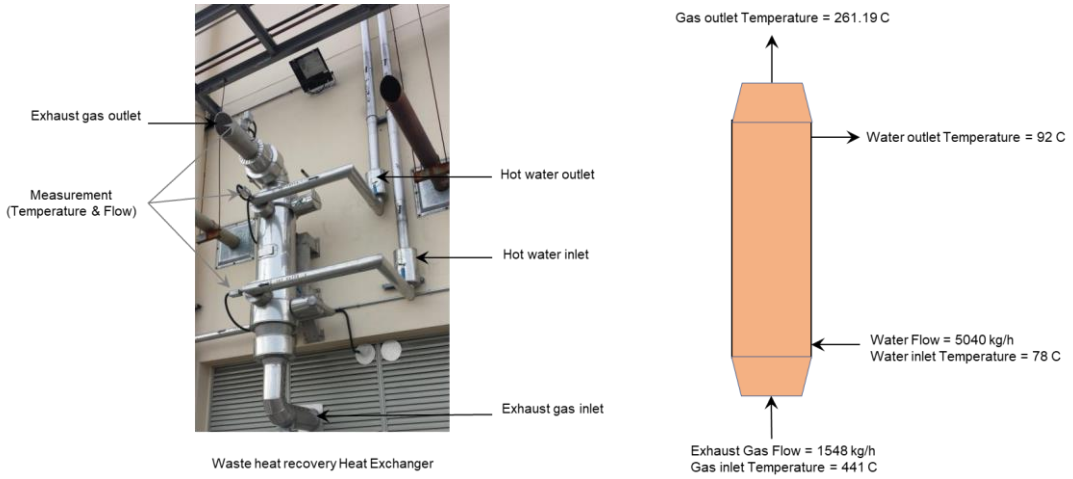

Actual Testbed Design Condition

Figure. 5. Waste heat recovery system: a) Actual system; b) Design conditions

Figure 5 shows the actual WHRS supporting various experiments and testing smart technologies and its design conditions (Table 1). The performance of the WHRS deteriorates over time due to fouling at the inner and outer tubes due to exhaust gas and water, respectively. The carbon and salt deposit builds up gradually, increases the thermal resistance significantly, and reduces the heat transfer between gas and water. The fouling on the interior of the tubes reduces the gas flow area, increases the pressure drop, and influences the back pressure of the generator and its performance. The fouling on the exterior of the tubes reduces the flow area of water and increases the pressure drop and pumping power. Therefore, real-time estimating of fouling is important to understand the system condition and plan maintenance optimally.

Table 1. WHRS designed inlet and outlet properties.

Parameters	Design Condition
Flue gas inlet Flow & Temperature	1548 kg/h and 441 C
Water inlet Flow & Temperature	5040 kg/h and 78 C
Flue gas inlet & outlet pressure	105 and 104.2 kPa
Water inlet & outlet pressure	1000 and 998.5 kPa
Flue-gas fouling factor	0.6 W/mK
Water scaling factor	2.941 W/mK

The actual operational data is the prerequisite for predictive maintenance methodologies. Representative operational data should capture wide operation conditions (i.e., all possible inlet and scaling

cases). Unfortunately, in the actual system, the possibility of collecting broad operational data is difficult because (i) fouling occurs in the long run, (ii) all variables cannot be measured online, especially fouling thickness [6], and (iii) the actual operating range is limited, not wide-ranging. Hence, this study exploits a thermodynamic model to generate complete data under diverse operational conditions.

3.1 WHRS Performance Characteristics and Effects of Fouling

Figure 6 shows the derived outlet condition of WHRS under diverse fouling conditions derived using the e-NTU model. Both carbon deposits and water fouling reduce the heat exchange between exhaust gas and water; therefore, the outlet temperature of exhaust gas increases and the outlet temperature of water decreases compared to the rated outlet condition. The carbon deposit greatly influences the outlet temperature more than water scaling because the heat flows from the gas to the water, and the carbon deposit has low thermal conductivity and imposes high resistance. For example, flue gas resistance is roughly five times higher than that of water. Figure 7 shows the expected performance of the heat exchanger under diverse fouling conditions.

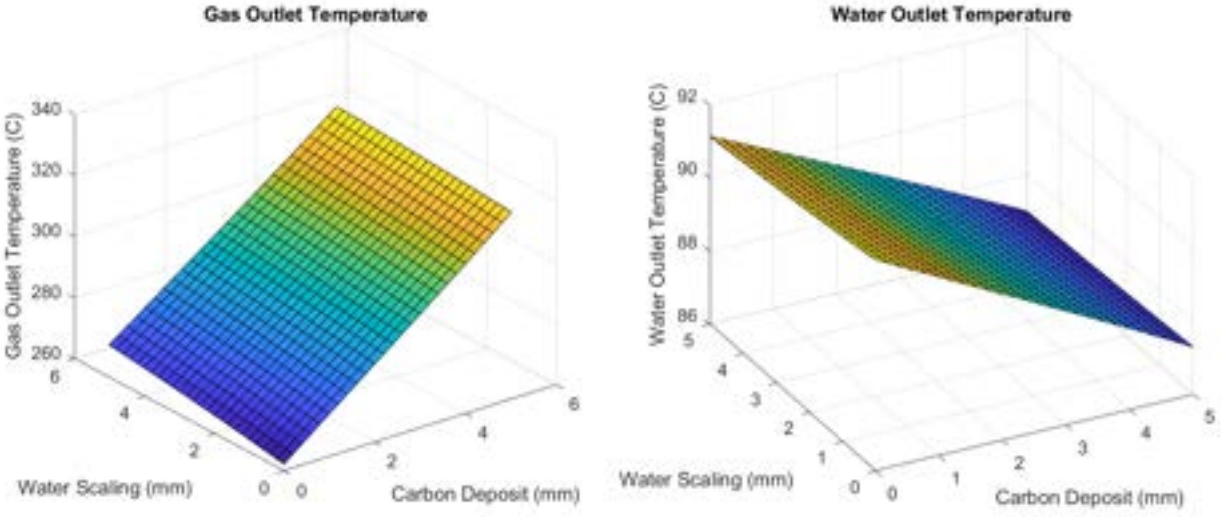

Figure. 6. WHRS performance at diverse fouling (at rated inlet conditions)

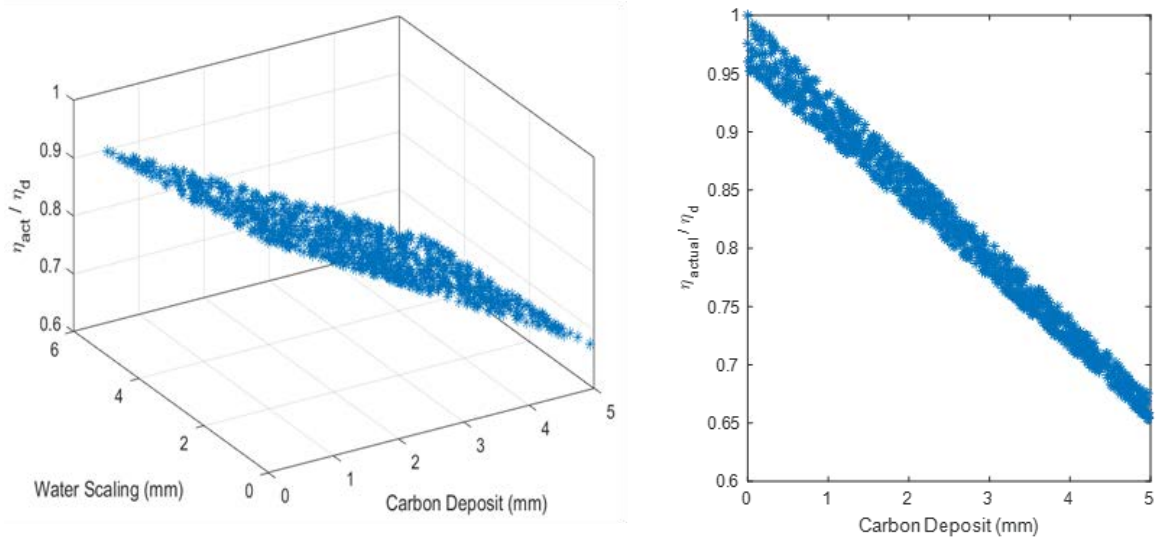

Figure. 7. Normalized performance of WHRS at different fouling (at rated inlet conditions)

In real-world operation, the inlet exhaust gas flow and temperature to the WHRS change with upstream processes such as generator loading and return water conditions. Table 2 shows the operating range

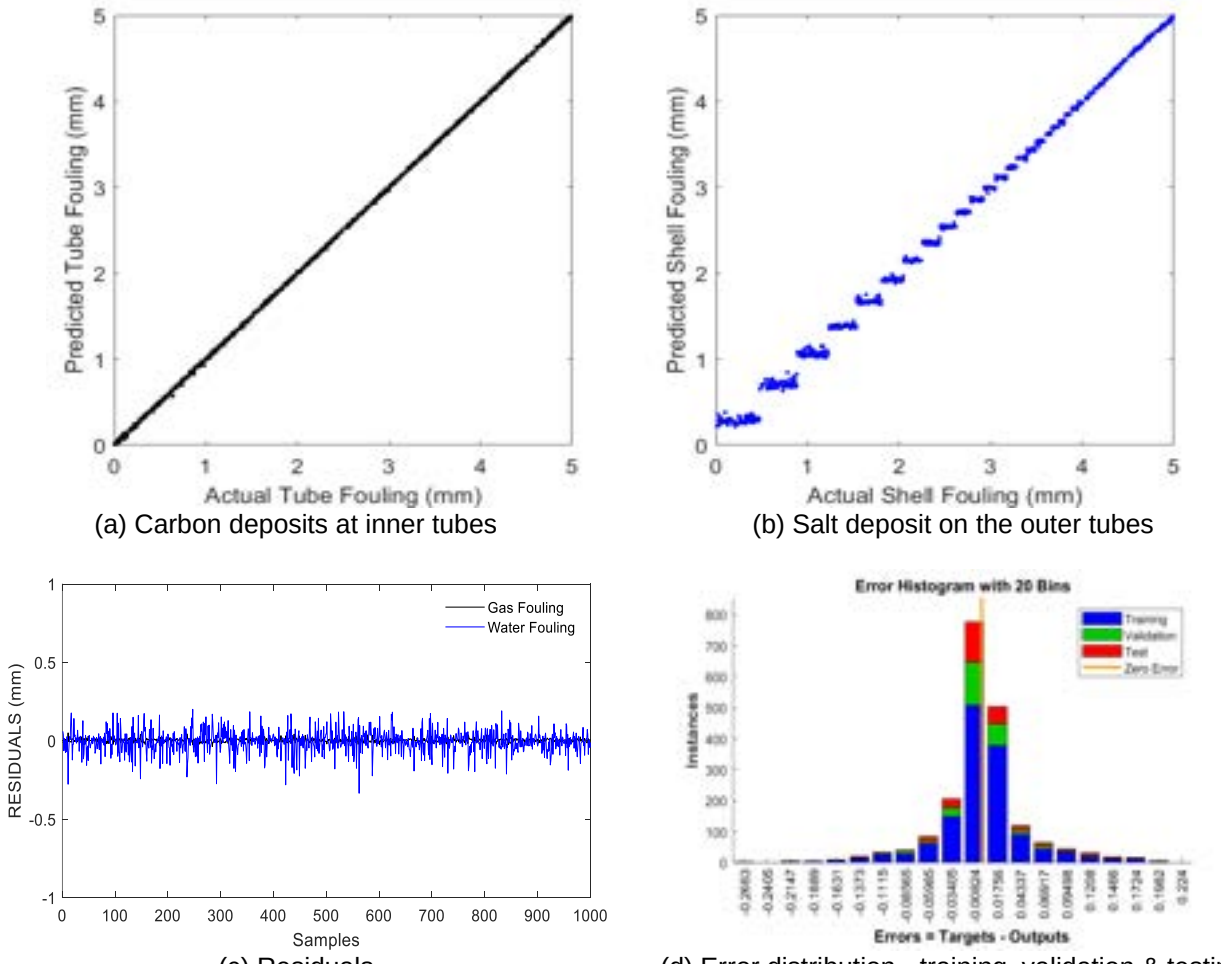
extracted from the historical data of the WHRS. Regrettably, the fouling information is not readily available; therefore, the e-NTU method was exploited to estimate the fouling thickness. The next section will discuss the development of a prediction model to support the predictive maintenance of the WHRS.

Table 2. WHRS Operation Range.

Inlet and outlet streams	Operating range
Flue gas inlet flow	60-100% of designed gas flow
Flue gas inlet temperature	441 – 492.1 C
Water inlet flow	60-100% of designed water flow
Water inlet temperature	78 – 84 C

3.2. AI-NN Fouling Prediction Model

The required performance data was generated for 1000 operational scenarios (uniformly distributed) covering design and off-design conditions, accounting for the actual operation range (as stated in Table 2), and the corresponding fouling estimated by solving the e-NTU model using the EES solver [21]. The AI-NN model with five hidden layers offers acceptable prediction accuracy (R^2 = 99.87% and MSE = 0.005). Figure 8 shows the actual and predicted fouling thickness on the inner and outer tubes (shell sides). The fouling on the inner tube is dominant due to high resistance (as mentioned in Table 1) compared to the fouling on the outer tube. Figure 8c and Figure 8d confirm the error is within an acceptable range and well below ±0.3 mm. To keep in mind, the performance data utilized is smooth; however, in the real application, the actual data may contain instrumentation errors and measurement noises that need to be pre-processed cautiously before applying to the prediction model.



(a) Carbon deposits at inner tubes

(b) Salt deposit on the outer tubes

(c) Residuals

(d) Error distribution - training, validation & testing

Figure. 8. (a) and (b) show the actual and predicted fouling thickness on the tube and shell side. (c) and (d) shows the residuals and prediction error of training, validation, and testing set.

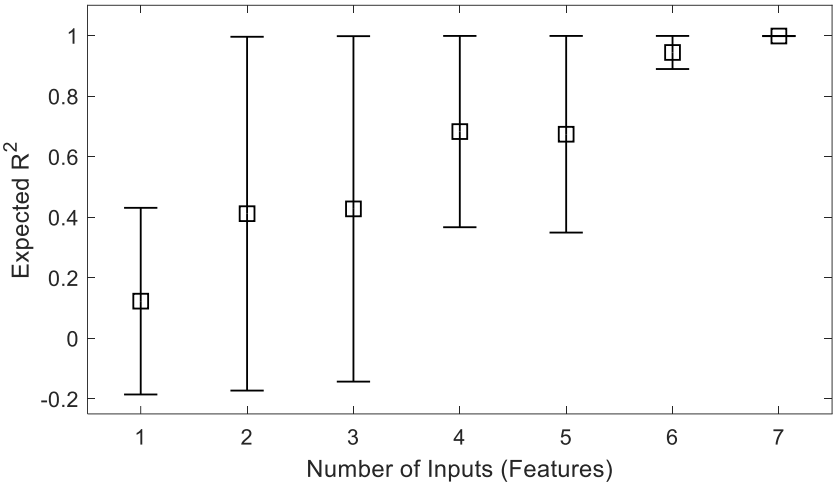


Figure. 9. Number of features and the expected prediction accuracy in regression coefficient.

Even though the above model can predict the fouling thickness accurately, it is essential to understand the importance of each feature to reduce the complexity of the prediction model and operational data requirements. Various recursive feature elimination methods such as random forest, SVM, k-nearest, and neural networks can be useful to study the importance of the features. These methods conduct model training repeatedly and eliminate the weakest feature in each iteration until the specified number of features is reached. The feature selection is purely based on the coefficients; in the case of decision tree-based models (i.e., random forest), the feature selection is based on the importance attribute. This study employed Random Forest for feature selection, which identifies the best feature to split at the next node from a subset of features based on a criterion such as mean squared error, which explains variance reduction to minimize the loss [22]. Figure 9 shows the expected prediction performance when using a different number of features. For example, using three features, the expected prediction performance ranges from 0 to 99.79%.

Table 3. Best features and the expected prediction accuracy

Features	Best Features	R^2 %	MSE x10^{-3}	$\pm\sigma$ mm
1	Tgo	43.08	-	-
2	Tgo and ΔPw	99.59	19.1	6.6
3	Tgo, ΔPw and ΔPg (or Mg)	99.79	9.3	4.1
4	Tgo, ΔPw, ΔPg and Mg	99.87	5.5	2.9
5	Tgo, ΔPw, ΔPg, Mg and Tgi	99.87	5.4	2.9
6	Tgo, ΔPw, ΔPg, Mg, Tgi and Two	99.87	5.4	2.9
7	Tgo, ΔPw, ΔPg, Mg, Tgi, Two and Twi	99.87	5.2	2.8

The best combination of input features offering high prediction accuracy is studied using a feature search algorithm using recursive learning. Table 3 shows the best features and the expected prediction performance; it shows the accuracy improves with the number of features. Especially for this application, a minimum of three features are required to get reasonable accuracy. Using the right number of features would also reduce the data requirements and model complexity. The deployment of the developed prediction model estimates the fouling thickness (on the inner and exterior of the tubes) continuously and aids monitoring and analysis. In the CHP system, fouling occurs slowly over a long period of time; therefore, a minimum of six to twelve months of data is required for complete analysis. Generally, the efficiency of WHRS is a key factor in deciding maintenance. For example, maintenance is activated when the efficiency drops below 20% compared to the design condition. By knowing the actual root cause factors, such as fouling thickness, one can decide on appropriate maintenance methods. The proposed prediction model accurately estimates the root cause factors and their severity, which allows the operator to decide on the right maintenance options and cut down on unnecessary downtime and maintenance costs. Even by knowing the root cause, one can

cautiously redefine the tolerance level (i.e., efficiency losses) considering the dependent process system and costs.

Conclusion

This study proposed a predictive maintenance methodology for waste heat recovery systems to identify an optimal time frame accounting for efficiency loss, maintenance cost, and downtime. An AI-based fouling prediction model is a critical requirement for maintenance methodology and was developed using actual data and supplemented data obtained from the thermodynamic model. The developed model helps identify the root cause and predict the fouling thickness with acceptable accuracy. To simplify the prediction model and data requirements, the importance of each feature and its effects on prediction accuracy were examined. The exhaust gas outlet temperature, the pressure drop of the water and gas streams, and the mass flow of exhaust gas are critical inputs or features required for the AI-based prediction model. Interestingly, the pressure drop data greatly helps the fouling prediction as it inherently accounts for the flow and the effective diameter influenced by the gas and water side fouling. The rest of the features help to improve the prediction accuracy and show a marginal effect. Deploying the developed fouling prediction model in the energy management system provides a fouling trend that greatly supports a project in the future time frame to identify the key time or sweet spot for maintenance accounting, proper redundancy, and mitigation plans.

Abstract:
The construction of energy-efficient buildings is one of the most important measures to reduce the impact of buildings on our environment. The dynamic simulation of the energy systems of these buildings can improve the design and performance and thus reduce the emissions that impact the environment. However, the process of creating models for dynamic simulations is time-consuming and error-prone. By using already existing digital models from the planning process the process of model generation can partially be automated. This paper presents the tool `bim2sim` and its underlying methodology for the application of automatic model generation for dynamic hydraulic energy system simulation with *Modelica* based in Building Information Modeling models with the open exchange format IFC. The tool is applied to the use case of an example energy system and a manual comparison modeling is performed for the energy system in *Modelica*. The comparison shows that automatic model generation saves a significant amount of time even for comparatively simple systems.

Keywords:
Building Information Modeling, Hydraulic energy simulation, Modelica, Model generation

1. Introduction

Operation of buildings is responsible for 34 % of energy use and 37 % of carbon emissions worldwide [1]. Improving the energy efficiency of building energy systems can help to reduce the environmental impact of buildings. To increase the efficiency of buildings, dynamic simulation models of building energy systems are becoming increasingly important for both design and operation of buildings. However, the generation of these simulation models is a time-consuming process that requires a high level of expertise. Especially because buildings and their energy systems are unique for every building [2]. In order to increase the dissemination of dynamic simulation models in practice, the effort required to create these models must be reduced. The partially automated creation of models on the basis of already existing digital planning data, such as Building Information Modeling (BIM), is a promising approach. In the field of dynamic energy system simulation, however, there are very few approaches that attempt to convert existing BIM models directly into simulation models. By using the open exchange format IFC and the programing language *Python*, this paper presents a tool and the underlying methodologies to achieve a semi automatic model generation of simulation tools based on BIM models.

2. Related Work

The idea of using data models from digital design and, in particular, BIM data is not new. Especially in the field of thermal building simulation, there are already various approaches to avoid redundancy in the double modeling of planning and simulation models [3–7]. In the area of hydraulic-focussed energy simulations or Heating, Ventilation and Air Conditioning (HVAC) simulation in general, the number of existing approaches is smaller. Bazjanac et al. dealt with the issue of transferring HVAC information from IFC in 2002 and 2004 [8] [9]. The presented *IFCtoIDF* tool used EnergyPlus and the IFC2x2 standard, but the tool is not published. Hauer et al. analyze the presentability of HVAC components in the IFC schema [10]. The most important findings are that the IFC schema even in version IFC 4 does not yet provide sufficient options to represent all relevant components of a HVAC system. Accordingly, linked data must be used for a complete description. Furthermore, they give recommendations for possible extensions of the IFC schema with focus on the energy generators. Andriamamonjy et al. present a methodology for deriving thermal building and plant simulations based on the IFC [11]. The IFC is imported to *Python* with *IfcOpenShell* and the output is a *Modelica* simulation model. The focus is on the analysis of different life cycles and planning stages of the building. The approach uses a direct mapping of the BIM data into the *Modelica* library IDEAS. The presented *IFC2Modelica* approach

and its code is not published as an open source project. In his PhD thesis, Pauen invented the TUBES System Ontology (TSO) and the tool IFC2TSO to provide better understanding of the HVAC systems [12].

A necessary aspect to create executable simulation models is the creation of a control for the energy system. In order to represent this control in the simulation model, the control logic itself, as well as the linking of this logic with the signals of the associated sensors and actuators, are necessary.

Benndorf et al. present the implementation of a control in the IFC scheme using the example of a heating curve, a time-controlled volume flow controller and a temperature control. For this purpose, the IFC schema had to be supplemented by own new components. Furthermore, the concept of linked data sources was also used by using the *IfcOwl* schema to establish connectivity with the building automation control. However, it is noted that the use of BIM in the context of building control and automation is just being developed and existing BIM models and modeling tools cannot yet represent control, which is why they had to be subsequently added to the Revit export of the BIM model using *IfcOpenShell*. [13]

Sporr et al. use the IFC data format in their work to develop a methodology for mapping the control of an energy system for building heating. The methodology uses a combination of TRNSYS and Simulink and relies on additionally created data in addition to the IFC, since the IFC does not provide the necessary information on the producer side. [14]

Existing research already covers investigation and usage of BIM-data for simulation model generation in the HVAC domain, but non of the existing approaches was released in form of a public available tool. Furthermore, most approaches are based on the assumption of a perfect IFC model that contains no errors or lacks information. In reality, BIM models are currently often not yet perfect, for three main reasons. Authoring software has shortcomings regarding the export to IFC (1), the IFC format itself has shortcomings as not all relevant components and their semantic data is covered by the current IFC4 standard (2) and last but not least, model creators often do not add the relevant data to the BIM model, especially semantic data is often missing. Based on the existing shortcomings, a new approach is developed that provides an easy extendible and open source approach that works with non-perfect IFC data to create *Modelica* simulation models based on IFC4 data.

3. Methodology

Even though this article focuses on creating hydraulic energy simulations of HVAC systems, we want to give a brief overview on what `bim2sim` can do in general. In short, `bim2sim` is a tool that includes methods and concepts to read data from an IFC file, convert it to a simulation-oriented `meta-class` structure by collecting as much information as possible from the IFC, perform various types of processes and simplifications on the `meta-classes`, and export the results to a simulation model. This process can be used for HVAC simulations as presented here, but we also implemented methods and concepts to perform Building Performance Simulation (BPS) .The basic idea was already published [15] as well as the application on BPS [5, 16].

The workflow that is used specific for HVAC simulation is shown in figure 1. The Computer Aided Design (CAD) model that is created with a BIM authoring software is exported to an IFC model. This IFC model is loaded into `bim2sim` using *IfcOpenShell* and the relevant IFC elements are converted into a `meta-class` structure in *Python*. This `meta-class` structure is designed regarding the needs of the simulation domain. The `meta-class` instances are then transferred into a graph network that allows to run various simplification processes on the HVAC system to make it exportable to a simulation model. In the following sections the different steps are explained in more detail.

3.1. Importing data from IFC

Since two different object types are used in the conversion process, they are formatted differently for better distinction. *IfcElements* are displayed in italics, and *Python* `meta-class elements` are displayed in code style.

To get the relevant information from the IFC file to perform a semi-automatic simulation model generation, we use the *Python* implementation of *IfcOpenShell* to import the IFC data into *Python*. As Amor has shown, the number of entities, and thus the ability to represent systems in IFC, has increased significantly with the release of IFC 4 [17]. For this reason, `bim2sim` supports only IFC 4.

IfcOpenShell allows us not only to get the relevant data for every component but also to get metadata about the authoring software which is needed later in the process to enrich missing data.

3.2. Preliminary Model Check

In the next step we perform a model check against the loaded IFC. First basic validations are performed, e.g. to check that all *IfcElements* have a unique GUID. Subsequently, element specific checks are performed regarding the existence and correctness of attributes (e.g. the capacity of a boiler). In the last step HVAC specific checks are performed. E.g. all *IfcDistributionElements* are checked if they have ports assigned via the *IfcRelConnectsPortToElement* relationship

The results are displayed in form of an interactive HTML report. The goal is that the engineer who is in charge

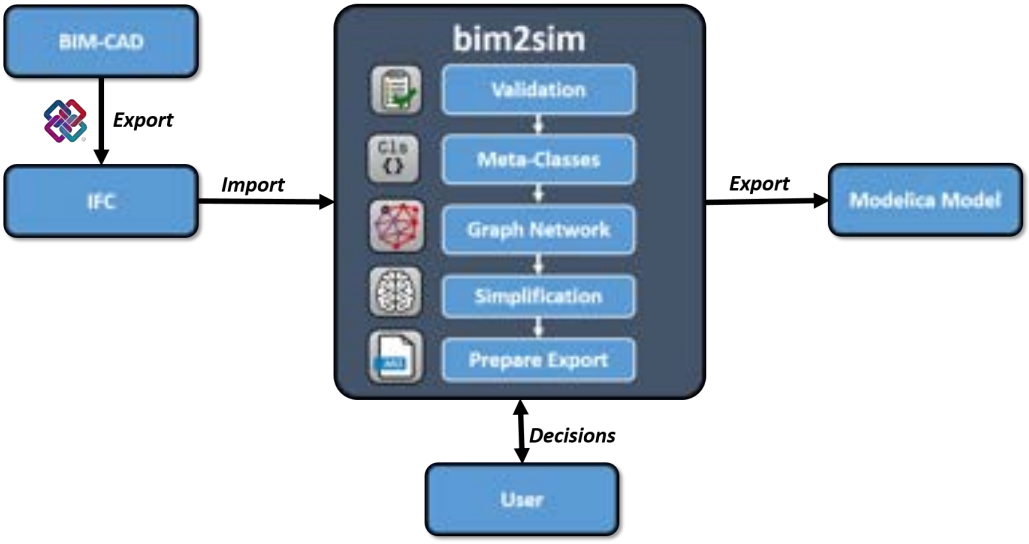

Figure 1: Process of `bim2sim` for HVAC domain.

for the simulations has a document which can be given to the BIM model creator. This document should provide the necessary information about all missing or wrong information inside the IFC model. The BIM model creator can update the IFC export afterwards based on the report.

3.3. Conversion to meta-structure

If the check succeeds the *IfcElements* are converted into the simulation orientated meta structure. This step makes sense, since BIM models for HVAC simulations are still partially insufficiently parameterized. The usage of the meta-structure allows obtaining the relevant information for the simulation from different sources in the IFC. For example, the surface roughness of a pipe can only be taken from the semantic information, but the length and diameter can also be determined via the calculation of the geometry if semantic information is missing. The conversion process consists of two parts. First, the physical instance of the *IfcElement* to be mapped must be identified and second, all relevant information about this class that can be obtained from the BIM data must be collected. The whole process of a `meta-class` element creation for the example of a boiler is shown in figure 2 and is explained in more detail below.

3.3.1. Class mapping

To keep the system modular and easy extendible, we use the class based structure in *Python* to represent each needed element with its own *Python* class. First, we have the base class *IFCBased*, which takes care of general processes such as calculating absolute position and orientation, which is required for all *IfcElements* regardless of their domain. Then we have the *HVACProduct* that inherits from *IfcBased* and adds additional functionality like the connections between ports and elements. This domain specific class is inherited to every element specific class, like the *Boiler* `meta-class`. In this element specific class we define the mapping rules, how to obtain the attributes and additional functions that are required for this process.

The IFC standard uses two information to define an instance of an *IfcElement*: the *IfcElement* itself and the *IfcTypeEnumeration* which allows further specification of the element. In current IFC data, especially in the HVAC domain, we often encounter missing correct declaration of the *IfcElement* and instead dummy classes like *IfcElementProxy* are used. But even if the *IfcElement* is correctly defined, the *IfcTypeEnumeration* is often set to USERDEFINED or completely missing. To overcome these problems and allow `bim2sim` to be used with non-perfect IFC-files, we implemented the possibility to add patterns in the form of regular expressions to look for in the semantic data of the element. This is useful, because even if the *IfcElement* is not correctly defined, the model creator might have entered the relevant information to identify the element as a string in the description of the element.

To make the structure extendible for new elements, these can easily defined as shown in the following example.

```
class Boiler(HVACProduct):
    ifc_types = {'IfcBoiler': ['*', '-EXCLUDING_TYPE']}
    pattern_ifc_type = [
        re.compile('Kessel', flags=re.IGNORECASE),
        re.compile('Boiler', flags=re.IGNORECASE),
    ]
```

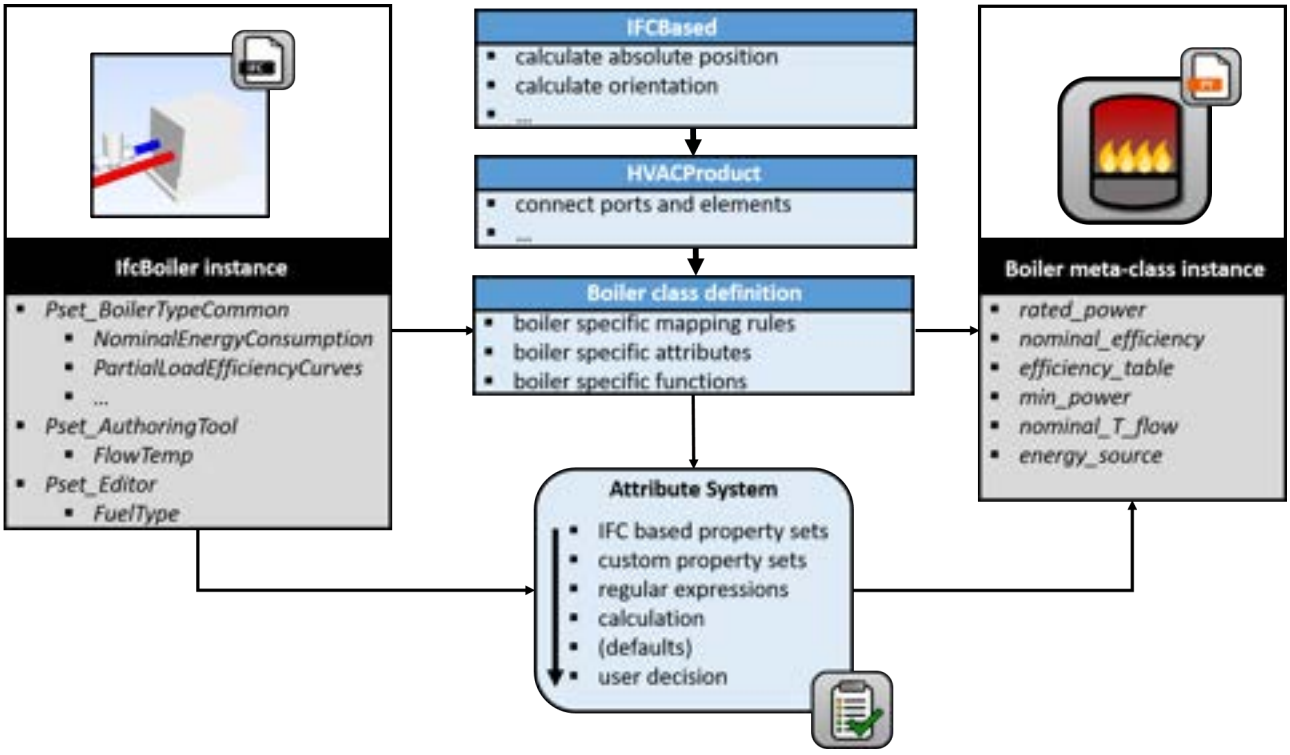

Figure 2: Process of meta class element creation for a boiler.

Based on this definition, the mapping process will first look for elements that are classified as *IfcBoiler* by taking all enumeration types (due to the '*) but the '-EXCLUDING_TYPE' into account. Additionally the process will look for every element that has the strings 'Boiler' or 'Kessel' (german for boiler) in their description. If multiple possible mapping classes are found, a user decision will be triggered.

Based on the defined classes all elements in the IFC will be converted into `meta-class` elements. An overview about all currently implemented classes for HVAC domain and their mapping is listed in Table 1.

Table 1: Mapping between IFC and Meta-structure. *:= all TypeEnumerations are included.

Groups	IFC Element	IfcTypeEnumeration	Meta-Classes
Connections	*IfcDistributionPort*	DUCT, PIPE	`HVACPort`
	IfcDistributionSystem	*	`Medium`
Energy Conversion	*IfcBoiler*	*	`Boiler`
	IfcElectricGenerator	CHP	`CHP`
	-	-	`HeatPump`
	IfcChiller	*	`Chiller`
Hydraulic Distribution	*IfcTank*	STORAGE	`Storage`
	IfcPump	*	`Pump`
	IfcValve	*	`Valve`
	IfcValve	MIXING	`ThreeWayValve`
	IfcPipeSegment	*	`Pipe`
	IfcPipeFitting	*	`PipeFitting`
	IfcPipeFitting	JUNCTION	`Junction`
	IfcDistributionChamberElement	*	`Distributor`
	IfcDistributionSystem	*	`Medium`
Heattransfer	-	-	-
	IfcSpaceHeater	*	`SpaceHeater`
	IfcHeatExchanger	*	`HeatExchanger`
	IfcCoolingTower	*	`CoolingTower`

The *IfcDistributionPort* and *IfcDistributionSystem* have a special role, as they are used to connect the different elements to each other and define the flow direction between the elements. The concept used in IFC to represent connections is shown in figure 3. The `meta-classes` use this concept as well by assigning the respective *HVACPorts* to every `meta-class` element and get additional information about the medium in a circuit from *IfcDistributionSystem*.

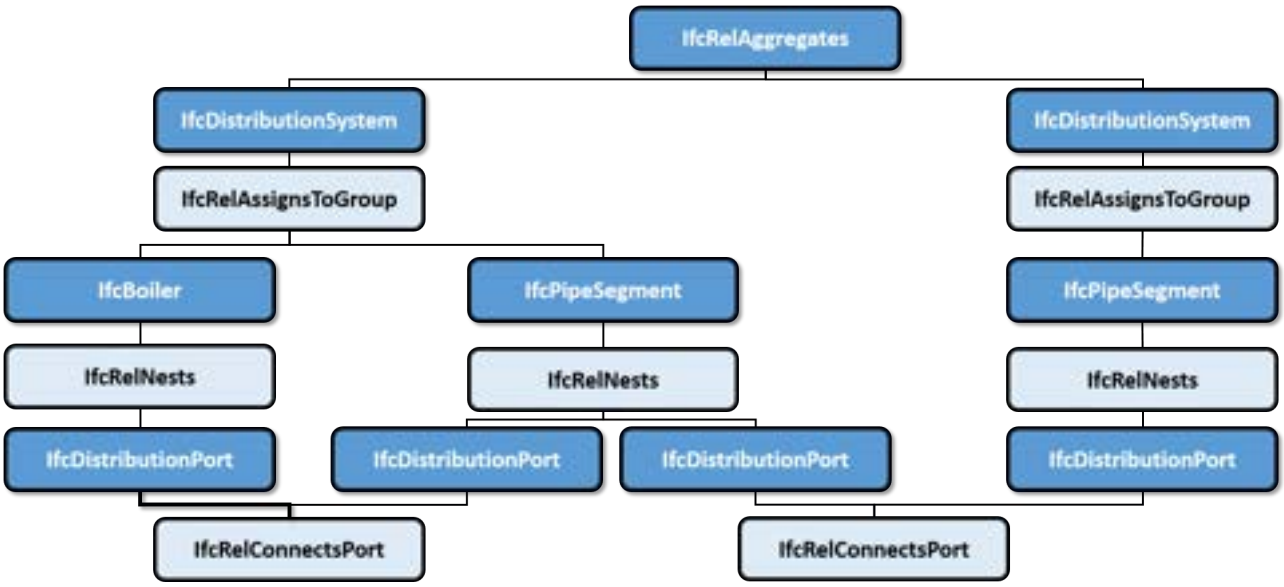

Figure 3: Concept of IFC to represent connections.

It's to mention that due to the fact that the IFC standard does not offer the possibility of directly mapping thermally active components, such as underfloor heating or concrete core activation, are taken care of via the concept of aggregations. Aggregations are explained in more detail in the section 3.4..

3.3.2. Attribute system

The created `meta-class` elements now needs to be filled with the relevant semantic information. On the left side in figure 2, we can see that the *IfcBoiler* provides semantic information included in three *IfcPropertySets* that represent the three different types of property sets that the `bim2sim` tool takes into account.

1. The *Pset_BoilerTypeCommon* as well as the belonging properties are IFC-schema compliant.
2. The *Pset_AuthoringTool* represents a property set that is not IFC schema compliant, but which is nevertheless typical for a specific authoring tool.
3. The *Pset_Editor*, which is a fully custom property set added by an editor. This one is not following any rules.

All three *IfcPropertySets* hold information that are relevant for the simulation model. The first one can be taken directly by implementing the IFC schema into the code. For the second one, additional information for every known export tool needs to be stored. For the last one, regular expressions can be used to find relevant information. Another challenge is that information might be stored implicit, but an additional calculation process is needed to obtain the final data that the simulation model requires.

To obtain all relevant information from the IFC-data we implemented the *Attribute*-system. The *Attribte*-system is a hierarchical approach that searches for a defined information by multiple approaches. The structure in figure 4 shows the usage of the *Attribute*-system to obtain the `nominal_efficiency` and the `rated_power` of the boiler as the IFC standard does not offer pre-defined options to input this data.

In this example, all implemented possibilities to retrieve information from the IFC are covered:

- `default_ps`: get information from property set that is defined in IFC standard
- `functions` and `dependant_attributes`: calculate/convert information into the direct form based on other attributes
- `patterns`: search for attributes based on regular expressions
- `JSON`: an additional file which is used to define typical places where specific authoring tools place information

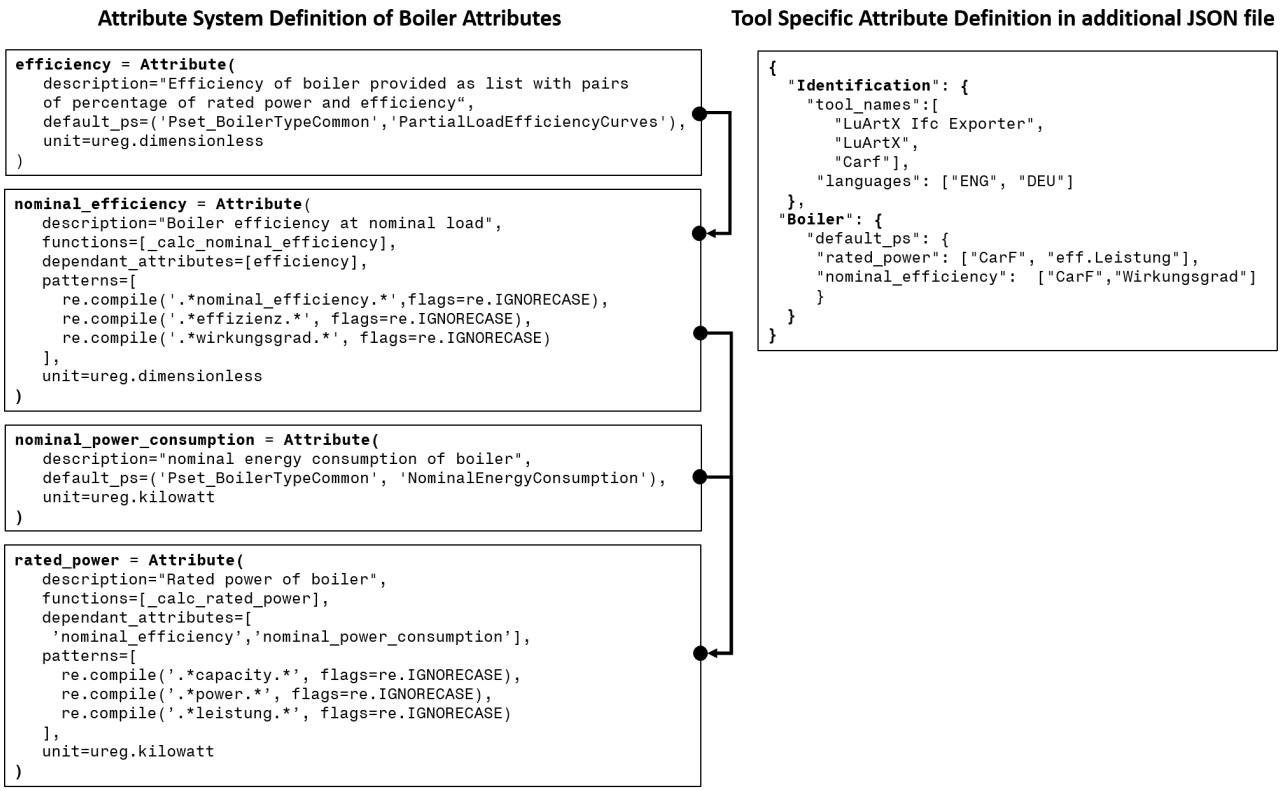

Figure 4: Excerpt of the attribute definition for the boiler `meta-class`.

The IFC-standard only allows defining the efficiency curve as a list of pairs of part load power and part load efficiency, but not `nominal_efficiency` itself. Still, the curve information can be used to calculate the `nominal_efficiency`. The `rated_power` can't be defined in the IFC as well. But based on the calculated `nominal_efficiency` and the `nominal_power_consumption` which can be defined in the IFC, the `rated_power` can be calculated as well.

To meet the goal of being able to generate simulation models even without perfect IFC models, all attributes can also be found in the IFC through the regular expressions as shown. Furthermore, the attribute system searches for dependent properties in the IFC based on the authoring tool defined in `JSON` on the right of the figure. For this purpose, the authoring tool is stored when the IFC file is loaded. As a last option, a user decision is created to retrieve the needed values. However, this is only executed against when the corresponding attribute is needed, either for a calculation of another attribute, or for the export to the simulation model to maximize the level of automation. This is described in more detail in the section 3.5. In addition, the attribute system ensures that all parameters are correctly converted to the specified units, based on the *IfcUnits* specified in the IFC. By using the *Python* package pint [18], it is ensured that later conversions are correct. All these functionalities aren't complex but adding the functionality for all relevant elements in the HVAC domain and in the other domains that `bim2sim` supports without defining a clean, unify and easy to extendible structure would result in non-maintainable code.

3.4. Processing and Simplification

3.4.1. Graph Network Generation

To analyze and simplify the hydraulic circuits the created `meta-classes` and the related HVAC-Ports are converted into a network graph. Network graphs offer the potential to use existing graph algorithms to perform efficient analysis against the hydraulic circuit. `bim2sim` uses two graphs, the `PortGraph` and the `ElementsGraph`. The `PortGraph` uses every `HVACPort` as a node and the edges between the nodes mark the fluid flow between the ports. In the `ElementsGraph` no ports are used, but the elements like a Boiler are the nodes. The `ElementsGraph` graph is an abstraction of the `PortGraph` and is mostly use for visualization. The `PortGraph` is used for most analysis, because it offers information how ports of the same element are connected to each other. This is important as for example a heatpump has four ports, but only two of them are connected with each other in pairs (evaporator and condenser side). `bim2sim` uses the *Python* package *NetworkX* [19] to create network graphs and analyze them.

3.4.2. Aggregations

The concept of `Aggregations` is used in the HVAC part of `bim2sim` to simplify the hydraulic circuit and reduce the numbers of elements to export to the ones relevant for the simulation. This is needed as an export of every `meta-class` instance created based on the IFC directly to a *Modelica* instance would result in an infeasible or at least very slow system of equations in *Modelica*. The simplest example of an `Aggregation` is the `PipeStrand`, which aggregates chains of contiguous connected meta-class elements without junctions to a single `PipeStrand` with an equal total length $l_{total} = \sum_{i=1}^{n} l_i$ and equal diameter $d_m = \sum_{i=1}^{n} l_i \cdot d_i / l_{ges}$. The equivalent parameters are calculated to obtain a simulation model with an equal pressure drop and heat loss. A special case of a `PipeStrand` are coils used for thermal activated building structures, like underfloor heating or concrete core activation. These are specified through the density of pipes (length and number of elements) in a certain area, the distance between the center lines of the pipes.

Using the network graph allows using existing analyze algorithms and classifications. For example, the chain of connected elements can be determined using the degree of the nodes of the graph. The degree of a node is defined as $d_G(v)$ and is calculated based on the number of connections a node has. To find the chain of connected instances without junctions only nodes with a degree of $d_G(v) = [1;2]$ are taken into account which are of the type `Pipe` or `PipeFitting` or `Valve`.

`bim2sim` also includes more advanced aggregations, two of them will be explained in more detail below, the aggregation of parallel pumps and generator cycles. In practice, parallel circuits consisting of several identical pumps are often used in large hydraulic networks for better scalability. In this way, only the required number of pumps can be switched on, depending on the load. For simulation, these parallel circuits can be converted into a single component to reduce the number of equations of the system of equations to be solved and thus the complexity and simulation time of the corresponding model. In 5, the graph network of an example system is shown, which consists of four pumps in the initial state (a), where one of the pumps has a lower power (purple) and three pumps have an identical power (red). There is also a bypass connected in parallel with the four pumps (green).

The algorithm developed allows both a grouping that groups only parallel pumps of the same power and the option to group all parallel pumps. In addition, the an `AggregatedPipeFitting` is also needed, since other connections at the nodes, such as the bypass shown here, should be kept. The result for the case where only pumps of the same power are aggregated is shown in (b), and in addition to the successful aggregation, it also shows that the bypass (green) is still present and the pump with a different power (purple) was not included in the aggregation. The rest of the graph network remains untouched, since only the aggregation for `ParallelPumps` was performed.

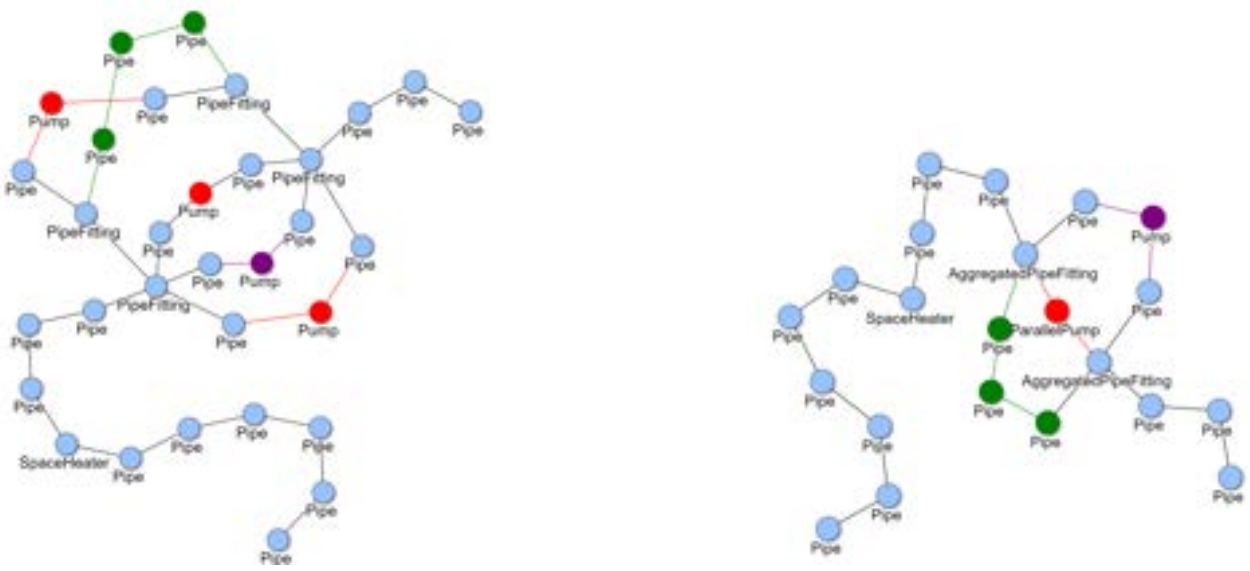
Besides just reducing the elements to be represented later in the simulation model, all relevant information is converted into semantic data. In the case of the aggregation `ParallelPump`, these are in particular the total power of the pumps, the combined nominal volume flow as well as the total length and the average diameter of the adjacent pipelines, which are relevant for the pressure loss.

The aggregation `Generators` is relevant because generator circuits consist of many individual components, most of which have no meaning for the simulation or at least do not need to be represented as individual components.

Figure 6 shows the original state of an example in (a). The example consists of a generator circuit with boiler (red), pump (blue), a bypass with valve (green), an expansion tank (purple), and some other pipe elements. The generator circuit is connected to a distributor (gray), to which four other pipe strands are connected, which represent a simplified consumer.

In (b) the result of the aggregation is shown. The simplified consumer circuit with the four pipe elements remains unchanged. However, the generator circuit can be aggregated into a single component, the `GeneratorOneFluid`. This component contains the information about the type and power of the generator, whether there is a separate pump in the circuit, what the power of this pump is, and the information about an existing bypass. Since the expansion tank is not relevant to the simulation, this information is not tracked further. The algorithm can be applied to parallel generators beyond the example shown. In this case, the parallel generators are converted into one generator that provides the total power.

There are limitations in terms of generator types. So far, only algorithms for generators with one external fluid circuit, such as boilers and Combined Heat and Power (CHP), have been included. Generator aggregation for generators with multiple circuits, such as a heat pump, has not yet been created, since mapping a heat pump in the IFC schema is currently only possible with workarounds.



(a) Before Aggregation

(b) After Aggregation

Figure 5: Graph of `meta-class` elements for `ParallelPump` Aggregation

3.5. Exporting to *Modelica*

3.5.1. Export Libraries

The simplified hydraulic network of the `meta-class` elements must now be translated into *Modelica* models in the next step. As introduced before, we implemented a *Plugin* system to allow multiple tools and libraries to take advantage and reuse the concepts that we built with `bim2sim`. Each *Plugin* that uses *Modelica* can build its own export for the used library by creating *Python* classes that inherit from the base instance. In the current version, `bim2sim` holds two *Plugins* for *Modelica* HVAC export: *AixLib* and *HKESim*. *AixLib* is an open source *Modelica* library that holds simulation models for HVAC simulation as well as BPS and is based on the IBPSA core library [20]. *HKESim* is a non-public library used by the ROM Technik company, who significantly contributed to the creation of `bim2sim`. Its focus is on HVAC simulation. Additionally, some basic components are implemented for the *Modelica* Standard Library (MSL).

Every `bim2sim` *Modelica* export class holds information about the path to the *Modelica* model it is exported to, the `bim2sim` instance it represents and the parameters that should be requested before exporting the model. The most basic definition of an export model is as follows:

```
class StaticPipe(StandardLibrary):
    path = "Modelica.Fluid.Pipes.StaticPipe"
    represents = [hvac.Pipe, hvac.PipeFitting, aggregation.PipeStrand]

    def request_params(self):
        self.request_param("length", self.check_length)
        self.request_param("diameter", self.check_diameter)
```

The `self.check_length` and `self.check_diamter` are optional functions to define, to implement plausibility checks against the parameters. Additional functions might but must not be implemented for a basic export. Table 2 shows the current status of which models are used regarding the libraries.

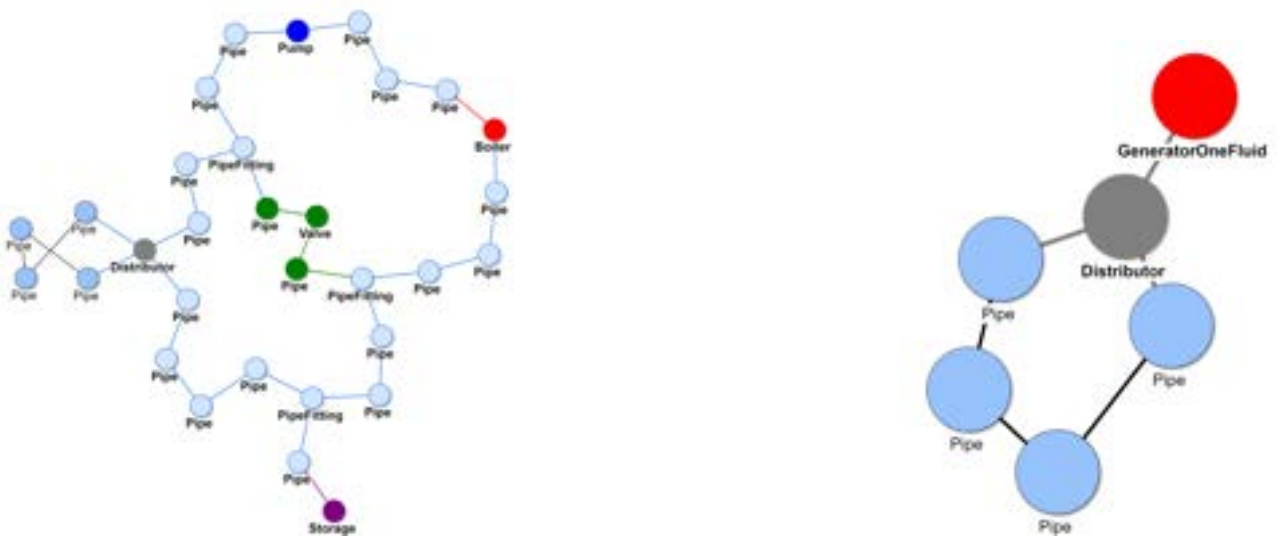
Not all `meta-classes` have a *Modelica* export yet in all libraries, but more export models are currently under development. Furthermore, based on the modular structure, other libraries can be easily added.

3.5.2. Base export instance

To continue the modularity of the built workflow, the export is based on a class structure that can be easily extended. To ensure modularity, we implemented a base class for a *Modelica* export instance that contains the all relevant functionality and can be extended by any *Modelica* instance, regardless of which library it is used in.

Translate *Python* into *Modelica* parameters

Python and *Modelica* both hold the logic for different types of parameters, like boolean, arrays, lists, integers



(a) Before Aggregation

(b) After Aggregation

Figure 6: Graph of `meta-class` elements for `Generator` Aggregation

and floats with unit. To keep extensibility simple, the conversion from *Python* to *Modelica* is defined in the base class. The conversion thus subsequently runs in the background and no longer needs to be taken into account when extending a library with new models.

Unit conversion As mentioned, we use the package *Pint* inside *Python* to obtain and maintain the correct units from the IFC file. To ensure that no conversion errors occur, the output unit for the *Modelica* model can be defined. By default, the values obtained from IFC are always converted to SI units during export.

Numerical validation checks These checks allow the definition of value ranges within which individual values may lie. This way, it should be prevented that unphysical values get into the model.

Keep track of corresponding IFC element(s) For traceability between IFC model and *Modelica* simulation model, each *Modelica* component is assigned the GUID of the corresponding IFC object as a parameter.

Parameter request system As written before, not all parameters relevant for the simulation can be extracted from the BIM model for various reasons. Nevertheless, it should be ensured at the time of export that all parameters relevant for the simulation model are available or at least have been requested. At the same time, the number of user inputs should be minimized. To achieve this, only those decisions are queried during the process whose result is needed immediately. An example of this would be the decision of what type an IFC element has if the IFC class is not uniquely defined (e.g. when using *IfcBuildingElementProxy*). Such a decision must be made directly, because it has an impact on the further process. Information that is only required for the final simulation model export will only be executed during export.

This avoids in many cases that parameters, which are no longer relevant for the exported model, are queried. For example, the parameter for the volume of a storage, which is identified during the process as a pressure equalizing vessel that is not relevant for the simulation model. If a user decision is skipped, or a parameter fails the final numerical validity check, that parameter is noted as unknown in the exported model. Thus, it can be directly recognized in the model which parameters have to be reworked.

Translate port logic The AixLib and HKESim as well as the MSL use the *FluidPorts* of the MSL to connect instances with each other. The definition inside *Modelica* is that *Port_a* is the incoming port of a Model and *Port_b* is the outgoing port. The `HVACPort` of the `meta-class` system and the simplified graph network hold the needed information to connect the respective *Modelica* instances with each other during export.

3.5.3. Usage of modules

Table 2 already included the `GeneratorOneFluidModule` and `ConsumerHeatingDistributorModule`. Equivalent to the `aggregations` used in the simplification of the graph network, new module-based models for the AixLib and HKESim libraries are currently implemented for export. These modules are pre-configured combinations of already existing components of the library, which reduce the needed number of parameters to minimum. These modules also contain basic control strategies, which allows the export of almost ready to run simulation models. The basic control strategies however can easily be overwritten by user defined control strategies which can be connected to the BUS connectors of the modules. For AixLib we already implemented a boiler module

Table 2: Current state of `bim2sim` *Modelica* export to different libraries.

Meta-class	AixLib	HKESim	MSL
`Boiler`	X	X	
`GeneratorOneFluidModule`	X		X
`HeatPump`	X		
`Chiller`	X		
`CHP`	X		
`Storage`	X		
`Pump`	X	X	
`Valve`			X
`ThreeWayValve`	X	X	
`Pipe`			X
`PipeFitting`			X
`Junction`	X	X	X
`Distributor`	X	X	
`Radiator`	X	X	
`Consumer`	X		
`ConsumerHeatingDistributorModule`	X	X	

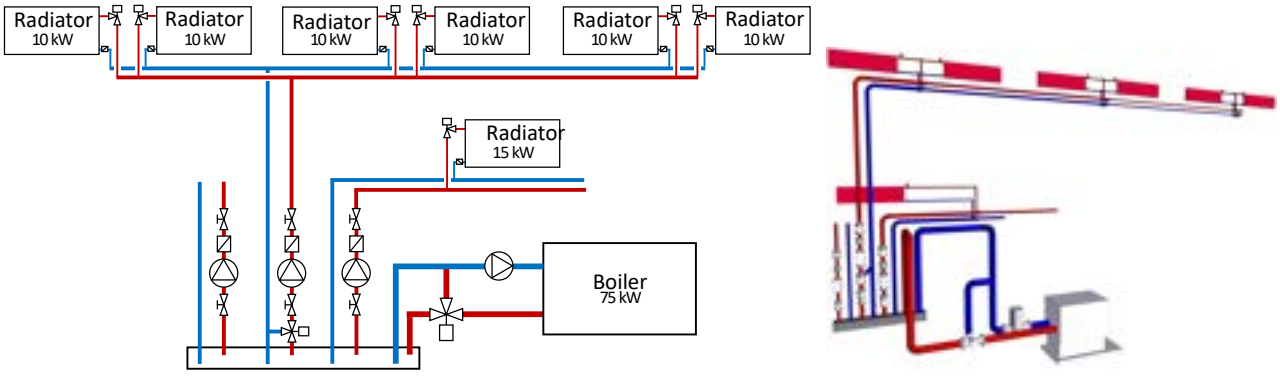
and a consumer module which can be found on GitHub[1]. HKESim won't be discussed because it's an in-house library and not public available.

3.5.4. Export process

The conversion into *Modelica* models is performed based on a dynamic *Mako* template [21]. This template is filled based on the instances and their parameters and connections that are gathered through the previously discussed concepts. During the export, required, but missing parameter trigger decisions to the user. If these decisions are skipped, the parameters will be left empty in the exported simulation model, but a red annotation will be placed on the top level of the model, that gives feedback which parameters are missing. Additionally, the export tries to arrange the *Modelica* instances in a useful pattern, based on the position information from the IFC.

4. Proof of Concept

To prove the functionality of the developed tool, we have created an example use case in cooperation with the software manufacturer LuArtX. This is shown in figure 7 as schematic drawing (a) and screenshot of the IFC model (b).



(a) Schematic drawing (b) IFC model

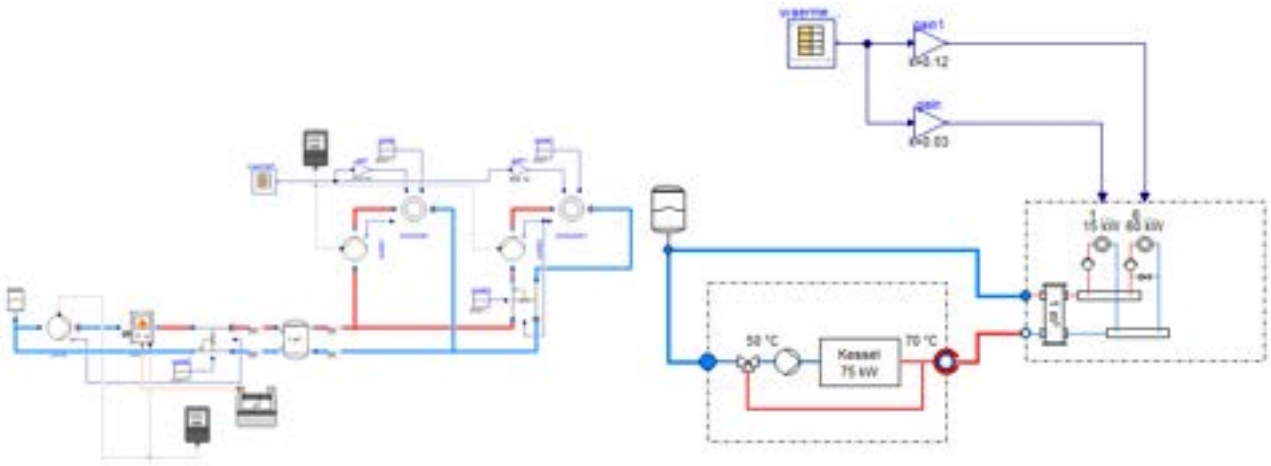
Figure 7: Use case example

The use case consists on the generation side of a boiler for heat generation, a pump, a three-way valve and a bypass for return flow boosting. The consumer side has a distributor, two consumer strands with several

[1] `https://github.com/RWTH-EBC/AixLib/tree/issue1147_ConsumerAndBoiler`

radiators as consumers, of which six radiators are connected in parallel. Each consumer strand has a pump and a valve. One of the consumer strands is an open end and one has a bypass for flow temperature control. The software manufacturer LuArtX improved their CAD software CARF throughout the creation to implement correct export for *IfcPorts*.

Since the creation of *Modelica* models based on plans or 3D models is a common task at the industry partner, both a manual model creation and a partially automated creation by `bim2sim` were performed to demonstrate the potential of the developed tool. The two model exports, both using the in-house library of the industry partner, are shown in figure 8



(a) Manual created model

(b) Automatic created model with `bim2sim`

Figure 8: Exported *Modelica* HKESim models

It took a *Modelica* expert from the industry partner 2 hours and 33 minutes (153 minutes) to manually create the model. This includes the understanding of the energy system based on the BIM model, the parameter gathering and entering, modeling in *Modelica* including connections and sensors, creating usage profiles and removing any errors. Creating the simulation model with `bim2sim` took 6 minutes, including adding the missing parameters and demand profiles. This results in a time saving of 95 %.

5. Conclusion

In this paper, the authors presented a brief review of existing approaches in the field of simulation model generation for the HVAC domain based on digital planing data in the form of BIM models. Based on the discovered gap of public available tools which are able to create *Modelica* simulation models based on non-perfect BIM data in form of IFC, the `bim2sim` tool, and it's application for the HVAC domain were introduced. The core of `bim2sim` is the *Python* library with the same. This includes methods easy extendible methods based on orientated programming to convert IFC data into *Modelica* simulation models. The underlying methodology was explained, and the tool was applied to an example use case to prove the concept. The example showed that even for comparatively simple systems, a significant amount of time can be saved.

Currently, the embedded methods are focussed on hydraulic systems. In the future, the authors plan to extend the functionality to duct systems to simulate ventilation as well. Also, the presented use case covered only a small example system. The next step will be bigger systems with multiple generation devices for heating and cooling.

This paper only gives an overview about the functionality and methodology of `bim2sim`. For more information, the authors refer to the GitHub[2] repository, where documentation and the presented example use case can be found.

6. Acknowledgements

The authors gratefully acknowledge the financial support of the German Federal Ministry for Economic Affairs and Energy in the project “BIM2SIM” (project number 03ET1562A) and "BIM2Praxis (project number 3EN1050A). The authors also want to thank the RD department of Rud. Otto Meyer Technik GmbH & Co. KG and especially Christian Warnecke for the extensive contributions to the code.

Abstract:

District heating networks have proven their higher conversion efficiency, economic viability and environmental benefits when compared to decentralized and individual heating systems. These benefits are achieved through the ability to incorporate a wide variety of production means, including renewable intermittent sources but also via the use of short-term and/or inter-seasonal storage.
Due to the numerous interactions between these components, their different dynamic aspects and operating constraints, physical simulations are computationally heavy so that running optimization tasks become prohibitively expensive and time consuming. Therefore, new control optimization schemes need to be drawn up to accelerate the predictive control and to facilitate the decision-making process.
In the present work, we assess the application of geometric deep learning as a surrogate modeling framework for district heating simulations. Beyond processing non-Euclidian data, this deep learning approach aims to encode geometric and topological understandings of data as inductive biases in deep learning models. More precisely we trained Graph Neural Networks to emulate a thermo-hydraulic simulator of district heating network. This statistical inference method allows us to drastically reduce simulation time, hence unlocking further optimization loops and parametric space exploration. In addition, their permutation equivariance and stability to perturbations are assessed to discuss their scalability to more complex network topologies and control schemes.

Keywords:

District heating networks simulation, graph neural networks, transient dynamics.

Nomenclature

Letter symbols

c	specific heat, $\mathrm{J/(kgK)}$
T	temperature, K
$\dot{m}$	mass flow rate, $\mathrm{kg/s}$
N	number of nodes
N_b	number of branches
M	incidence matrix, $\in \mathbb{R}^{N \times N_b}$
KS	area independent heat transfer coefficient of pipe, $\mathrm{W/K}$
V	volume of the fluid contained in the control volume, $\mathrm{m^3}$
F_ω	inference function

Greek symbols

$\gamma,\ \phi$	differentiable functions
ω	learnable parameters (weights) of inference function
σ	non-linear activation function

Subscripts and superscripts

i	node i
l	at layer l
t	time-step or learning step
s	relative to soil
b	relative to branches
ext	relative to exterior

1. Introduction

Anthropic activities have increased net greenhouse gas emissions since 2010 in all major sectors (industry, energy, transport, agriculture, construction). A study by IPCC Group III [1] investigated ways to mitigate climate change and reduce greenhouse gas emissions. According to their report, switching from fossil fuels to low-carbon energies is essential to limit climate change. In Europe, the production of heat and cold represents half of the energy consumption and is mainly based on fossil fuels [2]. Since the last century, district heating networks (DHN) have been deployed mainly due to their economical and efficiency benefits. For example, having a joint production process, a higher conversion rate and less maintenance allows to decrease the operating and maintenance costs. Moreover, DHN are well suited for areas of mixed use with strong anchor clients [3]. In recent years, due to the rapid development of renewable energy technologies, the 4th generation of DHN have been identified as a viable option to decarbonize the heat production sector [4, 5]. First, they operate at lower temperatures, hence reducing heat losses and increasing the efficiency of conversion systems. They also take advantage of various heat sources including renewable and recycled ones such as biomass, geothermal, solar thermal, and waste heat. Finally, coupling these sources with thermal energy storage (TES) and optimal control should allow a better peak management. However, the use of TES and various heat sources, some of which are intermittent, adds a new complexity to the system including the stochastic character of some variables such as resources availability, weather conditions and electricity price, which therefore implicitly integrate a predictive character in the control and optimization methods of these systems.

In order to successfully operate these advanced thermal networks, an intelligent control strategy is required. A detailed review on control strategies for DHN can be found in [6]. This study shows that the current tendency is to use hybrid control schemes based on multi-agent systems and model predictive control (MPC). This method falls in two parts: first, solving an operational optimization centrally i.e. energy planning, and then it is distributed to other decentralized agents related to consumers and the different producers connected to the network. This strategy involves the simulation of the dynamic behavior of the considered DHN. In fact, the controller needs to understand and predict the behavior of the system and its response to various scenarios of control variables which requires multiple simulations over variable large time horizons. To accomplish this, accurate models of the network's different components and their interactions are required. Several studies have been carried out to develop numerical models of DHN [7–11]. They can be classified in two main categories: dynamic and pseudo-dynamic models. The latter approach considers only the thermal transient and assumes instantaneous hydraulic changes as fluid dynamic perturbations (i.e. pressure variations) are quickly transferred to the whole network, about 1000 times faster than temperature variations [8]. More importantly, when considering intermittent heat sources like solar thermal, it is crucial to use an adapted small time-step for the simulations. Consequently, this makes running iterative optimization methods computationally heavy and time consuming.

One solution to overcome this limitation is the formulation of a numerically efficient and stable surrogate model of DHN simulations. There are several surrogate modeling approaches [12] such as reduced order models, Gaussian kriging, radial basis functions, etc. But lately and due to extensive research and advances in computing technologies, different studies investigated the application of machine learning algorithms as surrogate models for different engineering systems including energy conversion and distribution processes [13–17]. For example, the study in [16] consisted on training a graph neural network to approximate the optimal solution of power flow optimization problem for electric grids. The results showed that the surrogate model is 10^5 faster than the interior point optimization method and it exhibits much better scalability to larger networks. A tutorial review on using neural network for MPC is given in [17]. More specifically, it highlights the use of recurrent neural networks (RNN) to predict the state of the process model. The authors applied this approach to drive the reactants concentration of a non-isothermal continuous stirred-tank reactor (CSTR) to the optimal steady-state point by controlling heating rate and inlet concentration. It was found that the physics based RNN-MPC system converges faster and requires less computational time.

In the field of DHN design optimization and control, machine learning was applied at two different levels. The first one focuses on predicting the thermal load [18, 19] and the second, more recent, on applying deep reinforcement learning to train autonomous agents to optimal DHN operation [20]. However, to the best author's knowledge, no attempt to formulate a surrogate model of DHN simulation using machine learning have been made. Therefore the primary contributions of this work are as follows:

- A flexible physical pseudo-dynamic simulator of district heating network has been developed based on graph theory.
- To the best author's knowledge, this is the first attempt to apply GNN as surrogate model for physical district heating network transients.
- This approach is validated through the prediction of district heating network behavior as the temperatures evolution in each node of the network.
- Using this framework allows to significantly reduce simulation time from hours to seconds, $\sim 10^4$ faster.

This opens the possibility to further develop quasi instantaneous optimal control schemes.

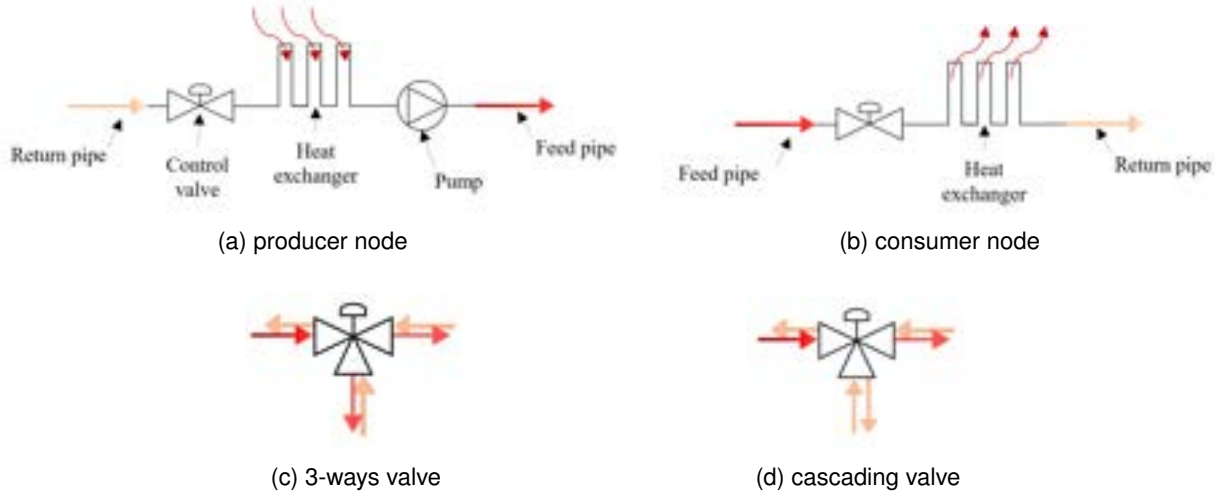
The remaining of the paper is organised as follows: Section 2. describes the physical model that has been developed to simulate transient dynamics in DHN. Section 3. briefly introduces fundamentals of machine learning with a focus on GNN and the final architecture of our surrogate model. Then, section 4. presents the application case that was chosen to evaluate our approach. Finally, the results, limitations and future developments are presented in section 5.

2. Physical model

The physical model that has been developed is intended to serve as a data generator for DHN simulations similarly to what has been done on the electrical network side with the MATPOWER test cases project [21]. The choice of pseudo-dynamic resolution is justified as the time-step of DHN simulations is generally around one hour and recently minutes with the development of IoT sensors. The hydraulic changes are in fact quick and are transferred to the whole network in a period of time of seconds.
The model has been developed in `Python` language. We used `TESPy` (Thermal Engineering Systems in Python) package [22], an open-source physical solver previously validated on different use cases [23–25]. To simulate steady and transient dynamics of DHN, a customised code layer has been built upon this physical solver. Mainly, the first step consisted on defining the topology of the network using graph theory, then physical properties were assigned to each component in order to run the simulations.

2.1. Graph representation

The topology of each DHN is defined using graph theory. Let $\mathcal{G} = (V, E)$ be a graph with a set of N nodes V and a set of N_b edges E. Physically, the edges are the pipes of the network, while the nodes can be either consumers, producers or distribution/control valves. As the flow direction is an important variable, DHN are represented as directed graphs. Therefore, the simulator needs two variables to completely define the DHN. The first is the *oriented incidence matrix* $M \in \mathbb{R}^{N \times N_b}$, which has a row for each node i and a column for each edge j such as $m_{ij} = 1$ if edge j enters the vertex i, $m_{ij} = -1$ if the edge leaves the node and $m_{ij} = 0$ if the two elements are not connected. The second variable is the *nodes vector* $V_0 \in \mathbb{R}^N$ that defines the type of each node with regard to a predefined set of supported node types schematized in Fig.1.
Currently, the consumer nodes are considered to be heat sinks without modeling the sub-station part, producer nodes can be one of the heat sources implemented at this time: gas boiler, biomass boiler and solar thermal collectors. Finally, two types of distribution valves are modeled, 3 ways valves and cascading consumers valve. The next step is to assign the suitable physical characteristics to each component. The methodology and the physical models implemented are detailed in appendix A.



(a) producer node

(b) consumer node

(c) 3-ways valve

(d) cascading valve

Figure 1: The components of each node type supported by the physical simulator

2.2. Numerical methods

Following the graph representation of DHN, the simulator solves the corresponding thermo-hydraulic equations based on the pseudo-dynamic regime assumption. Via a control volume approach, simulating transient dynamics of DHN yields to the following equations for the hydraulic part (see [9]):

$$M \cdot G + G_{ext} = 0, \tag{1}$$

$$M^{\intercal} \cdot P = R \cdot G - W. \tag{2}$$

In Eq.1, $G \in \mathbb{R}^{N_b}$ is the vector containing the flow of each branch, $G_{ext} \in \mathbb{R}^{N}$ the vector containing the extractions or injections of flows that occur at the nodes.
In Eq.2 $R \in \mathbb{R}^{N_b \times N_b}$ is a diagonal matrix containing the hydraulic resistance of each pipe, $W \in \mathbb{R}^{N_b}$ contains the pressure increases due to the work of the pumps and $P \in \mathbb{R}^{N}$ the vector containing the values of the *total pressure* in each node. It should be noted that equations 1 and 2 form a non-linear system given that R depends on G. This system is solved using Newton-Raphson algorithm, G and P being the unknowns of the system.
After the steady hydraulic regime is solved, i.e. the pressure and mass flow rate in each node are known, the thermal transient regime is obtained by following the direction of flow in the network and considering each pipe as a control volume with the outlet temperature as unknown (Fig.8a):

$$\rho c_p V_j \frac{dT_i}{dt} = c_p G_j \left(T_{i-1} - T_i\right) - K S_j \left(\frac{T_{i-1} + T_i}{2} - T_s\right) \tag{3}$$

In case of more than one pipe entering a node i, the temperature of this node is calculated considering a perfect mixture assumption. The heat losses are calculated considering the average temperature of each pipe, this assumption is generally applied in numerical models considering that the temperature drops very slightly along a single pipe segment between two nodes [27]. Formulating Eq.3 for the whole network leads to a linear system that is solved using Euler implicit scheme.

3. Surrogate model

In this section we introduce the surrogate model (SM) architecture that was used for our imitation learning problem. The output of the model can be any variable of interest, but without loss of generality, in this work the SM is trained to predict the evolution of the return temperature at each node given the network topology, its physical characteristics, heat demand and a set of control laws.

3.1. Supervised learning

The aim is to train the SM to emulate the thermo-hydraulic simulator of a DHN. More precisely, let X be the set of inputs given to the physical model and Y the outputs through the physical equations detailed in section 2.2. The SM takes the same inputs and imitate the physical simulator by constructing an *inference function* F_ω such that $Y_\omega = F_\omega(X)$ where ω is a vector of parameters, called weights, that are adjusted during the training step to minimize a specific loss function $\mathcal{L}_\omega$ (i.e. residual function), for example the L_2 norm (i.e. Euclidean norm) $\mathcal{L}_\omega = \|Y_\omega - Y\|_2$.
This is known as a supervised learning problem since we have both the input and output data, unlike unsupervised learning where the goal of the model is to find patterns in the input data to classify them for example. More schematically, the learning process corresponds to an optimization loop where the weights of the model are corrected iteratively in order to reach a global minimum of the loss function as illustrated in Fig.2. The figure also introduces the first *hyper-parameter* of the SM: the learning rate α which modulates the convergence speed of the model.

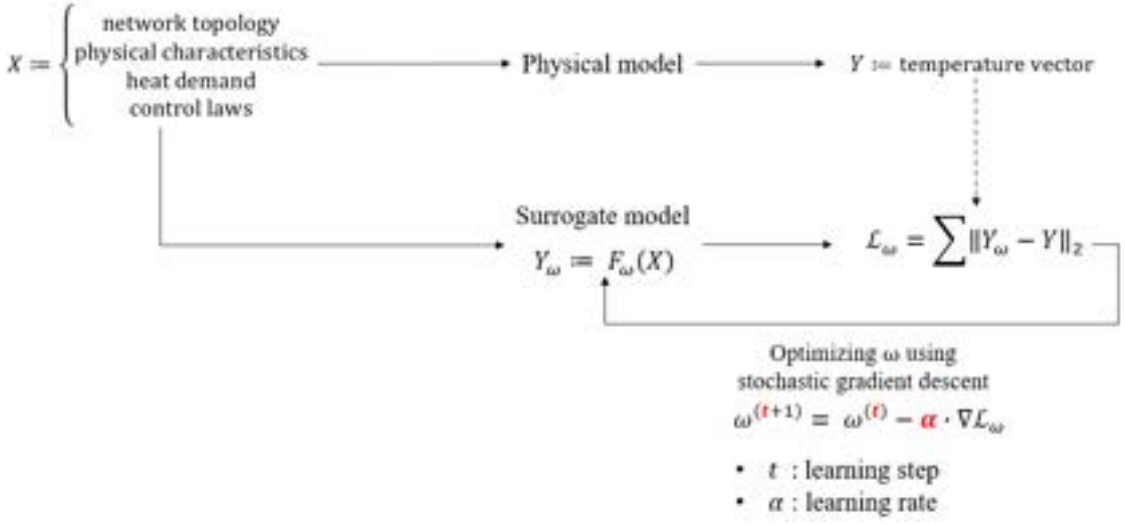


Figure 2: Supervised learning loop of a surrogate model

3.2. Multi-Layer perception networks

The task of constructing the inference function F_ω is an active research area in machine learning. However, deep learning is a particular sub-domain of machine learning where extensive developments are being made continuously. This framework is mainly based on artificial neural networks (ANN) as the learning structure. The simplest ANN is called Multi-Layer Perceptron (MLP) which consists of interconnected layers of artificial neurons, named perceptrons. The neurons in each layer are connected to the neurons in the next layer, forming a directed acyclic graph. Each neuron receives inputs from the neurons in the previous layer, applies a linear transformation to the inputs, and passes the result through a non-linear activation function. The output of a neuron i in layer l is computed as follows:

$$x_i^{(l+1)} = \sigma\left(\sum_{j=1}^{n_l} w_{ij}^{(l+1)} x_j^{(l)} + b_i^{(l+1)}\right), \tag{4}$$

where $x_j^{(l+1)}$ is the output of neuron j in the previous layer, $w_{ij}^{(l+1)}$ is the weight of the connection from neuron j in layer (l) to neuron i in layer $(l+1)$, $b_i^{(l+1)}$ is the bias of neuron i in layer $(l+1)$, n_l is the number of neurons in layer (l) and σ is a non-linear activation function, for example the rectified linear unit function $\texttt{ReLU}(t) = \max(0, t)$. Intuitevely, the activation function either allows the neurons to communicate its output to the next one (i.e. activated) or not when the output does not meet the activation criterion.
Finally, the output of the MLP is the output of the last layer of neurons $\hat{y} = x^{(L)}$. Where $\hat{y}$ is the predicted output, and L is the number of layers in the MLP.

3.3. Graph neural networks

Message passing operation

GNN are a class of neural networks designed to operate on data represented as graphs. GNN aim to learn representations of nodes or the entire graph, which can be used for various tasks such as node classification, node regression, link prediction, etc. The key idea behind GNNs is to iteratively update the representation of each node by aggregating information from its neighboring nodes. This is done by *passing messages* between nodes using a set of learnable parameters. The message passing operation can be formulated as in [28]:

$$\mathbf{x}_i^{(l+1)} = \gamma_\omega\left(\mathbf{x}_i^{(l)}, \bigoplus_{j\in\mathcal{N}(i)} \phi_\omega\left(\mathbf{x}_i^{(l)}, \mathbf{x}_j^{(l)}, \mathbf{e}_{j,i}^{(l)}\right)\right), \tag{5}$$

where $x_i^{(l)}$ is the representation of node i at layer l, $\bigoplus$ a differentiable permutation invariant function (sum, mean, etc.) and $\mathcal{N}(i)$ is the set of neighboring nodes of node i. Finally, γ_ω and ϕ_ω are differentiable functions with learnable weights ω such as MLPs defined in section 3.2. $\mathbf{e}_{j,i}$ is the edge representation connecting node j to node i.
In each layer of a GNN, the representations of all nodes are updated using the message passing operation, resulting in a new set of node representations at the next layer. This process is repeated for multiple layers, allowing the GNN to capture increasingly complex dependencies between nodes. $X^{(l)} = [x_1, \dots x_N]^\intercal$ is the matrix containing the updated representations of the nodes at layer l. If the GNN has L layers, then one has $X^{(0)} = X$ i.e. the initial inputs of the model and $X^{(L)} = Y_\omega$ i.e. the final outputs. For a more guided and detailed presentation on GNN, see [28–30].

Graph attention networks

Graph Attention Networks (GATs) are a type of GNN that uses attention mechanisms to selectively aggregate information from neighboring nodes [31]. The attention mechanism allows GATs to learn different weights for different neighbors of each node, depending on their relevance to the prediction task. Following the definition in Eq.5, the graph attention operation is written as:

$$\mathbf{x}_i^{(l+1)} = \sigma\left(\alpha_{i,i}\mathbf{W}\mathbf{x}_i^{(l)} + \sum_{j\in\mathcal{N}(i)} \alpha_{i,j}\mathbf{W}\mathbf{x}_j^{(l)}\right), \tag{6}$$

where $\alpha_{i,j}$ is the attention coefficient for each neighbor j of node i and σ a non-linear activation function. In a GAT, the representation of each node i at layer l is computed as a *weighted sum* of its neighbors' representations, where the weights are learned using an attention mechanism [31]. The interest of this method here is that physically, nodes in a DHN are first impacted by their upstream neighboring node along the direction of flow, and then by the other nodes in a lesser degree.

4. Study case

4.1. Model architecture

The inference problem shown in Fig.2 involves the use of heterogeneous inputs. Here we will distinguish them according to their static or dynamic character and then according to whether these data are local or global, in other terms whether they are defined at nodes and edges levels or at graph level. First, let $\mathcal{H}$ be the horizon of prediction of the SM and Δt the time-step such that $\mathcal{H} = p \times \Delta t$ and p the number of data points. We define:

- Static nodes attributes: here we simply map the node type to a predefined scalar $\{producers = 0,\ valves = 0.5,\ consumers = 1\}$. This input will be noted $X_s \in \mathbb{R}^N$
- Static edges attributes: as each edge represents a pipe, the attributes are the pipe length L, inner diameter D and its equivalent thermal resistance KS. Subsequently, this variable is noted $E_s \in \mathbb{R}^{N_b \times 3}$.
- Dynamic nodes attributes: it consists of a matrix containing the evolution of heat demand at each node that will be noted $X_d \in \mathbb{R}^{N \times p}$. For distribution valves and producers, the heat demand is computed as the sum of the heat load at their children nodes.
- Global dynamic attributes: this input includes the control signals that affect the whole network, in our case these will be the evolution of the supply temperature $T_s \in \mathbb{R}^p$ and total mass flow rate $G_{tot} \in \mathbb{R}^p$. This input also holds the evolution of the external temperature along the prediction horizon $T_{ext} \in \mathbb{R}^p$.

The network topology is implicitly included during the learning phase via the *adjacency* list that is used by the graph attention operation in order to select the neighbors of each node. Following the above definitions, the SM architecture is in the form of an encoder-processor-decoder as shown in Fig.3. The encoder consists of two MLPs that transform the input data and project it into a latent space where each node is assigned two hidden vectors representing respectively its local attributes (heat demand) and also information from global variables updated with neighbors representations using three graph multi-head attention layers. The processor parts consists on transforming the node hidden representations using three multi-headed attention operations, found to be more efficient than single headed attention in [31]. Finally the decoder is composed of two linear layers that maps the nodes representation to the output space. The model was implement using `Pytorch geometric` library [33].

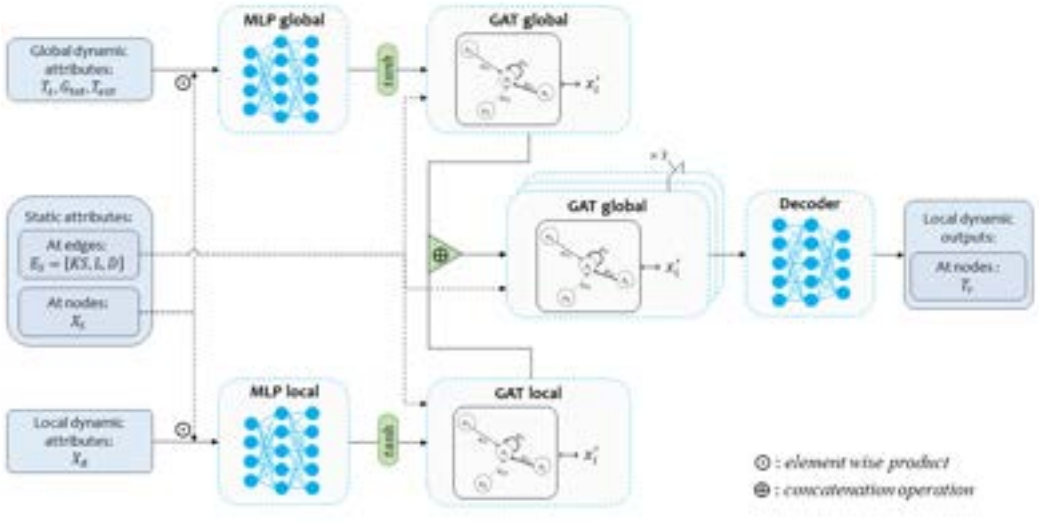

Figure 3: Surrogate model encoder-processor-decoder architecture

4.2. Data generation

In order to assess our approach, we chose to apply it on the academic study case modeled in [32]. This choice is based on the availability of data needed by the physical simulator. The site includes buildings of different usage profiles as shown in Fig.4 where the number under each node indicates its index. Given the annual heat load for each consumer and a typical external temperature variation, we generate an hourly consumption profile for each building using the geometric series approach implemented in `demandlib` library [34], a Python package that allows to create heat profiles from annual values. The supply temperature T_s depends on the outside temperature according to the adapted water law from [35]. For the total flow rate G_{tot}, it is determined

by energy balance over the entire network. The network operation is then simulated for one year with a time step $\Delta t = 600s$. The simulation time is equal to $t_{sim,4c} = 182.1min$ using a four cores CPU processor, which is equivalent to $t_{sim,1c} = 636.2min$ of single core CPU time.
The outputs are time series of $8760 \times 6 = 52560$ data points for each node, representing the evolution of temperatures. Then, we split the data into two datasets, 75% for training and 25% for validation. The horizon of prediction defined in section 4.1. is set to 1 week $= 7 \times 24 \times 6 = 1008$ data points. Thus 39 weeks are used for training and 13 for the validation. Typical values were used for the model hyper-parameters:

- The learning rate α is set to $\alpha_0 = 1 \cdot 10^{-3}$ with an exponential decay factor of $k = 5 \cdot 10^{-4}$, meaning that $\alpha = \alpha_0 \times e^{-kt}$ where t is the epoch number. Therefore, the learning rate is reduced as the training advances which slows down the gradient descent as the loss function approaches its minimum.
- The batch size is the number of samples processed before the model is updated. Here it is set to 8, a compromise between the volume of available data and a large batch size.
- The number of epochs is the number of complete passes through the training dataset. In our case, the model was trained over 200 epochs.
- Finally, L_2 norm was used as the loss function.

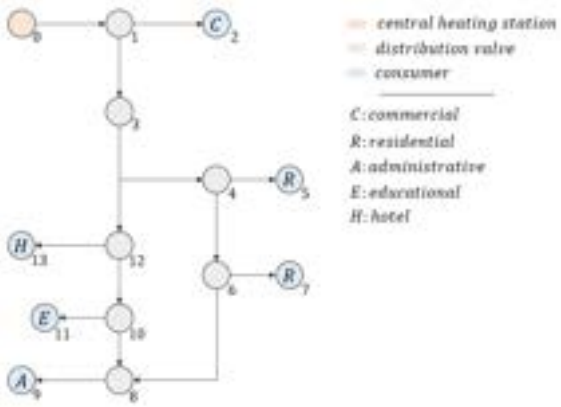

Figure 4: DHN topology of the study case adapted from [32]

5. Results and discussion

After the training phase, the model has been tested on the validation dataset. The root mean squared error (RMSE) is used to evaluate the model performances. It can be seen from table 1 that the error stays below 0.7K for all nodes. Moreover, we report a more visual plot in Fig.5a & 5b for predictions of the node 9, which is an administration building, and the furthest consumer node from the central heating plant. Also, the predictions for node 13, which is a different consumer type, are given in Fig.5c & 5d. More precisely, we plot the normalized temperature (Eq.7), this scaled variable is inherent to the the SM training that fits better with normalized variables (both inputs and outputs) which helps to stabilize the gradient descent step.

$$T^* = \frac{T - T_{min}}{T_{max} - T_{min}}, \tag{7}$$

It can be seen that the prediction results are very close to the values obtained from the physical simulation.

Table 1: RMSE for return temperatures prediction on validation dataset

node	0	1	2	3	4	5	6	7	8	9	10	11	12	13
RMSE (K)	0.5	0.3	0.7	0.2	0.3	0.3	0.5	0.3	0.2	0.1	0.1	0.1	0.1	0.1

The biggest deviations are found at the peaks where the SM underestimates the minimum temperature values and slightly overestimates the maximum values. We also added the Pearson correlation coefficient r that is equal to 0.84 in this case, reflecting a good correlation. The inference time is equal to $t_{inference} = 0.15s$ against $t_{sim,4c} = 2700s$ for the physical simulation on the validation dataset which accounts for approximately 1.8×10^4 time gain.

The regularity observed in the return temperature is the direct effect of the heat profile of the consumer and also the small impact of the control variables that vary quite moderately. Additionally, the same results are shown for node 4 in Figs.5e & 5f. In this case, we observe that the trend is not perfectly fitted while the SM still captures the peak values. Given the scales on both figures, the error, RMSE $= 0.3K$ is still small and acceptable. However, this overestimation of temperature will impact the energy balance on the graph level. This indicates a lack of physical representation in the SM parameters.

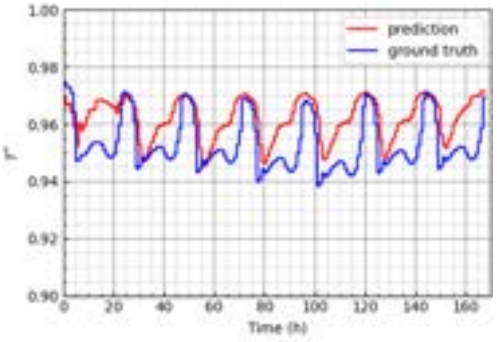
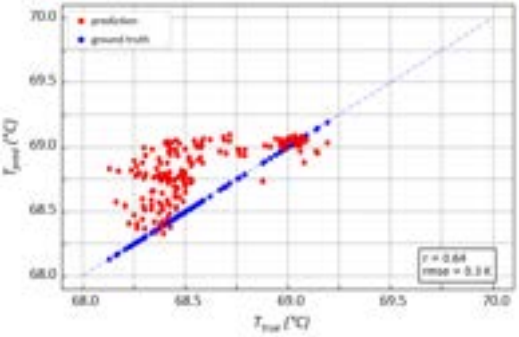
(d) Predicted values as a function of ground truth values for node 13



(e) Temperature prediction over 1 week for node 4



(f) Predicted values as a function of ground truth values for node 4

Figure 5: Example of predictions for nodes 4 (valve), 9 (administration building) and 13 (hotel)

In order to test further the model adaptability and its sensitivity to control laws, we tested it with new simulations where the supply temperature curve and the total mass flow rate were changed more often. Physically, this implied that the return temperature at each node was more affected by the control variables than the heat load itself. The model was not able to capture the correct patterns as illustrated in Fig.6. This limitation originates from an imbalance between the two encoding blocks where the local MLP seems to affects more the prediction. One way of adressing this problem is to incorporate physical laws during the learning phase. More precisely, it is possible to add physical constraints on the predicted values as part of the loss function, in our case this

could be the mass and energy conservation equations that have to be verified at each iteration. Another line of exploration is to use recurrent neural networks such as Gated Recurrent Units (GRU) or Long-Short Term Memory (LSTM) cells that better incorporate the notion of temporality and time dependence into the inference function. Finally, another option is to train the model on more data and different network structures which will allow the SM to better emulates the physical behaviour of DHN.

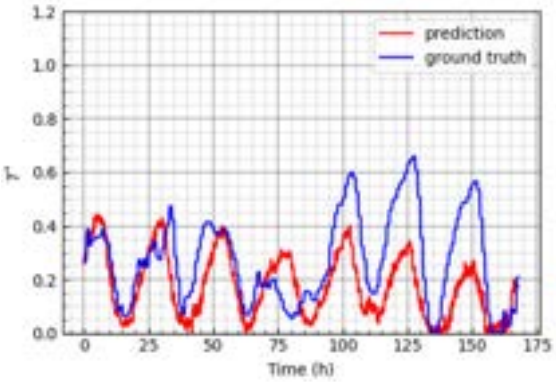


Figure 6: Example of prediction for node 13 (hotel) with a different control law

6. Conclusion

To conclude, the use of geometric deep learning as a surrogate modeling framework for district heating simulations has been evaluated in this study and offers promising results. By leveraging the ability of this approach to process non-Euclidean data and incorporate geometric and topological understandings of data into deep learning models as inductive biases, Graph Neural Networks were trained to emulate a thermo-hydraulic simulator of a district heating network. This statistical inference method has enabled us to significantly reduce simulation time by 10^4 orders of magnitude. Nevertheless, this approach was inadequate to properly capture the physical relations when the control laws are sharper. Therefore, we are currently working on incorporating physical constraints in the surrogate model to alleviate this limitation along with using recurrent structure to leverage more the time dependencies of the data. These improvements will be the subject of a future publication.

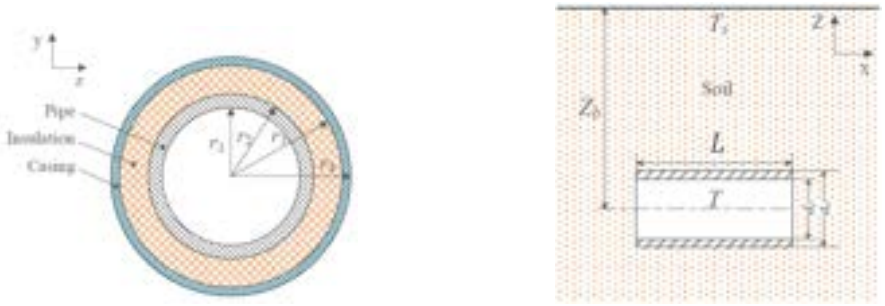
Appendix A Adding physical inputs to the simulator



(a) pipe cross section (b) buried pipe

Figure 7: Schematic diagram of an insulated pipe [26]

Once the network topology defined, the physical properties of each component are fed to the model:

- Branches: the *oriented incidence matrix* M allows to create connections between nodes. Each edge corresponds to two pipes, the feeding pipe and the return one. We implement two layers insulated pipes as in [26]. Therefore, all the geometrical quantities $(L, r_1, r_2, Z_b \dots)$ shown in Fig.7 are inputs to the model, in addition to thermal conductivities k and roughness ϵ for determining pressure loss in the pipes.

- Producers: here, the inputs to the model vary depending on the heat source type. As the study case in section 4. considers only gas boiler, the required inputs are $\dot{Q}_{max}$ which is the maximum heat rate of the plant, pr the outlet/inlet pressure, and the isentropic η_s efficiency of the pump coupled to heat source.
- Valves: a quasi-incompressible fluid is assumed, which is always the case for liquids. The fluid flow between the inlet and the outlet of the valve is assumed to be isenthalpic. The flow rate is governed by the equation 8 derived from Bernoulli's law. K_ν is the required input by the model.

$$\dot{V} = K_\nu \sqrt{\Delta P}. \tag{8}$$

- Consumers: similarly the outlet/inlet pressure ratio is needed, and the heat load can be either a scalar if steady state resolution or a vector in the case dynamic simulation.

Finally, the model also needs global inputs that are the external and ground temperatures. The solver comes with its proper verification tools that make sure the system is nor over or under determined. Depending on the resolution scheme and the aim of the simulation, the unknowns of the system have to be chosen carefully. However, and without loss of generality, we will consider the particular case where the DHN is already designed, the variables of our system are the supply temperature at the heat source T_s and the total mass flow rate G_{tot}.

Abstract:

Residential and commercial buildings account for more than one-third of global energy-related greenhouse gas emissions. Integrated multi-energy systems at the district level are a promising way to reduce greenhouse gas emissions by exploiting economies of scale and synergies between energy sources. Planning district energy systems comes with many challenges in an ever-changing environment. Computational modelling established itself as the state-of-the-art method for district energy system planning. Unfortunately, it is still cumbersome to combine standalone models to generate insights that surpass their original purpose. Ideally, planning processes could be solved by using modular tools that easily incorporate the variety of competing and complementing computational models. Our contribution is a vision for a collaborative development and application platform for multi-energy system planning tools at the district level. We present challenges of district energy system planning identified in the literature and evaluate whether this platform can help to overcome these challenges. Further, we propose a toolkit that represents the core technical elements of the platform. Lastly, we discuss community management and its relevance for the success of projects with collaboration and knowledge sharing at their core.

Keywords:

Energy System Planning; District Energy Planning Platform; District Data Model; Renewable Energy Integration.

1. Introduction

In the effort to accelerate the transition towards climate neutral energy supply at the district scale, many tools exist that aim to solve individual parts of the district energy system planning process [1], from stochastic occupancy simulation [2, 3] and thermal building simulation [4] via building and district level energy technology sizing [5], to simulations of heat and electrical grids [6, 7]. It is the combination of numerous data sources and tools that is required to provide solutions to the heterogeneous tasks of energy system design.

For each step of the planning process, research is published on how to improve predictions, models and simulations; new models and tools will continue to come. Therefore, whoever wishes to combine tools into a district energy system planning workflow needs to go through continuous efforts to keep up with newly developed tools, improved methods and updated data [8, 9]. The following paragraphs provide an overview of challenges, existing tools and platforms in the field of district energy system planning.

Keirstead et al. [10] review urban energy system models and identify model complexity, data quality and uncertainty, model integration, and policy relevance as the prevailing challenges in urban energy system modelling. They see opportunities in creating an integrated framework where sensitivity analysis, data collection and integration techniques and activity-based modelling, promise advances in the aforementioned challenges. Yazdanie et al. [11] review gaps and solutions for advancing urban energy system and modeling approaches. They state that numerous models and planning tools as well as review articles discussing their features exist, but the gaps and corresponding solution suggestions are rarely discussed. They identify key methodological solutions to be: integrated modeling approaches and comprehensive energy modelling scenarios including social factors and system imperfections and data collection using privacy control, robust and secure communication architecture and improved data sharing platforms.

In between the two review articles, several tools and frameworks have been published, that attempt to solve some of the identified challenges. Bollinger et al. [8] introduce a Holistic Urban Energy Simulation Platform (HUES). They motivate the platform with the need to reuse and integrate existing computational models for urban multi-energy simulation for integrated studies of urban infrastructures. Multi-model ecology is the defining concept of their platform. Fonseca et al. [12] present the CityEnergyAnalyst, a framework for the analysis and optimization of city and district energy systems. It supports the analysis of energy, carbon and financial

benefits of competing design scenarios of optimal distributed generation systems by estimating local energy potentials and simulating energy systems and building energy performance. El Kontar et al. [13] present URBANopt, an open-source software development kit for community and urban district energy modelling. The developers argue that a wide variety of building modeling tools exist, but to address planning problems at an urban scale, these tools need to be combined, which motivates a platform where multiple input formats are supported and this data is mapped onto underlying simulation engines. The combination of modules allows for customized workflows. Wehkamp et al. [14] analyze the challenges of planning and evaluating district energy systems and present a workflow using open-source tools and special purpose models that were demonstrated on a district in northern Germany. The authors identify complex stakeholder structures as an issue requiring further research.

Coming from this state of the literature, we provide a brief overview of the challenges faced in integrated district energy system planning. We then present the components of the collaborative district energy system planning platform as a suitable starting point for further development. Due to the ever-changing landscape of tools under current and future development, we expect different tools to extend or replace the initial toolkit. Finally, we discuss how community management is a potential differentiator between failure and success for this vision.

2. Problem setting

District energy system planning is an interdisciplinary field where planning problems vary widely in terms of the scope to be considered. For clarity, we introduce the system boundaries of district energy systems (DES), which frame the challenges considered in this work. Related literature sometimes refers to urban energy systems (UES), which we consider to be a superset of DES. We address the considered scope of DES planning and the challenges associated with it.

2.1. Considered scope of district energy system planning

Several dimensions need to be considered when planning DES. DES planners have to take into account not only energy conversion, but also policy frameworks, stakeholder interests and business models [10]. Key issues to be addressed during planning include sector coupling, centralized versus decentralized energy supply, demand forecasting, building refurbishment and competing stakeholder interests.

In DES, the energy consumption sectors (e.g. households, commerce, and mobility) as well as the energy supply sectors (e.g. electric power, heat and gas) co-exist. During the planning of energy systems, synergies can be leveraged by considering all sectors at once. Whether it is the use of waste heat from nearby industry or the integration of bi-directional e-mobility into a district power grid, successfully linking the consumption sectors requires the development of appropriate business models, which may be complicated by regulation. Coupling the energy sectors, especially heat and electricity, enables the efficient use of locally generated renewable energy. Therefore, both electricity and district heating networks are crucial for DES planning.

Local energy generation (energy hubs) can play a central role in this [8]. Since conditions vary in each district, various technologies (e.g. heat-pumps, photovoltaic, fuel cells) with different operating and investment costs and both decentralized (building supply) and centralized energy systems (energy hub) should be investigated.

In order to be able to plan DES, the energy demand of the district must be known or determined. Since the available demand data is often incomplete, many methods to generate load profile data have been developed over the recent years [12]. The energy demand depends, among other influences, on building types, type of use, refurbishment status and user preferences [15]. For this reason, optimizing the refurbishment status of the buildings is another important research field and part of a holistic DES planning.

Figure 1 illustrates the system boundaries of DES planning. A district usually consists of a heterogeneous building stock or newly planned buildings. As the type of use and the state of renovation have a strong influence on the energy demand, both are part of the system boundaries. The secure energy supply of the district is guaranteed by transmission networks. In the context of energy transition, heating networks play an increasingly important role, as does the consideration of e-mobility.

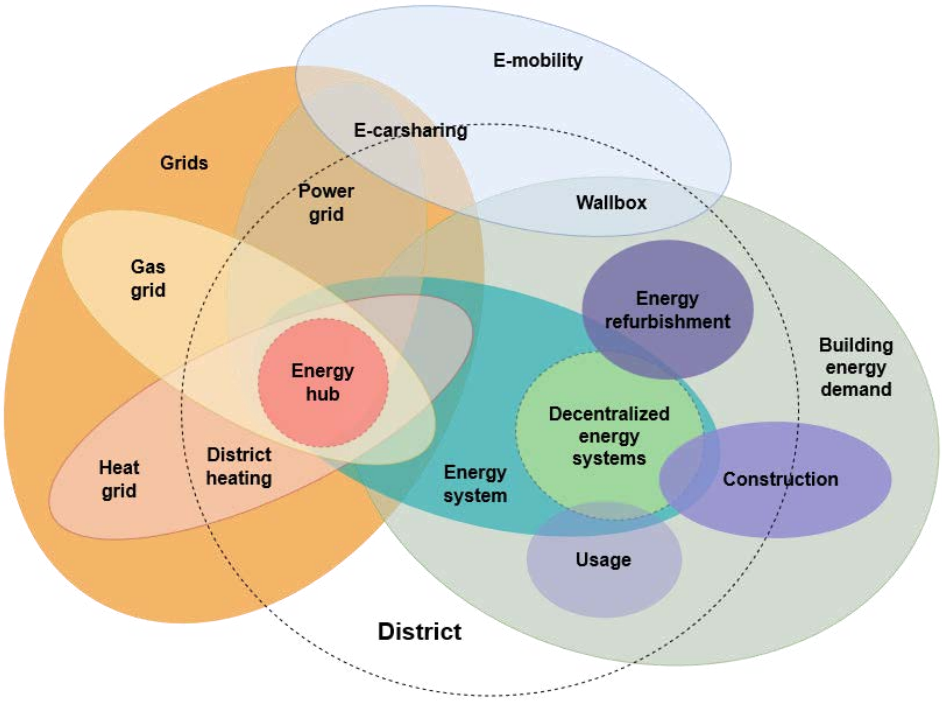

Figure 1. System boundaries of district energy system planning

DES planning is largely influenced by political and institutional decisions. Whether an energy system or business model is economically viable depends not only on technical and economic factors, but also on influences by government subsidies and the regulatory framework; such as carbon pricing or fees and taxes for the use of the electricity grid. Furthermore, many stakeholders are involved in the planning of district projects, such as investors, proprietors, residents, as well as district operators, e.g., residential real estate companies or municipal utilities [14, 16]. In an optimal planning process, all these perspectives are taken into account.

2.2. Challenges of district energy system planning

The various dimensions (e.g. technical, economic and political dimension) of DES planning come with a wide range of challenges. In this section we selected important challenges from the literature and categorized them according to the dimensions of DES planning. Yazdanie et al. [11] reviewed over 30 review studies, over 90 local-scale case studies and 40 surveys and interviews to identify gaps and challenges in energy modeling. Keirstead et al. [10] reviewed 219 papers to analyze approaches, challenges and opportunities of urban energy system models. Wehkamp et al. [14] discussed challenges and tools for planning DES using a German district as a case study. Coming from this extensive collection of challenges in district energy system planning, Table 1 contains clusters of these challenges including an assessment of whether they can be solved through our platform approach. The following paragraphs briefly discusses the most relevant challenges.

Model integration – Numerous models address different dimensions of DES planning. Sensibly combining these existing models, rather than modeling larger and more complex models, is a challenging task. A platform can support this task, e.g. by providing interface standards.

Validating models – Validation of individual models is cumbersome and time-consuming. When models are integrated into generic tools of a platform, they can be evaluated more easily. Furthermore, platform standards and community exchange can improve the validation process of models.

Considering data and geometry heterogeneity – Models require data of different form and levels of granularity. The data exchange between models can thus be hindered. In an integrated platform, a central data model can help with the transferability of data by defining a common standard for models' data requirements.

Handling data gaps and data availability – A common problem in DES planning are data gaps and data availability. This platform can hold a variety of tools for generating synthetic data as well as pre-processed data sets from open data sources. In addition, data preparation done by one user or developer does not need to be redone by a second individual.

Conflicting interests – DES planning centers around conflicting interests. Some models focus on individual perspectives, while others offer multi objective planning. In any case, the more tools are available to compare, the better, different stakeholder interests can be portrayed and represented.

Support for decision making – Decision-makers need reliable and verified results that are presented and visualized in a comprehensible way. By increasing the number of users and benefiting from proof reading of the open-source community, this platform can offer the required level of robustness.

Table 1. Challenges of district energy system planning

	Challenges of DES planning	Platform
Technical and economic challenges	Model integration (combining existing models) [8, 10, 11, 13]	x
	Model complexity and resolution [10–12, 17]	x
	Modelling external factors such as human behavior, economic development and weather [8, 11, 14, 17]	
	Considering novel energy technologies [11, 14]	x
	Improving existing methods [14]	x
	Validating models [8]	x
	Quantifying and handling uncertainty [10, 11, 17]	x
	Considering data and geometry heterogeneity [13, 18]	x
	Balancing model resolution with data availability [17]	
	Handling data gaps and data availability [10, 11, 14, 19]	x
Political and institutional challenges	Conflicting interests [11, 14, 19]	x
	Support for decision making [10–12, 14]	x
	Political uncertainty [10, 17, 19]	
	Sustainable, affordable energy [14, 17]	x
	Energy security [17]	x
	Administrative complexity [19]	x
	Monetizing aggregated flexibility [14]	

The following section presents the tools and technical components of the platform. It also discusses technical considerations that may influence the success of the platform.

3. Platform components

This section presents the components of the platform that would provide a reasonable starting point for the evolving toolkit. This initial collection would be capable of providing meaningful results for standard planning workflows. It would also demonstrate the type of additional methods and tools that could be added in the future. The intention is that the collection of tools and data on the platform will be combined to produce insights beyond the functionality of any individual component. The tools contain data processing logic that leverages various numerical and analytical methods required for DES planning.

The main objectives of the platform are:

- Enabling flexible integration of novel computational methods
- Visualizing planning and optimization interdependencies
- Improving data availability and homogeneity
- Increasing visibility of data uncertainty
- Handling variants and scenarios

The idea of such an initial toolkit is that it can easily be updated, manipulated or replaced, based on the users' and developers' preferences. Each tool is considered a container for many methods to solve a particular problem. Within a tool, a predefined architecture directs researchers and developers, on how new methods can be injected into the tool. The main flow of data would not be altered by switching between methods. The compatibility of tools bases on the commitment to a central data model. To cover the essential elements and processing steps of district planning, we suggest the components displayed in Figure 2. The boxes represent tools and cylinders represent databases; the dashed lines indicate useful extensions, that must not be part of an initial toolset.

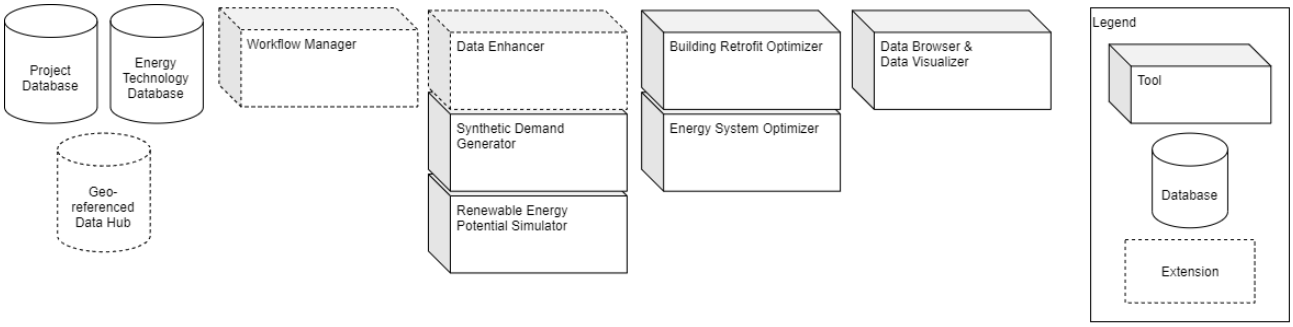

Figure 2. Initial platform toolkit

All tools work with a central district data ontology. The data model is the digital representation of districts including all physical and hypothetical building and energy system components. Tools operate either on a district data object that is transferred between processing steps in an ongoing computation, or they write and read the district data object to and from a database for intermittent processing. The latter would be beneficial for collaborative planning of districts, where multiple planners solve sub-problems successively.

The *Workflow Manager* enforces a structure that separates processing steps programmatically and visually, which improves interpretability and reproducibility. Data sources and functionality can be programmed into the structure of a directed acyclic graph, where nodes represent computations and directed arcs represent information flow and thereby node dependencies. Tools could certainly also be run using a simple script to call the processing steps of the planning problem. This would however result in more heterogeneous planning workflows that would be harder to compare and build upon.

The *Data Enhancer*, *Synthetic Demand Generator* and *Local Energy Potential Quantifier* are all pre-optimization steps, that generate arbitrary data, e.g., timeseries that are fed into energy system simulation and optimization. Usually the available data about existing, and even future buildings is sparse and incomplete. Filling up data gaps using appropriate estimations is therefore a crucial step in the total planning process.

The *Building Retrofit Optimizer* creates plausible retrofit variants by providing adapted building objects to the Synthetic Demand Generator. It either outputs a final optimized retrofit, or it feeds different variants of the building to the proceeding energy system optimization.

The Energy System Optimizer sizes system components based on optimal energy dispatch. This optimization provides answers to the trade-off between decentral and centralized technologies of all energy sectors and thereby defines which form of energy supply dominates. Additional tools could be introduced for more detailed optimizing of heating and electrical grids.

The *Data Browser & Data Visualizer* improve the interpretability of the optimization and simulation results. They output different types of tables, plots and reports, based on the requirements of the audience.

The following paragraphs discuss technical properties of the platform that are not specific to energy system planning, yet greatly affect the quality of the platform and its potential to sustain.

Extendibility – The platform should be easily extendable. By choosing Python as the development language, tools consist of Python packages that run platform independently and are easily updated and shipped to services like the Python Package Index [20]. Interested users, researchers and developers can choose which tools to use, how and where to run them and whether to extend the platform or workflow by some additional or improved functionality. By providing placeholders for typically required tools in district energy planning, it is easy to identify interfaces between processing steps. Documentation can be built into the tools in the form of comments, test cases and demo scripts, and be made available in a web compatible format.

Level of coupling – Introducing a central data model to ensure compatibility comes with advantages and disadvantages. It improves data consistency and integration. This results in fewer errors and inconsistencies while improving efficient development and data flow by reducing transformations. However, a central data model can become very large, having to serve requirements of many different applications. This increases development and maintenance efforts. It further increases the dependency of tools from this data model, which might require updating tools, when updating the data model.

Flexibility and maintainability – Energy system planning is a dynamic environment, where data models and tools regularly need to be updated to cope with novel problems and requirements. Data structures should therefore be flexible enough to cope with unforeseen needs during initial development. Practices that can help are modular data structure components, leveraging industry standards and implementing backward compatibility. Further, the choice of database technology can greatly affect the success of the project due to different levels of flexibility, performance and maintenance effort.

Usability – Usability is to a large extend subjective and experienced differently based on the familiarity with different kinds of interfaces. The main user group is expected to be energy system researchers and engi-

neers who have basic knowledge of Python. We therefore suggest to either provide tools as Python packages, with command line interfaces, or with a graphical user interface. Python has become one of the most popular languages for tools in the energy academic community [21], providing well-designed high-level functions for newly developed tools can be a good balance in terms of usability and flexibility for users familiar with Python. As a high-level programming language, Python makes it easy for beginners to get started, which is important for interested users to start generating results [22]. Due to the expected rapid development in research and application of district energy planning methods and software, this focus on code-based usability is motivated because of the low overhead in interface design. To integrate tools of different languages command line interfaces are sensible. Providing a graphical user interface comes with a higher level of user-friendliness and is particularly useful for presenting a lot of information at once. Developing and maintaining a GUI adds additional work and is therefore expected to be used mostly for result presentation and not necessarily for data processing. Python packages and command line interfaces are also easier to integrate into automation procedures of recurring workflows.

Integrated computing – DES planning quickly becomes computationally demanding. Therefore, we suggest to integrate computational resources into the platform. While the processing and data handling could all be done locally, it would be sensible to integrate computing capacity that supports tools in highly intensive processing tasks. Using a centralized solution can result in lower overhead due to the stronger integration of software and hardware. The data storage could also be hosted on a central machine, which benefits data availability, integration and performance.

The following section discusses community management and its potential influence on the success of the envisioned platform.

4. Platform community management

Open-source community management is the process of building online communities and facilitating active collaboration. This involves engaging community members, moderating communication, facilitating discussion, hosting community events, responding to user questions and generating informational and promotional content [23]. When collaboration and knowledge sharing are at the heart of the project, technical features and robustness do not alone affect the individual's choice to use the platform or to contribute. A platform that builds on the idea of collaborative development requires a community to be engaged and willing to share information, which his particularly sensitive in the early stages of development and research; this requires successful community management [24].

Open-source community management is a topic that has received attention in the context of the most successful open-source projects [24], but to our knowledge it has not been considered a central part in the effort to engage a community of researchers and users of district energy system planning tools. Successful community management can support compatibility of tools and data, bridge the gap between research and application and support active knowledge sharing and sustainable development of the platform. In efforts towards collaborative research and application in district energy system planning, the level of community engagement can be a potential differentiator between failure and success for a collaborative multi-energy system planning platform.

Community management centers around community managers, who connect various groups such as researchers, practitioners, policymakers to facilitate the exchange of experiences, knowledge and best practices and thereby drive innovation and the quality of the platform.

Important aspects of community management are:

- Clear communication of goals, expectations and policies
- Inclusiveness and empathy within the community
- Active engagement of potential contributors
- Decision-making transparency

A collaborative multi-energy system planning platform’s success not only depends on technical aspects, but also on the level of engagement in the community, the user's choice to commit to this platform and potentially contribute themselves, the willingness to share knowledge and the community's ability to make decisions and move forwards. Community management covers these aspects and can help to accelerate research and application of superior methods in district energy system planning.

5. Conclusion

In the context of district energy system planning, we have motivated the need for a collaborative platform to cope with the rapid development of new models and tools by academia and the requirements of practitioners. Due to the interdisciplinary nature of the problem, we expect individual groups to struggle with providing solutions to all elements of the problem. Some platforms exist with fine or major distinctions, of which currently none seems to be established as the status quo for integration for models and tools in district energy

system planning. A platform that is modular and extendable can be the common ground for all parties involved.

Based on existing literature, we see model integration, validating models, considering data and geometry heterogeneity, handling data gaps and data availability, conflicting interests and support for decision making to be the prominent challenges to be solved by the envisioned platform. Concretely, we expect the platform to enable flexible integration of novel computational methods, expose planning and optimization interdependencies, improve data availability and homogeneity, increase visibility of data uncertainty and handle variants and scenarios. For consistent data handling we propose the definition of a central data model as the foundation for tool integration and data consistency. Further, we present a set of essential tools, that we consider indispensable to solve a wide scope of district planning problems.

Fostering openness and effective collaboration potentially is a key differentiator between success and failure of such platforms. Collaboration, communication and decision procedures pose a challenge for ventures like this to thrive in the open-source world. Analyzing these aspects of the problem should be subject of future work.

Setting the groundwork for this vision is a complex task, and no one in the sphere of district energy system planning naturally has the obligation to start. However, it does require an initial definition of standards and interfaces, for this platform to manifest in something tangible. Further, a combination of central guidance and community driven decision making is required to maintain the platform and react to future developments.

Abstract:

Anomalous energy consumption detection is a valuable strategy for pursuing energy efficiency. In commercial buildings, such as supermarkets, abnormal consumption can occur due to non-adequate equipment, such as lighting devices and refrigeration systems, or non-efficient HVAC plant management. Anomaly detection is usually performed on a single building by comparing its energy consumption to its usual behaviour and applying statistical or artificial intelligence-based techniques. Still, no anomaly emerges if its energy consumption is systematically high (or low). However, a more effective method for detecting anomalies would be to compare the energy consumption of a single building with that of others possessing similar characteristics. This paper then proposes an alternative approach based on clustering analysis. From this perspective, energy consumption data from a group of supermarkets are gathered in clusters to detect which presents abnormal behaviour compared to others with similar characteristics, such as the dimension and external weather conditions. An unsupervised density-based clustering algorithm for outlier detection (DBSCAN) is applied to a pool of 87 supermarkets located in Tuscany (Central Italy) to detect the abnormal ones, considering as input features the floor area, the electrical and thermal consumptions available from monthly bills, the type of the air-conditioning units, and the outdoor temperature. The analysis is performed over three years to detect recurring outliers on an annual and monthly scale to investigate possible seasonal effects. During the three years, approximately 15% of the supermarkets were consistently identified as outliers on both a monthly and annual basis. These findings were subsequently validated through an on-site inspection conducted by the energy manager of the supermarkets, revealing that 50% of the identified outliers exhibited exceptionally high thermal and electrical consumption due to improper plant operation.

Keywords:

Anomaly detection; DBSCAN; Energy efficiency; Unsupervised clustering.

1. Introduction

Pursuing energy efficiency in buildings, industry, transport, and energy supply sectors is one of the central policies imposed by the European Council to meet the 2030 emission targets [1]. Through the years, most attention has been dedicated to reducing energy consumption in the building sector since it is responsible for more than 30% of the CO_2 global emissions [2]. Beyond that, relevant emission cuttings can be achieved by actuating energy efficiency strategies also in the non-residential sector, which includes schools, offices and commercial activities. Non-residential buildings are characterised by higher energy intensities than residential ones and are responsible of the 5% of the total share of CO_2 emissions [3]. This highlights the potential for good energy efficiency practices to have a greater impact. Among this category, food-related commercial activities (i.e., supermarkets) are one of the most energy-intense because of the energy consumption related to space cooling and heating and refrigeration for food preservation [4].

Energy efficiency in existing supermarkets has been pursued mainly by replacing old devices with more efficient ones (HVAC units, refrigeration systems and lighting systems) [5], retrofitting the thermal insulation to minimise thermal losses [6] and implementing renewable generation sources [7]. Although widespread, these strategies often require a significantly high investment cost. On the other hand, efficient strategies for energy consumption management can be cheaper to implement. The most common management strategies involve applying optimal control schemes for HVAC units [8], and the refrigeration units [9] by replacing the traditional

PID control schemes with Model Predictive Control. In addition, the consumption optimization has also been pursued by implementing demand-side management paradigms [10,11].

Besides the cited traditional methods, data-based practices for energy consumption monitoring and fault detection are now gaining interest to make residential and non-residential buildings more efficient. In residential buildings, as well as in supermarkets, a large amount of data is usually collected and stored, thanks to the several measurement sensors spread over the energy plants. Using data for energy monitoring can be beneficial to spot abnormal energy consumption due to suboptimal operation of the HVAC or non-adequate equipment operation (i.e., lighting) [12]. Anomalous energy consumption can be identified using state-of-the-art statistical outlier detection methods, such as z-score [13]. Although statistical methods are effective and easy to implement and interpret, with these techniques, outlier detection is typically driven by a single feature (e.g., the energy consumption time series). More advanced data-driven techniques based on Machine Learning (ML) algorithms allow, instead, to perform the outlier detection over a dataset with multiple features, e.g., considering the weather conditions and the building characteristics beyond the only energy consumption data. So far, most academic research papers focus on using ML for anomalous consumption detection of residential buildings. Still, a similar methodological approach can be applied to commercial activities to investigate its potentiality [14].

AI-based energy monitoring techniques aim to detect anomalous energy consumption. Particularly, Unsupervised Clustering (UC) techniques are gaining interest in the energy sector thanks to their simplicity and the broad range of applicability [15]. Mainly, UC is useful to identify abnormalities only considering the intrinsic behaviour of the energy consumption without knowing a priori if it is normal or not. Several UC techniques for anomalous energy consumption exist, such as k-means clustering [18], Gaussian Mixture Model (GMM) [19] and density-based algorithms [20]. The latter category is particularly suitable for outlier detection since it is based on detecting anomalies by dividing the dataset into clusters with high-density data (regular consumption instances) and clusters with low-density data (abnormal consumption instances) [21]. Local Outlier Factor (LOF), Isolation Forest (IF) and Density-Based Spatial Clustering for Application with Noise (DBSCAN) are the most popular algorithms [22]. Unlike the k-means clustering approaches, density-based algorithms do not require initialising the number of clusters. DBSCAN is particularly suitable for outlier detection, since its capability of clustering data and identifying a specific cluster dedicated to outliers [23]. The clustering emerges from data by setting specific parameters defining each cluster's threshold radius of influence and the minimum number of points that define a cluster. outliers Although setting these parameters can be challenging since they cannot be optimised, some automatic strategies can be applied. DBSCAN found many applications for outliers detection in time series so far [24]. Regarding the energy sector, in [25], the authors propose the DBSCAN algorithm for anomalous energy consumption detection in residential buildings. In this case, the setting of the parameters is automatised, and the clustering results are explanatory and reasonable. Focusing only on time series can bring some limitations, though. Energy consumption patterns, indeed, naturally vary due to seasonal trends, making it hard to distinguish if the wrong operation is systematic or due to an extraordinary change in the boundary conditions (e.g., exceptionally hot or cold seasons). For this reason, authors in [26] perform anomaly detection of a building through a two-step procedure, firstly comparing the building energy consumption with past data and then comparing it with a pool of buildings with similar characteristics.

Given this framework, this work aims to apply the DBSCAN clustering for anomalous energy consumption detection of a group of supermarkets. The paper contribution aims to cover some literature gaps, summarized as follows:

- Despite several papers contributing to this topic, most refer only to residential buildings even though commercial buildings are widespread and their energy consumption is more intense than residential ones. Identifying abnormal consumptions could foster significant energy savings in this context.
- The outlier detection is not performed over a single time series related to a single building but within a pool of supermarkets, defining, then, whether the consumption is normal or abnormal compared to the behaviour of the other supermarkets with similar characteristics (such as the floor area and weather conditions). The clustering is performed both on a monthly and yearly basis, repeating the analysis over three different years. The supermarkets, then, are marked as outliers if their anomaly shows systematically.
- The analysis is performed using consumption data extracted from monthly bills for electricity and gas consumption. Though buildings have several sensors, data collection and management can be expensive. Monthly bills are, instead, easy to collect, making the proposed outlier detection method attractive for situations in which detailed data are unavailable.

2. Case study

The selected case study comprises a group of 108 supermarkets in the Tuscany region, in the north centre of Italy. The group is heterogeneous, including mini-markets (floor area of up to 2000 m^2) and superstores (floor area of up to 5000 m^2). Most of the supermarkets, around 80%, use gas boilers for space heating during the

winter season, while the remaining 20% are equipped with electric heat pumps. The weather conditions mainly determine space heating consumption. The stores are located at latitudes between 42° and 44° N and correspond to specific climatic regions established by the Italian government regulation [27]. Most supermarkets are in the D zone, where heating space is allowed between November 1 and April 15. The remaining are in the E region, characterised by more demanding weather conditions, with an allowed heating season from October 15 to April 15.

The energy management division of the supermarkets provided data about consumption and weather conditions and some characteristics of the building over three years, from 2019 to 2021. The available data are as follows:

- **Electrical consumption data** E_{el}**:** electrical consumption data are provided from the monthly bills. The electrical consumption (kWh) is related to the space air conditioning during the summer and winter seasons (only for those supermarkets that are equipped with electric heat pumps), Medium Temperature (MT) refrigerators for fresh food conservation, Low Temperature (LT) refrigerators for frozen food conservation, lighting devices and food processes (e.g., grocery and bakery).
- **Thermal consumption data** E_{th}**:** The monthly bills also provide thermal consumption data measured with Standard cubic meters (Sm^3). The thermal requirement refers to the space heating (during the winter season) and hot water used by the employees for personal usage and food processing actions. Some supermarkets do not have thermal consumption because the air conditioning is electrified.
- **Buildings data:** The information about the building characteristics consists of the monthly opening hours H_o (for a total of about 4000 h/year) and the floor area A_f.
- **Weather data:** The weather conditions consist of two variables: the outdoor temperature and the outdoor humidity measured through sensors positioned outside the building location. These data are provided with a 15-minute timestep. The weather conditions will be expressed as Heating Degree Days (HDD) and Cooling Degree Days (CDD) (Eq. 1), which give a measure of the heating/cooling demand related to the outdoor temperature and the heating/cooling period. In Eq. (1) $T_{sp,i}$ is the indoor temperature set point for air conditioning, $\bar{T}_{ext,i}$ the outdoor temperature mean value over the day, and N is the number of considered days in the heating/cooling period.

$$HDD = \sum_{i=1}^{N} \max\left(T_{sp,i} - \bar{T}_{ext,i}, 0\right); \qquad CDD = \sum_{i=1}^{N} \max\left(\bar{T}_{ext,i} - T_{sp,i}, 0\right) \tag{1}$$

Figure *1* provides a summary of the sample data ranges. The histograms illustrate the distribution of the data across the group of supermarkets, indicating the number of buildings in the total population (n/n_{tot}) that share similar characteristics.

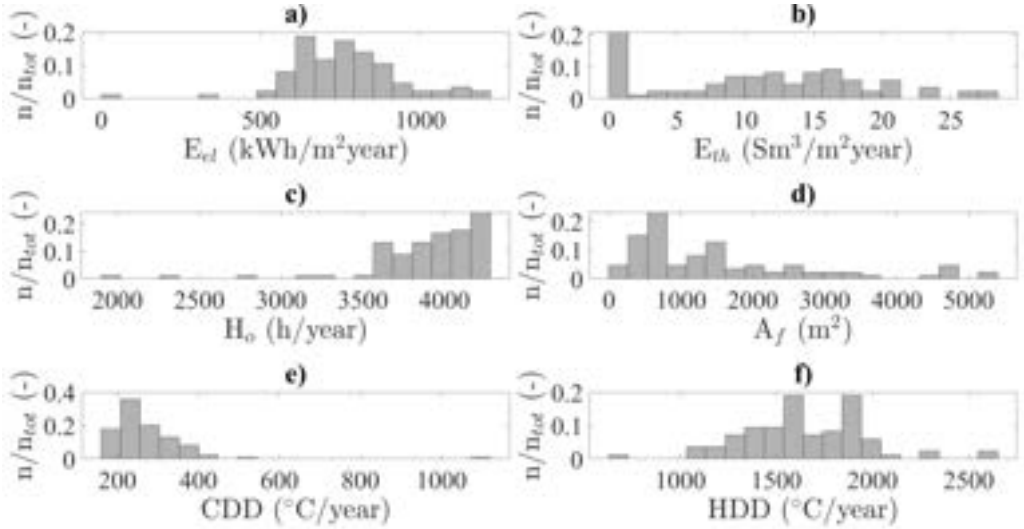

Figure 1. Characteristics of the pool of supermarkets plotted as a fraction of the total supermarkets n/n_{tot}. a) Specific annual electrical consumption E_{el} (kWh/m^2year); b) Specific annual thermal consumption E_{th} (Sm^3/m^2year); c) Annual opening hours Ho (h/year); d) Floor area A_f (m^2) e) Annual Cooling Degree Days CDD (°C/year); f) Annual Heating Degree Days HDD (°C/year).

2.1 Analysed cases

Anomaly detection is performed by considering annual aggregated data and monthly data. The yearly analysis aims to detect which supermarkets have an overall anomaly in energy consumption over the year. Using yearly aggregated data makes this analysis computationally inexpensive and results in the preliminary identification of probable outliers. However, it could also be possible that some supermarkets have abnormal energy consumption only in specific months of the year due to seasonal effects. For example, anomalies could emerge

only during the winter months caused by non-efficient gas boiler usage, while the air conditioning units work correctly in the summer. Monthly analysis can overcome this limit and highlight seasonal effects. For this reason, monthly clustering is also performed even though it is a more computationally expensive analysis since it is repeated every month over three years.

3. Methodology

The methodology section includes the description and preliminary results of the data pre-processing, feature selection, dataset construction and clustering algorithm settings. All the analyses have been realised in Matlab version 2021b.

3.1 Data pre-processing

Pre-process procedures are essential to make raw data usable. Mainly, preliminary operations regarding missing data handling and data aggregation were performed as follows:

- Missing consumption data (both thermal and electric) were not replaced since outlier detection must be performed over actual data to spot anomalies. Supermarkets with missing consumption data were excluded from the analysis, reducing the pool from 108 to 87 supermarkets.
- If possible, missing weather data were interpolated or taken from external databases. Missing periods lower than 24 hours were interpolated linearly. Missing periods longer than one day were replaced with data from the database *IlMeteo.it* [28], which offers historical daily average values for outdoor temperature and humidity. In this case, missing data were replaced with new data, measured not in the proximity of the supermarket but at the closest weather station, usually located in the same municipality.
- Consumption data were aggregated starting from monthly values to obtain yearly global consumption. This operation is necessary to perform monthly and annual clustering to consider seasonal effects, as described in the Case Study Section. Weather data are aggregated into monthly and yearly values starting from the 15-minute time interval measurements.

3.1.1 Feature engineering and feature selection

Few additional features are created starting from the available data to help the clustering algorithm find patterns. The following two features are then created:

- A categorical variable that indicates the air-conditioning plant typology. Supermarkets which use electrical heat pumps for the summer and winter air-conditioning are marked with category E. In contrast, supermarkets which use the gas boiler during the heating season are marked with category EG. Following the standard procedure for categorical variables handling, this feature is processed as a dummy variable [29].
- HDD and CDD. Average values of outdoor air temperature are not particularly meaningful, mainly if the average refers to an extended period (month or year). HDD and CDD, instead, quantify the overall heating/cooling demand, involving the length of the heating/cooling season and the difference between the indoor set point temperature and the outdoor conditions.–Once the set of available variables is defined, feature selection is performed to remove unnecessary data and improve the clustering performance [30]. For this reason, a correlation analysis is performed to identify the more significant features. The feature selection is performed through the evaluation of the Spearman correlation coefficient ρ_s. Spearman correlation coefficient is a statistical measure of the correlation within the variable *x* and *y* based on rank assignment. For the calculation, the values of *x* and *y* are converted into ranks following an ascending or descending order. Then a high correlation score is assigned where a high rank of *x* corresponds to a high rank of *y.* Unlike the Pearson's coefficient, Spearman's is able to calculate the correlation between two variables even if their relationship is not strictly linear. The only assumption is that the relationship has to be monotonic [31]. The calculation of ρ_s is performed as shown in Eq. (2), where D_i^2 is the rank distance between variable *x* and *y*, and N the number of points which constitutes the cluster. The correlation is considered strong when $0.7 \leq |\rho_s| \leq 1$, moderate for $0.3 \leq |\rho_s| < 0.7$ and weak for $|\rho_s| < 0.3$.

$$\rho_s = 1 - 6 \cdot \frac{\sum_{i=1}^{N} D_i^2}{N(N-1)}\,; \qquad D_i = x_i - y_i \tag{2}$$

Correlation analysis is not performed for the yearly aggregated values because no monotonic relationship emerges considering annual data. Correlation analysis is then performed only for the monthly values. Particularly, ρ_s is computed across the following variables:

- Electrical specific consumption E_{el} $(kWh/m^2 month)$
- Thermal specific consumption E_{th} $(Sm^3/m^2 month)$
- Degree Days DD $(°C/month)$. The generic symbol DD refers to HDD for winter months and to CDD for summer months
- Outdoor Relative Humidity RH $(\%)$
- Opening hours H_o (h).

The preliminary results of feature selection are shown in **Figure *2***. The heatmap shows the correlation coefficients ρ_s across the combination of variables for one of the supermarkets as an example. The other supermarkets of the pool showed the same behaviour and are not shown for brevity. As expected, the correlation analysis shows that electrical and thermal consumptions are strongly related to the external temperature conditions (DD). RH showed no correlation with energy consumption, so it is removed from the analysis. Finally, since H_o showed only a moderate correlation with electrical consumption, it was included in the first tests. However, its impact was not significative for the outliers detection, so it was removed in the final dataset. In this plot, the correlation with the floor area was not computed because only one supermarket is considered (so the area does not vary).

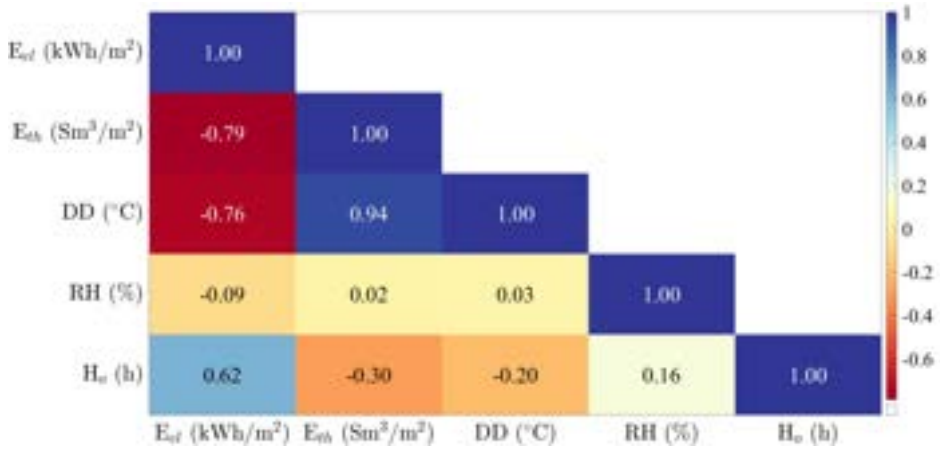

Figure 2. Spearman correlation values for the considered features E_{el}, E_{th}, DD, RH and opening hours. Data are related to one of the supermarkets of the pool as an example.

3.1.2 Dataset construction

As a result of the correlation analysis and considerations given in the previous sections, the annual and monthly datasets are finalised, as **Table *1*** summarises. Finally, each dataset is normalised to ease the clustering procedure. Normalised data are all in the same range, so undesired effects due to different data scales will not affect the clustering results. In this work, data are normalised with the 2-norm approach, in which the Euclidean norm of the variable normalises each data observation (row). Eq. (3) shows the normalisation approach. The generic data x_i is normalised, becoming $x_{i,norm}$, dividing it by the 2-norm, where N is the number of rows of the variable.

$$x_{i,norm} = \frac{x_i}{\left[\sum_{k=1}^{N} |x_k|^2\right]^{1/2}} \quad (3)$$

Table 1. Dataset with selected features for annual and monthly clustering

	Features included in the dataset
Annual clustering	• $E_{el}\ (kWh/m^2 year)$ • $E_{th}\ (Sm^3/m^2 year)$ • $A_f\ (m^2)$ • Air-conditioning units type: E/EG
Monthly clustering	• $E_{el}\ (kWh/m^2 month)$ • $E_{th}\ (Sm^3/m^2 month)$ • $A_f\ (m^2)$ • $DD\ (°C/month)$ • Air-conditioning units type: E/EG

3.2 DBSCAN algorithm

DBSCAN algorithm is an unsupervised clustering technique that identifies high-density regions (normal behaviour) in the k-dimensional space representing the dataset and a few low-density regions where the outliers are located (abnormal behaviour). High-density areas, i.e., the clusters, are defined based on the neighbourhood concept, for which two points are in the same neighbourhood if their distance is below a threshold ε, called the neighbourhood parameter. The pairwise distance from a point to the surrounding ones can be defined in several ways, but the Euclidean distance is used in the analysis. Particularly the

neighbourhood of a point *x,* $N_\varepsilon(\mathrm{x})$, is defined as in Eq. (4), where D is the set of points in the dataset, dist(x,y) is the Euclidean distance between two points *x* and *y,* and ε is the threshold distance [32].

$$N_\varepsilon(\mathrm{x}) = \{\mathrm{y} \in \mathrm{D} | \mathrm{dist}(x,y) \leq \varepsilon\}; \qquad \mathrm{dist}(x,y) = \sqrt[2]{\sum_{i=1}^{N}(x_i - y_i)^2} \tag{4}$$

The cluster definition must include an additional parameter to identify high-density regions correctly. Particularly, $N_\varepsilon(\mathrm{x})$ cannot be constituted by less than a number of points equal to *minPts* (a scalar number ≥ 1). The DBSCAN algorithm operates as represented in **Figure 3**.

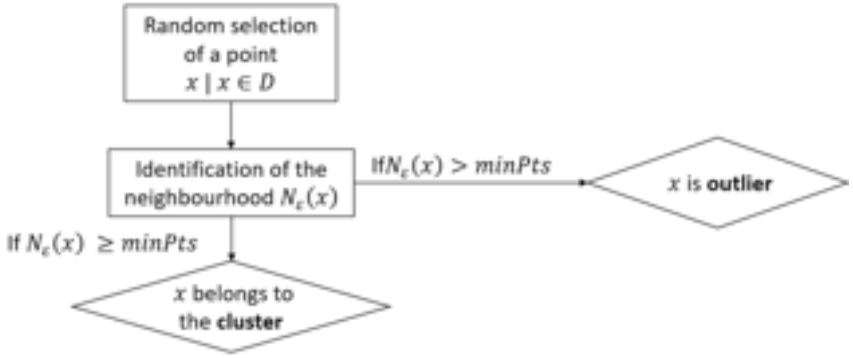

Figure 3. Clustering process using DBSCAN algorithm.

3.2.1 Parameters setting

Since the abnormal energy consumption detection for this case study is unsupervised, the DBSCAN model cannot be trained based on the experience of some previously labelled data which constitute the benchmark (normal or abnormal). For this reason, the parameter setting cannot be optimised by minimising a specified loss function, as happens for supervised cases. The choice of the parameters ε and $minPts$, then, is driven by some specific considerations related to the dataset. However, some general guidelines can be followed to have a proper estimation of suitable values of ε and *minPts*:

- The choice of *minPts* depends on the configuration of the dataset. This work performs a sensitivity analysis varying minPts from 2 to 8. These values are selected considering the size of groups of supermarkets with similar characteristics, like the floor area or the geographical location, in the dataset.
- The choice of ε is based on the method proposed in [33]. To determine a meaningful ε value, the pair-wise distance is calculated from each point in the dataset to all the other *minPts* number of points. The obtained distances are then plotted against the sorted points. Since the number of anomalies is usually limited (i.e., less than 20%), the sorted distances show a typical linear trend for the points in the high-density areas. A fast slope change occurs in the proximity of the so-called "elbow", where the remaining sorted distances are substantial because they are related to the low-density areas (where the outliers are located and the points tend to be distant from each other). The selected ε value, then, is the distance value corresponding to the "elbow*".* Since the results can be affected by the value of ε (i.e., the larger ε, the lower the number of outliers), we performed a sensitivity analysis with different values near the *elbow*, and the results proved to be robust in this range*.* The value selected for ε varies for each simulated case, ranging from 0.0286 to 0.0853.

3.2.2 Key Performance Indicators

The quality of the unsupervised clustering is not quantitative but qualitative since data are not labelled a priori. Results will then be shown with graphical scatter plots to represent clusters and outliers. Despite the limitation of the unsupervised nature of the problem, some additional considerations can prove that one supermarket can be considered an outlier. The clustering analysis is repeated for each year in the dataset (2019-2020-2021) to support this thesis. The number of recurrent outliers is then collected over single or multiple years. Concerning the annual analysis, the fact that a supermarket has been marked as an outlier for more than one year suggests that an issue of some sort occurs systematically.

On the other hand, supermarkets marked as outliers for a single year probably faced some extraordinary operative conditions which never repeated. The same considerations are valid for the monthly clustering. In this case, supermarkets were marked as outliers over one year if they were outliers for at least three months. This value is reasonable because it can reflect seasonal effects due to the heating or cooling periods. Two Key Performance Indicators (KPIs) are then evaluated to quantify the cited results:

- Percentage of outliers n_{out} over 1, 2 or 3 years compared to the total number of supermarkets n_{sup} (Eq. 5):

$$k_{t,sup} = \frac{n_{out}}{n_{sup}} \cdot 100\% \tag{5}$$

- Percentage of outliers over 1, 2 or 3 years compared to the total number of outliers $n_{out,tot}$ (Eq. 6):

$$k_{t,out} = \frac{n_{out}}{n_{out,tot}} \cdot 100\% \quad (6)$$

4. Results and discussion

This session will provide at first step results about the clustering quality by visualising scatter plots with non-anomalous clusters and outliers. After that, the analysis of the KPI will help to understand the supermarkets which showed a systematic anomaly, which can be classified as actual outliers. Finally, the outliers found by the algorithm are verified by plant inspections conducted by the energy manager to validate the clustering results.

4.1 Qualitative clustering

The results of the annual clustering in **Figure *4*** are scattered in a three-dimensional plot that includes the three features defined in the dataset (E_{el}, E_{th} and A_f). The clustering is sensible since the main characteristics of the supermarkets are represented. The regions of the dataset with the highest density are clustered in Group 1 and Group 2. The two clusters are related to supermarkets with electric pumps (category E) and supermarkets with gas boilers (category EG). Smaller clusters indicate limited groups of supermarkets which are similar. Group 3 represents superstores (i.e., most extensive floor areas) with electric heat pumps, while Group 4 concerns superstores with gas boilers for space heating. Outliers emerge beyond regular clusters and are located mostly in low-density regions. Among the whole group of outliers, some show low consumption compared to the average of the surrounding clusters, while others show high consumption. The latter outliers were verified through an on-site plant inspection, finding some explanations for the abnormalities. For example, supermarkets 29, 74 and 51 are outliers because the electrical consumption is abnormal despite the A_f and E_{th} being similar to other supermarkets. In these cases, the anomaly was found to be due to obsolete lighting devices or thermal losses of LT and NT refrigerators that are not closed. The electrical consumption anomalies related to the air-conditioning units are rare since supermarkets of category E are recent, efficient, and monitored. Supermarkets 7, 6 and 45 have abnormal thermal consumption. In these cases, the anomaly is primarily due to sub-optimal operation or out-of-range setpoint temperatures on the heating boilers. Supermarkets of category EG are indeed older than the ones in category E, so the heating plants are not monitored in real-time.

On the other hand, a few supermarkets are marked as anomalous because of lower energy consumption than the neighbourhood, so the on-site inspection was not performed. In some cases, this behaviour is due to the low-quality data, which are partially missing (supermarket 31). In other cases, the low consumption is due to favourable climate conditions during the considered year or the wrong consumption estimation on the bills. The weather conditions effects emerge through the monthly analysis, in which HDD and CDD are used as predictors. **Figure *5*** can also be interpreted qualitatively as for the annual clustering results. In this case, some anomalies can be interpreted thanks to the additional information about the climate conditions. Exceptionally high DD are responsible for some detected abnormalities. For example, supermarkets 76 and 7 have similar DD to many supermarkets of the pool but significantly higher thermal consumption. The heating plants' sub-optimal management set point temperatures can be responsible for these abnormalities. Compared to these, Supermarket 48 is less alarming because it has higher E_{th} due to higher DD. Finally, supermarkets 18 and 25 have lower thermal consumption than the neighbourhood, but this is due to lower DD, indicating that the outdoor temperature was exceptionally lower than usual that month.

4.2 Systematic outliers

The qualitative considerations help support the clustering results, which cannot be compared to a benchmark. Despite this, the interpretation of the results may be impractical as it must be supported by visuals, and every outlier requires some additional effort to be confirmed or denied. Automating this process can be challenging, but iterating the analysis over multiple years can help to strengthen the outlier labelling with more reliability.

Figure *7* highlights the capability of the monthly clustering in understanding systematic seasonal effects that did not emerge from the annual analysis. The analysis is valid for all the months of the year except for September. In this case, data concerning E_{th} of September 2019 were missing, so the statistics could not be computed for this month since the data quality still was not good enough despite data pre-processing. However, the analysis is still relevant for the other eleven months. This graph shows that during winter months, from November to March, a high percentage of supermarkets are outliers over the whole three years. These systematic abnormalities highlight an improper operation of the heating systems, so abnormal consumption in the cold season is highly probable.

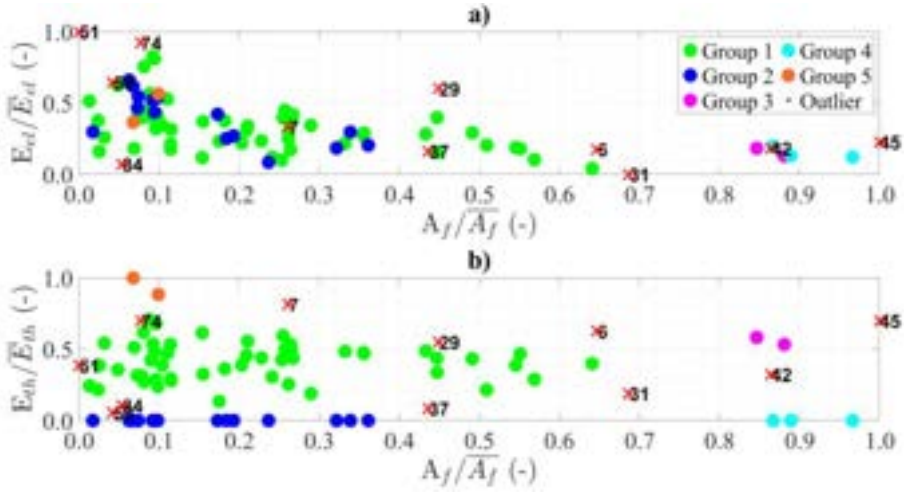

Figure 4. Annual clustering results for the year 2021, as an example. a) Specific electrical consumption Eel versus floor area A_f. b) Specific thermal consumption E_{th} versus floor area. All the variables are normalised with the maximum values $\bar{E}_{el}$, $\bar{E}_{th}$, $\bar{A}_f$ for data privacy. Outliers are marked with red crosses and are associated with a numerical ID.

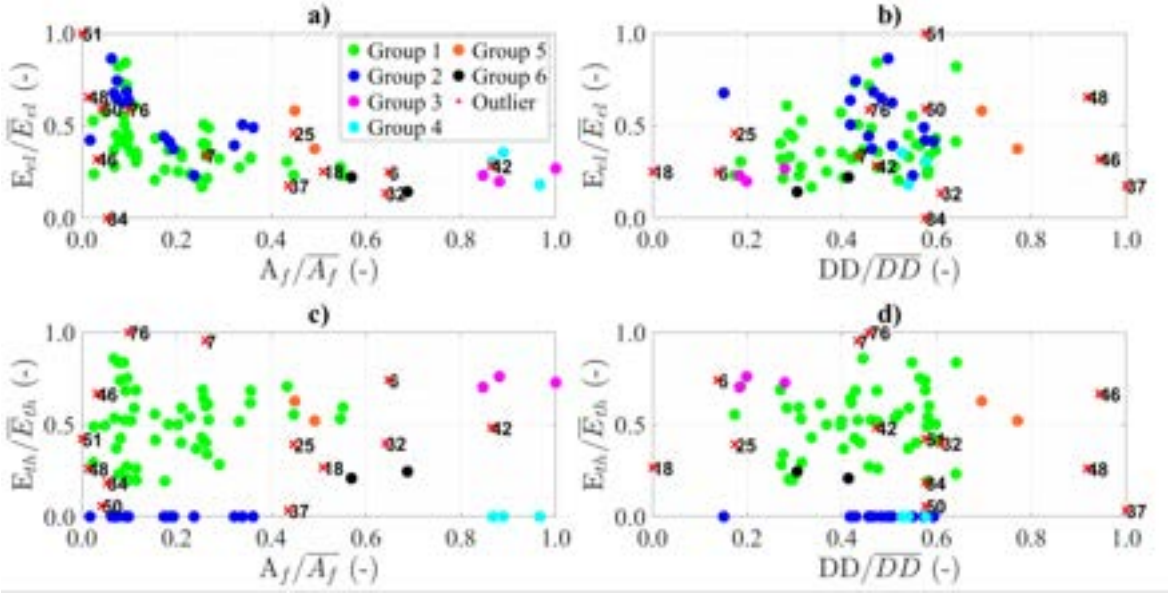

Figure 5. Monthly clustering for January 2021, as an example. a) Specific electrical consumption E_{el} versus floor area A_f. b) Specific electrical consumption E_{el} versus Degree Days DD. c) Specific thermal consumption E_{th} versus floor area A_f. d) Specific thermal consumption Eth versus Degree Days DD. All the variables are normalized with the maximum values $\bar{E}_{el}$, $\bar{E}_{th}$, $\bar{A}_f$ and $\overline{DD}$ for data privacy. Outliers are marked with red crosses and are associated with a numerical ID.

Figure *6* shows how many supermarkets were marked as outliers for 1/3, 2/3 or 3/3 years of the investigated period. Around 10% of the supermarkets had abnormal consumption for only one year over three, highlighting that these abnormalities are not systematic but exceptional. Instead, the green stacked bar highlights the percentage of supermarkets that were marked as outliers for all three years. In this case, since the anomaly is systematic, these supermarkets probably have operating issues related to the consumption of their subsystems. This result is strengthened by comparing the annual and monthly $k_{t,s}$ and $k_{t,out}$ indicators. Regarding 1/3 years and 2/3 years outliers, there are a few differences. The monthly analysis in **Figure *7*** highlighted occasional outliers (orange stacked bar), thanks to its capability of catching seasonal anomalies that cannot appear in the annual analysis, so the results are slightly different. Regarding the 3/3 years abnormalities, yearly and monthly clustering showed almost the same percentage. This result highlights that around 10% of supermarkets in the pool have systematic anomalous consumption that emerges independently from the weather conditions, so it strictly concerns operational issues of the plants. This result is then valuable information for the energy management unit of the supermarkets since it suggests that a plant check is necessary. As a final remark, thanks to this analysis, systematic anomalous supermarkets are marked as outliers with sufficient certainty. The cost of the on-site plant inspection to verify these results and eventually fix the anomaly, then, is justified and can bring to potential savings. **Table 2** provides the validation of the

results through the on-site plant inspection. The 50% of the recurrent outliers proved to have some issues that caused the abnormal consumption, such as the faulty operation of the HVAC units and old lighting equipment. Only in one case the abnormality was caused by a wrong estimation of the monthly bills. The remaining 50% were not found to be outliers, mainly because they were the cases that showed a positive abnormality (i.e., with consumptions lower than supermarkets with similar features).

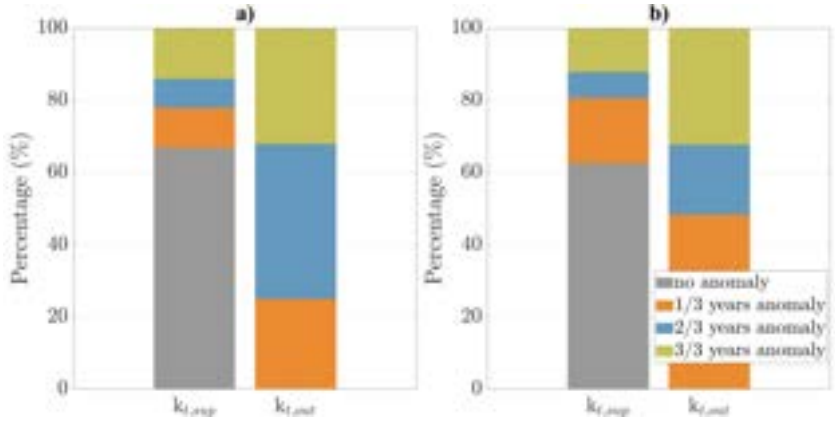

Figure 6. Abnormalities share for a) Annual analysis; b) Monthly analysis.

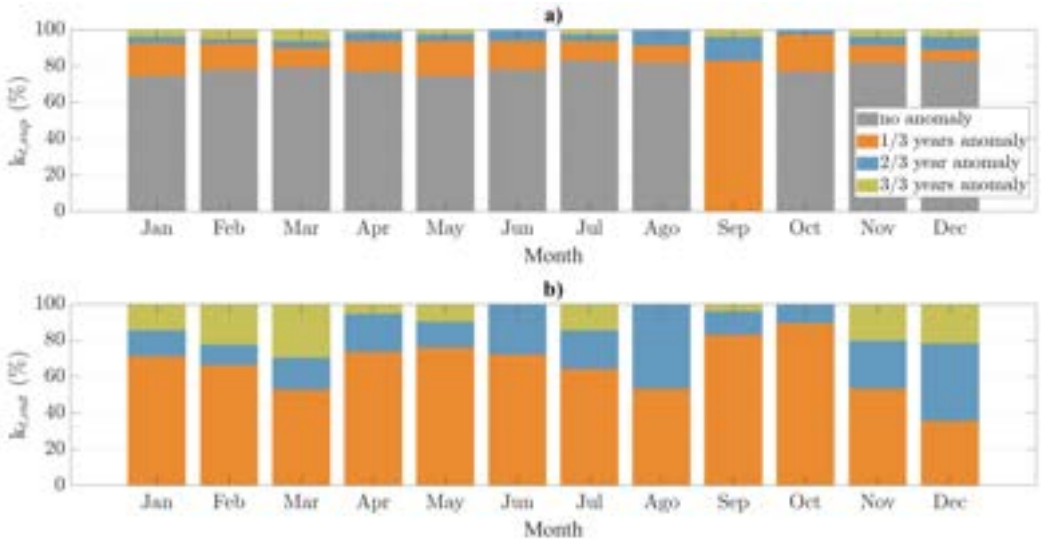

Figure 7. Abnormalities share for monthly analysis for KPIs: a) percentage of outliers among the total number of supermarkets; b) percentage of outliers among the total number of outliers.

Table 2. Results validation for recurrent outliers emerged from the monthly clustering analysis.

Anomalous supermarket	Years of anomaly	Anomaly cause
6	3/3	Old lighting devices; Heating system
7	3/3	Heating system
19	2/3	Heating system
29	3/3	Old lighting devices; HVAC system
30	3/3	Old lighting devices
43	3/3	Heating system
56	3/3	Wrong bill estimation
75	2/3	Heating system

5. Conclusions

The paper investigated the potentialities of using an unsupervised clustering approach for anomalous energy consumption detection in a group of 87 supermarkets in Italy. The final goal of the study was to implement a computationally powerful strategy to identify anomalous supermarkets compared to the others in the group. Unlike standard statistical techniques, this approach helped to identify the outliers considering many features simultaneously, such as thermal and electrical consumptions, the dimensions and weather conditions. The analysis was performed using the DBSCAN algorithm, which is suitable for outlier detection for datasets mainly composed of high-density regions (regular consumptions) and a few low-density regions (abnormalities).

Although this methodological approach had already been applied for anomalous energy consumption detection, it was rarely applied to non-residential buildings, which can easily suffer from non-optimal energy usage because of their higher complexity and energy intensity. In addition, most of the papers performed the outlier detection by comparing one building to its past energy consumption, making it impossible to identify systematic anomalies. The work then tried to bridge these research gaps by observing numerous similar supermarkets, starting from monthly electrical and thermal consumption bills, which are data easy to collect and manage.

Firstly, the results proved that the proposed set of clustering parameters effectively represented the dataset adequately by identifying the main clusters in relation to the air-conditioning plan typology. Once the good quality of the clustering was verified, the annual clustering identified the anomalous supermarkets using consumption data and the floor area as features. After that, weather conditions were embedded in the monthly analysis, which was able to identify the supermarkets that behave anomalously only in particular months due to seasonal effects. Finally, the analyses went beyond the simple labelling as *normal* or *abnormal* consumption by repeating the clustering over the three available years of the dataset. By doing so, supermarkets labelled as outliers over the three years can be considered very likely outliers. Approximately 10 % of the supermarkets of the pool showed an anomaly over 3/3 years. This result was confirmed by comparing the annual and the monthly analyses so that supermarkets systematically affected by significant abnormal energy consumption are identified with improved confidence. This improvement is particularly meaningful since it overcomes the issues of the traditional unsupervised clustering, in which the non-optimal setting of the parameters brings uncertain results. In addition, the monthly analysis highlighted that around 50 % of supermarkets are outliers for only 1/3 years. These supermarkets are not particularly alarming since their abnormality is not systematic and is probably due to non-frequent wrong operation or extreme weather conditions. Repeating the clustering over different time scales and different years then helps to detect the *false positive* outliers and focus the effort on the systematic ones. This result is validated by the on-site inspection of the potential anomalous plants, which proved to have operational issues.

Further improvements could concern the integration of additional features, as far as the data are available (like the occupancy, the type of refrigeration units and so on). In addition, if the supermarkets change during the investigation period, additional characteristics of new equipment could improve the clustering quality. However, since this kind of data is usually difficult to collect, the paper proposes a methodology involving data which are easily accessible.

Towards rule extraction for sector-coupled energy systems based on optimization models

David Wackerbauer[a], Thomas Schreiber[a] and Dirk Müller[a]

[a] RWTH Aachen University, E.ON Energy Research Center, Institute for Energy Efficient Buildings and Indoor Climate, Aachen, Germany, david.wackerbauer@eonerc.rwth-aachen.de

Abstract:

Today conventional rule-based control strategies dominate the control of energy systems in urban districts. Due to many interactions in urban districts, commissioning local energy systems and defining rules for optimal setpoint control is a challenge. Currently, expert knowledge based on comparable systems serve as basis to set up increasingly complex controls. Moreover, this process is becoming increasingly challenging due to the growing use of technologies such as heat pumps or storage systems to increase the share of renewable energies in the building energy sector. In academia complex systems are often controlled via computationally intensive methods such as model predictive control. Disadvantages are the complex initial commissioning, high computing demands, and a lack of interpretability of the system's behavior. To capture the complex interrelationships, the proposed method extracts simple rules from artificial optimal control. The energy system is first represented by a mathematical optimization model. The model determines the optimal plant operation for given demand time series. The optimization results are fed into white box machine learning models, such as Decision Tree Classifiers, to determine the revalent influencing factors and dependencies that are decisive for the determined operation. The process yields the relevant variables and setpoints for a simplified rule-based control. The extracted rules for an existing energy system are validated against the existing rule set and the theoretical optimum according to the optimization results by simulation. The rules can be interpreted by technical staff and applied to existing programmable logic controllers. This study introduces a toolchain to automate the creation of rule-based controls for complex energy systems.

rule-based control, optimization, machine learning, energy hub, sector-coupling, district energy system

1. Introduction

In order to achieve the climate targets that have been decided in the European Union, the emissions in CO2 equivalents in the building sector and here in particular also the direct emissions through the heating, cooling and electricity supply must be reduced. [1] To this end, renewable energies are increasingly unsed and integrated into existing energy systems in order to cause fewer emissions from fossil fuels. In the course of the energy transition in the building sector, control of the energy systems play a crucial role, as large potentials are wasted by inefficiency, but also the control of energy systems becomes more complex due to the use of new generation plants, the coupling of sectors and the integration of volatile renewable sources. [2]

The control complexity of an energy system increases with the following characteristics:

- The use of different generators.
- Coupling of sectors and inter-dependencies of sectors and generators.
- Different minimum loads of generators.
- Size and use of storage.
- Integration of own renewable generation such as photovoltaic (PV).
- Variable electricity and gas prices, as well as variable revenues for supply of surplus electricity to the public power grid.
- Utilization of flexibility for grid efficiency in the electricity sector.

Some of the listed factors offer the potential to make the provision of heating, cooling and electricity more efficient and to improve the integration and utilization of renewable energy sources. Due to the complexity of these systems, potentials may remain unused if no benefit is derived from the potentials in practice through simple control strategies.

In practice, the setup of the controls of complex energy hubs [3] that contain different generators coupling the heating, cooling and electricity sectors is an individual and time consuming task. For simple energy systems, containing only few units for energy supply and storage, it is feasible to find a standard procedure that is applicable on multiple reoccurring systems and control problems. With rising complexity and rising demands on the control of modern energy systems there are no normative or systematic procedures to setup the controls. Advanced control strategies, that are promising for complex control tasks, like model predictive control (MPC) or reinforcement learning (RL), have not yet made a leap into broad real world application due to implementation and acceptance barriers. [4] [2] Rule-based-control (RBC) operation is often based on the experience of the technician and individual considerations of the production costs for heating, cooling and electricity by the plants used. These are then implemented by a technician, for example, in the form of a generator sequence control. A common procedure for optimizing the energy system is to evaluate the current operation supported by monitoring and to determine control parameters in an iterative process, to yield satisfactory operation. This is measured and evaluated by the plant operator on the basis of key performance indicators such as the average operating point, efficiencies and prevention of short cycling of the plants.

The present work demonstrates a systematic procedure for deriving feasible operating rules for RBC of a district energy hub, that provides heating, cooling and electricity. The idea is based on the calculation of the theoretical optimum operation by means of mathematical optimization, taking into account dynamic boundary conditions and influencing variables. The results are then analysed in order to derive control rules for the supervisory level of the RBC. This is intended to circumvent barriers of complex control methods such as MPC in order to realize short-term potentials by improving the control of energy hubs in practice.

2. Literature Review

In this section selected sources dealing with rule extraction methods for energy systems in general are used summarize different methods for optimizing RBC systems. Furthermore examples of successful applications are given and challenges are adressed to identify open research questions.

May-Ostendorp et al. have discussed the possibilities of rule extraction from the results of an offline MPC in [5], [6] and [7]. In each case, the goal was temperature control in buildings using extracted rules from a training dataset containing time series data from an offline MPC. A distinction between closed-loop and open-loop learning is introduced in [6]. The closed-loop approach describes how time series data that is extracted from a system with a closed MPC loop with feedback and disturbances from the system is used to train the behavior of this MPC. In the open-loop approach, training is based on optimization results, which are used separately from the system and the actual control. The use cases described by May-Ostendorp et al. each include the building automation system and various parts of the indoor air conditioning system. The generator side is not considered. The derived rules are interpretable and were successfully tested on the building automation system for the studies.

Maier et al. [8] and Yang et al. [9] use Machine Learning (ML) models to approximate the controller behavior of a MPC. This kind of control is also referred to as approximate MPC (AMPC). The methodology of the studies can therefore be classified as closed-loop learning. The primary goal of these studies is to reduce the complexity for implementation in practice. Maier et al. uses a system to supply heating and cooling to a building using a heat pump and thermal storage. With a training data set of 2 years, it was possible to mimic the discrete modes that the MPC specifies for operation. Yang et al. uses a recurrent neural network (RNN) to learn the MPC behavior for a building's HVAC system. While the AMPC model achieves promising cost savings, the MPC is more able at ensuring comfort in the building.

Drgoňa et al. [10] use miltivariate regression algorithms to emulate optimization-based MPC. It is a closed-loop learning approach, which is demonstrated on the example of the control of a multi-zone building. The approximation of MPC yields very good results with the deep time delay neural networks (TDNN) and regression tree (RT) models employed. The application is successfully implemented and demonstrated on embedded hardware in the study.

Domahidi et al. [11] describe rule extraction using a closed-loop approach. Here, binary decision rules are extracted for the supervisory level of a building automation system using the ML models SVM and AdaBoost. Péan et al. [12] compare in their study different control concepts to exploit flexibilities of heat pump systems on the supervisory control level. The use case is the provision of flexibility for the public power grid. Studies with RBC and MPC are compared and it is shown how far RBC can also be used for control with the flexibility objective.

Robillart et al. [13] use the statistical method beta regression to learn from the optimization results. The use case is a residential building which is heated electrically and dynamic electricity tariffs are exploited by load shifting. The results show that the optimal behavior could be reproduced well under drastic reduction of the computing capacity and also outperforms a simple heuristic control.

In their study, Yu et al. [14] use a two-stage ML procedure to extract interpretable rules from a simulated MPC using an EnergyPlus model. Therefore the approach is a closed-loop-learnning procedure. The results of the multi-objective optimization are first clustered by an unsupervised clustering procedure to identify recurrent control decisions. In a second step, a decision tree classification is then used to reassign the clusters to the corresponding initial situations in the space for control. The method shows only slightly lower performance for the control of room air conditioning for the use case compared to the MPC, which serves as a reference.

Kanwar et al. [15] compare a MPC and a RBC approach for a microgrid that includes PV systems and de-centralized storage systems. The control approaches are intended to control the microgrid in such a way that the fluctuating renewable generation is self consumed and the degree of energy utilization is increased via the storage system. The MPC approach shows the best results due to the optimization with included predictions for renewable generation. Here, the rule-based approach consists of if-then-else loops based on engineering considerations that control the system depending on storage levels and electricity prices.

In general, the procedures in the literature can be divided into open-loop and closed-loop procedures as described by May-Ostendorp et al. [6]. The presented studies can also be subdivided with respect to the rule extraction procedure and the applied ML models. On the one hand, there are studies that apply rule mining to directly extract rules and limits for a rule-based system. For this purpose, ML models are used that establish interpretable relationships, such as decision tree classifiers and clustering algorithms. On the other hand, there are studies that aim to approximate the behavior of MPC using the ML models and replace the online MPC with a meta-model, which can significantly reduce the computational effort. For this method, ML models can be implemented on low level hardware to interact and control the energy system. In this case no interpretable relationships between input and output of the controls are given.

The application fields of the literature presented here describe, among others, building energy systems and the supervisory level in the building automation system. The control problems to be solved for RBC partly focus mainly on special problems (control of windows [7]) or the control of individual elements of the energy supply system, such as the utilization of storage units [15]. A research gap is identified that addresses control extraction methods for so called ”multiple input multiple output” (MIMO) problems for the coordination of larger energy systems, such as district energy systems and energy hubs with different generators and the coupling of energy sectors.

This study shall showcase the possibilities by describing the energy hub as a mathematical optimization model for the systematic creation of an optimized RBC. In addition, the comparison with existing RBCs implemented by engineers in practice shows that the methodology can also take other variables into account in order to fulfill requirements such as flexibility for the public grid in a rule-based mannor.

3. Use case

The energy system of the presented use case supplies a city district with heating, cooling and electricity. The generation plants are located in an energy hub, the heating and cooling supply of the buildings in the district is carried out via thermal networks. The district is characterized by mixed use, which includes office buildings, hotels, retail, restaurants, industrial enterprises, sports facilities and cultural institutions. The demand profiles show a high simultaneityof heating and cooling demands throughout the year. The connected industry has a year-round cooling demand. Some of the buildings are supplied with domestic hot water via the local heating network. Therefore a year-round heat and cold supply is provided by the thermal networks and the energy hub. In addition to the energy hub, the system is also connected to the public power grid. Some of the buildings have own additional generators for support, such as decentralized heat pumps, which are, however, neglected in this study and are controlled independently of the energy hub. Decisive for the optimization problem are the thermal and electrical loads, which are supplied by the energy hub to the district.

Figure 1 shows the different sectors and all the supplies and demands, that are located in or connected to the energy hub. The heat supply can be provided by different plants.Two combined heat and power plants (CHP) are available, each with a thermal output of 1111 kW and a nominal electrical output of 851 kW, a gas boiler with a nominal thermal output of 1870 kW, a high-temperature heat pump (HT-HP) with a nominal thermal output of 1284 kW, and an electrical heater (EH) with a nominal thermal output of 250 kW. Cooling is primarily provided by two absorption chillers (AC) with a nominal cooling capacity of 787 kW and a heat demand of 1049 kW nominal each. The ACs are connected to free coolers via a recooling circuit, which can also be used as free coolers at outside temperatures below 0 °C. The ACs are connected to the free coolers via a re-cooling circuit. The re-cooling circuit of the AC also serves as a heat source for the HT-HP. Due to this coupling, the HT-HP can only be used when the chillers are running, which, however, is always the case due to the high year-round cooling demand as long as the free coolers are not used. While the CHP units are decoupled from the heating network via two buffer storages with a total capacity of 24,000 l, all the other heat generation units feed directly into the heating network. Therefore an optimal sceduling of the devices in regard to current demand, efficiency and minimal part load to reduce on/off cycles is crucial for the control of the energy hub.

The structure of the supply system makes it possible to provide both positive and negative flexibility for the public power grid through appropriate control. This is due to the coupling of the electricity and heat sectors via CHP and HT-HP. The flexibility potentials of energy systems are often achieved with temporary measures, such as the utilization of storage facilities and the thermal inertia of buildings. In this context, only limited amounts of energy can be shifted at certain times. The present energy system can also provide permanent flexibility to the public grid depending on the heating, cooling and electricity demands by shifting the load to other generators. This aspect will be discussed in more detail in the result section 5. when considering different electricity and gas prices as an economic incentive.

The current control is based on a generator sequence, which is carried out via the storage levels of the thermal buffer storage. Currently, the CHP are prioritized to provide the base heat load. The HT-HP is switched on manually when the AC are running and there is a heat demand from the local heating network. The gas boiler and electric heater serve as backup and are used manually in certain situations: If the heat demand from the local heating network and the AC exceeds the capacity of the CHP units, a CHP unit is switched off in favor of the gas boiler, since the gas boiler can provide a higher heat output for the gas used. In addition, the gas boiler serves as a redundancy for, among other unplanned downtime, service times of the CHP units. The electric heater has a relatively low output and is also kept in reserve for peak loads. Although the current control system is largely automated, there are still manual interventions and the limits and prioritization of individual generators are adjusted by a technician in the course to manage an economical operation. This is also the motivation for the methodology to implement a mathematically optimized rule-based operation.

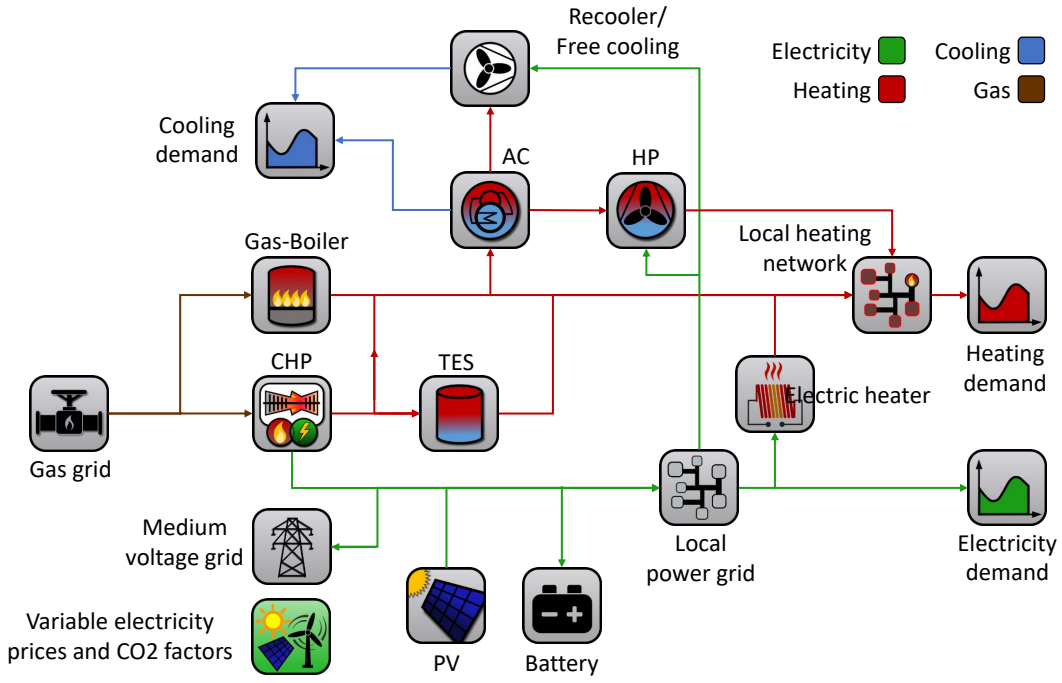

Figure 1: Structure of the sector coupled energy system

4. Methodology

Figure 2 presents the main parts of the methodology. Time series data for heating, cooling and electricity demands, which must be generated by the energy hub serve as input for the optimization model. The time series data must be available for the optimization model in the appropriate temporal resolution. This data can be provided in the form of measurement data from an existing energy system, or from a dynamic building simulation. In addition to the energy requirements, technical and economic constraints are transferred to the optimization model as parameters.

A Mixed Integer Linear Program (MILP) is used as the optimization model. A detailed description of the model is given in section 4.2.. The objective function of the optimization minimizes the operating costs, which, in addition to the costs for purchased electricity and gas, takes into account the revenues for sales to the tenants of the supplied district, as well as lump-sum deductions for start-up costs of the plants and taxes for CO2 emissions. The results of the optimization model are output as a set of time series data per parameter variation. This

contains the current outputs of all plants and storage levels for each time step of the optimization. In addition to these raw data, plant performance indicators such as a start-up counter, energy quantities provided and utilization or average operating points are also outputs.

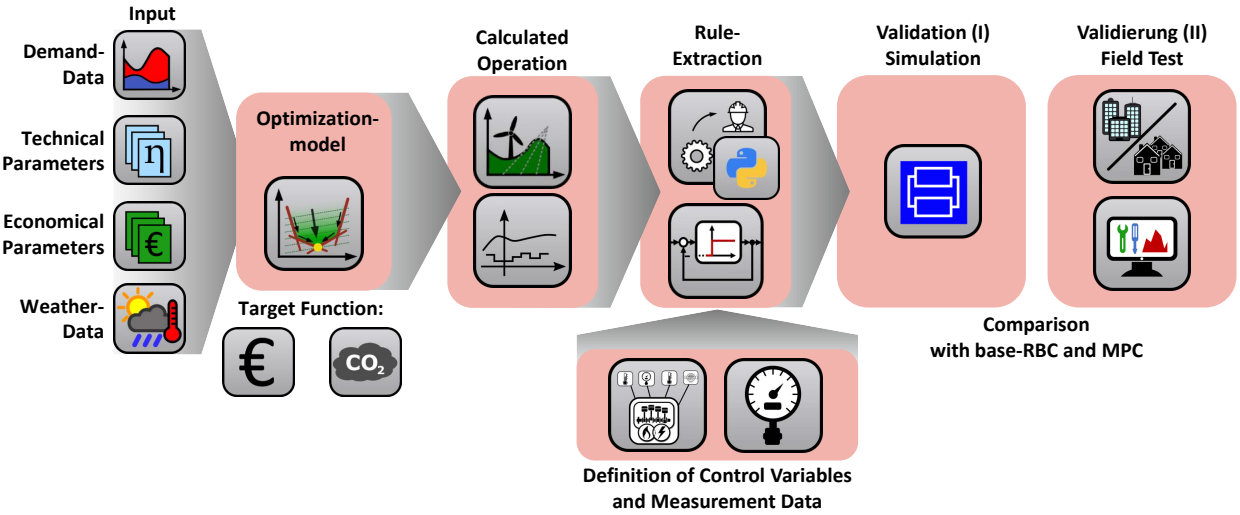

Figure 2: Structure of the Methodology

For the subsequent rule extraction process, the measured datapoints available in the real energy system and the variables to be controlled must be defined. The rule extraction process should use interpretable ML models to establish relationships between the measurable variables and the desired controlled variables for the supervisory level of control of the energy hub implementable by technicians with a corresponding education. In the last step, the rules are validated. On the one hand, an existing simulation model of the energy hub is used, which was implemented in Dymola using the open-source model library AixLib [16]. The comparison can be made in the simulation with the existing RBC of the energy hub, as well as with other control approaches such as an ideal MPC with perfect forecast as an upper-bound comparison. In addition, the rules should also be implemented in practice if they offer potential for improvement compared to the previous mode of operation.

4.1. Data preprocessing

The demand time series for the heating, cooling and electricity demands of the district, which are used for the optimizations, are real measurement data from the project, which were recorded via a monitoring platform. Since cooling can only be provided via the AC, only the heat flow required for the AC, which is recorded via heat meters, is taken into account in order to further simplify the optimization model.

Since data gaps for individual data points occur in the monitoring data set, the time series are subjected to preprocessing. Gaps with a duration of less than 2 hours are closed by the mean value of the adjacent time steps. If a larger gap occurs in one of the time series, the faulty segment removed from the data set. The optimization is then performed for one contiguous segment at a time, with continuity for the thermal storages being maintained by a constraint that the storage levels must be identical at the beginning and the end of each cycle.

4.2. Optimization model

The energy system is formulated as a mathematical optimization problem in Python. The optimization is performed with the commercial solver Gurobi [17]. The coarsest temporal resolution of the underlying measurement data from the real energy system is 15 min. Accordingly, the time step size of the optimization problem is also set to 15 min. The results from the optimization are output as time series data in a structured way.

The main model parameters are described below:

- The thermal and electrical efficiencies of all plants, as well as the coefficient of performance of the HT-HP. The efficiency curve of the gas boiler and the CHP units is approximated by a stepwise linearization, while the EH and the HT-HP are represented by a constant efficiency and coefficient of performance, respectively. Analysis of the measured data shows that the source and sink temperatures of the HT-HP in the application are almost constant, and therefore the assumption of a static COP was assumed to be sufficiently accurate for the case study.
- Minimum partial loads are specified as constraints for all generators.

- Due to the size of the equipment, special consideration must be given to the cost of wear and maintenance due to frequent start-ups. These start-up costs are provided as parameters in the model. The CHP units are the most expensive with 50 EUR per cycle, the gas boiler and the HT-WP with 10 EUR per cycle each and the electric heater with 3 EUR per cycle. The values were estimated with partners from practice.
- Minimum run times for the following components are specified as constraints: The CHP must run for 30 min, the gas boiler and the HT-WP for 15 min each, and the EH for 1 min before they are allowed to be shut down again by the optimization. In addition to the start-up costs, these constraints were chosen to prevent the plants from cycling and to force a solution with longer run times.
- Generator dependencies in the system were specified by constraints: Due to the high temperatures required for the AC, they can only be supplied by the CHP units or the gas boiler.
- The gas connection is limited to a capacity of 5 MW, which is why only two of the gas-fired plants (Two CHP units and one gas boiler) may be operated at a time.
- The costs for the purchase of electricity from the public grid, the purchase of gas, CO2 emission costs and revenues for the sale of surplus electricity to the public grid are each specified by constant parameters. However, the option is provided to run optimizations via a parameter grid variation. These parameters have a sensitive influence on the optimization result and the use of individual generators. Using the parameter-grid, their influence on the results can be displayed for any time-step and later be used in the automated rule extraction.

The parameters listed were implemented according to the manufacturer's specifications.

The procurement prices for electricity and gas were assumed to be constant, but the model is designed to run optimizations for a parameter grid for different electricity, gas and CO2 prices, so that the influence of these costs on the generation sequence can also be mapped at any point in time.

4.3. Rule extraction

The methodology presented in this paper is intended to provide results through the rule extraction procedure that can be interpreted by a technician and used for setting the control in practice. Therefore, only ML methods that allow this form of interpretation are considered. Existing literature provides examples for the use of Decision Tree Classification, Clustering methods, Support Vector Classification and AdaBoost as discussed in 2..

Currently, two ways are being tested to represent the complex dependencies of this MIMO system from the optimization model in a form that can be directly transferred to the automation system in practice. Enabling of generation units depending on the important decision variables such as current heating and cooling demand, as well as electricity and gas costs can be reproduced using Decision Tree Classification. However, the accuracy of the model trained using optimization data does not yet allow conclusions to be drawn about the performance of the control in practice. Validation is still pending. Another possibility is to transfer the optimization results to operating modes that can also be mapped in the automation system. Thus, the data set can be grouped using clustering. The decisive variables and transition conditions between the modes must be determined in a further step.

4.4. Simulation Model

The simulation model to be used for validation of the optimized RBC is implemented in the Modelica language. It is based on physical models of the simulation library AixLib [16] and is modeled by means of plans for the interconnection of the energy hub, as well as the parameters according to the manufacturer's data sheets. Many of the simplifications in the optimization model, which are based on the simplified mathematical description of the system, are more accurately represented in the simulation model. For example, the model uses fluid models that represent the thermodynamic properties of water. Inertias, as well as start-up processes of the plants and temperature wave propagation in the system are taken into account and the temporal triggering in the model is minute-by-minute. The model contains all interfaces for control using logic expressions in Modelica or for integration as a Functional Mockup Unit (FMU) for co-simulation in another environment, e.g. for embedding in a Python program.

5. Results

The optimization model was tested for several years on measured data and for different model parameters to determine their influence. In particular, a systematic variation of variables that change in reality, such as electricity, gas and CO2 certificate prices, is important in order to learn their influence on the basis of the optimization results for improved control.

For the example plots below, the optimization was carried out for a parameter grid of varying electricity and

gas prices. The months of July and December 2021 were used as examples to consider one month in and one month out of the heating period. The plots in figures 3 and 5 each show the relative utilization of the generating units for the heating sector as a percentage. The plots in figures 4 and 6 each show the total operating costs, the revenue generated by selling surplus CHP electricity to the public grid, and the local CO2 emissions generated by the gas-fired plants.

In the month of December, the heat supply for the AC is distributed between the first CHP and the gas boiler depending on the electricity and gas prices. When gas prices are low and electricity prices are high, the first CHP is utilized as much as possible. The second CHP is also partially added when gas prices are low and electricity prices are high. Apparently, the generation of heat and electricity by both CHPs is worthwhile, even if the electricity generation from the CHPs exceeds the captive demand in this case, as shown by the plot of revenues for electricity sales in Figure 4. With increasing gas prices and also decreasing electricity prices, there are parameter pairings that increasingly switch to the gas boiler and also the electric heater for optimal supply. The result is due to the larger amount of heat that can be provided by the gas used through the gas boiler, along with the less economical electricity generation by the CHP units at lower electricity prices. In general, heat generation from the HT-HP is in any case the most economical variant of heat generation for the local heating network, since it is in operation almost continuously high for all variants. Only at the corner of highest electricity costs and lowes gas prices the HT-HP operation is reduced in favor of higher utilization of both CHPs. This is why for the control of the HT-HP, the required waste heat from the AC and sufficient offtake from the local heating network should be decisive and should be preferred to the other generators for heat supply for most cases.

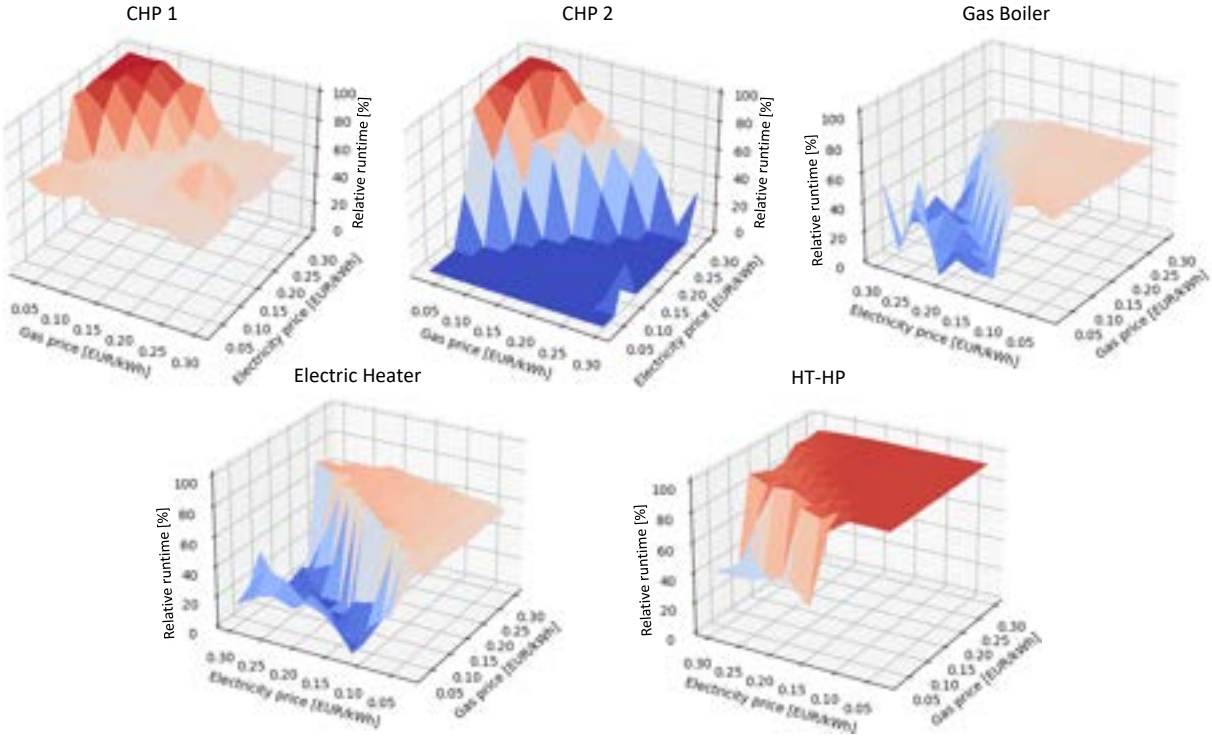

Figure 3: Optimization results for December 2021: Relative runtime of different generators for heating supply

In the month of July, a different generator composition is evident from the plots in figure 5. The share of the second CHP is further reduced for cases of lowest gas prices and highest electricity prices. The gas fueled generators (CHPs and gas boiler) show an only slightly reduced utilization, which is due to the rather constant high temperature heat demand from the ACs that is at a similar level all year round. The heat demand here in July, outside the heating season, is mainly driven by the heat demand of the AC and supplemented from the heat grid only by a small load due to domestic hot water supply. This is clearly evident from the utilization of the HT-HP, which remains at low part load for the entire parameter grid. This can be explained by higher utilization of the generators, which run anyway for the heat supply of the AC, and by the high minimum partial load of the heat pump. Since the heat pump is directly coupled with the heating grid and cannot use a buffer storage volume, a certain minimum demand from the grid is required to operate the HT-HP economically.

The two example months and parameter variations show exemplarily that by a simple analysis of the optimization results rules for the generator enabling can already be derived. In the example, these are dependent on

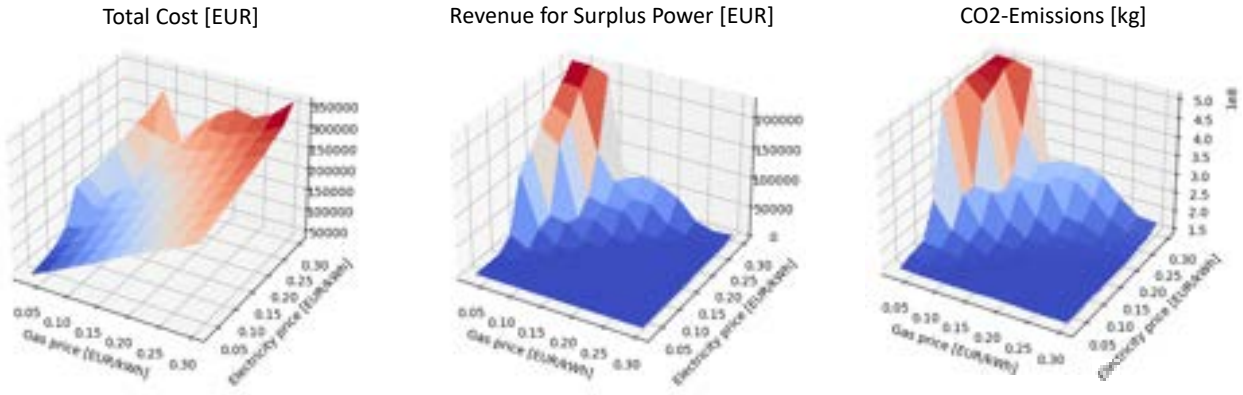

Figure 4: Optimization results for December 2021: Total cost, revenue for surplus power and local CO2-emissions for a parameter-grid of varying gas an electricity costs

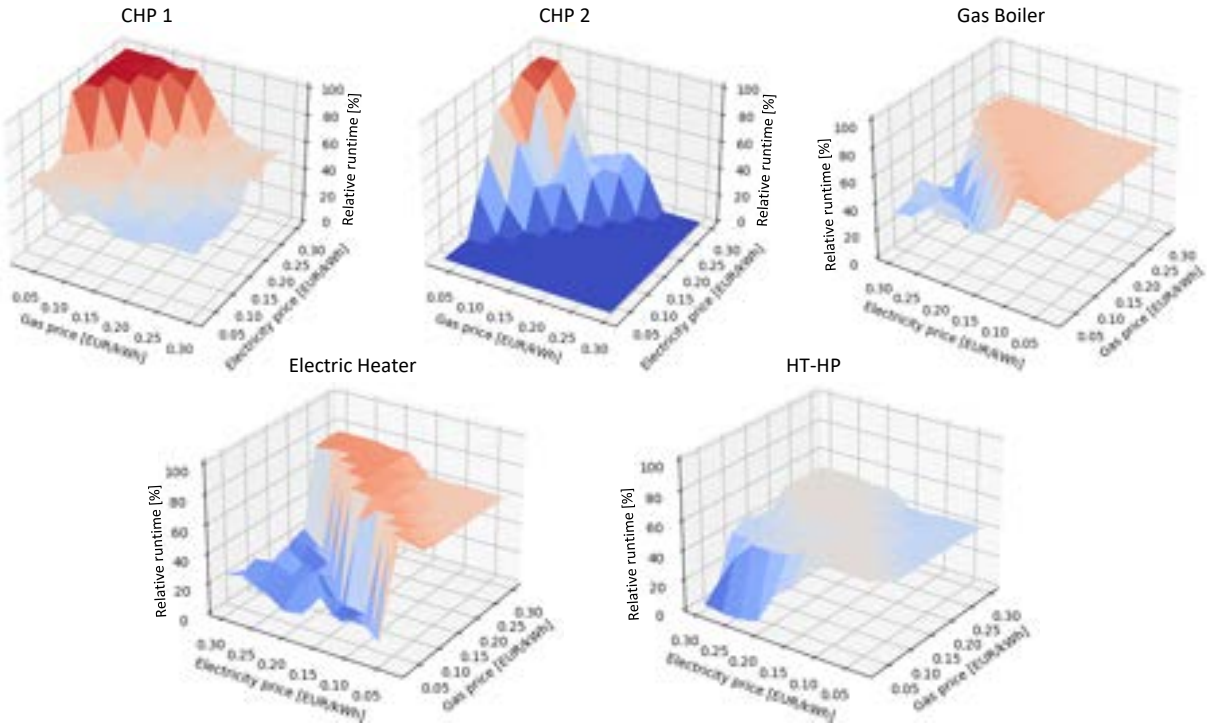

Figure 5: Optimization results for July 2021: Relative runtime of different generators for heating supply

the electricity and gas prices, as well as the season and the correlating heating and cooling demand of the neighborhood and the constraints specified by the model.

The evaluation of different parameter variations shows the dependence of the utilization of individual heat generation plants in the model and the sequence of generators on the influencing variables gas price and electricity price. In particular, if these variables are not fixed in practice by corresponding long-term contracts for periods of time, but are subject to high fluctuations through trading on the energy markets, there is considerable optimization potential here. The previous control-based mode of operation does not include the variable costs described above as decision variables for the control, although in the current situation the prices for electricity purchases and sales are traded directly on the stock exchange. Only gas purchases and CO2 taxes are currently fixed.

6. Summary and Outlook

So far, the study shows the general methodology for systematic optimization of rule-based energy systems using mathematical optimization models. While the mathematical modeling and the representation of the

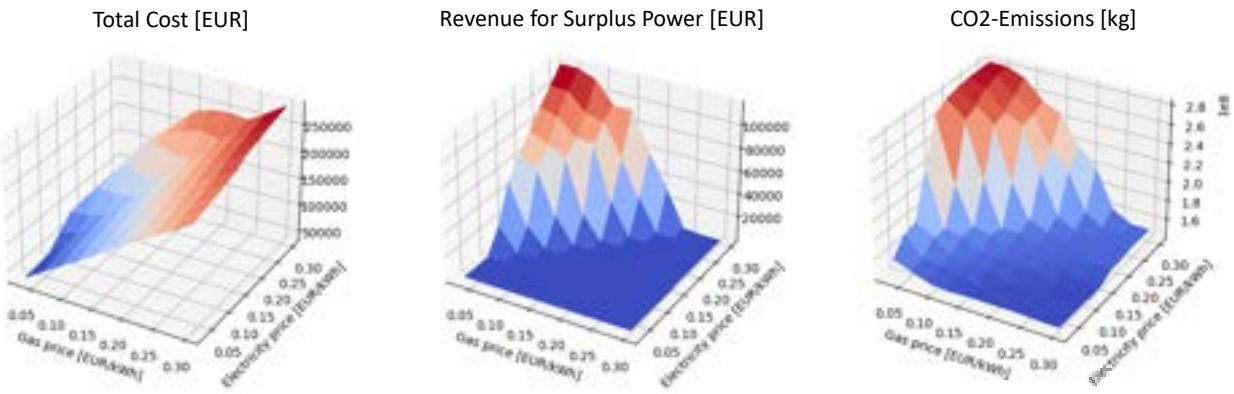

Figure 6: Optimization results for July 2021: Total cost, revenue for surplus power and local CO2-emissions for a parameter-grid of varying gas an electricity costs

energy system using Modelica models have been completed, the automated rule extraction and validation of the entire methodology on simulation and real energy systems are still pending.

The presented methodology can be used to determine the relevant decision variables and extract set-points for an optimized rule-based system, taking into account technical and economic constraints. The iterative procedures for the improvement of rule-based systems, which are common in practice, can be supported by the presented procedure in order to reach an applicable mode of operation faster.

The presented results of the optimization model show exemplarily how the current RBC should be supplemented by further decision variables for the control. Even if validation and the use of automatic control extraction methods are still pending, the influence of variables not yet taken into account in the control, such as the electricity and gas price, can already be derived directly manually.

For systems of high complexity or complex control requirements, the methodology shall also indicate when operation cannot be satisfactorily tuned using a rule-based approach and when it is worth the effort to implement more advanced control strategies, such as MPC.

In further investigations a comparison to conventional RBC and more advanced MPC approaches will be made to demonstrate which of the optimization potentials can already be achieved by an optimized RBC and for which problems more complex controls like MPC are necessary to achieve a satisfying operation.

The influence of the model accuracy of the underlying optimization model on the extracted rules needs to be investigated in more detail. Further studies should show which temporal resolution and properties of the plants i.e. constraints in the optimization model are important for the rule extraction. Provided that the method already delivers satisfactory results for rule-based operation in generic design optimization procedures with lower model accuracy and temporal resolution, this would significantly improve the transferability of the methodology.

In addition, follow-up studies will show whether the accuracy achieved in rule extraction procedures such as clustering or decision tree classification already allows conclusions to be drawn about the performance of the control in reality, or whether it needs to be validated in general.

Abstract:

This paper investigates the transfer learning mechanism to improve the prediction accuracy of the energy system model. Artificial intelligence techniques are increasingly being adopted in the energy domain to predict energy system characteristics and performance. However, in many energy systems, the relationship between interested variables and their distributions differs (data and concept drift) with time due to system degradation and aging. There is a requirement for re-training and re-testing AI models to ensure reliable performance over time, which may require extensive latest operational data. Transfer learning helps to confront this challenge by leveraging valuable knowledge from a pre-trained model and reducing the requirement of new operational data significantly. To address these issues, this paper focuses on a gas turbine, a critical energy system widely deployed in diverse applications, and shows performance degradation over its lifetime. The energy model of the gas turbine is a multivariate type that predicts energy efficiency, fuel consumption, and heat energy based on power setpoints and weather conditions. This paper examined transfer learning mechanisms that can capture the latest characteristics of the gas turbine and their effects on prediction accuracy. The developed transfer learning model predicts fuel consumption accurately above 99%, whereas the pre-trained model under-predicts up to 4%, which may lead to suboptimal operation decisions when employed in the scheduling algorithm. Some of the other targets, such as heat energy, show marginal drift, as expected from the gas turbine characteristics. The knowledge gained from the transfer learning mechanism and its efficacy boost assists operational decisions, which helps improve energy efficiency and cost savings.

1. Introduction

Commercial buildings account for 32% of global energy consumption and are expected to face an annual growth of around 1.3% and 2% for the Organization for Economic Co-operation and Development (OECD) and non-OECD countries [1]. The building sector wastes around 20% of its energy due to faults in energy systems [2,3] which further emphasises the importance of assessing the operational performance of these systems. The increasing trend of energy consumption urges efficient monitoring to improve the efficiency and life span of these systems and reduce carbon footprints and unnecessary downtime. Decarbonization drives distributed energy resources (DER) comprising renewables and local generation to support diverse buildings and communities. Urban communities are moving towards local DERs to gain additional efficiency benefits and strengthen reliability and resilience. Advancements in smart grids, the Internet of Things (IoT) and artificial intelligence (AI) boost adoption to automate and optimize various energy processes. The most common applications in buildings are AI-based energy management systems [4], fault detection and diagnosis [5], and load and renewable forecasting [6]. Traditionally, physics-based models were employed to address these problems and require more specific information about buildings and technologies [7,8]. Now, AI techniques cut short and ease the development and deployment process and offer scalability to larger problems [9] through generalized models. Despite the many advantages of these approaches, a major drawback is the requirement of sufficiently large datasets to produce accurate models [10]. For example, deep learning models not only require large datasets but also extensive training times and computational resources [11], and often compiling

such a dataset can be expensive, time-consuming, and even impractical on certain occasions[12]. This study focuses on developing an AI model of a gas turbine using minimal latest operational data and exploiting most of the information from the pre-trained model.

1.1 Importance of Learning Models

The performance of energy systems degrades over time; some of the performance losses can be recovered through proper maintenance, whereas the non-recoverable losses are due to system wear and tear. Such situations may change the characteristics and performance of the energy system, i.e., the changes in the outputs (dependent variables) for given inputs (independent variables). This process is often referred to as concept drift in literature. It is pre-eminent that predictive models operating in such settings need to account for these changes to retain prediction accuracy. Learning methods are widely used to address some of the performance drift challenges involving data shortages. The learning methods apply a knowledge transfer process and achieve substantial improvements in many domains, including computer vision, natural language processing, speech recognition, bioinformatics, and reinforcement learning [5].

Adaptive learning techniques are applied in dynamic environments where the performance data (system characteristics) varies with time. Adaptive learning consists of four building modules comprising memory, change detection, learning, and loss estimation [13]. The memory module updates the latest information and simultaneously discards irrelevant old information. The change detection module characterises and quantifies concept drift by examining data and its distribution between two-time windows, as well as validating the predicted values with actual measurements. The learning module updates the prediction model through retraining and the incremental method. The retraining mode discards the existing model and develops a new model using both old and new data [14]. In contrast, incremental methods update the current model with the most recent data as it becomes available. The final module is loss estimation, which is related to performance metrics used to estimate the algorithm performance during adaptive learning. Several articles incorporated adaptive learning to account for degradation in their workflow, thus improving the efficiency of systems. These studies focus on batteries and fuel cells, which are prone to significant capacity degradation. Li et al. developed a fuel cell degradation model for a hybrid bus energy management system to account for different decay rates during varying operating conditions [15].

On the other hand, transfer learning uses the knowledge gained in one problem and applies it to a different but related problem, such that the development process is simple and eliminates the need for development from scratch and a complete dataset [16]. Lu et al. applied transfer learning to tackle limited data for improving the thermal load forecasting model and developed a similarity measurement index to select a source task that is most like the target task [17]. Chen et al. [18] proposed a neural network based on control theory for fault detection in actuators and utilized transfer learning to account for degradation in the system. In the context of degrading energy systems, transfer learning aims to update a pre-trained NN model using the latest operation data to capture the changes in the system's behaviour. This type of problem is categorized as domain adaptation, where the model inputs and outputs are still within the same space, but the distribution or system characteristics change due to ageing [19]. Figure 1 shows a general overview of the domain adaptation problem, where the neural network model is developed using a comprehensive dataset, resulting in a pre-trained network. Later, this pre-trained model is adjusted or fine-tuned using the latest dataset to capture the behaviour and performance of the current state of the system. During the finetuning process, the learned weights and biases of the pre-trained model are further adjusted to minimize the loss function in relation to the latest operational data. The fine-tuning process usually leads to shorter training periods because the pre-trained model has already learned useful features.

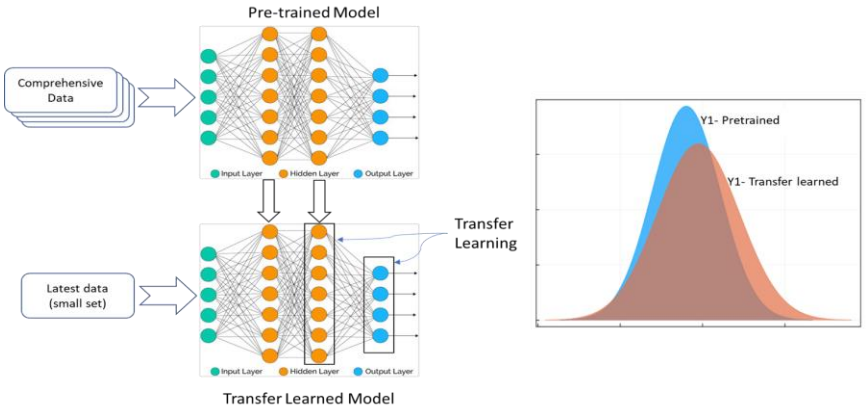

Figure. 1. General schematic of transfer learning for domain adaption problem

In energy systems, transfer learning has been applied to a variety of problems. Liu et al. designed a convolution-based neural network (CNN) to diagnose faults in building chiller plants [5]. Besides transfer learning, other methods solve similar problems involving data limitations; for example, semi-supervised learning takes advantage of unlabeled data together with some labeled data to improve prediction performance [20], but both datasets are required from the same distribution. Multi-view learning leverages multiple different feature sets or views available for additional data description [21]. This study aims to comprehend the transfer learning mechanism and develop transfer learning models to improve the prediction accuracy of the energy system. This study investigates and compares two transfer learning mechanisms that can capture the changes in the energy system characteristics (referred to as data drift) with the limited latest operational data and extract other useful information from the pre-trained model.

2. Methodology - Transfer Learning for Degraded Energy Systems

In degraded energy systems, the transfer learning mechanism is to improve the prediction accuracy of the AI model by using the latest operational data and capitalizing on useful information from the pre-trained AI model. To achieve this, firstly, an AI model was developed using the comprehensive dataset to depict the initial characteristics of the system. Later, this pre-trained model is adjusted to capture the latest characteristics as the performance of the system degrades. The adjusted model is often referred to as the fine-tuned model. In such situations, the dataset representing a degraded system may be limited; however, this requirement is acceptable as this data does not need to represent all characteristics of the system. Figure 2 shows the schematic of the transfer learning mechanism, where data processing is the starting point to extract useful information (i.e., features and targets) from the operational data and eliminate outliers and noise. Develop a multi-layer perceptron neural network (MLP-NN) model to predict energy system behaviour and performance. Data normalization was employed as a pre-processing step to improve model convergence and prediction accuracy, whilst K-Fold cross-validation was used to evaluate model performance considering the network architecture with different hidden units, which defines the complexities of the model that can be varied to achieve desired prediction accuracy. The deployment of the developed NN model in the energy management system supports scheduling algorithms in deriving key operation setpoints and dispatch decisions.

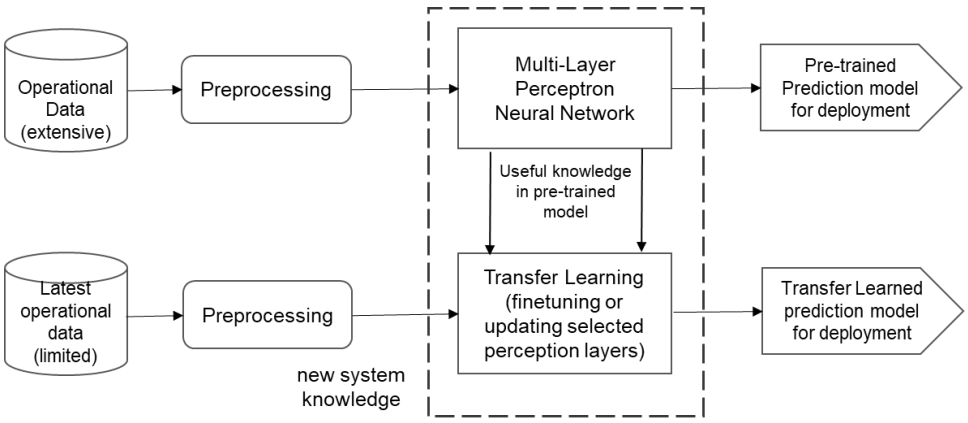

Figure. 2. Schematic of Transfer Learning Mechanism

The performance or prediction accuracy of the developed model is expected to drop over time due to changes in the actual system. Eventually, this model will become obsolete and not useful. Transfer learning helps to revitalise the prediction model using the latest operational (limited) data and critically utilize the useful information from the pre-trained model. Transfer learning can be carried out in different fashions, such as finetuning or updating the coefficients of the output layer or the whole pre-trained NN model using the latest operation data. This mechanism requires less data compared to the NN model developed from scratch. The transfer learning mechanism also helps to include or exclude targets to support any changes in the prediction model requirements. The next section will describe the workability and benefits of the transfer learning mechanism for the energy system application.

3. Case Study – Gas Turbine and Performance Prediction

Generators, renewables, and energy storage are the key distributed energy systems that help to generate, store, and support various forms of electrical and thermal energy. In the long run, some of the DERs show performance degradation due to wear and tear, especially those types of equipment with rotation or fast-moving parts. Even a non-rotating system such as solar PV and batteries shows performance degradation due

to ageing and depreciation of internal components. Interestingly, the solar PV manufacturer provides the expected performance degradation, whereas for other DERs, equipment usage and operation patterns play a dominant role in the performance degradation. This study focuses on gas turbines' critical distributed energy resources, categorized as a dispatchable system where the operation can be easily controlled based on the power requirements to fill the power deficit and synchronize with the grid frequency to absorb the fluctuations. This section will describe the necessity of a transfer learning algorithm for the gas turbine model and its benefits.

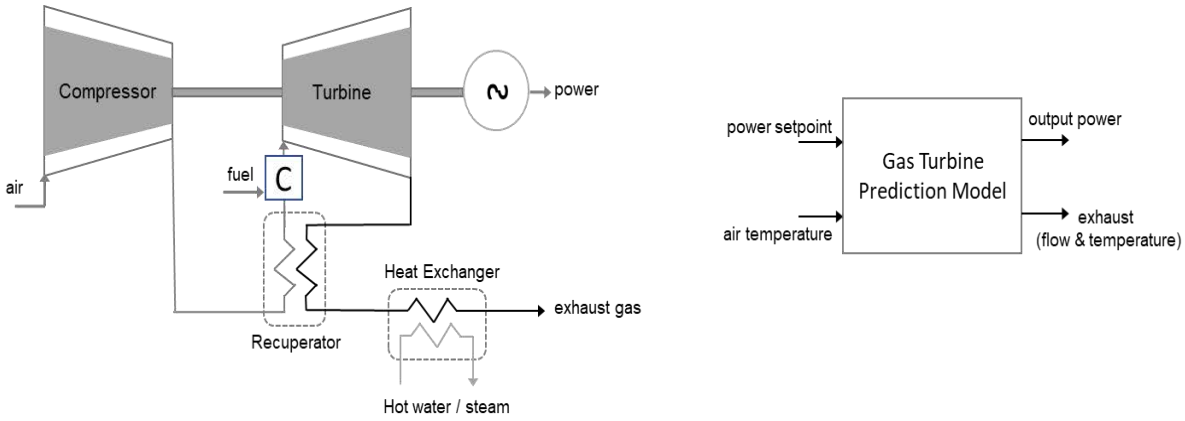

Figure. 3. Schematic of Gas turbine and AI-based prediction model

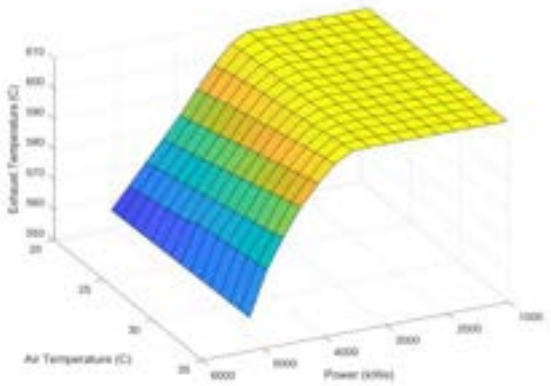
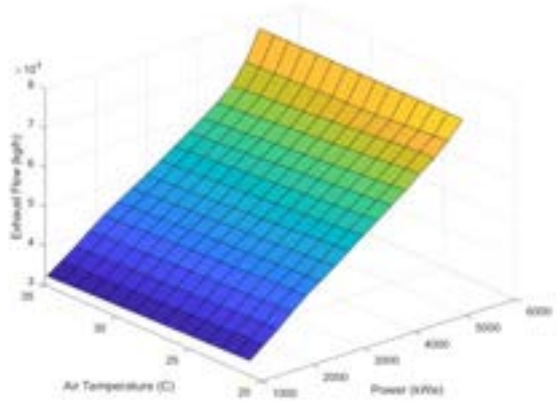
Gas turbines are widely employed to generate electrical power using clean fossil fuels such as natural gas, and even the waste heat available in the exhaust gas is recovered to support thermal loads. Figure 3 shows the schematic of a gas turbine, where fuel and air drive the turbine to generate power and exhaust gas. The heat energy in the exhaust gas has the potential to produce steam or hot water when diverted through boilers or heat exchangers. The recovered heat energy can be utilized in exhaust-driven absorption chillers to produce chilled water for air conditioning purposes [22]. Gas turbines are available in diverse capacities, ranging from a few kW to over hundred MW scale. Like any other system, a gas turbine provides high efficiency at rated conditions and low efficiency during off-load conditions. The life of the gas turbine is around 150000–200000 hours, or 20 years with regular maintenance and overhauls. Experts and manufacturers confirm that this system shows performance degradation over time; some degradation effects are recoverable through proper and regular maintenance [23], whereas performance degradation due to ageing (due to wear and tear) are permanent and cannot be recovered. Any degradation in performance could result in sub-optimal operation conditions, affect the energy cost, and incur the risk of supply shortages. Therefore, actual performance needs to be accurately accounted for to understand the operation cost of the gas turbine and decide on the right combination of systems for dispatching purposes.

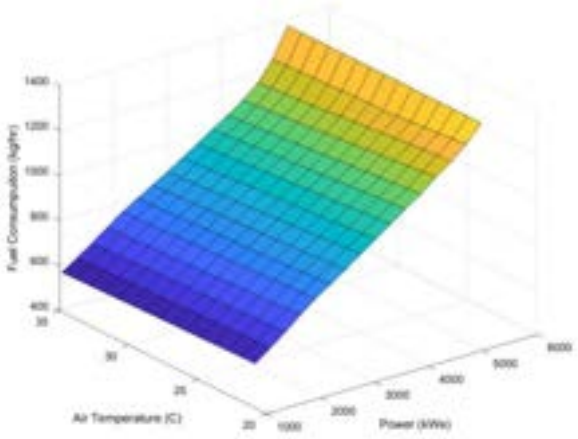
Commonly, performance charts or technical data were widely used to gauge power output, fuel consumption, and fuel cost. Unfortunately, it is quite abstract and covers design conditions at standard temperature and pressure. Experts exploit physics-based models to generate performance charts for diverse conditions [24], this study utilized the gas turbine simulator adapted from TRNSYS to generate the performance data and understand the effect of degradation on the performance factors. TRNSYS is a state-of-the-art commercial simulation tool for industry and academia, based on an object-oriented approach that enables the simulation of the transient behaviour of systems focused on assessing the performance of thermal and electrical energy systems. The software is made up of two main parts: a simulation engine to solve the dynamic mathematical problem and a large library of built-in components or types (e.g., gas turbines, compressors, pumps, mixers, diverters, heat exchangers, etc.), often validated by experimental data. Type 625 has been adopted, utilizing technical data and performance maps of 3.5 MW gas turbines [25]. Exploiting the Type 625 model, the gas turbine performance parameters are derived for diverse output power and inlet air temperatures. Figure 4 shows the performance characteristics of a new gas turbine, where the fuel consumption increases with the output power and the air intake temperature. The air temperature and output power also show an effect on the exhaust gas flow and temperature.



(a) Variation in the exhaust gas temperature



(b) Variation in the exhaust gas flow



(c) Variation in the fuel consumption

Figure. 4. Performance characteristics of Gas Turbine (without degradation) with reference to part-load behaviour and air intake (ambient) temperature

Model GTD is a multi-layer perceptron (MLP-NN)-based neural network architecture prediction model developed using the performance data (17x15 = 256 data points covering 17 part loads and 15 air temperatures) representing a new gas turbine. Data normalization is applied explicitly to ease the convergence process and prevent any bias due to different data scales. Due to a smaller number of data points, K-Fold cross-validation was employed during training to obtain a more accurate estimate of the model's performance. The model GTD was trained using an ADAM (Adaptive Moment Estimation) optimizer with mean squared error as a loss function. The training epochs and the model complexity (hidden units of 8, 16, 32, and 64 units) are varied to identify the right architecture that provides acceptable accuracy during training and validation. Finally, the Model GTD with 64 hidden units was able to predict the gas turbine outputs with the required accuracy of 0.998 R2 on the validation set.

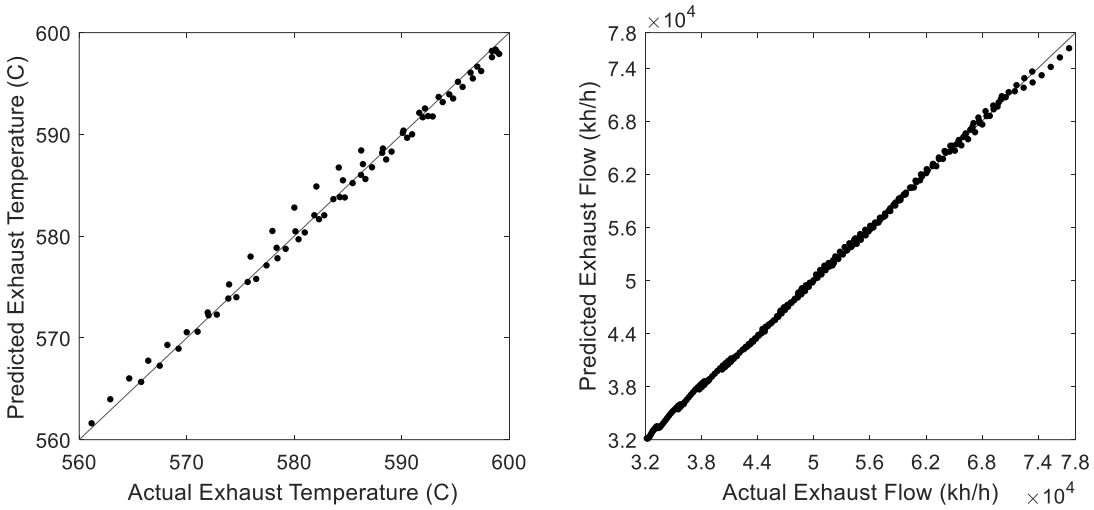


Figure. 5. Actual Exhaust Gas and Model GTD predictions (R2: 99.8%)

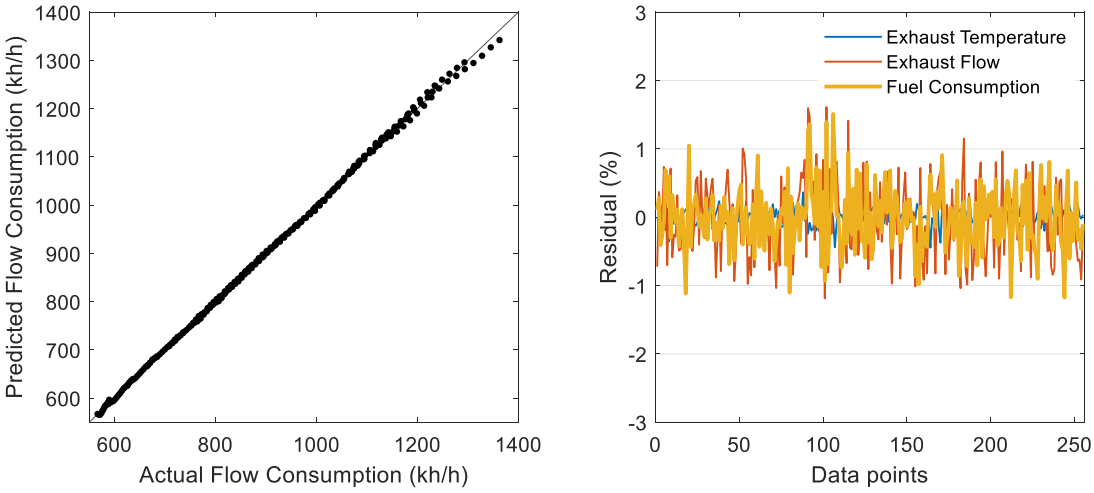

Figure. 6. Actual Fuel consumption and Model GTD predictions (R2: 99.8%)

The accuracy of the developed Model GTD model is shown in Figures 5 and 6. This model helps the scheduling algorithm make optimal operational decisions on an hourly or sub-hourly basis. The normalizers and coefficients, or weights, of the prediction model are preserved for later use.

4. Performance of Pretrained and Transfer Learning Models

The Model GTD prediction is expected to deviate over time because the actual gas turbine characteristics drift due to ageing and degradation. Any inaccuracy in the prediction could lead to suboptimal or inferior scheduling or operation decisions that may result in high energy costs or a potential supply risk. To retain prediction accuracy, a new prediction model needs to be developed from scratch using the latest operational data. In a real application, the gas turbine's operation depends on the loads and operation of other integrated energy systems. Therefore, it is challenging to get the latest performance data over a wide range. The possible collection of real-time operational data is limited and not comprehensive. In such cases, the transfer learning algorithm helps to develop the prediction model for the degraded system by capitalizing on the available information in the pre-trained model and the limited new performance data. This study leverages TRNSYS software to derive the performance data of the degraded gas turbine by applying reported recoverable and non-recoverable performance losses [28]. To account for the practical situation, only a few operational data points (roughly 10% of the 256 data points) of the degraded system were randomly selected for transfer learning.

Previously trained Model GTD (with the same architecture and coefficients) are employed in transfer learning. The key advantage is that the preserved coefficients of the pre-trained model were adjusted instead of learning from a fresh start.

- Model TL1 is the transfer learning model developed by updating the coefficient of the whole pre-trained model (Model GTD) using the latest available operational data.
- Model TL 2 is the transfer learning model developed by updating the output layer coefficient of the pre-trained model using the latest available operational data.

Interestingly, transfer learning requires less effort at around 100 epochs for coefficient adjustment to achieve reasonable predictions.

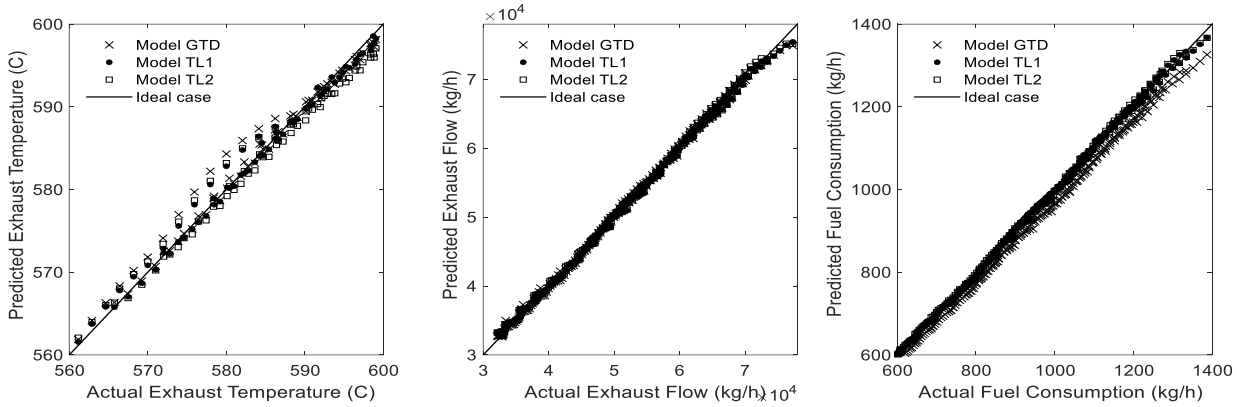

Figure. 7. The actual and predicted gas turbine outputs (exhaust gas temperature, exhaust flow and fuel consumption)

Figure 7 shows the accuracy of three prediction models, Model GTD, Model TL1, and Model TL2, with reference to the latest operational data comprising 256 points. Model GTD failed to predict the gas turbine performance accurately, and it deviates significantly in the fuel consumption estimation (as shown in Figure 8). Even the predicted exhaust temperature values deviated moderately from the actual values. The Model TL1 provides better performance than the Model GTD, and interestingly, the predicted fuel consumption and exhaust gas flow are within the acceptable range. On the other hand, the predicted exhaust gas temperature deviates to a certain extent, especially at partial loads. Model TL2 provides superior performance over Model GTD and Model TL1. The prediction accuracy is around 99.5% (R2), within acceptable limits. Generally, Model TL2 is preferred when the user requirement (output variable or number of output variables) changes or its distribution changes. Consequently, Model TL1 is expected to perform better because all coefficients are adjusted using the latest operational data. Some of the deviations could be due to limited data.

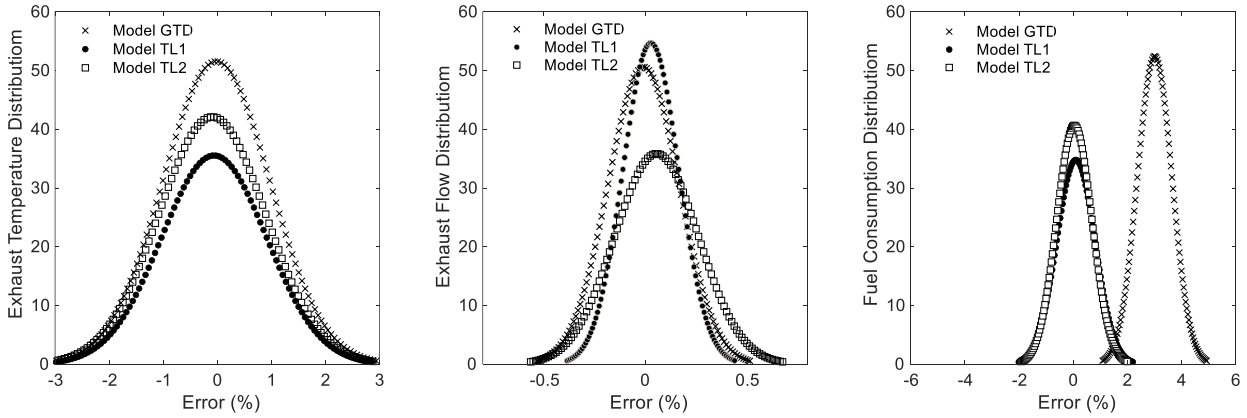

Figure. 8. Error distribution in the predicted gas turbine outputs (exhaust gas temperature, exhaust flow and fuel consumption)

Fuel consumption is the key variable that greatly reflects the operation cost of the gas turbine. Regarding fuel consumption, the performance of Model TL1 and 2 are similar, showing marginal differences at certain data points. Deploying Model TL1 or 2 in the scheduling algorithm can improve operational decisions that lead to improvements in energy efficiency and a reduction in energy costs. Applying transfer learning regularly (once or twice) in a year is important to prevent plant-model mismatches by retaining the accuracy of the prediction model and safeguarding optimal operation decisions. Through careful deployment, this process can be automated to reduce manual involvement by predefining the data extraction, training, and update rules. This approach can be applied to other energy systems, especially those subjected to performance degradation over time, such as chiller systems, heat exchange equipment, etc. In summary, the performance of certain energy systems degrades significantly over time. Not accounting for the performance degradation could lead to suboptimal or inefficient operations of energy systems. While deriving the operational decision, the actual performance characteristics are essential to derive optimal operation set points. Therefore, the prediction model needs to be updated regularly to capture changes in the energy system's characteristics. In this context, transfer learning could assist in retraining or updating the prediction model with the limited operational data to capture and predict the performance of the degrading energy systems.

Conclusion

This study developed transfer learning models for the gas turbine system to improve prediction accuracy by eliminating plant-model mismatch and supporting operational decisions to gain energy and cost savings through efficient operations. The pretrained model cannot predict the degraded system performance and shows significant deviation, which highlights the need for transfer learning. Two transfer learning mechanisms were explored: Model TL1 was obtained by tweaking the coefficients of the whole pre-trained model, and Model TL2 was developed by tweaking the coefficients of the output layer alone. Both mechanisms utilized the latest (and limited) operational data and capitalized on most of the information from the pre-trained model. Interestingly, both models provide better accuracy than the pre-trained model. Comparing transfer learning models, TL2 outperforms TL1, which could be due to limited data availability to fine-tune all coefficients. Deploying Model TL1 or 2 in the scheduling algorithm could reflect the actual performance of the gas turbine and improve the operational or economic dispatch decisions for high energy efficiency and optimal energy cost. This approach can be applied to other energy systems whose performance characteristics are expected to change over time due to ageing and degradation.

Nomenclature

Abbreviations

ADAM	adaptive moment estimation
AI	artificial intelligence
CNN	convolution neural network
DER	distributed energy resources
IoT	internet of things
MLP	multi-layer perceptron
Model GTD	gas turbine model at design condition
Model TL1	transfer learned model by updating the coefficient of the whole pre-trained model
Model TL2	transfer learned model by updating the output layer coefficient of the pre-trained model
NN	neural network
OECD	organization for economic co-operation and development
PV	photovoltaic
R2	coefficient of determination
TL	transfer learning

Abstract:
Building integrated photovoltaic (BIPV) systems are a crucial component of the transition to a low-carbon energy system. However, current simplified models of PV cells and modules used in building and urban energy simulations may not accurately capture the performance of various PV technologies under partial shading conditions. In this paper, we propose a novel framework for modeling parametric BIPV arrays using a high-resolution irradiance grid and a power model that operates from the evaluation of IV-curves at the cell level to the AC to DC conversion in the inverter. This allows us to combine PV modules of varying sizes and electrical configurations based on the selected inverter type, and to capture the operative benefits of multiple types of cell technologies, module designs, and electrical layouts in building-based PV applications. We evaluate the proposed framework by comparing its performance to measurement data and to three other frameworks found in the literature through the simulation of two BIPV façades and a tilted rooftop array. The results show that the proposed framework is necessary to account for partial shading (if present) as well as provide operative details when the type of inverter to be used is in question. Overall, this paper presents a novel framework for modeling the performance of PV cells and modules in building and urban energy simulations, which has significant implications for the design and optimization of building-based PV systems.

Integrated PV, BIPV, Partial Shading, Simulation, Urban.

1. Introduction

Photovoltaics (PV) are becoming increasingly common elements of building and urban energy systems research and optimisation [1, 2, 3]. However, we find that much of the research employs coarse level performance modeling frameworks to parameterise expected PV output. Current standards within research rely on low resolution irradiance estimations and simplistic conversion efficiency methods. These models were originally developed for PV systems that were largely unobstructed and used standard PV modules, such as the arrays found in utility-scale ground mount systems and on rooftops. However, the low cost of PVs and the need for rapid urban energy decarbonisation is leading to their use in environments where the boundary conditions are less than ideal. Due to high degrees of partial shading, heat, and the need for custom module sizing many systems may be installed and produce lower overall system efficiencies than envisioned during planning. This has the potential to translate into less realistic assessments of lifecycle cost and carbon performance at the system scale and grid stability and energy availability at the urban scale. Towards the goal of reducing the performance gap for building and urban energy systems research we compare the results of different PV performance modeling frameworks.

1.1. Objectives

In this paper we demonstrate that a highly detailed performance model can help modelers understand the potential loss in an urban PV system. Additionally, we show that the high level of resolution may not always be necessary and is dependent on the context of the geometry model (i.e. the spatial context of the surface being evaluated). We describe a proposed modeling framework compiled from the literature, compare an initial set of simulated performance indicators from the proposed framework to measured data sets. Then we apply the proposed framework to several theoretical building integrated PV (BIPV) arrays; two façade arrays and one tilted rooftop array. The results of these simulations will be compared to three common frameworks to modeling BIPV performance, briefly described in Table 1. We compare the results in terms of modeling effort and calculated PV yield and outline in which context which modeling resolution is best suited.

1.2. Research Questions and Hypotheses

We ask the following questions with proposed hypotheses for help guide the reporting of the research:

Framework	Description
Surface Face	The surface is divided by a single grid dimension and the center points of each resulting face are used for irradiance simulations. Power is then extracted using a simple power conversion model from the irradiance of the sensor point and the area of the face.
Module Center	The surface is divided by a BIPV array. The center point of the resulting modules are used for irradiance simulations. Power is then extracted using a simple power conversion model from the irradiance of the sensor point and the area of the module.
Cell Center	The modules created by the Module Center framework are further divided into cells. The center point of the resulting cells are used for irradiance simulations. Power is then extracted using the power conversion model from the irradiance of the sensor point and the area of the cell.
Cell IV	The center point of the cells from the Cell Center framework are used for irradiance simulations. Power is then extracted using a single-diode equivalent circuit model from the irradiance of the sensor point and parameters of the selected module/cell.

Table 1: Descriptions of the four modeling frameworks used in the paper.

- Does the proposed framework produce accurate results?
    - Evidence in the literature suggests that the proposed framework is a viable method of predicting the yield of all module types. We aim to improve upon existing methods to bring more flexibility to the framework and providing further clarification of when a more detailed method should be applied over simpler methods.
- In what situations is it recommended to use the proposed framework over simpler methods (e.g. NOCT or performance ratio)?
    - We suspect that surfaces that are subject to mostly diffuse light or mostly direct light are candidates for the simpler methods, while those that see a mixture of direct and diffuse light will not be accurately characterised by these methods and require the more detailed method described in this paper. We expect to see results diverge the most between the *Cell IV* and the other frameworks for the façades while the rooftop arrays will be more consistent between the frameworks.

2. PV Modeling Frameworks

We define a PV performance modeling framework as a set of models and protocols that assist modelers in assessing the power output of a PV array from the definition of the surface to the calculation of performance indicators such as self-consumption (PVSC, i.e. how much of generated electricity is consumed). A framework has three components:

1. Definition of the array geometry through the discretization of a surface.
2. Simulation of the effective irradiance (G_{eff} $[\frac{\text{W}}{\text{m}^2}]$) on the array surfaces.
3. Conversion of the G_{eff} to power (P [W]), either in direct-current (P_{DC}) or alternating current (P_{AC}), typically expressed per timestep which is usually in hours, thus Watt-hours (Wh).

In the following sections we provide a review of the various PV performance modeling frameworks summarised in Table 1. The first group, discussed in Section 2.1. are often found in the literature, vary in their degree of spatial resolution, and utilise one of several power conversion methods. There are often functions of efficiency and performance ratio, to convert G_{eff} into P_{DC}. After reviewing these methods we introduce, in Section 2.2. the proposed high-resolution framework that we have compiled from several sources in the literature. This framework relies on detailed spatially accurate models of module and cell placement, as well as high accuracy irradiance simulations. The power conversion model is a single-diode equivalent circuit model from Bishop (1988) [4] to characterise the electrical attributes of each cell before merging them system wide. It is commonly applied in a less spatially resolute context (i.e. module center points) in power systems modeling for large unobstructed PV arrays.

2.1. Existing module and surface based modeling approaches

The yield from a PV cell is, at its most basic level, a function of the solar irradiance of the cell and the cell's ability to act as a semiconductor through the photovoltaic effect to convert this energy into an electrical charge. In practical terms for a modeling framework this can equate to simply multiply G_{eff} of a module by an efficiency (η) factor associated with the module. This simple conversion can enable very rapid assessment frameworks. Rapid rooftop assessment platforms such as Google's Project Sunroof or Mapdwell have been in place for nearly a decade and rely on a combination of photogrammetry and often proprietary algorithms to estimate the shading on a roof due to nearby objects such as trees or buildings. While these tools do allow individuals to assess their rooftop PV potential quickly and with little to no barriers beyond data availability in their own region. While accessible these tools are not extensible to facades and results for the same location vary greatly between models, suggesting a high degree of inaccuracy is present [5]. In Switzerland a public tool called Sonnenfassade [6] exists for any building in the countries database of 3D models and quickly calculates irradiance using a performance ratio (PR) approach It uses this 3D model of a building along with local climatic data and a shade horizon profile built up of nearby mountains, hills, buildings, and vegetation to estimate the average yearly irradiation value in the middle point of the building's façades. This is then multiplied by the façade area and a PV PR of typically 80% to determine an annual potential yield value.

This was improved upon by Saretta et al. (2020) [7] due to a core inability in distinguishing potential windows and balcony type projections on the façade. The update equation uses three reductions factors to more accurately account for facade area based on a statistical database connected the the building age and type.

While more spatially accurate this approach still relies on the *PR* variable which is difficult to calculate without measured data of a similar system or an accurate model of the system. Additionally, a system's PR varies with time and when considering the dynamics of grid pricing and storage is a key parameter to understand. A temporally resolved approach exists in [8, 9], which employs similar methods to characterise potential irradiance, but does so for each hour of the year through the input of Typical Meteorological Year (TMY) weather data and angular modifiers to model reflection on the glass surface of a PV module. Other models exist as well such as Huld's modification of King's model [10] or the PV Watts method [9]. These methods employ more advanced methods of calculating output from the PV cell that are temperature dependent. To calculate module temperature (T_{mod} [°C]) the nominal operating cell temperature (*NOCT* [°C]) model is often employed [11], shown in Eq. 1, where *NOCT* is a parameter typically given on PV module data sheets and T_{air} ([°C]) is the ambient air temperature, and G_{eff} must be given in $[\frac{\text{mW}}{\text{cm}^2}]$.

$$T_{\text{mod}} = T_{\text{air}} + \frac{NOCT - 20}{80} \cdot G_{\text{eff}} \tag{1}$$

While these models employ more complexity to characterise module performance through various uses of cell temperature, but do not increase the level of detail used for calculating G_{eff}. This increase in spatial resolution can be found in the models employed in urban and building energy modeling tools such as in Fonseca et al. (2016) [12] and Waibel et al. (2017) [13]. These approaches use 3D scenes to simulate irradiance on any number of sensor points. In the former surfaces are discretized using a small amount of sensor points, typically 2-5 m^2 per sensor points, to reduce computation time. Daysim [14], a form of the validated lighting simulation engine Radiance [15], is then used to conduct ray tracing for the sensor points, taking into account any obstructions in the scene along with their reflectivity and transparency. The received irradiance is then used with a variation of Eq. 2 to calculate the yield for an hour of the day. Here G_{STC} is the irradiance during standard test conditions (STC) and $P_{\text{DC,STC}}$ [W] the power output. Similarly the latter framework uses ray tracing and view factors to rapidly assess potential irradiance on a sensor point and use it as input to a variation of Eq. 2.

$$P_{\text{DC}} = \frac{G_{\text{eff}}}{G_{\text{STC}}} \cdot P_{\text{DC,STC}} \left(1 + \gamma \left(T_{\text{mod}} - T_{\text{ref}}\right)\right) \tag{2}$$

These methods improve upon the spatial resolution of the irradiance gathering portion of a necessary PV performance modeling framework, but do not necessarily allow modelers to look at the performance of an array from a module-specific perspective, as they still rely on generic parameters for the type of cell. For module-specific calculations a method such as that employed in EnergyPlus [16] is necessary. The Sandia Performance Model (SPM) [17], utilises module and cell specific parameters to characterise the performance of the module being examined. It is also extended into a larger ecosystem of arrays and systems to account for transmission loss, inverter loss, and other factors such as maintenance to provide a value for system-wide grid-ready power $P_{AC,sys}$. The limitation is that while the SPM uses a cell-based approach of sorts it does not record the current-voltage (IV) curve of the module, just the output power for a timestep. This makes assessing its performance within a larger electrical topology such as a central or string inverter based system difficult as one needs to be able to calculate the maximum power point (MPP) that would come from the inverter or maximum power point tracking device (MPPT).

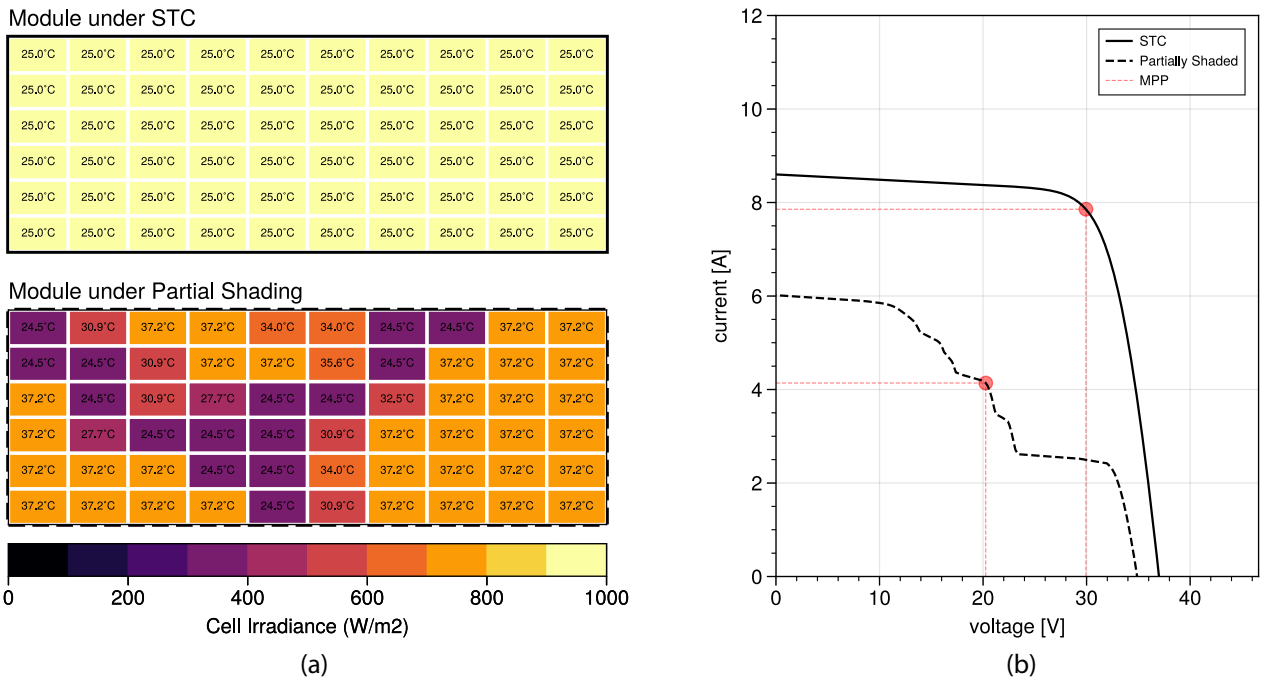

Figure 1: An example of a module under the partial shading of a tree branch (a) and its impact on the IV-curve and power output (b) as compared the a module under standard test conditions. These results were calculated using the proposed framework.

2.2. Existing cell based modeling approaches

When a module is partially shaded, as shown in Figure 1, it operates below optimum. This is due to unshaded cells (high current) reverse-biasing shaded cells (low current) in a string, which leads to overheating in the shaded cells and potential damage, referred to as mismatch. This is mitigated by bypass diodes to reduce the risk of catastrophic failures, but at the expense of total output. It is therefore vital to parameterise these effects in models of PV arrays if they are expected to operate under conditions with a great deal of partial shading. Furthermore, new module types, such as half-cut modules employ less straightforward configurations of cell arrangement and BIPV modules are typically highly customised such that contextualising the cells in module not only in their series placement but also in parallel is necessary to entirely account for the location of bypass diodes.

Additionally, specifying the type of electrical topologies as a part of the modeling framework is necessary to account for the entire impact of partial shading on system performance[18, 19, 20, 21]. This is due to the way in which current and voltage are accumulated when the IV curves of the cells and modules do not match.

Therefore, a highly detailed modeling framework should be able to model the impact of partial shading on a bespoke module's performance as well as throughout a larger electrical topology. Meyers et al. (2017) [22] and Chaudhari et al. (2018) [23] describe a modeling framework for characterising the mismatch in PV cells and modules to better account for partial shading on systems. Walker et al. (2019) [24] developed a workflow to simulate PV modules using a cell-based approach that begins from simulating the irradiance on the cell or an even finer resolution.

Both of the above approaches employ techniques for characterising cell performance that are crucial for modules under highly uneven irradiance such as reverse bias and bypass diodes. Additionally, modelers may want to study arrays with different sized modules (which is common in BIPV design) or explicitly model changes to modules such as front covers for aesthetics, or different bypass diode configurations during parametric optimisation.

3. Methodology, Data, and Tools

In this section we describe the models and methods used to conduct our comparative analysis of PV performance modeling frameworks.

First, we then describe the measured PV yield data (Section 3.1.) to which we compare the proposed framework. For the simulations we use a common monocrystalline module type, Sharp Solar 235Wp (Sharp-NU-U235F2). It was selected due to the availability of its parameters in the California Energy Commission's module

database [1] and it is the sole module found in the measured data. Then, in Section 3.2. the two 3D models that contain the façades and rooftop arrays which we use to compare the performance of the modeling frameworks are described. Then, the four modeling frameworks are summarised. The first (Section 3.3.) is currently common within the literature and employs simpler methods and lower levels of details than the third (Section 3.6.), which is the framework which we are proposing. We also describe the two other levels of detail that operate between these two methods that improve on the spatial resolution of the first, but utilise the same power conversion model; *Module Center* in Section 3.4. and *Cell Center* in Section 3.5..

3.1. Measured Datasets

We use a sub array from a rooftop installation at the United States of America National Institute of Standards and Technology (NIST) to evaulate the performance of the proposed modeling framework's power conversion model. The dataset for the sub array (SC3) is reported on in detail by Boyd (2015) [25]. It contains minute averages for a variety of sensors placed throughout a large rooftop array. The dataset was chosen for its availability and clean data. Ideally the dataset to compare against would be one that is vertically oriented and subject to partial shading. However, to the knowledge of the authors this does not exist. The array comprises of 84 modules of the module mentioned in Section 3.. Of the 84 modules there are seven strings of 12 modules that are combined in parallel to create a single DC output stream. The recorded data from this output was resampled into hourly data and compared against the IV-curve based framework. For the input G_{eff} and T_{cell} we rely on the measured data from within the array. G_{eff} comes from a single silicon reference cell in the array. T_{cell} is a mean value gather from several back-of-module sensors throughout the array. We evaluate the model results using mean absolute error (MAE) and a qualitative comparison of the result distribution.

3.2. 3D Building Geometry

We conduct a comparative analysis between the proposed framework (i.e. *Cell IV*) and the frameworks from the literature to describe the differences in their output and identify situations in which it may not be worth the computational cost of the more detailed method. To make the analysis more relevant to a broader audience we identify two Representative façades to simulate through a clustering analysis of buildings in a district in Zurich Switzerland. A third surface was added as well to compare a minimally obstructed rooftop situation. Clustering was done on building morphology metrics extracted from the urban region following Biljecki et al. (2022) [26]. Principal Component Analysis (PCA) was used to reduce the parameter space before applying a K-Medoids clustering process.[2].

Clustering returned three archetypal buildings, for which the southern-facing façades were extracted. On one of the buildings the extracted façade was unobstructed and it was decided to remove this from the analysis, leaving the two buildings and façades shown in Figure 2. The upper roof section of Building B was used for the roof analysis, where a 30° tilt facing south was assigned to the array. The buildings were modeled in a Rhino/Grasshopper [27] 3D environment and a script was developed to add BIPV and rooftop module arrays with each cell parameterized based on a landscape orientation of the PV module in the NIST dataset. Nearby opaque context was modeled with a 20% reflectivity. A tree exists near one of the residential buildings. This was modeled following Peronato et al. (2018) [28]. The scenes were used for ray-tracing to gather annual irradiance profiles with hourly timesteps.

3.3. Surface-based framework

The existing approach for urban-scale analysis of photovoltaics is to evaluate one or several sensor points on a facade and use those as the basis for the power conversion model. The surface's are discretized using a moderate resolution of two meters between each sensor point to reduce possible error to a negligible amount, as recommended by Peronato et al. (2018) [28]. We remove the area where the window faces intersect with the discretized grid cells to accurately account for the area available to potential PV. In the case of the rooftop array, the flat surface of the roof was split into faces and the center points were assigned the surface normal that would be associated with tilted modules, instead of rotating the faces themselves.

Typically the irradiance simulation would only be done for the sparse sensor points on the surface being analysed. However, due to the stochastic nature of the Radiance engine we use the irradiance map created for the cell-based approach described in a later section. For this we simply take the mean value of the three nearest points to each sensor point on the surface. This irradiance value, for both direct (G_{dir}) and diffuse irradiance (G_{diff}), is used to calculate G_{eff} using Eq. 4 and Eq. 3.

G_{dir} and G_{diff} are simulated for each sensor point using the enhanced 2-Phase ray-tracing method found in Subramanian (2017) [29] using Radiance.[3] They can be modified for any front-covers that an integrated PV module may have using Eq. 3, which in the case of this study is a clear solar glass. Here G_{x0} is the initially calculated irradiance for the sensor point, either direct or diffuse. For f_{loss} a factor is dependant on the colouring

Figure 2: The two archetypal façades and unobstructed roof (highlighted) used in the study are shown next to their 3D models. In (a) we utilise a lower rise building in the district with a moderately obstructed facade and nearby vegetation. In (b) we utilise a larger facade with more obstruction.

of the front cover and comes from [30].

$$G_x = G_{x0} \cdot (1 - f_{loss}) \tag{3}$$

To calculate G_{eff} for each sensor point we account for the reflectivity of the glass and front cover with an angle of incidence modifier (AOI), shown in Eq. 4 for each timestep based on the location, orientation of the surface, and tilt of the surface.

$$G_{eff} = G_{dir} K(\Theta) + G_{diff} K(60^\circ) \tag{4}$$

K is the angular response factor calculated following Martin and Ruiz (2001) [31], formulated in Eq. 5. K is dependent on Θ and a dimensionless fitting parameter, a_r, which is fixed at 0.17.

$$K = \frac{e^{\frac{1}{a_r}} \left(1 - e^{\frac{\cos(\Theta)}{a_r}}\right)}{e^{\frac{1}{a_r}} - 1} \tag{5}$$

Given G_{eff} of each sensor point, the power conversion model for each hour of the year, shown in Eq. 6, is based on the nominal efficiency of the module(η_{nom}), total surface area available for modules (*area*), and a performance correction dependant on the maximum power temperature coefficient of the module (γ_{ref}) and cell or module temperature (T_{sensor}) which comes from Eq. 1. In this instance we calculate *area* by subtracting the area of windows found within each discretized section the façade from the area of the section. We account for losses in the system due to soiling, cabling, and inverter loss using I_{misc}, which is fixed at 0.10.

$$P_{AC} = \left(\frac{G_{eff}}{G_{stc}} \cdot P_{peak} \cdot [1 + \gamma_{ref} (T_{sensor} - T_{stc})]\right) \cdot (1 - I_{misc}) \tag{6}$$

For the surface-based analysis we calculate P_{peak} using Eq. 7 where $P_{nameplate}$ denotes the standard module capacity, $C_{nameplate}$ denotes the number of cells in a standard module, $A_{nameplate}$ denotes the area of the standard module, and A_{face} denotes the area associated with sensor point in the discretized surface:

$$P_{peak} = \frac{P_{nameplate}}{C_{nameplate}} \cdot \frac{C_{nameplate}}{A_{nameplate}} \cdot A_{face} \tag{7}$$

3.4. Module-based framework

To represent another existing approach to modeling the performance of PV in urban arrays we evaluate simulated performance of modules placed into the surfaces analysed in the previous method. The modules are assessed using a single irradiance sensor point located at the module's center and the power conversion model of Eq. 6, with the only difference being the input for P_{peak} where we employ each module's unique size. The modules are created in a 3D model of the surface which begins by assuming that no windows or impediments exist on the surface. Where they does exist the modules are cut into smaller rectangles. Then we replace A_{face} in Eq. 7 with the area of each individual module.

3.5. Cell-based framework

We increase the resolution of the previous framework by calculating power for the center point of each cell in the array's modules using Eq. 6. The modules modeled in the previous framework are discretized by the cell dimensions, frame width, and spacing between the frame. The input for A_{face} in Eq. 7 is then calculated based on the cell dimensions.

3.6. IV curve-based framework

In this section we describe the proposed modeling framework for high-resolution BIPV analysis that is the focus of this paper. Given the spatially discretized grid from the previous approach we improve the model resolution here by changing the power model. We build on an existing approach for cell-based modeling found in Walker et al. [24]. With this approach we have included a more flexible input for the module type that enables the use of module sizes that are non-standard, which is common in BIPV design and occurs in the 3D models being assessed in this study. With the modules and cells modeled in the 3D space, string connections of modules are built up by first grouping modules of the same cell count into strings. Then the string with the standard module size is split into separate strings with each string having the same modules of the same vertical height. In preparation for the power calculation, each module is assigned four numerical arrays. The first contains the Cartesian position of each cell's center point. The second contains the surface normal of the cells. The third represents to which bypass diode in the module that each cell belongs to. The final is used if a module has multiple sub-modules in parallel, such as in a Half-Cut module, and represents to which sub-module each cell belongs.

G_{eff} is calculated in the same way as the previous framework but is applied to a different power model. The power conversion model is more detailed in this approach as we calculate the IV-curve for each cell. Then, the module IV-curve is compiled based on bypass diodes and string or parallel connections. With each module's IV characteristics, we evaluate the arrays for several electrical topologies: micro-inverter, string inverter, central inverter.

The initial IV-curve for a cell is calculated following Bishop (1988) [4], using Eq. 8. This formulation follows the common single-diode equivalent circuit model that is also applied by EnergyPlus [16] and in the method of Walker et al. (2019) which we build upon. It is assumed that a single cell can be modeled as a portion of the larger module. This is important as the parameters necessary for the single-diode model are typically only given for a module as it was characterised during manufacturer testing. This approach uses the five-parameter input from De Soto et al. (2006) [32]. This uses G_{eff}, T_{cell} (which comes from Eq. 1), the short-circuit temperature coefficient (α_{sc}), diode ideality factor (n_D), number of cells in series (N_{s}), the thermal voltage across the cell (V_{th}), light generated photocurrent at reference conditions ($I_{\text{L,ref}}$), diode reverse saturation current at reference conditions ($I_{0,\text{ref}}$), shunt resistance at reference conditions ($R_{\text{sh,ref}}$), and series resistance at reference conditions ($R_{\text{s,ref}}$). The calculations provided by De Soto et al. produce the diode voltage (V_{d}), photocurrent (I_{L}), saturation current (I_0), series resistance (R_{s}), shunt resistance (R_{sh}), and *nNsVth*. We use the default parameters for breakdown factor (a, 0.0), breakdown voltage (V_{br}, -5.5), and the breakdown exponent (m, 3.28). We include $\frac{d^2}{\mu\tau}$ for completeness, but it is not used in this study as it is only relevant for amorphous silicon cells, therefore it is assigned a value of 0. With the parameters assembled the IV-curve is calculated for each cell, envisioning it as a single module. The resulting curve's V values are divided by the number of cells in series and the I values are divided by the number of cells in parallel.

$$I = I_{\text{L}} - I_0 \left(\exp \frac{V_{\text{d}}}{nN_s V_{\text{th}}} - 1 \right) - \frac{V_{\text{d}}}{R_{\text{sh}}} - \frac{I_{\text{L}} \frac{d^2}{\mu\tau}}{N_s V_{\text{bi}} - V_{\text{d}}} - a \frac{V_{\text{d}}}{R_{\text{sh}}} \left(1 - \frac{V_{\text{d}}}{V_{\text{br}}} \right)^{-\text{m}} \tag{8}$$

This model enables the characterisation of the cell in the second quadrant of the IV-curve plot. This is the characterisation of the reverse-bias potential of the cell. If two cells with mismatched curves are connected in series and operated with the more illuminated cell's maximum power potential, then the less illuminated cell will draw current from the first cell. Thus, the real operation of these cells would require the more illuminated cell to be operated at the level of the lower cell, limiting maximum power potential (MPP). It is this phenomenon that is common in partial shading and we suspect is not well captured in the other three frameworks. Using this approach all cell IV-curves are calculated and first connected in series within each diode pathway, following Kirchoff's circuit laws. Then the various diode pathways of a module are connected in series. If parallel connections exist within the module then these are made to finalise the characterisation of each module's IV-curve.

From here the approach branches to simultaneously evaluate performance of the array using multiple electrical topologies. This is essential for properly characterising MPP in each module as explained earlier, devices under different illumination can limit each other to avoid reverse-bias.

First, individual modules are evaluated using a micro-inverter approach where DC to AC inversion occurs

along with the maximum power point tracking (MPPT). Then, using the same principles of series and parallel connection within the module, strings of modules are connected and the MPPT and inversion is applied to extract MPP for each string. Lastly, strings are connected in parallel to evaluate their power using a single central inverter. We apply a simple 95% inverter efficiency to all inverter operations.

4. Results & Discussion

Here we present and analyse the results of the two portions of the study. First, the proposed modeling framework is evaluated alongside a measured dataset. Second, the simulation results of the proposed framework and surface-based framework are compared.

4.1. Evaluation of High-Resolution Proposed Framework

Figure 3 describes the two power outputs against G_{eff} with a linear curve fitted to the data scatter. Qualitatively, we observe generally good agreement between the two models at lower irradiance levels. However, with higher irradiance levels the proposed model produces a larger P_{DC} response. MAE and root mean squared error (RMSE) of the two data sets is 0.73 kWh, and 1.41 respectively. Additionally, we do not observe in the modeled data very low P_{DC} response at high levels of irradiance, such as seen in the measurement data. We suspect that in this case that much of the measurement array was covered by a shadow, but the censor cell was not. Despite these points the standard deviation and variance of the measurement dataset is lower than that of the model output.

The lack of multiple sensors throughout the array impedes our ability to model the array under heterogeneous conditions, which is likely closer to reality. Factors such as cloud cover that may cover much of the array while the sensor cell is still directly illuminated would then not be captured by the model. This could lead to the over prediction that we witness. Additionally, the proposed framework is meant for vertical facades in an environment with a lot of shading and a only slightly ventilated air cavity between the model and mounting surface. A dataset that contains these attributes would be a better tool to evaluate and eventually validate the proposed framework.

4.2. Comparison of Modeling Frameworks

Here we compare the outputs of the modeling frameworks and discuss their implications for use in larger models. First we evaluate the received irradiance for each framework. Irradiance results for each framework are influenced by the number of sensor points available to the ray-tracing simulation as this allows the ray-tracing to more accurately depict objects that might shade the receiving surface. In Figures 4a-4c we show difference between the irradiance, normalised by available surface area, levels across both of the 3D models through their probability distribution functions. A trend emerges with each in that the *Cell Center* and *Cell IV* framework have overlapping curves, while the *Surface Face* is closely aligned, and the *Module Center* framework contains a time series of larger values. This is due to the self-shading of the array not being captured by the center point on the module, whereas in the *Cell Center* and *Cell IV* a shared sensor grid is used that has many points. The close alignment of the *Surface Face* model is interesting, due to it having many less sensor points. This is worthwhile for future research.

In Figure 5a we show the discretized modules of the Commercial Building's rooftop array. The selected date was chosen for being the hour of the year with the maximum variance amongst the G_{eff} values within each modules, the value being indicated in Table 2. We can see that for the majority of the modules there is a shaded section caused by the module in front. This leads to a high degree of variance across the module. In the case of the *Module Center* the shaded portion of the module is not captured as only the central point is

(a-c) The probability distribution function for the irradiance intensity time series (8760 hours) for each of the three surfaces examined. (d-f) Yield comparison resampled for monthly sums. (g-i) Linear regression of the irradiance intensity of the module and the yield for each framework on the three arrays.

sampled to calculate G_{eff}. This inability to capture self-shading extends to the *Surface Face* framework as well, but due to the lack of rotation of the face the total irradiance available to these surfaces is limited anyway.

Looking at the other arrays in Table 2 we see some degree of variance across the modules but with means around 1 and 3 $\frac{W}{m^2}$. This contributes to the yield of the arrays being more consistent amongst the different frameworks, shown in Figures 4e-4f.

Simpler models such as the *Module Center* of *Cell Center* could be used in place of the much more computationally expensive *Cell IV* approach if the conditions for shading are met. In Figures 4g-4i we show linear regression of yield and irradiance intensity on the module. As the variance found in the Commercial Facade and Residential Facade are quite low the regressed models fit the data well. While still a good fit, the lowest r^2 is seen in the *Cell IV* framework of the Commercial Rooftop where, the regression is fit to a wider spread of data points. For the same levels of irradiance intensity different levels of yield are found. This is because the plot shows the irradiance intensity across the entire array, and does not reflect the activity in the modules under mismatch conditions. The results shown for the *Cell IV* framework are those for a system with micro-inverters. This type of electrical topology is able to handle the mismatch conditions well as maximum power (MP) tracking occurs at the module level. We show in Figure 5b the same array conditions in Figure 5a. Here the string inverter system controls the MP of each row of modules independently while the central inverter controls the MP of all modules. We see a drop in the yield if the system is configured with a central inverter due to the need of the system to operate the southern-most row of modules at the same level as the other strings.

Computationally speaking the *Cell IV* approach requires the most setup, although all require the same 3D geometry. From a computational standpoint the *Cell IV* require on average 800 seconds for each simulation of a surface, while the other methods require around 120 seconds.[4]

[4]These numbers come from operating the models on a 2021 Macbook Pro with 8-cores (ARM).

5. Conclusion

In this paper we proposed a detailed modeling framework for the simulation of building-based PV performance through the characterisation of system-wide IV-curves. This approach is based on existing work in the field with some adjustments to capture a variety of potential electrical topologies. We evaluated this model's performance against measured data and found that the model generally over-predicts, with a mean absolute error of 0.65 kWh. We propose that to better tune the framework a better measurement dataset is needed that can provide a more comprehensive picture of array-wide irradiance and cell temperature characteristics. Additionally, the measurement data should be for vertical arrays under partial shading.

We compared the proposed framework to three common approaches found in the literature. We found that in systems with self shading, the proposed framework is capable of capturing the impact on the modules while surface based and module center based methods are not. The similarly spatially accurate cell center based framework yields similar results, but with less computational expense. The three frameworks found in the literature do not provide a way to compare between electrical topologies, which in the case of partially shaded modules is necessary to evaluate which topology to choose. If you need to analyse different electrical topologies the *Cell IV* framework is necessary.

Beyond this, more research is necessary to compare this framework to the proposed to determine in what cases the more expensive method should be used. We believe though that this suggests that the type of shading cast on the array is important in determining which model is necessary to most accurately predict system yield. Future research should be dedicated to understanding the shading profiles and objects that occlude arrays in order to classify them so we might use the type of shading to select the power conversion model.

Abstract:

Energy communities are key actors in the energy transition since they optimally interconnect renewable energy capacities with the consumers. Despite versatile objectives, they usually aim at improving the self-consumption of renewable electricity within low voltage electricity networks to maximize the revenues of the community. In addition, energy communities are an excellent opportunity to supply renewable electricity to regional and national grids. However, effective price signals have to be designed to coordinate the needs of the energy infrastructure with the interests of local stakeholders.

The aim of this paper is to demonstrate the potentials of energy communities at the national level with a bottom-up approach. A district energy system having a building scale resolution is modelled in a mixed integer linear programming problem. The Dantzig-Wolfe decomposition is applied to reduce the computational time. The methodology lies within the framework of renewable energy hub, characterized by a high share of photovoltaic. Both investments into energy capacities and their operation are considered. The model is applied on a set of typical districts and weather locations representative of the whole Switzerland.

The extrapolation to the national scale revealed a heterogeneous photovoltaic potential throughout the country. The actual electricity tariffs promote maximal investment into photovoltaic panels in every region, reaching a capacity of 28 GW and generating 32 TWh per year. Since the forecast national energy need is between 12 and 18 TWh per year, a coordinated design is needed to prevent unnecessary investments. An uncoordinated design increases the total costs of the residential energy system by 31% and curtails 24% of the onsite generated electricity. Moreover, the $CO_{2,eq}$ emission of the unnecessary investment is equivalent to 9% of the actual emissions in the residential sector.

Keywords:

Energy communities; Renewable energy hub; National systems integration; MILP; Multi-objective optimization

1. Introduction

In 2018, the European Parliament has emphasized the role of energy communities in the energy transition and has set up directives to facilitate their creation [1]. Their purpose includes the penetration of renewable energies, the reduction of energy poverty [1], the enhancement of technological acceptance [2] and the improvement of the democratic process [3]. Energy communities aim at supplying the energy needs with high self-consumption of local energy sources. The reduction of the electricity grid reliance prevents costly grid reinforcements, therefore supporting a rapid electrification of the heating and mobility services. By 2050, Photovoltaic (**PV**) installations are expected to represent 50% of the electricity generation capacity worldwide [4]. More specifically, in Switzerland, the electricity demand is expected to reach 55 TWh/yr in 2050, from which 33 TWh/yr will be supplied by hydro power [5, 6]. The remaining electricity will mainly be supplied by PV capacities (11 TWh/yr), wind turbine (4.2 TWh/yr) and geothermal energy (4.3 TWh/yr). The success of PV integration seems to rely on a coordinated integration of energy communities within the infrastructure [1]. The involvement of these actors in investments and operation decisions dictates the energy flows exchanged between the communities and the infrastructure, ultimately affecting the whole energy network structure.

The definition of an energy community is broad but a consensus estimates that it is a local energy system possessing distributed sustainable energy conversion units, both on the supply and demand sides [2]. The concept of energy hub is usually used to model such systems. Multi-energy sources supply a multi-service demand with conversion units being optimally interconnected and operated. Extensive reviews have been carried out on this topic [7, 8]. The scale considered varies from local energy hubs, such as a residential area to

large scale systems including a whole country. Energy communities are usually built at the neighborhood scale since the proximity facilitates the community governance while being large enough to promote an economy of scale. Based on the literature review (Table 1), the scope of the studies mostly consider a single case study on a neighborhood, resulting in a lack of generality. Some studies investigated the broad impact of local residential systems with typical clusters and extrapolation but the scope relied on single building energy system [9, 10]. Therefore, the potential of energy communities to support the energy transition of the overall infrastructure with renewable integration is yet not assessed.

Table 1: Literature review on energy communities: The resolution indicates the considered scale for the investment or demand profiles. The approach shows how the authors handled the complexity of the problem, either by simplifications or by decomposition. The interdependent system feature highlights whether the study considered decision interactions between buildings and between national and local decisions.

Due to its network structure, modeling an energy community at the district scale with building scale resolution usually exceed the computational power. Facing this problem, a popular method is to fix some degrees of freedom by making assumptions and scenarios based on expert knowledge (Table 1). As an example, half of the literature is assuming energy demand profiles or pre-determines the energy system configuration. To promote grid services and renewable energy supply, energy communities should be approached from a service demand perspective rather than an energy demand one. This change of approach is beneficial since it does not assume the type of conversion units [26]. Therefore, it provides flexibility to consider additional constraints, such as the infrastructure capacity or trade-offs between investment and operational costs. In addition, considering each sub-systems within a single optimization reveals the inter-dependency of the decisions and do not force the acceptance of a decision without accounting for the interests of the actors concerned [26]. Therefore, assumptions and scenarios should be considered with care since they tend to oversimplify the view on the problem. Despite the extensive literature existing on the topic of energy communities, a holistic framework is usually not considered.

The main limitations found in the literature are the assumption taken on the type of conversion units installed and the lack of systemic understanding on the role of energy communities. It is yet not clear to which extent these communities can supply renewable electricity to the national energy system considering the actual infrastructure capacity. The performance extrapolation of various local case studies to the national scope is very rare in the literature. Therefore, based on these research gaps, the present study aims at answering the following research questions:

- What are the investment and operation decisions taken within energy communities?
- How does the decisions change with the geographic context?
- What is the potential for energy communities to supply renewable electricity in a country?
- What is the impact to consider the infrastructure capacity constraints?

2. Methodology

The energy community is modelled as a renewable energy hub, being defined as a system optimally interconnecting multi-energy streams and conversion units [27]. Additionally, the energy hub is characterized by a high share of renewable energy and aims at maximizing self-consumption. The renewable energy hub is at the district scale within a low-voltage electricity grid deserved by a low to medium voltage transformer. Service demands of each building, such as domestic hot water, domestic electricity and space heating, are supplied by conversion units and a gas and electricity utility. A mixed integer linear programming (**MILP**) formulation optimizes the investment into conversion units and the operation of the energy system. The main decision variables are the decision to install a unit (binary variables) and the size of the units installed (continuous variables). The conversion units include thermal units (air-water heat pumps, gas boilers, electrical heaters) and storage units (thermal tanks and lithium ion batteries). PV panels are the main source of renewable electricity and can be installed on the roof and facades of buildings. Their orientation is a decision variable as described by Middelhauve et al. [27].

Energy and mass balances as well as heat cascade are the main constraints of the model. Electricity and natural gas balances are applied at the building and district scale, allowing synergies between buildings and between energy carriers. Equation (1a) shows the electricity balance between the building electricity fluxes $\dot{E}^{gr}_{b,p,t}$ and the LV/MV transformer exchanges $E^{tr}_{p,t}$. A positive symbol represents an import of energy and a negative one an export. Decision variables are highlighted with **bold** characters. Additionally, technical constraints are considered to model conversion unit and to account systemic capacity. Constraint (1b) is applied to restrict the power exchanged on the transformer level to a specified value $\dot{E}^{tr,max}$. The electricity balance allows sharing renewable electricity within the community to increase the self-consumption, thus reducing operating costs and minimizing the transformer usage. To reduce computational burdens time series are clustered into typical and extreme operating periods using the K-medoids algorithm. The model consider four sets: buildings B, typical periods P, timesteps of the typical period T and units U. More details on the problem formulation are given in the following thesis [9, 27].

$$\sum_{b \in \mathrm{B}} (\dot{\boldsymbol{E}}^{\boldsymbol{gr,+}}_{\boldsymbol{b,p,t}} - \dot{\boldsymbol{E}}^{\boldsymbol{gr,-}}_{\boldsymbol{b,p,t}}) \cdot d_p \cdot d_t = \boldsymbol{E}^{\boldsymbol{tr,+}}_{\boldsymbol{p,t}} - \boldsymbol{E}^{\boldsymbol{tr,-}}_{\boldsymbol{p,t}} \qquad \forall p \in \mathrm{P}, \quad \forall t \in \mathrm{T} \tag{1a}$$

$$\dot{\boldsymbol{E}}^{\boldsymbol{tr,\pm}}_{\boldsymbol{p,t}} \leq \dot{E}^{tr,max} \qquad \forall p \in \mathrm{P}, \quad \forall t \in \mathrm{T} \tag{1b}$$

2.0.1. Objective functions

The objective functions are described in (2a) to (2e). The total costs (**TOTEX**) encompass operating costs (**OPEX**) and capital costs (**CAPEX**). The OPEX correspond to the annual energy costs and revenues from the utilities. The electricity and gas retail tariffs are respectively $c^{el,+}$ and $c^{ng,+}$ and the feed-in tariff is $c^{el,-}$. The variables E^{tr} and $H^{gr,+}$ correspond to the annual electricity and gas exchanges with the utility at the district level. The CAPEX (Eq. 2c) encompass investments and replacement costs of conversion units. The costs are annualized over an n years horizon with an interest rate i. The investment costs C^{inv} are linearized with fixed ($i^{c1,u}$) and variable ($i^{c2,u}$) costs and multiplied by the bare modulus b^u [9]. The CAPEX is dictated by two decision variables, the decision to install a unit (y^u) and the size installed (f^u). When a conversion unit has a lifetime l_u lower than the project horizon n, the replacement cost is given by the number of replacements R over the horizon n. Multi-objective optimization is performed to evaluate the solution space at the interplay of two conflicting objectives, the operating and capital costs. One objective is upper-bounded by a pre-defined values using an ϵ-constraint while the second objective is minimized. Pareto fronts are generated by varying the ϵ-constraints and by exchanging the objectives constrained and minimized.

$$\boldsymbol{TOTEX} = \boldsymbol{OPEX} + \boldsymbol{CAPEX} \tag{2a}$$

$$\boldsymbol{OPEX} = c^{el,+} \cdot \boldsymbol{E}^{\boldsymbol{tr,+}} - c^{el,-} \cdot \boldsymbol{E}^{\boldsymbol{tr,-}} + c^{ng,+} \cdot \boldsymbol{H}^{\boldsymbol{gr,+}} \tag{2b}$$

$$\boldsymbol{CAPEX} = \frac{i(1+i)}{(1+i)^n - 1} (\boldsymbol{C}^{\boldsymbol{inv}} + \boldsymbol{C}^{\boldsymbol{rep}}) \tag{2c}$$

$$\boldsymbol{C}^{\boldsymbol{inv}} = \sum_{u=1}^{U} b^u \cdot (i^{c1,u} \cdot \boldsymbol{y}^{\boldsymbol{u}} + i^{c2,u} \cdot \boldsymbol{f}^{\boldsymbol{u}}) \tag{2d}$$

$$\boldsymbol{C}^{\boldsymbol{rep}} = \sum_{u=1}^{U} \sum_{r=1}^{R} \frac{1}{(1+i)^{r \cdot l_u}} \cdot (i^{c1,u} \cdot \boldsymbol{y}^{\boldsymbol{u}} + i^{c2,u} \cdot \boldsymbol{f}^{\boldsymbol{u}}) \tag{2e}$$

2.1. Decomposition

The energy community model has a building scale resolution, with case studies up to 100 buildings. Due the network structure and long computation time, the Dantzig-Wolfe decomposition is applied on the original MILP problem. The methodology is described in detail in [27]. The constraint matrix of the original problem is block-angular. Each building energy system represents a subsystem independent from other subsystems except for the resources balance and capacity constraints, being linking constraints. The model is decomposed into two problems: a master problem (**MP**) and several sub problems (**SPs**). Linking constraints, such as energy balances, epsilon constraints or the transformer capacity are included in the MP and represent the district energy system problem. The MP receives building energy system designs from the SPs and selects an optimal configuration for each building by a linear combination of the proposals. Each design account for an investment into conversion units and associated energy flows with the district low voltage grid. Within an iteration loop, the SPs find new design proposals based on price signals sent by the MP. The latter correspond to the dual values of the linking constraints that are inserted in the SPs objective function as Lagrangian multipliers. The SPs are formulated as reduced costs, meaning that a solution with a negative value has the potential to improve the MP objective. The algorithm terminates when the SPs cannot find negative reduced costs.

2.2. Key performance indicators

Key performance indicators (**KPI**) are used to quantify solutions performance. The self-consumption (**SC**) is the share of onsite generated electricity being consumed within the district. The self-sufficiency (**SS**) corresponds to the share of the electricity demand being supplied by onsite generated electricity. PV curtailment is the share of onsite generated electricity being neither self-consumed, nor sold to the grid. Finally, similarly to the total cost, the global warming potential (**GWP**) accounts for both the construction and operation emissions from the consumption of energy resources (3d) as described in [27]. Emissions related to conversion units installation are taken from the Ecoinvent database and are calculated with the method IPCC 2013 and the version 3.6.

$$\mathrm{SC} = (E^{gen} - E^{curt} - E^{tr,-})/E^{gen} \tag{3a}$$

$$\mathrm{SS} = (E^{gen} - E^{curt} - E^{tr,-})/(E^{gen} - E^{curt} - E^{tr,-} + E^{tr,+}) \tag{3b}$$

$$\mathrm{PVC} = E^{curt}/E^{gen} \tag{3c}$$

$$\mathrm{G}^{op} = \sum_{\substack{p\in P \\ t\in T}} \left(g^{el,TR}_{p,t} \cdot (E^{tr,+} - E^{tr,-}) + \sum_{b\in B} g^{ng}_{p,t} \cdot H^{gr,+}_{b,p,t} \right) \tag{3d}$$

2.3. Case Study

Since Switzerland possesses 17'844 LV/MV transformers [28], a kmedoid clustering algorithm is applied to find the most representative districts. The case study is built under a geographic information system (**GIS**) approach to adequately describe the energy demand and sources. Clustering features consider real-estate typologies (heating surface, roof area, service demands, building category, construction year) and geographic ones (annual solar irradiation, average temperature, infrastructure density). Typical Swiss weather profiles had been assessed for each district by Stadler et al. [9]. With this approach, versatile district typologies are considered within a single case study. The five most representative districts are selected for this case study. The representative roof area of each typical district is used for extrapolation to the national scale. Figure 1 presents the distribution of each typical district within Switzerland and Figures 8 to 12 provide a geographical visualization of the district in the Appendix. The present study aims at analysing the impact of energy communities on the national energy system. Therefore, it is assumed that each district in Switzerland is an energy community.

Most data are open source and provided by the Swiss government. The building characteristics, such as the height, heated areas or types of construction come from cantonal and federal Official Buildings Registry [29]. Energy standards such as the envelope heat transfer, building heat capacity and domestic electricity demand as well as the internal and external heat gains are calculated based on Swiss national standard norms [30]. These data are used to build the 1R1C thermal model of the buildings [31]. The outdoor temperature and solar irradiation come from Meteonorm [32]. These time series are clustered into ten typical periods and two extreme periods using k-medoids clustering. The project horizon is 20 years and an interest rate of 2% is taken. The electricity and gas retail tariff are respectively fixed to 0.27 CHF/kWh and 0.14 CHF/kWh and the feed-in tariff is 0.17 CHF/kWh. These values are based on the average energy tariffs in Switzerland for the years 2022-2023 [33]. The carbon content of electricity are taken from [34] and equals 0.1 kg CO_2/kWh$_{el}$ both at the import and export. More details on buildings, units and weather data parameters are detailed in [27].

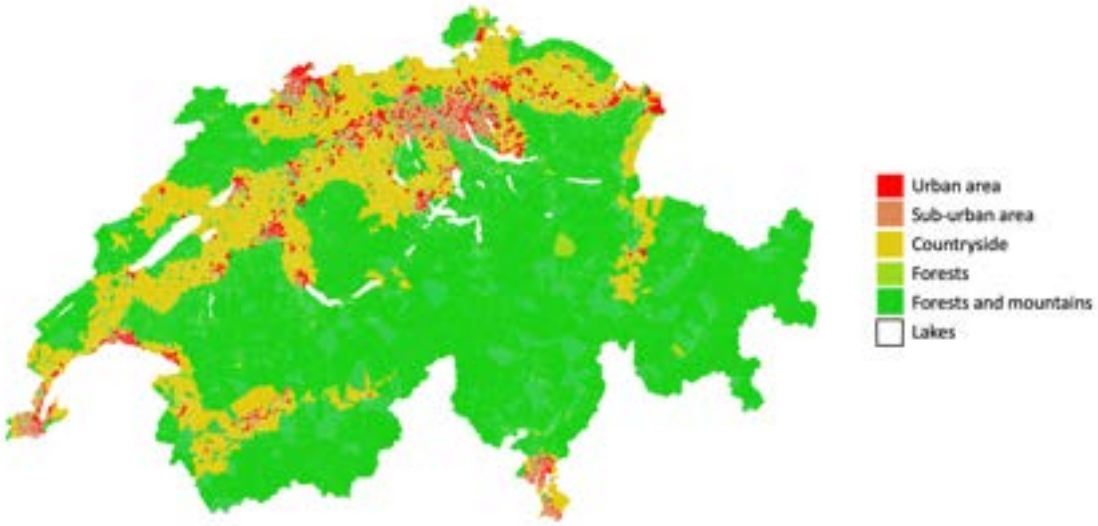

Figure 1: Typical districts distribution in Switzerland. The centroids differentiate the urban and weather typologies of Switzerland.

3. Results and Discussion

The discussion follows two axis. First, the decision trends taken within energy communities are analysed and contextualised with their geographic and urban density characteristics. Multi-objective optimization between the capital and operating costs is performed to extract the solution trends. Then, the solutions are aggregated and extrapolated to the whole country. The potential of energy communities is analysed in terms of renewable electricity supply. Finally, grid constraints and curtailment are applied to assess the cost and energy efficiency impact of a coordinated and uncoordinated investment strategy.

3.1. Region specific Energy Community Investments

Investment trends into energy conversion units are summarized in Figure 2. The investment and operating cost breakdown are presented respectively with red/yellow and green colors. The total cost of the system is located on the right with the blue columns and the revenues from selling electricity corresponds to the white columns. The figure shows the solution spectrum for the typical district 3, representing the countryside districts. The gas boiler solution corresponds to the one with the lowest investment and highest operational cost. The latter is decreased by substituting the base load heat supply from the boiler with a heat pump. Then, the operating costs are further decreased by a progressive investment into solar panels. Due to the profitable electricity tariffs, the energy community reaches net zero operating cost with an average investments into PV units. The operating costs are further decreased by an investment into batteries, allowing a larger investment into PV units and a higher self-consumption. Depending on the interest of the actors, the energy community moves from a passive energy consumer to a renewable electricity supplier for the utility. Similar solution trends are found throughout the other typical districts, even though the magnitude of the investments varies. Figure 3 presents the pareto optimal solutions for each of the typical district. Within the positive operating cost region solutions are similar since they correspond to solutions with few PV integration. Therefore, heating and electricity services are mainly supplied by purchasing energy from the grid and there is no interests into renewable electricity sharing. On the other hand, within the region with high PV integration, the solutions diverge based on the geographic location. The energy community with the lowest operating cost corresponds to the countryside one due to the low building density, large roof surface area and a sufficiently large community allowing economies of scale. On the other side, the district 4 has the highest operating cost, mainly due to the small size of the community. Between the two extremum are located dense urban areas having a large economy of scale but a large energy demand density and small mountain villages with low economies of scale and high thermal demand but large roofs surfaces and high solar irradiation.

3.2. National scale impact of Energy Communities

The electricity tariff of today favors a high implementation of PV. Figure 4 presents a sensitivity analysis on the annual renewable electricity generated by energy communities in Switzerland for a range of feed-in and retail tariffs. Below a certain energy tariff, the PV investment is not profitable due to the affordable electricity cost from the grid. The investment threshold is delimited by the lower black line. On the other side, the up-

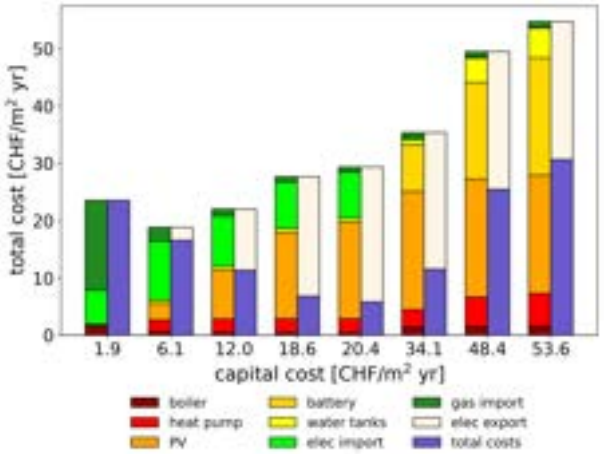

Figure 2: Cost breakdown of the pareto optimal solutions for the district 3 (Figure 11). The left column represents the costs. The right column stacks the total cost (blue) and the electricity revenues (white).

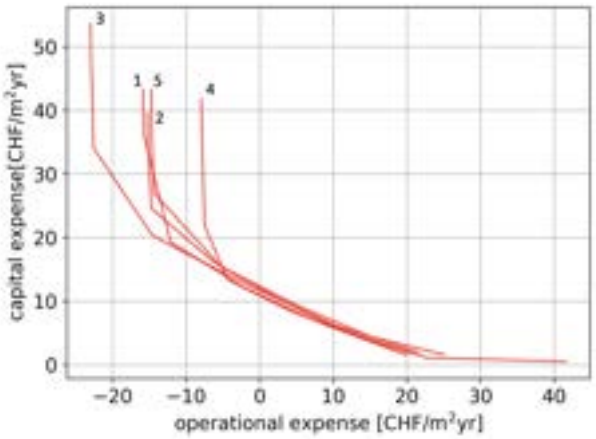

Figure 3: Pareto front for the 5 typical districts. The number refers to the district label in Figures 8 to 12.

per investment limit maps the region where the PV capacity reaches its maximum of 28 GW, representing an annual electricity production of 32 TWh/yr. Since the PV potential varies throughout the typical districts, there exists a spectrum of solutions. First, the district with high solar potential are activated at low electricity tariffs, then investments with lower profitability are activated as the price signals sent by the national infrastructure becomes more attractive. Actual energy tariffs promote a full investment into PV panels, reaching a potential of 32 TWh/yr. However, the optimal PV deployment in Switzerland ranges between 12 and 18 TWh/yr [5, 35]. Therefore, the price incentives should be located in the yellow and green areas. As a conclusion, there is a discordance between the price signals sent by grid operators and the needs of the infrastructure, which could result into costly grid reinforcements or curtailment. Such situations are socially unfair since the former induces costs to customers and the latter might render some investments unprofitable. Ultimately, this conflicting situation might generates mistrust in renewable deployments, therefore in the energy transition. In the following section, the impact of curtailment is analysed in terms of energy efficiency and costs.

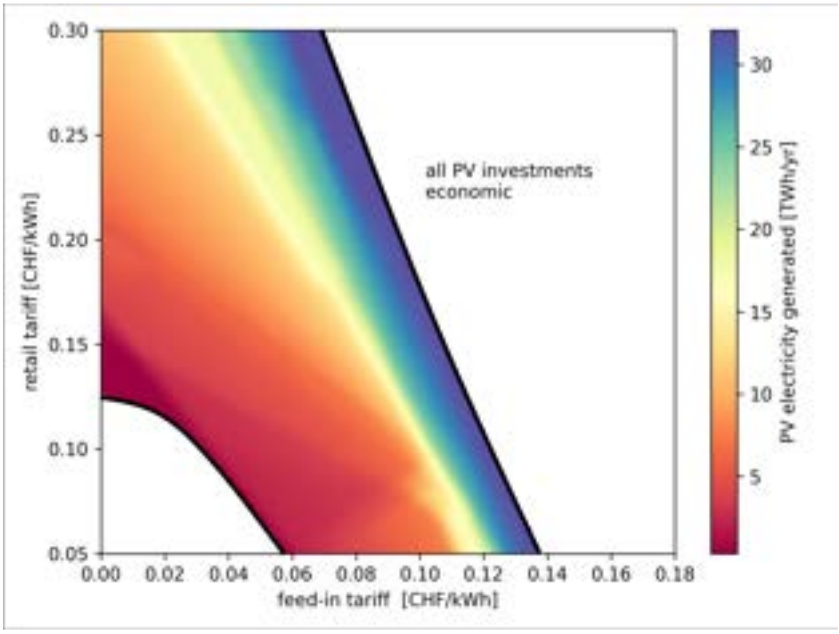

Figure 4: Yearly renewable electricity generation from PV units in energy communities for the whole Switzerland. The electricity supply is presented based on the electricity retail and feed-in tariffs. Data were calculated for the minimum total costs.

To support the analysis, two scenarios are considered. In the first one, an investment decision in PVs and heat pumps is taken today. Then, PV curtailment is applied on the energy system. The operation and investment into batteries are optimized with fixed sizes of PV and heat pump units. In the second scenario, the investment and operation decisions of the overall energy systems are taken considering grid curtailment. Therefore, the PV and heat pump capacities vary with the level of curtailment. The aim of these two scenarios is to assess the impact of grid curtailment on a decision taken today. Figure 5 shows the load duration curve of the electricity fluxes between energy communities and the national grid. The electricity tariffs promote a net export of electricity of 26 TWh/yr, 6 TWh/yr being self-consumed within the communities. The curtailed system reduces by half the maximum export power. In the first scenario, most of the peak is removed while the base load remains stable. This outcome is beneficial for the grid utility since the annual export is less intermittent and decreases to 19 TWh. However, from the perspective of the households, the PV investment is oversized since the optimal export with variable PV capacity would have been 15% lower (dashed red line).

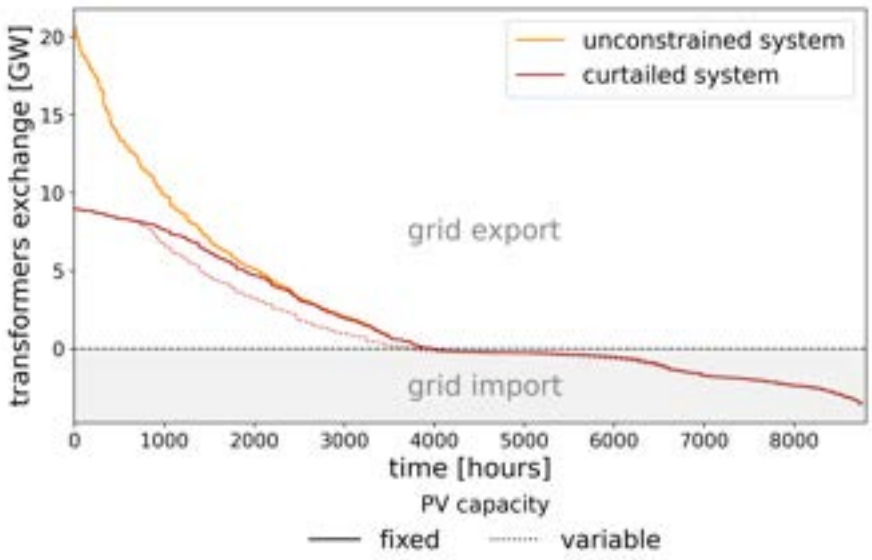

Figure 5: Load duration curve of the electricity imports and exports for energy communities in Switzerland. The unconstrained solution is constrained to reduce the maximum power peaks by half. Two design scenarios are considered, one accounting curtailment in the investment decision (variable PV) and the other one being imposed curtailment after investment decision (fixed PV).

Figures 6 and 7 further detail the energy efficiency, costs and impacts of the two scenarios. They compare metrics to the level of annual electricity export. Based on the renewable needs of the national energy system, an annual electricity export reduction by 8 TWh/yr is needed, decreasing the energy communities exports from 26 TWh/yr to 18 TWh/yr. With a fixed PV design, energy communities invest into batteries to compensate the PV over-investment with self-consumption (Figure 6). For an electricity export reduction of 8 TWh/yr, the battery investment is still not profitable and the SC and SS respectively increase to 18.5% and 50%. In the second scenario, the consideration of the grid capacity in the planning phase decreases the PV capacity by 22%. This decreases the SS from 48% to 46% but increases the SC from 17% to 22% and minimized grid curtailment (5%). The latter is 5 times higher in the first scenario (24%). While a coordinated design promotes self-consumption with a well sized PV capacity, the uncoordinated one reduces export peaks only with curtailment. The energy system is designed to generate large amount of electricity. Therefore, the high presence of renewable electricity in energy communities makes the SS high and the system less flexible to reduce the power peaks with self-consumption.

Since the peak shaving strategy of the second scenario is to decrease the PV capacity, the onsite generated electricity decreases faster with peak reduction compared to the first scenario. To generate the renewable electricity needs of the country, a peak reduction of respectively 41% and 58% is needed in the first and second scenarios (Figure 7). This trend is as well visible on Figure 5 since the scenario with fixed PV capacity has a flatter profile than the one with variable capacity. The oversized PV capacity and curtailment induces a total cost difference of 31% between the two scenarios. The larger amount of electricity sold to the grid in the first scenario do not compensate for the high investment cost on the contrary to the second scenario

where the total costs are balanced between lower electricity revenues and lower investments. From the GWP perspective, both scenarios are usually net negative since they contribute to reduce the carbon content of the grid. At an electricity export reduction of 8 TWh/yr, the scenarios respectively decrease the GWP by -1.5 and -2.1 kg $CO_{2,eq}/m_2$. This has to be contextualised with the actual Swiss GWP of the residential sector, being 6.6 kg $CO_{2,eq}/m_2$ [36]. The difference of 0.6 kg $CO_{2,eq}/m_2$ between the two scenario is due to the embodied carbon content of the PV installation in the first scenario. It represents 9% of the Swiss residential GWP and 1.5% of the direct GWP in the whole country [36].

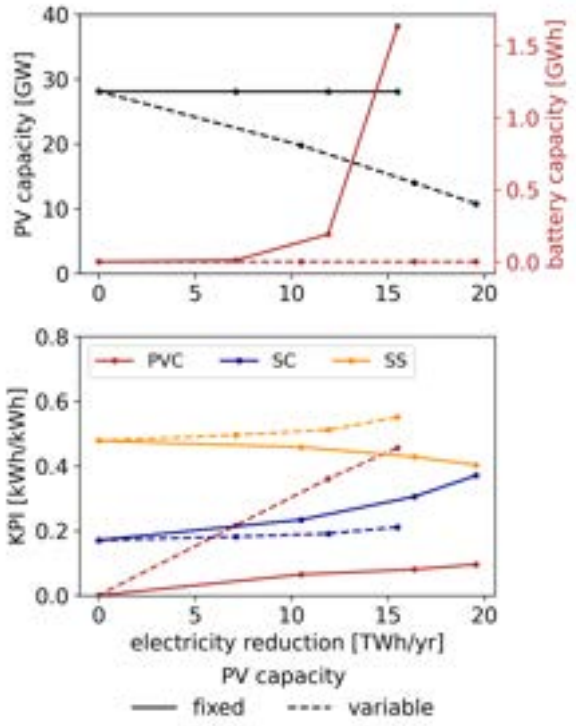

Figure 6: PV and battery capacity with PV indicators for the two scenarios based on the level of electricity export reduction. A reduction by 8 TWh/yr of the unconstrained solution is needed in Switzerland.

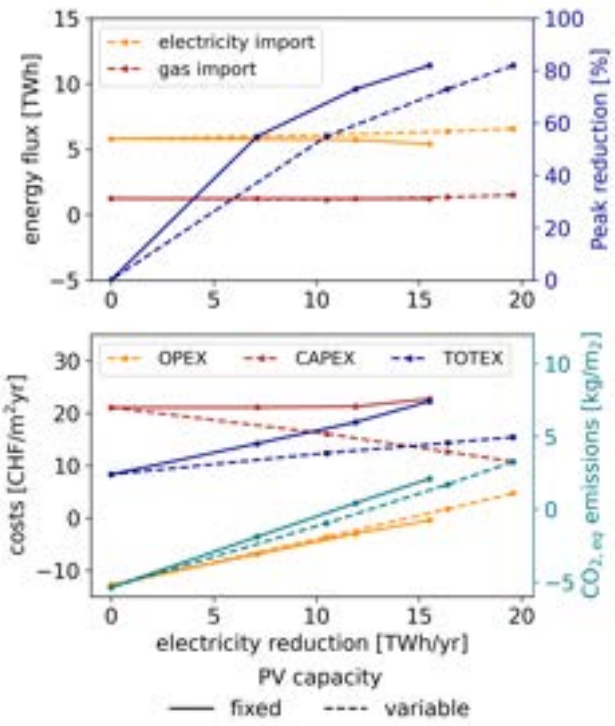

Figure 7: Energy fluxes with the utility, costs and $CO_{2,eq}$ impact metrics. All values are given after extrapolation to the whole country.

4. Conclusion

The objective of this paper was to highlight the decisions trends within energy communities and their integration in the national energy infrastructure. The community is modeled as a renewable energy hub with investment into conversion units. Typical districts are considered to extrapolate the results to the national scale. Multi-objective optimization and grid constraints are applied to meet the renewable electricity supply from the communities to the forecast national needs in 2050. The main outcomes of the study are listed below:

- The investment trends are homogeneous throughout the typical energy communities, even though the investment magnitude into solar panels differs between urban, countryside and isolated areas.
- The PV potential of the residential sector in Switzerland reaches 32 TWh/yr. The associated PV capacity is 28 GW.
- The actual electricity tariffs promote an excessive PV integration in the national electricity system. Based on national guidelines, the annual electricity supply from PV panels could exceed by a factor two the demand, being between 12 and 18 TWh/yr.
- Uncoordinated price signals induce an oversized PV capacity. Grid constraints curtail 24% of the generated electricity and increase by 31% the total costs compared to a coordinated planning, where the energy communities design their energy system based on the needs of the infrastructure. Moreover, the GWP difference between the uncoordinated and coordinated designs represent 9% of the residential total emissions.

The presented results contribute to a better understanding on the decision inter-dependency between small scale actors and national energy systems. The holistic approach encompassing various stakeholders within a single optimization favors a coordinates energy transition and increases the technological acceptance into a decision. Grid operators and national institutions should communicate properly the right price signals to local stakeholders to prevent unfair investments and mitigate costs and emissions. The extension of the work includes a better definition of the national infrastructure, accounting its energy flows and reinforcement costs. To this extent, bi-level and nested decomposition methods have a high potential at linking optimization tools modeling the various decision levels.

7. Nomenclature

Table 2: Nomenclature Table

Abbreviation	Definition
PV	Photovoltaic
MILP	Mixed Integer Linear Programming
CAPEX	Capital cost
OPEX	Operating cost
TOTEX	Total cost
MP	Master Problem
SP	Sub Problem
KPI	Key Performance Indicator
SC	Self-Consumption
SS	Self-Sufficiency
GWP	Global Warming Potential
GIS	Geographic Information System
$E^{tr,+}$	Electricity import from the low voltage transformer
$E^{tr,-}$	Electricity export to the low voltage transformer
$E^{gr,+}$	Electricity import from the microgrid
$E^{gr,-}$	Electricity export to the microgrid
E^{gen}	Onsite generated electricity
E^{curt}	Curtailed electricity
$H^{gr,+}$	Natural gas import from the gas utility

Abstract:
This paper investigates the potential of building attached / integrated Photovoltaic (PV) and vehicle-to-grid (V2G) coupling for the city of Singapore. Using the city's 55 planning areas as spatial units, a linear programming (LP) optimization model is developed to determine economically optimal PV scaling and charge/discharge strategies within and across planning areas. Mobility flows between planning areas are assessed using a large set of GPS mobile phone records, from which electric vehicle (EV) schedules are derived. Local electricity demand and solar potentials are modelled using a bottom-up approach based on building geometries and land use information, and loads are calibrated to match measured aggregate city loads. Parametrized assumptions in our model are systematically tested through scenario analysis, including varying carbon taxes, PV system cost, EV penetration, wholesale electricity prices, and local building self-consumption levels. Our study finds significant economic and environmental potential for PV systems, while economic benefits of V2G are strongly scenario dependent but generally limited. This may be explained by the high on-site PV electricity self-consumption potential due to the electricity loads generally exceeding PV generation. However, through the aggregation to the planning area level in our model, local building-resolved mismatches in production and demand were partially flattened, and thus the potential for V2G to act as intermediate storage can be expected to be higher when modelled at a finer spatial resolution. In order to gain further insight, future research could focus on combining large-scale city dynamics with more fine-grained local analysis, e.g., by limiting the analysis to one district only, as well as incorporate explicit grid balancing constraints in the model.

Keywords:
Vehicle-to-grid, Photovoltaic, Linear Programming, District Energy, Optimization.

1. Introduction

Substituting fossil fuel-based energy generation with renewable sources, such as Photovoltaics (PV), and the promotion of electric vehicles (EV), are two of the key measures to decarbonisation [13]. The aim of this paper is therefore to investigate possible synergies between the two technologies, PV and EV, and study the impact on energy-related cost and emissions if vehicle to grid (V2G) technologies were widely adapted at a city scale. V2G relies on bidirectional chargers allowing EVs not only to charge their batteries but also discharge stored electricity back into the grid. In this capacity they can be used as temporary storage devices for excess electricity from renewable sources, participate in electricity arbitrage or even increase grid stability by providing ancillary services.

1.1. V2G at a city scale

With the development of EVs as a potentially low carbon alternative to vehicles with internal combustion engines (ICE), research has investigated their integration into the existing infrastructure. One area of concern is the impact of large-scale EV adoption on grid stability, with studies highlighting the importance of charging speed [25] and grid-related benefits of nighttime off-peak charging [18]. Control schemes can be specifically designed to avoid grid overloads [7], or to optimize for either user preferences or grid cost [23]: When optimizing for user preference (i.e., optimal state-of-charge, SOC, for mobility demand), electricity may be drawn from the grid during peak demand, leading to potential shortage concerns, whereas a grid-cost minimization can relax the load on the power system. Smart charging strategies are therefore central to successfully combine EVs with the intermittent production of renewable energies such as PV. The objective of coordination is often to increase the self-consumption of locally produced PV-electricity by storing excess production in EV-batteries [10].

Further increasing synergies between local production and EVs is attempted through bidirectional charging. Energy stored in the EV battery can be discharged and consumed on site or fed back into the electricity grid

*These authors share first authorship.

(V2G). In this capacity vehicles can deliver stored PV energy at times of high demand or high electricity prices or even provide ancillary grid services. Such concepts have been explored at the level of individual homes [8] or in more aggregated forms such as parking lots [21]. At larger scale and with a focus on generating realistic EV mobility patterns, Lin et al. (2018) [16] developed a multi-agent system to test the impact of different charging schemes on a generated energy hub. By defining the behavior patterns of different agents (EVs, coordinators etc.), an attempt was made to model realistic behavior patterns including parking duration and charge probability. The study found that peak demand increased under uncontrolled charging scenarios, but through coordinating behaviors the demand could be pushed into the valley period. When V2G was employed the overall electricity demand increased significantly, but the operation of a supplementary gas turbine could be reduced and heating and cooling costs fell significantly suggesting synergies between technologies.

V2G analyses at the city scale are scarce in the existing literature. One example is Kobashi et al. (2020) [15], where the authors looked at PV and V2G interactions for the entire city of Kyoto with real world data. A techno-economic analysis was conducted using hourly electricity demand and PV production at a city aggregate resolution. Significant environmental and economic benefits were found when both technologies, PV and V2G, were deployed in conjunction with each other. The study estimates average mobility patterns from survey information and derives gasoline use and park times. However, due to the aggregation to the city level, local mobility patterns or energy demands are not differentiated in the analysis.

1.2. Mobility flows from mobile phone data

Several studies employ mobile phone data to generate mobility patterns. This data can be obtained for a large fraction of the population and is available in locations where other forms of statistics may be limited. Iqbal et al. (2014) [14] demonstrate that mobility flows can be captured in the form of origin-destination matrices using mobile phone Call Detail Records (CDR) and minimal traffic information without the need for detailed demographic and mobility statistics. As such CDR data can also be used for traffic or infrastructure planning in developing countries where data availability is low [9].

Mobile phone data has also been employed in relation to EV technology. Vazifeh et al. (2019) [26] used CDR data of one million users to determine the optimal positioning of charging stations in Boston. To the authors' knowledge Schläpfer et al. (2021) [24] have been the only ones to use mobile phone data to assess local V2G charging and discharging patterns and relate it to V2G infrastructure planning. The data used is not CDR data but collected from a variety of apps. This allows for the implementation of different tracking modes and offers the potential for more complete movement patterns. Using Singapore as case study, the city-state was separated into a grid of 250m-by-250m cells and a trajectory for each user was derived as their recorded locations moved to different cells. From these trajectories aggregate movement patterns were determined which were then translated to EV vehicle movements. Simple, uncoordinated charging schemes were deployed, where users preferably charged their vehicles during the sunny hours and discharge at night, maximizing PV consumption. It was assumed that charging and discharging was possible in any location where a user stayed for more than one hour.

The study found that a large part of the electricity was discharged outside of residential neighborhoods in primarily commercial zones such as the Singapore Downtown Core. This contradicts the assumption that V2G can mainly provide electricity to residential areas and encourages the inclusion of complex mobility patterns in research. Household electricity was estimated and compared to V2G output assuming that 3% of the mobility flows were covered by EVs. It was found that districts could cover up to 40% of the nighttime household demand using V2G, although most districts fell between 10% and 20%. Comparing charging demands to a simple estimate of PV potential found that local PV alone could likely not cover peak charging demands, requiring other solutions such as smart charging or grid imports.

1.3. Contributions

PV and V2G are both essential elements of the Singapore Green Plan 2030 published by five government Ministries as an outline towards the ecological transformation of the city-state [20]. The plan sets several concrete targets to be reached by 2030. Included is the target to increase electric mobility by providing 60'000 EV charging stations throughout the island and the target to install 2 GWp of PV capacity (system peak demand in Singapore by 2030 is projected to be 9 GW [1]). In this context, Singapore provides a good case for studying the integration of PV and V2G. Therefore, the following research questions are investigated in this paper:

- How does the penetration of EVs and V2G technologies affect optimal scaling of building attached / integrated PV systems, as well as cost and emissions of electricity?
- What levels of self-consumption and self-sufficiency can be achieved at a district scale?
- What is the impact of different boundary conditions, including local (i.e. building) self-consumption rates, carbon taxes, PV system cost, EV penetration, and wholesale electricity prices on cost, emissions and PV capacities?

The specific contributions are:

- As compared to Kobashi et al. (2020) [15], we increase the spatial resolution to the district scale in order to capture local effects of a heterogeneous system.
- Building on Schläpfer et al. (2021) [24] as a first assessment of PV and V2G potential, we now investigate economic feasibility in our study.
- Using a similar method for V2G mobility flow assessment, our study includes economic factors to assess feasible PV scaling and optimal charge/discharge patterns in various scenarios.
- We also estimate and implement the full electricity load of Singapore at planning area scale and not just total household demand.
- Finally, building energy demand and PV potentials for rooftops and facades are estimated using bottom up simulations at a high 3D spatio-temporal resolution.

2. Methods

We develop a linear programming (LP) optimization model for the techno-economic investigation of optimal PV scaling and EV charge / discharge schedules at the level of the 55 planning areas of Singapore. The LP is described in section 2.1. and illustrated in Fig. 1. Other methods employed center around the LP to generate following relevant spatio-temporal input data: electricity demand (section 2.2.), solar potentials (section 2.3.), and mobility patterns (section 2.4.).

2.1. Optimization model

The LP model captures electricity, cost, and emission flows for each of the 55 planning areas in Singapore. The temporal resolution is one hour. Calculations are made for one year. However, due to computational constraints only four representative weeks were modeled. These were derived by clustering similar weeks together. Results for each modeled week were then multiplied by the number of weeks in that cluster in order to scale up to a full year. For each district a set of electricity consumers and producers with associated electricity flows was defined. Three main components are included: Buildings, PV Systems, and EVs. Fig. 1 shows the basic structure of the model.

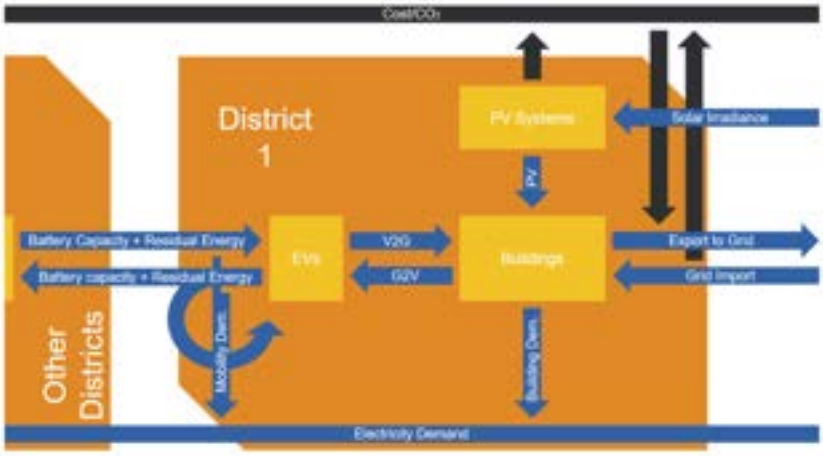

Figure 1: Overview of the LP optimization model. Blue arrows represent electricity flows, black arrows monetary flows and emissions. Yellow boxes represent the main actors contained in the model, orange defines planning area borders.

The majority of consumption in each planning area can be associated to buildings, with modeled demand described in section 2.2.. The main way of meeting the building demand is through grid imports with associated costs and emissions. Alternatively, demand can be met through installed PV systems. Unlike grid imports, PV systems do not incur costs per kWh but rather one time installation and yearly operational costs irrespective of electricity produced. The LP model can optimally scale PV over potential areas, deciding where it is financially viable to install systems. Produced power that exceeds the local demand of a planning area can be exported through the national grid. Exported PV generates revenue. Singapore offers contestable consumers the option to buy and sell electricity at the wholesale electricity price (WEP). For modeling, this WEP was taken as the basis for trading.

The final component represents EVs. When stationary, they can be charged or discharged using V2G. Discharged electricity is fed back into the local energy balance and can be consumed within the planning area

or be exported through the national grid. When EVs drive from one district to another they carry their battery capacity as well as the electricity stored in their battery with them. Since the spatial resolution is the planning area, all EVs in a location at a given time are represented by a single battery and are assumed to have the same state-of-charge (SOC). If an EV enters a district with lower charge, the energy difference is subtracted from the representative battery, and EVs with higher charge add their excess energy to the local battery. Electricity consumed by driving is subtracted from the EVs battery.

The objective function of the LP represents total costs associated with Singapore's electricity flows to meet the total electricity demand and aims to maximize revenue:

$$\max_{x \in \mathbb{R}} (f_{\text{Export}} - f_{\text{Import}} - f_{\text{GridFee}} - f_{\text{PV}}), \quad \text{s.t. } x \in \Omega, \tag{1}$$

where x include operational variables for power flow within and between planning areas and design variables for installed PV per planning area and different orientations (North, East, South, West, roof), and Ω are the system constraints describing the energy balance and technology behavior. f are linear expressions describing revenue generated from generated PV electricity or discharged electricity exported to the grid, as well as cost occurring from imported grid electricity, market support charges on grid transmissions applied to imports and to a fraction of local production to account for local transmission within planning areas, and annualized PV installation cost. Grid carbon emissions are additionally priced with a carbon tax. Prices are obtained from EMC (2022) [6]. A complete formulation and list pf parameters and model constraints can be found in Caviezel (2022) [4]. The model was generated using the `Python` package `Pyomo` and solved using `Gurobi`.

2.2. Building energy demand modeling

The electricity demand for each planning area was modeled with a bottom-up approach using the energy modeling software `City Energy Analyst` (CEA) [11]. The open-source tool can determine different energy related time series for individual buildings based on building attributes, weather input, and site surroundings. A pre-populated database with building archetypes and demand schedules exists for Singapore. For accurate modeling, several attributes were derived for each building in Singapore. For the rest of the variables, CEA-defaults were used.

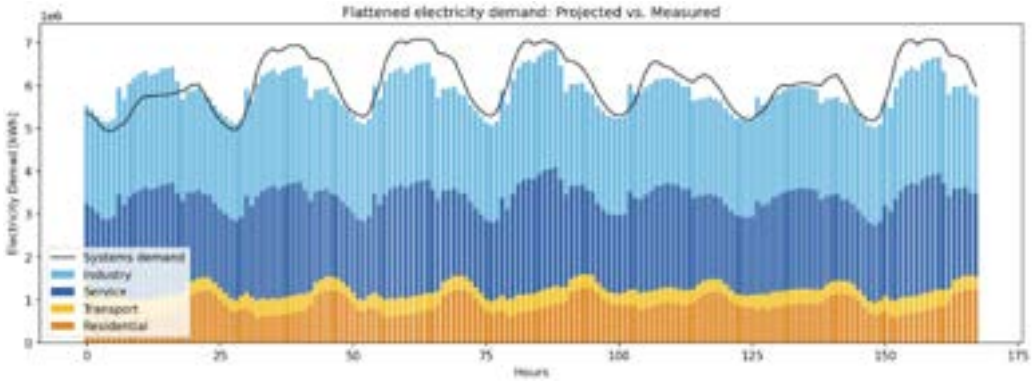

Figure 2: Modeled electricity demand by sector after scaling and amplitude adjustment vs the total systems demand. Period shown is January 1st to January 7th 2019.

2.2.1. Missing building heights

Individual building polygons with height and use type information were obtained from `Open Street Maps` and data from the Urban Redevelopment Authority (URA), resulting in a total of 111'485 buildings. Only 21'755 of the buildings had associated height information. We estimated the height of the remaining buildings using a feed-forward artificial neural network (ANN), using the `Keras` library. After testing different ANN architectures and manually tuning hyper-parameters, the final model resulted in a mean absolute error of 4.64 m and an R-squared value of 0.75, indicating significant correlation. Considering Singapore's large share of high-rise buildings, we consider the error to be acceptable.

2.2.2. Clustering

Due to computational constraints, instead of simulating the 111'485 buildings of Singapore explicitly, we clustered them into groups, similar to the approach taken by Murray et al. (2020) [19]. We used the following 5 attributes for clustering: (i) building use type, (ii) number of attached neighbouring buildings (0, 1, 2 and more), (iii) total floor area, (iv) envelope to volume ratio, and (v) height/distance ratio to neighbouring buildings (sum of the height of each neighbor divided by the distance to that neighbor). The clustering resulted in a total of 445

differentiated groups, representing combinations of the categorical attributes (i) and (ii). For each cluster, the energy demand of the central sample was modeled in CEA and using a typical meteorological year weather file for 2020 as generated from Meteonorm. To represent shading effects, for each modeled building (i.e., cluster centroid), neighboring structures within a 50m radius were included as surroundings.

2.2.3. Calibration

To correct for the mismatch between simulated and actual electricity loads, the load curves were calibrated to measured load curves. We could only find specific hourly loads for the residential sector in Raman & Peng (2021) [22], representing aggregated loads of over 10'000 residential buildings. The demand curves of these measured and aggregated profiles were found to have a smaller amplitude and the evening peak occurred later than in the CEA profiles. Additionally, some days had a morning peak, others did not. The latter were assumed to be weekends when inhabitants did not need to go to work. By adjusting the appliance, lighting and hot water loads in CEA, a custom demand profile was generated which better matches these measured profiles.

The Energy Market Authority (EMA) publishes the annual electricity consumption by sector [3]. The previously generated building demands were summed by sector and compared to these published values. The energy use intensities (EUIs) of service, residential, and industry sectors were scaled to match annual values for 2019, which was chosen as the year before the COVID-19 pandemic, where demand was not yet skewed.

High resolution demand information summed over the entire island is published by EMA in form of half hourly systems demand. After scaling the modeled profiles to match the yearly demand, the systems demand was used to assess hourly load distribution. It was found that the timing of minimum and maximum loads matched well, however the amplitude of the modeled demand curve was much higher than that of the measured systems demand. These differences were corrected by scaling the energy demands around their individual means. Fig. 2 shows the final, adjusted demand for the same period in January 2019. To get local hourly demand curves, the adjusted demands for all buildings in a planning area were summed.

2.3. Solar modeling

Hourly solar irradiation for all building surfaces (roof and façade) was simulated on a 0.7m $\times$ 0.7m grid, resulting in several million hourly solar profiles for the whole city of Singapore. The same weather file as for the building demand simulation is used. Building geometry information was taken from Open Street Maps, and data was kindly provided by researchers from Singapore [2]. The sum of geometrically available surface area per category and planning area was adjusted according to scaling factors found in the SERIS PV Roadmap (2020) [1] in order to get area suited for PV installations. Scaling factors are dependent on building and surface type and were correlated to the sectors assigned in section 2.2.. Since using several million solar profiles would lead to excessive computing cost in the optimization model, solar profiles were clustered into 5 categories (North, South, East, West, roof) for each of the 55 planning areas respectively using k-Medoids. Thus, per district, 5 annual hourly solar profiles were utilized in the PV sizing optimization to represent the bulk aggregate surface areas for each orientation. The software ClimateStudio, which is a plug-in for the CAD program Rhinoceros 3D, was used for simulating solar irradiation. An excerpt of the simulation results is shown in Fig. 5a.

2.4. Mobility patterns generation

To estimate local battery capacity, mobility demand, and the movement of residual energy in EV batteries, mobility patterns were derived. Continuous patterns for one week were generated from a dataset of individual mobile phone logs.

2.4.1. Dataset

A dataset containing mobile phone records collected from September 1st to September 30th, 2020 was obtained from Citydata [5]. During the 30-day period a total of 108'971'459 logs were captured. Each log contains a user ID, GPS coordinates and a timestamp. A total of 1'291'343 unique users are registered. The set covers the whole island of Singapore. The number of logs captured varies throughout the month and throughout each day (Fig. 3 (A)). 4:00 to 5:00 is the hour with least activity. This hour was therefore chosen as starting and ending time for all modeling periods in order to minimize period overlapping activity. The data was collected from users of a wide variety of mobile applications with a geospatial component. Citydata provides application developers with an add-on software component which records anonymized location data. Different tracking modes and log frequencies can be set by developers ranging from "manual" where records must be manually triggered to "HawkEye" with continuous tracking. According to Citydata, around 80% of developers chose "stay detection" which is triggered by the crossing of geofences and thus mainly captures movement (Yeow Leong Lee, personal communication 22.6.2022). The frequency of registrations for individual users varies strongly. Often, bursts of logs are followed by long periods without records. Other users are captured once and then disappear from the dataset (Fig. 3 (B)). Due to the prevalence of "stay detection" tracking, an assumption can be made that in many cases movements are recorded and periods without logs indicate that users remain stationary. The recording mode of individual logs is not indicated in the dataset.

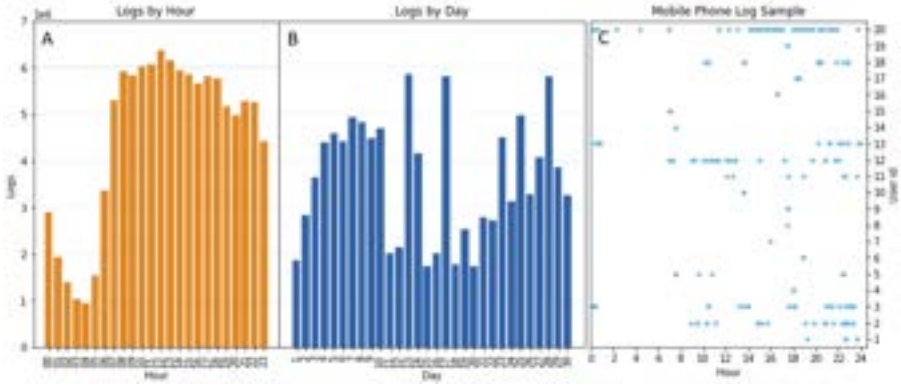

Figure 3: Mobility dataset overview. (A) Cumulative logs contained in the dataset by hour of the day. (B) Cumulative logs by day of the month. (C) Registration times for a random set of users.

Figure 4: (A) Schematic of the routing algorithm. Movement takes place from left to right. Points are classified into route points (orange) or intermediate points (black). (B) An example route generated using OSRM starting at the green waypoint and ending at red. Blue waypoints are routing points, grey ones are intermediate points.

2.4.2. Generating trajectories

In order to generate mobility patterns for a full week, the data was separated into four one-week periods starting on September 2nd, 9th, 16th, and 23rd. Weeks were analyzed separately and later merged. One day before and one after each period were considered for establishing the start and end location of the users. For each time period, only users who had at least one log per day were considered to be reliably tracked and processed further. A total of 56'794 unique IDs remained.

For each user an hourly trajectory was generated. Individual user logs were categorized into route points and intermediate points. The route points were used to determine user trajectories while intermediate points were dropped from further analysis. The first registration of a user in a period was taken as the first route point. Subsequent points were classified as route points if the direct distance to the last route point exceeded 500m or planning area boundaries were crossed. Fig. 4 (A) shows this in a schematic form. Starting with the first orange route point on the left and moving right, points are classified into route points (orange) or intermediate points (black).

Real world driving paths between route points were generated using the open-source routing machine `OSRM` [12]. `OSRM` also provides an estimated driving duration. The registration time of a route point was taken as the arrival time at its location. From this the estimated driving duration was subtracted to get the departure time from the location of the last route point. To match with the time resolution of the LP, users were classified as moving during hourly time steps where they either departed, continued a trip, or arrived at a new destination. During full hours with no movement, users were considered to be stationary and associated with EVs available for charging or discharging. Finally, the routes from all four weeks were combined into one aggregated week. As it is assumed that users follow similar mobility patterns throughout the different weeks, users tracked in multiple weeks were weighted accordingly. Movements by a user included in three of the four weeks were therefore only counted as one third in each of these three weeks.

2.4.3. Anomalies

In occasional cases, logs from individual IDs were observed to jump between far apart locations in very short intervals. In Singapore, car traffic is limited to 90 km/h and the public transport lines do not exceed 100 km/h. A maximum speed of 120 km/h with respect to the direct distance of two log points is therefore set as an upper limit. Logs implying speeds above this threshold are assumed to be GPS anomalies and are not counted as route points. A second anomaly was detected in relation to routing. Occasionally, routes generated by `OSRM` follow long and unintuitive paths between two route points. This is generally the case when points do not follow

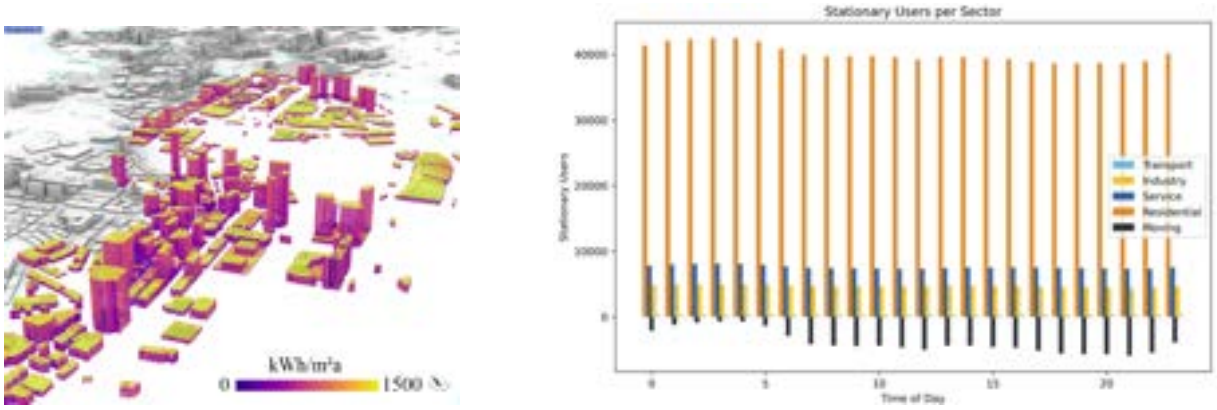
the road layout either because the user is taking another mode of transport (e.g. walking or train) or due to GPS inaccuracies. To reduce exaggerated distances and travel times, routes with route distance of more than 2.5 times the direct distance were corrected to have the average ratio between direct distance and route distance. Travel times were adjusted accordingly.

3. Results

3.1. Inputs to Optimization

Fig. 5 and Fig. 6 shows some of the inputs used throughout the studied optimization scenarios. In Fig. 5a, an excerpt of the 3D solar simulation is shown. According to our simulations, PV on buildings can generate up to 15.2 TWh of electricity with 14.2 GWp capacity installed, assuming a conversion efficiency of 20% and an installation threshold of 500 kWh/m^{2}a solar irradiation on surfaces (see Fig. 3 in Waibel et al. 2021 [27] for feasible thresholds in Singapore based on optimization). Alternatively, with a threshold of 750 kWh/m^{2}a, we can achieve a generation potential of 11 TWh and a capacity of 7.5 GWp. This compares well to the SERIS PV roadmap [1], which reports a capacity of 8.6 GWp at 750kWh/m^{2}a threshold, but also including PV on infrastructure and floating PV. The total electricity demand of Singapore for 2019 was reported to be 51.7 TWh, where the industry sectors accounts for 21.5 TWh (41.5%), the commercial and service sectors for 19.3 TWh (37.3%), households for 7.7 TWh (14.8%), and the transport sector for 3.0 TWh (5.8%) [3] (Fig. 6a). Therefore, PV on buildings could potentially cover 21% (750 kWh/m^{2}a threshold) or 29% (500 kWh/m^{2}a threshold) of total annual electricity demand. In this paper, however, the optimization model will decide on the actual PV capacities installed per district.

The annual electricity demand per floor area and planning area is shown in Fig. 6c; the annual solar irradiation is shown in Fig. 6b. Districts dominated by transport have the highest average irradiation of 808 kWh/m2a, followed by Industry with 796 kWh/m2a and Service with 756 kWh/m2a Planning areas with mainly residential buildings have the lowest average solar irradiation per area with 663 kWh/m2a. As for electricity demand, values vary significantly across planning areas, with residential electricity demand intensity being the lowest and industrial the highest.



(a) Annual solar irradiation on roof and facades around Downtown Singapore.

(b) Non-stationary users on the negative axis, and stationary users by predominant sector of the planning area they are located in.

Figure 5: Inputs to the optimization: solar potentials and mobility patterns.

Fig. 5b portrays users tracked in the mobility dataset classified as stationary or parked. Planning areas are grouped by predominant sector. Users in motion are plotted on the negative axis. A distinct driving pattern can be observed with lowest activity during the night hours and peaks in the morning and evening. However, shifts of occupancy between sector types throughout the day are minimal. Planning areas of all sector types have their highest occupancy levels at night. These drop during the day. The sum of users is constant, drops in overall stationary users represent users on the move.

3.2. Scenario Analysis

Multiple scenarios were generated by deviating individual parameters from a base scenario. The base scenario reflects targets of the Singapore Green Plan 2030 [20]. Where possible, parameters were modified to represent either current values (low environmental considerations) or targets and predictions for 2040 (high environmental considerations). Amongst others, local self-consumption (LSC) [17] is used as a parameter in our study. It is defined as PV electricity consumed directly by an individual building. Excess electricity needs

to be sent through the local grid, even if it is reconsumed within the same planning area in which case grid charges apply. The LSC factor attempts to correct for this effect by applying scaled grid transmission charges to electricity transferred within a planning area. The charge is applied to all local production (PV and V2G) but is reimbursed when electricity is exported outside of the district, as in this case the full transmission fees are paid in the planning area where the electricity is imported to. In contrast, *district level* self-consumption (SC) is a dependant variable in our study and calculated with $d^{\text{total}}_{w,t,l} = d^{\text{building}}_{w,t,l} + x^{\text{charge}}_{w,t,l} - x^{\text{discharge}}_{w,t,l}$, where x are operational decision variables for charging and discharging batteries (including EVs), d is demand, and w, t, l are indices for week, timestep (hours), and location (district). Detailed and complete parameter values are reported in [4]. Fig. 6d to 6i show the fraction of PV production exceeding local demand at a time of production, district

(d) Excess PV (base). (e) Self-consumption (base). (f) Self-sufficiency (base).

(g) Excess PV (best). (h) Self-consumption (best). (i) Self-sufficiency (best).

Figure 6: Singapore with results shown by planning area. Diagonal lines mark districts where no data was registered.

level self-consumption, SC, and district level self-sufficiency* for the base scenario and an (environmentally) *best case* scenario. In the base scenario a LSC value of 40% is chosen (between typical self-consumption values without storage and values with dedicated storage found in [17]) and in the best case scenario 80% an optimistic value still found in the literature, since Singapore has high demand compared to its PV production capacity. In the base scenario, the prepandemic WEP from 2019 was chosen as a stable baseline. By 2022 the WEP had risen by a factor of 2.8. This was used as a multiplication factor to generate the best case WEP from that in the base scenario. Additionally, full EV-penetration (600'000 EVS) was implemented compared to 10% penetration in the base scenario. In the best case scenario the fraction of excess PV increases to an average of 6% under the best-case scenario with complete utilization of surface potential. All of this is found in predominantly residential planning areas where the average is 10% with values reaching up to 49%. Excess in other sectors is negligible. Self-consumption remains high with 95% and a range from 100% to 56%. Self-sufficiency averages at 18% but can reach levels of 40% in districts where PV production is high compared to local demand. It should be noted that, when running a scenario without V2G, the effect on average planning area self-consumption and self-sufficiency was minimal with V2G increasing self-consumption by about 0.5% and self-sufficiency by 0.03%. This can be explained by the generally already high levels of SC where EV

*Self-consumption represents the fraction of PV consumed locally while self-sufficiency describes the fraction of local demand covered by PV.

electricity demand is negligible in comparison to total electricity demand.

3.2.1. Scenario Comparison

Fig. 7 shows a comparison of all studied scenarios and the difference in system cost, optimal PV capacities, and CO_2 emissions. Following parameters are used in the various scenarios: CO_2 tax in S$/t$CO_2$eq. = 0 (low), 60 (base), 95 (high); EV penetration in number of EVs = 3000 (low), 60'000 (base), 600'000 (high); PV CAPEX = estimates from 2022 (low), 2026 (base), 2031 (high) as from [1]; wholesale electricity price (WEP) = prices from 2019 (base), base $\times$ 2.76 (high), base $\times$ 0.5 (low); LSC in % = 20 (low), 40 (base), 80 (high). Furthermore, some scenarios are calculated with or without PV, and with or without V2G. The colorbar range is set to -30 to +30 %, but numeric values are indicated in the cells.

Results show that increasing LSC made PV systems significantly more viable with investment increasing by 257 Mio S$ or 59%, decreasing self-consumption reduced investment by 42 Mio S$ or 10%. Installed PV capacity reached 8.6 GWp (57% higher than in the base scenario), import related costs decreased significantly and export revenue increased with higher levels of self-consumption. Electricity related CO_2 emissions are reduced by 0.6 Mt/a in a high LSC scenario, while they marginally increase by 0.1 Mt/a in a low LSC scenario. In summary, achieving high degrees of high LSC shows both significant economic and environmental benefits.

In all scenarios PV installations are able to significantly reduce costs and emissions of the Singapore electricity market. The optimal installed capacity determined by the model ranges from 4 to 14 GWp depending on the scenario. Under the base assumptions for 2030, the optimally installed capacity is 5.5 GWp. As such, economically viable PV potential is significantly larger than the 2 GWp capacity targeted set in the Singapore Green Plan 2030 [20]. Under base scenario assumptions PV systems can reduce carbon emissions from electricity generation by around 3 Mt or 15% compared to the same scenario without PV.

The impacts of V2G are strongly scenario dependent. In the base scenario cost reductions due to V2G technology come to only 7 S$ per EV and year. Savings can be increased up to 127.65 S$/EV/a under the best-case scenario. The economic potential of V2G for self-consumption increase and electricity arbitrage is therefore severely limited in all scenarios. Additionally, V2G increases CO_2 Emissions in the base and best-case scenario by increasing the overall electricity imported. Synergies between PV and V2G are minimal although V2G does increase the economically viable PV area in one scenario (High LSC w/o V2G to High LSC scenario).

3.2.2. Demand vs PV production

Fig. 8 shows average hourly building energy demand and PV production with optimal capacities from the base scenario for a predominantly residential, industrial, and service dominated planning area, respectively. It is striking that only in the first district, PV production exceeds demand, while in most other districts PV electricity can only provide a fraction of total demand. Considering that the majority of total electricity demand stems from industry and service/commercial use, most districts will not be able to export PV (also see Fig. 6d and 6g). For the commercial- and service sector, this is due to the constantly high cooling loads throughout the year.

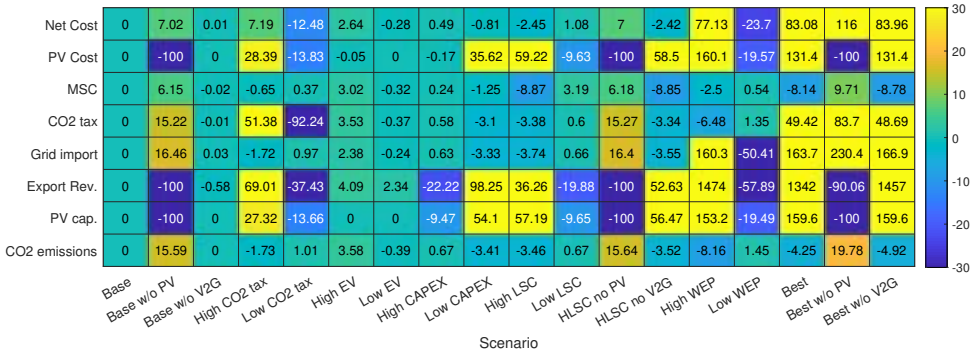

Figure 7: Comparison of all studied scenarios with values shown as % deviation from the base scenario. Net cost = PV Cost + MSC + CO2 tax + Grid import - Export revenue; MSC = market support charge; HLSC = High LSC; WEP = wholesale electricity price.

3.2.3. Charging Schedules

Two modes of EV charging can be differentiated: Charging from the grid and charging using excess PV electricity. The second is defined as charging at times when local PV production exceeds local demand. Average daily charge and discharge patterns for the entire EV fleet of Singapore are shown in Fig. 9, with optimization results for the base scenario in Fig. 9a and for a high LSC scenario in Fig. 9b. In the base scenario, the two charging modes are clearly separated. Grid charging takes place almost exclusively during the night when

electricity prices are low. Excess PV is available during the day but in much smaller quantities. Only 2.21% of charging takes place using excess PV-power. V2G discharging takes place almost exclusively in the hour from 10:00 to 11:00 when electricity prices hit their highest point. The vast majority of annual charging electricity is consumed through driving, a fraction is lost during the charging process. Only 7.2% are discharged back into the grid. In the high LSC scenario, charging still took place primarily during the night and from the grid, however the fraction of charging from excess PV is increased to 18.7%. Discharging was spread more evenly with peaks during the morning and afternoon.

4. Discussion

Kobashi et al. (2020) [15] found that V2G in combination with PV systems could significantly reduce energy related costs and emissions in Kyoto. The difference in conclusions likely owes to both different model assumptions as well as real differences between the two locations. The most significant difference appears to be the result that local rooftop PV in Kyoto can cover approximately the entire annual electricity demand of the city. This means, times of overproduction are much more frequent and the possibility of storing electricity for later use becomes more valuable compared to this study, where PV generation rarely exceeded local demand. Kyoto is stated to have a rooftop area of 51.1 km^2 and an annual load of 8.1 TWh. In comparison, the area sum of the buildings in Singapore is 90.0 km^2 but the annual demand in 2019 was 51.7 TWh. This means that the demand per roof area is significantly higher in Singapore. Additionally, Kobashi et al. assume that 70% of roof area can be covered by PV whereas scaling factors used in this paper are significantly lower. Additionally, the study aggregates the city to a single unit. No transmission fees within the city are applied.

Schläpfer et al. (2021) [24] used the same mobility dataset and a similar method for extracting mobility patterns for Singapore. They also aggregated to the planning area level and found that for specific planning areas, up to 40% of nighttime *household* electricity demands could be covered by V2G, but for most districts this value was between 10% and 20%. These results were found using a first method assessment relying on a simple charging/discharging scheme where economic effects were excluded. Our study now investigated charging/discharging and PV capacity sizing based on a cost minimization. We found that under base assumptions for 2030 V2G under best case assumptions vehicle discharge made up 4% of the islands total demand (or 26% of *household* demand). However, cost optimal charging took place predominantly from the grid during night hours and discharging happened during the day. As such the transfer from PV electricity produced during the day to the night hours was not observed. Our results show that future work should also increase spatial resolution to better capture local mismatch of demand. This model assumes perfect foresight and focuses on overall economic optimization and not e.g. load balancing or individual benefits to stakeholders. Control schemes operating under bounded information and alternate optimization strategies could be explored.

5. Conclusion

This paper investigated the effects of electric storage from V2G technologies on optimal PV sizing on buildings and associated system costs and operational emissions at the district scale for the city of Singapore. Scenarios were based around the country's climate targets (Singapore Green Plan 2030). Energy and mobility flows were captured in an LP optimization model which defined PV scaling and charge/discharge patterns minimizing total systems cost. Carbon emissions were included in the form of a CO_2 tax. Three main inputs were generated: (i) City scale mobility patterns derived from a large set of mobile phone GPS records, (ii) energy demand at district level modeled using a bottom-up approach, and (iii) PV potentials using building geometries and 3D solar irradiation data. Different levels of local self-consumption were studied in a scenario analysis and compared to a base case.

Average self-consumption at the district level was very high in all scenarios; under base scenario assumptions it was 98% with a self sufficiency rate of 13%. These values were barely affected by V2G. In the best-case scenario with maximum PV installations average sufficiency increased to 18% and self-consumption at planning area scale dropped to 95% but with a significant range. In this scenario V2G was able to increase self-consumption by around 0.5%. Although impacts of V2G were low, the general expected effects were found. V2G was able to increase self-consumption and reduce exports to the grid. Reasons for low impact as compared to other studies are likely twofold. On the one hand Singapore's economically viable building PV potential is low compared to a relatively high demand. This means that PV only exceeds local demand in specific locations and times. Especially residential areas with a demand curve that is low and runs counter to PV production can generate significant overproduction and could be candidates for V2G. On the other hand, through the aggregation to the planning area level, local mismatches in production and demand were partially flattened and thus the potential for V2G to act as intermediate storage was reduced.

In order to gain further insight into the potential of V2G in cities like Singapore, future research could focus on improving mobility demand predictions, and combining large scale city dynamics with more fine-grained local analysis. Investigating additional cities could reveal location based effects. Finally, specific grid dynamics could be modelled explicitly to account for further benefits of V2G such as grid balancing and frequency regulation.

Acknowledgments

This research was conducted at the Future Cities Lab Global at Singapore-ETH Centre and ETH Zurich. Future Cities Lab Global is supported and funded by the National Research Foundation, Prime Minister's Office, Singapore under its Campus for Research Excellence and Technological Enterprise (CREATE) programme and ETH Zurich (ETHZ), with additional contributions from the National University of Singapore (NUS), Nanyang Technological University (NTU), Singapore and the Singapore University of Technology and Design (SUTD). Input was gratefully received from Luis Santos from the Cooling Singapore group at SEC on electricity modeling, and from Dr. Alina Galimshina from the Chair of Sustainable Construction at ETH on embodied emissions of PV systems. Acknowledgement also goes to Citydata for providing the mobility dataset and related support.

Abstract:
As one element of power system transition, distributed cross-sectoral energy systems (DCES) can provide flexibility for the electricity market. So far, no applicable method for quantifying the flexibility potential of DCES operation exists. Nonetheless, by comparing the flexibility demand of the electricity market and the electricity flow between a DCES and the electricity grid it becomes possible to quantify market-serving flexibility of DCES operation. In this work, we categorize aim and scope of already known flexibility quantification methods and develop a new method to assess DCES market-serving flexibility covering residual load (RL). Part of this method is the new developed quantification indicator *Flexibility Deployment Index* (FDI), integrating two factors: The RL of the electricity market and the electricity purchase and feed-in of a DCES. By normalizing both factors, operation of different DCES concepts and scenarios regarding their flexibility can be compared. The developed quantification method is applied in a case study of a hospitals' DCES in Germany. Using a MILP optimization model with different technology concepts and scenarios, we study FDI variation for a fixed tariff, a dynamic tariff and a CO_2-emission-optimized operation. The results of the case study prove that high-capacity combined heat and power units combined with thermal storage units lead to high flexibility provision. Also, the results outline higher flexibility provision in the winter than in the summer period.

Keywords:
Distributed cross-sectoral energy system; Flexibility; Optimized operation; Quantification indicator; Residual load.

1. Introduction and motivation

The aim of this work is to develop a method to quantify the flexibility provision of distributed cross-sectoral energy systems (DCES).

According to [1] flexibility demand results from the difference of electricity power consumption P_{el} and the renewable energy (RE) generation P_{RE} indicated by the residual load (RL) P_{RL} in (1).

$$P_{RL} = P_{el,consumption} - P_{RE,generation} \tag{1}$$

Presently, in the higher-level energy system of Germany, the requirement for flexibility demand of RL is primarily fulfilled by conventional power plants, controllable RE, and storage power plants ([2, 3]). However, with the phasing out of coal and nuclear electricity generation [§ 4 art. 1 cl. 2 KVBG; § 7 art.1 AtG], significant flexibility capacities are going to vanish, leading to the emergence of a potential flexibility gap ([4, 5]).

To address this challenge, one possible solution could be to explore the flexible operation of DCES. However, assessing the flexibility potential of DCES is a non-trivial task due to the absence of a standardized method for evaluating DCES flexibility.

Pina et al. [6] defines energy systems as cross-sectoral when they include at least one polygeneration unit, such as a combined heat and power (CHP) unit, that can be supplemented by additional energy conversion units and storage. These systems are referred to as distributed energy systems (DCES) when they serve as local energy systems. DCES are primarily deployed in industrial, district, and building facilities with high energy demands, such as hospitals, swimming pools, universities, and shopping centers.

DCES primarily serve the energy demand of their respective facilities. Any surplus capacity can be provided to the higher-level energy system. However, since the availability of this capacity is time-dependent due to

the volatile nature of facility demand, the flexibility potential of DCES cannot be accurately measured by their installed generation capacity alone.

To develop a suitable characteristic value we firstly draft an understanding of flexibility in 1.1.. Based on this, we define flexibility of a DCES in 1.2.. We show a literature review giving an overview of existing quantification methods in 1.3.. We present various flexibility indicators and discuss whether they are sufficient for the targeted quantification. Subsequently, we define requirements for a new quantification indicator in 2.1. and deduce and introduce it in 2.2.. In section 2.3., we present a case study in which we performe a plaubility check of the quantification indicator and in 3., we present the results of the case study. In 4., we conclude our results of the study.

1.1. Flexibility in the energy system

In [7–10], flexibility is described as a balancing service for a higher-level energy system. The flexibility purpose is RE market integration and RE curtailment reduction by flexible electricity purchase and electricity feed-in. Load-shifting is a technical implementation to offer this flexibility. Negative load-shifting is characterized by the reduction of electricity generation, increase of load and charging of storage. Positive load-shifting is characterized by the increase of electricity generation, reduction of load and discharging of storage. To gain flexibility by load-shifting the requirements of the higher-level energy system need to be considered.

According to literature, flexibility provision can be divided into different characteristics ranging from capability services up to technical assertions:

1. *Flexibility options* are technologies and operating modes of different fields of function in the energy system that can provide flexibility. In Fig. 1 [11–14] show an overarching definition of these technologies and operating modes and allocate them to the fields of flexible generators, flexible consumers (demand), flexible storage and the expansion of the electricity grid. In this approach the flexibility options cover RL.

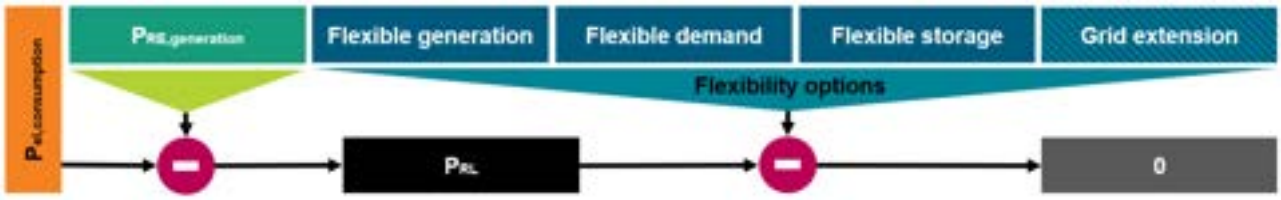

Figure 1: Fields of functions in an energy system with flexibility options covering RL. Figure in accordance with [15].

2. According to [16]], three areas of *flexibility applications* exist. They describe the point of view of a flexibility option:
    - *Market-serving flexibility* does not depend on any physical necessity. It is exercised solely by preferences on the demand side. It comprises of the operation of individual market players, who optimize their operation following an objective function regarding external signals (e. g. electricity price and CO_2 emissions).
    - *System-serving flexibility* is intended to ensure the quality of supply in the electricity grid and thus the security of supply. The main objective is to maintain the frequency by using balancing power for the stability of the system balance of generation and demand. One instrument for providing system-serving flexibility are operating reserves.
    - *Grid-serving flexibility* is provided by the transmission system operators for energy system stability. The focus is on grid congestion management for the interconnected systems and prevention of bottlenecks. In Germany one instrument for providing grid-serving flexibility is e.g. 'Redispatch'.
3. According to [10, 17], flexible operation can be provided on different *flexibility levels* in the energy system - the consumer, producer and storage level.
    - The *consumer level* includes mainly energy demands. Consumer level flexibility can be divided into consumption-side flexibility and load management. These are differentiated by their influence on the energy consumer. The consumption-side flexibility has no influence on the consumer's behavior, as it results from flexibility of the energy supply units on the demand side. In contrast, load management, also called demand-side management (DSM), has an impact on the demand time series and thus has an impact for the consumer and the consumers behavior. The consumer level can also be named *prosumer level*, if the consumer is also able to provide electricity to the grid.

- The *producer level* includes controllable power plants that can be operated flexibly without external constraints.
- The *storage level* includes large-scale storage facilities that can store electrical energy directly or indirectly and thus provide storage flexibility.

4. In [18–20] the term *flexibility potential* is defined as the flexibility that a flexibility option can theoretically provide. [19] differentiates the flexibility potential into the terms technical potential, technically usable potential, socio-technical potential, economic potential and regulatory potential. [18] relates these potential terms to each other according to Fig. 2. In this logic, the differentiation of technical potential from theoretical potential is in accordance with the technical restrictions of the flexibility option. The technical potential is further constrained by the frequency of its flexibility call-ups, defined as the technical usable potential. The technically usable potential is finally reduced to the usable potential by the economic, socio-technical and regulatory potential. The economic restrictions of the technical usable potential are affected by the economic viability of a callable flexibility option, which is mainly characterized by the revenue of selling flexibility services. The socio-technical potential is the willingness of adjusting operation and services for providing flexibility and depend on the extent to which the provision of flexibility leads to restrictions in normal operation or the original intended use of the flexibility option. The regulatory restrictions are defined by legislations of authorities and regulations of market access.

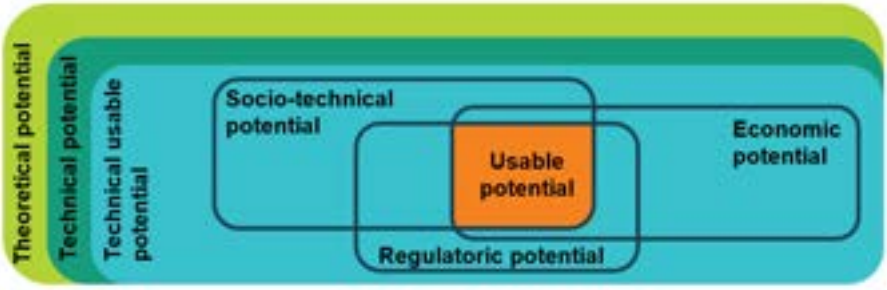

Figure 2: Classification of different flexibility potentials. Figure in accordance with [18].

1.2. Flexibility of a DCES

We classify the flexibility offered by a DCES considering the supply of electricity, heating, and cooling for a facility, and we formulate an understanding of why and how DCES flexibility covers RL.

In this study the DCES is containing energy conversion and storage technologies in the form of a CHP, a gas boiler, a compression chiller (CC) and thermal energy storage units (TES). Every unit represents a flexibility option: The CHP unit, the gas boiler and the CC are flexible generators. The TES are flexible storage units. In the following we consider the entire DCES as one flexibility option. The DCES can thereby provide flexibility to the higher-level energy system by the electricity flows through the public grid connection.

As the focus in this study is on the cost-minimal operation, the flexibility application of the DCES operation can be understood as market-serving flexibility. Though, it should be noted that market-serving flexibility can also be interpreted as system-serving flexibility, as markets for balancing energy exist. According to [21], DCES can also run in a grid-serving manner by considering grid bottlenecks. In this case, they might be installed close to consumers.

The flexibility level of the DCES is the consumer level providing consumption-side flexibility. The DCES offers load-shifting by sector coupling with the CHP and time flexibility with the TES. As no active adjustment of the demand time series exists, DSM is not possible.

In this study, we focus on the usable flexibility potential of the DCES. The economic and regulatory framework conditions are mainly determined by the electricity markets. The socio-technical restrictions are set by the premise that the facility's demand needs to be fulfilled at any time.

Based on this classification we define the flexibility understanding of the DCES in this study in an application context: *Constrained by the socio-technical, regulatory and economic restrictions, the DCES contains a usable flexibility potential of market-serving consumption-side flexibility. The flexibility service does not primarily follow a physical necessity. It follows the optimal operation of the DCES. The optimized operation is controlled by an external signal under the premise that all DCES' facility energy demands are covered at any time. Dependent on the DCES' energy conversion technologies and storage units, the DCES operation covers RL in the higher-level energy system and thus, becomes a flexibility option.*

1.3. Review of flexibility indicators

To quantify the flexibility of DCES, several approaches can be found in literature. These approaches pursue different understandings of flexibility and pursue different flexibility objectives and result in a variety of indicators. However, none of these indicators allows to quantify the previously defined understanding of flexibility covering RL.

The existing indicators are valid for different time periods. Beginning with the quantification of points in time in [24, 26–29, 32], the period of the flexibility provision in [22, 23] and the quantification of a freely selectable period in [22,27,28,30,31,33,34]. The indicators also differ in the use of a reference operation or no reference operation in [22, 24, 26–29, 33, 34]. Based on the different approaches, also the number and types of used parameter varies. As in [22–24] only the time t of a flexibility provision is considered, in [22, 24, 26–29] also the power generation P is taken into account. In [22, 27, 28, 30, 31] both parameters of time and power are combined to quantify flexibility with a parameter of the unit energy E. In [27, 30–34] also external parameters of mostly cost signals and electricity prices are used. A distinction can also be made between relative result values in [24, 26, 27, 31, 33, 34] and absolute result values in [22, 23, 27–30, 32] with parameters of the units time, power, energy or costs.

The indicators from the literature can be categorized into indicators for time flexibility in [22–24], power flexibility in [22, 24–29], energy flexibility in [22, 27, 28, 30, 31], energy efficiency in [27, 28, 32] and the quantification of flexibility through external variables or signals in [27, 30, 31, 33, 34]. The indicators for time flexibility, power flexibility, energy flexibility and energy efficiency focus on flexibility definitions concerning only single energy units or separate energy systems. Only the quantification indicators of flexibility through external variables or signals consider also the higher-level energy system. Though, RL is not considered in any indicator.

2. Method

As no adequate flexibility indicator exists in literature to quantify the above defined flexibility, we determine a new indicator.

2.1. Requirements for a new quantification indicator

The new indicator is intended to quantify to which extend the market-serving flexibility of a DCES covers RL of the higher-level energy system. The indicator should enable a quantification of the usable flexibility potential. The focus is on quantifying the concurrence of the DCES operation with the higher-level energy system. The indicator should be able to distinguish between positive and negative load-shifting at times with high or low RL. Due to the wide range of other possible DCES configurations, it is important that the quantification takes place on the basis of parameters which are applicable for a wide variety of DCES concepts. As the flexibility understanding focuses on the electricity sector, the used parameters should also be electrical values. The indicator should provide comparability of different DCES in different facilities and in different operation modes. Therefore, it is advisable to use normalized values. Usually this leads to an appropriate outcome between zero and one, which also presents the results in an easily and meaningful way. Further, the indicator should work for different quantification periods (QP).

2.2. The flexibility deployment index

We develop the new quantification indicator *Flexibility Deployment Index* (FDI). It consist of different electrical parameters. We consider on the one hand the electrical load-shifting through the grid connection of the DCES to and from the higher-level energy system and on the other hand we consider the RL of the higher-level energy system. Therefore, we set the system boundary around all DCES units and consider the DCES as a black box.

We display the flexibility offer with the load-shifting of the DCES by the *Flexibility Potential Factor* ($F_{DCES,t}$). As can be seen in (2), the $F_{DCES,t}$ includes the electricity purchase P_{pur} and the electricity feed-in P_{in} of the DCES at a time step t within QP as the set of all time steps. To align the power with the capacity of the DCES and its facility's demand, we normalize the power with the maximum and minimum electricity flow in QP. The denominator is determined by a case distinction, depending on whether power is purchased or feed in. If power is fed in (positive numerator), the maximum power feed-in during the QP is used as denominator. If power is purchased (negative numerator), the maximum purchased power in the QP is used as denominator. The $F_{DCES,t}$ has a possible range from -1 to +1, in which -1 represents the maximum possible flexibility potential from negative load-shifting. Conversely, +1 represents the maximum possible flexibility potential from positive load-shifting.

$$F_{DCSE,t} = \frac{P_{in,t} - P_{pur,t}}{|P_{DCSE,max}|} \qquad \text{with } P_{DCSE,max} = \begin{cases} \max\limits_{t \in QP}(P_{in,t}) & \text{if } P_{in,t} - P_{pur,t} > 0 \\ \max\limits_{t \in QP}(P_{pur,t}) & \text{if } P_{in,t} - P_{pur,t} < 0 \end{cases} \tag{2}$$

We display the flexibility demand based on the RL of the higher-level energy system by the *Residual Load Factor* ($F_{RL,t}$). As can be seen in (3), the $F_{RL,t}$ includes the ratio of the RL $P_{RL,t}$ at a time step t to the absolute value of the maximum positive or negative RL $P_{RL,max}$ within QP. For $P_{RL,max}$ we apply a case distinction. If the RL is positive at a time step t, the maximum RL of the QP is used for $P_{RL,max}$. If the RL is negative, the minimum RL of the QP is used for $P_{RL,max}$. Accordingly, the $F_{RL,t}$ differentiates between positive and negative RL. It has a possible range of values from -1 to +1, where -1 corresponds to the maximum need for negative load-shifting and +1 corresponds to the maximum need for positive load-shifting.

$$F_{RL,t} = \frac{P_{RL,t}}{|P_{RL,max}|} \qquad \text{with } P_{RL,max} = \begin{cases} \max\limits_{t \in QP}(P_{RL,t}) & \text{if } P_{RL,t} > 0 \\ \min\limits_{t \in QP}(P_{RL,t}) & \text{if } P_{RL,t} < 0 \end{cases} \tag{3}$$

As a typical DCES provides flexibility services predominantly in a kW or low MW range and the RL is to be classified in a high MW or GW range, normalizing the load-shifting and RL values allows appropriate comparison of the two values resulting in the *FDI*. The comparison of absolute values would lead to very small values, which would impede the comparability. Thereupon, the *FDI* in (4) puts the technical flexibility offer of a DCES $F_{DCES,t}$ and the flexibility demand of the higher-level energy system's RL $F_{RL,t}$ in relation to each other.

$$FDI_t = \begin{cases} 1 & \text{if } FDI_{k,t} > 1 \\ FDI_{k,t} & \text{if } 1 \leq FDI_{k,t} \leq -1 \\ -1 & \text{if } FDI_{k,t} < -1 \end{cases} \qquad \text{with } FDI_{k,t} = \frac{F_{DCSE,t}}{F_{RL,t}} = \frac{P_{in,t} - P_{pur,t}}{P_{DCSE,max}} \times \frac{P_{RL,max}}{P_{RL,t}} \tag{4}$$

A positive value indicates that the DCES load-shifting does support covering RL of the higher-level energy system and a value of + 1 corresponds to maximum possible RL coverage by the DCES. A negative value indicates that the DCES load-shifting does not support covering RL of the higher-level energy system and a value of - 1 corresponds to maximum addition of RL by the DCES. Due to the division of the two factors, an FDI_t greater than 1 would occur in the case that $F_{RL,t}$ is smaller than $F_{DCES,t}$. For this case, the assumption is made that even with a small $F_{RL,t}$, the absolute RL exceeds the absolute power flow of the DCES. Accordingly, in cases where $F_{DCES,t}$ and $F_{RL,t}$ both have a positive or a negative algebraic sign, it results in a positive effect for the higher-level energy system. If the factors have different algebraic signs, the FDI_t is negative.

Averaging the values of FDI_t over the number of all time steps n_{QP} in (5) results in the *average Flexibility Deployment Index* $\overline{FDI}$. It shows the mean *FDI* over the QP resulting in a value between - 1 and + 1.

$$\overline{FDI} = \frac{\sum\limits_{t \in QP} FDI_t}{n_{QP}} \tag{5}$$

2.3. Case study

To apply the defined flexibility indicator, we carry out a case study for the DCES of a hospital in Hattingen, Germany. The hospital includes around 270 beds. Its heat consumption is 4239 MWh and its electricity consumption is 2457 MWh per year. To determine the operation of the DCES, we use a mixed integer linear programming (MILP) optimization model. We create the DCES model with our self-developed optimization tool ESyOpT, which is based on the Python optimization-modelling library Pyomo ([35]) and the open energy modelling framework oemof ([36]). With the mathematical solver Gurobi ([37]) we calculate the optimized operation for the minimum operating costs and for the minimum CO_2 emissions of the optimized electricity and natural gas purchase and feed-in. The demand data is obtained from measurements of the hospital.

We use two different energy system concepts of the DCES in three tariff scenarios. We perform the calculation for one year in a resolution of 15 minutes.

2.3.1. Demand time series

For the input demand time series, we use the electricity, heating and cooling demands of the hospital measured in [38]. The input demand data for one exemplary year has an electricity base load of about 250 kW and an electricity peak load of about 400 kW. The heating base load is about 350 kW in summer and about 650 kW in winter. Cooling is predominantly needed in summer. The cooling base load is around 35 kW at night. During the day the demand rises to a peak of about 75 kW.

2.3.2. Energy system concepts

In the case study we consider two DCES concepts including a CHP, a gas boiler, an emergency cooler, a CC, a TES for heating and a TES for cooling. The unit interdependencies are analyzed in [38]. Depicted

in Table 1, we conceptualize one reference concept (*ref*) and one optimized concept (*opt*), which enables a flexible operation. The *ref* concept includes a CHP with an electrical nominal load of the electrical base load of the hospital. The *opt* concept includes a CHP with an electrical nominal load of the electrical peak load of the hospital.

Table 1: Units and parameters of the concepts in the DCES model.

concepts	$CHP_{nominal\ load}$,		$CHP_{part\ load}$,	gas boiler,	heating TES,	emergency cooler,	CC,	cooling TES,
	kW_{el}	kW_{th}	%	kW_{th}	kWh_{th}	-	kW_{th}	kWh_{th}
ref	250	348	n.a.	1500	n.a.	yes	600	n.a.
opt	400	557	50 - 100	1500	519	n.a.	600	95

2.3.3. Scenario time series

We carry out the optimization for different tariffs. Depicted in Table 2, we use two electricity price tariffs and one tariff, which implies the CO_2 emission factor (EF). Furthermore, for the quantification with the FDI, we use an appropriate RL time series.

2.3.3.1 Optimization tariff scenarios

We optimize the DCES operation according to the minimal costs and the minimal CO_2 emissions. To simulate the actual tariff structures we use a fixed price tariff (*fix*), including a fixed price for electricity and natural gas. To simulate a optimized market-led operation of the DCES, we use a dynamic electricity tariff (*dynamic*) and an *EF* time series of the higher-level energy system.

The *fix* tariff includes a fixed electricity price of 17.9 ct/kWh for electricity purchase and a revenue of 15.5 ct/kWh for electricity feed-in. We adjust the prices to the mean prices of the *dynamic* tariff to keep the same price level. The purchase and feed-in prices vary by taxes and levies.

The *dynamic* tariff includes the German intraday auction market price of 2021 (see Fig. 3a). The mean purchase price is 17.9 ct/kWh and the mean feed-in revenue is 15.5 ct/kWh. The volatility is 1.42 ct/kWh determined by the hourly standard deviation. The purchase and feed-in prices vary by taxes and levies.

The *EF* tariff includes the specific CO_2 emissions of the marginal power plant in the merit order in every time step by the approach of [39] (see Fig. 3a). We use data of [40–42] for the German electricity mix in 2021. Therefore, we use an average marginal EF of 589.1 g_{CO_2}/kWh, which ranks between the EF of conventional gas turbines (EF = 619 g_{CO_2}/kWh) and combined cycle gas turbines (EF = 411 g_{CO_2}/kWh). The maximum EF is 1093 g_{CO_2}/kWh for lignite-fired power plants and the lowest EF is 0 g_{CO_2}/kWh for RE power plants. No EF for the electricity feed-in of the DCES is needed to calculate the optimized operation.

In all tariffs we use a fixed natural gas price of 3.77 ct/kWh with an EF of 201 g_{CO_2}/kWh ([40]).

Table 2: The *fix, dynamic* and *EF* tariffs are the external signals for the optimization model.

tariff	el. purchase	el. feed-in	volatility[a]	natural gas
fix	17.9 ct/kWh	15.5 ct/kWh	-	3.77 ct/kWh
dynamic	ϕ 17.9 ct/kWh	ϕ 15.5 ct/kWh	1.42 ct/kWh	3.77 ct/kWh
EF	ϕ 589.1 g_{CO_2}/kWh	-	90.06 g_{CO_2}/kWh	201 g_{CO_2}/kWh

[a]hourly standard deviation

2.3.3.2 Residual load time series

For calculating the FDI in every timestep, we require the time specific RL (P_{RL}). As the RL depends on the net electricity consumption ($P_{el,consumption}$) and the RE electricity generation ($P_{RE,generation}$), we use consumption and generation data from [43] for 2021. Figure 3b shows the composition of the average RL for the winter time, the summer time and for one year.

3. Results

We calculate the DCES' operation modes of the different concepts and scenarios and determine the FDI for each operation.

3.1. FDI dependency on unit operation and RL demand

We analyze the changes of the FDI_t in accordance with the DCES operation and the RL of the higher-level energy system. Figure 4a shows the DCES electrical key figures in quarter-hourly resolution of the *opt* concept

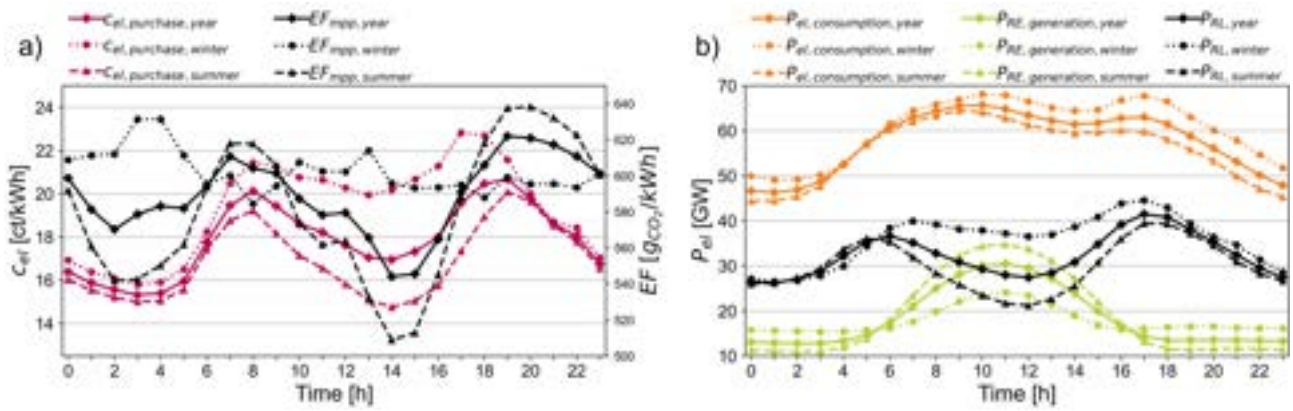

Figure 3: a) Hourly average electricity costs and hourly average EF. b) Composition of the hourly average RL.

in the *EF* tariff and the absolute RL for an exemplary day in winter. Figure 4b shows the corresponding $F_{DCES,t}$ and $F_{RL,t}$ for every time step resulting in the FDI_t.

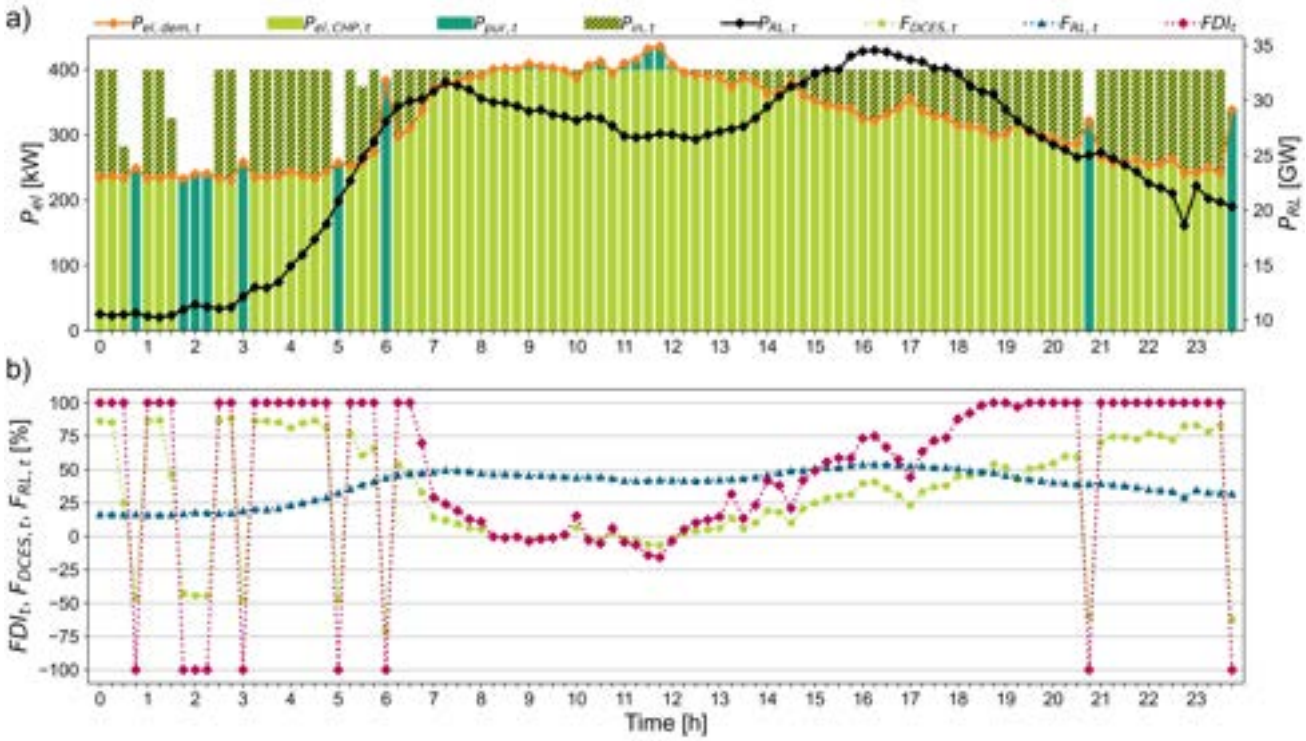

Figure 4: a) The DCES electrical key figures in quarter-hourly resolution of the *opt* concept in the *EF* tariff and the absolute RL for an exemplary day in winter. b) The corresponding $F_{DCES,t}$ and $F_{RL,t}$ for every time step result in the FDI_t.

Due to the high heat demand in winter, the CHP unit operates almost continuously at nominal load. But in some time steps, the CHP operation becomes restricted by the *EF* tariff optimization. This CHP restrictions result in additional electricity purchase. A detailed analysis of the DCES unit operation modes can be found in [38].

Table 3 shows the resulting values of the FDI_t for selected time steps. Among others, in the time steps at 04:00 am and 06:45 am a positive $F_{DCES,t}$ is present resulting from the electricity generation and surplus feed-in. In the cases of no electricity generation at 00:45 am or additional electricity purchase at 11:30 am, the $F_{DCES,t}$ becomes negative. Since the RL is positive for the whole day, the $F_{RL,t}$ is also positive in every time step.

At 06:45 am, the DCES feeds electricity into the public grid and a positive RL exists in the higher-level energy system. This coherency supports covering RL. So, the FDI_t results in a positive value of 69.8%. At 04:00 am, the DCES operation covers the RL even more as now the $F_{DCES,t}$ is greater than the $F_{RL,t}$. The FDI_t is at 100%.

Table 3: FDI_t calculation for single time steps of Figure 4.

Time step, t	$F_{DCES,t}$, %	$F_{RL,t}$, %	FDI_t, %
00:45 am	- 45.9	16.7	- 100
04:00 am	81.2	23.4	100
06:45 am	33.0	47.3	69.8
11:30 am	- 5.9	41.9	- 14.1

A positive $F_{RL,t}$ and a negative $F_{DCES,t}$ result in a negative FDI_t. At 11:30 am, the RL is similar as at 06:45 am, but now the DCES purchases additional electricity from the grid resulting in more RL for the higher-level energy system. So, the FDI_t results in a negative value of - 14.1 %. At 00:45 am, the absolute value of $F_{RL,t}$ is smaller than the absolute value of $F_{DCES,t}$ but with different signs. The FDI_t is at -100%.

3.2. Flexibility assessment over the quantification period

In Fig. 5 we calculate the $\overline{FDI}_{QP}$ of the case study for the winter time, the summer time and one year.

As the *ref* concept contains a CHP with low nominal load and no TES, almost no load-shifting is possible. So, the operation mode in every tariff optimization is the same and the $\overline{FDI}_{QP}$ of the *ref* concept is also the same in all operation modes.

Accordingly, in the *ref* concept electricity feed-in occurs only in a few time steps when the electricity demand is lower as the nominal load of the CHP. In most other cases, electricity is purchased as the demand is mostly higher as the generation. Thus, no differences in operation modes are possible and the FDI is mainly dependent on the facility's demand and the RL. This results in a FDI of -15.4% for one year for the *ref* concept. This result shows that the DCES operation is increasing instead of reducing the RL.

The *opt* concept is useful to cover RL in the QP of one year in all tariffs as the $\overline{FDI}_{year}$ results in positive values. The highest value for $\overline{FDI}_{year}$ is achieved for the operation mode in the *dynamic* tariff, followed by the *EF* and the *fix* tariffs.

The seasonal differences result primarily from the different heating demands of the facility. In the *opt* concept the CHP generates more electricity in the winter time, as it has lower restrictions of its' heat excess. In the summer time, the heat demand of the facility is lower, so the generated electricity by the CHP is lower. This reduces the number of time steps with a positive FDI_t.

In the *opt* concept only slight differences exist between all tariffs. Although the operation mode regarding the *fix* tariff achieves the lowest $\overline{FDI}_{year}$, the $\overline{FDI}_{winter}$ is higher than in the other tariffs. As Pagnier and Jacquod [44] have proven a correlation between the RL and the electricity stock-market price in an energy-only-market, we have expected the highest $\overline{FDI}$ in the optimized operation modes regarding the *dynamic* tariff in every QP. Also, we have expected the $\overline{FDI}$ in the *EF* tariff to be higher than in the *fix* tariff in every QP as the *EF* might be connected with the RL. Though, the $\overline{FDI}_{winter}$ is highest in the *fix* tariff. This gives an indication that although the DCES operations have been optimized according to an external signal that supposedly correlates with the RL, the operations still do not result in an optimized operation mode regarding the RL. Because of the volatility in the *flex* and *EF* tariffs, the data show an arbitrage trading in the optimized operation modes using the TES. This arbitrage trading is at the expense of RL coverage resulting in a lower $\overline{FDI}_{winter}$ compared to the $\overline{FDI}_{winter}$ in the *fix* tariff.

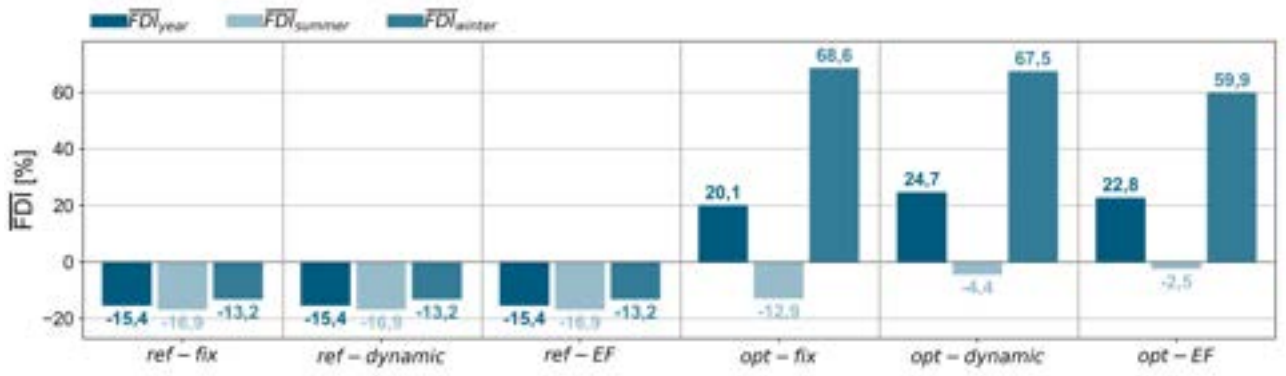

Figure 5: The FDI of relevant QPs for two concepts in three tariff scenarios. The $\overline{FDI}$ is presented for the QP of one year, summer time and winter time.

4. Conclusion and discussion

With the FDI we provide a new method to quantify the flexibility of DCES operation to cover RL of the higher-level energy system. As one element of power system transition optimized DCES operation regarding the best possible FDI might thus cover RL and potentially substitute flexible fossil powered energy plants.

To deduce the FDI, we have outlined different understandings of flexibility and presented a specific definition for flexibility considering the characteristics of a DCES. In this definition we have taken into account the usable flexibility potential of a DCES and its flexibility level as a consumer, respectively a prosumer. We have considered the flexibility of the DCES' operation modes and its connection with the higher-level energy system. We have noted that DCES can be a flexibility option for covering RL in the higher-level energy system with an flexibility potential.

We demonstrated in a case study that regarding the supplied facility's demands and the DCES concept, the DCES might not have a high flexibility potential and therefore a low FDI when storage capacity and electricity generation are low. In this case, the FDI can only be increased by changing the DCES units or the facility's energy demand. We also studied the FDI of a DCES concept with high electricity generation and high storage capacity. In this case, the FDI was higher. As Pagnier and Jacquod [44] have proven a correlation between the RL and the electricity stock-market price in an energy-only-market, it was to be expected that an optimized operation regarding a dynamic tariff might also lead to a higher FDI. Though, the effect was low compared to changing the DCES electricity generation and storage units. Only minor differences between a fix and a dynamic tariff could be noted. Also, the optimization regarding CO_2 emissions of the marginal power plant led only to little changes in the FDI. An optimization regarding the average CO_2 emissions of the electricity mix might lead to a higher FDI, but has to be investigated further. Furthermore, the RL of the higher-level energy system has an influence on the FDI, as it varies regarding the RL curve of the considered QP. It might be helpful to define an appropriate reference QP when using the FDI to compare different DCES operations.

Unlike other flexibility indicators, the FDI allows a quantification without a reference concept. Due to the use of normalized factors it might be valid to compare the FDI of a DCES with other DCES of different facilities including different units (e. g. heat pump, absorption chiller etc.) and variations in capacity within the same higher-level energy system RL scenario. Though, in this study, the FDI was only applied for two DCES concepts of the same facility. Following the principle of the FDI quantification, the method might be adapted for even more energy applications interacting with the higher-level energy system. In this study the method was applied within an energy-only-market and the assertion of the results is directly connected to this kind of market design. Therefore, the presented quantification method needs to be proven in further studies for different DCES concepts, facilities, energy applications and market design.

In summary, the results of the case study show that a higher electricity generation capacity and bigger storage unit capacity in a DCES lead to a higher FDI. With the FDI we have developed an indicator to quantify the flexibility to cover RL regarding the higher-level energy system.

Abstract:
Key elements of the energy system transformation are decentralisation, decarbonisation and sector-coupling. Local energy systems are often customarily designed using heuristics for the technology layout. However, optimisation of the design and operation of energy systems is considered a powerful tool. Therefore, we investigate the influence of an optimised layout and the coupling of the electricity and heat sector on economic, ecological and technological criteria. Three variations from a reference energy concept are regarded for a case study of unrenovated, residential buildings in the city of Düsseldorf, Germany. The concepts supply the heat and electricity demands at different levels of sector-coupling. In a first step, the concepts are mathematically optimised by mixed-integer linear programming with the objective of minimising costs. Afterwards, the results of the criteria metrics are combined in an overall performance score obtained by the Analytic Hierarchy Process. We find that the concepts with an optimised layout do not only have lower costs, but also lead to a significant decarbonisation by several hundreds of kg of CO_2 annually. In the case of optimised layout, heat pump and storage units have smaller capacities. Especially, storages are oversized under the used heuristic. Nevertheless, the photovoltaic units are expanded by up to 300% in comparison to the heuristic layout. We thus find an advantage of the optimised layout on the multi-criteria assessment, even though the optimisation has only an economic objective. The coupling of the heat and electricity sector leads to CO_2 emission savings and a higher self-consumption of the PV energy produced within the system. The coupled system achieves the highest score under the three criteria, irrespective of the building type. The overall best performance under a sensitivity analysis of the criteria weights is found for the sector-coupled concept in the optimised layout.

1. Introduction

The decentralisation and decarbonisation of national energy systems have been the focus of attention in energy system analysis during the recent years. National targets have been set up by many countries. These targets influence the design of energy systems down to the scale of buildings. Consequently, local energy supply concepts are required to be renewable and efficient. While the building owners and residents have a direct influence on the installation and design of the buildings' energy supply concepts, these building concepts can also be a potential business model for utility companies [1].

When it comes to designing the energy concept, rules of thumb are often taken into account. This form of layout, we call it the *heuristic layout*, can be compared to a layout which results from a mathematical optimisation, which we call the *optimised layout*. A comparison of different layout approaches has been performed by Ogunmodede et al. [2]. The authors found that the technology layout was smaller for the case of optimisation and therefore the system costs were lower. However, the system costs in the *heuristic layout* were already lower than those in the given reference system which corresponded to a fully grid-dependent supply.

Another structural change, that is associated with the transformation of the energy system, is the coupling of energy sectors. It has been shown that the sector-coupling has accelerated the decarbonisation of the European energy system [3]. Thus, we enlarge upon these findings by investigating the effect of sector-coupling on a building scale.

Moreover, the recent shifts in energy system analysis have been accompanied by the need for including multiple criteria in the analysis. Besides economic metrics, further factors have been considered: ecology [4–7], technology [4,6–10], sociology [6,7] or regulatory framework [6]. The use of methods for Multi-Criteria Decision

Analysis (MCDA) to assess energy systems is widely spread [7, 11, 12]. Many studies have thereby applied the Analytic Hierarchy Process (AHP) [4–6, 8–10]. Hence, the energy concepts regarded in this paper are analysed with AHP under multiple criteria.

The aim of this paper is to investigate the multi-criteria behaviour of local energy supply concepts under the aspect of an *optimised layout* and the coupling of the electricity and heat sector. We examine the following questions:

- What impact does an optimised layout have on local energy supply concepts considering economic, ecological and technological criteria?
- How does the coupling of the electricity and the heat sector affect local energy supply concepts in terms of economic, ecological and technological criteria?

In a first step, we describe the methodology of optimisation and assessment used in this paper (Section 2.). Afterwards, we present the case of application and describe the investigated concepts in Section 3. The results of the multi-criteria analysis are shown in Section 4. and discussed in Section 5. Finally, we give a conclusion and outlook in Section 6.

2. Methodology

The methodology of this investigation is described by a two-stage approach. In the first stage, the local energy supply concepts are mathematically optimised under a cost objective. In the second stage, the different optimised concepts are regarded as alternatives and assessed under multiple criteria. Parts of this methodology have already been described in [13].

2.1. Mathematical energy system optimisation

In order to calculate key performance indicators of the concepts, we perform a mathematical optimisation under a cost minimisation objective. The concepts are thereby modelled as Mixed-Integer Linear Programs (MILP) with ESyOpT®, a modelling tool based on the python package oemof-solph [14]. The considered optimisation problems are solved by the Gurobi solver [15] with a branch-and-cut algorithm. The optimisation horizon comprises one year with an hourly resolution.

The python package oemof-solph provides a modular modelling framework of energy systems in which each component, or technology respectively, comes with its own specific constraints for the operation and installation. The energy flows in the system are uniquely set by connections among the components. For the regarded energy concepts of this work, we model the following components: the electricity grid, the gas grid, gas boilers, thermal storages, photovoltaic (PV) modules, batteries and air-water heat pumps. The gas and electricity grids as well as the PV modules are modelled as sources. The PV plant can be used in the building's energy system to meet the electricity demand, but the generated electricity can also be fed into the grid again. The grid feeding is modelled as a sink of the system. The household demands for electricity, space heating and hot water are represented as sinks, too. To implement the other components, we use the class *Transformer* provided by oemof-solph to write our own models.

The gas boiler and the heat pump have an operational constraint on the outflow due to the minimum part load (MPL). This means they can only be operated within the range of the MPL and the nominal power P_{nom}. The gas boiler moreover has a constant efficiency while the heat pump has a time-resolved coefficient of performance (COP) that is dependent on the ambient and the supply temperature, but not on ambient humidity. The COP ranges from 1.53 to 6.40 according to a high-temperature air-water heat pump with a R407c refrigerant [16]. The heat storage is modelled with a capacity-dependent loss [17] and a level-dependent loss [17]. The battery is modelled with a fixed self-discharge loss of 0.025% per day [18] and degradation is not considered. The normalised power output per kW_{peak} of the PV plant is calculated using a pvlib-python model [19]. Data for investment and maintenance cost were taken from studies and market data [20–23].

We distinguish between two optimisation objectives and modelling approaches respectively - a *heuristic layout* and an *optimised layout*. For the case of *heuristic layout*, we perform a dispatch optimisation with a rule of thumb layout of each technology (Section 3.3.). We compare this to the case of an *optimised layout* in which both dispatch and size of the technologies are optimised. The methods differ in their objective function f and the components' set of decision variables.

In the case of a *heuristic layout*, the objective function consists of the annual maintenance and operational costs ($OPEX$) of the concept:

$$min\,(f_{heuristic}) = min\,(OPEX_{annual}) \tag{1}$$

For the case of the *optimised layout*, the objective function consists additionally of the annual investment and installation costs (*CAPEX*) of the concept and therefore equals the total costs (*TOTEX*):

$$min\left(f_{optimised}\right) = min\left(TOTEX_{annual}\right) = min\left(CAPEX_{annual} + OPEX_{annual}\right) \tag{2}$$

The mostly non-linear relations between the components' sizes and their total *CAPEX* are linearised into a fixed term $CAPEX_{fix}$ and a variable term $CAPEX_{variable}$ to be incorporated in the MILP representation. In this manner, scale effects can be considered. The total *CAPEX* are further discounted over the lifetime of the technology to the year of investment, using the weighted average cost of capital (WACC).

$$CAPEX_{annual} = \left(CAPEX_{fix} + CAPEX_{variable} \cdot SIZE\right) \cdot \frac{WACC \cdot (1 + WACC)^{LIFETIME}}{(1 + WACC)^{LIFETIME-1}} \tag{3}$$

The set of decision variables of the *heuristic layout* comprises operational variables $Y_{op}(t)$, which are binary variables indicating whether the component is operating in timestep t, and the power in- and outflow $P_{in/out}(t)$ of the component. The nominal power P_{nom} of the energy supply technologies and the capacity E_{cap} of the storage technologies have to be given for the case of the *heuristic layout* (Section 3.). In the case of the *optimised layout*, however, these variables are optimised as well.

2.2. Multi-criteria decision analysis

The optimised concepts are assessed and ranked under economic, ecological and technological metrics. In order to compare and rank the alternatives by only a single metric, a MCDA method is used. Since we aim at obtaining one performance score for each alternative, we choose a method that follows a Full Aggregation Approach [24]. The method used in this paper is the AHP [10, 25].

In a first step, the metrics for the respective criteria are chosen. Afterwards their preference weights are determined. And finally, the decision metric is determined.

2.2.1. Choice of criteria metrics

The chosen economic metric is the total annual costs ($TOTEX_{annual} = CAPEX_{annual} + OPEX_{annual}$). For the *heuristic layout* the annual *CAPEX* are calculated in the postprocessing of the optimisation using the heuristic sizes of the technologies. In the case of the *optimised layout*, the economic metric corresponds exactly to the objective function.

The chosen ecological metric is the concepts' total annual direct CO_2 emissions which are caused by the grid connections in the modelled energy concepts and do not consider indirect emissions that are caused by production.

The technological metric, the energy performance *EP*, is computed from the self-sufficiency and the self-consumption of the concept. The self-sufficiency *SES* is a measure for the grid-independence. This is calculated as the relative amount of energy produced within the system boundaries (independent from a grid connection) and used for the demands from all the energy in the system which fulfils the demands. A value of 0 indicates a complete dependence on gas and/or electricity grids while a value of 1 indicates a full independence from these grids.

$$SES = \frac{used\ energy\ which\ is\ produced\ within\ the\ systems\ boundaries}{total\ used\ energy} \tag{4}$$

The self-consumption *SEC* gives the ratio of energy produced within the system boundaries and used in it from all the energy produced within the system boundaries. A value of 0 indicates no use of the energy produced within the system boundaries for the system, while a value of 1 indicates full use of the energy produced within the system boundaries for the system.

$$SEC = \frac{used\ energy\ which\ is\ produced\ within\ the\ systems\ boundaries}{total\ energy\ which\ is\ produced\ within\ the\ systems\ boundaries} \tag{5}$$

The *EP* is finally calculated as the average of the two performance indicators:

$$EP = \frac{SES + SEC}{2}. \tag{6}$$

2.2.2. Determination of criteria weights with AHP

The AHP was first introduced by Saaty [25] as a method of measurement with ratio scales. The method can be used for criteria weight determination and alternative assessment. Both are used in this paper. The method's

Table 1: The AHP scale adapted from Saaty [25].

Absolute scale	Definition	Explanation
1	Equal importance	Two activities contribute equally to the objective
3	Moderate importance of one over another	Experience and judgement moderately favour one activity over another
5	Essential or strong importance	Experience and judgement strongly favour one activity over another
7	Very strong importance	An activity is strongly favoured, and its dominance demonstrated in public
9	Extreme importance	The evidence favouring one activity over another is one of the highest possible orders of affirmation
2,4,6,8	Intermediate values between the two adjacent judgements	When compromise is needed

basis is a fundamental scale (Table 1) by which the preferences of the criteria and the alternatives concerning the criteria are identified via pair comparisons. For the determination of the criteria weights, a pair of criteria (i, j) is compared according to the AHP scale. If i is preferred over j, the value in the pair comparison matrix takes the value v_{AHP} from the scale: $a_{ij} = v_{AHP}$, while $a_{ji} = \frac{1}{v_{AHP}}$, and vice versa. Note that all $a_{ii} = 1$. The eigenvector of the first eigenvalue of the pair comparison matrix equates to the criteria weights.

The pairwise comparison of the criteria was performed through a survey in which employees of a local utility company participated. The survey contained a pairwise comparison of economic, environmental and technological criteria. In total, eleven employees of the local utility company filled out the survey and each resulting set of criteria weights was determined using the AHP method and the weights were then averaged. The final set of criteria weights resulted in:

- economic: 0.33,
- ecological: 0.26,
- technological: 0.41,

which were used as default weights for the application of the ranking assessment with the AHP method.

2.2.3. Ranking of alternatives with AHP

The second step of Saaty's method is the ranking of alternatives [25]. In order to perform a ranking of the different alternatives, they are assessed according to the criteria and their weights. If the criterion is qualitative, the algorithm goes equivalent to the process of weight determination (Section 2.2.2.). The alternatives are pairwise compared concerning the criteria according to the AHP scale and the pairwise comparison matrix is built. The first eigenvector of this matrix is calculated for all these qualitative criteria and saved for the next step of the algorithm. The procedure for quantitative criteria deviates from the above-described step in the sense that the normalised vector is built from the alternatives' values for the given criterion. In case the quantitative criterion has a negative ordered scale (meaning, a lower value is preferable), the alternatives' values need to be inverted in a first step, so that the highest value of the normalised vector corresponds to the best parameter value for the given criterion. The matrix of the vectors for all the (qualitative and/or quantitative) criteria is eventually multiplied with the vector of criteria weights. The performance score indicates the multi-criteria metric for each alternative and the ranking of the alternatives follows these performance scores with the best alternative being the one with the highest score.

3. Case study

To illustrate the described methodology, an exemplary case study for unrenovated, residential buildings in the city of Düsseldorf, Germany, is carried out. We take three different typical buildings into account that comprise one flat (single-family house, SFH), eight flats (multi-family house, MFH8) or twenty flats (multi-family house, MFH20), respectively.

3.1. Input data

The assumptions that are made for the annual energy demands and PV potential of each building type are summarised in Table 2. Synthetic load profiles are simulated following VDI 4655 [26]. The norm provides

Table 2: Assumed annual energy demands and PV potential for each building type.

building type	total space heating demand [kWh]	total hot water demand [kWh]	total electricity demand [kWh]	roof area [m^2]
SFH	21000	2800	4000	65
MFH8	56000	9520	14320	175
MFH20	112000	21000	33000	175

reference load profiles of existing residential buildings for ten categories of typical days. These categories are dependent on the seven-day-rolling-average of the ambient temperature, the cloudiness, and the day of the week. Moreover, geographical information is used to multiply the reference profiles by a correction factor. Through the algorithm provided in the norm, the annual demand is distributed over the year accordingly.

The optimisation results are obtained using the test reference year weather data set provided by Deutscher Wetterdienst [27] and historical energy market data. The reference year for the energy market data is the year 2021. We assume a household electricity tariff of 33.7 ct/kWh, a gas tariff of 8.3 ct/kWh and a PV feed-in tariff of 7.3 ct/kWh. For the emission factors of the grid-related direct CO_2 emissions we assume 420 $g\ CO_2/kWh$ [28] for the electricity grid and 201 $g\ CO_2/kWh$ for the gas grid.

3.2. Cross-sectoral local energy supply concepts

The reference energy supply concept (*REF*) consists of an electricity grid connection and a gas boiler with a gas grid connection and a thermal storage to supply electricity, space heating and hot water to residential buildings. A schematic graph of the energy flows in the reference concept is shown in Fig. 1. In our analysis, we first adapt the electricity sector of the reference concept, then the heat sector and finally a combination of both adaptations in order to investigate the effect of sector-coupling. The adaptation in the electricity sector (*EA*) is performed through adding the electricity supply option of PV modules on the buildings' roofs with a battery storage. The adaptation in the heat sector (*HA*) is performed through exchanging the gas boiler with an air-water heat pump. These adapted concepts are shown in Fig. 2. Finally, both sectors are adapted simultaneously in a coupled manner (*SC*) so that the PV power can be used for operating the heat pump. The corresponding energy flows of the coupled concept are shown in Fig. 3.

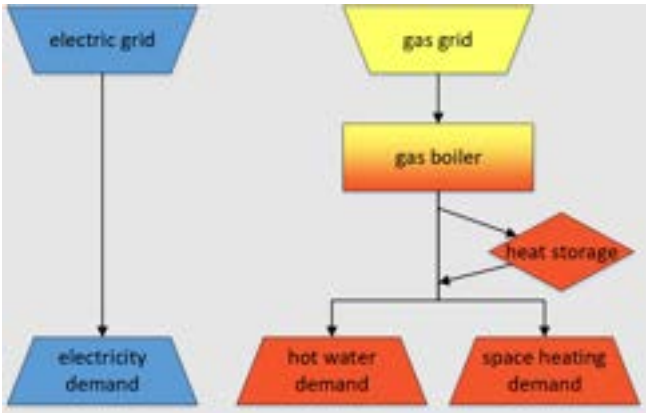

Figure 1: Reference concept (*REF*). The electricity, gas and heat sectors are indicated in blue, yellow and red, respectively.

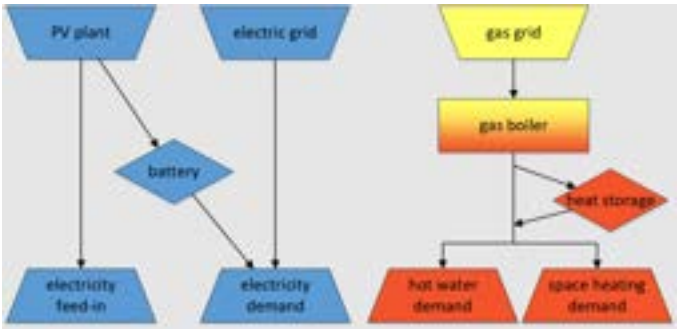
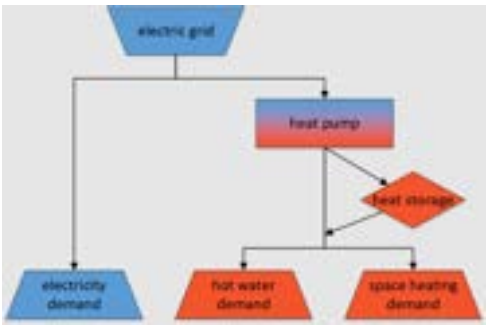
3.3. Heuristic layout of energy concept technologies

As mentioned in Section 2.1., one of the optimisation approaches is a *heuristic layout* in which the nominal power and capacities of the technologies are kept constant. The heuristics apply to all concepts except for the reference concept. A *heuristic layout* is given for the heat pump, the thermal storage, the PV plant and the battery. A summary of all layouts is given in Table 3.



(a) Electricity adapted concept (*EA*).



(b) Heat adapted concept (*HA*).

Figure 2: Concepts that have been adapted in one sector. The electricity, gas and heat sectors are indicated in blue, yellow and red, respectively.

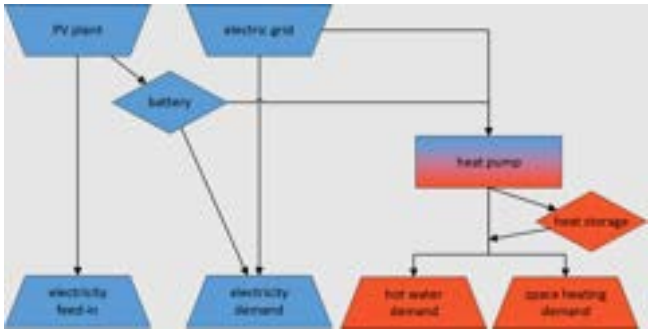


Figure 3: Sector-coupled adapted concept (*SC*). The electricity and heat sectors are indicated in blue and red, respectively.

The heuristic nominal power of the heat pump is computed according to the norm DIN-EN 12831, Supplement 2. According to the norm, the power is dependent on the hours of operation, the heating threshold temperature T_{lim} as well as the ambient temperature T_{amb} and the annual space heating and hot water demands. In this paper, we refer the hours of operation only to the heating period when $T_{amb} < T_{lim}$.

The heuristic to determine the peak power of the PV plant follows the simple rule that 1 kW_{peak} is assumed to be able to produce up to 1000 *kWh* of electricity per year. Therefore, we divide the annual electricity demand by the factor 1000 to determine the PV peak power.

The heuristic for the storage capacities of the thermal storage and the battery corresponds to the layout of a 24h-storage, meaning that the storage capacity is chosen so that an average daily amount of energy in the heating period can be stored. The in- and outflow power of the storages are configured so that the average energy that is necessary in one hour can flow from or to the storage.

4. Results

4.1. Results of the different concepts and building types under the three indicators

The mathematical optimisation of all three concepts has been performed under the two different optimisation objectives and for the three different building types. Additionally, the reference concept was optimised for each building type. This equals to a total of 21 sets of obtained results.

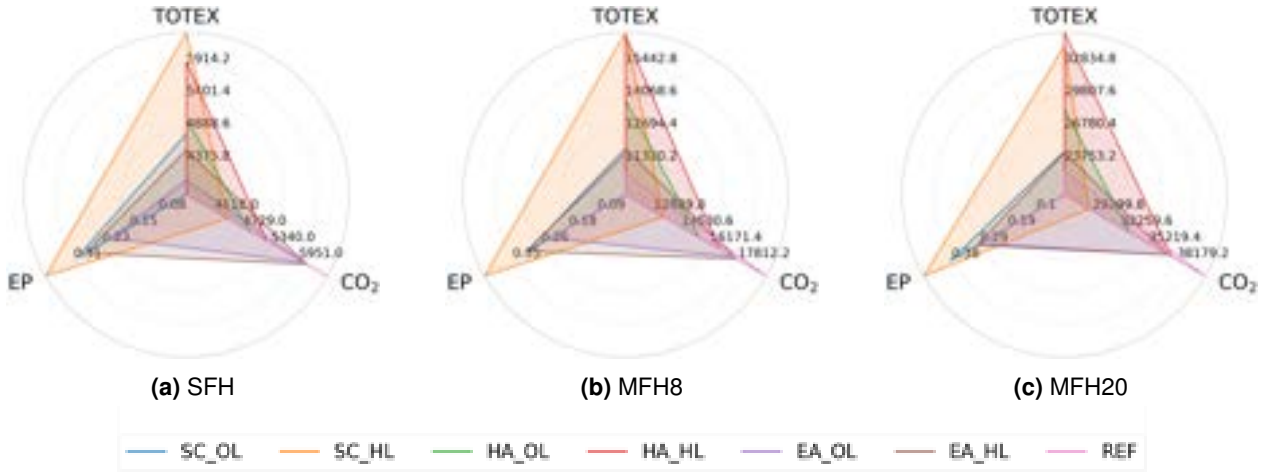
When comparing the implemented sizes of the energy technologies in the case of heuristic layout (HL) with the optimised layout (OL), we find that the storages have smaller capacities in the optimisation than according to the heuristic. We also find that the heat pump does not need as much installed power if the concept is optimised. However, the PV plant is built up to the limiting size of the roofs in the case of optimisation. For the single family house, this corresponds to an amplification of about 300 % in comparison to the HL.

For all 21 sets of concept results, we analyse the three criteria metrics presented in Section 2.2.1. An overview of the distribution of the criteria values is given in the radar charts in Fig. 4. Each axis of the graph represents one criterion and spans the value range of the criterion's metric in the set of results.

Table 3: Heuristic power and capacity of the implemented technologies. (hp=heat pump, tes=thermal storage, ba=battery)

building type	$P_{nom,\ hp}$ [kW]	$P_{peak,\ PV}$ [kW]	$E_{cap,\ tes}$ [m^3]	$P_{in/out,\ tes}$ [kW]	$E_{cap,\ ba}$ [kWh]	$P_{in/out,\ ba}$ [kW]
SFH	14.86	4	2.81	2.72	12.82	0.46
MFH8	40.03	14.32	7.74	7.48	45.91	1.63
MFH20	82.48	33	15.7	15.18	105.79	3.77

The reference concept is found to be the concept yielding the highest CO_2 emissions, irrespective of the building type. This concept, plus the two concepts with the electricity adaptation, lead to $EP = 0$ because they are fully grid-dependent. As expected, we observe for all concepts that the *TOTEX* decrease in the OL by on average 27%. What is more surprising, the CO_2 emissions also decrease by on average 11%. On the contrary, the HL shows a better performance of *EP*. The latter is explained by the high *SEC* in the HL concepts.



(a) SFH **(b)** MFH8 **(c)** MFH20

Figure 4: Radar charts of the performance of the seven concepts in the three criteria for each building type. The axes are defined by the resulting values from the concepts.

4.2. Results of the AHP ranking for the three building types

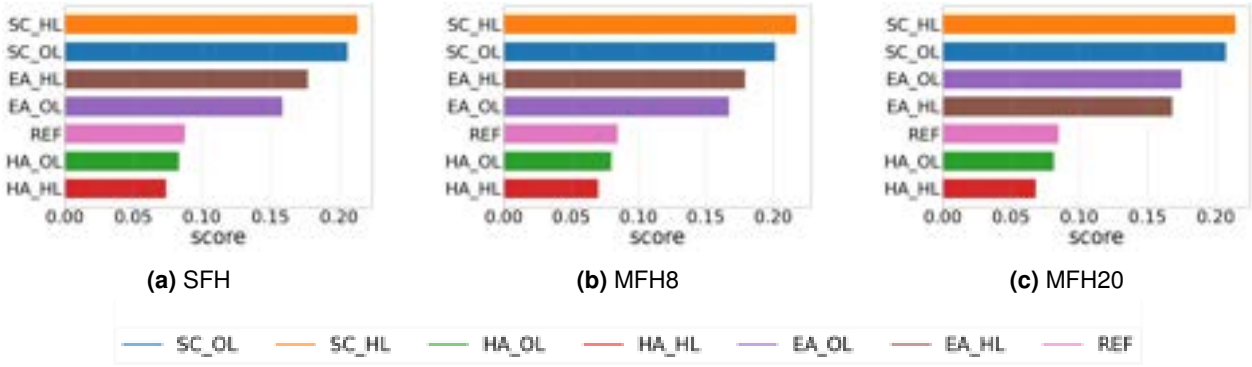
In order to condense the information about the concepts, we used the AHP method to determine overall performance scores for each concept. Under the usage of the criteria weights presented in Section 2.2.2., we determine the final rankings as shown in Fig. 5. The ranking orders of the concepts are mostly identical for the different building types. For the MFH20, the ranking order of the two *EA* concepts is swapped. In all cases, the sector-coupled concept with the HL obtains the highest performance score. This is to some extent surprising as it performs worse in the economic and the ecological criterion than the OL of the sector-coupled concept. However, the technological performance is higher than in the OL and it has the highest weight (Section 2.2.2.) and is therefore dominating when the overall performance score is built with AHP.

In the rankings, we also find that the sector-coupled (*SC*) and the electricity adapted (*EA*) concept, in both layout specifications, make the top four positions. On the other hand, the reference (*REF*) concept and the heat adapted (*HA*) concept obtain a significantly lower score. This, again, can be explained by the high weight on the technological criterion and the fact that these three concepts are fully grid-dependent.

4.3. Sensitivity analysis of the criteria weights in the AHP method

The ranking results are highly dependent on the choice of the criteria weights. Therefore, we perform a comprehensive local sensitivity analysis of the criteria weights on the AHP performance score. The criteria weights from the survey are regarded as default weights. Additionally, we vary each weight in the interval [0.0, 1.0] with a step size of 0.1. While varying one weight, the other two weights are adapted while keeping the exact relation that they had in the default weights. The ratio of the economic to ecological weight is 56 : 44, the economic to technological weight is 45 : 55 and the ecological to technological is 39 : 61, respectively.

The resulting graphs are shown in Fig. 6. It is clearly seen how the concepts' performance differs under



(a) SFH **(b)** MFH8 **(c)** MFH20

Figure 5: AHP Ranking results for each building type.

varying weights. From the graphs, it is noticeable that the scores of the *REF* and *HA* concepts, for the increase in each weight, show opposite trends to the *SC* and *EA* concepts. Moreover, the trends are equal for the economic and ecological weight, while the trends are swapped for the technological weight. However, there is one exception to this observation. The score of the electricity adapted concept in the OL rises with increasing economic weight. From Fig. 4 we see that this concept has either the lowest or second to lowest *TOTEX* (depending on the building type) and therefore the overall score benefits from a higher emphasis on the economic criteria. Another observation is that the value range of the resulting scores is the highest in the case of a high technological weight. This is induced by the value of *EP* = 0 for the three grid-dependent concepts which makes them uncompetitive. On the contrary, for high economic weight or high ecological weight, the scores of all concepts are close to each other.

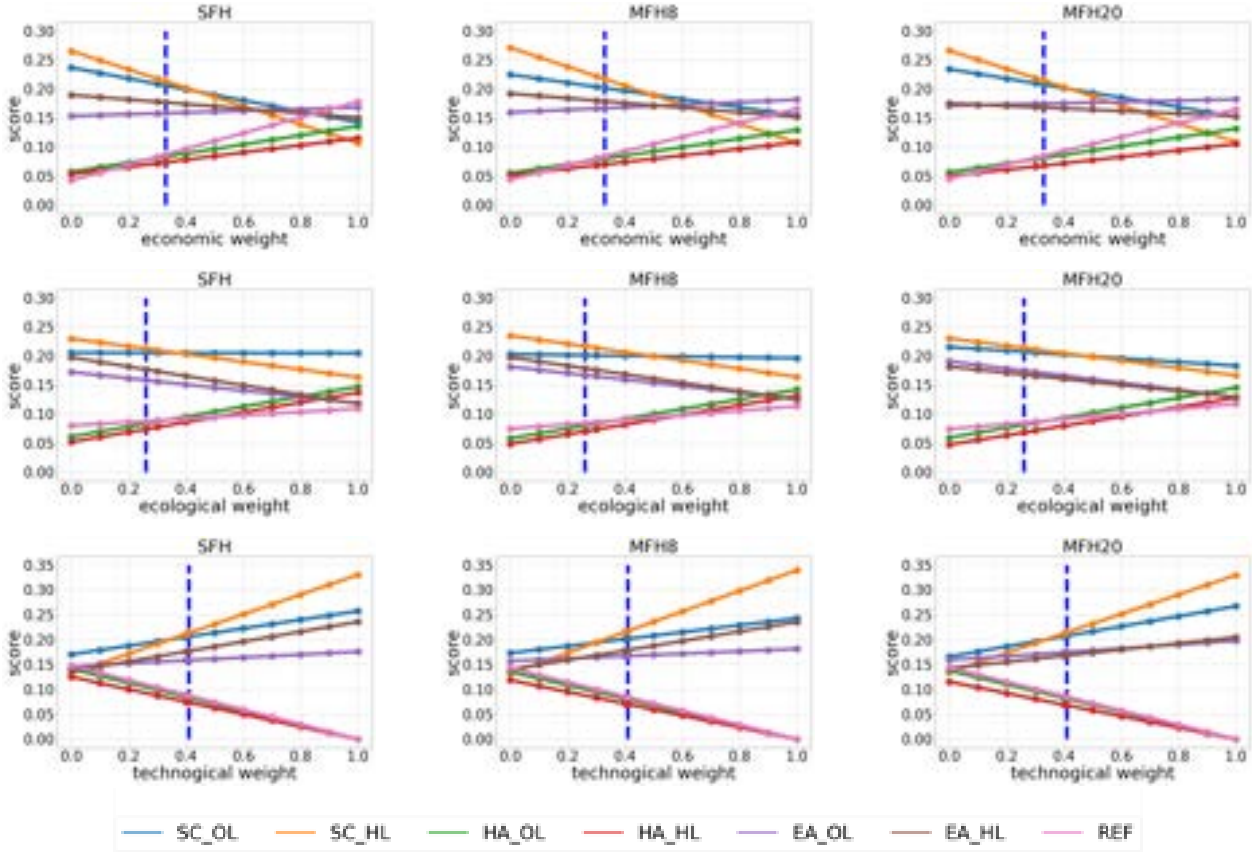


Figure 6: Sensitivity analysis on each criterion for each building type. The blue dashed line in each graph indicates the position of the default weight ranking. The top, middle and bottom row shows the analysis of the economic weight, the ecological weight and the technological weight, respectively.

The results of the sensitivity analysis are further used as a sample for the overall performance analysis of the concepts. The data points of Fig. 6 build a representative set of the concepts' performance results under multiple criteria. Each concept with a corresponding layout choice has been assigned a performance score

and a ranking position under different criteria weight choices. Based on all these ranking positions, including the one corresponding to the default weights, we determine the average ranking positions for each concept. The results of this analysis are summarised in Table 4.

Table 4: Average ranking order of the concepts for each building type.

rank	SFH	MFH8	MFH20
1	SC OL	SC OL	SC OL
2	SC HL	SC HL	SC HL
3	EA HL	EA HL	EA OL
4	EA OL	EA OL	EA HL
5	REF	REF	REF
6	HA OL	HA OL	HA OL
7	HA HL	HA HL	HA HL

The table shows that the *SC* concept in the OL reaches the highest average position in all rankings produced by the sensitivity analysis. Except for the *EA* concept for the SFH and MFH8 building types, all concept alternatives in the OL reach higher average ranking positions than their HL partner concept. The *HA* concept performs worse than the *REF* concept because even though it has lower CO_2 emissions, the extra cost are significant enough to lead to a lower overall performance score for the totality of all regarded weight variations.

5. Discussion

The OL does not only lead to a decrease in total annual costs, but also to a decrease in the total annual direct emissions. This can be explained by the better operational use of the installed energy technologies. In the case of the OL, the installed power/capacity of each technology is perfectly matched to meeting the demands. Since the operational costs and the direct emissions have the same origin - the grids - the reduction of either is directly coupled to the other. The contrary effect is the installation of new technologies for the *EA*, *HA* and *SC* concept, which comes with installation costs. For the *HA*, the heat pump is built with a lower nominal power in the case of optimisation, so that the *TOTEX* are lower for the OL than for the HL. For *EA* and *SC* we observe that the PV is dimensioned much bigger if the layout is optimised. This comes with higher installation costs. However, the storages (battery and heat storage respectively) are installed at lower capacities in the case of an OL. For the *EA* and *SC* concept this balances the higher PV costs out and still, the *TOTEX* decrease for the OL. The strong decrease in installed capacity of the storages if the layout is optimised, shows how much the capacities were overestimated with the used heuristic. The capacities of the storages, moreover, influence the *SEC* and thereby the *EP*. The high capacities in the HL lead to a high *EP*.

The sensitivity analysis of the criteria weights has shown a uniform behaviour of the economic and the ecological criterion. With varying weight, the same concepts show the same behaviour for both criteria. This behaviour is inverted in the technological criterion. The fact that for a high weight on either economic or ecological criterion or a low weight on the technological criterion, the score of all concepts lie closer to each other, shows that the gap between the concepts' performance results mostly from the values of the technological metric and their competitiveness is balanced out if the other metrics have a higher importance.

To answer the second research question, we observe that the two concepts associated with the sector-coupled concept are the two highest ranked for most of the weight variations. Only for a high economic weight, these two concepts obtain lower positions in the ranking. Thus, the coupling of the heat and electricity sector specifically reduces CO_2 emissions and increases the energy performance which leads to a high ranking of the respective concept in the MCDA under the three given metrics.

Finally, the reference concept is found to perform well in the economic criteria as it has low *TOTEX* for all building types, but it shows the worst performance for CO_2 emissions and *EP*. This effect occurs for the given case study because we do not regard installation costs in *REF*. We assume that the gas boiler is already installed and the investment has been made in the past and is not part of the optimisation horizon.

The method used to calculate an average ranking is based on the ranking position that resulted from each weight variation in the sensitivity analysis. A different approach would be to compute the average performance score instead and base the overall ranking on this score. The approach of comparing ranking positions takes equidistant positions between the concepts, while a comparison on performance score could show dominance

between the concepts. However, the ranking position is taken as the supporting indicator for performance of the concepts.

6. Conclusion and outlook

To conclude, we investigated local heat and electricity supply concepts with a different level of coupling the sectors and different layout approaches. We find that the OL decreases the total annual costs by on average 27% and decreases the total annual direct CO_2 emissions by on average 11%. The installation of PV is enforced if the layout is optimised instead of following a rule of thumb. A coupling of the heat and electricity sector leads to CO_2 emission savings and a better energy performance. Between the three different building types we find almost no difference. Yet, the study can be extended towards other building archetypes including non-residential buildings. Furthermore, the energy price markets have recently faced a lot of instabilities. Hence, the robustness of the rankings against different price inputs can be investigated. Lastly, the investigation at hand only refers to the use of one specific MCDA method. However, different methods can lead to different ranking decisions. It can therefore be advised to repeat the analysis with other methods and check if the concepts obtain similar ranking positions.

Abstract:

A multi-energy system is composed of four main subsystems: i) energy conversion, ii) energy transportation, iii) energy supply, and iv) energy storage. Recent works in the literature dealing with the design and operation optimization of multi-energy systems usually include only one of the above-mentioned subsystems at a time and neglect the others or consider them as constraints imposed a priori. That kind of approach may lead to near optimal system configurations. In fact, the global optimum can only be achieved by the synthesis, design and operation optimization of the system in its entirety. Here, a mixed integer linear programming (MILP) approach is proposed to simultaneously optimize the size of the energy conversion and storage plants, the capacity of the energy networks, and the operation of the whole multi-energy system. The objective function consists in minimizing the life cycle cost of the system while imposing an upper bound on greenhouse gas emissions. Moreover, this upper bound can be iteratively reduced to consider increasingly stricter decarbonization targets. A district composed of commercial and residential buildings, with their own electricity and heating demands and operating in a microgrid, is considered as a case study. Heat is provided to the end users via a district heating network, while electricity can be either generated on site or imported from the national grid. Results shows a reduction potential in carbon emissions of 45% for the considered system, together with an 8% reduction of the life cycle cost, with respect to a reference scenario.

Keywords:

Decarbonization; District heating; Microgrid; Multi-energy systems; Optimization.

1. Introduction

The increasing threat of climate change requires timely interventions to drastically reduce the anthropogenic emissions of greenhouse gases By accounting for 75% of the global carbon emissions, the energy sector is the main responsible of global warming. However, the increasing availability at low cost of energy conversion technologies based on Renewable Energy Sources (RES) can pave the way to a deep decarbonization process. To this scope, fostering the distributed generation, electrifying the energy consumption and exploiting the synergies between different final energy sectors, as, for instance, the electricity and heating ones, can play a crucial role in improving the penetration of RES while decreasing the consumption of fossil fuels [1]. All these actions contribute to the development of Multi-Energy Systems (MESs).

A MES is defined as an energy system of any spatial extent (a single building, a district, a city, a nation, …) that involves different types of energy carriers (electricity, heat, fossil fuels, biomass, …) and provide energy in various forms to the end users [2]. It is composed of four main subsystems.

1. Energy conversion. The fleet of the energy conversion plants that provides the end users with the required energy in the required forms.

2. Energy transportation. The energy networks collecting energy from the conversion plants and delivering it to the end users.
3. Energy supply. The end users of the system with their specific energy demands.
4. Energy storage. Components that allow storing energy in different forms in a certain moment and delivering it in a later one. They can be integrated at any level (energy conversion, transportation, supply).

A holistic approach to the study of MESs should consider all the above-mentioned aspects. Thus, the complete optimization of a MES accordingly to a certain objective function should involve three levels of analysis.

1. Synthesis, which targets the topology of the energy networks and the number, type and location within the system of the energy conversion and storage plants required to fulfil the energy demands of the end users.
2. Design, which targets the sizing of the energy conversion and storage plants and the capacity of each branch of the energy networks.
3. Operation, which targets the management of the dispatchable plants, the management of the power and mass flows within the networks, and the application of eventual demand response strategies [3].

Such kind of optimization problems, referred to as Synthesis, Design and Operation (SDO) optimization, is the most complete in the field of energy systems, but also the most challenging to solve, due to the high number of decision variables, either continuous or integer/binary [4].

This paper focuses on MESs at the district level including microgrids and district heating networks (DHNs). An increasing number of works in the recent literature deals with the optimization of such kind of systems. However, most of those works do not embrace a holistic approach but focus on a specific optimization problem (synthesis, design, operation) or a specific aspect of the MES (energy conversion, storage, transportation, supply).

Integrated district energy networks were studied by several authors. Lund et al. [5] highlighted the importance of integrating different energy networks (e.g., district heating, electricity distribution and natural gas supply) at the district level to shape the smart energy system of the future. In this context, decreasing the supply temperature of DHNs (e.g., with 4th and 5th generation DHNs) can facilitate the integration of RES, power to heat technologies and other smart energy systems (e.g., microgrids). Leitner et al. [6] stated that the components required to build up smart energy systems are well known and already available in the market, whereas there is a lack of analyses at a system level. Their study focuses on a modelling and simulation approach for coupled district heating and electrical distribution networks. The DHN is defined by a dynamic thermal-hydraulic model, whereas the electrical distribution network by a quasi-static model. The model is complete but does not involve any kind of optimization, which would probably result in a computational intractability. Other authors, e.g., Nazari-Heris et al. [7], studied the optimal operation of highly integrated MESs involving many energy or energy-related networks (e.g., electricity, heating, natural gas and water networks). However, these models are computationally expensive (they are typically applied to one-day operation) and cannot be applied to the design optimization of those networks. Talebi et al. [8] reviewed the optimization approaches to the design of DHNs and highlighted the relevant role that optimization tools can have in designing district energy systems integrating a high share of RES and energy storage technologies. Moreover, they found out that the most used design optimization techniques are based on numerical approaches, as Mixed Integer Linear or Non-Linear Programming (MILP and MINLP, respectively), or meta-heuristic approaches, as evolutionary or genetic algorithms. Röder et al. [9] developed a MILP optimization framework for the SDO optimization of a DHN. They considered a mixed residential-commercial district in Germany and searched for the cost-optimal topology, capacity, and operation of the DHN supplying all the users of the district. However, they did not optimize the generation and storage sides of the system as they fixed in advance the position, type and capacity of the energy conversion and storage plants providing the network with the required heat, and they did not consider the electricity network.

On the other hand, many authors focused on the optimal design and/or operation of the energy conversion and storage plants supplying a district MES. Rech et al. [10] studied the optimal operation of a fleet of energy conversion plants providing electrical and thermal energy to a mountain village. Heat is generated by means of biomass-fuelled boilers or combined heat and power (CHP) plants, and delivered to the end users via DHN, which is modelled as a black box collecting heat from the generators to fulfil the aggregated heating demand of the village. Ghilardi et al.[11] developed a MILP model for the operation optimization of a University campus MES involving a district heating/cooling network and the thermal management of buildings. They found out considerable advantages in terms of cost reduction, energy saving and integration of RES thanks to the optimal management of the thermal comfort in buildings, the optimal dispatch of the available energy conversion systems and the optimal management of the temperature levels of the district heating/cooling network. In a previous work [12], the authors of the present paper proposed a method for the design and operation multi-objective optimization (economical and environmental) of the energy conversion and storage plants providing electricity and heat to an energy community. Demand response was also applied, but no district energy networks were modelled, assuming that the community members directly interface with the national power grid and fulfil their heating demand autonomously. Wirtz [13] proposed a web tool for the optimal conceptual design

of a district MES generation mix. By means of a Linear Programming (LP) approach, the proposed tool allows defining the optimal size of the energy conversion and storage plants available in an energy hub fulfilling the electricity, heating and cooling demands of the district. Heating and cooling can be also provided via district heating and/or cooling networks. Wirtz et al. [14] also proposed a model for the optimal planning of a 5th generation district heating and cooling network. This model optimizes the design (i.e., the size) of the energy conversion and storage plants available at two levels: i) the energy hub and ii) the end users' buildings, which interface with the heating and cooling network by means of heat pumps and chillers. As a last example, Mashayekh et al. [15] developed an optimization tool for the design of the energy conversion and storage plants supplying a multi energy microgrid involving both electricity and heating networks. The optimization addresses the generation mix selection and sizing, the resource siting and allocation, and the operation scheduling. They found out that considering the spatial distribution of a MES, modelled as a multi nodal system, allows a more realistic assessment of the generation portfolio, which can be otherwise non-optimal if the same system is modelled as a single node.

A lack emerges. On one hand, works dealing with modelling of energy networks either neglect the design of energy conversion and storage systems or build complex models that are not suitable for design optimization procedures. On the other hand, works dealing with design-operation optimization of MESs do not consider the optimization of the topology and capacity of the district energy networks, which are considered only as constraints.

A pioneering work about the SDO optimization of a district MES was proposed by Mehleri et al. [16] and further developed in [17]. In these works, a MILP framework is introduced to optimize the selection (capacity and allocation) and operation of the distributed energy conversion plants supplying the district MES, but also the design (topology and capacity) of a DHN connecting the buildings. However, the weakness of the proposed approach is that the DHN is defined by a set of direct heat exchange connections between two buildings that follow the path of minimum "geometrical distance" (i.e., the straight line connecting two buildings). This is a strong simplification because obstacles that can interrupt the path between two buildings are not considered. A more reliable approach in the design of a network should consider the "geographical distance" between nodes, i.e., the "real" path that a network branch must follow to connect two nodes. Accordingly, a typical approach to DHN design (see, for instance, in [9]) consists in constraining pipelines to follow pre-determined paths, which are usually the streets of the district.

To overcome the above-mentioned weaknesses, this work proposes a holistic MILP approach for the optimal design and operation of a district MES, modelled as a multi-nodal system. The goal consists in finding the size of the available energy conversion and storage plants, the capacity of each branch of the available energy networks, and the operation of the whole system that minimize the life cycle cost of the MES, while fulfilling the energy demands of the end users. Moreover, an environmental constraint is imposed on the maximum amount of carbon dioxide (CO_2) emissions. By iteratively decreasing the value of this constraint, a sort of multi-objective optimization can be carried out, in order to obtain the Pareto front of the cost-optimal system configurations that meet increasingly stricter decarbonization targets. A district located in Padova, Italy, composed of commercial and residential buildings with their own electricity and heating demands, and operating in a microgrid is considered here as a case study to highlight the potentiality of the proposed approach. Heat is provided to consumers via DHN, while electricity can be either generated on site or imported from the national grid.

The novelty introduced in this paper consists in proposing a holistic and integrated method for the design and operation optimization of both conversion/storage plants and energy networks of a MES, while maintaining an accurate representation of the networks, which are modelled with the "geographical distance" criterion, instead of the simplified "minimum geometrical distance" one.

Note that the synthesis problem, i.e., the definition of the topology of the networks and of the number, type and position within the system of the energy conversion and storage plants, is not addressed here. Conversely, the topological data are provided as input to the model. However, the proposed approach is intended as a sub-problem of a wider optimization method that addresses the synthesis problem too, in order to provide a complete SDO optimization tool for district MESs. The idea is to implement the overall SDO problem by means of a two-level evolutionary algorithm, in which the first level deals with the synthesis problem. The topology of the system defined in the first level is then passed to the second level, which deals with the design and operation sub-problem (i.e., the model proposed here). Since the design and operation sub-problem must be run several times for each iteration of the evolutionary algorithm, it must be maintained as simple as possible in order to avoid computational intractability. For this reason, the model presented here is maintained linear by means of proper simplifications of the characteristic curves of the technologies and cost data. A similar two-level approach for the SDO of a district heating system with distributed CHP plants was developed by Casisi et al. [18]. However, they only consider DHN and not the electrical network, and they assume a given topology of the DHN.

The rest of the paper is structured as follows. Section 2 presents the case study, while section 3 presents the developed optimization method. Section 4 discusses the results and, finally, section 5 draws the conclusions.

2. Case study

The case study considers a small mixed residential-commercial district located in Padova, Italy. The district is composed of five buildings (end users), with their own electricity and heating demands, and operates in an autonomous microgrid connected to the national power grid. Heat is provided to the end users via DHN, while electricity can be either generated on site or imported from the national grid. The system is modelled as a multi-nodal MES with 16 nodes in total. Figure 1 shows the layout of the considered system. The buildings located at nodes 3, 5 and 15 are residential buildings, the remaining two (nodes 9 and 11) are commercial buildings. Each building owns a photovoltaic plant (PV) and an electrical energy storage (EES) based on lithium batteries. An energy hub located at node 7 and including a gas-fuelled CHP internal combustion engine (ICE), a gas boiler (BOIL), an air-water heat pump (HP) and a thermal energy storage (TES) feeds the DHN that delivers the required heat to the end users. To maintain the model linear, the operating parameters of the networks are fixed a priori and assumed to remain constant during the operation, as in [9]. This simplification allows modelling the networks by considering only the power or heat flows circulating inside them. The supply and return temperatures of the DHN are set at 70°C and 40°C, respectively. The microgrid voltage is 380V.

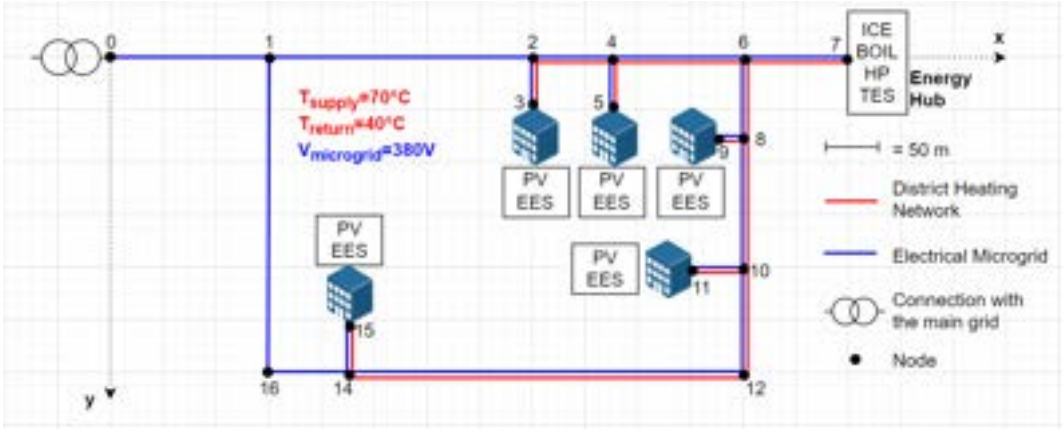

Figure 1 Layout of the multi-energy system considered as case study. The white rectangles contain the conversion and storage plants available at the node where they are located.

The topology of the energy networks can be derived from a geographical map of the district, where the available paths for the network branches are the streets. Accordingly, the layout of the DHN is designed by considering the tree path of "minimum geographical distance" connecting the energy hub to all the end users. In other words, the overall length of the pipelines is minimized, with the constraint of following only the available paths. The same holds true for the electrical microgrid, apart from the inclusion of node 0, which allows the power exchange with the national grid, and the inclusion of the branches between nodes 0-1, 1-2, 2-16 and 14-16, which define a network ring that increases the system reliability.

Table 1 shows the yearly electricity and heating demands of the end users (integral over one year of the hourly demands) and the corresponding demand peaks occurring during the year (maximum values reached by the hourly demands). Since one hour is the time resolution of the model, hourly demands are expressed in unit of power (kW).

Table 1 Yearly electricity and heating demands ($D_{el,year}$ and $D_{th,year}$, respectively) of each end user and aggregated, with the associated demand peaks over the year ($D_{el,peak}$ for electricity, and $D_{th,peak}$ for heating).

Node	$D_{\mathrm{el,year}}$, MWh	$D_{\mathrm{th,year}}$, MWh	$D_{\mathrm{el,peak}}$, kW	$D_{\mathrm{th,peak}}$, kW
3	89.77	73.54	25.0	60.0
5	125.68	98.06	35.0	80.0
9	175.42	20.76	70.0	60.0
11	125.30	17.30	50.0	50.0
15	143.63	122.57	40.0	100.0
Aggregated	659.80	332.23	176.3	344.4

3. Method: MILP optimization

The MILP optimization problem can be formulated in a general form as in Eq. (1) [19].

$$min_{\boldsymbol{x},\boldsymbol{y}}\{f(\boldsymbol{x},\boldsymbol{y}) = \boldsymbol{c}^T\boldsymbol{x} + \boldsymbol{d}^T\boldsymbol{y}\}$$
$$subject\ to\ \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{y} = \boldsymbol{b} \quad (1)$$
$$with\ \boldsymbol{x} \geq 0 \in \Re^{N_x}, \boldsymbol{y} \in \{1,0\}^{N_y}.$$

f is the objective function, $\boldsymbol{c}$ and $\boldsymbol{d}$ are the cost vectors associated with the continuous and binary variables, $\boldsymbol{x}$ and $\boldsymbol{y}$, respectively; $\boldsymbol{A}$ and $\boldsymbol{B}$ are the constraint matrices and $\boldsymbol{b}$ is the vector of the known terms; N_x and N_y indicate the dimension of $\boldsymbol{x}$ and $\boldsymbol{y}$, respectively.

The considered MES is modelled as a multi-nodal system, with $N = 16$ nodes. In the next sections, the constraints, decision variables and objective function of the problem are introduced. The decision variables are highlighted in bold. The subscript $n = 1,2,\dots,N$ refers to the nodes, $k = 1,2,\dots,K$ to the typical days (or cluster centers), and $h = 1,2,\dots,24$ to the hours of the day. The optimization model has been developed in Python and solved with the Gurobi solver.

3.1. Time series aggregation

To be solved, the proposed optimization model requires some time series as input. These are i) the electricity demand of each final user, ii) the heating demand of each final user, iii) the global solar irradiation on the horizontal plane, necessary for calculating the PV generation, and iv) the temperature of the ambient air, necessary for calculating the electrical power consumption of the HP. These time series are available for a reference year subdivided in days with an hourly resolution, for a total of $24 \times 365 = 8760$ timesteps for each time series. However, including the time series in their entirety into the optimization model would result in a computational intractability. In fact, the number of decision variables required to solve the operation problem is proportional to the total number of timesteps. Thus, it is necessary to reduce the total number of timesteps and, in turn, the computational burden.

Following Hoffmann et al. [20], a K-medoids clustering approach is applied here to aggregate time series into typical days, which must be representative of the entire year. The chosen number of typical days is eight. Moreover, the two days of the year having the maximum peak value in i) aggregated electricity demand and ii) aggregated heating demand are added to the clustering process as new cluster centers. Thus, the final number of typical days is $K = 10$. Neglecting the extreme peak periods in defining typical days would lead to underestimate the size of the energy conversion plants, which could not meet the extreme demand peaks occurring during the year. The hourly resolution of the time series is preserved, being each typical day composed of $H = 24$ time steps. In this way, the number of decision variables associated with the operation, proportional to the total number of timesteps, is drastically reduced. In fact, the total number of timesteps is diminished from 8760 to $H \times K = 240$. The time series aggregation also returns the weight w_k of each typical day k (with $k = 1,2,\dots,K$), which corresponds to the number of days of the year represented by that typical day. The Python package "*tsam*" has been utilized for time series aggregation.

3.2. Energy conversion and storage systems

The energy conversion plants are modelled according to [21], the energy storage systems according to [22].

3.2.1. Photovoltaic plant

The electrical power (P_{PV}) generated by a photovoltaic plant, in kW, is given by Eq. (2).

$$P_{PV,n,k,h} = \boldsymbol{C_{PV,n}} \frac{I_{sun,k,h}}{I_{sun,ref}}. \quad (2)$$

$\boldsymbol{C_{PV}}$ is the capacity of the PV plant in kW of peak (kW_p) and is a decision variable, I_{sun} is the global solar irradiation in W/m^2 and is provided as a time series, $I_{sun,ref} = 1000\mathrm{W/m^2}$ is the global solar irradiation in the reference conditions in which the kW_p is defined. It is assumed that 1 kW_p of PV requires 7 m^2 of area.

The PV capacity is bounded in between a minimum value, corresponding, for instance, to the area of a single PV module, and maximum one, corresponding to the entire available area at a node, as reported in Eq. (3).

$$C_{PV,min,n} \leq \boldsymbol{C_{PV,n}} \leq C_{PV,max,n}. \quad (3)$$

If PV is not available at the node n, then $C_{PV,min,n} = C_{PV,max,n} = 0$ and, in turn, $\boldsymbol{P_{PV,n,k,h}} = 0$.

3.2.2. Gas-fuelled internal combustion engine in combined heat and power mode

The fuel (natural gas) consumption (F_{ICE}) of the CHP internal combustion engine (ICE), in kW, and its thermal power (Q_{ICE}), also in kW, are given by Eq. (4) and Eq. (5), respectively, as a linear function of the engine power.

$$F_{ICE,n,k,h} = \boldsymbol{P_{ICE,n,k,h}}\alpha + \boldsymbol{\delta_{ICE,n,k,h}}\beta. \quad (4)$$

$$Q_{ICE,n,k,h} = \boldsymbol{P_{ICE,n,k,h}}\rho + \boldsymbol{\delta_{ICE,n,k,h}}\sigma. \quad (5)$$

$\boldsymbol{P_{ICE}}$ is the electric power in kW and is a decision variable, $\boldsymbol{\delta_{ICE}}$ is a binary decision variable equal to 1 if the ICE is working and equal to 0 otherwise. The linearization coefficients of the ICE characteristic curves are $\alpha = 2.42$, $\beta = 11.0\mathrm{kW}$, $\rho = 1.24$, $\sigma = -1.65\mathrm{kW}$.

The capacity $\boldsymbol{C_{ICE}}$ of the ICE, in kW of nominal electric power, which is a decision variable, is associated with the auxiliary decision variable $\boldsymbol{\vartheta_{ICE}}$ in order to avoid nonlinear constraints [23] of the type $\boldsymbol{P_{ICE}} \leq \boldsymbol{C_{ICE}}\boldsymbol{\delta_{ICE}}$. Equations (6), (7), and (8) bound $\boldsymbol{C_{ICE}}$ and $\boldsymbol{P_{ICE}}$.

$$\boldsymbol{\delta_{ICE,n,k,h}} C_{ICE,min,n} \leq \boldsymbol{\vartheta_{ICE,n,k,t}} \leq \boldsymbol{\delta_{ICE,n,k,h}} C_{ICE,max,n}. \quad (6)$$

$$\left(1 - \boldsymbol{\delta_{ICE,n,k,h}}\right) C_{ICE,min,n} \leq \boldsymbol{C_{ICE,n}} - \boldsymbol{\vartheta_{ICE,n,k,h}} \leq \left(1 - \boldsymbol{\delta_{ICE,n,k,h}}\right) C_{ICE,max,n}. \quad (7)$$

$$\gamma_{ml,ICE} \boldsymbol{\vartheta_{ICE,n,k,h}} \leq \boldsymbol{P_{ICE,n,k,h}} \leq \boldsymbol{\vartheta_{ICE,n,k,h}}. \quad (8)$$

$\gamma_{ml,ICE} = 0.7$ is the ratio between the minimum load at which the ICE can operate and its nominal capacity, and $C_{ICE,min}$ and $C_{ICE,max}$ are the minimum and maximum bounds of the ICE capacity, respectively. If the ICE is not available at the node n, then $C_{ICE,min,n} = C_{ICE,max,n} = 0$ and, in turn, $\boldsymbol{P_{ICE,n,k,h}} = \boldsymbol{F_{ICE,n,k,h}} = \boldsymbol{Q_{ICE,n,k,h}} = 0$.

3.2.3. Gas boiler

The fuel (natural gas) consumption (F_{BOIL}) of the gas boiler (BOIL), in kW, is given in Eq. (9) as a function of the thermal power ($\boldsymbol{Q_{BOIL}}$), in kW, which is a decision variable.

$$F_{BOIL,n,k,h} = \frac{\boldsymbol{Q_{BOIL,n,k,h}}}{\eta_{th,BOIL}}. \quad (9)$$

$\eta_{th,BOIL} = 0.9$ is the boiler efficiency. Equations (10) and (11) bound the thermal power ($\boldsymbol{Q_{BOIL}}$) and the boiler capacity ($\boldsymbol{C_{BOIL}}$), expressed in kW of nominal thermal power, which is another decision variable.

$$C_{BOIL,min,n} \leq \boldsymbol{C_{BOIL,n}} \leq C_{BOIL,max,n}. \quad (10)$$

$$0 \leq \boldsymbol{Q_{BOIL,n,k,h}} \leq \boldsymbol{C_{BOIL,n}}. \quad (11)$$

$C_{BOIL,min,}$ and $C_{BOIL,max}$ are the minimum and maximum bounds of the boiler capacity, respectively. If the boiler is not available at the node n, then $C_{BOIL,min,n} = C_{BOIL,max,n} = 0$ and, in turn, $\boldsymbol{F_{BOIL,n,k,h}} = \boldsymbol{Q_{BOIL,n,k,h}} = 0$.

3.2.4. Air-water heat pump

The electric power consumption (P_{HP}) of the heat pump (HP), in kW, is given in Eq. (12) as a function of the thermal power ($\boldsymbol{Q_{HP}}$), in kW, which is a decision variable.

$$P_{HP,n,k,h} = \frac{1}{COP_{ideal,k,h}} \left(\boldsymbol{Q_{HP,n,k,h}}\mu + \boldsymbol{\delta_{HP,n,k,h}}\omega\right). \quad (12)$$

$\boldsymbol{\delta_{HP}}$ is a binary decision variable equal to 1 if the HP is working and equal to 0 otherwise, $\mu = 1.80$ and $\omega = 2.65$kW are the linearization coefficients of the HP characteristic curves (similarly to the ICE), COP_{ideal} is the coefficient of performance calculated in ideal conditions (Carnot equation) between the ambient temperature T_{amb}, in K, provided as a time series, and the supply temperature T_{supply} of the DHN, in K. Equation (13) shows the ideal coefficient of performance.

$$COP_{ideal,k,h} = \frac{1}{1 - \frac{T_{amb,k,h}}{T_{supply}}}. \quad (13)$$

The capacity ($\boldsymbol{C_{HP}}$) of the HP is a decision variable expressed in kW of nominal thermal power, and is associated with the auxiliary decision variable $\boldsymbol{\vartheta_{HP}}$ to avoid nonlinear constraints. Equations (14), (15), and (16) bound $\boldsymbol{C_{HP}}$ and $\boldsymbol{Q_{HP}}$.

$$\boldsymbol{\delta_{HP,n,k,h}} C_{HP,min,n} \leq \boldsymbol{\vartheta_{HP,n,k,h}} \leq \boldsymbol{\delta_{HP,n,k,h}} C_{HP,max,n}. \quad (14)$$

$$\left(1 - \boldsymbol{\delta_{HP,n,k,h}}\right) C_{HP,min,n} \leq \boldsymbol{C_{HP,n}} - \boldsymbol{\vartheta_{HP,n,k,h}} \leq \left(1 - \boldsymbol{\delta_{HP,n,k,h}}\right) C_{HP,max,n}. \quad (15)$$

$$\gamma_{ml,HP} \boldsymbol{\vartheta_{HP,n,k,h}} \leq \boldsymbol{Q_{HP,n,k,h}} \leq \boldsymbol{\vartheta_{HP,n,k,h}}. \quad (16)$$

$\gamma_{ml,HP} = 0.5$ is the ratio between the minimum load at which the HP can operate and its nominal capacity. $C_{HP,min,}$ and $C_{HP,max}$ are the minimum and maximum bounds of the HP capacity, respectively. If the HP is not available at the node n, then $C_{HP,min,n} = C_{HP,max,n} = 0$ and, in turn, $\boldsymbol{P_{HP,n,k,h}} = \boldsymbol{Q_{HP,n,k,h}} = 0$.

3.2.5. Energy storage systems

The decision variables associated with the thermal energy storage (TES) are its capacity ($\boldsymbol{C_{TES,n}}$), in kWh, the charging heat ($\boldsymbol{Q_{TES,chrg,n,k,h}}$) and discharging heat ($\boldsymbol{Q_{TES,disch,n,k,h}}$), in kW, and the state of charge ($\boldsymbol{SOC_{TES,n,h,k}}$), in kWh. The decision variables associated with the electrical energy storage (EES) are its capacity ($\boldsymbol{C_{EES,n}}$), in kWh, the charging power ($\boldsymbol{P_{EES,chrg,n,k,h}}$) and discharging power ($\boldsymbol{P_{EES,disch,n,k,h}}$), in kW, and the state of charge ($\boldsymbol{SOC_{EES,n,h,k}}$), in kWh. Refer to [22] for the model of energy storage systems. Note that both intra-day and inter-

day storage is allowed. If a storage system is not available at node n, then all the corresponding decision variables are set equal to zero.

3.2.6. Electricity import from/export to the national power grid

The microgrid interfaces with the national power grid at node 0. Here, it is possible to import/export electricity. Thus, two additional sets of decision variables are required: $\boldsymbol{P_{imp,n,k,h}}$, in kW, for import, and $\boldsymbol{P_{exp,n,k,h}}$, in kW, for export. $\boldsymbol{P_{imp,n,k,h}} = \boldsymbol{P_{imp,n,k,h}} = 0$ if $n \neq 0$.

3.3. Energy networks

The system includes $P = 12$ district heating pipelines, and $L = 16$ electrical microgrid lines.

3.3.1. District heating network

For each pipeline p (with $p = 1,2, \dots, P$) connecting two nodes n and m, the decision variables involved in the model of the district heating network (DHN) are: the capacity of the pipeline ($\boldsymbol{C_{DHN,p,nm}}$) connecting the two nodes, in kW, the heat flow from node n to node m ($\boldsymbol{Q_{DHN,nm}}$), in kW, and the heat flow from node m to node n ($\boldsymbol{Q_{DHN,mn}}$), in kW. The heat flows are bounded by the pipeline capacity, as shown in Eq. (17).

$$\boldsymbol{Q_{DHN,nm,k,h}} + \boldsymbol{Q_{DHN,mn,k,h}} \leq \boldsymbol{C_{DHN,p,nm}}. \quad (17)$$

Note that, due to the DHN layout (see Figure 1), heat is constrained to flow from the energy hub (node 7) to the end users (nodes 3, 5, 9, 11, 15). Thus, for each pipeline, the flow in one of the two directions is always zero. If two nodes n and m are not connected by a DHN pipeline, then $\boldsymbol{C_{DHN,p,nm}}$ is not defined, and $\boldsymbol{Q_{DHN,nm,k,h}}$ and $\boldsymbol{Q_{DHN,mn,k,h}}$ are set equal to zero.

3.3.2. Electrical microgrid

For each electric line l (with $l = 1,2, \dots, L$) connecting two nodes n and m, the decision variables involved in the model of the electrical microgrid (EMG) are: the capacity of the network line ($\boldsymbol{C_{EMG,l,nm}}$) connecting the two nodes, in kW, the power flowing from node n to node m ($\boldsymbol{P_{EMG,nm}}$), in kW, and the power flowing from node m to node n ($\boldsymbol{P_{EMG,mn}}$), in kW. The power streams are bounded by the network line capacity, as shown in Eq. (18).

$$\boldsymbol{P_{EMG,nm,k,h}} + \boldsymbol{P_{EMG,mn,k,h}} \leq \boldsymbol{C_{EMG,l,nm}}. \quad (18)$$

If two nodes n and m are not connected by a EMG line, then $\boldsymbol{C_{EMG,l,nm}}$ is not defined, and $\boldsymbol{P_{EMG,nm,k,h}}$ and $\boldsymbol{P_{EMG,mn,k,h}}$ are set equal to zero.

3.4. Energy balances

Two energy balance constraints are imposed for each node, typical day, and time step of the typical day. The "+" sign is assigned to power/heat flows entering a node, the "–" sign to power/heat flows exiting a node.

Equation (19) shows the electrical energy (electricity) balance.

$$-D_{el,n,k,h} - \sum_m \boldsymbol{P_{EMG,nm,k,h}} + \sum_m \boldsymbol{P_{EMG,mn,k,h}}(1 - \lambda_{EMG}) - \boldsymbol{P_{exp,n,k,h}} + \boldsymbol{P_{imp,n,k,h}} - P_{HP,n,k,h} + P_{PV,n,k,h} + \boldsymbol{P_{ICE,n,k,h}} - \boldsymbol{P_{EES,chrg,n,k,h}} + \boldsymbol{P_{EES,disch,n,k,h}} = 0. \quad (19)$$

D_{el} is the hourly electricity demand in kW, m is the set of nodes connected to the node n, $\lambda_{EMG} = 0.02$ is the constant loss factor of the microgrid.

Equation (20) shows the thermal energy (heat) balance.

$$-D_{th,n,k,h} - \sum_m \boldsymbol{Q_{DHN,nm,k,h}} + \sum_m \left[\boldsymbol{Q_{DHN,mn,k,h}}\left(1 - len_{p,nm}\lambda'_{DHN}\right) - len_{p,nm}\lambda''_{DHN}\right] + \boldsymbol{Q_{HP,n,k,h}} + Q_{ICE,n,k,h} - \boldsymbol{Q_{TES,chrg,n,k,h}} + \boldsymbol{Q_{TES,disch,n,k,h}} = 0. \quad (20)$$

D_{th} is the hourly heating demand in kW, m is the set of nodes connected to the node n, len_p is the length of the pipeline in m, $\lambda'_{DHN} = 5.4 \times 10^{-5}\ 1/\mathrm{m}$ and $\lambda''_{DHN} = 7.4 \times 10^{-3}\ \mathrm{kW/m}$ are the linearization coefficients of the district heating losses calculated according to [9] as a function of the pipeline capacity and supply, return and ground temperatures ($T_{supply} = 70°\mathrm{C}$, $T_{return} = 40°\mathrm{C}$, and $T_{ground} = 10°\mathrm{C}$, respectively).

3.5. Objective function

The objective function f, to be minimized, represents the life cycle cost of the system actualized to one-year operation. f is composed of two contributions: f', associated with operation costs, and f'' associated with investment costs. Thus, $f = f' + f''$. f' and f'' are given in Eq. (21) and Eq.(22), respectively.

$$f' = \sum_k w_k \sum_n \sum_h \left[c_{gas}\left(F_{ICE,n,k,h} + F_{BOIL,n,k,h}\right) + c_{el,buy}\boldsymbol{P_{imp,n,k,h}} - c_{el,sell}\boldsymbol{P_{exp,n,k,h}}\right]. \quad (21)$$

$$f'' = \{\sum_n \sum_g [\tau_g (c_{inv,var,g} \boldsymbol{C_{g,n}} + c_{inv,fix,g})]\} + \{\sum_p [\tau_{DHN} len_p (c_{inv,var,DHN} \boldsymbol{C_{DHN,p,nm}} + c_{inv,fix,DHN})]\} +$$
$$\{\sum_l [\tau_{EMG} len_l (c_{inv,var,EMG} \boldsymbol{C_{EMG,l,nm}} + c_{inv,fix,EMG})]\}. \quad (22)$$

w_k is the weight of the typical day k, $c_{gas} = 70€/\text{MWh}$ is the purchasing cost of natural gas, $c_{el,buy} = 200€/\text{MWh}$ is the purchasing cost of electricity from the national grid, and $c_{el,sell} = 50€/\text{MWh}$ is the selling price of electricity to the national grid. The subscript g (with g = PV, ICE, BOIL, HP, TES, EES) refers to the set of energy conversion and storage technologies; $c_{inv,var}$ and $c_{inv,fix}$ are the linearization coefficients of the investment cost of a technology or network (they are reported in Table 2 with their units); $\boldsymbol{C}$ is the capacity (decision variable); len refers to the length of a network branch in m; τ is the actualization factor of a technology or network and is calculated in Eq.(23), where $r = 0.05$ is the interest rate and a is the lifetime of a technology or network (see Table 2).

$$\tau = \frac{r(1+r)^a}{(1+r)^a+1}. \quad (23)$$

Note that operation and maintenance costs of the installed components are not shown in Eq. (22) for simplicity. However, they are included and calculated as a share of the investment cost.

Table 2 Linearized investment cost and lifetime of the energy conversion and storage technologies and energy networks.

Quantity	PV	ICE	BOIL	HP	TES	EES	DHN	EMG
$c_{inv,var}$	1250€/kW	1740€/kW	65€/kW	117€/kW	244€/kWh	880€/kWh	103€/kW/m	34€/kW/m
$c_{inv,fix}$	0€	32050€	1625€	2145€	970€	3495€	0.2€/m	0.05€/m
a, years	20	20	20	20	20	20	40	40

The function Φ defines the CO2 emissions of the system in one year of operation, as shown in Eq. (24).

$$\Phi = \sum_k w_k \sum_n \sum_h [e_{gas}(F_{ICE,n,k,h} + F_{BOIL,n,k,h}) + e_{el,grid} \boldsymbol{P_{imp,n,k,h}}]. \quad (24)$$

$e_{gas} = 197\text{kg/MWh}$ is the direct emission factor of natural gas, $e_{el,grid} = 356\text{kg/MWh}$ is the indirect emission factor associated with the electrical energy withdrawn from the national grid.

A reference scenario is defined by assuming that the aggregated electricity demand of the system is fulfilled by withdrawing electricity from the national grid, whereas the aggregated heating demand is met by burning natural gas in gas boilers. The resulting life cycle cost over one year of operation is $f_{ref} = 135.4\text{k€}$, whereas the CO2 emissions are $\Phi_{ref} = 307.6\text{ton}$.

A global constraint can be imposed on the maximum amount of CO2 emissions, in order to meet certain decarbonization targets. Equation (25) shows such a constraint, where $\varepsilon > 0$ is a fixed parameter.

$$\Phi \leq \varepsilon \times \Phi_{ref}. \quad (25)$$

By iteratively decreasing the value of ε, it is possible to carry out a sort of multi-objective optimization (the so-called ε-constrained multi-objective optimization) in order to obtain the Pareto front of the optimal solutions achieved for increasingly stricter reduction targets in carbon emissions.

4. Results

4.1. Cost-optimal system layout

Initially, the optimization model has been tested without imposing the constraint on CO2 emissions (Eq. (25)). Thus, the obtained results correspond to the cost optimal solution. The resulting value of the objective function, i.e., of the life cycle cost over one year, is $f = 124.3\text{k€}$, which is 8.2% lower than the reference scenario. The operation costs contribute for $f' = 52.1\text{k€}$, whereas the investment costs for $f'' = 72.7\text{k€}$. The total CO2 emissions over one year are $\Phi = 167.8\text{ton}$, which are 45.4% lower than the reference scenario. Hence, a sensible reduction in CO2 emissions results to be economically convenient even without imposing decarbonization targets.

Figure 2 shows the optimal layout of the energy networks, with the capacity of the district heating pipelines and electrical microgrid lines. Table 3 reports the optimal capacity of the energy conversion and storage plants at the node in which they are installed. The capacity of the DHN pipelines decreases by moving from the energy hub towards the end users. This is due to the mono-directionality of the heat flow, which only flows from the hub to the users. Note that the capacity of the DHN is higher than the one strictly required for meeting the heating demand of the end users because of the DHN losses, which have a not negligible impact on the system (79 MWh of losses in one year, more than 20% of the total heating demand). The installed capacity of PV is predominant, with 443.9 kW, for a yearly electricity production of 661.1 MWh that corresponds to a utilization factor of 17% (equivalent hours at the nominal power compared to the 8760 hours of one year). The

installed capacity of the ICE is 57.8 kW, for a yearly electricity production of 198.8 MWh corresponding to a utilization factor of 39%. The gas boiler allows covering the heating demand peaks. Its installed capacity is of 183 kW, for a yearly heat production of 43.6 MWh corresponding to a utilization factor of 3%. The HP covers the heating demand not covered by ICE and BOIL. Its installed capacity is 77.7 kW, for a yearly heat production of 134.2 MWh corresponding to a utilization factor of 20% The installed capacity of TES allows improving the operation flexibility of ICE and HP, thereby increasing their utilization factor. The installed capacity of EES is negligible. The electricity export to the national grid prevails on the electricity import because of the high capacity of PV. This is reflected by how the capacity of the electrical microgrid lines is distributed. In fact, it increases moving from the end users towards node 0, in which the system interfaces with the national grid.

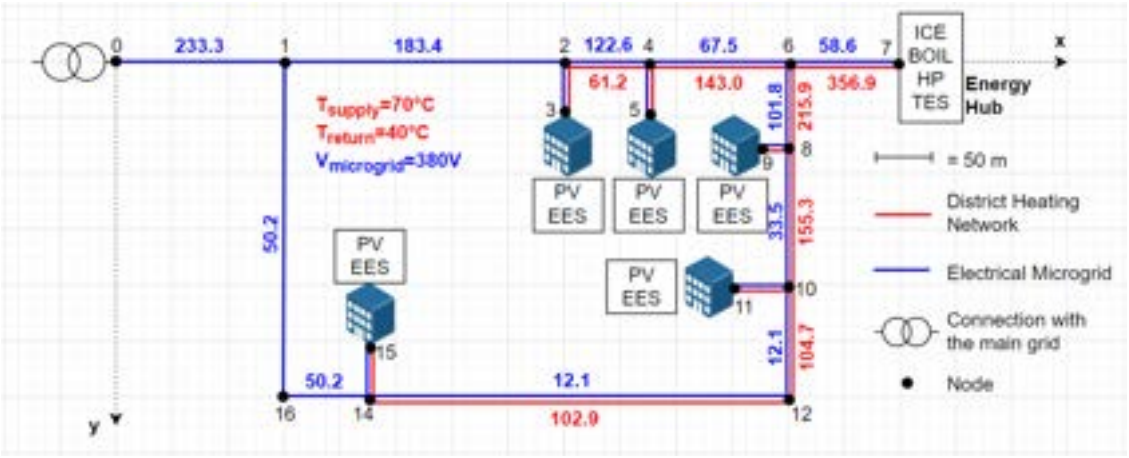

Figure 2 Cost-optimal layout of the energy networks. The capacities of the district heating pipelines and of the microgrid lines, in kW, are shown in red and blue, respectively.

Table 3 Capacity of the installed energy conversion and storage plants.

Node	PV, kW	ICE, kW	BOIL, kW	HP, kW	TES, kWh	EES, kWh
3	100.0	0	0	0	0	0.5
5	100.0	0	0	0	0	0.5
7	8.0	57.8	183.0	77.7	95.1	0
9	95.2	0	0	0	0	0.5
11	48.4	0	0	0	0	3.7
15	92.3	0	0	0	0	0.5

Figure 3 shows the energy balances (electricity and heat) of the whole system over one year, with a daily resolution. It is obtained by replacing each day of the year with the typical day representing it. The predominance, in terms of energy, of PV generation is clear, as also the prevalence of the electricity export compared to import. Globally, 77% of the total electricity demand is covered by electricity generated on site, whereas 37% of the generated electricity is exported. The ICE is more exploited during the cold season because of the contemporary need of electricity and heat by the end users, which makes more effective a CHP operation. The HP share on the daily generation of thermal energy is higher during the warm season, because of the high availability of “free of charge” electricity from PV. However, in absolute terms, the HP generates more in winter, when the heating demand is higher. The role of the boiler in covering the heating demand peaks is clear.

4.2. Variation of the reduction target on carbon emissions

The effect of imposing stricter reduction targets in CO_2 emissions has also been analysed. This corresponds to a decrease in the value of ε in Eq. (25), which represents the share of CO_2 emissions compared to the reference scenario. The cost-optimal system configuration, which does not consider that constraint, already implies a reduction in CO_2 emissions of 45%, corresponding to $\varepsilon = 0.55$. Thus, ε has been varied from 0.55 towards 0. Figure 4a shows the obtained Pareto front. It is evident that, starting from $\varepsilon = 0.55$, the minimization of the life cycle cost and the minimization of the carbon emissions are two contrasting objectives. Thus, reducing ε results in increasing the life cycle cost. It is possible to reduce the CO2 emissions until 120ton/year (60% reduction compared to the reference) while maintaining the economic effectiveness of the system with respect to the reference scenario. Accordingly, a further reduction of ε results in compromising the economic convenience of the proposed system. Moreover, CO_2 emissions cannot be reduced to zero because of the saturation of the PV and EES potentials (i.e., the available area for installing PV and space for installing EES become fully exploited). The minimum value that CO_2 emissions can reach is 69 ton/year, 78% less than in the reference scenario. However, the corresponding life cycle cost is 45% higher than the cost-optimal case.

Figure 4b shows how the capacity of the installed energy conversion and storage plants and largest network branches (EMG line 0-1, DHN pipeline 6-7) varies with ε, i.e., with decreasing CO_2 emissions (the plot should be read from right to left). The most evident result is the progressive increase in PV, HP, EES and EMG capacities. Moving from the cost-optimal system configuration to the minimum emitting one, the PV capacity almost doubles, the HP capacity increases of 130%, the EES capacity increases of more the 100 times, and the EMG capacity increases of 85%. The reason is that PV is the only renewable-based technology available. Thus, the increase in PV capacity is accompanied by an increase in HP capacity, in order to decarbonize the heating demand, and an increase in EES capacity, in order to decarbonize the electricity demand during the hours in which PV generation is not available. The EMG capacity increases too, in order to accommodate the increasing generation surplus from PV. The boiler capacity slowly decreases with decreasing ε. The ICE capacity remains more or less constant, except for a sharply decrease (-91%) to allow the last marginal reduction in CO2emissions. This reflects a sharply increase (+93%) in TES capacity, which is required to improve the flexibility of the HP and, in turn, its utilization factor. The DHN capacity remains constant.

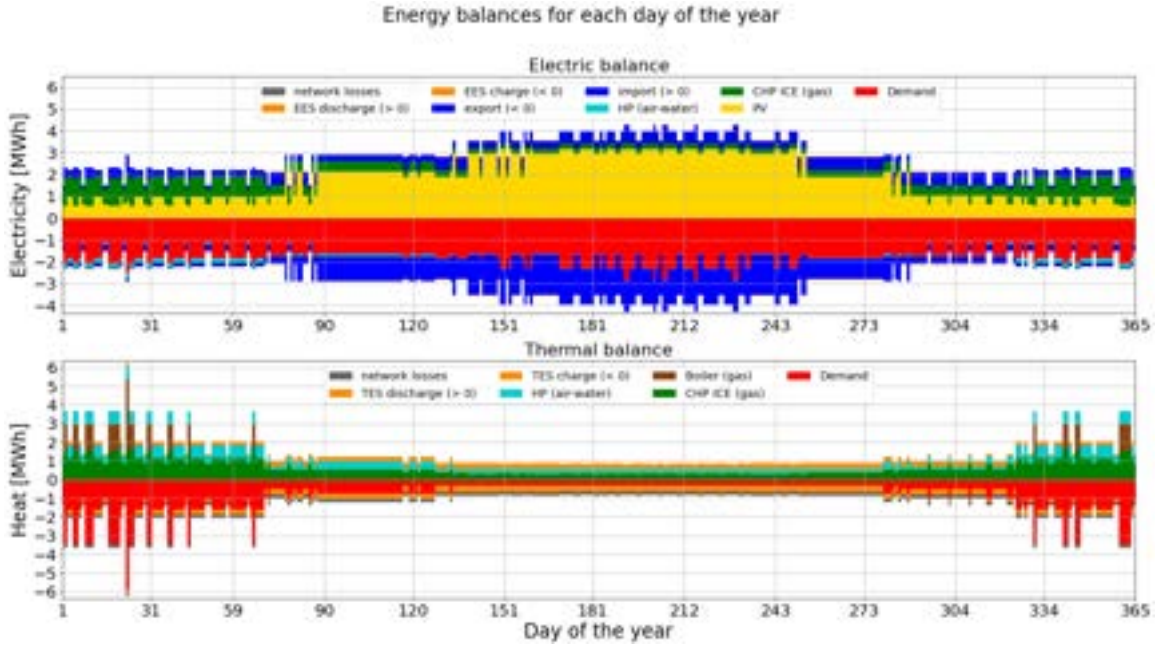

Figure 3 Yearly energy balances of the considered multi energy system with a daily resolution.

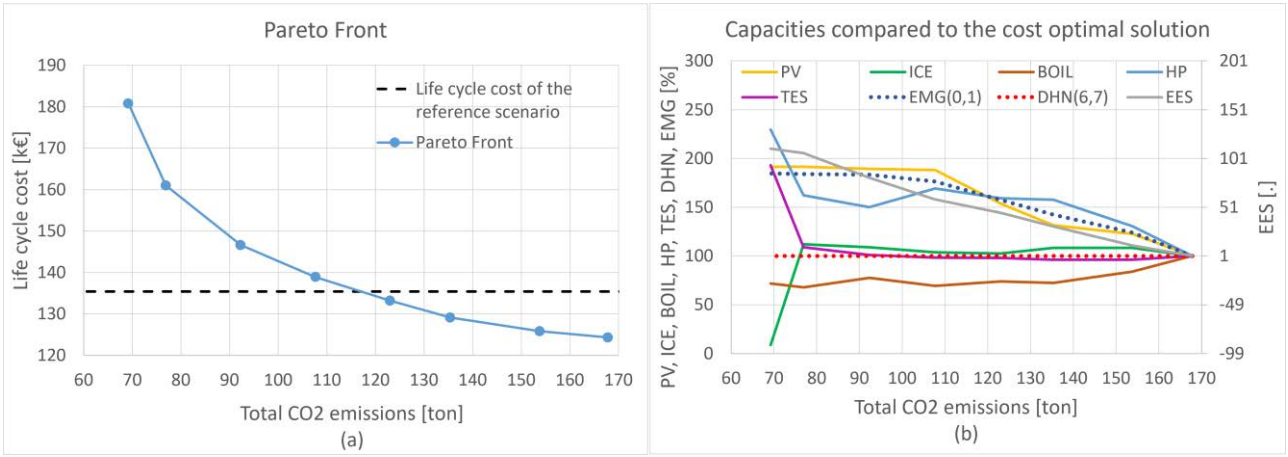

Figure 4 Results of the optimization for increasingly stricter constraints on CO2 emissions: a) Pareto front and b) share of the installed capacities compared to the cost-optimal solution.

5. Conclusions

This paper presents a general method for the design and operation optimization of multi-energy systems integrated with energy networks, with the goal of defining cost-effective system configurations to meet increasingly stricter decarbonization targets. The proposed method makes it possible to concurrently optimize the capacity of the available energy conversion and storage plants, the capacity of each branch of the available networks, and their operation, in order to minimize the life cycle cost of the system for a given cap on carbon

emissions. A district multi-energy system composed of residential and commercial buildings, with their electricity and heating demands, and including a district heating network and an electrical microgrid has been considered as a test case. Without imposing any constraints on CO2 emissions, results show that it is possible to reduce the carbon emissions of the system of 45%, while also decreasing the life cycle cost of 8%, with respect to a reference scenario in which the entire electricity demand is fulfilled by withdrawing electricity from the national grid and the entire heating demand is met by burning natural gas in gas boilers. However, a further decarbonization compromises the cost-effectiveness of the system because of the investments in carbon-neutral technologies and electrical microgrid, the installed capacity of which steeply increases.

The main findings of the study are summarized below.

- Photovoltaic is a promising solution for decarbonizing the electricity demand, by contributing for more than 75% to the total electricity generation. Electrical storage systems are necessary for a deep decarbonization.
- The higher share of photovoltaic generation in deeply decarbonized scenarios requires increasing the capacity of the electrical microgrid up to 85% compared to the cost-optimal system configuration.
- The economic convenience of distributed electricity generation is mainly due to the self-consumption, which approaches 80% of the electricity demand, rather than to selling energy to the national grid.
- Heat pumps are very effective in decarbonizing the heating demand if a surplus of photovoltaic generation is available on site. Their contribution to the thermal power generation approaches 100% in deeply decarbonized scenarios. Moreover, thermal energy storage allows improving their utilization factor.
- Gas-fuelled combined heat and power internal combustion engines can contribute to the decarbonization of both electricity and heating demand in a first phase. However, the scarce heating demand of commercial-residential districts during the warm season sensibly worsens the utilization factor of this technology, which results to be lower than 40%.
- The capacity of the considered tree-shaped district heating network depends only on the heating demand of the end users, thereby remaining unchanged when the decarbonization target varies.

The proposed paper is intended as a part of a wider study aiming at defining a method for the complete synthesis, design and operation optimization of multi energy systems integrated with energy networks. This means that the present work will be further developed in order to include the synthesis of the networks' topology, the selection of the number and type of the energy conversion and storage plants, and their siting within the system into the optimization problem. The idea is to solve the overall synthesis, design and operation problem by means of an evolutionary algorithm, in which the method proposed here is run many times at each iteration for different configurations of the networks' topology and plants' position.

Abstract:

Small-medium scale decentralized polygeneration systems can provide multiple energy services for urban districts like universities and hospitals, with several energetic, economic and environmental benefits. Indeed, their impact on both energy efficiency, cost and emissions reduction might be disruptive especially in urban districts located in a tropical region, where the cooling demand is approximately stationary throughout the whole year. In this paper a multi-objective optimization model for distributed energy system in tropical climate is presented. The superstructure of the system comprehends a district cooling network that connects the users to medium-scale gas turbine system, solar PV plant, thermal and electrical chiller and a thermal storage. The optimization aims to determine the optimal design structure of the system, the size of each component inside the optimal solution and the optimal operation strategy. The multi-objective optimization is based on a three-level structure: 1) the simulation level developed in TRNSYS; 2) the optimization level based on a pareto-search algorithm developed in Matlab; 3) the Matlab-TRNSYS interface level. In this way the Pareto Front is identified and the possible improvements in both economic and environmental terms can be highlighted. The model has been applied to a specific real case study, namely a polygeneration system to be installed in the NTU campus located in Singapore, and it has been optimized for two different superstructure configurations. The results contribute significantly to developing an efficient and cost-effective energy storage polygeneration system and revealed that the optimized operation of the decentralized energy systems reduces energy costs and CO_2 emissions, as compared with a scenario without integration of renewables and electric energy storage system as well as conventional energy supply systems. Indeed, numerical results show that the Pareto frontier provides good balancing solutions for planners based on economic and sustainability priorities.

Keywords:

1. Introduction

The energy demand for space heating and cooling is growing faster in buildings and already causing enormous strain on electricity systems in many countries, as well as driving up emissions [1][2]. The sustainability of heating and cooling is of high priority, and the strategy lists to achieve the sustainability goals are decreasing demand, increasing efficiency, and switching to renewable primary energy sources. To this end, the concept of decentralized polygeneration system and microgrid should be recognized as an enabling technology system with great potential. Polygeneration energy systems using multiple energy sources (e.g., wind, biomass, solar) and delivering multiple energy services (i.e., heating, cooling, and electricity) have potential economic and environmental benefits over traditional energy generation systems [3,4]. Indeed, simultaneous production of heating, cooling and power in a combined cooling heating and power system results in higher overall efficiency in comparison with the separate heat and power production [3]. Furthermore, having the energy supply system close to end users offers several other advantages such as lower distribution and transmission cost, less power loss through the transmission and

distribution line, alleviated environmental impacts, and enhanced resilience of the utility grid [5] . Mancarella [3] studied the status of existing models and evaluation methods for performance investigation of multi-energy systems (MES). A complete overview of MES considering various perspectives was provided. Jana et al. [6] presented the status of polygeneration technologies and their capacity to provide a sustainable energy solution. This study highlighted the necessity to conduct more research on multi-criteria optimization of polygeneration systems. Furthermore, the incorporation of innovative storage and generation units in complex polygeneration systems were suggested. A short review on optimization of polygeneration systems in urban applications was presented by Ghaem Sigarchian et al. [7]. The study emphasizes the necessity of further investigation on complex polygeneration systems to achieve results as close as possible to reality. Calise et al. [8] showed that for a combined production of electricity, cooling and heating to satisfy a defined end-user demand, distributed polygeneration systems (DPS) are the most efficient and sustainable way to simultaneously guarantee flexibility and reliability. Indeed, if a high penetration of unpredictable renewable energy sources is thought to be promoted, distributed polygeneration systems could allow to significantly increase the resiliency and flexibility of the power production and distribution networks [9]. Although almost no geographical region is at this stage yet, a potential promising outlook for energy infrastructures would then be a global spread of decentralized energy generation in which larger share of final energy consumption will be produced in a distributed way [10].

Directly responding to this ambitious target, a novel district scale demonstrator has been currently proposed and developed in Singapore [11], aiming to significantly contribute achieving the goal imposed by the country's national agenda on sustainable development [12]. Based on the concept of distributed cryo-polygeneration system, namely an integrated rapidly deployable and highly energy-efficient solution that utilizes cold energy from Liquefied Natural Gas (LNG) and waste heat from power generation, the project might help in meeting the growing energy needs of urbanization and industrialization, especially in tropical and sub-tropical areas. In order to maximize the benefits from the cryo-polygeneration system while still providing the same quality of energy services produced by conventional energy system, the optimal design of the plant layout is necessary and it requires the techno-economic analysis of single components in order to maximize the efficiency of the available energy resources [13]. Indeed, in order to avoid incurring unnecessary costs while still providing the required resilience and reliability, decentralized polygeneration systems require accurate components design [14]. Nevertheless, profitability of the cryo-polygeneration system might not be the only driver for the design optimization of the system: indeed, considering as objective function the CO_2 emission, the optimization might lead to alternative system design. In such a context, a multiobjective approach helps identify balancing solutions to promote participation in the decision-making process and facilitate collective decisions. To this end, a multi-criteria optimization with respect to economic and ecological aspects and thus determination of Pareto optimal solutions has been methodologically developed. In literature the multi-objective optimization of distributed polygeneration systems has been the subject of many researchers within the recent years. Ahmadi et al. [15] presented the thermodynamic modelling and multi-objective optimization of an energy system for the simultaneous generation of electricity, heating, cooling and hot water. Gabrielli et al. [16] analyzed the design of a multi-energy system involving seasonal energy storage and based on a case study in a neighbourhood in Zurich, Switzerland, which is optimized in terms of total annual costs and carbon dioxide emissions. Ghaem Sigarchian et al. [17] applied a multi-objective optimization methodology to a small-scale decentralized polygeneration system: the distributed polygeneration systems reduces both CO_2 emissions and annualized total cost up to 29% and 19%, respectively.

Nevertheless, there seems to be a lack in the literature of studies addressing the optimal operation and design of distributed polygeneration systems in cooling dominated geographical region, as for the urban district in a tropical area characterized by high and uniform temperature and humidity throughout the year. Indeed, although the investigation of energy systems in a cooling dominated context is gaining momentum in literature with few studies highlighting the benefit of district cooling [24] and energy storages in tropical areas [25,26], overall, a systematic and generalized research with an on-site real application on the decarbonization in tropical climate by means of decentralized polygeneration systems is still lacking [24]. In this framework, the present paper aims to go a step further by significantly improving the knowledge on this topic. Indeed, in this paper the multi-objective

optimization model is applied to the cryo-polygeneration concept, and the Pareto frontiers associated to two different system configurations are evaluated. The results of the optimizations can be used to identify the best trade-off solutions. The main objective of the multi-objective optimization is to determine the optimal design (sizing) and the optimal operation strategy for any component within the optimal solution. Indeed, the analysis aims to evaluate the economic and environmental benefits of the integration between gas turbine, PV and energy storage solutions when the optimal synthesis and operation of the whole energy supply system are adopted.

2. Methodology

2.1. Cryo-polygeneration concept

The proposed cryo-polygeneration system concept (developed in TRNSYS) is shown in **Fig. 1**, consisting diverse technologies for electricity and cold energy generation and storage. The electric power is produced from the gas turbines (GT) and photovoltaics (PV) modules whereas the LNG regasification unit (RU), an absorption chiller (ABC) utilizing the waste exhaust heat from the gas turbine and vapour compression water-cooled chillers (WCC) are mainly to support the cooling loads. Cold thermal energy storage (CTES) and battery electrical energy storage (BESS) act as a buffer to complement the unpredictability of renewable energy sources and as a bulk storage to maximize the exploitation of excess thermal energy and electricity. More information regarding the simulation model can be found in Ref.[18].

Two design scenarios are considered to study the economical and environmental benefits of the critical distributed technologies (**Table 1**). The adopted search space values are set according to the demand and the available footprint area for each component. Scenario 1 consists of well-established technologies such as gas turbines, LNG regasification units, thermal (ABC) and electrical (WCC) chillers. In scenario 2, the photovoltaics (PV) system and thermal/electrical energy storage solutions (CTES and BESS) are included to understand the role and impact of renewable combined with energy storage. Conversely, the case where all the demands of the buildings are supplied by the electricity in a grid connected environment is taken as the baseline case scenario (**Fig. 2**). The performance results of this configuration will provide a reference for the two scenarios under investigation.

Table 1 Cryo-polygeneration design case scenarios and optimization search space.

Components	Search Space				
	BC	1	2	Minimum	Maximum
GT	-	✓	✓	0	10000 kW_e
PV	-	-	✓	0	25000 kW_p
BESS	-	-	✓	0	80000 kWh_e
LNG RU	-	✓	✓	-	-

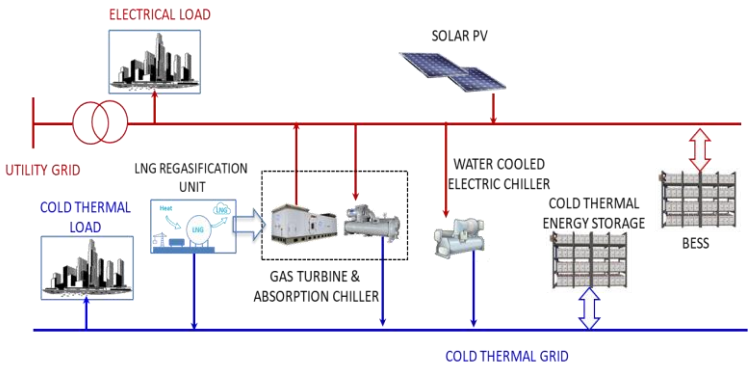

Fig. 1. Superstructure of the Cryo-polygeneration system.

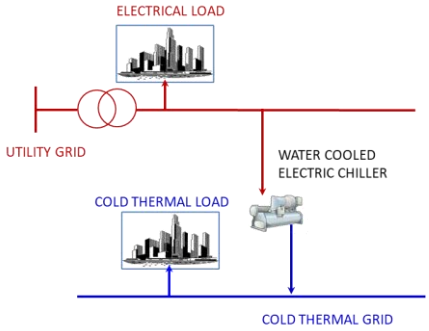

Fig. 2. Superstructure of the baseline case scenario.

2.2. System model

The layouts described in Section 2.1 were dynamically modeled and simulated in TRNSYS environment. TRNSYS is an object-oriented based software that enables to simulate the transient behavior of systems predominantly focused on assessing the performance of thermal and electrical energy systems. The software is made up of two main parts: a simulation engine to solve the dynamic mathematical problem and a large library of built-in components or types (e.g., pumps, mixers, diverters, heat exchangers, etc.), often validated by experimental data. **Fig. 3** shows the cryo-polygeneration system layout implemented in TRNSYS environment: red lines refer to the electricity stream; brown line represents the waste heat flow from the gas turbine to the absorption chiller; green line refers to the LNG stream and blue lines represent chilled water stream.

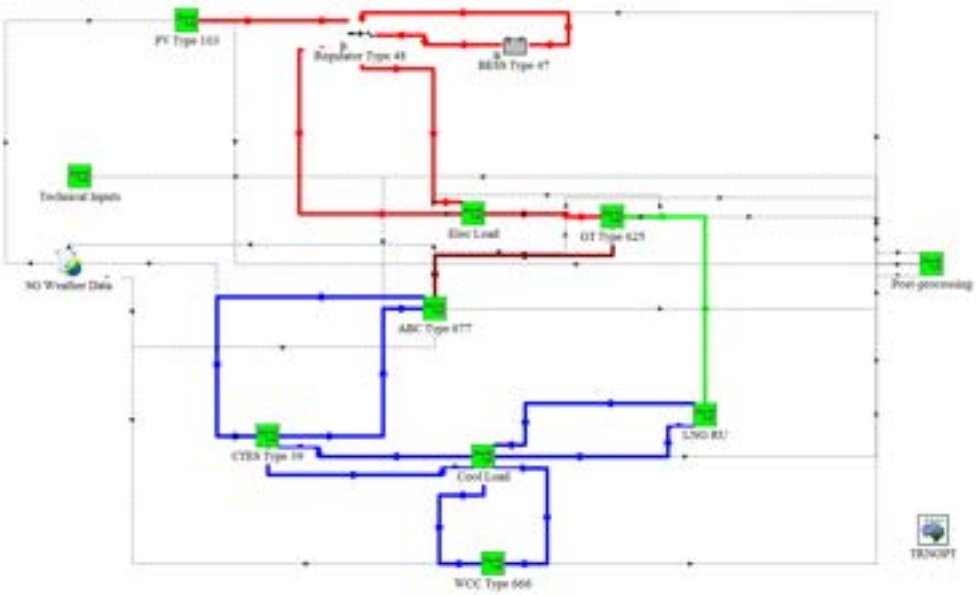

Fig. 3. General layout of the TRNSYS-Cryo-polygeneration system.

2.2. Mathematical problem

Electricity demand and electricity required by vapour compression chiller can be satisfied by grid power, by the electricity provided by the gas turbines, PV, and by the electricity discharged from the BESS. It is assumed that all the electricity provided by GT and PV is self-consumed, while no extra electricity is sold back to the power grid. Space cooling demand can be satisfied by thermal energy provided by the GT through the absorption chiller, vapour compression chillers, and by thermal energy discharged from the CTES.

2.2.1 Decision variables

In the optimization problem, the decision variables include: the existence and sizes of energy devices; operation status (on/off) and energy rates provided by energy devices; capacities of electrical and thermal storage devices; electricity and heat rate input and output to/from electrical and thermal storage devices.

2.2.2 Economic objective function

The total annualized cost (TAC) is the first objective function of the optimization process, a premier economic index taking into account all the expenses during the yearly operational of the project, defined as:

$$TAC = CAPEX_{ann} + OPEX_{UG} + OPEX_{fuel} + OPEX_{O\&M} + OPEX_{CO2} \quad (1)$$

The key parameters for the economic analysis are defined for the different scenarios as follows.

$CAPEX_{ann}$ is the annualized sum of the capital costs, the balance of plants and installation costs of the kth component of the system computed as:

$$CAPEX_{ann} = \sum_k CAPEX_k \cdot CRF_k = \sum_k SC_k \cdot C_k \cdot CRF_k \quad (2)$$

Where SC_k and C_k are the specific capital cost and the capacity of k^{th} component, respectively; CRF is the capital recovery factor of the k^{th} component which takes into account the effect of annual interest rate "i" and the component lifetime "N_k" expressed as:

$$CRF = \frac{i \cdot (1+i)^{N_k}}{(1+i)^{N_k} + 1} \quad (3)$$

$OPEX_{UG}$ accounts for the annual operational cost due to the utilization of the utility grid. It comprises three main factors, namely a) the contracted capacity charge, b) the electricity purchased at a certain electricity tariff *ET,* daily subject to peak and off-peak time periods and c) the use of systems or transmissions costs:

$$OPEX_{UG} = P_{UG,max} \cdot C_{cap,ch} + \int_0^{365} P_{UG} \cdot [ET(t) + UOS(t)] \cdot dt \quad (4)$$

$OPEX_{fuel}$ accounts for the annual operational cost related to the total amount of LNG purchased (m_{LNG}) at a defined price (p_{LNG}):

$$OPEX_{fuel} = \int_0^{365} m_{LNG} \cdot p_{LNG}(t) \cdot dt \quad (5)$$

$OPEX_{O\&M}$ are the annual operational and maintenance costs of the k^{th} component expressed as a fraction ($\phi_{O\&M,k}$) of the total $CAPEX_k$:

$$OPEX_{O\&M} = \sum_k CAPEX_k \cdot \phi_{O\&M,k} \quad (6)$$

As of now, conforming to the Paris Agreement, an increasing number of countries promote energy efficiency measures and the adoption of renewables by including a carbon tax [47,48]. To this end, an operational annual cost related to this tax (taxCO2 expressed in $/tonCO2) is included in the economic analysis as OPEXCO2 computed as:

$$OPEX_{CO2} = \int_{0}^{365} m_{CO2}(t) \cdot tax_{CO2} \cdot dt \quad (7)$$

The key input data for the techno-economic analysis used in this work are depicted in **Table 2**.

Table 2. DES Economic parameters [17,19–23].

Parameter	GT	PV	BESS	LNG RU	ABC	WCC	CTES
SC	1200 \$/kW$_e$	883 \$/kW$_e$	380 \$/kWh$_e$	43.5 \$/kgh	230 \$/kW$_c$	150 \$/kW$_c$	31.8 \$/kWh$_c$
ϕ [%]	3	0.5	1	0.5	2	2	1
Lifetime [years]	30	30	20	30	30	30	30

2.2.3 Emissions objective function

The environmental objective is to minimize the environmental impacts in terms of CO_2 emission from the electricity grid and the consumed fuels. The CO_2 emission due to the use of electricity from the electricity grid is evaluated by multiplying the grid emission factor of the electricity grid (GEF [kg_{CO2}/kWh_e]), and the total amount of electricity purchased from the grid. The carbon intensity of the electricity grid that the cryo-polygenerator is connected to is the amount of CO_2 emission per unit of electricity generated which depends on the fuel mix of Singapore [24]. The CO_2 emission due to the natural gas consumption is evaluated by multiplying the carbon intensity of the fuel, (CI_{NG} [kg_{CO2}/kg_{NG}]), and the total amount of fuel consumption of the cryo-polygenerator system:

$$m_{CO_2} = \int_{0}^{365} P_{UG} \cdot [GEF] \cdot dt + m_{fuel} \cdot CI_{NG} \quad (8)$$

2.2.4 Constraints

The objective function is constrained to the energy balance equation following the rules and limitations of the operating strategies. Some of the critical constraints accounted in the design optimization problem are:

- The electricity and cooling demands are fulfilled at all periods. Otherwise, a high dynamic penalty is imposed on the objective function based on the deviation from the desired value (complete load satisfaction).

- The operation of the gas turbine is prevented below recommended minimum partial load ratio (PLR) to increase its lifetime and decrease the emissions [25]. This constraint is implemented in TRNSYS by a differential controller component limiting the gas turbine operation as follows:

$$0.2 \leq PLR\ (t) \leq 1 \quad (9)$$

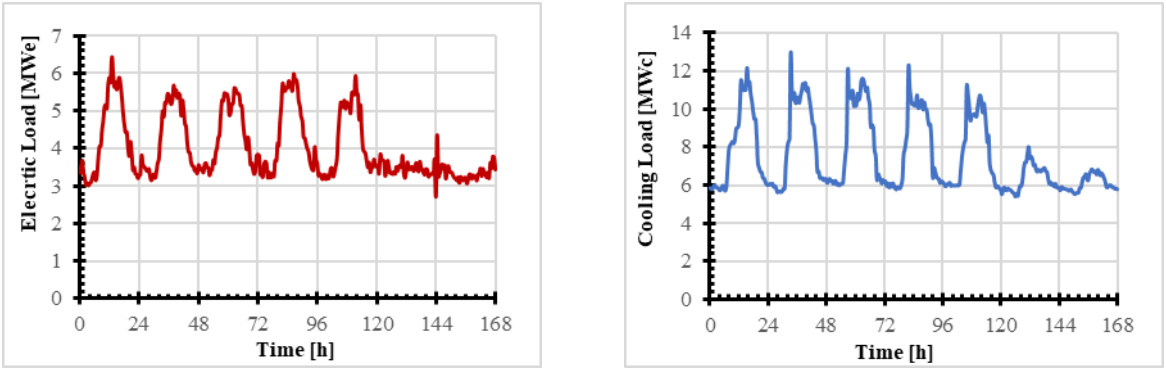
- The capacity of the DPS components is limited to the identified optimization search space. The adopted search space values are set according to the demand and the available footprint area for each component.
- The operations of the electrical and thermal energy storage (BESS and CTES) are limited to their maximum and minimum state of charge.
- Revenues from the PV electricity feed-in are not accounted in the TAC equation as it is not within the scope of this work to merely maximize this profit by operating a small power plant. Nevertheless, this component can be further analyzed in future works.

2.2.5 Optimization method

In this section, the general structure of the optimization tool and the optimization technique has been explained. The optimal design (sizing) and operational strategy of the cryo-polygeneration components are based on a three-level configuration. The simulation level (TRNSYS [26]), the “multi-objective genetic algorithm” (gamultiobj) level [27]) and the interface for the communication between those two levels (Matlab [28]). In particular, TRNSYS is dynamic simulation software whose solver calls the subroutines present in the input file and tries to solve the equations for each simulation time step. Gamultiobj is a multi-objective optimization algorithm that minimizes multiple objective functions subject to a set of constraints. The Matlab code developed by the authors acts as an interface between TRNSYS simulator and the “gamultiobj” algorithm and streamlines the optimization process. The multi- objective genetic algorithm in-built in MATLAB, i.e. the gamultiobj function [64], is based on the very popular Non-dominated Sorting Genetic Algorithm – II [27], and is frequently utilized in literature [29] for the accuracy of the Pareto front.

3. Results

This section discusses the optimal DERs capacities obtained for the cryo-polygenerator system and compares the economics and environmental benefits of polygeneration configurations with reference to the base case. The objective functions are estimated by performing TRNSYS simulation for one year with a half an hour time resolution. The electricity and cooling demands are defined on half an hourly basis and are available thanks to smart meters connected directly with the building. Fig. 2 shows representative weekly electrical and cooling demand, a segment of yearly demands considered in this study. Other crucial input data such as fuel price, Singapore weather data, future projections are assumed for all scenarios. The economic analysis was carried out based on 30 years project lifetime. Given those input data, by solving the multi-objective optimization problem, the Pareto front, consisting of the best possible trade-offs between the two objectives, can be obtained. Each point of the Pareto front corresponds to a different operation strategy of the DES. The operators of DESs can choose the operation strategy from the Pareto front based on the economic and environmental priorities.



(a) (b)

Fig. 4. Weekly electricity (a) and cooling (b) demands for the building located in NTU campus.

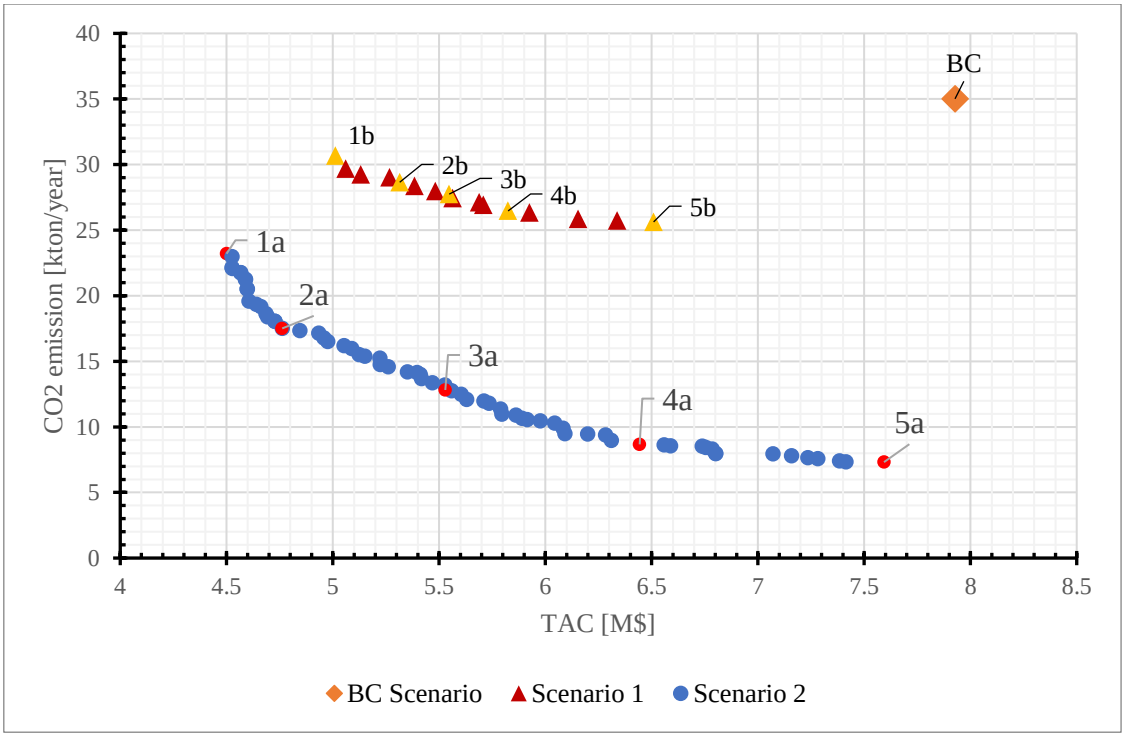


Fig. 5. Pareto front for Scenario 1 and Scenario 2.

In order to understand how the operation strategies of the DES affect the TAC and the CO2 emission, the results at various trade-off points are shown in **Fig. 5** illustrating the Pareto Fronts obtained for both scenarios. For the sake of comparison, the optimal point of operation for the baseline case scenario previously computed in Ref.[18] has been added in **Fig. 5**. Indeed, the baseline scenario represents the business-as-usual configuration where the utility grid provides the electricity to cover the electric and cooling demand and therefore the electricity cost is predominant (≈95 %) compared to all the other TAC cost components. From **Fig. 5**, it can be noticed that for all scenarios the TAC and the carbon emissions are conflicting objectives, i.e. the higher the TAC is the lower the carbon emissions are.

For both scenarios, all the optimal solutions outperform the baseline scenario both in terms of TAC and CO_2 emissions. Furthermore, the optimized solutions of Scenario 1 experience a lower variance of the objective functions compared to scenario 2 with average values of 5.6 MUSD and 27.67 ktonCO$_2$/year for the TAC and CO2 emissions, respectively. The reason for this is the smaller number of available technologies, hence there are less degrees of freedom. Despite a quite evident environmental benefits due to the introduction of renewables and electric energy storage with an average decrease of the CO_2 emissions (13.88 ktonCO$_2$/year), Scenario 2 provides a more diversity pool of optimal solutions with similar average of the TAC compared to Scenario 1. In order to provide a more accurate analysis of the results, for each scenario, component sizes for five different solutions (highlighted in **Fig. 5**) are evaluated. For each solution the component sizes are numerically reported in **Table 3** while the different TAC cost breakdown are plotted in **Fig. 6**-**Fig. 7**. As previously mentioned, Fig. 4 can be utilized by the operators of the cryo-polygeneration system to economically and environmentally assess different design point of the plant, helping thus identifying balancing solution to simultaneously promote cost savings and sustainability. Indeed, by looking at the five different solutions in the two Pareto fronts in **Fig. 5**, it can be noticed that for the same TAC user can choose solution 4a instead of solution 5b to gain ≈66% environmental benefits in terms of carbon emissions. Another potential greener choice would be selecting solution 2a in place of solution 1a to reduce 25% carbon emissions at the expense of only ≈6% increase in TAC.

In Scenario 2, it is evident that, as solutions move towards the carbon emissions objective the capacity of less carbon intensive technologies, such as PV and BESS, is increased, simultaneously reducing the GT capacity. The absorption chiller capacities follow the same trend of the gas turbines with a general decrease due to the reduction of the available waste heat at the GT outlet. As a result, the size of the WCC increases to balance the reduction of the cooling fulfilled by the ABC. Nevertheless, as shown in **Fig. 8a**, reporting the ratio of the current ABC capacity to the potential

ABC capacity exploiting 100 % of the waste heat available (f_{ABC}), it can be seen that it is not anymore economically convenient to enhance the ABC capacity. Indeed, when the PV capacity started to be predominant over the gas turbine, part of the green electricity produced by the PV is conveyed to cover the electricity consumption of the WCC, whose technology is significantly cheaper than absorption chiller. As a result, the maximum available potential capacity of ABC is not fully exploited and the ratio f_{ABC} decreases along the Pareto front. Conversely in Scenario 1 (**Fig. 8b**), since PV is not considered in the optimization search space, the ratio f_{ABC} increases as the GT capacity decreases in order to maximize the exploitation of the available waste heat.

Table 3. Optimal Technologies capacities from Multi-objective optimization for 5 different solutions.

Solutions	P_{GT} [kW_e]	Q_{ABC}[kW_c]	Q_{WCC} [kW_c]	P_{PV} [MW_p]	V_{CTES} [m^3]	C_{EES} [MWh_e]	TAC [M$]	CO2 em [kton/year]
Scenario 2								
1a	4532	8373	6285	6700	4783	2.69	4.50	23.20
2a	3346	6074	10107	14629	3109	3.58	4.76	17.51
3a	2488	3463	10405	20494	3494	21.42	5.53	12.82
4a	2260	2569	10669	22793	3483	50.98	6.44	8.67
5a	2254	2453	11029	22841	3955	73.95	7.59	7.31
Scenario 1								
1b	5389	7862	4742	-	3098	-	5.01	30.68
2b	3895	7238	4763	-	3235	-	5.31	28.65
3b	3375	7217	5298	-	3423	-	5.55	27.75
4b	2682	6084	5379	-	3554	-	5.82	26.47
5b	1754	4085	7646	-	3675	-	6.51	25.63

By evaluating the TAC breakdown of the different optimal points for both Scenarios (**Fig. 6**-**Fig. 7**), different optimal strategies can be identified. Indeed, the analysis of the inhomogeneous distribution of the main cost components' shares within the TAC provides further insights to explain the economic and environmental performance of the cryo-polygeneration system at the different optimal points. Since Scenario 1 relies only on the electricity provided by the GT and the electric grid, the operational costs due to fossil fuels consumption (Fuel_cost) and the ones due to the electric grid (OpexUG and Opex_capacity) are inversely proportional shifting to greener configurations. In addition, due to the decrease of the GT and ABC capacity, the CAPEX share in the TAC tends to decrease as well. Conversely, in Scenario 2, moving from solution 1 to solution 5 characterized by lower CO_2 emissions, the CAPEX becomes predominant with the highest TAC share (≈71 %) followed by operational cost due to the electricity grid (≈15 %). Indeed, in order to guarantee lower CO_2 emissions, the optimization algorithm prefers to enhance the capacity installation of the most expensive technologies such as PV and BESS, at the cost of sacrificing the TAC of the plant exponentially increased with the CAPEX. Simultaneously, despite the highest PV (23 MW_p) and BESS (73 MWh_e) capacities adopted for solution 5, the cryo-polygeneration system does not manage to satisfy the electricity peaks further increasing the necessity to tap into the electricity grid. This is particularly verified for intermediate solutions (2-3) while the operational cost due to the electricity grid starts to decrease for solution 4-5 with the heavily installation of the BESS capacity capable to partially satisfy the peak of the electric demand.

4. Conclusions

This paper discussed a design multi-objective optimization framework of novel cryo-polygeneration systems consisting of different distributed energy resources. The developed model has been applied to a real case study, a cryo-polygeneration system, expected to be operative during 2024 Q1, capable to cover the electric and cooling demand of a building located in a Singaporean university campus (NTU). The results confirm the workability of the framework that effectively determines the best possible trade-offs (Pareto fronts) between the total annualized cost and CO_2 emission. Thus, the operators of DESs can choose the operation strategy from the Pareto front based on their cost and environmental priorities. The results also indicates that the implementation of renewables and electric energy storage in the cryo-polygeneration system (2^{nd} scenario) has significant economic and environmental benefits over the 1^{st} scenario, reducing the total annualized cost and the carbon emissions up to 30 % and 10 %, respectively. Furthermore, in this scenario, by further increasing the PV and BESS capacities, different greener solutions can be achieved, although to the detriment of the total annualized cost due to the current high capital cost of the BESS. In future investigations, the model will analyze the effects of: 1) the island mode scenario; 2) PV electricity exported to the grid; 3) different operating strategies and load characteristics on the performance of cryo-polygeneration systems as well as the design of DES under uncertainty to provide more robust results; 4) the potential carbon emissions related to the construction of the decentralized energy systems.

Abstract:

District heating systems in northern Europe experience large seasonal differences in heat demand, rendering summertime profitability marginal at best. This study discusses a novel concept of a district heating substation that increases heat consumption during the summer period for the purpose of conversion into cold for an air conditioning system. Cold is generated by an adsorption chiller driven by heat from the district heating system. The study numerically models the system and examines its operation during a 24-hour period. The research indicated the need for a cold storage unit to cover cooling demand when ambient temperature limits the operation of the chiller. Additionally, a heat storage unit is required in order to equalize heat consumption from the district heating network.

Keywords:

District heating network, district heating substation, adsorption chillers, PCM storage

1. Introduction

District heating networks (DHNs) are a key element in strategies designed to meet the goals set by the European Union's Renewable Energy Directive [1] as they help deliver reductions in emissions of greenhouse gases among other things. This study deals with bolstering the profitability of DHNs by increasing heat consumption during the summer period [2]. In Poland, the typical heat consumption curve in a DHN is extremely seasonal, with the ratio of summer to winter heat demand being 1:10, as shown in Figure 1 below.

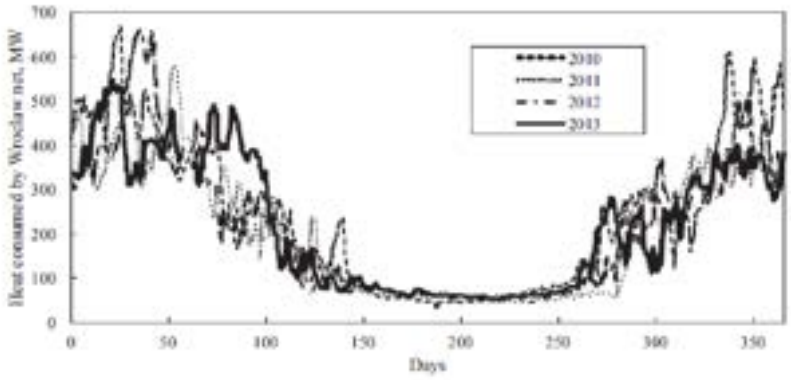

Figure. 1. Annual profile of heat consumption in a mid-sized Polish city, as per Chorowski [3]

Researchers report very similar heat demand profiles in other European countries, e.g., in the Netherlands [4] and Finland [5]. Extreme seasonal fluctuations put the profitability of DHNs into question and this issue is driving research into increasing heat consumption during the summer period. A review of district heating and cooling systems by Lake [6] concluded that DHNs could be enhanced with new technologies. The author cited thermal energy storage and absorption chillers as possible avenues to increase DHN efficiency.

The idea of cold district heating is widely discussed in the available literature [7], which defines it as cold water distribution in the range 10°C to 25°C. Pellegrini [7] notes that water cooling in such systems is done by electric reversible heat pumps. However, these pumps increase electricity consumption and fail to make use of the DHN. In contrast, replacing compressor heat pumps with adsorption refrigeration units boosts summertime consumption of heat thereby reducing summertime heat losses.

Grzebielec et al. [8] examined the possibility of using an adsorption refrigeration unit in a district heating substation (DHS). The authors concluded that it is feasible to use adsorption heat pumps for cold generation, and that this appears to be a promising solution because it uses existing infrastructure for cold generation on the customer's side without requiring long-distance cold transmission. Halon et al. [9] reported on an adsorption heat pump driven by heat from the DHS. The heating temperature was 55°C and the released heat was directed to a rooftop cooling tower.

Wu et al. [10] analyzed a composite heating substation with another type of absorption heat pump with water-LiBr as the working agent and a two-plate heat exchanger. The paper sought to improve the utilization efficiency of geothermal water and the primary supply water.

Another idea of improving DHS efficiency was reported by Turski [2], where the authors compared a 150 kW DHS operating with and without a heat storage accumulator: heat storage accumulators improved the efficiency of the entire heating system by 22%.

McNally et al. [12] experimentally investigated the performance of an adsorption chiller operation in two modes:

- Constant hot water temperature – to represent the DHN.
- Varying hot water temperature – to represent the heat from flat plate solar collectors.

The temperature variations of hot water impacted performance more than the flow variations. Therefore, adsorption chillers are suitable for use with DHNs.

The issue limiting the integration of adsorption chillers for cold generation is the temperature of the heating medium, which is too low for commercial adsorption heat pumps. The temperature of the available heat source could be raised by upgrading the substation with thermal storage tanks linked to renewables [15]. A promising heat storage technology is the PCM storage unit, as it requires 40% less volume than a water-based heat accumulator [13]. Due to a paucity of publicly available information, the potential of PCM heat storage is not widely recognized [14]. The influence of using heat storage with PCM on inlet and outlet temperatures in substations was investigated by Nogaj et al. [15]. The authors examined the integration of PCM with a single-function substation whose thermal power is 150 kW. Once the PCM was integrated, the difference in average return water temperature fell from 7.15K to 2.29K. This allowed the accumulation of 69.5% of excess heat and improved the efficiency of the entire heating system by 22%. The authors concluded the use of PCM accumulators gives potential energy savings of up to 6.7%.

1.1. Paper objective

A review of available literature indicates an opportunity to implement new technologies in DHNs in order to achieve enhanced efficiency. The study models a novel hybrid district heating substation designed to ensure increased summertime heat consumption; the period when heat losses peak due to very low heat consumption. The concept is to supplement the DHS with an adsorption chiller, which will be used to generate cooling for the air conditioning system of a building. The proposed solution uses existing DHN infrastructure for trigeneration and generates cooling directly on site. Thus, heat from the hybrid district heating hub will be used for heating the building in winter, and in summer will drive a chiller for air conditioning needs.

This paper introduces the following novelties:

- Concept of a novel hybrid DHS for cold generation
- Integration of PCM heat and cold storage units for heat load consumption equalization and to provide cold for air conditioning systems in very hot periods.

The concept is verified with a numerical study, which examined system behavior in Polish conditions.

2. Theory

The substation is a key element of the DHN, which is responsible for transferring heat from the medium that circulates in the DHN to the internal heating system inside buildings. Currently, summertime use of heat is very low. Integrating the cooling loop in the DHN would boost summertime heat consumption as it will be used for cold generation by adsorption heat pumps.

The general concept of the hybrid DHS is shown in Figure 1. The main system elements are an adsorption heat pump, DHS heat exchangers, and cold and heat storage units. The idea is to deliver cold for an office air conditioning system. The DHS is tasked primarily with producing cold by means of an adsorption chiller driven by heat from the DHN. The DHS is also equipped with cold and heat storage units. The heat storage unit is used to equalize heat consumption from the DHN, while the cold storage unit covers peak cooling demand

from the storage units. Thus, the installed capacity of the adsorption chiller could be lower in terms of power than the maximum peak power and its operation will be smoother.

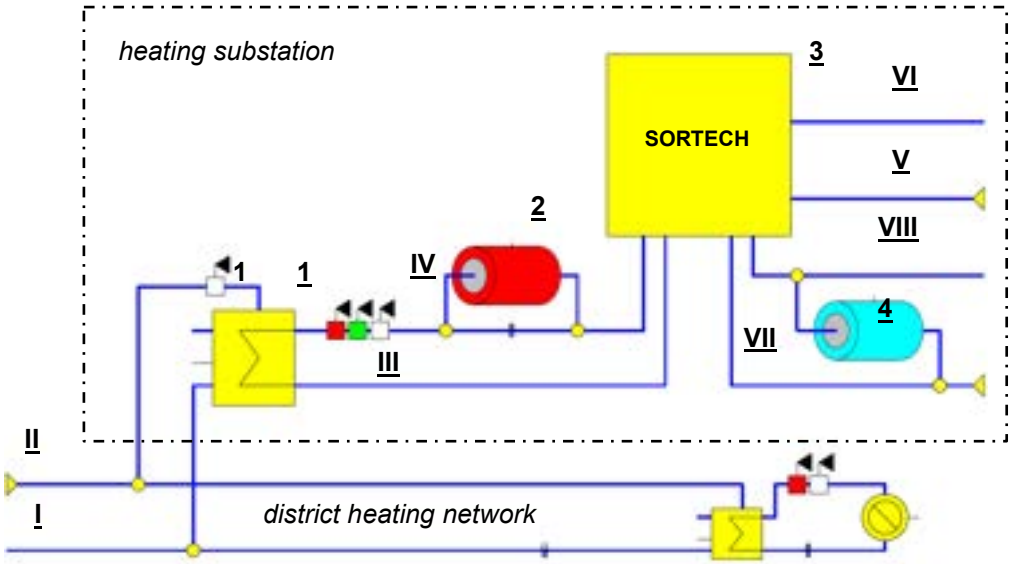

Figure 2. Topology of a hybrid DHS, (1) heat exchanger, (2) PCM for heat storage, (3) adsorption chiller, (4) PCM for cold storage

The thermodynamic parameters for the nominal operating points are shown in the table 1. The points from the table correspond to the above topology diagram.

Table 1. Basic thermodynamic parameters

Point	Temperature	Mass flow rate	Comment
I	65.0°C	10 kg/s	DHS heat supply pipe
II	64.5°C	10 kg/s	DHS return pipe
III	55.0°C	0.607 kg/s	Return pipe
IV	60.0°C	0.607 kg/s	Heat for driving adsorption heat pump
V	28.2°C	1.33 kg/s	Return from dry cooler
VI	25.0°C	1.33 kg/s	Heat for dry cooler
VII	16.0°C	0.806 kg/s	Cold for air conditioning
VIII	14.3°C	0.806 kg/s	Return from air conditioning

For the purpose of this study, we assumed the DHS delivers heat and cold to an office building of total area 142 m^2, total volume 426 m^3 with 6 rooms. Cooling demand is determined by a mathematical model, where the air conditioning is to maintain the interior at a temperature not exceeding 25°C during the summer period. Air temperature inside the rooms changes as per the equation:

$$\frac{\partial T}{\partial t} m \cdot c_p = \dot{Q}_{air} + \dot{Q}_{el} + \dot{Q}_{people} + \dot{Q}_{wall,out} + \dot{Q}_{wall,in} + \dot{Q}_{floor} + \dot{Q}_{ceil} + \dot{Q}_{window} + \dot{Q}_{sun,window}, \quad (1)$$

To simplify the model, $\dot{Q}_{floor}$, $\dot{Q}_{ceil}$ and $\dot{Q}_{wall,in}$ were omitted in the final calculations. The resulting cold demand for the office is shown in Figure 2 below.

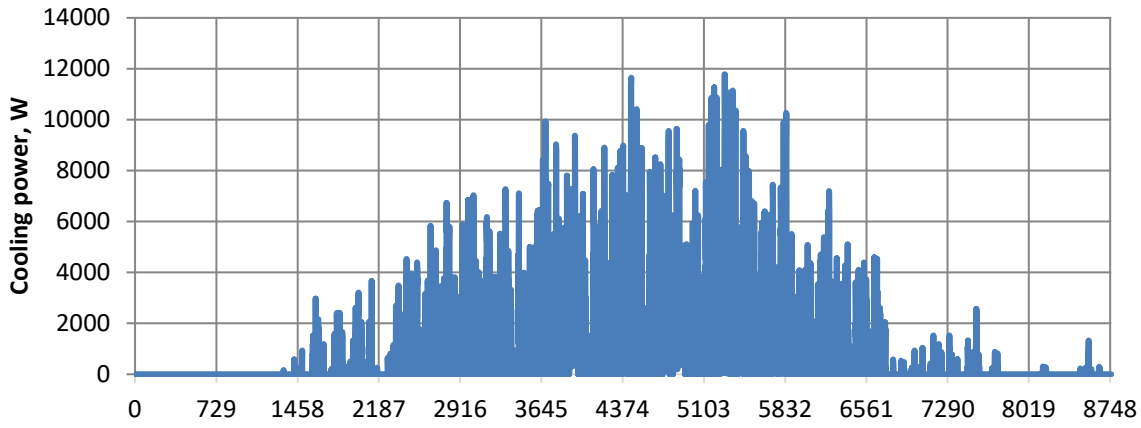

Figure 3. Demand for cooling power of the office building for each hour in the year

To investigate system behavior, the system was modeled in Ebsilon v.15, which is recognized as a robust tool for the simulation of energy systems [11,12]. The topology of the DHS implemented in Ebsilon is shown in Figure 1. The cold is generated by an adsorption chiller, which is driven by heat from the DHN. The DHS operates with SORTECH eco 2.0, which generates cooling water at a temperature of 16°C.

The basic technical data of adsorption heat pump SORTECH, eCoo 2.0 are presented in Table 2.

Table 1. Basic thermodynamic parameters

Parameter	Value
Cooling power	16 kW
Heating power	50 kW
COP	0.65 kW
The temperature of hot water	50 .. 95°C
Recooling water temperature	22 .. 40°C
Cooling water temperature	8 .. 21°C

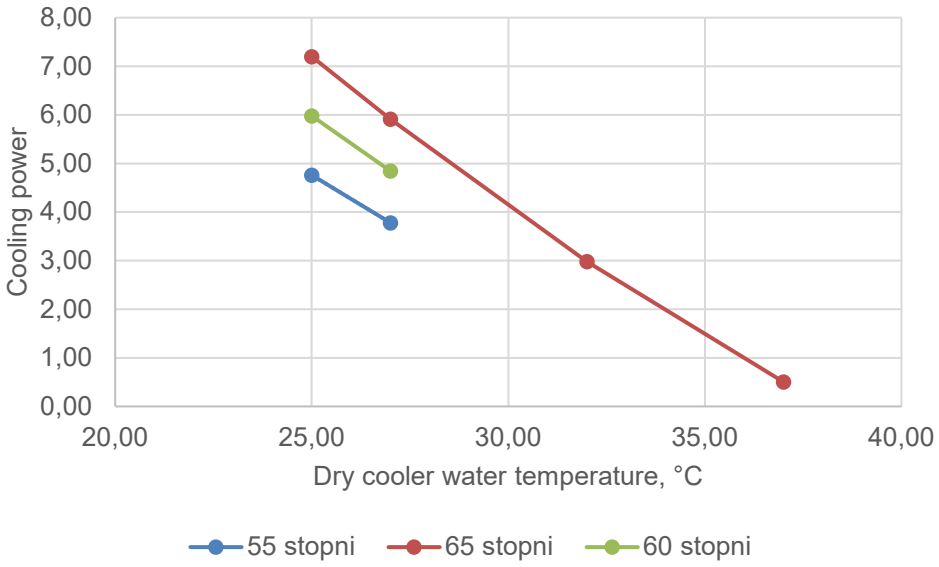

Figure 4. Cooling power of an adsorption chiller as a function of dry cooler water temperature for various temperatures of water in DHS

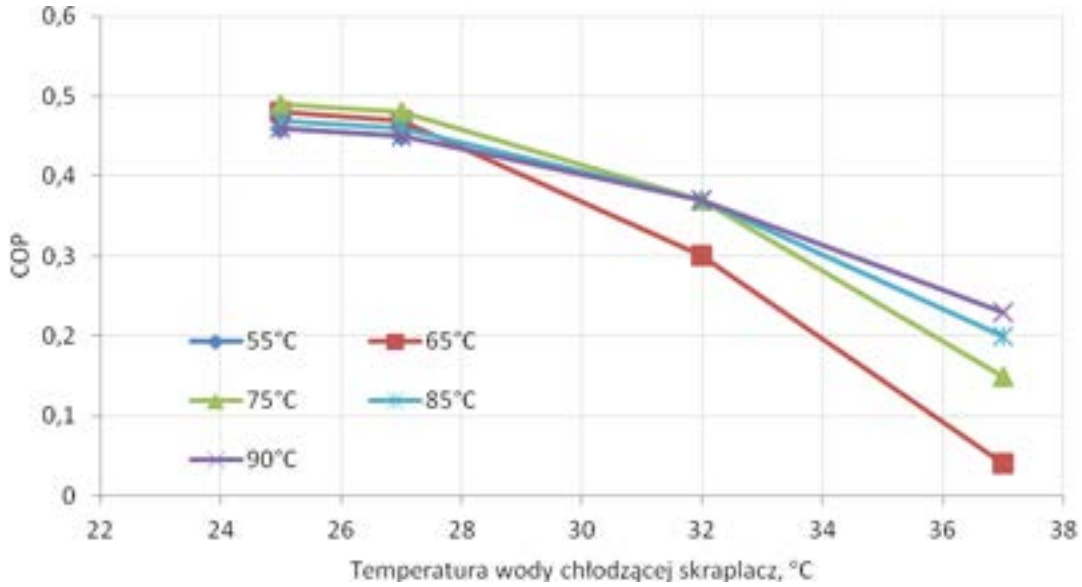

Figure 5. COP of an adsorption chiller as a function of cooling water, for various temperatures of DHS

For simulation purposes, we implemented SORTECH characteristics to determine the performance of an adsorption chiller. The adsorption chiller power as a function of cooling water is shown in Figure 3. The system is driven by the water network at temperature 60°C. Figure 4 shows that the COP of the chiller reaches very low values when the cooler water temperature rises above 34°C. Thus, a higher temperature of the driving source is required in order to increase COP. However, as the driving source is the DHN, it is not always possible to increase the temperature.

The DHS has two PCM storage units for storing heat and cold. CrodaTherm 60 PCM and CrodaTherm 15 were selected for heat and cold storage, respectively. Their storage properties are shown in Fig. 5.

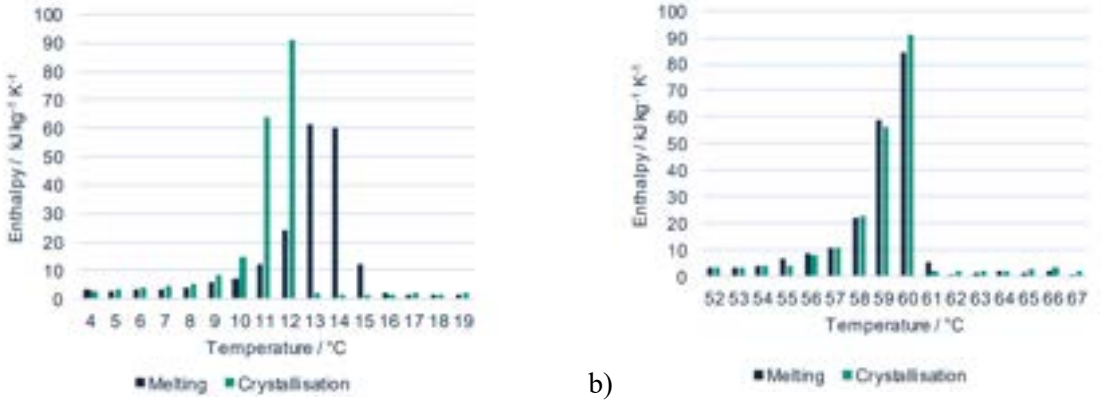

Figure 6. Thermal profile of heat and cold storage units, a) and b) respectively

The PCM storage units are simulated by component 119 Indirect Storage, which calculates the non-steady state heat exchange of the material with the fluid that flows through and around it. Based on the initial state of the temperature field, component 119 calculates the change in the temperature field of the pipe due to a change of the determining factors within a defined period of time. The determining factors are defined by the specification values of the component and by the state variables of the fluid at the component inlet. For the purpose of the study, the characteristics curve for heat and cold storage PCM, respectively, were implemented for this component, as shown in Fig. 5a and 5b.

3.Results

The behavior of the hybrid DHS was tested on operational data from the DHN in the town of Ostrołęka in northeastern Poland. The DHN operates at varying water flow rates and supply temperatures. The design operating temperature is 120/65°C, which corresponds to ambient temperature -20°C. The summertime heating medium is 65°C and the return water is 50°C. The heating medium is water, whose pressure is 0.9 MPa and 0.2 MPa during winter and summer, respectively. The temperature variations with respect to ambient temperature are shown in Fig. 7.

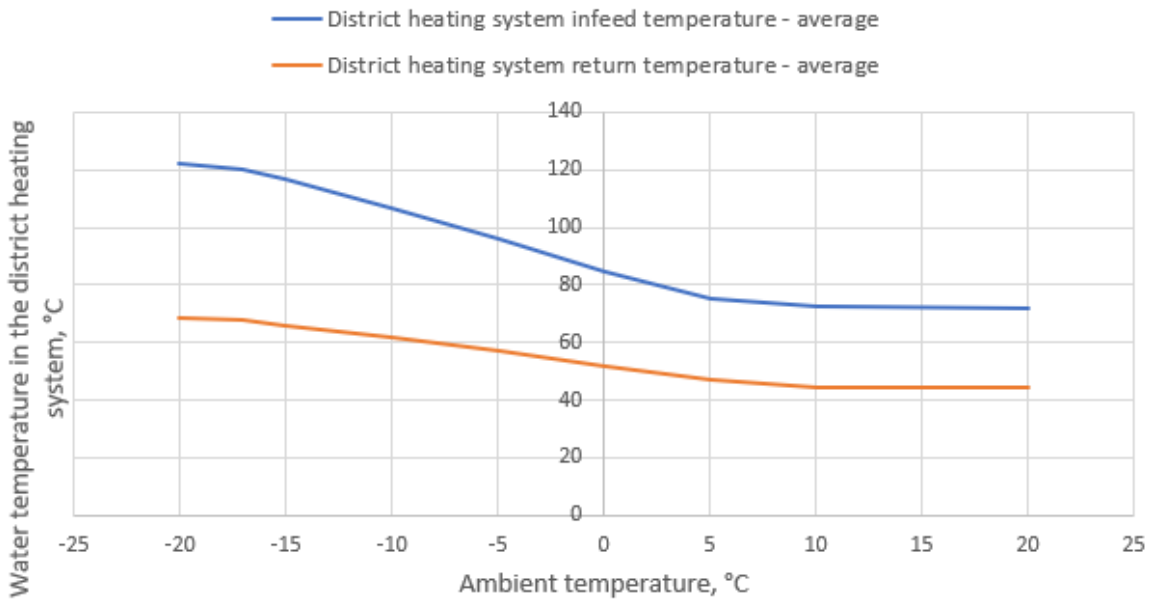

Figure 7. Hot and cold pipe temperature variations as a function of ambient temperature

The behavior of the novel hybrid DHS was examined during a 24-hour sunny summer day operation. Demand for cold and ambient temperature are shown in Figure 6 below.

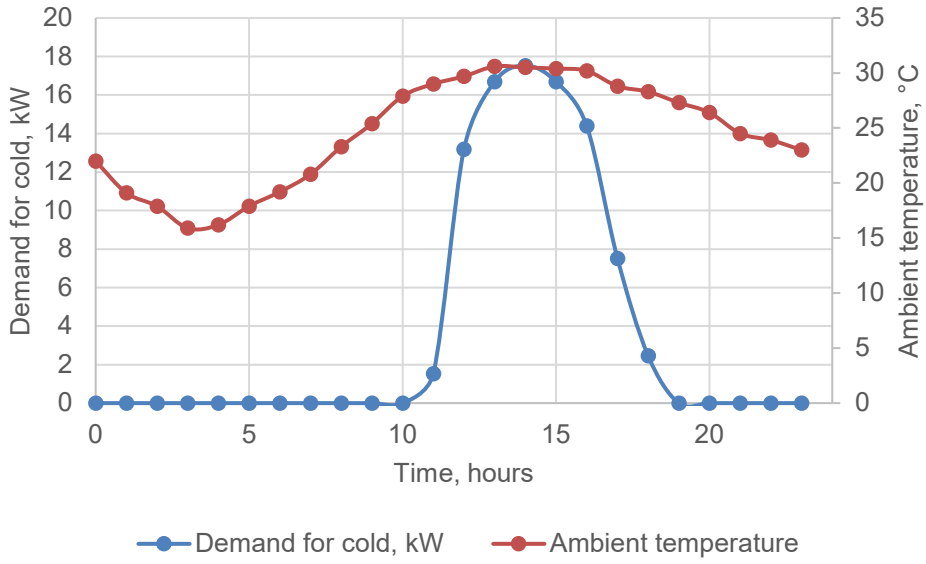

Figure 8. Adsorption chiller power as a function of hour of day

Firstly, the study revealed that the adsorption chiller does not operate when the ambient temperature exceeds 25°C (see Figure 7). Therefore, either the refrigeration technology must change or a cold storage facility is required. A cold storage unit was selected, as it can cover demand for cold during hot periods.

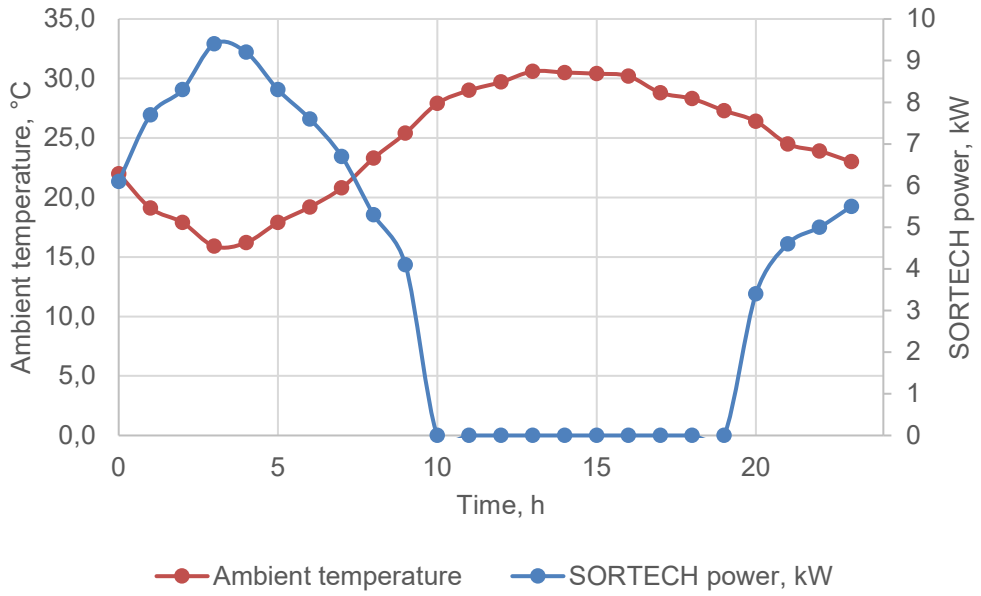

Figure 9. Adsorption chiller power during the day

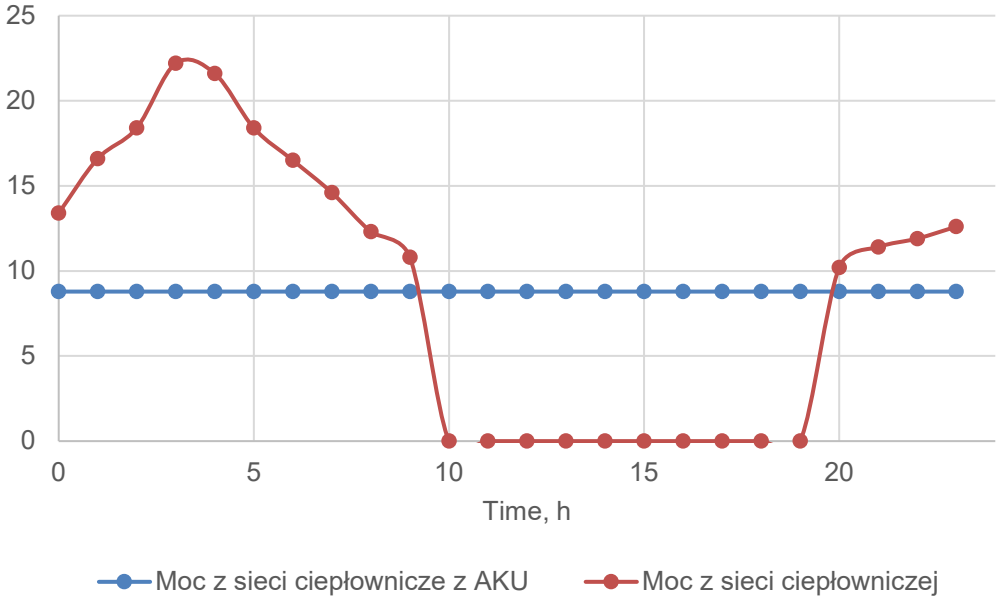

Figure 10 Heat consumption with system with PCM heat storage (blue line) and without (red line)

Figure 10 shows heat consumption from the DHN for two scenarios: operation with and without a heat storage accumulator. The implementation of heat storage enables constant heat consumption by the DHS.

The loading/unloading curves of heat and cold storage units are shown in Figure 9.

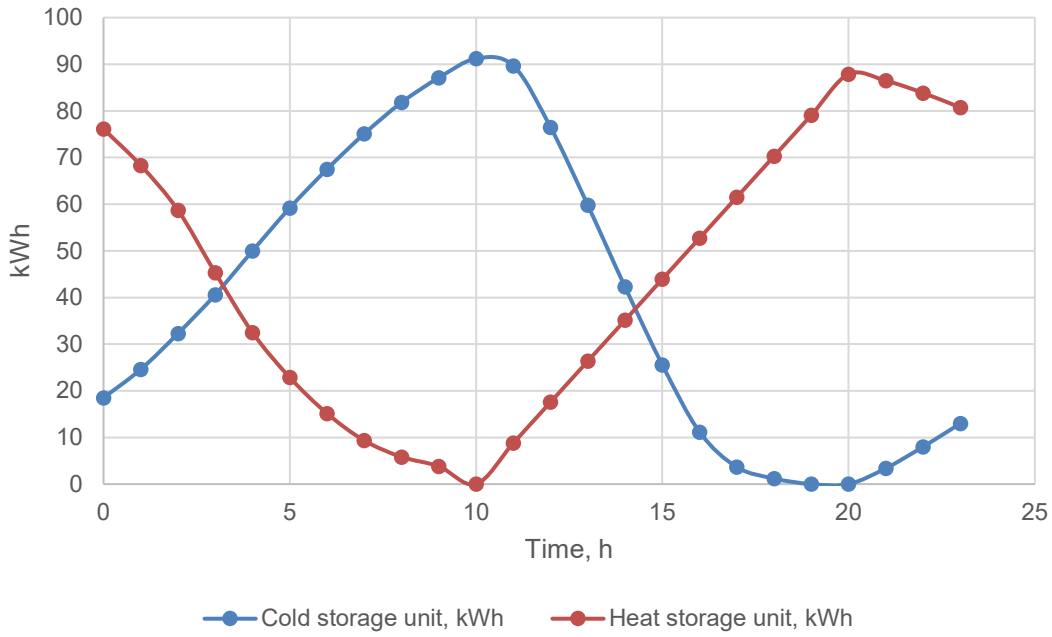

Figure. 11. Loading and unloading curves for heat and cold storage units

The above chart shows that the heat storage units are loaded until 10 am and when the adsorption chiller is unable to operate due to the high ambient temperature, heat storage loading begins (red line).

4. Conclusions

The aim of the research was to examine the concept of a hybrid district heating substation for heat and cold generation. The operation of the DHS was examined using representative data from the system operating in a small city in northeastern Poland, where the summertime temperature of the medium is 65°C. The DHS was assumed to deliver cold for an office air conditioning system. Cold was generated by an adsorption heat pump (SORTECH eCO 2.0) supported by two accumulators: for heat and cold storage.

Operation of the system was simulated across a 24-hour period on a sunny day, when ambient temperature reaches the maximum possible value of 30°C. The examination revealed there is a limiting ambient temperature for the selected adsorption heat pump, i.e., it is unable to operate when the ambient temperature exceeds 25°C, and the cold for the office air conditioning system has to be supplied from the PCM cold storage unit. System operation indicated a need to use a heat storage accumulator to equalize heat consumption, which should reduce summertime heat losses from the DHS.

To conclude, the numerical study proved the concept for the novel hybrid DHS and indicated the operating limits for this technology. The main advantage of our solution is the ability to use existing heating infrastructure to generate cooling with adsorption chillers. This reduces electricity consumption for air conditioning and boosts summertime heat consumption, increasing the efficiency of the DHN. The preliminary study revealed that the modeled DHS is a promising solution to increase heat consumption during the summer period, which should deliver increased profitability for DHNs. However, more detailed study is required to optimize PCM storage tanks and control strategy selection.

ACKNOWLEDGEMENTS

This work was financially supported by the National Research and Development Center in Poland in the framework of the POIR.04.01.04-00-0100/17-00 research project "Innovative heat and cold storage with PCM, operating in a modern installation intended to generate system heat", project acronym: Innostorage.

Nomenclature

DHS	district heating substation
DHN	district heating network

T	indoor temperature
m	mass of the air,
c_p	specific heat of the air,
$\dot{Q}_{air}$	heat exchanged via ventilation,
$\dot{Q}_{el}$	heat gain from electric devices,
$\dot{Q}_{people}$	heat coming from people inside,
$\dot{Q}_{wall,out}$	heat exchanged via convection on the outer walls,
$\dot{Q}_{wall,in}$	heat exchanged via convection on the inner walls,
$\dot{Q}_{floor}$	heat exchanged via convection on the floor,
$\dot{Q}_{ceil}$	heat exchanged via convection on the ceiling,
$\dot{Q}_{window}$	heat exchanged via convection on the windows
$\dot{Q}_{sun,window}$	heat exchanged via solar radiation through the windows.

Quantifying Demand Flexibilities of Buildings for an optimal Design and Operation of integrated District Energy Systems

Kai Niklas George[a], Michael Rath[a,b], Rolf Bracke[a,c]

[a] Fraunhofer Research Institution for Energy Infrastructures and Geothermal Systems (IEG), Bochum, Germany, kai.george@ieg.fraunhofer.de,

Abstract:

The EU's ambitious climate targets have highlighted the need for novel methodologies in the integrated energy system planning and the development of sector-coupled operation strategies. In order to balance generation and consumption in the electricity grid with a high share of renewable energies, energy storage potentials have to be utilized across all sectors and new demand-side management strategies have to be developed. The energy storage potentials of buildings could benefit the grid stability and support the exploitation of renewable energy sources. Still, these potentials are not well quantified and are not considered in today's planning methods for district energy systems. This paper presents the derivation of widely applicable linear building models that capture both detailed demand characteristics and storage characteristics from dynamic building simulations, while accounting for thermal comfort. These models are integrated into linear energy system optimization models, enabling the hourly optimization of air source heat pump operation and the heat emittance into the buildings. The resulting approach allows for the quantification of flexibility indicators and provides insights into efficient operation strategies for buildings with varying thermal characteristics. The results indicate that all investigated buildings show economically viable potential for utilizing their thermal flexibility. While well-insulated buildings demonstrate higher potential for longer-lasting preheating and storage periods, still buildings with poor or moderate insulation also offer potential for shorter periods of utilization.

Keywords:

Building demand flexibility; Building simulation; District energy system planning; Energy system optimization.

1. Introduction

With the agreement of the UN Climate Conference in Paris in 2015, 195 parties worldwide agreed to limit global warming to below 2 °C compared to pre-industrial levels and to reduce greenhouse gas emissions worldwide. As a result, with the European Green Deal, the EU has set itself the goal of zero net greenhouse gas emissions by 2050 [1]. This requires far-reaching measures in many areas and a drastic turnaround in the energy sector in particular. In 2019 over 53.1% of total final energy consumption in Germany was required for heating [2], with just 14.9 % coming from renewables [3]. This leaves the heating sector facing a challenging transformation. According to the German Ministry for Economic Affairs and Energy [4], the building sector, was the largest end energy consumer in Germany in 2020 with a share of 43.8 %, consisting of private households as well as commercial, trade and service properties. If the expansion of renewable electricity generation is driven forward, sector coupling technologies such as power-to-heat will strongly increase in importance [5]. Growing shares of renewable energy in the energy system lead to higher fluctuations in the power generation and creates a growing need to adapt the demand to the fluctuating generation. Therefore, demand side management of buildings, districts and district heating networks can play a crucial role in exploiting renewable energy sources.

1.1. State-of-the-art

According to the IEA-EBC Annex 67 [6], energy flexibility of buildings needs to be utilized across a large share of buildings and districts, in order to meet the minimum energy reduction to supply grid services and integrate sufficient amounts of renewable energy. The IEA EBC Annex 67 defines energy flexibility of buildings as: "*the ability to manage demand and generation according to local climate conditions, user needs, and energy network requirements. Energy Flexibility of buildings will thus allow for demand side management / load control and thereby demand response based on the requirements of the surrounding energy networks*." [6]. To provide demand side management, both energy and power adaptions of the demand side are of interest, as well as

the time in which they can be provided [7]. Demand side management includes all measures modifying the demand, including permanent retrofitting measures like renovations [8]. Demand response on the other hand is a subset of demand side management and only covers non-permanent actions, including load shifting and load shedding [8]. In this terminology the energy flexibility of a building is understood as the potential for demand response actions. Therefore, energy flexibility of buildings can be provided on the one hand by storing energy in batteries, in hot water tanks or inside the thermal mass of buildings and on the other hand by shifting the generation in time or by switching to other generation sources [9].

1.2. Flexibility indicators

Reynders et al. [10] review common quantification methods for the flexibility of buildings and identify three common characteristics: *i) temporal flexibility, ii) amplitude of power modulation and iii) the associated costs*. Reynders et al. [11] introduce a generic quantification method for thermal energy flexibility in buildings. As a key indicator they define the available capacity for active demand response C_{ADR} which can be used to quantify upward flexibility and describes the amount of surplus heat, that is additionally emitted into the building before the demand is reduced:

$$C_{ADR} = \int_0^{I_{ADR}} \left(\dot{Q}_{ADR} - \dot{Q}_{Ref}\right) dt. \tag{1}$$

Where I_{ADR} is the duration of the active demand response, $\dot{Q}_{ADR}$ the adapted heat flow during the time of the demand response and $\dot{Q}_{Ref}$ the reference heat flow, that would occur without the demand adaption. They further introduce an efficiency indicator as the ratio between the demand reduction achievable through the demand response event and the additional demand required to achieve the reduced demand:

$$\eta_{ADR} = \frac{Demand\ Reduction}{Add.Demand} = 1 - \frac{\int_0^{\infty} \left(\dot{Q}_{ADR} - \dot{Q}_{Ref}\right) dt}{C_{ADR}}. \tag{2}$$

Kathirgamanathan and Péan et al. [9] analyse three adaptions of these indicators that are used in further literature [12–14]. They find that all indicators show relatively high robustness to different building types, climates and control schemes and consolidate a generic indicator for the available capacity as presented in equation (1). The indicator describing the efficiency of the demand response can vary between different applications and depends on the point of view of the stakeholder. Kathirgamanathan and Péan et al. show that different definitions are necessary to distinguish between downward flexibility, a shift of the generation to later times, and upward flexibility, a shift of the generation to earlier times.

A third indicator introduced by Reynders et al. [11] is the power shifting capability t_δ of the buildings. The power shift $\dot{Q}_\delta$ is described as the difference between the actual heating power during the demand response $\dot{Q}_{ADR}$ and the heating power that would occur during standard operation $\dot{Q}_{ref}$:

$$\dot{Q}_\delta = \dot{Q}_{ADR} - \dot{Q}_{ref}. \tag{3}$$

The power shifting capability t_δ is defined as the duration this shift can be maintained without violating the restrictions of the building zone temperature for thermal comfort:

$$t_\delta = t\left(\dot{Q}_\delta\right). \tag{4}$$

1.3. Quantification of flexibility in buildings

Vandermeulen et al. [15] evaluates the energy flexibility of buildings based on Belgian typologies with the flexibility functions introduced by [6]. They use a resistance-capacitance (RC) building models based on Protopapadaki et al. [16] and the DIN EN ISO 13790, which has been recently replaced by the DIN EN ISO 52016 [17]. Dréau and Heiselberg [18] assess the thermal flexibility of two representative buildings from the Danish building stock using detailed building simulations in EnergyPlus [19]. They show that poorly insulated buildings can still be modulated over a short period of time. Furthermore, they demonstrate that the heating system of well-insulated buildings can be shut off for more than 24 hours and the flexibility potential is highly influenced by the type of insulation and the heating emitter system. Yang et al. [20] analyse the thermal dynamics of low-energy buildings connected to a district heating system using detailed Modelica models. They optimize the strategy to unlock flexibilities inside a building connected to a district heating network using a variable heat price. Nevertheless, the planning of demand side response strategies for district energy systems is still in the beginning and planners and operators are missing the right tools to quantify the flexibilities of their district energy systems and identify potential savings in the energy import costs and investments. In addition to monetary reductions, modelling the flexibility of buildings can also identify more efficient integration strategies of available renewable energy sources.

1.4. Modelling the thermal flexibility of buildings in energy system optimization frameworks

There are lots of existing frameworks and different approaches to optimize the operation or the design of district energy systems. The most common approaches are mixed-integer linear programming (MILP) models and include linear formulations of components like sinks, sources, busses, transformers and storages. This

allows the representation of most elements in an energy system. The application of these frameworks usually requires connecting and parameterizing these components to create the mathematical expression of the overall optimization model. Nevertheless, the structure of only a few abstract components in energy system optimization frameworks has its limitations. When it comes to characterizing flexibilities in the building operation, simple sinks with fixed demand time series are no longer sufficient. Therefore, [21] and [22] introduce a demand model in the optimization framework oemof [23], capable of providing upper and lower capacities for demand responses. Kotzur [24] includes a 5R1C building model in their frameworks that was introduced by [25]. Both use the indoor room temperature as a variable in their models and optimize the temperature inside certain boundaries. It allows a flexible operation of the heating system while integrating one capacity for the whole building. However, as shown in Bacher et al. [26], low order RC models are not always sufficient to represent the thermal dynamics of the buildings. Hence, these methods usually do not take into account the limitations in the power shift, which is caused by the inertia of the heat transfer mechanisms and the time required for the heat to reach the deeper parts of the buildings. This highlights the need for a procedure to estimate these limits and quantify the storage properties of the buildings. Therefore, detailed building models and simulations are necessary to quantify the heat transfer from the room into different layers of the building.

1.5. Quantifying thermal demand flexibilities for a selection of representative buildings

The aim of this paper is to quantify and analyze the thermal demand flexibilities of a selection of representative buildings in Germany, with a focus on utilizing the models in the diverse planning processes of district energy systems. Therefore, a procedure is presented to model thermal flexibilities in buildings for energy system optimization frameworks, using the building database TABULA/episcope [27] and the building simulation standard EN ISO 52016 [17]. The potential of utilizing the flexibility of the building selection is analysed in an existing energy system optimization framework and established flexibility indicators are calculated. By not being oversimplified and yet easy to apply, the method presented in this paper can assist planners of district energy systems to quantify the demand response potentials, identify optimal design and operation strategies or integrate new renewable energy sources more efficiently. This enables the evaluation of thermal flexibilities for diverse applications in the planning of district energy systems.

2. Method

In this section, a procedure is presented to quantify the thermal flexibility of a selection of buildings from the German building stock. First, the chosen buildings analysed in this work are presented. Then, the building simulation model is introduced, that is used to analyse the dynamic heat transfer mechanism for each building. Afterwards, a procedure to determine the thermal storage characteristics of the buildings is presented and the building model for the energy system optimization is displayed. Last, the chosen energy system optimization framework and the modelling approaches to quantify the thermal demand flexibilities of the buildings are presented.

2.1. Building selection

The analysis of heating demand flexibilities in domestic buildings is carried out for a selection of building types in Germany. The building information are based on data from the European building database TABULA/episcope [27]. A single-family house (SFH) built between 1958 and 1968 is chosen as a reference. This type of building accounts for the largest share of all residential buildings in Germany, at around eight percent [28]. In addition, two further SFH are chosen, built before and after the reference building age class. All buildings have a net floor area of 160 m² and are investigated in three states of insulation. The data for geometries, heat transfer coefficients, heat losses and internal heat gains can be found in [27]. Internal solar gains are determined in hourly time steps depending on all transparent surfaces and their tilts and azimuths, using test reference year weather data from the German meteorological service (DWD) for a representative year between 2031 and 2060 [29].

2.2. Building model

To analyse the dynamic characteristics of the buildings and calculate their heating demands, the buildings are modelled and simulated according to DIN EN ISO 52016 [17]. The procedure can be used for residential and non-residential buildings and allows hourly calculations of heating and cooling demands and indoor temperatures. The calculation methods include internal solar gains, ventilation, infiltration and internal heat gains. Each building can be modelled using several zones and opaque and transparent building elements. All opaque building elements are modelled in five nodes, representing the different layers of the components. All layers are set with a heat capacities and heat transfer coefficients depending on the structures of the elements. For the zone and for each node, an energy balance is set up, taking into account the heat transfer mechanisms of conduction, convection and radiation as well as heat storage properties. Effective heat capacities of all building components are assigned according to [17] for average construction types. For simplification, it is assumed that all buildings consist of one heated zone, four walls, two roofs and six window areas, with varying orientations, as well as one floor and one door. Given a certain input, the zone temperature and all node

temperatures can be simulated. To calculate the heating demand required to maintain the set point of the indoor temperature, the energy balance of the zone can be solved for the heating and cooling demand $\dot{Q}_{demand,ref}^{building}(t)$. This modelling approach takes into account the inertia of the heat transfer mechanisms in the different layers of the building elements and is used quantify the heat demand flexibility in the buildings. It further allows to simulate ideal heating and cooling demands for fixed zone temperature setpoints.

2.3. Modelling building and it's flexibility in an energy system optimization framework

Due to diverse building types, building structures and refurbishment conditions, different buildings show varying dynamic characteristics in the heat transfer and the charging of their thermal masses. To quantify all flexibility potentials using the common indicators presented in 1, the demand response events need to be specified. An optimal demand response depends on several factors, including the availability of renewable energy sources, electricity price signals and building parameters such as insulation properties, heat capacities and current temperatures. All these variables influence the quantification of the flexibility indicators. Therefore, the buildings characteristics are integrated in a MILP energy system optimization that allows optimizing the utilization of the buildings flexibility in different applications. To model the heating demand as well as the thermal flexibilities of a building in an energy system optimization framework, a combination of a generic sink and a generic storage is selected. The chosen interconnection is shown in Figure 1. The sink is assigned with a demand time series $\dot{Q}_{demand,ref}^{building}(t)$, resulting from a building simulation based on [17] and taking into account detailed heat transfer mechanisms. The storage component is set to represents the deviation to the normal operation of the building and characterizes the additional heat storage properties and losses. It is therefore referred to as an additional virtual storage (vs). The additional heat losses of the building $\Delta\dot{Q}_{add\_loss}^{building}(t)$ and the losses of the virtual storage $\dot{Q}_{loss}^{vs}(t)$ correspond to the difference between the heating demand at an increased zone temperature $\dot{Q}_{in,increased}^{building}(t)$ and the heating demand at a normal operation $\dot{Q}_{demand,ref}^{building}(t)$:

$$\Delta\dot{Q}_{add\_loss}^{building}(t) = \dot{Q}_{loss}^{vs}(t) = \dot{Q}_{in,increased}^{building}(t) - \dot{Q}_{demand,ref}^{building}(t). \quad (5)$$

The virtual storage component is further defined by a loss rate r_{loss}^{vs}, a nominal storage capacity $C_{nominal}^{vs}$ and a limit in the inflow and outflow power $\dot{Q}_{charging}^{vs}$ and $\dot{Q}_{discharging}^{vs}$. The loss rate r_{loss}^{vs} is the fraction of lost energy per time. The heat losses of the virtual storage $\dot{Q}_{loss}^{vs}(t)$ can therefore be described as the product of the loss rate and the current energy content of the storage $E^{vs}(t)$:

$$\dot{Q}_{loss}^{vs}(t) = r_{loss}^{vs} \cdot E^{vs}(t). \quad (6)$$

Since both, the additional heat losses $\dot{Q}_{loss}^{vs}(t)$ and the storage level $E^{vs}(t)$, show an almost linear dependency on the temperature increase of the zone $\Delta T_{increased}^{Zone}$, the loss rate is assumed to be constant. It can be determined from the ratio between the maximum additional heat loss of the building with a zone temperature of 22 °C ($\dot{Q}_{loss,22°C}^{vs}$) and the storage capacity $C_{nominal}^{vs}$:

$$r_{loss}^{vs} = \frac{\dot{Q}_{loss}^{vs}(t)}{E^{vs}(t)} = \frac{\dot{Q}_{loss,22°C}^{vs}}{C_{nominal}^{vs}}. \quad (7)$$

The storage capacity is set to correspond to the amount of heat that can be stored inside the building and utilized at later times. It is therefore defined as the total heat demand decrease during the discharging event after the system is fully charged and the zone temperature is at its upper limit:

$$C_{nominal}^{vs} = \int_{I_{charged}}^{I_{discharged}} \left(\dot{Q}_{demand,ref}^{building}(t) - \dot{Q}_{in,decreased}^{building}(t)\right) dt. \quad (8)$$

While the heat flow $\dot{Q}_{demand,ref}^{building}(t)$ corresponds to heat demand that is necessary to keep the zone temperature at its lower limit in a static environment, $\dot{Q}_{in,decreased}^{building}(t)$ describes the heat demand that is necessary after the system is fully charged and has reached an equilibrium with a zone temperature at the upper limit. However, not only the storage capacity of buildings varies significantly with the year of construction and the level of insulation, but also the maximum heat flow that can additionally be emitted into the building during the charging process $\dot{Q}_{charging}^{vs}$ and the maximum heating power that can be used again at the discharging process $\dot{Q}_{discharging}^{vs}$ differ depending on the building. During the charging process, a high inflow rate can only be maintained for a short period of time, otherwise the energy cannot be transported into the deeper parts of the building and the zone temperature will exceed its limit. Therefore, a maximum heat input rate needs to be set for the internal storage component as well as a maximum heat output rate.

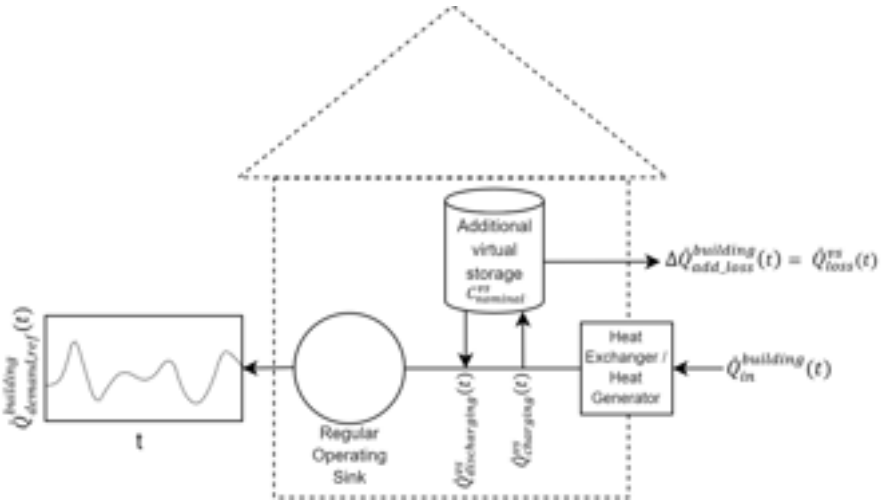

Figure 1. Approach to model the Buildings Demand and Flexibility Characteristics in the Energy System Optimization Framework.

2.4. Quantification of thermal storage characteristics

For the quantification of the storage characteristics of the buildings, building simulations are performed, in which the buildings are exposed to a lift in the indoor temperature setpoint. In this simulation, the ideal heat demand, required to maintain the zone temperature, is determined. Internal solar gains and internal heat gains are neglected in the static test environment, as for the quantification of the additional storage properties it is assumed that their influence on all zone temperature setpoints is equally effective. After an initialization period, to balance all heat transfer mechanisms, the zone temperature setpoint is lifted by a defined maximum temperature lift of 2 K from 20 °C to 22 °C. For another period, the required heat demand is calculated that keeps the zone temperature at the exact defined setpoint. The resulting demand profile defines the maximum heat input that can be emitted into the zone during an active demand response event, without exceeding the indoor temperature limit. Once the system is balanced again, the zone temperature setpoint is reset to 20°C and the reduced heat demand is calculated.

To parameterize the linear storage models of the buildings for the energy system optimization model, the additional storage capacity and the limits on the heating power must be set to constant values. Therefore, seven sets of storage parameters are determined from the simulation. Each set consists of the nominal storage capacity $C_{nominal}^{vs}$, the maximum charging heating power $\dot{Q}_{charging,max}^{vs}$, the maximum discharging heating power $\dot{Q}_{discharging,max}^{vs}$ and the heat loss rate. The sets are selected by varying the relation between the nominal storage capacity and the maximum charging heating power. The resulting relation describes the power shift capability t_δ, the duration in which the buildings can either be heated with the additional maximum charging power $\dot{Q}_{charging,max}^{vs}$ or the heat stored inside the building can be utilized again with the maximum discharging power $\dot{Q}_{discharging,max}^{vs}$, without exceeding the indoor temperature limits. In a linear building model, high power shift capabilities t_δ result in longer charging durations with lower maximum heating powers $\dot{Q}_{charging,max}^{vs}$, whereas low power shift capabilities result in the opposite.

If the power shift capability is fixed and the nominal storage capacity in this work is defined as the usable energy stored inside a building, the capacity can be determined by the product of the maximum discharging heating power $\dot{Q}_{discharging,max}^{vs}$ and the power shift capability t_δ:

$$C_{nominal}^{vs} = \dot{Q}_{discharging,max}^{vs} \cdot t_\delta. \quad (9)$$

For each set of parameters, a separate storage model is set up and used in the energy system optimization. This results in seven different flexible building models that are investigated in the following, representing different characteristics and utilization possibilities of the buildings. The best modelling approaches depend on the exact building type, its insulation, its storage properties and the exact application and are therefore analysed in an energy system optimization model.

2.5. Energy system optimization model

To determine optimal flexibility possibilities, the building characteristics, corresponding to the heating demands and the storage potentials, are integrated in the energy system optimization framework oemof [23]. The objective function is composed of the discounted investment costs of the heat generation plants c_{inv}^{hg} and the electrical energy purchases as shown in equations (10). The main additional constraints are stated in equations (11) - (13). An air source heat pump is selected as the heat generator using a variable coefficient of performance $COP^{hp}(t)$ depending on the outdoor temperature. The coefficient of performance is calculated using the correlations from [30]. The 2020 Day Ahead market prices are used as variable costs for electricity

$c_{el}(t)$. Further constant electricity levies, taxes and duties are neglected. The model optimizes the utilization of the buildings $\dot{Q}^{vs}_{charging/discharging}(t)$, the operation of the heat pump $\dot{Q}^{hp}_{out}(t)$ and the nominal heating power of the heat pump $\dot{Q}^{hp}_{nom}$ to minimize the costs for electricity C_{el} and the investment costs for the heat pump C^{hp}_{inv}:

$$\underset{\dot{Q}^{vs}_{discharging},\dot{Q}^{vs}_{charging},\dot{Q}^{hp}_{out},\dot{Q}^{hp}_{nom}}{\text{minimize}} \quad C_{total} = C_{el} + C^{hp}_{inv} = \sum_{t=0}^{8760} c_{el}(t) \cdot \frac{\dot{Q}^{hp}_{out}(t)}{COP^{hp}(t)} + c^{hp}_{inv} \cdot \dot{Q}^{hp}_{nom} \tag{10}$$

$$s.t. \quad \dot{Q}^{hp}_{out}(t) = \dot{Q}^{building}_{demand,ref}(t) - \dot{Q}^{vs}_{discharging}(t) + \dot{Q}^{vs}_{charging}(t) \tag{11}$$

$$E^{vs}(t) = E^{vs}(t-1) \cdot \left(1 - r^{vs}_{loss}(t)\right) - \dot{Q}^{vs}_{discharging}(t) + \dot{Q}^{vs}_{charging}(t) \tag{12}$$

$$\dot{Q}^{vs}_{discharging}(t) \geq 0 \text{ and } \dot{Q}^{vs}_{charging}(t) \geq 0 \text{ and } \dot{Q}^{hp}_{out}(t) \geq 0 \text{ and } \dot{Q}^{hp}_{nom} \geq 0. \tag{13}$$

The optimization is performed over a period of one year with time steps of one hour. First, for each building type and each state of refurbishment, a single optimization is performed to dimension the heat pump. Then, for each building the operation is optimized without including the investment costs for the heat generator. The results are used to calculate the annual costs reductions for electricity, when the flexibility is utilized, compared to the electricity costs of the same building without a flexible operation. Furthermore, an efficiency for the utilization of the virtual storage $C^{vs}_{nominal}$ is calculated that is based on equation (2). It is defined by the ratio between the total usable heat $\dot{Q}^{vs}_{discharging}$ and the heat that is additionally induced into the building $\dot{Q}^{vs}_{charging}$:

$$\eta_e = \frac{\int_0^{8760} \dot{Q}^{vs}_{discharging}(t)dt}{\int_0^{8760} \dot{Q}^{vs}_{charging}(t)dt}. \tag{14}$$

3. Results

In this section, the results of the individual building simulations and optimizations are introduced and the resulting flexibility indicators are presented. First, the building heating demands are presented under normal conditions without the utilization of their flexibilities. Afterwards, the results of the storage quantification procedure are displayed. Then, for all selected buildings and all storage model approaches the resulting nominal storage capacities, the maximum charging and discharging powers and the power shift capabilities are summarized. Finally, the flexibility efficiencies and the annual electricity cost savings are presented for all individual buildings.

3.1. Building heating demands

Figure 2 shows the heating demand time series $\dot{Q}^{building}_{demand,ref}(t)$ for the reference building in three different states of refurbishment under standard conditions and for a fixed indoor zone temperature. The influence of the insulation is shown in the reduction of the total heat demand as well as the reduced peaks.

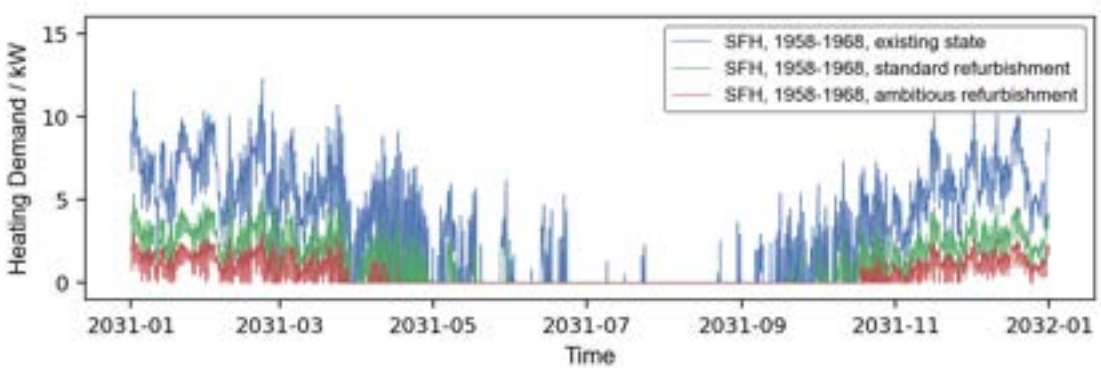

Figure 2. Heating demand time series for the reference single-family house built between 1958 and 1968 in three states of refurbishment, using weather data friom a test reference year from [29].

3.2. Quantification of individual building storage characteristics

Table 1 presents the results of the building simulations in the test environment. With a constant zone temperature of 20° C, each building balances at an individual constant heat demand $\dot{Q}^{building}_{const,20°C}$. When the zone temperature setpoint is raised from 20 °C to 22 °C, all buildings show an increase in the heat demand, that is required to meet the increased zone temperature setpoint. After reaching a maximum value of $\dot{Q}^{building}_{charge,max}$ instantly after the raise of the setpoint temperature, the demand decreases and diverges to a constant value at a zone temperature of 22 °C $\dot{Q}^{building}_{const,22°C} > \dot{Q}^{building}_{const,20°C}$. The profile describes the ideal heat input, that would keep the zone temperature at the upper value of 22 °C. The difference between the upper and lower constant

heat demand $\Delta\dot{Q}_{22°C-20°C}^{building}$ describes the additional heat losses of the building, due to the increased zone temperature. The difference in the heating demand $\Delta\dot{Q}_{22°C-20°C}^{building}$ is nearly constant and almost independent of the ambient temperature, since it only describes the additional losses compared to the heating demand under normal conditions. When the building is in balance again, the zone temperature setpoint is set back to 20 °C and the heat demand decreases in analogy to the lift of the zone temperature setpoint.

Table 1. Overview of the heating power demands in the static test environment of the selected single-family buildings with a net floor area of 160 m² and in dependence of the additional storage model approach.

Building description			Heating power demands / kW				
Building Type	Age class	State of refurbishment	$\dot{Q}_{const,20°C}^{building}$	$\dot{Q}_{const,22°C}^{building}$	$\Delta\dot{Q}_{22°C-20°C}^{building}$	$\dot{Q}_{charge,max}^{building}$	$\dot{Q}_{discharge,max}^{building}$
SFH	1919-1948	Existing state	22.41	24.71	2.30	29.84	17.20
		Standard	7.45	8.32	0.87	14.58	0.0
		Ambitious	4.07	4.61	0.54	10.99	0.0
	1958-1968	Existing state	15.81	17.48	1.67	23.08	10.20
		Standard	6.98	7.81	0.83	14.04	0.0
		Ambitious	3.85	4.38	0.53	10.74	0.0
	2010-2015	Existing state	5.58	6.27	0.69	12.53	0.0
		Standard	4.93	5.57	0.64	11.88	0.0
		Ambitious	3.21	3.68	0.47	10.04	0.0

3.3. Quantification of capacities, maximum charging and discharging powers and power shift capabilities

The results are used to determine the storage nominal capacity $C_{nominal}^{vs}$, the loss rate r_{loss}^{vs} and the maximum additional charging and discharging powers $\dot{Q}_{charging,max}^{vs}$ and $\dot{Q}_{discharging,max}^{vs}$. All parameters are calculated depending on the power shift capability t_δ, as described earlier. The results define the storage properties of the flexible building models that can be integrated in the energy system optimization. Table 2 presents the nominal virtual storage capacities $C_{nominal}^{vs}$ for all buildings and the storage model approaches.

Table **3** shows the corresponding maximum charging and discharging heating powers. Poorly-insulated buildings show their highest usable storage capacity at low power shift capabilities. The SFH built between 1919 and 1948 in an existing state of renovation reaches a nominal storage capacity of 6.58 kWh and a maximum charging power of about 1.28 kW. On the other hand, well-insulated buildings can utilize more capacity when they are charged over a longer period. The building built between 2010 and 2015 with ambitious refurbishments shows the maximum usable storage capacity at a power shift capability of 8 hours and a maximum charging power of 0.91 kW. Each building shows an increase in the utilizable capacity when the state of renovations increases. In the same time, the loss rate decreases due the better insulation of the building envelope.

3.4. Energy system optimization results

The potential of utilizing the heating flexibility is analysed in the energy system optimization model for all building types, using the different sets of parameters for the additional storage component. Figure 3 shows the difference between the optimized heat input and the heat demand without utilizing the flexibility potentials of a single-family house built between 1958 and 1968 in a standard state of renovation. While the green areas correspond to the amount of heat that is additionally emitted into the building compared to the normal operation, the blue areas illustrate the optimized decrease of the heat input. The storage component is parameterized with a nominal storage capacity of 8.78 kWh, a maximum charging power of 2.13 kW, a maximum discharging power of 2.22 kW, and a power shift capability of 4 hours. The optimized heat input is the result of the energy system optimization, which minimizes electricity import costs and leads to fluctuations in the actual zone temperature. It is shown, that the optimized heat input deviates from the original demand during a typical week in the heating period. To validate the modelling approach and the optimized building operation, the optimized heat input is integrated into the building simulation model according to the DIN EN ISO 52016. The resulting zone temperatures from the building simulation are also shown in Figure 3. The temperatures vary between 19.7 °C and 21.75 °C. Figure 4 shows the optimized heat input and the resulting indoor temperature profile in the same week for the same building but without any renovation measures. The amount of energy that can be stored inside the buildings is less, due to higher losses through the building envelope. Still, a few hours during the week can be used to take advantage of a low electricity prices. The indoor room temperatures vary between 19.9 °C and 21.4 °C during the week. The optimal energy storage duration is also less due to the higher loss rate. On the other hand, a single-family house built between 2010 and 2015 in an ambitious state of refurbishment shows a higher potential for electricity cost savings as shown in Figure 5.

Table 2. Overview of the resulting nominal storage capacities of the selected single-family buildings with a net floor area of 160 m² and in dependence of the power shift capability of the additional storage model.

Optimized building heat input and resulting zone temperature in comparison with the heating demand at a constant zone temperature of 20 °C of a single-family household built between 1958 and 1968 in a standard state of renovation. The storage component of the building model is parameterized with a charging duration of 4 hours at full charging power.

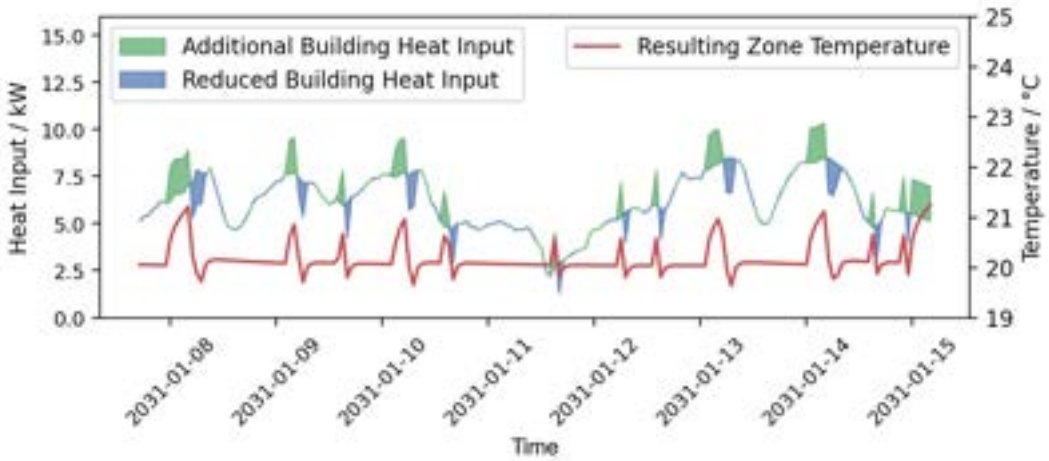

Figure 4. Optimized building heat input and resulting zone temperatures in comparison with the heating demand at a constant zone temperature of 20 °C of a single-family household built between 1958 and 1968 in the original state of renovation. The storage component of the building model is parameterized with a charging duration of 4 hours at full charging power.

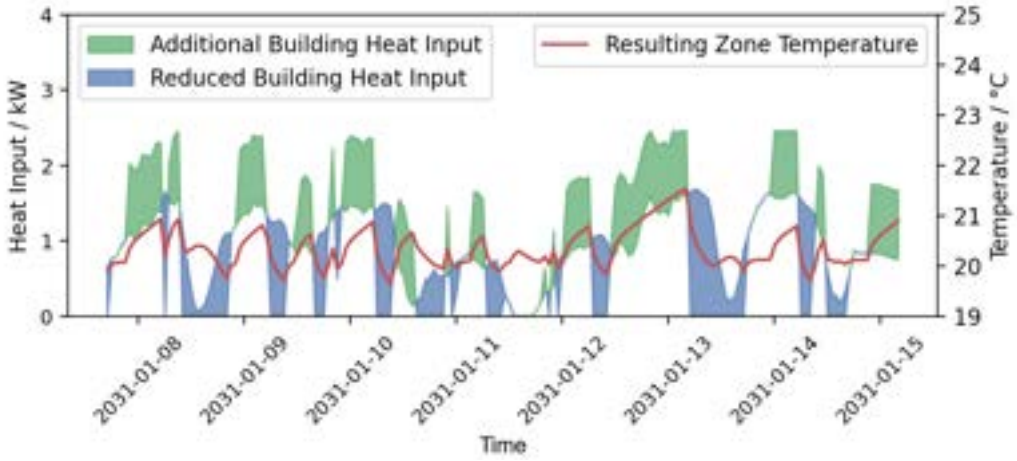

Figure 5. Optimized building heat input and resulting zone temperatures in comparison with the heating demand at a constant zone temperature of 20 °C of a single-family household built between 2010 and 2015 in an ambitious state of renovation. The storage component of the building model is parameterized with a charging duration of 8 hours at full charging power.

3.5. Flexibility quantification of individual buildings

The utilization of the flexibility potentials in the operation of the investigated buildings varies significantly with the building age class and the state of refurbishment. To quantify the flexibility potentials, the flexibility efficiencies and the annual electricity cost savings are calculated for all demand response events during the year. The results are presented in Table 4 and Table 5. The highest annual electricity cost savings of 131.45 € can be reached by the well-insulated building constructed between 2010 and 2015 in its original state, which corresponds to about 12.5% of its original annual electricity costs without utilizing the thermal flexibility. In general, most fairly well-insulated buildings show relatively high saving potentials. It is noteworthy, that the very well insulated buildings have less total electricity cost savings than the worse insulated buildings of the same class, due to the decrease in the total energy demand. The relative annual savings, compared to the costs for electricity without utilizing the thermal flexibility, increase with better insulation for all buildings. The highest utilization efficiencies of the virtual storage are reached by the buildings built between 1919 and 1948 and the building built between 1958 and 1968, both in an ambitious state of refurbishment. In the chosen environment, most buildings show the best efficiency with a power shift capability of 4 hours. Nevertheless, buildings with well-insulated envelopes show an optimal modelling approach using a power shift capability of 6 or 8 hours. Therefore, poorly-insulated buildings with high heat loss rates show higher potentials for short-term energy storage use while well-insulated buildings display higher potentials for longer energy storage durations.

Table 4. Overview of the annual electricity cost savings from the energy system optimization of a SFH with a net floor area of 160 m² and in dependence of the power shift capability of the additional storage model.

Building description			Annual electricity cost savings

4. Discussion

In the present work, a modelling approach considering the thermal flexibility of buildings is presented and the flexibility potentials of a selection of representative buildings is quantified. It is shown that the presented building model can be integrated in an energy system optimization framework, in order to help utilizing the flexibility potentials of the individual buildings as well as a building group, district or district heating network. The building model approach used to simulate the buildings takes into account the heat transfer and storage characteristics using five nodes for each opaque building element. However, this approach is still a simplification and the real heat transfer mechanisms may differ from the results in this work. The linear representation of the buildings storage characteristics in the energy system optimisation only accounts for parts of the real flexibility potential and a non-linear representation could lead to better performances of the buildings. In addition, more detailed analyses to quantify the storage parameters are necessary and broader test environments must be implemented to improve the robustness of the models. Nevertheless, the representation of a building using a generic sink and a generic storage component allows the integration in most optimization frameworks and the application in diverse planning processes of different stakeholders, while still allowing to take into account more detailed heating demand analyses. The approach is validated by integrating the optimized heat input in the building simulation model and testing the resulting room temperature to ensure that the specified limits are not exceeded. It is shown that utilizing thermal flexibilities can lead to annual cost reductions in the energy import of up to 130 € for a single-family house built between 2010 and 2015 with a net floor area of 160 m². For the application of the building models and the quantification of their

flexibility in a district energy system or district heating systems, the best performing flexible building models can be chosen and integrated in an optimization model. The best storage model approaches for optimizing the buildings operation depend on the building type and the state of refurbishment. While well-insulated buildings indicate a more economically efficient utilization with longer storage durations and lower charging and discharging heating powers, poorly and moderately insulated buildings show higher potentials in the short-term utilization of their flexibility. Therefore, different building types should also be utilized accordingly. A modern district with 100 buildings built between 2010 and 2015 in a standard state of refurbishment could lead to annual electricity cost reductions of up to 12 300 € if the flexibility potential is utilized. The available storage capacity for this district is up to 1 046 kWh and the possible power shift is 215 kW for the charging event and 251 kW for the discharging event. The annual electricity cost reductions linked to the renovation from the original state to the standard state of renovation without the exploitation of the flexibility are 15 552 €, without including taxes and other fees in the calculation. An exemplary district with 100 SFH, equally distributed in both non-refurbished and standard refurbished condition, can achieve annual electricity cost savings of up 9 550 €, when the flexibility is utilized and provide 772 kWh of virtual storage capacity and 250 kW or 224 kW of power shift during the charging or discharging event. If additional renewable energy from own generation plants, such as photovoltaic systems, can be integrated into the energy system, the savings from exploiting flexibility can be further improved. Investigating the impact of these systems will be part of future studies.

In addition to the findings off the present work, the consideration of thermal flexibilities in the energy system design optimization could lead to savings in the investment costs and identifying efficient and cost-effective operation strategies. The optimization of the energy system can take into account the availability of waste heat, the fluctuating efficiency of heat generation units and the conditions of available heat sources. Utilizing the thermal flexibility of buildings can therefore benefit the integration of local renewable energy sources like wind energy, solar power or waste heat, especially when exploited on a district level. However, since individual households do not have excess to the day-ahead electricity market, the buildings flexibility is most likely to be utilized on a district level or a district heating network. Therefore, new pricing-models for heat must be developed. Yet, in district energy systems and district heating networks, the drawback often lies in the metering devices or the operational control of the buildings. Hence, multi-family buildings might be more likely to be considered to provide flexibility, and therefore the quantification of flexibility should be extended to more building types.

5. Conclusion

The transformation of the heating sector in buildings will face the challenge of integrating fluctuating renewable energy sources to become sustainable. To adjust the heating demand to the volatile generation of renewable energies, it is necessary to use comprehensive methods and tools to quantify the flexibility of the buildings and to incorporate this potential into the diverse planning processes of integrated energy systems, particularly on a district level and for district heating networks. By characterizing the heat transfer dynamics of a selection of buildings with a simulation based on the DIN EN ISO 52016, a generic approach is used to model the building demands and flexibility properties in an energy system optimization framework. By following this procedure, building flexibility indicators can be quantified and appropriate utilization strategies can be identified for individual buildings, building groups, or districts in a variety of applications. Based on a variable day-ahead electricity price and a realistic heat pump coefficient of performance, it is shown how the flexibility of single-family houses can be exploited to reduce energy costs. Depending on the building type and the state of insulation, there are different opportunities for exploitation. When only linear modelling approaches are used, well-insulated buildings tend to be more cost-effective by gradually increasing the heating input and storing the energy for a longer period, while poorly insulated buildings tend to perform better with shorter storage durations and higher charging powers. Still, all investigated buildings show the possibility of cost reductions when utilized and can play an important role in an integrated energy system. Future research should expand the flexibility analysis to include a wider variety of building types and groups. Multi-family buildings, larger apartment blocks, and commercial buildings, in particular, may exhibit different energy flexibility potential and could also play distinct roles in integrating renewable energy into the energy system. Furthermore, energy storage capabilities of district heating networks could be assessed in a similar way and help finding operation strategies or identify optimal supply and return line temperature profiles. In addition to the building analysis, deeper understanding of the flexibility in the operation of the heat generation units and heating emitter systems is necessary. Utilizing flexibilities promises to play an important role in an integrated energy system, especially when exploited on a district level. Until now, the heat generation of large-scale heat pumps in district energy systems mostly covers the base load operation. Nevertheless, the flexible operation of heat generation plants is crucial to leverage variable electricity prices and cope with fluctuating renewable energy sources.

Abstract:
Accurate estimations of future energy consumption are crucial for decision-makers to better plan the future design and operation of production and distribution systems. The existence of uncertainties in the inputs of the planning process can affect the quality of the model's outcomes and potentially can lead to sub-optimal solutions. This work proposes an investigation of input uncertainties of an Electrical Power System Model (EPSM) based on dynamic linear optimal power flow. The considered model inputs are the electricity demand curves of the buses of the grid. A set of forecasted demand time series is used to generate a probability model of their variability at each time step of the period studied. This probabilistic model is applied to generate the uncertainty of the demand curves and the associated input macro indicators (IMI) which are used to define the experimental design of the sensitivity analysis. The results show that input uncertainties on the demand have significant effects on the results in terms of Levelized Cost of Energy (LCOE) and system design like the installed capacity of Wind Turbines (WT), extracted energy from Classic Generators (CGs), and Battery Energy Storage (BES) location and sizing. In addition, it is shown that the input demand uncertainties can affect the results on the distribution performance parameters like the level of saturation of the different grid branches.

1. Introduction

Load forecasting models are used to predict future demand behaviors to be used as input for optimal planning models. They rely on long-term expectations for the parameters influencing the load profile (e.g., temperatures, occupancy, behavior, etc.). Therefore, they are likely to give estimations of low accuracy [1]. This could affect the accuracy is the model's output. Thus, there is a need for robust and rigorous techniques that can provide quantifiable information about the impact of uncertainty on model outputs. Sensitivity Analysis (SA) technics incorporate a set of methods that aim to identify the most important input parameters driving the model output variability in addition to the non-influential parameters whose uncertainty can be safely ignored.

In the literature, sensitivity analysis in energy models considers different uncertain input parameters e.g., the intermittent renewable generation, final energy demand, primary energy prices, economic growth, etc. [2]. These uncertain parameters are generally associated with randomness and temporal variability [3]. However, uncertainty in demand estimation introduces additional complexity alongside energy planning scenarios, including Renewable Energy Sources (RES) and Battery Energy Storage (BES) sizing and placement. Under such conditions, it is crucial to understand how demand curves uncertainty affects the optimal design and to identify the most influential uncertain parameters [4].

For the SA of demand curves, two different approaches exist. The first one is the total demand uncertainty applied to the demand patterns directly measured or extracted from the load forecasting models. To assign uncertainty on energy demand profiles, the most commonly used approach is applying Probability Density Function PDF to each time step of the demand time series, like normal distribution [5], uniform distribution [6], etc. The second one is the model-based uncertainty in which the uncertainty is assigned to the input parameters of the load forecasting tool and is propagated to obtain a series of demand patterns. The model-based uncertainty approach is applied in the literature for different types of demand patterns. In Mavromatidis et al. [7], using a building performance simulation tool, the uncertainties are attributed to the building material properties, occupancy patterns, hot water services, ventilation, and climate parameters, etc. Probability distributions are attributed to these parameters (normal, triangular, etc.), and the distribution parameters are then estimated. Thousands of profiles are then extracted and represented in the form of probability distribution to sample them to generate random energy demand profiles for the following study steps. The same approach is applied for the load forecasting model called MOSAIC in [8] developed by the principal French DSO (Enedis [9]), where the input variables are classified into four types: quantitative continuous (local height, coefficient of

performance for heater, temperatures, etc.), qualitative binary (e.g., presence of air conditioner or not), quantitative discrete (e.g., number of occupants) and qualitative nominal (e.g., thermal performance level). The variability range of the parameters are defined, and probability density distributions are attributed to continuous variables. Multiple demand patterns are then extracted from MOSAIC.

Various methods of sensitivity analysis on energy models are performed in the literature while considering the energy demand uncertainty; a local sensitivity analysis is used to study the demand effect on life cycle cost and loss of power supply in Sadeghi et al.[10]. A two-stage elementary effect - variance based technique is developed by Mavromatidis et al. [4] to study the effect of energy demand on the total cost of the system. Many other sensitivity analysis models are developed in [11], [12], [13] and [14], etc. Basically, SA models are classified into three major groups : *1- screening models* that coarse sorting of the most influential inputs from a large number (e.g. Morris method [15]), *2-measure of importance* or quantitative sensitivity indices (e.g. linear regression [16]) and *3- deep exploration of model behavior* that measure the effects of inputs over their total range of variation (e.g., Metamodels-based SA [17]). The selection of the most appropriate method is based on the number of input parameters and the model's complexity.

This paper uses the total demand uncertainty characterization for the extracted curves using the probabilistic techniques presented in [18]. Then Input Macro Indicators IMI are defined to describe these demand curves. The electric demand curves are used as input for the energy planning model that aims to optimally size and place the RES and storage in the existing electrical distribution network. Different indicators are then defined to describe the resulted scenarios aiming to perform the sensitivity analysis. In the studied case, features are assigned to the input curves as macro-parameters indicators and their correlation to the output indicators is studied. Based on the size (the number of model simulations is about 10 times the number of input parameters) and type of the data set, the linear regression (Pearson) is selected for the sensitivity analysis.

2. Methodology

The methodology summarized in Figure 1 aims to investigate the uncertainties in the Electrical Power System Model (EPSM). The EPSM used is the Dynamic Linearized Optimal Power Flow (DLOPF) model detailed in [18]. The model inputs considered are the demand curves. The uncertainties and variability of the demand are first characterized at each time step according to probability models which are used to generate additional demand curves. This set of generated demand profiles are used as inputs of the EPSM on a predefined distribution network to create different planning scenarios. Besides the IMI describing the patterns, output indicators are then determined to help measuring the sensitivity of model's outputs to inputs uncertainties implied by the variability of the demand. Finally, the sensitivity analysis is implemented in order to identify the most effective correlations between the input and output parameters of the model.

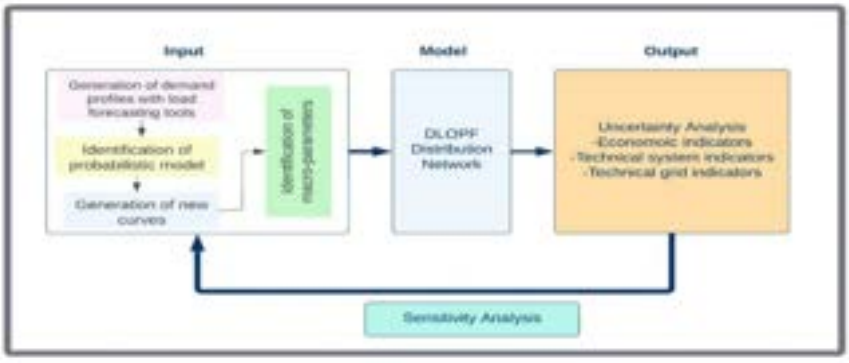

Figure 1. General workflow for uncertainty/sensitivity investigation in EPSM

2.1. Input Data

The electricity demand curves are the input data on which this uncertainty study is based. These curves are generated using a bottom-up load forecasting model called MOSAIC [19]. This tool is based on the characteristics of French loads built from a crossing of different databases: INSEE's residences database (French National Institute on Statistics and Economical Studies; French Distribution System Operators databases).

The total load curves by HTA/BT transformer are generated. For the studied area, MOSAIC simulations are repeated 25 times and therefore 25 curves per HTA/BT substation covering a whole year are obtained. The difference between curves is due to the attributed assumptions from the input data (building parameters,

weather data, etc.). These assumptions contain values and associated probability laws [20]. MOSAIC uses these values and makes random draws, according to the assumptions, to calculate a possible scenario.

The time-dependent uncertainties of the load curves are then characterized using the probability laws tests as explained in [18]. The Gamma law is proved to be the most appropriate law to describe these uncertainties. Then, based on the identified parameters describing the Gamma law at each time step, N=300 load curves are generated for each HTA/BT substation.

The demand curves are generated for one year. Hence, to reduce the simulation time, a clustering method is applied to choose 9 typical days (3 periods of 3 days) representing three different demand levels (high, medium, and low). The variation of the total demand over the 300 cases at each time-step (t) is shown in Figure 2.

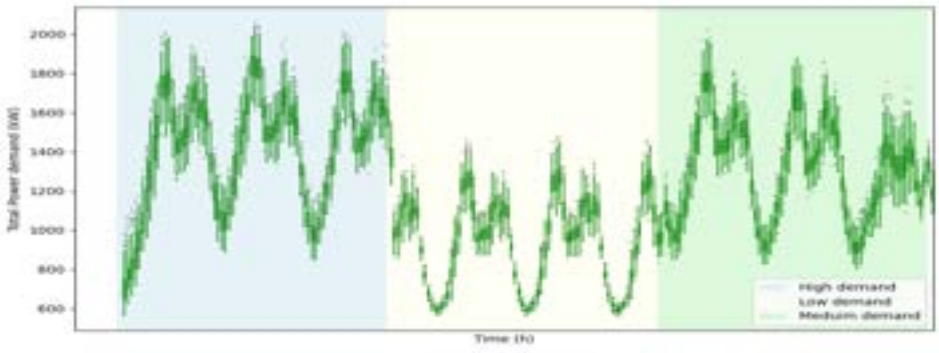

Figure 2. Ranges of variation of the generated energy demand curves

Several input macro indicators can be defined to describe load variation. The chosen parameters are detailed in the followings:

2.1.1.Peak demand values

The peak demand represents the higher demand value recorded in a time frame. The peak demands in each bus (i) are collected for the N_c cases (e) using the following equation (1) where the number of buses $\mathcal{N} = 14$, the time steps $\mathcal{T} = 216$, and the number of cases $N_c = 300$.

$$P_{i,e}^{max} = \max_{t} (P_{i,t,e}) \qquad i \in [1:\mathcal{N}] \quad t \in [1:\mathcal{T}] \quad e \in [1:N_c] \tag{1}$$

2.1.2.Standardized Variances

The variances ($Var_{i,e}$) in load demand curves designates the spread between demand values in each curve. More specifically, variance measures how far each value number in the curve is from the mean (average). The variances are calculated using Eq. (2)

$$Var_{i,e} = \frac{1}{\mathcal{T}} \sum_{t=1}^{\mathcal{T}} (P_{i,t,e} - \frac{\sum_{t=1}^{\mathcal{T}} P_{i,t,e}}{\mathcal{T}}) \tag{2}$$

2.1.3.Duration of maximum loads

The maximum demands are defined here as demands higher than 95% of the total peak demand. The number of hours during which these demands are encountered are defined as maximum durations Du_e.

2.1.4.Total energy demand variation

For that, three different parameters are defined summarizing the total demand in each clustered period (low, medium, and high).

These parameters are calculated using the following formulas Eq. (3)

$$E_e^{lev} = \sum_{t \in \Gamma_{lev}} \sum_{i=1}^{\mathcal{N}} P_{i,t,e} \tag{3}$$

Where $\boldsymbol{lev} \in \{\boldsymbol{Low}, \boldsymbol{Medium}, \boldsymbol{High}\}$ is the demand level and $\boldsymbol{\Gamma_{lev}}$ is the time period corresponding to the demand level $\boldsymbol{lev}$.

2.1.5. Simultaneity factor (Load coincidence)

The simultaneity factor represents how much consumers tend to consume simultaneously. The maximum demand for each bus may not occur at the same time. The ratio of the aggregated maximum demand of the whole network during a particular time to the sum of the maximum demand of individual consumers is called simultaneity factor eq. (4).

$$SF_e = \frac{P_e^{MAX}}{\sum_{i=1}^{Nbus} P_{i,e}^{max}} \tag{4}$$

Where P^{MAX} is the total load maximum value and P_i^{max} is the maximum value of bus i. SF_eranges between 0 and 1 if all peak demands occur at the same time.

2.2. DLOPF model used.

Performing uncertainty and sensitivity analysis requires many simulations (300 in our case). An electrical planning model is used. This DLOPF model takes as initial conditions the Photovoltaic (PV), Wind Turbines (WT), and BES available surfaces and possible locations. The main outputs are the optimal scenario for sizing and placement of PV, WT, and BES in addition to the network simulation with time series variables.

$$min\, F_{obj} = min \frac{\left(\Gamma_{op} + \Gamma_{o\&m}\right) + \Gamma'_{inv}}{\sum_{\boldsymbol{i}=1}^{\mathcal{N}} \sum_{t=1}^{\mathcal{T}} \frac{P_{i,t}^{l}}{(1+ra)^t}} \tag{5}$$

Such that

$$\Gamma'_{inv} = \mathcal{I}^{wt} + \mathcal{I}^{pv} + \mathcal{I}^{st} \tag{6}$$

$$\mathcal{I}^{st} = \sum_{s=1}^{\mathcal{N}^{st}} I^{st}.\boldsymbol{E_{max}^{st}} \tag{7}$$

$$\mathcal{I}^{pv} = \sum_{s=1}^{\mathcal{N}^{pv}} I^{pv}.\boldsymbol{A_s^{pv}} \tag{8}$$

$$\mathcal{I}^{wt} = \sum_{w=1}^{\mathcal{N}^{wt}} I^{wt}.\boldsymbol{R_w^{wt}} \tag{9}$$

$$\Gamma_{op} = \mathcal{C}^{cg} + \mathcal{C}^{vg} + \mathcal{C}^{wt} + \mathcal{C}^{pv} \tag{10}$$

$$\mathcal{C}^{cg} = \sum_{t=1}^{\mathcal{T}} \sum_{c=1}^{\mathcal{N}^{cg}} \frac{C^{cg,p}.\boldsymbol{P_{c,t}^{cg}}.\Delta t + C^{cg,q}.\boldsymbol{Q_{c,t}^{cg}}.\Delta t}{(1+ra)^t} \tag{11}$$

$$\mathcal{C}^{vg} = \sum_{t=1}^{\mathcal{T}} \sum_{i=1}^{\mathcal{N}^{vg}} \frac{(C^{vg,p}.\boldsymbol{P_{i,t}^{vg}}.\Delta t + C^{vg,q}.\boldsymbol{Q_{i,t}^{vg}}.\Delta t)}{(1+ra)^t} \tag{12}$$

$$\mathcal{C}^{wt} = \sum_{t=1}^{\mathcal{T}} \sum_{w=1}^{\mathcal{N}^{wt}} \frac{C^{wt}.\boldsymbol{P_{w,t}^{wt}}.\Delta t}{(1+ra)^t} \tag{13}$$

$$\mathcal{C}^{pv} = \sum_{t=1}^{\mathcal{T}} \sum_{s=1}^{\mathcal{N}^{pv}} \frac{C^{pv}.\boldsymbol{P}_{\boldsymbol{s,t}}^{\boldsymbol{pv}}.\Delta t}{(1+ra)^t} \quad (14)$$

$$\Gamma_{o\&m} = \frac{\sum_{i=1}^{\mathcal{T}}(O^{pv}.\boldsymbol{A}^{\boldsymbol{pv}} + O^{wt}.\boldsymbol{R}^{\boldsymbol{wt}} + O^{cg}.P^{cgT})}{(1+ra)^t} \quad (15)$$

The optimization model used aims to minimize the Levelized Cost of Energy (LCOE) of the system. The objective function is presented by (eq.(5)). It includes the total investment cost (Γ'_{inv}), production cost (Γ_{op}) and operation & maintenance cost ($\Gamma_{\mathrm{o\&m}}$). This sum is divided by the sum of demand ($\mathrm{P}_{\mathrm{i,t}}^{\mathrm{l}}$) (in all buses ($\mathcal{N}$)/ i: bus index $\epsilon\, \mathcal{N}$) for the defined period ($\mathcal{T}$) in years / t: time index $\epsilon\, \mathcal{T}$) over a function of the discount rate of the project (ra).

The total investment cost (Γ'_{inv}) presented by (eq. (6)) considers:

- The batteries investment cost ($\mathcal{I}^{st}$) in (eq. (7) where $\boldsymbol{E}_{\boldsymbol{max}}^{\boldsymbol{st}}$is the maximum energy and I^{ST} is the battery investment cost per unit of capacity.
- The PVs investment cost ($\mathcal{I}^{pv}$) in (eq. (8) where $\mathbf{A}^{\mathbf{pv}}$ is the installed area of PVs is an optimization and I^{pv} is the PV investment cost per unit of surface .
- The WTs investment cost ($\mathcal{I}^{wt}$) in (eq. (9) where $\mathbf{R}^{\mathbf{wt}}$ is the continuous design variable that defines the ratio of installed power capacity to a maximum installable capacity ($\mathbf{R}^{\mathbf{wt}^{\mathbf{max}}}$) of local wind energy and I^{wt} is WT the investment cost of $\mathbf{R}^{\mathbf{wt}^{\mathbf{max}}}$

The total actualized operational costs (Γ_{op}) is represented by Eq. (10). The $\mathcal{C}^{cg}$ is the actualized operational cost of the Classic Generators (CG)s and $\mathcal{C}^{vg}$ is the actualized operational cost of Virtual Generators[1] (VG)s. Solar and wind power operational costs ($\mathcal{C}^{wt}, \mathcal{C}^{pv}$) are supposed to have very low values since they are clean energy sources. The total operational cost for CGs ($\mathcal{C}^{cg}$) is given by eq.(11) where both the sum of active ($\boldsymbol{P}^{\boldsymbol{cg}}$) and reactive ($\boldsymbol{Q}^{\boldsymbol{cg}}$) produced power are multiplied by their corresponding costs ($\mathcal{C}^{cg,p}$ for active and $\mathcal{C}^{cg,q}$ for reactive). Like Eq.(11), Eq.(12) gives the virtual generation cost ($\mathcal{C}^{vg}$). In each bus, virtual generators have generation costs significantly higher than other generators (both $\mathcal{C}^{vg,p}$ and $\mathcal{C}^{vg,q}$). The total operational costs of WTs ($\mathcal{C}^{wt}$) and PVs ($\mathcal{C}^{pv}$) are represented respectively by Eq.(13) and Eq.(14). Γ_{op} is variable according to the energy consumed.

Actualized operation and maintenance cost $\Gamma_{o\&m}$ is given by Eq.(15). It is dependent on the sizing of WTs, PVs and the existing CGs. and their O&M costs (O^{wt}, O^{pv}) in addition to the existing CGs maintenance costs (O^{cg}) multiplied by the total installed power of CGs (P^{cgT}). This cost is a fixed cost for the year regardless of the amount of production. The other equations that form the EPSM model are the linearized power flow equations of the DLOPF. These equations are the same presented in [21] and [18].

3. Case study

A theoretical case study is selected. The chosen topology is a Medium-voltage rural distribution benchmark network shown in

Figure 3. The benchmarking network comprises two separate subnetworks supplied by classic generators located in buses 1 and 12. These subnetworks are connected by buses 8 and 14. In this case, WTs, PVs and BESs could be added to specified buses concerning available surfaces for PVs and the existing potential of WTs. BES systems could also be added within the limit of maximum allowed capacities. This information is detailed in Table 1 with the corresponding costs.

3.1. Output

For the uncertainty analysis step, 300 simulations of the EPSM are performed. Four different types of output indicators are studied:

- Technical indicators of energy production and storage technologies: energy extracted from CG – Installed PVs, WTs capacities – Total produced energy – Batteries capacities.
- Technical grid indicators: branches' saturation levels (Δ_{ij}) – Duration in which this percentage is less than 10% (D_{ij})

[1] [1]Virtual Generators are defined as producers supposed to be added to all the buses to guarantee a feasible solution

- Losses

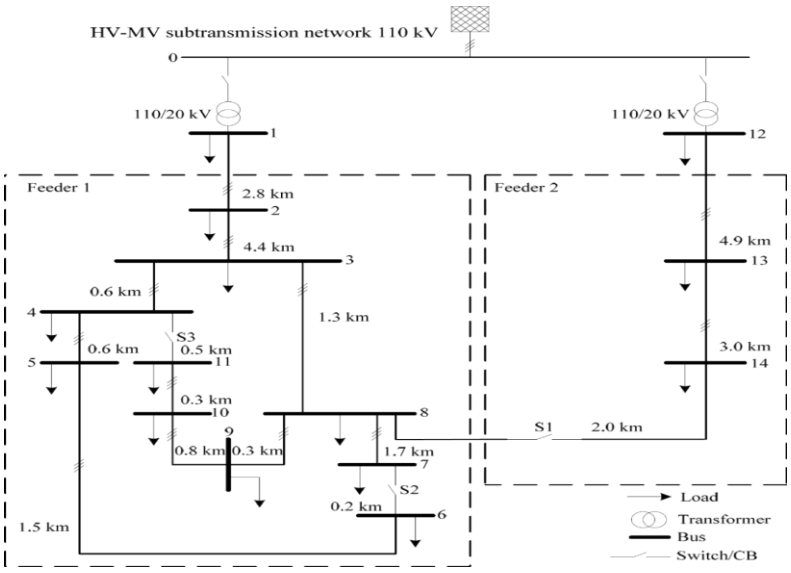

Figure 3: Medium voltage rural distribution benchmark network [22]

Table 1. Summary of buses specifications

Production type	Buses	Maximum capacity	Costs [23]		
			Production ($/MWh fuel)	Investment	O & M ($/MW/yr)
PV	3,4,7,11,13	$A^{pv^{max}} = 800\ \mathrm{m}^2$ $\mathrm{PV_t}$ (peak load) =205 W/m²	$\mathrm{C^{pv}} = 0$	J^{pv} =178 ($/m²)	$\mathrm{O^{pv}} = 8000$
WT	2,3,4,5,10,14	$R^{wt^{max}} = 10$ $\mathrm{WT_t}$ (peak load)=1000 KW	$\mathrm{C^{wt}} = 0$	$\mathrm{J^{wt}}$ = 997 000 $/MW	$\mathrm{O^{wt}} = 33000$
CG	1, 12	20 MW	$\mathrm{C^{cg,p}}, \mathrm{C^{cg,q}} =$ 36	0 (already installed)	$\mathrm{O^{cg}} = 10500$
VG	all buses	10000 KW	$\mathrm{C^{vg,p}}, \mathrm{C^{vg,q}} =$ 10^9	0	0
BES	2,3,4,5,7,9, 10,11,13,14	100 kWh	0	I^{ST}=350 $/kWh	0

3.1.1.Impact on the economic indicator: LCOE

The impact of load data uncertainty on the economic indicator is important since the objective function here is initially based on minimizing the LCOE. The violin plot of Figure 4 represents the shape of the LCOE results from the 300 cases generated above.

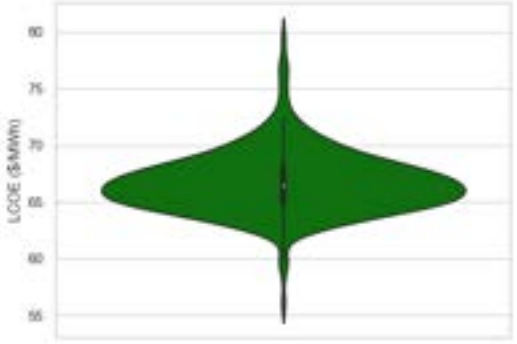

Figure 4. Violin plot for the variation of the levelized cost of energy in the different cases

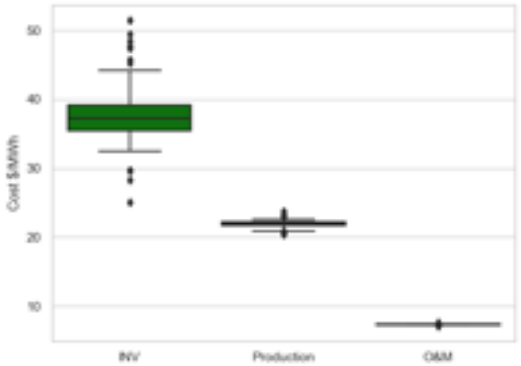

Figure 5. Cost details over the lifetime

The results are centered around the median value (white point) and are almost symmetrically distributed in within -15% and +20% of the variation around the median value. The LCOE analysis revealed that the randomness of the input variables significantly impacts the LCOE and results in a variation of 28 $/MWh which represents millions of dollars over the project lifespan.

The variation in the LCOE is a combination of variations between the investment, production, and O&M costs. These variations are presented in Figure 5. The LCOE variation is mainly due to the investment cost (between 25$/MWh and 51$/MWh) since this includes the investment in WTs, PVs, and batteries. This LCOE is affected to a minor extent by the production cost which is based on the CG production. The O&M cost variation is insignificant compared to others and has a negligible effect on the LCOE.

3.1.2. Technical system indicators

The impact of uncertainties affects the technical indicators of energy production and storage technologies differently. These indicators include the extracted energy from the existing CGs, the installation surface of PVs, the fraction of installed WTs, and the total energy produced in addition to the total installed capacity of the batteries. The results are summarized in the parallel coordinate plots of Figure 6.

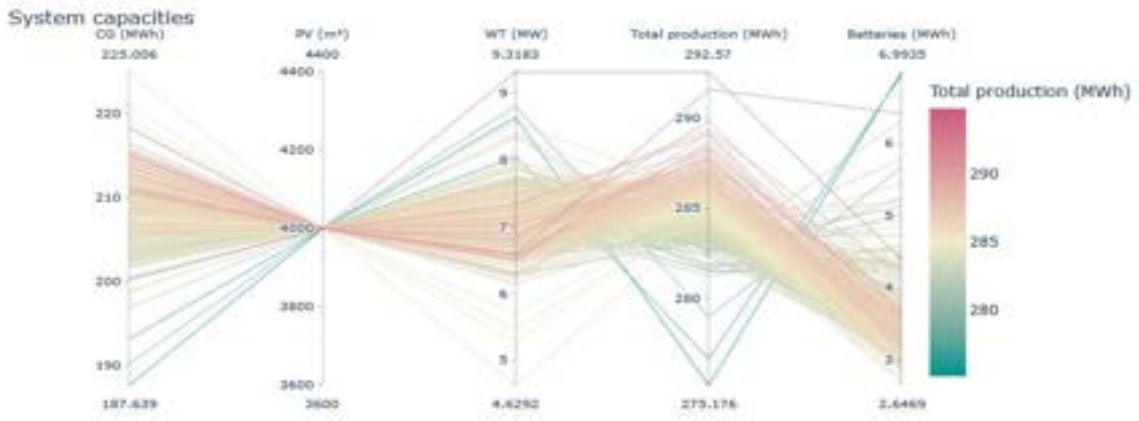

Figure 6. Parallel coordinate plots for the different cases results

The quality of the input data has no effect on the investment cost of the PVs. The installed area is constant at the maximum level for all cases (4000 m²), which means that the model always prioritizes the investment in the cheapest production technology compared to the other sources (CGs and WTs) so that the variations in investment and production amounts will be concentrated in the CGs and WTs. Moreover, substantial variations (16.6%) are shown in the energy extracted from the classic generators (up to 40 MWh) as well as in the installation of WTs (50.2%). The variation in the total production (5.94%) is less important than in the WT and CG since the sum contains both, and this balances the total variation because tracking the extreme points, we notice a maximum energy extracted from CG (225 MWh) that corresponds to a minimum installed WT power (4.6 MW) and a minimum CG (187.6 MWh) corresponds to a significant WT (8.6 MW). The variation in the WTs and PVs that produce intermittent energy induces the variation in the dimensioning of the batteries that aim to compensate for this intermittence. As long as the installed power of PV does not vary, the installed power of WT causes this important variation in the battery installation (62.13%).

3.1.3. Technical grid indicators

To focus on the network itself, technical indicators are used related to the grids, especially the amount of power flowing in the branches. The first indicator is the percentage of saturation of the branches (Δ_{ij}) and the second is the time (D_{ij}) during which the saturation is low and does not exceed 10%.

- The percentage of saturation (Δ_{ij}) in apparent power is calculated using eq.(16)

$$\Delta_{ij}\ (\%) = \frac{S_{ij}}{S_{ij}^{max}} \times 100 \tag{16}$$

The power flow behavior is depicted in **Erreur ! Source du renvoi introuvable.Erreur ! Source du renvoi in trouvable.** for four different branches of one of the 300 simulated cases during the three typical days. In the high demand period, some branches are almost fully saturated, like branch 3-4; this branch also reaches a complete saturation in specific hours in medium (72h to 75h) and low (190h-195h) demand periods. Since this branch transmits power to several other branches, it affects the power delivery to the succeeding buses during these saturation periods, and therefore, it may influence the installation of generation sources to compensate for the lack of power delivery.

Other branches do not reach a saturation point that exceeds 60% of their capacity (e.g., branches 11-4). The maximum Δ_{ij} reached are identified for each branch in the 300 cases. The boxplots of Figure 7 show the repartition of the 300 values attributed to each branch. The uncertainties in input demand do not affect the maximum saturations of the first four branches. The first 3 branches are saturated most of the time because they are responsible for the delivery of energy to other branches. Full saturation is noticed in branches 6-7 also, and it comes back to the non-possibility of installation of RES and BES on bus 6. However, the maximum saturation rates achieved in the other branches vary by ranges of about 5% (12-13, 13-14, etc.).

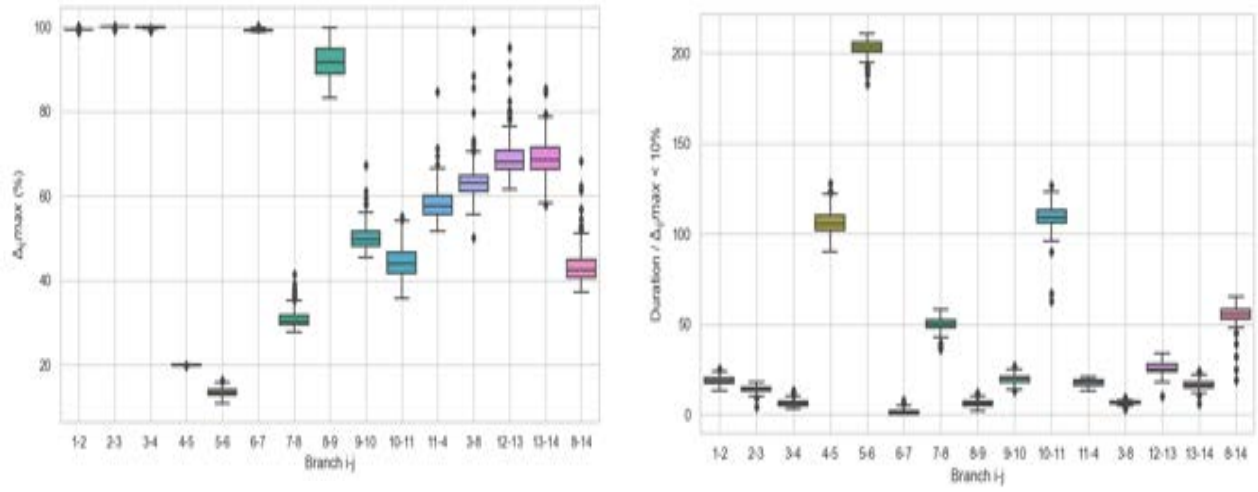

Figure 7. Boxplots of the apparent power saturations (a) and the duration of low saturation (less than 10 %) (b) in each branch

- The duration with very low branch saturation is expressed in eq.(17)

$$D_{ij} = duration\ of\ \ \Delta_{ij} < 10\ \% \qquad (17)$$

The time during which the branches are within 10% of their saturations over the defined duration is considered as a technical indicator for the grid since it concerns the grid's branches dimensioning and their maximum apparent power. The results of the 300 cases are presented in the boxplots of Erreur ! Source du renvoi i ntrouvable. for each branch.

D_{ij} is varying more in the branches where its values are more significant than in those where D_{ij} is about few hours that corresponds to the branches with higher maximum Δ_{ij}. The more the branches are saturated, the less they reach saturation less than 10%. For better understanding, we select the most critical branches (with Δ_{ij}> 80% and D_{ij} < 25 hours). The selected branches are, therefore (1-2, 2-3, 3-4, 6-7 and 8-9). The first branch (1-2) is critical since it is one of the main branches importing power from the classic generators to an important part of the network. The other two branches (2-3 and 3-4) are part of the branch (1-12) that will feed an important part of the network; in addition, they contain RES and BES that satisfy their demands first and transmit as much as possible for the rest of the network. Branches 6-7 and 8-9 are critical because they are connected to buses 6 and 8, where no installation is possible (neither RES nor BES) as shown in **Table *1***. Therefore, these branches deliver power with their maximum capacity to be able to saturate the demand for these buses.

- The grid losses

The grid losses are estimated by calculating the difference between production and demand. The results are presented in the following **Erreur ! Source du renvoi introuvable.**. In most cases, losses have less than 1% o f differences since they vary between 7.1 % and 7.8%. In some cases, losses are at the level of 9.8 %, while minimum observed losses are around 4%.

4. Sensitivity Analysis

The objective of sensitivity analysis is to determine which model parameters are important and their relative impact on the results. This gives insights about the efforts or resources needed to reduce the total uncertainty of the system's forecasts. Among the different SA technics presented in the literature, quantitative tests are made for sensitivity analysis using correlation analysis.

Tests based on correlation analysis.

The Pearson correlation coefficient is widely used in the literature. It measures the association between each input considered separately and the output. A number between -1 and 1 measures the strength and direction of the relationship between two variables. The correlation is given by the eq.(18).

$$r = \frac{\sigma_{xy}}{\sigma_x . \sigma_y} = \frac{\sum_i (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_i (x_i - \bar{x})^2}\sqrt{\sum_i (y_i - \bar{y})^2}} \qquad i = 1, \dots, N \tag{18}$$

Where N is the number of samples.

The values of r are interpreted as follows [24]:

- Between 0 and 1: a positive correlation exists between variables (strong r > 0.5, moderate 0.3< r < 0.5 and weak 0 < r < 0.3) – when one variable changes, the other variable changes in the same direction.
- 0: No correlation (there is no relationship between the variables)
- Between 0 and -1: a negative correlation exists between variables (strong r < -0.5, moderate -0.3> r > -0.5 and weak 0 > r > -0.3) – when one variable changes, the other variable changes in the opposite direction.

To perform the Pearson correlation test, both variables should be quantitative. They should be normal or a little non-normally distributed. In the studied case, this distribution is visualized by the diagonal of Figure 10. In Pearson correlation tests, choosing a sample size of up to 258 variables means a correlation test with a power 90%, an error 5% and an alternative correlation 0.2 as detailed in the sample size guideline for correlation analysis [25].

The input parameters are therefore $\boldsymbol{P_{i,e}^{max}}$, $\boldsymbol{Var_{i,e}}$, $\boldsymbol{Du_e}$, $\boldsymbol{E_e^{Low}}$, $\boldsymbol{E_e^{Meduim}}$, $\boldsymbol{E_e^{High}}$ and $\boldsymbol{SF_e}$. The output indicators are $LCOE_e$, WT_e, PV_e, BES_e, $losses_e$, $\Delta_{ij,e}$ and $D_e = \sum D_{ij,e}$ with i: bus index, e: case index and ij: branch index. The results of the test of linear relationships between the parameters ($\mathrm{Var_{i,e}}$, $\mathrm{P_{i,e}^{max}}$) and indicators are presented respectively in the following **Erreur ! Source du renvoi introuvable.** and **Erreur ! Source du renvoi introuvable.**. The Pearson correlation index r is calculated for the remaining parameters and represented in Figure 10. The indicator of PVs is excluded since it is demonstrated that the uncertainties do not affect this investment.

From **Erreur ! Source du renvoi introuvable.**, it can be noticed that 4 buses (1,3,10 and 14) have marked an effect of variances on the output indicators. The increased standardized variances of buses 1, 10 and 14 cause an increase in the installed WT power and a decrease in the extracted CG energy. The batteries are affected by the variances in buses 3 and 14. The LCOE increases with the increase of standardized variances of buses 3, 10 and 14. Even if the correlation exists, it is considered weak (r < 0.3). The most influencing bus based on variances is the last one (bus 14) since the increase of load variance in bus 14 also causes an increase in the duration of minor saturations, and a decrease in losses.

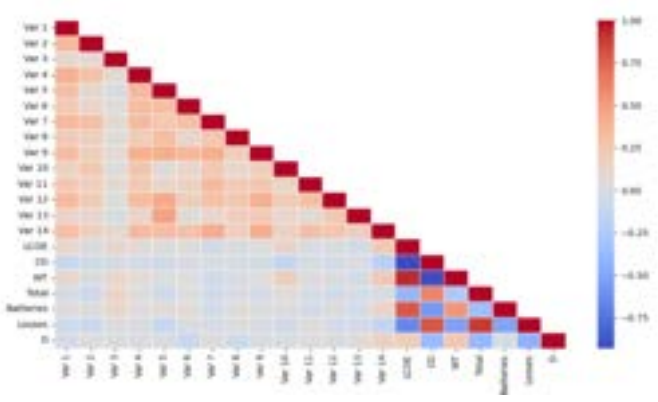

Figure 8. r values resulted from Pearson correlations tests of standardized variances ($Var_{i,k}$) on each bus with the output indicators

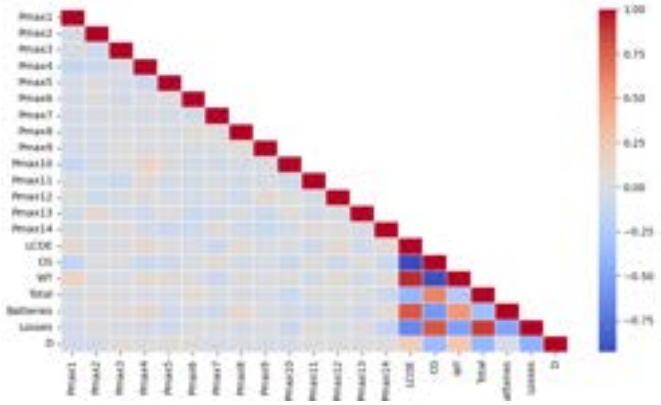

Figure 9. r values resulted from Pearson correlations tests of P^{max} on each bus with the output indicators

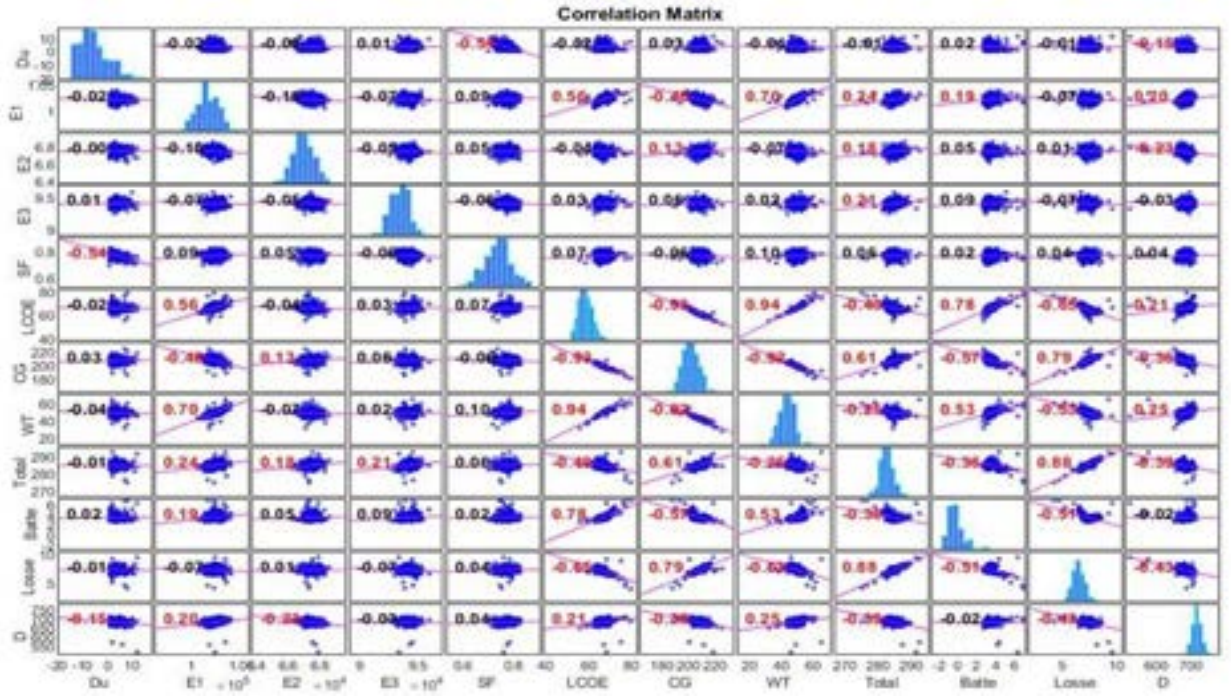
In **Erreur ! Source du renvoi introuvable.**, the results show that 4 buses (1,4,8 and 14) could affect the indicators but also with weak correlations (r < 0.15). An increase in the peak power of bus 1 leads to an increase in WT investment and a decrease in CG extraction because this bus conveys power to other buses; when the demand increases, the saturation effect of the branch decreases the quantity conveyed, and consequently the

system invests more in WTs. Increasing the peak power of bus 8 leads to an increase in battery investment since this bus does not contain a RES or BES and is fed from the grid. This increase in peak demand will be compensated by the storage of the power injected into the network, and then more investment in batteries.

The five input macro-parameters correlations with output indicators are displayed in Figure 10. The increase of the first parameter (the maximum duration parameter (Du)) leads to a decrease in the duration with very low branch saturation D_k (r = -0.15). By the fact that as long as the maximum demand values are reached, the low saturations of the branches appear less.

Figure 10. Tests on the different input parameters correlations with the output



The total energy demands at each demand level calculated by eq.(3) are expressed in Figure 10 respectively by $\mathrm{E1}$ for $\mathrm{E_e^{High}}$, $\mathrm{E2}$ for $\mathrm{E_e^{low}}$ and $\mathrm{E3}$ for $\mathrm{E_e^{Medium}}$. The values of LCOE increase with the high demand total energies $\mathrm{E_e^{High}}$ increasing. Thus, E1 has a strong effect (r = 0.56) on the LCOE, while others have moderate effects (r = -0.04) for E2 and (r = 0.03) for E3. When the total low demand energy $\mathrm{E2}$ increases, the extracted energy from CGs increases also (r = 0.13) which means that this low-level energy is mainly extracted from CGs. This returns to the grid behaviour in the low-demand period when the branch limits are not reached, and the energy from the classic generators can be continuously transmitted. In addition, E2 coincides with a period where renewable energy is less present and therefore increased use of batteries which is less competitive with classic generators. The increasing in $\mathrm{E2}$ also results in a decrease in the $\mathrm{D_k}$ ($\mathrm{r} = -0.23$) because this demand period is the one with a high occurrence of the hours of less than 10% of Δ_{ij}. So, a decrease in the demand increases these durations.

High total energy demand $(E1)$ is the most impactful parameter. An increase in $E1$ leads to a strong increase in investment in WTs ($r = 0.7$) and, therefore, an increase in battery dimensioning ($r = 0.19$). This leads to a decrease in CGs energy extraction ($r = -0.48$) and a significant decrease of the LCOE ($r = -0.5$). An increase in duration D_k is observed ($r = 0.2$). This is because of decentralization of producers (WTs and BES) and the limitation of the transition of the power from CGs, which reduces the saturation of the nearest branches to CGs after recourse to renewables and batteries.

The simultaneity factor (SF) has very weak influences on the indicators ($\mathrm{r} < 0.1$).

The distribution of the parameters is shown in the diagonal of Figure 10. The Gamma test is applied to the output indicators distribution, and the results give p-values lower than 0.05, so the hypothesis of this law is rejected this means that the probabilities of accepting the hypothesis (the data are gamma-distribut) are less than 5% [26].The difference in distributions between the input parameters and the output indicators means that the model does not propagate uncertainties in a linear way between inputs and outputs. The distribution of most parameters is close to a normal distribution as shown in the distributions of E1, E2, E3, SF, CG, Losses, etc. Therefore, the use of Pearson correlations is validated.

5. Conclusions

This paper uses an EPSM model to perform uncertainty and sensitivity analyses. Input macro-parameters were defined to describe an quantify the model's inputs uncertainties. A sensitivity analysis is performed using the correlations between the input parameters and the output indicators to identify the most influential parameters. The results show that the uncertainties have considerable effects on the results. In economic terms, uncertainties lead to a 35% variation range of the LCOE. In terms of system design, there is a need to increase the installed capacity of wind turbines, extract more energy from power plants, and/or install more BES depending on the case. Uncertainties also affect grid saturation in the branches. The analysis enabled the identification of the most important parameter which is the total energy demand during the high demand period (winter), as this parameter strongly affects the defined indicators. This makes this parameter a key parameter in the sizing of RES, BES and thus in the network planning.

Nomenclature

Variables

P	Active power [MW]
Q	Reactive power [MVAr]
F	Objective function
$\mathcal{C}$ / $\mathcal{I}$	Total operational/investment cost by production
Γ	Total cost by category
CC	Capital Cost
A	Installed surface of PV [m²]
R	Ratio of installed WT capacity [MW]
E	Active energy
r	Correlation parameter
Var	Variances
Du	Duration of maximum loads
SF	Simultaneity factor
Δ	Percentage of brunch saturation
D	Duration of less than 10% of brunch saturation

Parameters

C	Elementary operational cost
J	Elementary investment cost
O	Elementary O&M cost
LT	Lifetime
ls	Lifetime of the overall system
ra	Discount rate of the project

Indices and sets

$\mathcal{N}$	Set of buses, $i, j \in \mathcal{N}$
$\mathcal{T}$	Set of all times, $t \in \mathcal{T}$
$\mathcal{B}$	Set of batteries
Nb	Number of batteries
c / u / s / w	Indices of buses with CG/VG/PV/WT
k	Iteration number in DLOPF
inv	Investment
$o\&m$	Operation and maintenance
op	Operational
e	Case index

Upper-scripts

cg / vg	Classic generator/virtual generator
pv / wt / st	Photovoltaic/wind turbines/Storage
b	BES index
l	Load index at a bus
p / q	Active/reactive power
max	Maximum value for the upper limit
low	Low energy levels
$medium$	Medium energy levels

$high$	High energy levels

Abstract:

The novel concept of Smart Energy Systems has emerged over the last decade within the context of the energy transition toward a carbon-free sustainable future. For an energy system to be “smart”, several factors have to converge: (i) a high integration of renewable energy sources, (ii) the flexibility required to deal with their fluctuating nature, (iii) the exploitation of digital technologies and (iv) the cross-sectoral approach that uses synergies between various energy domains (sector coupling). Indeed, the traditional domain-specific energy flows from production to usage are overcome in favor of an integrated approach, in which energy is converted or stored into the most convenient vector. Coupling energy sectors, however, requires smart management and control strategies that are able to drive a system toward minimal energy use (or minimal cost), despite its increased complexity. Furthermore, the advanced management strategy of a smart energy system may vary significantly depending on its spatial dimensions, from the national/regional level to small-scale energy communities or islands. Hence, pointing out the latest progress on smart management is paramount for orienting future research and practice, and fostering the energy transition. This work reviews the available methods and tools for enabling the optimal operation of smart energy systems at different spatial and temporal scales. They are categorized according to relevant features such as the energy vectors and infrastructures involved, the presence of short-term or seasonal storage, the time horizon and specific application. The paper also summarizes research guidelines and drivers for the continuous development and expansion of smart energy systems at all levels. It was found particularly relevant to investigate optimal management at multiple time and space scales at the same time, for exploiting not only synergies between sectors, but also between neighboring communities. The tools should also have the possibility to include additional energy vectors (e.g. different types of chemicals) and their verification in demonstration cases should be promoted.

Keywords:

Control; Hybrid energy systems; Modeling; Optimization; Sector coupling; Smart energy systems; Smart management; System integration.

1. Introduction

Over the last few decades, the decarbonization of all human activities has become a global priority recognized by the international scientific community. Reducing greenhouse gas emissions is indeed a fundamental step to mitigate the effects of human activities on the climate and environment. Being one of the most carbon-intensive areas, the energy sector offers significant room for improvement. To this end, researchers have devoted great efforts in investigating and developing new concepts for the energy sector of the future [1].

In this context, the necessary steps to take are the implementation of energy efficiency actions, and the more rational exploitation of available resources and fuels. Hence, the energy system is progressively undergoing a transition toward a new paradigm, also referred to as sector coupling [2]. This indicates the interconnection between different sectors achieved by integrating multiple energy carriers and exploiting their synergies to enhance overall conversion efficiency. A system with these features is often regarded as an Integrated Energy System (IES) and is shown in Figure 1.

The very first example of this concept was the combined production of heat and electricity within a single plant, i.e. cogeneration unit. This is a high efficiency technology that recovers heat otherwise lost in the environment. Additional steps have been taken with the electrification of heat production and the transport sector.

The rise of new technologies and the possibility to exploit unconventional energy carriers (such as synthetic fuels and chemicals) has led to the integration and interconnection of all energy sectors in a unique circular framework, from the production of electricity to heat at different temperature levels, and even to mobility. While the traditional shape of a generic energy system comprised linear energy flows that were sent from the source directly to the final use, in the new framework the energy flows extracted from the sources can undergo multiple

passages before being used [3]. Some examples of these passages that characterize an IES are 1) conversion into a more cost-effective energy form, 2) accumulation into a storage device, and 3) supply into a distribution network.

The advantages of this new concept, compared to the previous one, are determinant:

- The cross-sectoral approach exploits the synergies between energy domains, so that energy can be transferred in the most convenient form depending on the specific conditions. For example, thermal demand can be translated into electrical demand by means of heat pumps. The deriving heat can be stored (more easily than electricity) or injected into heat distribution infrastructures for supplying entire communities. In parallel, excess electricity (e.g. from renewable sources) can also be converted into a chemical vector through Power-To-Gas systems, to be used at a later time or in a different location.
- An IES presents more degrees of freedom thanks to the different operation possibilities descending from the previous points, thus providing sufficient flexibility to deal with varying conditions.
- The higher flexibility, in turn, makes it possible to reduce the risk of curtailment of non-programmable renewable energy sources, and to operate programmable plants in a more profitable operating range.
- The available local resources can be put at the disposal of a larger community, so that energy can be produced and self-consumed locally, reducing grid losses. An example of this is the constitution of Renewable Energy Communities (REC), according to the recent European legislation.

Although this growing interconnection represents a key part of the energy transition due to the aforementioned benefits, it determines new challenges that deserve to be addressed. The most crucial is that the profitable layout and operation of a given system does not depend only on the single user or single plant, but is highly influenced by the neighboring users and entire infrastructure, including all connected elements and networks.

In this sense, IESs have to become Smart Energy Systems (SES), the definition of which is not limited to the co-operation of different energy infrastructures. A key feature of a SES is that it is planned, designed, operated, or optimized with the aid of dedicated digital tools. In more detail, tools for smart management are particularly relevant for dealing automatically with the complexity of the new paradigm. Indeed, they eliminate the risk of bad operations and relieve operators and technicians from the duty of locally controlling the energy flows of a complex new system for which neither expertise nor data are available.

Until recent years, major efforts have been directed toward the optimization of the electricity sector at all levels, as in the case of REC. Nonetheless, as shown above, the greatest benefits can be enabled by integrating all sectors, especially heat which constitutes at least half of the final energy use in Europe. A recent paper summarizes the development tools for the plant design and control of electro-thermal systems [4]: a system-level framework for the modeling, control, and design of multi-domain systems is defined, with a list of control methods as well as implementation tools (e.g. software and toolboxes). However, the focus is limited to future electrified vehicles. Similarly, Mishra et al. [5] review the technologies for sizing and operating innovative control in renewable integrated energy systems, with the sole focus on stand-alone and grid-connected electricity systems. Here, the term “integrated” is adopted to define an electricity-based system including a wide range of renewable technologies.

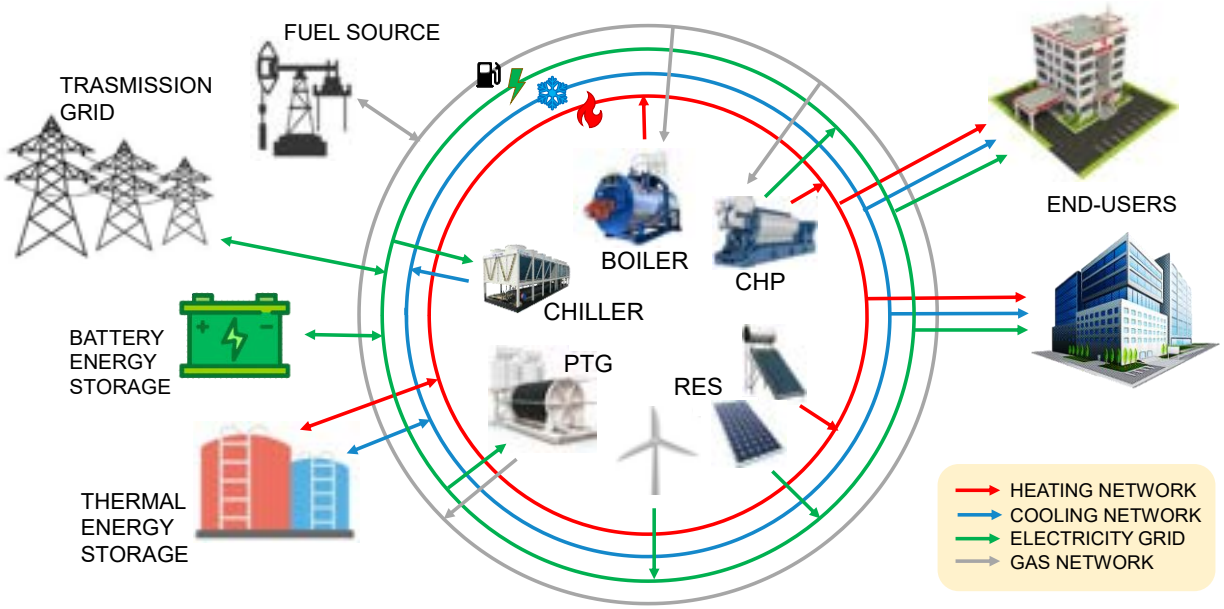

Figure. 1. An example of an integrated energy system in the framework of sector coupling with the electricity, heating, cooling and gas infrastructures. CHP: Combined Heat and Power plant, RES: Renewable Energy Sources, PTG: Power-To-Gas.

Whilst purely electrical infrastructures often have similar features in terms of time scale, due to their very fast dynamics, when coupling different sectors, the differences in time dynamics should be carefully investigated, and also considered in the related optimization tool. In addition, an IES can be implemented in different spatial dimensions, ranging from the IES for an individual building, to its community-scale application, to the whole national energy system of a country. When communities and networks are concerned, there are also large differences in system layouts and network topology.

All these aspects make the development of tools for IES smart management challenging but also critical for the energy transition. Indeed, it is firstly determinant to choose the appropriate tool, algorithm or methodology depending on the desired time or space scale, or even depending on the specific application. Since sector coupling and IES investigation is a rather novel topic, the state-of-the-art research does not offer a detailed overview of these tools. Despite the fact that tools for IES simulation and modeling have been surveyed in [6], to the best of the authors' knowledge, no unique set of tools for smart management exists in the literature.

This paper aims to provide a catalogue of the most recent works that presents tools for optimization and management of IES in the perspective of sector coupling. A particular distinction is made regarding the spatial dimension and time horizon in which each selected tool is supposed to be applied, or offers the greatest benefits. This analysis includes a thorough review of the literature, the selection of the most relevant papers for this purpose, and the extraction of the features of the proposed tools. To restrict the research field, this review aims to give an answer to the following research questions:

- How can smart management be applied to integrated energy systems at different spatial levels?
- Which are the tools that can enable system planning, design, optimization and management when considering different time horizons?

Finally, a set of drivers and guidelines based on the obtained results are given as indications for future research in the field.

2. The concept of sector coupling

2.1. Definition

It can be seen from the literature that a clear contextualization of sector coupling is missing. As noted by Ramsebner et al. [2], the term is often misinterpreted: it is used in a wide range of cases, from the bare inclusion of renewable energy sources, to the coupling of the production of energy and transportation. By contrast, if the scope is restricted to the field of energy production, distribution and utilization, available sources and research works adopt different terms to define the same concept (IES, in the scope of this research).

The focus of this paper is to produce an overview of the tools to achieve the optimal management of IES in the framework of sector coupling. This task is therefore subordinated to the preliminary identification and explanation of the terms used in the literature to refer to IES (as in the meaning given in Section 1). These definitions, which are detailed in Table 1, also represent the main keywords used in the literature search.

With reference to the term "hybrid energy systems" [7], it is worth specifying that, apart from the scope of sector coupling, the term can also identify the following concepts:

- A system in which different conversion units are integrated to pursue the same scope (e.g. supplying electricity). This is the case of renewable energy sources coupled with conventional power plants.
- A system in which different components are integrated within the same power plant to enhance plant efficiency (e.g. fuel cells coupled with gas turbines).

Hence, when analyzing the literature and selecting relevant papers as well as the related tools, particular attention has to be paid to this term.

2.2. Infrastructures

The whole energy system is based on infrastructures that can connect the energy conversion systems with users or storage devices at different scales. These infrastructures are shaped as networks that may have different topologies according to the specific domain. In particular, it is worth mentioning electrical grids, natural gas networks, and heating and cooling networks [8].

Electrical energy and natural gas can be transferred for long distances and then distributed in a widespread manner to the single users. Therefore, in general, these networks are structured with transmission networks (e.g. at high voltage or pressure in order to reduce dissipation) and distribution networks (e.g. where voltage and pressure are progressively decreased toward the users).

Conversely, heat cannot be efficiently transported for more than a few kilometers. Therefore, its production must be close to the users and the networks are only for its distribution. Another peculiarity of heating and cooling networks is that they use a medium for heat distribution (e.g. steam or water) and, therefore, they are composed of supply and return piping.

All these infrastructures were traditionally intended as passive and one-directional, with the energy transferred from a small amount of source points (e.g. power plants) to a high number of sink points (e.g. houses and

factories). Starting from the electrical grid they are becoming progressively more active and bi-directional with an increase in the number of production points and the presence of points that can alternatively be a source or a sink (i.e. the so-called prosumers).

Storage technologies [1] are a key part of the infrastructures, and have become more relevant over the past decades to decouple energy production (often deriving from discontinuous or uncontrollable sources) from its utilization. From the temporal perspective, in this paper the storage technologies are grouped into two categories:

- Short-term storage: this kind of storage technology is characterized by high power but low capacity and therefore it can act over time scales up to one day. It includes, for example, flywheels, batteries and thermal energy storage tanks.
- Long-term storage: this kind of storage technology is characterized by high power and high capacity and can act over time scales from days to months. It comprises, for example, flow batteries, pumped hydro, compressed air, chemicals, seasonal heat storage (e.g. pit thermal energy storage).

Besides the aforementioned energy networks, there is another energy distribution infrastructure, that was traditionally considered disconnected, but which is becoming progressively integrated: fuel for transportation.

2.3. Coupling technologies

Within an IES, the infrastructures described above are connected by means of coupling technologies, which can also be defined as bridging technologies. They are energy conversion units that convert an energy vector into one or more different energy vectors.

Conventional coupling technologies are (i) boilers (i.e. from fuels to heat); (ii) engines (coupled with alternators), which when configurated as cogeneration units can bridge the fuel domain with both the electrical energy and heat domains; and (iii) chillers (i.e. from electrical energy to cooling energy).

The most innovative technologies are heat pumps [1] and Power-To-Gas (PTG). Heat pumps are based on the same working principle of the electric chillers, but in heat pumps the output is the heat that it is delivered at high temperature. Heat pumps can work in a reversible way (i.e. using the electricity to produce heat in winter time and cooling energy in summer time) or they can also have a double effect (i.e. the production of both a cold and warm vector at the same time).

PTG refers to a technology that converts electrical energy into a gaseous fuel (e.g hydrogen or methane). It is therefore composed of an electrolyzer that produces a hydrogen stream, which can be stored or combined with a carbon dioxide stream to feed a reactor for their conversion into methane and water. The water can be removed by condensing it and the methane can be stored or injected into the network.

Table 1. Terms used in the literature to identify integrated energy systems in the context of sector coupling.

Name	Detailed explanation	References
Sector coupling	“The concept of SC encompasses co-production, combined use, conversion, and substitution of different energy supply and demand forms—electricity, heat, and fuels”	[9]
Integrated energy systems	“(IES) combine on-site power generation technologies with technologies for heating and cooling” and “bring together all forms of cooling, heating and power […] combined heat and power […], and cogeneration technologies.”	[10]
Multi-energy systems	“A system designed to allow the operator to choose between multiple energy sources”; and also systems “whereby electricity, heat, cooling, fuels, transport, and so on optimally interact with each other at various levels”	[3,11]
Hybrid energy systems	“Hybrid energy systems are combinations of two or more energy conversion devices (e.g. electricity generators or storage devices), or two or more fuels for the same device, that when integrated, overcome limitations that may be inherent in either.”	[7]
Energy hub	“A unit where multiple energy carriers can be converted, conditioned and stored. It represents an interface between different energy infrastructures and/or loads”	[12]
Smart energy systems	“an integrated holistic focus on the inclusion of more sectors (electricity, heating, cooling, industry, buildings and transportation) and allows for the identification of more achievable and affordable solutions to the transformation into future renewable and sustainable energy solutions”	[8]

By broadening the focus also to the transportation sector, charging infrastructure for electric vehicles can be considered as a bridging technology. It is worth mentioning that this coupling can also enable storage technologies such as Vehicle-to-Grid. This involves batteries of electric vehicles connected to charging stations being provisionally at the disposal of the power grid as storage to aid its operation.

3. Methodology

The methodology adopted to carry out the investigation in this work involved a thorough search of the current scientific literature concerning the subject of integrated energy systems in the framework defined in Section 2.1. The search in international scientific databases was conducted with a combination of keywords to identify both the subject and specific aim of each work. To this end, the keywords defined in Table 1 were in turn combined with keywords such as “optimization”, “control”, “management” and “operation”, in order to restrict the analysis to smart management tools.

Since sector coupling has become a broad topic over the last few years, and research papers have been growing continuously since the first definition, the output of this search was filtered adopting the following criteria for inclusion in the review:

- the paper covers a system with at least two energy vectors or networks;
- the paper presents a novel tool for the design, optimization or management of an IES;
- the spatial scale in which the proposed tool is applied is clearly identified within the scope of the paper;
- the time framework (e.g. time discretization, time horizon) for the application of the proposed tool is clearly determined.

The last two points are particularly relevant to this review. Indeed, the aim of this investigation is to classify the innovative methods and tools that allow an IES to be analyzed and optimized considering the differences that derive from the spatial and temporal dimensions.

To achieve this goal, the selected papers were thoroughly examined to extract their relevant features related to: (i) energy vectors tackled by the proposed tool; (ii) space and time scales; (iii) the presence of storage; (iv) the main aim of the tool; and (v) specific notes on the algorithms or software packages used. In addition, geographical and technical details on the case studies, if present, are noted. The features, divided into categories, are explained in Table 2.

Finally, the deriving information was collected in a broad table that presents an overview of the available studies, in order to:

- View the characteristics of each selected paper;
- Make comparisons between the presented tools;
- Understand which are the most covered aspects and, by contrast, the major gaps that should be tackled by future research;
- Verify if there are tools that tackle more than one feature at the same time, with reference to the same category.

Table 2. Features for the categorization of the selected papers.

Category	Features	Description
Energy vectors	Electricity, heating, cooling, natural gas, hydrogen, steam, other fuels, transportation*	The energy vectors comprised in the IES or included in the tool
Spatial scale	Building, community, city, region, nation or greater (Europe)	The spatial scale of application of the tool, ranging from individual buildings to systems spanning different nations
Time scale	Hours, days, weeks, year, or even multiple years	The time horizon for the investigation performed by the tool
Time discretization	Quarter hours or smaller, hour, day	The time-step for subdivision of the time scale of the tool
Storage	Short-term, long-term	The tool or application considers one or more types of storage, specifying its time scale
Aim of the tool	Simulation, optimization, management, design, long-term planning	Specific aim or aims of the tool (management is related to operation scheduling as well as real-time control)
Algorithms	-	If relevant, this field defines the existing algorithms or software used
Case study	-	If relevant, this field collects the main technical and geographical information of the case studies presented as applications

*Despite being a sector and not an energy vector, transportation was added to consider the aspects of mobility that can be integrated into a broader energy system (e.g. electric vehicles).

It is particularly relevant to consider the last point because, with the growing expansion of IES with different characteristics, it will be necessary to use versatile and multi-scale methods, and not just case-dependent tools that are tailored to a single application. The table of papers obtained in this review makes it possible to identify multi-scale studies (either spatial or temporal) and to verify where room for improvement can be found.

4. Results

The results of the investigation carried out in this work (and outlined in Section 3) are reported in Table 3, which lists the selected papers and the specific features of the proposed tools for the optimal design and operation of IES. The table aims to provide a basis for 1) making comparisons between methods, 2) selecting the most adequate method for a given application, and 3) understanding research gaps and drivers for the future. All these tasks are relevant to the expanding research field of IES.

Overall, 34 papers were selected for the scope of this analysis (and for the sake of space limitations), 4 of which were published before 2020 while the other 30 were published between 2020 and 2023. This distribution reflects the fact that, from the first definitions of sector coupling and IES in the mid 2000s, the number of works has dramatically increased over the last few years. However, it should not be concluded that, before 2020, researchers were not investigating these concepts. This literature search was conducted with precisely identified keywords, most of which were specified quite recently, and broadly adopted by researchers even more recently. Thus, most likely, the tools and methods proposed at earlier times were not labelled with the same definition. In addition, this literature search, which does not presume to be exhaustive, gave priority to more recent works, in order to delineate the latest tools available.

Various useful comments can be drawn from this overview:

- The sectors that are taken into consideration by the most part of papers are electricity, heating (sometimes coupled with cooling in district heating and cooling networks), and natural gas. These infrastructures are indeed the most advanced in current energy systems. However, it is expected that in the future other fuels (e.g. hydrogen, methanol and other non-conventional chemicals) will be an important part of an IES. This highlights a gap that deserves investigation.
- With regard to the building scale, it is common to only consider electricity and heating or cooling, i.e. the vectors that can be distributed internally, while few papers consider natural gas.
- On the contrary, at the scale of a wide region or an entire country, it is more common to include different types of fuels, whereas the aim of the analyses is mainly the optimal planning of capacity development in long-term scenarios (up to 2050). Real-time optimal management of PTG technologies was not found within the scope of this research.
- As already noted, large spatial scales are mainly devoted to simulating the system for future years, planning their development, or determining the optimal capacity and combination of sources for the considered area. In such cases, the time horizon for optimization is at least one year, but the management (with such a long time perspective) is carried out with typical days or typical weeks in the year. Thus, it is not representative of a real-time management tool.
- Investigations at community level are widespread, where community is often viewed as a district with a multiplicity of end-users, but it can also be seen as a set of coordinated power plants feeding a non-specified end-use. Particular attention should be paid to the end-use of each application. In any case, the community is equally analyzed with short time-scales (in the range of days, with the purpose of determining, in the best case, optimal control of the IES) or long time-scales (to schedule the operation of the system over an operating year).
- Storage technologies are almost always taken into consideration, since they enable flexibility and allow the full exploitation of optimal management, planning or design tools. Nevertheless, seasonal storage can be included in very few available tools, and only for those that view a relatively long time horizon.
- Overall, modeling and optimizing all energy sectors with fine discretization in terms of space and time can be computationally demanding. A feasible possibility is to increase the size of the time-steps or to select a few representative periods [13]. This strategy, however, can lead to biases in the generated optimal (or sub-optimal) solution.

An additional result of this research is the in-depth analysis of a selection of tools for each spatial scale, enriched with details on algorithms and case studies, where present. This is reported in Table 4.

It can be noted that a widely used method when dealing with optimal management at building and community scales is Model Predictive Control (MPC), which is an advanced control strategy that requires a model of the system. This feature, promising for the good performance of the management strategy, may make the problem intractable when the number of variables of the system grows. In general, the MILP formulation, a deterministic method that guarantees optimality, is the most used. For larger spatial scales, energy system models and sets of simulations with sensitivity analysis are used to deal with an increase in decision variables.

In light of the above, more studies and systematic reviews will be necessary to further outline the existing bibliography, and to investigate the links and relationship between all the presented features.

From this outline, it is also possible to derive research gaps that should be addressed to improve the smart management of future IES. Three significant drivers for further research are listed below:

- Optimal management of IES is generally tackled with a short time horizon, whereas it should be carried out with more than one time scale, one of which of the order of magnitude of months (up to one year). In this way, the IES control systems are able to account for the effects of long-term storage, large distribution networks and, most of all, storage into chemicals through PTG.
- Optimal management of IES is generally carried out at community level, by means of deterministic optimization algorithms that are subject to a drastic increase in computational time when the size of the system or the number of plants increase. Sector coupling implies indeed that all systems are always connected to neighboring areas. A potential solution to this issue is the decomposition of the problem into communicating sub-problems, each related to a spatial dimension. For this reason, research should focus on tools that consider more than one spatial level and can be implemented with similar features from buildings to wider regions.
- Most available tools for smart management are still at low levels of market readiness, as they are generally demonstrated with simulations or sensitivity analysis. Despite being challenging due to system size, it would be relevant to bring the proposed solutions to demonstration in an operational environment, in order to foster their uptake and see an actual impact on real systems.
- The use of hydrogen and other synthetic fuels produced by surplus electricity should be a determinant part of smart management tools, especially in the perspective of increasing the energy contribution from non-programmable RES.

5. Conclusions

Integrated Energy Systems (IES) have emerged over the last decade within the context of the energy transition toward a carbon-free sustainable future. They provide several advantages in terms of integration of renewable energy sources, system flexibility, and a cross-sectoral approach that uses synergies between various energy domains. However, this new framework requires smart management tools that can automatically drive an IES to optimal operation, overcoming system complexity and lack of expertise. This paper presented an overview of the available tools for the optimization and management of IES in the perspective of sector coupling. The focus of the analysis was to highlight the spatial dimension and time horizon for which the tools were designed. After a thorough review of the literature, the most relevant papers were selected, and their features were extracted and classified in a broad illustrative table. In addition, particularly representative tools for each spatial scale were further illustrated with their algorithm and case study technical details. It was possible to draw conclusions on the most commonly studied energy sectors and methodologies, as well as to identify gaps and guidelines for future improvement. In particular, the following aspects deserve further studies: i) tackling optimal management over multiple time scales (for considering long-term effects and real-time management simultaneously), ii) combining multiple spatial levels through decomposition methods, iii) including synthetic fuel production also at community level, and iv) promoting the demonstration of the tools in real case studies.

Evaluation of Energy Sharing on a Local Energy Market Through Comparison of Energy Management Techniques

Joel David Schölzel[a], Sarah Henn[a], Rita Streblow[a] and Dirk Müller[a]

[a] Institute for Energy Efficient Buildings and Indoor Climate, E.ON Energy Research Center, RWTH Aachen University, Aachen, Germany, joel.schoelzel@eonerc.rwth-aachen.de (CA)

Abstract:

Local energy markets (LEMs) are a promising way to solve the challenges of the increasing extension of decentralized energy systems and to promote the further integration of renewable energy sources. LEMs enable costumers with distributed energy resources to trade and share their electrical energy with each other. In the existing literature, the research focus is mostly on the development and evaluation of specific elements of LEMs, such as bidding strategies or market designs. The paper contributes a comprehensive evaluation of a LEM and the quantification of its benefit regarding the market-based device operation. For the evaluation in terms of financial outcome and local energy exchange, a centralized and a decentralized operation optimization serve as upper and lower references. In centralized optimization, the system boundary comprises the entire neighbourhood. In decentralized optimization, each building is balanced separately. For the LEM, we introduce a distributed market design with the involvement of an auctioneer. We focus there on the implementation of learning bidding strategies and a double-sided auction with non-iterative market clearing rules. For all three energy management techniques, the operating schedules of the devices are determined using mixed-integer linear programming. In several case studies we investigate different neighbourhoods in order to evaluate the influence of different technologies and their penetrations as well as the impact of the building stock in terms of building type and construction year. We evaluate the market outcome with multiple key performance indicators (KPIs) such as the supply- and demand-cover-factor, the total operation costs and the peak load. The results show that total energy costs can be reduced by up to 6.4 %. For the energy exchange, it is shown that the electricity surplus is up to 72 % and the electricity demand of the QUartier decreases by up to 6.8 % compared to the decentralized optimization and increases by up to 14.3 % compared to the centralized optimization. Further, we noted up to 46.2 % higher peak loads.

Keywords:

Local Energy Market, Evaluation, Energy Trading, Optimization Approaches

1. Introduction

For a successful energy transition, the energy supply in neighborhoods has to undergo substantial developments. Two of these developments are the increasing integration of distributed energy resources (DERs) as well as the electrification of the heating and mobility sectors. The end-users are responsible for the purchase of the corresponding devices. LEMs however can promote the further integration of renewable energy sources by giving households financial incentives. Auction-based local energy markets enable the trading and the exchange of energy between producers and consumers within a local area and participating households can reduce their energy costs this way.

For LEMs various market designs have already been developed. They differ with regard to the degree of centralization and topology, which influences the market clearing as well as the decision-making processes of operating and bidding strategies [1, 2]. Market clearing rules which select the admitted participants, determine the trading volumes and prices can be different for LEM. Further, several pricing mechanisms such as uniform pricing or pay-as-bid can be used in electricity markets [3, 4]. Also markets auctions can be divided into different types. These include whether the auction is open-cry or sealed-bid and whether it is one-sided or double-sided [5]. Various bidding strategies with different computation methodologies can be applied for placing promising bids on the market [6].

However, to fully understand the potential benefits and drawbacks of market processes there is a need of finding appropriate evaluation methods. They help to identify the most relevant technical aspects of the market design that increase efficiency and profitability of the electricity trading between consumers and prosumers on LEMs.

Within this work, we propose an evaluation methodology for LEMs in which decentralized and centralized optimization serve as worst-case and best-case references. We specify an auction-based market and a neighborhood of 20 households. The building energy systems (BES) of the households contain of heat pumps (HPs), combined heat and power plants (CHPs), thermal energy storages (TES) as well as photovoltaic (PV) and batteries (BAT). With different scenarios we analyze the influence of the different technology shares and the usage of a price signal for the LEM. We analyze the operation of a neighborhood regarding the energy exchange within and with the superordinate grid, the costs and revenues as well as the the caused emissions.

1.1. Evaluation of Local Energy Markets

The concept of LEMs has gained great traction in recent years for promoting renewable energy and energy efficiency. Evaluations of LEMs are important for understanding the market dynamics like trading volumes within a neighborhood and the resulting prices for the single households. Comprehensive and detailed evaluations are necessary to improve market outcomes in terms of trading efficiency, price fairness and thus cost savings for the households.

Zhou et al. [7] evaluated three different energy sharing mechanisms and two techniques for the convergence of market trading. The used mechanisms were supply-demand-ratio, mid-market rate and bill sharing mechanisms which mainly differ in terms of their iterative pricing. To achieve convergence in trading, change rates of prices and energy volumes were limited and a learning process is involved in the prosumers decision-making process. Three economic indexes and three technical indexes are proposed for the evaluation. The economic KPIs measure the realized overall benefits, the individual benefit compared to trading with fixed tariffs and the income equality within the households. With the technical KPIs the energy exchange with the superordinate grid, the peak power and the electricity demand that is covered by local generation are measured.

Okwuibe et al. [8] analyzed the electricity trading in hierarchical LEMs for different market structures. The market structure differs in the number of layers which result by introducing sub-LEMs that limit the number of trading end-users. Additionally, two market clearing mechanisms which are the double-sided pay-as-bid and the double-sided pay-as-clear are investigated. The different combinations of market structures and market clearing mechanisms are evaluated with KPIs like cost savings through market trading, the internal and external energy exchange, and average trade rate with varying market clearing mechanisms. Finally, the individual savings of different consumer and prosumer types are analyzed.

Sousa et al. [9] gave a comparison of different market designs with differences in the level of centralization and communication structure. A full peer-to-peer, a community-based, and a hybrid peer-to-peer market were analyzed and compared in terms of welfare, total import costs and export revenues to the superordinate grid as well as energy exchange within the market.

El-Baz et al. [10] identified the major factors influencing the market outcome and energy exchange. Several aspects of market design, microgrid configurations and user behavior were investigated for selected scenarios. For example the number of installed PV systems and their capacities are studied. Based on a double-sided auction-based LEM simulation the impact on the market dynamics and energy balance are analyzed and evaluated. For the evaluation, a reference model without a market-based operation is implemented. The four key performance indicators self-sufficiency, self-consumption, peak load and costs were calculated.

Schiera et al. [11] simulated a LEM with two trading systems that differ in terms of the pricing mechanisms. The pricing mechanisms and different member compositions were evaluated regarding the benefits of the neighborhood to identify new considerations in market design. A central mixed-integer linear programming was used as optimization model. The selected member compositions had various penetrations of PV systems and batteries. The results were evaluated with economic and technical indicators like single and total savings, the imported and exported energy as well as the self consumption ratio and the peak-to-average ratio.

Cramer et al. [12] compared an iterative auction-based LEM with a central optimization approach and a self-consumption approach. By aiming to maximize social welfare, an independence indicator is determined that relates self-consumption and traded energy to electricity demand within the neighborhood. This indicator determined for different flexibility levels.

1.2. Contributions

Most papers concentrate on analyzing different market designs to evaluate specific aspects of the design like market structure, market clearing rules or bidding strategies. However, there is a lack of publications that provide comprehensive evaluations of LEM by comparing them with other energy management techniques for neighborhoods. While there are many publications that provide detailed analysis of different market designs with a bunch of KPIs, only few publications deal with LEM using other optimization approaches and these existings ones rather offer superficial/simplified evaluations.

Furthermore, few studies still deal with the participation of flexible heat generators in LEM while most studies focus on the participation of prosumers that have PV systems and batteries.

The main contributions of this paper to research are:

- We implement two operational optimization approaches to evaluate the performance of an auction-based LEM in a comparative and comprehensive way. The decentralized optimization approach provides a lower benchmark without energy trading or coordinated energy exchange. The centralized optimization approach provides a upper benchmark with a controller having all informations.
- We implement an auction-based LEM where individual market participants perform their decision-making processes autonomously without information about other's trading behavior.
- We analyze the impact of the heat generators' shares by varying the number of the corresponding devices.
- We analyze the importance of approaches for shifting consumption and generation to the same times with the exemplary application of a price signal.
- We compare different prosumer types within the neighborhood, namely prosumer with PV systems and batteries and prosumer with CHP.

The following sections are structured as follows. In section 2., we firstly highlight the differences in modeling and balancing of the decentralized and centralized optimization approaches and introduce the evaluated LEM. Afterwards, we present the KPIs and the analyzed scenarios. We compare and evaluate the results on the scenarios in section 3.. The evaluation results finally are discussed and further research needs identified in section 4..

2. Methodology

2.1. Decentral and central optimization approaches

Decentralized optimization and centralized optimization are two different approaches to set-up optimization problems. The key difference between these optimization approaches are the degree of coordination and the decision-making authority. The difference in balance boundaries is shown in figure 1 by the red dashed lines.

Decentralized optimization refers to a scenario where the components or agents act autonomously and communicate with each other only when requested. Decentralized optimization can be more robust and efficient in situations where communication between agents is limited or when the system is large and complex. [1]

Centralized optimization refers to a scenario where a single entity, typically a central controller, collects all relevant information and decides based on that information to optimize the entire system. The central controller has complete control over every entity of the system and can optimize it as a whole. A centralized optimization model can run quickly into high complexity and scalability problems. [1]

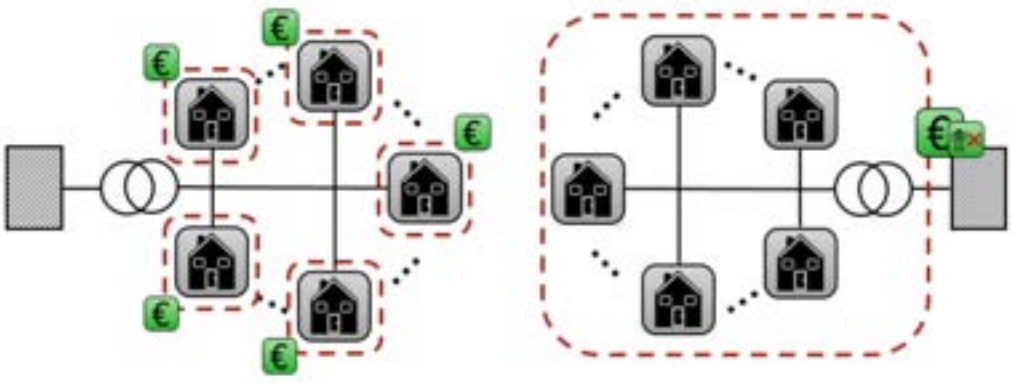

Figure 1: Balance boundaries (red dashed lines) for decentralized optimization (left) and centralized optimization (right)

For the optimal operation of the single BES and the entire neighborhood, we implement mixed-integer linear programs (MILP) of the corresponding systems. The BES model consists of constraints for the minimum and maximum power of the devices as well as for the maximum capacity of the energy storages. The state-of-charge of the storages is inserted as time-coupling constraint. The electricity balance of the BES is given by

equation 1 in which the power of the devices is coupled for every time step t with electrity demand from and the feed-in power into the grid. Thus, we assume that each building is connected to the local distribution network.

$$P_{\text{imp,t}} + P_{\text{PV,t}} + P_{\text{CHP,t}} + P_{\text{BAT,dch,t}} = P_{\text{inj,t}} + P_{\text{HP,t}} + P_{\text{ER,t}} + P_{\text{dom,t}} + P_{\text{BAT,ch,t}} \tag{1}$$

The objective functions of the decentral optimization approach are the minimization of the operational costs incurred from the purchasing minus the revenues for feed-in (equation 2).

$$min \quad C_{\text{BES}} = \Delta t \cdot \sum_{t \in T} (p_{\text{gas}} \cdot P_{\text{gas,t}} + p_{\text{imp}} \cdot P_{\text{imp,t}} - p_{\text{inj}} \cdot P_{\text{inj,t}}) \tag{2}$$

For the modeling of the entire neighborhood, the previously mentioned equations are extended by the electricity purchase and the electricity feed-in of the neighborhood into the superordinate grid level at the grid connection point (GCP) as well as the natural gas purchase (equations 3 - 5).

$$P_{\text{gas,t}} = \sum_{n} P_{\text{n,gas,t}} \tag{3}$$

$$P_{\text{GCP,imp,t}} = \sum_{n} P_{\text{n,imp,t}} \tag{4}$$

$$P_{\text{GCP,inj,t}} = \sum_{n} P_{\text{n,inj,t}} \tag{5}$$

For the centralized optimization approach, the objective function is the minimization of the operating costs and additionally of the peak load. In this case, the operating costs are the purchasing costs minus feed-in revenues at the local network station, because the system boundary includes the entire neighborhood.The peak load is considered in the objective function through a penalty factor (equation 6).

$$min \quad C_{\text{NH}} = \Delta t \cdot \sum_{t \in T} (p_{\text{gas}} \cdot P_{\text{gas,t}} + p_{\text{imp}} \cdot P_{\text{GCP,imp,t}} - p_{\text{inj}} \cdot P_{\text{GCP,inj,t}}) + pen \cdot P_{\text{GCP,inj,t}} \tag{6}$$

2.2. Local Energy Market Model

In this work, we evaluate an auction-based LEM with a hierarchical structure. This structure consists of two levels, the market platform and the operating system, as shown in the figure 2. On the market platform, the auctioneer performs market trading according to predefined rules. On the operating level, the building energy management system of each household determines autonomously the operational schedules of the corresponding devices taking into account a price signal sent by the market platform.

In the first step of the market procedure, each BES performs its operational optimization considering the price signal in the objective function instead of the fixed tariffs. With the information of the external power demand or the energy surplus to be fed into the power grid, the market agents create then the bids. In addition to the amount of energy, these bids also consist of the bid price. The market agents determine the bid price by using a Roth-Erev learning algorithm as bidding strategy. This algorithm combines two principles, namely reinforcing propensities regarding positive outcomes and flattening the learning curve over time. By this, the market agents consider the results of the historical market rounds as well as the success of the bids, which is incorporated into the probability distribution for future bidding [13]. [14, 15] have shown that the Roth-Erev learning algorithm enables the households to achieve promising economic benefits in energy trading.

In the second step, the auctioneer collects all the submitted bids of the supply side and the demand side and sorts them in step functions according to the bid prices. The underlying auction mechanism determines the market clearing price and the clearing quantity based on the received bids. In this work, the uniform pricing mechanism and therefore the intersection of the sorted supply and demand step functions is used to determine the market clearing price and the clearing quantity. [4]

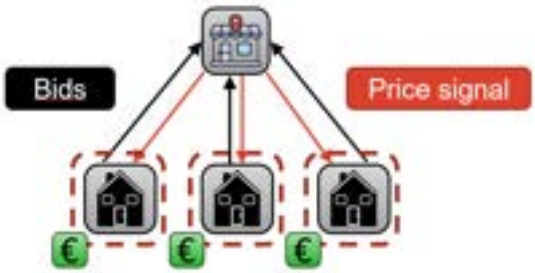

Figure 2: Structure of the local energy market and data exchange during market procedures

After the market clearing, the auctioneer sends the respective market outcome back to the market agents and the successful trades are performed. If in some market rounds there is insufficient local generation to satisfy the demand or excess generation, a superordinate grid with constant tariffs serves as a backup. Finally, a price signal is computed with the supply-demand-ratio mechanism and sent to the BES. This signal indicates, how the price trend for trading is going to develop in the next market rounds. The calculation is based on the hourly values of total supply and demand in the future time steps [7].

2.3. Key Performance Indicators

In this section, we introduce the following KPIs used to analyze the neighborhood operations of the three approaches and to and evaluate the auction-based market trading.

- Single costs and revenues: summed costs and revenues of the individual households within the neighborhood.
- Import and export energy: summed energy quantities imported from and exported to the superordinate grid.
- DCF and SCF: two energetic indicators that are calculated based on load and feed-in profiles of the BES. With them the coverage of the local electrical load by the local electrical generation and the share of self-used generation within the neighborhood are calculated. [16]
- Peak load: incurred during operation measured at the neighborhood's GCP.
- Emissions: caused by device operation in the neighborhood.

2.4. Use Case And Scenarios

To model the neighborhoods, we use our developed tool called "districtgenerator" [17]. It generates the annual profiles of the electrical load and heat demands of each building by using different tools. Using the TEASER tool, envelope areas and building physics parameters are calculated based on building type, floor area and construction year [18]. Additionally, it simulates thermal demands using a 5R1C model, while generating annual electrical load profiles and domestic hot water profiles through stochastic methods [19–21].

The building energy systems within the neighborhood contain electricity based heat generation devices for the heat provision. The single-family houses are equipped either with heat pumps or gas boilers, while the multi-family houses are heated with combined heat and power plants or gas boilers. Accordingly, electricity is also generated locally in the multi-family houses by the combined heat and power plants. Electricity generation at the single-family houses is achieved by PV systems in selected scenarios. Thermal storage and electrical battery storage systems are also taken into account. The technology penetrations vary across the studied scenarios and are presented in table 1.

In this study, we size the heat generators in accordance with german standards [22] and thermal energy storages based on [23]. The PV modules have standard size of 1.65 m^2. In the scenarios with PV systems, there are 20 modules per single-family house with a south orientation and an inclination of 35°, whereby the peak power is 6.38 kW. Furthermore, we use the specified discharge/charge power of 3.4 kW and storage capacity of 5 kWh, which data of commercial batteries.

Scenario	Constr. year	HP	CHP	Boiler	PV	BAT
16 HP	1996	80 %	20 %	0 %	0 %	0 %
8 HP	1996	40 %	20 %	40 %	0 %	0 %
0 HP / 4 CHP	1996	0 %	20 %	80 %	0 %	0 %
8 PV	1996	40 %	0 %	20 %	40 %	0 %
8 PV + BAT	1996	40 %	0 %	20 %	40 %	40 %

Table 1: Selected scenarios with the construction year and the share of devices

For the centralized and decentralized optimization approaches, the purchase electricity price is 42.0 ct/kWh, the feed-in tariffs are 8.2 ct/kWh for PV and 19.28 ct/kWh for CHP. The cost of the gas is 13.4 ct/kWh. For energy trading on the LEM, the purchase electricity price represents the maximum bid price and the feed-in tariffs represent the minimum bid price. We perform the operational optimization approaches and the LEM for a time horizon of an entire year.

For the Roth-Erev learning algorithm, we selected an experimentation parameter of 0.99 and a recency parameter of 0.08. Each scenario was pre-simulated for one year to obtain pre-learned propensities.

3. Results

3.1. Impact of the heat generator shares and the price signal

This section analyzes the summed costs and revenues of the households and the energy exchange at the GCP for different shares of heat pumps. Figure 3 shows the corresponding results. The costs for electricity and gas (dashed bars) as well as the revenues for electricity feed-in (lightened bars) are compared for different shares of heat pumps. Additionally, the electricity supply and feed-in (lightened bars) to the superordinate power grid are considered. The number of heat pumps supplying single-family homes varies, while all four multi-family homes are supplied with CHPs.

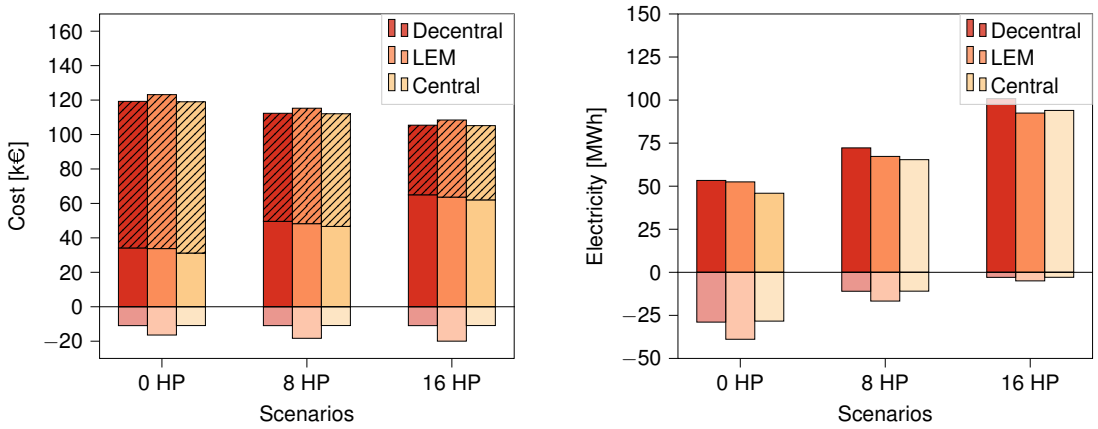

Figure 3: Summed costs and revenues of the households (left) and the energy exchange at the GCP (right) for different shares of heat pumps

In all three scenarios, the summed electricity costs of the households are highest with the decentralized optimization approach, amounting to 34.1 k€, 49.6 k€, and 65.0 k€, respectively. In contrast, the total costs for electricity consumption with the centralized optimization approach are the lowest, amounting to 31.2 k€, 46.6 k€, and 62.0 k€, respectively. Through electricity trading on the LEM, the total costs amount to 33.8 k€, 48.2 k€, and 63.7 k€. Compared to the decentralized optimization approach, the costs are thus reduced by 1.1 % to 2.7 %, while compared to the centralized optimization approach, the costs are 2.7 % to 7.6 % higher. Regarding electricity feed-in, households can achieve the highest compensation through trading on the LEM. These amount to 16.4 k€, 18.3 k€, and 20.0 k€, and are thus up to 83.0 % higher compared to both the decentralized and centralized optimization approach. Noticeable about the results is that the gas costs are highest with 44.8 k€, 67.0 k€ and 89.4 k€ for market-based operation. Thus, compared to the centralized optimization approach, 3.8 % more gas is consumed. Compared to the decentralized optimization approach, gas consumption is up to 10.7 % higher.

The price signal ensures that loads are shifted over time and that heat storages are loaded higher. This increases households' chances of benefiting from lower market prices, but also results in higher energy losses of the heat storages. To compensate these losses, the electricity demand of the heat pumps increases on the

one hand, and on the other hand the gas consumption of the CHPs increases. Furthermore, the operation of the heat pumps is no longer exclusively optimized for favorable outside temperatures to achieve the highest COP, which further increases the electricity demand of the heat pumps.

Another noticeable aspect are the higher revenues for electricity feed-in with an increasing share of heat pumps while the number of CHPs remains constant. The reason is the resulting market clearing prices of the individual scenarios. The average market clearing price is 30.7 ct/kWh in the scenario without heat pumps, 32.8 ct/kWh in the scenario with 8 heat pumps, and 34.2 ct/kWh in the scenario with 16 heat pumps. This increase in the average market price can be explained, on the one hand, by the increased demand for electricity and, on the other hand, by the learning bid strategies. With increased demand and a constant supply on the LEM, bids with higher prices are offered by the learning bidding strategy in the long term to increase the chance of being considered in the market clearing process.

Considering the total energy costs minus the revenues, the LEM performs better up to 1.4 % in the scenario without heat pumps, up to 4.3 % in the scenario with 8 heat pumps, and up to 6.4 % in the scenario with 16 heat pumps. The best result in the last scenario is mainly due to the high revenues. The highest average market price of 34.2 ct/kWh in this scenario, explains the highest revenues, although the number of CHPs and thus the electricity generation remains approximately the same. The high market prices are further an indication that the sellers profit more from energy trading than the buyers, because the difference from the market prices is on average smaller to $p_{\max}$ than to $p_{\min}$.

		CO_2e [t]	Peak load [kW]	SCF [%]	DCF [%]
16 HP	Decentral	148	65	95	35
	LEM	159	95	93	43
	Central	155	63	95	36
8 HP	Decentral	210	40	81	39
	LEM	222	62	77	46
	Central	216	34	81	4
0 HP	Decentral	274	31	49	34
	LEM	287	33	47	40
	Central	280	24	50	38

Table 2: Results of caused emissions, peak load, self-cover-factor and demand-cover-factor

As shown in figure 3, the amounts of electricity fed into the superordinate grid are highest in all three scenarios for the market-based operation. Compared to the centralized optimization approach, these amounts are 37.2 % to 72.0 % higher, and compared to the decentralized optimization approach they are 34.4 % to 69.4 % higher. These results can be explained by the fact that increased load shifts in market-based operation of the CHPs lead to greater heat losses and the compensation of these losses results in increased electricity generation. These results are also reflected in the results of the self-cover-factor as seen in table 2. With a high share of heat pumps, the absolute difference in electricity feed-in between market-based and optimization-based operation is significantly lower. Electricity consumption is up to 6.8 % lower than in the decentralized optimization approach in all scenarios. Compared to the centralized optimization approach, the electricity consumption of the quarter is 14.3 % and 3.0 % higher in scenarios 1 and 2, respectively, while it is 1.6 % lower in scenario 3. These results show that the used price signal improves local electricity consumption, which is also supported by the demand-cover-factors in table 2.

Figure 4 exemplarily shows the course of the residual load for a cold week of scenario 2. During this period, three peak loads can be seen for the decentralized optimization approach. These peak loads are avoided both with the centralized optimization approach and with the market-based operation under usage of the price signal. Nevertheless, the results of the peak loads for the entire seasonal period (table 2) show that the peak loads are significantly higher at individual time steps. This presumably happens when the price signal triggers opposing operational adjustments. Heat pumps collectively shift their electricity consumption to a favorable time step, while the power generation of the CHPs is shifted away from it.

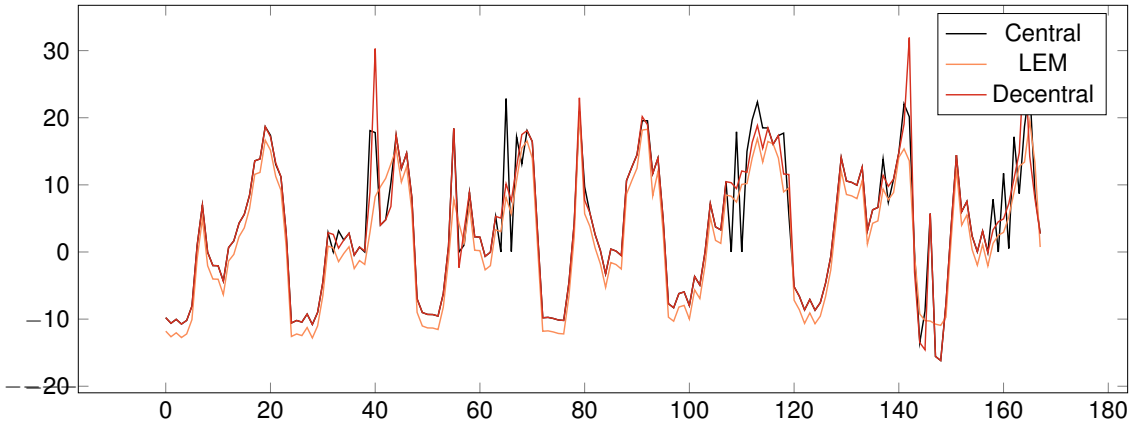

Figure 4: Residualload of the neighborhood at the GCP

3.2. Impact of the PV systems and batteries

The following section analyzes the impact of the electricity generation systems on the market outcomes and electricity exchange of the neighborhood. Scenario 2, in which four CHPs provide electricity generation in the neighborhood, scenario 6, in which six PV systems generate electricity in the neighborhood, and scenario 7, in which BESs have battery storage in addition to PV systems, are compared. In these three scenarios, heat is provided to six single-family homes by heat pumps.

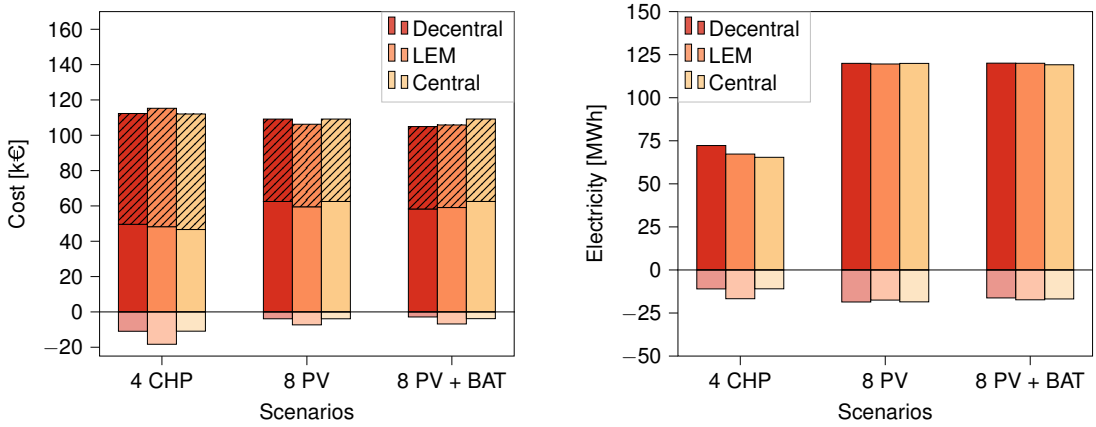

Figure 5: Summed costs and revenues of the households (left) and the energy exchange at the GCP (right)

Figure 5 shows the results of the summed costs and revenues of the households and the energy exchange at the GCP. As seen in the previous section, the revenues are again higher for the scenarios with PV systems with the market-based operation than with the optimization-based operations. While the cost of electricity and gas is slightly lower for the PV scenarios compared to the CHP scenario, the revenues are lower.

Figure 5 further shows that the market-based operation with price signal has only a slight impact on the electricity exchange at the GCP. This is due to the electricity demand of the heat pumps, which exists especially in the cold periods. At these times, however, there is less solar irradiation and thus less power feed-in from the PV systems. Consequently, the potential energy exchange and the trading volume is significantly lower.

		CO_2e [t]	Peak load [kW]	SCF [%]	DCF [%]
4 CHP	Decentral	210	40	81	39
	LEM	222	62	77	46
	Central	216	34	81	41
8 PV	Decentral	175	58	61	19
	LEM	172	57	63	20
	Central	175	47	61	19
8 PV + BAT	Decentral	174	58	53	13
	LEM	172	76	65	19
	Central	174	47	64	20

Table 3: Results of caused emissions, peak load, self-cover-factor and demand-cover-factor

Table 3 shows the remaining results. When comparing operating methods, again that the market-based operation with the usage of the price signal causes significantly increased peak loads. The comparison between generation technologies shows that PV systems causes significantly less emissions, but also results in lower local self-supply and local self-consumption compared to the scenario with CHPs.

4. Conclusions

In this study, we proposed an evaluation of a local energy market by comparing it with a decentralized and a centralized optimization approach. An auction-based LEM with uniform pricing as market clearing process was introduced and learning bidding strategies for the market agents were implemented. To obtain convergence in supply and demand on the market, a price signal was sent to the building energy systems, which served as input to the operational optimization. We examined a neighborhood with single-family and multi-family buildings and analyzed several scenarios with different shares of heat pumps, combined heat and power plants, PV systems and batteries.

We demonstrated that auction-based energy trading can reduce household electricity costs compared to operating the decentralized optimization approach. However, we must emphasize that in the decentralized and centralized optimization approaches, no deviating tariffs for electricity purchase and feed-in were possible. Therefore, it should be examined whether the costs and revenues of the two optimization-based approaches should be allocated with adjusted tariffs in the future in order to improve comparability.

For the overall cost and revenue analysis, the costs and revenues of each household were summed. In the future, a comprehensive evaluation should also examine individual costs and revenues more detailed to determine the fairness of the energy trading.

We have also shown that market-based operation leads to more energy inefficient operation of heat generators. The operation of the heat pumps is no longer geared only to outdoor temperature, and the increased use of heat storage increases heat losses in the neighborhood. Therefore, an indicator should be considered in the future that takes the energetic losses into account.

By using the price signal, we were able to show that the energy exchange and trading compared to decentralized operation can be improved. However, higher maximum peak loads indicate that at individual time steps, load shifting from the generation and demand side can result in opposite directions. Considering that we have used a price signal based only on supply and demand quantity, in the future parameters should include in the calculation of the price signal, which avoid higher peak loads. In addition, to improve energy exchange and trading for auction-based LEM, further techniques for convergence of generation and demand need to be identified and analyzed.

Abstract:

Mediterranean islands have always struggled with power supply, with the high cost of electrical submarine cables prompting the pursuing of energy self-sufficiency with renewable energy sources (RES). Despite being clean and sustainable, RES are intermittent and unpredictable, hence the integration of a storage system is crucial to match load with production. Modern batteries are a valuable solution for short term storage, but they are unsuitable for long term storage for both technical and economic reasons. Green hydrogen is among the most promising options to enable a year-long autonomous operation, but it is still an expensive option, with many technical issues that still need to be addressed. One of the key factors hampering a reduction of the levelized cost of green hydrogen (LCOH) is the low number of working hours that an electrolyzer can exploit when connected to low-capacity factor RES. Starting with real production data of a wind turbine and a PV farm in a Mediterranean island, this study aims to assess the optimal combination of wind and solar power to decrease the LCOH (intended as its production cost only) and thus the cost of storage.

The study is made of three steps. First, a comprehensive parametric optimization is carried out to determine the optimal combination of electrolyzer and PV field size to minimize the LCOH produced from the surplus power generated on the island. Secondly, an additional analysis is performed to calculate the minimum PV field expansion required to achieve a complete energy self-sufficiency and to estimate the resulting LCOH in such case. Lastly, the implementation of a fleet of hydrogen buses is proposed to both reduce the carbon footprint of the island transportation system, and further lower the cost of hydrogen production.

Keywords:

Green Hydrogen; Island; Wind; Photovoltaics; Techno-economics; LCOH.

1. Introduction

The focus of the present study is the estimation of the cost of producing green hydrogen on the island of Tilos, as a potential upgrade of the hybrid energy system (HES) currently in use. Nowadays, the system involves a 800-kW wind turbine, a 160-kWp PV field, and a 2.88 MWh battery in proximity of two villages. These villages experience a peak demand of 960 kW during the summer season.

More specifically, the objective is to assess the potential for hydrogen production using the excess power generated by the HES due to the mismatch between intermittent renewable energy production and demand. This excess power is harnessed for water splitting using an alkaline electrolyzer.

The analysis first evaluates the energy deficit and surplus of the HES, initially considering only the RES production and then assessing the storage potentiality. An electrolyzer model is then used to analyze the H_2 production potential from the power excess profiles generated by different scenarios resulting from the upgrade of the PV field. For each simulated couple of increased PV power and electrolyzer sizes, the levelized cost of hydrogen (LCOH) is calculated. Next, the annual hydrogen generation is compared with a preliminary estimation of the amount of hydrogen required to achieve 100% self-sufficiency by reconverting it back to electricity using a fuel cell. The aim is to identify the configuration that produces the cheapest hydrogen in the case a form of seasonal storage is needed. Additionally, this study explores the possibility of using hydrogen excess to power a fleet of buses, which would help in the decarbonization of public transport during the summer

season without imposing an additional strain on the electrical grid. Moreover, it is demonstrated how an increase in the amount of produced hydrogen could further lower the LCOH.

This preliminary assessment aims to evaluate the green hydrogen production potential in remote islands. Those communities may largely benefit from a suitable mean of seasonal storage, due to their highly variable energy demand during the year.

1.1. Tilos project

Tilos belongs to the Greek Non-Interconnected Islands (NIIs) group, i.e., remote communities in the Aegean sea whose electricity requirements have been almost entirely supplied by a local generation based on outdated thermal power stations that rely on diesel and heavy oil [1]. Due to the high solar radiation and pretty high wind speeds that characterize the region, the energy production of the area could be shifted towards a more sustainable generation based on renewable sources. Funded by the European Horizon 2020 project, the hybrid energy system (HES) of Tilos was completed in 2019 and comprises of an Enercon E-53 800-kW wind turbine and a 160-kWp photovoltaic field. In addition, a 2.88-MWh high temperature battery was selected as the storage medium to manage the intermittent energy fluxes from renewable generators [2]. Today, the HES is owned and managed by Eunice Energy Group (EEG), which kindly provided real operational data used for the analyses.

1.2. Green hydrogen production in islands

As a complement to the introduction of RES, green hydrogen and power-to-gas technologies are seen as promising for a variety of applications for the island of Tilos and other similar communities. Due to the significant variation of the electrical energy demand resulting from the seasonal variation of the population, green hydrogen tanks could be in fact a suitable option to store the energy generated in the winter season, when the population is minimum. Then, H_2 can be converted back to electricity during summer when tourists make the population triple.

Several studies have already proven that green hydrogen can be used for seasonal storage. H_2 produced by means of water electrolysis driven by renewable power produced by PV and wind generators can be stored in tanks and, when needed, reconverted into electricity via fuel cells or thermal machines. Lubello et al. [3] assessed the feasibility to utilize hydrogen for long-term storage in energy systems. Despite being inconvenient in normal scenarios, an island could be a suitable candidate for this kind of applications because of its remote location and thus high costs of connection with the main grid. Another viable and promising option is the export of clean fuels. Vilbergsson et al. [4] investigated the potential of producing green hydrogen in remote locations with abundant renewable resources. If electrolysis is utilized to exploit the energy surplus of those communities, a suitable option could also be to export the fuel towards the mainland. Even considering transport, authors proved that hydrogen produced in this way could have a lower environmental impact than yellow hydrogen produced using grid electricity in some European countries.

The possibility of producing hydrogen in a Greek island has been previously investigated by Lykas et al. [5]. The authors performed a dynamic investigation and optimization of a solar-based unit for green hydrogen production by means of a PEM electrolyzer and found that their system can meet the variable demand of an island. The present work builds upon the same main concept and considers a similar location, but different RES generators and another, yet similar, electrolyzer technology, while additional scenarios for hydrogen use are introduced. One factor that may hinder the introduction of this energy vector in islands is the high production cost. To this end, the correct sizing of the hydrogen production plant for an optimal exploitation of all components is key to minimizing the expense. The levelized cost of hydrogen (LCOH) of generating hydrogen from a mix of solar and wind power in different locations with different capacity factors was computed by Tang et al. [6]. In the study, authors calculated the price difference of producing hydrogen in locations with a different availability of renewable sources and proved that LCOH may vary from 7.2 €/kg in low windy areas to 3.5 €/kg if the plant has a high availability of the renewable resource. This result reinforces the interest in investigating the hydrogen production potential of islands, due to their high-RES potential.

1.3. Aims of the study

This study assesses the green hydrogen production potential of the hybrid energy system (HES) of the island of Tilos and the resulting cost for producing it. Figure 1 represents the layout of the considered plant and schematizes how clean power produced by renewable generators, supported by the battery energy storage, satisfy the island load. In addition, the power excess is considered as the input for an alkaline electrolyzer that splits water molecules in oxygen and hydrogen. The hydrogen can then be utilized by users or stored in high pressure tanks for further applications. A first sensitivity analysis on a wide range of electrolyzer sizes and possible PV upgrades was used to assess which configuration can produce hydrogen in Tilos at the lowest cost exploiting the power production excess of the island.

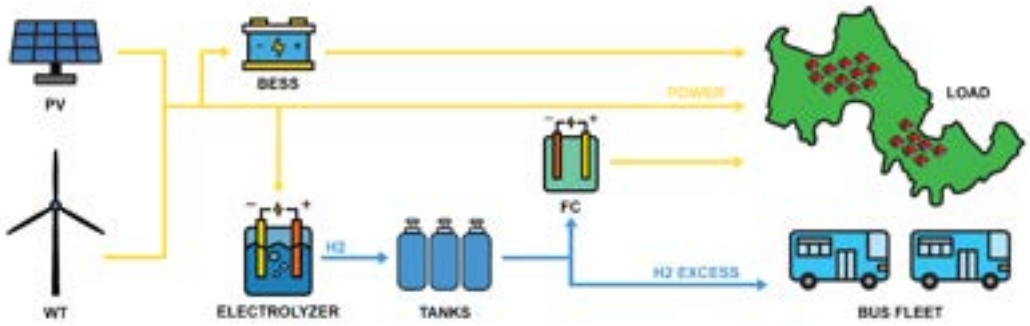

Figure. 1. Tilos HES layout paired with green hydrogen production from power excess and an example of its possible utilization

Then, the possibility of using such hydrogen as seasonal storage is presented, which is supposed to be achieved by means of a fuel cell that converts the gas back to electricity. The hydrogen production capability of different configurations is compared to their hydrogen demand to reach 100% self-sufficiency. The scope is to assess the minimum required upgrade of the PV field to reach total energy independence and to figure out what would be the LCOH in that case. Finally, the LCOH of the hydrogen excess produced by those systems is quantified and a possible exploitation of that excess is proposed. Hydrogen can indeed represent a clean fuel for the decarbonization of the public transport system of the island, and a reduction in the cost of the production excess can make it a competitive fuel with respect to current fossil alternatives.

2. Materials and methods

2.1. Available data

Historical production data of the HES have been made available by EEG, the owner and manager of the system. These data cover eleven months of operation, from November 29th, 2020, to October 29th, 2021, and contain solar production and wind speed measurements sampled with a 1-minute time resolution, directly harvested by the energy management system (EMS). During the first phase of the work available data have been analyzed to produce a consistent input for the hydrogen production model and missing data have been filled. In addition, to carry out relevant production estimations and compare results with literature, a year of operation is required. To address this, PV and wind production datasets were further filled and extended as described in the following section.

2.1.1 Reconstruction of missing data

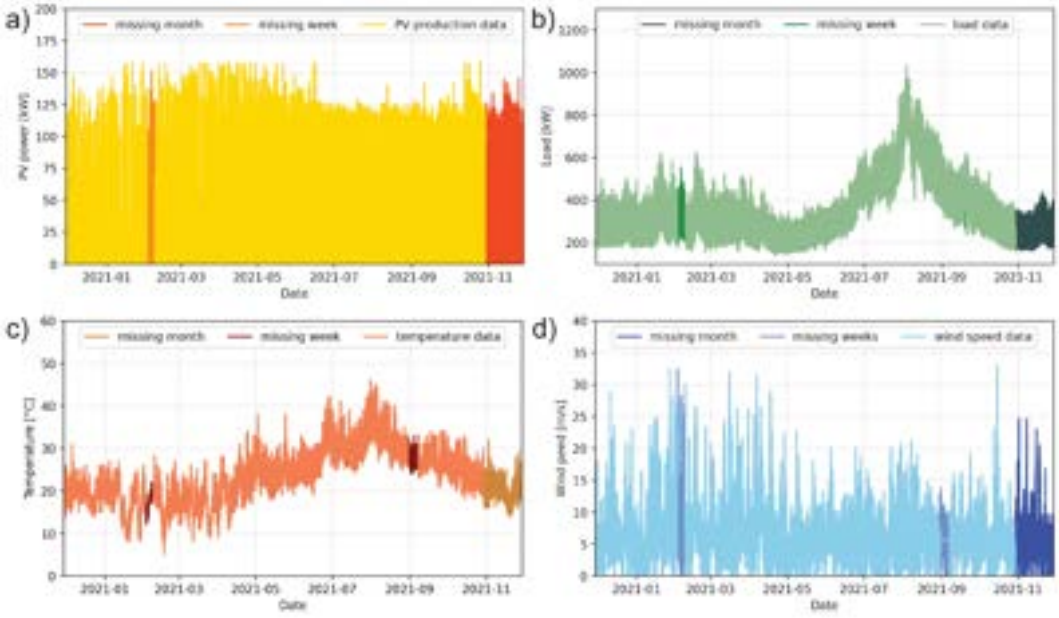

Figure. 2. Time trend during the considered period operation and highlight on reconstructed data related to missing weeks and missing month for a) PV production, b) load, c) ambient temperature, and d) wind speed.

PV power – Regarding the PV production dataset, a linear interpolation was first carried out to fill missing production for hourly periods. This simple yet effective method produced satisfying results for short time intervals. Production data filled using linear interpolation are represented in yellow in Figure 2 (a). The analysis showed that, for each quantity, the period between Feb 2nd and 8th 2021 is missing. To fill this missing spot, a support vector regression (SVR) was applied to find the correlation between the missing data and the value recorded one, two, three and four weeks before. This reconstruction is visible, in orange, in Figure 2 (a). SVR was also applied to reconstruct the missing month from 29th October to 29th November 2021, finding correlations with the previous month and two months prior. The filled month is again visible in Figure 2 (a), in red.

Load and temperature - Load and temperature datasets were cleaned and filled in a similar way. The load dataset was cleaned by abnormal data points. Outliers too far from the moving average of the load time series were removed, as well as isolated missing values given by measurement errors. Then, gaps shorter than 5 hours were again filled by a linear interpolation with satisfying results. After that, short missing periods in the order of days to one week were filled using again SVR trained on the autocorrelation of the series with its own past values. In Figure 2 (b), the resulting reconstructed periods are highlighted in green. Finally, the missing month was reconstructed by means of a multi-layer perceptron regression. Because of the shape of the series, the method was trained on the first 3 months of data. Figure 2 (b) shows the final obtained load trend. The temperature dataset was pre-processed, cleaned, and filled as well. Using the same methods described for the load dataset, missing periods were reconstructed. The whole year temperature time trend is presented in Figure 2 (c).

Wind speed - The wind speed dataset was lacking the same week of February and the final month of November 2021. Due to the small length of the period and low autocorrelation of the wind series, it was chosen to copy measures from previous days to fill the gaps. In this case, an abnormal measure characterized the period between August 31st and September 8th, 2021, for which a constant value was reported for the wind speed, due to a malfunctioning of the acquisition system. Those data were rejected and substituted using the same procedure utilized for the missing week. Then, for the missing month, winter days were sampled from the dataset at random to reconstruct the missing data. Figure 2 (d) reports the wind speed related to the eleven months in light blue, the reconstructed missing weeks in blue, and the reconstructed missing month in dark blue. Finally, via the ideal power curve of the Enercon E-53 800kW wind turbine, the power production was estimated from the obtained wind speed data for the entire year.

2.2. Resource assessment

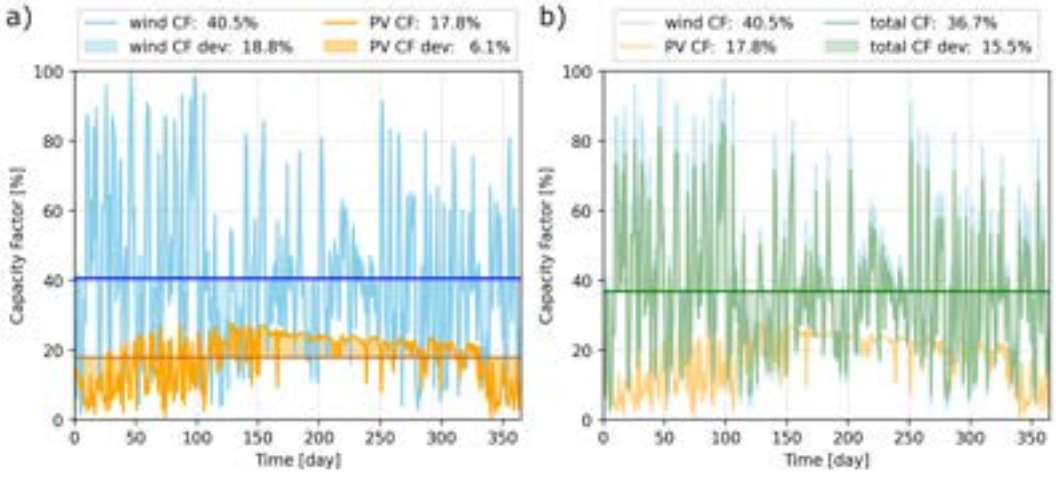

Figure. 3. Daily variation of average capacity factor (CF) and yearly mean value for: a) wind turbine (in blue) and PV field (in orange) and b) hybrid energy system composed by the previous two.

In Figure 3, power production data have been reorganized from January to December, moving the first month of the original dataset to the end, in order to appreciate the seasonal variation of the two resources. Instead of the power production itself from each generator, the energy assessment was based on the generator capacity factor (CF), i.e., the ratio between the actual energy production in each time frame and the energy that the same generator would have produced during the same interval if working at rated power. Figure 3 (a) shows the daily average CF of the wind turbine (in light blue) and PV field (in orange). The CF of the wind turbine is normalized with respect to its nominal power, 800 kW, while the one of the PV is normalized to its peak power of 160 kWp. The dark blue and dark orange flat lines represent the average CF of generators, 40.5% for the WT and 17.8% for the PV. This remarkably high wind capacity factor would in practice be much lower due to the frequent curtailments made by the grid operator to avoid instability problems [7], again proving the need

for a suitable energy storage system. It is apparent how the capacity factor of the PV is higher during the summer season than in the winter season, due to the higher solar radiation and light hours. On the other hand, the wind turbine tends to produce slightly more during winter and spring season. In general, as expected the two resources show a certain degree of complementarity, and their combination may lead to steadier energy productions during the year. Figure 3 (b) shows in green the total CF of the system, given by the sum of power generated by the two resources. Its average value (36.7%) is lower than the one related to the single turbine, but its deviation is lower: 15.5% vs 18.8% of the WT because of the lower variation of the PV (6.1%).

2.2.1 Power surplus and deficit during the year

Figure 4 (a) illustrates the match between the weekly average power production (in black) and the average island demand (in red). As discussed, the weekly average power production shows how the synergy between wind and solar energy makes the power production average almost constant during the year. On the other hand, the island demand is characterized by a clear peak during the summer season, primarily due to the presence of tourists that greatly increase the population of the island and thus its energy needs. Therefore, a considerable power deficit of around 1046 MWh affects summer months. During the rest of the year, especially in the first part, the decrease in the island population creates a power excess of around 1125 MWh.

2.2.2 Battery supported operation

A 2.88 MWh lithium-ion battery is considered to simulate how an electrochemical storage device, close to the actual one installed in the island of Tilos, would shift the power profile. Because of the strong seasonal variation of the island load, the current storage size cannot shift the entire power excess towards the power deficit. In our preliminary estimation, the 2.88 MWh BESS still creates an energy deficit of 755 MWh during summer, and the system reaches 74.9% of self-sufficiency. In that scenario, the power excess of more than 781 MWh created in winter months, when the load is covered by the current RES generation and the battery is already full, has the potential to be converted to hydrogen for seasonal storage. Figure 4 (b) clearly shows how the BESS could fill the gap between surplus and deficit energy, although the daily averaged profile of the delivered power slightly differs from the original one. Thus, a seasonal storage device seems the perfect candidate for meeting this residual requirement.

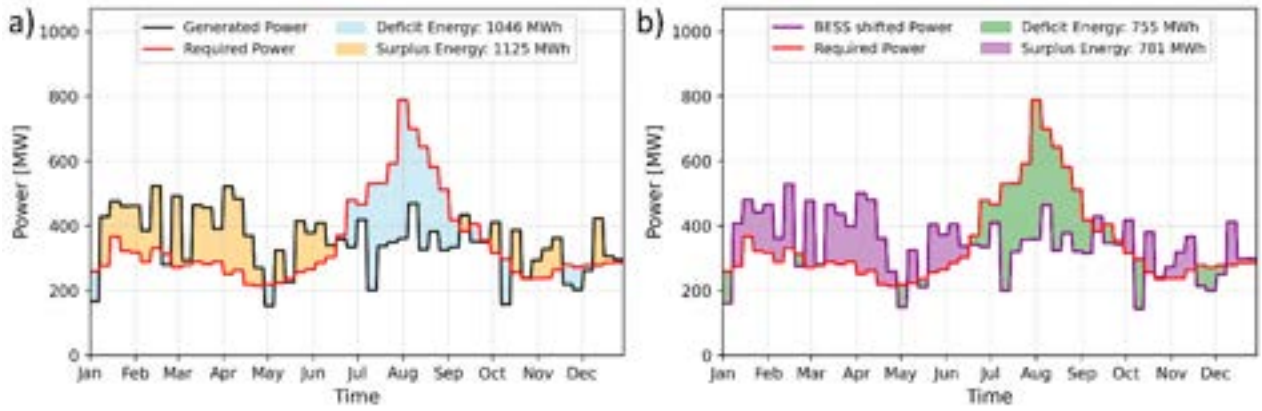

Figure. 4. Match between the daily averaged power production (black line) and the island demand (red line). Highlight on energy surplus (orange/purple areas) and energy deficit (light blue/green areas) for a) RES production and b) BESS-shifted production.

2.3. Green hydrogen production

An in-house alkaline electrolyzer model was developed by some of the authors and was already applied to some other case studies for the green hydrogen production from wind farms [8]. The model was based on the 1MW commercial electrolyzer produced by McPhy, a leading alkaline electrolyzer manufacturer. Since the current Tilos HES has a nominal power of 960 kW, the electrolyzer stack had to be resized to meet the power excess magnitude of the system. Power absorbed by a cell is given by the product of its current and voltage (Eq. 1) and, in this case, corresponds to roughly 9.45 kW. The stack of the commercial 1MW electrolyzer is thus composed of roughly 106 cells connected in series. In this work, customized stacks made by the series connection of a variable number of cells were considered to reach various power levels between 200 kW (22 cells) to 1.5 MW (150 cells), to match the total nominal power level of the HES composed by the wind farm and the PV field.

The operating voltage of the electrolyzer varies due to the performance degradation in time and cool down effect when the H_2 production stops. This time, the main component responsible for the thermal loss, the gas-liquid separator, is scaled according to the considered number of cells to maintain the proper mass flow rate of hydrogen. At each timestep, the conversion factor of the stack is updated according to Eq. 1.

$$\varphi = \frac{H_{2,id}}{I_{id} \cdot n_{cells} \cdot (V_{ideal} + \Delta V_{time,deg} \cdot h_{work} + \Delta V_{Thermal,deg} \cdot (T_{rated} - T_{el}))} \quad (1)$$

To analyze the H_2 exploitation, a fuel cell with a fixed conversion efficiency was considered for the conversion of gas back to electricity. According to IRENA [9], the efficiency of this technology typically ranges between 50 to 68%, thus an average value of 60% was considered for this analysis.

2.5. LCOH

$$LCOH = \frac{\sum_{t=0}^{20} \frac{(CAPEX_t + OPEX_t)}{(1+i)^t}}{\sum_{t=0}^{20} \frac{H_{prod}}{(1+i)^t}} \quad (2)$$

The levelized cost of hydrogen (LCOH) was selected as the main techno-economic metric for comparing different plant layouts. It represents the cost of producing a unit of hydrogen over a selected period of time (20 years in this case) by means of a certain configuration. The LCOH can be computed, according to Eq. 2, as the ratio between the actualized sum of capital (CAPEX) and operating (OPEX) costs and the actualized hydrogen yield of the plant (H_{prod}), considering in this case a discount rate *i* of 6%.

Capital costs (CAPEX) consider the investment cost for the electrolyzer. According to IRENA [9], a 1MW electrolyzer stack has a specific cost of 270 €/kW and accounts for 45% of the total price of the device. Consequently, the electrolyzer price cost was scaled when smaller or bigger stacks were considered, while the balance of plant (BOP) cost was kept constant. CAPEX also includes the substitution costs that must be faced when a part or a whole component must be substituted. The electrolyzer stack has an expected lifetime of 10 years, thus a replacement is expected halfway the plant life.

Operational costs (OPEX) consider instead the necessary maintenance to keep the electrolysis in proper operating conditions, in this case assumed equal to 2.75% of its initial investment. OPEX also accounts for the cost of energy generated by the wind turbine and the PV panels. Since generators first aim to feed the load of the island, only the cost of the consumed energy by the electrolyzer is considered here for the preliminary LCOH calculation, and it was assumed equal to the LCOE of RES. According to IRENA [10], the LCOE was 33 €/MWh for offshore wind and 48 €/MWh for PV in 2021. For this study, because of the energy mix of Tilos HES, such cost was considered equal to 40 €/MWh. Because of the uncertainty and variability of this cost, the present analysis assumed a constant LCOE even when the PV share in the energy mix increases.

Storage, distribution, and utilization costs of the hydrogen have been excluded from the calculation since the scope of the current work is to evaluate the theoretical production cost of H_2 in the island. Possible utilizations of the gas presented in section 3 are studied mainly to assess the required H_2 annual yield, functional to correctly estimate the size of components and key for the LCOH calculation.

3. Results

This section presents the main results related to the hydrogen production potential of several configurations involving different sizes of the photovoltaic field and electrolyzer power levels, assessed by means of the previously described framework. Electrolyzers are fed by the excess power of the HES, after that the wind turbine and the augmented PV field have satisfied the load of the island with BESS support. For each of those configurations, a year of operation was simulated and, together with the amount of hydrogen that each of those can provide, the LCOH and the annual yield were assessed to compare their performance.

3.1. LEVELIZED COST OF HYDROGEN

To provide a general overview of the optimal combination of PV and electrolyzer power to reach the minimum LCOH on the island of Tilos, Figure 5 displays the LCOH for every computed combination of electrolyzer power ranging between 200 and 1400 kW fed by PV power ranging between 0 and 1600 kW, in addition to the fixed 800-kW wind turbine. Inefficient combinations of high PV power and small electrolyzer modules, as well as low PV powers and high electrolyzer power combinations, can be observed in yellow areas. As previously mentioned, it is essential to maintain a right balance between the two to correctly exploit the system.

The area in which combinations lead to the cheapest green hydrogen is characterized by intermediate electrolyzer sizes, between 400 and 800 kW, paired with high PV powers (dark blue region). Overall, increasing the PV size makes the energy surplus high enough to enhance the electrolyzer exploitation and recover the initial investment cost. To optimally utilize the energy surplus of current Tilos HES, a 475-kW electrolyzer should be installed. The analysis shows that a kilogram of hydrogen produced in that way would cost 6.46 €. If the upgrade of the PV field peak capacity is allowed so as to reach the nominal power of the wind turbine of 800 kW, a 520-kW electrolyzer would bring down the price to 5.04 €/kg.

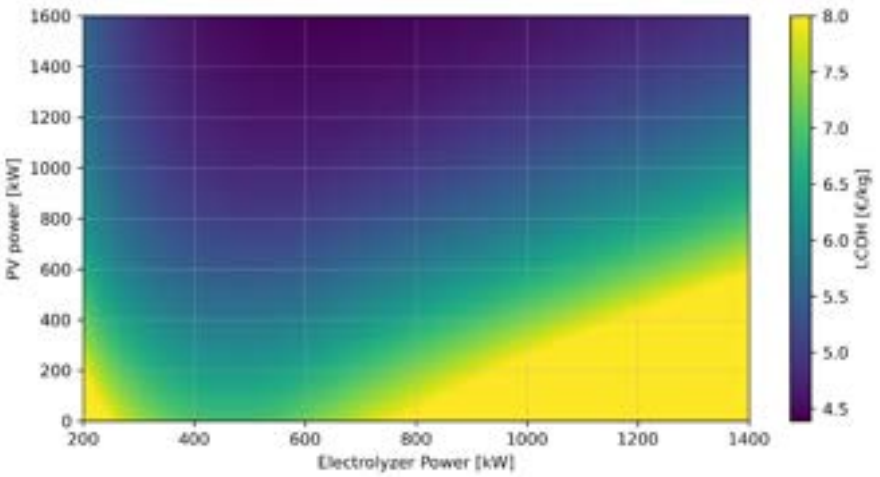

Figure. 5. Colormap showing the levelized cost of hydrogen (LCOH) for each considered combination of electrolyzer and PV power. High LCOH in yellow and low LCOH in dark blue.

It is worth mentioning that the lowest price achieved by the simulation is 4.38 €/kg and given by the combination of a 615-kW electrolyzer with 1600-kWp PV field. However, such a high installed capacity cannot be easily installed in the island. Depending on the hydrogen production requirements that could arise if green gas must be utilized for seasonal storage or other applications, a higher production cost may be acceptable to increase the annual yield. To put those numbers in perspective, the next subsections consider possible uses of green hydrogen.

3.2. HYDROGEN AS SEASONAL STORAGE

This section presents the results of a scenario in which green hydrogen is used as seasonal storage. Hydrogen generated during winter is converted back to electricity during summer to reach 100% energy independence. Figure 6 (a) displays the mass of hydrogen required to reach 100% self-sufficiency (in light blue), varying the installed PV power. Increasing the installed PV capacity generates more renewable power in the summer season, when the demand peaks, leading to an increase of self-consumption. As a result, the required hydrogen curve shows a decreasing trend. The same figure also shows the hydrogen amount that electrolyzers of different sizes (ranging between 0.5 to 1 MW) can produce by exploiting the power excess of the system, always varying the PV capacity.

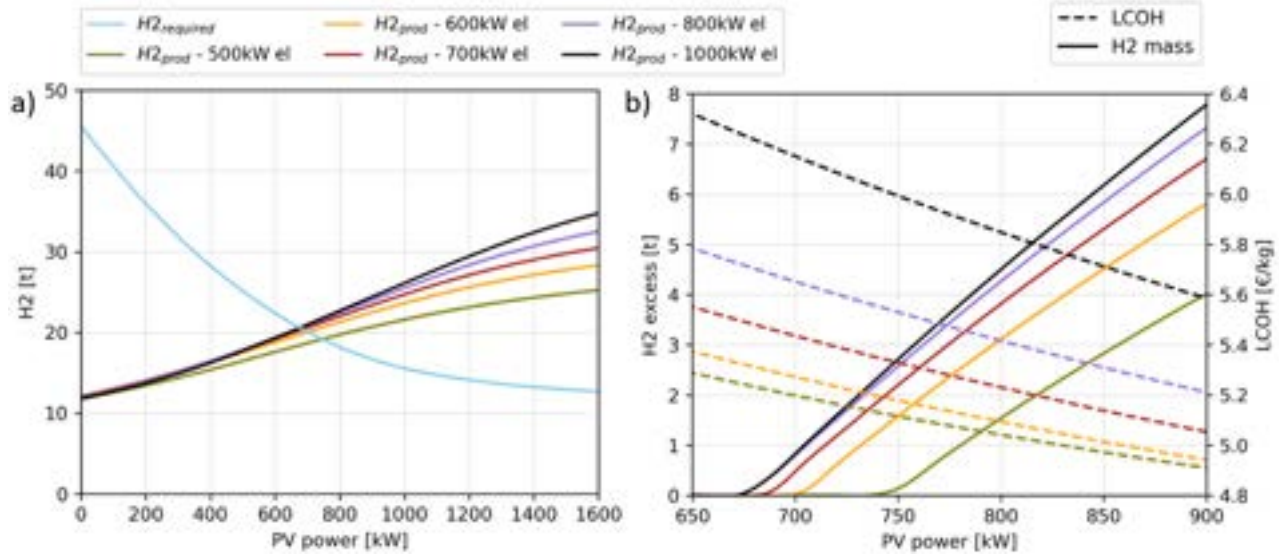

Figure. 6. a) Hydrogen mass required to reach 100 % self-sufficiency (light blue curve) and H_2 production capability from different electrolyzer power varying the PV installed power (line in different colors); b) magnitude (continuous lines) and LCOH (dashed lines) of the hydrogen excess.

With the current HES of Tilos, 37.8 tons of hydrogen would be required to satisfy the energy deficit in summer. However, only 13.6 tons of H_2 can be produced by exploiting the production surplus in winter. This means that, even if hydrogen is employed as a seasonal storage, the system could reach a maximum self-consumption rate of 82.6%, hence requiring a PV field upgrade for full energy independence. The intersection points

between the hydrogen demand and the hydrogen production curves occur at a PV power between 650 and 750 kWp. This is the bare minimum PV power to both increase the self-consumption of the system (up to around 87% without H_2 reconversion) and produce enough hydrogen for the seasonal storage.

After having assessed the required PV upgrade to reach self-sufficiency, Figure 6 (b) focuses on PV capacities ranging from this value up to 900 kWp, slightly higher than the nominal capacity of the wind turbine. In Figure 6 (b), continuous lines show the hydrogen excess that would be produced if the PV capacity is increased, while dashed lines show the resulting costs of hydrogen. Upon examination of the results, an 800-kW electrolyzer is required to achieve total self-sufficiency with the smallest possible PV upgrade. The purple line shows that, coupled with a 675-kWp PV field, this configuration reaches energy independence with an LCOH of 5.66 €/kg.

On the other hand, the green line shows that the configuration that allows reaching 100% self-sufficiency with a lower hydrogen cost (5.11 €/kg) only requires an additional PV upgrade to 750 kWp, since it better exploits a 500kW-only electrolyzer. Dashed lines in Figure 6(b) also show that the increase of the PV power allows for a reduction of the hydrogen cost for all considered electrolyzer levels in addition to the benefit of producing additional hydrogen for other purposes. If the PV power is increased up to 900 kW, a 600-kW electrolyzer can produce almost 6 tons of extra hydrogen at a competitive price of 4.92 €/kg. In the following section, one example of possible use of this extra-production is proposed in the context of a new fleet of buses for a carbon neutral public transport for the island. It is worth remembering that the aim behind the following analysis is to estimate what could be done with extra H_2 that, if correctly justified, may bring to a further reduction in the LCOH.

3.2. HYDROGEN FOR TRANSPORTS

Even today, locally produced green hydrogen may be a cost-competitive fuel in remote islands. Focus of the following calculation is only put on the potential fuel cost, thus excluding the cost of substitution of the current transport fleet, which will represent the topic for future analyses. To calculate the number of hydrogen-fed buses that can be used during the summer season, the existing Solbus was taken as a reference. This bus, with a capacity of 63 passengers, is able of driving 16.39 km on 1 kg of hydrogen [11]. A 7% energy loss was assumed when compressing the hydrogen from 30 to 350 bar, which is the required pressure in the storage tank of the bus. This loss was based on the needed compressor power of a multistage compressor [12]. It is estimated that a bus can drive the whole route on the island 7 times per day. The route was based on the actual bus stops on Tilos. When the bus is only used in the summer season (corresponding to approximately 90 days) the total amount of kilometers driven per year, and thus the required kilograms of hydrogen per year, can be calculated. Figure 7 shows that the number of buses that can drive on the island increases from 0 with a PV power of 700 kW, to 3 or 7 (depending on the electrolyzer size) with a PV power of 900 kW.

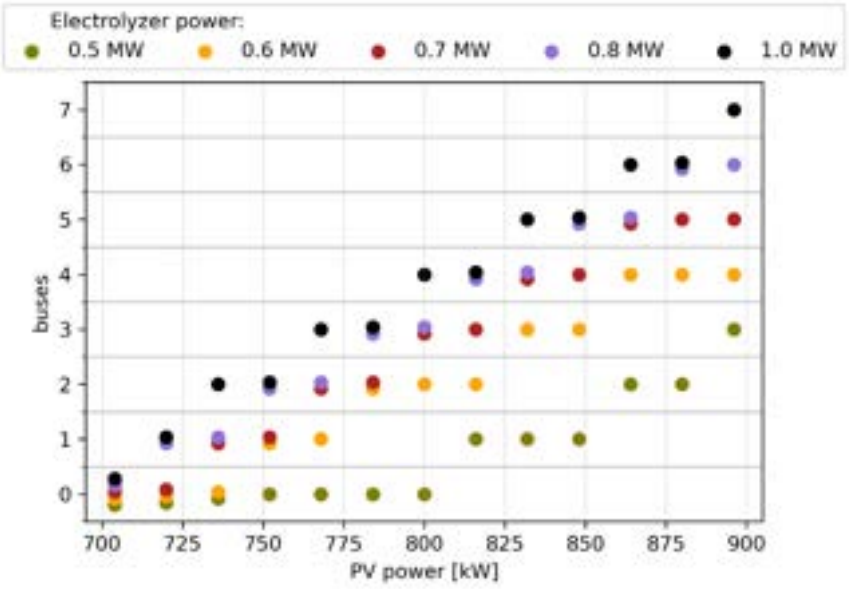

Figure. 7. Number of hydrogen buses that can be powered by the hydrogen surplus coming from different electrolyzer sizes paired with an increasing PV installed power.

Currently, most buses worldwide (including the Greek bus company KTEL) use diesel as a fuel. Assuming a consumption of 24 liters diesel per 100 km [13] would already make the hydrogen competitive with diesel with an average diesel price of €1.81 per liter in Greece [14]. The diesel prices do, however, vary across Greece. On a remote island the price for one liter of diesel is higher than on the mainland. This difference can partially be explained by the extra transportation costs from the Greek mainland to the island. On average petrol prices

are 3-4 cents higher on islands compared to the mainland, or even more for particularly remote islands. The prices for fuel and electricity should probably be higher, but the costs are subsidized and shared by all mainland consumers through a levy on electricity bills [15][16][17]. When hydrogen is produced locally, no transportation costs are required. A rough estimation shows that the cost for hydrogen with an LCOH of 6 €/kg will be around € 37 per 100 kilometers versus € 43.20 for diesel with a cost of € 1.80 per liter. Another advantage of hydrogen over diesel is the fact that a hydrogen bus emits no carbon dioxide or other air pollutant during operation. Different studies show that diesel buses emit over 1.5 kg CO2 per kilometer, which would result in 26.5 tons emission when running 90 days on Tilos. This does not include the transportation from the refinery to the fuel station which might be responsible for an even bigger share of emission [18][19].

Another option to decrease pollution would be to electrify the buses. Hydrogen has however the advantage over electricity that it is produced in winter when there is an electricity surplus. Using electricity would mean that the consumption peak in summer will increase even more. Furthermore, a hydrogen bus does not need to refuel during a day while an electric bus might have to recharge.

4. Discussion and conclusions

The high capacity factors of both the wind turbine and PV field demonstrate the abundance of renewable resources on the island of Tilos. This significantly impacts the competitive LCOH results and highlights the areas' clear potential for H_2 production.

The resulting LCOH was calculated for different scenarios considering both the current system and foreseeable upgrades that could lead to 100% self-sustained operation, and to the decarbonization of the public transport fleet. Table 1 summarizes results of the most remarkable configurations analyzed in the present study.

Table 1. Results from most significant plant configurations: 1) current Tilos' HES, 2) smallest PV upgrade for 100% self-sufficiency, 3) smallest electrolyzer for 100% self-sufficiency, 4) PV upgrade for LCOH abatement and H_2 excess for buses and 5) global lowest LCOH.

Config n°	PV power [kWp]	El. Power [kW]	LCOH [€/kg]	H_2 request [t/y]	H_2 prod. [t/y]	Self-suff. [%]	H_2 excess [t/y]
1	160	475	6.46	37.8	12.7	82	-
2	675	800	5.66	20.3	20.3	100	-
3	750	500	5.11	19.1	19.1	100	-
4	900	600	4.92	16.5	22.5	100	6
5	1600	615	4.38	12.7	28.5	100	15.8

Tilos' HES is equipped with an 800-kW wind turbine and a small 160-kW PV field (Configuration 1). The seasonal variation of the local demand creates a considerable energy deficit during summer, the tourist season. Considering a fuel cell with a conversion efficiency of 60%, it was estimated that more than 37.8 tons of hydrogen are required to achieve 100% self-sufficiency. However, results have shown that an alkaline electrolyzer fed by the power excess of the current HES is able to produce only 12.7 tons of H_2. It is thus evident that there is a need of upgrading the PV field to achieve energy independence. The analysis pointed out that a minimum installed PV power of 675 kWp (Configuration 2) is required to produce the same amount of hydrogen that the island needs. To generate enough hydrogen with this power capacity, an oversized stack of 800 kW must be installed, but this results in a LCOH higher than 5.66 €/kg.

To size the stack correctly, one must consider an additional upgrade of the PV field to 750 kWp (Configuration 3). When paired with a 500-kW electrolyzer, this system achieves 100% self-sufficiency at an LCOH of 5.11 €/kg. Configuration 4 moreover shows that, if it is possible to expand the photovoltaic generator further, excess hydrogen production means a better utilization of the installed electrolyzer and a further reduce the LCOH. A 900-kWp PV field paired with a 600-kW electrolyzer would produce an additional 6 tons of hydrogen at a competitive price of 4.92 €/kg. Without strict limitations on the photovoltaic field expansion, Configuration 5 shows that a high capacity PV field (1600 kWp) could optimally utilize a 615-kW stack and achieve an LCOH of 4.38 €/kg. Results thus show that scaling up components is a suitable strategy to lower the LCOH.

Hydrogen buses have been proposed as a possible use for the excess of hydrogen. Such a fleet could decarbonize the public transport during the touristic season without the introduction of an additional burden to the electric grid, as an electric bus fleet would do. Since their introduction would justify an increase in the hydrogen yield, this technology could contribute to a further decrease of the LCOH. Further developments of the study could include a better assessment of the energy required for hydrogen compression, as well as an estimation of the footprint of the required PV expansion and hydrogen tanks. Furthermore, a variable efficiency fuel cell model, similar to the one employed for the electrolyzer, would produce more accurate results regarding the actual electrical energy coming from the gas-to-power conversion.

Acknowledgments

The Authors would like to acknowledge Eunice Energy Group for providing data of the island of Tilos, as well as the guidance for analyzing them. Thanks are also due to McPhy Energy for providing the constants to calibrate the electrolyzer model.

Abstract:

Energy communities could benefit from an optimal match between total energy generation and demand, resulting in economic gains. A main issue is the distribution of the optimal economic gain of an energy community among its members. Several works apply a single criterion of cost/profit allocation within an energy community, neglecting the impact of different criteria on different members. This paper aims at evaluating and comparing two different cost/profit allocation mechanisms, i.e., the cooperative "Shapley value", based on the marginal contributions of members to any coalition within the energy community, and the "Uniform pricing", which relies on a uniform price that is independent of the cooperation among members. According to the Italian legislation, a centralized Renewable Energy Community with virtual energy sharing scheme is analysed. The community encompasses one consumer and two prosumers with shiftable electrical demands that are representative of the tertiary, residential and commercial sectors, and prosumers own photovoltaic plants with/without the electrical storage system. A cooperative model of this energy community is presented, and the daily operational profit is maximized by a Mixed-Integer Non-Linear Programming optimization. Subsequently, the mechanisms of Shapley value and Uniform pricing are applied to allocate the optimal profit of the energy community. Uniform pricing leads to daily profits of 1.95€, 0.69€ and 5.71€ for the tertiary, residential and commercial members, respectively. Conversely, results of the Shapley value are fairer towards prosumers, allocating daily profits of 9.57€ and 3.81€ to the residential and commercial prosumers, and a daily cost of 5.03€ to the tertiary consumer.

Keywords:

Renewable Energy Community; Profit allocation; Cooperative game; Shapley mechanism; Fairness.

1. Introduction

Renewable energy communities (RECs), defined by the recast of the Renewable Energy Directive (RED II) [1], represent a regulatory tool to foster the distributed generation and consumption driven by renewable sources. RECs can help achieve the energetic and environmental targets indicated by the "Fit for 55" document of the European Commission [2] (i.e., renewables share of 40%, increase of energy efficiency by 36% in the final energy consumption and emissions reduction by at least 55% compared to the levels of 1990), beyond leading several economic and social benefits to the European citizens. In the Italian context, the regulation about the technical management of RECs has been recently updated by GSE [3], the Italian Energy Services Operator, while the economic incentives have been defined by ARERA [4], the Italian Regulation Agency for Environment, Network and Energy. In such a context, this paper focuses on the economic benefits associated with the configuration of the Italian REC and of its participants. The current and emerging literature on energy communities is very broad and, for this reason, the literature review in this paper summarizes the main recent works in the following identified fields.

Some works in the literature dealt with business models, policies and modelling techniques that can foster the development of Energy Communities (ECs) [5-7]. Lowitzsch et al. [5] presented a holistic analysis of the already existing and still untapped business models for ECs, identifying different structure and design options (e.g., application technology, cooperating partners, geographical location, types of investors and ownerships etc.). Ceglia et al. [6] assessed the energy, environmental and economic performances of an Italian REC, highlighting its higher electricity self-consumption (till 56%) with respect to other energy-sharing models, e.g., the "System of Efficient Users" (till 12% of electricity self-consumption) that is based on directives released before 2018. Gerundo et al. [7] proposed a methodology to identify potential geographical areas that are

suitable for the development of RECs, while taking into account the constraints of installation for the generation technologies and social benefits as the reduction of the energy poverty.

Other works focused on the optimization of the design and operation of the generation and storage technologies within ECs [8-10]. Cutore et al. [8] conducted a design and operation optimization of a residential REC in Italy to maximize the net-present value (including investment and operational costs) and, then, calculated different indexes to analyse its energetic, environmental and social performances. The centralized configuration of the REC results more profitable compared to the distributed one, because the former exploits only virtual energy sharing that is more incentivized (in the Italian context) compared to physical self-consumption (the distributed configuration can exploit both virtual energy sharing and physical self-consumption). Chang et al. [9] proposed a methodology, based on K-means clustering, to allocate different options of community energy storage among households of an EC, the operational cost of which is minimized by a Mixed-Integer Linear Programming (MILP) optimization. Lazzari et al. [10] developed an optimization framework for the planning and operation of RECs with the aim of increasing their energy sharing. The optimization outcomes, validated with real data of consumption profiles of households in Barcelona, show that a REC with 7 residential users could achieve a self-consumption of 100% and a relevant amount of avoided CO2 emissions till 7 kg/day.

Another relevant issue to be addressed is the distribution of economic benefits (costs or profits) within an EC [11-14]. Casalicchio et al. [11] allocated the total cost saving of a residential EC by applying the Vickrey-Clarke-Groves mechanism that evaluates the contribution of each member to the cost saving of the whole community. This approach is compared to other business allocation criteria by introducing a fairness index that represents the number of members without an economic gain within the community. Zheng et al. [12] analysed the impacts of demand side flexibility and of a Peer-to-Peer (P2P) energy sharing mechanism within an EC, made of commercial prosumers, finding that the P2P strategy could minimize the operational cost by 24.6% compared to a Peer-to-Grid (P2G) operation where each member exchanges energy with the electric grid only. The profit of the EC is distributed among members by the P2P mechanism, which relies on the definition of internal trading prices that depend on the supply-demand ratio of the community. Zatti et al. [13] optimized the capacities of different generation and storage units within an Italian EC comprised of commercial and residential users. The “Shapley value” mechanism, based on a cooperative game theory approach, is applied to allocate the total benefit of the community by quantifying the contributions of members to the economic revenue of any coalition within the community. Siqin et al. [15] formulated a distributionally-robust optimization for the dispatching of a multi-EC system. An improved Shapley value approach was proposed to allocate higher profits to the participants with higher solar PV consumption. Notice that, in the previous papers, a single cost/profit allocation mechanism (e.g., Shapley value) was applied, neglecting the potential results with other allocation criteria.

Vespermann et al. [16] explored different cooperative allocation mechanisms for an EC, including the Shapley value, and analysed their properties of efficiency, individual rationality and stability. Cremers et al. [14] reviewed different applications of the Shapley value for ECs, proposing also a new method (called “Stratified expected value”) to approximate the calculation of the Shapley value in the case of communities of up to 200 prosumers. The authors highlighted the need to further investigate different allocation criteria, other than Shapley, to assess the fairness of the cost/profit distribution within ECs. Li and Okur [17] conducted an operation optimization of an EC and applied Uniform pricing (also called “flat energy pricing method”), time-of-use energy pricing and segmented energy pricing as cost allocation criteria. However, the authors neglected the possible cooperation between the members of the EC and, thus, cooperative allocation mechanisms as the Shapley value were not applied. It is worth highlighting that the above works did not apply both cooperative allocation mechanisms (e.g., Shapley value) and other mechanisms not derived from cooperative game theory.

In the above literature, works dealing with the allocation of economic costs/profits within an EC *i)* apply one single criterion, without assessing the impact of different allocation mechanisms on the benefits of EC members, and/or *ii)* do not compare cooperative allocation mechanisms (e.g., Shapley value) with other mechanisms not based on cooperative game theory (e.g., Uniform pricing). To the best of authors’ knowledge, the application of different allocation criteria for the economic benefit of a REC, according to the Italian framework, represents a first gap in the literature. Moreover, as highlighted in [14], the literature lacks of more in-depth discussions about the fairness of the cost/profit distribution within ECs and, in particular, within RECs. This paper fills in these gaps, and the objective is to present and evaluate two different allocation mechanisms in the context of a REC, i.e., the cooperative “Shapley value” [18] and the “Uniform pricing” criteria [19], with a subsequent insight of the fairness of allocation.

First, a REC with a centralized configuration and a virtual energy sharing scheme, according to the Italian framework, is modelled and its operation is optimized (i.e., the flexible demands of members and the operation of the electrical energy storage system) based on a Mixed-Integer Non-Linear Programming (MINLP) formulation. Subsequently, this work applies the cooperative mechanism Shapley value and the Uniform pricing mechanism to distribute the economic benefits among the members, with the aim of evaluating the differences between these two criteria.

This paper contributes to the current literature with the following novel points:

- Application and comparison of two different allocation criteria, i.e., the cooperative Shapley value and the Uniform pricing, to distribute the total economic profit of an Italian REC among its members;
- Evaluation of how fair is the distribution of economic benefits, based on the Shapley value and the Uniform pricing, within the analysed REC.

The paper is structured as follows. Section 2 describes the Shapley value and Uniform pricing mechanisms. Section 3 reports the mathematical model of the REC, according to the Italian legislation, and the input data for the MINLP optimization. Section 4 discusses the results of the MINLP optimization and subsequent application of Shapley value and Uniform pricing. Conclusions summarize general guidelines retrieved from this work.

2. Materials and method

This Section describes the two cost/profit allocation mechanisms considered in this work, i.e., the cooperative Shapley value (Section 2.1) and the Uniform pricing (Section 2.2). As reported by Berka and Creamer [20] and Gjorgievski et al. [21], the cost/profit allocation within an Energy Community (EC) is an important aspect that is still not exhaustively addressed in the literature. Different allocation mechanisms of the costs/profits of ECs are available in the literature, and they usually refer to approaches from the cooperative game theory or to approaches that define prices for the EC members in relation to their profiles of energy demand [17].

2.1. Shapley value

Game theory is a large field that encompasses techniques to model a group of interacting players [22] under a cooperative or non-cooperative framework. Cooperative games assume that cooperation exists among the players, for example the members of an EC, thus leading to a "grand coalition" of members (e.g., the energy community), with the aim of achieving a common objective (e.g., minimization of the total cost of the EC, improvement of the total renewable self-consumption or self-sufficiency, etc.). On the contrary, the game is non-cooperative when the players pursue independent and, sometimes, conflicting objectives, thus leading to a Nash equilibrium solution. However, this work assumes that the members of an EC can cooperate and, therefore, the focus here is on cooperative games. A cooperative game is defined by a pair *(N,v)*, where *N* refers to the number of players participating into the game, and forming the "grand coalition", while *v(S)* is the "value" function of any possible coalition *S* of players within the grand coalition [23]. The "value" function of a coalition *S* is a mathematical function that takes real values:

$$v(S)\colon 2^N \to R \tag{1}$$

where 2^N represents the set of all coalitions within the grand coalition, included the grand coalition itself and the empty coalition (i.e., the coalition without players). The "value" function represents the "value" in forming the coalition *S*, e.g., the total cost/profit associated with players cooperating in the coalition *S*. In the framework of ECs, notice that the value of the grand coalition corresponds to the total cost/profit of an EC, while the value of the empty coalition is zero. To clarify, consider an EC with three members (players *1,2,3*) that cooperate to minimize the total operational cost. The value of the coalition *{1,2}*, given by the players *1* and *2*, is the total cost of the cooperation between these members, thus neglecting player *3*.

This work adopts the Shapley value as cooperative allocation mechanism because it can lead to a fair distribution of economic gains in a cooperative game. Indeed, this approach allows to allocate higher gains (e.g., higher profits or lower costs) to players that contribute the most to the "value" of all coalitions they could take part in within the grand coalition. According to the Shapley value, the gain, or payoff x_i, allocated to member *i* is calculated as follows:

$$x_i = \sum_{S \subseteq N, i \in S} \frac{(|S|-1)!\,(N-|S|)!}{N!}\big(v(S) - v(S \setminus \{i\})\big) \tag{2}$$

where $|S|$ refers to the size of the coalition *S* and $\big(v(S) - v(S \setminus \{i\})\big)$ is the contribution of member *i* to the value $v(S)$ of coalition *S*. Hence, the Shapley value assigns to each player a payoff that represents his weighted average marginal contribution to the value of any coalition, within the grand coalition, he could take part in. However, the main drawback of the Shapley value, which requires to consider 2^N coalitions, is the computational complexity arising with a high number of players *N*. In the following, a basic example of the Shapley calculation is provided. Let us consider a grand coalition with three players, assuming the values of the 8 (2^N) possible coalitions, where each of these values could be derived by solving a specific cooperative optimization problem with the players involved. Table 1 reports the coalitions analysed and their corresponding assumed "values", where {} represents the empty coalition.

Table 1. Example of a grand coalition with three players, with the "values" of all coalitions.

Coalition	{}	{1}	{2}	{3}	{1,2}	{1,3}	{2,3}	{1,2,3}
Value [€]	0	0	2	3	3	5	6	12

Eq. (2) is applied to compute the Shapley payoff for each of the three players. Player 1 appears in coalitions {1}, {1,2}, {1,3} and {1,2,3} and, therefore, its payoff considers its weighted average marginal contribution to the values of these four coalitions:

$$x_1 = \frac{(1-1)!\,(3-1)!}{3!}\left(v(\{1\}) - v(\{\})\right) + \frac{(2-1)!\,(3-2)!}{3!}\left(v(\{1,2\}) - v(\{2\})\right) + \frac{(2-1)!\,(3-2)!}{3!}\left(v(\{1,3\}) - v(\{3\})\right) + \frac{(3-1)!\,(3-3)!}{3!}\left(v(\{1,2,3\}) - v(\{2,3\})\right) = \frac{1}{3}(0) + \frac{1}{6}(3-2) + \frac{1}{6}(5-3) + \frac{1}{3}(12-6) = \frac{15}{6}$$

Player 2 can participate in coalitions {2}, {1,2}, {2,3} and {1,2,3}, and its payoff is:

$$x_2 = \frac{(1-1)!\,(3-1)!}{3!}\left(v(\{2\}) - v(\{\})\right) + \frac{(2-1)!\,(3-2)!}{3!}\left(v(\{1,2\}) - v(\{1\})\right) + \frac{(2-1)!\,(3-2)!}{3!}\left(v(\{2,3\}) - v(\{3\})\right) + \frac{(3-1)!\,(3-3)!}{3!}\left(v(\{1,2,3\}) - v(\{1,3\})\right) = \frac{1}{3}(2) + \frac{1}{6}(3-0) + \frac{1}{6}(6-3) + \frac{1}{3}(12-5) = 4$$

Player 3 can participate in coalitions {3}, {1,3}, {2,3} and {1,2,3}, and its payoff is:

$$x_3 = \frac{(1-1)!\,(3-1)!}{3!}\left(v(\{3\}) - v(\{\})\right) + \frac{(2-1)!\,(3-2)!}{3!}\left(v(\{1,3\}) - v(\{1\})\right) + \frac{(2-1)!\,(3-2)!}{3!}\left(v(\{2,3\}) - v(\{2\})\right) + \frac{(3-1)!\,(3-3)!}{3!}\left(v(\{1,2,3\}) - v(\{1,2\})\right) = \frac{1}{3}(3) + \frac{1}{6}(5-0) + \frac{1}{6}(6-2) + \frac{1}{3}(12-3) = \frac{11}{2}$$

According to cooperative game theory, this payoff allocation is defined as an “imputation” because it guarantees simultaneously the properties of “efficiency” and “individual rationality”. The property of efficiency ensures that the “value” of the grand coalition is allocated to all players, while the property of individual rationality means that each player benefits from participating into the grand coalition compared to operating as an independent player. In the example above, efficiency is ensured since the sum of payoffs is equal to the “value” of the grand coalition (i.e., 12 €). Moreover, the payoff allocation satisfies the property of individual rationality because the payoff allocated to each player is higher than the “value” of the coalition including only that player (e.g., for player 2, the payoff in the grand coalition is 4 € while its value *v({2})*, as an independent player, is 2 €).

2.2. Uniform pricing

Time-of-use energy pricing, segmented energy pricing and Uniform pricing (also called “flat energy pricing method”) are cost/profit allocation mechanisms, reported by Li et al. [19] and Li and Okur [17], that do not consider the cooperation among EC members. These mechanisms allow to allocate the economic benefits of the EC by defining different prices in relation to the individual energy demands. Time-of-use energy pricing sets high prices in peak hours (i.e., when peak demand occurs) and low prices in off-peak hours (i.e., when low demand occurs), thus promoting load shifting of the energy demands from peak to off-peak hours. Segmented energy pricing establishes a threshold of the energy demand, under which a low price is charged, while a high price is charged above this threshold. Uniform pricing is based on a unique price calculated as the ratio between the total cost (or profit) and the total demand of the EC:

$$c_u = \frac{TC}{\sum_{i=1}^{n}\sum_{t=1}^{T} E_{i,t}} \tag{3}$$

where TC is the total cost (or profit) of the EC and $E_{i,t}$ is the hourly energy demand of member *i*. Uniform pricing mechanism is simple to be implemented and well accepted by network regulators [24].

3. Case study

The Renewable Energy Community (REC) under analysis comprises of three members, one consumer of the tertiary sector and two prosumers that are representative of the residential and commercial sectors. It is assumed that the residential prosumer owns only a Photovoltaic plant (PV), whereas the commercial prosumer owns a PV plant and a battery as electrical storage system. Section 3.1 reports the main equations and constraints associated with the Mixed-Integer Non-Linear Programming (MINLP) optimization model of the Italian REC, developed from a previous work of the authors [25]. Section 3.2 lists the input data of the model.

3.1. Mathematical model of the Renewable Energy Community

The operation of the PV plant of a member *i* is described by Eq. (4):

$$P_{i,t}^{PV} = \eta^{PV} \cdot A_i^{PV} \cdot I_t^{PV} \tag{4}$$

where $P_{i,t}^{PV}$ [kW] is the power generated by the PV plant in time step *t*, η^{PV} [-] is the average efficiency of the PV plant, A_i^{PV} [m^2] is the available PV area and I_t^{PV} [kW/m^2] is the global solar irradiance (on a tilted surface) in time step *t*. In the following, energy and power variables have, respectively, [kWh] and [kW] as units of measurements.

The operation of the battery of a member *i* is given by the following equations and constraints:

$$E_{i,t}^{bat} = E_{i,t-1}^{bat} + P_{i,t}^{bat,c} \cdot \eta^{bat,c} \cdot \Delta t - \frac{P_{i,t}^{bat,d} \cdot \Delta t}{\eta^{bat,d}} \tag{5}$$

$$E_{i,t}^{bat} \leq E_i^{bat,cap} \tag{6}$$

$$P_{i,t}^{bat,c} \leq P_i^{bat,peak} \cdot \delta_{i,t}^{bat,c} \tag{7}$$

$$P_{i,t}^{bat,d} \leq P_i^{bat,peak} \cdot \delta_{i,t}^{bat,d} \tag{8}$$

$$\delta_{i,t}^{bat,c} + \delta_{i,t}^{bat,d} \leq 1 \tag{9}$$

$$E_{i,1}^{bat} = E^{start,end} \cdot E_i^{bat,cap} \tag{10}$$

$$E_{i,24}^{bat} = E_{i,1}^{bat} \tag{11}$$

Eq. (5) describes the energy balance of the battery, where $E_{i,t}^{bat}$, $P_{i,t}^{bat,c}$ and $P_{i,t}^{bat,d}$, $\eta^{bat,c}$ and $\eta^{bat,d}$, and Δt are, respectively, the hourly energy stored in the battery, the hourly charging (*c*) and discharging (*d*) power, the battery charging (*c*) and discharging (*d*) efficiency, and the time step of the MINLP optimization model, i.e., one hour. Constraint (6) states that the hourly energy stored in the battery is bounded by the battery capacity $E_i^{bat,cap}$. Constraints (7)-(8) bound the hourly charging and discharging power of the battery by the maximum value $P_i^{bat,peak}$. The binary variables $\delta_{i,t}^{bat,c}$ and $\delta_{i,t}^{bat,d}$, which make the model non-convex, avoid charging and discharging in the same time step *t*, as indicated by constraint (9). The initial and final energy levels of the battery ($E_{i,1}^{bat}$ and $E_{i,24}^{bat}$) are fixed as ratio of the battery capacity by parameter $E^{start,end}$, as shown in Eqs. (10)-(11).

The shifted electrical demand of each member *i* is subject to the following constraints:

$$\sum_{t=1}^{24} E_{i,t}^{el,shift} = \sum_{t=1}^{24} E_{i,t}^{el} \tag{12}$$

$$E_i^{el,min} \leq E_{i,t}^{el,shift} \leq E_i^{el,max} \tag{13}$$

$$(1 - D^{var}) \cdot E_{i,t}^{el} \leq E_{i,t}^{el,shift} \leq (1 + D^{var}) \cdot E_{i,t}^{el} \tag{14}$$

Eq. (12) states that shifting the hourly electrical demand of a member does not change its total daily electrical demand, where $E_{i,t}^{el,shift}$ and $E_{i,t}^{el}$ are, respectively, the shifted and input electrical demands in time step *t*. Constraints (13) and (14) bound $E_{i,t}^{el,shift}$, where $E_i^{el,min}$, $E_i^{el,max}$ and D^{var} are the hourly minimum and maximum of the input electrical demand and the hourly maximum fraction of the load that can be shifted.

According to the Italian legislation, the members of the centralized REC are directly and separately connected to the same low-medium voltage distribution grid. The energy shared among the members occurs within the distribution grid, in conformity with the concept of “virtual energy sharing” of the Italian REC. The legislation defines two hourly energy balances for the total energy withdrawn from (E_t^{imp}) and injected to (E_t^{exp}) the grid as reported by Eq. (15) and Eq. (16), respectively:

$$E_t^{imp} = \sum_{i=1}^{n} (E_{i,t}^{el,shift} + E_{i,t}^{bat,c}) \tag{15}$$

$$E_t^{exp} = \sum_{i=1}^{n} (E_{i,t}^{PV} + E_{i,t}^{bat,d}) \tag{16}$$

where $E_{i,t}^{PV}$, $E_{i,t}^{bat,c}$ and $E_{i,t}^{bat,d}$ are, respectively, the energy generated by PV, the energy charged and discharged of the battery, for each member *i* in each time step *t*.

The total energy withdrawn from and injected to the grid are limited by the following constraints:

$$E_t^{imp} \leq E^{grid,max} \tag{17}$$

$$E_t^{exp} \leq E^{grid,max} \tag{18}$$

where $E^{grid,max}$ is the maximum allowed energy exchanged with the grid.

The Italian REC benefits from an economic incentive for the "virtual energy shared", $E_{s,t}$, among its members, that is defined as the hourly minimum between E_t^{imp} and E_t^{exp}:

$$E_{s,t} = min(E_t^{imp}, E_t^{exp}) \tag{19}$$

where constraint (19) is non-linear and, therefore, makes the model non-linear.

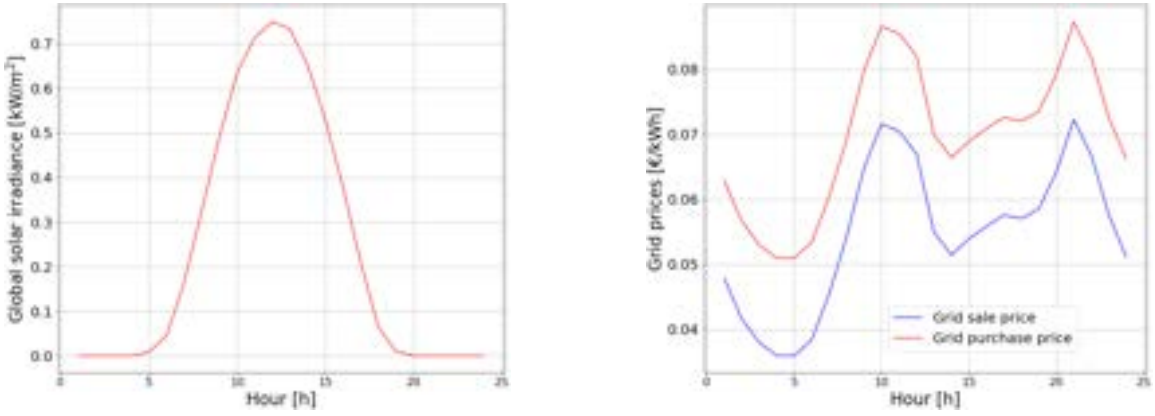
The REC under analysis aims at maximizing its total daily profit and, therefore, the objective function to be maximized is:

$$c^{REC} = \sum_{t=1}^{24} (E_t^{exp} \cdot c_t^{exp} - E_t^{imp} \cdot c_t^{imp}) + inc_{REC} \cdot \sum_{t=1}^{24} E_{s,t} \tag{20}$$

where c_t^{exp}, c_t^{imp} and inc_{REC} are, respectively, the grid sale price, the grid purchase price and the incentive of the REC (that consists of the sum between a feed-in premium and a feed-in tariff, the latter linked to the avoided network losses within the REC). The first summation represents the difference between the revenue for the energy sold to the grid ($E_t^{exp} \cdot c_t^{exp}$) and the cost for the energy purchased from the grid ($E_t^{imp} \cdot c_t^{imp}$). The last term is the revenue due to the incentive for the virtual energy shared. Notice that the optimal profit of the REC (i.e., the optimal value of the objective function c^{REC}) corresponds to the value of the grand coalition including, as players, all the members of the REC, as explained in Section 2.

3.2. Input data

Figure 1 (a) and (b) show, respectively, the profile of the global solar irradiance on an inclined surface (optimal tilted angle of 38°) for the location of Padua (Italy) derived from the PVGIS database [26], and the profiles of the grid purchase and sale prices [27], in a characteristic day of the spring season. Figure 2 reports the daily electrical demands of the energy users, within the analysed REC, that are representative of the tertiary (consumer "Ter"), residential (prosumer "Res") and commercial (prosumer "Com") sectors [28]. Given the chosen electrical demands, it is worth highlighting that the REC presents a heterogeneous composition that improves its operational flexibility. Table 2 lists the values of other input parameters for the mathematical model described in Section 3.1.



a) *b)*

Figure 1. a) Global solar irradiance on an inclined surface (optimal tilted angle of 38°) in Padua (Italy) and b) grid purchase and sale prices, in a characteristic day of spring.

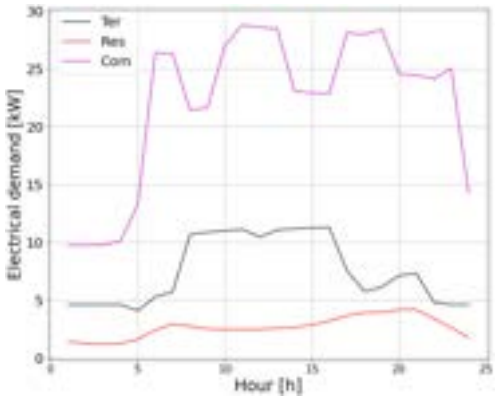


Figure 2. Electrical demands of the tertiary consumer (Ter), residential (Res) and commercial (Com) prosumers.

Table 2. Values of the input parameters in the MINLP optimization.

Parameter	Value	Source
η^{PV} [-]	0.17	assumed
A_i^{PV} [m^2]	60 (Res), 250 (Com)	assumed
$\eta^{bat,c}$, $\eta^{bat,d}$ [-]	0.95	[9]
$E_i^{bat,cap}$ [kWh]	50 (Com)	[29]

4. Analysis and discussion of results

Section 4.1 reports the results of the Mixed-Integer Non-Linear Programming (MINLP) optimization, conducted on the mathematical model described in Section 3.1, and solved by the Gurobi software [30]. Subsequently, Section 4.2 presents the outcomes of the distribution of the optimal total profit for the REC among the members, by application of the mechanisms of Shapley value and Uniform pricing.

4.1. Optimization results

Figure 3 (a) shows the optimal shifted electrical demands of the tertiary consumer ("Ter"), residential ("Res") and commercial ("Com") prosumers, as well as the total PV power generation for the two prosumers, within the REC. The optimal load shifting of the electrical demand of the commercial prosumer results more evident compared to the other optimal demands, since the commercial prosumer can exploit the electrical battery storage and, thus, has a higher flexibility compared to the other members of the REC. Figure 3 (b) exhibits the optimal operation of the electrical battery storage of the commercial prosumer within the REC, in terms of power charging (red line), power discharging (green line) and energy stored (blue line). Notice that all the shifted electrical demands increase compared to the input demands during hours 7-9 (Figure 3 (a)), when the PV power generation is still low, thus requiring the power discharging of the battery in the same period (Figure 3 (b)). In the middle of the day, during hours 10-15, the total PV power generated is high (maximum value of 39 kW at hour 12), and this allows to charge the battery till almost the maximum capacity (50 kWh) at hour 15. After hour 15 the available PV power decreases and, therefore, power discharging of the battery helps meet the total electrical demand. Figure 4 displays the daily profile of the virtual energy shared within the REC. According to constraint (19) in Section 3.1, the virtual energy shared is defined as the hourly minimum between the total energy withdrawn from the grid (i.e., sum of the total shifted electrical demand and energy charged into the battery) and the total energy injected into the grid (i.e., sum of the total PV energy generation and energy discharged from the battery). At hour 2, the virtual energy shared corresponds to the energy discharged from the battery (7 kWh) that is lower compared to the value of the total shifted electrical demand (17 kWh). At hour 12, the virtual energy shared is the maximum PV energy generated (39 kWh) that is lower compared to the sum between the values of total shifted electrical demand (37 kWh) and energy charged into the battery (7 kWh). Hence, these outcomes demonstrate that a REC with renewable energy plants (as PV) and energy storage systems can effectively exploit the energy sharing and, in turn, achieve higher economic revenues due to the incentive for the energy shared according to the Italian legislation.

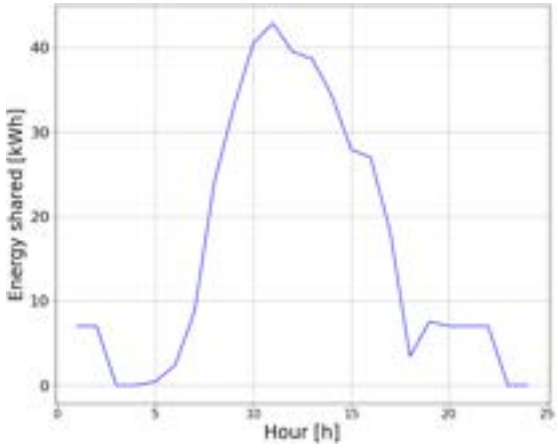

Figure 4. Optimal virtual energy shared in the analysed Italian REC.

4.2. Results of the profit allocation

The Mixed-Integer Non-Linear Programming (MINLP) optimization leads to an optimal daily profit of the REC (optimal value of the objective function, Eq. (20) in Section 3.1) equal to 8.35 €. This total profit is allocated to the members of the REC by applying, separately, the cooperative Shapley value and the Uniform pricing mechanisms, described in Section 2.1 and 2.2, respectively.

The calculation of the Shapley value, according to Eq. (2) in Section 2.1, requires the identification of all coalitions of members within the REC and the computation of their "values" (i.e., the total costs/profits of coalitions, see Section 2.1). In the analysed REC with three members, the 8 possible coalitions are *{}*, *{Ter}*, *{Res}*, *{Com}*, *{Ter, Res}*, *{Ter, Com}*, *{Res, Com}* and *{Ter, Res, Com}*, where the first and last coalitions are, respectively, the empty coalition and the grand coalition that constitutes the REC. *Ter*, *Res* and *Com* refer, respectively, to the tertiary consumer, the residential and commercial prosumers. Notice that the value of the empty coalition is 0, while the value of the grand coalition is the optimal daily profit of the REC (8.35 €). To obtain the value of a specific coalition, it is sufficient to solve the model in Section 3.1 considering only the equations and constraints associated with the members involved in that coalition. For instance, coalition *{Ter, Res}* is made of one consumer (Ter) and one prosumer with only a PV plant (Res), thus the equations and constraints from (5) to (11) (in section 3.1) of the battery energy storage are not used in solving the optimization problem, and the variables of the battery in Eqs. (15)-(16) are not considered as well. Moreover, for coalitions *{Ter}*, *{Res}*, *{Com}*, representing the energy users operating independently, and without cooperation with other community members, the term of energy shared in the objective function (20) is not included. Table 3 reports the "values" calculated for all coalitions within the REC, where negative and positive values refer to net costs and net profits, respectively. For example, the coalition *{Ter}* includes only one consumer, leading to a daily cost of 12.85 €. On the other hand, the coalition *{Res, Com}* is based on the cooperation between the residential and commercial prosumers and, thus, presents the highest daily profit of 20.09 €. Once obtained the values of all coalitions, the formula of the Shapley value (Eq. (2) in Section 2.1) is applied to compute the Shapley payoff of each member of the REC.

The Uniform pricing mechanism is implemented by calculating a uniform price within the REC, as reported in Eq. (3) of Section 2.2, where the numerator is represented by the optimal daily profit of the REC (8.35 €) and the denominator is the optimal shifted demand of the REC. According to Uniform pricing, the payoff of each member is found by multiplying the uniform price with its optimal daily demand.

Table 4 displays the payoffs (positive for profits and negative for costs) allocated to the members of the REC under the Shapley value and Uniform pricing mechanisms. A first outcome is that both allocation mechanisms are efficient (see Section 2.1) because the sum of their payoffs is equal to the optimal daily profit of the REC (8.35 €), i.e., the value of the grand coalition. Both Shapley value and Uniform pricing also guarantee the property of individual rationality and, therefore, all members of the REC have higher gains (higher profits or lower costs) within the REC compared to the case without cooperation. For instance, the tertiary, residential and commercial members have higher daily profits within the REC according to the uniform pricing allocation (profits of 1.95 €, 0.69 € and 5.71 €, respectively, in Table 4) compared to the case in which they operate independently in separate coalitions (costs of -12.85 €, -1.03 €, -22.20 €, respectively, in Table 3). With Uniform pricing all members have daily profits, included the tertiary consumer, while the Shapley allocation shows daily profits for prosumers and a daily cost for the tertiary consumer. Hence, it seems that Uniform pricing is more economically profitable than Shapley value, at least for the tertiary consumer. However, the application of the Shapley value mechanism favours the prosumers of the REC that provide a major contribution in increasing the total daily economic profits, derived from the energy sold to the grid and the incentivised energy shared within the REC. For example, Table 4 shows that the residential prosumer receives the highest payoff, according to Shapley, equal to 9.57 €, highlighting the relevant contribution of this prosumer to the total profit of the REC. Hence, the Shapley value can be considered a fair allocation mechanism in the sense that prosumers, who promote self-consumption and virtual energy sharing within the REC, receive higher payoffs compared to consumers (in any case the latter have economic convenience to be part of the REC instead of operating independently). On the contrary, with the Uniform pricing mechanism, the resulting payoffs are more homogeneous (i.e., all members obtain daily profits) within the REC, without higher rewards to prosumers with respect to consumers.

Table 3. Coalitions of the REC and their calculated "values", which represent daily operational profits (positive) or costs (negative).

Coalition	*{}*	*{Ter}*	*{Res}*	*{Com}*	*{Ter, Res}*	*{Ter, Com}*	*{Res, Com}*	*{Ter, Res, Com}*
Value [€]	0	-12.85	-1.03	-22.20	-6.95	2.70	20.09	8.35

Table 4. Payoffs of all members of the REC according to Shapley value and Uniform pricing.

	Payoffs [€]	
Member	*Shapley value*	*Uniform pricing*
Ter	-5.03	1.95
Res	9.57	0.69
Com	3.81	5.71
Total	8.35	8.35

5. Conclusions

This paper focuses on the issue of costs/profits allocation within the emerging Renewable Energy Communities (RECs). In the current literature, most of the works apply one single allocation mechanism or does not apply and compare different allocation mechanisms that belong to the field of cooperative game theory or other fields. Contrary to the current literature, this work applies two different allocation mechanisms, i.e., the "Shapley value" based on cooperative game theory and the "Uniform pricing", with the aim of evaluating the impact of these mechanisms on the economic benefits of the members of a REC. The cooperative mechanism Shapley value allows to allocate the optimal cost/profit of the community, considering the average marginal contributions of members to the "value" (i.e., total cost or profit) of any coalition of the community in which they could participate. On the other hand, the mechanism of Uniform pricing distributes the optimal cost/profit of the REC by defining a uniform price that is the ratio of the optimal cost/profit and the total electrical demand of the community. This work considers a REC, according to the Italian framework, as case study. The analysed REC includes three members belonging to different sectors, i.e., a tertiary consumer, one residential and one commercial prosumers. The residential prosumer owns only a Photovoltaic (PV) plant (available area of 60 m^2), whereas the commercial prosumer owns a PV plant (available area of 250 m^2) and an electrical battery

storage (capacity of 50 kWh). A Mixed-Integer Non-Linear Programming (MINLP) optimization is carried out to maximize the daily operational profit of the REC under analysis, considering the Italian framework and the related economic incentive for the energy shared. The optimal daily operational profit of 8.35 € of the REC is allocated to the members by applying, separately, the “Shapley value” and “Uniform pricing” mechanisms. Given the payoffs distributed by both Shapley value and Uniform pricing, the three members of the REC always find economically convenient the participation into the community (therefore, higher profits and lower costs) compared to their independent operation, which is characterized by daily costs of 12.85 €, 1.03 € and 22.20 € for the tertiary consumer, residential and commercial prosumers, respectively. Uniform pricing allows to achieve daily profits of 1.95 €, 0.69 € and 5.71 € for the tertiary consumer, residential and commercial prosumers, respectively. On the other hand, the allocation by Shapley value leads to a daily cost of 5.03 € for the tertiary consumer and to daily profits of 9.57 € and 3.81 € for the residential and commercial prosumers, respectively. Eventually, the outcomes of the allocation mechanisms highlight that Uniform pricing can provide more homogeneous payoffs among the members of the REC, whereas Shapley value is fairer towards prosumers (in particular, the residential one), in the sense that “awards” the higher contributions of the prosumers to the optimal daily profit of the REC by giving them higher payoffs than those of consumers. A future research direction of this work could cover the analysis of the economic stability of the REC, strictly dependent on the costs/profits distributed by the implemented allocation mechanisms, to avoid the case of members willing to exit from the REC.

Acknowledgments

The authors thank Professor Andrea Lazzaretto of the University of Padova, for the support in the conceptualization of this work, and “Fondazione Ing. Aldo Gini” of the University of Padova for the economic support provided.

Nomenclature
